Preface

Eating disorders can profoundly affect the individual, family unit, and local community. Changes in the individual include disturbances in body perception, organ damage, and increased risk factors leading to ill-health in later years. The family unit is affected by the psychological burdens imposed by eating disorders, including increased anxiety and depression in siblings or spouses. There is also the cost burden to consider: for example, in some countries, without a free health service, family members or insurance underwriters are expected to pay for treatments. Local communities are saddled with poor productivity, reduced attainment, and discordant interactions with colleagues and friends. There is thus a fundamental requirement to adequately diagnose, treat, and manage those individuals with eating disorders. However, this is problematic as there are many types of eating disorders, which the American Psychiatric Association have recently categorized (DSM-5) into Anorexia Nervosa, Bulimia Nervosa, Binge Eating Disorder, Other Specified and Unspecified Feeding or Eating Disorders. The categorization of Binge Eating Disorders is new and the previous category of Eating Disorders Not Otherwise Specified has been removed from DSM-5. Nevertheless, in some circumstances, there is continual usage of old terminology, and some groups use their own categorizations.

There are numerous types of instruments and questionnaires which are used for categorizing or studying eating disorders. Some have been rigorously scrutinized and tested, whereas others are new and may eventually become "gold standard" instruments. Treatment regimens are also varied as there are complex relationships between physiological, nutritional, and psychological facets of eating disorders. Treatment protocols can include nutritional supplements or psychobehavioral modifications but will of course depend on the consequences of the eating disorder. In some cases, organs are directly affected, growth is impacted, and fetuses compromised in utero. Treatment regimens can address the multiple concerns, involving both psychiatry and dietetics.

It is thus apparent that there is a wide range of eating disorders, methods of diagnoses, and treatments. The impact of eating disorders are extensive. Thus, finding all the relevant information in a single coherent publication has hitherto

been problematic since there is a wide range of material. This, however, is comprehensively addressed in *Handbook of Eating Disorders* which embraces a holistic approach. It has six main parts:

1. **General Aspects, Overviews, and Setting the Scene**
2. **Anorexia Nervosa**
3. **Bulimia Nervosa**
4. **Binge Eating Disorder**
5. **Other Specified and Unspecified Feeding or Eating Disorders**
6. **Diagnosis, Delective Questionnaires, and Resources**

There are unique features in each chapter, with sub-sections on the following:

- **Applications to Other Eating Disorders**
- **Key Facts**
- **Mini-Dictionary of Terms**
- **Summary Points**

Applications to Other Eating Disorders is particularly important as it highlights the translational aspect of research into eating disorders; their causes, impact, and treatments. **Key Facts** give important information about individual components in each chapter. The **Mini-Dictionary of Terms** is suited for both the non-expert and also those working in other fields or areas. **Summary Points** encapsulate the entire chapter in brief sets of simple sentences.

Handbook of Eating Disorders is designed for dieticians, nutritionists, psychologists, healthcare workers, and research scientists. The audience is multi-intellectual: from undergraduates, masters, and doctoral students to research scientists, lecturers, professors, and heads of groups. Contributions are from leading national and international experts including those from world renowned institutions.

About the Editors

Vinood B. Patel, BSc, PhD, FRSC, is currently Reader in Clinical Biochemistry at the University of Westminster. He presently directs studies on metabolic pathways involved in liver disease, particularly related to mitochondrial energy regulation and cell death. Research is being undertaken to study the role of nutrients, antioxidants, phytochemicals, iron, alcohol, and fatty acids in the pathophysiology of liver disease. Other areas of interest are identifying new biomarkers that can be used for the diagnosis and prognosis of liver disease and understanding mitochondrial oxidative stress in Alzheimer's disease and gastrointestinal dysfunction in autism. Dr. Patel graduated from the University of Portsmouth with a degree in Pharmacology and completed his PhD in protein metabolism from King's College London in 1997. His postdoctoral work was carried out at Wake Forest University Baptist Medical School studying structural-functional alterations to mitochondrial ribosomes, where he developed novel techniques to characterize their biophysical properties. In 2014, he was elected as a Fellow to The Royal Society of Chemistry. Dr. Patel is a nationally and internationally recognized researcher and was involved in several NIH-funded biomedical grants related to disease. Dr. Patel has edited biomedical books in the area of diet, nutrition, and health prevention. He has published over 150 articles.

Victor R. Preedy, BSc, PhD, DSc, FRSB, FRSPH, FRCPath, FRSC, is Emeritus Professor of Nutritional Biochemistry at King's College London. He is also Professor of Clinical Biochemistry and Pathology at Kings College Hospital (Hon) and Honorary Professor at the University of Hull. He was Director of the Genomics Centre of King's College London from 2003 to 2020. Professor Preedy has an Honours Degree in Biology and Physiology with Pharmacology. He gained his University of London PhD on protein metabolism and later gained his second doctorate (DSc) for his outstanding contribution to protein metabolism in health and disease. Professor Preedy has been elected as a Fellow to The Royal College of Pathologists, The Royal Society for the Promotion of Health, The Royal Institute of Public Health, The Royal Society for Public Health, The Royal Society of Chemistry, and The Royal Society of Medicine. Professor Preedy has carried out research at the National Heart Hospital (part of Imperial College London), The School of

Pharmacy (now part of University College London), and the MRC Centre at Northwick Park Hospital. Prof Preedy is a leading expert on the science of health and has a long-standing interest in diet, nutrition, and disease. He has lectured nationally and internationally. To his credit, Professor Preedy has published over 750 articles, which includes peer-reviewed manuscripts based on original research, abstracts and symposium presentations, reviews, and numerous books and volumes.

Part I

General Aspects, Overviews, and Setting the Scene

Enhanced Cognitive Behavior Therapy for Eating Disorders

1

Riccardo Dalle Grave

Contents

Abstract

Enhanced Cognitive Behavior Therapy (CBT-E) is a psychological treatment specifically designed for eating disorders. Based upon the original cognitive behavior therapy for bulimia nervosa (CBT-BN), it has been termed "enhanced" because it uses various innovative strategies and procedures to maximize its effectiveness. It addresses flexibly and individually the transdiagnostic processes maintaining the eating-disorder psychopathology. CBT-E was initially designed for adult outpatients with eating disorders, but has subsequently been adapted for adolescents, intensive settings of care (i.e., intensive outpatients and inpatients), and complex cases featuring medical and psychiatric comorbidities. CBT-E has been trialed in both research and real-world clinical settings, and is recommended

V. B. Patel, V. R. Preedy (eds.), *Eating Disorders*,
https://doi.org/10.1007/978-3-031-16691-4_1

as the most effective treatment for all clinical presentations of eating disorders in adults, and the most valid alternative to Family-Based Treatment for the management of eating disorders in adolescents. Future challenges are to further establish the validity of CBT-E, increase its effectiveness, improve its promotion, and maximize its availability.

Introduction

Enhanced Cognitive Behavior Therapy (CBT-E) is a form of cognitive behavior therapy (CBT) specifically developed for eating disorders (Fairburn et al. 2003). Based on the original CBT for Bulimia Nervosa (CBT-BN) it is a transdiagnostic treatment designed to address in a flexible and individualized way the key cognitive and behavioral processes maintaining eating-disorder psychopathology, rather than targeting a single diagnostic classification. In other words, it is equally suitable for treating anorexia nervosa, bulimia nervosa, binge-eating disorder, or "other eating disorders" (a broad term used to encompass the eating disorders that do not fit neatly into the above).

CBT-E is termed *"enhanced"* because it introduces a variety of innovative, evidence-based strategies and procedures specifically developed to enhance the effectiveness of the original CBT-BN. Though designed initially for adult outpatients with eating disorders (Fairburn et al. 2003; Fairburn 2008), it has now been adapted to be suitable for adolescents (Dalle Grave and Calugi 2020; Dalle Grave 2019; Dalle Grave and Cooper 2016), day-hospital patients and inpatients (Dalle Grave et al. 2008; Dalle Grave 2012, 2013), and complex cases involving medical and psychiatric comorbidities (Dalle Grave et al. 2021a). CBT-E has been assessed in numerous clinical trials, and is recommended as both the most effective treatment for

all clinical eating-disorder presentations in adults (National Guideline Alliance 2017), and the most valid alternative to Family-Based Treatment (FBT) for the management of eating disorders in adolescents (National Guideline Alliance 2017).

This chapter begins by describing the origin of CBT-E. It goes on to provide an overview of transdiagnostic cognitive behavior theory and treatment and its current status, and then concludes by discussing the main challenges that still remain to be addressed.

The Origins of CBT-E

The rationale behind CBT-E is closely linked with early reports describing recurrent objective binge-eating episodes and self-induced vomiting in normal-weight persons. This abnormal eating behavior pattern, initially called "bulimarexia" (Boskind-Lodahl and White 1978), was proposed as a specific eating disorder diagnosis by Gerald Russell in his landmark 1979 paper *Bulimia nervosa: An ominous variant of anorexia nervosa* (Russell 1979). In this, Russell described 30 normal-weight patients who, in addition to a fear of becoming fat, displayed recurrent binging and purging behavior. He gave the name "bulimia nervosa" to the disorder, and, intriguingly, claimed that the disorder was "intractable."

In the same period, Christopher Fairburn, a young psychiatrist working in Oxford, started to see cases with similar features to those described by Russell, and observed that these patients had three specific behaviors and concerns, specifically:

1. Unusual form of dieting, characterized by sustained attempts to follow extreme, rigid dietary rules
2. Recurrent episodes of loss of control over eating (binges) followed by self-induced vomiting or laxative misuse (purging); the binges tended to be triggered by dietary rule-breaking
3. Extreme concerns about shape and weight (which he termed "overvaluation of shape, weight and their control")

He noted that these three common features appeared to interact, serving to reinforce, or "maintain," the eating disorder, which led him to propose a theory focused on the psychology "maintaining," rather than causing, bulimia nervosa (illustrated in Fig. 1). He then developed a psychological treatment designed to address each of the maintenance mechanisms described in the theory. The outpatient treatment, called "CBT-BN," consisted of 20 sessions over 20 weeks, focused on addressing binge-eating episodes, dietary restraint and concerns about shape and weight, and achieving a full and lasting response (Fairburn 1981, 1985).

Multiple studies evaluated the efficacy of CBT-BN, and by 2004 over 30 randomized control trials had been conducted. These demonstrated that CBT-BN is more effective than all the treatments with which it had been compared, including a wide range of psychological therapies (e.g., supportive psychotherapy, focal

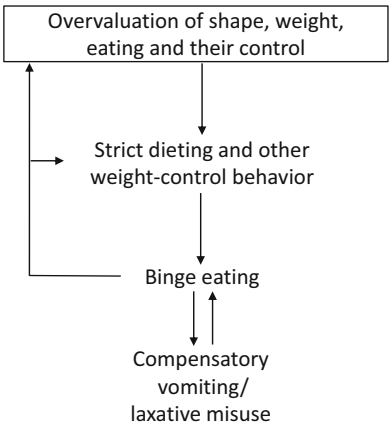

Fig. 1 The cognitive-behavioral theory of bulimia nervosa. (From Fairburn et al. (2003). Reprinted with the permission of Elsevier)

psychotherapy, supportive-expressive psychotherapy, hypnobehavioral treatment, stress management, nutritional counseling, and behavioral versions of CBT-BN), as well as various forms of exposure with response prevention, and pharmacological treatments (Wilson and Fairburn 2002). The only treatment with comparable effects to CBT-BN was interpersonal psychotherapy (IPT), but that was much slower to act (Agras et al. 2000; Fairburn et al. 1993). Summarizing the findings, 40–50% of adult patients with bulimia nervosa treated with CBT-BN displayed a complete response, which appeared to be well maintained over time. These results led the National Institute for Health and Clinical Excellence to recommend CBT-BN for adults with bulimia nervosa – a grade A recommendation (i.e., strong empirical support from well-conducted randomized trials) (National Collaborating Centre for Mental Health 2004).

Despite this, the research into the efficacy of CBT-BN made clear that the treatment is not effective enough as, at best, only half of the patients achieve full and lasting remission. Analysis of the reasons for this yielded two main clinical observations (Fairburn et al. 2003):

1. *Many of the clinical features present in bulimia nervosa are also present in anorexia nervosa and the other eating disorders* (i.e., eating disorders share a specific psychopathology – see Table 1), *and many patients' eating disorder diagnosis shifts from one to another* (e.g., from anorexia nervosa to bulimia nervosa or vice versa, the so-called "diagnostic migration" – see Fig. 2). This observation led to the idea that many of the processes that maintain bulimia nervosa, and are targeted by CBT-BN, also maintain the other eating disorders.
2. *There were consistent reasons for a lack of response to CBT-BN.* A case-by-case analysis of non-response led to the conclusion that the efficacy of CBT-BN might be extended to more patients in two main ways:

Table 1 Eating disorders share the same features

a) By developing more effective strategies and procedures to address not only extreme concerns about shape and weight, but also ambivalence to change.
b) By addressing the co-existing psychopathology that appeared to maintain some patients' eating disorders (identified as clinical perfectionism, core low self-esteem, marked interpersonal difficulties, and/or mood intolerance).

Accordingly, a "transdiagnostic" theory of the maintenance of eating disorders was proposed, and a transdiagnostic treatment based on this theory, called "CBT-E," was developed (Fairburn et al. 2003).

Transdiagnostic Theory

The transdiagnostic theory accounts for the range of processes that maintain any eating disorder diagnosis, irrespective of its presentation. According to this theory, a distinctive self-evaluation scheme, termed the *overvaluation of shape, weight, eating and their control* is the "core," or central feature maintaining eating disorders. People who display this trait judge their self-worth mainly, or even exclusively, on their shape, weight, and ability to control them. This psychopathological preoccupation with eating, weight, shape, and control seems to drive the other clinical features characteristic of eating disorders, including extreme weight-control behaviors (e.g., *dietary restraint and restriction, purging* and *excessive exercising*), *feeling fat,* and various forms of *body checking and avoidance*. From the transdiagnostic perspective, these features of eating disorders are expressions of an individual's belief that controlling their weight, shape, and eating is vital to their self-evaluation.

The one behavior that is not a direct expression of this core eating disorder feature is *binge eating*. A large subgroup of people with eating disorders experience binge-eating episodes, which seem to stem indirectly from the overvaluation of shape, weight, and eating through the following mechanisms:

1. *Severe undereating*. The overvaluation of shape, weight, eating and their control can lead an individual to undereat. Doing so produces several neuroendocrine signals that control food intake, messaging hunger over satiety.
2. *Extreme and rigid dietary rules.* People with eating disorders tend to react in a negative and extreme (often all-or-nothing) way when these extreme and rigid dietary rules are, almost inevitably, broken, and even small transgressions tend to be interpreted as evidence of a personal failing and lack of self-control. This often results in a temporary abandonment of the effort to restrict the diet, triggering a binge-eating episode. In turn, this episode intensifies concerns and beliefs regarding their lack of control over shape, weight, and eating, and encourages further dietary restriction, thereby increasing the risk of subsequent binge-eating episodes.
3. *Self-induced vomiting or other compensatory behaviors*. The false belief that purging behaviors effectively prevent calorie absorption removes a major deterrent (i.e., the fear of gaining weight) to relaxing the dietary rules and binge eating.
4. *Events and associated mood changes.* These seem to maintain binge-eating episodes through three main mechanisms:
    a) It is more difficult to maintain a high level of dietary restriction when life difficulties and associated emotional changes inevitably occur, and such events facilitate the breaking of extreme and rigid dietary rules.
    b) Binge eating distracts from problems and temporarily improves mood. It may therefore be adopted as a dysfunctional means of coping with life's difficulties and uncomfortable emotions.
    c) Binge eating may be used to gratify and reward oneself (a common process reported by people with binge-eating episodes and obesity).

In persons with the anorexia nervosa presentation, binge-eating episodes are usually subjective or absent, while undereating and being underweight predominate. These lead to the development of several *starvation symptoms*, such as hunger, dizziness, weakness, feeling cold, early sense of fullness, irritability, mood swings, social withdrawal, reduced sexual desire, and preoccupation with food (Keys et al. 1950). These, like undereating, binge-eating and the other eating-disorder features, perpetuate the preoccupation with and overvaluation of shape, weight, and eating control, ensuring that the *eating-disorder mindset* becomes locked in place. This occurs through several mechanisms (see Table 2).

This vicious and debilitating cycle can be conceptualized and illustrated to patients via a transdiagnostic *formulation*, featuring the core processes involved in the maintenance of eating disorders according to transdiagnostic cognitive-behavioral theory (Fig. 3). This can be adapted to reflect any diagnostic category of eating disorders, or rather individual manifestations of the eating-disorder psychopathology, with minimal changes. For example, the formulation of a person with bulimia nervosa does not contain the box "low weight and starvation symptoms," but may include all the other characteristics described in the array of possible eating disorder symptoms. In contrast, the formulation of a patient with anorexia nervosa restricting type will always include the box "low weight and starvation symptoms," but not the "binge-eating" and "self-induced vomiting and "misuse of laxatives" boxes. A patient with anorexia nervosa of the binge-eating/purging type will display the greatest number of maintenance processes, while those with binge-eating disorder will have the smallest number.

As mentioned briefly above, in addition to the core eating-disorder maintenance processes, transdiagnostic cognitive behavioral theory proposes that one or more of the following additional mechanisms may be operating in some patients (Fig. 4) (Fairburn et al. 2003): (i) clinical perfectionism, (ii) core low self-esteem, (iii) marked interpersonal difficulties, and (iv) mood intolerance. If present and marked, these "external" maintenance mechanisms interact with the core processes, perpetuating the eating disorder and hindering its treatment (see Table 3).

Overview of CBT-E

CBT-E is a specialized psychological treatment for eating disorders based on the transdiagnostic cognitive behavioral theory described above. It was initially devised by Fairburn and colleagues at the Centre for Research on Eating Disorders at Oxford (CREDO) to treat eating disorders in adults with a body mass index (BMI) of between 15.0 and 39.9 (Fairburn et al. 2003; Fairburn 2008). It was then adapted by Dalle Grave and colleagues at the Villa Garda Hospital Department of Eating and Weight Disorders, Italy, to be suitable for both adolescents of at least 12 years of age (Dalle Grave and Calugi 2020; Dalle Grave 2019) and more intensive settings of care (Dalle Grave 2012, 2013), such as day-hospital and residential units, where patients with severe eating disorders and or BMI <15.0 are generally treated. The

Table 2 Principal maintaining mechanisms of eating disorders

Dietary restraint and dietary restriction
• Increase the preoccupations with eating
• Cause anxiety every time one eats
• Restrict the way one eats
• Contribute to binge-eating episodes
• Are the major cause of becoming and remaining underweight
• Can be used to manage events and associated mood changes in a dysfunctional way
• Impair interpersonal relationships
Objective and subjective binge-eating episodes
• Increase concerns about shape and weight
• Intensify dieting to compensate for the calories consumed during the binges
• Favor the use of compensatory behaviors (e.g., self-induced vomiting, laxative, and/or diuretic misuse)
• Can be used to manage events and associated mood changes in a dysfunctional way
Excessive exercising
• Increases the preoccupations about weight and body shape
• Promotes binge eating (when used as a compensatory behavior)
• Is a cause of becoming and remaining underweight
• Can be used to manage events and associated mood changes in a dysfunctional way
Purging (self-induced vomiting, laxative, and diuretic misuse)
• Relax the control of diet as the individuals think incorrectly that they are able to eliminate all the ingested calorie through purging
• The prolonged use of laxatives can lead to chronic constipation, which can in turn increase general concern with eating and stomach shape and perpetuates the perceived need to use more of these drugs
• Some people think that if they do not evacuate regularly, they will gain weight
Underweight
• Some starvation symptoms are interpreted by individuals with an eating disorder as a threat to their control over eating (e.g., hunger potentially prompting them to eat more than they had planned) or as their failure to control their food intake (e.g., the early sense of fullness being seen as a sign that they have overeaten)
• Other starvation symptoms, such as social withdrawal, induce individuals to isolate from external "normal" experiences that could serve to reduce their overvaluation of shape, weight, and eating control by introducing/reinforcing other self-evaluation domains
• Some starvation symptoms (e.g., hunger, dizziness, weakness, and feeling cold) are interpreted in a positive light, seeing them as signs of their success in controlling eating and weight
Body checking
• Frequent weighing leads to misinterpreting the minimal variation of body weight – generally due to change of body hydration – as "having gained weight" and encourages the intensification of dieting or the adoption of other extreme weight control behaviors
• Repetitively scrutinizing disliked parts of the body amplifies the perceived flaws and intensifies the body dissatisfaction, which encourages the intensification of dietary restriction
• The superficial and rapid observation of body parts of a filtered subgroup of thin and attractive people or with distinct physical features confirm that one's body shape is wrong, and maintain body dissatisfaction

(continued)

Table 2 (continued)

Body avoidance
• Allows concerns and fears about body weight and shape to persist in the absence of an objective reflection of what one looks like (false beliefs regarding body weight and shape remain unchallenged)
• Denies the possibility of receiving positive comments from others and therefore maintains negative beliefs about their bodies
• Restricts interests, does not allow an intimate life, and leads the persons to isolate themselves focusing more and more on the control of their body shape and weight
• Avoiding weighing maintains the fear of weight gain and facilitates weight gain or loss, as it prevents the use of measures to address the changes in weight
Feeling fat
• It tends to be equated with "being fat" by both underweight and non-underweight individuals with an eating disorder

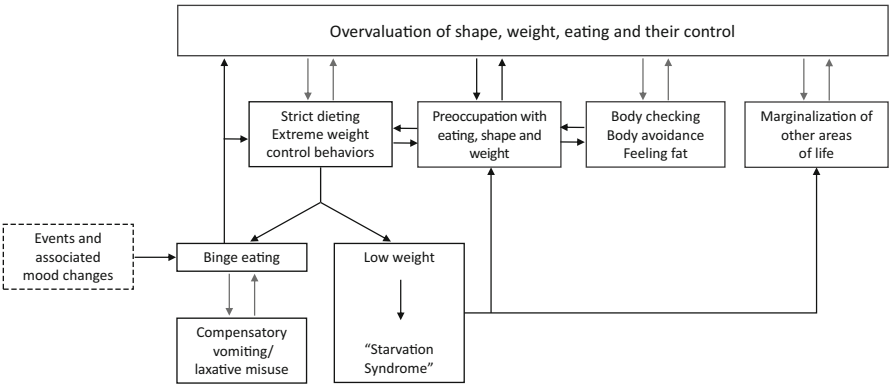

Fig. 3 The core processes involved in the maintenance of eating disorders, according to transdiagnostic cognitive-behavioral theory

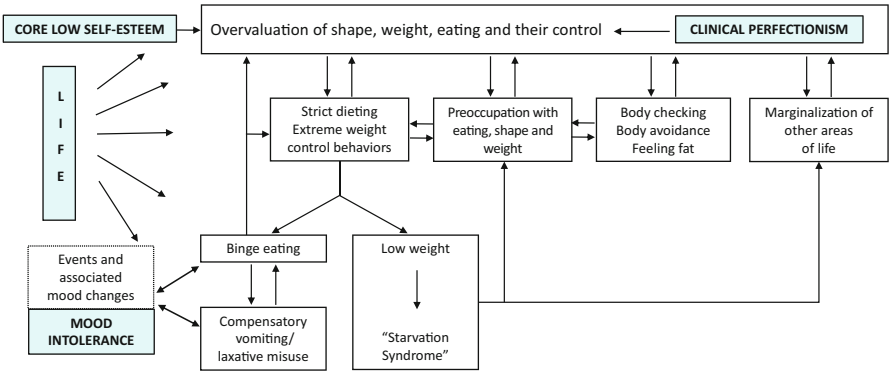

Fig. 4 Composite transdiagnostic formulation of eating disorders featuring additional maintenance processes. "Life" is shorthand for interpersonal life

Table 3 "External" mechanisms operating in a subgroup of persons with eating disorders

Clinical perfectionism This refers to overvaluation of achievement and achieving demanding personal standards, despite the adverse consequences. It maintains the eating-disorder psychopathology through two main mechanisms:
1. The individual's self-evaluation system focuses on the commitment to trying to achieve "perfect" control of shape, weight, and eating, as well as in pursuing demanding standards in other domains of life (e.g., work or sport performance)
2. It intensifies some aspects of the psychopathology of eating disorders (e.g., dieting and/or excessive exercising), making this more difficult to treat
Core low self-esteem This is characterized by a pervasive negative valuation of self-worth which is not affected by either events or changes in the state of the eating disorder. It maintains the eating-disorder psychopathology through two main processes:
1. It creates a sense of helplessness and a lack of confidence in the ability to change, negatively influencing treatment adherence
2. It encourages the individual to pursue success in some areas that are judged important for improving their self-esteem (e.g., control of shape, weight, and eating) with determination, thereby making it even more difficult to enact change in these areas
Marked interpersonal difficulties These maintain eating-disorder psychopathology through various mechanisms. Examples include:
• Family tensions may intensify dietary restriction, especially in younger patients. A process that reflects the intensification of their need to have a sense of control is shifted to control over eating
• Some interpersonal environments (e.g., school and family) intensify concerns about control over shape, weight, and eating
• Adverse interpersonal events and associated emotional changes can affect eating control and promote binge-eating episodes
• Persistent interpersonal difficulties may undermine self-esteem and prompt patients to struggle even harder to achieve certain "positive" goals such as success in controlling shape, weight, and eating
Mood intolerance This is defined as an inability to tolerate intense moods, or excessive sensitivity to mood states, which are managed using "dysfunctional mood-modulation behaviors," such as excessive alcohol intake, substance misuse, or self-harming behaviors (e.g., cutting or burning the skin). It maintains the eating-disorder psychopathology through the following mechanism:
• Binge-eating, self-induced vomiting, and excessive exercising are used as means to modulate mood

management of patients with eating-disorder psychopathology and a BMI equal to or greater than 40 has also been described (Dalle Grave et al. 2018).

Goals of CBT-E

CBT-E has four general goals:

1. To engage the patient in treatment by motivating them to recover and involving them actively in the process of change
2. To help them overcome their eating-disorder features (e.g., dietary restraint and restriction, low weight, self-induced vomiting, laxative misuse, excessive exercising, and preoccupation with shape, weight, and eating)
3. To correct the mechanisms maintaining the eating-disorder features
4. To ensure lasting change and prevent relapse

General Treatment Strategy

CBT-E is a time-limited, personalized psychological treatment designed to treat an individual's psychopathology. It does so by addressing the behavioral and cognitive processes maintaining their eating-disorder features through a flexible and personalized set of strategies and procedures. It has been developed as a comprehensive, standalone treatment, and is therefore not to be combined with other forms of therapy. It is equally well suited to males and females, and is designed to involve the patient actively in all phases of treatment, from the decision to start to the choice of which problems to address and how. This fosters a sense of personal control, as does the progressive education a patient receives to help them make informed decisions.

At the very beginning, patients are taught about the two main ways of understanding eating disorders, namely the so-called "disease" and "psychological" models, and the treatment approaches based upon them. Specifically:

1. The *disease model* postulates that the psychopathological features displayed by the patient are the result of a specific disease – in this case anorexia nervosa or bulimia nervosa, etc. – and are therefore outside their control. As such, they are told not to trust their thoughts about shape, weight, and eating, as these are symptoms of their disease, and asked to adopt a passive role in the treatment of their illness. In other words, the disease model is the grounds for a traditional prescriptive approach to treatment, in which the patient must simply follow the instructions of their doctors, psychologists, and dietitians to recover.
2. The *psychological model* adopted by CBT-E, on the other hand, is based on a psychological explanation of the patient's eating disorder; specifically, the affected person has difficulties seeing dieting and low weight as a problem because their self-evaluation scheme has become skewed, and is predominantly based on shape, weight, eating and their control. This explains why being able to diet and achieving a low weight is associated with a sense of triumph and realization, despite its negative consequences. However, according to this stance, patients can be helped to understand the psychological mechanisms maintaining their eating disorder and that their self-evaluation system is dysfunctional. They can actively decide to find other, more functional solutions for reaching a stable and balanced self-evaluation scheme, and therefore recover from their illness.

The psychological model explains why CBT-E never uses "prescriptive" or "coercive" procedures. Indeed, asking a patient to do things that they are unwilling to is only likely to increase their resistance to change. For example, in underweight patients one of the first major goals is not weight regain itself, but instead to decide whether or not to actively address weight regain by helping them understand how their eating problem operates and is maintained. If they do not conclude that they have a problem to address, the treatment cannot start or must be postponed for a time, but this is seldom the outcome. This "informed decision-making" approach is also used to address other egosyntonic features of eating-disorder psychopathology, like dietary restraint and/or excessive exercising. To this end, a key CBT-E strategy is to collaboratively create with the patient a personalized formulation (or set of hypotheses) of the main mechanisms maintaining their individual eating-disorder psychopathology, which they will actively decide to target one by one during treatment.

Once the patient is engaged in the process of change, their eating-disorder psychopathology is addressed via a flexible set of cognitive, behavioral, and interpersonal treatment strategies and procedures, integrated with ongoing education. Patients are encouraged to observe how the processes illustrated in their formulation operate in real life, and to monitor their eating, and the events, thoughts, and feelings that have influenced their eating, in real time. They are asked, if they agree, to make gradual behavioral changes, and analyze the effects and implications of each change on their way of thinking. By empowering the patient to disrupt the main eating-disorder maintenance mechanisms, this approach usually produces a gradual reduction in their preoccupation with shape, weight, eating and their control. In the later stages of treatment, when patients report experiencing periods free from such concerns, CBT-E focuses on helping them to recognize the early warning signs of eating-disorder mindset reactivation, and to de-center from it quickly, with a few to averting relapse.

If the patient is an adolescent, their parents are actively involved in creating an optimal home environment for change and, with the young person's consent, providing support as they address the main mechanisms maintaining their eating problem. A similar strategy is used with adult patients if both the therapist and the patient agree that involving their significant other(s) might aid their recovery.

Forms of CBT-E

CBT-E can be administered in two forms:

1. *Focused form*, which only targets their eating-disorder psychopathology
2. *Broad form*, which focuses on both their eating-disorder psychopathology and one or more of their external maintenance mechanisms (i.e., clinical perfectionism, core low self-esteem, mood intolerance, or marked interpersonal difficulties), if deemed necessary

The focused form is indicated for most patients, whereas the broad module(s) are introduced if the external psychopathology is pronounced, appears to reinforce the eating disorder, and interferes with the treatment. The decision to use the broad form is taken in a review session held after 4 weeks in not-underweight patients, or one of the review sessions later on in underweight patients.

Versions of CBT-E

Outpatient CBT-E for Adults

The outpatient version of CBT-E lasts 20 weeks in non-underweight patients and 40 weeks in underweight patients. It is recommended for most adult patients with an eating disorder (Fairburn 2008), and can in some cases be shortened, for example, in patients with binge-eating disorder whose binge eating rapidly ceases and who have little other psychopathology to address. More often, however, there is a case for extending treatment. Examples include when the treatment has been disrupted (e.g., by the onset of clinical depression or an interpersonal crisis), or when a patient is benefitting from the treatment but is still underweight. Under these circumstances, the treatment should be continued for some additional months, with a detailed review of progress every 4 weeks to ensure continuation is justified.

Outpatient CBT-E for Adolescents

CBT-E has been adapted for adolescents based on the consideration of two factors that distinguish them from adults, namely physical health concerns and the need for parental involvement. Indeed, some medical complications associated with eating disorders, e.g., osteopenia and osteoporosis, may be severe in this age range and have lifelong repercussions. Therefore, regular medical assessment and a lower threshold for hospital admission are integral parts of CBT-E for adolescents. The treatment lasts 20 weeks in non-underweight patients, but in underweight patients, the "standard" 40 weeks may be shortened to about 30 weeks, as the evidence shows that adolescents tend to return to normal body weight faster than adults (Calugi et al. 2015).

In the great majority of cases, parental involvement is beneficial to treatment. Parents are asked to participate alone in an interview lasting approximately 90 min during the first week, and subsequently the patient and parents are seen together for 15–20 min immediately after the fourth to sixth sessions (in patients who are not underweight) or the eighth to tenth sessions (in patients who are underweight). Table 4 describes the core elements of the adolescents' version of CBT-E for underweight patients.

Intensive Outpatient CBT-E

This version of treatment is designed for patients who may need more professional input than outpatient CBT-E can provide, but whose conditions are not sufficiently severe to warrant hospitalization. This adaptation of CBT-E incorporates all of the

Table 4 The core elements of the focused CBT-E version for not-underweight adolescent patients

Step one – starting well and deciding to change The aims are to engage the patient in treatment and change, including addressing weight regain The appointments are twice weekly for 4 weeks and involve the following:
• Jointly creating a formulation of the processes maintaining the eating disorder
• Establishing real-time self-monitoring of eating and other relevant thoughts and behaviors
• Educating about: body weight regulation and fluctuations, the adverse effects of dieting, and, if applicable, the ineffectiveness and physical complications of self-induced vomiting and laxative misuse as a means of weight control
• Introducing and establishing weekly in-session weighing, and becoming proficient in interpreting and coping with weight fluctuations
• Introducing and adhering to a pattern of regular eating, with planned meals and snacks
• Thinking about addressing weight regain
• Involving parents to facilitate treatment
Step two – addressing the change The aim is to address weight regain and the key mechanisms that are maintaining the patient's eating disorder The appointments are twice a week until the rate of weight regain stabilizes, at which time they are held once a week. This step involves the following CBT-E modules:
• Underweight and undereating: creating a daily positive energy balance of about 500 kcal to achieve a mean weekly weight regain of about 0.5 kg
• Overvaluation of shape and weight: providing education on overvaluation and its consequences; nurturing previously marginalized domains of self-evaluation; reducing unhelpful body checking and avoidance; re-labeling unhelpful thoughts or feelings such as "feeling fat"; exploring the origins of the overvaluation and learning to identify and control the eating-disorder mindset
• Dietary restraint: changing inflexible dietary rules into flexible guidelines, and introducing previously avoided foods
• Events and mood-related changes in eating: developing proactive problem-solving skills to tackle such triggering events, and developing skills to accept and modulate intense moods
• Setbacks and mindsets: providing education about setbacks and mindsets; identifying eating-disorder mindset reactivation triggers; spotting setbacks early on; displacing the mindset; exploring the origins of the overvaluation
Review sessions These are held 1 week after Step One and then every 4 weeks, for the purposes of:
• Collaboratively reviewing treatment compliance and progress
• Identifying barriers to change, both general (e.g., school pressures) and features of the eating disorder itself (e.g., difficulties in weight regain, presence of dietary restraint)
• Adjusting the initial formulation in light of progress and/or emerging issues
• Deciding to continue with the focused form of CBT-E rather than the broad form[a]
Step 3 – ending well The aims are to ensure that progress made during treatment is maintained, and that the risk of relapse is minimized. There are three appointments, 2 weeks apart, covering the following:
• Addressing concerns about ending treatment
• Devising a short-term plan for continuing to implement changes made during treatment (e.g., reducing body checking, introducing further avoided foods, eating more flexibly, maintaining involvement in new activities) until the post-treatment review session
• Phasing out treatment procedures, in particular self-monitoring and in-session weighing
• Education about realistic expectations and identifying and addressing setbacks

(continued)

Table 4 (continued)

• Devising a long-term plan for maintaining body weight, and averting and coping with setbacks
Post-treatment review session
• Reviewing the long-term maintenance plan around 4, 12, and 20 weeks after treatment has finished

[a]The broad form of CBT-E includes four additional modules (i.e., clinical perfectionism, low self-esteem, interpersonal difficulties, and mood intolerance), one of which may be added to the focused modules in Step Two. This form of treatment is indicated if clinical perfectionism, low self-esteem, interpersonal difficulties, or mood intolerance are marked, and appear to be maintaining the disorder and obstructing change

strategies and procedures of outpatient CBT-E, but includes several additional features developed specifically for this new approach (Dalle Grave 2012, 2013).

Intensive outpatient CBT-E can be flexibly adapted to both the clinical needs of the patient and the logistical characteristics of the clinical service that delivers it. However, it should include the following procedures on weekdays: (i) supervised daily meals; (ii) individual CBT-E sessions; (iii) sessions with a CBT-E-trained dietitian to plan and review weekend meals; and (iv) regular reviews with a CBT-E-trained physician. Intensive outpatient treatment lasts for a maximum of 12 weeks, but may be shorter if patients successfully progress in the areas in which they were struggling in outpatient CBT-E (e.g., lack of progress in weight regain, reducing binge eating, and/or eating regular meals). Toward the end of intensive treatment, patients who have responded well are gradually encouraged to eat meals outside the unit, thereby allowing the treatment to evolve into conventional outpatient CBT-E.

Inpatient CBT-E

Inpatient CBT-E is indicated as a first-line option for patients who require close medical supervision, or for those who are not responding well to the less intensive versions. The treatment features all the main strategies and procedures of outpatient CBT-E, which are delivered in group format as well as individual sessions, but has three main features that set it apart (Dalle Grave 2012, 2013). First, the treatment is delivered by a non-eclectic multidisciplinary team, rather than a sole therapist. This will comprise physicians, psychologists, dietitians, and nurses who have all been fully trained in CBT-E. Second, assistance with eating is provided in the early weeks of treatment. This is to help patients overcome their difficulties in real time. Third, adolescent patients are given the opportunity to continue their studies during hospitalization with the aid of on-site educators. Inpatient CBT-E also includes the following additional elements, designed to reduce the high rate of relapse typically seen after discharge from hospital (Dalle Grave et al. 2008):

- The inpatient unit is open, with patients being free to go outside. This is so they are not sheltered from the environmental stimuli that tend to trigger their eating-disorder mindset and behaviors, but can rely on professional support.

- Before the scheduled discharge, the CBT-E team will work with the patient to identify likely environmental setback triggers. These will then be addressed during the individual CBT-E sessions in the final weeks of inpatient treatment.
- Toward the end of treatment, parents are helped to create a positive, stress-free home environment in readiness for the patient's return.

Post-inpatient Outpatient CBT-E

In order to capitalize on and reinforce the progress made during inpatient treatment, this is generally followed with 20 sessions of outpatient treatment over 20 weeks. Post-inpatient outpatient sessions are held twice weekly in the first month after discharge, and thereafter less frequently. The main objectives of these sessions are to help patients to consolidate the changes they have achieved during their residential treatment, to provide them with strategies for dealing with the difficulties that occur once they return home, and to identify and address any residual maintenance and control mechanisms, with a view to preventing relapse.

The Status of CBT-E

CBT-E has been tested in England, Australia, Denmark, Germany, Italy, and the USA on patients from all diagnostic categories of eating disorders. Focusing on the studies in which CBT-E was delivered well, the evidence suggests that about 80% of patients who are not significantly underweight complete treatment. Among these, about two-thirds achieve full remission, which appears stable over time. Many of the remaining patients improve, but do not achieve remission. The remission rate is similar with underweight patients, but treatment is only completed by about 65% of such patients.

In general, the research findings can be summarized as follows:

- CBT-E is suitable for treating all diagnostic categories of eating disorders in adult (Fairburn et al. 2009, 2013, 2015; Byrne et al. 2017) and adolescent patients (Le Grange et al. 2020; Dalle Grave et al. 2013b, 2015, 2019). This is not true of any other treatment (Dalle Grave et al. 2021b).
- In bulimia nervosa, CBT-E for adults has proven to be superior to all the psychological treatments it has been compared with, including psychoanalytic psychotherapy (Poulsen et al. 2014) and interpersonal therapy (IPT) (Fairburn et al. 2015).
- In anorexia nervosa, outpatient CBT-E has demonstrated promising results in adult patients (Fairburn et al. 2013). It was found to be more effective than Specialist Supportive Clinical Management (SSCM) and Maudsley Model Anorexia Nervosa Treatment for Adults (MANTRA) in helping patients achieve a physically healthy weight (in 59%, 47.5%, and 44% of participants, respectively), albeit not significantly so (Byrne et al. 2017).
- In inpatient settings, CBT-E has good outcomes in both adolescents and adults. Eighty-five percent complete the treatment, and among completers, about 50%

still display a full response at 60-week follow-up (Dalle Grave et al. 2013a, 2014, 2020).

- CBT-E has also displayed efficacy in patients with severe and extreme anorexia nervosa, who are seldom included in clinical trials due to their supposed intractability. A completion rate of 66% has been reported in such outpatients, and about 50% of these exhibited a full response at 60 weeks of follow-up (Calugi et al. 2021). In another sample, 85% completed inpatient CBT-E, and 33% of completers displayed a full response at 12-month follow-up (Calugi et al. 2017).
- In adolescent patients with anorexia nervosa, about 72% completed outpatient CBT-E, and among completers about 62% displayed a full response at follow-up (Dalle Grave et al. 2013b). These outcomes were similar to FBT at 6- and 12-month follow-up (Le Grange et al. 2020). Comparably encouraging results have also been achieved when delivering the treatment in real-world clinical settings (Dalle Grave et al. 2019).

Implications for Clinical Services

The results obtained through CBT-E in both research and real-world settings have important implications for clinical services providing treatment for eating disorders. CBT-E is the logical first-line treatment for all eating disorders, as patients can be treated via a single, well-delivered, evidence-based treatment, rather than the common evidence-free "eclectic" approach.

To achieve optimal outcomes, therapists need to be adequately trained in CBT-E. However, clinicians only have to learn a single psychological treatment to treat most adults and adolescent patients with any eating disorder, with substantial clinical and financial benefits. Moreover, multistep implementation of CBT-E, by offering outpatient, intensive outpatient, inpatient, and post-inpatient treatment (Dalle Grave 2013), minimizes the problems associated with transitions from outpatient to intensive treatment. In a unified multistep service, patients avoid the confusing and counterproductive changes in therapeutic approach that commonly accompany such transitions.

Remaining Challenges

Several research and clinical challenges will need to be addressed in the future in order to make the treatment more effective, efficient, and available. Future studies should: (i) clarify the relative effectiveness of CBT-E and FBT in the treatment of younger patients; (ii) identify moderators of the effects of CBT-E; (iii) assess the effects of the broad form of CBT-E; and (iv) develop and test specific modules to address comorbidities (e.g., obesity, post-traumatic stress disorder). It is also crucial to study how to increase the effectiveness of CBT-E, identifying, for example, the reasons for non-response and the mediators of the effects of CBT-E, and then modify the treatment accordingly.

To maximize CBT-E availability, currently under investigation are two strategies, specifically (i) how best to train more therapists via digital training while offering supervision by experts in CBT-E; and (ii) how to make CBT-E more scalable via innovative forms of digital treatment (Fairburn and Patel 2017). It will also be important to improve the promotion of CBT-E via social networks and other modern communication strategies. To this end, a website (www.cbte.co) devoted to the treatment has been recently created for the general public, therapists, and patients.

Applications in Other Eating Disorders

This chapter reviewed "enhanced" cognitive behavioral therapy (CBT-E) for eating disorders. CBT-E is a "transdiagnostic" treatment for all forms of eating disorders, including anorexia nervosa, bulimia nervosa, binge-eating disorder, and other similar states. CBT-E was developed as an outpatient treatment for adults, but is available as an intensive version for day patients and inpatients. There is also a version for younger people. CBT-E addresses common eating disorder maintenance mechanisms, reflecting their shared and evolving psychopathology, rather than the specific diagnosis. The treatment is highly individualized, and the therapist creates a specific version of CBT-E to suit the individual issues of the person receiving treatment. CBT-E is effective in all forms of eating disorders encountered in adults and adolescents. Therapists need to receive training in CBT-E to obtain optimal effects.

Mini-Dictionary of Terms

- **Body checking:** repeated and frequent checking of one's body weight and shape
- **Core psychopathology:** the overvaluation of shape, weight, and eating control characteristic of most eating disorders
- **Dietary restraint:** attempts to limit the amount of food eaten
- **Dietary restriction:** undereating in the physiological sense
- **Dietary rules:** highly specific rules on what, when, and how to eat, etc.
- **Enhanced**: a term used to highlight that the treatment uses various innovative strategies and procedures to enhance the effectiveness of the original cognitive behavior therapy developed for bulimia nervosa
- **Objective binge eating:** episodes of eating characterized by the following: (1) eating a large amount of food given the circumstances, and (2) a sense of lack of control during such episodes
- **Overvaluation of shape, weight, eating and their control:** judging self-worth largely, or even exclusively, in terms of one's shape, weight, and ability to control them
- **Starvation symptoms:** the physical and psychosocial symptoms that occur secondary to dietary restriction and undereating

- **Transdiagnostic:** a mechanism that is present across disorders, irrespective of the specific diagnosis

Key Facts of Enhanced Cognitive Behavior Therapy for Eating Disorders

- Enhanced Cognitive Behavior Therapy (CBT-E) is a specific form of therapy for eating disorders.
- It is focused on the eating disorder psychopathology operating in the patient (not the eating disorder diagnosis).
- It uses strategies and procedures sequentially but flexibly to treat each patient's individual psychopathology.
- Developed as an outpatient treatment for adults, it is now available for younger people and as an intensive version for day patients and inpatients.
- About two-thirds of those who begin treatment make a full recovery with CBT-E. Although fewer patients who are substantially underweight complete treatment, their response rate is similar.

Summary Points

- Enhanced cognitive behavior therapy (CBT-E) is a specialized psychological treatment for eating disorders.
- It was initially devised to treat eating disorders in adults with eating disorders, but has since been adapted for adolescents of at least 12 years of age and intensive settings of care.
- CBT-E is designed to treat the patient's psychopathology. It does so by addressing in a flexible and personalized way the behavioral and cognitive processes maintaining the eating-disorder features of the patient.
- CBT-E can be administered in two forms: (i) the focused form, addressing only the eating-disorder psychopathology; or (ii) a broad form, also incorporating modules for one or more of the following external psychopathologies, as indicated: clinical perfectionism, core low self-esteem, and marked interpersonal difficulties.
- About 80% of not-underweight patients complete treatment, and among them, about two-thirds achieve full remission, which appears well maintained over time. In underweight treatment is completed in about 65% of cases, but the remission rate is similar.
- Future challenges to address are: (i) to further validate CBT-E; (ii) to study how to increase the effectiveness of CBT-E; (ii) to improve the promotion of CBT-E; and (iv) to maximize CBT-E availability, training more therapists and making the treatment more scalable.

Abstract

During pregnancy, women might improve their diet and adopt a healthier eating behavior. However, this is not the case for women suffering from eating disorders (ED), who experience comorbidities such as depression, anxiety, binge eating, and increased concerns about weight gain. EDs, especially anorexia nervosa (AN), might interfere with fertility due to weight loss. Furthermore, maternal (impairments in fluid and electrolyte metabolism, miscarriages, cesarean deliveries) and fetal (wheezing in the offspring, prematurity, small head circumference) complications are apparent. The birth weight of the infants is positively associated with maternal pregravid bodyweight (BW). Although bulimic behaviors ameliorate during pregnancy, they resurface postpartum. Bulimia nervosa (BN) has been associated with low-birth-weight infants, fetal abnormalities, prematurity, and complications at delivery. On the other hand, women with binge eating syndrome tend to deliver heavier and larger babies. Other EDs present in pregnancy include orthorexia nervosa (ON) and pica. A multidisciplinary approach is recommended for the treatment of EDs during pregnancy, emphasizing adequate intake of nutrients and BW gain.

Keywords

Pregnancy · Trimester · Prenatal · Pica · Vomiting · Fertility · OFSED · Disordered eating · Binge eating · Orthorexia · Obsessions · Pregorexia · Small for gestational age · Feeding disorders

Abbreviations

AN	Anorexia nervosa
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
BW	Bodyweight
ED	Eating disorders
GWG	Gestational weight gain
IDA	Iron deficiency anemia
IUGR	Intrauterine growth retardation
LGA	Large for gestational age
NINFEA	Nascita e INFanzia gli Effetti dell'Ambiente
ON	Orthorexia nervosa
SGA	Small for gestational age
TfR	Transferrin receptor
U/OSFED	Unspecified or other specified feeding or eating disorder

Introduction

For developing a healthy fetus, pregnancy is characterized by various maternal physiological and psychological adaptations. In particular, proper nutrition is important for meeting the high perinatal energy demands and assuring the provision of all essential nutrients to the fetus. Women may use pregnancy as an opportunity for change (Olander et al. 2018) by improving diet quality (Tsigga et al. 2011), abandoning unhealthy eating habits, and increasing the levels of physical activity (Wise et al. 2020). According to Olander (Olander et al. 2018), the behavioral change during pregnancy is explained by psychological and social terms: behavioral change is inextricably linked to the promotion of the maternal-fetal relationship (Bergh and Simons 2009), and the increased motivation for the latter is both innate-driven and facilitated by the community's expectations.

Nevertheless, eating behaviors may reach extremes, introducing eating disorders (EDs). Numerous systematic reviews have pointed out a high prevalence of EDs or unspecified/other specified eating and feeding disorders (U/OSFED) in pregnant women, associated with symptoms of binge eating, anxiety, depression, and concerns regarding bodyweight (BW) (Dörsam et al. 2019; Martínez-Olcina et al. 2020). Many women enter pregnancy with a history of EDs, and others tend to develop an ED/OFSED during pregnancy. Pregnancy can complicate an underlying ED or trigger the development of a new one. Two mechanisms lead to the development or exacerbation of ED/OFSED during pregnancy, the first being the gestational weight gain (GWG) associated with body dissatisfaction and increased appetite and the second stemming from the need for adopting a more "controlled" and "healthy" diet.

EDs and Fertility

For women with EDs/OFSED, fertility is an issue of concern as many are experiencing sexual dysfunction and miscarriages (Boutari et al. 2020). In anorexia nervosa (AN), women are often anovulatory secondary to reduced body fat (Burke and Vangellow 1990). Nevertheless, there are occasional women with AN who ovulate and become pregnant. As many women may have mistaken beliefs regarding pregnancy, in both AN and bulimia nervosa (BN), unplanned pregnancies are common (Morgan et al. 1999), as they do not take any contraceptive measures (Easter et al. 2011). Time-to-conception is generally longer in women with Eds compared to the general population, with the majority seeing fertility specialists (Easter et al. 2011). When women with a history of AN diagnosis were examined, they exhibited a delayed first birth age and lower parity compared with those with a history of BN, the general population, and their sisters of similar age (Tabler et al. 2018). This finding indicates that the degree of weight loss, which is greater in AN compared with BN, is positively associated with fertility.

EDs in Pregnancy

A previous ED may be triggered again by gestation, as approximately 22% of women are relapsing during the perinatal season (Koubaa et al. 2005). The severity of the ED is important concerning maternal, pregnancy, and fetal outcomes, with women who were hospitalized being at a higher risk for adverse events (Sollid et al. 2004). Women with EDs in remission during the time of conception exhibit greater GWG and deliver babies with higher birth weights and 5-min Apgar scores than those who conceived while demonstrating ED symptomatology (Stewart et al. 1987). According to a systematic review (das Neves et al. 2021), obstetrical and fetal outcomes are dependent on the type of underlying ED: AN and BN have been associated with low birth weight and slow fetal growth and binge eating with the delivery of children with increased birth weight. Figure 1 details the maternal-fetal effects of EDs and OFSED during gestation. EDs are associated with vomiting, hyperemesis, bleeding, anemia, impaired hydration, acute fluid and electrolyte shifts, and a decrease in circulating plasma volume, all of which may increase the risk for

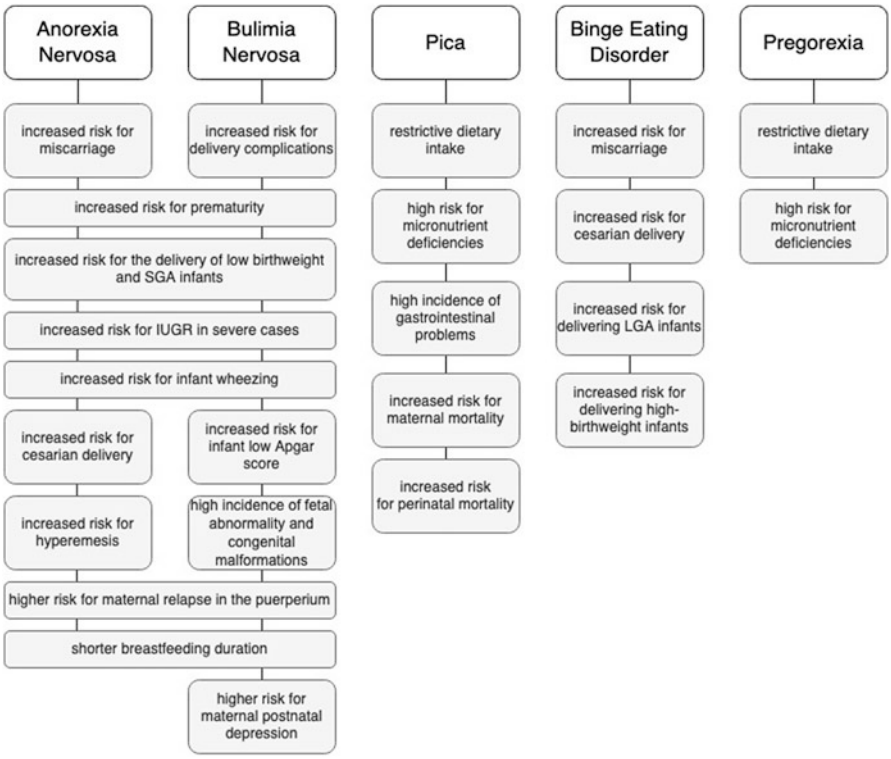

Fig. 1 Results of EDs and OFSED during gestation, on maternal, obstetrical, and fetal outcomes. *IUGR*, intrauterine growth retardation; *LGA*, large for gestational age; *SGA*, small for gestational age

maternal, obstetric, and fetal complications (Burke and Vangellow 1990; das Neves et al. 2021). In severe ED states, intrauterine fetal growth retardation (IUGR) cases have been reported (Burke and Vangellow 1990).

According to the Nascita e INFanzia gli Effetti dell'Ambiente (NINFEA) Internet cohort, infants born to mothers with lifetime EDs exhibit a greater risk of developing wheezing, and this risk is multiplied when the disorders were active during gestation (Popovic et al. 2018). Moreover, previous or active ED diagnoses during pregnancy are associated with several risk factors for the offspring, including wheezing, low birth weight (double risk), prematurity (70% higher), smaller head circumference, microcephaly, small for gestational age (SGA) (80% increase), and a shorter breastfeeding duration (Sollid et al. 2004; Koubaa et al. 2005; Linna et al. 2013; Popovic et al. 2018). Many mothers return to their prepregnancy eating behaviors and thoughts during the postnatal period (Fogarty et al. 2018).

Gestational AN

AN is a complex situation, often encountered among pregnant women (Dinas et al. 2008). Women with underlying AN tend to report negative attitudes toward pregnancy (Easter et al. 2011). Those who achieve conception face a greater burden of miscarriages, cesarean deliveries, prematurity, infant wheezing, and low birth weight (Bulik et al. 1999; Popovic et al. 2018). Moreover, the offspring of women with AN exhibit an even lower birth weight when the mothers have a history of BN (Bulik et al. 1999). These lower birth weights in the offspring of women with AN result from lower pregravid body mass index (BMI) (Micali et al. 2007).

On the other hand, recovery from AN, as indicated by body weight restoration, appears to normalize reproductive function, including fertility, pregnancy, and childbirth rates. According to a recent meta-analysis (Chaer et al. 2020), the pooled odds of childbirth rate between women recovered from AN and the general population was not different. Subsequently, the management of EDs in fertility clinics encompasses the full remission of the patient before any fertility treatment can be initiated (Norré et al. 2009).

Gestational BN

BN during gestation is associated with an approximately doubled risk of induced abortion compared with healthy women (Linna et al. 2013). Prospective studies of untreated, normal BW pregnant women with BN revealed that pregnancy progression induces a need to eat in a healthy way, tampering down bulimic symptoms (Lacey and Smith 1987; Morgan et al. 1999). Thus, with each ascending trimester of gestation, the frequency of binge eating and self-induced vomiting is sequentially reduced. By the last trimester, approximately 75% of the women cease any bulimic behavior, with the remaining 15% exhibiting a less severe disturbed eating pattern than the beginning of pregnancy. Interestingly, the existing literature agrees that BN

symptoms tend to relapse during the puerperium, with approximately 50% of the women exhibiting abnormal eating in a more disturbing severity postnatal than before conception (Lacey and Smith 1987; Morgan et al. 1999; Morrill and Nickols-Richardson 2001). Only one-third of women recover entirely after delivery (Morgan et al. 1999). Relapse is predicted by behavioral persistence, previous co-existence of AN ("type II" BN), unplanned pregnancies, and a diagnosis of gestational diabetes mellitus (Morgan et al. 1999).

Concerning fetal and obstetrical outcomes, BN is associated with a high incidence of fetal abnormality (cleft palate, cleft lip) and congenital malformations, low birth weight, prematurity, increased risk for wheezing, low Apgar scores, and delivery complications, including breech presentation and need for surgical intervention (Lacey and Smith 1987; Morrill and Nickols-Richardson 2001; Popovic et al. 2018). Maternal postnatal depression is also high, particularly among those with BN and AN, alcohol misuse, and increased symptom severity and persistence (Morgan et al. 1999).

Binge Eating Disorder (BED) in Pregnancy

BED diagnosis during pregnancy affects birth outcomes directly or indirectly via maternal body weight and GWG (Bulik et al. 2009; Nunes et al. 2012). BED during pregnancy is associated with disturbed sleep patterns (Ulman et al. 2012), possibly due to the night-eating syndrome. Compared with healthy controls, pregnant women with BED have an approximately triple risk for miscarriage, complicating the conception process (Linna et al. 2013). Concerning pregnancy outcomes, pregnant women with BED tend to give birth to babies with high birth weight, low risk of SGA babies, and a higher risk for large-for-gestational-age (LGA) babies and cesarean section (Bulik et al. 2009; Linna et al. 2014).

Pica in Pregnancy

Pica is the continued consumption of nonnutritive substances that are considered inappropriate according to the developmental level and do not consist of a culturally supported or socially normative practice (Mishori and McHale 2014). This behavior must have a duration of 1 month at least.

The most common nonfood items reported during pica bouts include soap (including laundry detergent), pagophagia (ice and freezer frost), geophagy (earth, soil, dirt, clay, chalk), amylophagy (raw starch), or other substances (Horner et al. 1991; Young et al. 2010; Young 2010; Ezzeddin et al. 2015; Epler et al. 2017). Proposed etiologies of pica include cultural expectations, maternal psychological stress, increased appetite and hunger, micronutrient deficiencies (in particular Fe), dyspepsia, and protection against toxins and pathogens (Young 2010). Depending on the region studied, the prevalence of pica among pregnant women varies between 8.3% (Ezzeddin et al. 2015) and a greater prevalence among less industrialized

countries. Other researchers suggest an overall prevalence of 20%, which manages to go undetected by health-care professionals (Horner et al. 1991). The prevalence of pica appeared on the treadmill during the World War period, demonstrating a decline after that (Horner et al. 1991).

Research has associated pica practices during gestation to low maternal educational attainment, African-American or non-Caucasian background, childhood or family history of pica, living in rural areas, experiencing unwanted pregnancies and pregnancy complications, and experiencing food insecurity, with low levels of economic satisfaction, while receiving iron supplementation during pregnancy (Horner et al. 1991; Ezzeddin et al. 2015; Roy et al. 2018).

The research appears unanimous that pica is associated with iron deficiency anemia (IDA) or low iron scores (Young et al. 2010; Young 2010; Epler et al. 2017), although it is not known which one (pica or IDA) is preceding the other. Pica practices have been associated with high concentrations of the transferrin receptor (TfR) (Roy et al. 2018) and hemoglobin levels (Young et al. 2010). The condition usually represents itself with esophagitis, gastritis, gastrointestinal distress, nausea, abdominal pain, and IDA (Young et al. 2010; Epler et al. 2017), and, if undiagnosed, it can often lead to maternal and perinatal mortality (Horner et al. 1991). A parenteral iron infusion may result in the resolution of all cravings acutely (within hours), suggesting that possibly IDA or low iron stores are triggering the cravings (Epler et al. 2017).

Pregorexia

Orthorexia nervosa (ON), an unhealthy obsession for healthy eating (Bratman and Knight 2000), is often encountered during gestation, under the term "pregorexia." In a Turkish study (Taştekin Ouyaba and Çiçekoğlu Öztürk 2021), high levels of nutritional information and motivation were associated with a healthy eating obsession, propelling ON tendencies in a pursuit for improved health outcomes. Despite the limited evidence, approximately 26.6% of pregnant women demonstrate ON tendencies (Taştekin Ouyaba and Çiçekoğlu Öztürk 2021). However, the lack of a consensus regarding the diagnosis and the subsequent lack of diagnostic tools according to the diagnostic criteria result in a wide variation in this prevalence. Moreover, some OFSED, like ON, merit further investigation during pregnancy.

Bottlenecks for the Management of EDs and OFSED Before Fertility Treatment and During Gestation

Although research unanimously propagates the need for early screening to detect disturbed eating behaviors, this is rarely the case in clinical practice (Morrill and Nickols-Richardson 2001). According to Palaskis and de Zwaan (2019), clinical algorithms for the management of EDs for gynecologists and fertility specialists are practically inexistent. Moreover, the care of women with EDs who become pregnant

requires coordination between various health professionals. The latter must attain a high level of understanding of the complex pathophysiology of EDs/OFSED, including these patients' psychological and physiological characteristics (Burke and Vangellow 1990). Treatment must be multidisciplinary, emphasizing adequate energy and nutrient intakes and appropriate GWG, all aiming to achieve improved pregnancy outcomes (Morrill and Nickols-Richardson 2001). Pregnancy can be seen as an opportunity for intervention, acceptance of body image changes, and developing long-term healthy eating habits (Morrill and Nickols-Richardson 2001; Fogarty et al. 2018). Finally, postnatal treatment interventions should primarily focus on avoiding relapse and diagnosis and managing postnatal depression (Morgan et al. 1999).

Application to Other EDs

This chapter reviewed the literature regarding complications of EDs in pregnant women. Pregnant women suffering from EDs have co-morbidities such as depression, anxiety, and increased concerns about weight gain (Martínez-Olcina et al. 2020). The most common EDs are AN, BN, and BED. However, other less common disorders can occur during pregnancy. Unspecified or other specified feeding and eating disorders (U/OSFED) are often mental disorders in pregnant women. Obsessions with healthy eating, which can reveal ON in the general population, can occur in pregnant women as "pregorexia." These obsessive tendencies might afflict as many as 25% of pregnant women (Taştekin Ouyaba and Çiçekoğlu Öztürk 2021). However, the lack of proper screening should be considered in evaluating their prevalence. Furthermore, consuming substances other than foods (pica) might afflict 20% of pregnant women. Pica has been associated with iron deficiency, and iron infusion might resolve abnormal cravings (Epler et al. 2017). In addition, the prevalence of night eating in pregnant women ranges from 15% to 45%, and the potentially disturbing circadian rhythms might affect the metabolic outcomes (Loy et al. 2020). Night-eating syndrome has been associated psychologically with depressed mood and sleep disturbances and metabolically with higher insulin and lower high-density lipoprotein (HDL) concentrations and insulin resistance (Allison et al. 2012; Deniz et al. 2019).

Mini-dictionary of Terms

- **Binge eating disorder**: A DMS-5 disorder in which recurrent episodes of binge eating occur. During these episodes, the individual might rapidly consume its foods and in larger-than-usual proportions.
- **Orthorexia nervosa**: Often encountered during gestation and is also known as "pregorexia" and is characterized by an obsession to follow a healthy diet. It is not classified in the DSM-5.

- **Other specified feeding or eating disorders**: In the Diagnostic and Statistical Manual of Mental Disorders Version 5 (DSM-5), this category includes eating and feeding disorders not meeting the diagnostic criteria of other classified disorders, and the clinician communicates a reason for this. Along with the unspecified feeding or eating disorders, it replaced the category of EDs not otherwise specified.
- **Pica**: A DSM-5 disorder characterized by consuming substances other than foods such as soap, ice, and soil.
- **Small for gestational age**: Infants weighing at birth lower than the tenth percentile for their gestational age.
- **Unspecified feeding or eating disorder**: A disorder not falling under any other DSM-5 category.

Key Facts of EDs During Pregnancy

- Mechanisms for developing EDs during pregnancy include concerns about GWG and the need to adopt a healthy diet.
- A previous diagnosis of an ED might lead to relapse during pregnancy; many women relapse to disordered behaviors or thoughts postpartum.
- Recovery from AN ameliorates reproductive complications and the childbirth rate.
- Postnatal depression is prevalent in mothers with anorexia or BN.
- Fetal complications of AN include wheezing, prematurity, small head circumference, and low birth weight.
- Fetal complications of BN include cleft lip and palate, congenital malformations, wheezing, low birth weight, and low Apgar scores.
- Pica might be associated with nutrient deficiencies; for iron deficiency, iron infusions result in ameliorating the cravings.

Summary Points

- EDs during pregnancy are accompanied by comorbidities such as depression, anxiety, binge eating, and increased concerns about weight gain.
- Complications affect both the mother and the child.
- In AN, low maternal pregravid body weight is associated with low offspring birth weight.
- Bulimic behaviors decrease during pregnancy but resurface after delivery.
- BED is associated with the delivery of heavy and large babies.
- ON and pica are apparent during pregnancy.
- Treatment of EDs should set appropriate weight goals, provide adequate nutrition, and deal with postpartum depression.

Eating Habits During Pregnancy

3

Irene Cetin, Chiara Bianchi, and Arianna Laoreti

Contents

Abstract

Nutrition and lifestyle during pregnancy and preconceptional period represent a major public health challenge, influencing the development of the embryo, fetus, and placenta, with considerable potential to influence not only maternal health but also that of future generations.

However, the risk of inadequate maternal nutrition is high both in underdeveloped and in industrialized countries, especially for selected groups of women of childbearing age: those following exclusion diets, women affected by eating disorders, underweight or overweight/obese, smokers, and adolescents.

These dietary inadequacies are due to complex sociocultural and economic interacting factors, and it is mandatory to incorporate in clinician's appointment brief nutrition discussions to propose simple and personalized multidisciplinary interventions.

Understanding the relationship between maternal nutrition, pregnancy, and birth outcomes may provide a basis for developing nutritional interventions that will improve maternal well-being, birth outcomes, and long-life health of the

Introduction

Pregnancy and infancy comprise the most critical stages for conditioning an individual's health, with a number of implications for subsequent risks of morbidity, mortality, and reproductive health.

Maternal nutrition is recognized as one of the major environmental factors influencing the development of the embryo, fetus, placenta, and maternal tissues. Poor maternal nutritional status and lifestyle, along with maternal body composition, metabolism, and placental nutrient supply, are the main factors that can negatively or positively influence fetal development, affecting the growth trajectory and immune system of the fetus and infant, and have been strictly related to adverse pregnancy outcome and expression of fetal genetic potential.

Understanding the link between maternal nutrition and birth outcomes may provide a basis for developing nutritional interventions and optimizing the "window of opportunity" offered by pregnancy to improve long-term maternal and infant health.

Role of Maternal Anthropometrics and Nutrition on Short- and Long-Term Outcomes

Pregnancy, from conception to birth, is a period when women undergo important metabolic and physiological changes.

According to the "Developmental Origin of Health and Disease" or "Early Metabolic Programming" paradigm, environmental factors including nutrition during pre- and postnatal phases of human development have a significant impact on health in adult life (Barker 2007; Koletzko 2014; Mandy and Nyirenda 2018; Farias et al. 2020). This has been the basis of increasing focus on "the first thousand days" of life – arbitrarily defined as the time between conception and the end of a child's second year – as a period of significant "development plasticity." During this period, phenotypic development is more susceptible to change in response to environmental factors (Koletzko et al. 2014; Lorite Mingot et al. 2017) (Fig. 1).

First of all, an adequate body mass index (BMI) is crucial even in the periconceptional period (Moshe et al. 2019; Adair and Adair 2014): a preconceptional BMI <18.5 kg/m^2 increases the risk of intrauterine growth restriction (IUGR), preterm birth, and iron deficiency anemia (Cetin et al. 2013), while a preconceptional

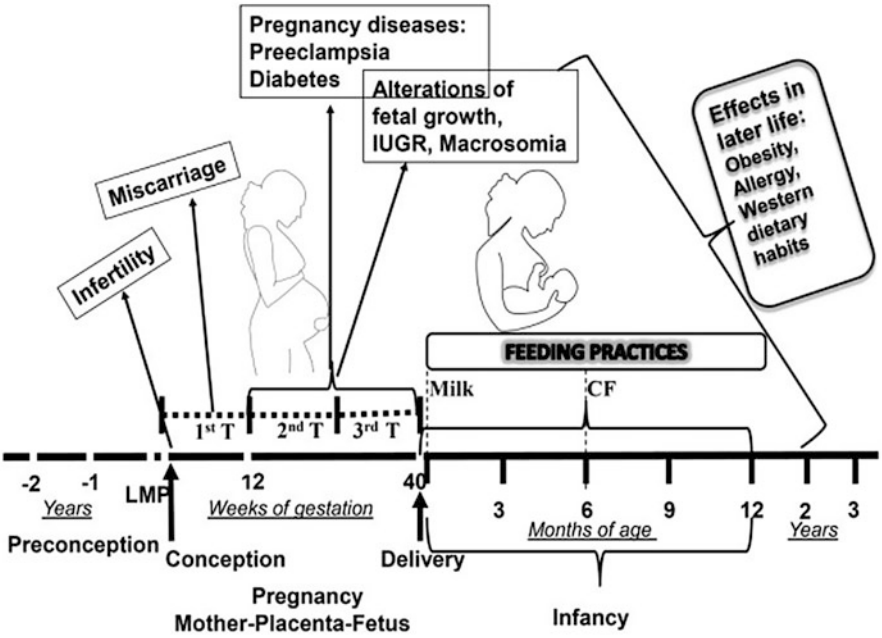

Fig. 1 Role of maternal nutrition on short- and long-term outcomes. The continuum of interplay between a woman of reproductive age, the nutritional environment, and the offspring's lifelong health from conception, through pregnancy, until the cessation of breastfeeding. (Country of Berti et al. 2017)

BMI >25 kg/m^2, and especially obesity, increases the risk of infertility, hypertensive disorders of pregnancy, gestational diabetes mellitus (GDM), structural anomalies, large-for-gestational-age infants or IUGR, preterm birth, fetal and neonatal death, caesarean delivery, and non-communicable diseases in offspring, including obesity, metabolic syndrome, cardiovascular disease, and type 2 diabetes mellitus (Samuels-Kalow et al. 2007; Chu et al. 2007; Delhaes et al. 2018; Black et al. 2013; McDonald et al. 2010; Kristensen et al. 2005; Reynolds et al. 2013).

Moreover, during pregnancy, it is mandatory to obtain an adequate gestational weight gain (GWG) (IOM 1990): a lower GWG is associated with decreased birth weight and failure to initiate breastfeeding, while an excessive GWG is associated with increased birth weight, caesarean delivery rate, and postpartum weight retention. In addition, excessive GWG is associated with subsequent obesity and long-term comorbidity, with the odds of overweight in offspring at age of 7 years old increased by 3% for every 1 kg of gestational weight gain (Tanentsapf et al. 2011; Siega-Riz et al. 2009).

Several studies have demonstrated that imbalances in both macronutrient and micronutrient intakes may affect pregnancy and birth outcomes.

Negative effects in terms of weight and length of the newborn at birth could be associated with insufficient protein, folate, iron, and vitamin D intake

(Blumfield et al. 2012a; Prentice 2011; Parisi et al. 2017a; Peña-Rosas et al. 2015), while excessive weight of the newborn, insulin resistance, glucose intolerance, and inadequate weight control are associated with an excessive amount of high glycemic index carbohydrates (Walsh et al. 2012, 2014).

The risk of stillbirth and fetal growth restriction could be associated with inadequate protein or vitamin D or folate intake (Ota et al. 2012; Ji et al. 2019; Mirzakhani et al. 2016), while the risk of preterm birth could be associated with inadequate protein intake or with low n-3 PUFA or iron intake (Middleton et al. 2018).

Fetal brain and retinal development are influenced by n-3 PUFAs: DHA is the major n-3 polyunsaturated fatty acid contained in the human brain and retinal rods and, thus, is essential for brain and retinal development of the fetus during pregnancy, and it plays a major role in the psychomotor neurodevelopment also in the first months of life (Koletzko et al. 2011; Massari et al. 2020a).

Iodine intake is critical for maternal and fetal thyroid function and fetal neurological development, leading, in case of maternal untreated hypothyroidism, to "iodine deficiency disorders" (abortion, congenital anomalies, deafness, neurological cretinism, neurocognitive delay, mental retardation, as well as attention-deficit/hyperactivity disorders) (Trumpff et al. 2015).

It has been recently demonstrated that periconceptional folate intake and status significantly correlate with embryo growth (Parisi et al. 2017), birth weight, and adverse pregnancy outcomes; folate inadequate intake can cause megaloblastic anemia, leukopenia and thrombocytopenia, and hyperhomocysteinemia and can increase the risk in the offspring of neural tube defects, congenital heart disease, and placental vascular disorders (de Regil et al. 2015; Fekete et al. 2012; Burdge and Lillycrop 2012).

In addition, it is demonstrated that low calcium or vitamin D intake, especially when a deficient status coexists, increases the risk of developing hypertensive disorders of pregnancy (WHO 2013; Hofmeyr et al. 2014; Robinson et al. 2010).

With regard to long-term outcomes, nutrients are involved in enzymes, signal transduction, transcription pathways, oxidative stress, and epigenetic modifications, since the periconceptional period (Cetin et al. 2009). Macro- and micronutrients affect the availability of methyl donors, substrates, and transcription factors which are direct regulators of DNA stability and gene expression. By this mechanism, nutrients are able to influence the complex biological pathways involved in gametogenesis, in embryogenesis, as well as in placental and fetal growth, permanently modulating gene expression and altering developmentally plastic systems, with implications in terms of predisposing or not the fetus to noncommunicable diseases (NCDs) in later life by influencing physiological thresholds of energy balance regulation. This is of fundamental importance considering that NCDs, including obesity, metabolic syndrome, cardiovascular disease, and type 2 diabetes mellitus, represent the leading causes of illness and mortality in the world.

Current Maternal Nutrition Is Inadequate Even in Industrialized Countries

The caloric requirements for healthy, normal weight women with a moderately active lifestyle undergo a moderate increase during pregnancy (dependent on pregnancy stage), which can be met by slightly increasing energy intakes, in a balanced equilibrium between macronutrients within the recommendations of nutritional guidelines (proteins (10–35%), carbohydrates (45–60%), and fats (20–35%)). On the other side, micronutrient requirements increase more than those of macronutrients during pregnancy, and inadequate intakes (and, thus, a low nutritional quality of the diet) can have significant consequences for both the mother and the developing fetus (Marangoni et al. 2016).

Good nutrition is defined as a well-balanced diet that provides all essential nutrients in optimal amounts and proportions, whereas malnutrition is the state produced by an inadequate intake of a good-quality diet, and this can refer to an inadequate intake of macronutrients such as calories and protein (i.e., undernutrition), to an inadequate intake or increased losses of specific or multiple vitamins and minerals (i.e., micronutrient malnutrition) because of an unbalanced diet or to an intake of too many macronutrients (i.e., overnutrition), or to an excessive amounts of inappropriate substances (i.e., alcoholism) (Cetin et al. 2009).

Nutritional deficiencies often coexist among women of reproductive age in low- and middle-income countries, and they are exacerbated in pregnancy due to these increased demands of the developing fetus. Despite the availability of economic and nutritional resources, most women fail to meet the right energy, macronutrient, and micronutrient needs also in industrialized countries, where dietary patterns, typified by fast foods, snacking, breakfast skipping, soft drinks, and energy-dense convenience foods rich in sugars and oils, are nutritionally unbalanced (Parisi et al. 2014).

A large meta-analysis by Blumfield, comparing the dietary intakes of pregnant women with the adult national dietary guidelines in each respective country or geographical region, showed that food intakes among pregnant women in developed countries (the United States/Canada, the United Kingdom, Europe, Australia/NZ, Japan) did not meet national dietary intake recommendations for folate, iron, or vitamin D, while calcium intakes in Japan were lower than those in other developed regions and were below Japanese recommendations (Blumfield et al. 2013). In addition, energy and macronutrient recommendations did not match with reported intakes of pregnant women: energy and fiber intakes were consistently lower than recommendations, total fat and saturated fat intakes were generally above recommendations, and carbohydrate and PUFA intakes were either lower or borderline low compared to recommendations (Blumfield et al. 2012).

Among the deficient micronutrients, iron, iodine, folate, zinc, and vitamin A are the most widespread since they commonly contribute to growth, and in their absence, perinatal complications, intellectual disorders, and increased risk of morbidity-mortality are observed (Bailey et al. 2015).

A recent Cochrane review suggests a positive impact of multiple micronutrient supplementation with iron and folic acid on several birth outcomes, such as preterm births, low birth weight, and small for gestational age (Keats et al. 2019).

Evidence suggests that optimal mineral supplementation can significantly reduce a wide range of pregnancy complications (including anemia, gestational hypertension, gestational diabetes, hyperthyroidism, miscarriage, and preeclampsia) and infant health problems (including anemia, asthma/wheeze, autism, cerebral palsy, hypothyroidism, intellectual disability, low birth weight, neural tube defects, preterm birth, and rickets) (Adams et al. 2021).

Single micronutrient and vitamin supplementation also show improvements for specific outcomes, such as calcium on the risk of preeclampsia/eclampsia, iron on maternal anemia, vitamin D on preterm births, and vitamin A on serum/plasma retinol concentration in mothers (Oh et al. 2020). These findings highlight that micronutrient-specific supplementation should be tailored to specific groups or needs for maximum benefit.

Dietary Patterns and Feto-maternal Outcomes

When evaluating maternal diet and associated outcomes, it is clear that identifying the potential influence of single substances is often difficult. Therefore, the use of dietary patterns, a measure of overall dietary behavior, has become widespread in nutrition research in recent years as an alternative approach to studying individual components of the diet.

Dietary patterns are population specific, since they are influenced by sociocultural factors and food availability, but strictly related to adverse pregnancy outcome and expression of fetal genetic potential (Cetin and Laoreti 2015).

A predominantly "Mediterranean" dietary pattern characterized by joint intakes of fruit, vegetables, vegetable oil, alcohol, fish, legumes, and cereals and low intakes of potatoes and sweets has been associated with a decreased risk of spina bifida in the offspring, with higher levels of serum folate and serum vitamin B12 and lower plasma homocysteine (Vujkovic et al. 2009), and in general, fetus from women with a "prudent dietary pattern" were at lower risk of neural tube defects (NTDs) and some heart defects (Sotres-Alvarez et al. 2013). In addition, a low adherence to the Mediterranean diet has been associated with several adverse outcomes, both in pregnancy (e.g., birth defects, gestational diabetes mellitus, hypertensive disorders, preterm birth) and childhood (e.g., atopy, cardiovascular risk profile, body composition) (Amati et al. 2019; Raghavan et al. 2019; Timmermans et al. 2012; Karamanos et al. 2014; Zhang et al. 2019; Castro-Rodriguez et al. 2010; Garcia-Marcos et al. 2013; Schoenaker et al. 2015). Even in the preconceptional period, the Mediterranean diet has been demonstrated to contribute to enhanced fertility in couples seeking to conceive (Toledo et al. 2011; Vujkovic et al. 2010; Salas-Huetos et al. 2017): most reproductive failures originate during the periconceptional period and may be influenced by the lifestyle of the parents-to-be. In particular, inadequate

pre-pregnancy diets may impact the overall reproductive and/or pregnancy cycle (Steegers-Theunissen et al. 2013).

Lately, maternal dietary patterns have been associated with embryonic growth and congenital anomalies: a recent study conducted on Rotterdam cohort showed that the "high fish and olive oil and low meat" and the "high vegetables, fruit and grain" dietary pattern were associated with accelerated embryonic development in spontaneously conceived pregnancies (Parisi et al. 2018; Parisi et al. 2017).

Data derived from the MoBa cohort (Norwegian Mother and Child Cohort Study) demonstrated that women with high scores on a pattern characterized by high intake of vegetables, plant foods, and vegetable oils were at decreased risk of preeclampsia, whereas a dietary pattern characterized by high consumption of processed meat, sweet drinks, and salty snacks increased the risk of hypertensive disorders of pregnancy (Meltzer et al. 2011; Brantsaeter et al. 2009; Torjusen et al. 2014).

Several authors showed that great adherence to the New Nordic Diet, based on consumption of Nordic fruits, root vegetables, potatoes, salad, onion, garlic, whole-grain cereals, fiber-rich bread, wild fish, milk, and water, was associated with a lower risk of developing preeclampsia and spontaneous preterm delivery among nulliparous women (Hillesund et al. 2014; Englund-Ögge et al. 2014). Similarly, a study from the DNBC (Danish National Birth Cohort) reported that Western-type diet, high in meat and fats and low in fruits and vegetables, is associated with increased odds of induced preterm birth (Rasmussen et al. 2014).

Data from the Nurses' Health Study II showed that a high consumption of red and processed meat was also positively associated with the risk of GDM, contrary to a prudent dietary pattern high in fruit, green vegetables, fish, and protein and fat from vegetable food sources (Zhang et al. 2006; Bao et al. 2014).

In addition, many studies have also specifically evaluated the importance of fish consumption during pregnancy. Fish is of particular importance for the content in long-chain ω-3 fatty acids like DHA. Dietary intake of ω-3 FAs during pregnancy and lactation has biologically important effects on gestational length and the risk of preterm delivery and may have an effect on other pregnancy outcomes such as fetal growth, preeclampsia, and postpartum depression. Similarly, DHA supply to the fetus and the neonate is associated with beneficial effects on later cognitive development and visual function (Leventakou et al. 2014; Cetin and Koletzko 2008; Koletzko and Cetin 2007). For these reasons, women of reproductive age should achieve an average dietary intake of DHA at least 200 mg/day (Massari et al. 2020). However, due to potential presence of contaminants such as mercury and dioxins, the advice is to eat fish on average 2 times per week avoiding fish with higher contaminant levels such as tuna and swordfish.

Studies conducted in different population from Mexico and Brazil to Europe, Japan, and New Zealand found a positive association between dietary pattern and birth weight, with a decreased rate of small-for-gestational-age (SGA) infant and fetal growth restriction in healthy diet (Saunders et al. 2014; Colon-Ramos et al. 2015; Wolff and Wolff 1995; Okubo et al. 2012; Thompson et al. 2010; Coelho et al. 2015).

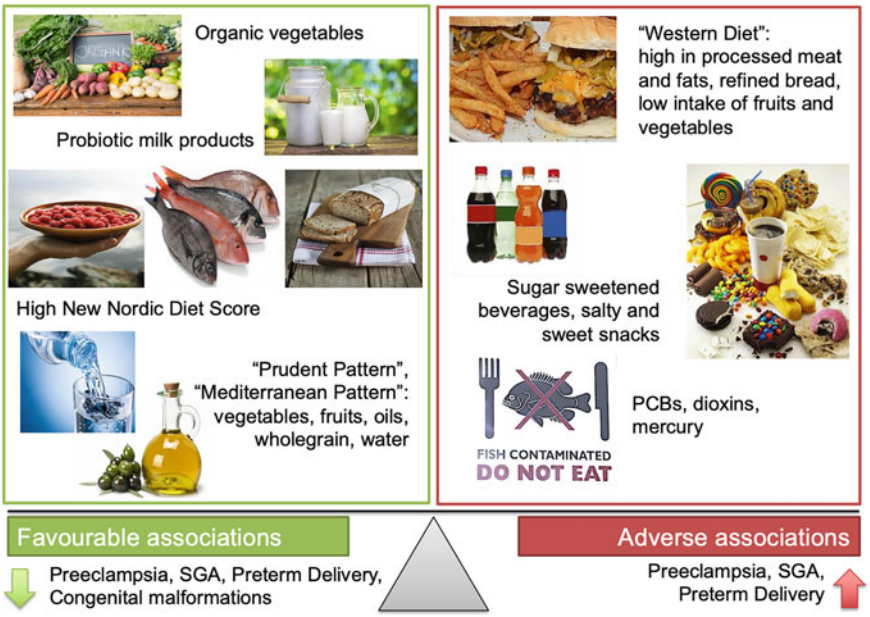

Fig. 2 Maternal dietary patterns and pregnancy and infant outcomes. Matenal dietary patterns of cohorts' population studies and associated pregnancy and infant outcomes. (Adapted from Cetin and Laoreti 2015)

Lastly, caffeine intake has been consistently associated with lower birth weight and higher odds of small-for-gestational-age offspring, not only when consumption exceeds the World Health Organization's recommendation (300 mg/die) but also when it exceeds the recommendation in Nordic countries and the United States (maximum 200 mg/die), which suggests a risk of small-for-gestational-age infants even at very low intakes of caffeine (Sengpiel et al. 2013).

Figure 2 summarizes some of the main results for the investigated dietary patterns of cohorts' population studies.

Conclusion

In conclusion, evidence derived from studies clearly suggests that unhealthy maternal diet during the periconceptional period and throughout pregnancy significantly contributes to impaired pregnancy and offspring outcomes, influencing individual health even before birth, with long-life consequences.

Unfortunately, most women during reproductive age, as well as during pregnancy, fail to meet the right energy, macronutrient, and micronutrient needs also in

industrialized countries, where the recent drop in the adherence to dietary patterns with better micronutrient intakes (green leafy vegetables, fruits, whole-grain breads/cereals, oily fish, etc.) has been demonstrated to have a negative influence on pregnancy outcome and fetal development.

During pregnancy, women may be more motivated to make diet or lifestyle changes: pregnant women welcome diet-, weight-, and nutrition-related discussions and show desire for nutrition to be addressed as "part of the process" in antenatal care, considering diet as one of the factors that are in their control and that can help protect their health and that of the future child. Therefore, clinicians have the responsibility to incorporate brief nutrition and weight discussions as part of their standard appointment, proposing simple but personalized multidisciplinary interventions, and have the ability to improve the health of their patients and that of future generations.

Mini-Dictionary of Terms

- **BMI:** Body mass index
- **GDM:** Gestational diabetes mellitus
- **IUGR:** Intrauterine growth restriction
- **GWG:** Gestational weight gain
- **PUFAs:** Polyunsaturated fatty acids
- **NCDs:** Non-communicable diseases
- **NTDs:** Neural tube defects
- **DHA:** Docosahexaenoic acid
- **SGA:** Small for gestational age

Summary Points

- Nutrition during pregnancy represents a major public health challenge, influencing the development of the embryo, fetus, and placenta and affecting not only women's health but also that of future generations.
- Healthy maternal nutrition, along with adequate body mass index (BMI), is crucial even already in the periconceptional period.
- The risk of dietary inadequacies is high both in underdeveloped and in industrialized countries, and it is due to complex sociocultural and economic interacting factors.
- It is mandatory for clinicians to incorporate in routine preconceptional and antenatal appointments brief nutrition discussions to recognize possible inappropriate habits or nutritional deficiencies and to propose simple and personalized multidisciplinary interventions, leading to healthful dietary practices prior to conception and eventually to tailored supplementation.

Stress and Disordered Eating Patterns

4

Fotini Tsofliou, Chloe Casey, and Christina Hughes

Contents

Abstract

This chapter provides a review of the relationship between stress and eating behavior, with emphasis on aspects of altered eating patterns in the presence of stress, and the physiological and psychological underpinning of this. This chapter does not focus on clinically diagnosed eating disorders; however, the eating behaviors discussed could be a precursor to their development. It encompasses the different forms of stress and explores the biological consequences such as endocrine and metabolic changes and increased inflammation and oxidative

stress. The social determinants of eating patterns are also discussed, such as socioeconomic status, culture, and environment. In contrast, the bidirectional effect of nutrition and stress is debated, providing recommendations for the intake of specific nutrients or adherence to dietary patterns that may reduce the physiological and psychological consequences of stress. Individual differences and the two-way relationship of stress on food intake are also explored, outlining how some individuals increase their energy intake, while others reduce their consumption. Finally, the chapter recommends how an individual can be encouraged to cope with stress in more adaptive ways.

RA	Receptor antagonist
SCFA	Short-chain fatty acids
SNS	Sympathetic nervous system
TNF	Tumor necrosis factor
VTA	Ventral tegmental area

Introduction

The experience of stress has always been part of life in mankind, and in prehistoric times our progenitors relied on the adaptive response to stress, known as the "fight-or-flight" pattern, in order to escape a dangerous life-threatening situation, defend themselves from a predator, and survive in harsh environmental conditions (Price 2003). But high stress levels can damage health when they become chronic and are not resolved. In this case, increased stress has been associated with a broad range of adverse health outcomes such as cardiovascular disease, hypertension, stroke, obesity and related metabolic disorders, immune impairment, and mental illness (O'Connor et al. 2021). Most modern societies show a common problem: the concomitant experience of stress and ill health related to noncommunicable diseases such as diabetes, cardiovascular disease, and cancer. Recent stress prevalence statistics, from an online study undertaken in the United Kingdom on 4619 adults, found that 74% of participants were feeling stressed and unable to cope because of stress (Mental Health Foundation 2017). Predominately this is more common among younger individuals known as Generation Z (Gen Z) teens (ages 13–17) and Gen Z adults (ages 18–24) than all other generations. In the United States, a recent stress survey among 3409 adults highlighted a mental health crisis. The reported stress levels were significantly elevated in young adults (Gen Z), and declining mental health affected all Americans broadly (*American Psychological Association* 2020). Recent research suggests that stress is a key element in developing mental health problems such as depression and anxiety if people are not coping with stress well and are unaware of management approaches.

People's mental health deteriorated during the coronavirus pandemic worldwide, and evidence showed that there was a concurrent increase in obesity, consumption of unhealthy diet, and physical inactivity (Melamed et al. 2022). There are various self-management approaches that people can use to moderate stress and the risk of stress-related mental illness efficiently. Lifestyle strategies are of primary importance and can include healthy eating, physical activity, and enough sleep (Firth et al. 2019). Eating a healthy, high-quality diet is becoming increasingly significant for mental well-being, and evidence-based recommendations have strongly advocated the role of high-quality eating patterns for reducing stress and low mood (Sarris et al. 2015). The present chapter will aim to provide a review of the evidence regarding the relationship between stress and eating behavior, with emphasis on aspects of altered eating patterns in the presence of stress.

Stress Responses

In 1950, Hans Selye (1950) published an influential manuscript and critically stated that "anything that causes stress endangers life, unless it is met by adequate adaptive responses; conversely, anything that endangers life causes stress and adaptive responses. Adaptability and resistance to stress are fundamental prerequisites for life, and every vital organ and function participates in them." It means that there are

adaptive intelligent responses which help people to deal and balance stress so that they can function and live a healthy everyday life. Stress can be caused by various situations which cause an emotional or physiological challenge. These can be broadly divided into environmental or psychological stressors.

There are three main forms of stress: acute and current, acute and episodic, or can be ongoing on daily basis and chronic. Acute stress can be caused by short-term event such as a threat to personal safety or getting involved in an interpersonal conflict (Yau and Potenza 2013). The acute episodic stressors are frequent brief events such as work deadlines, and the chronic stressors are experienced with job pressures, unemployment, family struggle, and mistreatment of physical or psychological nature (Torres and Nowson 2007). These stressors, particularly when they become prolonged and intense, will dampen the adaptive response to stress (stress-related homeostasis) and contribute to disease predisposition such as increased risk and delayed recovery of infectious conditions (Yau and Potenza 2013). It has been shown that chronic stress and mental illness can increase inflammation via biological pathways of automatic nervous system sympathetic activity, oxidative stress, transcription factor nuclear factor-κB activation, and pro-inflammatory cytokines (Kiecolt-Glaser 2010). This type of observations has triggered a vast scientific interest to explore further and get an insight into the relationship between stress, health, and well-being across the life span.

Physiology of Stress

Stress can disrupt the physiological homeostasis of our bodies and brains, ensuing activation of neural and endocrine mechanisms to re-establish homeostasis. This stress response is highly adaptive, with two primary interacting pathways: the autonomic nervous system (ANS) and the hypothalamic-pituitary-adrenal (HPA) axis. During periods of acute stress, the sympathetic branch of the ANS (known as the sympathetic nervous system (SNS)) is commonly activated. Signals are sent through the autonomic nerves to the adrenal glands, which responds by releasing catecholamine's epinephrine (adrenaline) and norepinephrine (noradrenaline) into the circulatory system. These hormones then circulate the body and bring on several physiological changes, such as increased heart rate, and adjust blood vessel diameters to redirect blood flow to the muscles, heart, and brain. The HPA axis, a group of hormone-secreting glands from the nervous and endocrine systems, stimulates the production of glucocorticoids (GCs) during times of stress. Corticotropin-releasing factor (CRF) is secreted from the paraventricular nucleus (PVN) of the hypothalamus, which in turn occupies receptors at the anterior pituitary, releasing adrenocorticotropic hormone (ACTH). ACTH triggers the production of GCs such as cortisol (or corticosterone in rodents) in the adrenal cortex. These GCs have numerous effects that help the body to deal with stress, primarily mobilizing energy by promoting gluconeogenesis in the liver. This increased supply of glucose, with the increased blood flow to the muscles due to SNS activation, aid survival. Together, the ANS and HPA axis interact to produce a state of preparedness, known as the

"fight-or-flight" reaction. Activities which conflict with this evolutionarily adaptive response to survive are typically inhibited. These include food intake, digestion, and reproduction. For instance, elevated levels of noradrenaline are known to result in reduction of appetite in obese patients (Lean and Finer 2006). Additionally, the physiological responses to acute stress such as slowed gastric emptying and inhibition of blood from gastrointestinal tract to muscles might be related to reduce food intake in the short term (O'Connor et al. 2021). Thus, explaining the stereotypical stress response of suppression of appetite and food intake.

Stress can therefore activate both physiological and behavioral responses which influence health outcomes; however, a stress-eating paradox emerges. As discussed, by producing a physiological response to homeostasis, there is a disruption of eating behavior in terms of inhibition, but this is counterintuitive given that increased eating is also associated with the stress (Torres and Nowson 2007). In humans, individual differences in food intake response are similarly noted, with stress leading to both under and overeating; this will be discussed further later in the chapter. Though the relationship between stress and eating behavior is complex, and little is known about what determines the direction of eating, physiological changes appear to be an underling mechanism. The HPA axis has shown to have a particular role in this relationship due to sharing the same neuroanatomy (structure and function of the nervous system) with the pathways that regulate food intake. Thus, each system can influence each other in stimulating a response.

Role of the HPA Axis and Glucocorticoids in Eating Behaviors

The HPA axis is an integrated system where GCs negatively feedback to the areas of the brain such as the hypothalamus and hippocampus, inhibiting the continued production. This effectively shuts down the stress response, thus keeping concentration stable and limiting the duration of GC exposure. GCs also act on the hypothalamus to stimulate appetite by interacting with several appetite regulators (Dallman et al. 2004). Therefore, a GC-mediated stimulation of eating behavior during stress recovery serves to replace the energy used when dealing with the stressful event (Sominsky and Spencer 2014). However, under conditions of chronic stress, where there is repeated or sustained activation of this physiological stress response, there are elevated basal and stress-evoked GC levels. Indeed, high circulating cortisol levels have been found in people who live with chronic stress. It is these high levels of GCs which have been linked to disordered eating behaviors, affecting the amount of food eaten, as well as the types of foods that are chosen, with heightened preference to hyperpalatable energy-dense foods.

In terms of increased appetite, GCs upregulate neuropeptide Y (NPY) and agouti-related peptide (AGRP) by increasing AMP-activated protein kinase (AMPK) signaling (Shimizu et al. 2008). These neuropeptides are considered orexigenic, stimulating appetite (Luo et al. 2011). The increase in GCs has been additionally implicated in dysregulation of appetite-related hormones such as leptin. While Leptin is known as an appetite suppressant which GC stimulates to be

released from adipose tissue; GCs also reduce the brain sensitivity to leptin, contributing to leptin resistance (Jéquier 2002). This therefore results in the converse effect by limiting appetite suppression. Furthermore, the loss of leptin signaling increases the expression of NPY and AGRP. This disruption in the balance between leptin and NPY, enhancing the activity of the latter, increases appetite and food intake especially in overweight and obese people (Björntorp 2001).

Additionally, GCs also influence the insulin, a metabolic hormone which acts at the hypothalamus by inhibiting orexigenic and exciting anorexigenic neurons. While at acute levels GCs stimulate insulin secretion from the pancreas (Strack et al. 1995), and therefore have an appetite-suppressant effect, during chronically activated levels, GCs have been shown to exert diabetogenic effects by interfering with number of mechanisms leading to GC-mediated insulin resistance. Namely, GCs promote proteolysis, lipolysis, free fatty acid production, and in the liver increased steatosis (Ferris and Kahn 2012). Much like leptin, GCs therefore have an intermediate role between insulin sensitivity and increased appetite by contributing to a reduced ability of insulin to inhibit NPY and AGRP. As a result, elevated stress-induced GCs lead to impaired sensitization of satiety signals.

GC relationship with insulin can also offer an explanation to the increase in preference for energy-dense palatable foods. Evidence from experimental animal studies shows that when given a choice, under stressed conditions rats prefer foods that are high in fat and sucrose, suggesting energy-dense food intake is relative to a corticosterone-insulin interaction (la Fleur et al. 2004; Warne et al. 2009). Corticosterone was shown to dependently provoke dose-related increases in total energy intake, while the food source choice the energy was derived from was influenced by insulin levels. Therefore, working both independently and interactively to regulate energy balance and intake. Humans similarly make stress-related changes in food choice to high fat and sugary foods (Oliver et al. 2000) even in the absence of hunger (Rutters et al. 2009). It is also suggested that the "hunger" hormone ghrelin potentiates the motivation for food reward and wanting for high-calorie foods which can be induced by stress (Liu 2015). There is some preliminary evidence to suggest that higher chronic stress, cortisol levels, and higher ghrelin levels were predictive of food cravings and weight gain over 6 months in overweight people. Future rigorous studies are needed that can measure concurrently stress hormones (catecholamines and cortisol), appetite-related hormones (ghrelin, leptin, insulin), and eating behavior in randomized controlled trials to elucidate the causal relationship of stress and eating behavior to fully understand their interactive role in obesity and related metabolic and mental illness. Furthermore, more research is needed to investigate whether diet-based interventions targeting reduction of stress and maintenance of normal cortisol response might be useful strategies in prevention of stress in high-risk groups in the community.

Overall, GCs have a significant influence on neurons and hormones in homeostatic regulation of hunger, chronic stress leading to increased appetite and an impaired capacity to inhibit eating. Additionally, chronic stress has been related to heighted preference for hyperpalatable, energy-dense foods, high in sugar and fat.

HPA Axis and Dopamine Reward Pathway

The mesolimbic dopaminergic system is a key component of reward processing, in which the neurotransmitter dopamine is used to communicate to the different regions in the brain involved in reward and pleasure. When exposed to or expect to receive a rewarding stimulus, dopamine neurons in the ventral tegmental area (VTA) are activated. These project to the nucleus accumbens (NAcc), amygdala, prefrontal cortex (PFC), and other forebrain regions. The NAcc is associated with motivation and reward, the amygdala with emotion, and the PFC with decision-making. The HPA axis has been linked to this system having direct and indirect effects on dopamine neurons, overriding the homeostatic regulation of appetite and food intake (Schellekens et al. 2012).

High GC levels, through administration of corticosterone in rats, significantly increased brain stimulation reward and positively correlated to dopamine transporters binding in the NAcc shell (Barr et al. 2000). A GC and dopamine interrelationship is also seen in humans where stress-induced cortisol levels proportionally enhanced dopamine release in the ventral striatum, which contains the NAcc (Wand et al. 2007). Activation of dopamine neurons in this region associated with motivation and "wanting" has been implicated in behavioral guidance toward natural rewards, such as food and water (Ikemoto and Wise 2004), and is believed to be similar, if not identical, to drug rewards (Carelli 2002).

GCs exert their effects via binding to two types of receptors: mineralocorticoid receptors (MR) and glucocorticoid receptors (GR). MR has a high affinity for GCs and is nearly fully occupied, whereas GR has a lower affinity for GCs and so is occupied when GC concentrations are high, such as after stress. The interaction between GCs and dopamine is suggested to be GR-dependent as administration of GR antagonists induced a drop in dopamine levels, whereas MR antagonists had no effect (Marinelli et al. 1998). This interconnectivity between the dopamine and stress suggests an important role for GC-activated GR in dopamine-related emotional behavior.

Energy regulators leptin and insulin (which are associated with the HPA axis as earlier discussed) can also target the dopamine neuron system due to their broad expression of receptors in several brain regions. This includes the VTA, a key structure in the reward processing pathway (Figlewicz et al. 2003), serving to mediate the effects of these hormones on reward-seeking behavior. Intraventricular insulin and leptin in rats were shown to decrease sucrose self-administration and reverse place preference conditioned with high-fat diet, suggesting a role in modulating reward-related feeding (Figlewicz et al. 2004, 2006). Thus, insulin and leptin influence the brain reward pathway, decreasing the rewarding effect of food through decreased dopamine output.

However, studies in rats show obesity reduces sensitivity to insulin through decreased adipose signals or resistance at receptor level (Ikeda et al. 1986), and therefore this decrease in the hedonic value of food discussed above is impaired. Additionally, evidence also shows that consumption of hyperpalatable foods may negate chronic stress-induced inhibition of dopamine release. This shows that the

hedonic and emotional aspects of feeding can affect food behaviors as well as the caloric and nutritional value of food.

Hedonics and Addictive Properties of Food

Alongside motivation to eat, stress-generated reward system sensitization can lead to excessive intake of hyperpalatable food. Research into food intake has shown there is a significant overlap with substance addictions on the reward center, with both pathways also driven by negative reinforcement. Stress, particularly uncontrollable stress, is a potent reinforcement type that promotes acquisition of drugs of abuse (Sinha 2008).

In regard to eating behavior, the consumption of high-fat, high-sugar diets and activity of the HPA axis have been shown to be influential on each other. Animal studies provide evidence that stressed rats with ad libitum access to calorically dense lard and sucrose displayed reduced ACTH responses compared to those with access to normal diet only (Pecoraro et al. 2004). This is described as "self-medication" with food. Additionally, in this 2 × 2 study, the same rats also increased the proportion of hyperpalatable foods consumed compared to their non-stressed controls. Similar reduction in chronic stress responses was found when increased plasma corticosterone, hypothalamic CRH, and reduced hippocampal GR expression were normalized after consuming palatable high-fat diets (Maniam and Morris 2010). Hyperpalatable foods also have the ability to activate the reward pathway through both the fast sensory inputs and post-ingestion consequences such as raising glucose concentration in the blood and brain as well as adiposity (Volkow and Wise 2005).

Moreover, addiction-like neuroadaptive responses in reward pathways have been observed. For example, rats showed a decreased dopamine release in the NAcc after deprivation following a high sucrose diet, in comparison to those on an unrestricted diet (Avena et al. 2008). Such neuroadaptations can lead to increased compulsive eating behaviors and drive to eat, with accumulating evidence that hyperpalatable food has properties that promote dependence. Animal studies have provided evidence that rats fed hyperpalatable, high-sugar, and high-fat diets developed patterns of increased consumption as well as withdrawal symptoms when returned to normal diet (Johnson and Kenny 2010; Avena and Hoebel 2003; Lutter and Nestler 2009). These food-seeking behaviors are also seen in humans. After a monotonous diet, cues of favorite foods produced greater activation of the hippocampus, insula, and caudate, three areas reported to be involved in drug craving (Pelchat et al. 2004).

An explanation for the seemingly "addictive" property of palatable food comes from evidence that it can cause a repeated increase in dopamine, similar to that of substance misuse, and endogenous opioid dependence (Rada et al. 2005; Colantuoni et al. 2002). Endogenous opioids terminate the HPA axis stress response as a defensive mechanism against its detrimental effects (Kreek and Koob 1998). In terms of opioid's impact on eating behaviors, rats injected with opioids responded by overeating, and in contrast, when injected with an opioid antagonist, rats suppressed overeating of hyperpalatable food (Kelley et al. 2000; Apfelbaum and

Mandenoff 1981). Thus, opioids and palatable food engage in a bidirectional relationship such as that palatable foods can sustain opioid release and opioid release can increase palatable food intake. Overall, with food shown to provide reward, and hyperpalatable foods offering short-term pleasure and negative reinforcement, it may motivate stress-related eating as a way to regulate stress responses.

Stress and Eating Patterns

Indirectly stress can lead to behavioral changes, and these include eating too much or eating unhealthily, starting or increasing drinking and smoking (Gonzalez and Miranda-Massari 2014). It is widely accepted that stress can change eating behavior and trigger irregular eating patterns; however, these associations are mainly relying on cross-sectional studies, and underpinning mechanism has not been fully unraveled. Additionally, the relationship between stress and eating behavior is not simple and has been described as bidirectional. Eating pattern is considered healthy when people consume regular meals and snacks of varied dietary composition which enables them to maintain healthy body mass over time and prevent diet-related chronic disease. Eating patterns and food choices are influenced by a variety of factors which relate to socioeconomic status, culture and environment, gender and age demographics, health literacy, education attainment, overweight and underweight status, and psychological stress. The relationship between stress/negative mood and eating behavior has been studied in dietary studies looking into behavior outcomes such as snacking, choices of specific foods, overall energy consumption and diet patterns/quality, and psychological stress outcomes such as perceived stress and perceived negative affect/mood (Khaled et al. 2020a).

In terms of the impact of stress on food consumption, whether stressed people will eat more than usual amount of food intake or undereat seems to depend on the stressor severity (acute vs. chronic). There seems to be a tendency for eating less as the severity of stressor is increasing in humans (Torres and Nowson 2007). There is some evidence from longitudinal and cross-sectional studies that chronic life stress will lead people to choose hyperpalatable and comfort foods such as take-away food and sweet, high-fat, and savory snacks. Sometimes the consumption of these energy-dense foods occurs in the absence of true homeostatic hunger; this is when stress can be linked with hedonic overeating and weight gain in the long term (Wardle et al. 2011). When the effect of stress on food consumption and selection of food is examined in artificial laboratory environment, evidence is still scarce, and the stress induced in artificial lab-setting has produced equivocal effects on eating behavior change, all of which will be discussed in depth later in this chapter.

The Impact of Eating Patterns on Stress and Mood

The therapeutic role of high-quality diets and healthy nutrients in management of stress and stress-related mental illness is an emerging area in the field of nutritional

psychiatry. Different national and international organizations (Mental Health Foundation 2017; Jacka et al. 2014) advocate that healthy dietary patterns, such as the Mediterranean diet (MD), which includes foods of anti-inflammatory (omega 3 long-chain fatty acids in fish), antioxidant (polyphenols in fruits, legumes, olive oil), and healthy gut microbiota properties (dietary fiber, fermented dairy), can exert metabolic and brain neuroendocrine benefits to preserve mental health (Firth et al. 2020a). The International Society for Nutritional Psychiatry Research has published a consensus report which states that lifestyle factors such as diet should be modifiable targets for management of stress and related comorbidities (Sarris et al. 2015). Importantly, diet modification can be a noninvasive and cost-effective prevention and treatment strategy for mental ill-health.

Our recent meta-analysis of epidemiological studies found an association between poor diet quality (i.e., high in saturated fat, sugar, and salt and low in fiber, fruit, and vegetables) and stress in women of childbearing age (Khaled et al. 2020a). We have also corroborated further these findings with new evidence. Our previous work highlighted that the more childbearing women adhered to a high-quality diet, i.e., MD, the less stressed they felt. Conversely, consumption of a Western-style diet (highly processed food and refined grains), common in childbearing-aged women, was associated with higher stress (Khaled et al. 2020b, 2021).

Compelling evidence suggests that psychological stress and low mood can be somewhat preventable through "whole diet" improvements, though very little is known about how a high-quality whole-food diet can influence stress and consequently mood; the molecular mechanisms involved are not fully understood (Firth et al. 2020b). A recent meta-analysis on healthy dietary indices demonstrated that good adherence to healthy diet patterns and in particular to a MD pattern seems to decrease the risk of depression ($N = 36{,}556$, OR = 0.67, 95% CI: 0.55–0.82, I2 = 33.1%), with low heterogeneity between studies (Lassale et al. 2018). A large cross-sectional study ($n = 1634$, aged 18–65 years, 68% females, from the Netherlands) has investigated whether this association can be attributed to some MD food components or to all MD food groups. When looking into food groups in isolation, they found that non-refined grains, vegetables, and to some extent moderate alcohol intake appeared to be related to lower depression and anxiety. A low-quality diet as a whole was linked to higher depression symptoms (Gibson-Smith et al. 2020). The findings of this study can be possibly relatable to other north European populations with comparable food consumption patterns. For instance, fish intake in the Netherlands is only 53 g/week, and the majority (75%) is white fish (Gibson-Smith et al. 2020), and in the United Kingdom, mean consumption of oily fish was equivalent to 56 g/week in adults (NDNS 2019; Public Health England 2022). This is deemed well below the recommended one portion (140 g) of oily fish per week in all age groups. A recent meta-analysis of randomized controlled trials demonstrated the efficacy of dietary interventions in improving low mood in nonclinical depression. These dietary interventions overall had comparable aims, i.e., to replace the consumption of junk foods (refined, processed, and high in fat, sugar, and salt foods) with consumption of healthier options such as vegetables and pulses, thus increasing

dietary quality overall (Firth et al. 2019). Several RCTs have started to also highlight the benefits of MD on reducing depressive symptoms on those with clinically diagnosed depression (Jacka et al. 2017; Parletta et al. 2017; Francis et al. 2019). The proposed mechanism appears to be complex but tends to implicate the interactional effects of anti-inflammatory and antioxidant foods and nutrients of a classical anti-inflammatory dietary pattern such as the MD (Marx et al. 2021).

The relationship between chronic low-grade inflammation and stress is widely reported, and high circulating levels of pro-inflammatory cytokines have been found in people with elevated stress or depressive symptoms compared to healthy counterparts (Dowlati et al. 2010). Pro-inflammatory cytokines, such as interleukin (IL)-1β, IL-1 receptor antagonist (RA), IL-6, tumor necrosis factor (TNF)-α, and interferon (IFN)-γ, are part of the innate immune response. Both acute and chronic stress can cause an inflammatory response, but the exposure to chronic stress in particular will challenge endocrine and immune function and cause pathophysiological abnormalities such as chronic low-grade inflammation. If this inflammation is sustained in the long term, then it might contribute to the progression to depression. Indeed, pro-inflammatory dietary patterns such a Western diets are associated with a significantly higher prevalence of depressive symptoms, even among those without diagnosed mental disorders (Firth et al. 2019).

The MD is suggested to have an optimum nutrient profile that can offer protection from pro-inflammation and inflammation (Simopoulos 2008) and thus might prevent progression to stress and related mental disorders. Vegetables and fruits, non-refined grains, pulses, nuts, and olive oil are high-quality sources of minerals, fiber, alpha-linolenic acid (i.e., 18:3 *n*-3 polyunsaturated fatty acids (PUFA)), oils and vitamins, and antioxidants. Some vitamins (e.g., folic acid), minerals (e.g., zinc), essential fatty acids (such as long-chain *n*-3 PUFA), and polyphenols which are found in abundant amounts in plant-based foods could act in synergy to offer antioxidant and anti-inflammatory benefits. Antioxidants such as polyphenols can downregulate reactive oxygen species (free radicals) and thus reduce oxidative stress, which was found to be increased in people with chronic metabolic disease and mental illness (Jiang et al. 2021).

The anti-inflammatory profile of a MD is importantly attributed to the moderate consumption of oily fish and almost ideal ratio of omega-6 (*n*-6) to omega-3 fatty (*n*-3) acids of 2:1 of the diet. Current Western diets are characterized by a ratio of around 15:1, reflecting lack of *n*-3 fatty acids and surplus amount of *n*-6 fatty acids (Simopoulos 2008). The *n*-3 and *n*-6 PUFAs compete for the same enzymes in similar metabolic pathways; therefore, a balanced dietary intake is important for metabolic health. Increased intake of dietary *n*-6 fatty acids from refined plant oils (corn and sunflower) will be metabolized to arachidonic acid (AA) and AA-derived *n*-6 eicosanoids which increase production of circulating pro-inflammatory cytokines. On the other hand, *n*-3 PUFAs from diets high in fish, fish oil, and walnuts can reduce the production of AA metabolic, pro-inflammatory products (Kiecolt-Glaser 2010). Epidemiological studies show that people who consume a healthy diet which has higher levels of *n*-3 PUFAs as well as lower *n*-6/*n*-3 ratios have lower pro-inflammatory cytokine production and greater mood compared to counterparts

with at-risk mental health (Berger et al. 2017; Zhang et al. 2020). Additionally, marine *n*-3 PUFAs can downregulate pro-inflammatory cytokines (e.g., TNF-α) at molecular level and reduce postprandial inflammation typical after consumption of high-fat meals, thus blunting the pro-inflammatory potential of the Western diet (Calder 2015). Interestingly, olive oil consumption, the main source of fat and monounsaturated fatty acids (MUFAs) in the MD, has been found to associate with greater mood state and suppression of cortisol secretion which might indicate potential role of olive oils on reducing stress in the short term. This observation requires further corroboration with rigorous evidence (Mitsukura et al. 2021).

The low glycemic load (GL) of a MD pattern might also contribute to maintenance of low stress levels. A low GL diet supports a steady regulation of glucose homeostasis compared to frequent and rapid changes in blood glucose levels seen in unhealthy dietary patterns, such as the Western diet. A diet-induced hypoglycemia will trigger the autonomic nervous systemic to secrete compensatory stress-related hormones (cortisol, catecholamines, glucagon). Western diets with high content of refined grains and sugars will tend to stimulate repeatedly this metabolic and hormonal profile, therefore generating a chronic stress response.

The gut microbiome and its relationship to stress and mood present a cutting-edge research area. There is growing evidence that acute and chronic psychosocial stress might disrupt the microbial diversity and composition of the gut microbiota and consequently increase the pro-inflammatory response, influencing physical and mental health (Hantsoo and Zemel 2021). The gut microbiome is largely modified by diet composition. The MD pattern is known to promote a healthy gut microbiota because of its high content in fermented dairy foods and plant-based dietary fibers. All these foods are natural probiotics and prebiotics and can "feed" the gut microbiota with healthy bacteria and stimulate the production of beneficial by-products (e.g., short-chain fatty acids (SCFAs), neurotransmitters). Serotonin is a neurotransmitter produced in the gut and is known to mediate healthy mood via the gut-brain-axis system (Marx et al. 2021). More research is needed in humans to investigate the role of gut microbiome as a key moderator in the association between stress and inflammation.

The causal relationship between dietary patterns and risk of stress is not fully elucidated. Nevertheless, health promotion approaches can aim to raise the public's awareness and knowledge about the mental health benefits of healthy eating patterns and the detrimental impact of unhealthy meals. In this way, individuals can be empowered to adopt themselves a healthy lifestyle as a self-management approach to mitigate the risk of stress and low mood.

Individual Differences and Disordered Eating

There has been much research demonstrating the two-way relationship of stress on food intake, with some individuals increasing energy intake and others reducing their consumption in reaction to stress. Several studies have identified that almost equal proportions of individuals increase their food intake than decrease their food

intake. However, other studies suggest different levels of under- or overeating in reaction to stress. This issue of individual differences has attracted much research attention.

Stress and Undereating

Back in 1915, a book by Walter Cannon (1915), *Bodily Changes in Pain, Huger, Fear and Rage*, introduced the concept of reduced dietary intake in reaction to perceived stress. When conducting animal studies as a medical student, he discovered that when cats were frightened or alarmed, their digestion slowed or halted. In contrast, when the cats were comforted, their gastrointestinal activity returned to normal. He began to identify the physiological responses of stress in animals, focusing on the reactions of the SNS, such as increases in heart rate, rapid breathing, and the elevation of glucose in the blood stream. It is widely understood that in humans this "fight-or-flight" biological stress response was useful in evading predators. In response to threat, the body halts digestion and appetite signals, reallocating energy to focus on fighting or fleeing. However, our bodies still respond to stress in this manner, even when there is no serious threat.

Researchers have investigated the underpinning of undereating in humans in reaction to stress. However, different studies suggest varying rates of undereating in response to stress. For example, some studies suggest that equal number of normal eating individuals tended to decrease their energy intake than increase their energy intake in reaction to stress. A key study by Oliver and Wardle (1999) indicated that 42% of individuals self-reported that they ate less than usual in comparison to 38% who reported that they eat more than usual during periods of stress. However, other research reports much higher prevalence rates, suggesting that up to 70% of individuals may experience reduced appetite (Krumbacher and Meyer 1963) and up to 55% may eat less in response to emotional stress (Popper et al. 1989). This also indicates that there are two mechanisms that may be affected in reaction to stress, the reduced motivation to eat and the behavior of reduced dietary intake, and that reduced appetite may not necessarily correlate with reduced calorie intake.

When comparing underweight individuals to normal weight and overweight groups, it has been reported that those who were underweight ate less than their counterparts in times of stress. However, the underweight individuals tended to eat more during positive emotional states in comparison to the other groups, but this did not compensate for the calorie deficit during stressful periods. Geliebter and Aversa (2003) summarized that undereating during stressful states may contribute to the low body weight of the underweight individuals. More recently, a study conducted in the United States investigated eating habits and stress in reaction to the COVID-19 pandemic (Khubchandani et al. 2020). They found that one in ten participants engaged in unhealthy eating practices during the early stages of the pandemic in 2020. Of the individuals who changed their eating behavior, 51% reported undereating in reaction to stress: engaging in skipping meals, restricted eating, or fasting. The individuals who reported these unhealthy eating habits due to the stress

of the pandemic reported significantly higher perceived stress levels, indicating a cyclic pattern.

Stress and Overeating

As explained, there is ample evidence that a proportion of individuals tend to undereat in reaction to stress. However, systematic review evidence supports the notion that emotions, including stress, consistently elicit increased food intake (Devonport et al. 2019). Some studies have reported that twice as many participants increased than reduced their food intake (Kandiah et al. 2008). Alternatively, other research demonstrates that acute stress results in decreased calorie intake, whereas chronic, long-term stress results in increased consumption. However, it is not just overall calorie intake that can change in reaction to stress; in addition, it has been demonstrated that people tend to choose different kinds of food too. As previously discussed, hyperpalatable foods are thought to induce pleasure and reward, even triggering addiction or compulsion (de Macedo et al. 2016).

Studies have also demonstrated increased preference for energy-dense foods and a shift toward consuming more "snack-type foods" in times of stress (Torres and Nowson 2007). Specifically, individuals display a preference for sweet, salty, or high-fat snack food (Adam and Epel 2007), namely, chocolate, crisps, and ice cream (Costarelli and Patsai 2012). In turn, individuals also tend to report a decrease in their consumption of "meal-type" foods, such as meat, vegetables, and fruit (Wansink et al. 2003). However, the reasons underlying these choices are not confirmed. It is unclear the extent to which the biological reward pathway is responsible for the increased consumption of snack-type foods, meaning individuals are attempting to regulate their stress through the consumption of these foods. Or, alternatively, individuals may simply opt for snack-type foods due to time constraints and convenience during stressful periods. It is also unclear whether this equates to higher overall calorie intake and therefore the likelihood of weight gain. This evidence indicates that food choice needs to be considered in addition to energy intake to understand the stress-eating behavior relationship, especially due to the known role these hyperpalatable foods may play in the development of obesity.

On the other hand, research that focuses on emotional eating supports the notion that "emotional eaters" do seek these hyperpalatable foods to manage their negative emotions. Emotional eating is a term used to explain how individuals attempt to regulate their emotions by increasing food intake (Macht 2008). Emotional eaters might engage in increased eating as a pleasuring activity that helps to distract from the negative feelings associated with stress, but it is thought to be explained by high-cortisol reactions to stress in emotional eaters (Epel et al. 2001). In addition, emotional eaters are more likely to consume more sweet and high-fat foods in response to stress in comparison to nonemotional eaters (Oliver et al. 2000). Emotional eaters also tend to report more intense cravings and higher consumption (Macht and Mueller 2007). Emotion-related eating is of interest to researchers due to its confirmed association with weight gain and the development of obesity

(Torres and Nowson 2007). Coping with stress through eating has been highlighted as a significant barrier to healthy eating (Bennett et al. 2013) and maintaining a healthy weight.

This tendency to overeat in times of stress appears to be particularly evident in individuals who are restrained eaters. Research defines restrained eaters as those who continually limit their overall calorie intake by dieting chronically to manage or maintain their body weight. Paradoxically, these restrained eaters tend to be overweight or obese due to sporadic episodes of overeating triggered by stress (Herhaus and Petrowski 2021). Much cognitive attention and demand is involved in maintaining this constant state of dieting, exerting constant control over one's eating behavior. In research where brain region activity was studied, weaker cognitive control and conflict monitoring has been identified in unsuccessful restrained eaters (Zhang et al. 2021). It is understood that successful restrained eaters tend to display very high levels of self-awareness, constantly evaluating themselves in comparison to perceived standards and expectations, and are often highly concerned about how they are viewed by others.

According to restraint theory (Polivy and Herman 1985), these restrained eaters consistently exhibit this counter-regulation behavior, meaning that they consistently eat little and avoid the urge to eat, but when they have a temporary lapse in control, this will trigger overeating. In comparison, non-dieters maintain normal regulation in these situations. Herman and Polivy have conducted much research into the behavior of restrained or restrictive eaters, finding that when calm, these individuals maintain their low dietary intake. However, when a disinhibitor disrupts their usual restraint, they release their suppressed eating and tend to overeat. A disinhibitor could be alcohol, depression, or stress; these factors distract them from their usual chronic restraint, diminishing impulse control. However, this was not always the case. One such example is an experiment conducted by Heatherton et al. (1993), where restrained eaters were asked to complete a puzzle. One group of restrained eaters who failed the puzzle was asked to evaluate their performance by watching a videotape of themselves failing the task. This group of restrained eaters did not experience disinhibited eating after the task as other groups did. The researchers surmised that this was due to maintaining their high level of self-awareness while watching the video feedback; therefore, they remained restrained in their eating behavior.

The research consensus is that overeating or binging when experiencing stress can be a paradoxical consequence of restrained eaters' constant attempts at restricting their calorie intake. Further research showed that when restrained eaters are stressed, they tend to overeat the foods that they normally avoid to maintain their body weight, such as high calorie, high fat, or sugar snack-type foods. Kandiah et al. (2008) confirmed that highly restrained eaters tend to choose significantly more types of sweet foods and beverages in times of stress than low-restrained eaters. Restrained eaters are also reported to experience intense guilt when giving into food cravings (Macht and Mueller 2007) and are said to be more punishment sensitive, engaging in behaviors to punish themselves to avoid undesirable outcomes, such as weight gain (Jonker et al. 2021). This indicates the

potential negative psychological consequences of a restrained eater's lapses of self-control and how this can consequently feed into a cycle of self-punishment and continual restrained eating.

Coping Strategies

How one chooses to deal with stress can be a major determinant of health outcomes. Prolonged overconsumption of unhealthy or "comfort foods" in times of stress may contribute to the development of obesity, and studies have found that they do not provide comfort beyond that of other foods or no food at all. On the other hand, it is important to consider the physical and mental health problems that one could face due to chronically decreasing food intake in times of stress. Coping mechanisms can be employed to reduce these irregular stress-eating patterns. Coping refers to the behaviors in which individuals engage in to manage, tolerate, reduce, or rectify stressors including emotion-focused strategies, problem-focused strategies, or avoidance behaviors. Emotion-focused methods of coping tend to focus on managing or relieving the emotional reaction to the stressor, whereas problem-focused strategies attempt to tackle the problem, including seeking instrumental support, planning, or inputting boundaries and time management. Avoidance coping encompasses activities individuals engage in to avoid dealing with the stressful situation itself. It is important to note that emotion and avoidance coping is not always disadvantageous. Avoidance is considered maladaptive as it does not tackle the stressor in question; however, it can be useful to temporarily relieve the negative emotions.

Coping is fundamental to understanding how individuals deal with stress and the long-term consequences this can have on physical and mental health, specifically in disordered eating. Review evidence suggests a mediating factor between stress and subsequent unhealthy eating behavior (over- or undereating) may be the individual's learned coping strategies (Ball and Lee 2000). It is well understood that those with eating pathology have more difficulty in managing stress and display maladaptive coping techniques, such as avoidance and rumination (Rawal et al. 2010). Recent research supports the link between repetitive negative thinking (also known as rumination) and eating problems in both clinical and nonclinical samples. Therefore, coping skills are an important component in the treatment of eating pathology (Vanderlinden et al. 2007). It is well established that more adaptive, problem-focused techniques can be learned and improved when individuals are provided resources to promote more effective coping responses. Such methods that might be useful in breaking the link between stress and unhealthy eating behaviors include mindfulness practice (Hernando et al. 2019) or therapy based on tackling rumination (Kaplan et al. 2018).

Applications to Other Eating Disorders

Previous research has shown that individuals with EDs have difficulties in self-regulating and coping with stress. In this chapter, we discussed potential psychological interventions to strengthen ways of coping with stress and mitigate the tendency to engage in unhealthy eating patterns, including mindfulness practice or therapy based on tackling rumination or maladaptive repetitive thought. Mindfulness has been widely implemented within research into the treatment and prevention of EDs. Systematic review evidence from Beccia et al. (2018) recommends mindfulness as an evidence-based strategy to reduce ED risk factors and increase protective factors, such as self-esteem. Several EDs have been associated with high levels of ruminative thoughts and preoccupation with body shape and weight. Therapy that addresses rumination has been proven an effective non-pharmacological intervention in other psychiatric disorders. Further research in larger clinical samples of eating disorder sufferers is required to fully understand the potential benefits of this type of psychological intervention.

Mini-Dictionary of Terms

- **Adrenocorticotropic hormone:** a polypeptide tropic hormone of HPA axis, which regulates cortisol production.
- **Agouti-related peptide:** an energy balance peptide, increasing food intake when stimulated.
- **AMP-activated protein kinase:** enzyme in cellular energy homeostasis which regulates diverse metabolic pathways in multiple peripheral tissues.
- **Autonomic nervous system:** it comprises two parts, the sympathetic and para-sympathetic nervous system, and controls involuntary physiological processes.
- **Catecholamine:** hormones released in response to physical or emotional stress consisting of dopamine, adrenaline, and noradrenaline.
- **Corticotropin-releasing factor:** a peptide hormone with several actions. In the HPA axis, it stimulates ACTH release.
- **Cytokines:** small proteins released from activated cells of the immune system influencing the nervous system activity, mediating and regulating immunity, inflammation, and hematopoiesis.
- **Eicosanoids:** the compounds derived from arachidonic acid or other polyunsaturated fatty acids of 20-carbon length.
- **Endocrine system:** network of glands that make hormones.
- **Glucocorticoids:** corticosteroids involved in metabolism with anti-inflammatory and immunosuppressive effects.
- **Hypothalamic-pituitary-adrenal axis:** the interaction between the hypothalamus, pituitary gland, and adrenal glands.
- **Mesolimbic dopaminergic system:** connects the VTA in the midbrain to the ventral striatum of the basal ganglia in the forebrain, the reward pathway.
- **Neuropeptide Y:** stimulates increased appetite and food intake.

- **Oxidative stress:** imbalance between the reactive oxygen species (free radicals) and antioxidant defenses.
- **Transcription factor nuclear factor-κB:** regulates genes responsible for both the innate and adaptive inflammatory and immune responses.

Key Facts

- Stress prevalence statistics show nearly three quarters of adults report feeling stressed, with elevated levels in young adults.
- Stress has been found to be a key element in developing adverse health outcomes, mental health problems, and behavioral change such as altered eating patterns.
- The "flight-of-sight" stress response is characterized by increases in heart rate, rapid breathing, blood glucose levels, and decreased digestion and appetite signals.
- Food intake response is similarly noted when stressed; 42% self-reporting eating less and 38% self-reporting eating more than usual.
- The relationship between stress and eating behavior is complex and bidirectional, although the physiological changes and type of stress appear to be underling mechanisms.
- When stressed there is heighted preference for hyperpalatable, energy-dense foods, high in sugar and fat, which have properties that promote dependence and neuroadaptive responses much like drug addictions.
- Pro-inflammatory dietary patterns can exacerbate symptoms, while anti-inflammatory dietary pattern such as the Mediterranean diet reduces stress.

Summary Points

- High stress levels can damage health when they become chronic and are not resolved.
- Glucocorticoids (GCs) stimulate eating during stress recovery to replace energy used during a stressful condition.
- High levels of GCs have been linked to disordered eating behaviors.
- High circulating levels of pro-inflammatory cytokines are found in people with elevated stress or stress-related mental illness.
- Mediterranean dietary pattern can offer optimum nutrient profile to protect from pro-inflammation and inflammation.
- Psychological stress and low mood could be preventable through "whole diet" improvements.

5 Gene Variants Involved in the Etiopathogenesis of Eating Disorders: Neuropeptides, Neurotransmitters, Hormones, and Their Receptors

Maria Rachele Ceccarini, Matteo Bertelli, Elisabetta Albi, Laura Dalla Ragione, and Tommaso Beccari

Contents

Abstract

Eating disorders have a deep social, mental, and physical impact and multifactorial origins, but the strong genetic component is universally corroborated. Genetic factors account for approximately 56–84% of liability to anorexia nervosa, 28–83% of liability to bulimia nervosa, and 41–57% to binge eating disorder.

V. B. Patel, V. R. Preedy (eds.), *Eating Disorders*,
https://doi.org/10.1007/978-3-031-16691-4_6

Twins studies have provided an irrefutable proof on the heritability of these disorders. Other types of genetic studies in human and in animal models followed, including single nucleotide polymorphisms association studies, genome-wide association studies, whole genome sequencing, and linkage analysis, which allowed to delineate the etiology of eating disorders and to identify the genes and their variants associated with the pathologies. In this scenario, Next Generation Sequencing technologies can be considered as an ideal diagnostic approach. This chapter summarizes the present knowledge on the molecular etiology and genetic determinants of eating disorders including serotonergic genes, dopaminergic genes, opioid genes, endocannabinoid genes, appetite regulation genes, and others. Furthermore, the growing scientific interest to identifying causal genes behind EDs leads to identify some rare genetic variants. Eating disorders have been considered "sociocultural creations," but probably the environments alone cannot explain the etiology. Genetic factors together with environmental triggers, mental status, and social pressure to thinness are interconnected and may influence epigenetic mechanisms and consequentially gene expressions.

Keywords

Eating disorders · Anorexia nervosa · Bulimia nervosa · Binge eating disorders · Genetic test · Polymorphisms · Serotonergic genes · Dopaminergic genes · Opioid genes · Endocannabinoid genes · Appetite regulation genes · Rare genetic variants · Genome-wide association studies · Whole-exome sequencing

Abbreviations

5-HT	5-Hydroxytryptamine
5-HTTLPR	5HT-transporter-linked polymorphic region
ACTH	Adrenocorticotropic hormone
AEA	Arachidonoylethanolamine
AGRP	Agouti-related protein
AN	Anorexia nervosa
ANGI	Anorexia Nervosa Genetics Initiative
ANKK1	Ankyrin repeat and kinase domain containing 1
BDNF	Brain-derived neurotrophic factor
BED	Binge eating disorders
BN	Bulimia nervosa
CART	Cocaine and amphetamine regulated transcript
CCK	Cholecystokinin
COMT	Catecholamine-O-methyltransferase
DA	Dopamine
DRD2	Dopamine receptor 2
DRD4	Dopamine receptor 4
DSM-V	*Diagnostic and Statistical Manual of Mental Disorders Fifth Edition*

EDs	Eating disorders
ESRRA	Estrogen-related receptor alpha
FAAH	Fatty acid amide hydrolase
GCAN	Genetic Consortium for Anorexia Nervosa
GLP-1	Glucagon-like peptide 1
GWAS	Genome-wide association studies
HDAC4	Histone deacetylase 4
OXM	Oxyntomodulin
PEA	Palmitoylethanolamide
POMC	Proopiomelanocortin
PP	Pancreatic polypeptide
PPARγ	Peroxisome proliferator-activated receptor gamma
PYY	Peptide YY
SNPs	Single nucleotide polymorphisms
WTCCC-3	Wellcome Trust Case Control Consortium-3

Introduction

Eating disorders (EDs) are divided in eight categories according to the *Diagnostic and Statistical Manual of Mental Disorders Fifth Edition* (DSM-V) (American Psychiatric A 2013) and represent serious psychiatric illnesses (Treasure et al. 2020; Martinussen et al. 2017) with a high mortality rate (Arcelus et al. 2011; Smink et al. 2012) and an important genetic component (Yilmaz et al. 2015), confirmed firstly by twin and family surveys (Bulik et al. 2000) and secondly by single nucleotide polymorphisms (SNPs) association studies (Rask-Andersen et al. 2010; Paolacci et al. 2020). Even if DMS-V describes different categories with specific feeding behaviors and psychiatric/mental comorbidities, this chapter will focus on the three most common EDs, anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED), due to a current lack of genetic and epidemiological research on other EDs groups.

Family Studies

Twin, family, and adoption studies have shown that EDs are heritable (Thornton et al. 2011). In detail thorough results are available for anorexia nervosa (AN) with 56–84% of hereditability (Strober et al. 2000; Bulik et al. 2000; Klump et al. 2001; Munn-Chernoff and Baker 2016), bulimia nervosa (BN) with an average of 47% (Strober et al. 2000; Munn-Chernoff and Baker 2016), and binge eating disorder (BED) with 41–57% (Javaras et al. 2008).

Different and independent research works demonstrated that the risk of developing AN is approximately 11-fold greater for a first-degree relative of individuals with AN or BN than for the general population (Bulik et al. 2000; Klump et al. 2001). The relative risk for BN is around 4 times greater for female relatives of affected

probands (Bulik et al. 2000). A recent study on full-sisters and maternal half-sisters shows that AN and BN overlap between phenotype and may share up to 60% of genetic effects (Himmerich et al. 2019; Yao et al. 2021).

Candidate Gene Association Studies

Candidate gene association approach for EDs is widely used to understand the etiology of these complex and multifactorial disorders (Rask-Andersen et al. 2010; Yilmaz et al. 2015), which are caused in part from a genetic predisposition, but also from the psychological factors together with environmental risks: vulnerability, life transition, sexuality, dieting, childhood abuse or traumatic events, media, sociocultural pressure, family values, and others triggers (Fig. 1). Accumulating pieces of evidence have suggested that different SNPs and also VNTRs are associated with abnormal feeding behavior; in particular these polymorphisms are placed on crucial genes related to I) *mental illness*, such as serotonin receptor family (*5-HT2AR, 5-HT3AR, 5-HT3BR, 5-HT1DR*), brain-derived neurotrophic factor (*BDNF*), and norepinephrine (*NE*); II) *feeding motivation and reward system*, among these dopamine receptor family (*DRD2, DRD3* and *DRD4*), ankyrin repeat and kinase domain containing 1 (*ANKK1*), opioids (*OPRD1*), cannabinoids (*CNR1*), and catecholamine-O-methyltransferase (*COMT*); III) *appetite regulatory system*, for example, leptin, ghrelin, agouti-related protein

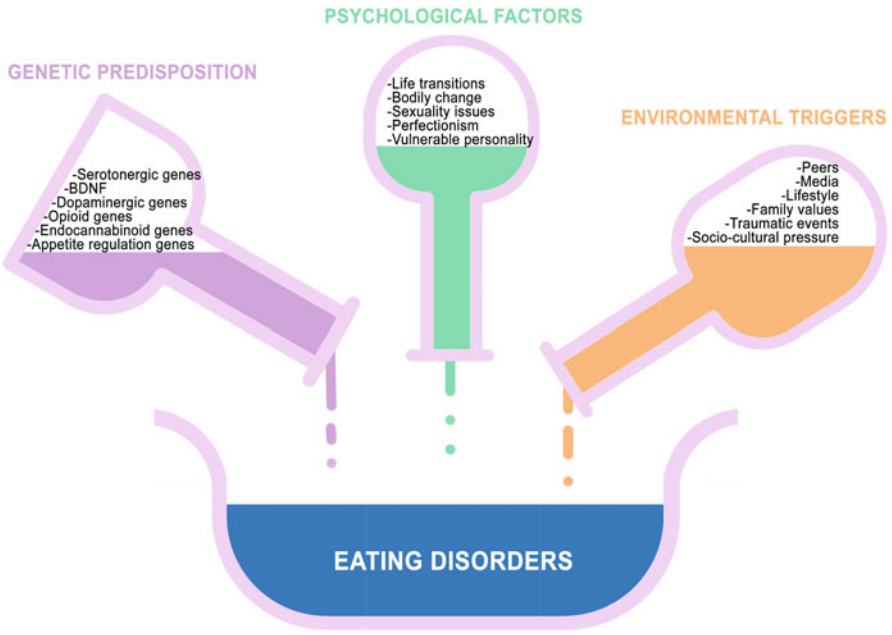

Fig. 1 Triggering causes underlying eating disorders

(*AGRP*), glucagon-like peptide (*GLP-1*), cholecystokinin (CCK), melanocortin 4 receptor (*MC4R*), neuropeptide Y (*NPY*), pancreatic polypeptide (*PPY*), and oxyntomodulin (*OXM*); IV) *neuroendocrine system and sex hormones*, estrogen receptor 2 (ESR2); V) *immune system and inflammatory response*, such as tumor necrosis factor-alpha (TNF alpha); and VI) other pathways under investigation or until now unexplored.

Genome-Wide Association Studies

Nowadays genomic-wide association studies (GWAS), thanks to high throughput genomic sequencing technology and with the collaboration of Psychiatric Genomic Consortium, have started to unlock the biological basis and genetic contributions of particular EDs as defined in DMS-V. Until now, five different GWAS have been conducted (Nakabayashi et al. 2009; Wang et al. 2011; Boraska et al. 2014; Duncan et al. 2017; Watson et al. 2019) with large cohort of patients from different ethnicities affected by particular EDs versus healthy controls (CTRs). AN, probably one of the most severe psychiatric diseases difficult to treat, reveals that several loci have been involved and 133 genes are implicated in the etiology of disease with an important hereditability, around 11–17% for common genetic variants. Unfortunately, this approach yielded results so far only for AN (Bulik et al. 2019), so a major effort is required to the scientific world for future discoveries. Together with an increase of GWAS sample size, other phenotypes beyond AN must be included, not only to improve genetic contribution knowledge, but also to open the way to novel and effective treatments for EDs patients, still now inadequate (Davis and Attia 2019).

Gene Variants

Several neuropeptides, neurotransmitters, hormones, and receptors are involved in EDs. Moreover, a lot of patients present comorbidity, such as anxiety, mood disorders, impulsive-compulsive disorders, and personality disorders, and for this reason understanding the etiology of EDs is extremely difficult.

Genetics research can improve knowledge about the heritability of EDs, but we should not forget the importance of environment factors, childhood abuses, family context, aesthetic canons in industrialized society, and media and websites messages of thinness, that contribute to development of EDs (Fig. 1). The complex network of involved neuropeptides, neurotransmitters, hormones, and their receptors requires a multimodal treatment approach.

In this chapter we decided to describe the growing scientific interest to identifying causal genes behind EDs, bringing back the most relevant scientific researches with strong evidences and associations, confirmed in independent works.

Serotonin Pathway

The serotonin or 5-hydroxytryptamine (5-HT) system, which comprises 14 or more receptor subtypes and the 5-HT transporter (5-HTT), is involved in mood, food intake, and body weight regulation (Yokokura et al. 2019) and for this reason is surely the most investigated pathway, together with dopamine system.

Due to the psychological profiles of patients, in particular affected by AN, which show an altered perception, personality, and mood, it has been hypothesized that 5-HT activity is altered in the acute illness state of AN. In fact, serotonin is involved in a broad range of functions and acts as anorexigenic factor that promotes satiety. As with AN, BN patients develop an egosyntonic personality, so it is a conceivable role of serotonergic system dysfunction in this particular eating disorder onset and progression (Kaye et al. 2005).

Most positron emission tomography studies of AN patients have targeted the 5-HT1A and 5-HT2A receptors and 5-HTT, also known as 5-HTTLPR, encoded by the *SLC6A4* gene (Boehm et al. 2020). Positive correlations have been found between re674386 SNPs in the 5-HT1A receptor and restrictive type of AN in independent works (Brown et al. 2007). Several laboratories and groups of research around the world have been found a strong association between -1438A/G polymorphism in *5-HT2A* receptor gene (re6311) and AN (Hinney et al. 1997; Enoch et al. 1998; Nishiguchi et al. 2001; Ricca et al. 2002; Ceccarini et al. 2020). Similar results were obtained for BN (Ricca et al. 2002), but not for BED (Ricca et al. 2002; Ceccarini et al. 2020).

A 43-basepair insertion/deletion in serotonin transporter gene *SLC6A4* (5-HTTLPR), generating a long (L) and short (S) genotypes respectively, was extensively studied in AN, BN, and BED with different and sometimes conflicting results (Hinney et al. 1997; Monteleone et al. 2006; Tasegian et al. 2016). Abnormalities in peripheral 5-HT uptake have been observed in BN patients (Steiger et al. 2011), but there are conflicting results (Polsinelli et al. 2012; Trace et al. 2013). Additionally, Monteleone and co-worker, who analyzed the 5-HTTLPR polymorphism in obese people, found L-allele overexpression in 77 BED patients (Monteleone et al. 2006). On the other hand in a group of obese women, the mean BMI was higher for the SS genotype than for combined LL and LS genotypes (Sikora et al. 2013).

Other polymorphisms, such as rs6318 (Cys23Ser) in 5-HT2C receptor, have been examined in EDs, but allele frequencies were unchanged in patients and healthy control group.

Anyway, it is unlikely that this pathway is the only one involved in the onset of EDs because it is associated with numerous psychiatric disorders and therefore cannot be considered a specific vulnerability factor for AN, BN, or BED (Paolacci et al. 2020; Trace et al. 2013).

Brain-Derived Neurotrophic Factor Gene

Brain-derived neurotrophic factor (*BDNF*) is a neurotrophic protein that supports the growth, survival, and differentiation of neurons. BDNF is ubiquitously expressed and in terms of eating behavior is involved in appetite suppression by downstream regulation of melanocortin signaling in the hypothalamus (Ribasés et al. 2004). The BDNF level in serum was deeply investigated in EDs patients, and the results demonstrated that it was significantly reduced in particular in AN and BN (Mercader et al. 2007; Saito et al. 2009) with a strong correlation with low body mass index (BMI). For this reason, BDNF plasma levels were suggested as a candidate biomarker. In terms of genetic variations, one of the most extensively researched SNPs in the coding region of *BDNF* gene is the rs6265, where the common G allele that encodes for valine in position 66 is replaced with A allele that codifies for methionine (commonly referred to as Val66Met). This SNP has been strongly associated with different sub-groups of EDs (AN, BN, and BED) in different ethnicities (Ribasés et al. 2004; Mercader et al. 2007; Rosas-Vargas et al. 2011; Ceccarini et al. 2020), suggesting that this neurotrophic protein may act in both appetite and satiety brain centers as orexigenic and anorexigenic signal through complex interactive network. A complete functional characterization of this SNP needs to be deeply studied in the near future.

Another SNP in the promoter region of the same gene is rs56164415 (commonly referred to as −270C/T) and is associated with EDs predisposition. Its role remains still controversial, especially due to the challenges associated with studying this low minor allele frequency SNP in small study samples (Mercader et al. 2007; Yilmaz et al. 2014).

Dopamine Receptor Family

Dopamine (DA) is a catecholamine neurotransmitter highly expressed in the central nervous system (CNS) and implicated in wide array of brain functions including feeding behavior, motor activity, and reward (Sobik et al. 2005). Based on these evidences, genes coding for enzymes, receptors, and transporters involved in DA pathways have been considered candidates for gene association studies in patients affected by EDs.

In particular different SNPs located in ankyrin repeat and kinase domain containing 1 (*ANKK1*), dopamine receptor 2, 3, and 4 (*DRD2*, *DRD3*, and *DRD4*) genes, have been found to be significantly associated with EDs in several studies (Ariza et al. 2012; Davis et al. 2012; Duncan et al. 2017).

A1-allele of rs1800497 SNP (also known as Taq1A allele or AA) in the *ANKK1* gene has been reported to reduce receptor activity with lower availability in striatal D2/D3 receptors (Eisenstein et al. 2016). Its frequency was significantly higher in obese group than in lean controls (Ariza et al. 2012), whereas BED patients that showed a higher proportion of homozygotes for the A2-allele (GG) (Davis et al.

2012). BED Italian patients homozygous for the G-allele of ANKK1-rs1800497 exhibited a significant association with binge eating episodes.

rs6277 SNP in the *DRD2* gene (commonly referred to as C957T) has been associated with changes in DRD2 expression and dopamine neurotransmission (Hirvonen et al. 2009), and T-allele homozygosity has been found highly correlated with BED risk (Davis et al. 2012).

In the same gene, rs1799732 SNP (-141C indel), previously shown to affect DRD2 transcription efficiency, has been showed to have a positive susceptibility in 191 AN patients, but no replication studies have been carried out (Bergen et al. 2005).

Recently, it has been proved that AN patients carrying the homozygous variant Gly9Gly genotype in the dopamine D3 receptor (*DRD3*) have a more severe symptomatology (Duncan et al. 2017).

Several studies have demonstrated a correlation between EDs and -521C/T SNP (rs1800955), located in the promoter region of *DRD4*; notably the T allele is associated with personality traits related to AN (Munafò et al. 2008).

Recently, for the first time, it was observed a strong association between another SNP (rs936461) situated in the promoter of DRD4 gene (A809G) and two specific EDs subgroups, BN and BED, which showed a strong prevalence of homozygous GG. This data needs to be confirmed.

Another interesting polymorphism is the 120-base pair (bp) tandem repeat (TR), located in the promoter region of DRD4. This polymorphism consists of a long (L) and a short (S) allele with opposite effects on the DRD4 expression level: L-allele is a negative modulator whereas S-allele induces higher transcriptional levels of the gene (D'Souza et al. 2004). Interestingly, the S-allele has been associated with AN bingeing/purging subtype but not with AN restrictive subtype, and interestingly, patients with AN carrying the S-allele displayed significantly higher weight and height than patients not having the S-variant (Gervasini et al. 2013). Recently it has been demonstrated a significant association between the 120 bp TR polymorphism and BN and BED susceptibility. Indeed, SS and SL genotypes have significantly more presence in the BN and BED groups in comparison with the healthy control. Moreover, it was found a higher BMI in BED patients carrying SS or SL genotypes compared to LL homozygotes.

Probably, the most widely studied is a variable number of tandem repeats, known as 48-bp VNTR, in the exon 3 of *DRD4*. The allele with 7 repeats has been shown to reduce the receptor expression and affinity for DA and was strongly associated with overeating, obesity (Gervasini et al. 2018), drug abuse, and related comorbidities (Botticelli et al. 2020). Women, carrying at least one copy of an allele with 7 or more repeats (>7R), have increased BMI, with the highest BMI values observed in 7R/7R homozygotes (Sikora et al. 2013). The same genotype (7R/7R) is also associated with a greater risk for AN (Gervasini et al. 2013). Probably this association is due to the reducing receptor expression that leads to a disturbing reward pathway and an abnormal food intake.

Opioids and Their Receptors

Opioid peptides play a key role in feeding behavior generating motivation and pleasure in food consumption, raising suspect that opioid genes also play a decisive role in EDs (Fuss et al. 2015).

Several SNPs in the opioid delta 1 receptor (*OPRD1*) located in chromosome 1, such as rs536706, rs760589, rs204081, rs569356, rs521809, and rs4654327, were associated with risk of AN by independent studies (Brown et al. 2007).

Some reward-related brain dysfunctions have been described also in rodent animal models of BN by affecting opioid levels (Avena et al. 2008). The BN treatment with naloxone that is an opioid receptor blocker is very effective (Valbrun and Zvonarev 2020).

The opioid antagonist treatments decrease intake of fat and sucrose diets and suppress palatable food intake (Naleid et al. 2007). Memantine, a drug commonly used to treat the symptoms of Alzheimer's disease, attenuated the expression of opioid physical dependence in humans, indicating that glutamatergic neurotransmission at the NMDA receptor site contributes to the maintenance of opioid dependence. Interestingly, in rat BED model, memantine treatment blocks the compulsivity associated with the intake of the highly palatable food (Popik et al. 2011).

Endocannabinoid Pathway

Endocannabinoid system plays a key modulatory role of energy balance by controlling food intake through central and peripheral mechanisms that orchestrate energy homeostasis. Endocannabinoids (eCBs) are lipid messengers that are involved in overall body weight control. In fact, the cannabinoid receptors, CB1 and CB2, are expressed in the hypothalamus and other brain regions that control food intake (González et al. 2021). Genetic variants in *CNR1* and *CNR2* genes coding for cannabinoid receptors CB1 and CB2 affect body weight and food intake and are associated with AN (Soria-Gòmez et al. 2007). Systemic and local administrations of both exogenous cannabinoids (i.e., THC) and endocannabinoids (i.e., AEA, 2-AG) increase food intake in animals. This hyperphagic action is mediated by CB1 receptors since they are blocked by specific CB1 receptor antagonists (Scopinho et al. 2011). Cannabidiol, a constituent of *Cannabis sativa*, can prevent the hyperphagic effect induced by the CB1 receptor agonist (McLaughlin et al. 2003). Instead, CB1 receptor antagonists are hypophagic and reduce body weight (Riedel et al. 2009). Also, the phyto-9 cannabinoid-tetrahydrocannabivarin, which behaves as a CB1 receptor antagonist, decreases food intake and body weight (Siegfried et al. 2004). Genetic variants in *CNR1* gene are thought to contribute to AN susceptibility. The involvement of *CNR1* trinucleotide repeats could mediate the non-Mendelian inheritance of AN, but functional studies are needed to prove the differential effect of the various (AAT)n repeats on the CB1 receptor (Fuss et al. 2015).

Monteleone et al. demonstrated that rs1049353 (also known as 1359 G/A) in the *CNR1* gene and rs324420 (cDNA 385C to A) in the endocannabinoid degrading enzymes fatty acid amide hydrolase (FAAH) are significantly associated with both AN and BN with a synergistic effect of the two SNPs in AN (Monteleone et al. 2009). An association of a *CNR2* polymorphism with BN has also been observed (Scherma et al. 2014).

The role of the cannabinoid receptors is also supported by studies performed on anandamide, also known as N-arachidonoylethanolamine (AEA), which plays a key role in feeding behavior generating pleasure in food consumption (Rueda et al. 2002). By binding to CB1R, anandamide inhibits neuronal differentiation and causes the retraction of neurites (Gaetani et al. 2008). Plasma levels of anandamide were down-regulated in AN patients.

Palmitoylethanolamide (PEA) is an endogenous fatty acid amide that binds the peroxisome proliferation-activated receptor α (PPARα) and the cannabinoid-like G-coupled receptors GPR55 and GPR119. The transcription factor PPARα in the small intestine controls the anorectic action of exogenous PEA (Clayton et al. 2021). PEA might function as a biosensor for dietary fat because intestinal concentration of PEA decreases in response to high-fat feeding in mouse (Monteleone et al. 2015). In AN patients, plasma PEA concentration increases after exposure to a non-favorite meal and in hedonic eating.

Appetite Regulatory System

The communication between gut and hypothalamus involves appetite hormones that include orexigenic and anorexigenic hormones, such as ghrelin, leptin, cholecystokinin (CCK), peptide YY (PYY), pancreatic polypeptide (PP), oxyntomodulin (OXM), and glucagon-like peptide (GLP)-1. This complex interaction between the central nervous system and the intestinal tract by humoral factors and neuronal pathways has been named brain-gut-axis.

After feeding, anorexigenic peptides are released while the levels of the orexigenic peptide ghrelin reduce. Ghrelin (also called the hunger hormone), the natural leptin antagonist, is an appetite stimulating hormone produced in the stomach and pancreatic cells. Its level is inversely associated with body mass index (BMI) in the general population, and it has effects on feeding behavior, reward mechanisms, reproduction, and growth (Perry and Wang 2012). AN patients have higher levels of ghrelin in the plasma, likely in response to prolonged starvation (Blauwhoff-Buskermolen et al. 2017). Leu72Met (rs696217) in ghrelin gene (GHRL) is one of the most studied SNPs and was associated with BED patients and with the risk to developing an ED (Monteleone et al. 2007). In a family trios study, Dardennes et al. found a prevalence of transmission of Leu72Met in AN patients, in particular the purging AN-subtype (Dardennes et al. 2007). Polymorphisms in ghrelin and its receptor *GHSR1a* are not associated with BN (Monteleone et al. 2006). Other SNPs in GHRL gene and its receptor *GHSR1a* were investigated, such as

rs4684677 (Gln90Leu) and rs34911341 (Arg51Gln), but conflicting results were obtained.

Leptin, on the other hand, is a hormone produced by adipocytes and enterocytes, involved in the food intake and regulation of energy balance both long and short term (Steiner and Romanovsky 2007). There are low levels of plasma circulating leptin in cerebrospinal fluid (hypoleptinemia) in AN patients (Föcker et al. 2011). Even if the serum level of leptin is significantly decreased in AN patients, it is only moderately increased in obese patients. Moreover, a positive correlation of plasma leptin levels and BMI in subjects with BN has been described. The plasma leptin levels are restored in remitted BN patients and are a relevant factor for remission (Homan et al. 2014). Because leptin is able to modulate reward-related behavior, leptin gene (LEP) and its receptor (LEPR) were investigated in a lot of candidate-gene association studies, but no evidences in AN and BN were yielded so far. Yilmaz and co-worker in 745 individuals with AN, 245 individuals with BN, and 321 controls found a negative association with two SNPs located in LEPR, rs1137100 (Lys109Arg) and rs1137101(Gln223Arg), previously associated with EDs in a small group of patients (Yilmaz et al. 2014). Although leptin modulates reward-related behavior that has a relationship with BN, currently conflicting results were obtained on the association of reward learning and plasma leptin levels in BN. However, a positive correlation of plasma leptin levels and BMI in subjects with BN has been described. The plasma leptin levels are restored in remitted BN patients and are a relevant factor for remission (Homan et al. 2014).

The brain homeostatic control of feeding involves not only neural circuits located in the hypothalamus (hunger signals, initiating feeding behavior), but also the brainstem (satiation signals) (Cuesto et al. 2017). Hypothalamic NPY/AGRP neurons produce neuropeptide Y, and agouti-related peptide produces an orexigenic signal by increasing the release of adrenocorticotropic hormone (ACTH), cortisol, and prolactin and is involved in appetite regulation. These neuropeptides are associated with high food intake by up-regulation in AN (Galusca et al. 2015). Orexins are orexigenic neuropeptides involved in endocrine system regulation, with an important function in insulin, glucagon, and leptin secretion in response to glucose (Park et al. 2015). An increased concentration of NPY, which mediates leptin receptors, is associated to body mass deficiency with high concentrations of leptin, suggesting defects in the regulatory axis. AGRP rs13338499, a SNP located in a putative transcription factor-binding site, upstream of *AGRP* gene with a possible regulatory role, was significantly associated with lowest BMI in AN patients (Yilmaz et al. 2014).

CCK, a peptidic hormone of the gastrointestinal system, secreted into the duodenum from cells of mucosal epithelium, is another actor that promotes satiety, but has been also associated with anxiety, panic, and hallucinations. CCK stimulates digestion of proteins and lipid in the small intestine. Its plasma levels in AN patients and control group are similar both prior to and after feeding, but more data are necessary because in some analysis, CKK plasma in AN patients showed a post-prandial increase in CKK plasma levels (Cuntz et al. 2013; Richard et al. 2014). Five SNPs in the 3′ untranslated (UTR) region of the *CCK* gene were analyzed by De

Krom et al. (2006), and a strong association was found only for one SNP, rs11129946; in particular the researchers demonstrated a higher number of AC carriers (heterozygous) in AN group (De Krom et al. 2006). BN patients, on the contrary, seem to have impaired secretion of CKK that is a satiety factor and PYY secretion inductor. Hence, depressed PYY levels may result from reduced CCK secretion. Moreover, there is a negative correlation between PYY increase and ghrelin decrease. For which a pathway involving peripheral hormonal signals, such as ghrelin and PYY, may be related to BN (Smitka et al. 2013). However, only one association study has been performed in Japanese population in AN and BN subjects with positive correlation (Miyasaka et al. 2006), but further investigation will be needed because the ethnicity is a fundamental and essential point to take into consideration when we talk about genetic association studies.

Another neuropeptide involved in EDs is proopiomelanocortin (POMC) synthesized mainly in the anterior pituitary and cleaved in a-MSH, ACTH, and the opioids beta-endorphin and Met-enkephalin. POMC is an anorexigenic peptide, is mainly expressed in the arcuate nucleus, and associated with appetite regulation, as well as the secretion of glucocorticoids. Moreover, cocaine- and amphetamine-regulated transcript (CART) is an anorectic peptide widely expressed in both the central and peripheral nervous system which as POMC is regulated by leptin and it has been related with addictive behaviors and stress responses (Bakhtazad et al. 2016). The most common SNP located in *POMC* gene is rs104257 because it is considered a putative transcriptional binding site. Until now negative results were obtained.

Other Genes

Other metabolic pathways together with a huge number of genes are under investigation, but *FTO* (fat mass and obesity-associated) gene located in the chromosome 16 deserves a particular attention. Several SNPs in the coding region of *FTO* gene (in particular in the first intron) are strongly associated with obesity in young and in adults. rs9939609 is for sure the most frequently described, and the A-allele is strongly associated with obesity and with type 2 diabetes mellitus. Even if *FTO* is indisputably correlated with obesity, uncertainty remains about the potential association of this gene with EDs such as AN and BN or BED. 6101 individuals from three European countries (Germany, Italy, and Spain) divided in AN, BN, and CTRs were recruited, and results highlight an important association of the A-allele at rs9939609 with both AN and BN groups (Müller et al. 2012). Besides, the same A-allele was associated with BED (Castellini et al. 2017); for this reason it is possible to hypothesize that this crucial SNP represents a potential additive risk factor for EDs persons, with bodily disorders to develop higher emotional eating and binge eating behaviors.

Rare Genetic Variants

With the recent advancements in high-throughput sequencing, it is now much easier to detect rare variants (minor allele frequency of less than 1%). The role of rare and structural variants in EDs was explored by studies of whole-exome and whole-genome analyses. The previous gene expression studies had offered insight into the genes and molecular mechanisms that influence EDs. However, such data are available so far mainly for AN patients but not for other sub-groups.

For example, a whole-exome analysis in two independent studies found pathogenic variants in the neuronatin (NNAT) gene. The first one to report this association between AN and NNAT gene was Lombardi et al. (2019). We independently confirmed this data in our Italian cohort (Ceccarini et al. 2021), and in particular found three variants in NNAT gene in four probands out of a total of 68 patients analyzed (6% of total samples). Two variants had been previously reported by Lombardi et al. (2019), one nonsense (p.Trp33*) and one rare variant in the 5′UTR, while one variant has never been associated with AN yet (Ceccarini et al. 2021).

Moreover, we found in our study potential deleterious variants in two other genes, PDE11A and SLC25A13, and we predicted deleterious variants in the following 12 genes, CD36, CACNA1C, DRD4, EPHX2, ESR1, GRIN2A, GRIN3B, LRP2, NPY4R, PTGS2, PTPN22, and SGPP2 (Ceccarini et al. 2021), but these data need to be confirmed in a large cohort of AN patients.

Novel non-synonymous and missense variants in the exons of SLC6A4 gene, using Sanger sequencing, were found in 86 Mexican patients with AN and BN (Hernández-Muñoz et al. 2020). Recently, a positive relationship between the SLC6A4 methylation levels (15 CpG sites in the gene promoter) and the resting-state functional connectivity between the dorsolateral prefrontal cortex and the salience network has been found in AN patients (Boraska et al. 2014; Boehm et al. 2020).

Bienvenu and co-worker have found seven de novo missense variants in four potential genes (CSMD1, CREB3, PTPRD, and GAB1) which belong to the same signaling pathway involving neuron differentiation and dopamine pathway in nine studied AN patients (Bienvenu et al. 2020).

A whole-exome sequencing analysis in AN patients identified genes carrying damaging variants belonged to three crucial pathways: (a) neuropeptide hormone signaling, (b) inflammatory pathway, and (c) cholinergic neurotransmission (Lutter et al. 2017). Another whole-exome sequencing study in EDs patients was carried out by Bergen et al. in 2019 and identified novel variants in seven genes: TTC22, MRPS9, DNAJC30, HEPACAM2, USP20, ESF1, and CDK5RAP1 (Bergen et al. 2019). It should be stated that the functional relevance of all these gene variations for the etiology of EDs remains to be demonstrated. They all could represent polymorphisms without biological effects.

A single genome-wide association study recognized a locus on chromosome 12 (lead rs4622308 SNP) related to AN in a region that regards also diabetes mellitus type 1 and autoimmune disorders. Successively the Anorexia Nervosa Genetics

Initiative (ANGI), the Genetic Consortium for Anorexia Nervosa (GCAN), and the Wellcome Trust Case Control Consortium-3 (WTCCC-3) along with UK Biobank have detected eight chromosomal regions, comprising 120 genes, significantly associated with AN. Analyses in silico and research by available large-scale in vitro data have revealed that four of the genes of these chromosome regions might be more likely to be associated to the AN etiology: *CADM*1, *MGMT*, *FOXP1*, and *PTBP2* (Watson et al. 2019; Paolacci et al. 2020; Yokokura et al. 2019).

In a large screening of 152 candidate genes by GWAS, rare variants associated to AN were identified in *EPHX2* that encode a protein involved in cholesterol metabolism. Moreover, variants in *ESR2*, encoding the estrogen receptor 2, can be associated with AN in female (Cui et al. 2013).

However, at the base of the limits of these studies in AN, there are several factors, such as the winner's curse, small sample size, moderator variables explaining, and lack of heterogeneity of the cohorts (Watson et al. 2019, 2021). Anyway, the results obtained in these studies support the view that AN is a highly polygenic and multifactorial disease.

Finally, by whole-genome sequencing and linkage analysis to analyze two families with recurrence of EDs were detected a missense variant co-segregating with the affected family members in Estrogen Related Receptor Alpha gene (*ESRRA)*, and a potentially damaging variant in histone deacetylase 4 (*HDAC4*) that plays a significant role in the estrogen system. Transcriptional studies revealed that expression of the *HDAC*4 deacetylase repressed the transcription of ESRRA-induced target genes, whereas *ESRRA* and *HDAC4* exhibited interaction in both in vivo and in vitro studies. For which variants in *ESRRA* and *HDAC4* cause a decrease in the activity of ESRRA and an increase in the likelihood of AN onset (Sild and Booij 2019).

Conclusions

To date, the genetic risk architecture underlying EDs remains largely unexplored; however, like most other psychiatric illnesses, the heritability of EDs appears to follow both a non-Mendelian pattern and in part a Mendelian pattern, suggesting that large numbers of genes spanning multiple regions of the genome are involved in susceptibility.

Summary Points

- EDs have a deep social, psychological, and physical impact and are associated with a high level of mortality.
- Several neuropeptides, neurotransmitters, and hormones are involved in EDs.
- Genetic determinants of EDs include serotonergic genes, dopaminergic genes, opioid genes, endocannabinoid genes, appetite regulation genes, and others.
- Genetic test can be considered as an ideal diagnostic approach, especially by use of NGS technologies.

- Genetic variants and environmental triggers could modify the epigenome that, in turn, influence the onset of EDs.

Genes and Eating Disorders

6

A Focus on the Solute Carrier Family 6 (Neurotransmitter Transporter, Serotonin), Member 4 (*SLC6A4*) Gene

Beatriz Camarena and Sandra Hernández-Muñoz

Contents

Abstract

Eating disorders are complex and multifactorial disorders, in which social, familial, and genetic factors are involved. The serotonin transporter is a key molecule in modulating eating behaviors. The *SLC6A4* gene codes for the serotonin transporter protein, and it has been suggested as an important candidate in ED.

In this chapter, we described the findings of the association between *SLC6A4* gene variants and ED. Most genetic studies have focused on the analysis of a polymorphism located in the promoter region, the 5-HTTLPR, which has been

reported to predict a change in the gene expression. Furthermore, the association between psychiatric comorbidities related with a dysfunction in serotonin pathways suggests an involvement in the susceptibility to ED.

In the future, it will be interesting to carry out the analysis of genetic variants in populations not studied to identify variants that to date have not been observed in Caucasian populations.

Keywords

Eating disorders · *SLC6A4* · Gene · Genetic variants · SERT · 5-HTTLPR · 5-HTT · Association study · Serotonin transporter · Interaction · Environment · Anxiety · Anorexia nervosa · Bulimia nervosa · Binge eating disorder

Abbreviations

5-HT	5-Hydroxitriptamine, serotonin
5-HTTLPR	Serotonin transporter-linked polymorphic region
AN	Anorexia nervosa
ANP	Anorexia nervosa purgative
ANR	Anorexia nervosa restrictive
BED	Binge eating disorder
BN	Bulimia nervosa
BNP	Bulimia nervosa purgative
CNS	Central nervous system
DSM-5	*Diagnostic and Statistical Manual Version 5*
ED	Eating disorders
ICD-11	International Classification of Diseases version 11
SERT	Serotonin transporter protein
SLC6	Solute carrier 6 transport family
SLC6A4	Solute carrier family 6 member 4 (*Homo sapiens*, human)
SRIs	Serotonin reuptake inhibitors
TM	Transmembrane protein
VNTR	Variable number of tandem repeats
WES	Whole-exome sequencing
WGS	Whole-genome sequencing

Introduction

Eating disorders (ED) are severe psychiatric disorders defined by abnormal food consumption patterns. The *Diagnostic and Statistical Manual Version 5* (DSM-5) (American Psychiatric Association, 2013) and the International Classification of Diseases version 11 (ICD-11) include anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED). Eating disorders are complex disorders that involve severe changes in attitudes and behaviors related to food intake in response to perceptual distortions about body dimensions, as well as the phobic

fear of gaining weight. The etiology of ED is unknown; however, it is suggested as a multifactorial disorder that results from a complex interaction of predisposing, precipitating, and perpetuating factors. Family and twin studies suggest that heritable components play an important role in the susceptibility to develop an ED (Strober et al. 2000).

The restriction of food intake normally reduces the levels of serotonin (5-HT, 5-hydroxitriptamine) in the central nervous system inducing hyperphagia and obesity; however, in AN patients, the low serotonin level does not decrease the food intake remaining a reduced body weight (Kaye et al. 1984). Thus, disturbances in the brain serotonin system have been related to ED, such as in psychopathology traits that contribute to the vulnerability to develop an ED. In addition, AN and BN patients respond to serotonin reuptake inhibitors (SRIs), which act by blocking the serotonin reuptake through the serotonin transporter protein.

The serotonin transporter (SERT) is a key protein responsible for terminating the synaptic action of serotonin after the neurotransmitter release modulating the serotonin function in the brain. The serotonin transporter is encoded by the *SLC6A4* gene, and there have been several genetic studies proposing this gene as an interesting candidate gene for eating disorders. Also, it has been implicated in anxiety, depression, impulsivity, and obsessiveness traits related to the risk to develop an ED.

One of the most studied polymorphisms of the *SLC6A4* gene is the 5-HTTLPR (serotonin-linked polymorphic region) located in the promoter region and characterized for conferring protein gain or loss of function. In this book chapter, we review the investigations about the genetic studies related to *SLC6A4* and eating disorders in several populations.

Role of Serotonin in Eating Disorders

The neurobiological studies have provided information on dysfunctions of neurotransmitter function in the modulation of appetitive behaviors and emotional states in the eating disorder etiology (Kaye et al. 2009, 2013). The interest in the role of serotonin in ED is supported for their important role in postprandial satiety. Steiger (2004) suggests that an increase in the 5-HT tone is related to a reduction in food consumption, whereas a low serotoninergic tone is related to an increase in food consumption and promotion of weight gain, characteristics observed in patients with AN and BN (Bailer et al. 2007; Yokokura et al. 2019).

Also, the disturbances observed in the 5-HT activity may be involved too in the vulnerability to develop risk psychopathological traits in AN and BN patients. Interestingly, patients with AN present several traits related to increased serotonin neurotransmission such as obsessiveness, perfectionism, anxiety, and harm avoidance; and BN patients showed traits related to a decrease in serotonin neurotransmission such as impulsivity, dysphoric mood, and emotional dysregulation. The co-occurence of some ED symptoms after the recovery may suggest premorbid traits contributing to pathogenesis of AN and BN.

Characteristics of the Serotonin Transporter (SERT)

The solute carrier family 6 (SLC6) transport family is a secondary active co-transporter formed for 12 hydrophobic membrane-spanning domains with cytoplasmic NH2 and COOH termini. The TM3 and TM4 are separated by a large hydrophilic loop that carries two canonical sites for glycosylation. SERT also contains potential phosphorylation sites for several kinases (Hoffman et al. 1991; Kristensen et al. 2011; Pramod et al. 2013).

The protein is preferentially located in the presynaptic space at the axonal terminals and is also found in cells specialized in the storage or systemic inactivation of 5-HT, including the specialized cells of the intestine, placenta, platelets, and blood lymphocytes (Faraj et al. 1994; Gordon and Barnes 2003; Tao-Cheng and Zhou 1999). The SERT is a protein responsible for introducing 5-HT into the cell into the synaptic space of the serotonergic neuron, consequently reducing the availability of 5-HT in the extracellular environment; it has become the key protein for maintaining serotonergic homeostasis in the paraventricular nucleus (Murphy et al. 2008; Murphy and Moya 2011; Schwartz et al. 2000).

Transporters have been associated with a series of complex diseases in humans that make this family a critical target for study, and several members of this family are directly involved as therapeutic targets in pharmacological treatments. Also, it has been proposed that genetic variants in the serotonin transporter gene can alter the functionality of SERT and compromise the serotonergic homeostasis in the brain (Hu et al. 2006; Prasad et al. 2009).

SLC6A4 Serotonin Transporter Gene

The SERT protein is encoded for *SLC6A4* gene in humans, and it is located on chromosome 17q11.2, composed of 15 exons. The sequence predicts a 630-amino acid protein with 12 transmembrane domains (Lesch et al. 1994; Ramamoorthy et al. 1993). Differential splicing in exons 1A, 1B, and 1C result in several mRNA species regulating tissue-specific expression in humans (Murphy et al. 2008).

Studies of genetic variation have identified several variants in the coding and non-coding regions of the gene. The high allelic heterogeneity observed in the *SLC6A4* gene may explain the controversial findings reported in the different populations analyzing eating disorder patients. In particular, a polymorphism in the promoter region is one of the most studied, denominated 5-HTTLPR (serotonin transporter-linked polymorphic region), and characterized for an insertion/deletion of 43 base pairs, defining a short (S allele) and a large allele (L allele) related with changes in the activity and expression of SERT (Heils et al. 1996). Nakamura et al. (2000) identified an A to G (rs25531) single-nucleotide polymorphism in the L allele defining a triallelic system with a functional expression of the L_G variant similar to the S allele compared with the L_A (Hu et al. 2006; Wendland et al. 2006).

Additional gene variants have been identified in the *SLC6A4*. A variable number of tandem repeat (VNTR) was identified in intron 2 showing enhancer-like

properties (MacKenzie and Quinn 1999). Also, non-synonymous SNPs have been identified in the *SLC6A4* gene such as Gly56Ala, Ile425Val, Leu362Met, Ser293Phe, and Thr4Ala showing differential 5-HT transport activity of SERT-coding variants in transfected HeLa cells compared with hSERT cDNA (Prasad et al. 2005).

In exon 3, it was reported a change of amino acid Leu255Met that at the extracellular level changes the loop, away from the glycosylation and phosphorylation sites in the protein. In exon 9, the Ile425Val localized in the TM8 transmembrane region confers gain of function and altered the affinities at substrate 5-HT and, also, modifies the secondary structure of the alpha helix by affecting SERT (Sutcliffe et al. 2005; Prasad et al. 2009). It is possible that the combination of common and rare variants of *SLC6A4* gene may confer risk to express differential expression of SERT in the susceptibility to develop several psychiatric and psychopathological conditions.

Genetic Association Studies

The important role of SERT in the brain and body process suggests that a dysfunction in the serotonin pathways may be involved in the etiology of ED; therefore, it has been analyzed in several genetic association studies proposing it as an interesting candidate gene (Hernández-Muñoz and Camarena-Medellin 2014).

Most genetic association studies of the *SLC6A4* gene have focused on the analysis of the 5-HTTLPR polymorphism. Family-based association studies reported a preferential transmission of the S allele in families with AN (Hinney et al. 1997; Urwin and Nunn 2005; Chen et al. 2015), and a case-control study observed the finding of an association between S allele and AN (Matsushita et al. 2004). Also, it was observed a significant association between the S variant and BN in the Caucasian population. In particular, patient carriers of two copies of the short allele showed a seven times higher risk of BN (Di Bella et al. 2000). Other findings reported an association between the L variant and BNP (Monteleone et al. 2006). Analysis of triallelic polymorphism 5-HTTLPR/rs25531 found an association between the S/L_G alleles and BN in the Mexican population (Camarena et al. 2018). Previous studies analyzing the triallelic polymorphism showed that the S allele was associated with AN; however, other findings did not find an association (Calati et al. 2011; Lee and Lin 2010; Solmi et al. 2016). Two meta-analysis studies showed an association between the low activity allele and anorexia nervosa (Lee and Lin 2010; Calati et al. 2011); however, a meta-analysis in the largest sample of ED patients analyzed did not find an effect of biallelic and triallelic polymorphisms on the risk to develop ED (Solmi et al. 2016). The analysis of this polymorphism in binge eating disorders did not show an association (Monteleone et al. 2006; Palmeira et al. 2019). Future studies in ED should explore the role of ethnicity in the variability of allele frequencies and the psychiatric comorbidity as a possible source of bias in the replicability of the findings to understand the role of the gene in ED (Tables 1 and 2).

Table 1 Family-based association studies of *SLC6A4* in eating disorders

Study	Polymorphism	Trio families	Findings
Urwin et al. (2003)	5-HTTLPR	AN = 106	No association
Urwin and Nunn (2005)	5-HTTLPR	AN = 114	Association with S allele
Camarena et al. (2012)	Gly56Ala	AN = 79	Major transmission of Ala56 allele
Chen et al. (2015)	5-HTTLPR	AN = 198	Major transmission of S allele

Table 2 Case-control association studies of *SLC6A4* in eating disorders

Study	Polymorphism	Sample	Findings
Hinney et al. (1997)	5-HTTLPR 5-HTTLPR	AN = 55 Ob = 385 Uw = 112	No association
Di Bella et al. (2000)		AN = 112 BN = 50 Controls = 120	Association with S allele in BN
Sundaramurthy et al. (2000)	5-HTTLPR	AN = 138 Controls = 90	Association of S allele
Fumeron et al. (2001)	5-HTTLPR	AN = 67 Controls = 148	Association with S allele
Lauzurica et al. (2003)	5-HTTLPR-VNTR Intron 2	BNP = 102 Controls = 107	No association
Matsushita et al. (2004)	5-HTTLPR	AN = 77 BN = 118 Controls = 290	High frequency of S allele in ANR and ANBP
Rybakowski et al. (2006)	5-HTTLPR	AN = 132 Controls = 93	There was no association
Steiger et al. (2009)	5-HTTLPR	AN = 17 BN = 108 EDNOS = 60	Association between L_A allele and ED and AN subtype inhibitory/compulsive
Steiger et al. (2011)	5-HTTLPR	AN = 244 BN = 442 EDNOS = 112	No association
Camarena et al. (2012)	Gly56Ala	AN = 72 BN = 189 Controls = 226	Association between rare variant 56Ala and AN
Camarena et al. (2018)	5-HTTLPR/ rs24531	BN = 189 AN = 72 Controls = 337	Association with S/L_G alleles and BN ($p = 0.0088$)

VNTR, variable number of tandem repeats; Ob, obese; Uw, underweight

The analysis of a VNTR polymorphism located in intron 2 did not show an association in BNP patients. Also, haplotype analysis of 5-HTTLPR and VNTR-2 intron did not find significant differences between cases and controls (Lauzurica et al. 2003).

Interestingly, the analysis of the Gly56Ala variant in a case-control study reported an association with ED. In particular, it was observed a high frequency of 56Ala rare

allele in ED patients compared with controls (Camarena et al. 2012). The analysis of additional variants located in the *SLC6A4* gene may support additional information about the region that in linkage disequilibrium may be related to the susceptibility to ED.

Studies of Association of the SLC6A4 Gene and Psychopathological Traits in Eating Disorders

The presence of psychopathology has been estimated in 53 to 93% of ED patients (Garner 1993; Barajas-Iglesias et al. 2017). Interestingly, the *SLC6A4* gene is related with the susceptibility to develop several psychopathological traits, which are associated with a heightened risk of eating disorder. Also, the comorbid psychopathological features are related to the symptomatic expression and maintenance of an eating disorder (Bruce and Steiger 2013; Cassin and von Ranson 2005; Hollander 2013). The ED are complex psychiatric disorders, and identified homogeneous subtypes maybe help to identify the risk genes to develop the disorder. Therefore, several genetic association studies support the view that candidate genes do not participate in the susceptibility to ED but predispose to develop risk traits related to the ED.

In particular, patients with BN carriers of S allele 5-HTTLPR polymorphism showed an increased harm avoidance, elevated affective instability, comorbid borderline personality disorder, and impulsivity (Monteleone et al. 2006; Steiger et al. 2005, 2007). Two studies reported an association between the S variant and increased severity of depressive and bulimic symptoms in adolescents with ED (Castellini et al. 2012; Mata and Gotlib 2011). A latent class analysis observed an association between L_A allele of the triallelic polymorphism 5-HTTLPR/rs25531 and inhibited/compulsive group compared with dissocial/impulsive and low psychopathology groups (Steiger et al. 2009).

Interestingly, GWAS (genome-wide association studies) have been performed in AN identifying some variants related to psychiatric and metabolic conditions; however, the studies did not identify variants in the gene most analyzed in ED, the *SLC6A4* gene. No GWAS in BN has been conducted, and BED has been analyzed in comorbidity with bipolar disorder (Bulik et al. 2021). To date, the Eating Disorders Working Group of the PGC (Psychiatric Genomics Consortium) is interested in the inclusion of participants of diverse populations that facilitate the identification of variants in AN, BN, and BED (Hübel et al. 2018).

Gene x Environment Interaction Studies in Eating Disorder

Twin studies support evidence about environmental factors related to the risk to develop an ED. In particular, it has been reported that stressful life events increased susceptibility to ED.

Gene-environment interaction studies, such as the one performed in AN, reported interaction between a non-shared environment (personal problems) and the S-HTTLPR variant (Karwautz et al. 2011); also, a study reported an interaction between the S variant and insecure attachment in BN patients with a history of physical abuse and sexual activity during childhood (Steiger et al. 2007). In another study, an interaction was reported in patients with ED between self-mutilation behaviors and suicide attempts and the L-5-HTTLPR variant (Steiger et al. 2011). Studies in adolescent participants showed an interaction between S/L_G alleles of the triallelic system, and higher levels of childhood trauma showing several eating behaviours (Stoltenberg et al. 2012), and interaction between S allele and the experience of sexual abuse is related with higher binge eating and drive for thinness scores (Akkermann et al. 2012). A meta-analysis study analyzing the role of 5-HTTLPR and environmental and psychological factor interactions in the risk to ED showed that the S allele interacted with sexual and physical abuse to predict increased risk of bulimia-spectrum eating pathology (Rozenblat et al. 2017).

Studies of Sequence of SLC6A4

Whole-genome sequencing (WGS) and whole-exome sequencing (WES) are useful tools to identify the genetic architecture of complex diseases. These methodologies are based on the hypothesis of identified rare variants in common diseases that may be etiologically relevant (Dickson et al. 2010; Raychaudhuri 2011). To date, the exome-wide association studies in ED did not identify variants in the *SLC6A4* gene (Cui et al. 2013; Scott-Van Zeeland et al. 2014; Lutter et al. 2017; Lombardi et al. 2019; Bienvenu et al. 2019).

Interestingly, sequencing studies of the *SLC6A4* gene reported a genetic variant located in exon 9, the rs28914832, associated with compulsive traits and AN (Ozaki et al. 2003). Sequence analysis of five candidate exons of the *SLC6A4* gene identified in AN restrictive two novel variants (g.130delA and c.1740G>A), three synonymous variants (rs57172732, rs55908624, rs74478645), and a missense variant (rs11803088111) considered as deleterious and damaging variant (Fig. 1). In BNP were identified two novel variants (g.295C>G and c.1725G>A) and a non-synonymous variant (rs28914832), reported as benign (Fig. 2). Also, it was observed the 425 V variant in three patients with BN variant reported in patients of obsessive-compulsive spectrum (Hernández-Muñoz et al. 2020).

Conclusions

The current evidence suggested that the relationship between the *SLC6A4* gene and ED could be the result of multifactorial factors. The genetic susceptibility of the *SLC6A4* gene to ED and the comorbidity observed in the patients may suggest that both conditions share common variants related to the etiology and the phenotypic characteristics; therefore, it may be important to identify homogeneous phenotypes

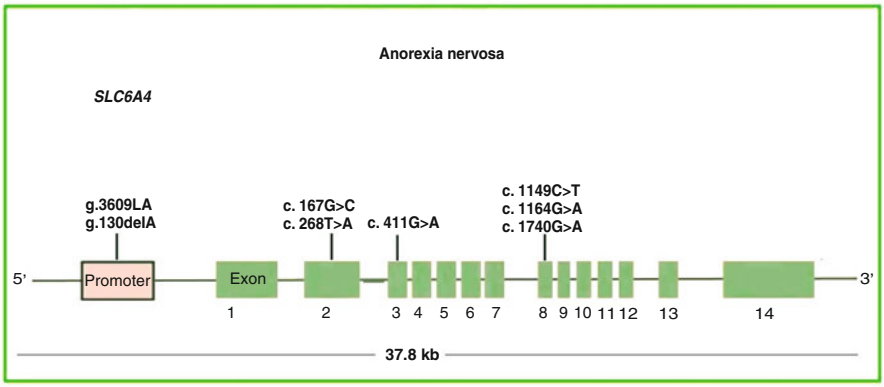

Fig. 1 Genetic variants identified in the gene in anorexia nervosa patients

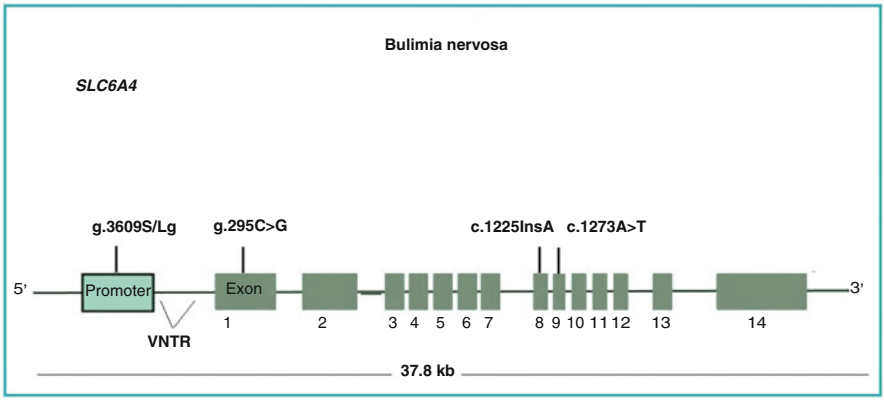

Fig. 2 Genetic variants identified in the gene in bulimia nervosa patients

that help us to detect the risk genes associated with the susceptibility to develop a particular phenotype.

Future studies in large sample sizes of patients with AN, BN, and BED are required to identify variants with a causal effect that helps us to understand the role of the *SLC6A4* gene in the susceptibility to develop an eating disorder.

Key Points

- 5-HTT key protein. Regulation of serotonin reuptake in the synapsis.
- Genetic variants. Modulate the gain of function of the protein.

Key Facts of Genes and Eating Disorders: A Focus on the Solute Carrier Family 6 (Neurotransmitter Transporter, Serotonin), Member 4 (*SLC6A4*) Gene

- Dysfunctions in the serotonin pathways are related to the etiology of eating disorders.
- Genetic variants of the *SLC6A4* gene are associated with anorexia nervosa and bulimia nervosa.
- The *SLC6A4* gene is associated with psychopathological risk traits in anorexia nervosa and bulimia nervosa.
- The biallelic and triallelic polymorphisms of the promoter region have been associated with eating disorders.
- Sequence analysis identified rare and low-frequency variants associated with anorexia and bulimia nervosa.

Summary Points

- The serotonin transporter is a key molecule that participates in the satiety signal in the brain participating in the susceptibility to eating disorders.
- Genetic studies suggest that the SLC6A4 gene is a candidate gene for eating disorders.
- The most studied polymorphism is the 5-HTTLPR located in the promoter region, which has been associated with susceptibility to eating disorders and psychopathological risk traits.
- Some studies support the evidence of Gene x environment interaction is related with the risk to develop an ED.
- The analysis of diverse populations may help to identify variants that confer genetic vulnerability to eating disorders.

Applications to Other Areas

The acknowledgment of the genes involved in the etiology of ED and with the clinical characteristics of a particular phenotype helps to develop new pharmacological treatments. In addition, the subjects at risk to develop an ED might receive genetic counseling to help to understand the risk of these diseases for the patient and their family.

The identification of the psychopathological traits related to the worsening of ED symptoms may help to find psychological therapies aimed to treat the severity of the disorder, for example, impulsivity in BN or perfectionism in AN.

An integrative treatment in ED patients that include psychologist, genetic counselors, psychiatrists, nutritionist, and physicians may be important to identify a personalized treatment and support for the patient and their family.

Identifying the medical comorbidities in the ED may help physicians in the treatment of medical complications and nutritional rehabilitation to develop personalized and integrative treatments.

Mini-Dictionary

Allele	It is one of two or more versions of DNA sequence at a given genomic location.
Chromosome	Threadlike structures made up of DNA that serve to carry the genomic information from cell to cell.
Exon	A polynucleotide sequence in a nucleic acid that codes information for protein synthesis.
Family study	Studies analyzing whether a disease or trait runs in a family
Gene	A specific sequence of nucleotides located in a chromosome and that is the functional unit of inheritance.
GWAS	Genome-Wide Association Study (GWAS) is an approach that involve scanning marker across the genomes of many people to identify genetic variants associated with risk of traits or diseases.
HeLa	It is an immortal cell line used in scientific research.
Interaction	It is the process by which two or more genes influence one another or with environmental factors in different ways affecting a phenotype.
Polymorphism	Two or more variant forms of a specific DNA sequence that can occur among different subjects or populations.
Promoter	A short DNA region where transcription of a gene begins.
Reuptake	Prime mode of inactivation of a neurotransmitter that is released from neurons.
Synapse	The site of transmission of electric nerve impulses between two nerve cells (neurons).
Transmembrane protein	A type of integral membrane protein that spans the entirety of the cell membrane.
Twin study	Studies conducted on identical or fraternal twins to analyze the contribution of genetic and environmental influences for traits or diseases.
Variant	A change in the DNA sequence.
VNTR	Variable number of tandem repeat (VNTR) is a location in the genome where a short nucleotide sequence is organized as a tandem repeat.
WGS	Whole genome sequencing (WGS) is a methodology to determine the entire DNA sequence of an organism at a single time.
WES	Whole exome sequencing (WES) is an approach that involves sequencing the protein-coding regions of the genome.

Eating Disorders in Athletes

7

Melda Pelin Yargic and Faik Ozdengul

Contents

Abstract

Eating disorders (EDs) and disordered eating behaviors are common among athletes, more common in female athletes than males. Certain sports disciplines put athletes at more risk than others. Special attention should be given to the athletes of aesthetic sports, endurance sports, and weight category sports in terms of the risk of EDs. However, these risk factors should not result in creating a stereotype of "the athlete with ED" as such stereotyping may lead to an overlooked diagnosis of EDs in different athletes. In fact, male athletes have a higher rate of EDs than general population. Particular personality traits are common

between EDs' patients and athletes. This intersection certainly creates a difficulty in identifying athletes that are especially at risk due to their personality characteristics, but this challenging situation also holds promising possibilities for treatment. Unhealthy weight management strategies are often observed among athletes. Comprehending the systemic effects of energy deficiency in sports is crucial for a multifaceted understanding of ED in athletes. Health-care professionals' awareness and knowledge on EDs in the athletic population and specific tools for screening may help in preventing irreversible consequences.

Introduction

Engaging in regular exercise is beneficial to one's health in numerous aspects. It protects against cardiovascular diseases, diabetes, hypertension, obesity, stroke, several types of cancer, and so on (Ruegsegger and Booth 2018). It also has positive effects on mood states such as anxiety, stress, and depression (Mikkelsen et al. 2017). Besides all these substantial benefits, engaging in sports is associated with an increased risk of eating disorders (EDs) (Currie 2010). In fact, EDs are quite common among athletes (Bratland-Sanda and Sundgot-Borgen 2013).

Sports nutrition is a delicate subject. High energy and micronutrient demands of athletes can be met with rigorous planning and a painstaking application. And this needs to be maintained regularly for many years. Most athletes begin training at very early ages, and their preoccupation with food begins with it. As athletes reach adolescence, sensitive body image issues come to the stage. Unfortunately, the culture of specific sports almost promotes EDs during childhood and adolescence. Additionally, using/abusing sports supplements-drugs is common at all levels of sports (Ozkan et al. 2020; Yargic et al. 2021). Things get even more complicated if an athlete becomes famous. Being constantly under media attention, receiving frequent criticism from referees, fans, and sports commentators on their bodies put athletes, particularly ones with a perfectionist personality trait, at high risk for EDs

(Currie 2010). Such intersections are common in sports, as many athletes consider themselves to be perfectionists, many athletes are under performance pressure, and many have high media attention. Unfortunately, it is not always possible for athletes to get proper and high-quality counseling either, because health professionals also have very variable levels of knowledge and awareness about athlete nutrition and EDs in athletes (Curry et al. 2015; Özdengül and Yargic 2020). Understanding and hopefully preventing EDs in athletes is particularly important not only for their own health and well-being but also because they are role models to many children and adolescents.

In this chapter, we will try to review the risk factors, sports disciplines with high association with EDs, prevalence of EDs in athletes, ED in male athletes, special considerations for different types of EDs, and finally valid screening tools specifically developed for athletes.

Prevalence of EDs in Athletes

Prevalence studies on EDs consistently report more EDs in females than in males (Bratland-Sanda and Sundgot-Borgen 2013). This is also true when it comes to athletes; female athletes have a higher prevalence of EDs than male athletes. Schaal et al. reported that 4% of male vs. 6% of female athletes suffered from an ongoing ED, while 5.5% of male vs. 11.2% of female athletes suffered from a lifetime ED (Schaal et al. 2011). Nichols et al. reported 20.0% prevalence of disordered eating behavior among high-school female athletes (Nichols et al. 2007). In the study of Sundgot-Borgen and Torstveit, a prevalence rate of 20% was reported in female athletes vs. 8% in male athletes, while male controls' ED prevalence was 0.5% and female controls' was 9% (Sundgot-Borgen and Torstveit 2004). Byrne and McLean evaluated female and male elite athletes' and controls' eating behavior via structured diagnostic interviews and revealed that ED rates are as follows: female athletes 22%, male athletes 4%, female controls 5.5%, and male controls 0% (Byrne and McLean 2002). Although numbers vary, a consistent finding is that athletes are at higher risk than controls and females are higher than males.

Risk Factors

Some of the risk factors are common to the general population, while others are specific to athletes. Some of the general risk factors are female gender, body dissatisfaction, certain personality traits (such as perfectionism), low self-esteem, and history of abuse. Some of the risk factors specific to the athletic population are pressure from the coach, pressure to be successful, early onset of sport-specific training, and early onset of puberty (Sanford-Martens et al. 2007; Bratland-Sanda and Sundgot-Borgen 2013). Several situations were additionally identified as triggering factors for EDs in athletes. These include dieting for an extended length of

time, frequent weight swings, a rapid increase in training volume, and traumatic occurrences such as an injury or the loss of a coach (Sundgot-Borgen 1994).

Which Sports Disciplines Are at Higher Risk for EDs?

It is well known that prevalence of EDs is higher in athletes than in general population (Sundgot-Borgen and Torstveit 2004). However, the difference is much more prominent in certain sports disciplines.

In aesthetic sports, where athletes succeed according to the referee's opinion and aesthetic evaluation, physical appearance and leanness gain special importance. Gymnastics, rhythmic gymnastics, figure skating, roller skate figure skating, ballet, and dancing are examples of such sports. The frequency of EDs is found to be increased in the competitive athletes of these branches (Krentz and Warschburger 2011) (Fig. 1).

In endurance sports, a common belief is that being leaner would lead to faster paces because the athlete wouldn't have to carry the extra weight (Schotzko 2021),

Fig. 1 A young female gymnast. It should be a priority of sports-health professionals to keep those who are at high risk of ED safe. (Image: Freepik)

Table 1 Examples of sports disciplines with higher risk of EDs

"Lean" sports		
Aesthetic sports	Endurance sports	Weight category sports
Gymnastics, rhythmic gymnastics, figure skating, roller skate figure skating, ballet, dancing	Distance running, rowing, cycling	Judo, taekwondo

and in accordance with this belief, a high prevalence of EDs is observed in endurance runners and cyclists (Sundgot-Borgen and Torstveit 2004).

In many sports disciplines, such as wrestling, karate, and judo, athletes compete in narrow weight categories. Commonly, these athletes lose and gain weight rapidly, using unhealthy methods. These athletes are also at higher risk for EDs according to studies (Sundgot-Borgen and Torstveit 2004; Ackerman et al. 2011) (Table 1).

EDs in Male Athletes

EDs are predominantly studied in female athletes. This may be creating an erroneous representation of people who are at high risk for EDs in the eyes of physicians. Also, screening tools focus on female athletes with questions regarding menstrual health. However, research shows clearly that male athletes have higher rates of EDs than nonathlete males (8% vs. 0.5%) (Sundgot-Borgen and Torstveit 2004). EDs were found to be common among male rowers, cyclists, and even bodybuilders (Thiel et al. 1993; Goldfield et al. 2006; Riebl et al. 2007).

The image of a female gymnast that comes to mind first when it comes to "EDs and sports" is, of course, based on a scientific basis. However, stereotyping this example should not result in ignoring the EDs of many different athletes.

Special Considerations on Anorexia Nervosa in Athletes

In 1983, researchers reported that a subgroup of male runners' psychological traits were very similar to those of female anorexia nervosa patients. They called these male runners "obligatory runners." The common traits and behaviors were inhibition of anger, perfectionism, unrealistic high self-expectations, physical resilience, refusal to acknowledge possibly substantial debility, tendencies toward depression, weight preoccupation, rigid dieting, and running to compensate for overeating (Yates et al. 1983). Later, it was proposed that some characteristics of athletes which are often associated with anorexia nervosa are perhaps the reason behind these athletes' success (Thompson and Sherman 1999).

Many similarities between AN patients and athletes definitely complicate defining athletes who are at higher risk of EDs due to their personality traits, but it should be kept in mind that they may also assist in the treatment process.

Special Considerations on Bulimia Nervosa and Binge Eating Disorder (BED) in Athletes

Athletes need to maintain a certain body weight and composition for a long period of time (Yargic et al. 2020). For this purpose, many of them often utilize unhealthy weight management strategies. Such unhealthy behaviors include strict dieting, fasting, restricting fluids, spitting, excessive exercising, training in heated rooms, self-induced vomiting, and using laxatives/enemas/diuretics (Artioli et al. 2010; da Silva Santos et al. 2016). Such pathological weight management methods are sometimes accompanied by binge eating attacks as well. These combined make up for a substantial part of the diagnostic criteria of bulimia nervosa. One study with 218 female gymnasts revealed that more than one third of participants reported binge eating at least once a week, almost half of them (48.6%) exercised in order to burn calories for more than 2 hours a day, and one fifth did strict diets or fasting in the previous year. Indeed, in this study, 4% of participants have met the full criterion of bulimia nervosa (Petrie and Stoever 1993). Such behavior is not only common in female gymnasts but in a broader athlete population, including among male athletes that engage in power sports. For example, high prevalence rates of binge eating (48%), bulimia nervosa (30%), and preoccupation with body weight and body image (84.6%) were observed among competitive male body-builders (Goldfield et al. 2006). Although a wide range of athletes are at risk of bulimia nervosa and BED, special attention should be given to athletes who compete in weight categories, as they practice rapid weight loss methods more often.

Special Considerations on Orthorexia Nervosa in Athletes

Orthorexia nervosa, unlike other EDs, is shaped around an obsession with healthy eating, which has no relation to body weight or body perception. In this regard, the control of body weight is not in the focus. Instead, food sources, the way the food is prepared and packaged, naturalness, and healthiness are at the forefront. There is a moderate correlation between exercise addiction and orthorexic eating, but this correlation doesn't imply that all athletes are prone to orthorexia (Strahler et al. 2021). It's not infrequent that elite athletes develop unhealthy habits, such as substance, alcohol, or drug abuse (Reardon and Creado 2014; Martens 2017). Therefore, the inference that elite athletes adopt a healthy lifestyle and thus should be more inclined toward orthorexic behavior cannot be made so easily. Indeed, research examining ON tendencies of athletes shows a great deal of diversity in results. Some studies find that being an elite athlete, recreational athlete, or a sedentary person doesn't affect one's tendency toward ON, whereas others report ON to be a frequent ED among athletes (Segura-García et al. 2013; Özdengül et al. 2021).

Relative Energy Deficiency in Sport (RED-S)

A relative deficiency in energy refers to the mismatch between the energy that the athlete receives with the diet and the energy that she/he spends on exercise. Energy that will support the functions necessary to maintain the ideal health and performance of the body cannot be contained in the system. Available energy is calculated by subtracting the energy consumed by exercise (kcal) from the energy received by diet (kcal) and dividing the difference by lean body weight (kg). The ideal available energy level for the physiological function of women has been determined as 45 kcal/kg FFM/day (Loucks and Thuma 2003). On the other hand, the value of 30 kcal/kg FFM/day has been determined as a value where the functions of many systems are disrupted and energy availability is low (Williams et al. 2015) (Fig. 2).

A very important issue regarding the RED-S syndrome is that it is not always related to a disordered eating behavior. An athlete can simply be unaware of the negative energy balance. Additionally, many athletes suffer from asymptomatic vitamin deficiencies regardless of their eating habits (Dönmez et al. 2018). Mostly, this is due to being reckless of their dietary needs. Even so, understanding RED-S and its multisystemic effects is crucial in evaluating and treating athletes who are in energy deficit due to an ED (Fig. 3).

This syndrome was previously known as the female athlete triad, which had a narrower scope. The female athlete triad is a diagnosis limited to bone and reproductive health. On the other hand, the diagnosis of a relative lack of energy in sports also includes disorders associated with the endocrine system, immune system, cardiovascular system, gastrointestinal tract, hematological system, metabolic system, and growth and development (Mountjoy et al. 2018) (Table 2).

Tools for Screening EDs Specifically in Athletes

There are several validated tools to screen for disordered eating in athletes and some are in development. The College Health-Related Information Survey (CHRIS-73) is one of these available instruments. It is validated among college student athletes and consists of four factors (mental health, eating problems, risk behaviors, and

$$\text{Available Energy} = \frac{[\text{Calorie input (kcal)} - \text{Calorie expended by exercise (kcal)}]}{\text{Lean body mass (kg)}}$$

Fig. 2 Equation of available energy level

Fig. 3 Interpretation of available energy levels in females

Table 2 Effects of energy deficiency on systems

Endocrine	Disturbed hypothalamic-pituitary-gonadal axis Disturbed thyroid function Alterations in appetite regulatory hormones Decreased insulin and insulin-like growth factor 1 Increased growth hormone resistance Elevated cortisol levels Disrupted gonadotropin-releasing hormone pulsatility Alterations of LH and FSH release Decreased estradiol and progesterone levels	Nattiv et al. (2007), Misra (2014), Allaway et al. (2016), Gordon et al. (2017)
Bone	Decreased bone mineral density Impaired bone microarchitecture Higher risk for bone stress injuries Decreased bone formation and increased bone resorption	Hind et al. (2006), Ackerman et al. (2011), Papageorgiou et al. (2017)
Cardiovascular	Early atherosclerosis Endothelial dysfunction Disturbed lipid profile Valve pathologies Pericardial effusion Bradycardia Hypotension Arrhythmias	Rickenlund et al. (2005), O'Donnell et al. (2011), Spaulding-Barclay et al. (2016)
Immunological	Increased upper respiratory symptoms Lower immunoglobulin A secretion rates Increased risk of illness	Shimizu et al. (2012)

performance pressure) (Steiner et al. 2003). Another tool, which was developed for female athletes, is the ATHLETE questionnaire. The ATHLETE questionnaire has five factors (drive for thinness and performance, social pressure on eating, performance perfectionism, social pressure on body shape, and team trust). All of these factors are predictive of disordered eating in female athletes (Hinton and Kubas 2005). As EDs are more common in females, more tools are developed for identifying them in females. Another example of such questionnaires is the FAST (the Female Athlete Screening Tool). With high internal consistency and high discriminative validity, FAST is a valid tool for detection of disordered eating in female athletes (McNulty et al. 2001). The Low Energy Availability in Females Questionnaire (LEAF-Q) consists of 25 items. It doesn't only question disordered eating but

also injuries and gastrointestinal and reproductive function because the LEAF-Q was originally developed as a screening tool for the female athlete triad (Melin et al. 2014) (Table 3).

Application to Other EDs

Athletes are prone to almost all types of EDs. Athletes' shared personality traits with anorexia nervosa patients, unhealthy weight management strategies shared with bulimia nervosa patients, binge eating shared with binge ED patients, and frequent disordered eating habits shared with eating disorders not otherwise specified (EDNOS) patients paint a picture of the grift and complex situation. Understanding, evaluating, preventing, or treating EDs is challenging in the athletic population. Considering the high prevalence of EDs in athletes, screening should be done periodically for all types of EDs.

Mini-Dictionary

- **Lean sports:** Sports disciplines that put high emphasis on physical appearance and leanness.
- **Non-lean sports:** Sports disciplines such as ball sports or power sports with no special emphasis on having a lean appearance.
- **Relative energy deficiency in sport:** A multisystemic syndrome that results from low energy availability in athletes.
- **Energy availability:** The energy difference between dietary intake and exercise-related expenditure in proportion to lean body weight.
- **Prevalence:** The proportion of a specific population that has a certain condition/disease/disorder in a given time.

Key Facts of EDs in Athletes

- Certain sports are categorized as "lean sports." Athletes of these sports disciplines share the belief that leanness is associated with athletic success. These disciplines include aesthetic sports (such as gymnastics, dancing etc.), endurance sports (such as running, cycling, rowing, etc.), and weight category sports (such as judo).

Summary Points

- Athletes that perform lean sports are at higher risk for EDs.
- Female athletes are at higher risk for ED than male athletes, but disordered eating is common among male athletes as well.
- Certain personality traits of athletes are common with anorexia nervosa patients.
- Unhealthy weight management strategies are often utilized by athletes.
- There are tools for screening EDs specifically in athletes.

Abstract

Eating disorders (ED) are prevalent comorbid conditions in children and adolescent with attention deficit hyperactivity disorder (ADHD). It is estimated that children with ADHD have up to threefold increased risk for eating disorders compared to healthy controls most predominately for binge eating disorder and bulimia nervosa. Psychiatric comorbidities like depression, anxiety, and substance use disorders are common in children and adolescents with both ADHD and ED that need to be addressed early for optimal management. The roles of psychopathology, emotional regulation difficulties, and impulsivity features of ADHD as mediators between ADHD and ED have been widely highlighted in the literature. The chapter goes on to investigate the association between ADHD and ED in pediatric population based on review of the literature. Besides, studying disordered eating behaviors, and risk factors and underlying mechanisms for ED in children and adolescents with ADHD, is needed to develop effective intervention modalities for ADHD and ED.

Keywords

ADHD · Adolescents · Anorexia nervosa · Attention deficit hyperactivity disorder · Binge eating · Bulimia nervosa · Children · Disordered eating behaviors · Eating disorders · Eating habits · Food addiction · Food restriction · Obesity · Teenagers

Abbreviations

ADHD	Attention deficit hyperactivity disorder
AN	Anorexia nervosa
ARFID	Avoidant/restrictive food intake disorder
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
DSM-V	American Psychiatric Association's Diagnostic and Statistical Manual, fifth edition
EAT-26	Eat Attitudes Test-26
ED	Eating disorders
ERD	Emotional regulation difficulties
LOC	Loss of control
RDS	Reward deficiency syndrome

Introduction

Attention deficit hyperactivity disorder (ADHD) is the most common neurodevelopment disorder that affects children and adolescents less than 17 years old. Despite the variance in the prevalence rate of ADHD across countries, a meta-

analysis of over one million participants across the world found that ADHD prevalence estimate is around 7.2% (Thomas et al. 2015). ADHD is marked by its behavioral manifestation that can occur in childhood, but persists into adulthood. Individuals with ADHD can show persistent symptoms of either inattention, hyperactivity-impulsivity, or a combination of inattention and hyperactivity-impulsivity. These behavioral symptoms in school-aged children and adolescents are associated with developmental issues and impairments in social, academic, and occupational functioning resulting in dysfunctions in the individual and family life (Berger 2011).

ADHD coexists with some comorbid conditions, nonpsychiatric and psychiatric, that can complicate the path to recovery and make the management of such chronic illness more complex (Akmatov et al. 2021). Predominant ADHD comorbid conditions include conduct disorder, oppositional defiant disorder, behavioral problems such as substance use, learning difficulties, and anxiety and mood disorders (Rader et al. 2009; Bélanger et al. 2018). Eating disorders (ED) is one of these co-occurring diagnoses that has received high attention. There is compelling evidence suggesting that individuals with ADHD have three times increased risk for ED (Jahrami et al. 2021b).

Intensive investigation of ADHD comorbid conditions like eating disorders is vital for developing an optimal treatment approach since comorbidities can affect the clinical presentation and severity of illness, response to therapeutic intervention, and prognosis (Bélanger et al. 2018). This chapter aims to investigate the association between ED and ADHD in children and adolescents and highlight its implications for effective treatment management.

ADHD: A Prevalent Neurodevelopmental Disorder in Children and Adolescents

ADHD Diagnosis and Etiology

After depression and anxiety, ADHD is the third most prevalent mental health disorder worldwide, affecting more males than females in a 3:1 ratio (Polanczyk et al. 2015). ADHD is classified as a neurodevelopmental disorder by the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-V), and is defined as "a persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development and negatively impacts social and academic/occupational activities" (2013). The presentation of ADHD is affected by gender; it has been discovered that males have a higher risk of developing ADHD, specifically the combined presentation hyperactivity/impulsivity, while inattention presentation is more common in females. To meet DSM-V diagnostic criteria for ADHD, the child must present with a 6-month history of inattention, distractibility, hyperactivity, fidgetiness, and/or impulsivity, and these symptoms should be present in multiple settings including home, school, and/or clinical settings. ADHD is mostly identified in school-aged children as child behaviors become noticeably inconsistent with their developmental age and cause distress,

poor academic performance, and functional and social impairments at home and school.

Although a definite causality of ADHD remains unknown, ADHD has multiple etiologies, including a mix of genetic, neurological, and environmental factors. Factors affecting brain development or linked to brain injuries, such as hypoxic-anoxic brain injuries, epilepsy disorders, and traumatic brain injury, are the most common neurological factors contributing to ADHD risk. Pregnancy and birth complications such as low birth weight and preterm birth and uterus exposure to excessive alcohol and tobacco are among environmental risk factors for ADHD (Banerjee et al. 2007). Besides, exposure to adverse life events, unhealthy family environment, psychopathology of parents, and poor parenting strategies/style are associated with ADHD symptoms (Huhdanpää et al. 2021). It can be proposed that the interaction between the genetic and environmental factors throughout illness account for the complexity of ADHD.

The management of ADHD is based on behavioral intervention, pharmacologic therapy, or combined. Nonetheless, behavioral interventions are the most common intervention. It consists of life skills and social skills training, behavioral modification, parenting skills training, and family support groups. The pharmacologic therapy is based on the use of psychostimulant medications, such as methylphenidate and mixed amphetamine salts, or non-psychostimulants, such as atomoxetine. The psychostimulant treatments are associated with a reduction in symptomatology and improvement in functional and academic performance. The adoption of combined pharmacologic and behavioral interventions has been highly recommended as behavioral interventions can aid in reducing the need for a high dosage of medications, thereby reducing some of its undesirable side effects (Rader et al. 2009).

ADHD Comorbidities

ADHD has multiple comorbidities that determine the course of illness and prognosis. The most predominant comorbid conditions are represented in the Fig. 1.

It is worth showing that these comorbid conditions share some commonality with ADHD in terms of symptom similarities and etiologies, many of which are listed as part of the 16 differential diagnoses for ADHD set by the DSM-IV, while the rest are conditions that are frequently misdiagnosed as ADHD (Bélanger et al. 2018). This makes the diagnostic process of ADHD challenging, especially with the variations in diagnostic methods and the absence of biological markers.

The prevalence of ADHD comorbid conditions in children is high. It has been estimated that more than one-third of children with ADHD had at least one or more comorbid conditions. Fifty percent of these children are likely to have ADHD symptoms in adulthood. The main predictors that account for symptom persistence include severe symptomatology, ADHD combined subtype (inattention/hyperactivity), and psychiatric comorbidity, namely, mood disorders, multiple comorbidities, and parental anxiety (Lara et al. 2009).

Fig. 1 Attention deficit hyperactivity disorder comorbid conditions. Common comorbid conditions associated with attention deficit hyperactivity disorder

Eating Patterns of Children with ADHD

The association between ADHD and obesity has been extensively researched since both conditions are major public health problems that impact people of all ages and are linked to high morbidity and mortality rates. Contrary to the presumption that ADHD can be associated with weight loss due to hyperactivity symptoms, it has been found that children and adults with ADHD have significantly higher rates of more than average body mass index (BMI) and/or obesity. Based on the findings of a recent meta-analysis of 42 studies involving a total of 728,136 individuals (48,161 ADHD subjects; 679,975 comparison subjects), 70% of adults with ADHD and 40% of children with ADHD had an increased risk for obesity compared to the general population (Cortese et al. 2016). It is worth noting that the obesity prevalence was significant in included studies after adjustment for age, gender, race/ethnicity, family status and structure, and parental

education. It has been found that both males and females with ADHD hyperactive-impulsive presentation had considerably higher BMI compared to those without ADHD, yet only females with ADHD inattentive presentation had significantly higher BMI. However, most of the published studies did not control for the effect of medication and psychiatric comorbidity, especially that besides ADHD, depression, and anxiety are associated with obesity among children and adolescents. Conversely, several research evidences pointed to the high prevalence of ADHD symptomatology in children seeking obesity treatment. Considering the mixed findings related to whether ADHD precedes obesity or obesity leads to ADHD symptoms, this bidirectional relationship between the two conditions is complex and unclear, requiring rigorous testing. Some argue that the interplay between genetic factors and shared unhealthy lifestyle factors, including diet, sleep, and physical activities by family members, may explain the correlation between obesity and ADHD in children (Cortese 2019).

The link between ED, obesity, commonly known weight-related problems, and ADHD is established, and eating patterns of children with ADHD have been widely investigated. This section will address key findings related to disordered eating patterns in children and adolescents with ADHD.

Loss of Control (LOC) Eating/Binge Eating

In pediatrics, LOC eating is a form of disinhibited or binge eating behaviors that is characterized by frequent consumption of large amounts of food and difficulties resisting the urge to eat. LOC eating also is predictive for excessive weight gain and negative psychological consequences. Recurrent LOC or binge eating is the hallmark behavior of ED diagnoses including bulimia nervosa (BN) and binge eating disorder (BED). It has been noted that only a few children and adolescents meet the criteria for BED; therefore, the adoption of LOC eating term over BED is more favorable for this population group (Tanofsky-Kraff et al. 2008).

It has been found that around two-thirds of adolescents with obesity experience LOC eating (Wentz et al. 2019). Besides, the odds of LOC eating are significantly higher in children with ADHD; it is estimated to be 12 times more in those with than without ADHD (Reinblatt et al. 2015b). There is a positive correlation between ADHD symptoms and overeating behaviors in the aspects of unhealthy diet intake, increased frequency of overeating episodes and diet speed, and emotional eating, in which the person tends to overeat in response to emotional distress, eating for pleasure, and eating in response to external cues such the deliciousness and appearance of food (Kaisari et al. 2017). Some of the prominent aspects of LOS eating in youths include eating in reaction to stimuli, eating alone or while watching TV, and having poor awareness of the amount of food consumed or what is going on in the moment (Tanofsky-Kraff et al. 2008). It has been suggested that those youths with LOC eating are at greater risk for developing a disordered eating attitude and depressive and anxiety symptoms in the long term (Tanofsky-Kraff et al. 2011).

A study evaluated response inhibition in youth with LOC eating, adopting performance-based measures as objective measure and parent rating scale as a subjective measure, found that the manifestation of impaired response inhibition is significantly higher among those with than without LOC eating. This can represent the role of impulse control deficits as a potential mediator between ADHD and LOC (Reinblatt et al. 2015b). Impaired impulse control and impaired executive function are hypothesized to be mechanisms contributing to disinhibited eating behaviors. There is growing evidence suggesting the role of childhood impulsive behaviors to be above inattention and hyperactivity effects in predicting pathological eating behaviors during adolescence. Moreover, conflictual parent and child relationships and high emotion expression are common in families having children with ADHD and are assumed to be a predictive factor for disordered eating in girls with ADHD. Nevertheless, it has been found that families with high emotional expressions characterized by high levels of criticisms and punitive parenting style can predict eating pathology only after controlling for ADHD. This may support the notion that internalized variables such as impulsivity, rather than externalized ones, have a role in pathological eating behaviors (Mikami et al. 2008).

Binge Eating Disorder (BED)

Recurrent episodes of binge eating/LOC eating have been found to have a clinically significant association with eating disorders. Numerous studies have demonstrated the association between ADHD and BED in adults. Only a few studies have affirmed this association in pediatric population. Data from a cross-sectional study based on clinical mental health settings has shown that children with ADHD had 16 times increased odds for developing BED, based on rigorous diagnostic criteria, compared to their counterparts without ADHD. It is estimated that 24% of children with ADHD had met the diagnostic criteria for BED (Reinblatt et al. 2015a). Besides, those children with BED and ADHD had higher rates of depressive symptoms and greater BMI and obesity rates, with those who were prescribed antidepressants having significantly higher BMI. It is worth noting here that the role of psychiatric comorbidity as a potential mediator between ADHD and BED has not been investigated in most published pediatrics studies. Interestingly, recent evidence on adults with ADHD pointed out that after adjusting for comorbid psychopathology, the association between BED and ADHD did not reach statistical significance (Ziobrowski et al. 2018). Such evidence may support the hypothesis that underlying psychopathology may affect the association between binge eating and ADHD; thus, taking psychopathology into account is pivotal to best understand this association between BED and even other ED and ADHD.

Bulimia Nervosa (BN)

During binge eating episodes, adolescents have greater tendencies to develop concerns such as overeating, weight, and shape (Hilbert and Czaja 2007). The development of bulimia nervosa (BN) in pediatrics with childhood ADHD is high (Cortese et al. 2007), and is likely to manifest during mid-adolescence (Mikami et al. 2010). Owing to body weight and shape dissatisfaction and potentially peer pressure, adolescents with ADHD have higher tendencies to engage in purging and other inappropriate compensatory behaviors to prevent weight gain following binge eating. Similarly, some suggest that obese youth with bulimic behaviors are likely to present with ADHD symptoms (Cortese et al. 2007). Both conditions share similar clinical features in terms of impaired impulse control. Some argue that childhood impulsivity is a strong predictor for BN symptoms during adolescence. Moreover, Schweickert et al. (1997) argued that disordered eating in adolescents with ADHD is a maladaptive compensatory mechanism to manage frustration associated with deficits of attention and organization skills. It is possible to argue that the inattention dimension of ADHD may contribute to disordered eating patterns. Still, the compulsive eating behaviors can interrupt one's activity, leading to worsening of inattention symptoms.

Anorexia Nervosa (AN) and Avoidant/Restrictive Food Intake Disorder (ARFID)

Eating and weight-related problems lead to the adoption of unhealthy weight control behaviors such as dieting and skipping meals, which were found to be a predictor for weight-related issues in adolescence (Neumark-Sztainer et al. 2007). The interplay between negative body image, weight control-related social pressure, and restraint eating can contribute to development of AN characterized by extreme self-starvation. AN is prevalent mostly in female but far less compared to BED. Attempts to establish a connection between AN and ADHD were weak, and the association between these concurrent conditions was not significant (Råstam et al. 2013).

The onset of restrictive food behaviors can start early in young children and lead to nutritional deficits. Avoidant/restrictive food intake disorder (ARFID) has proven to be common co-occurring eating disorder with ADHD. Unlike AN, food restricting behaviors in ARFID are not attributed to distorted body image or weight concerns. Rather, it can be related to decrease interest in food, repulsion of some food characteristics, or fear from eating. Similar to children and adolescents with ADHD, pediatrics with ARFID has higher vulnerability for anxiety disorders. It has been proposed that anxiety affects the reasoning behind restrictive food behaviors in ADHD, thereby serving as a trigger for ARFID (Nicely et al. 2014). Attention should be directed toward unfavorable side effects of some

stimulant therapy drugs for ADHD management, namely, loss of appetite especially for those with ARFID, which can aggravate food restraint behaviors (Pennell et al. 2016).

Children with ADHD are likely to have difficulty adhering to meals' time schedule with a higher frequency of irregular eating time and skipping meals. ADHD children's diet is characterized by lower nutritional value as they incline to consume less fruit and vegetables but high sweetened beverages. Also, children with ADHD have limited involvement in physical activities (Ptacek et al. 2014). It worth mentioning that patients with ADHD may present with normal weight, but still suffer from disruptive eating behaviors that require early detection and intervention. Even in the absence of disordered eating, higher ADHD symptomatology predicts high fat mass on later ages (Bowling et al. 2018) and increased risk for malnutrition (Güngör et al. 2016).

Prevalence of ED in Children and Adolescents with ADHD

Our research group has published a case-control study on the prevalence of ED in a sample of children and adolescents with ADHD conducted in the Child/Adolescents Psychiatry Unit – Kingdom of Bahrain. Seventy cases with ADHD aged between 8 and 19 years old were recruited and matched with 140 healthy controls. The Eating Attitudes Test-26 (EAT-26) was used as measure to estimate risk of ED. We found that children and adolescents with ADHD have a threefold higher risk for ED than healthy controls (Jahrami et al. 2021b). These findings are in line with Nazar et al. (2016) results that patients with ADHD have threefold increased risk for ED, while patients with ED have twofold risk for ADHD. Our data also revealed that increased BMI/body weight is a predicator for increased risk of ED. In addition, we found that female has slightly increased risk for ED than male though it did not reach statistical significance which is perhaps due to the small sample size (Jahrami et al. 2021b). The increased risk of ED among female cases is consistent with preliminary evidence from epidemiological studies in which ED is more common in females than males (Striegel-Moore et al. 2009).

The Table 1 represent the key findings.

The greater manifestation of ADHD symptomatology in patients with ED is associated with more severe eating pathology, though differences do exist between ED subtypes. The table below represents estimated prevalence rate of different ED in pediatrics with ADHD. BN is the most prevalent form of ED among people with ADHD (Nazar et al. 2016). Similarly, it has been found that patients with BN and BED, characterized by poor impulse control, are more likely to present with more ADHD symptoms compared to those with AN (Fernández-Aranda et al. 2013) (Table 2).

Table 1 Sociodemographic characteristics and risk of eating disorder: comparison between cases and controls

Characteristics	Cases/($N = 70$)	Controls (N-140)
ED status measured by EAT-26		
Normal At risk	68.57 31.43	87.86 12.14
Medication CNS stimulants methylphenidate	38.57	—
Categorical variables (%)		
Gender (male)	74.29	74.29
Gender (female)	25.71	25.71
Overweight	18.57	47.86
Obese	4.29	14.29
ADHD type		
Inattentive. Hyperactive-impulsive. Mixed type.	24.29 17.14 58.57	
Continuous variables (mean)		
Age	13.45	15.62
Body mass index (BMI)	19.02	25.57

Key findings of risk of eating disorders among children with attention deficit hyperactivity disorder compared to controls. From Jahrami, AlAnsari et al. (Jahrami et al. 2021b) with permission

Table 2 Prevalence rate of different eating disorders in pediatrics with attention deficit hyperactivity disorder

Eating disorder diagnoses	Prevalence in children and adolescents with ADHD (%)
Bulimia nervosa	9–34.9
Binge eating disorder	19.8
Anorexia nervosa	3–16.2

Estimated prevalence rate of different eating disorders in pediatrics with attention deficit hyperactivity disorder based on recent research evidence

The Role of Gender in the Prevalence of ED Among Children and Adolescents with ADHD

There is an interesting evidence suggesting the ADHD precedes the development of ED. In other words, ADHD is a risk factor for ED in youths and adult. There is consensus that both girls and boys with ADHD are at increased risk for ED. Nevertheless, the findings are mixed regarding the effects of gender on the ADHD and ED. It has been found that girls with ADHD and ED are more vulnerable to depressive and anxiety disorders and behavioral disturbances, including addictive behaviors, than those girls with ADHD only indicting heightened risk for morbidity and dysfunction (Biederman et al. 2007). Longitudinal study revealed that girls with ADHD have higher prevalence of anxiety and depressive symptoms but a lower prevalence of antisocial disorders compared to boys (Biederman et al. 2010). The

level of BN symptoms is higher in girls than boys with ADHD, while binge eating manifest more in boys. There are no significant gender differences in the age and body weight of patients with ED at presentation (Welch et al. 2015). The size of increased risk of ED diagnoses in pediatrics with ADHD is very similar to that of adults. Given that growing body of evidence has showed the association between ADHD and obesity, the risk association between ADHD and ED in both genders is around double that association with obesity (Nazar et al. 2016).

Risk Factors for ED in Children and Adolescents with ADHD

Psychiatric Comorbidities and Emotional Regulation Difficulties (ERD)

Depression, anxiety, and substance use disorders are common psychiatric comorbid conditions linked to ED, and, likewise, it has been linked to ADHD. It has been found that individuals with ADHD and ED are at greater risk of psychiatric comorbidity compared to those with ED or ADHD only. As stated earlier, it can be argued that psychiatric comorbidity may account partially for the association between the two diagnoses (Ziobrowski et al. 2018). Consequently, it can complicate the management of both disorders as those with high psychiatric comorbidities are likely to experience greater occupational and psychosocial dysfunction and poorer patient and family quality of life (Kandemir et al. 2014).

Emotional regulation difficulties (ERD) are facets of response inhibition problems and are identified as a core risk factor for both ADHD and ED (Christian et al. 2020). Emotional regulation constitutes five processes: situation selection, situation modification, attentional deployment, cognitive change, and response modulation (Sheppes et al. 2015). During negative emotional state, individual's perceptions and modulation of situations and ability to manage emotional regulation processes can be impaired, consequently increasing tendency to involve in inappropriate actions/maladaptive behaviors including pathological eating, which in turn can induce negative affectivity. The role of ERD in predicting persistence of ADHD symptoms overtime is established (El Archi et al. 2020). Greater ERD at baseline account for higher ADHD symptomatology at follow-up (Masi et al. 2020) leading to functional impairments and psychosocial dysfunction. It has been found that youth diagnosed with ADHD has lower tolerance for stress and frustration than those without ADHD (Barkley 2016) and is at greater risk for suicidal and self-harm behaviors, poor adherence to treatment, and greater stress level (Seymour et al. 2012). The inattention features of ADHD correlate with impaired situation identification, while hyperactivity-impulsivity features are related to poor emotional response inhibition. Robust evidence has revealed that relationship between ADHD and disordered eating (addictive-like eating) is mediated by emotional regulation as illustrated in Fig. 2. Similarly, ERD in adolescents with ADHD account for increased vulnerability for various addictive disorders such as games and food addictions (Evren et al. 2018) and substance use (Poon et al. 2016).

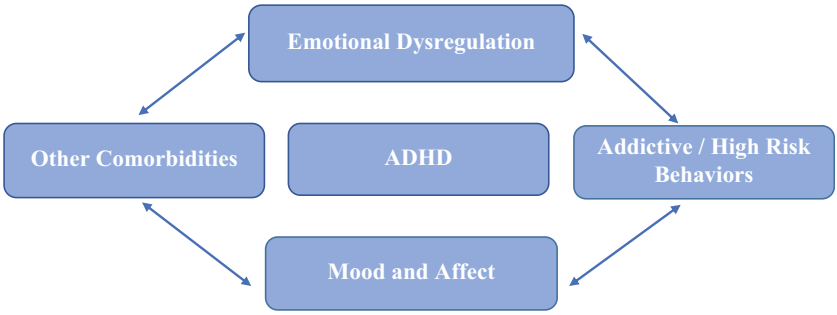

Fig. 2 The role of emotional regulation difficulties as a mediator between attention deficit hyperactivity disorder and disordered eating. The link between attention deficit hyperactivity disorder symptoms, emotional dysregulation, affect, and addictive/high-risk behaviors

Sleep Disturbances: The Overlooked Factor for Disordered Eating

The interrelationships between sleep disturbances and ADHD are complex and potentially multifactorial. Sleep disturbances are more prevalent among children and adolescents with ADHD compared to the general population. It is estimated that between 25% and 50% of children and adolescents would present with sleep problems including difficulty initiating and/or maintaining sleep along with daytime sleepiness (Cortese et al. 2009). Interestingly, excessive daytime sleepiness has been positively associated with symptoms of hyperactivity, inattention, and impulsivity in children. Nováková et al. (2011) argue that circadian system subtle differences between children with ADHD and those without are contributing factors that can affect sleep quality, attention, and activity level, thereby imposing greater consequences on daytime functioning. Moreover, individuals with ED have significantly higher risk for sleep problems, obesity, and daytime dysfunction.

Studies have pointed out that sleep deprivation can contribute to disruption of appetite-regulating hormones leading to weight gain and obesity and an increased risk for mood disorders (Allison et al. 2016). Indeed, sleep intervention for children and adolescents with ADHD is crucial to manage the disorder and its comorbidities. Authors emphasized the importance of sleep and other lifestyle factors as they are directly linked to the presentation, progression, and management of ADHD and its comorbidities. Sleep health intervention for children with ADHD is effective in promoting sleep quality and generating positive psychosocial functioning in terms of improving physical and mental well-being and social functioning (Keshavarzi et al. 2014).

Digital Media Use Influences on Body Satisfaction and Eating Behaviors

Numerous studies raised the concern about the negative influences of excessive use of digital media among children and adolescents. With the ongoing coronavirus

pandemic, a surge in the use of digital media among people of all ages has been reported as the transition to digital world has become inevitable. A recent evidence highlighted the connection between increased exposure to digital media, namely, gaming and social media, among children with ADHD and increased severity of ADHD core symptoms, executive function impairments, negative emotions, and other behavioral problems (Shuai et al. 2021). Social media use has been found to contribute to various psychiatric disorders including affective disorders and eating disorders. Digital media use, especially appearance-oriented social media, has been linked to increased body dissatisfaction, drive for thinness, and eating issues with adolescents especially more prone to these impacts due to their developmental characteristics (Rodgers and Melioli 2016). Popular youths' websites place great emphasis on physical appearance which is perceived by adolescents as the central component of online identity that has been normally targeted during cyberbullying (Berne et al. 2014). Besides, the importance of thinness is frequently reaffirmed in the content of the websites, many of which present eating disorders as a life-choice rather than a severe form of psychiatric disorder. Clearly, the influences of digital media use among children with ADHD are vast and are associated with worsening of health outcomes as illustrated in Fig. 3.

Fig. 3 Digital media use influences on children and adolescents with ADHD. The influences of excessive digital media use on the cyber-psychosocial behaviors of children and adolescents with ADHD

Besides, nomophobia (no mobile phone phobia) has become an emerging phenomenon affecting all people in our digital era but mostly youths, which is linked to an increased risk for psychopathology. Nomophobia has been found to be positively associated with anxiety symptoms in young individuals (Güneş and Özdemir 2021). A recent study examined the association between symptoms of nomophobia, food addiction, and insomnia found that the rate of moderate to severe nomophobia among young adults is approximately 93%, while the rate of food addiction is around 19% and rate of moderate to severe insomnia is 14%. Interestingly, in this study, nomophobia has been significantly associated with insomnia but not food addiction (Jahrami et al. 2021a). Considering that this study specifically targets young adults, future studies should examine the association between nomophobia, ADHD symptoms, and disordered eating in adolescents with ADHD.

Possible Mechanisms Underlying the Association Between ADHD and ED

The role of dopaminergic signaling system in explaining the linkage between ADHD and ED has been widely highlighted. Reward deficiency syndrome (RDS) is related to the reward circuitry of the brain, resulting in hypodopaminergic function. The abnormality of brain dopamine (DA) function has been reported in individuals with ADHD, SUD, and ED making them more susceptible to reward sensitivity including food-related rewards than the majority of people and tendencies for craving behaviors (Broft et al. 2012).

The effect of impulsivity, inattention, and hyperactivity on the severity of eating disorder symptoms has been widely investigated. Evidence has revealed that inattention and impulsivity (but not hyperactivity) combined predicted bulimic behavior 5 years following an ADHD diagnosis (Cortese et al. 2007). A possible link between impulsivity and BN has been discovered by various authors. Recent evidence has affirmed the positive relationship between impulsivity and bulimic symptoms, drive for thinness, as well as other disordered eating patterns (Christian et al. 2020). Childhood impulsivity is related to increased vulnerability for ED during adolescence. Nevertheless, direct causal relationship between impulsivity dimension of ADHD and ED is not established and is still questionable and can be only answered by longitudinal studies.

Ample evidence has demonstrated that obese ADHD patients at risk for eating disorders were primarily inattentive. It is possible that poor awareness to internal signals of hunger and satiety associated with the inattention dimension of ADHD contributed to pathological eating behaviors both binge and restrictive (Kaisari et al. 2018). Moreover, alterations in executive function including impairments in attention, decision-making, cognitive flexibility, and response inhibition do affect functional tasks including food-related tasks. To sum up, the possible mechanisms underlying the association between ADHD and ED are complex and not clear, and it can be described as a combination of biological, psychological, and social/environmental factors as illustrated in Figs. 3 and 4.

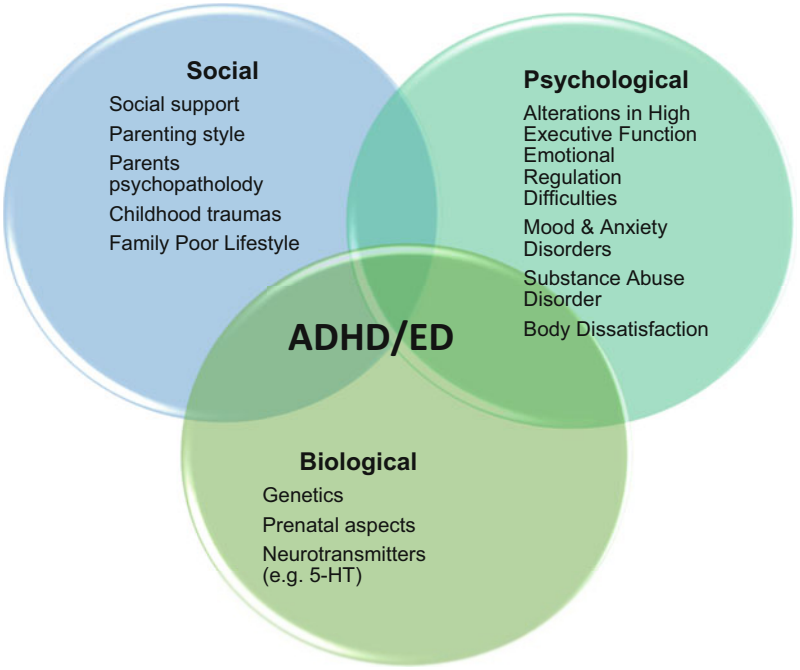

Fig. 4 Main factors associated with attention deficit hyperactivity disorder and eating disorder comorbidity. Key proposed factors underlying the association between attention deficit hyperactivity disorder and eating disorder

Clinical Implications/Clinical Management of ADHD and Eating Disorder

Essentially, a comprehensive assessment of children and adolescents with ADHD entails investigation of potential comorbidities, physical examination, and detailed history of child behaviors from multiple informants as some core symptoms of ADHD might not be observed in clinical settings. This can aid in narrowing ADHD differential diagnosis considerably. Besides, continuous follow-up of ADHD over time from childhood till adulthood is essential for capturing comorbidities and providing early multidimensional interventions that should firstly address conditions causing major distress and functional impairments. Central to this process is understanding the interplay between environmental and genetic factors and modifying environmental risk factors at early stages as part of prevention interventions. At the same time, children and adolescents with ED or obesity should be screened for ADHD symptoms pertaining to the increased prevalence of ADHD symptoms among obese children (Cortese et al. 2016).

A combination of pharmacologic interventions to manage ADHD and ED core symptoms and cognitive behavioral therapy to manage maladaptive behaviors,

ERD/negative affectivity, and control impulses is highly desirable. The psychostimulant treatment can bring about positive changes in high executive and organization skills and impulse control that account for normalization of eating patterns in the long term. Previous evidence revealed that the continuation of ADHD treatment for obese patients over 1 year generates favorable outcomes as it was associated with an average 15 kg weight loss compared to 3 kg weight gain among non-treated (Levy et al. 2009). It is worth noting that weight management issues need to be considered when prescribing medication for ADHD either for children or young adults. Moreover, the dietary pattern and physical fitness of children with ADHD should be addressed and monitored systematically by healthcare workers and lifestyle counseling should be offered to patients and families, even for those with normal body weight who may exhibit disordered eating patterns. Sleep interventions to regulate children sleeping schedule can improve daytime function and enhance emotional well-being and promote social behaviors (Keshavarzi et al. 2014). Supervision of digital media usage is recommended for the management of ADHD core symptoms (Shuai et al. 2021).

As implications for future studies, in order to develop better insight into the relationships between ADHD and ED, longitudinal studies should examine full range of eating patterns and behaviors including loss of control over eating and restraint eating and explore possible shared mechanisms between ADHD, impulse control and attention deficits, and emotional dysregulation. Additionally, in-depth examination of ADHD comorbidities during adulthood is equally important even when symptoms are less disabling especially that ADHD progression from childhood to adulthood is not linear (Weissenberger et al. 2017). Besides, pubertal stage and adjustment for comorbid disorders should be considered in prospective studies examining the association between ADHD and ED. Similarly, screening adolescents with obesity and/or eating problems for ADHD symptoms is worth considering. Targeting behavioral factors that promote excessive weight gain or other weight-related issues may be a potential point of intervention. Moreover, clarification of relevant behavioral factors is required before prevention efforts may be designed and implemented.

Applications to Other Eating Disorders

In this chapter, we review evidence on the prevalence of ED among children and adolescents with ADHD and the association between both disorders. The increased prevalence of ED in individuals with ADHD up to three times necessitate screening those with ADHD for ED symptoms (Jahrami et al. 2021b) and vice versa (Cortese 2019). In-depth screening for comorbidities like depression, anxiety, and addictive disorders, likely to lead to poor functional outcomes, from childhood to adulthood is of relevance. This has implications for other eating disorders since psychopathology plays a key role in mediating the correlation between ED and ADHD plus predicting

health outcomes (Ziobrowski et al. 2018). ED prevention and treatment should focus on managing ERD and negative affectivity in vulnerable population such as youths with neurodevelopmental disorders from early stages (Christian et al. 2020). Additionally, managing impulsive behaviors and alterations in executive function which may affect one's ability to process sensory information related to body's basic needs as hunger/satiety is imperative (Kaisari et al. 2018). Enhancing functional connectivity of brain reward through achieving DA homeostasis in the brain can decrease tendencies for multiple addictive, compulsive, and impulsive behaviors, thereby helping in not only managing food addictive behaviors but also lowering risk for SUD commonly seen in those with ED (Broft et al. 2012). To achieve this, a combination of both pharmacologic therapies specifically ADHD stimulants drugs and behavioral interventions are suggested. The combined intervention has been proven effective in regulating disordered eating patterns though further longitudinal studies are required (Rader et al. 2009). Central to behavioral interventions for an optimal management of ED is the provision of lifestyle interventions that do not only target dietary pattern but also tackle weight management issues, physical fitness, and sleep intervention. Modifying the lifestyle behaviors within the social environment in which patient with ED and family live is highly valuable. Since binge and bulimic eating are related to obesity and ED in children and adolescents, comprehensive assessment of eating attitude is deemed important as part of preventative measure for both obesity and other ED.

Mini-Dictionary of Terms

- Dopamine is a critical neurotransmitter in the brain that is normally released when the brain is expecting a reward; thus, it plays a role in how we feel pleasure.
- Emotional regulation difficulties (ERD) are defined as poor responsiveness to emotions due to dysfunctional understanding, reactivity, and management or response modulation (Mennin et al. 2007)
- Nomophobia is a form of situational phobia characterized by excessive fear or worries of not having own mobile phone or not being able to use it.
- Response inhibition is a cognitive process related to one's ability to suppress actions considered to be inappropriate in a given context, thereby helping in adopting more appropriate goal-driven behaviors.
- Reward deficiency syndrome (RDS) is a hereditary and epigenetic condition that causes damage to the reward circuitry of the brain, resulting in hypodopaminergic function. RDS is caused by the combination of several strong neurotransmitters, resulting in aberrant seeking behaviors.
- Stimulant is a type of medicine that speeds up the transmission of signals between the brain and the body by boosting the levels of certain brain chemicals, like dopamine and norepinephrine, making someone feel more aware, alert, or energetic.

Key Facts of Eating Disorders in Children and Adolescents with ADHD

Key Facts of Reward Deficiency Syndrome (RDS)

- Both ADHD and ED rely on the same dopaminergic signaling system.
- Patients with ED show abnormalities in brain dopamine (DA) function similar to those seen in people who abuse substances (Broft et al. 2012).
- Dopaminergic signaling is essential for motor activity and emotional responses and behavior, including learning, motivation, sleep, mood, and attention.
- Abnormalities in DA lead to poor reward response inhibition and addictive-like eating.
- The linkage between ADHD and dopaminergic system helps in explaining its association with ED and many other comorbidities.

Key Facts of Stimulant Drugs for ADHD

- Stimulants are the first line of drug treatment for children with ADHD. They include methylphenidate (Ritalin) and amphetamine (Adderall).
- Stimulants target receptors of the brain chemical DA as DA is related to many health disorders such as ADHD, SUD, schizophrenia, and obesity.
- Stimulants are considered effective in improving ADHD symptoms in about 70% to 80% of children.
- Some stimulants can cause loss of appetite, weight loss, and trouble sleeping.
- Stimulants are used either alone or in combination with behavioral therapy.

Summary Points

- There is significant positive association between ADHD and ED.
- Children and adolescents with ADHD have been found to have threefold increased risk for ED besides increased risk for obesity and increased BMI.
- ED as ADHD comorbidity is associated with increased prevalence of psychiatric comorbidities, namely, depression, anxiety, and addictive disorders leading to negative psychosocial consequences.
- The prevalence of BN and BED is high among children and adolescents with combined subtype compared to those with AN.
- Impulsivity is a common clinical feature for both ADHD and ED that may account for the association between both disorders.
- ERD are among risk factors for both ADHD and ED that are hypothesized to be a mediator between ADHD and disordered eating.
- The adoption of combined pharmacologic and behavioral interventions in the management of ADHD can contribute to symptom reduction, thereby aiding in

regulating disordered eating patterns and promoting academic and social functioning.
- Screening for comorbidities in children with ADHD is required for effective management
- Sleep problems are prevalent in both ADHD and ED and associated with daytime dysfunction. Sleep interventions have been found effective in managing ADHD and its comorbidities.
- Limiting high exposure to digital media is required to manage ADHD core symptoms and minimize its influences on body image and eating behaviors.

Abstract

Sleep and eating are both essential life functions. Dysregulation in either sleep or eating behaviors can result in significant problems with physical and mental health. Insomnia is a common sleep complaint, in which people report difficulty with initiating or maintaining sleep or waking up too early. When these symptoms are frequent, chronic, and associated with daytime dysfunction, then individuals may meet the criteria of insomnia disorder. Despite emerging evidence suggesting that insomnia symptoms and insomnia disorder are elevated in people with eating disorders, there remains much to be learned about the mechanisms underlying the association between insomnia and eating disorder pathology. In this chapter, we provide the reader with an overview of the nature of insomnia disorder in people with eating disorders, potential mechanisms for their co-occurrence, and current evidence-based psychological methods of treating insomnia symptoms. Future directions for research are offered to drive further study, which has implications for how both eating disorders and insomnia symptoms are treated.

Insomnia in Eating Disorders

Insomnia disorder is one of eleven sleep disorders described in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*), and by far the most common (American Psychiatric Association 2013). In addition to the significant psychosocial and occupational impairment caused by insomnia disorder, the economic burden is high; for example, in the United States, insomnia disorder is associated with $100 billion in yearly healthcare costs (Taddei-Allen 2020).

Considering the widespread effects of sleep on health and functioning, insomnia and its treatment is a promising area of study, most notably in the mental health literature where insomnia has recently been linked to the onset, course, and severity of various forms of psychopathology, including affective disorders and substance-use disorders (Hertenstein et al. 2019; Lancel et al. 2021). In fact, treating insomnia in adjunct to treating these other psychiatric conditions can produce treatment effects on both the psychiatric condition and insomnia symptoms (Taylor and Pruiksma 2014). Such results have ignited hope in the arena of eating disorders, where insomnia disorder is highly prevalent.

The nature of the association between insomnia disorder and eating disorders and options for treatment of co-occurring symptoms remains relatively understudied. Thus, the purpose of this chapter is to increase understanding within the community of eating disorder providers and researchers of the diagnostic criteria and theoretical

models of insomnia disorder, explore the co-occurrence of insomnia disorder and eating disorders, and explicate treatment options.

Defining Insomnia

Insomnia disorder is characterized by difficulty initiating or maintaining sleep, or waking up earlier than desired, with daytime impairment, despite adequate opportunity and circumstances to sleep for at least 3 nights per week for at least 3 months (Table 1). Typically, a threshold of 20 to 30 min is used to define the point at which sleep onset or failure for maintenance is non-normative (American Psychiatric Association 2013). Insomnia disorder is unique from many other sleep disorders because it requires sleep disturbance *and* subjective complaints of impairment. Specifically, individuals must report clinically significant daytime dysfunction, which can include problems like fatigue, difficulty concentrating, mood disturbances, irritability, or worrying about sleep that affect social, occupational, and academic functioning. Consequently, it is not recommended that certain objective sleep measurements, such as polysomnography, are exclusively used for diagnosis, as they may fail to distinguish between people with and without insomnia (Schutte-Rodin et al. 2008).

Insomnia symptoms fall into two categories: acute or persistent (also known as chronic insomnia or insomnia disorder). Acute insomnia is determined when symptoms are experienced for more than 1 month but less than 3 months and is reported by approximately 30–50% of the population each year (Ellis et al. 2012). Persistent insomnia occurs when symptoms are experienced for more than 3 months and is reported by approximately 10% of the population (Morin et al. 2015). Unless readers carefully examine the duration of symptoms assessed in different insomnia disorder measures, whether a study assessed acute or persistent insomnia disorder may not be explicitly known. A closer look at the literature suggests that, in general, studies

Table 1 DSM-5 criteria for insomnia disorder

Criteria	Detail
Dissatisfaction with sleep quantity or quality (one or more symptoms) despite adequate opportunity to sleep	Difficulty initiating sleep Difficulty maintaining sleep Awakening earlier than desired with an inability to go back to sleep
Symptom frequency	Minimum 3 nights per week
Symptom duration	Minimum 3 months
Clinically significant daytime dysfunction	Impairment or distress related to social, work, educational, or other domains of functioning
Rule-out diagnoses	Not attributable to the physiological effects of a substance Not better explained by or occur exclusively within the course of another sleep-wake disorder Not better explained by co-occurring mental disorders or medical conditions

investigate persistent insomnia, which we will refer to as insomnia disorder from hereon. Even with this general acknowledgment, prevalence and incidence differ across studies based on the criteria used to define the disorder (Bos and Macedo 2019). Notably, insomnia disorder prevalence is elevated in psychiatric populations, with one study using a mixed psychiatric sample of people with affective and psychotic disorders finding that 32% of patients met *DSM-5* criteria (Seow et al. 2018).

Insomnia symptoms and insomnia disorder are not meant to be interchangeable; rather they represent dimensional and categorical conceptualizations of a type of problematic sleep behavior. As a parallel, the difference between insomnia symptoms and insomnia disorder can be likened to the difference between "eating disorder symptoms" and "eating disorder" – specific criteria related to duration of symptoms and impairment must be met to receive a diagnosis. Nonetheless, many studies use insomnia disorder, insomnia symptoms, and sleep disturbance interchangeably and may not explicitly identify how insomnia disorder is operationalized or measured. Similarly, studies often use terms like "sleep disturbance," "poor sleep," "short sleep," or "sleep restriction" and measure these concepts with objective measures of sleep (i.e., sleep polygraph variables, slow wave sleep, EEG) and/or self-reported measures of sleep duration, fragmentation, or quality; however, shortened sleep duration or sleep disturbances are not necessarily indicative of insomnia. For example, shortened sleep duration may represent normal sleep patterns for some people and solely relying on the objective measure without measuring impairment could result in incorrectly classifying people as having insomnia. On the other hand, people may have insomnia with or without shortened sleep duration (Bathgate et al. 2016). Another challenge with interpreting the literature on insomnia is one of differential diagnosis. In some cases, sleep disturbances may be incorrectly classified as insomnia symptoms, rather than other sleep disorders that result in disrupted sleep patterns (e.g., obstructive sleep apnea, nightmare disorder, delayed sleep-wake phase disorder). Thus, careful examination of the frequency, duration, and impairment related to insomnia symptoms, as well as understanding the limitations of certain self-report or objective measures, is critical for interpretation.

Insomnia as Transdiagnostic Across Psychopathology

The study and interpretation of insomnia is complicated by the transdiagnostic nature of insomnia symptoms across mental disorders (Dolsen et al. 2014; Harvey 2008), which can make it difficult to determine whether insomnia exists independently or dependently of another psychological disorder. This can be especially challenging when insomnia symptoms are part of the diagnostic criteria of other common co-occurring psychiatric disorders, such as major depressive disorder or generalized anxiety disorder. However, insomnia disorder can be diagnosed *in addition* to another mental disorder when symptoms meet certain diagnostic thresholds (i.e., difficulty initiating or maintaining sleep for $\geq$3 nights/week $\geq$3 months, along with daytime dysfunction) and are associated with distress and impairment

independent of the "primary" condition. Although insomnia disorder may begin with the onset of a psychiatric disorder, it often develops its own unique maintaining factors that persist regardless of the presence or absence of the other condition (Spielman et al. 1987). Indeed, even when co-occurring psychological conditions such as depression or anxiety disorders are successfully treated, insomnia disorder frequently does not remit without specialized insomnia treatment (Carney et al. 2007, 2011; Cousineau et al. 2016; Mason and Harvey 2014), which further supports the distinction as an independent diagnosis. In sum, it is important for readers to understand that insomnia disorder is an independent psychiatric diagnosis which often co-occurs with other forms of psychopathology (Harvey 2001) and is associated with concurrent increased severity of psychopathology and poorer well-being (Lancel et al. 2021).

Understanding insomnia disorder as a co-occurring condition is valuable because insomnia disorder may influence the trajectory of psychological disorders. For example, elevated insomnia symptoms at discharge from successful treatment for depression, anxiety, and substance-use disorders are associated with increased risk of relapse for these conditions (e.g., Babson et al. 2013; Chen et al. 2017; Manber et al. 2008; Ohayon and Roth 2003; Short et al. 2017). Importantly, treating insomnia disorder can alter the risk of relapse for co-occurring disorders, as in one study which found a sustained reduction in depression symptoms for 1 year after treatment for insomnia disorder (Cheng et al. 2019). This may be particularly relevant for eating disorders because psychological disorders for which insomnia symptoms are a common feature, including major depressive disorder, post-traumatic stress disorder, and generalized anxiety disorder (Hertenstein et al. 2019; Li et al. 2016; Thun et al. 2019), are associated with increased severity and poorer treatment outcomes in eating disorders (Becker and Grilo 2015; Keshishian et al. 2021; Mitchell et al. 2021; Trottier 2020).

Based on the extant body of literature on insomnia as a risk factor for other forms of psychopathology, it is highly warranted to examine if insomnia symptoms, and more specifically, insomnia disorder, function as a similar risk factor for onset, severity, and treatment outcomes in eating disorders. Such knowledge would be critical in informing the use of interventions to treat co-occurring insomnia in people with eating disorders and potentially enhance treatment outcomes among eating disorder populations.

Insomnia Disorder and Symptoms in Eating Disorders

The comorbidity between eating pathology and sleep problems has been supported in the literature for decades (e.g., Crisp et al. 1971; Franklin et al. 1948; Latzer et al. 1999), but only recently has there been an increased focus on insomnia disorder and its symptoms, specifically. Currently, the investigation of insomnia symptoms and insomnia disorder in eating disorders is limited to populations with anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), and night eating

syndrome (NES). There is virtually no data on insomnia in feeding disorders such as pica, rumination disorder, or avoidant/restrictive food intake disorder (ARFID).

Of the existing research focused on insomnia in eating disorders, subjective measures of insomnia reveal relatively similar prevalence rates, degree and severity, and level of impairment among the eating disorder categories, such as AN, BN, and BED (Allison et al. 2016; Cinosi et al. 2011; Kim et al. 2010). There have also been attempts to use objective measures of sleep disturbance, which provide varying conclusions about the differences between types of eating disorders compared to self-report measures of insomnia disorder. For example, objective measures of sleep behaviors have found that AN is more likely to be associated with poor sleep quality and hypersomnia (i.e., increased duration of sleep), people with BN more commonly report problems with sleep latency (i.e., difficulty falling asleep), and people with BED and NES report more frequent awakenings (Cinosi et al. 2011; Lundgren et al. 2008). It is important to note, however, that because the diagnosis of insomnia disorder also requires subjective impairment, it is not surprising that objective measurements of sleep patterns do not always converge with self-report measures of insomnia.

Another, arguably more effective, way to understand insomnia in eating disorders is to focus on the similarities, rather than the differences, of insomnia symptoms across eating disorder diagnoses. Taking a shared-features approach like this aligns with the widely adopted transdiagnostic approach to psychological disorders, which is particularly relevant in the case of eating disorders where diagnostic migration between types of eating disorders is common (Ackard et al. 2011; Milos et al. 2005). When eating disorder populations are studied together, prevalence rates are as high as 50.4% (Kim et al. 2010), with the most common insomnia symptom being difficulty initiating and maintaining sleep (e.g., Asaad Abdou et al. 2018; Bos et al. 2013) and increased impairment of daytime functioning (e.g., Tromp et al. 2016).

Insomnia symptoms can also be examined based on the behaviors common across eating disorders, such as engagement in restriction, compensatory behaviors, or loss-of-control eating. With this approach, it is apparent that insomnia symptoms are especially prevalent among people presenting with binge-purge symptoms, both in non-clinical (e.g., Aspen et al. 2014; Bos et al. 2013; Goel et al. 2020; Kandeger et al. 2019; Lin et al. 2020; Lombardo et al. 2020; Natale et al. 2008; Serra et al. 2020; Soares et al. 2011; Tromp et al. 2016) and clinical populations (e.g., Allison et al. 2016; Asaad Abdou et al. 2018; Cooper et al. 2020; Della Marca et al. 2004; Lauer and Krieg 2004; Lombardo et al. 2015; Ralph-Nearman et al. 2021; Tanahashi et al. 2017). Finally, the severity of insomnia symptoms is often proportional to the severity of eating disorder symptomology at a single point in time as well as after eating treatment (Bos et al. 2013; Lombardo et al. 2015). These findings suggest that insomnia appears to be a clinical marker of current behavioral disturbances among eating disorders and may be of interest as a secondary parameter to eating disorder recovery.

Hypotheses for Understanding the Underlying Mechanisms of Insomnia and Eating Disorders

Part of unlocking the potential for treating insomnia in people with eating disorders is understanding the link between the two disorders. The mechanisms underpinning the association between eating disorders and insomnia are complex, and likely involve an interplay of psychological, biological, and social factors (e.g., Christensen and Short 2021). Key theories in both the insomnia and eating disorder domains can help us to understand what may differentiate those who go on to these conditions from those who do not. In the following sections, we outline potential shared areas of overlap that may explain the co-occurrence of insomnia disorder and eating disorders.

Hypothesized Psychological Factors

According to the Cognitive Model of Insomnia (Harvey 2002), insomnia symptoms are perpetuated by an interaction between maladaptive cognitive processes, behaviors, and emotional responses. In this model, maladaptive cognitive processes include misconceptions about normal sleep, excessive worry about the consequences of inadequate sleep, and other sleep impairing dysfunctional cognitions (e.g., cognitive inflexibility, rumination). One such example of a dysfunctional cognition includes commonly reported thoughts like "I will not be able to function tomorrow if I do not get 8 hours of sleep tonight." Behavioral mechanisms that perpetuate insomnia involve maladaptive sleep-incompatible behaviors (also known as "safety behaviors," e.g., daytime napping to compensate for a night of poor sleep) and sociocultural variables and trends (e.g., technology use) which reinforce sleep-incongruent cognitions (Bos and Macedo 2019). Therefore, according to this model, sleep problems are developed and maintained when worry about not obtaining adequate sleep (cognition) impedes the ability to fall asleep (behavior), which induces rumination about the implications of sleep disturbances (cognition), resulting in heightened negative affect (emotion), thereby perpetuating the inability to fall asleep (behavior).

According to the transdiagnostic Cognitive-Behavioral Model of Eating Disorders (Fairburn 2008; Fairburn et al. 2003), eating disorders are also developed and maintained through an interplay between cognitive processes, behaviors, and emotional responses. To provide one example, preoccupation with body shape and weight (cognition) may drive attempts at food restriction (behavior). When food is eventually and inevitably consumed (behavior), a negative self-evaluation (cognition) and negative emotionality (emotion) may ensue, which then perpetuates the preoccupation with body shape and weight (cognition), potentially driving increased engagement in restriction, purging, or excessive exercise (behavior).

We hypothesize that placing these psychological models together may offer insight into mechanisms driving the association between insomnia and eating disorders (Fig. 1). For instance, worry and unrealistic expectations about sleep

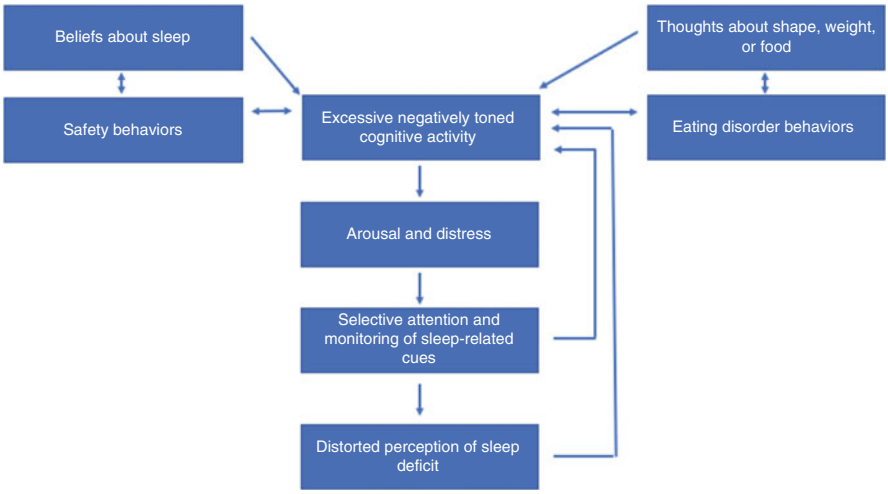

Fig. 1 Proposed integrated cognitive-behavioral model of insomnia and eating pathology extended from Harvey (2002) and Fairburn et al. (2003)

(cognition) and preoccupation with body weight and shape (cognition) could increase arousal and therefore interrupt the ability to fall asleep (behavior). In turn, this may increase vulnerability to negative affect (emotion), which could result in decreased ability to inhibit rumination about body weight and shape (cognition) and which may heighten arousal and interfere with sleep processes. Increased arousal due to distress about sleep or eating behaviors could then result in increased use of eating disorder behaviors to reduce negative affect (behavior), thereby perpetuating eating disorder symptoms. Thus, our proposed integrated cognitive-behavioral model of sleep and eating behaviors suggests a complex interaction between cognitions, affect, and behavior that heighten symptoms of both insomnia disorder and eating disorders.

Another hypothesis linking insomnia symptoms to eating disorders is that they share a common variance with depression and anxiety symptoms (e.g., Daga et al. 2011; Staner 2010; Xiao et al. 2021), and thus, there is a common diathesis for these disorders (Aspen et al. 2014). In other words, the relationship between insomnia and eating disorders is driven by these third variables related to internalizing psychopathology. On one hand, some studies show no difference in insomnia symptoms in the presence or absence of depression (Latzer et al. 1999) and that the link between insomnia symptoms and eating disorders remained after accounting for depression (Nagata et al. 2020). However, other studies show that depression and anxiety mediate the association between insomnia symptoms and eating disorder pathology in non-clinical (Goel et al. 2020; Lombardo et al. 2014) and clinical populations (Lombardo et al. 2015).

Hypothesized Biological Factors

Several hormones and neuropeptides have been implicated in both sleep and eating behaviors, and their interaction may underlie dysfunction present in both insomnia disorder and eating disorders. For example, insomnia symptoms are associated with dysregulated levels of leptin and ghrelin (e.g., Motivala et al. 2009; Spiegel et al. 2004; Taheri et al. 2004), which are appetite-regulating hormones that influence hunger, satiety, and consumptive behavior. Ghrelin and leptin interact with a neuropeptide called orexin, which influences sleep and arousal (Willie et al. 2001). One theory is that when people are not experiencing eating disorder symptoms, glucose and leptin suppress orexin, allowing for normal sleep-wake patterns; however, for people with eating disorders, glucose and leptin levels can become altered, thereby causing dysregulated orexin neuronal firing. Similarly, when people experience malnutrition, there may be alterations in the availability of orexin receptors. It is hypothesized that these changes in orexin levels and/or orexin receptor availability increase arousal, thereby impairing sleep processes (Willie et al. 2001); however, the literature on the association between plasma orexin levels and BMI has shown mixed findings (Bronsky et al. 2011; Janas-Kozik et al. 2011; Sauchelli et al. 2016; Steward et al. 2019).

Given that eating disorders and insomnia disorder occur more frequently in women compared to men, there may be sex-related biological factors that contribute to higher symptom co-occurrence. For example, reproductive hormones, such as estradiol, progesterone, and testosterone, are linked to eating disorder symptoms and eating behaviors (Baker et al. 2012; Ma et al. 2020; Mikhail et al. 2021), as well as to insomnia symptoms (Marver and McGlinchey 2020; Suh et al. 2018). Interestingly, both binge eating behaviors and insomnia symptoms are more prominent during the premenstrual week and during the first few days of menstruation than at other times (e.g., Baker and Driver 2004; Gladis and Walsh 1987).

Some studies have posited that insomnia symptoms may interact with body mass or nutritional status in people with eating disorders. First, some people with higher or lower body weights may experience physical discomfort due to their size, which can result in sleep difficulties (Lundgren et al. 2008). Second, neurobiological differences associated with low body weight may be associated with insomnia symptoms (Della Marca et al. 2004); however, it is also possible that these differences may be driven by malnutrition. It is important to note that malnutrition is not distinct to anorexia nervosa or low-weight eating disorders and that people with all eating disorder diagnoses can be malnourished. Disentangling the effects of weight versus nutritional status is an important next step for this line of inquiry. Finally, there is limited literature suggesting that weight gain in people being treated for AN was associated with improved subjective sleep (Ghoch et al. 2016; Pieters et al. 2004); however, it is unclear the extent to which this is driven by weight status itself versus malnutrition status or changes in other psychological variables (e.g., reduced anxiety). Interestingly, in one study, although the authors found that sleep latency became more normative after weight restoration, there was a persistence in increased wake

time after sleep onset, suggesting that weight changes were not sufficient to resolve insomnia symptoms (Ghoch et al. 2016).

Similarly, the possibility of weight driving insomnia in eating disorder populations is challenged by studies where the relationship between insomnia symptoms and eating disorder pathology persist even after controlling for body mass index (Schmidt and Randler 2010; Soares et al. 2011). These findings suggest that it may be behavioral and physiological characteristics of eating disorders such as weight fluctuations, binge eating, purging, exercise, and metabolic and endocrine changes that result in the significant sleep problems characteristic of insomnia (Lauer and Krieg 2004; Tromp et al. 2016). For some people, the act of bingeing and purging can be physically exhausting or results in temporary relief of fears of weight gain and therefore has a calming effect. In these cases, it is not uncommon for people to want to nap after a binge-purge episode (Benca and Schenck 2005). Daytime napping can throw off the sleep-wake cycle and lead to difficulty falling asleep later that day. Alternatively, some people may experience a surge of energy or adrenaline as a result of bingeing and purging, and if this is the case late at night, the person will have trouble falling asleep. Accordingly, intervening on eating disorder behaviors, especially bingeing and purging, has the potential to reduce insomnia symptoms.

Hypothesized Social Factors

Social timing and behaviors have the potential to influence sleep and eating pathology. Eating patterns are considered to be a zeitgeber (i.e., factor that influences circadian rhythms); as such, when dysregulated, they may also alter sleep processes (Stephan 2002). Furthermore, one can consider the instability in sleep and eating times resulting from social engagements or work demands that conflict with natural circadian rhythms. People may have differing sleep schedules across the week, such that they may stay up later and sleep in on weekends or non-work days when they have decreased obligations. These changes may lead to difficulty falling asleep at typical hours on the non-work days due to dysregulated biological rhythms and lack of opportunity to build sleep drive (Wolfson and Carskadon 1998). Over time, this could lead to the development of insomnia symptoms and insomnia disorder (Brandão et al. 2021; Foster et al. 2013; Henderson et al. 2019). Similarly, such fluctuating schedules may also alter the timing of meals and natural hunger drives. When individuals stay up late to socialize, they may consume food at later times, which can impact arousal and quality of sleep. For example, one study found that when food was consumed less than one hour prior to bedtime, there were increased reports of waking after sleep onset accompanied by increased sleep duration, which the authors hypothesize is an attempt to compensate for the inefficient sleep caused by frequent awakenings (Iao et al. 2021). More frequent or late-night eating behaviors due to increased time awake may also increase the drive for individuals to engage in compensatory behaviors to make up for perceived excessive calories consumed. Furthermore, sleeping in may also result in meal skipping, which could reinforce maladaptive eating patterns. The inconsistency resulting from these

fluctuating sleep cycles may make individuals with eating disorders experience dysregulated hunger and fullness cues, which could maintain eating disorder pathology.

There are also developmental considerations in terms of control over sleep and eating behaviors. Both are characterized by decreased personal control in childhood and adolescence (e.g., caregivers more likely to determine timing), with increased control gained as people age. In particular, emerging adulthood is characterized by changes in responsibility and identity development, which includes independence over health behaviors including sleeping and eating (Miller et al. 2002). For many, there is often an abrupt shift in sleep schedules, which can increase the risk of experiencing insomnia symptoms (Gellis et al. 2014; Maslowsky and Ozer 2014; Wolfson and Carskadon 1998). The unstable and unstructured nature of this developmental period is a time of increased vulnerability to the onset of mental health problems (Kessler et al. 2005), including eating disorders (e.g., Lipson and Sonneville 2017). Further developmental milestones, such as pregnancy and parenthood, can also have dramatic impacts on both sleep (Da Costa et al. 2021; Parfitt and Ayers 2014; Román-Gálvez et al. 2018; Sedov et al. 2021) and eating behaviors (Bye et al. 2021) and understanding how to support people as they navigate these times of increased stress is critical. Longitudinal studies are needed to better understand how insomnia and eating disorder symptoms may be associated with increased risk at developmental transition periods.

Treatment Implications

Despite the effect that insomnia symptoms can have on eating disorder symptoms and treatment trajectory (Allison et al. 2016; Aspen et al. 2014; Cinosi et al. 2011; Lauer and Krieg 2004; Lundgren et al. 2008; Tromp et al. 2016), there is little data on how to tailor sleep interventions to eating disorder populations and address insomnia symptoms as a means of improving treatment.

Insomnia symptoms and insomnia disorder may be treated using either non-pharmacological (i.e., behavioral sleep medicine) or pharmacological approaches (e.g., medications such as benzodiazepines or "z-drugs"). Currently, the American Academy of Sleep Medicine recommends that non-pharmacological interventions, such as cognitive-behavioral or behavioral therapy, be used as a first line treatment for insomnia disorder (Edinger et al. 2021). Cognitive-behavioral therapy for insomnia (CBT-I; Morin 1993) has demonstrated strong empirical support in reducing insomnia symptoms and dysfunctional beliefs about sleep at end-of-treatment, with effects maintained over a year-long follow-up period (Soh et al. 2020; Thakral et al. 2020; van der Zweerde et al. 2019). In CBT-I, factors that contribute to the maintenance of insomnia are addressed with techniques such as psychoeducation about sleep, stimulus control techniques (i.e., limiting activities in bed to sleep and sexual activity), sleep restriction and titration (limiting time in bed to consolidate fragmented sleep and/or reduce sleep latency), sleep hygiene, and cognitive restructuring of dysfunctional beliefs about sleep.

CBT-I is a highly flexible treatment program. It is typically conducted over a period of 4–8 weeks and can be delivered effectively in group or individual formats. Furthermore, telehealth-delivered CBT-I has demonstrated noninferiority to in-person interventions, meaning that the current evidence supports the use of either modality (Soh et al. 2020). Further, CBT-I is a robust treatment that remains efficacious even when comorbid mental or physical health disorders are present (Wu et al. 2015).

Unfortunately, there is a dearth of research into the best ways to apply CBT-I for treating insomnia symptoms or insomnia disorder in people with eating disorders. The extant evidence from the literature on insomnia disorder co-occurring with post-traumatic stress disorder, with depression, or with anxiety disorders suggest that integrating CBT-I into treatment for these disorders shows promise for improving insomnia symptom severity, as well as the reducing symptoms of the co-occurring diagnoses (e.g., Belleville et al. 2016; Colvonen et al. 2018; Manber et al. 2008; Talbot et al. 2014; Taylor et al. 2018). Furthermore, given the impacts of insomnia on factors such as emotion regulation, concentration, and memory, treating insomnia symptoms prior to engagement in treatment for eating disorders could be helpful for increasing the efficacy of eating disorder interventions. This rationale has been applied to post-traumatic stress disorder treatment, with one case study suggesting the use of CBT-I as a preparatory treatment for exposure therapy for post-traumatic disorder (Baddeley and Gros 2013). However, the literature on the most effective timing of insomnia treatment deployment is still developing, and more trials are needed to determine the most appropriate approach to treatment staging. Within the field of eating disorders, there has yet to be a comprehensive trial testing the efficacy of CBT-I in this population, much less trials on how to optimize timing of insomnia treatment delivery (i.e., whether treatment of insomnia should occur prior to or after treatment of the so-called primary disorder). However, researchers are beginning to study this question (e.g., Christensen et al. 2021). This is a notable gap in the clinical literature, particularly given the prevalence of clinically significant insomnia symptoms in eating disorder populations.

Another limitation for the delivery of insomnia interventions to people with eating disorders at this time is that there is a dearth of treatment providers who offer evidence-based behavioral sleep medicine interventions. Across the field of clinical psychology, training in behavioral sleep medicine is lacking; for example, a 2020 survey of clinical psychologists found that only 5% had received instruction in treating sleep disorders during their career, although many identified this as an important area of interest (Zhou et al. 2020). To address this need, a free web-based CBT-I training program called *CBTIweb* has been developed to offer comprehensive education in the assessment and treatment of insomnia (Taylor et al. 2021). Eating disorder treatment providers interested in becoming competent in CBT-I may consider this program, as well as resources offered by the Society for Behavioral Sleep Medicine, an international society dedicated to the scientific study of sleep, and the Board of Behavioral Sleep Medicine, a non-profit organization that credentials providers in behavioral sleep medicine (specifically, the Diplomate of Behavioral Sleep Medicine or DBSM).

Finally, another difficulty for eating disorder treatment providers who may wish to address insomnia symptoms in their practice is that few, if any, resources for CBT-I have been tailored to the treatment needs of this population. This is important because current recommendations found in CBT-I may or may not be appropriate for use with people with eating disorders and may fail to adequately address the ways that maladaptive eating behaviors maintain insomnia symptoms. For example, practitioners who use CBT-I may recommend moderate daytime exercise as a way of helping lower arousal for nighttime – in many people with eating disorders, such a recommendation may be contraindicated for their recovery or must be carefully monitored to ensure that it does not exacerbate their symptom profile. Similarly, as part of CBT-I, providers may identify and challenge negative thought processes, such as worry, which are posited to interfere with sleep onset. In the case of people with eating disorders, it is certainly possible that rumination or intrusive thoughts related to shape, weight, or control over eating may comprise these negative thought processes. In this case, tailoring aspects of CBT-I to specifically target eating-related concerns that maintain problematic sleep patterns may be critical. For example, the "worry time" recommended in CBT-I to reduce arousal in bed could be specifically designated for times to worry about body shape and weight concerns. Similarly, clinicians may wish to identify if eating behaviors (e.g., hunger or loss-of-control eating) are interfering with ability to fall and stay asleep. More research is needed on the best ways to address the specific needs of clients with eating disorders and how to translate this into effective insomnia disorder treatments.

Conclusion

Tremendous progress has been made over that past two decades, and investigating the role of insomnia in various forms of psychopathology has provided interesting insights on etiology and treatment that have great potential for the field of eating disorders. Overall, the literature supports the idea that insomnia symptoms are common and associated with increased eating disorder symptom severity. There remains much to be explored about the specific biopsychosocial mechanisms linking insomnia symptoms and eating disorder symptoms, and consequently the co-occurrence of insomnia disorder and eating disorders. In particular, it is necessary to move our direction of research from *if* the two conditions are linked to *how* and *why*, as well as research investigating the best ways to treat their co-occurrence (e.g., Christensen et al. 2021). Longitudinal studies that explore how these symptoms fluctuate over time relative to each other could offer insight into mechanisms. Similarly, researchers and clinicians may wish to consider incorporating measures of insomnia symptoms into treatment studies to better characterize the influence of insomnia symptoms on eating disorder treatment trajectory, which could provide important insights into how to approach treatment. Finally, overall greater education for eating disorder treatment providers in how to identify and treat insomnia is necessary so that clinicians can feel empowered to intervene on these often-debilitating symptoms. Overall, the study of sleep and eating disorders is rich with

opportunities across the translational spectrum, from mechanisms to implementation, and has great potential to improve quality of life for people with eating disorders.

Applications to Other Eating Disorders

In this review, we take a transdiagnostic approach to discussing the association between insomnia and eating disorders; thus we cover literature related to anorexia nervosa, bulimia nervosa, binge eating disorder, and other eating disorders.

Mini-dictionary of Terms

- **Cognitive-Behavioral Therapy for Insomnia**: An empirically supported, first-line treatment for insomnia disorder, which has shown to have strong effects on reducing insomnia symptoms and maintaining remission from insomnia disorder over time.
- **Ghrelin**: A hormone involved in the regulation and signaling of hunger.
- **Insomnia disorder**: Insomnia symptoms (difficulty falling asleep, staying asleep, or waking up too early) accompanied by daytime impairment that occurs at least three times per week for a minimum of three months.
- **Insomnia symptoms**: Sleep disturbances characterized by difficulties falling asleep, staying asleep, or waking up too early, despite having adequate opportunities for sleep.
- **Leptin**: A hormone involved in regulation and signaling of satiety.
- **Orexin**: A neuropeptide involved with sleep-wake processes and arousal.

Key Facts of Insomnia and Eating Disorders

- Insomnia symptoms and insomnia disorder can have serious impacts on physical and mental health.
- Insomnia disorder has been associated with increased risk for the onset, exacerbation, and relapse of internalizing disorders.
- Insomnia disorder often requires insomnia-focused treatment to fully remit.
- Insomnia symptoms and eating disorder symptoms share common psychological, biological, and social substrates that may increase the odds of co-occurrence.
- Insomnia and eating disorder symptoms are most likely linked through bidirectional associations.

Summary Points

- People with eating disorders report elevated insomnia symptoms.
- Insomnia disorder is an independent mental health condition that may co-occur with eating disorders and, thus, requires separate assessment and treatment.

- The co-occurrence between insomnia disorder and eating disorders likely occurs due to psychological, biological, and social factors.
- Cognitive and behavioral treatments show strong evidence for reducing symptoms of insomnia disorder.
- To date, there is limited information about the best way to treat insomnia symptoms and co-occurring insomnia disorder in people with eating disorders.

Abstract

Uric acid (UA), the end product of purine metabolism, is actively reabsorbed and may modulate behaviors relevant to eating disorders (ED) and play a role in its pathophysiology. Previous evidence suggests higher UA levels among anorexia nervosa–binge eating/purging (AN-BP) subtypes and tophaceous gout as a potential complication in long-standing severe cases. Several factors may affect UA levels including fructose and purine dietary intake, hydration status, reproductive hormonal levels, and renal function, with chronic laxative and diuretic use and repeated vomiting associated with renal dysfunction and hyperuricemia. High UA levels have been proposed in turn to exert a central effect augmenting foraging-like, impulsive–addictive behavioral tendencies and may thus contribute to AN-BP pathophysiology. Larger case–control studies prospectively documenting UA among ED patients stratified according to restrictive and binge eating/purging subtypes are important to validate UA abnormalities in ED and establish its potential utility as an aid in clinical assessment and follow-up. UA and purinergic neurotransmission may constitute novel thitherto unexplored targets for the treatment of behavioral manifestations among AN-BP patients.

Keywords

Uric acid · Salivary biomarkers · Eating disorders

Abbreviations

AN-BP	Anorexia nervosa–binge eating/purging subtype
AN-R	Anorexia nervosa restrictive subtype
ATP	Adenosine triphosphate
BED	Binge eating disorder
BMI	Body mass index
CNS	Central nervous system
CSF	Cerebrospinal fluid
ED	Eating disorders
HPRT	Hypoxanthine–guanine phosphoribosyltransferase
LNS	Lesch–Nyhan syndrome
MSU	Monosodium urate
SUA	Serum uric acid
UA	Uric acid
XOR	Xanthine oxidoreductase

Introduction

Levels of uric acid (UA), the waste product of purine metabolism, are higher in apes and humans due to an evolutionary loss of uricase activity and active renal reabsorption mechanisms, suggesting important physiological roles as an antioxidant and a neural modulator of behavior. Its proposed evolutionary advantage

increasing foraging behaviors under conditions of food shortage has been further suggested to exert potentially hazardous consequences under conditions of fructose- and purine-rich diets, contributing to obesity and metabolic disorders and potentially serving to augment impulsive addictive behavioral tendencies through its central actions. Preliminary evidence including case reports and initial studies points to potential alterations of UA levels among ED patients, with AN-BP patients demonstrating excessive UA levels. In the following chapter, we will briefly summarize relevant physiological and pathophysiological aspects of UA; survey previous data implicating a role for UA in neuropsychiatric disorders; concentrate on evidence linking it with the clinical course and pathophysiology of ED, highlighting potential factors affecting its levels among ED subtypes; and discuss potential implications for UA as a clinically useful biomarker and putative novel therapeutic target for addressing some of the behavioral tendencies gone awry among ED patients.

UA Physiological Roles and General Pathophysiological Aspects

UA is the end product of purine metabolism in all cells, produced through the oxidation of xanthine and hypoxanthine by xanthine oxidoreductase (XOR), allowing elimination of nitrogen waste products (Hille 2005). Produced by oxidative phosphorylation in mitochondria, adenosine triphosphate (ATP) constitutes the major energy transfer coenzyme in the body. It is first metabolized to adenosine, which is then metabolized to inosine via adenosine deaminase and finally to urate via XOR (Cipriani et al. 2010).

The normal serum uric acid (SUA) concentration, largely derived from hepatic degradation of purines, with a range of 3.0–6.8 mg/dL (178–400 μM) is affected by multiple factors including age, gender, and several disease processes. The pathophysiologic role of UA is not clearly understood despite decades of research. UA represents the most abundant antioxidant in human plasma, appearing as monosodium urate (MSU) under physiological PH (Mikami and Sorimachi 2017). Elevated plasma urate among humans and higher primates is the result of urate oxidase inactivation, preventing its degradation to allantoin, consequent to evolutionary mutations timed to the Miocene era that are believed to have perpetuated by conferring a selective advantage through elevating blood pressure and antioxidant capacity (Johnson et al. 2005). Under physiological conditions, UA accounts for 30–50% of the antioxidant capacity, scavenging free oxygen radicals and preventing lipid peroxidation (Crawley et al. 2022). Mechanisms for its active reabsorption by the kidney further point to an important physiological role for UA (Bobulescu and Moe 2012). Recent changes in the industrialized world, with increasing availability of purine-rich food sources such as meat and fructose, have led to increased UA plasma concentrations nearing the limits of its solubility, resulting in increased rates of urolithiasis and gout (Choi et al. 2004). UA concentrations beyond its plasma solubility can lead to chronic deposition of MSU crystals in human joints resulting in inflammatory manifestations as well as joint damage produced by tophi in gout arthritis (Shiozawa et al. 2017). As SUA oversaturation results in crystallization of

MSU and clinical gout, drugs have been developed to lower SUA, through inhibition of the XOR enzyme, increasing urinary UA excretion (uricosurics) or degrading soluble urate (uricases) (Terkeltaub 2010).

Reducing SUA to subsaturation levels allows dissolving of MSU crystals, preventing gout exacerbations, and clearing tophi Shiozawa et al. 2017). Increasing SUA concentrations have been associated with the current pandemic of metabolic syndrome, obesity, hypertension, insulin resistance, and ensuing cardiovascular and renal complications (Johnson et al. 2005; Sharaf El Din et al. 2017). While UA's antioxidant action may exert a beneficial role against oxidative cellular damage and aging, excessive SUA may become prooxidant contributing to metabolic syndrome, cardiovascular disease, chronic heart failure, and metabolic syndrome (Lippi et al. 2008). More recently, a U-shaped association of SUA with all-cause mortality has been suggested with SUA appearing to exert both systemic pro-inflammatory effects that contribute to disease as well as protective antioxidant properties, with XOR enzymatic activity, which catalyzes the last two steps of purine degradation, contributing to both reactive oxygen species and UA formation, both affecting vascular redox hemostasis (Crawley et al. 2022). Indeed, recent evidence suggests both elevated and low SUA may be risk factors for renal, cardiovascular, and pulmonary disorders (Crawley et al. 2022).

UA Measurement in Body Fluids

While serum UA levels constitute the current gold standard for the clinical detection of hyperuricemia and gout, several studies have reported the use of salivary UA concentrations as a disease biomarker. Salivary UA has a robust consistent linear correlation with serum UA ($r = 0.69$) (Riis et al. 2018) and has been suggested as a noninvasive alternative in various clinical settings, (Singh et al. 2019; Soukup et al. 2012; Puschl et al. 2020; Maciejczyk et al. 2020) and several methods for determination of saliva UA concentrations have been developed (Liu et al. 2021; Bukharinova et al. 2021). Of note however, saliva UA measurement may be biased by high abundance of proteins, bacteria, and cells in the oral cavity as well as gingival bleeding and food and drink residues (Liu et al. 2021) that need to be controlled for. Female UA values are generally somewhat lower than male values, (Adamopoulos et al. 1977) and large representative studies among healthy age- and gender-stratified populations are required to establish clinically accepted normative value ranges for salivary UA.

Gender Effects on SUA

Women of reproductive age generally manifest lower UA than men, in part related to both estrogen and progesterone increasing renal UA clearance (Adamopoulos et al. 1977). Consequently, gout afflicts men much more often and is infrequent among women before menopause (Jung et al. 2018). As luteinizing hormone reverts to

prepubertal secretion patterns among AN-R patients, lower estradiol levels result in hypothalamic oligo-amenorrhea (Misra and Klibanski 2016) and would be expected to lower renal clearance of UA, elevating SUA levels. Normal menstrual cycle fluctuations in estrogen and progesterone levels are dose dependently correlated with SUA levels during the menstrual cycle (Mumford et al. 2013). Among postmenopausal women receiving combined estrogen–progestogen treatment, though not with estrogen therapy alone, supplemental hormonal therapy has been shown to reduce UA levels (Jung et al. 2018) and the incidence of gout (Bruderer et al. 2015).

UA in the Central Nervous System (CNS)

Most of the peripheral circulating UA is generated by the liver and with SUA concentrations typically tenfold higher in the periphery than cerebrospinal fluid (CSF) levels (Parkinson Study Group S-PDI et al. 2014). There is evidence to suggest that UA may exert antioxidant and neuroprotective roles in the CNS (Cipriani et al. 2010), with a number of neurodegenerative disorders associated with lower plasma UA levels. Purinergic receptors and enzymes degrading ATP into adenosine and inosine are ubiquitous in multiple brain regions including the cerebral cortex, hypothalamus, basal ganglia, hippocampus, and other limbic areas (Burnstock 2008). Both adenosine and ATP stored in nerve terminals act as purinergic neurotransmitters and co-transmitters in both nerve and glial cells (Burnstock 2008). The actions of ATP are mediated via ionotropic P2X and metabotropic P2Y receptor subfamilies, whereas adenosine actions are mediated via P1 (A1 or A2) adenosine receptors (Krugel 2016).

UA in Neuropsychiatric Disorders

Lesch–Nyhan syndrome)LNS) is a rare inherited X-linked recessive disorder, caused by HPRT1 gene mutations encoding a dysfunctional hypoxanthine–guanine phosphoribosyltransferase (HPRT), resulting in enzymatic deficit and early developmental accumulation of extreme UA levels with renal and neurological complications and gout arthritis (Nyhan et al. 1993). Despite general cognitive disability among LNS that results in compromised discernment of specific behavioral symptoms, patients typically present with compulsive self-injurious behaviors that range from explicit physical self-mutilation, to coprolalia, spitting, and self-induced vomiting, to more subtle displays including refusing recompenses, engaging in self-defeating behaviors, and frustrating and infuriating caregivers when affection is desired (Gualtieri 2002). Enzymatic deficiency early in development interferes with neurodevelopment, and while treatment with the XOR inhibitor allopurinol reduces UA levels, it does not remedy the self-injurious behavioral manifestations (Bell et al. 2016). Furthermore, LNS variant phenotypes that possess over 1% enzymatic HPRT activity do not express self-injurious behaviors, and it is thus less

probable that such manifestations result from the central action of extreme UA levels (Bell et al. 2016).

UA and purinergic neurotransmitters including adenosine and ATP have been shown to contribute to the regulation of important CNS functions including convulsive threshold, memory, cognition, sleep, activity, appetite, mood, social interaction, drive, impulsivity, and intelligence (Alvarez-Lario and Macarron-Vicente 2010; Ortiz et al. 2015). Purinergic neurotransmission has been mechanistically implicated in multiple CNS pathological processes including traumatic brain injury, cerebral ischemia, neurodegenerative diseases, multiple sclerosis, and epilepsy, neuropathic pain, and migraine, as well as in several neuropsychiatric disorders including affective and anxiety disorders, schizophrenia, and alcohol and drug addiction (Burnstock 2008). Several neurodegenerative disorders including Parkinson's disease, (Chen et al. 2012) Alzheimer's disease, (Du et al. 2016) and amyotrophic lateral sclerosis (Abraham and Drory 2014) have been associated with lower SUA and thus suggested to support a neuroprotective role of UA in aging and neurodegeneration. Increased SUA has been reported among bipolar disorder patients (Bartoli et al. 2016), and lower SUA levels among major depression and anxiety disorder patients (Black et al. 2018) that normalize after treatment (Bartoli et al. 2018). Allopurinol has been demonstrated to exert a specific therapeutic effect in manic episodes, (Chen et al. 2018) and as altered XOR activity has been associated with free radical-mediated neurotoxicity, cell damage, and inflammation, XOR inhibitors have been suggested as having therapeutic potential worth exploring for various psychiatric disorders (Martorell et al. 2021).

UA in Eating Disorders (ED)

Several lines of evidence implicate a role for altered UA metabolism in ED. Ostojic and Maas (2018) summarize evidence based on the proposed role of evolutionary uricase loss as driving foraging behavior during food shortage epoch, a neurostimulant role for adenosine neurotransmission, SUA associations with different personality traits, and additional pathophysiological aspects (Simeunovic Ostojic and Maas 2018). Fructose, via its metabolic end products vasopressin lactate and UA, promotes energy storage in the form of fat and glycogen, decreasing mitochondrial ATP and increasing glycolysis, gluconeogenesis, insulin resistance, sodium retention, vasoconstriction, blood pressure elevation, innate immunity stimulation, and foraging behaviors with hyperosmolality-driven thirst and leptin resistance inducing hunger as a mechanism to increase weight (Johnson et al. 2020). The loss of uricase activity among early hominoids during the mid-Miocene era results in higher UA response to fructose, associated with higher stimulation of fat and glucose production. While converging to facilitate survival advantage under conditions of scarce nutrient resources, excessive fructose increases risk for obesity, metabolic diseases, dementia, and cancer (Johnson et al. 2020). Excess dietary fructose intake and high UA levels have been proposed to result in a hyperactive foraging response and contribute to behavioral disorders including attention-deficit hyperactivity

disorder, mania, and aggressive–impulsive behaviors including bulimia, substance use disorders, and risk taking (Johnson et al. 2021).

Several previous small observational studies have documented SUA levels in ED. Two small early studies reported a higher than expected percentage of ED patients presenting with abnormally high SUA levels. In one study, 11 of 27 chronic AN patients had excessive UA at presentation for treatment (Umeki 1988). Another small study reported 9% of a cohort of consecutive ED patients presented with elevated UA at presentation, proposing a potential link with excessive physical exercise-related ATP utilization or starvation-related decrease in renal clearance of UA (Gupta and Kavanaugh-Danelon 1989). A retrospective cohort study reported a threefold higher frequency of renal calculi among AN, with 16% having UA urolithiasis, compared with only 5% among female controls (Denburg et al. 2017). Whereas ammonium urate stones are infrequent in clinical practice, they are repeatedly reported in AN and associated with laxative abuse (Fukai et al. 2017; Dick et al. 1990). Several observations of excessive SUA with tophaceous gout as a possible complication of chronic AN have been reported and ascribed to chronic laxative use resulting in pseudo-Bartter syndrome secondary to laxative abuse, (Adam and Goebel 1987) chronic diuretic use (Hayem et al. 1996; Nakazawa et al. 2004 or chronic kidney impairment accompanying dehydration and low potassium levels with recurrent self-induced vomiting (Kishibe et al. 2010). We reported higher salivary UA levels among a cohort of adolescents with ED, mostly presenting with AN-R compared with age- and gender-matched healthy controls (Giesser et al. 2020). Patients were at the initial phases of illness, and none suffered gout, kidney stones, or renal failure upon medical examination. There was a trend for higher salivary UA levels among ED groups with purging behaviors ($n = 9$), suggesting these may contribute to elevate UA among the ED groups. However, salivary UA remained significantly higher among the larger AN-R groups ($n = 30$) compared with control values, suggesting additional factors underlie elevated UA among AN-R. None of the patients reported diuretic or laxative abuse, and all had normal renal function (Giesser et al. 2020). Only 6 of 83 subjects in our entire sample reported oral contraceptive use, while most AN patients had secondary amenorrhea, which may have contributed to elevated SUA. A larger study reported SUA levels sampled at admission and following hospitalization among 160 adult patients with severe AN or avoidant restrictive food intake disorder (Watters et al. 2022). Serum UA tended to be at the low normal range for a majority of AN-R patients at admission and attributed to malnutrition and low dietary intake of nutrients containing purine and fructose. However, elevated initial SUA, sometimes to abnormal values, were observed among AN-BP patients and correlated with higher urea and creatinine (Watters et al. 2022). Whereas a mean increase in SUA was observed following hospitalization and suggested to relate to improved nutritional status, AN-BP patients with high SUA at admission tended to decrease to normal levels following treatment and suggested to relate to improved hydration and renal function (Watters et al. 2022). Patients with low serum UA levels on admission took longer to gain weight, required more calories for effective refeeding, and had a longer hospitalization. Furthermore, patients presenting with SUA below the normal

range were more likely to suffer comorbid anxiety and depression (Watters et al. 2022). While SUA data in this study were derived from larger metabolic panels routinely drawn from hospitalized patients and lacked a matched control comparison group, resorting instead to population reference values, they point to a potential dynamic interplay of several factors that may be affecting SUA among ED and suggest a potential value for considering SUA in the clinical evaluation and follow-up of ED patients. Results also point to the importance of stratification of SUA levels between restrictive and binge eating–purging subtypes (Watters et al. 2022). Larger prospective studies accounting for menstrual phase and correlating UA with reproductive hormonal levels among AN during exacerbation and remission phases, as well as UA changes in response to oral contraceptives, are required to shed further light on such contribution. Differing dietary compositions have been associated with altered UA levels (Schmidt et al. 2013) and could potentially account for some of the UA differences observed. Thus, a high fructose/purine diet that would account for increased UA levels (Choi et al. 2004) could partly contribute to increased SUA among AN-BP patients. A positive correlation with SUA has been previously noted among high BMI subjects, which may represent part of a metabolic syndrome (Krzystek-Korpacka et al. 2011). In our adolescent sample (Giesser et al. 2020) as well as the larger adult sample, (Watters et al. 2022) BMI did not significantly correlate with UA levels. Elevated SUA was reported to accompany late-stage extreme starvation, resulting from protein degradation after fat stores have been depleted and serving to stimulate foraging behavior (Johnson et al. 2009). Such mechanism may take place among patients with severe AN-R suffering extreme cachexia, requiring further study.

Conclusion

UA levels may be altered in ED through several factors including nutrient intake, hydration status, and renal impairment resulting from dehydration related to chronic diuretic use, vomiting, or laxative use. UA may act as a neuro-stimulant, increasing foraging-related impulsive–addictive behaviors, and may thus be hypothesized to increase binge eating–purging-type behavioral manifestations, thus contributing to a vicious cycle. This is in line with previous case reports as well as preliminary studies by us (Giesser et al. 2020) and others (Watters et al. 2022) observing increased UA levels among purging AN patients. Peripherally produced UA has been reported to produce hypothalamic gliosis and alter leptin response, through triggering the expression of pro-inflammatory cytokines and activating the NF-κB pathway (Lu et al. 2015). Larger case–control prospective studies beginning at the premorbid phases among high-risk adolescents and extending to the exacerbation and remission phases are required to further elucidate on a putative role for UA as a state or trait prognostic marker, among stratified ED subtypes (restrictive vs. binge eating/purging subtypes), aided by the availability of noninvasive salivary measures, and are required to further explore the clinical utility of UA as a biomarker during the

assessment and follow-up phases of ED treatment protocols. Prospectively documented correlations with complicating clinical course measures and endocrine, metabolic, behavioral, and cognitive aspects, including structured quantitative measures encompassing personality traits and impulsivity and addictive indices, are required to further shed light on its putative role in ED pathophysiology. Intriguingly, just as allopurinol has been shown to have promise in the treatment of bipolar manic episodes, (Machado-Vieira et al. 2008) UA and purinergic neurotransmission may present an unexplored avenue for the treatment of binge eating/purging aspects of ED.

Applications to Other Areas

Increased SUA has been reported in bipolar disorder, and allopurinol has been shown to exert a beneficial effect in the treatment of mania, suggesting involvement of the purinergic system in regulating energy levels and impulse control. Importantly, the suggestion that UA may promote increased impulsive–addictive tendencies may cross diagnostic boundaries, as indirectly supported by above positive correlations of excessive SUA with the food craving and binge eating/purging subtype of AN. Such observations may be confounded however by dietary composition, renal impairment, dehydration due to recurrent vomiting, diuretic and laxative use, etc. A study comparing obese individuals with binge eating disorder (BED) to obese subjects without binge eating found the former to have higher SUA after controlling for BMI (Succurro et al. 2015). While such observations cannot differentiate a causal role for UA in promoting BED, given the mechanistic basis for UA's central behavioral modulatory effects cited above, applying Mendelian randomization strategies (Konig and Greco 2018) and directly examining a role for pharmacologically reducing SUA levels in alleviating such behavioral tendencies appear warranted. If proven viable, the potential implications of such interventions may extend beyond ED and other psychiatric diagnostic categories to the much broader problem of obesity in developed countries.

Mini-Dictionary of Terms

- Uric acid (UA): The end product of purine metabolism.
- Monosodium urate (MSU): UA crystals deposited in human joints resulting in inflammatory manifestations as well as the joint damage produced by tophi in gout arthritis.
- Lesch–Nyhan syndrome)LNS): A rare inherited X-linked recessive disorder, caused by HPRT1 gene mutations encoding a dysfunctional hypoxanthine–guanine phosphoribosyltransferase (HPRT), resulting in enzymatic deficit and early developmental accumulation of extreme UA levels with renal and neurological complications and gout arthritis.

Key Facts

- UA is the end product of purine metabolism.
- Humans have high UA levels due to lack of uricase activity and active renal reabsorption.
- UA plays important physiological roles and is a major antioxidant.
- Excessive UA levels can result in gout and are associated with metabolic disorders.
- Several factors may alter UA levels, making it a clinically relevant biomarker among ED patients.
- Salivary UA constitutes a noninvasive measure correlating with serum UA.
- UA may act as a behavioral modulator in the CNS promoting impulsive addictive eating patterns.

Summary Points

- UA, the final purine degradation nitrous waste product, is not further degraded and actively reabsorbed in humans, possessing significant antioxidant capacity, but may exert detrimental pro-inflammatory effects at very high and low concentrations.
- Salivary UA concentration possesses a consistent linear correlation with serum UA levels and suggested to constitute a noninvasive alternative in clinical settings.
- UA adenosine and ATP participate in purinergic neurotransmission, affecting key CNS functions; altered SUA levels have been associated with neurodegenerative processes and psychiatric disorders; and allopurinol has been demonstrated to exert a specific antimanic effect in bipolar disorder and may possess a potentially beneficial behavioral modulatory effect in AN-BP and BED.

The Virtually Delivered Body Project (vBP): A Viable Option for Large-Scale Prevention of Eating Disorders

11

Ata Ghaderi

Contents

Abstract

Eating disorders (EDs) are common conditions. No more than 25% of those afflicted seek professional help, and of the minority who receives evidence-based treatments, only about 50% recover completely. Consequently, prevention is an imperative. The currently most investigated and effective prevention strategy for EDs is the dissonance-based intervention, known as the Body Project. In order to make it more suitable for implementation of prevention on a large scale, we adapted the Body Project to be delivered virtually. This intervention exerts its effect most optimally if it is delivered in a group context. Virtual Body Project (vBP) provides more flexibility in terms of facilitating participation as the

participants do not have to travel to meet in groups, recruitment on a large scale, strategies to decrease the stigma that might hinder participation in prevention efforts, and efficient ways of providing booster sessions. Our first evaluation of the efficacy of the vBP has shown promising outcomes. The vBP was compared to a credible placebo condition (expressive writing, EW) for a duration of 24 months and a waitlist control group for 6 months. The incidence of EDs in vBP (three cases: 2%) across 24-month follow-up was 77% less than among participants in the EW condition (13 cases: 8.8%), which denotes a significant difference (hazard ratio: exponential $B = 0.26$, 95% confidence interval [0.075, 0.92], $p = 0.037$). If the outcomes are replicated in future studies, the vBP might be a viable option for future evaluation of scalable prevention of EDs.

Introduction

Eating Disorders in Context

Eating disorders (EDs) are common conditions among adolescents and young adults. Between 1% and 3% of young adult females suffer from a full syndrome ED, and at least twice as many meet the criteria for subclinical diagnoses of EDs (Ghaderi and Scott 2001; Hudson et al. 2007). Adding the adolescents into the equation and given the early onset of EDs, the emerging picture suggests that 13% of females suffer from a full or subthreshold ED (Allen et al. 2013; Stice et al. 2013; Swanson et al. 2011). A large number of young females experience significant difficulties in relation to eating and their body image, with marked impact on their quality of life, everyday functioning, and behaviors that make them more vulnerable for the development of EDs (Ghaderi 2001; Ghaderi and Scott 1999, 2001). What is also worrying is the increased rate of extreme dieting and physical exercises as a probable consequence of excessive preoccupation with healthy eating and fitness due to influences exerted via various social media channels. Normative data for men are lacking, and available studies might provide a biased estimate of EDs among men. This might be due to several factors such as differences in clinical characteristics of males and females (Welch et al. 2015), lower likelihood of receiving a diagnosis of ED (Currin et al. 2007), and lower tendency to seek treatment among males (Striegel

et al. 2012), as well as a more pronounced stigma related to EDs for men as EDs are stereotypically viewed as a female disorder (Griffiths et al. 2014). Although lack of data makes it difficult to provide a clear picture of the prevalence, effect, and outcome of EDs for men, a substantial portion of those suffering from EDs are men, and future research needs to include them in the studies of EDs to a much higher extent. It is also important to consider other gender minority groups in this context as they generally seem to have a higher risk for psychopathology including EDs (Mensinger et al. 2020; Ngata et al. 2020). However, the scarcity of data on outcomes of interest from these groups makes it necessary to focus on females only, in this chapter.

EDs are characterized by emotional distress, functional impairment, relapse, and chronicity (Arcelus et al. 2011), as well as significantly increased mortality rate (Welch and Ghaderi 2014). Sadly, the majority (around 75%) of those with EDs do not seek professional help (Hudson et al. 2007; Keski-Rahkonen et al. 2009; Kessler et al. 2013). This might partly explain the high prevalence of EDs among middle-aged women. Micali et al. (2017) reported a 1-year prevalence of EDs of 3.6% among middle-aged females (Micali et al. 2017). Furthermore, not all the patients who seek help receive evidence-based treatment, many relapse and need additional treatment, and the cost of treatment is high. It has been shown that the age-adjusted costs for the treatment of anorexia nervosa and bulimia nervosa are comparable to the cost of treatment for schizophrenia (Striegel-Moore et al. 2000).

To summarize, EDs are prevalent, they tend to have a chronic course, and they have a profoundly negative impact of the quality of life and functioning of those afflicted. The majority of those with ED do not seek professional help, and a significant portion of those seeking help do not recover. Thus, a contextual perspective on EDs raises the imperative of prevention, as in many other severe mental disorders.

Prevention

Although we axiomatically believe that prevention is always a more optimal and efficient choice than treatment, it certainly is an empirical question in reality, given the conditions under which prevention is implemented. Issues such as the availability of prevention interventions with known efficacy, the acceptability of such programs, the infrastructure for providing the intervention and reaching the target population, the level of prevention (i.e., universal, selective, or indicative), the costs of providing the program, the sustainability of the intervention across time, and the need for cultural adaptions would determine whether a certain prevention intervention under specific conditions would be efficacious or not. Another important issue is the potential discrepancies between efficacy and effectiveness interventions and the need to implement prevention strategies on a large scale if we aim to make a difference on the public health level. Below, a summary of what we know about prevention of EDs will be presented to put the currently most investigated prevention method called the Body Project and its virtual version into a context.

The Main Prevention Strategies for EDs

The prevention strategies within the field of EDs might be divided into three categories: (1) first-generation, mainly didactic, psychoeducational strategies including programs presenting symptoms and outcomes of EDs; (2) strategies based on multicomponent programs focusing on factors such as critical thinking about media messages, improving self-esteem, and coping with stress, as well as programs based on the principles driven from cognitive behavior therapy; and (3) strategies based on cognitive dissonance theory, such as the Body Project that targets at-risk groups and focuses on amenable and crucial risk factor for EDs. These three main categories are illustrated in Fig. 1.

The first category reflects very early efforts to prevent EDs. These first-generation prevention programs were basically unsuccessful at reducing risk factors for EDs (Stice and Shaw 2004). As expected, concerns were raised at an early stage regarding potential iatrogenic effect of such programs (O'Dea and Abraham 2000; Russell and Ryder 2001), which according to Levine et al. (1999) was no cause of despair or defensiveness, given that these efforts presented initial steps in prevention of EDs compared to, for example, extensive theory and research on the prevention of substance abuse (Levine et al. 1999). These programs were later on developed further into multicomponent psychoeducational programs and in some cases incorporated skills-building, which represent the second category of prevention strategies. The second category constitutes several prevention programs. Those with more empirical evidence of efficacy are, for example, the Student Bodies (Taylor et al. 2006), the Girl Talk (McVey et al. 2003), and the Weigh to Eat (Neumark-Sztainer et al. 1995). The third category comprises dissonance-based prevention programs, commonly referred to as the Body Project. The last category has currently the most empirical support including efficacy trials, effectiveness studies, and comparative trials, all with independent replications (Stice et al. 2019a). vBP is one of the most

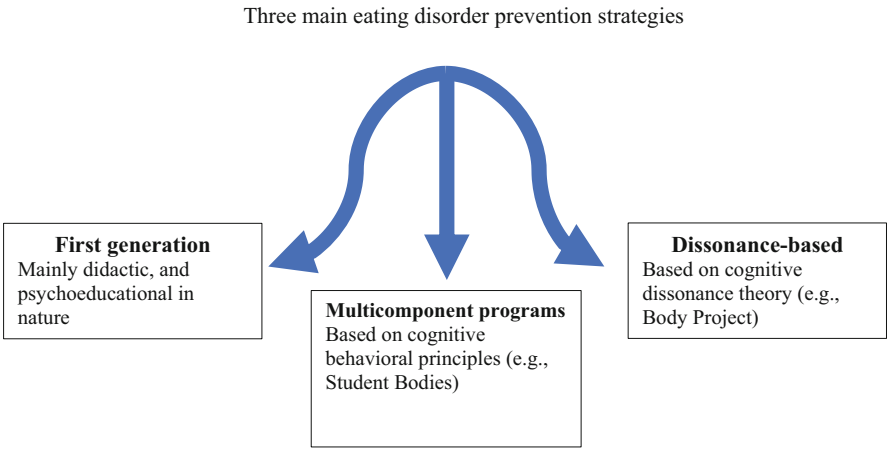

Fig. 1 The three main categories of prevention programs for EDs

recent extensions of the Body Project to approach the goal of building an efficacious prevention intervention that can be implemented on a broad basis to make a difference in public health.

Cognitive Dissonance Theory and Its Implication for Prevention

Dissonance-based interventions are built upon cognitive dissonance theory (Festinger 1957). According to Festinger (1957), we feel psychological discomfort when we have inconsistent cognitions, and the discomfort motivates us to alter our cognitions in order to reach a higher level of consistency in our cognitions (beliefs, assumptions, facts, images, etc.). To help people change the attitudes that are not serving them in the long run (e.g., "It's important to be thin and fit to be successful"), one possible strategy is to ask them act in a way that is inconsistent with that attitude (e.g., talk about the negative outcomes of such an attitude, write a letter or a brief manifesto to criticize the thin ideal, ask other people to consider these negative outcomes, act contrary to their practical habits related to being thin, etc.). Such acts seem to generate cognitive dissonance, as they represent counter-attitudinal stance. As we tend to avoid cognitive dissonance, we will be prone to change our original attitude to reduce the dissonance and experience consistency in our cognitions. Interestingly, we also tend to change our future behavior to reduce cognitive dissonance (Aronson 1980). The processes in a cognitive dissonance-based intervention are illustrated in Fig. 2.

As seen in Fig. 2, the new information that is acquired during the intervention leads to a state of cognitive dissonance due to the inconsistency that emerges as a consequence of taking a new stand, arguing for new ideas or behaviors that go against the previous perception, belief behavior, or attitude, and makes the individual prone to make changes in his or her attitudes to once again return to a state of balance and harmony.

As noted by Festinger (1957), an important precondition for emerging dissonance is the sense of voluntary inclusion and processing of a counter-attitudinal stance. If we take a counter-attitudinal stance (e.g., writing a letter) as a consequence of the circumstances (e.g., due to external demand, or for receiving monetary compensation for the time we devote on the task), then we attribute our act to such circumstances and do not feel any dissonance (e.g., "I did it because I had to," or "I needed that money"). Thus, we need to create a situation in which the participants engage in counter-attitudinal acts in a curious and open manner to feel they take possession of the new attitudes that underlie their stance. This is usually more easy to do in a group format, and taking a counter-attitudinal stance in a group context seems to produce more dissonance (Green et al. 2005). When we take a stance for something in a group context, compared to when we read and write about it on our own without sharing it with anybody else, we are perceived as a proponent for that idea, and in the same manner as our self-concept is a reflection of our understanding of how others perceive us, then we internalize the idea. This produces cognitive dissonance and lays the ground for change in the original attitude and corresponding behaviors.

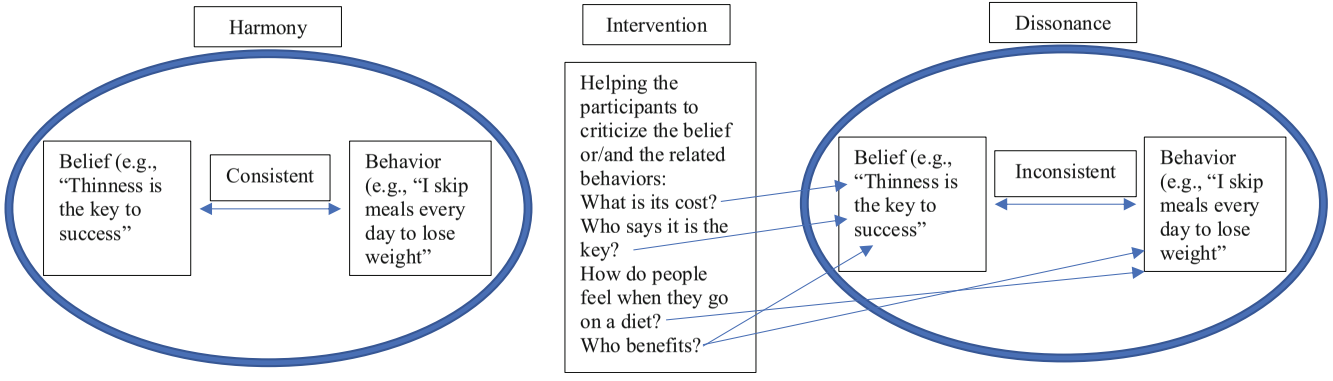

Fig. 2 Illustration of how an intervention based on cognitive dissonance theory may influence beliefs and/or behaviors. The upcoming dissonance due to emerging inconsistency (right side) motivates the individual to change his/her beliefs or behaviors in line with newly acquired information to return to a state of harmony

Dissonance-Based Intervention and Body Project

Based on the evidence on the efficacy of the dissonance-based intervention in many areas such as safe sexual practice (Stone et al. 1994), smoking onset (Killen 1985), and substance use (Barnett et al. 1996), Stice et al. (2000) developed a dissonance-based intervention for targeting thin-ideal internalization, which is one of the best established and malleable risk factors for EDs (Stice 2001). The choice of the thin-ideal internalization was also based on the dual pathway model of bulimia nervosa (Stice 1994) and its putative effects on negative affect, body dissatisfaction, dieting, and ED symptoms (Stice 2001). As noted by Stice et al. (2008), the dual pathway model has some similarities with the cognitive behavioral model of EDs (Fairburn et al. 2009), in which overevaluation of controlling eating, weight, and shape increases the likelihood of restraint and dieting that in turn increases the risk for ED symptoms.

The development of the dissonance-based intervention for EDs has been an iterative process (Stice et al. 2008). In its first version, it consisted of three 1-h group sessions that later on expanded to four sessions, and its efficacy and effectiveness has been investigated in a large number of studies with promising results. The intervention is now recognized as the Body Project since the publication of the first manual with the same name (Stice and Presnell 2007).

The four-session version is the one most extensively investigated. The main content of the vBP is summarized in Table 1.

In the first session, the participants receive a brief rationale for the intervention: Discussing the costs and consequences of the beauty ideal that is currently maintained through different mechanisms in our societies might help them feel more satisfied with their bodies. The intervention is not presented as a strategy to prevent EDs but as a way of improving body image. Voluntary commitment to try the approach is solicited basically each session. The group then tries to collectively define the origins of the thin ideal and how it is maintained. Other important questions that are discussed interactively are the impact of messages related to the beauty ideal from different persons and who (e.g., various corporates) actually benefits from internalization of this message. Finally, as a homework assignment, the participants are asked to write a letter to a young girl about costs of pursuing the thin ideal and to stand in front of a full-size mirror and note positive self-qualities in terms of behavioral, social, emotional, and physical features. The participants are asked to complete these exercises before the next session and to bring them to discuss in the group.

The second session starts with reviewing the homework exercises (i.e., reading their letters and discussing their positive qualities lists). Next, they engage in a role-play during which they dissuade the group facilitator out of pursuing the thin ideal. The homework assignments before the next session are to generate a top 10 list of things females of the same age can do to challenge the current thin or beauty ideal and to write a letter to someone who has pushed them to pursue the thin ideal, including how this affected them and how they would react to it now.

Table 1 Brief description of the main content of the vBP through sessions 1–4

Sessions	Homework assignments
Session 1 Declaring voluntary nature of participation in the group[a] Brief rationale for the intervention Origins of thin/beauty ideal Costs and consequences of the beauty ideal Who benefits from this ideal?	**Session 1 homework assignment** Write a letter to a girl of the same age about the costs of pursuing the thin ideal Mirror exercise: note positive self-qualities: social, emotional, behavioral, and physical
Session 2 Reading their letters and discussing Role-plays: to dissuade the group leader out or pursuing the thin ideal	**Session 2 homework assignment** Generate a top 10 list of things to challenge the current ideal of beauty Writing a letter to someone who pushed them to pursue this ideal
Session 3 Reviewing the homework exercise Diverting thin-ideal comments through role-plays Discussing personal body image concern	**Session 3 homework assignment** Challenge your body image concerns (behavioral experiment) Act on an item on the list of things to do to challenge the current thin ideal
Session 4 Reviewing the experience of behavioral challenge and body activism Resisting future pressure to be thin (role-play and discussion) The benefits of the group discussions	**Session 4 homework assignment** Self-affirmation exercises Writing a letter to a girl of same age who avoids body image concerns Engaging in future activism

[a] This is repeated at each session

The main content of the third session is to review the home exercises, to complete role-plays wherein they divert thin-ideal comments posed by the facilitator, and to discuss personal body image concerns. They are also asked to complete two homework assignments. One is to engage in behaviors that challenge their body image concerns using behavioral experiments (e.g., wearing clothes they have been avoiding due to their body dissatisfaction), and another one is to choose one of the items on their list of things that females of the same age can do to challenge the current ideal and to act on it, after sharing their list and discussing it with the group.

The last session consists of discussing the home exercises (i.e., their experience with the behavioral challenge and body activism); how to resist future pressure to be thin, and especially subtle messages conveying the thin ideal, by discussing and role-playing responses to such pressure; and how the group has been beneficial to them. As final homework assignments, they are asked to engage in some self-affirmation exercises (e.g., appreciating positive comments about their looks instead of invalidating them) and to write a letter to another young girl about avoiding body image concerns and to engage in further body activism.

The Efficacy and Effectiveness of the Body Project

The Body Project has been evaluated in a large number of studies. Several reviews are available, and the most recent meta-analytic review of the dissonance-based interventions (Stice et al. 2019a) has shown promising effect in terms of reduction of thin-ideal internalization, body dissatisfaction, dieting, negative affect, and ED symptoms, both when compared to a minimal intervention and a credible alternative intervention. A previous meta-analysis of all prevention trials for ED (Stice et al. 2007) showed larger effects for programs that were interactive, selective (i.e., focusing on participants with a risk for ED compared to universal prevention), and multisession and only focused on females. These characteristics are the defining structural features of the Body Project. In line with the theory and outcome from previous trials, the most recent meta-analysis (Stice et al. 2019a) of the dissonance-based intervention also found larger effects when more dissonance-inducing activities were included, groups were larger, participant was voluntary, and body dissatisfaction was required (selected prevention). Interestingly, effects were larger when intervention was delivered in person versus online (Stice et al. 2019a). However, the online intervention was not done in group but delivered as an individual intervention, and in addition to significant heterogeneity of the effects of online delivery of the method, the online versus group delivery of the intervention only moderated one of the five outcomes.

Until recently, a full online delivery of the Body Project, using the group format, and peer facilitators that were trained and supervised had not been evaluated. Such a format might have major implications for broad implementation of the Body Project, especially as the Body Project has currently the best evidence of efficacy for prevention of EDs.

Influencing Public Health: Prevention on Broad Basis

How useful is a prevention program if it cannot be implemented on a broad basis to make a difference on public health? Researchers have succeeded to develop a good number of efficacious prevention programs within different areas such as depression and anxiety in young people (Werner-Seidler et al. 2017), suicide prevention among youth (Wasserman et al. 2015), parent training to prevent conduct disorder among children (Kellam et al. 2011), and programs for prevention of substance use (Arango et al. 2018), prevention of transition to psychosis (Hutton and Taylor 2014), and EDs (Stice et al. 2019a). However, very few efficacious prevention programs are broadly implemented to improve mental health problems on a societal level, beyond randomized controlled trials, and effectiveness research. As have been argued in the case of prevention of depression, efforts to implement prevention programs might only succeed if they are structurally embedded at local, regional, and national level and target the strongest determinants of risk (Ormel et al. 2019). To facilitate structural embedding of prevention programs into existing institutions within the domains of health care, child care, and education, factors such as the intensity of the

programs, demands on resources, special education for delivery and time needed to implement an intervention, format of delivery, and flexibility and level of complexity are important to consider, in addition to political decision to implement such programs. We are currently in an era of digital revolution with smartphones and Internet that brings a fresh array of possibilities for broad implementation of prevention of mental disorders, including EDs.

The Promise of Internet and Digital Techniques

With increasing access to Internet and smartphones, most people are getting access to more education and opportunities than before. Efficacious prevention programs have largely remained in the shadows of the heavy burden on mental health professionals and low access to psychological treatment for those in need of such services. With the new technology, several obstacles can be overcome, and prevention can be more easily provided broadly. Interventions using mobile technology and Internet have been shown to be effective in the treatment of many types of psychiatric disorders (Andersson et al. 2019). This promise might be extended to prevention. We do not any longer need to think of prevention as an activity that has to be delivered to a group of people gathering at a specific location. The mobile and Internet technologies provide a great range of flexibilities and possibilities such as momentary monitoring, automatic or personalized feedback, digital meetings, and apps that can be accessed at any time to obtain information or to visualize and foster skills. In addition, the technology makes it possible to provide makeup sessions through recoding of meetings for participants who miss some sessions. Finally, this technology might also be helpful in combating the shame and stigma associated with mental health issues. It provides possibilities for a new way of interacting with both information and other people.

Given these opportunities, it was a logical next step to investigate the efficacy of the Body Project when delivered digitally. In addition, although previous efforts to provide the Body Project through Internet did produce some beneficial effects (Stice et al. 2012), the long-term outcome was not as favorable as the face-to-face trials of the Body Project (Shaw et al. 2016; Stice et al. 2014). The Internet version of the Body Project was previously delivered as an individual treatment. The group context of delivery was absent in this mode of delivery (Stice et al. 2012). It turned out that ED onset was significantly lower in the peer-led version of the Body Project compared to the Internet version (Stice et al. 2017). The lower efficacy of the individually delivered version of the Body Project through Internet was theoretically expected, as higher level of dissonance is produced in group format and higher dissonance is in turn related to better outcome. Consequently, we adapted the Body Project to be delivered virtually (thus virtual Body Project: vBP) with a group leader and no more than six participants per group.

vBP

In the vBP, we retained the content and principles basically identical to the original version (Stice et al. 2017) and made minor adjustment for smooth delivery through the Internet (Ghaderi et al. 2020). When the trial was running, the freely available videoconference technologies were not stable enough to allow more than five to eight participants. During the last years, and due to the pandemic, these technologies have advanced, and inclusion of larger group and more than one group leader is nowadays possible without subscription to very expensive online videoconferencing services. Smaller groups are easier to constitute, and fewer people will face difficulties in agreeing on a time point for the each of the 4 weeks of the intervention. Smaller groups might be a more efficient choice for future implementation of the vBP, but current technology allows test of the efficacy of larger groups too.

We recruited 431 female participants, aged 15–20 years, from across Sweden. The study was approved by the Regional Ethics Board in Stockholm (Dnr. 2015/841–31/2 and 2015/2051–32) and registered on ClinicalTrials.gov (NCT02567890). The main inclusion criteria were to report a subjective sense of body dissatisfaction, which is a known risk factor for the emergence of EDs (Ghaderi and Scott 2001). Exclusion criteria were symptoms of severe depression or anxiety in need of treatment, indications of suicidality, concurrent psychological treatments, meeting the DSM-5 diagnostic criteria (American Psychiatric Association 2013) for a full diagnosis of EDs or other specified EDs, or other serious conditions such as bipolar disorder that required psychiatric care.

Participants were randomized into three conditions: (1) vBP, which consisted of four interactive occasions, some homework assignments, and monitoring; (2) expressive writing (EW) (placebo/attention control); and (3) a waitlist control condition. Those in the waitlist condition received the vBP as soon as they completed the 6-month follow-up assessment. The EW condition was designed to match the frequency of the vBP. It consisted of brief written instructions sent to participants weekly over 4 weeks. They were asked to write about their thoughts, emotions, and images as well as any other content that comes to their mind in relation to their body. They were asked to write for 40 min each week. This was somewhat different compared to previous trials of the Body Project where the EW has been used as placebo condition. In previous trials, the participants were asked to write about emotionally significant topics and not specifically issues related to their body image or body dissatisfaction. Also, in contrast to previous versions of the Body Project, in the vBP, participants also received a written booster reminder at the 12-month follow-up. They were reminded of the issues raised during the intervention, and those in the EW conditions were asked to once again take some time to write about anything that comes to mind in relation to their body.

Direct and long-term effects of the interventions (6, 12, and 18 months post-intervention) were investigated by systematic measurements. ED diagnoses were assessed using the Eating Disorders Examination (Fairburn 2008; Fairburn and Beglin 1994), and risk factors and other outcomes were investigated using established self-report questionnaires. For details, please see Ghaderi et al. (2020).

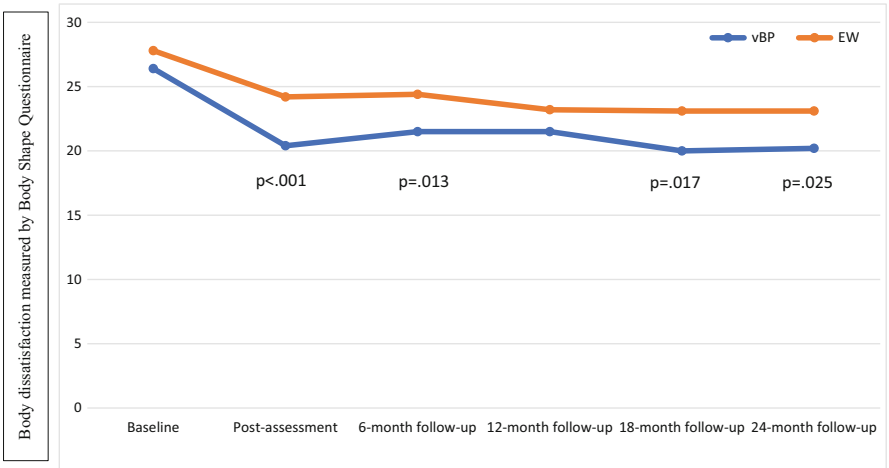

Fig. 3 The change in body dissatisfaction in the vBP versus the placebo condition (EW) across the 24-month follow-up. The difference between the conditions is significant (based on Sidak post hoc test) at posttreatment, as well as 6-, 18-, and 24-month follow-up

The incidence of ED onset over 24-month follow-up was 3 in vBP (2.0%) and 13 in EW (8.8%), which denotes a significant difference (hazard ratio: exponential $B = 0.26$, 95% confidence interval (CI) [0.075, 0.92], $p = 0.037$). Incidence of ED onset in vBP participants was 77% less than among participants in the EW condition.

Participants in the vBP condition reported significantly greater reduction in ED symptoms and clinical impairment, as well as internalization of thin ideal compared with the waitlist participants at postintervention and 6-month follow-up.

Body dissatisfaction is a major risk factor for ED. The intervention resulted in significantly larger reduction of body dissatisfaction in the vBP condition compared to the placebo condition. The pattern of change across the 24-month follow-up is illustrated in Fig. 3.

Compared to participants in the EW, which was perceived as a credible intervention, those in the vBP reported greater reduction in ED symptoms, restraint, body dissatisfaction, and internalization of thin ideal at the end of the intervention, as well as at 6-, 12-, 18-, or 24-month follow-up. Interestingly, participants in the EW condition reported significantly greater reduction in clinical impairment and body dissatisfaction at postintervention compared with the waitlist participants.

Although the intervention was delivered virtually, rather than in person, the reduction in the incidence of EDs was notable. If these outcomes are replicated in future trials of the vBP, it might be a viable option for future evaluation of scalable prevention of EDs. The vBP provides more flexibility and makes it easier to participate and to compensate for missed sessions by reviewing the recorded sessions ahead of the coming one whenever the participants miss a session. In addition, the virtual delivery allows the participants to participate in the intervention anonymously in the group if they wish, which probably decreases the stigma related to

EDs. The intervention can also be delivered by trained peers who do not have to be present at a specific location to run the groups. Although we allowed the participants to be fully anonymous, if they wished so, none chose to participate anonymously. Smartphone and computers are becoming more and more available globally, and especially smartphones are becoming more affordable even for people in poor countries, which brings a promise for increased possibility of preventive efforts for not only EDs but for mental health problems in general.

Applications to Other EDs

Most studies conducted on the Body Project target older teenagers and young adults, but they encompass the ages 11 to 64 years across trials (Stice et al. 2019a). The vBP did also target the same age group (15–20 years old). Although a few studies of the Body Project have been evaluating the outcome among a younger target group (Halliwell and Diedrichs 2014; Rohde et al. 2014), it seems that the results are stronger for those aged 15 and above (Stice et al. 2019b). This might be due to the fact that the peak risk period for the onset of EDs occurs between 16 and 19 years of age (Hudson et al. 2007) or that the intervention per se is more effective for older participants. This means that the intervention has not been evaluated in as many trials for younger children and adolescents, which is a significant issue, as a mentionable number of cases of anorexia nervosa have a fairly early onset. More trials of the efficacy and effectiveness of the vBP should be conducted on the younger age group.

Any advances in the prevention of EDs might have broader implications for the prevention of other mental health problems. The lessons learned from the vBP might be efficiently used in the prevention of other conditions and problems among children, adolescents, and adults.

Mini-Dictionary of Terms

- Body Project: A manualized intervention, based on cognitive dissonance theory to reduce the risk for onset of EDs.
- Virtual Body Project: Digitally delivered version of the Body Project, with one group facilitator and four to six participants.
- Risk factors: Variables such as thin-ideal internalization or body dissatisfaction that in prospective studies have been shown to predict onset of EDs.
- Universal prevention: Prevention efforts that target the entire subset of general population (e.g., all children attending schools in grades 5 to 8).
- Selective prevention: Prevention efforts that target those who are at risk of developing the condition that we want to prevent (e.g., young people with body dissatisfaction).

- Indicated prevention: Prevention that targets individuals who already exhibit some signs of the condition that we want to prevent (e.g., individuals with some early symptoms of EDs).

Key Facts of the Virtually Delivered Body Project (vBP) and EDs

- The incidence of EDs in the vBP was 77% less than in the placebo condition.
- The vBP provides a more flexible format for delivering the intervention than the face-to-face mode.
- The vBP seems to decrease the incidence of EDs through the same mechanisms (reducing the internalization of the thin ideal) as in the in-person version of the Body Project in general.
- The vBP seemed to be acceptable to the participants, and all the participants chose to participate without concealing their identity, although they all had the choice to participate anonymously.
- Booster sessions can more easily be delivered in the vBP compared to in-person delivery of the intervention.

Summary Points

- EDs are prevalent conditions and present a major source of suffering, morbidity, and mortality for adolescents and young adults.
- Dissonance-based intervention (mainly the Body Project) is currently the most researched and efficient prevention program for EDs.
- Efficacious prevention programs need to be delivered in a format that builds the ground for scalable implementation to make a difference in public health.
- vBP is a step forward, as it simplifies the delivery of the Body Project.
- Despite being implemented virtually, rather than in person, it resulted in notable reduction in incidence of EDs.
- vBP might be a viable option for future scalable prevention of EDs, if its outcomes and processes are replicated in independent studies.

Time-Related Changes in Eating Disorders 12

Tomoko Harada, Dai Miyawaki, and Tsuneo Yamauchi

Contents

Abstract

This chapter provides an overview of changes in the trends of anorexia nervosa (AN) and bulimia nervosa (BN) over time. The concepts of AN and BN have barely changed since they were incorporated into the operational diagnostic criteria in the 1980s. Epidemiological studies in Western countries have revealed increases in AN and BN since the 1930s and 1970s, respectively. Subsequently, AN has remained constant since around the 1970–1990s, although its incidence has increased among young women, whereas BN peaked around the 1990s and has since decreased. Further, compared to Western countries, reports from

non-Western countries are insufficient in number and detail. Research participants with eating disorders (EDs) have expanded to include not only young women, but also men and middle-aged women. Further research is needed on EDs across global regions, cultures, genders, and ages.

Abbreviations

AN	Anorexia nervosa
AN-BP	Anorexia nervosa – binge/purging type
AN-R	Anorexia nervosa – restricting type
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
BN-NP	Bulimia nervosa – non-purging type
BN-P	Bulimia nervosa – purging type
DSM	Diagnostic and Statistical Manual of Mental Disorders
ED	Eating disorder
ICD	International Classification of Diseases

Introduction

Cases of disordered eating behaviors were first reported in the England in 1680s, evolving into the current concept of eating disorders (EDs). As of 1980s, they were regarded as culture-bound syndromes existing only in Western cultures. It was assumed that the pathology of EDs stemmed from certain characteristics of Western culture (Prince 1985; Swartz 1985). When they began being reported in non-Western countries, it was speculated that the introduction of Western sociocultural factors in these regions influenced their occurrence (Keel and Klump 2003). The term "socio-cultural" includes not only a variety of perspectives that began in the West, such as industrialization, urbanization, modernization, and globalization, but also aspects of Western culture, such as ideal thinness and the Western diet (Weissman 2019). Furthermore, the concept of acculturation, defined as the process of psychosocial change that occurs when an individual or group encounters another culture, has received attention for its impact on EDs (Alvidrez et al. 1996; Weissman 2019; Melisse et al. 2020). Unique cultures of non-Western countries have also been shown to influence EDs (Pike and Borovoy 2004). Thus, EDs can be described as "culture-reactive" rather than "culture-bound" (Di Nicola 1990; Keel and Klump 2003; Alfalahi et al. 2021).

Although genetics plays a significant role in the development and maintenance of EDs (Bulik et al. 2016), sociocultural factors are consistently recognized as impacting their cause, progress, and outcome (Pike et al. 2014; Weissman 2019). However, it is difficult to directly prove the relationship between sociocultural factors and the development of EDs.

This study thus aims to understand how EDs have changed over time. First, we will attempt to describe how EDs have been viewed historically and how their conceptions have altered with time. We will then explain the epidemiological time trends regarding EDs in Western and non-Western countries. Finally, we will detail the shift in the population that suffers from EDs worldwide.

Changes in the Concept and Diagnosis of EDs

In this section, we will describe how disordered eating behavior was historically viewed and came to be conceptualized as anorexia nervosa (AN) and bulimia nervosa (BN), as well as the changes in diagnostic criteria for these conditions since their conceptualization as psychiatric disorders.

Anorexia Nervosa (AN)

In the ancient West, long before the conceptualization of EDs, the practice of "self-starvation" was a component of religious rituals. Its purpose was to practice asceticism, obtain forgiveness for sins, lose weight "so as to pass through the narrow gates of heaven," protect oneself from demons, purify oneself, and gain psychic powers. Ascetic fasting was practiced by early Christian monks (Bemporad 1997) and medieval Chinese Daoist priestesses (Lo et al. 2012), to seek the salvation of the soul by abstaining from all desires.

From the medieval to the early modern period, there seemed to be an increase in the number of saints who undertook intense fasts to approach God, believing that they could not obtain salvation unless they purified their own bodies. Their intense fasting sometimes led to death by starvation. An example was Caterina Benincasa of Italy, known as "Saint Catherine of Siena" and venerated as one of the patron saints of Europe. She began strict fasting at a young age, eating only bread, raw vegetables, and water by the age of 16, ultimately consuming almost nothing but the Eucharist by the age of 25. She refused to eat even when others attempted to force her and remained consistently active until her death at the age of 33: the same age as Christ (Bell 1985). Although it is unclear whether such "holy anorexics" desired thinness and feared becoming fat, they share similarities with present-day AN patients who exhibit extreme fasting beyond normal asceticism, social withdrawal, and stubborn refusal to eat.

EDs first appeared in medical literature in 1689. Morton (1694) described two cases in England of a teenage boy and girl, detailing restricted eating and severe weight loss, which may be similar to AN today. Gull (1873), also from England, first

used the term "anorexia nervosa" to describe a starvation condition caused by psychological problems. He described several treatment strategies, including living away from family and a nutritious diet. Simultaneously, Laségue (1997), from France, gave a detailed clinical report on the psychopathology of AN and the difficulties of its treatment. After this period, additional psychological features of AN, such as weight phobia, were also reported.

In 1914, German pathologist Simmonds reported Simmonds' disease, a disorder of the pituitary gland with symptoms including anorexia, atrophy of sexual features, absence of libido, hypotension, bradycardia, and hypoglycemia. This led to the continued misconception that AN was caused by pituitary disease. However, Berkman's (1930) study comprising 117 patients revealed that psychic disturbance is followed by anorexia; the resulting small intake of food leads to inanition, which is associated with a low rate of metabolism. Furthermore, Sheehan (1939) reported that emaciation due to Simmonds' disease was rare, resulting in the differentiation of AN from Simmonds' disease. The misconception that AN was caused by a pituitary disease was corrected, and the psychological cause theory was reapplied. Habermas (2015) claimed that, in Nazi Germany, political background contributed to the focus on the somatic aspects of AN, as the regime systematically murdered psychiatric patients, making it far safer for them to have their AN treated as a somatic rather than as a psychiatric condition. Regarding reaffirmation of the psychological causes of AN, Ryle (1936) described the understanding and treatment behind AN in detail, including its mental, physical, and psycho-behavioral characteristics, which can be considered the basis for the modern interpretation of AN. In the 1940s, the psychopathology of AN was interpreted based on psychoanalytic theory (Lucas 1981).

In the 1970s, psychological research on AN, developing into modern psychotherapy, began to be conducted. Bruch (1973) posited problems in body perception, emotional processing, and interpersonal relationships as the core aspects of AN, developing her theory of psychopathology through animal studies on attachment, noting that many psychological problems resulted from starvation. In 1972, Feighner et al. proposed a diagnosis of AN from the standpoint of operational diagnostic criteria for psychiatric disorders, based on descriptive symptoms, avoiding past theoretical and etiological perspectives. In these criteria, AN was defined not only as weight loss; a desire for thinness; lack of insight; and a distorted, implacable attitude toward food and weight; but also in terms of physical signs of binge eating; self-induced vomiting; and emaciation (e.g., amenorrhea, lanugo, and bradycardia). In addition, the age of onset was defined as less than 25 years, indicating that AN is considered an adolescent-onset disorder.

Bulimia Nervosa (BN)

Binge eating in individuals with AN was described by Gull in 1873, as follows: "Occasionally for a day or two, the appetite was voracious." However, binge eating and self-induced vomiting, without accompanying underweight, did not receive much attention for a long time. There is speculation that "nervous vomiting,"

which was medically described in the late nineteenth century, may have been BN (Van Deth and Vandereycken 1995). However, its psychological characteristics were not described.

Little attention was paid to BN until the 1970s. After binge eating was noticed in an AN group, individuals within the normal weight range suffering from binge eating, vomiting, and laxative abuse were identified. The term "bulimia nervosa" was coined in 1979 by Russell in England, who defined it as an irresistible urge to overeat, followed by self-induced vomiting or purging, and a morbid fear of becoming fat. Since most individuals with BN had a history of AN, he described BN as "an ominous variant of AN."

It is possible that the nature of EDs has contributed to the difficulty in describing their history. This is because, in general, individuals with EDs deny engaging in food restriction, excessive exercise, binge eating, and self-induced vomiting.

Transition of Diagnostic Criteria for AN and BN

Figure 1 shows the changes in diagnostic criteria for AN and BN.

The Diagnostic and Statistical Manual of Mental Disorders (DSM)-III was published by the American Psychiatric Association (1980). It proposed the diagnostic criteria for AN, largely following the Feighner criteria, and the new criteria for bulimia. While the Feighner criteria emphasized self-directed attitudes toward thinness, the DSM-III incorporated characteristics such as disturbance of body image and intense fear of becoming obese. Bulimia was considered a syndrome involving recurrent episodes of binge eating, with depressed mood and self-deprecation following the bingeing episodes. Its diagnostic criteria also included the presence of weight loss attempts (severely restrictive diets, self-induced vomiting, or use of cathartics or diuretics) and weight fluctuations, which were not an essential part of the criteria. Bulimia could be diagnosed simply by repeated episodes of binge eating that were difficult to control, without compensatory behavior. It was distinguished from AN by the fact that the weight loss was not as severe as in AN and bulimic episodes were not considered to be caused by AN. However, in "rare instances," AN and BN could be listed together if both the criteria were met.

DSM-III was revised to DSM-III-R (American Psychiatric Association 1987), and "bulimia" was changed to "bulimia nervosa." The diagnosis of BN is now based on the requirement that the patient regularly engages in behaviors that prevent weight gain (self-induced vomiting, use of laxatives or diuretics, strict dieting or fasting, or vigorous exercise). In DSM-III-R, as in DSM-III, both AN and BN diagnoses were given to individuals exhibiting all symptoms of being underweight, binge eating, and purging.

Subsequently, in DSM-IV (American Psychiatric Association 1994), the diagnostic criteria for AN included two subcategories: the restricting type (AN-R) and the binge eating/purging type (AN-BP). BN was clearly distinguished from AN for the first time by the addition of the item "The disturbance does not occur exclusively during episodes of Anorexia Nervosa." It was also divided into two subcategories:

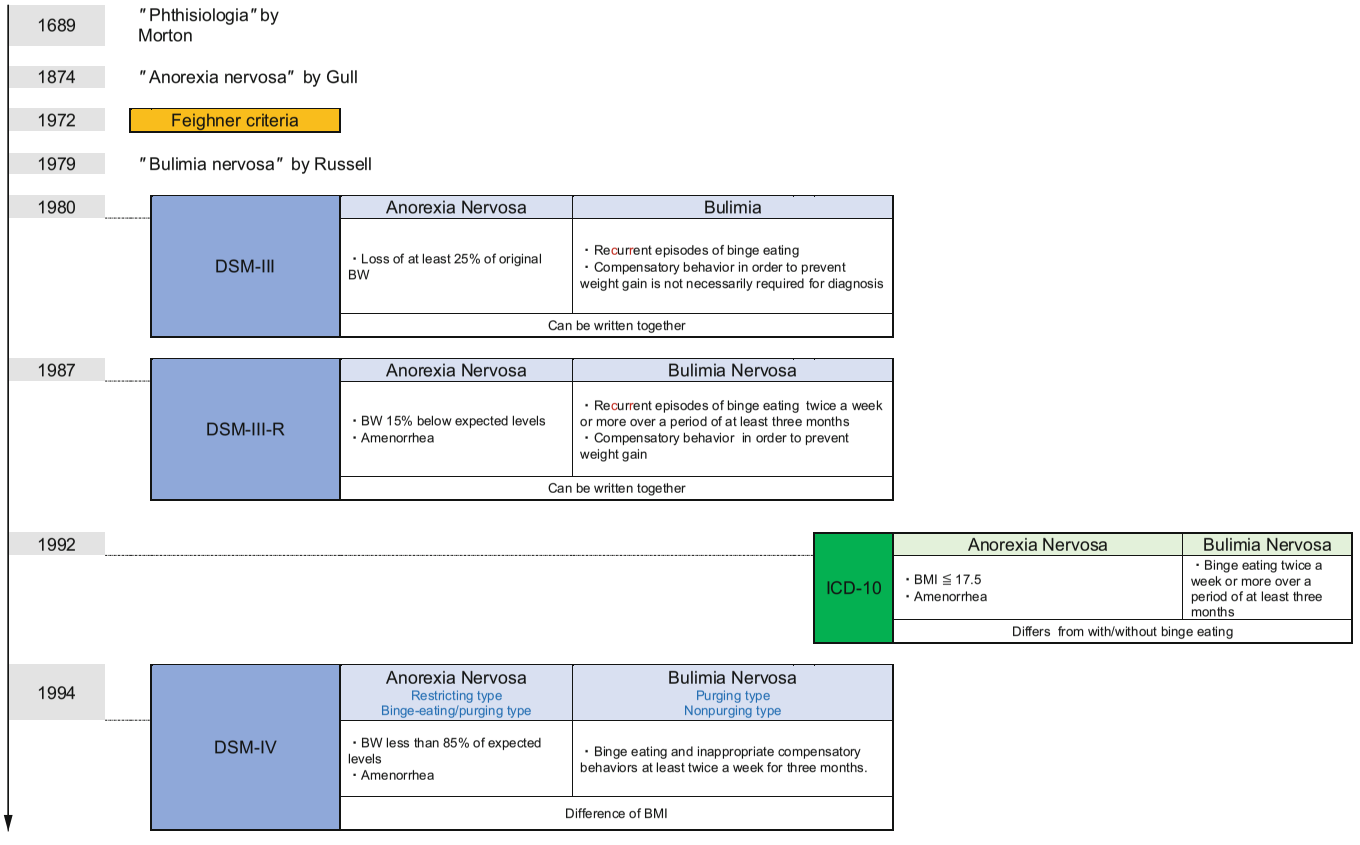

Fig. 1 Changes in diagnostic criteria for anorexia nervosa and bulimia nervosa. *BW*, body weight; *BMI*, body mass index

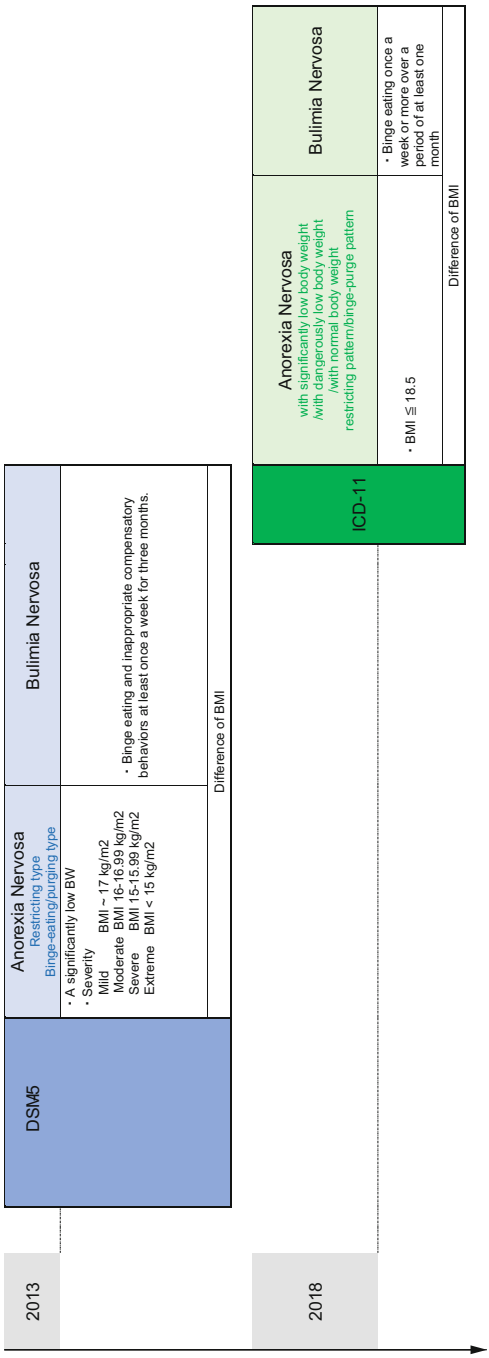

Fig. 1 (continued)

the purging type (BN-P), using self-induced vomiting or the misuse of laxatives, diuretics, or enemas as compensatory behaviors to prevent weight gain, and the non-purging type (BN-NP), involving fasting or excessive exercise.

In DSM-5 (American Psychiatric Association 2013), the diagnostic criteria for AN included the phrases "intense fear of gaining weight or of becoming fat, or persistent behaviors that interfere with weight gain." Although there were clear behaviors that prevented weight gain, AN could be diagnosed even if there was no obvious desire for thinness or fear of obesity. The BN subcategories of purging and non-purging were eliminated. In addition, a new diagnosis, binge eating disorder (BED) – primarily characterized by recurrent episodes of binge eating without repetitive inappropriate compensatory behaviors to prevent weight gain – was incorporated.

Contrarily, the World Health Organization (1992) published the International Classification of Diseases 10th Revision (ICD-10), listing AN and BN in the ED section. Since DSM-III and DSM-III-R defined the characteristics of AN and BN as being underweight and engaging in binge eating, respectively, individuals exhibiting both characteristics were diagnosed as having both AN and BN, leading to a complexity. To avoid this, ICD-10 simply separated AN and BN based on the presence or absence of binge eating, regardless of weight. In the subsequent DSM-IV and DSM-5, AN and BN were classified according to Body Mass Index (BMI). The ICD-11 (World Health Organization 2021) also classified AN and BN according to BMI, in a way similar to DSM-5. In ICD-11, AN can be coded according to BMI severity and further coded in terms of the causes of being underweight (restricting patterns and binge-purge patterns).

Thus, with regard to the diagnostic criteria for EDs, the following have been changed with each revision to the DSM and ICD: the definition of low BMI, frequency of binge eating and compensatory behaviors, duration of symptoms, and whether or not amenorrhea is included (Fig. 1). However, the basal concepts of AN and BN have remained largely consistent for over 40 years.

Time Trend of Incidence and Prevalence

This section describes the time trends in the incidence and prevalence of EDs in Western and non-Western countries. Methodological issues must be understood to interpret the incidence and prevalence of EDs, which are often excluded from epidemiological surveys for reasons of efficiency, because of their relatively low incidence and prevalence in the general population. Therefore, most epidemiological reports are based on primary care outpatient case registries, cases from mental health facilities, or those identified through inpatients, rather than among the general population. It is important to note that both incidence and prevalence can vary widely depending on the study population. They are lower in the general population, primary care facilities, and specialist hospitals, in that order (Martínez-González et al. 2020). This low trend is related to the access to health care and the choice of health care facilities according to the severity of the ED, stigma around mental

illness, and the ED pathology of denial. (Ali et al. 2017; Raisanen and Hunt 2014). In addition, the different diagnostic criteria used reflect varying rates of incidence and prevalence (Galmiche et al. 2019; Mustelin et al. 2016). If a syndrome is newly named as a disease, or if recognition of the disease by medical professionals and society in general increases, the detection and consultation rates of patients will increase (Weissman 2019).

Incidence reflects the number of new cases of a disease per year, being expressed as the number of cases per 100,000 person-years. Prevalence counts the cases of the disease at a particular time, regardless of its onset, thus including both existing and new cases. Keel and Forney (2015) explained the incidence and prevalence of EDs as follows: Incidence can be used to not only understand whether a disease is becoming more or less common in a population over time, but also explore etiology; prevalence is useful to not only understand the public health impact of a problem and the need for prevention and treatment, but also examine the differences in disease risk among various populations. Regarding EDs, incidence is more likely to be used when addressing the etiological theory that sociocultural changes contribute to their development (Keel and Forney 2015).

We attempted to use incidence information as much as possible to understand the temporal trends in the onset of EDs; however, limitations exist, especially for non-Western countries, where incidence rates are not well-reported. After describing the epidemiological changes in Western countries, where fluctuations in the incidence of EDs over time are better understood, the non-Western regions will be discussed.

Western Countries

Incidence studies in Western countries originated with the report by Willi and Grossmann (1983). Many reports indicate that the incidence of AN among young women has increased since the 1930s. Some researchers report that the overall incidence of AN had increased since the 1930s and has remained constant since the late twentieth century (Van Eeden et al. 2021), while others report that it continues to increase (Martínez-González et al. 2020). In contrast, it appears that the incidence of BN, on which epidemiological data has been collected since the 1970s, peaked in the 1990s and has since decreased in these countries.

Anorexia Nervosa

EDs, both AN and BN, tend to occur in adolescent girls and young adult women (Treasure et al. 2020). Most incidence and prevalence studies on AN have focused on these populations (Martínez-González et al. 2020). Table 1 shows the incidence of AN per 100,000 females in the following reports from three countries.

In the United States, studies on trends related to the incidence of AN in Rochester, Minnesota, for more than 50 years – 1935 to 1989 – reported an increase during the observation period. Population-based studies were feasible in Rochester, where health care was largely self-contained within the community, and Lucas et al. (1999)

Table 1 Incidence of anorexia nervosa per 100,000 females

This table is based on Table S3 and S4 by Martínez-González et al. (2020)
Feighner, Feighner criteria; *DSM*, Diagnostic and Statistical Manual of Mental Disorders
[a]Sex-adjusted per 100,000 inhabitants/year White population in Monroe country
[b]Incidence per 100,000 person-years directly age adjusted to 1970

counted the AN cases in the medical records of all local health care providers, including general practitioners and specialists. They found no increase in its incidence either in women aged over 25 or in men. However, the incidence among females aged 15–24 years underwent a long-term linear increase over the 50-year study period, from 26.5/100,000 (95% confidence interval (CI) 13.68–46.25) in 1935–1949 to 75.5/100,000 (95% CI 54.87–101.37) in 1980–1989. The increase in overall incidence of AN since 1950 was due to an increase in the number of young women.

In a study conducted in Switzerland, the incidence of severe AN was observed for 40 years, from 1956 to 1995, in a geographically defined region over five sampling periods. The same methodology was used across all periods, except that, after 1983, the DSM-III-R diagnostic criteria were used instead of the previous DSM-III criteria (Willi and Grossmann 1983; Willi et al. 1990; Milos et al. 2004). Data were obtained from the case records of almost all internal medicine, pediatric, and psychiatric clinics in the region, and medical records of all hospitals in the canton of Zurich were screened to identify the first hospitalization of each female patient with AN. The incidence among females aged 12–25 years was 4.0/100,000 (95% CI 1.92–7.36) in 1956–1958, 6.8/100,000 (95% CI 3.96–10.89) in 1963–1965, 16.8/100,000 (95% CI 11.89–23.06) in 1973–1975, 16.4/100,000 (95% CI 12.12–21.8) in 1983–1985, and 19.7/100,000 (95% CI 14.15–26.75) in 1993–1995. These data indicate that the incidence of AN among the at-risk population increased until the 1970s, after which it reached a plateau. In a review that included these studies and examined the period up to about the year 2000, Hoek (2006) noted that the incidence of AN increased steadily until 1970 and then stabilized.

Later, in the Netherlands, the incidence of AN was reported to have stabilized around the year 2000 (Smink et al. 2016). A study investigated changes in the incidence of EDs in a large representative sample of the Dutch population, using primary care data from 1985 to 2009 (Van Son et al. 2006; Smink et al. 2016). The overall incidence of AN among women was quite stable over the observation period: 13.4/100,000 (95% CI 9.92–17.63) in 1985–1989, 15.2/100,000 (95% CI 11.36–19.44) in 1995–1999, and 11.8/100,000 (95% CI 8.5–16) in 2005–2009. The incidence among women aged 15–24 years was 47.6/100,000 (95% CI 32.1–67.92) in 1985–1989, 69.5/100,000 (95% CI 45.31–92.44) in 1995–1999, and 66.1/100,000 (95% CI 43.53–96.11) in 2005–2009, suggesting that although the incidence among women in this age group increased during the 1980s and 1990s, it has remained stable since (Smink et al. 2016). Hoek (2016) provided a review of studies, including those of Van Son and Smink et al., again concluding – as in his previous review (2006) – that the incidence of AN has been stable since 1970.

Recently, a meta-analysis reported an increased incidence of AN among women of all ages and among younger women (10–30 years). Martinez-González et al. (2020) conducted a systematic review based on articles published from 1980 to 2019, mainly from Western countries, performing a meta-analysis of 31 studies divided into outpatient health care services and hospital admission, considering the fact that the incidence of AN varied widely among the study population depending upon the methodology. The results showed that the linear trend increased among women of all ages, both in studies with hospital admission records and in those based

on outpatient health care services. The incidence of AN was 8.8/100,000 (95% CI: 7.83–9.80) for studies with outpatient women and 5.0/100,000 (95% CI: 4.87–5.05) for studies with inpatient women. In young women, the incidence of AN was 63.7/100,000 (95% CI 61.21–66.12) among outpatients and 8.1/100,000 (95% CI 7.60–8.53) among inpatients. The incidence of AN among women, thus, varied widely, from 0.5–318.0/100,000. Cohort studies were also reviewed in this report (Martínez-González et al. 2020). A much higher incidence of 120.0 to 318.9/100,000 was observed in females compared to previous studies (Ghaderi and Scott 2001; Lahortiga-Ramos et al. 2005; Keski-Rahkonen et al. 2007). Martínez-González et al. (2020) concluded that the high values in their review were to be expected, given the use of adolescent and young female samples, and the screening strategies implemented to detect cases. Although the overall incidence was reported to be increasing in women, Van Eeden et al. (2021) stated in their review that the increased incidence of AN might be explained by greater public awareness, better detection, and the use of broader diagnostic criteria, and that the overall incidence rate of AN has remained considerably stable over the past decades.

The prevalence of AN was reported to be less than 1–4% in a review in Europe (Keski-Rahkonen and Mustelin 2016).

In conclusion, the incidence of AN among adolescent and young adult women has increased over the years since the first half of twentieth century. It is, however, unclear whether this reflects an increase in incidence or an earlier age of detection (Van Eeden et al. 2021). The incidence of AN among women peaked around the 1970–1990s. Since then, some reports have indicated that it has remained stable while others claim that it has been increasing. Time trends in incidence must be understood carefully, as they are constantly subject to methodological problems, and their interpretation may vary depending on the length of the study period.

Bulimia Nervosa

Since BN was recognized as a diagnosis (Russell 1979) approximately 100 years following AN, there is less information available on its incidence compared to that of AN. According to observations over time, the incidence of BN peaked around the 1990s and has been declining since.

Hall and Hay (1991) reported that the number of patients seen by community ED services in New Zealand increased from 6/100,000 to 44/100,000 between 1977 and 1986. In the Netherlands, a primary care survey showed an upward trend in the incidence of BN in the 1980s, increasing from 7.2/100,000 (95% CI 4.0–13.1) in 1985 to 15.2/100,000 (95% CI 10.0–23.1) in 1989 (Hoek et al. 1995). However, long-term studies have since shown that the incidence of BN was 8.6/100,000 (95% CI 6.7–11.0) in 1985–1989, 6.1/100,000 (95% CI 4.5–8.2) in 1995–1999, 3.2/100,000 (95% CI 2.0–4.9) in 2005–2009 (95% CI 4.5–8.2), and 3.2/100,000 (95% CI 2.0–4.9) in 2005–2009 (Smink et al. 2016). Therefore, it is estimated that BN has been on a downward trend since peaking around 1990.

In the United Kingdom, incidence studies of BN in primary care have shown a similar declining trend, peaking in the mid-1990s. In a 1988–1994 study, the incidence of BN among women aged 10–39 years more than tripled, from 14.6/

100,000 (95% CI 7.2–22.0) in 1988 to 51.7/100,000 (95% CI 45.6–57.9) in 1993 (Turnbull et al. 1996). However, continuous research has shown that the subsequent time trend of the incidence of BN among women aged 10–39 years peaked in 1996 and that incidence then declined to 30.7/100,000 (95% CI 24.3–40.0) in 2000.

A Danish study based on nationwide psychiatric register data detected an increasing incidence of BN between 1995 and 2010, ranging from 6.3/100,000 to 7.2/100,000 (Steinhausen and Jensen 2015). However, after adjusting for the rate of increase in the use of mental health services, the incidence of BN showed a declining trend, ranging from 6.3/100,000 to 4.2/100,000, and was the same among women in the 16–19 and 20–29 age groups, which had the highest incidence.

Another study conducted in Norway with data obtained from the National Patient Register (Reas and Rø 2018) confirmed a significant decrease in the overall incidence of BN in secondary care between 2010 and 2016, from 18.5/100,000 (95% CI 16.9–20.2) in 2010 to 16.1/100,000 (95% CI 14.6–17.2) in 2016, with a significant decrease in the average annual percentage point change(−4.2%). There was a significant decrease in incidence among all age groups, except for girls aged 10–14 years who showed an increasing trend, suggesting an earlier age of onset or detection. The peak incidence was reported among women aged 20–29 years.

The prevalence of BN was reported to be less than 1–2% in a review by Keski-Rahkonen and Mustelin et al. (2016) covering Europe as a whole.

Non-Western Countries

In this section, non-Western countries – including East Asia, West Asia, Latin America, and Africa – are discussed to explain the changing epidemiology of EDs. Research on non-Western EDs began much later in comparison to the West and is currently limited, especially in most African countries. Epidemiological data on mental disorders, in general, vary widely among regions of the world (Baxter et al. 2013), with scarce information on time trends of EDs in the non-Western world, outside some regions of East Asia.

East Asia

Japan was one of the first non-Western countries to report EDs. First, several case reports of AN were published in the 1960s (Ishikawa et al. 1960), followed by an increase in cases of AN and BN in the 1970s (Pike and Borovoy 2004). The first cross-sectional epidemiological survey was conducted in 1981 and showed that the incidence of AN in the 10–29 age group was 16.6/100,000 in 1981, 21.8/100,000 in 1992, and 76.4/100,000 in 1998. BN was first surveyed in 1992, with an incidence of 7.8/100,000 in 1992, 39.4/100,000 in 1998, and 38.4/100,000 in 2014 (Nakai et al. 2018). Thus, while the incidence of AN has been increasing, that of BN has not changed since the 1990s (Nakai et al. 2021). However, Nakai et al. (2021) claimed that the incidence of BN may have been underestimated, because the survey was conducted in a hospital rather than at a primary care setting, mainly dealing with individuals with BN. It should also be noted that the results are not strictly

comparable because the diagnostic criteria and participants included in the surveys differed from one time period to the other. However, the prevalence of EDs in Japan is said to have reached a high level, similar to that of Western countries, by the 1980s (Pike and Borovoy 2004; Hoek 2006) and has continued to increase after 1990 (Nakai et al. 2021). In addition, a Japanese clinical sample showed a decreasing trend in BMI and worsening psychopathology related to AN-R over a 30-year period from 1988 to 2018 (Harada et al. 2021). This suggests that while the incidence of AN among Japanese women is on the rise, BMI and ED-related psychopathology is also becoming more severe.

In Taiwan, an epidemiological time trend was reported using national health insurance claims data from 2002 to 2013 (Tseng et al. 2020). During that period, the incidence of AN did not change, although it increased slightly among the 10–14 and 30–39 age groups; however, the incidence of BN increased significantly in the years before 2009 and then decreased. The overall stable pattern of AN, increasing in younger age groups, and the increasing-then-decreasing pattern of BN are similar to those of Western countries. The incidence of AN and BN during the study period was 1.1/100,000 (95% CI 1.05–1.15) and 6.1/100,000 (95% CI 6.02–6.26), respectively. The incidence of AN was lower than that in other countries, while that of BN was within the range reported in Western countries. The low incidence of AN could be attributed to a lack of awareness and the low standard weight of Taiwanese, which makes it difficult to detect disease-related weight loss (Tseng et al. 2020). The most common age at which AN and BN were first detected was between 20 and 29 years, which was higher than that reported in Western Europe (Tseng et al. 2020).

West Asia

Due to the lack of valid data for this region, it is difficult to examine how incidence and prevalence have changed over the years (Melisse et al. 2020). In Arab countries, curvy bodies are considered to indicate fertility, and there is no traditional ideal of thinness. However, a review of studies conducted in Arab countries between 1986 and 2019 found that 13–55% of individuals were at a high risk for ED, and the prevalence of EDs was higher among females and adolescents than among males and older individuals, respectively, mirroring the trends in Western countries (Melisse et al. 2020). In addition, Alfalahi et al. (2021) identified studies from the United Arab Emirates, Israel, Iran, and Pakistan, all of which used semi-structured interviews to diagnose EDs and identify prevalence from 1990 to 2020. Point prevalence was found to be 1.59% (95% CI 0.77–11.17) for AN and 2.41% (95% CI 0.04–8.24) for BN (Kazim et al. 2017; Pasternak et al. 2012; Jahromi et al. 2013; Suhail and Zaib-u-Nisa 2002; Alfalahi et al. 2021). While the findings should be interpreted cautiously due to the different backgrounds of the study subjects, the prevalence is comparable to that in the Western countries (Alfalahi et al. 2021).

Latin America

There are few reports from Latin America. Kolar et al. (2016) performed a literature review on the prevalence of EDs in Latin America and conducted a meta-analysis of studies from Argentina, Brazil, Chile, Colombia, Mexico, and Venezuela on the

general population. The point prevalence was 0.1% (95% Cl 0.02–0.23) for AN and 1.16% (95% Cl 0.55–1.98) for BN. They noted that prevalence appeared to be lower in AN and the same or higher in BN compared to Western countries. However, the time trends for incidence and prevalence were not examined.

Africa

Data from Africa are considerably limited, and reports are available only from few specific regions. Van Hoeken et al. (2016) conducted a review of the epidemiology of EDs on the African continent based on articles published between 2014 and 2016, reporting that only four articles provided accurate diagnostic assessments of AN and BN. They were from Egypt (Nasser 1994), Ghana (Bennett et al. 2004), Tanzania (Eddy et al. 2007), and Kenya (Aillon et al. 2014). Among 1476 young women, point prevalence according to the DSM-IV criteria was 0% for AN and 0.87% for BN (95% CI 0.22–1.51) (Van Hoeken et al. 2016). Williams et al. (2020) reported changes in the number of AN and BN admissions over time (21 years) in a tertiary ED care unit in South Africa from 1993. The number of AN cases remained constant, while the number of BN cases decreased, but no significant statistical difference was evident due to the small number of cases. To the best of our knowledge, there are no other reports of incidence or prevalence based on correct diagnostic criteria or their time trends in Africa.

Changes in Clinical Picture

As mentioned earlier, young women constitute the main population of patients with EDs (Van Eeden et al. 2021). However, over time, research has highlighted the need to recognize that those who fall outside this group – primarily older women and men – can also develop EDs (Nagata et al. 2020; Samuels et al. 2019). It is necessary for health care professionals to understand and reflect, in their clinical practice, the fact that disordered eating behavior and eating-related distress can occur regardless of gender or age. Thus, in this section we will focus on middle-aged women and men with EDs.

Middle-Aged Women

EDs were formerly considered to occur rarely after the age of 30 (Javaras et al. 2015), leading to an exclusion of middle-aged women from study samples (Hoek 2006; Smink et al. 2013). However, studies have found that a considerable number of middle-aged adults also have EDs (Podfigurna-Stopa et al. 2015). A prospective population-based study of all patients aged 15 years and older in Spain from 2005 to 2009 unexpectedly observed newly diagnosed patients aged 45 and older (Larrañaga et al. 2012). In this study, the incidence of EDs among 15–24-year-olds was 4.4/100,000, while that among over 45-year-olds was as high as 1.1/100,000; moreover, most of these patients were females (Larrañaga et al. 2012), indicating that there may

be several non-negligible female patients with EDs of a wider age range than previously thought. Middle-aged patients with EDs have either young-onset prolonged or late-onset ED (Kodama et al. 2017). Prolonged cases are often clinically problematic, with repeated treatment failures and physical severity (Kotilahti et al. 2020). On the other hand, it has been argued that patients diagnosed after midlife may have prolonged adolescent-onset ED rather than late onset ED (Scholtz et al. 2010). Brown et al. (2020) conducted a prospective study in which 900 male and female college students, averaging 20 years of age, were followed up every 10 years for 30 years. By the end of the study, approximately 70% of both men and women were still being followed up. Although the prevalence of EDs decreased with age, some women were first diagnosed with an ED at the age of 50, suggesting that EDs could occur in middle age, with a point prevalence of 0.42 (Brown et al. 2020). In addition, a prevalence study of a longitudinal community-based sample found that although 15.3% of women had met the criteria for a lifetime of any ED by midlife, only few middle-aged or older women had access to health care services for ED (Micali et al. 2017). Moreover, there were a significant number of sub-threshold patients who did not fully meet the diagnostic criteria in middle age (Micali et al. 2017). However, even for EDs below a broadly defined threshold, middle-aged women have been reported to exhibit distress and disability comparable to women who fully satisfy the diagnostic criteria for EDs (Mangweth-Matzek et al. 2014a). Given all of this, we must determine the broad age range of EDs without underestimating middle-aged women.

Men

Although one of the earliest reports on EDs was the case of an adolescent male by Morton (1694), males have often been excluded from ED studies. In DSM-5 (American Psychiatric Association 2013), the amenorrhea criterion was removed. As a result, compared to DSM-IV, medical professionals can more easily diagnose male patients with AN. Recently, studies on male patients have received more attention (Raevuori et al. 2014; Murray et al. 2017).

In clinical samples, the male-to-female ratio of ED patients has been described as 1:10 (American Psychiatric Association 2013), based on several studies conducted at specialized hospitals in the 1990s (Andersen 1990). A lifetime prevalence study of AN and BN in the general population was conducted in the United States from 2001 to 2003; however, it reported a male-to-female ratio of 1:3 (AN 0.3%, 0.9%, BN 0.5%, 1.5%; Hudson et al. 2007). In addition, the 2008 Australian Epidemiological Survey ratio of adults reporting ED behaviors such as strict dieting/fasting or binge eating ranged from 1:3 to 2:3 (Mitchison et al. 2013). This underrepresentation of male patients in clinical practice may be attributed to stigma and a lack of awareness among the general public, which discourages men from seeking medical attention (Raisanen and Hunt 2014; Murray et al. 2017). In addition, males with EDs are understood to have maladaptive muscularity-oriented attitudes and behaviors, which are less likely to fit the pathology of the internalization of thinness ideals, which are

considered typical among females with AN (Murray et al. 2017). This may be reason why males may not be identified as having an ED using the existing diagnostic criteria and screening instrumentation (Murray et al. 2017; Mangweth-Matzek et al. 2016).

Early onset EDs in male children and adolescents have also been reported. An Australian study from 2002 to 2005 of children and early adolescents aged 5–13 years, who visited a specialist pediatric institution, revealed a boy-to-girl ratio of 1:3 (Madden et al. 2009). A 2005–2006 study of children and adolescents (<13 years old) from a specialized facility in the UK revealed that the male-to-female ratio was 1:4 (Nicholls et al. 2011). Mangweth-Matzek et al. (2014b) conducted an epidemiological review of EDs in middle-aged and older adults, reporting that the overall prevalence of EDs according to the DSM-5 criteria was 1–2% in middle-aged and older men, and approximately 3–4% in women. Furthermore, Brown et al. (2020) found that even among middle-aged women, the prevalence of ED diagnosis decreased with age, while it remained stable in men; thus, by age 50, there was no longer a significant difference in point prevalence between men and women. Apart from the adolescent-to-young-adult age group, which has been highlighted as the most common target for EDs – that is, children, middle-aged adults, and older adults – sex differences in prevalence may be small.

Conclusion

This chapter provided an overview of how EDs have changed, chronologically, over time.

A case discovered by Morton in 1689 is considered the first report leading to the current understanding of EDs. The concepts of AN and BN have barely changed since 1980, when they were incorporated into the operational diagnostic criteria of the DSM and the ICD.

Epidemiological studies that began in the late twentieth century in Western countries have reported an increase in AN and BN. AN in young women has continued to increase, while overall AN has remained constant or has increased since around the 1990s. In contrast, BN increased from the 1990s to the 2000s and then decreased. However, reports from non-Western countries are insufficient, making it difficult to draw a comparison with reports from Western countries. In non-Western countries, the adoption of Western culture, especially the idealization of thinness, has been reported to increase EDs, although Western culture is not the only factor that influences their development.

Furthermore, the population recognized as being affected by EDs has expanded over time to include not only young women, but also men and middle-aged women. However, the current diagnostic criteria do not adequately address all such non-typical cases of EDs.

The time-related changes in EDs indicate the need to perceive them as multifarious and multifaceted disorders. Further research is needed to understand not only

individuals with EDs across different cultures, genders, and ages, but also the differences among them.

Applications to Other Eating Disorders

In this chapter, we described how anorexia nervosa (AN) and bulimia nervosa (BN) have been viewed historically and how their conceptions have changed with time. We also explained the epidemiological time trends related to AN and BN in Western and non-Western countries. Finally, we covered details regarding shifts in the population that suffers from AN and BN worldwide and the understanding thereof. However, we have not discussed the history and epidemiological time trends for other new subtypes of EDs, such as avoidant restrictive food intake disorder (ARFID) and binge eating disorder (BED), due to the lack of research. The main diagnostic feature of ARFID is avoidance or restriction of food intake manifested by a clinically significant failure to meet nutritional requirements or insufficient energy intake through the oral intake of food. ARFID neither include the features of AN – such as the fear of gaining weight or of becoming fat – nor specific disturbances in relation to the perception and experience of one's own body weight and shape. Similarly, BED involves binge eating, but not the recurrent inappropriate compensatory behavior (e.g., purging, driven exercise) exhibited in BN.

EDs have been considered to include an aspect of culture-reactiveness. Further, individuals with AN and BN typically have a culture-reactive desire for a slim physical shape; in contrast, ARFID and BED do not seem to display such culture-reactive features. Historical and epidemiological research on ARFID and BED may allow us to confirm the extent to which culture affects these EDs, in comparison to AN and BN. This could contribute to prevention and treatment policies for EDs.

Mini-dictionary of Terms

- **Acculturation**. Acquisition or assimilation of a particular society's culture by an individual or group from another culture, or a psychological change associated with it.
- **Culture bound syndrome**. A combination of signs and symptoms that are confined to a limited cultural area by specific psychosocial characteristics.
- **Incidence**. The rate of new cases of a disease, occurring in a specific population over a particular period. It is used to determine whether a disease is becoming more common in a population over time.
- **Prevalence**. The rate of cases of a disease at a particular time, regardless of when the onset occurs, thus including both existing and new cases.
- **Westernization**. Adoption or the process of adopting Western culture by a given society, not only in areas such as diet and attitude of high concern toward body shape, but also more broadly, such as in industry, technology, science, education, politics, economics, law, religion, and philosophy.

Key Facts of Time-Related Changes in Eating Disorders

- Eating disorders (EDs) are serious mental illnesses characterized by disordered eating and related psychological distress.
- EDs such as anorexia nervosa and bulimia nervosa are more common in young women, while men and middle-aged and older women also suffer from eating behavior problems and associated distress.
- EDs were first conceptualized in Western countries, but they have also increased in non-Western regions where Western culture has been introduced.
- This chapter describes the history of EDs, epidemiological changes, and EDs worldwide, with the goal of understanding how EDs have changed over time.
- Understanding time-related changes in EDs worldwide teaches us that an ED is more than just a disease associated with the idealization of thinness.

Summary Points

- Diagnostic criteria for EDs in the DSM and the ICD have not changed significantly since the 1980s.
- There are methodological issues in assessing the epidemiological time trends of EDs.
- In Western countries, the overall incidence of AN increased until 1970–1990s and then stabilized, although its incidence among adolescent and young women has continued to increase. The incidence of BN peaked around the 1990s and has been declining since.
- More epidemiological studies on EDs conducted in non-Western countries are needed.
- A considerable number of middle-aged women and men also have eating behavior problems.

Abstract

Eating Disorders (ED) and Substance Use Disorders (SUD) commonly occur. In fact, approximately 50% of individuals with an ED report abusing alcohol or an illicit substance. Given the high rates of co-occurrence of ED and SUD, it is important to understand the connection between these disorders to guide prevention and treatment efforts. This chapter reviews shared etiological factors connecting ED and SUD. More specifically, neurobiological and candidate gene studies independently exploring SUD and ED suggest that similar genetic variants in both the dopamine and serotonin systems might influence ED-SUD comorbidity. Connections between ED and SUD are accounted for by shared characteristics related to reward sensitivity, impulsivity, executive function deficits, and emotion dysregulation. Additional shared risk factors include stress, environment, and trauma. These shared etiological factors highlight the importance of treating transdiagnostic mechanisms that contribute to both ED and SUD. Interventions that target the reward system, temperament, emotion regulation, and stressor-related symptoms are all essential to this work.

Keywords

Substance use disorders · Eating disorders · Emotion regulation · Impulsivity · Trauma · Reward sensitivity · Transdiagnostic · Neurobiology · Genetics · Executive function

Abbreviations

5-HIAA	Serotonin metabolite 5-hydroxyindoleacetic acid
5-HT	Serotonin
ACC	Anterior cingulate cortex
ACE	Adverse childhood event
ACT	Acceptance and commitment therapy
AN	Anorexia nervosa
AN-BP	Anorexia nervosa, binge/purge type
AN-R	Anorexia nervosa, restricting type
AUD	Alcohol use disorder
BED	Binge-eating disorder
BN	Bulimia nervosa
CBT	Cognitive behavioral therapy
CSF	Cerebrospinal fluid
DA	Dopamine
DBT	Dialectical behavior therapy
DSM-5	Diagnostic and Statistical Manual of Mental Disorders, 5th Edition
ED	Eating disorder
ED-SUD	Persons with comorbid ED and substance use disorder
ER	Emotion regulation

MBRP	Mindfulness-Based Relapse Prevention
OBE	Objective binge episode
OSFED	Other specified feeding or eating disorder
PTSD	Posttraumatic stress disorder
SUD	Substance use disorder
UFED	Unspecified feeding or eating disorder

Introduction

While much has been studied of the assessment, treatment, and etiology of substance use disorders (SUDs) and of eating disorders (EDs), the research is only now catching up to understanding the unique implications of co-occurring eating and substance use disorders (ED-SUDs). In fact, studies indicate that approximately 50% of individuals with EDs also misuse substances, which is five times the abuse rate seen in the general population (CASA 2003). As a result, these individuals experience lower rates of treatment response, higher relapse rates, more severe medical complications, and higher risk of early mortality (Harrop and Marlatt 2010; Lindblad et al. 2016).

Commonly abused substances found among the ED population include alcohol, cannabis, illicit drugs such as opiates and stimulants, over-the-counter medications such as laxatives and diuretics, as well as prescribed medications such as benzodiazepines. Misuse of nicotine and caffeine is also found to be highly correlated in this population due to the appetite-suppressant qualities of these substances. Women with Bulimia Nervosa (BN) and Anorexia Nervosa, Binge-Purge subtype (AN-BP) are at the highest risk of comorbid alcohol or illicit drug use (Bulik 1987).

This high-risk subset of the ED population is often limited in their access to appropriate treatment services because of the lack of assessment, intervention, and training of co-occurring disorders in such settings. Without specific knowledge or education in the area of ED-SUDs, many providers do not feel adequately equipped to manage the medical, physical, or behavioral symptoms that present within this patient population. As a result, treatment programs tend to provide either sequential treatment, whereby the most acute disorder is treated first, or concurrent treatment, whereby different providers offer specialized services apart from each other. Neither of which have proven to be effective long-term treatment approaches.

It is therefore no wonder that providers, clinicians, and carers may feel challenged in supporting ED-SUD patients in receiving the care and treatment that they need. Confounding factors such as neurobiology, temperament, and trauma play an integral role in the etiology and presentation of ED-SUDs. As such, locating comprehensive, integrated care models to address the unique needs of this population can be challenging at best.

This chapter aims to clarify the link between EDs and SUDs by outlining the unique considerations of these disorders. Given the high rates of co-occurrence of ED and SUD, it is important to understand the connection between these disorders, as well as how they present together. In this chapter, we provide an overview of the

genetic, neurobiological, personality, and temperament factors contributing to the development of ED and SUDs, and shared risk factors such as stress, environment, and trauma. Finally, we will highlight the clinical implications of treating this high-risk patient population. Our hope in exploring the connection between ED and SUD is to better guide prevention and treatment efforts for these commonly co-occurring disorders.

Eating Disorders

Eating disorders (EDs) are serious psychiatric illnesses that are associated with significant morbidity and mortality (Arcelus et al. 2011). The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*; APA 2013) recognizes five EDs. Anorexia nervosa (AN) is characterized by a significantly low body weight given considerations such as age, sex, developmental trajectory, etc. Persons with AN exhibit a fear of gaining weight or becoming fat and/or engage in behaviors that interfere with weight gain (e.g., dietary restriction). They also report an undue influence of their body weight or shape on their self-evaluation and/or denial of the seriousness of their low body weight. AN has two subtypes: The binge/purge subtype (AN-BP) is characterized by objectively large binge-eating episodes (see Bulimia Nervosa below for further definition) and/or purging behaviors (e.g., self-induced vomiting, laxative misuse, thyroid medication manipulation, etc.). Either binge or purge behaviors must be present to diagnose AN-BP (both may occur but is not necessary to diagnose this subtype). Persons with the restricting subtype (AN-R) do not engage in binge/purge behaviors and typically exhibit significant dietary restriction. They may also engage in compensatory exercise to interfere with weight gain.

Bulimia nervosa (BN) features objective binge episodes (OBEs), which are characterized by intake of an objectively large amount of food (i.e., greater than what most people would eat in similar situations) over a discrete period (e.g., 2 h). The OBE must also feature a sense of loss of control over eating (e.g., feeling as though one cannot stop eating). BN also features inappropriate compensatory behaviors, such as self-induced vomiting or dietary restriction. Persons with BN display an overvaluation of body weight or shape on their self-evaluation. For example, someone with BN may use their body shape to determine whether they are a good or bad person. Additionally, persons with BN cannot be at a significantly low body weight. Binge-eating disorder (BED) also features OBEs; however, the OBEs occur in the absence of inappropriate compensatory behaviors. Persons with BED also display cognitive symptoms related to binge eating (e.g., eating alone because of embarrassment associated with binge eating). Additionally, persons with BED may not be at a significantly low body weight.

The other two EDs recognized in the *DSM-5* (APA 2013) are "Other specified feeding or ED" (OSFED), which is a residual diagnostic category for clinically significant ED symptoms that do not meet diagnostic criteria for AN, BN, or BED, and "Unspecified feeding or ED" (UFED), which is a diagnostic category meant to

denote clinically significant eating pathology with insufficient information to assign one of the ED. It is worth noting that OSFED and UFED are no less serious or impairing than the other EDs and that the most prevalent ED diagnostic category in epidemiological samples is OSFED (Mitchison et al. 2020).

Substance Use Disorders

Substance use disorders (SUDs) are a class of psychiatric illnesses associated with the maladaptive use of one or more substances (e.g., drugs, medications, etc.; APA 2013). There are ten classes of substances recognized in the *DSM-5* SUD classification system (alcohol, cannabis, anxiolytics/sedatives/hypnotics, caffeine, hallucinogens, stimulants, inhalants, opiates, tobacco, and "other"). Eleven SUD diagnostic criteria describe problems subsequent to substance use (e.g., interpersonal problems, medical complications) and at least two criteria must be endorsed to diagnose a SUD. The severity of the SUD is based on the number of symptoms reported concurrently (i.e., mild = 2–3 symptoms, moderate = 4–5 symptoms, severe $\geq$6 symptoms). Persons with SUDs tend to exhibit impulsivity and emotion-regulation deficits (see "Temperament" section below for further description).

As discussed in the chapter Introduction, there are several classes of substances that persons with EDs are more likely to abuse. Individuals with EDs who abuse alcohol or cannabis may do so in order to impact their eating behaviors. For example, lowered inhibitions that may accompany alcohol use may result in the person feeling as though they have "permission" to engage in binge-eating behaviors, which the person may otherwise refrain from engaging in when not under the influence. Similarly, persons with EDs may use cannabis to induce feelings of hunger, and/or to regulate negative emotions. In contrast, persons with EDs may abuse stimulants (e.g., cocaine, Adderall), caffeine, or nicotine for their appetite-suppressant effects and in order to facilitate weight loss. Other substances that can be relevant to persons with EDs include laxatives, diuretics, enemas, suppositories, thyroid hormone, insulin, anabolic steroids, and diet pills. Although many of these substances have medical usefulness (e.g., persons with Type I diabetes must take insulin), their use can be considered maladaptive if the recommended dosage is manipulated and/or they are used for purposes unintended by the manufacturer (e.g., laxative abuse for the purpose of weight loss). In summary, persons with EDs may abuse substances in order to directly impact their ED (e.g., stimulant abuse to suppress appetite), to cope with negative emotions (e.g., cannabis abuse to escape distress), or both.

Genetics

Extensive research demonstrates genetic contributions to the development of SUD and ED independently. Family studies exploring disorder risk among first-degree relatives consistently reveal that both SUD and ED aggregate within families (Strober et al. 2000; Wang et al. 2012). Twin studies further corroborate the familial

components of SUD and ED (Trace et al. 2013; Wang et al. 2012). Molecular genetic approaches also highlight the associations between specific genes that influence the emergence of SUD and ED. Below is a review of research implementing these study designs that highlight the genetic variations impacting serotonin and dopamine that might contribute to the association between SUD and ED.

The Role of Serotonin

A prominent molecular genetic approach includes candidate gene studies, which investigates the relation between a specific genetic variant and a disorder. Serotonin has been studied extensively using candidate gene studies in both SUD and ED independently. The data on SUD and the polymorphism of a serotonin transporter gene, 5-HTTLPR, are robust. Meta-analytic data reveal that the short allele of 5-HTTLPR is significantly associated with alcohol dependence (e.g., McHugh et al. 2010). Data are mixed regarding the association between 5-HTTLPR and nicotine or related phenotypes, with some studies indicating a relation with the short allele, some with the long allele, and others suggesting no relation exists (Herman and Balogh 2012). Research investigating the 1438G/A polymorphism in the HTR2A gene demonstrates the G allele is significantly associated with alcohol dependence (Nakamura et al. 1999). The A allele of the 1438G/A polymorphism in the HTR2A gene also emerges as significantly associated with tobacco smoking (Polina et al. 2009).

The majority of research exploring the serotonin system in ED has also concentrated on 5-HTTLPR. Meta-analytic data suggest that individuals with at least one copy of the short allele of this gene were more likely to have AN (e.g., Lee and Lin 2010). Evidence for the influence of this polymorphism in BN and BED is mixed, as some research supports the impact of 5-HTTLPR in patients with BN and BED and others lack data to suggest a significant association (Lee and Lin 2010). Meta-analytic data have also identified a significant association between the HTR2A promoter region polymorphism(−1438G/A, rs6311) and AN (Gorwood et al. 2003).

The Role of Dopamine

Candidate gene studies have also explored dopamine in both SUD and ED independently. Research on SUD and dopamine is extensive, given the role dopamine plays in reward and motivation. Meta-analytic work investigating the TaqIA polymorphism indicates the A1 allele is significantly associated with alcohol dependence (Tammimäki and Männistö 2010) and increased risk for nicotine dependence (e.g., Munafò et al. 2004). The A1 allele also emerges as significantly related to greater heroin consumption and an increased risk for a cannabis-related "high" at an earlier age (Conner et al. 2005). Studies exploring the Val158Met polymorphism suggest that the presence of the Val allele significantly increases the risk for smoking and

cannabis use. Notably, no relation has been identified between the Val158Met polymorphism and alcohol dependence (Tammimaki and Mannisto 2010). Further data suggest other genetic variants in the catechol-O-methyltransferase (COMT) gene and the dopamine system are associated with cocaine use or dependence (Haile and Kosten 2007).

Less research is available investigating the role of dopamine genes in ED. Population-based data highlight that the A1 allele in the TaqIA polymorphism (i.e., rs1800497) in the dopamine D2 receptor gene (DRD2/ANNK1) is associated with greater food craving and motivation for food (Epstein et al. 2007). Available research in ED specifically suggests that the A1 allele is associated with psychological characteristics of AN and BN (i.e., drive for thinness, feelings of inadequacy, and worthlessness) and sensation seeking among women with bulimia-spectrum disorders (e.g., Groleau et al. 2012). Alternatively, other data indicate that as the number of A2 alleles of the TaqIA polymorphism increases, the larger the association with AN-BP (Bergen et al. 2005). The Val allele of the Val158Met polymorphism emerges in some research as significantly associated with AN and BN (Mikołajczyk et al. 2006; Yilmaz et al. 2011); however, other data reveal that the Met allele is associated with AN or do not establish any association between ED and alleles in the COMT gene (Brandys et al. 2012).

Genetics and ED-SUD

Available research investigating ED-SUD comorbidity is limited to family and twin study designs. Data examining familial co-aggregation are rather sparse and, generally, results support independent transmission of ED and SUD. In contrast, twin studies offer data to suggest shared familial association. The first exploration of genetic similarities between alcoholism (alcohol dependence or problematic drinking) and BN indicated a small overlap (6%; Kendler et al. 1995). Further research investigated genetic overlap between BN symptom count and several SUD, estimating correlations with AUD at 0.53, any illicit drug use disorder at 0.37, and smoking 0.35 (Baker et al. 2010). More genetic correlations were observed between alcohol misuse and inappropriate compensatory behaviors, estimated at 0.61, and alcohol misuse and binge eating, estimated at 0.31 (Slane et al. 2012). An assessment of overlap between AUD and combined binge-eating and inappropriate compensatory behaviors identified a genetic correlation of 0.33 (Munn-Chernoff et al. 2013). Taken together, results from recent twin studies suggest that ED-SUD comorbidity might be more related to specific ED symptoms, rather than a specific diagnosis. Indeed, this might explain the higher frequency co-occurrence of SUD with binge-purge type ED (Munn-Chernoff and Baker 2015).

In sum, candidate gene studies independently exploring SUD and ED suggest that similar genetic variants in both the dopamine and serotonin systems might influence ED-SUD comorbidity (Munn-Chernoff and Baker 2015). Evidence from twin studies specifically examining this comorbidity suggest genetic overlap,

especially in regard to SUD and binge-purge symptomatology. Molecular genetic studies exploring cross-disorder association analyses are an important area for future research to further understand the genetics involved in ED-SUD comorbidity.

Neurobiology

Research exploring central neurotransmitter systems and brain circuitry in SUD and ED independently offer data to suggest similar patterns of dysfunction. Serotonin (5-HT) plays a major role in a number of behavior and psychological functions, such as behavioral inhibition, appetite regulation, and mood; therefore it has been extensively studied in patients with ED, and to a lesser extent with individuals with SUD. As dopamine (DA) is closely involved in the processing and response to rewarding and punishing stimuli, it also has been studied in samples of ED and SUD. More recent neuroimaging research exploring the brain reward system offers evidence to suggest that neural pathways related to DA might also be important in the connection between ED and SUD.

Neurobiology of SUD

Exploration of 5-HT in SUD at is relates to pathology is complicated, as acute consumption of substances, such as alcohol, stimulants, cocaine, and opioids, initially increases extracellular 5-HT but promptly suppresses 5-HT neurotransmission (Kirby et al. 2011). Further, 5-HT neuronal response seems to normalize with long-term exposures to substances; however, 5-HT neurotransmission appears to cease with withdrawal (Kirby et al. 2011). This observation likely contributes to dysphoric mood states and cravings, thereby triggering substance seeking and consumption to modulate negative mood (Kirby et al. 2011).

Cerebral spinal fluid (CSF) research examining serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) levels presents mixed findings across various substances. Overall, some data indicate that individuals who abuse alcohol and ecstasy demonstrate significantly low 5-HIAA when compared to healthy controls; whereas other data have found no differences among those with alcohol dependence or cocaine abuse and controls (e.g., Agartz et al. 2003; Roy et al. 2002). Similarly, brain imaging research exploring the 5-HT transporter in substance abuse provides mixed findings, with support for increased, normal, or decreased 5-HT availability (e.g., Cosgrove 2009).The amount of literature on 5-HT in SUD is sparse and does not provide a uniform description; however, available data indicate that chronic substance use might be associated with lower CSF 5-HT metabolites, and alterations in 5-HT system activity might contribute to mood fluctuations and associated emotional difficulties.

Neurobiology of ED

For ED, CSF studies evaluating patients currently diagnosed with AN-R reveal significant reduction in 5-HIAA (e.g., Jimerson et al. 1990). Alternatively, recovered AN-R individuals exhibit increased concentrations of CSF 5-HIAA. A similar pattern exists in BN, with more severe patients currently diagnosed with BN displaying lower CSF 5-HIAA levels (Jimerson et al. 1992) and recovered BN individuals exhibiting elevated concentrations of the metabolite (Kaye and Weltzin 1991). It appears that increased 5-HT brain levels might precede the development of ED. Depletion of the dietary precursor of 5-HT, tryptophan, through restriction might impact affective states for individuals predisposed to ED that trigger and reinforce disordered eating behaviors. Specifically, acute tryptophan depletion in AN seems to reduce dysphoric mood states, reinforcing restriction, while it seems to exacerbate dysphoric mood states in BN, reinforcing binge eating.

Brain imaging research demonstrates elevated 5-HT_{1A} receptor binding across most brain regions in samples of individuals currently diagnosed with AN-R and AN-BP, as well as AN-BP after recovery. Alternatively, recovered AN-R individuals displayed normal 5-HT_{1A} receptor binding mesial temporal and subgenual cingulate regions, which has been associated with harm avoidance (Bailer et al. 2005). Individuals with symptomatic BN also exhibit increased 5-HT_{1A} receptor binding, specifically in the medial prefrontal cortex, posterior cingulate, and angular gyrus of the parietal cortex (Tiihonen et al. 2004); yet, data suggest BN individuals continue to display increased 5-HT_{1A} binding when recovered (Bailer et al. 2010). Further, both symptomatic and recovered AN individuals present with reduced 5-HT_{2A} receptor binding in the frontal, parietal, and occipital cortices (e.g., Audenaert et al. 2003). Recovered BN individuals also demonstrate reduced 5-HT_{2A} receptor binding in orbitofrontal cortex (Kaye et al. 2001), which research implicates is associated with inhibitory processes. This altered 5-HT receptor function likely impacts mood dysregulation in ED.

Neurobiology of ED-SUD

Available research suggests that both SUD and ED might share an important overlap in 5-HT that relates to inhibition, appetite, and affective challenges. Although more data in this area are needed, it appears the behavioral manifestation of low CSF 5-HT metabolites in SUD and BN display similarities, in that reduced levels are associated with dysphoric mood states that contribute to the consumption of substances and/or food.

In contrast to 5-HT, research examining DA in SUD is much more extensive, as it is involved in the rewarding effects of drugs. Brain imaging studies indicate that individuals currently addicted to substances, including cocaine, heroin, alcohol, methamphetamine, and nicotine, exhibit significant reductions in DA D2 receptor availability and DA release in the striatum, and this persists months after detoxification (e.g., Volkow et al. 2007). Consumption of substances is associated with large

and fast increases in extracellular DA in the striatum, mimicking those induced by physiological dopamine, therefore reinforcing substance use (Volkow et al. 2009). Indeed, lower DA D2 receptor availability in the ventral striatum is associated with greater alcohol craving (Heinz et al. 2004), higher consumption (Martinez et al. 2005), and larger risk for relapse (Guardia et al. 2000). Notably, low premorbid DA D2 receptor levels might increase vulnerability to developing SUD, as high levels of D2 DA receptor availability in the striatum appear protective against the reinforcement of substance use (e.g., Volkow et al. 2002).

Similar to substances, DA is also involved in the rewarding effects of weight and feeding behaviors. Research on individuals recovered from AN identified increased binding of DA D2/D3 receptors in the anterior ventral striatum (Frank et al. 2005). In contrast, patients currently with BN exhibit decreased DA D2/D3 receptor binding in the striatum, in addition to reduced DA release (Broft et al. 2012). Moreover, data suggest a significant negative association between the frequency of both binge eating and vomiting and the striatal DA response (Broft et al. 2012). Consumption of palatable food is also associated with DA release, therefore reinforcing overeating and purging. Notably, individuals recovered from BN and AN-BP demonstrate normal DA D2/D3 striatal binding, suggesting that frequent binge-eating and vomiting behavior leads to the downregulation of DA receptors in the striatum (Broft et al. 2012).

Taken together, it appears that BN and SUD might share DA D2 receptor-related vulnerabilities to the rewarding aspects of substances and highly palatable foods. Specifically, it seems that decreased DA D2 receptor binding availability and DA release in the striatum are markers of both disorders. The consumption of both food and drugs might be an attempt to alleviate the reduced reward and self-medicate a hypoactive dopaminergic system (Broft et al. 2012). On the other hand, contrasting DA D2 receptor patterns in AN might contribute to individuals with the disorder being "protected" from SUD (Kaye et al. 2013).

Neuroimaging Findings in SUD and ED

Neuroimaging studies examining the brain reward systems that are related to DA function highlight the neural circuity contribution to behavioral symptoms. Research in this area investigating SUD suggests disrupted function of the prefrontal cortex through its involvement in higher-order executive functioning and regulation of limbic brain regions. These deficits in the prefrontal cortex contribute to impaired response inhibition, related to dorsal anterior cingulate cortex hypoactivity, and increased activation in many prefrontal cortex regions (e.g., ventral striatum, anterior cingulate cortex [ACC], amygdala) in response to visual drug-related cues (e.g., Goldstein and Volkow 2011).

Functional magnetic resonance imaging studies investigating ED demonstrate altered activity within and/or between ventral limbic and dorsal cognitive circuits,

brain regions associated with inhibitory control, and reward-related behaviors. Individuals with ED demonstrate altered reward sensitivity associated with limbic circuitry, with increased behavioral inhibition related to exaggerate dorsolateral cognitive circuity in AN, and decreased inhibitory control related to impaired frontostriatal circuitry in BN (e.g., Wierenga et al. 2015). The deficits in circuity associated with self-regulatory control in individuals with BN likely contribute to binge eating, difficulty resisting urges to purge, and other impulsive behaviors. Further, individuals with AN exhibit reduced activation in the insula, lateral prefrontal cortex, and parietal lobe, and increased activation in the medial prefrontal cortex, when presented with visual food-related stimuli (e.g., Holsen et al. 2012). On the other hand, individuals with BN exhibit increased activation in the insula, ACC, and ventral striatum when exposed to visual food-related stimuli (e.g., García-García et al. 2013). The differences in circuity related to the anticipation of food rewards likely drives the contrasting drives to approach and avoid food observed between AN and BN.

The deficient activation of brain regions related to inhibitory control in BN mirrors similar patterns of activation identified in SUD (Goldstein and Volkow 2011). Further, the increased activation in response to visual food cues observed in BN parallels increased activation in these regions in SUD exposed to visual drug cues. Notably, patients with AN demonstrate contrasting patterns of neural activation in response to rewards, which likely relates to lower rates of SUD among these individuals. Overall, it appears that the same neural pathways that reinforce motivation to approach food are also activated in response to drugs of abuse.

Temperament

Individuals with temperamental traits of reward sensitivity and impulsivity may be at high risk of developing SUD and ED. As previously highlighted in the neurobiological section of this chapter, reward sensitivity appears to play a central role in the development of both EDs and SUDs.

Impulsivity is an important mechanism believed to underlie both disordered eating and substance use. Impulsivity is a multidimensional construct that incorporates components of lack of planning and rash behavior without careful deliberation or consideration of consequences (e.g., Moeller et al. 2001). As part of this multidimensional construct, researchers have focused on two emotional aspects of impulsivity that appear to contribute to both ED and SUDs. *Positive urgency*, the tendency to act rashly when experiencing a positive mood, and *negative urgency*, the tendency to act rashly when experiencing negative mood. Impulsivity, specifically the components of positive and negative urgency, may account for how individuals respond to stress and intense emotion. Therefore, someone who engages in disordered eating or substance use may impulsively turn to these behaviors when in distress or feeling intense emotions to relieve distress and alter mood in the short term.

Impulsivity in SUD and ED

To date, there is considerable research indicating that individuals with SUD typically display impulsive behaviors and are impaired at delaying gratification of rewards (Hester et al. 2010). Numerous studies show that individuals who misuse substances report higher levels of impulsivity and novelty seeking than nonclinical controls. Studies using behavioral measures show that when given a choice, substance users engage in rash and impulsive decision-making and show greater preference for small, immediate rewards over larger, delayed rewards (e.g., Petry 2002). Furthermore, longitudinal research with college students shows that positive urgency predicts engagement in illegal drug use, increased quantity of alcohol consumption, and problems associated with alcohol use (Cyders et al. 2009). Similarly, negative urgency is associated with increased alcohol consumption and negative outcomes (Cyders et al. 2009).

In EDs, impulsivity appears to contribute particularly to binge-eating behaviors. Research suggests that individuals who binge eat tend to make risky decisions and have difficulty focusing attention and delaying rewards (Manwaring et al. 2011). Similarly, individuals who binge and purge tend to be characterized more by impulsivity and score higher on measures of sensation seeking than AN-R or healthy controls (e.g., Cassin and von Ranson 2005). Furthermore, higher levels of self-reported negative urgency predicts binge-eating symptoms in BN and BED (e.g., Fischer et al. 2008). On the other hand, research indicates that individuals with AN tend to be higher in self-directedness and lower in novelty seeking than those who binge eat or do not have an ED (Cassin and von Ranson 2005). This further highlights the unique role of impulsivity to binge-eating behaviors, and may also account for the higher association of SUD to those with EDs with a binge-eating component.

Impulsivity may also explain why individuals with SUDs and EDs engage in behavior that is rewarding in the short term (e.g., substance use, binge eating), despite their negative consequences in the long term. Consistent with this theory, existing findings indicate that affective instability, impulsivity, and novelty seeking are common in patients with EDs who engage in substance abuse (Aldao et al. 2010). This heightened impulsivity underlying both ED and SUD may account for the range of impulsive behaviors often seen in the ED-SUD population, including suicidal behavior, self-injury, and shoplifting (e.g., Fichter et al. 1994). This connection may also explain poor treatment outcomes and high relapse rates for both ED and SUD (e.g., Nederkoorn et al. 2007).

Executive Function Deficits

Executive function deficits are common features of both ED and SUD that are closely linked to impulsivity. Executive functioning generally refers to a group of cognitive processes responsible for self-regulatory and goal-oriented behaviors. This includes cognitive functions such as decision-making, cognitive flexibility, and

inhibitory control. Inhibitory control refers to the ability to suppress, interrupt, or delay an overt behavior (behavioral inhibition) or cognitive process such as attention (cognitive inhibition).

Executive Function Deficits in SUD and ED

Research suggests that individuals with SUD show greater deficits in executive functions compared to healthy controls. For example, AUD has been associated with deficits related to inhibition and attention. Difficulties with executive control may serve as a risk factor for the development of SUD (Tarter et al. 2003). In support of the theory of executive function deficits in SUD, individuals who misuse alcohol and drugs tend to demonstrate poor performance on behavioral tasks reflecting impulse control, such as delay discounting and Go/No-Go tasks (e.g., Bickel et al. 2007). One confounding variable in exploring the connection between executive control and substance use is that chronic substance use may also lead to worsening executive control deficits throughout the course of the addiction (de Wit 2009).

For ED, deficits in behavioral control may play a particularly important role in the development of binge eating due to the loss of control over eating that is a key element of the experience of a binge-eating episode. In support of this theory, research highlights both cognitive and behavioral control deficits in BN (Wu et al. 2013). Meta-analyses show that patients who engage in binge eating, including AN-BP, BN, and BED have impaired control in general and particularly related to disease-specific stimuli (food/eating/weight) compared to healthy controls (Wu et al. 2013). Difficulties with behavioral control may also explain why rates of other impulsive behaviors are higher among individuals with BN, including elevated rates of substance use compared to AN (without binge-eating behaviors). In AN, on the other hand, theories posit that increased cognitive control may promote and maintain excessive control over food intake. Research support indicates that individuals with AN do not generally show difficulties with behavioral inhibition.

Limited empirical data exist examining the neuropsychological profile of ED-SUD. However, findings indicate that individuals with ED who also engage in substance abuse demonstrate greater problems with executive control compared to ED patients without substance abuse (e.g., Lozano-Madrid et al. 2020).

Emotion Regulation

Emotion regulation (ER) is an important mechanism identified in the development and maintenance of both SUD and ED (Baker et al. 2004). Emotion regulation is a multidimensional construct defined as a complex set of abilities including (a) awareness, understanding, and acceptance of emotions, (b) ability to control behavior when experiencing negative emotions, (c) ability to use situationally appropriate strategies to modulate emotions flexibly in order to meet individual goals and situational demands, and (d) willingness to experience negative emotions

(Gratz and Roemer 2004). When someone experiences emotion dysregulation, they exhibit difficulties in one or more of these dimensions of emotion regulation. Theoretically, an individual who has difficulty with emotion regulation may engage in maladaptive behaviors such as disordered eating and substance use in order to avoid or modulate emotional experiences.

Emotion Regulation in SUD and ED

Data suggest that ER difficulties are an important risk factor for the development of SUDs, and several theoretical models of SUDS point to emotion dysregulation as motivator for ongoing drug use and risk of relapse. Substances play an important role in mood regulation. They can act by increasing positive emotions as well as alleviating negative emotional states (e.g., anxiety reduction, relieving pain, reducing sadness). Thus, for individuals with ER deficits, substances serve as a compelling way to regulate emotional experience. Those with SUDS demonstrate poorer ER skills than healthy controls (e.g., Fox et al. 2008), and ER deficits and emotional suppression are associated with increased substance use (e.g., Berking et al. 2011). Furthermore, SUD patients show impairments in emotional awareness and clarity, as well as deficits in accepting and tolerating negative emotions (Fox et al. 2008).

Individuals with ED display a broad pattern of deficits in various dimensions of ER, and greater degree of ER difficulties is associated with more severe ED behaviors in both AN and BN (Lavender et al. 2015). Similar to the function of substances, ED behaviors such as binge eating, purging, and food restriction serve as an attempt to modulate mood, forming and maintaining maladaptive ER strategies. For example, a review of individuals with AN-R, AN-BP, and BN shows that across these diagnoses, individuals reported a limited repertoire of skills to regulate emotions and reported maladaptive strategies and reduced capacity for tolerating emotional distress (Lavender et al. 2015). Furthermore, there is evidence to suggest that individuals with binge-purge behaviors may experience greater ER difficulties than those with restricting-type behaviors.

In support of the connection between ER underlying both ED and SUDs, existing findings indicate that affective instability and negative urgency are common in individuals with EDs who also engage in substance abuse (e.g., Fisher et al. 2012). Research examining ER in adults presenting to ED treatment suggests that those with ED-SUD demonstrate greater ER difficulty, including engaging in goal-directed activity when distressed, higher impulsivity, and limited emotion regulation strategies when compared to individuals with ED alone (Claudat et al. 2020).

Additional Shared Risk Factors for SUD and ED

Research consistently points to the impact of exposure to severe adversity, especially in childhood, on health. Indeed, early life trauma is associated with later development of both substance-related problems and disordered eating (e.g., Leza et al.

2021). Theoretically, substances and/or food might both be employed to self-medicate and alleviate trauma-related distress among individuals struggling with emotion regulation.

Adverse Events, Trauma, and SUD

Studies exploring child maltreatment consistently reveal its association with an increased risk of SUD. A scoping review exploring the link between adverse childhood events (ACE) and SUD identified a higher prevalence of ACE in SUD than the general population. A positive association between ACE and the development and severity of SUD was also observed (Leza et al. 2021). Moreover, childhood adversity is associated with an increased risk of posttraumatic stress disorder (PTSD; Widom 1999). Research exploring samples of individuals seeking treatment for SUD indicate a significantly high prevalence of childhood adversity and PTSD, and in the majority of cases, PTSD preceded SUD (Dansky et al. 1994). The observed rates of childhood maltreatment in individuals with PTSD and SUD suggest a relation between childhood trauma and later development of these disorders.

Adverse Events, Trauma, and ED

Individuals with ED endorse a history of childhood adversity more frequently than the general population, and the experience of childhood abuse exacerbates the severity of ED symptoms (Guillaume et al. 2016). Traumatic events seem to be a significant causative risk factor for the development of binge-eating and purging behaviors, specifically, while results are mixed for restricting behaviors (Caslini et al. 2016).

An important mediator between a history of adversity and the development of ED is the presence of PTSD or related symptoms. Patients with comorbid BN and PTSD endorse larger increases in negative affect before purging, larger decreases in negative affect after purging, and larger increases in positive affect after purging when compared to patients with BN alone (Karr et al. 2013). Data suggest that childhood adversity is associated with later development of ED, and comorbid PTSD might worsen prognosis.

Adverse Events, Trauma, and ED-SUD

Data suggest that individuals with comorbid SUD and ED often endorse a history of adverse experiences. For example, significantly higher rates of prior sexual abuse emerge in patients with comorbid SUD and ED (Deep et al. 1999). In individuals with ED, childhood adversity is associated with a higher number of impulsive behaviors, including alcohol and illicit drug abuse (Corstorphine et al. 2007).

Further, patients with BN who endorse a history of sexual or physical abuse demonstrate higher rates of PTSD, substance dependence, and more severe ED pathology (Matsunaga et al. 1999). Data from the National Comorbidity Survey Replication observed the highest rates of PTSD and subthreshold PTSD in patients with comorbid SUD and ED (specifically, individuals with bulimic symptomatology) when compared to either disorder alone or no disorders (Brewerton and Mitchell 2012).

Notably, early traumatic experiences might prompt neurobiological changes that contribute to the pathophysiology of SUD and ED. Early stressors contribute to the dysregulation of the hypothalamic-pituitary-adrenal axis, which is involved in the pathophysiology of SUD and ED (e.g., Liu et al. 1997). Early stressors can also result in increased noradrenergic activity, which might increase the neurobiological vulnerability to the development of PTSD, SUD, and ED (e.g., Sanchez et al. 2001). Further, research reveals the impact of early trauma on the neurotransmitters involved in reward-related behaviors, indicating that childhood adversity might predispose individuals to develop SUD and ED by directly influencing the reinforcing effects of food and substances (e.g., Meaney et al. 2002).

As not all individuals with a history of trauma develop significant psychopathology, other factors, like genetics, might also impact the development of SUD and ED following traumatic experiences. Research demonstrates that individuals with the 5-HTTLPR S allele and a history of childhood trauma are more likely to experience comorbid BN-spectrum disorders and SUD (Richardson et al. 2008). Overall, data suggest that adverse experiences contribute to the later development of both SUD and ED, and individuals with the comorbid diagnoses experience more severe pathology.

Clinical Implications

To date, there are no evidence-based treatments or formal protocols for treating individuals that present with both ED and SUD. This results in very few treatment centers comprehensively targeting ED and SUD at the same time. As such, individuals experience fragmented treatment, with individuals presenting to SUD treatment targeting their substance use primarily, and individuals presenting to ED treatment primarily targeting their disordered eating. The challenge of this is that neither of the symptoms is being addressed in an integrated fashion, thus leading to vacillation of symptomatology over time. This phenomenon is often described by clinicians as the "Whack-a-mole" effect. Whereas, addressing one set of symptoms only results in an increase in the other addictive or problematic behaviours. Overall, this contributes to higher rates of relapse in this population (e.g., Dennis and Helfman 2010).

Given these limitations, experts have called for more integrated treatments to concurrently treat ED and SUD, implemented by a treatment team that is trained in evidence-based treatments for both disorders. As part of integrated treatment for ED-SUD, it is recommended providers utilize motivational interventions to engage individuals in treatment. As cognitive-behavioral therapy (CBT) has a strong

Table 1 DSM-5 substance use disorder diagnostic criteria (APA 2013)

DSM-5 substance use disorder diagnostic criteria		
A.	A problematic pattern of substance use leads to clinically significant impairment of distress, as manifested by at least two of the following, occurring within a 12-month period:	
	1.	The substance is often taken in larger amounts or over a longer period than was intended.
	2.	There is a persistent desire or unsuccessful efforts to cut down or control the substance use.
	3.	A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from the effects of the substance.
	4.	Craving, or a strong urge to use the substance.
	5.	Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home.
	6.	Continued substance use despite having persistent or recurrent social or interpersonal problems cause or exacerbated by the effects of the substance.
	7.	Important social, occupational, or recreational activities are given up or reduced because of substance use.
	8.	Recurrent substance use in situations in which it is physically hazardous.
	9.	Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.
	10.	Tolerance, as defined by either of the following: (a) A need for markedly increased amount of the substance to achieve intoxication or desire effect. (b) A markedly diminished effect with continued use of the same amount of the substance.
	11.	Withdrawal, as manifested by either of the following: (a) The characteristic withdrawal syndrome for the substance. (b) The substance (or a closely related substance) is taken to relieve or avoid withdrawal symptoms.

evidence base for both ED and SUD, CBT interventions are typically utilized, such as self-monitoring, functional analysis, contingency management strategies, and education on coping skills . Another recommended component of treatment is assessing the adaptive function of eating disorder behaviours and substance use, to understand the underlying motivation behind engaging in these behaviors (e.g., reduce anxiety, avoid unpleasant emotions, control appetite, etc). Psychotropic medications are making their mark on the recovery landscape, as they are effective in stabilizing mood and comorbid psychiatric conditions that are often present in ED-SUD (Table 1). Additionally, medical monitoring is essential both for ED and SUD (Dennis et al. 2014).

More recently, treatment providers have begun adapting and implementing treatments that are more transdiagnostic in their approach, rather than focusing primarily on ED or SUD symptoms and behaviors. These transdiagnostic approaches typically incorporate components of mindfulness practice, with the aim of assisting individuals in reducing their dysfunctional behavior by increasing their ability to accept and allow their internal experiences and emotions. One potentially promising transdiagnostic

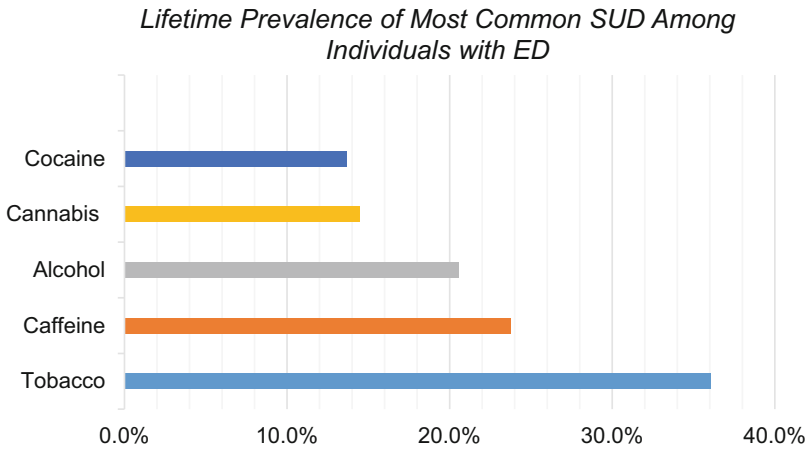

Fig. 1 Lifetime prevalence of most common SUD among individuals with ED (Bahji et al. 2019)

treatment approach is Dialectical Behavior Therapy (DBT; Linehan 1993). In DBT, individuals are encouraged to accept their emotional experiences, while also learning adaptive strategies to cope with their emotions. DBT is a well-established treatment for individuals with severe and multiple psychological disorders, and provides a framework to target multiple problem areas in an integrated manner. Although only one study has investigated the application of DBT for co-occurring EDs and substance use, findings from this study are promising, and indicate that integrated DBT for ED-SUD was associated with decreased substance use severity and frequency, as well as decreased emotional eating (Courbasson et al. 2012). More research is needed in this area; however, data are hopeful (Figs. 1 and 2).

Conclusions

The overlap of shared etiology for ED and SUD highlighted in this chapter has significant implications for the treatment of ED and SUD. We understand many features of EDs and many of SUD; however, linking the two has received considerably less research and clinical attention. As such, many professionals continue to struggle in the treatment of ED-SUD. Understanding the overlap of ED and SUD may help guide prevention and treatment efforts by highlighting the importance of treating the underlying, transdiagnostic mechanisms that contribute to both disorders. Interventions that target the reward system, temperament, and emotion regulation are all essential to this work. Furthermore, given the significant link between adverse events, trauma, and stressors to both eating disorders and substance use disorders, it is important that treatment approaches address trauma and other stressor-related symptoms to aid in the recovery process. Continued work on elucidating the connection between ED-SUD is essential in improving our prevention and intervention efforts for this high-risk population.

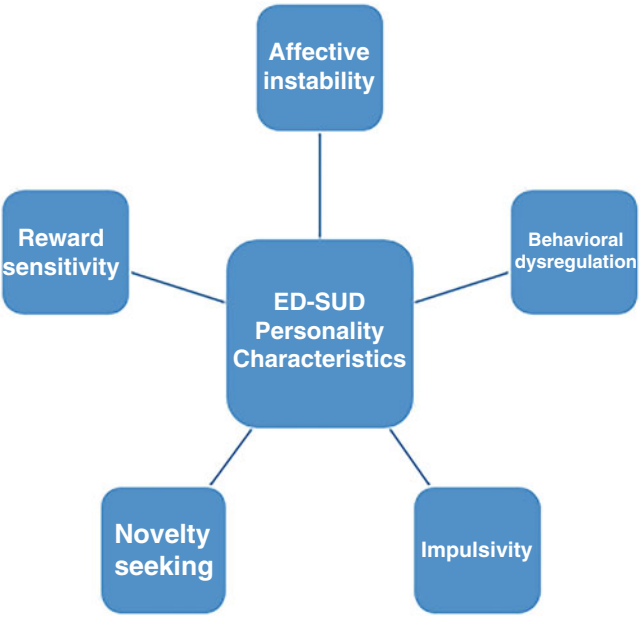

Fig. 2 Personality characteristics common among comorbid SUD and ED

Mini-dictionary of Terms

- **Adverse childhood event**. A traumatic experience occurring during childhood (e.g., child maltreatment)
- **Emotion regulation**. A complex set of abilities including (a) awareness, understanding, and acceptance of emotions, (b) ability to control behavior when experiencing negative emotions, (c) ability to use situationally appropriate strategies to modulate emotions flexibly in order to meet individual goals and situational demands, and (d) willingness to experience negative emotions
- **Executive functioning**. A group of cognitive processes responsible for self-regulatory and goal-oriented behaviors
- **Dopamine**. A neurotransmitter closely involved in the processing and response to rewarding and punishing stimuli
- **Negative urgency**. The tendency to act rashly when experiencing a negative mood
- **Positive urgency**. The tendency to act rashly when experiencing a positive mood
- **Serotonin**. A neurotransmitter involved in the regulation of mood, sleep, learning, memory, and physiological processes such as vomiting
- **Temperament**. Biologically based differences in individual behavior
- **Trauma**. An emotional response to a serious event that oftentimes involves threat of harm or death

- **"Whack-a-mole" effect**. Behavior change targeting one symptom/set of symptoms that leads to vacillation of symptomatology over time (e.g., addressing ED behaviors which leads to increased SUD behaviors)

Key Facts of Substance Use Disorders

Substance use disorders (SUDs), as defined in the DSM-5 (APA 2013), are a class of psychiatric illnesses associated with the maladaptive use of one or more substances (e.g., drugs, medications, etc.)

Symptoms of SUD fall into four categories including: impaired control, risky use, social problems, and physical dependence.

There are ten classes of substances recognized in the *DSM-5*: alcohol, cannabis, anxiolytics/sedatives/hypnotics, caffeine, hallucinogens, stimulants, inhalants, opiates, tobacco, and "other."

The severity of the SUD is based on the number of symptoms reported concurrently (i.e., mild = 2–3 symptoms, moderate = 4–5 symptoms, severe $\geq$6 symptoms).

The coexistence of both a mental health and a substance use disorder is referred to as co-occurring disorders.

Summary Points

- Substance use disorders and eating disorders commonly co-occur, and they share many etiological factors
- Candidate gene studies independently exploring SUD and ED suggest that similar genetic variants in both the dopamine and serotonin systems might influence ED-SUD comorbidity, as they impact reward and mood
- Affective instability, impulsivity, and novelty seeking are common in patients with EDs who engage in substance abuse
- Individuals with SUD, as well as individuals who engage in binge eating (including AN-BP, BN, and BED) show greater deficits in executive functions compared to healthy controls
- Early life trauma and adverse events are associated with later development of both substance-related problems and disordered eating
- There are currently no evidence-based treatments or formal protocols for treating individuals that present with both ED and SUD
- Research highlights the importance of targeting the underlying, transdiagnostic mechanisms that contribute to both ED and SUD, including the reward system, impulsivity, emotion regulation, and trauma and stressor-related symptoms

Fluid Restriction in Eating Disorders

14

Elizabeth Hamlin

Contents

Abstract

Although eating disorders are traditionally conceived of as disorders of food intake (American Psychiatric Association, Diagnostic and statistical manual of mental disorders, 5th edn. American Psychiatric Publishing, Arlington, 2013), patients with eating disorders can also experience dysregulated fluid intake, including intentional restriction of fluids. This clinical phenomenon has been observed and documented over the past two decades but remains under-recognized and poses a danger to patients and a source of frustration for treatment

providers, who often struggle to successfully address this challenging behavior. This chapter examines the phenomenon of intentional fluid restriction even though little has been written about it, assessing its prevalence, its associated psychiatric diagnoses, and how to recognize fluid restriction in clinical work with patients with eating disorders. Motives underlying intentional fluid restriction are explored through detailed case presentations, and interventions focusing on behavioral and psychological change are discussed.

Introduction

Eating disorders characterized by intentional restriction (anorexia nervosa, bulimia nervosa, and atypical anorexia) are traditionally conceived of as disorders of food intake (American Psychiatric Association 2013), in which patients become preoccupied with weight and shape and so alter their patterns of eating and/or digesting food. However, patients can also experience dysregulation in fluid intake (Hart et al. 2005), which can be manifested either by drinking fluids to excess (Marino et al. 2009) or intentionally restricting fluid intake (Lowinger et al. 1999; Hart et al. 2005, 2011; Abraham et al. 2006; Hamlin 2020). This chapter represents an attempt to examine the phenomenon of intentional fluid restriction in patients with eating disorders, with a focus on how this behavior manifests and alters the course of treatment in the psychiatric inpatient setting, with adult and young adult patients, since this is the setting in which all previous studies of this behavior have been conducted. As will be discussed in this chapter, it is nonetheless likely that at least some form of intentional restriction of fluids also occurs in outpatient and day treatment settings. Intentional fluid restriction does occur in the child and adolescent population as well, though this chapter focuses on older teenagers and adults.

In the inpatient setting, fluid restriction is often observed in patients who exhibit many other eating disorder behaviors, including restricting food, purging, and abuse of laxatives and diuretics (Hamlin 2020). Despite occurring in the context of a number of different eating disorder behaviors, intentional fluid restriction often comes to be "the star of the show" and the focus of clinical attention due to the significant attendant medical decompensation (orthostatic tachycardia, hypotension, dizziness, and falls) that occurs as a result of this behavior. At times, intentional fluid restriction becomes the chief issue prolonging the inpatient hospital stay (Hamlin 2020; Lowinger et al. 1999).

Although intentional fluid restriction may come to be the focus of inpatient treatment, patients rarely identify restriction of fluids as a reason for seeking treatment and may not even disclose this behavior as a concern during the admission process or in initial meetings with the treatment team. The treatment team (broadly including nursing staff, patient support staff, therapists, dietitians, and psychiatrists) may notice that a patient is not drinking very much but assume that this is unintentional. Unfortunately, even once recognized as intentional, fluid restriction remains difficult to treat, and patients continue to believe that this behavior is necessary for physical and emotional regulation (Hamlin 2020, 2022).

This chapter provides an overview of intentional fluid restriction in patients with eating disorders, beginning with how to recognize this behavior when it occurs. The chapter discusses how patients who restrict fluids understand this behavior and attempt to provide insights into what factors make this behavior so difficult to treat. In order to illuminate the complexities underlying intentional restriction of fluids in patients with eating disorders, this chapter provides three detailed case presentations. Treatment of intentional fluid restriction from biological, behavioral, and psychological standpoints will be discussed. Ultimately, this chapter argues that, by narrowly focusing on eating disorders as related to weight and shape, the DSM overlooks many of the psychological factors that lead to fluid restriction and to the perpetuation of eating disorder symptoms more generally, contributing to the lack of recognition of this phenomenon in the eating disorder treatment community and associated scientific literature.

Recognizing Intentional Fluid Restriction

Intentional fluid restriction is easiest to recognize in highly structured treatment approaches, such as inpatient or residential units, simply because these are the settings in which staff are present throughout the day and night who are trained to monitor how much a patient is drinking. Some treatment centers may even mandate that a patient drink a certain quantity of fluids with each meal or snack – in this case, it is evident when a patient is not doing so despite prompting. Additionally, most eating disorder treatment centers attempt to ensure that patients are not dumping out fluids (or food) in sinks or in the trash. Patient self-report of past or current behaviors surrounding fluid intake is often attempted during admissions screenings or in initial assessments on the unit, but the data may be unreliable (Zerbe 2008; Zerbe and Bradley 2018). A patient who is attempting to come into a hospital setting may work to convince the treatment team that she (female pronouns are used in this chapter for convenience, though men also experience eating disorders) is "sick enough"; conversely, a patient who is attempting to avoid a particular treatment intervention may tell her family and her treatment provider that she is hydrating appropriately.

In the outpatient setting, where it is more difficult to monitor fluid intake, much more is of necessity based on the patient's self-report, though many outpatient treatment programs incorporate some supervised meal situations. However, other factors may signal that a patient is dehydrated, and, if a patient is unable to correct

this dehydration with prompting and encouragement, this may be a sign of intentional fluid restriction.

One of the most common signs of dehydration, for example, is a change in pulse. Because of the decrease in circulating blood volume, the heart must beat faster in order to circulate the appropriate volume of blood around the body. Thus, dehydration may be signaled by an increase in pulse. Over 100 beats per minute meets the definition of tachycardia; in patients who restrict fluids, 120 or 130 beats per minute is not uncommon. An increase in pulse when the patient changes position (orthostatic tachycardia) is also often observed. With this change in pulse, there may also be a drop in blood pressure, a sign that the heart is not able to compensate completely for the decrease in circulating volume (Jequier 2010). A drop in blood pressure is not uncommon in patients who primarily restrict food. However, in these patients, who are restricting food but not fluids, a bradycardia is often observed, rather than the tachycardia of acute dehydration (Mehler and Andersen 2010). Laboratory findings consistent with dehydration include increased BUN and increased creatinine, especially with BUN:creatinine ratio of 20:1 or greater (Mehler and Andersen 2010).

In addition to the objective signs of dehydration, symptoms of dehydration that patients may report include dizziness, especially with position change, at times accompanied by vision change (vision briefly going black or spotty). Patients may report loss of consciousness or falls, especially with position changes. In patients who intentionally restrict fluids, the experience of dizziness is often a conflicted one (Hamlin 2020) – on the one hand, they do not like the sensation, on the other, they also rely on it to feel like they are suffering enough or are deserving of treatment. When patients stop feeling dizzy or show improvement in vital signs, they may report concerns about being "sick enough."

How Much Fluid Does a Patient Need?

In treatment settings in which a dietitian is available, it is optimal to rely on the dietitian's expertise in calculation of how much fluid is needed for a given patient. However, not all treatment settings may have ready access to dietitians. There are several different ways to calculate fluid needs. Two will be discussed here – the Holliday-Segar formula (Holliday and Segar 1957), which relies primarily on a patient's weight, and a simpler calculation that takes age and weight into account when determining fluid requirements.

The Holliday-Segar formula is based on a patient's weight in kilograms. It calculates energy expenditure in kcal based on weight and calculates fluid needs using a 1 kcal expenditure = 1 mL fluid equation. Although this formula was originally developed for children, it is also used to calculate an adult's fluid needs. It is important to bear in mind, however, that the calculation yielded by both this equation and the subsequent one reflect total fluid needs, not free fluid needs. Therefore, some of the patient's fluid needs will be met by food, which contain some amount of water, or milkshake-textured nutritional supplements.

An alternative calculation of fluid requirements estimates a need for fluids in adults over 30 of 30–35 mL/kg, in young adults of 35–40 mL/kg, and in adolescents of 40–60 mL/kg (Sucher and Nelms 2016). This calculation can be adjusted up or down depending on the patient's underlying medical conditions or medication use.

These two methods of calculating fluid requirements do yield different results. For a 45 kg adult patient, the Holliday-Segar formula yields daily fluid need of 2000 mL. The alternative calculation based on weight yields a fluid need between 1350 and 1575 mL. If the patient were a younger adult, this range would change to 1575 mL and 1800 mL.

Ultimately, although calculation of fluid requirements can be roughly estimated using either of these formulas, a dietitian's input is essential to consider the multitude of factors that make each patient unique, including underlying medical conditions, co-occurring use of medications, energy expenditure, and degree of dehydration.

Who Restricts Fluids?

It is difficult to estimate the prevalence of patients with eating disorders who restrict fluids, and, in fact, none of the existing literature addresses this issue. In part, this relates to the discussion above – unless the patient is in an inpatient setting where her fluid intake is closely monitored, it is difficult to determine when a patient is restricting fluids. Much is based on self-report (Hart et al. 2005), which can be exaggerated or minimized for various reasons (Zerbe 2008; Zerbe and Bradley 2018). Additionally, even when a patient in the inpatient or residential setting is observed to be restricting fluids, it is not always evident whether this behavior is intentional or an unintended consequence of restriction of food (Logue 2018; Engell 1988). To determine whether fluid restriction is intentional or unintentional, it is generally necessary to discuss this with the patient and to seek her perspective on her behaviors.

Even assessing basic demographic characteristics of which patients tend to intentionally restrict fluids is difficult, with different studies showing vastly different results. Patients either tend to be adolescents (Lowinger et al. 1999; Hart et al. 2005) or they are often well into adulthood (Hamlin 2020). Patients tend to have low weight (Lowinger et al. 1999; Hart et al. 2005), or their weight tends to be above their ideal body weight (Hamlin 2020). Intake of fluid occurs before improvement with food intake (Lowinger 1999) or occurs long after improvement with food and often becomes the primary factor prolonging inpatient hospitalization (Hamlin 2020). Hamlin (2020) examines co-occurring psychiatric diagnoses in patients who intentionally restrict fluids and finds that depressive disorders, anxiety disorders (especially generalized anxiety disorder), borderline personality disorder, and/or post-traumatic stress disorder occur in the vast majority of patients. Other studies do not discuss diagnostic comorbidities (Lowinger et al. 1999; Hart et al. 2005), and an attempted search for personality traits linked with fluid restriction did not discover any personality traits that correlated with different patterns of fluid intake (Abraham et al. 2006). The only demographic characteristic on which all published studies

agree is that patients who restrict fluids, similar to patients with anorexia nervosa and bulimia generally, are primarily female.

It is unclear why studies differ so greatly in terms of demographic findings. Notably, Hamlin's examination of fluid restriction occurs about 10 years after the other studies cited. In the intervening decade, it may be the case that hospitalized patients have simply become sicker and more complicated to manage; anecdotal data certainly supports this observation. Additionally, Hamlin's (2020, 2022) data comes from an inpatient eating disorder unit in the USA, whereas other groups cited work out of the UK (Abraham et al. 2006) and Australia (Lowinger et al. 1999).

Another possible explanation of differences may relate to the technological changes that have occurred even in the intervening 7 years since Hart's 2011 paper, and certainly in the 19 years since Lowinger et al. (1999) first commented on the phenomenon of fluid restriction. Over this decade, the Internet has become an increasingly common way for patients to learn both not only about recovery from eating disorders but also about perpetuation of these disorders in Internet fora devoted to "pro-ana" behaviors (Barth 2016; Wooldridge 2014). It is possible that various "pro-ana" sites also identify fluid restriction as a desirable behavior, and this may help to account for the increasing visibility of this phenomenon.

Why Do Patients Restrict Fluids?

Patients report varying reasons for why they restrict fluids. Often, they cite reasons similar to those offered for restriction of food – namely, "wanting to be in control" and "wanting to feel empty" (Hart 2011). Patients also cite concerns about fear of fullness and about "water weight" (Hamlin 2020, 2022). However, just as with restriction of food, patients often offer multiple reasons for their behaviors – after all, "wanting to be in control" or "to feel empty" can be accomplished through any number of different (maladaptive) behaviors, and it is the job of the treatment provider to determine what other reasons coexist with the automatic response of "water weight."

Hamlin (2020) summarizes some of the other reasons patients offer for restricting fluids. Some patients tentatively report a belief that their body simply does not require fluids or requires much less fluids. This belief at times approaches delusion. Patients speak longingly of a desire to exist without a body. They hate and fear the feeling of being bound to a fleshy, vulnerable, needy body, and they try to deny it through all possible means.

Other patients offer associations between intake of fluids and specific past traumas. Some of these traumas involve the ingestion of fluids – near-drownings or forced ingestions of alcohol – and others involve genital traumas, and patients' subsequent difficulty being aware of their genital region when they need to urinate.

Finally, though this list is not exclusive, some patients admit to the inpatient unit without any difficulty with fluid intake but develop intentional fluid restriction during their hospital admission, often when other patients are also displaying this behavior. Patients may formulate their new symptom of fluid restriction as a way to

convey their deep conflict about relinquishing eating disorder symptoms; they may also acknowledge that it serves as a communicative behavior, intended to elicit a specific response from the patient's treatment team or someone else who is important in the patient's life.

Ultimately, like most eating disorder behaviors and psychiatric symptoms more generally, intentional restriction of fluid often has multiple meanings. The best way to find out the meaning of the behavior for a specific patient is to ask her. While the patient may initially simply respond that she is concerned about weight or control, a more detailed inquiry into the behavior (Sullivan 1976) that remains curious and respectful will usually elicit other fantasies, fears, and beliefs. Patients readily give voice to their hatred of their bodies and subsequent desire to deprive and destroy them.

Clinical Cases

Identities of all patients have been disguised. In some cases, the description of a patient represents a composite of several similar patients.

Case 1: Adele

Adele was a married woman in her early fifties with a long history of an eating disorder that had endured despite multiple attempts at inpatient treatment. Adele restricted food and fluids, purged, and used laxatives. With a BMI of 36, Adele's eating disorder fell under the criteria of Other Specified Feeding or Eating Disorders, specifically the subheading of Atypical Anorexia (American Psychiatric Association 2013). Adele presented with multiple physical complications related to her eating disorder behaviors, including feeling chronically dizzy, struggling to think clearly, and falling frequently. Due to her orthostatic hypotension and tachycardia, dizziness, and refusal to drink fluids, a nasogastric tube was placed at time of admission.

Developmentally, Adele reported a history of severe and prolonged trauma, including ongoing sexual abuse by both her father and an uncle that had started in childhood and continued until she left home at age 14, following a pregnancy resulting in a miscarriage. Adele's mother had been aware of the abuse but had not interfered, viewing the abuse as the cost of maintaining her own marriage. While still a teenager, Adele married a man with significant mental health issues of his own. Around this time, Adele's eating disorder began; its subsequent severity resulted in repeated hospitalizations. In the 30 years prior to her admission, the longest Adele had stayed out of a structured hospital or day hospital setting was about 6 months.

Prior to Adele's admission, her husband had lost his job, forcing them to move back into the family home with Adele's mother. Adele's eating disorder symptoms had increased in intensity following this move, but Adele denied strong feelings about this, acknowledging only that she felt "annoyed." Notably, this was characteristic of Adele's emotional responses throughout the course of treatment. All affect

was split off into intense loathing of her body. Outside of this, she experienced few emotions in the rest of her life, even when thinking or talking about her trauma, which she did dispassionately.

After 2 weeks of inpatient treatment, Adele was able to resume eating food but continued to restrict fluids. A significant accomplishment for her was to be able to swallow medications with a few sips of water; her normal routine was to swallow them dry. Adele was ambivalent about the possibility of drinking more fluids. On the one hand, she liked not feeling as weak and dizzy as she had prior to admission, and she recognized that this related to being hydrated through the fluids in the nasogastric tube. On the other hand, however, she hated her body, which she felt had betrayed her so deeply, so intensely that perhaps she did deserve to feel dizzy and to fall, if it meant that her body suffered. Adele described a feeling of being at war. She did not want to die, yet she wanted to destroy her body completely.

In addition to this, Adele also described a more specific rationale for her intentional restriction of fluids: She did not wish to urinate. As a result of her childhood trauma, Adele tried strenuously to ignore her genitals. Any sensation in her genital area resulted in dissociation, often followed by superficial self-injury to ground herself. Since urination was viewed with fear and disgust, hydration equaled retraumatization, perpetuating Adele's desire to deny or destroy her body.

Ultimately, despite an extended course of treatment on the inpatient unit, Adele's need to punish her body prevailed at least partially: She was able to accept fluid delivered via nasogastric tube and the urination that resulted, but she was unable to hydrate orally. Adele used her body as a receptacle for her intense emotional pain, and she feared that any change would result in the unbearable emotional pain that she so assiduously split off. Adele discharged from inpatient treatment to her mother's home eating an oral meal plan but with nasogastric tube in place and a plan for continuous hydration at nights.

Case 2: Bianca

Bianca was slightly younger than Adele, a married woman in her early 40 s with a long history of difficulties with eating dating back to adolescence. She presented to treatment because her family physician had become concerned by Bianca's recurrent episodes of syncope and hypotension, which resulted from her severe restriction of food and fluids. In addition to these behaviors, Bianca used diet pills to control her appetite and give her energy. Despite these symptoms, which had resulted in her near-total inability to function in her daily life, she remained only slightly under ideal body weight. Diagnostically, she met criteria for Anorexia Nervosa, Restricting Type (American Psychiatric Association 2013). Like Adele, the severity of Bianca's restriction of food and fluids necessitated placement of a nasogastric tube shortly after admission.

Bianca had been raised in a family in which a woman's appearance mattered. She had been an attractive child. Her mother and grandmother were proud of her good looks and hoped that these would result in a marriage out of the family's

working-class background. They cautioned her, however, about a familial tendency to become overweight, and, from puberty onward, they encouraged her to carefully monitor her diet and exercise.

Her family's wishes paid off, and in her early 20s Bianca married a business executive. She had children and did not work outside the home. During her children's early years, Bianca was relatively content – she took care of the home and the children and scrupulously maintained her weight and appearance according to her husband's preferences. However, as her children aged, Bianca became less and less content with this arrangement, feeling neglected by her husband's frequent travels for business and leisure. The stressors precipitating Bianca's move to severe restricting appeared to be her son's increasing independence as well as a golf trip planned by her husband that coincided with their wedding anniversary.

Once on the unit, Bianca struggled to increase oral intake of food and fluids, citing both concern about weight and appearance as well as a fear that, if she were to resume eating and drinking, her life would revert to the way it had been previously, which Bianca increasingly felt to be unacceptable. Her pattern on the unit was to make some progress with eating and drinking, then to experience a conflict with her husband, who expressed frustration with her prolonged hospital stay, and then to regress with oral intake, at times needing to be sent out to the medical hospital for intravenous fluids due to her dizziness, hypotension, and falls.

Bianca's eating disorder behaviors did not arise solely in response to her conflicts with her husband and anxiety about her son's independence – concerns about weight and shape clearly dated back to her family of origin, with their preoccupation about Bianca's weight and need to impress a husband. Bianca, in her feelings of anger and abandonment, chose consciously to use what had always been prized – her thin body – as a weapon, attempting through her restriction of fluids to communicate her anger and to simultaneously punish her husband and to keep him close. Although she was able to make some consistent improvement with eating, she struggled to make progress with drinking fluids, since she believed that, if she improved, she would return home to an unchanged and intolerable situation, a belief confirmed by family sessions with Bianca and her husband. Ultimately, Bianca identified a social event occurring in her community that she was motivated to attend. This led to improvement in fluid intake – although she protested that this was occurring only because she was "forced" to do so – followed by discharge home.

Case 3: Celia

Celia (see Hamlin 2020 for a full discussion of this case), in her early 20s, was much younger than Adele or Bianca. She engaged in extreme restriction of food and fluids, limiting herself to under 500 calories a day, and drinking about a cup of fluids. She also abused laxatives, diuretics, and diet pills, and frequented "pro-ana" websites (Wooldridge 2014). Celia was very focused on her body image and hated her body shape and weight, which, despite her reported behaviors, had remained within normal range. Like Adele, she thus met diagnostic criteria for Other Specified

Feeding or Eating Disorder, specifically the subheading of Atypical Anorexia (American Psychiatric Association 2013). She was determined to lose weight and identified a goal weight that was so dramatically low as to be likely incompatible with life. She reported, without particular distress, that because of her eating disorder behaviors, she had been falling and "blacking out," and she was no longer able to work.

Celia was the younger of two children, raised primarily by her father after a messy divorce when she was five. (Celia's favored older brother, by contrast, was raised by their mother.) Celia's father struggled with chronic physical pain, depression, and substance addiction, and he and Celia moved in with her paternal grandparents when she was ten, who also struggled with chronic pain, sequelae of their many years of factory work. Celia's father and grandparents clearly cared for her but struggled to meet her needs as they battled their own illnesses. Celia attempted to live with her mother and brother briefly during her teenage years, but she was encouraged to return to her father – Celia's own depression and chronic pain were perceived to be too difficult to handle by her mother and stepfather. Shortly after returning to her father and grandparents, Celia's depressive symptoms increased significantly, resulting in frequent hospitalizations during her late adolescence.

On the inpatient eating disorder unit, Celia continued to refuse food and fluids, resulting in unstable vital signs and intense dizziness. Her physical concerns did not appear to cause her any emotional distress, and she often asked to know her blood pressure, wanting this value as low as possible. Nonetheless, she readily agreed to placement of nasogastric tube for supplemental nutrition and hydration. With this intervention, within 3 weeks of admission, Celia resumed normal eating behaviors, but she continued to refuse to drink fluids, insisting that she could not tolerate the feeling of fluid in her body and that she dreaded "water weight." Notably, however, she continued to receive fluids from the nasogastric tube without issue – it was only the thought of drinking independently that led to the concerns about "water weight."

Because of Celia's minimal progress with oral hydration and her long history of psychiatric hospitalizations, the treatment team began to wonder whether she had become dependent on the hospital setting and decided to try a different tack. Instead of having fluids run continuously and at a low rate through the nasogastric tube, which, staff worried, might prevent Celia from feeling any impetus to drink independently, the pump attached to the nasogastric tube would be stopped. Throughout the day, Celia would be encouraged to drink orally, and, if she did not, then a nurse would rapidly bolus the volume of fluids she was supposed to have consumed through the tube.

This intervention backfired spectacularly. Although intended to encourage Celia to be more independent in drinking fluids, its result was that Celia became even more reliant on staff. Celia valued being sought out by staff and encouraged to drink. She valued the brief physical contact that came with being bolused with fluids. Unlike her early life, in which her brother had been favored and in which she herself had been relegated to the background, here, it was Celia who was being selected for special attention and cared for. Unfortunately, there was no incentive here to move toward independence with fluids, and the treatment team decided to resume the

standard intervention of running supplemental fluids through the nasogastric tube at a constant low rate.

However, the experiment of bolusing fluids did demonstrate how much Celia longed for others to take care of her physically and emotionally, something that Celia was increasingly able to acknowledge verbally as treatment progressed. Slowly, Celia was able to discuss her feelings of having been abandoned by her mother, and of her desperate longing for her mother to care for her. Like Bianca, Celia used fluid restriction to communicate deep feelings that she struggled to articulate. Unlike Bianca, however, Celia's fluid restriction was not done consciously, and the target of her communication (her mother) was no longer available to receive Celia's message. As Celia became increasingly able to discuss her feelings of abandonment and despair, she was gradually able to make progress with fluid intake, and ultimately, she left the hospital to return to her father and grandparents.

Treatment of Fluid Restriction

Fluid Replacement

Patients who restrict fluids do require replacement of fluids. Especially when fluid restriction is accompanied by other maladaptive coping behaviors, or arising in context of borderline personality disorder, treatment providers may struggle with feeling angry or frustrated, and may even conclude, "She'll drink when she's thirsty." Unfortunately, this is not the case. As patients restrict food and fluids, their appetites and thirst ultimately decrease (Engell 1988; Logue 2018), and as in the cases discussed above, patients' motivations to restrict fluids are often stronger than any biological imperative to drink. Thus, patients may require supplemental fluids.

In medical hospitals, supplemental fluids are often provided intravenously (IV). The benefit of this approach is that fluids are delivered directly into the circulatory system, which can serve to stabilize blood pressure and pulse. When a patient is admitted into a medical hospital, she often receives IV fluids continuously, and, depending on her degree of dehydration and underlying physical condition, this approach may at least initially be required. A downside of this intervention, however, is that it places the patient in a relatively passive position, often lying in a hospital bed for days or weeks. An associated downside is that this intervention is generally possible only in a medical, rather than a psychiatric or outpatient, facility: Psychiatric facilities are generally not medically able to support IV treatments, and there may be concerns about suicide risk or infection in allowing a patient to ambulate freely around a psychiatric unit with an IV running. Similarly, continuous IV fluids are not usually possible in the outpatient setting.

Alternately, when a patient is in an inpatient psychiatric setting or outpatient, she might be sent to an emergency department (ER) or outpatient medical setting that can offer IV fluids. In this setting, one or two liters of IV fluids are administered over a period of a few hours. Following this administration, the patient is then able to

return to her previous environment. Of course, with this intervention, if the patient continues to restrict fluids, her body will again become dehydrated over a period of some days, requiring repeated administrations of IV fluids.

In inpatient psychiatric settings, the nasogastric (NG) tube is often used to administer supplemental fluids in addition to supplemental nutrition. (Tubes like NJ tubes, which extend into the jejunum rather than the stomach, are sometimes used; these require imaging when placed and so are more often used in environments that have access to radiology.) NG tubes can be programmed to administer fluids at a low rate over a several-hour period, or even continuously. Alternately, NG tubes can be used to bolus a larger quantity of fluids periodically throughout the day, often contingent upon the amount of fluid the patient is able to consume orally.

Whether fluids are administered via NG tube at a continuous low rate or as boluses often depends on the preferences of the patient and the treatment provider, as well as institutional regulations, which may mandate one option over the other. Each option does have benefits and drawbacks. Some patients and treatment providers advocate for the bolus method, arguing that, if the patient receives all her fluid needs via NG tube, she is disincentivized to drink orally, especially when she has a concern about "too much" fluids causing "water weight." Since the amount of fluid bolused often relates to how much the patient has drunk orally, she is then able to see her progress as she improves her own intake in requiring less fluid to be bolused. However, as is demonstrated in the case of Celia, some patients view the opportunities for closeness and staff attention inherent in bolusing fluids as a disincentive to drink orally. While NG tubes running continuously do also require staff attention for maintenance, the patient is not put in a position where she is being directly "fed" or nourished by staff, which many patients find appealing. (Some of the more unusual treatment approaches in real life and depicted on screen appear to be based on patients' underlying fantasies of dependency. These include the film "To the Bone" (2017) as well as the treatments provided by Peggy Claude-Pierre in the 1990s (Osgood 2018).)

In the outpatient setting, NG tubes are often impractical, though there have been cases in which outpatients have been able to successfully utilize these interventions, as in the case of Adele. It is often difficult logistically to set up this intervention, as it requires minimum a physician willing to order the supplies and some access to home health. For patients who are chronically unable to take fluids orally and have poor IV access, sometimes a port is placed. This is an exception rather than the rule, and it will not be discussed fully in this chapter.

Ultimately, in the outpatient setting, patients and providers must rely primarily on oral fluids. Some creativity is needed here in working with the patient to identify a fluid that feels tolerable. Many patients will report preference for caffeinated fluids, especially coffee or diet soda. These fluids are often used to provide energy, to induce a diuretic effect, or to alter metabolism and promote weight loss. When the patient is prompted to select a noncaffeinated fluid to drink, she will often state that she "does not like water" (Hamlin, unpublished data) or that she is frightened of calories in fluids. (One of the injunctions that comes from diet culture and often forms an early rule in the development of an eating disorder is "Don't drink your

calories.") Low-calorie lemonade or flavoring packets may be more tolerable to patients than water, although even the low number of calories per packet may feel excessive. Especially in patients who struggle with electrolyte abnormalities as may occur from purging or laxative use, drinks containing electrolytes, such as Gatorade or its lower-calorie alternatives, may feel tolerable to patients.

Behavioral Interventions

Once a suitable fluid replacement has been selected, the question remains of how a treatment provider can help a patient to be able to drink enough of it. There are a few behavioral interventions that are often attempted and that can be helpful.

One intervention that is often utilized in the outpatient setting is a variant of a food/fluid diary. The patient and treatment provider together set a daily goal for fluid intake, and the patient is encouraged to write down everything she drinks over the course of the day (Hart et al. 2005 use this approach in the inpatient setting also). The patient can record this on paper or electronically. There are several phone applications also designed for this purpose, including ones in which the information is sent daily to the outpatient treatment provider, often a dietitian, who can review in real time. If the patient feels it is helpful, a reward system can be instituted if the patient meets her fluid goals, which should be discussed in advance by the patient, her family (if applicable), and her treatment provider.

If this intervention is being used, it is important that the structure of treatment allows for frequent meetings between the treatment provider and patient, including the possibility of electronic meetings. (It is likely not feasible, for example, to have the patient attempt this approach for a month without checking in.) Additionally, it is important to engage in collaborative, rather than prescriptive, goal-setting, even if the initial goal that the patient identifies still does not meet her oral fluid needs. This is another reason why frequent visits become necessary, so that progress can be reviewed, and goals can be adjusted.

In the inpatient setting, a variant of this intervention is often attempted. The patient and treatment provider discuss the patient's fluid needs and collaboratively set a goal for fluid intake at each meal or snack. (Eating disorder programs in the USA are generally set up to provide three meals and three snacks daily.) At each meal or snack, the specified amount of fluid is present on the patient's tray, and she receives support and encouragement to drink that amount.

The next step after this is to help the patient internalize the ability to know when she needs to drink. This can be accomplished by having staff label a water bottle with various marks, indicating how far down the bottle the patient should drink by certain times of day. (There are water bottles available commercially for this purpose that come premarked.) The patient is encouraged to carry the water bottle with her throughout the day and to refer to it to remind herself what she should be doing.

These interventions, however, do not address directly the patient's anxiety about drinking or reluctance to do so. Rather, they capitalize on any existing motivation the patient may have as well as whatever therapeutic rapport exists in terms of setting

and working toward goals. An additional intervention that can be used in fluid restriction as well as in other settings that begins to blend the behavioral with the psychological is exposure and response prevention therapy (ERP) (Gallagher et al. 2018).

In ERP, the patient and treatment provider work together to develop a ranked list or hierarchy of situations that cause intense anxiety for the patient. These situations can include things the patient may do or even things that she may see or imagine. For patients who restrict fluids, some of these feared situations may include drinking a glass of water, imagining drinking a glass of water, or even seeing a picture of a glass of water. The hierarchy is organized from situations causing relatively little anxiety to those that would cause panic, and, systematically, the patient and treatment provider work together to progress through this hierarchy, using techniques of habituation to accustom the patient to a situation that would induce a relatively low level of anxiety before moving to those that would cause more intense anxiety. The intent of this technique is to help the patient to habituate progressively to lower levels of anxiety, thus enabling the patient to progress to more and more difficult exposures. When ERP is used, it needs to be applied frequently (ideally daily) and consistently. Additionally, because the patient is going to be intentionally entering into situations that provoke intense anxiety, she does need to have some ability to tolerate distress – treatment using this approach can be derailed if it is met by an intensification of self-harm or suicidal behaviors. Thus, it may be necessary to simultaneously do work with the patient on distress-tolerance and grounding techniques.

Because ERP is most effective when it is initially targeted toward a level of anxiety that a patient is able to manage, there is sometimes frustration for the treatment provider in that it may seem that little progress is being made. Again, patience and consistency are key here. While the patient is working on habituating to exposures to small amounts of fluid, she may continue to require supplemental fluids as discussed above.

Psychological Interventions

Although, in some cases, the behavioral interventions discussed above are sufficient to help the patient to improve her fluid intake, in other cases, these interventions fail to gain ground. These patients are likely the ones discussed initially by Lowinger et al. (1999) as the set of patients "where fluid restriction was a major behavioral problem" (p. 392). The cases of Adele, Bianca, and Celia discussed above also describe patients for whom behavioral approaches, including ERP, are insufficient to help the patient be able to drink on her own. In these patients, it is essential to consider the patients' understanding of their behaviors, what purpose it serves, and what the feared consequence is if fluid restriction is given up. These cases are discussed below to demonstrate how additional psychological interventions may be used in patients who restrict fluids. While potential interventions are discussed from a perspective that is generally psychoanalytic in orientation, reflecting the

author's training and background, the practitioner of CBT, DBT, schema therapy, or any number of therapies will likely be able to identify applicable interventions along these lines.

As discussed above, initially patients often link their fluid restriction to concerns about weight and caloric intake (Lowinger et al. 1999; Hart et al. 2011; Hamlin 2020). However, in many cases, a respectful detailed inquiry can result in additional explanations for their symptoms. Often, this additional material opens a way forward for psychological interventions to gain ground. As anyone who has worked with patients with eating disorders knows, attempting to argue with patients about calories, weight, and the need for hydration is doomed to failure (Hamlin 2022), since eating disorders are almost always about more than just weight (Bruch 1978).

Each of the cases discussed above demonstrates different determinants governing fluid restriction. The case of Adele demonstrates the intensely conflicted relationship that a survivor of sexual trauma may have with her body. Adele, like many traumatized patients with eating disorders (Zerbe 2008), experiences her body as a weak, untrustworthy *thing*, somehow separate from her and something that has fundamentally failed her. Her fluid restriction allows her to avoid experiencing body sensations linked with trauma while simultaneously expressing her contempt in a form of retaliation – since Adele's body has let her down so many times, she too will ignore its needs. Psychological interventions for Adele, although ultimately unsuccessful in the inpatient setting, would need to help Adele to identify the anger that is so noticeably absent when she discusses her traumatic past. Adele has created a vertical split (Goldberg 1975) such that she struggles to experience emotion other than a feeling of anger at her body (and even this feeling is often difficult for her to access, since her behaviors have become so automatic).

Initial interventions may focus on helping Adele to identify emotions as they arise during the course of the day. DBT work can be very helpful in this area, using emotion-identification wheels and frequent check-ins with the patient to help her monitor changes in affect as they occur. This can help the patient to feel more attuned to her own experience and ultimately to pay attention to and to be curious about her own emotional experiences, something that Adele clearly struggles with.

Ultimately, as Adele gained knowledge of her day-to-day emotions, she would be increasingly able to access anger. Initially, this anger would again arise in an everyday context, with the patient able genuinely to experience anger related to interpersonal frustrations, for example, something much less threatening than experiencing anger related to past traumas. Over time, she would be able to begin to acknowledge and bear her trauma-related anger, reclaiming this affect from the war waged on her body. Of course, during this entire course of treatment, Adele would still need extensive hands-on support with nutrition and hydration.

In contrast to Adele, Bianca was very aware of the anger that motivated her, yet her body remained the battleground on which she fought for the recognition from her husband that she craved. Like Adele, Bianca felt betrayed by her body, but for different reasons. Bianca's body had been formulated by her family and culture (referring here not to a specific ethnic or geographical culture, but rather to the unspoken set of rules governing the family and particular society in which Bianca

was raised) as a tool for getting what she wanted (Orbach 1986). An implicit bargain had been made – if she kept her body a certain way, she would be rewarded with love, admiration, and financial success. As she aged, it seemed that this bargain was no longer being upheld, and Bianca was furious. She turned to the tool she knew to rectify this situation and, by ruthlessly attacking her body, hoped desperately to convince her husband to return to the unstated terms of their agreement.

Psychological interventions for Bianca would need to introduce her to the idea that verbal processing of emotion was acceptable, an idea not supported by the reality in which she lived. The flip side to this encouragement to process emotion, however, was the need for Bianca to be aware that verbally expressing a wish or a need did not mean that this need would be fulfilled. Again, this is a dilemma that many therapeutic modalities address. Many patients with eating disorders value their disordered behaviors because they derive a sense of control from them, a control that is absent when attempting to interact verbally with another person with their own feelings and thoughts. Motivational interviewing techniques (Paris and Martino 2018) could be helpful for Bianca in persuading her to try a new way of relating; DBT interpersonal effectiveness skills (Linehan 1993) might help her communicate her anger in a way her husband and family would be more likely to hear. Ultimately, Bianca would need to relinquish her tried-and-true method of communicating with her body for the more uncertain, messier, but potentially more rewarding method of direct verbal communication. As with Adele, initial frustrations inherent in this new approach would likely lead to repeated assaults on her body, and she would likely need significant support with nutrition and hydration as she attempted to negotiate a new way of being.

Adele and Bianca's restriction of fluids were strongly related to anger, Adele's anger directed almost entirely at her body, and Bianca's directed outward but expressed using her body in order to communicate. Celia's restriction of fluids is again different. For Celia, some unacknowledged anger was present in her fluid restriction, anger at her mother who had so easily walked away. But much of what Celia worked to acknowledge in treatment was grief. Her restriction of fluids had been an attempt to communicate how much she needed someone to care for her, how ill-equipped she felt to care for herself, and the person whom she had wanted to receive that communication had been her mother, and specifically the mother who had rejected child-Celia.

As Celia was able to discuss her feelings of rejection and anger, she also could acknowledge both verbally and emotionally that the loss she had experienced was irreversible. There would be no chance to relive her childhood with the mother she had needed. If she were to go on in the world, it would always be as someone who had not gotten what she had needed. This deep grief that arises with acceptance of an unalterable loss is an important component of many different modalities of psychotherapy – mourning as described by Freud (1917), Klein's depressive position (1935), both of which are aspects of psychoanalytic theory, and radical acceptance as described in DBT (Linehan 1993). It is a version too of the serenity prayer commonly used in 12-step programs, "accepting the things that can't be changed."

The grief and feeling of helplessness that arises in this process is difficult for clinicians to bear as well; unfortunately, some clinicians are unable to tolerate it. This often results in attempts to repair or reparent the patient trying to fulfill her unmet needs in the past by gratifying those needs in the present. This is what the intervention of bolusing fluids represented for Celia. These interventions, although well-intended, are doomed to failure. No amount of gratification of wishes in the present can correct for what has been lost in the past. Psychotherapeutic work with Celia worked to help her mourn and to try to move forward in the world despite her losses.

Applicability to Other Eating Disorders

"An eating disorder needs to be considered a disorder of fluid intake, as much as a disorder of food intake" argues Hart et al. in 2011. Nonetheless, in the decade since that statement was made, intentional fluid restriction continues to be under-recognized in work with patients' eating disorders. What has led to the broader reluctance to acknowledge that disordered drinking behaviors, and specifically restriction of fluids, often play large parts in disordered eating?

One argument relates to the way the Diagnostical and Statistical Manuals (American Psychiatric Association 2013) conceives eating disorders. The DSM takes patients' concerns about weight, shape, and body size at face value and formulates eating disorders as fundamentally being about weight and shape. (Two of the three diagnostic criteria for anorexia nervosa are related to weight and body image; a criterion for bulimia nervosa also indicates that a patient's "self-evaluation [must be] unduly influenced by body shape and weight" (American Psychiatric Association 2013)). In fact, the concerns about weight and shape are the only psychological, rather than physical or behavioral criteria, offered by the DSM in its diagnostic formulation. Underlying issues that often contribute to eating disorders, including but not limited to control, concerns about maturity, displaced anger, and attempts to cope with trauma, which are widely recognized (Bruch 1978; Zerbe 2008, among others) by clinicians working with patients with eating disorders, are ignored.

Because eating disorders have been defined diagnostically by being primarily about weight and shape, behaviors that do not directly relate to weight and shape are easy to overlook. Clinicians new to the field of eating disorders are often surprised to find patients who restrict fluids, since water, at any rate, has no calories and does not cause weight gain. If the point of the illness is to lose weight, they wonder, then what is the reason for restricting a calorie-free substance? (Indeed, the phenomenon of hydroloading, alluded to in the beginning of this chapter, in which patients intentionally drink excessive amounts of water in order to feel full and suppress appetite, is also a behavior that sometimes occurs in eating disorders.) The DSM's narrow focus on weight as a motivation for eating disorders creates a blind spot when it comes to intentional fluid restriction. Unfortunately, this narrow focus also obscures underlying issues present in other forms of eating-disordered behavior.

This chapter introduces the phenomenon of intentional restriction of fluids in eating disorders, and, in doing so, attempts to demonstrate the heterogeneity of

eating disorders. Unlike the classic view of the eating disorder patient as an emaciated high-functioning adolescent (Bruch 1978), this chapter shows eating disorder behaviors occurring at patients across a range of body weights and shapes. Unlike some descriptions of patients with eating disorders as sullen, hostile, and unable to tell their own stories (Boris 1984), this chapter demonstrates patients' fundamental desire to communicate their experiences of themselves and their bodies. Intentional fluid restriction is a behavior that is often frustrating for the clinician and challenging to treat. It is often a sign of deep unverbalized emotion, especially of anger and grief, but, like all eating disorder behaviors, it serves as both a symbol and concrete action, since it is constantly being acted out upon the body, resulting in real physical consequences. As this chapter has shown, fluid restriction is a behavior that must be addressed on all levels. On the physical level, the patient requires hydration to maintain hemodynamic stability. Behaviorally, the patient needs to be able to make change in how she approaches drinking fluids so that she can function outside of the hospital setting and move toward a healthier and more fulfilling life. Yet it is also imperative to work toward a psychological understanding of fluid restriction as a behavior that can help to illuminate some of the underlying emotions perpetuating the eating disorder as a whole. Psychological understanding and the subsequent interventions it facilitates help to connect the eating disorder patient's preoccupations with her body with her deep emotional distress, linking up her split-off emotions. Although this process of change is discussed in this chapter only in relation to fluid restriction, understanding the patient's underlying emotions is important in the successful treatment of all eating disorder behaviors.

Mini-dictionary of Terms

- Affect – emotion, feeling
- DSM – the Diagnostic and Statistical Manual of Mental Disorders, 5th edition. A manual that provides diagnostic criteria for all recognized mental disorders
- Fluid restriction – intentionally not drinking fluids, or trying to limit the amount of fluids one drinks
- Hydroloading – intentionally drinking excessive amounts of fluids, usually water, to fill the stomach and suppress feelings of hunger. Sometimes patients will hydroload when they know that they are going to be weighed by a treatment provider in order to manipulate the number on the scale
- Water weight – belief often held by patients who intentionally restrict fluids that ingestion of fluids leads to weight gain

Key Facts About Fluid Restriction

Patients with eating disorders sometimes restrict fluids as well as food. This is often overlooked because fluids do not have calories and do not fit into a model of eating disorder that is only about weight. Patients do need to be hydrated even when they do

not feel able to drink – forms of hydration include intravenous fluids, fluids delivered through nasogastric tubes, and oral fluids. Patients may have many different reasons for intentional fluid restriction related to other issues, including trauma or interpersonal stressors. It is essential to work with the patient to understand these issues in order to help the patient change the behavior.

Summary Points About Fluid Restriction

- It is often under-recognized because it is often not looked for.
- Patients have many different reasons for restricting fluids. The best way to know why a patient is restricting fluids is to ask.
- Patients who restrict fluids often engage in many other kinds of eating disorder behaviors. Nonetheless, some remain at or above ideal body weight. This does not mean that their eating disorder is any less severe.
- Patients require simultaneously to be hydrated, to work behaviorally on improving their own hydration, and to work psychologically on associated issues.

prodromal or nonspecific symptoms before the onset of the disease. The duration of untreated illness has a great impact on the development of an ED; therefore, emerging programs to promote the prevention and an early detection should be considered. In this sense, primary care has an important role since they are generally the first stage of assessment and detection of these patients. For this reason, continued medical training is appropriate to take nonspecific or prodromal symptoms into account and promote early referrals to specific units.

Introduction

Eating disorders (EDs) are serious mental disorders with a relatively high prevalence specially around young women and are associated with significant psychiatric and medical consequences. Mortality is increased in all EDs with anorexia nervosa (AN) having the highest mortality rate of any psychiatric illness (Arcelus et al. 2011). While the overall incidence rate remained stable over the past decades, there has been an increase in the high-risk group of 15–19-year-old girls. It is unclear whether this reflects earlier detection or an earlier age at onset (Smink et al. 2012). Nevertheless, within the recent past, it is relevant to take into account that the impact of the COVID-19 pandemic on ED has created a global context likely to increase risk factors and symptoms (Rodgers et al. 2020). Apart from that, regarding early intervention of ED, arguments are compelling, given the lasting impact of symptoms on brain, body, and behavior (Schmidt et al. 2016). As a matter of fact, not only in ED but, for example, in psychosis, intervening during early stage, when symptoms are likely to be more malleable, is seen as critical in promoting favorable long-term outcomes (Penttilä et al. 2014).

Further, a growing body of evidence suggests that the onset of the disease in adolescence could play an important role as a key factor when prefrontal brain areas, important in self-regulation, are developing (Keverne 2004). Therefore, since neuroprogression or neurobiological changes may alter the trajectory of illness, highlighting the importance of illness duration is particularly pertinent (Treasure et al. 2015).

The research to date has tended to focus on the etiology and treatment of ED rather than the duration of untreated ED (DUED) itself. However, it has long been known that in AN illness duration is a key predictor of outcome (Steinhausen 2002). Furthermore, although the etiology of ED still remains unknown, evidence suggests an interaction between genes and environment contributing to the risk (Culbert et al. 2015). It is well known that there are certain factors that may increase the risk of having an ED, and therefore it is very important for the mental health professionals

and general physicians to consider them to start an early treatment. Likewise, it is particularly relevant to encourage early referral from primary care in view of the fact that here the risk factors, symptoms, or even prodromes are assessed in a first stage (Brown et al. 2018).

Risk Factors and Prodromes as Predictors for Future Emergence of EDs

We use the term "prodrome" particularly in clinical practice to determine an early symptom or cluster of symptoms that appear prior to the development or onset of the full disorder. Therefore, prodromes and risk factors are essentially different from the ED-related symptoms which are a specific feature of the ED (Table 1). While prodromes are the previous step of the disease, risk factors show a vulnerability to developing the disorder and may remain out of view or latent for a long period of time, or what is more, the patients may never progress to clinically significant eating pathology. Nonetheless, both prodromes and risk factors precede the onset of the syndrome (Stice et al. 2010).

What we know about risk factors is largely based on cross-sectional and retrospective studies. Consequently, several factors such as parental factors and family

Table 1 Summary of key constructs

Term	Definition	Measurement
Prodrome	Symptom or symptoms that can indicate the future onset of a disorder that are also a feature of the disorder. For example, the elevated body dissatisfaction or self-reported dieting that initiates the onset of an ED would be considered prodromes	Diagnostic interview, such as the eating disorder diagnostic interview
Risk factor	Factors that increase the probability of developing the disorder	Depends on the risk factor (e.g., dieting and can be measured by self-report; thin-ideal internalization can be measured by self-report or a diagnostic interview)
Subthreshold eating disorder/ partial syndrome ED	Descriptive label for a cluster of symptoms that meets some of the criteria for an ED, but not enough symptoms are present for full diagnosis	Diagnostic interview
Eating disorder symptoms	Symptoms that are defining features of an eating disorder	Diagnostic interview or self-report
Eating pathology/ disordered eating	Abnormal eating behavior	Diagnostic interview or self-report (i.e., binge eating or dietary restriction)

and peer environment have been identified (Pike et al. 2008). Moreover, the known period of risk spans from the early prenatal period to adulthood.

To date, the most consistent risk factors are the following: perceived pressure to be thin, pursuit of the thin ideal, weight concerns and body dissatisfaction, self-reported dieting, negative affect, and substance use (Stice et al. 2010). However, as before mentioned, risk factors affect 30–70% of adolescent girls, whereas eating pathology affects fewer than 10% of adolescent girls (Barker and Bornstein 2010) and therefore does not always represent potential prodromes of an ED.

In order to highlight the importance of risk factors in terms of heritability, family studies have determined a well-established linkage between ED and genetics, which could play an important role in the development of the disorder (Hubertus Himmerich, Jessica Bentley 2019). Indeed, the first-degree relatives of individuals with AN have an approximately tenfold greater lifetime risk of falling ill with an ED than relatives of unaffected individuals (Lilenfeld et al. 1985). Further, research studies investigating genetic risk factors (e.g., genome-wide association studies, twin studies, or family studies) have recently identified specific loci for AN suggesting a polygenic nature with several genetic variants of small effect being involved particularly in AN (Wang et al. 2011; Duncan et al. 2017). However, genetic studies in other ED are relatively scarce.

On the other hand, less is known about prodromes in ED and specially how to identify them as they may present differently depending on diagnosis or culture. Several studies investigating prodromes have come to the conclusion that both weight concerns and dietary restraint may be prodromes indicating an onset of threshold or subthreshold pathology. Thus, a prodromal stage has been defined indicating features of a full disorder, a phase that is very well known across other psychiatric disorders such as psychosis (Barajas et al. 2017), where its delineation has demonstrated significant clinical and economic impact (Savill et al. 2019).

It is estimated that patients receive their first treatment after an average of two and a half years up to 6 years (Austin et al. 2020). In consequence, since, as mentioned above, the DUED is very important for the prognosis of the disease, a reasonable approach to tackle this issue would be to better understand ED prodromes and the features of medical consultations before the onset of the disorder and, thus, provide early intervention strategies.

Features of Medical Consultations Before the Onset of EDs

Medical consultations before the onset of the disorder specially in primary care are crucial for the development of effective prevention or early intervention due to the fact that are mostly the entry point to specialist care for ED patients. Only few studies have studied the features of medical consultations prior to the onset. Gomez del Barrio and colleges have recently retrospectively analyzed data from the year prior to the diagnosis observing that patients attended more consultations (primary care,

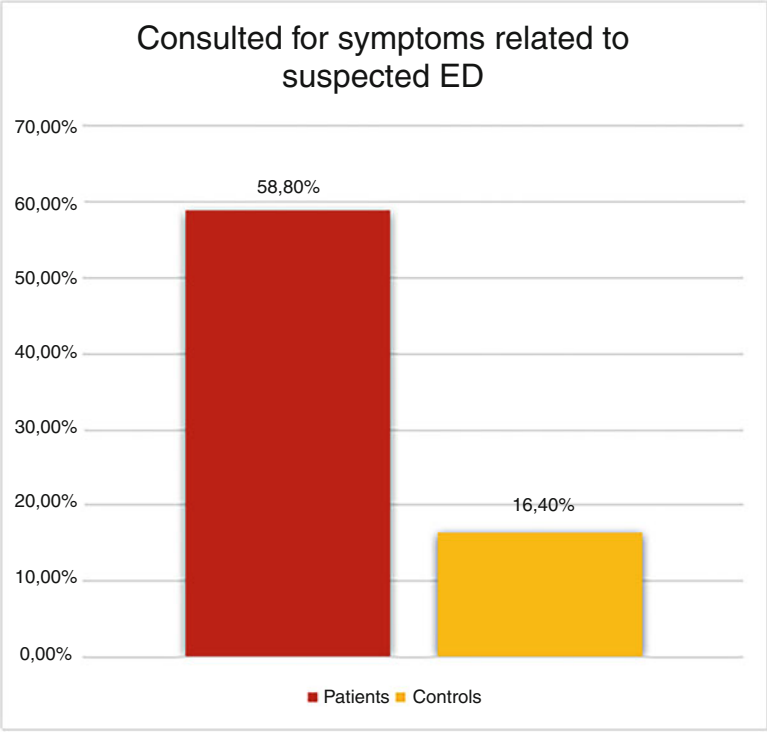

Fig. 1 Prodromal symptoms in medical consultations in primary care

specialized care, and emergency department) than controls. It is interesting that more than half of them were likely to be related with prodromes (Fig. 1) although the mean duration of untreated illness (DUI) was about 7 months, which means that they were not correctly identified. These results may indicate that not enough attention to prodromes is paid in primary care from where patients are mainly referred and there is strong rationale for early intervention in ED as it is not well established yet (Gómez Del Barrio et al. 2021).

This study draws our attention to the nonspecific ED symptoms that could play an important role in the diagnostic approach to these disorders in early stages or even before the onset. To some extent, they found several nonspecific symptoms that are likely to be prodromes hiding an incipient ED such as gynecological symptoms (e.g., amenorrhea or menstrual irregularities) and digestive symptoms such as abdominal pain, epigastralgia, constipation, or even lumbar pain. Besides, analytical changes such as anemia or electrolyte changes (hyponatremia from excess water intake; hypocalcemia from vomiting) should also be considered by clinicians as part of an initial stage of the disease. Malnutrition symptoms are also a relevant point in these disorders, and, therefore, medical consultations must also contemplate its consequences such as dizziness, syncope or fainting, and paleness in patients.

Other Important Features of EDs

Regarding the basic facts of ED according to the Academy for Eating Disorders, clinicians should know that they frequently affect teenagers and young people but also children and adults of all genders, ethnic backgrounds, cultures, and body weights, and, therefore, nonjudgmental management is critical. It is important to remember that they are not lifestyle choices but serious mental disorders that imply self-destructive behaviors that the patient cannot control.

In addition to the common symptoms that show these patients, they sometimes may present with other signs and/or nonspecific symptoms as a consequence of dieting, food and water restriction, nutritional deficiency, and binge eating and purging behaviors. For this reason, the Academy for Eating Disorders has recently reported a document to promote recognition and prevention describing critical points for a better understanding and clinical approach to these disorders. Table 2 illustrates the different signs and symptoms can occur in patients with an ED; however, it should be noticed that sometimes they are not so obvious (AED report 2021).

Taking the above into account, since patients may not easily recognize the seriousness of their illness and/or may not readily disclose their symptoms to healthcare providers, a comprehensive assessment by clinicians should be performed. Laboratory or basic diagnostic tests recommended for all patients with a suspected ED are shown in Table 3. However, referrals for evaluation and treatment by ED specialists are still far from being appropriate to make a great impact on the prognosis of the disease. Indeed, it is thought that young patients with a short DUI could be more worried about their symptoms (Gómez Del Barrio et al. 2021) and thus consult more often about prodromal or nonspecific symptoms, thereby representing a crucial opportunity for the recognition and referral for specialty intervention (McClelland et al. 2018).

Considering the importance of a short illness duration and a rapid early intervention and the necessity of a higher knowledge about ED among clinicians specially in primary care, practical support or continued training is required.

To solve this problem, an early intervention program named first episode rapid early intervention for eating disorders (FREED) was recently developed in England reducing waiting times of assessment and thus the DUED. It is based on easy access, encouraging early referral from primary care to deliver a rapid, person-centered, and effective service (Brown et al. 2018).

On the other hand, a recent systematic review performed by McClelland and colleagues identified a broad range of ED-specific symptoms (e.g., early eating difficulties, dietary restriction, fasting, body dissatisfaction, and weight/shape concerns) and other psychiatric disorder-related symptoms (e.g., depression and anxiety) prior to ED onset. Additionally, they discover that it may be possible to predict, to some extent, an ED phenotype following the symptom trajectories, for example, conflicts, struggles, and undereating in relation to AN and overeating in relation to bulimia nervosa (BN) (McClelland et al. 2020).

In addition, although binge eating disorders (BED) may not be as well known as AN or BN, they are the most prevalent of all ED. However, despite the high

Table 2 Different signs and symptoms that can occur in patients with an ED

General
Marked weight loss, gain, fluctuations, or unexplained change in growth curves or BMI percentiles in a child or adolescent who is still growing and developing
Cold intolerance, including hypothermia (low body temperature), general chilliness, or cool hands and feet which may or may not manifest a blue or purple color
Weakness
Fatigue and reduced energy
Presyncope (dizziness)
Syncope (fainting)
Greater focus on "healthy" or "clean" eating, rigid exercise patterns
Increased spending of money on binge foods
Using the bathroom after meals to purge
Evidence of purging found in the bathroom by other members of the household
Ear/nose/throat and eyes
Oral trauma, lacerations, petechiae on back of throat
Perimylolysis (dental erosion on lingual and occlusal tooth surfaces) and dental caries (cavities)
Parotid gland enlargement and pain
Cheilosis (cracked, sore skin at the corners of the mouth)
Dry eyes, blurred vision
Difficulty swallowing dry foods or liquids
Cardiorespiratory
Chest pain
Heart palpitations and cardiac arrhythmias
Bradycardia (low heart rate at rest)
Hypotension (low blood pressure)
Dyspnea (shortness of breath)
Edema (swelling)
Gastrointestinal and genitourinary
Epigastric discomfort
Abdominal bloating
Early satiety (fullness) and nausea
Gastroesophageal reflux (heartburn)
Hematemesis (blood in vomit)
Hemorrhoids and rectal prolapse
Constipation
Endocrine
Shakiness, weakness, sweating, chest pressure, confusion, or nausea, which may signal hypoglycemia (a significant cause of death in EDs); hypoglycemia may also be asymptomatic
Amenorrhea or oligomenorrhea (absent or irregular menses)
Low sex drive (related to suppressed sex hormone production of estrogen/testosterone)
Bone fractures, including stress fractures due to low bone mineral density/osteoporosis
Infertility
Neuropsychiatric
Depressive/anxious/obsessive/compulsive symptoms and/or behaviors

(continued)

Table 2 (continued)

Poor concentration or memory loss
Insomnia
Self-harm
Suicidal thoughts, plans, or attempts
Reduced flexibility, creativity, and spontaneity, with increasing rigidity around social engagements and mealtimes
Seizures
Substance use or abuse
Dermatologic
Lanugo hair growth
Hair loss
Carotenoderma (yellowish discoloration of skin)
Russell's sign (calluses or scars on the back of the hand associated with self-induced vomiting)
Poor wound healing
Dry, brittle hair and nails
Fragile, dry skin that bruises or tears easily
Sores or bruises over bony prominences

prevalence, it remains underrecognized and undertreated, suggesting that awareness and recognition should be improved by clinicians. Further, as previously mentioned, it is important to consider patient factors as many of them are even unaware of the disorder and often hide their eating behaviors (Kornstein 2017).

In addition to a thorough clinical assessment, clinicians should incorporate screening tools that may help to overcome communication barriers and contribute to a better recognition of the disease. A validated screening tool such as the SCOFF questionnaire (Table 4), which was designed for nonspecialists, may be useful in the recognition and identification of ED (Morgan et al. 1999).

There is, therefore, a definitive need for an early intervention through the recognition of specific and nonspecific symptoms as well as ED prodromes in a secondary prevention. In this respect, it is important especially for general practitioners and pediatricians to have competence regarding primary and tertiary prevention for EDs to facilitate and accelerate referral into specialist care (House et al. 2012). With regard to primary care, we talk about primary prevention and screening to identify people with emerging or early EDs ensuring access to early evidence-based treatment.

Prevention of EDs, Intervention Programs, and Impact

The past 20 years has seen the rapid development of prevention programs in multiple fields in medicine including preventive interventions in ED, given the significant public health burden and the consequences of the delay in the diagnosis and long-term effects (Grange and Loeb 2007). Treatment costs are high for AN and other EDs

Table 3 Laboratory studies recommended and potential findings

Basic diagnostic tests indicated for all patients with a suspected ED	**Potential abnormal findings in a patient with an ED**
Complete blood count	Leukopenia, anemia, or thrombocytopenia
Comprehensive metabolic panel to include electrolytes, renal function tests, and liver enzymes	Glucose: Low (poor nutrition) Sodium: Low (water loading or laxatives) potassium: Low (vomiting, laxatives, diuretics) Chloride: Low (vomiting, laxatives) Blood bicarbonate: High (vomiting), low (laxatives) Blood urea nitrogen: High (dehydration) Creatinine: High (dehydration, renal dysfunction), low (poor muscle mass) Calcium: Slightly low (poor nutrition at the expense of bone) Phosphate: Low (poor nutrition and early refeeding syndrome) Magnesium: Low (poor nutrition, laxative use) Total protein/albumin: High (in early malnutrition at the expense of muscle mass or milk of magnesia use), low (in later malnutrition) Aspartate aminotransaminase (AST), alanine aminotransaminase (ALT): High (starvation)
Electrocardiogram (ECG)	Bradycardia (low heart rate), prolonged QTc (>450 msec), other arrhythmias
Additional diagnostic tests to consider	**Potential abnormal findings in a patient with an ED**
Thyroid hormone testing	TSH: Low or normal T4: Low or normal (euthyroid sick syndrome) T3: Low if below metabolically healthy weight
Gonadotropins (LH and FSH) and sex steroids (estradiol and testosterone)	LH, FSH, estradiol (women), and testosterone (men) levels: Low or low normal
Erythrocyte sedimentation rate (ESR)	ESR: Low (starvation)
Prealbumin	Prealbumin: Low (in protein-calorie malnutrition) – But only reflective of the past 72 h pretest

Table 4 An example of a validated screening tool for EDs – the **SCOFF**

S – Do you make yourself *sick* because you feel uncomfortably full?
C – Do you worry you have lost *control* over how much you eat?
O – Have you recently lost more than *one* stone (6.35 kg or 14 lb.) in a 3-month period?
F – Do you believe yourself to be *fat* when others say you are too thin?
F – Would you say *food* dominates your life?

[a]Two or more positive responses on the SCOFF indicate a possible ED and should prompt referral for further evaluation

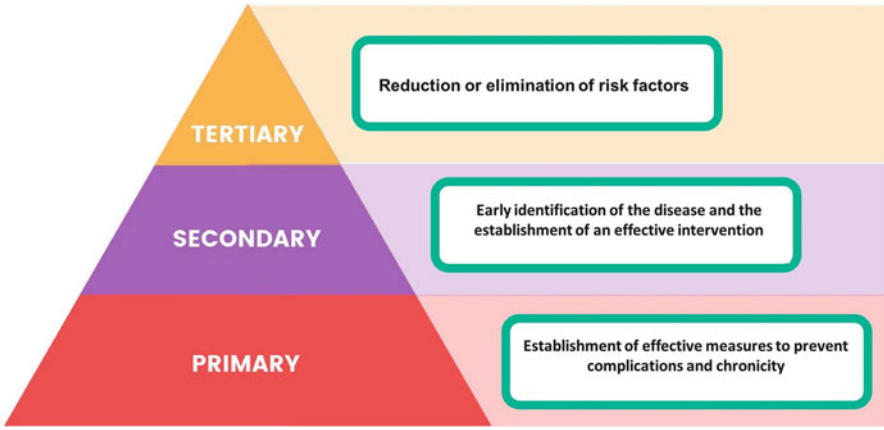

Fig. 2 Prevention stages in ED

that fail to respond to first-line therapies that, by some means, are not available to all (Ágh et al. 2016). However, it is important to consider that professionals with appropriate advanced training are probably insufficient and therefore it is necessary to focus on preventive programs of early intervention.

It is estimated that there is often a delay between presentation with clinically significant symptoms and referral or diagnosis (1 year for AN and around 4 years for BN). Therefore, early interventions even for mild cases or false positives are preferable (Allen et al. 2020).

Previous research findings into preventive interventions in ED show significant effects for risk factors and symptom reductions. A recent systematic review and meta-analysis of prevention in ED was reported by Le et al. (2017) concluding that several preventive strategies for ED could have potential benefits in reducing several risk factors targeting population with symptoms of the disorder (e.g., prodromes such as body dissatisfaction or weight concern) but not yet a diagnostic level.

Prevention has been traditionally classified into three different stages (Fig. 2). **Primary prevention** involves the reduction or elimination of risk factors that lead to the beginning of the disorder. **Secondary prevention** consists of early identification of the disease and the establishment of an effective intervention. **Tertiary prevention** implies the establishment of effective measures to prevent complications and chronicity (Caplan 1980).

It has been estimated that over half of the prevention programs have demonstrated effectiveness for reducing risk factors while 29% reduce actual and future eating behaviors (Shaw et al. 2009).

Generally, primary prevention is the standard or ideal strategy of prevention. ED prevention programs should be oriented toward the promotion of general health and the development of positive attitudes, incorporating basic aspects such as self-esteem improvement, basic training on nutrition, and fighting against social media pressure for thinness (Raich et al. 2007).

The role of general practitioners and pediatricians is to ensure health promotion, organize prevention activities in school or workplaces, work with the family, promote protecting factors among patients, and even improve levels of knowledge on the recognition of ED. On the other hand, tertiary prevention is also important to avoid chronicity and prevention of relapse, and it is therefore relevant to take into account that probably similar symptoms to the first-onset EDs emerge. For this reason, clinicians should keep an eye on medical consultations related to potential ED symptoms.

Interventions based on *cognitive behavioral therapy* (CBT) including interactive and Internet-based approaches have demonstrated to produce significant effects in reducing ED risk factors and onset risk in some high-risk populations. It is becoming increasingly difficult to ignore the importance of social media in these psychiatric disorders among young people in fact, growing evidence supports Internet-based programs for ED that appear to be substantially effective (Jacobi et al. 2012).

Cognitive dissonance (CD) interventions which are programs designed to reduce subscription to the thin ideal have produced a 60% statistically significant and clinically meaningful reduction (Stice et al. 2008).

Another intervention, promoting participant-driven improvements to dietary intake and physical activity, has also demonstrated a significant reduction of ED onset (Stice et al. 2013).

To sum up, health promotion paradigm is to date shown as the most effective method in the prevention of ED. Therefore, the main goal of a prevention program is to modify behaviors and attitudes and promote a higher knowledge of the disorder. This requires the utilization of implication techniques as well as an active participatory and experimental pedagogical methodology.

Applications to Other EDs

Those patients who do not meet the diagnostic criteria for any other ED such as other specified feeding eating disorder (OSFED) are characterized by less frequent symptoms, which could entail an obstacle in the recognition of the disorder. However, this category consistently represents the largest proportion of ED diagnoses although even much less research attention has been paid in the literature (Withnell et al. 2022). Other EDs, such as pica, rumination disorder, avoidant/restrictive food intake disorder (ARFID), and unspecified feeding or eating disorder (UFED), appear to be less frequent and subthreshold disorders. However, as a matter of fact, they are easier to be ignored by clinicians without specific training, and they remain largely underdiagnosed. In this sense, it is thought that these disorders are not well known and are difficult to identify by untrained clinicians as screening tools are made for threshold ED (i.e., AN, BN, and BED) and may not be useful for other EDs. Therefore, a better knowledge of this field or a proper communication between primary care and specific ED units is required to avoid both nutritional and psychopathological consequences of a delayed care.

Mini-Dictionary of Terms

- *Duration of untreated illness*: It is defined as the time between the onset of the disease and treatment initiation.
- *Prodromes*: They are early symptoms that indicate the impending onset of a psychiatric condition.
- *Risk factors*: They identify individuals who are at elevated risk for future emergence of the disorder.
- *Early intervention*: An intervention based on a "stage of illness" model that prioritizes young people who have recently (within 3 years) developed an ED.
- *Prevention programs*: They target at-risk but asymptomatic individuals or individuals with subsyndromal symptoms of a disorder.

Key Facts of Features of Medical Consultations Before the Onset of EDs

- Treatment is more likely to be successful when patients have suffered from an ED for a shorter period of time.
- A long DUI is a relevant outcome predictor associated with severe complications such as increased mortality.
- A higher knowledge of ED is required among clinicians to provide an early referral and intervention.
- Prodromes and nonspecific symptoms of ED are often overlooked in medical consultations.
- Prevention and early intervention programs have a great impact in the prevention, recognition, and prognosis of the ED.

Summary Points

All clinicians specially in primary care (general practitioners and pediatricians) play an important role in the assessment and recognition as well as follow-up of ED within a satisfactory communication and coordination with ED specialized units. In this respect, emerging technologies utilization may be suggested as a strong liason mechanism between primary care and specialized care by means of telehealth use or a specific coordination and supervision program. This highlights the importance of continued training in primary care to reduce illness duration and therefore medical and economic consequences of ED. Finally, investigation and clinical experience emphasize the importance of an early recognition based on adequate medical training among primary care clinicians to take nonspecific symptoms into consideration.

The Role of Parents and Other Caregivers in the Early Detection of Eating Disorders

Contents

Abstract

Early detection of emerging eating disorder symptoms is critical to rapid intervention, which can reduce the negative impact of illness on individuals, families, and society. However, the evidence base to guide these efforts is quite limited. This chapter reviews existing research related to early detection (noticing the earliest symptoms) and early intervention (targeting symptoms at the earliest point possible) for child and adolescent eating disorders, emphasizing the role of parents and other primary caregivers. Early intervention can be redefined to encompass distinct phases of an emerging eating disorder including risk factors, prodromal symptoms, and initial disorder onset. Extant research suggests that specific behaviors like extreme diet changes are the most easily detected by

others, although a variety of other behavioral and cognitive symptoms are present prior to eating disorder onset. Improving eating disorder education and support will be critical for parents and others in the early detection network (e.g., schools, healthcare providers). Once concerns are identified, parents have a role in carrying out early interventions to reverse the risk factors, early symptoms, or early disorder phase of illness. Interventions targeted to each phase will likely draw from eating disorders prevention science (particularly selective and indicated prevention approaches), treatment research, or both. Overall, research on early interventions is lacking, with most falling within child and adolescent anorexia nervosa. In general, research highlights the experiences of girls and young women from white Western European and North American backgrounds, leaving room for scientific advancement within early detection and early intervention for diverse individuals.

FBT family-based treatment

Introduction

Eating disorders are serious and persistent mental illnesses that often begin in adolescence. The presence of an eating disorder can create psychological and physical consequences for the young person and distress for parents and other primary caregivers (e.g., Cottee-Lane et al. 2004). For example, eating disorders can change family dynamics to include more unhelpful communication styles and high negative emotions (e.g., McDermott et al. 2002; Woodside et al. 1995). Family involvement in treatment is the standard of care for the majority of child and adolescent eating disorders (Hilbert et al. 2017), such as family-based treatment (FBT) where parents take the lead in reversing the impact of the illness. Some of the negative changes in family dynamics resolve after FBT (Ciao et al. 2015), suggesting the essential role of parents in promoting recovery from an eating disorder and restoring family functioning.

Treatment of pediatric eating disorders through specialized care has a relatively high success rate (e.g., Lock et al. 2010; Le Grange et al. 2015), especially compared to lower recovery rates in adult eating disorder treatments. Studies of children and adolescents with eating disorders show that recovery is more likely with a shorter duration of illness and a quick uptake of treatment, while recovery is less likely the longer the patient is ill (e.g., le Grange et al. 2012; Steinhausen et al. 2003). Earlier

intervention puts recovery in closer reach, as illnesses can become more severe over time. Given this, there is consensus that identifying the earliest symptoms possible–and intervening rapidly–is key to reducing the burden of eating disorders. These efforts emphasize pediatric populations (individuals younger than age 18), since eating disorders frequently emerge during adolescence and early adulthood and initial symptoms and risk factors can develop much earlier. And yet, there is surprisingly little research on *how* to detect eating disorders as early as possible within young people and what tools can be used to confidently conduct early interventions. Moreover, it leaves an important question unanswered: *who* is best situated to identify eating disorders in young people at their earliest possible point?

While parents and other primary caregivers may be ideally situated to support the eating disorder recovery process, they report hesitation surrounding early detection of symptoms. In particular, parents are uncertain about whether eating disorder symptoms are severe enough to warrant intervention (e.g., Cottee-Lane et al. 2004; Ciao et al. 2020; Eichhorn 2008), and they report low confidence about the appropriate steps in finding help (Ciao et al. 2020). In fact, families can take a year or more to seek professional help for restrictive eating disorders in childhood or adolescence that involve weight loss (Lebow et al. 2015). It is crucial to address this hesitation and reduce the help-seeking delay. Parents have an important role within early detection, since placing the burden of identification on the young person is most likely unrealistic. A lack of insight into the illness and its symptoms is part of the psychopathology of anorexia nervosa (Ali et al. 2017), and many eating disorder symptoms can be easily hidden or dismissed within a diet-focused culture that normalizes extreme diet and exercise behavior as well as weight and shape preoccupation (e.g., Starzomska and Tadeusiewicz 2016).

Throughout this chapter, we review the evidence to support parents and other primary caregivers as the ideal agents of early eating disorder detection. We also present existing research on how to empower caregivers to seek help as rapidly as possible and support recovery through early intervention programs. Since the onset of the earliest risk factors and symptoms of eating disorders are most likely to occur before adulthood, this chapter will focus on early detection and early intervention for individuals under 18 years old. When possible, we summarize research across eating disorder experiences, although the majority of research falls within child and adolescent anorexia nervosa. This emphasis on anorexia nervosa within pediatric research is likely due to the younger age of onset relative to other eating disorders and the significant risk of death associated with the illness (e.g., Auger et al. 2021). In general, the existing research also highlights the experience of girls and young women from white Western European and North American backgrounds. We recognize these limitations and are hopeful that future research will be more inclusive of the eating disorder experiences of diverse individuals including boys and young men, those with gender expansive identities, people with marginalized racial and ethnic identities, and those with fat bodies.

The Early Intervention Continuum

One practical barrier to advancing knowledge on early detection and early intervention for eating disorders is an inconsistency in defining exactly what constitutes "early." Research on this topic is in its infancy relative to other fields like psychosis where definitions and early interventions are more established (e.g., McGorry et al. 2008). Across studies in eating disorders, the term "early intervention" describes treatments geared toward different populations, including:

1. Individuals at **high risk** for developing an eating disorder (with one or more risk factors associated with eating disorder onset in longitudinal research).
2. Those with specific **prodromal eating disorder symptoms** (with one or more clinical symptoms of an eating disorder without reaching the full diagnostic threshold).
3. Individuals who were recently diagnosed with an eating disorder for the first time (i.e., who are experiencing their **first episode of the illness**). In theory, the diagnosis occurs shortly after the disorder begins to capture the true early period of illness, but the definition is sometimes looser (e.g., it could include the first several years after diagnosis, regardless of actual onset or start of the illness).

In addition, there is variation in how individuals are classified into the categories above, such as the suggestion that the prodrome encompasses risk factors like body dissatisfaction (Stice et al. 2010), and disagreement about whether to classify subthreshold eating disorder symptoms among children and adolescents as prodromal or more similar to a full-threshold case (Le Grange and Loeb 2007). Altogether, these inconsistencies present the field with a challenge, as the goals of early intervention will differ based on the target eating disorder experiences. This topic also bridges prevention science and treatment research, creating additional discrepancies in how language is used and interventions are applied. Objectives of early interventions can range from:

1. Reducing risk and preventing the emergence of any eating disorder symptoms (if targeting high-risk individuals).
2. Reducing initial symptoms and preventing the onset of a diagnosable eating disorder (if targeting prodromal symptoms).
3. Decreasing the amount of time between illness onset and help-seeking (if targeting the first episode of illness).

In an effort to standardize our definitions and advance progress in the fields of prevention and treatment research, experiences of emerging illness could easily be mapped onto a continuum of eating disorder development (e.g., using the staging model of Treasure et al. 2015). In a model like this, separate phases of illness can divide the experience of eating disorders into:

1. **Pre-disorder:** A phase where risk factors are absent or intermittent.
2. **Risk factor phase:** The presence of one or more longitudinally identified risk factors like dietary restraint and body dissatisfaction, which can become more rigid and dominating over time.
3. **Prodromal phase:** Persistent risk factors convert to one or more initial eating disorder symptoms (e.g., restraint becomes severe dietary restriction that leads to weight loss; body dissatisfaction transitions to organizing self-worth around weight and shape).
4. **Early disorder phase:** Initial symptoms worsen, accompanied by additional eating disorder symptoms and potentially other psychiatric symptoms. These symptoms coalesce in the first episode of illness.
5. **Established disorder phase:** Without intervention, the disorder persists, worsens, and/or transitions to another eating disorder.
6. **Severe and enduring phase:** Disorder eventually becomes a severe and enduring illness that can be resistant to treatment.

The time-based parameters for each phase are uncertain, with 1–3 years suggested as the early illness phase (e.g., Treasure et al. 2015) and greater than 7 years for severe and enduring (e.g., Touyz et al. 2013). We suggest that the early disorder phase is defined as the first year after onset to capture a critical period for early intervention on newly developed illness. The years after include the established disorder phase followed by severe and enduring. Research should continue to explore time-based indicators for each phase. While an eating disorder can begin at any age, if we assume an average age of onset, the risk factor phase would emerge during middle childhood, intensify during early adolescence, and transition to early symptoms and disorder onset during adolescence or early adulthood (Fig. 1).

While this continuum assumes a linear progression, with experiences developing in severity over time, this will not be the case for all individuals. It also is important to recognize that there is attrition across phases, with individuals in each phase recovering rather than becoming more severe. In fact, the *majority* of individuals would likely not progress to the next phase (Stice et al. 2010). We instead present this

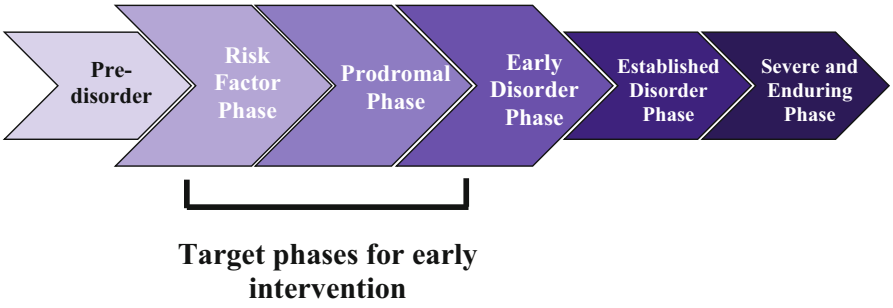

Fig. 1 The eating disorder continuum

model as a conceptual map for understanding how early detection can disrupt this developmental process, and when exactly early interventions might occur. **Early detection**–noticing the earliest symptoms that will become an eating disorder–would ideally occur in the late risk factor phase throughout the prodrome and continue into the initial early disorder phase. **Early interventions**–to relieve existing symptoms and stop them from progressing to the next phase–could occur across the risk factor, prodromal, and early disorder phases and be tailored in their intensity to match the phase (with more intensive interventions for later phases of illness). Early detection and early interventions targeting the eating disorder prodrome, when the first illness symptoms are emerging, are likely to have the greatest payoff in terms of identifying the individuals most likely to develop clinical eating disorders, but before symptoms become more severe and persistent.

Research evaluating early interventions for children and adolescents in these target phases is quite limited. Existing tools are drawn from eating disorder prevention research (selective prevention for the risk factor phase and indicated prevention for the prodromal phase), eating disorder treatment research (adapted for the prodromal phase and early disorder phase), or a blend of these approaches to address early and emerging eating disorder concerns. However, early intervention is defined, the task of detection–identifying symptoms when they first become concerning–still remains primary.

The Role of Parents in Early Detection

In theory, parents and other primary caregivers who are involved in their child's day-to-day life can observe eating and exercise habits and identify any concerning changes. And yet, there is poor understanding of the extent to which parents *do* notice emerging eating disorder symptoms. Across different mental illnesses, parents can miss or misidentify their child's psychological symptoms. Evidence for this includes discrepancies in parent-child reports of mental illness experiences. In general, parents and children are likely to agree on observable behaviors but disagree about the existence of internal symptoms (e.g., cognitions, mood; e.g., Salbach-Andrae et al. 2009). This highlights how internal experiences can easily remain private.

Eating disorders involve both observable behaviors (e.g., extreme diet or exercise changes, binge eating, compensatory behaviors) and internal symptoms (e.g., the cognitive experiences of body image disturbance), as well as physical changes such as weight loss or gain. Younger individuals may have significant denial of their illness and the psychological aspects of eating disorders (Le Grange and Loeb 2007), which makes parental reports especially important as complementary sources of information. However, research on the consistency of parent-child reports of an eating disorder (e.g., Mariano et al. 2013) suggests poor to moderate agreement about the presence of particular symptoms, with the lowest agreement for cognitive symptoms. Research in nonclinical samples also finds disagreement, where parents are less likely to identify bulimic symptoms compared to adolescents (e.g., Swanson et al. 2014; Bartholdy et al. 2017), but more likely to notice thinness and weight loss

(e.g., Swanson et al. 2014). Secrecy and shame can obstruct parental identification of bulimic symptoms. When these symptoms *are* noticed by parents, they may mark the severity of these behaviors, which makes swift intervention more urgent (Swanson et al. 2014).

Despite the challenges of identifying symptoms, studies of adolescents currently in eating disorder therapy show that parents *are* often the first to notice the symptoms and take action to find help (Ciao et al. 2020; Rosello et al. 2021a). The role of parents and other primary caregivers is particularly important when it comes to identifying anorexia nervosa (e.g., Laporta-Herrero and Latorre 2020), where patients may conceal or deny dietary restriction and weight loss and earlier help-seeking increases the chance of recovery. Taken together, this highlights the important role of parents and primary caregivers in noticing and intervening on eating disorder symptoms, particularly but not only for symptoms that may be under-recognized and/or underreported by the young person experiencing them. Efforts to improve early intervention should recognize the essential role of parents in detecting early symptoms and provide them with relevant support. It may be especially important to educate parents about the bulimic and cognitive symptoms of eating disorders that are harder to detect from the outside so they can increase their chance of recognizing them.

Another critical avenue for early detection is *not* relying solely on parents, but also educating other people who have regular contact with young people experiencing eating disorders (e.g., coaches, teachers) about the signs and symptoms of eating disorders and how to confront concerning symptoms (Ciao et al. 2020). In particular, school nurses and school counselors could be an ideal resource for those suffering from eating disorders, their caregivers, and the teachers and other school leaders who interact with them daily (e.g., Funari 2013). Primary care physicians also serve an important role in early detection efforts, as they have annual contact with young people and monitor growth in height and weight. They are often the first step for consultation about suspicions of an eating disorder, but research shows that primary health care providers feel under-equipped to adequately identify and refer cases of eating disorders (Johns et al. 2019).

Earliest Detectable Symptoms

Longitudinal research offers insight into modifiable factors that increase the risk of developing an eating disorder over time. These risk factors–primarily explored in female-identified individuals–include perceived pressure to be thin, internalization of thin body ideals, weight concerns, body dissatisfaction, dieting, negative affect, and substance use (Stice et al. 2010). However, these experiences are relatively common (e.g., they impact 30–70% of adolescent girls) while less than 10% of adolescent girls have symptoms of an eating disorder (Stice et al. 2010). Making broad risk factors a candidate for early detection means identifying many people who will never progress to an eating disorder. However, prevention interventions targeting the risk factor phase may have goals beyond reducing eating disorder onset,

for example reducing the distress of body dissatisfaction in and of itself to improve quality of life. And yet, more focused early detection–for example looking for persistent or rigid risk factors or symptoms within the eating disorder prodrome–may have greater payoff in terms of targeting individuals most likely to develop a full-blown illness. Even if prodromal symptoms do not progress, subthreshold eating disorders in adolescents are associated with distress and impairment similar to full-threshold cases (e.g., Stice et al. 2009), emphasizing the importance of detection and early interventions for this phase.

A recent systematic review suggests several candidates for early detection within the eating disorder prodrome. The authors evaluated longitudinal studies predicting eating disorder diagnoses in nonclinical samples of children and adolescents (McClelland et al. 2020). Although just over half of the 22 studies were rated as good quality, in general, a number of specific and general symptoms predated an eating disorder diagnosis. The earliest symptoms included problematic eating before age 10 (e.g., picky eating, conflicts around eating). Symptoms were more varied from ages 10–13, with both eating disorder symptoms (dieting, body dissatisfaction, and bulimic symptoms) and general psychiatric symptoms (anxiety and depression) associated with eventual eating disorder diagnoses. From age 15 onward, behavioral symptoms were most often related to later eating disorders, including binge eating, compensatory behaviors, and non-suicidal self-injury (McClelland et al. 2020). Conflicts around eating and distressing meal times have been suggested elsewhere to predate eating disorder onset in adolescence (Le Grange and Loeb 2007), making this a viable target for the earliest identification efforts, although these behaviors do not stand alone as prodromal symptoms (i.e., they are not clinical symptoms of an eating disorder). At later ages, a variety of specific–and mostly behavioral–eating disorder symptoms are candidates for early detection in the prodrome, such as dieting, body dissatisfaction, binge eating, and compensatory behaviors.

By asking young people and their caregivers to reflect on the time just prior to the start of an eating disorder (i.e., the potential prodrome), retrospective research can also inform early detection. In particular, the lived experience of parents provides unique insight into the symptoms of eating disorders that are the easiest to spot from the outside. Ciao et al. (2020) conducted qualitative interviews with 12 American caregivers of adolescents with an eating disorder diagnosis (1 biological father; 11 biological mothers; 93% white, 20% Hispanic) to solicit their experience identifying and responding to an eating disorder. The majority of parents who participated had a child with anorexia nervosa ($N = 8$), with the remainder diagnosed with other specified feeding or eating disorder ($N = 2$), bulimia nervosa ($N = 1$), or avoidant-restrictive food intake disorder ($N = 1$). Fifteen adolescent patients (ages 12–18; 100% female) shared their experiences separately. Weight loss and thinness were the earliest symptoms identified by parents, followed by extreme eating and exercise changes (e.g., severe dietary restriction, excessive exercise). While the early cognitive symptoms of eating disorders can be much harder to detect, adolescents in this study shared that body dissatisfaction *could* be observed by others (e.g., by looking for verbal comments of dissatisfaction with appearance). The majority of adolescents (60%) and parents (83%) reported that the parents–usually mothers–were the first

person to identify the disorder, but a variety of other individuals were also named as identifying the eating disorder early in its progression, including friends of the adolescent, teachers, coaches, and other adults (e.g., other family members and friends). This suggests both that parents can–and do–detect the early symptoms of eating disorders, and that other people notice these changes as well.

In a survey study with a similar aim, Rosello et al. (2021a) recruited the parents of 78 children and adolescents (ages 8–18; 94% female) with anorexia nervosa (64%), atypical anorexia nervosa (23%), or bulimia nervosa (13%). All patients were newly referred to a British child and adolescent eating disorder specialist service. This study mapped both symptom onset and length of time before seeking help. The earliest eating disorder symptoms observed by parents were changes in eating pattern (e.g., more rigidity or rules around eating; reported by 49 parents), followed by weight loss (reported by 27 parents). Other early symptoms included shape concerns (22 parents) and binge eating or compensatory behaviors (18 parents). Symptoms like weight concerns (2 parents), somatic symptoms (7 parents), and emotional changes (10 parents) were infrequently reported as first noticed. Strikingly, parents noticed weight and shape concerns an average of 1 year prior to the date the eating disorder diagnosis, with a large standard deviation (about 1 year). Changes in eating patterns were noticed an average of 10 months prior to diagnosis ($SD = 7.6$ months). Very few parents recalled symptoms more than 3 years prior to diagnosis (8%), suggesting that the year prior was an important period for the eating disorder's escalation. Of the parents in this study, a small proportion (6.4%) had consulted with a professional before seeking specialist intervention, hinting that changes are missed, normalized, or questioned for a long time.

In translating these study findings into actionable recommendations for parents and other primary caregivers, it is important to acknowledge the bias in parental recollections of concern, since the symptoms *did* eventually progress into a disorder. Increasing parental worry about specific symptoms (e.g., dieting) may result in overidentifying changes that could resolve without intervention. And yet for some, early detection could stall the progression to more serious illness. Across studies, the most consistent finding is that changes in eating patterns such as restrictive dieting commonly precede the onset of an eating disorder *and* are detectable by others for an extended period of time (Ciao et al. 2020; McClelland et al. 2020; Rosello et al. 2021a). Dieting changes between ages 10–13 could be particularly important to monitor closely (McClelland et al. 2020). Several studies hint that picky eating and conflicts around meals prior to age 10 might warrant additional screening (McClelland et al. 2020; Le Grange and Loeb 2007). Behavioral symptoms like binge eating and compensatory behaviors also predate an eating disorder diagnosis (McClelland et al. 2020), but these symptoms were mentioned less often by parents as the first to catch their attention (Ciao et al. 2020; Rosello et al. 2021a). This echoes the research that parents underreport bulimic symptoms relative to adolescents (Swanson et al. 2014; Bartholdy et al. 2017). However, given that behavioral symptoms are easier to detect from the outside than cognitive ones, raising awareness through education might result in increased detection.

There also was consistency across studies in identifying weight loss and thinness as a signal for concern (Ciao et al. 2020; Rosello et al. 2021a). However, it is important to note that weight changes are a downstream consequence of energy intake and expenditure changes. If observed too late, the diet and exercise changes may be routine and harder to disrupt. Furthermore, smaller body size is not a requirement for an eating disorder, and a screening approach that looks for excessive thinness alone would exclude restrictive eating disorders that occur within fat bodies. Although any significant or rapid weight change (e.g., a large shift in growth percentile) should be a sign of concern during childhood and adolescence, parents should also look for upstream behavior changes such as persistent eating and exercise habit changes, especially those tied to rigid cognitions (such as negative appraisals of body size or weight).

While these studies point to specific symptom targets for early detection, the execution of screening efforts is more difficult. The few studies addressing this topic suggest that parents should allow developmentally appropriate autonomy in eating and exercise domains while still being watchful of habit changes. For example, when reflecting on advice for earlier detection, both parents and adolescents suggested that being aware of the child's baseline behaviors would help to notice changes (Ciao et al. 2020). This included specific changes in eating habits (e.g., restriction, eating alone, negative relationships with food, eating "too healthy") and related behaviors like increased exercise and social withdrawal. Rosello et al. (2021a) suggest that parents look for persistent or excessive cognitions around weight, shape, size, or food control, and specific ties to behavior changes. Given that mood changes (e.g., anxiety, depression) can accompany eating-related changes and predate the eating disorder's onset (McClelland et al. 2020), parents can be on the lookout for constellations of symptoms and co-occurring changes across categories of behavior as a possible cause for concern. While early conversations about changes may seem unnecessary, more proactive steps to intervene as early as possible may keep symptoms from progressing. Parents and adolescents in the Ciao et al. study (2020) reflected that earlier intervention would have been helpful before symptoms became routine and incorporated into their daily lives (Table 1).

Barriers to Early Detection of Eating Disorders

A number of studies explore the challenges to identifying eating disorders within children and adolescents. Barriers exist across multiple contexts, including within the individual experiencing the disorder (e.g., hiding symptoms due to denial or shame; Laporta-Herrero and Latorre 2020; Swanson et al. 2014) and in the family context (e.g., parental hesitancy about the seriousness of symptoms when they emerge; Ciao et al. 2020; Cottee-Lane et al. 2004). Barriers also exist within the broader community of people who might detect concerning symptoms (e.g., lack of knowledge within primary healthcare providers; Johns et al. 2019). In addition, when symptoms or other aspects of the disorder (e.g., weight loss) progress slowly over time, it can be difficult to notice these changes. Since eating disorders often

Table 1 Early observable symptoms of child and adolescent eating disorders

Symptom	Observable examples	Source
Early problematic eating habits	Childhood picky eating Conflicts around mealtimes	Le Grange and Loeb 2007; McClelland et al. 2020
Extreme dieting or dietary restraint	Skipping meals Cutting or counting calories Rigidity or food rules (e.g., avoiding food groups) Avoiding social eating	Stice et al. 2010; McClelland et al. 2020; Ciao et al. 2020; Rosello et al. 2021a
Weight loss or thinness	Noticeable weight loss in short period of time (e.g., 3 months), regardless of starting weight	Ciao et al. 2020; Rosello et al. 2021a
Bulimic symptoms	Binge eating (losing control over type or amount of food eaten) Vomiting after meals Excessive exercise to compensate for food eaten	McClelland et al. 2020; Ciao et al. 2020; Rosello et al. 2021a
Body dissatisfaction	Comments about disliking appearance Efforts to conceal body (e.g., wearing baggy clothes) Negative remarks about shape or size Preoccupation with appearance	Stice et al. 2010; McClelland et al. 2020; Rosello et al. 2021a
Other social and emotional concerns	Anxiety Depression and other mood changes Non-suicidal self-injury Social withdrawal	McClelland et al. 2020; Stice et al. 2010; Ciao et al. 2020; Rosello et al. 2021a

begin during adolescence, symptom detection can be complicated by the normal developmental process of individuation, where children spend less time with their parents and are less likely to share their internal body image experiences with adults (Loeb et al. 2011).

Furthermore, the people who could potentially detect an eating disorder are embedded within a specific societal context, where normalization and praise of the early signs of eating disorders, such as eating "healthier" and increasing exercise, can make recognition challenging. Weight bias can lead to a failure to recognize problematic weight loss in individuals on the high end of the weight spectrum, even though emerging research shows the seriousness of anorexia nervosa across weight status (e.g., Garber et al. 2019). Stereotypes about who develops eating disorders–beliefs that they primarily impact young, affluent, white cisgender women–may impact the average person's understanding of these illnesses, who develops them, and whether treatment is warranted. Individuals whose identities and experiences depart from these eating disorder stereotypes (e.g., people of color, male-identifying and gender-expansive individuals, people with less financial affluence, people in fat bodies) experience barriers to identification and help-seeking (Sonneville and Lipson 2018).

Even when an eating disorder is correctly identified, the journey to finding appropriate treatment can be challenging. Parents may need additional information and support to intervene on emerging symptoms in their child. Research shows that family and friends seek out a variety of external resources to find help for an eating disorder, including self-help books, the Internet, and professional organizations and treatment centers (Ciao et al. 2020; Johns et al. 2019). Caregivers also seek out initial consultations within primary care (e.g., Cottee-Lane et al. 2004; Demmler et al. 2020; Johns et al. 2019; Laporta-Herrero and Latorre 2020), but report feeling like primary care physicians do not have adequate knowledge to intervene efficiently (Ciao et al. 2020). A systematic review identified multiple barriers to detecting eating disorders in healthcare contexts, including a lack of time and resources among providers and dismissing symptoms (Johns et al. 2019). Healthcare professionals themselves report challenges working with eating disorders, including their complexity, perceived low motivation for change, and a lack of training and resources (Johns et al. 2019). The lack of knowledge about eating disorders is a significant barrier to identification within primary care and referral to specialist care (e.g., Mitrofan et al. 2019; Johns et al. 2019). General practitioners need more support and training in screening for eating disorders (Reid et al. 2010), and utilizing appropriate referral channels for specialist services (Mitrofan et al. 2019).

Increased education on eating disorders is a proposed solution across studies that could address many of these barriers through improving mental health literacy (Ciao et al. 2020; Rosello et al. 2021a; Cottee-Lane et al. 2004). With increased access to educational and screening tools, parents, schools, and healthcare settings can serve as an important and interactive network for early detection of eating disorders. This includes understanding the central experiences within eating disorders (Bartholdy et al. 2017), including those symptoms that are more easily missed, hidden, or dismissed. It will be important to overlay this information with an awareness of typical and developmentally normal concerns around eating, weight, and bodies (Ciao et al. 2020). Education around eating disorder stereotypes can help to dispel myths and misunderstandings about who suffers from these illnesses and hopefully reduce stigma and shame surrounding help-seeking (Ali et al. 2017).

While primary caregivers are not solely responsible for detecting eating disorders, they are uniquely able to individualize educational information and adapt it to their family's culture and context. For example, parents should know that it is common for children and adolescents to have body dissatisfaction, particularly through puberty and if their bodies are different from dominant cultural appearance norms. Parents should also know when to be concerned, increase their monitoring, or start a conversation about these topics (Ciao et al. 2020). Close family members can know their child's typical habits and can be aware of the signs of an eating disorder that may match some changes they see – concerning changes that are not developmentally normal or normal for their individual child. However, parents need resources to serve as a first-line defense against emerging eating disorders, including adequate information *and* support. In a good example of this educational model, Loeb et al. (2011) outline the ways that anorexia nervosa can manifest during the developmental phase of middle childhood, with a focus on how parent-led

treatments can untangle the eating disorder from the developmental stage and promote recovery and a return to the previous trajectory.

Parent-Led Early Intervention Programs

Once emerging eating disorder symptoms are identified, parents and other primary caregivers have a unique role within early interventions. A limited number of parent-focused programs examine early intervention programs for children and adolescents across the risk factor, prodromal, and early disorder phases (Fig. 2).

Parent-Led Risk Factor Reduction

Many evidence-based risk factor reduction programs for children and younger adolescents are delivered within schools to universal audiences (Yager et al. 2013). In this context, everyone is included regardless of risk status (also called universal or primary prevention), placing programs just outside the scope of early intervention since they do not target high-risk individuals. Programs for older adolescents and young adults often screen for specific eating disorder risk factors (also called selective or secondary prevention), for example targeting adolescent girls with high body dissatisfaction through group dissonance interventions (e.g., Stice et al. 2010). While these programs can reduce eating disorder risk, decrease eating disorder symptoms, and even prevent the onset of eating disorders in girls and young women (Stice et al. 2019), they do not typically have a parental component. In fact, a 2014 review of parent-focused eating disorders prevention programs for children found that while 20 studies had at least a minimal parental component (e.g., providing parent materials to supplement a student-focused intervention), only two were high quality *and* significantly improved child eating disorder risk (Hart et al. 2015). This review included all types of prevention programs, regardless of the risk status of children.

Thus, to our knowledge just two programs investigate the potential for parent-led early intervention among high-risk individuals (parent-led selective prevention).

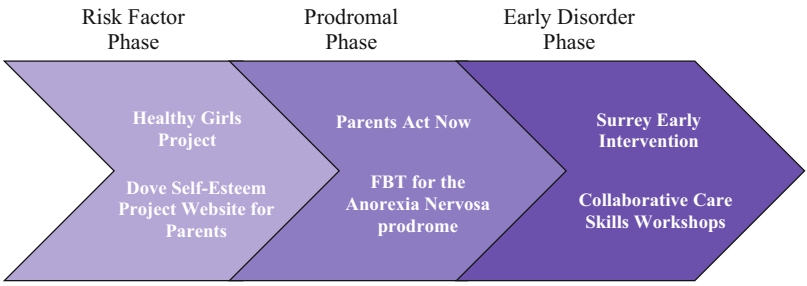

Fig. 2 Parent-focused early intervention programs

Table 2 Parent-focused programs for the risk factor phase

Program name	Program target	Key components
Healthy girls project	Mothers of girls ages 12–14 with body dissatisfaction	Four 90 min group workshops to address internalization of cultural beauty ideals Didactic content, behavioral activities, and discussion Homework to encourage conversations between mothers and daughters
Dove self-esteem project website for parents	Mother of girls ages 11–14 with body image concerns	Online platform with didactic materials, activities, and recommendations for body image behavior change Designed to promote body positivity in mothers and daughters

One of these programs was included in the parent-focused prevention review above (Hart et al. 2015) and one was published more recently; both programs target the mothers of adolescent girls with body image concerns (Corning et al. 2010; Diedrichs et al. 2016). Another parent-based program worth mentioning targets the early childhood years (ages 2–6; Hart et al. 2016). The *Confident Body, Confident Child* curriculum provides parents with strategies for building their child's healthy body image by addressing parenting factors known to increase the risk for childhood body dissatisfaction and subsequent disordered eating (e.g., parental criticism of weight). While this is an important program for broad-spectrum eating disorders prevention and promoting healthy body image, it currently falls outside of the early intervention framework because it does not target high-risk individuals or families (Table 2).

The ***Healthy Girls Project*** was designed for the mothers of American seventh and eighth grade girls (ages 12–14) with body dissatisfaction (Corning et al. 2010). A small randomized-controlled study recruited 31 mothers (ages 33–58; 83% European-American) to receive four weekly 90 min group workshops facilitated by a member of the research team or participate in assessments only. Workshop sessions addressed ways to reduce their daughters' internalization of cultural beauty ideals, a risk factor established to precede body dissatisfaction and dieting in a developmental model of eating disorder onset (Stice et al. 2000). Sessions included psychoeducation, behavioral activities, discussion, and homework. Mothers were provided with guidance on body image communication skills, and homework encouraged structured interactions around each topic (e.g., challenge your daughter to try an activity she has been avoiding due to body image concerns). Girls whose mothers participated in the workshop perceived less maternal pressure to be thin relative to the assessment-only control group through 3 month follow-up, suggesting that the *Healthy Girls Project* changed parent-child conversations surrounding body image. Girls also reported increases in body satisfaction after the intervention relative to the control group, but not through follow-up (Corning et al. 2010). While the benefits to the girls' own body image was limited, the impact on perceived

parental pressure highlights how a program like the *Healthy Girls Project* can be useful in raising awareness and changing familial conversations around appearance.

An intervention targeting a similar audience evaluated an online platform for mothers of daughters ages 11–14 with body image concerns (Diedrichs et al. 2016). The ***Dove Self-Esteem Project Website for Parents*** is an online platform designed to help mothers develop and maintain their daughters' positive body image, as well as their own. The *Dove Parents* website provides psychoeducational materials, activities, and recommendations for creating body image behavior change including critiquing media-based appearance ideals, changing negative conversations about appearance, discussing relational influences on body image, and engaging in body acceptance activities. In a randomized-controlled study, mother-daughter dyads in England ($N = 235$; mothers aged 28–54 and 93% white) either received a tailored version of the program (instructed to read specific articles), were given unstructured access to the web platform, or were allocated to assessment-only control. Exposure to the intervention was brief (30–60 min, on average). The tailored and unstructured interventions had some short-term impact on mother and daughter risk factors, but most changes were not maintained through 12 month follow-up. One important finding was that accessing the website increased the likelihood that mothers had conversations with their daughters about body image and sought additional help for their concerns (Diedrichs et al. 2016). This makes a resource like the *Dove Parents* website a viable candidate for promoting early detection of body image concerns and subsequent eating disorders.

Given the modest success of existing programs and the overall limited research in this area, it is still unclear exactly how to engage parents–and not just mothers–in eating disorders prevention for high-risk individuals. Importantly, existing research investigates only a portion of the individuals at highest risk for developing an eating disorder. For example, gender minority adolescents are uniquely high risk for developing eating disorders relative to their cisgender peers (Roberts et al. 2021), making gender-expansive youth important targets for future high risk programs. The current research on parent-led risk factor reduction is also limited to mostly white European and European-American participants. This neglects the racial and ethnic diversity within eating disorder experiences and the need to address the eating disorder vulnerability resulting from multiple marginalized identities (Burke et al. 2020). The lack of research on diverse experiences makes it difficult to draw conclusions about who may or may not benefit from parent-focused risk factor reduction. Diversity-focused body image programs exist for older, universal audiences (e.g., Ciao et al. 2021), and could be adapted to the parent-led context to support high-risk individuals within the early intervention spectrum.

It is interesting that the two existing parent-led programs for high-risk young people had a minimal long-term impact on young girls' body image. There are multiple explanations for this. It is possible that once eating disorder risk factors are present, intervening with parents alone is insufficient to create change. Parent-only interventions may also be a poor fit for this particular age range (both studies targeted early adolescence), or for cognitive symptoms like body dissatisfaction, or for programs that include only one parent or only mothers. However, both programs

had a positive impact on mother-daughter body image communication, and the *Dove Parents* program increased help-seeking for body image concerns (Diedrichs et al. 2016). These are important targets for the early detection of eating disorders. Given this, these types of parent-focused programs may be best used as adjuncts to individually focused programs such as dissonance-based interventions for girls and young women with body image concerns (Stice et al. 2019). They also could be shifted to include more education and support for parents surrounding screening and intervening on emerging eating disorder symptoms.

Parent-Led Treatments for the Prodromal Phase

Limited research has examined the role of parents once eating disorder risk transitions into clinical symptoms. This phase of early intervention bridges the gap between prevention and treatment. Indicated or tertiary prevention targets individuals experiencing initial symptoms of eating disorders; this also describes the prodromal phase of illness. To date, research on this topic is exclusive to children and adolescents with prodromal anorexia nervosa (Jones et al. 2012; Loeb et al. 2020) (Table 3).

An online program called ***Parents Act Now*** was developed for parents of girls ages 11–17 at high risk for developing anorexia nervosa (Jones et al. 2012; Jacobi et al. 2018). While the researchers describe the sample and program as targeting "high-risk" individuals, they include girls with an early anorexia symptom such as low weight or significant weight loss. In addition to the weight criterion, participants had either (1) high weight and shape concerns or high drive for thinness, or (2) at least one of four probable risk factors including high perfectionism, amenorrhea, excessive exercise, or a family history of an eating disorder. These inclusion factors situate the *Parents Act Now* intervention as a program for the prodromal phase of illness. The six session web-based program provides psychoeducation about eating

Table 3 Parent-focused programs for the prodromal eating disorder phase

Program Name	Program target	Key components
Parents Act Now	Parents of girls ages 11–17 with prodromal symptoms of anorexia nervosa	Six-session online program with FBT and eating disorder prevention techniques Eating disorder psychoeducation Encourages parents to intervene on concerning weight loss-related behaviors Parent discussion groups, weekly behavior monitoring and feedback
FBT for prodromal anorexia nervosa	Parents of children (any gender) ages 9–18 with prodromal symptoms of anorexia nervosa	14–50 min sessions over 6 months with FBT and eating disorder prevention techniques Family sessions following FBT phases and principles

disorders and encourages parents to intervene on any concerning weight loss-related behaviors using family-based treatment (FBT) and eating disorders prevention techniques. The program includes a moderated discussion group for parents and weekly monitoring of their child's weight, eating, and exercise behaviors with feedback provided by interventionists.

The feasibility, acceptability, and short-term benefits of the *Parents Act Now* program was established in an uncontrolled pilot study in Germany and the United States ($N = 46$; Jones et al. 2012), followed by a small randomized-controlled trial in Germany ($N = 66$; Jacobi et al. 2018). Unfortunately, there was low uptake of this program and high dropout among parents, with most parents failing to engage in a majority of the content (and 30% who never logged on at all). Among parents who participated, there was greater weight recovery among their children relative to a control group, with small to medium effect sizes (Jacobi et al. 2018). While the results of this study hint at the benefits of this early intervention, future research should attempt to understand parental barriers to accessing programs like these.

A more intensive program targeting young people with subthreshold anorexia nervosa examined the feasibility of an adapted version of **FBT for the anorexia nervosa prodrome** (Loeb et al. 2020). In a partially randomized design, young people in the United States ages 9–18 ($N = 59$; 85% female; 85% white) who had some but not all of the diagnostic features of anorexia nervosa were recruited to participate in either a 14-session manualized FBT intervention or 14 sessions of individual supportive therapy delivered by eating disorder therapists over a 6-month period. The adapted FBT treatment also drew from the eating disorders risk factor and prevention literature to ask parents to engage in new strategies such as modeling healthy, flexible eating for their child. The comparison supportive therapy intervention did not include a parental component. Results suggested the feasibility and potential benefit of both the family-based and individual interventions in improving symptoms of subthreshold anorexia nervosa (Loeb et al. 2020).

These two programs provide a limited view of how parent-focused interventions can help to reverse or improve the anorexia nervosa prodrome to prevent clinical cases of eating disorders. It is difficult to compare the interventions directly; although they shared a therapeutic approach (primarily FBT), they were delivered in very different doses (6 vs. 14 sessions) and through different modalities (online vs. in-person). Participants in both studies were predominantly female and from Western European and European-American backgrounds. Small sample sizes and a narrow focus on early anorexia nervosa highlight the need for additional research in this area and with broader eating disorder experiences. Programs that target the prodromal phase of illness to reduce initial symptoms and prevent clinical disorder onset are arguably one of the most important early intervention tools to expand in future research. When developing programs, researchers should involve parents in user-focused design of programming to ensure it meets their needs and to address any barriers to treatment uptake.

Parent Support in the Early Eating Disorder Phase

FBT has a relatively strong evidence base for treating children and adolescents with anorexia nervosa and modest empirical support for treating bulimia nervosa in this age range (Hilbert et al. 2017). FBT empowers parents to take charge of normalizing eating and exercise habits in their child to reverse the impact of the eating disorder. Although FBT is designed for children and adolescents at any stage of illness, research suggests that recovery is more likely when the duration of illness is shorter (e.g., le Grange et al. 2012). Therefore, several programs attempt to accelerate the uptake of evidence-based interventions and intervene during early stages of the illness. They also aim to increase parental support and success upon first beginning specialized clinical interventions like FBT (Table 4).

An adjunctive program called the ***Surrey Early Intervention*** for Child and Adolescent Eating Disorders offers parents additional information in a group format at the beginning of FBT (Nicholls and Yi 2012). Primary care referral systems in England recruit patients for the program, with an emphasis on early referral (shortly after a new eating disorder is diagnosed). The six-week program was designed to standardize the information typically provided to parents in the early stage of child and adolescent eating disorder treatment, with goals of increasing knowledge, skills, and parent confidence. Sessions are half didactic and half discussion, containing information on the impact of the disorder, identifying parental strengths, understanding stages of change, increasing communication, effective meal planning and refeeding, and managing disordered behaviors. A within-subjects design evaluated the parents of 64 children or adolescents (ages 8–18; 95% female) with a new diagnosis of anorexia nervosa or atypical anorexia nervosa. Parents attended the six 1.5 h therapist-led *Surrey Early Intervention* group meetings in addition to treatment as usual (Rosello et al. 2021b). Patients whose parents were in the program saw weight recovery success over time (through 6 months after the program) and improvement in eating disorder pathology (Rosello et al. 2021b). Although there

Table 4 Parent-focused programs for the early eating disorder phase

Program name	Program target	Key components
Surrey early intervention for child and adolescent eating disorders	Parents of children under age 18 (any gender) with anorexia-spectrum eating disorders	Six 1.5 h group sessions Adjunctive to FBT Didactic content to increase knowledge, improve communication, and promote FBT skills Group discussion
Collaborative care skills workshops	Caregivers of adolescent (15+) or adult patients (any gender) with an eating disorder	Six 2 h group workshops Adjunctive to outpatient therapy Didactic content to increase knowledge, support change, improve communication, and manage caregiving stress Exercises and practice

was no comparison group and it is difficult to separate the benefits of treatment itself from the adjunctive parent program, this suggests that parents may benefit from additional group support immediately after beginning family-based interventions for newly diagnosed anorexia spectrum eating disorders.

Other programs aim to provide support to caregivers during eating disorders treatment, but without the specific focus on the early eating disorder phase. One well-researched program is the ***Collaborative Care Skills Workshops***, which provide caregivers with skills to support their loved ones during outpatient eating disorders therapy (Treasure et al. 2007). Although the original workshops are not parent-specific and include all types of caregivers (e.g., spouses of adult patients), the program is available for patients as young as age 15. Across six 2 h sessions, caregivers are taught support skills based in communication strategies, motivational interviewing (meeting their loved ones where they are within the stages of change), and managing the stress of caregiving. Both the caregivers and the patients in the research on the *Collaborative Care Skills Workshops* are predominantly female identifying. Patients are between the ages of 15–33 and have a variety of eating disorders (most often anorexia nervosa). Initial studies among British caregivers found high program participation and positive improvements among caregivers, including increases in knowledge about caring for eating disorders and decreases in caregiving distress (e.g., Sepulveda et al. 2008). A small randomized-controlled study demonstrated similar benefits among Spanish caregivers participating in both skills-based and psychoeducation-based workshops (Sepúlveda et al. 2019).

Two adaptations of the *Collaborative Care Skills Workshops* target parents of adolescents specifically. *Experienced Carers Helping Others (ECHO)* was created for parents of adolescents under age 21 with anorexia nervosa (Hodsoll et al. 2017). Families were newly referred for specialist care within the National Health Service in the United Kingdom. The self-help program utilized books and DVDs, plus a study condition who received ten brief phone sessions (30–60 min). Unfortunately, program benefits were modest and uptake was relatively low (Hodsoll et al. 2017), warranting additional research before recommending this version of the workshops. A related Austrian intervention called *Supporting Carers of Children and Adolescents with Eating Disorders in Austria (SUCCEAT)* shows promise in supporting parents and other carers for adolescent anorexia nervosa as well as improving patient outcomes (Philipp et al. 2021; Truttmann et al. 2020). And yet, like the original *Collaborative Care Skills Workshop* programs, the *SUCCEAT* intervention does not focus on the early phase of illness in particular. However, adolescent-focused programs are likely to catch many individuals in the early phases of their disorder and are likely suitable for parent-led early intervention.

Two additional programs exist to reduce the gap between eating disorder onset and starting specialized treatment, which is an important target for early interventions aimed at the early disorder phase. These programs provide insight into system-wide strategies to encourage both early detection of eating disorders and rapid intervention uptake. The *First Episode Rapid Early Intervention for Eating Disorders (FREED)* is a transdiagnostic service model within England to encourage family involvement and evidence-based specialized eating disorder treatment for

emerging adults ages 16–25 (Schmidt et al. 2016; Brown et al. 2018). A primary aim of *FREED* is to reduce the duration of untreated illness by encouraging rapid specialist referral and reducing waiting time for specialty clinics, with the goal of beginning treatment within the first 3 years after eating disorder onset. Quasi-experimental pilot trials in England (e.g., Brown et al. 2018; McClelland et al. 2018) and a later multicenter implementation trial (Austin et al. 2021; Flynn et al. 2021) show success in these domains, as well as clinical improvement for patients in the service. *FREED* is a transdiagnostic service, targeting all eating disorders and is open to patients with all identities, although the majority of participants in research trials identify as female. Although it does not have the same early disorder focus, a similar health system model called *Psychnet* in Germany targets women of all ages with anorexia nervosa (Gumz et al. 2014, 2018). Health campaigns and systems management encourage early recognition of anorexia nervosa, reduce the duration of untreated illness, and encourage uptake of specialized evidence-based treatments.

This growing body of research suggests that caregivers and patients alike will benefit from additional information and caregiver support as they begin specialized eating disorders treatment. The changes to healthcare systems described within many of these research studies are impressive, with a focus on early detection of eating disorder cases, rapid referral to specialized care, and quick uptake of evidence-based interventions. In the child and adolescent age range, efforts focus on anorexia nervosa in the outpatient setting, and research takes place in Western Europe. Ongoing research should continue exploring these robust parent support programs delivered in other contexts and within different healthcare systems. In particular, parent-led programs targeting the early phase of illness will help to understand their role in supplementing FBT and other child and adolescent-focused eating disorder treatments.

Conclusion

Early detection and rapid intervention on emerging symptoms is essential to reducing the negative impact of eating disorders on individuals, families, and society. Redefining the period of early intervention to encompass multiple distinct phases of an emerging eating disorder will help to advance research and clinical interventions. We suggest that early detection can include high-risk behaviors and cognitions (e.g., dieting, body dissatisfaction), prodromal symptoms (e.g., severe dieting leading to weight changes, initial bulimic symptoms), and early illness (when symptoms pass the diagnostic threshold in the first episode of the eating disorder). Interventions targeted to each phase will draw from eating disorders prevention science (particularly from selective and indicated prevention approaches), treatment research, or both. An overall lack of research makes it difficult to highlight evidence-based parent-led programs for high-risk individuals, prodromal symptoms, or early phases of illness, but this leaves ample room for future research and intervention growth. Strengthening screening and early intervention efforts to target emerging symptoms and new eating disorder cases will be particularly important as cases of eating

disorders rise during and after the COVID-19 pandemic (e.g., Asch et al. 2021). Screening and early interventions for prodromal symptoms in particular may have the greatest payoff in terms of their potential to catch individuals most likely to convert to a full eating disorder that requires greater resources to treat.

Although research is still in its infancy, evidence suggests that parents and other primary caregivers can and should be part of the early detection system for emerging eating disorders. The behavioral symptoms of eating disorders (e.g., dietary changes) are an ideal candidate for parental early screening efforts, as these external symptoms are easier to spot relative to internal cognitive symptoms (e.g., body dissatisfaction). Other individuals in the daily lives of young people (e.g., teachers, coaches) are well placed to notice such changes, and primary healthcare providers are essential to early identification and referral systems. However, barriers to identification are present within each context, with a failure to identify concerning symptoms and refer to specialized treatment quickly. Some of these barriers can be addressed by increasing knowledge of eating disorders across contexts (particularly among parents, schools, and healthcare settings) and encouraging parents to situate this information within their own intimate knowledge of their child's habits. Parental support for early identification and early intervention efforts is essential, including programs and systemic changes to improve the entire early detection network.

Once symptoms are identified, early interventions should be tailored to the phase of illness. This includes prevention programs to diminish existing risk factors and to stop risk factors from progressing to clinical symptoms. However, the specific role of parents within this type of early intervention (also known as selective eating disorders prevention) remains uncertain. Two existing programs for mothers of early adolescent girls with body image concerns raise doubt about whether parent-only programs are sufficient to promote changes in high-risk individuals (Corning et al. 2010; Diedrichs et al. 2016). Ideally, parent-led prevention would promote body acceptance while reducing risk, and prevent the onset of eating disorder symptoms. While individually focused programs may have the greatest impact on these outcomes, more research is needed to explore the role of parents in reducing risk among diverse individuals. In the meantime, parent-focused programs for high-risk individuals might have a more important role in increasing education and awareness of eating disorders and catching emerging symptoms.

In fact, leveraging parents as the earliest detectors of eating disorders among children and adolescents may require involving them more heavily in prevention efforts for selective *and* universal audiences. Programs could draw on multiple bodies of literature:

1. Cross-sectional studies describing family factors that contribute to eating disorder risk such as weight-based criticism and weight loss encouragement (Gillison et al. 2016).
2. Cross-sectional and longitudinal research on family protective factors such as weight-neutral encouragement of healthy lifestyle and positive family communication (Gillison et al. 2016) and frequent family meals (Langdon-Daly and Serpell 2017).

3. Research on longitudinal individual risk factors in young people that strongly predict eating disorder onset such as body dissatisfaction and dieting (e.g., Neumark-Sztainer et al. 2011; Stice et al. 2010).

In addition to providing a more protective context for their child's body image development (e.g., by reducing weight-related comments), engaging parents in eating disorders prevention can increase their knowledge of and ability to screen for risk factors. Programs can provide tools for engaging with their child around identified weight, food, and body image concerns (e.g., teach skills for having conversations when concerns arise). Furthermore, programs should include specific information on eating disorders including seeking appropriate help for eating disorder symptoms. Importantly, programs should target the high-risk individuals and families who are underrepresented in current research, including those who are marginalized by dominant cultural appearance norms that overvalue white, cisgender, European features and bodies. One important caveat is that parents' own body image concerns, internalized weight bias, and disordered eating habits may interfere with their ability to provide the ideal supportive context to reduce their child's eating disorder risk. Programs could directly address these individual factors, as well as the structural barriers that influence them (e.g., diet culture, fat phobia).

There is a scarcity of research on parent-led early interventions for the prodromal phase of eating disorder illness. This is unfortunate, since the prodrome may be the optimal phase for early intervention to prevent disorder onset in highly vulnerable individuals. Two-parent programs based on principles of FBT show modest success for treating prodromal anorexia nervosa (Jones et al. 2012; Jacobi et al. 2018; Loeb et al. 2020), paving the way for future research to understand program tailoring and expansion to other eating disorders. This creates additional opportunities to draw from the fields of eating disorder prevention and treatment to create and evaluate brief interventions for varied prodromal symptoms.

Within the early eating disorder phase, parent-based early interventions draw from FBT and focus on supporting caregivers as they begin treatment for anorexia nervosa. For the early phase of other eating disorders, there is insufficient research to make evidence-based recommendations, but research addressing the early disorder experiences of bulimia nervosa, binge eating disorder, and other feeding and eating disorders will help to bridge this gap. Existing caregiver-focused programs are commendable for their transformative impact on healthcare systems, reducing the duration of untreated illness, and increasing access to evidence-based eating disorders care. However, as important as these programs are, they may not be serving the diverse range of individuals who suffer from eating disorders.

In general, research studies that inform the early detection and early intervention domains include a majority of presumed cisgender female participants with white Western European and European-American backgrounds. Future early intervention programs and research should address the diversity within eating disorders experiences, including racial and ethnic diversity, gender diversity, sexual diversity, ability, and more. Research shows that individuals with marginalized racial and ethnic identities are less likely to seek out initial eating disorder treatment compared to

those in racial majority groups (i.e., white individuals; Regan et al. 2017). A failure to include an intersectional focus within future studies will continue to limit access to individuals that already experience marginalization and contribute to exclusion, stigma within those communities, and exacerbation of illness. An understanding of unique risk and resilience surrounding body image, disordered eating, and eating disorders for those with intersecting identities will help to tailor early detection efforts and culturally adapt early interventions (Burke et al. 2020). Greater attention to systemic factors (e.g., white supremacy, capitalism, and diet culture) that contribute to body and appearance privilege and inequality will help to situate early eating disorder experiences within these broader forces.

The impact of the COVID-19 pandemic on eating disorder experiences is not fully understood, but some of the pandemic-influenced positive changes to the field (e.g., wide adoption of teletherapy) that have addressed treatment access barriers will hopefully persist for years to come. The eating disorder field can leverage these innovations to create and improve affordable and accessible digital health interventions that address early detection, prevention, and early interventions (Taylor et al. 2020). This includes online programs that parents can use more conveniently to increase their knowledge and skills needed to screen for and support eating disorder symptom recovery and similar programs for other important players in early detection such as schools and primary healthcare providers.

Applications to Other Eating Disorders

Research on the parental role in early detection and early intervention in children and adolescents is limited in its representation of different eating disorder experiences. The majority of research that informs early detection in this age group encompasses a variety of subclinical experiences, coming from general community samples to examine risk factors that predict eating disorder onset of all types (e.g., Stice et al. 2010) or disordered eating that encompasses varied experiences (e.g., McClelland et al. 2020). Once symptom severity worsens and early intervention programming begins, the research narrows. Parent-led risk factor reduction programs target body image disturbance specifically (Corning et al. 2010; Diedrichs et al. 2016). Research on parent interventions for prodromal symptoms of eating disorders in children and adolescents is limited to the anorexia nervosa spectrum (Jacobi et al. 2018; Loeb et al. 2020). Research on supporting parents in treating new eating disorder cases in this age range focuses on adolescent anorexia nervosa (Hodsoll et al. 2017; Philipp et al. 2021; Rosello et al. 2021b; Truttmann et al. 2020). Additional research is needed to explore parent-led interventions for other eating disorder experiences.

Mini Dictionary of Terms

- **Early detection:** Detecting the first possible symptoms of an emerging eating disorder (i.e., noticing changes shortly after they begin).

- **Early intervention:** Initiating interventions as quickly as possible after concerning symptoms emerge (e.g., intervening on persistent risk factors, prodromal symptoms, or new cases of eating disorders).
- **Family-based treatment (FBT):** Evidence-based intervention for child and adolescent eating disorders that utilizes parents and other primary caregivers to reverse eating disorder behaviors and promote the earliest stages of recovery.
- **Risk factor phase:** Period of time where an individual is experiencing one or more risk factors longitudinally associated with eating disorder onset.
- **Prodromal phase:** Period of time where an individual experiences one or several symptoms of a diagnosable eating disorder but does not reach the full clinical threshold.
- **Early disorder phase:** Period of time immediately after an individual crosses the threshold into an eating disorder, with a cluster of symptoms meeting the diagnostic threshold.

Key Facts of Parent-Led Early Detection

- Eating disorders are serious and persistent mental illnesses that often begin in adolescence and early adulthood.
- In children and adolescents, eating disorder recovery is more likely with a shorter duration of illness and a quick uptake of treatment, while recovery is less likely the longer the patient is ill.
- Identifying and intervening on the earliest symptoms of eating disorders will significantly reduce the burden of these illnesses, but there is limited research on early detection and intervention tools.
- Early detection refers to noticing the earliest symptoms of eating disorders, and early intervention targets symptoms at the earliest point possible.
- Early detection and early intervention efforts focus on the child and adolescent age range, when risk factors and initial symptoms are likely to develop.
- Given the challenges associated with self-identifying eating disorder symptoms, primary caregivers play an essential role in detecting the earliest symptoms among children and adolescents.
- Redefining the period of early intervention to encompass multiple distinct phases of an eating disorder will help to advance research and clinical interventions. Early detection and associated interventions can include high-risk behaviors and cognitions (e.g., dieting, body dissatisfaction), prodromal symptoms (e.g., severe dieting leading to weight changes, initial bulimic symptoms), and early illness (when symptoms pass the diagnostic threshold in the first episode of the eating disorder).
- Early detection and early interventions targeting the eating disorder prodrome, when the first illness symptoms are emerging, is likely to have the greatest payoff in terms of identifying the individuals most likely to develop clinical eating disorders, but before symptoms become more persistent.

Summary Points

- Across studies, the most consistent finding is that changes in eating patterns such as restrictive dieting commonly precede the onset of an eating disorder *and* are detectable by others for an extended period.
- Increasing education about both typical and concerning experiences surrounding eating, exercise, and body satisfaction is crucial for increasing the success of early detection efforts. This includes education for all in the possible early detection network, including parents, schools, and healthcare communities. Parents may benefit from education about the bulimic and cognitive symptoms of eating disorders in particular, as these can be hidden or more difficult to observe externally.
- Parent support for early identification and early intervention efforts is necessary, including programs and systemic changes to improve the entire early detection and referral network.
- Once concerns are identified, parents and other caregivers may have an important role in carrying out early interventions to reverse the risk factors, early symptoms, or early disorder phase of illness. Interventions targeted to each phase will draw from eating disorders prevention science (particularly from selective and indicated prevention approaches), treatment research, or both. However, the research is quite limited, particularly for parent-led risk factor reduction and interventions on the prodromal phase of illness.
- The majority of research on early intervention falls within child and adolescent anorexia nervosa, likely reflecting the prioritization of this illness due to its high risk of death. However, this leaves ample room for scientific advancement within other eating disorder experiences.
- In general, the existing research to inform early detection and early intervention efforts highlights the experience of girls and young women from white Western European and North American backgrounds.
- Future research should aim to be more inclusive of the eating disorder experiences of diverse individuals, including boys and young men, those with gender-expansive identities, people with marginalized racial and ethnic identities, and those with fat bodies.

Alexithymia in Eating Disorders: A Narrative Review

17

Cecilia Serena Pace, Stefania Muzi, and Wanda Morganti

Contents

Abstract

This chapter aimed to provide a narrative and critical review of the current knowledge of alexithymia in eating disorders. Results of previous reviews and meta-analyses on the topic have been reviewed and integrated with further studies retrieved through three searches in well-known databases (e.g., SCOPUS, EBSCO). Most of the research confirmed higher levels of alexithymia in all patients diagnosed with an eating disorder than in nonclinical individuals, with no clear differences according to the type of diagnosis (anorexia, bulimia, binge eating disorder, etc.), as well as in healthy individuals showing subthreshold

eating disorder symptoms. Alexithymia tends to longitudinal stability, and the various influences on treatment outcomes and therapeutic implications are reviewed. In conclusion, alexithymia could be a crucial treatment target to achieve improvements in ED symptomatology, but more research is needed to understand how to develop alexithymia-oriented efficient treatments for ED patients. Limitations and future lines of research are also discussed.

Introduction

The profound and complex involvement of alexithymia in body-related disorders has been known since the first definition of the construct itself by the psychotherapist Sifneos (1973), who defined the core characteristics of the alexithymia observing similarities in numerous patients with psychosomatic disorders.

According to his observations, some scholars have developed a widespread definition of alexithymia (Taylor et al. 1997), which includes four core characteristics: difficulties in identifying feelings differentiated by bodily sensations, difficulties in finding the words to describe feelings, externally oriented style of thinking focused on material and pragmatic aspects of the experience rather than on the inner life, and a general lack of fantasy. While the centrality of this last aspect is debated despite that it has been recently reassigned (Bagby et al. 2006), decades of research have identified the compresence of the first three characteristics in numerous clinical and nonclinical populations (Muzi 2020; Salminen et al. 1999), including both

individuals diagnosed with eating disorders (EDs) and those showing subthreshold symptoms of ED (Nowakowski et al. 2013).

Nonetheless, before deepening the substantial investigation linking alexithymia to eating disorders, some clarifications on the multiple definitions of alexithymia and methods of assessment may help a reader to better evaluate the research findings here summarized.

Types of Alexithymia

Given conspicuous literature establishes the higher alexithymia as a factor of vulnerability for an individual's physical and mental health (Hemming et al. 2019; Lumley et al. 1996), professionals and researchers in different fields have worked to better specify its definition and increase clinical usefulness (Goerlich 2018).

For instance, it is now possible to distinguish alexithymia based on its supposed etiology (Messina et al. 2014), distinguishing organic, primary, and secondary alexithymia. Specifically, organic alexithymia is due to innate or congenital malformations or damages in the structures of the brain used to process emotions independent of the individual's life experience. Instead, primary alexithymia is deemed as a consequence of dysfunctional or traumatic early interpersonal relationships with primary caregivers, for which a child is hindered in the interpersonal acquisition of the rudiments of emotional awareness and regulation necessary for autonomous emotional management, which could manifest as alexithymia later in development (Taylor et al. 1997). Lastly, the secondary alexithymia would occur later in the development, as a consequence of brain damages due to accidents or medical surgery, so that the cause is organic but due to a life experience and not innate (Messina et al. 2014). This distinction has been proved to be useful in forecasting treatment outcomes, e.g., the longer but less complex intervention on organic alexithymia than on primary one (Messina et al. 2014), as well as in understanding which type of alexithymia could more negatively affect individuals' health and well-being.

Moreover, scholars debated whether alexithymia can be considered as a stable trait of personality or a state able to change during development (Martínez-Sánchez et al. 2003). In the first perspective, alexithymia is considered as a trait existing or not existing in individuals, allowing categorical classifications for which beyond a certain level one is considered alexithymic. Following this perspective, researchers have proposed a cutoff score defining clinically relevant levels of alexithymia at the self-rating scale Toronto Alexithymia Scale (TAS; Bagby et al., 1994) in its multiple versions, i.e., TAS-R, TAS-20, and TAS-26. On the other side, proponents of the second perspective suggest that alexithymia can vary throughout the life cycle, for example, changing from adolescence to adulthood, or in response to a specific condition – i.e., increasing during the lockdown (Pace et al. 2022, under review) or decreasing following a psychotherapeutic intervention – and its levels should be measured on a continuum (da Silva et al. 2018; Muzi 2020).

Impact of Alexithymia Assessment on Research Findings

Although the abovementioned two perspectives can coexist and can be seen as complementary, this debate continues to influence both the choice and the development of alexithymia assessment tools (for a comprehensive review, see Bermond et al. 2015). When alexithymia is considered a stable trait of personality, it is possible to categorize individuals as alexithymic or not based on cutoff scores (so far defined only for the TAS), and the evaluation of children and adolescents would be discouraged as their personality is still under construction and not stably defined. Conversely, considering the alexithymia a state, changing during the development and present in a continuum among individuals, the assessment would be performed also in minors but exclusively with tools providing a continuous score of alexithymia, which are the majority.

Briefly, tools to assess alexithymia pertain to three main methodological approaches: self-rating scales, observation scales, and projection scales (reviewed in Bermond et al. 2015). Self-rating scales include all questionnaires and scales where the individual is asked to self-evaluate his/her alexithymia by agreeing with a list of sentences describing dimensions of alexithymia. The level of agreement expressed for each sentence corresponds to a score (depending on the scoring system of the tool), of which the sum or the mean provides a total score of alexithymia. The most used tool to assess alexithymia, the questionnaire TAS, falls into this methodology. Its last version is the TAS-20, where the person is asked to agree to a set of 20 sentences aiming to cover 3 main dimensions of alexithymia, difficulty to identifying feelings (DIF), difficulty in describing feelings (DDF), and externally oriented thinking (EOT), each one with a dimension score. The sum of the scores in the three dimensions is the total score, which expresses the level of alexithymia self-evaluated by the person. Another pretty used self-rating questionnaire is the 40-item Bermond-Vorst Alexithymia Questionnaire (BVAQ; Vorst and Bermond 2001), which contains 40 sentences aiming to capture 2 dimensions of alexithymia, the cognitive factor and the affective factor, of which score results by the combination of factor analyses in 5 subdimensions (inability to differentiate between emotions, inability to verbalize emotions, inability to analyze emotions, inability to fantasize, and inability to experience emotions). The BVAQ does not provide a total score of alexithymia, and maybe it is less used than the TAS-20 because it is longer to administrate and the scoring system may be perceived as sophisticated.

Self-rating scales are quick and economic, but the goodness of the result is completely due to the ability of the items to describe the various facets of alexithymia and to their clear understanding by the self-evaluating individual. Moreover, some authors consider it paradoxical to self-evaluate one's ability to describe emotions to others (Bagby et al. 2006).

These authors claim that this problem can be overcome by using the second approach, the observer-rating scales. These scales can also contain a set of items or checklist that an external rater filled based on his/her knowledge of the evaluated person, retrieved with clinical observation or through interviews or observation procedures. An example of a tool within this approach is the Observation

Alexithymia Scale (OAS; Haviland et al. 2000), where an external observer (a parent, a clinician, a teacher) fills a questionnaire to rate the alexithymia of another person, rating five subdimensions (distant, somatizing, uninsightful, humorless, and rigid) summed in a total score of alexithymia. Another example is the Toronto Structured Interview for Alexithymia (TSIA; Bagby et al. 2006), a 45-min interview of 24 questions, administered and rated by trained professionals. Based on the TAS-20, the professionals ask questions covering the dimensions of DIF, DDF, EOT, and lack of fantasy, assigning a score of 0–2 based on their evaluation of the interviewer's responses. The interview provides scores for each dimension, grouped two by two in the macro-dimensions of affective awareness and operative thinking and summed in a total score. Observer-rating scales are deemed more accurate, but the results can be distorted by the rater judgment and preparation, and the tools in this approach are usually expensive with a longer procedure of scoring.

The limits due to biases and judgment of the rater could be overcome with the application of projection scales, where ambiguous stimuli (usual drawings) are shown to the person, who describe what he/she sees or answer questions. The Rorschach Alexithymia Scale (Porcelli and Mihura 2010) seems the unique tool to assess alexithymia, and it consists of a specific coding system applied on the Rorschach test. A limit of this approach is to require time and training for administration and scoring.

All these approaches can be combined or independently valid depending on the purposes of the assessment, but the majority of research employ self-rating scales, probably because they are faster and more used, facilitating the comparability of results of different studies and a fast screening in certain settings, e.g., medical. Specifically, the most used is the TAS-20, maybe because it is the only tool for which cutoff scores have been defined, allowing to classify the individuals based on the total score as not alexithymic (total score under 51), moderately alexithymic (between 51 and 60), or alexithymic (total score 61 or more), meanwhile providing scores global and in subdimensions.

Structure and Rationale of the Current Review

The current narrative review reports the main findings on alexithymia and eating disorders, summarizing findings of previous reviews on the topic (Gramaglia et al. 2020; Nowakowski et al. 2013; Pinna et al. 2015; Westwood et al. 2017, summarized in Table 1), and integrating their gaps in terms of time laps (2013–2021 in Nowakowski et al. 2013) or alexithymia measurement as, for the first time, not only studies with the TAS-20 or TAS-26 but also studies employing other measures have been reviewed (see filters in Fig. 1 for a panoramic of measures of alexithymia considered in the search strategy and all databases checked).

This review includes studies with individuals with diagnoses or symptoms for all eating disorders as defined in the DSM-5 (APA, 2013), especially those with AN and BN diagnosis/symptoms, considering the ongoing systematic reviews on similar topics recorded on PROSPERO (e.g., Koutoufa et al. 2019; Nelson 2019).

Table 1 Synthesis of the previous reviews and meta-analyses on alexithymia in eating disorders

Author	Year	Type	Title	# Studies	Main results
Nowakowski et al. (2013)	2013	Critical review	Alexithymia and eating disorders: a critical review of the literature	59	• ED patients are more categorized as alexithymic compared to the community sample • ED patients reported higher total alexithymia scores and higher scores in two factors of the TAS-20: DDF and DIF • In nonclinical samples, ED behaviors are associated with DIF and DDF higher scores • Mixed results were found for the hypothesis of a mediation role of general distress/ depression/anxiety over the relationship between alexithymia and ED • AN appeared to have higher alexithymia levels, especially in expressing emotions, than BN • BED patients, similarly to AN and BN, reported higher levels of alexithymia • Alexithymia and depression were influenced negatively by childhood maltreatment, and both could lead to an increased risk to develop an ED

(continued)

Table 1 (continued)

Author	Year	Type	Title	# Studies	Main results
					• After psychological treatment, alexithymia scores decreased. However, in ED sample the level remained clinically significant and different from the control
Pinna et al. (2015)	2015	Systematic review	Alexithymia in eating disorders: therapeutic implications	15	• The results from the longitudinal studies here analyzed are mixed. Some of them reported no association between TAS score and outcome variables or dropout, while others found a prediction role of alexithymic level over outcomes, especially for the DIF subscale, and a relation between dropout and TAS scores • Cross-sectional studies highlighted how ED patients had higher alexithymia scores than community samples • People with high levels of alexithymia tended to receive more treatments than non-alexithymic patients

(continued)

Table 1 (continued)

Author	Year	Type	Title	# Studies	Main results
					• Referring to the effect of ED treatment on alexithymia, the studies reviewed reported conflicting results: some highlighted improvement in alexithymic levels, some reported no change, and others showed a reduction in TAS score that remained clinically significant • Significant differences in TAS score with large effect sizes between ED and community sample, except for BED which reported medium effect sizes
Westwood et al. (2017)	2017	Systematic review and meta-analysis	Alexithymia in eating disorders: systematic review and meta-analyses of studies using the Toronto Alexithymia Scale	48 for the qualitative synthesis and 44 for the meta-analysis	• They found a publication bias in all the diagnostic groups • Age appeared to be positively associated with an effect size of clinical outcome in AN and BN • In AN studies, differences in BMI influenced the differences in alexithymia, enlarging effect sizes. Therefore, the BMI could be implied in the relationships between anorexia

(continued)

Table 1 (continued)

Author	Year	Type	Title	# Studies	Main results
					and alexithymia, but the effect of the latter on symptoms remains significant even if the BMI is controlled • Depression and anxiety in some studies were considered confounding variables and modified the relationship between TAS and ED • There is a paucity of studies involving BED patients • The agreement between TAS and other alexithymia measurements is still debated, as one study found differences in the results from TAS and TSIA
Gramaglia et al. (2020)	2020	Systematic review	Alexithymia and treatment outcome in anorexia nervosa: a scoping review of the literature	10	• The treatments presented in the review are CREST, group psycho-pedagogic method, group cognitive-behavioral therapy, a three-phase treatment program composed of various approaches, and group therapy that combined cognitive-behavioral and a dynamic approach

(continued)

Table 1 (continued)

Author	Year	Type	Title	# Studies	Main results
					• Alexithymia in the studies reviewed tended to remain high after treatment even if other outcomes improved (e.g., ED symptoms) • The improvement in TAS scores after treatment is still debated as CREST (only in individual format), a mixed approach including different types of treatment and a psycho-pedagogic intervention led to a decrease in TAS score, while other studies didn't arrive at the same conclusion

Table 2 details the studies included in the current review. First, results from case-control studies which compared alexithymia in ED clinical and nonclinical samples are presented. Then, studies on nonclinical populations are illustrated, to have a frame of connections in low-risk samples, useful for prevention purposes. Further, alexithymia is investigated in clinical samples, with a special focusing on the diagnoses of anorexia and bulimia. Lastly, findings from longitudinal studies and concerning alexithymia-related therapeutic outcomes and implications are reported, together with critical reflections about limits and gaps of the current knowledge.

Findings from Case-Control Studies

The comprehensive critical review by Nowakowski et al. (2013) concluded that individuals diagnosed with EDs of all types show significantly higher scores of alexithymia than nonclinical participants. More specifically, Nowakowski et al. (2013) suggested that ED patients scored higher than controls in DIF and DDF alexithymia dimensions, but not in EOT one.

Fig. 1 Filter and records retrieved for the research on alexithymia in eating disorders. *WOS* Web of Science, *N.A.* not applicable, when the search cannot be performed in the database for technical reasons due to the database. Filter#1 searched studies on alexithymia and ED from 2013 to 2021, also with different tools than the Toronto Alexithymia Scale. Filter#2 searched studies on alexithymia-related treatment outcomes in ED different than anorexia, and Filter#3 updated the alexithymia-related treatment outcomes in anorexia

Westwood et al. (2017) confirmed this conclusion, providing meta-analytic data on 44 high-quality studies with the TAS-20 and TAS-26, that added information about case-control differences based on ED diagnosis, in terms of anorexia nervosa (AN, general and specified as binge-purge and restricting type separately), bulimia nervosa (BN), and binge eating disorder (BED) (Westwood et al. 2017). The mean difference in total higher alexithymia scores with healthy controls showed large

Table 2 Studies included in the current review on alexithymia in eating disorders

Author, year	Sample (size, type)	% Males	Measure of assessment		Main results
			Alexithymia	Eating disorder	
Case-control studies					
Espina (2003)	145, mixed: 73 couples of parents of women with ED (20 AN-R, 23 AN-B, 30 BN), 72 couples of parents of women from the community	0	TAS-20	Diagnosis	• No differences in TAS-20 both total score and subscales among the three ED groups • In fathers: significantly differences between ED and HC in TAS-DIF ($p = 0.014$), in TAS-EOT ($p = 0.001$), and in TAS-total score ($p = 0.002$) • In mothers: significantly differences between ED and HC in TAS-DIF ($p = 0.009$), in TAS-DDF ($p = 0.010$), in TAS-EOT ($p = 0.000$), and in TAS-total score ($p = 0.000$) • The two groups of mothers (ED and HC) differed significantly in alexithymia rates ($p = 0.001$) • Comparing the four groups (ANR, ANB, BN, and HC), there were significant differences in TAS scores both in fathers ($p = 0.041$) and mothers ($p = 0.001$)
Gramaglia et al. (2016)	87, mixed: 39 AN and 48 community	0	TAS-20	Diagnosis	• AN > HC in TAS-DIF ($p < 0.001$), TAS-DDF ($p < 0.001$), and TAS-total score ($p < 0.001$)

Guiducci et al. (2018)	142, mixed: 25 AN, 25 BN, 50 community, 20 parents of EDs (8 fathers), 22 parents of community (10 fathers)	0	TAS-20; OAS	Diagnosis of ED made by a public health service and SCID-I	• TAS-20 total score: EDs > HC ($p < 0.002$) • TAS-20-DIF: EDs > HC ($p < 0.002$) • TAS-20-DDF: EDs > HC ($p < 0.002$) • TAS-20-EOT: EDs > HC ($p < 0.05$) • No significant differences in alexithymia between the two parents' groups using TAS-20 • OAS-total score: EDs > HC ($p < 0.002$; large effect size) • OAS-distant: EDs > HC ($p < 0.002$; large effect size) • OAS-uninsightful: EDs > HC ($p < 0.002$; large effect size) • OAS-somatizing: EDs > HC ($p < 0.002$) (the only one with a medium effect size of 0.58) • OAS-humorless: EDs > HC ($p < 0.002$; large effect size) • OAS-rigid: EDs > HC ($p < 0.002$; large effect size) • Daughters' evaluations of mother: OAS-total score: EDs > HC ($p < 0.05$) • Daughters' evaluations of mother: OAS-distant: EDs > HC ($p < 0.002$)

(continued)

Table 2 (continued)

Author, year	Sample (size, type)	% Males	Measure of assessment		Main results
			Alexithymia	Eating disorder	
					• Daughters' evaluations of mother: OAS-humorless: EDs > HC ($p < 0.002$) • Daughters' evaluations of father: OAS-uninsightful: EDs > HC ($p < 0.05$)
Kerr-Gaffney et al. (2020)	147, mixed: 51 AN, 50 recovered AN, 46 community	7.9 in AN, 2 in recovered AN, 6.5 in community	TAS-20	EDE-Q	• TAS-20-total score: ANs > recovered ANs > HC
Marchiol et al. (2020)	121, mixed: 93 ED (34 AN, 30 BN, and 29 BED) and 28 community	0	TAS-20	EDI-2	• TAS-DIF scores were significantly different among every clinical group and the HC group (AN $p = 0.0001$, BN $p = 0.001$, BED $p = 0.01$) • TAS-DDF scores were significantly different only between AN and HC ($p = 0.05$) • TAS-EOT scores presented no differences among groups • TAS-total scores were significantly different among every clinical group and the HC group (AN $p = 0.01$, BN $p = 0.01$, BED $p = 0.05$)
Nalbant et al. (2019)	64, mixed: 32 AN and 32 community	0	TAS-20	EAT-40	• TAS-20 total score: ANs > HCs ($p < 0.005$) • TAS-20-DIF: ANs > HCs ($p < 0.005$)

					• TAS-20-DDF: ANs > HCs ($p < 0.005$) • TAS-20-EOT: n.s.
Pace et al. (2015)	93, mixed: 45 mothers of ED patients (23 AN and 22 BN) and 48 mothers of women without clinical symptoms	0	TAS-20; OAS	SCID-I	• No differences between the two mothers' groups in both the TAS-total score and the subscales • Daughters' reports of alexithymic levels in mothers showed some significant differences in OAS-total score (ED > non-ED, $p = 0.01$), distant (ED > non-ED, $p = 0.00$), humorless (ED > non-ED, $p = 0.01$)
Pace et al. (2021)	44, mixed: 22 BED and 22 community	0	TAS-20	BES	• No differences in alexithymia levels between the clinical and the control group
Redondo and Luyten (2020)	361, mixed: 38 AN and 323 community	0	TAS-20	EAT-26	• Alexithymia was positively associated with ED symptoms • TAS-20-DIF fully mediated the relationship between attachment insecurity and all the ED subscales
Rozenstein et al. (2018)	60 dyads, mixed: 27 dyads (mothers and daughters with normal-weight binge-purge eating disorder or EDNOS binge-purge type) and 33 dyads from community	0	TAS-20	Diagnosis made to be hospitalized in the eating disorder department in the Sheba Medical Center	• TAS-total score: daughters with diagnosis > control ($p < 0.01$) • TAS-DIF: daughters with diagnosis > control ($p < 0.01$) • TAS-DDF: daughters with diagnosis > control ($p < 0.01$) • TAS-total score and subscales, no differences between the two mothers' groups

(continued)

Table 2 (continued)

Author, year	Sample (size, type)	% Males	Measure of assessment		Main results
			Alexithymia	Eating disorder	
Sfärlea et al. (2019)	86, mixed: 26 AN, 25 MD, 35 community	0	TAS	Diagnosis based on ICD-10	• The two clinical groups didn't differ in alexithymic level, but they differed from the HC group ($p < 0.001$)
Cohort/community studies					
Benau et al. (2020)	279	36.6	TAS-20	EDI-3	• Alexithymia seems to not distinguish between men and women although DIF appeared to be more concerning men and DDF to women
Biolcati et al. (2021)	394	20.8	TAS-20	EAT-26	• Age and alexithymia are not significant predictors of EDs • Among the samples, those who exceed the cutoff score for EDs have significantly higher alexithymia
Boscoe et al. (2021)	544 General population divided in ED and non-ED based on the EAT-26 score	12.3 male and 2.6 other	TAS-20	EAT-26	• The TAS-20 score didn't differ significantly between the ED group and the non-ED group
Casagrande et al. (2020)	111 General population, divided into normal weight and overweight	40.5	TAS-20	EDI-2	• TAS-20 total score: overweight > normal weight ($p = 0.003$) • TAS-20-DIF: overweight > normal weight ($p = 0.004$)

					• TAS-20-EOT: overweight > normal weight ($p = 0.009$)
Doba et al. (2018)	451	0	BVAQ	EDI	• Alexithymia strongly mediates the relationship between a low level of self-differentiation and ED symptoms
Giles et al. (2020)	401	0	TAS-20	EDE-Q	• TAS-20-DIF predicted ED's symptomatology ($\beta = 0.163$; $p = 0.01$)
Goetz et al. (2020)	151	26	TAS-20	EDE-Q	• Alexithymia appeared to play a role in increasing difficulties in modulating emotional and behavioral responses under stress conditions that could lead to ED symptoms
Obeid et al. (2021)	787	32.4	TAS-20	ORTO-R and EAT-26	• A higher level of orthorexia nervosa appeared to correspond higher level of alexithymia ($p < 0.05$) • Alexithymia did not seem a feature of orthorexia per se; other dimensions such as emotion dysregulation have an impact on the disease
Perry and Hayaki (2014)	201	40	TAS-20	BULIT-R	• In both samples, BN symptoms were positively associated with alexithymia (for males $p < 0.001$ and females $p < 0.05$)

(continued)

Table 2 (continued)

Author, year	Sample (size, type)	% Males	Measure of assessment		Main results
			Alexithymia	Eating disorder	
Strodl and Wylie (2020)	332	7.2 and other gender 5.7	TAS-20	TFEQ-R21	• There were no indirect effects between childhood trauma and disordered behaviors through TAS-DIF and TAS-DDF • All eating behaviors displayed significant bivariate correlations with DIF and DDF
Vander Wal et al. (2020)	79	0	TAS-20	EAT-26	• The women who showed higher EAT scores reported higher TAS-20 total score ($p < 0.001$), TAS-DIF ($p < 0.001$), and TAS-DDF ($p < 0.001$) compared to the ones with lower EAT score • Controlling for depression (DASS-21-D), the differences between the two groups remained statistically significant only for the TAS-total score ($p = 0.038$) and the TAS-DIF ($p = 0.004$)
Vuillier et al. (2020)	121	16.5	TAS-20	EAT-26	• Alexithymia had a full mediation effect in the relationship between autistic traits and eating psychopathology, accounting for the 18% of the effect of autistic traits on eating psychopathology
Wheeler et al. (2005)		0	TAS-20; APRQ	EHC	• Binge eating was significantly correlated with TAS-DIF ($p < 0.001$) and TAS-DDF

					($p < 0.01$) • The two alexithymia measures were weakly correlated
Clinical studies					
Abbate-Daga et al. (2013)	108: 76 AN-R and 32 AN-BP	0	Structured interview for DPCR	EDI-2	• Alexithymia was present in 54.6% of the total sample and was overrepresented in the AN-BP sample even if the difference between the two subtypes didn't appear to be significant ($p = 0.52$) • The sample was divided into three subgroups based on the severity of psychosomatic symptoms; in this case, alexithymic levels were statistically different ($p = 0.001$) with the "severe psychosomatic group" reporting the higher scores
Balottin et al. (2014)	46: 16 AN adolescents and 30 parents	0	TAS-20 and TSIA	Diagnosis of AN via DSM-IV-TR	• Parents: TSIA scores > TAS-20 scores in total and all the components of alexithymia • Daughters: TSIA total score > TAS-20 total score and TSIA EOT > TAS EOT
Brown et al. (2018)	114: 54 AN-R and 60 BN	6.1	TAS-20	Diagnosis	• No significant differences between the two subgroups in TAS-total score and all TAS subscales
Carrot et al. (2019)	150 patients and their parents	0	BVAQ-B	Short-CIDI, GOAS, EDI-2, EDDS	• BVAQ-B improved from baseline to months 12 and 18 both in the patients and parents in both single and multifamily therapy

(continued)

Table 2 (continued)

Author, year	Sample (size, type)	% Males	Measure of assessment		Main results
			Alexithymia	Eating disorder	
					• EDI-2 and EDDS scores improved from baseline to months 12 and 18 in patients in both single and multifamily therapy
Di Monte et al. (2020)	54	NI	TAS-20; TSIA	Obesity diagnosis with BMI >30	• For the TSIA: both total and all scores except DDF were significantly and positively associated with weight (total $p < 0.001$; DIF $p < 0.001$; EOT $p < 0.5$; IMP $p < 0.05$) • TAS-20 mean scores in the sample were lower than those reported in the general population ($p < 0.01$) • TSIA mean scores in the sample were higher than those reported in the general population ($p < 0.01$)
Guillén et al. (2014)	103: 58 AN, 27 BN, 18 EDNOS	7.8	TAS-20	SCID-P	• No significant differences between AN, BN, and EDNOS in alexithymia prevalence ($p > 0.94$) and TAS-20 mean scores ($p > 0.82$)
Hobson et al. (2020)	96	0	TAS-20	Diagnosis	• The continuous TAS-20 score didn't predict meeting autism criteria, while being above the TAS-20 threshold for alexithymia was predictive of meeting the criteria ($p = .04$)

					• TAS-20 score correlated significantly with the ADOS-SA ($p = 0.031$) • TAS-20 scores predicted scores on social insight measured by ADOS ($p = 0.01$), even when controlling for depression
Keating et al. (2013)	300: 109 AN, 130 BN, and 61 EDNOS	0	TAS-20	Diagnosis	• Alexithymia accounts for the relationship between attachment avoidance and body esteem
Torres et al. (2019)	125	0	TAS-20	IDED-IV	• TAS-DIF and TAS-DDF were strongly correlated ($r = 0.72$) but were two different dimensions • TAS-EOT is a salient component too
Longitudinal studies					
Caslini et al. (2015)	8: 3 AN-R, 2 BN, 3 EDNOS	0	TAS-20	EDI-2	• At the 1-year follow-up evaluation, there was no significant difference between the pre- and post-psychotherapeutic treatment
Castro et al. (2021)	48, mixed: 24 AN and 24 community	0	TAS-20	IDED-IV	• TAS-20 total score: AN > recovered AN ($p < 0.001$) • TAS-20 total score: recovered AN and HC n.s. • TAS-20-DIF: AN > recovered AN ($p < 0.001$); recovered AN > HC ($p < 0.05$) • TAS-20-DDF: AN > recovered AN ($p < 0.001$) • TAS-20-EOT: AN > recovered AN ($p < 0.01$)

(continued)

Table 2 (continued)

Author, year	Sample (size, type)	% Males	Measure of assessment		Main results
			Alexithymia	Eating disorder	
					• n.s. differences between recovered AN and HC in TAS-DDF and TAS-EOT
Courty et al. (2015)	60: 52 AN-R and 8 AN-BP	0	TAS-20	EDI	• Higher levels of symptoms remained associated with higher alexithymia over 18 months, even if the strength of the association decreased across time • Higher alexithymia predicted more symptoms during treatment • After 18 months, the mean score on the TAS-20 was still higher than the control populations from the literature • The TAS-20-EOT scores were relatively stable from baseline to 18 months
Glisenti et al. (2018)	6 BED	0	TAS-20	SCID-I; BES; EDEQ	• After emotion-focused therapy, the median posttreatment score ranks were not statistically lower than pretreatment neither for the TAS-20 total score nor for the subscales
Harrison et al. (2020)	12: 3 AN-BP and 9 AN-R	8.33	TAS-20	EDE-Q	• Individual Cognitive Remediation and Emotion Skills Training for Adolescents: TAS-20 total score: before treatment > after treatment ($p = 0.01$; $d = 0.62$)

					• Group Cognitive Remediation and Emotion Skills Training for Adolescents: TAS-20 total score: before treatment > after treatment ($p = 0.01$; $d = 0.65$) • EDE-Q didn't decrease both in individual and group format after treatment
Larsson et al. (2020)	29: 4 AN, 9 BN, 9 atypical AN, 3 atypical BN, and 4 unspecified ED	0	TAS-20	EDE-Q	• After treatment, TAS-20 total score was reduced ($p < 0.001$; $d = 0.75$) • After treatment, EDE-Q total score improved ($p = 0.009$; $d = 0.33$)
Meneguzzo et al. (2021)	100: 53 AN, 36 BN, and 11 BED	0	TAS-20	EDE-Q	• The three groups show different levels of TAS-20 total scores ($p = 0.02$) • Of the 67 patients who completed the treatment, 48 were above the cutoff score for the TAS-20, and 19 were below • The high alexithymic group showed an improvement posttreatment ($p < 0.001$). However in this group, the scores remain clinically significant
Milos et al. (2021)	50: 42 AN-R and 8 AN-BP	N.A.	TAS-20	EDEQ	• Comparing AN with non-restored weight and AN weight-restored, the first group reported a smaller volume in the crus I of the right cerebellum

(continued)

Table 2 (continued)

Author, year	Sample (size, type)	% Males	Measure of assessment		Main results
			Alexithymia	Eating disorder	
					• It appeared that to lower volume in this region, corresponded higher alexithymia scores
Savidaki et al. (2020)	14: 7 to dance movement therapy and 7 in the control group	0	TAS-20	Diagnosis	• The sample who underwent dance movement therapy reported a slight tendency of decrease in TAS-total score and subscales (n.s.). The control group showed a tendency to increase TAS scores (n.s.)
Shank et al. (2019)	200	46	Alexithymia Questionnaire for Children	EDE interview	• Alexithymia was associated with loss of control eating ($p = 0.01$) and with eating-related psychopathology ($p = 0.01$)
Torres et al. (2020)	7	0	TAS-20	IDED-IV and DEBQ	• The major changes after an emotion-focused CBT occurred in the TAS-DIF
Vrieze (2018)	53: 29 AN and 24 BN	0	TAS-20	EDI-3	• TAS-total score: BN > AN ($p = 0.014$) • ANs with the high level of alexithymia and AN with the low level of alexithymia reported differences in posttreatment ED pathology (high alex > low alex; high, M = 44, SD = 8.93; low, M = 30, SD = 2.52) • BNs reported no differences in posttreatment pathology across levels of alexithymia ($p = 0.07$)

effect sizes for participants diagnosed with AN (of both types almost equally), $d = 1.44$, or BN, $d = 1.26$. Instead, the comparison including individuals diagnosed with BED revealed a medium effect, $d = 0.76$. Moreover, the mean difference between anorexic participants and controls showed large effect sizes in DIF and DDF dimensions, $d = 1.57$ and $d = 1.11$, and small effect size in the EOT dimension, $d = 0.48$. However, this small difference in EOT scores disappeared in the AN-restrictive-type group, suggesting that it would be present between only in AN purging-type patients and controls, but the paucity of studies reporting dimension scores in this last type of AN patients prevented Westwood et al. (2017) to make the analysis necessary to confirm this hypothesis. Concerning differences between BN patients and controls, large effect sizes for both DIF ($d = 1.58$) and DDF ($d = 0.89$) were found, and no difference on EOT, in line with Nowakowski et al. (2013). Regarding BED patients, only two studies (Aloi et al. 2017; Pinaquy et al. 2003) provide information on differences in subdimensions, so Westwood et al. (2017) were not able to analyze mean differences.

The current search revealed that after Nowakowski et al. (2013), from 2013 to 2021, six case-control studies were published on this topic.

All the studies employing the TAS-20 confirmed the conclusions of the previous reviews, reporting statistically significant higher levels of total alexithymia, DIF, and DDF in ED patients than in nonclinical controls (e.g., Nalbant et al. 2019; Kerr-Gaffney et al. 2020). This case-control difference was also significant when the clinical sample was composed by participants diagnosed with BED and eating disorder not otherwise specified (EDNOS) (Rozenstein et al. 2018) and remained significant even when the ED symptoms and alexithymia of the patients decreased after treatment (Castro et al. 2021). Only one study (Guiducci et al. 2018) used the OAS (Haviland et al. 2000) – fulfilled by ED patients' parents – together with the TAS-20, confirming that girls with ED showed higher levels of alexithymia, DIF, and DDF than nonclinical ones in the TAS-20, as well as in the total score and several subdimension of the OAS.

Findings in Cohort Studies with Community Samples Showing ED Symptoms

Nowakowski et al. (2013) synthesized those nonclinical adolescents and adults showed more eating disorder symptoms (e.g., binge eating attitudes, excessive dietary restriction, or compensative behaviors such as purging or exercise) along with more alexithymia. Specifically, higher scores in DIF and DDF were related to more ED symptoms, while the factor EOT was not, in line with results in case-control studies. The unique exception was for orthorexic behaviors, related to all alexithymia dimensions including the EOT (Obeid et al. 2021).

Findings of further research retrieved for this review mainly confirmed these associations (see Table 1). For example, Benau et al. (2020) found high levels of

alexithymia in athletes showing eating-disordered behaviors and also reported gender differences in terms of more relations with the factor DIF in men and with DDF in women. Biolcati et al. (2021) found higher alexithymia levels in a subgroup of nonclinical adults who surpassed the cutoff score for a clinical risk of EDs, compared to those not at risk.

Moreover, in a study by Casagrande et al. (2020), overweight individuals without ED diagnoses showed higher scores of alexithymia, DIF, and EOT than normal-weight ones.

As exceptions, two studies did not find differences in alexithymia between groups of community adolescents with or without binge eating attitudes (Pace et al. 2021) and adults (Boscoe et al. 2021) at risk for EDs and not at risk, after a cutoff-based screening.

In addition, some studies investigated the predictive role of alexithymia in increasing ED symptoms. Specifically, Giles et al. (2020) found that higher levels of DIF alone predicted 16% more ED symptoms, while other studies found that alexithymia moderated the impact of other conditions, by increasing the vulnerability to ED symptoms in the case of autistic traits (Vuillier et al. 2020), or of women with a history of childhood abuse or neglect (Mazzeo and Espelage 2002), and adolescents showing low self-differentiation (Doba et al. 2018).

Findings from Clinical Samples: Alexithymia Differences According to AN and BN Diagnosis

Nowakowski et al. (2013) concluded that individuals diagnosed with anorexia seemed to show higher alexithymia than those diagnosed with bulimia, and also Westwood et al. (2017) results seem to suggest a difference in alexithymia between AN and BN patients. Indeed, this meta-analysis found case-control differences in all alexithymia subdimensions in anorexic patients compared to nonclinical participants, while bulimic patients did not differ from healthy controls in EOT, although a meta-analytic comparison concerning alexithymia levels between AN and BN patients was not performed up to now.

Moreover, further research here reviewed on this topic report contrasting results. Opposite to Nowakowski et al. (2013)'s hypothesis, Vrieze (2018) reports more alexithymia in bulimic than in anorexic patients and a different impact of alexithymia on treatment outcomes (significant in anorexic patients but not in bulimic ones; see below). Brown et al. (2018) did not find any difference in alexithymia total and subdimensions scores between AN-R and BN patients, and Guillén et al. (2014) also did not find significant differences in prevalence and scores of alexithymia of patients diagnosed for AN, BN, or eating disorders not otherwise specified.

Longitudinal Findings and the Impact of Alexithymia on ED Treatment Outcomes

The findings on the impact of alexithymia on ED treatment outcomes are controversial. On the one side, Nowakowski et al. (2013) reported that different emotion-oriented treatments reduced alexithymia levels of ED patients with different diagnoses, but it was unclear whether the reduction of alexithymia has beneficial effects in reducing ED symptoms. On the other side, a specific systematic review on therapeutic implications of alexithymia in eating disorders (Pinna et al. 2015) concluded that higher alexithymia was related to higher dropout and poorer treatment outcomes in ED patients benefiting from different types of intervention (e.g., group or individual psychotherapy); therefore it could be a crucial treatment target. More in detail, findings from longitudinal studies revealed that higher alexithymia at baseline predicted worse treatment outcomes in patients diagnosed for AN (Speranza et al. 2011), BN, BED, and EDNOS (Balestrieri et al. 2013; Leweke et al. 2009), especially in case of higher scores of DIF and DDF. In particular, in the study covering the longer period (i.e., 3 years), Speranza et al. (2011) found that more alexithymic AN and BN patients were more likely to receive more treatment, antidepressants, and be rehospitalized, regardless of the type of diagnosis. In other studies (Becker-Stoll and Gerlinghoff 2004; de Groot et al. 1995; Schmidt et al. 1993), the alexithymia level at baseline was not influential, but the level of alexithymia during the period of the treatment influenced the outcomes, as less alexithymic patients showed more improvements concerning ED symptoms, that persisted longer posttreatment even if the length and the type of the treatments in these studies were different (multimodal, cognitive-behavioral, psychodynamic, etc.). Moreover, in the studies documenting variation of alexithymia levels during the treatment, the persistence of high levels of alexithymia after treatment negatively influenced the improvements in terms of reduction of ED symptoms, both in adults (Schmidt et al. 1993; Becker-Stoll and Gerlinghoff 2004; Iancu et al. 2006) and in adolescents (Ohmann et al. 2013), the latter also showing higher dropout tendency.

The few studies retrieved in the current review, not included in previously cited reviews, did not seem to solve these controversies.

First, Vrieze (2018) reported countercurrent results, founding more positive posttreatment outcomes in AN patients who showed more alexithymia at baseline, and no differences associated with alexithymia levels in BN patients. Second, examining the efficacy of emotion-focused treatments, contrasting results suggested different associations according to patients' age group. Indeed, Harrison et al. (2020) suggested that the reduction of ED symptoms was independent of alexithymia variations in adolescents, as alexithymia but not ED symptoms decreased after both individual-based and group-based CREST interventions in AN teenagers. Differently, Larsson et al. (2020) found a reduction in both alexithymia and ED symptoms in adult females with different ED diagnoses, treated with a mixed intervention based on Emotion Regulation Group Therapy, Unified Protocol, Dialectical Behavior Therapy, and Acceptance and Commitment Therapy. Similarly, Castro et al. (2020) and Torres et al. (2020) observed a decrease of both ED

symptoms and alexithymia during a treatment. Lastly, Goetz et al. (2020) highlighted an indirect role of alexithymia, which could lead to ED by increasing the difficulties in modulating emotions and behavioral responses under stress conditions, directly related to ED symptoms.

The Longitudinal Variation of Alexithymia: Does It Have an Effect?

From the above, readers can note that several authors have tried to link the results of the treatment for ED to observed longitudinal variations of alexithymia, without reaching consensus. Both in previous reviews and the current research, few studies documenting longitudinal variations of alexithymia were studies on ED treatment outcomes, and none of them aimed to investigate the variation of alexithymia per se.

Specifically, Westwood et al. (2017) detected only one longitudinal study responding to their inclusion criteria (Speranza et al. 2011), which documented a decrease in alexithymia levels of anorexic patients over 3 years. Including all diagnoses of ED, Pinna et al. (2015)'s review found other 11 longitudinal studies (Balestrieri et al. 2013; Becker-Stoll and Gerlinghoff 2004; Ciano et al. 2002; Clyne et al. 2010; de Groot et al. 1995; Iancu et al. 2006; Leweke et al. 2009; Ohmann et al. 2013; Schmidt et al. 1993; Shiina et al. 2005; Storch et al. 2011), for a total of 12 studies up to 2015, all employing the TAS-20. Later, Gramaglia et al. (2020) performed another review on treatment outcomes in AN, including other six studies not included elsewhere (Adamson et al. 2018; Elzakkers et al. 2017; Giombini et al. 2019; Leppanen et al. 2018; Lundbad et al. 2014; Tchanturia et al. 2015).

Despite not being focused on alexithymia variation, the findings of these longitudinal studies led all authors of the cited reviews (Nowakowski et al. 2013; Pinna et al. 2015; Gramaglia et al. 2020) to note that alexithymia levels can decrease after psychological treatment, even if the target of the treatment is ED symptoms. Indeed, with rare exceptions (Ohmann et al. 2013; Schmidt et al. 1993; Shiina et al. 2005), most of these studies found a decrease of alexithymia levels after 9.6 to 40-week intervention of different types, such as individual or group psychotherapy (e.g., CREST), or psychoeducational, or multimodal (e.g., combining cognitive-behavioral and psychodynamic therapeutic approaches with hospitalization).

This alexithymia's decrease has been observed also by three studies retrieved for the current review, both in AN and BED adults (Castro et al. 2021; Torres et al. 2020) and in ED adolescents (Harrison et al. 2020). Torres et al. (2020) also observed a particular reduction in DIF levels among BED patients. However, the other two studies retrieved for the current review suggest the stability of alexithymia in ED patients (Courty et al. 2015; Meneguzzo et al. 2021). Moreover, employing the BVAQ, Courty et al. (2015) report still significantly after-treatment higher levels of alexithymia in AN patients compared to controls, which aligns with a common observation by the authors of the cited reviews that the levels of alexithymia tend to remain high in ED patients, even after a posttreatment reduction (Nowakowski et al. 2013; Pinna et al. 2015; Gramaglia et al. 2020).

Altogether, literature results suggest that alexithymia is not a completely stable personality trait, but is nonetheless highly resistant to change in adult ED populations. This calls for specific and well-directed efforts to reduce alexithymia in ED patients, considering the additional obstacle posed by the heterogeneity of treatments leading to an alexithymia reduction, which makes it difficult to isolate the more efficient for this goal.

Therapeutic Implications and Applications

Speranza et al. (2011) explored the role of alexithymia in predicting AN and BN patients treatment options, documenting that when alexithymia is high at baseline, the patient is more likely to receive more and constant treatment of all types (psychological, pharmacological, hospitalization), while patients showing alexithymia only posttreatment are more likely to be hospitalized, recurring to psychotherapy irregularly. This suggests that considering the alexithymia profile of ED patients can help to forecast what and how frequently they will require treatment. For this purpose, a mixed-method approach or at least observed-rating measures like the OAS or the TSIA (Bagby et al. 2006) would be preferable to self-rating scales such as TAS when alexithymia is assessed in ED patients, in agreement with Westwood et al. (2017) comments. Indeed, these methods would allow controlling effects of social desirability and comorbid conditions of depression and anxiety, which are suggested as influential in some studies (Eizaguirre et al. 2004; Gilboa-Schechtman et al. 2006; Giles et al. 2020).

Moreover, a proper suggestion for professionals working in the eating disorders field would be focusing on evaluation and intervention on the dimensions of difficulty in identifying feelings (distinguishing them from bodily sensations) and describing them verbally more than on the dimension of externally oriented thinking, which does not appear crucial in ED patients (Müller et al. 2003). Besides, particularly in AN patients, these two crucial dimensions DIF and DDF may show different mechanisms of action (Torres et al. 2019), suggesting their separate evaluation in case of anorexia.

Further, Gramaglia et al. (2020) found individual rather than group conditions as beneficial, whereas a professional would employ the CREST treatment. Besides, regardless of the individual or group condition, Harrison et al.'s (2020) results may suggest considering also the patient's age group when an alexithymia-oriented intervention would be designed. When the ED patient is an adolescent, the intervention of the patient's alexithymia alone may not be enough, and the family should be involved as well. Indeed, different studies documented higher levels of alexithymia in parents of anorexic girls (Balottin et al. 2014; Guiducci et al. 2018; Pace et al. 2015), with Carrot et al. (2019) documenting significant reductions of alexithymia in both parents and anorexic daughters in case of family therapy, and Duclos et al. (2014) report beneficial effects of the involvement of parents (particularly of the father) in intervention on anorexic daughter's symptoms reduction.

Limitations and Future Lines of Research

The meta-analysis by Westwood et al. (2017) has highlighted that differences in alexithymia scores between AN patients and controls are more marked in acute stages of the anorexic disorder course and at older ages when patients are deemed to have suffered from anorexia for longer or would have more likely shown comorbidities (e.g., of depression, obesity). Given later studies confirmed these observations (Castro et al. 2021; Torres et al. 2019, 2020), this calls for future research to understand if an alexithymia treatment may be more or less beneficial in these specific conditions, especially because certain types of treatment accounted for heterogeneity in alexithymia among ED patients across studies in Westwood et al. (2017). Further, the effects of alexithymia in EDs can be moderated by other factors, such as depression, anxiety, attachment (Pace et al. 2021), perfectionism (Ruggiero et al. 2011), as well as certain parental characteristics, firstly the parental levels of alexithymia, and attachment states of mind (Balottin et al. 2014; Pace et al. 2015).

Another point deserving more investigation concerns the consequences of treatment of alexithymia on ED symptomatology. Most interventions tested (e.g., Becker-Stoll and Gerlinghoff 2004) showed efficacy in decreasing the levels of alexithymia, but the consequences of such decrease on EDs are not clearly defined, and they should be tested in the future follow-up or other longitudinal studies. Moreover, Beadle et al. (2013) report that alexithymia of AN patients decreased as weight increased during the treatment, suggesting that there is not a single direction in which alexithymia affects ED symptoms, but also the opposite, and this should be further investigated in its implications. In this regard, more research on specific alexithymia-oriented interventions should be tested on ED patients or in the case of subclinical symptoms, maybe considering also family dimensions or intervention, e.g., on parental alexithymia (Pace et al. 2015), as well as setting-related variables such as the therapeutic alliance (Sarracino et al. 2013).

Moreover, not surprisingly clinical studies involved almost exclusively females, with rare exceptions (e.g., Harrison et al. 2020; Leweke et al. 2009; Shiina et al. 2005), but especially research on nonclinical samples would improve efforts to involve males, as useful to underline mechanisms of risk and onset and eventual gender features that protect males from both EDs and alexithymia impact on them. This would be particularly preventive from an intergenerational point of view, given the father's role in anorexic daughter's symptoms (Duclos et al. 2014).

Another critical consideration regards the almost exclusive use of the TAS among studies. Despite that this instrument well operationalized the current shared definition of the multidimensional construct of alexithymia, many authors raised doubts on its content and discriminant validity (e.g., with anxiety and depression; Honkalampi et al. 2010; Deno et al. 2011) and its efficiency regardless of the level of psychological distress (Marchesi et al. 2014; Preece et al. 2020). Even beyond the methodological limits, if the research is done entirely with the same tool, the possibility of finding discordant ones is reduced, on which much of scientific progress is based. Many questions raised by this and other reviews could be enriched by future research

employing a broader range of assessment methods for alexithymia, such as the mentioned OAS, B-VAQ, and TSIA or the Perth Alexithymia Questionnaire (Preece et al., 2018) and the Alexithymia Questionnaire for Children (Rieffe et al. 2006; Di Trani et al. 2009) for children and adolescents. Also, Balottin et al. (2014) found discordant results in AN adolescents and parents employing the TAS-20 and the TSIA, suggesting a mixed-method approach as fruitful to achieve nuanced and fruitful results.

Lastly, as a common practice, only documents in English have been screened in the current and cited reviews, neglecting studies written in other languages, which may have included suggestions to dispel remaining doubts.

Conclusions

Although many fruitful efforts have been made to prove the high alexithymia in ED patients or at-risk non-diagnosed, this review has revealed that there are still many points to be clarified. Specifically, eventual differences in alexithymia according to ED diagnoses and the direct or indirect impact of alexithymia on treatment outcomes are still unclear, so that it is it seems premature to confirm that an alexithymia-oriented intervention may be beneficial for reducing ED symptoms, despite some promising results. Lastly, further efforts are needed to clarify the influence of gender, age, and other moderators on the relationship between alexithymia and eating-disordered behaviors.

Mini-Dictionary of Terms

- **Primary alexithymia**. Type of alexithymia that occurs during the development, due to adverse experiences and failures in the primary relationships with caregivers. For a child, the bodily sensations (e.g., hunger) and the different emotions are undifferentiated, and they are all potentially fearful because he/she does not understand or differentiate them. In the beginning, the caregiver discriminates and names the different physiological and emotional states for the child, reducing the child's fear associated with them during daily dyadic interactions. If this interpersonal process works, the child will later be able to do it on his/her own. If this process fails, bodily and emotional states remain undifferentiated and a source of fear for the child, who is more likely to show more alexithymia later.
- **Organic alexithymia**. Type of alexithymia due to organic causes, such as damages in brain areas involving in emotional processing (i.e., anterior cingulate cortex, corpus callosum, basal ganglia, and right hemisphere).
- **Secondary alexithymia.** Type of alexithymia consequence of an illness, or surgery, or medical conditions (e.g., decreased oxygen tension) which have effects on brain functioning and emotional processing.

- **Narrative review.** Type of literature review including a critical, objective, and comprehensive analysis of the existing knowledge on a topic. It is particularly helpful to identify current trends, gaps, or incongruences in the literature through an objective critic of limitations and possible future directions of research.
- **Systematic review.** Rigorous type of literature review, aiming to examine all the existing literature around a clearly defined research question. It aims to synthesize the current knowledge highlighting commonalities among studies. The process of literature search, screening, exclusion, and analysis are rigorously documented.
- **Meta-analysis.** An optional part of a systematic review is a secondary research tool aiming to statistically summarize data from different studies on the same topic.
- **Case-control study.** An observational study that compares on a defined outcome two groups differing on a supposed causal attribution (e.g., clinical versus healthy individuals).
- **Longitudinal study.** A study where one or more variables is/are observed over an extended period in the same group of participants.
- **Cohort study.** A form of longitudinal study where it sampled a group of people sharing a certain characteristic, i.e., a cohort, to collect data on them at different time intervals.

Key Facts of Alexithymia

- At least 10% of nonclinical adults show high levels of alexithymia and more than 20% of adolescents. This percentage grows in clinical and at-risk samples (e.g., it ranges the 38 and the 85% in institutionalized adolescents).
- There are gender differences in alexithymia, and usually, females appear more alexithymic, showing more difficulty in identifying and describing feelings. Males usually show more externally oriented thinking.
- The alexithymic dimensions of difficulty in identifying feelings and difficulty in describing feelings seem to be higher in teenagers. As teenagers get older, these dimensions tend to decrease, becoming more stable around the 30 years of age.
- Alexithymia appeared to be a transdiagnostic risk factor for a conspicuous number of health problems, such as diabetes, somatoform diseases, depression, suicidality, and anxiety.
- Alexithymia could be considered as a trait, being developmental and emerging during childhood or early adult years (primary alexithymia), or as a state, emerging at any time in life after a stressful situation or trauma (secondary alexithymia).
- Although many types of psychotherapy could help an individual to improve emotional awareness, decreasing alexithymia, specifically alexithymia-oriented treatments are still lacking.

Summary Points

- Patients diagnosed with an eating disorder (of all types) show higher levels of alexithymia compared to healthy controls without a diagnosis.
- The existence of differences in alexithymia between ED patients with different diagnoses is still not clear.
- Longitudinal studies found a decrease of alexithymia after psychological treatment, without identifying one more efficient than others for this scope.
- Findings on the impact of alexithymia on outcomes of treatments to reduce eating disorder symptoms are controversial. Few studies investigate the predictive role of alexithymia on ED treatment outcomes, with contrasting findings.
- The investigation of the connections between alexithymia and eating disorder should be implemented, particularly involving males from the community population for preventive utility.

Contents

Abstract

Previously published evidence assess the Quality of Life (QoL) in people with eating disorders (EDs). In past decade with increasing interest in healthy aging, vegan and vegetarian food diets, as well as increased awareness of autoimmune protocol in eating, this has been subject to considerable research interest. The World Health Organization defines QoL as "an individual's perception of their

position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards and concerns." It is a multidisciplinary construct that includes perceptions about various aspects of life, including physical, psychological, social, and emotional domains.

QoL measures are beginning to be recognized as a key patient-oriented measure of outcome. As previously observed, studies in EDs have indicated significantly reduced QoL in this patient group, to a degree that is comparable with QoL findings in various other serious illnesses and disorders, such as angina and anxiety disorders. What is highly noticeable from the published evidence is that mental health of the individuals with EDs seems to be particularly impaired.

It remains unclear how specific symptoms and behaviors associated with EDs impact on QoL and further discussions are needed.

Introduction

Eating disorders (EDs) present a type of serious mental health conditions that are divided into several categories. These categories include anorexia nervosa (AN) (Fig. 1), bulimia nervosa (BN) (Fig. 2), binge eating disorder (BED) (Fig. 3), and other specified feeding and eating disorders (OSFED) (Fig. 4). To the previously mentioned four EDs, two more should be added, which are attracting particular attention nowadays – avoidant/restrictive food intake disorder (ARFID) and unspecified feeding or eating disorder (UFED). This category of disorders is known by its serious and persistent problems in eating accompanied by disturbing thoughts and emotions. Early signs of an ED can also be behavioral, physical, or psychological. People who suffer from some form of ED usually eat restrictively, avoid certain foods, overeat, purify themselves by vomiting, abuse laxatives, or exercise compulsively. It is important to underline that there are very frequent variations in body weight, fatigue, and poor concentration, as well as the lack of

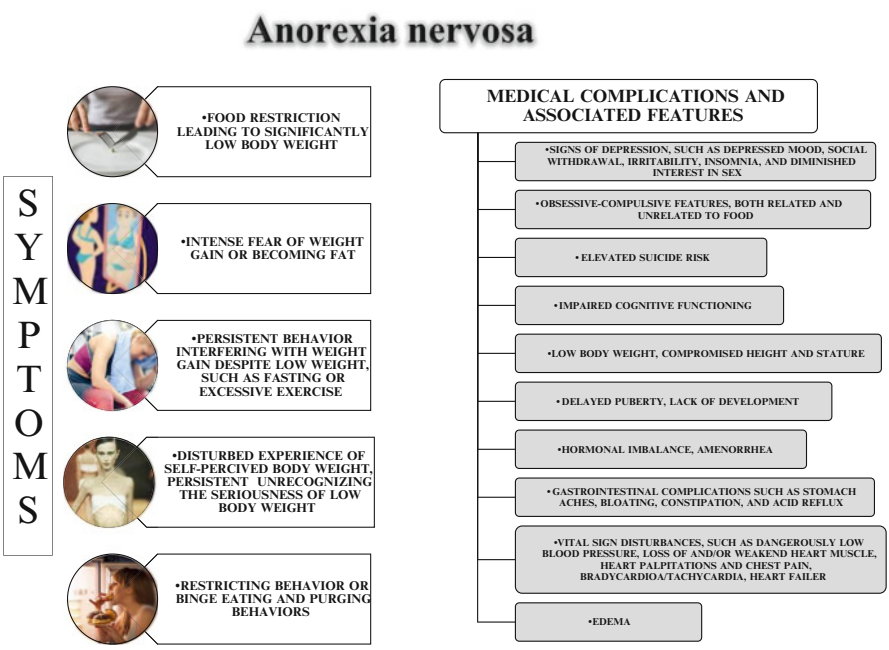

Fig. 1 Anorexia Nervosa: Symptoms and medical complications and associated features

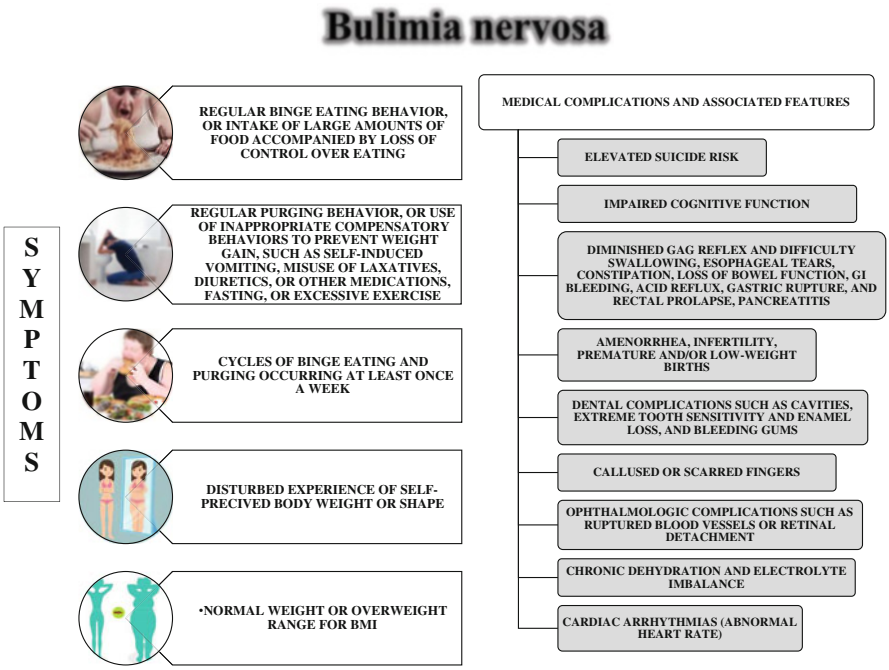

Fig. 2 Bulimia Nervosa: Symptoms and medical complications and associated features

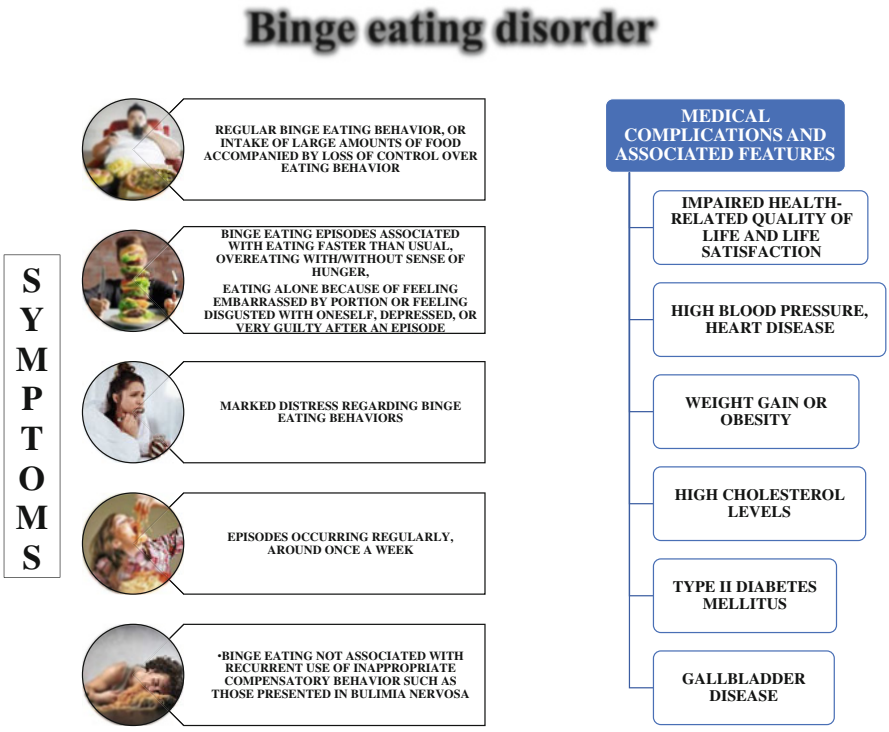

Fig. 3 Binge eating disorder: Symptoms and medical complications and associated features

energy to perform normal daily duties. The mentioned behaviors are manifested and repeated on a daily basis and that is why it even belongs to some kind of addiction (Walsh et al. 2020).

General Characteristics of EDs

It is often overlooked that EDs are actually very serious and potentially fatal diseases. When a person is preoccupied with food, their own weight, appearance, and body shape, it should arouse our suspicion that this may be the very beginning of this disorder (Treasure et al. 2010).

Globally, 5% of the population is affected by some form of ED. At first glance, it seems like a small number, but it is mostly harming young people, more precisely teenagers and adolescents who are already vulnerable due to increased maturing process. The estimations indicate that about several million people suffer from an ED at any given time. EDs can occur at any time of life and affect both men and women. However, they occur with a higher frequency in the female population between the ages of 12 and 35. In fact, it is anticipated that the number of people with ED is growing day by day for several reasons. EDs are a response to stress most often, so it

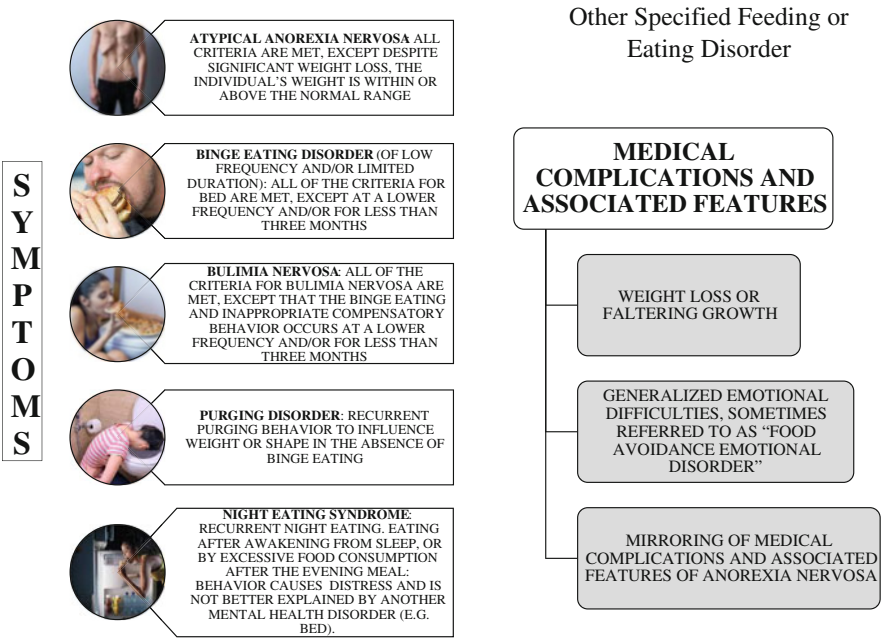

Fig. 4 Other specified feeding or eating disorder: Symptoms and medical complications and associated features

is not unexpected an increase in the number of the patients during the pandemic. Physicians are lately becoming more aware of the whole spectrum of the diseases that are under the category of EDs. On the good side, young people are more informed and seek help (Waller et al. 2014).

However, the causes of eating disorders are not fully understood, and perhaps additional understanding and research would help further understand the relationship between EDs and the QoL they lead. So far, the researchers have established that there is not just one cause but a whole range of aspects that are recognized so far: biological, social, psychological, and interpersonal causes. Equally important are the causes that lead to persistence of eating problems, given that EDs develop over a longer period of time, often several years (Currin et al. 2005).

For a better understanding of all EDs, it is very important to know the causes, clinical manifestation, therapeutic approach, and also the QoL they perceive. Each of the mentioned aspects equally contributes to that overall picture of how an ED affects an individual. Numerous analyses and studies have been done to show that people with an ED, of all subtypes according to the classification, lead a lower QoL than the control group, in this case people who do not have any subtype of eating disorder. Also, the same conclusions were reached when comparing with other psychiatric diseases. Poor QoL extends throughout the ED group regardless of the subtype the person suffers from, but it has been observed that people with BED report the worst QoL (Engel et al. 2009; De LA Rie et al. 2005; Jenkins et al. 2011).

Comorbidities of ED

It is very rare to see a person who has an isolated ED. Most often, in addition to ED, a person also has a mood disorder, anxiety disorder, or some other psychiatric illness.

Mental impairment of AN and BN patients varies. Comorbidity with affective disorders is found in AN patients. Comorbid affective disorders, anxiety disorders, substance-use disorders, and cluster B personality disorders are found in BN patients. As already mentioned previously in the text, complaints of patients with EDs includes preoccupation with food, shape, and weight and low self-esteem, but they also include body dissatisfaction, depression, and (social) anxiety.

In addition to psychological comorbidities, individuals can have a number of physical complications, may be exposed to emotional stress, poor social relationships, social isolation, and may have a poor QoL globally. The data show that in the group of psychiatric diseases, in the group of people with an ED, there is the highest risk of early death. On one side, this is precisely because of physical complications such as malnutrition, and on the other psychiatric disorders such as suicide (Weigel et al. 2016).

Relationship Between QoL and ED

Like many others serious psychiatric illnesses, ED directly affects the QoL and drastically impairs it. They can leave a deep negative impact on the life of an individual. The problem is not only based on the severity of these disorders but also on their duration. It should be emphasized that sometimes it takes a long time until the sick person gains insight into their condition and seeks for help. In the past, physicians also had difficulties to recognize the disorder in time and start with adequate therapy, but today a slight shift has been noticed in that aspect as well (Hay and Mond 2005; Padierna et al. 2000).

When it comes to predictive factors, studies have shown that organic or psychiatric comorbidities can have a much greater impact on the QoL on people diagnosed with EDs than age, BMI, psychiatric therapy, suicide attempt, or the number of emergency hospital visits.

An increasing number of studies have shown a need for specific measures of QoL, as well as that future research should measure comorbid anxiety and mood disorders as part of the assessment of the QoL of people with some of the EDs (DeJong et al. 2013; van Furth et al. 2016). Also, the question arises as to what are the factors that affect the length of the recovery itself and whether there are certain factors that indicate that a complete recovery will occur. The focus of further research could be to determine predictive factors for physical and mental aspects of QoL within AN, BN, and other eating disorders.

Taking into account the spectrum of damage that EDs bring with them, it is difficult to separate and especially underline which aspect is most affected. When we talk about physical impairments or medical complications that almost always accompany EDs, they are usually the result of disorders in eating and abnormal

compensatory behaviors such as self-induced vomiting or laxative abuse. People who have AN are malnourished, light body weight and, as a rule, have reduced bone density. Such bones are weak, brittle, and easily breakable with minimal trauma. Malnutrition directly affects the growth and development of children, the growth slows down. People are tired, listless, with a tendency to withdraw, a lack of energy for daily life obligations. They are very often ill and so they often miss school, everyday social activities, and in the end they feel alone, isolated, and excluded from social stories and currents. All this is reflected in professional life, changed interpersonal relationships, as well as family relationships.

Relationship Between System of Organs and EDs

Beside the mind and mental functions of the organism, the cardiovascular system, reproductive system, and urinary system, especially the kidneys, are also affected. People suffering from AN are at increased risk of developing arrhythmias and premature and sudden death. Anorexia nervosa is considered by many to be the most deadly psychiatric disorder. It is often underestimated that fat deposits have their physiological function, they are not necessarily something bad. Fat cells play a role in the production of hormones, both in women and men. A few fat cells will not be able to produce enough estrogen in women, or testosterone in men, which directly affects their reproductive function. Not everything is in hormonal disbalance, but also in the lack of vitamins, minerals, and proteins, together with the lack of hydration, which all together affect the reproductive system as well as all other organs and organ systems (Treasure and Schmidt 2005).

Special attention should be paid to reproductive health in both people with AN and people with BN. Studies have shown that EDs have a negative impact on the ability to stay pregnant. Also, it has been shown that this negative impact extends for years after the disease is in remission, which means that the negative impact is not exclusively related to the active and current form of the disease. Also, there is a higher chance that a person who suffers or had suffered from an ED will develop problem with the fertility. Considering the fertility and the possibility of conception, many medical professionals tend to only consider the potentials and health of females, while it is often forgotten that men who suffer from some form of ED are not spared. Irregular menstruation or even complete absence of the menstrual cycle for several months usually occurs in girls. With irregular menstruation comes ovulation disorder and therefore it is much harder for a woman to get pregnant. Studies have shown that women with low BMI, women who consume calories restrictively, or exercise excessively have some of the menstrual cycle disorders (Westmoreland et al. 2016) (Fig. 6).

Physical damage can also be expected in people with BN, if we know that the basis of this ED is overeating and then vomiting. That is why the most common changes are at the level of the upper parts of the digestive tract. The esophagus and stomach are most often affected, and sometimes problems with teeth also occur (Forney et al. 2016).

We can expect problems with digestion; due to provoked vomiting, the esophageal sphincter can be weakened, which can lead to gastroesophageal reflux disease, the acid returns from the stomach back to the esophagus. Stomach acid can also return to the laryngopharynx when coughing, hoarseness, sore throat, and dysphagia occur. Constant abdominal pain, bloating, and sometimes diarrhea or constipation may occur. A large number of stools on a daily basis can lead to damage to the anal blood vessels and the appearance of hemorrhoids, as well as to prolapse of the rectum. If a person uses certain medications and means for emptying, it can go to an addiction, emptying will no longer be possible or will be difficult without the use of additional means (Sansone and Sansone 2019). In practice, the abuse of diuretics can be seen, after which there are reduced values of potassium and dehydration. Such a condition additionally damages the kidneys; if such a condition of the organism lasts for a long time, their function may fail. We must not forget that low potassium levels can lead to arrhythmia, and cases of congestive heart failure and death have been reported (Brown and Mehler 2013).

Dynamics of ED and QoL

A special problem arises with the chronicity, all the previously mentioned impairments and difficulties that people face have a great impact on the further course of their lives. It has the enormous importance of assessing the quality of their lives. Also, changes in the diet, that is, a positive change in behavior in the diet itself will directly have a positive impact on QoL. We are talking about a vicious circle because the more severe the ED is, the worse the QoL, and such way of life is not stimulating for a person who suffers from any psychiatric illness. Described way of life directly stimulates a person to keep the previous eating patterns that are bad for their health (De LA Rie et al. 2005; Bijl and Ravelli 2000).

In patients with ED as well as in former patients with ED, self-esteem contributed the most to the QoL. Improving self-esteem seems to be important for a better QoL for both groups. Self-esteem and self-acceptance can be viewed as risk factors, but also as protective, preventive factors when we talk about EDs. Everything indicates that the QoL should be assessed in order to treat and assess the outcome itself, and not only in the assessment of the symptoms that the disorder gives. Today, QoL has become widely used in medical care as a measure of disease outcome, but its use as a measure of protection in mental health is less common. When the outcome criteria for recovery from an ED include an improved QoL for patients, then the focus of treatment should be both on reducing symptoms and improving QoL. By resolving the basic psychopathological mechanisms, low self-esteem and self-acceptance can reduce the bad consequences for other life domains of people with some form of ED. Consequently, treatments and therapies are more patient-centered rather than disease-oriented. This can help improve patient-centered care and can increase patient satisfaction with care, and thus we can expect a better therapeutic response (Fairburn et al. 2003) (Fig. 5).

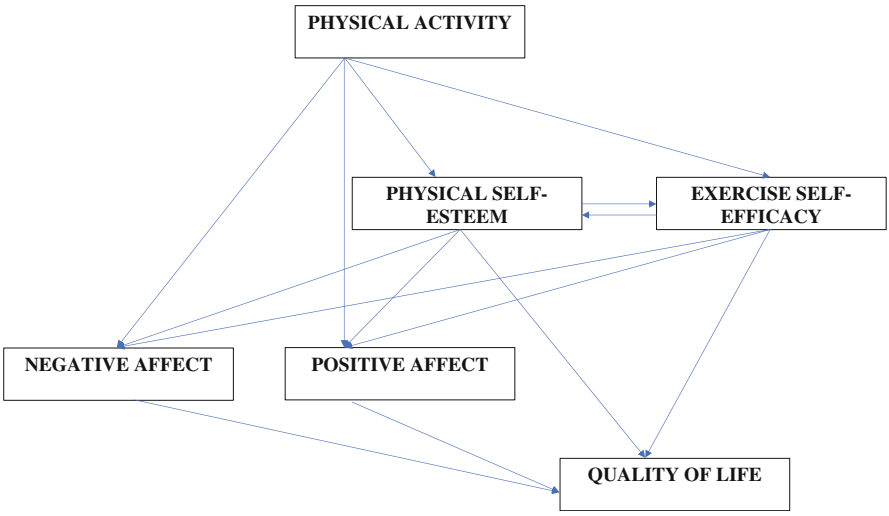

Fig. 5 Affect on quality of life

Considerations for Targeted Interventions for QoL in the Treatment of Patients with EDs

Targeted interventions that address QoL in the treatment of patients with EDs would be beneficial because improving QoL can contribute to resolution or improving symptoms. It should also be borne in mind that simply eliminating the symptoms of the disorder will not always and in every person completely solve the poor QoL reported by patients. QoL assessment is needed and should be the basis in treatment research, with a particular focus on a construct called quality of life related to health (HRQoL), which overlaps with QoL in the dimensions of physical, social, and mental health. Studies have shown that HRQoL improves after appropriate therapeutic approaches, but compared to patients with some other psychiatric illnesses (such as major depression), they were still dysfunctional. HRQoL is a multidimensional construct that reflects the degree to which an individual is healthy, comfortable, and able to enjoy life events, and should be studied with specialized psychometric tools in a particular disorder. It is significantly compromised in patients with EDs, due to the serious impact of the disorder on everyday life, and is associated with the cognitive and behavioral routines of the respondents, as well as interpersonal relationships (Meneguzzo et al. 2020). The use of general health quality of life helps to provide insight into the QoL of patient groups compared to other patient groups or the normal reference group. Whether current generic measures accurately quantify patients' QoL is a matter of debate (Carr 2001a, b; Muldoon et al. 1998) (Fig. 6).

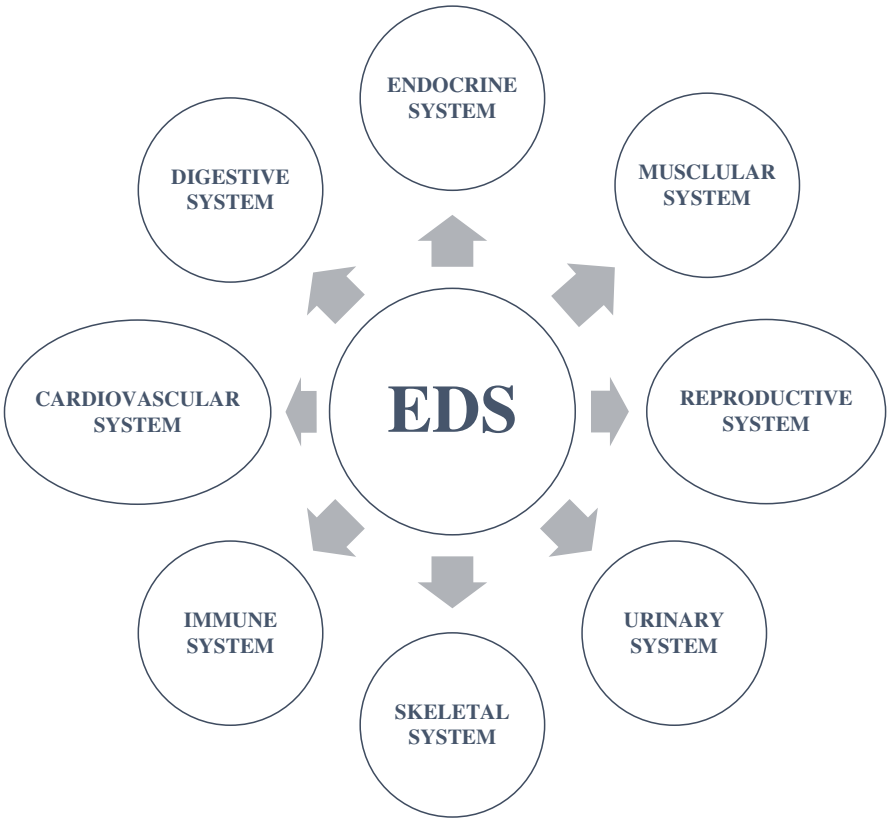

Fig. 6 Relationship between system of organs and EDs

In the large community study, they found that the QoL of ED patients was significantly worse than the QoL of the normal reference group and even worse than the QoL of patients with mood disorders, which is a great economic burden for a society. Former patients with ED continued to report poorer QoL than the normal reference group. The findings emphasize the impact of ED on physical, mental, and social well-being, even after symptom recovery. The impact of ED on QoL was even more serious than the impact of mood disorders. Self-esteem has shown the greatest association with QoL in both ED patients and former ED patients. In line with Padierna's findings, they found that severe pathology of EDs was associated with poorer QoL. One might hypothesize that although there has been a recovery in symptoms, the residual effects of the disorder may still have been manifest (Padierna et al. 2002). Beale and Ravelli found that people—with different types of psychiatric disorders—whose last psychiatric episode was more than 12 months earlier still show reduced functioning in the assessment (Bijl and Ravelli 2000).

Conclusion

QoL measures are beginning to be recognized as a key patient-oriented measure of outcome. As previously observed, studies in EDs have indicated significantly reduced QoL in this patient group, to a degree that is comparable with QoL findings in various other serious illnesses and disorders, such as angina and anxiety disorders. What is highly noticeable from the published evidence is that mental health of the individuals with EDs seems to be particularly impaired.

It remains unclear how specific symptoms and behaviors associated with EDs impact on QoL and further discussions are needed.

Mini Dictionary of Terms

- Bloating – Bloating is when your belly feels swollen after eating; it is usually caused by excess gas production or disturbances in the movement of the muscles of the digestive system.
- Chronicity – Continuing or occurring again and again for a long time.
- Constipation – Generally described as having fewer than three bowel movements a week.
- Diarrhea – Loose, watery, and possibly more frequent bowel movements.
- Fat cells – Also called adipocytes, they are connective tissue cells that have differentiated and become specialized in the synthesis (manufacture) and storage of fat.
- Hormones – Regulatory substances produced in an organism and transported in tissue fluids such as blood or to stimulate specific cells or tissues into action.
- Malnutrition – Includes undernutrition (wasting, stunting, underweight), inadequate vitamins or minerals, overweight, obesity, and resulting diet-related noncommunicable diseases.
- Menstrual cycle – During a normal menstrual cycle, the lining of a woman's uterus sheds; this cycle is part of a woman's reproductive system and prepares the body for a possible pregnancy.
- Reproductive health – Reproductive health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity, in all matters relating to the reproductive system and to its functions and processes.

Key Facts of Eating Disorders and Quality of Life

- Additional understanding of the causes of eating disorders will help us to better understand the relationship between EDs and the QoL, and for earlier recognition of the disorders.
- EDs have both physical and psychological consequences on the person.
- HRQoL reflects the degree to which an individual is healthy, comfortable, and able to enjoy life events, and it is significantly compromised in patients with EDs.

- QoL measures are patient-oriented measures of outcome.
- Comparing QoL in other serious illnesses and disorders, and in EDs we found out poor QoL in both groups.
- In the future, it should be resolved how specific symptoms and behaviors associated with EDs impact on QoL.

Summary Points

- EDs are actually very serious and potentially fatal diseases that most often affect younger population, generally women.
- EDs are multifactorial diseases, and some factors are recognized. Those factors are biological, social, psychological, and interpersonal.
- QoL is reportedly poor, and it does not depend on the ED subtype the person suffers, but the worst reported QoL is in the group of people with BED.
- Mood disorder, anxiety disorder, or some other psychiatric illness most often correspond with EDS.
- One of the main problems of the EDs are not only based on the severity of these disorders but also on their duration; sometimes it takes a long time to recognize ED both from a sick person and physicians.
- EDS affect and damage all organs and organ systems.
- Only eliminating the symptoms of the disorder will not always and in every person completely solve the poor QoL.
- Relationship between EDs and QoL can be presented as a vicious circle: the more severe the ED is, the worse the QoL, but positive change in behavior in the eating habits will directly have a positive impact on QoL.

The Role of Denial in Eating Disorder Development, Assessment, and Treatment

Contents

Abstract

Denial of disordered eating (i.e., the tendency to conceal behaviors which reflect symptoms of an eating disorder) can be conscious or unconscious, ranging from lack of insight to deliberate refusal to disclose. Accordingly, denial of disordered eating may stem from various motivations such as a defense of self, shame and stigmatization, and/or fear of intervention. Denial of disordered eating is important to study and understand because it is associated with a variety of maladaptive consequences, including interpersonal conflict, suicidality, and further disordered eating. Denial of disordered eating also poses unique challenges to the assessment

Introduction

The tendency to hide and conceal eating behaviors is common in individuals with eating disorders. In fact, most eating disorder patients deny that anything is wrong in the beginning months of their eating disorder, making denial of disordered eating a relevant construct in the field of eating disorder research, diagnosis, and treatment (Schoen et al. 2012). In this chapter, we will begin by defining denial of disordered eating, discuss the causes and consequences of denial and how to assess and treat individuals who engage in denial of illness, and discuss directions for future research.

Defining Denial of Disordered Eating

Denial of disordered eating can be considered a dimensional construct that exists along a spectrum, with lack of insight on one end and deliberate refusal of self-disclosure on the other (Konstantakopoulos et al. 2011). Lack of insight into the maladaptive thoughts and behaviors one has regarding one's body, eating, and related behaviors occurs unconsciously and refers to a lack of self-awareness and the inability to recognize that one has a mental illness (Konstantakopoulos et al. 2011). Lack of insight is often associated with a variety of mental health concerns, including psychosis, substance use, and mood, but is also a common feature of

eating disorders, one which contains clinical significance given that higher levels of insight are associated with better long-term outcomes (e.g., Greenfeld et al. 1991). To our knowledge, there is only one assessment instrument available to identify lack of insight pertaining to disordered eating (Konstantakopoulos et al. 2011), possibly because it takes awareness of a behavior or cognition to report on it, making assessment challenging. Conscious, or deliberate, denial of disordered eating may be easier to operationalize but poses its own challenges given that assessments of this kind ask participants to report on behaviors that they typically deliberately deny (Howard et al. 2020). In 1991, Vitousek and colleagues defined denial as any consciously or unconsciously motivated omission, concealment, or misrepresentation of behavior or internal experience. Recent research has adapted this definition to operationalize deliberate denial of disordered eating behaviors as any conscious omission, concealment, or misrepresentation of behavior related to disordered eating (Howard et al. 2020).

Etiology of the Denial of Disordered Eating

Individuals who experience disordered eating (i.e., behaviors which reflect symptoms of an eating disorder) may lie and conceal symptomatology for different reasons. An important distinction is made in the literature between denial in individuals who restrict food (i.e., limit the amount of food they eat) and denial in individuals who binge eat (i.e., lose control over their eating). People who restrict food may lie about disordered eating behaviors because they do not want someone to intervene on their behaviors, especially within a society that values thinness (Vandereycken 2006). For some individuals who engage in dietary restriction, their behaviors can become a part of their identity: a phenomenon known as egosyntonicity (Vandereycken 2006; Starzomska 2010). Therefore, a tendency to "fake good" and deny dietary restriction is in defense of their sense of self. This is particularly common in adolescence where we see a heightened egosyntonicity associated with identity development and decreased psychological flexibility (Fisher et al. 2001; Masuda et al. 2011). Other individuals who restrict food may deny eating disorder symptoms because their disordered eating behaviors give them a sense of self-efficacy or achievement, and they hide their behaviors from others so they will not lose this sense of control and success (Vitousek et al. 1991).

Individuals who binge eat differ from individuals who restrict their food intake in that they will more often conceal symptoms out of shame and fear of negative evaluation (Pettersen et al. 2008; Vitousek et al. 1991). Individuals who binge eat report feeling that others will view them as lacking will power and self-control (Pettersen et al. 2008). Although there may be differences in why denial is manifested in individuals who engage in different types of disordered eating behaviors, there are also some similarities, and it should be noted that eating disorders are often heterogeneous and many individuals who engage in restrictive dieting also engage in compulsive overeating. It is likely that, to some extent, individuals conceal eating disorder symptomatology regardless of specific disordered eating behavior,

because they do not want to be labeled or diagnosed with a mental illness and face stigmatization (Vandereycken 2006).

Understanding the etiology of denial may be important for identifying individualized treatment plans. For example, an individual whose symptomatology has become a part of their sense of self might engage in parts work (i.e., addressing conflicts between different parts of oneself; Schwartz and Sweezy 2020), whereas an individual who denies out of fear and shame might work on utilizing cognitive-behavioral strategies to challenge cognitive distortions (Beck 2011). Although attempts to deny disordered eating may arise from various motivations and thus have specific implications for treatment, they likely have similar deleterious impacts on relationships and eating behaviors.

Consequences of Denial of Disordered Eating

Social Consequences. One way in which the consequences of denial of disordered eating manifest is through the interpersonal impacts it has on the person and those around them. According to an interpersonal formulation of disordered eating, engaging in disordered eating behaviors can increase interpersonal problems, for example, individuals who engage in disordered eating may socially isolate to avoid intervention from others. Then, in turn, these interpersonal problems are believed to intensify disordered eating behaviors, for example, social isolation can lead to higher levels of depression and further engagement in disordered eating to regulate the higher levels of negative affect (Rieger et al. 2010). This interpersonal conceptualization of eating disorder development and maintenance emphasizes the link between disturbances of the self and the individual's perception of their social world, such that, as disordered eating behaviors increase, the way an individual views their social world becomes distorted (Wilfley et al. 2003). To date, interpersonal formulations postulate that disordered eating behaviors are ineffective strategies for regulating actual or perceived negative social evaluations (Rieger et al. 2010). For instance, the individual might attempt to escape from aversive affective states through engagement in disordered eating (Heatherton and Baumeister 1991). However, over time, disordered eating might act as a de facto social agent (one typically achieved through successful interpersonal interactions; Rieger et al. 2010), such that individuals attempt to regulate their mood through disordered eating as opposed to social engagement, ultimately leading to social isolation.

Lethal Consequences. Engagement in disordered eating, generally, is associated with an elevated risk of suicidality (Smith et al. 2018), with individuals with anorexia being anywhere from 18 to 31 times more likely to die by suicide than the general population (Preti et al. 2011). Given that denial of disordered eating behaviors may lead to social isolation, this puts an individual at increased risk for non-suicidal self-injury (NSSI) and suicidality (Howard et al. 2020; Rieger et al. 2010; Van Orden et al. 2010). Joiner's (2005) interpersonal theory of suicide suggests that the capability for suicide emerges because of high degrees of three states: acquired capability (i.e., exposing oneself to painful experiences), perceived

burdensomeness (i.e., the belief that one is a burden to others), and thwarted belongingness (i.e., decreased social connectedness; Van Orden et al. 2010). Denial of disordered eating behaviors may contribute to increased NSSI and suicidality because of the conflict and distancing it causes in relationships, contributing to a decreased sense of belonging. In fact, Howard and colleagues (2019) found that, among college women, deliberate denial of disordered eating behaviors accounted for significant variance in NSSI and suicidality above and beyond engagement in disordered eating alone, and individuals who engaged in denial of disordered eating were more likely to have engaged in lifetime NSSI and fall into an elevated suicide risk category compared to those who engaged in disordered eating but did not try to conceal it. These findings are important because they suggest that there are greater consequences for individuals who deny their disordered eating behaviors compared to those who engage in disordered eating without denial. The tendency to isolate oneself from others also poses a barrier to individuals receiving a formal eating disorder diagnosis given that these individuals tend to distance themselves from people who may intervene on their behaviors.

Help-Seeking Consequences. In clinical settings, it is widely understood that individuals who engage in disordered eating behaviors often conceal these behaviors (Vandereycken and Van Humbeek 2008), creating challenges for seeking treatment and frustration for providers. One of the most frequently cited barriers to seeking clinical help for disordered eating is individuals' denial of their illness and its overall severity (Ali et al. 2020). Despite the critical need for treatment of those with disordered eating symptoms, only a minority believe they need support for their condition (Webb and Schmidt 2021). Clinicians working with students at colleges and universities often report that it is difficult to get them the help they need given frequent denial of disordered eating and/or its severity (Webb and Schmidt 2021). This denial consequently results in delay of treatment for extended periods of time. This is an especially prominent concern for adolescents with anorexia nervosa, where denial is seen as a common feature of the disorder (Couturier and Lock 2006). Couturier and Lock (2006) studied symptoms of denial among 86 adolescents with anorexia nervosa and found that 42% of their sample either denied or minimized their symptoms. Denial was measured by a discrepancy between parent report of disordered eating symptoms and adolescent scores on the restraint subscale of the Eating Disorders Examination (EDE; Fairburn and Beglin 1994). Individuals who suffer from eating disorders notoriously pose issues to clinicians when it comes to accurate assessment, resulting in concerns of validity for diagnosis (Starzomska and Tadeusiewicz 2016). In fact, research suggests that the Eating Disorder Inventory (EDI; Garner et al. 1983) and Eating Attitudes Test (EAT; Garner et al. 1982) may not accurately reflect psychological components inherent in an eating disorder diagnosis due to denial of illness (Starzomska and Tadeusiewicz 2016).

Diagnostic Consequences. In the most recent version of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; American Psychiatric Association 2013), a diagnosis of anorexia or bulimia warrants the presence of psychological symptoms, such as intense fear of gaining weight, refusal to maintain normal body weight, and self-evaluation unduly influenced by shape and weight. Assessment of

psychological symptoms already poses challenges for clinicians, given increased subjectivity associated with psychological symptom assessment compared to behavioral symptom assessment, which creates ambiguity in diagnosis; however, this dilemma becomes especially difficult when a client does not recognize or endorse their symptoms due to lack of insight or intentional denial. Inaccurate assessment of these psychological symptoms often leads to missed or mistaken diagnoses (Becker et al. 2009). Luck and colleagues (2002) illustrated this issue when validating the SCOFF questionnaire as a screening tool for clinical use. The study sought to validate the SCOFF questionnaire by seeing whether it could detect individuals previously identified as having an eating disorder through clinical interview. Although the SCOFF questionnaire identified most individuals with an eating disorder (11 out of 13), it failed to detect two cases due to denial and nondisclosure, illustrating the reality of clinical challenges pertaining to diagnosis.

Failure to detect eating disorders due to denial plays out in nonclinical arenas as well. For example, among college athletes, who are at heightened risk for developing an eating disorder due to an increased emphasis on shape and weight, denial is a pervasive concern (Plateau et al. 2014). In fact, eating disorders often go unrecognized by the coaches of collegiate athletes, who have one of the most important roles in recognizing disordered eating patterns in their athletes before the onset of a diagnosable eating disorder (Plateau et al. 2014). However, in this qualitative study, one in five coaches reported that they have never identified disordered eating behaviors in athletes, and they struggle to do so because of lack of confidence in having conversations about shape and weight and the common occurrence of denial in those afflicted with disordered eating. In this study, male coaches reported difficulty talking about disordered eating and related constructs, such as the absence of a menstrual cycle, with their female athletes, which could further encourage denial of disordered eating among female athletes. In general, coaches reported that it is common for athletes to hide or conceal disordered eating behaviors, subsequently serving to deteriorate the relationship between coach and athlete (Plateau et al. 2014).

Comorbid Diagnostic Consequences. Denial serves as a barrier to diagnosis but also as a barrier to detect problems that frequently co-occur with disordered eating, such as comorbid mood and personality symptoms. For example, adolescents with eating disorders report lower levels of internalizing problems (e.g., depression, anxiety) on self-report questionnaires compared to their parents' reports of their adolescents' internalizing behaviors (Salbach-Andrae et al. 2008), which contrasts with studies conducted with participants without eating disorders that have found less differences between adolescent and parent reports of internalizing problems (e.g., Crystal et al. 2001). Salbach-Andrae and colleagues (2008) posited that their findings of discrepant reporting among adolescents with eating disorders may be due, at least in part, to denial and minimization of their symptoms. Similarly, Vitousek and Stumpf (2005) suggest that denial and distortion in self-report make it difficult to assess comorbid personality functioning among individuals with eating disorders. Comorbid problems, such as internalizing and personality disorders, are important to understand given the implications they have for treatment outcomes and

accurate diagnosis and assessment. Individuals who meet criteria for more than one mental illness should receive treatment that takes their full symptomatology into account. Taken together, the consequences associated with denial of disordered eating makes the ability to assess denial itself important albeit challenging.

Assessment

Assessing denial of disordered eating is inherently challenging given that these assessments may be asking people to report on behaviors that they typically deny or that they may not be consciously aware of. The first issue with assessing denial of disordered eating pertains to whether an instrument is aimed at measuring unconscious lack of insight or deliberate denial of disordered eating.

Underreporting. Several studies have inferred denial of disordered eating (both conscious and unconscious) from low scores on self-report symptom questionnaires by participants who previously met diagnostic criteria for an eating disorder (Couturier and Lock 2006; Newton et al. 1988; Pryor et al. 1995; Viglione et al. 2006). For instance, in one of the earliest assessments of denial of disordered eating, Newton and colleagues (1988) found that of 66 women referred for eating disorder assessment, the individuals who were more likely to be diagnosed with an eating disorder were also more likely to report lower scores on the EAT (Garner et al. 1982). Similarly, other research on denial in eating disorders focused on denial in terms of refusal to endorse disordered eating in self-reports (Couturier and Lock 2006; Pryor et al. 1995; Viglione et al. 2006). These studies measured denial in clinical populations by having patients with known eating disorder diagnoses fill out self-report measures of disordered eating, such as the EDI (Garner et al. 1983) or the EAT (Garner et al. 1982); they interpreted lower scores as suggesting denial (i.e., if an individual with a known eating disorder does not self-report disordered eating, they are denying the problem).

Self-Report. Beyond assessments of denial by measurements of underreporting, previous self-report measures of denial of disordered eating behaviors are Basile's (2004) Self-Disclosure about Body Satisfaction scale (SDBS) and the Self-Disclosure about Restrained Eating scale (SDRE). The SDBS and SDRE measure disclosure regarding body image and dieting with questions such as: "Do you tell others when you think you are too thin?" "Do you tell others when you are on a diet?" However, scoring low on either scale does not necessarily measure denial because not telling someone how you feel about your body, or your dieting behavior, is not the same as lying or lacking awareness. Furthermore, questions regarding disclosure of eating disorder symptomatology in Basile's scales are limited to "dieting behaviors," whereas disordered eating behaviors span beyond dieting (e.g., self-induced vomiting, over-exercising, binge eating), and many individuals with an eating disorder do not think of their eating disorder as a "diet."

One study has attempted to measure eating disorder-specific insight directly by modifying the Schedule for the Assessment of Insight (SAI; Kemp and David 1997) to be eating disorder-specific (Konstantakopoulos et al. 2011). The SAI is a

semi-structured interview that assesses the ability to recognize that one has a mental illness, compliance with treatment, awareness of psychological changes, awareness of the need for treatment, awareness of psychosocial consequences of the illness, and the capacity to label aberrant psychological events as pathological (Kemp and David 1997). In the modified version, items pertaining to compliance with treatment were removed, and items related to the need for physical and psychological treatment specific to eating disorders were added (Konstantakopoulos et al. 2011). In this study, 40 participants with anorexia or bulimia and 35 healthy controls completed the questionnaire. Only six participants with anorexia demonstrated severe impairment of insight, and more participants with eating disorders endorsed deliberate denial of illness compared to a lack of awareness of the illness (Konstantakopoulos et al. 2011).

There has also been one recent attempt to measure deliberate denial of disordered eating using self-report. This measure is known as the Deliberate Denial of Disordered Eating Behaviors Scale (DDEBS; Howard et al. 2020). The DDEBS is a 12-item self-report questionnaire that assesses conscious omission, concealment, or misrepresentation of behavior related to disordered eating and contains items such as: "How often have you been dishonest about how much you ate?" "How often have you told people you felt sick to avoid eating?" Items for the scale were developed by adapting items from Vandereycken and Van Humbeek's (2008) retrospective survey data (see below), using Vitousek and colleague's (1991) definition of denial, holding focus groups, polling an expert panel, and empirically through factor analysis. The scale demonstrated initial evidence of reliability and validity (Howard et al. 2020). However, it should be noted that a concern arose in the development of the DDEBS about the ability of participants to honestly report on behaviors that they typically lie about. Therefore, an Underreporting of Disordered Eating Behaviors Scale (UDEBS) modeled after the Minnesota Multiphasic Personality Inventory (MMPI) Lie (L) scales (Hathaway and McKinley 1943; Butcher et al. 1989; Ben-Porath and Tellegen 2011) was developed to be used in conjunction with the DDEBS to assess validity of responses (Howard et al. 2022).

Retrospective. There has also been one attempt to measure concealment of disordered eating behaviors retrospectively. This untitled retrospective questionnaire surveyed former eating disorder patients at various stages of recovery and asked them questions regarding their most frequently used concealing behaviors at the beginning phase of their eating disorder (Vandereycken and Van Humbeek 2008). The questionnaire asks participants to report on concealing behaviors such as avoidance of eating ("to avoid eating with others, I most often said. . .") and false impression of eating ("to give the impression I had eaten. . ."). One problem with any retrospective survey is that retrospection can be influenced by the current state of an individual. Unsurprisingly, in this study, the longer the retrospection duration period, the less likely individuals were to report concealing behaviors (Vandereycken and Van Humbeek 2008). Nonetheless, this retrospective questionnaire provides useful information on the rates at which individuals that engaged in disordered eating endorsed using specific concealing behaviors. For example, among the 401 individuals polled, to avoid eating with others, 39.4% of individuals stated that they most

often said, "I have eaten already," and to give the impression that they were eating when they were not, 25.7% of individuals stated that they would most often attempt to eat slowly. Continued research and recent advances in the development of psychometrically valid assessment tools may assist in accurate assessment of denial of disordered eating behaviors that could inform treatment.

Treatment

As discussed throughout this chapter, denial of disordered eating poses unique challenges for both researchers and clinicians in the diagnosis and assessment of eating disorders. Denial can also make treatment particularly challenging. In fact, anorexia nervosa is often seen as treatment resistant. A systematic review conducted in 2013 identified four main themes in treatment-resistant eating disorder research: denial of illness, motivation to change, maintaining factors, and the therapeutic relationship (Abbate-Daga et al. 2013). Poor insight can even assume delusional features, making it even more challenging to treat these patients (Konstantakopoulos et al. 2012; Steinglass et al. 2007). However, most treatment-resistant patients show a deliberate denial of illness as opposed to a lack of insight (Konstantakopoulos et al. 2012), which some researchers attribute to immature defense mechanisms (Steinglass et al. 2007).

Empirically Supported Treatment. Despite the challenges that may accompany treatment given frequency of denial, some treatments may be particularly well suited to address denial within the context of therapy. One such empirically supported treatment is acceptance and commitment therapy (ACT; Hayes et al. 2006). Denial of disordered eating may result from individuals who engage in disordered eating not being able to tolerate negative thoughts and feelings, leading them to not only engage in disordered eating but conceal their behavior from others to avoid this discomfort. This intolerance is characteristic of diminished psychological flexibility (i.e., an inability to be in contact with the present moment and respond to the context functionally; Hayes et al. 2006). An inverse relationship between concealment and psychological flexibility has been demonstrated empirically in a cross-sectional study using male and female undergraduates (Masuda et al. 2011). Given that the overarching goal of ACT is to increase psychological flexibility, this treatment may be particularly well suited to treat patients who deny disordered eating behaviors. Family-based treatment (FBT) for children and adolescents with eating disorders may also be fitting given that it directly targets and resolves family-level variables, including secrecy (Loeb et al. 2019). FBT proposes that a child's eating disorder often becomes the "elephant in the room," with the child protecting the symptoms through secrecy and the parents or caregivers unsure how to broach the subject. FBT works to reverse secrecy by discussing progress and strategies for treating the eating disorder as a cohesive family unit (Loeb et al. 2019). Lastly, motivational interviewing (MI) may be indicated as a brief pretreatment intervention or as a stand-alone therapy for individuals who deny disordered eating symptoms (Weiss et al. 2013). In the early stages of MI, feelings of ambivalence (common to the stage

of contemplation) and the experience of denial (frequently experienced in pre-contemplation) are discussed. In later sessions, self-monitoring and Socratic questioning are introduced to assist patients in raising their consciousness about their disordered eating behaviors.

Other empirically supported treatment protocols could be modified to address denial. Dialectical-behavioral therapy (DBT) focuses on helping clients do what is effective in the long term (Linehan 2015), and many clients develop long-term goals pertaining to creating or strengthening healthy relationships. Although denial of disordered eating might assist a client in getting what they want in the short term (e.g., not having to eat in front of others), it is likely to harm them in the long term (e.g., developing and maintaining healthy relationships; Linehan 2015). DBT for eating disorders (Safer et al. 2009) could develop specific interpersonal effectiveness skills pertaining to honesty, and interpersonal effectiveness scripts from DBT could be modified for this purpose as well (Linehan 2015). For example, a client might be encouraged to describe, express, assert, and reinforce (DEAR) their needs to a loved one (e.g., "I have difficulty being honest around my eating habits. I feel concerned about judgment from others. Would you be able to help hold me accountable? I would really appreciate your help.").

Treatment Approach. In addition to the specific treatment being utilized, the approach to therapy and/or assessment is important in addressing denial. Michel (2002) argues that a therapeutic approach to assessment is a critical first step in overcoming difficulties posed by denial, minimization, and lack of insight in eating disorders. Therapeutic assessment differs from the traditional information gathering model because the assessor works to develop an empathic relationship with the client, collaboratively establish goals for the evaluation, and allow the client to explore results in conjunction with the assessor and on their own. Michel (2002) reported that, from their own experience, therapeutic assessment allows the examinee to retain some control over the process, especially in hospital settings, which allows for higher degrees of self-disclosure. Similarly, Starzomska and Tadeusiewicz (2016) emphasize the importance of building an honest and trusting relationship within the context of therapy to bypass pitfalls associated with the influence of denial. Qualitative research conducted with 14 women with eating disorders explored ways in which these women were able to move from denial to awareness (Schoen et al. 2012). The process of increasing awareness was reported to be influenced by interpersonal feedback. Verbal feedback that was described as showing concern, was goal-directed, and came from a trusted source was most likely to move women from denial to awareness (Schoen et al. 2012).

Treatment Modality. A final consideration is modality of treatment. Web-based and self-help programs can reduce barriers associated with denial, such as shame and stigmatization (ter Huurne et al. 2013; Yim and Schmidt 2019), but this consideration should be balanced with increased rates of secrecy attributed to ease of hiding symptoms when using telehealth (Hunter and Gibson 2021). For those hesitant to seek treatment, web-based and self-help treatment are better than no treatment at all. An online self-help cognitive-behavioral treatment (CBT) for bulimia has been found to be an acceptable treatment option for those with bulimic-type symptoms,

despite some difficulties with motivation and implementation (McClay et al. 2013). Another widely successful web-based program is *Student Bodies*, which targets disordered eating behaviors in young college women (Dev et al. 1999). Research suggests that this 8-week program reduces weight and shape concerns in college women at high risk for developing an eating disorder (Kass et al. 2014). These well-validated web-based and self-help programs might be more acceptable to people unwilling or unable to seek more traditional therapies.

Future Directions

Although great strides have been made in understanding the causes, consequences, and treatment of denial of disordered eating, future research is warranted. For example, future research might utilize longitudinal designs to investigate over what timeframe engagement in denial of disordered eating behaviors precedes increases in disordered eating, interpersonal difficulties, treatment avoidance, and other clinical correlates. Most of the research that has investigated denial of disordered eating has utilized cross-sectional designs, which does not tell us anything about the temporal sequencing of events or cause and effect. Therefore, it should also be investigated experimentally whether interventions that encourage honesty can lead to positive outcomes (e.g., decreases in disordered eating, body dissatisfaction, and suicide/self-harm tendencies and increases in help-seeking behaviors).

To date, most of the research on denial has largely utilized White female samples (e.g., Newton et al. 1988; Plateau et al. 2014; Schoen et al. 2012). While denial is likely relevant to men, denial may present itself differently in this population. For example, denial related to dietary restriction may not be as applicable to men, while there may be other areas of denial associated with attaining muscle mass (e.g., steroid use) that have been understudied. It is also important to study denial in particular cultures, or subcultures, where mental illnesses, including eating disorders, see higher rates of stigmatization and possibly higher rates of denial, such as Black and Latinx communities (Ward et al. 2013). Black and Latinx women may be less likely than young White women to seek help for or acknowledge disordered eating due to a lack of trust in health-care providers (Becker et al. 2009), especially given past abuses by health-care systems (Chou et al. 2012). Black women may also face pressure to reflect historical body-positive ideals and thus deny potential concerns (Lovejoy 2001). Although Black women may have developed a healthy resistance to negative societal images of themselves, including a rejection of mainstream body ideals, this resultant pressure to project resiliency may also result in a tendency to deny vulnerabilities related to body image concerns and disordered eating behaviors (Hooks 1993). Lovejoy (2001) suggests that self-reports of positive body image and denial of disordered eating among Black women in social science surveys should "be more closely examined if we are not to collude in the silencing of Black women's health problems" (256).

In addition, future research should continue to investigate the impacts of denial using both clinical and nonclinical samples. Those more familiar with eating

disorders may be better at hiding symptoms in a manner that avoids detection in assessments of denial; therefore, the validation of lie scales, such as the UDEBS (Howard et al. 2022), with clinical samples is warranted. There are also certain clinical samples that may be particularly motivated to conceal disordered eating (e.g., individuals with eating disorders who are on civil commitment), and understanding how to assess and treat these individuals has implications for our legal system, such as determining when and if someone gets off a civil commitment. Understanding the causes and consequences of denial and, subsequently, the most efficacious treatments for those who deny disordered eating is important if we are to successfully prevent and treat eating disorders.

Summary

Denial of disordered eating (i.e., the tendency to conceal behaviors which reflect symptoms of an eating disorder) can be conscious or unconscious, ranging from lack of insight to deliberate refusal to disclose. Accordingly, individuals may conceal eating disorder symptomatology for various reasons, including fear of intervention and a defense of self, but also because they do not want to be labeled or diagnosed with a mental illness and face stigmatization. The tendency for individuals who engage in disordered eating to deny their problems can lead to interpersonal conflict, suicidality, further disordered eating, avoidance of treatment, and difficulties with accurate diagnosis. Assessing denial of disordered eating is particularly challenging given that these assessments may be asking people to report on behaviors that they typically deny or that they may not be consciously aware of. However, recent advances in the development of psychometrically valid assessment tools, such as the DDEBS, may assist in accurate assessment of denial of disordered eating behaviors, which could ultimately lead to more effective treatment. Certain treatments may already be particularly well suited to address denial within the context of therapy, such as ACT, FBT, and MI. Beyond the specific treatment, the approach and modality to treatment may be just as important when working with individuals who deny eating disorder symptomatology. However, more research is needed, and understanding denial of disordered eating is still in its infancy.

Applications to Other Eating Disorders

In this chapter, we have defined denial of disordered eating, discussed the causes and consequences of denial and how to assess and treat individuals who engage in denial of illness, and discussed directions for future research. We have discussed denial of disordered eating broadly such that it applies to all eating disorders; however, it is most seen in anorexia. We have also discussed how etiology of denial of disordered eating might differ based on the type of eating disorder. Future research should continue to investigate various causes and consequences of denial and how to assess and treat individuals who deny based on specific eating disorder types

(e.g., anorexia, bulimia, binge eating disorder). For example, researchers could develop assessment instruments that inquire about denial of specific disordered eating behaviors, such as binge eating or compensatory behaviors. These scales could include items such as: "How often have you made up excuses so you can be alone to binge eat?" that would be applicable to those with bulimia or binge eating disorder. However, assessments of this kind will need to be careful to distinguish between people who report they have not *denied* engaging in specific behaviors and those who have not *engaged* in a specific disordered eating behavior.

Mini-Dictionary of Terms

- **Deliberate denial:** Conscious omission, concealment, or misrepresentation of behavior or internal experience.
- **Denial of disordered eating:** The tendency for individuals who engage in disordered eating to lie about or conceal their behavior.
- **Disordered eating:** Unhealthy eating patterns that reflect symptoms of an eating disorder but may not meet full criteria for an eating disorder.
- **Insight:** Self-awareness.
- **Interpersonal formulation of disordered eating:** Engaging in disordered eating behaviors can increase interpersonal problems; in turn, these interpersonal problems are believed to intensify disordered eating behaviors.
- **Underreporting of disordered eating:** Reporting fewer disordered eating symptoms than one engages in, which may occur consciously or unconsciously.

Key Facts of Denial of Disordered Eating

- Of eating disorder patients, 75% deny that anything is wrong in the beginning months of their eating disorder
- The most frequently mentioned barrier to help-seeking for an eating disorder is shame and stigmatization (85%) followed closely by denial of and/or failure to perceive the severity of the disordered eating (69%)
- Anosognosia, or lack of insight, is a defining feature of anorexia
- Denial of disordered eating stems from various motivations, which can include a defense of self, shame and stigmatization, and/or fear of intervention
- Denial of disordered eating can lead to interpersonal conflict, suicidality, further disordered eating, and delays in help-seeking

Summary Points

- Denial of disordered eating (i.e., the tendency to conceal behaviors which reflect symptoms of an eating disorder) can be conscious or unconscious, ranging from lack of insight to deliberate refusal to disclose

- Individuals conceal eating disorder symptomatology for various reasons, including fear of intervention and a defense of self, but also because they do not want to be labeled or diagnosed with a mental illness and face stigmatization
- Denial of disordered eating can lead to interpersonal conflict, suicidality, further disordered eating, avoidance of treatment, and difficulties with accurate diagnosis
- Assessing denial of disordered eating is challenging given that these assessments may be asking people to report on behaviors that they typically deny or that they may not be consciously aware of
- Recent advances in the development of psychometrically valid assessment tools, such as the DDEBS, may assist in accurate assessment of denial of disordered eating behaviors
- Some treatments may be particularly well suited to address denial within the context of therapy, such as ACT, family-based therapy (FBT), and MI
- The approach and modality to treatment may be just as important as the therapeutic intervention when working with individuals who deny eating disorder symptomatology
- Future research on denial of disordered eating should utilize longitudinal and experimental designs, samples other than White females, and both clinical and nonclinical populations

Abstract

Current clinical practice guidelines support a multidisciplinary treatment approach to ensure individuals with eating disorders have access to medical, dietetic, and psychological interventions to maximize their chances of recovery. Dietitians play a key role in the treatment of eating disorders by assessing the severity of malnutrition, disordered eating patterns, and knowledge and skill deficits that prevent achievement and maintenance of optimum nutrition. Moreover, dietitians collaboratively develop individually tailored nutrition care plans which (1) address nutritional deficiencies and promote optimal nutritional status, (2) emphasize the role of adequate nutrition in addressing patients' individual and mental well-being, and (3) provide nutrition education to challenge inaccurate beliefs about food and eating. This chapter provides an overview of nutrition assessment and intervention for individuals with eating disorders broadly, as well as specific dietetic treatment considerations for individuals with anorexia nervosa, bulimia nervosa, and binge eating disorder.

Overview of Dietetic Treatment for Eating Disorders

Dietitians play a pivotal role in helping individuals with eating disorders (EDs) and their families understand the interaction between food, nutrition, and well-being, as well as supporting eating behaviors that align with treatment and recovery goals (Heruc et al. 2020). Specifically, the role of a dietitian is to identify and assess the severity of malnutrition, disordered eating patterns and knowledge, and skill deficits that prevent achievement and maintenance of optimal nutrition status (Setnick 2016). Dietitians help people with EDs and their families to develop individualized plans and encourage active learning opportunities to support new behaviors and acceptance of food-related tasks such as cooking and shopping (Setnick 2016). They also assess other comorbid conditions, such as refeeding syndrome, diabetes mellitus, food allergies, food intolerances, gastrointestinal conditions, and osteoporosis (Jeffrey and Heruc 2020), and ensure effective communication of nutrition care plans with other members of an individual's treatment team as well as families and carers.

Dietitians are responsible for managing the Nutrition Care Process defined by a comprehensive nutritional assessment, a nutritional diagnosis, implementation of a nutritional intervention, and monitoring progress toward treatment goals through an ongoing evaluation process (Jeffrey and Heruc 2020). This process should result in individually tailored nutrition care plans that correct nutritional deficiencies and promote optimal nutritional status, address the role of eating and adequate nutrition in physical and mental well-being, and provide education to challenge inaccurate beliefs about food (Setnick 2016; Hart et al. 2011b).

Practice standards for dietitians working with individuals with EDs have been published by the Australia New Zealand Academy for EDs (Heruc et al. 2020) and the Academy of Nutrition and Dietetics (Hackert et al. 2020). Dietitians should

consult these standards for detailed advice on the Nutrition Care Process to guide clinical practice and ensure effective, safe, and timely care in addition to consistent treatment approaches (Heruc et al. 2020).

Nutrition Assessment

Dietitians are likely to encounter individuals with EDs or disordered eating behaviors in their clinical work, even if EDs are not their specific area of practice. People with EDs may present to dietitians for seemingly unrelated nutritional issues that may include planning a vegetarian or vegan diet, support for food allergies or intolerances, or because they want to improve athletic performance. The general dietitian may encounter individuals with physical symptoms of an ED, electrolyte disturbance, or failure to gain weight despite apparent adequate intake that could be attributed to malnutrition or purging behavior. Other people at increased risk of an ED who may present to a dietitian include individuals with polycystic ovary syndrome (Lee et al. 2017), with type 1 diabetes mellitus (Young et al. 2013), seeking weight loss treatment or bariatric surgery with a history or diagnosis of other psychiatric illness (e.g., depression, alcohol misuse) (Mitchell et al. 2015), and with diagnoses requiring monitoring of dietary intake such as celiac disease (Satherley et al. 2016), inflammatory bowel disease (Abraham and Kellow 2011), or food allergies (Jafri et al. 2021).

As a result, all dietitians can be considered as "first responders" and have an important role in the identification of EDs, contributing to early intervention and access to treatment. Therefore, it is important that dietitians are aware of the clinical signs of an ED or individual at risk of an ED.

Nutritional Issues in Individuals with Eating Disorders

People with EDs engage in eating behaviors and dietary patterns with the aim of energy restriction for weight loss (Forbush and Hunt 2014). Underpinning these behaviors are disordered cognitions and beliefs relating to food and eating (Alvarenga et al. 2014). Nutritional issues and disordered dietary patterns commonly seen include:

- Avoidance of specific foods, including fat intake and other foods high in energy (Schebendach et al. 2011; Hart et al. 2018)
- Eating a limited and inflexible range of foods (Schebendach et al. 2011, 2012)
- Inadequate energy (calorie) intake (Chiurazzi et al. 2017)
- Nutritional deficiencies including calcium, fat-soluble vitamins, essential fatty acids, selenium, zinc, and B vitamins (Chiurazzi et al. 2017; Hanachi et al. 2019; Mehler 2017; Allen et al. 2013)
- Overconsuming low-energy foods; artificially sweetened products; "diet" foods, e.g., low-fat, low-carbohydrate, or low-sugar products (Hart et al. 2018); and excessive quantities of fruits and vegetables (Hart et al. 2018; Schebendach et al. 2017)

- Using fluids such as water, diet soft drinks, or coffee to suppress appetite and reduce the urge to binge eat (Forbush and Hunt 2014; Hart et al. 2018)
- A tendency to overestimate portion sizes (Dörsam et al. 2020)
- Counting calories (Levinson et al. 2017) or reading nutrition information panels on food packaging (Hart et al. 2008)
- Choosing foods with a "health halo" where a health benefit is attributed to the food making it more desirable (Schuldt et al. 2012)
- Over-involvement or avoidance of food preparation (Biddiscombe et al. 2018; Lock et al. 2012)
- Secretiveness including hiding or disposing of food and/or eating alone (Hackert et al. 2020)
- Disordered ways of eating such as inappropriate food utensils, excessive cutting of food, separating foods, and eating slowly (Hart et al. 2011b)
- Difficulty eating in social situations (Biddiscombe et al. 2018; Hart et al. 2018)
- Deficits in food literacy skills (i.e., the ability to plan and manage, select, prepare, and eat meals (Vidgen and Gallegos 2014)) including meal planning, preparation, and shopping
- Increased consumption of food-related content such as cookbooks and recipes (Grave et al. 2011) as well as social media content relating to fitness and dieting (Carrotte et al. 2015)

Nutritional issues which may be observed in individuals with binge eating disorder (BED) are listed below; however, current literature needs to be interpreted with caution as findings appear to vary depending on the methodology of dietary assessment used (Mourilhe et al. 2021):

- Foods high in sugar and fat, such as chocolate, cookies, and chips, are highly craved (Weingarten and Elston 1991; Reents and Pedersen 2021) and involved in typical binge eating episodes, compared to fruits and vegetables (Rosen et al. 1986).
- Energy intake is higher in females with obesity and BED on binge days compared to those with obesity without BED, as well as greater energy from fat compared to carbohydrate consumed by those with BED on binge days than those without (Raymond et al. 2012).
- Greater energy intakes (Raymond et al. 2012) and snacking (Harvey et al. 2011) reported at night.
- Breakfast is the least commonly consumed meal and the evening meal the most consumed meal (Harvey et al. 2011).

Nutrition Assessment for Eating Disorders

1. Food and nutrient intake
   - Premorbid and current dietary intake, with 24-h recall including fluid intake and macro- and micronutrient adequacy
   - Assessment of the risk of refeeding syndrome

2. Food and nutrient administration
   - How food is purchased and prepared, including planning, flexibility, timing of meals, and routines around food
   - Eating environment, considering location and with whom meals are eaten
3. Medication and complementary medicine use especially medications which affect appetite, resting metabolic rate, fluid excretion or metabolism, or misuse of medications such as insulin
4. ED-specific beliefs and behaviors
   - Knowledge, beliefs, and dietary rules about eating and reasons for these including the length of time and frequency of dietary restriction
   - The type, frequency, duration, and triggers of ED behaviors (e.g., binge eating, self-induced vomiting, hiding food, chewing and spitting, laxative, diuretic or other substance use)
5. Factors affecting access to food
   - Food insecurity
   - Confidence/ability to grocery shop, find appropriate recipes, and cook/prepare food
   - Access to appropriate kitchen and cooking equipment
6. Premorbid and current physical activity levels, including frequency, duration, type, and motivation
7. Nutrition-related person-centered measures
   - Goals of nutrition intervention and previous experiences with dietitians

Energy, fluid, and macronutrient requirements should be estimated, as well as recording of the following key anthropometric parameters:

- Current weight, height, and body mass index (BMI)
- Recent weight change and usual body weight
- Highest and lowest body weights and under what circumstances
- The impact of the ED on growth and development (e.g., in children, adolescents, and pregnant women)
- The individual's desired weight

It is important for the dietitian to liaise with a medical practitioner regarding specific medical complications associated with an ED. This will include monitoring of electrolytes, physical observations, and body weight. The most acutely concerning electrolyte abnormalities resulting from purging can be hypokalemia, hypochloremic alkalosis, hypomagnesemia, and/or hypophosphatemia. This may require emergency care and cannot be treated with dietary intervention alone (Setnick 2010).

Nutrition Intervention, Monitoring, and Evaluation

Key principles of nutrition intervention for the treatment of EDs include (Heruc et al. 2020; Hackert et al. 2020):

- Consideration of both psychiatric and medical risk factors and comorbidities
- Encouragement of a wide variety of foods from all food groups
- An emphasis on improving flexibility of food choice, eating socially with others and eating for enjoyment rather than to influence weight or shape
- The level of support available from carers/support people
- Monitoring and evaluation of chosen key nutrition indicators relevant to ED pathology as identified in the assessment

Eating adequately and regularly are core principles of treatment across all ED diagnoses and provide the basis of nutritional rehabilitation, to facilitate weight restoration (when required), and recovery from an ED. People with EDs should be prescribed an appropriate dietary regimen which meets nutritional requirements via three adequate main meals with two to three snacks. Eating regularly provides opportunities throughout the day to eat enough to meet energy requirements and prevent long gaps between eating, which can help in binge eating prevention. Additionally, blood glucose levels can be more stable, and there is opportunity to reconnect with body signals that support the intuitive eating process and regulate appetite. It is important to use an approach that does not focus on calorie counting, weighing or measuring foods. High-energy supplements and enteral feeding may also be considered. Nutrition intervention should also consider micronutrient requirements especially iron, calcium, and vitamin D which may require supplementation if adequate intake cannot be achieved orally, as well as ensuring fluids are not over- or under-consumed.

Nutrition Education and Counselling

Provision of nutrition education is a key aspect of nutrition intervention for EDs. Core nutrition education topics are provided in Fig. 1. It may also be appropriate for nutrition education to be provided to carers or support people of adults with an ED if consent is given. For children and adolescents, education is usually provided to the patient's parents/carers to facilitate their role in assisting their child normalize their eating. Nutrition counselling strategies which may be used by dietitians as part of nutrition intervention in EDs include motivational interviewing, goal setting, self-monitoring, and relapse prevention, as well as some components of cognitive behavioral therapy (CBT) such as graded exposure and behavioral experiments if the dietitian has received appropriate training and supervision.

It is essential to work with the treating team within the treatment model being implemented. For example, if a CBT intervention is being provided, dietitians can assist by providing education about metabolism, maintenance of body weight, and normal nutritional intake, which may promote engagement with CBT. In a family-based treatment approach, dietitians often consult with the family therapist around empowering the family to make appropriate choices around meal planning, adequate nutrition for age and physical activity level, and ensuring adequate food availability.

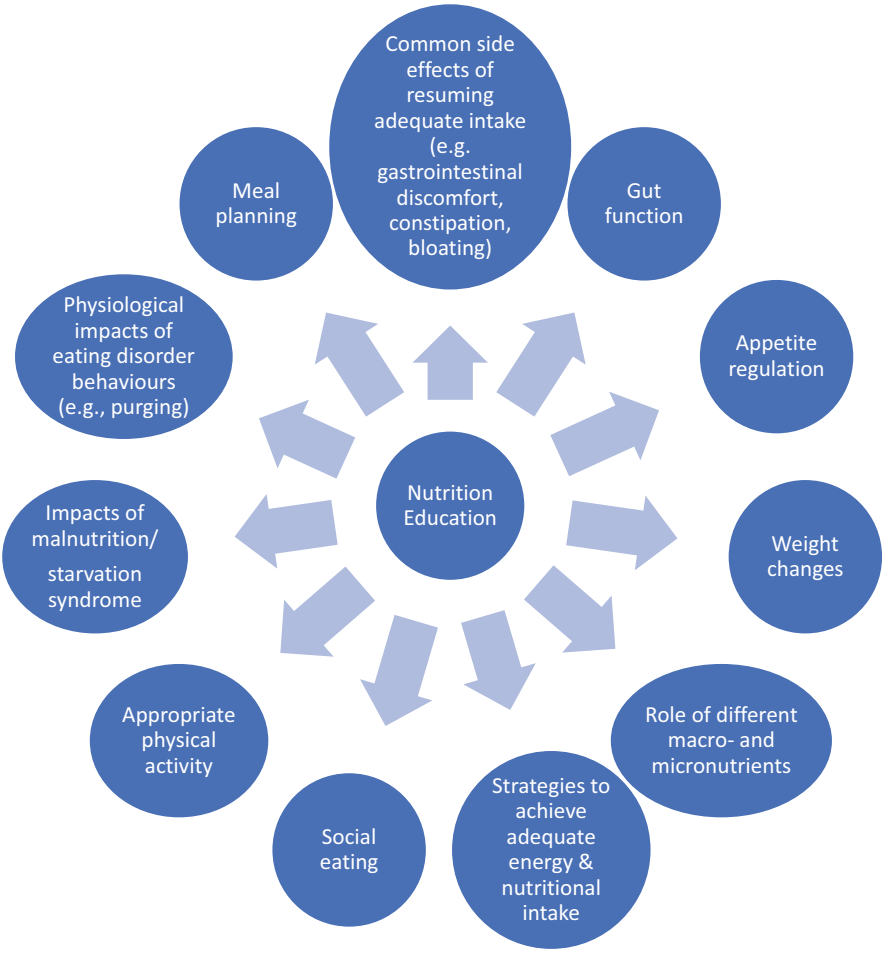

Fig. 1 Core nutrition education topics in nutrition intervention for eating disorders

Outpatient Dietetic Treatment for Eating Disorders

Goals of outpatient nutrition intervention for EDs include:

- Achieve a safe rate of weight restoration or weight maintenance.
- Reinstate or learn "normal" and healthy eating behavior, and provide nutrition education on the maintenance of long-term healthy eating essential for recovery.
- Increase intake from a variety of foods.
- Inclusion of "feared" foods.
- Increase intake of fats and oils to prevent essential fatty acid deficiencies if necessary.

- High intake of calcium-rich foods to improve bone density and prevent the early onset of osteoporosis if required.
- Minimize intake of low-energy foods/fat-reduced foods and "diet foods" where appropriate.
- Increase flexibility of food choices, eating out socially, and eating for enjoyment rather than for weight control.

There are a number of nutrition frameworks available that can be used to deliver nutrition intervention for EDs, including RAVES (Jeffrey 2021), the rule of threes (Herrin 2013), Plate-by-Plate Approach (Sterling et al. 2019), and The REAL Food Guide (Hart et al. 2018). All of these frameworks are practical tools to deliver an intervention to assist in meal planning and improving nutritional intake and are based on core nutrition and dietetic principles and the extensive clinical expertise of the authors as ED specialists. The latter framework, the REAL Food Guide, uses core principles of nutrition, with consideration of the belief systems that are frequently endorsed by individuals with an ED (Fig. 2).

Calcium Foods

Calcium foods are foods that are rich sources of calcium such as dairy products and calcium-enriched soy products. Fat-modified products, such as low-fat milk or diet yoghurt, are not recommended during nutritional rehabilitation. Because of restrictive eating behaviors, people with EDs severely compromise their chance of achieving peak bone mass and, as a result, often experience early onset of osteoporosis (Mehler 2017). Therefore, obtaining an adequate amount of dietary calcium is a key message and nutritional target for people with EDs. Avoiding or removing calcium-rich foods from the diet also means compromising adequate intake of many nutrients such as protein, vitamins (A, E, B12, and riboflavin), and other minerals (phosphorus, magnesium, potassium, and zinc). For those who choose not to have dairy products, calcium-*fortified* soy milk is the best option. It is essential that dietitians assess the brand, serving size, and frequency of calcium-rich foods as there is considerable variability in both the energy and calcium content of dairy alternatives.

Protein

A variety of animal and vegetarian protein foods are recommended daily. A simple method for achieving balanced meals at lunch and at dinner is to use the "thirds rule" (Fig. 3). This means that on an average-size dinner plate, one third of the plate should be filled by carbohydrate foods, one third by protein foods, and one third by vegetables. Many people with EDs choose a vegetarian diet because they believe it is a "healthier" way of eating (Zuromski et al. 2015). While it is possible to meet their nutritional needs with a vegetarian diet, it is important that alternative sources of iron and zinc are emphasized as part of their meal plan. It is also recommended

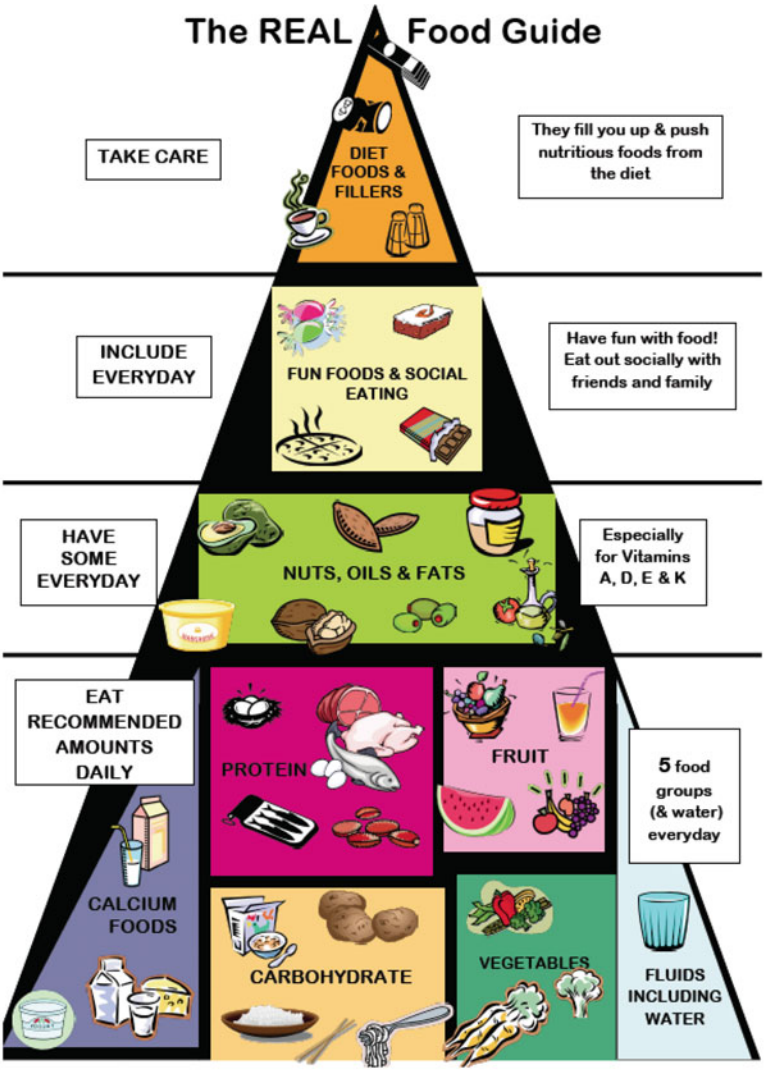

Fig. 2 The REAL Food Guide pyramid

that education is provided on factors that enhance and inhibit iron absorption, particularly as people with EDs may consume excessive volumes of tea and coffee with meals (Ahmad Fuzi et al. 2017), or as an alternative to eating adequately (Hart et al. 2018).

Current research indicates that adoption of a vegan diet before the onset of an ED might not necessarily be related to weight and shape motives or play a role in the development of an ED (Bardone-Cone et al. 2012; Heiss et al. 2017; Timko et al. 2012). However, individuals that adopt a vegan diet for weight and shape reasons are

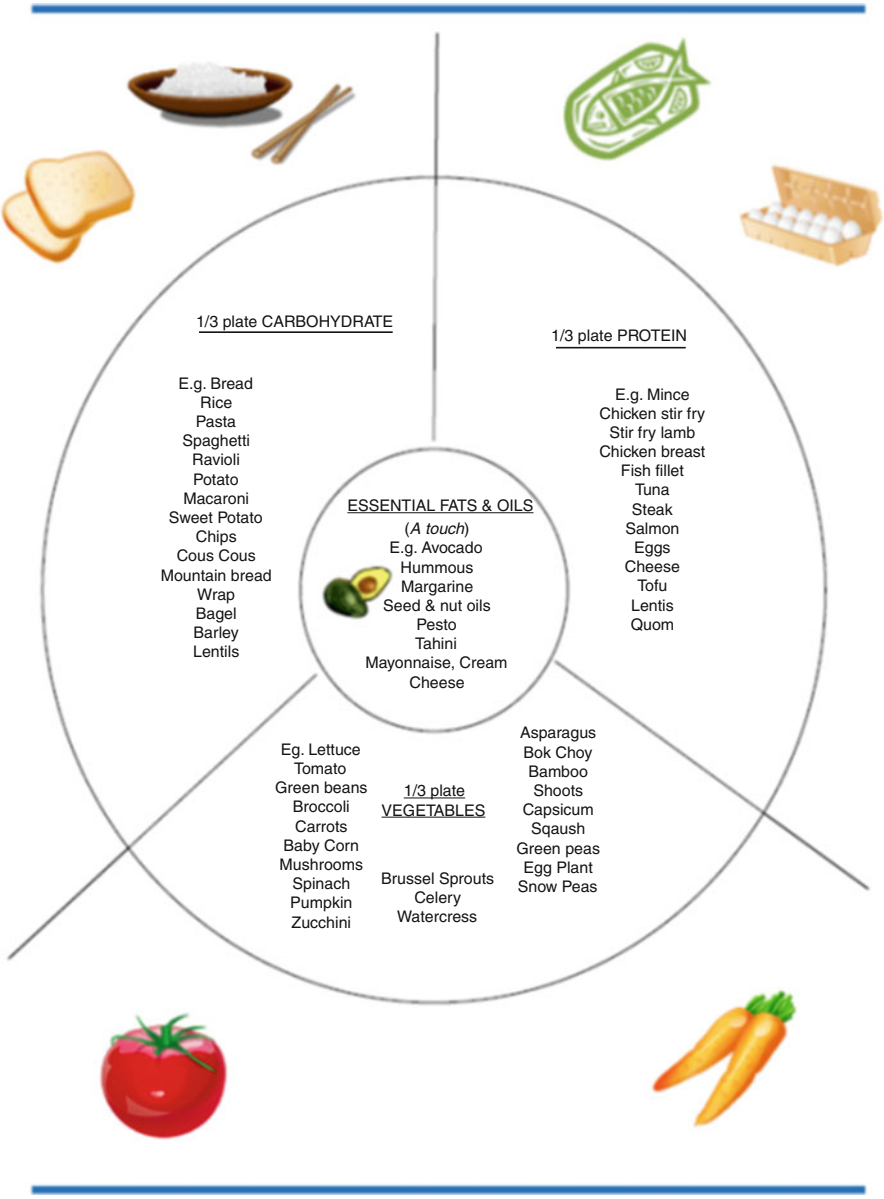

Fig. 3 Thirds rule for main meals

likely to be more at risk of an ED; and those who adopt meat avoidance and veganism after onset of the ED are more likely to be motivated to maintain their ED by the dietary adherence (Bardone-Cone et al. 2012). The dietitian should obtain a thorough history of the timing and motives of the onset of this dietary adherence in

order to provide the best advice to the individual. Nutrients that are at risk include iron, calcium, selenium, vitamin B12, and vitamin D, and supplementation may be required depending on the individual's intake of fortified foods. While there may be genuine ethical reasons for choosing a vegan diet, it is not recommended as a standard treatment for ED, and continued endorsement of such a diet involves restricted food choices, dichotomous thinking about food, hyper-vigilance about ingredient lists on food labels, and limitations on social eating such as avoiding restaurants or food prepared by others because of uncertainty about the ingredients used.

Carbohydrates

It is recommended that carbohydrate is included at breakfast, lunch, and dinner, as well as a snack option at least once per day. The amount of carbohydrate that is required is proportional to the amount of physical activity undertaken and if weight gain is required.

Fruits and Vegetables

A variety of different fruits and vegetables of different color are recommended daily. It is important fruits and vegetables are not eaten in excessive quantities as they are filling and push other nutritious food groups such as carbohydrate, fats, and protein foods from the diet.

Fluids

Water is included as a core food group of the REAL Food Guide to emphasize that adequate hydration is an important component of daily nutritional requirements and should be incorporated into meal plans. Disordered fluid intake is often observed in the majority of people with EDs, and fluid choices are often related to ED beliefs (e.g., as a weight control method by suppressing appetite or to aid vomiting (Hart et al. 2011a)). Some people with EDs will restrict fluid intake and put themselves at risk of dehydration, while others drink large quantities of fluid to manage feelings of hunger.

Nuts, Oils, and Fats

A balanced diet includes adequate amounts of dietary fats and oils and foods that contain them each day as low intake of fat-soluble vitamins and deficiencies of essential fatty acids have been documented in EDs (Misra et al. 2006; Allen et al. 2013; Swenne and Rosling 2012).

Fun foods and social eating are recommended to assist with meeting energy requirements and to challenge beliefs that these foods should be avoided or removed from the diet for good health (Hart et al. 2018). It is also clinically important from a dietary and psychological perspective to include higher-energy foods. Eating out and in social situations is recommended so that people with EDs practice skills that enable them to spend time with family and friends and participate in social activities that involve food, eating in a manner similar to others at a social event, and expanding eating experiences.

Diet Foods and Fillers

Low-energy foods are commonly used by people with EDs as a method of suppressing appetite and restricting energy for weight loss. From a nutrition standpoint, these foods become problematic when they make up a significant proportion of a daily intake as they replace or push out more nutritious foods from the diet. They may also keep individuals focused on dietary rules and restricting food, and the inclusion of diet foods and fillers is also counterproductive for weight restoration in those who need to regain weight. The recommendation is not necessarily to eliminate these foods but to "be careful" in regard to how they might affect overall dietary intake.

Inpatient Dietetic Treatment for Eating Disorders, Including Considerations for Individuals with Anorexia Nervosa

The majority of individuals with an ED can be managed in the community as an outpatient, but some individuals may require hospitalization. Reasons for an inpatient admission may include when thresholds for medical instability are triggered, when there is high frequency of compensatory behaviors, or there is minimal progress with outpatient intervention. Individuals who are well below an appropriate weight, such as those with a diagnosis of AN, may benefit from a greater level of structure or support provided in an inpatient setting. Goals of inpatient nutrition intervention for EDs include:

- Stabilize body weight and increase weight to a safer level through initiation of nutritional rehabilitation.
- Treat medical complications and restore medical stability.
- Reduce purging (i.e., vomiting/laxative use) or other disorder behaviors sufficient to restore medical stability.
- Initiate multidisciplinary care.
- Support development of appropriate eating behavior, allowing for continued medical stability in the community.
- Connect people with the next step of care for ED treatment on discharge.

Refeeding Syndrome

Refeeding syndrome describes a potentially fatal condition comprising metabolic and biochemical complications that can arise when malnourished individuals begin consuming an increased energy intake (Matthews 2019). These complications are considered to be a direct consequence of nutrient overload, particularly carbohydrate, fluid, and/or sodium, as the malnourished persons' weakened cardiopulmonary and gastrointestinal systems attempt to process larger quantities of oral, enteral, and/or parenteral nutrition (Matthews 2019; Skipper 2012). Refeeding syndrome's hallmark biochemical feature is hypophosphatemia, though a number of signs and symptoms may present during its development, ranging from hypokalemia to thiamine deficiency (Matthews 2019; Mehanna et al. 2008). Rebound hypoglycemia can also be an issue due to an influx of insulin in response to bolus carbohydrate. People with AN are typically considered to be at high risk of developing refeeding syndrome; however any person with an ED should be considered high risk, particularly if purging is a component of their presentation.

Refeeding syndrome is said to occur between days 2 and 5 of nutritional rehabilitation; however in a recent study with adult inpatients with EDs, electrolyte decreases were more common in the initial 24 h (Matthews et al. 2018). Prevention of refeeding syndrome is key. Nutritional rehabilitation should be commenced with care, combined with an awareness of risk factors. Prophylactic thiamine and multivitamin supplementation should be provided with consideration of phosphate supplementation. Regularly checking serum electrolyte levels (daily for at least the first 7–10 days), clinical monitoring (i.e., heart rate, blood pressure), and fluid status monitoring should also be provided in the early stages of nutritional rehabilitation.

Nutrition Support for Inpatients

While oral nutrition is most beneficial for people with EDs (Hart et al. 2013), continuous nasogastric (NG) feeds have benefits for medically compromised inpatients. This includes (1) energy and carbohydrate provision being easier to control (potentially reducing risk of refeeding syndrome), (2) fewer instances of hypoglycemic events (Matthews et al. 2018; Matthews-Rensch et al. 2021), (3) reducing physical discomfort for the person, (4) medicalizing the treatment (possibly reducing the power struggle between the person with an ED and treating team), and (5) transferring the responsibility of weight gain to the treating team (Hart et al. 2013).

Based on a nutritional assessment and particularly if there is no standardized protocol to guide clinical practice, it may be necessary for the dietitian to advise the treating team about the benefit of NG versus oral feeding. The greater the medical risk, the greater the importance of NG feeding to medically stabilize the inpatient. A time frame may be established in order to determine if the individual can eat adequately before NG feeding is started. Implementing close one-to-one nursing supervision if resources are available and use of food and fluid charts to document intake can be useful tools to inform the dietitian and the treating team. Meal support

therapy is also a useful strategy for inpatient staff to support oral intake of meals and snacks.

Feeding can be commenced once prophylactic vitamin supplementation has been commenced and serum electrolyte levels have been checked, with any abnormalities being corrected before and during feeding. A low-fiber, energy-dense enteral feed is recommended, with ≤50% of energy from carbohydrates. Traditionally, a "start low, go slow" method of feeding was recommended to prevent the development of refeeding syndrome (typically commencing at ~4000 kJ/day). However, research is now demonstrating that these methods have been too conservative and potentially placed inpatients at risk of the "underfeeding syndrome," longer lengths of stay, and further medical deterioration. Underfeeding syndrome refers to the weight loss and physical deterioration occurring in an inpatient because of failure to provide adequate nutrition support to reverse signs and symptoms of malnutrition. Adolescent inpatients with EDs have been safely commenced on feeds starting at 8000 kJ/day (Whitelaw et al. 2010; Garber et al. 2013; Parker et al. 2016; Golden et al. 2013), whereas adult inpatients have been safely commenced at 6000 kJ/day (Matthews et al. 2018).

Equations for estimating energy requirements are often inaccurate when calculated for individuals with AN (El Ghoch et al. 2012). Most overestimate requirements prior to nutrition repletion, when in a hypometabolic starved state (Cuerda et al. 2007). Energy requirements then increase disproportionately during the course of refeeding, and patients may become hypermetabolic (Wakefield and Williams 2009). Energy intake must be modified due to changes in resting energy expenditure (REE) during the course of refeeding in AN, which will impact the rate of weight gain (Mehler et al. 2010; Marzola et al. 2013). The increase in REE is multifactorial and thought to be due to an increase in lean body mass as the individual restores weight (El Ghoch et al. 2017), as well as the thermal effect of food (Moukaddem et al. 1997) (i.e., the increase in energy required to process, digest, and absorb nutrients), and psychological factors such as anxiety and fear of weight gain, which can also result in increased fidgeting and pacing (Marzola et al. 2013).

The optimal time to transition the individual from continuous NG feeds to oral nutrition has not been thoroughly investigated. Consideration should be given to the setting in which treatment is being provided, the individual's baseline weight, physical status, residual ED behaviors, and cognitive state, as the individual experiencing starvation syndrome is less likely to engage appropriately with an oral meal plan. Nasogastric feeding is a short-term strategy, and it is ideal to transition to the use of meal plans and meal support therapy to facilitate improved oral intake.

Considerations for Individuals with Bulimia Nervosa

Recurrent binge eating and compensatory behaviors (purging, dietary restriction, or excessive exercise) raise important nutritional issues for people with bulimia nervosa (BN).

Dietary restriction may be an important factor in binge eating behavior in BN (Latner and Wilson 2004; Masheb et al. 2011). This may place people at risk of semi-starvation, despite engaging in binge eating behavior (De Zwaan et al. 2002). Nutritional abnormalities occur and are dependent on the amount of dietary restriction during non-binge episodes and the extent of purging behavior (Henry and Ozier 2006). A recent study has also shown dietary restriction, even when arising from food insecurity, may increase or maintain BN by inhibiting regular eating patterns (Lydecker and Grilo 2019). It is important to be aware, however, that triggers for binge eating are complex and involve both internal (negative emotions and physical urges to eat foods) and external (dietary restriction) triggers (Chami et al. 2021). However, a recent study has found that skipping meals and dietary restriction were not associated with binge eating (Chami et al. 2021). It has also been highlighted that overeating behaviors may become habitual over time and can occur in the absence of internal cues (Treasure et al. 2018). This highlights the importance of targeting interventions to modify cognitive dietary restraint and as well as active dietary restriction.

Binge eating behavior can have significant physical and psychosocial impacts on people with BN. Physical impacts can include significant gastrointestinal symptoms, weight fluctuations, altered lipid profiles, and in some instances gastric dilatation or perforation (Gyurkovics et al. 2006). Increased risk of polycystic ovaries has also been reported (Waterhous and Jacob 2011). Self-induced vomiting and inappropriate use of substances for weight control (laxative agents or diuretics) are largely ineffective for weight loss and can raise significant nutritional risk (Hart 2016; Pomeranz et al. 2013). Dehydration and electrolyte abnormalities (particularly sodium and potassium) associated with purging are common in people with BN, and impairment of gastrointestinal and cardiovascular systems, hemorrhage, hepatic and renal complications, and chronic constipation or diarrhea can occur (Pomeranz et al. 2013).

Treatment Considerations for Individuals with Bulimia Nervosa

Cognitions and skills around food, eating, and body weight or shape, alongside dietary restriction, binge eating, and purging, are key areas for intervention. Nutrition interventions for people with BN aim to restore normal nutritional status and facilitate normal, regular eating behavior without the use of binge eating or compensatory behaviors. Strategies may include psychoeducation especially regarding the consequences of purging, assistance with meal and food planning, behavioral experiments, and self-monitoring. Medical guidance around stimulant laxative withdrawal and management, strategies to manage acid reflux symptoms, and encouraging adequate dental hygiene practices may be discussed. Dietary strategies to assist with bowel function include introducing adequate dietary fiber and fluid intake.

Regular patterns of nutritionally adequate dietary intake may assist in normalizing nutritional status, reduce urges to binge eat or purge, reduce preoccupation with food, improve feelings of hunger and satiety, and improve mood (AED 2020).

Frequent breakfast consumption has been found to correlate with more frequent meal consumption, reduced binge eating, and lower BMI (Masheb et al. 2011). Intuitive eating (where eating is guided by internal body cues) may also be associated with lower binge eating patterns (Linardon et al. 2020).

Particular consideration needs to be given to food shopping, food storage (impacting on accessibility of both "safe" foods and "trigger" foods), and the financial impact of purchasing increased quantities of food for an individual with BN. The macronutrient composition of the diet also appears to be important. One study found incorporating adequate protein in the diet of people with BN may reduce binge eating frequency (Latner and Wilson 2004). "Trigger" foods are incorporated gradually, alongside distraction and emotion regulation strategies. Targeted experiments with "trigger" foods are recommended by trained clinicians, for example, planning to introduce a small amount of the "trigger" food when there is limited opportunity to binge eat or purge. Self-monitoring of eating behaviors through food records, including factors that precede binge eating or compensatory behaviors, can raise self-awareness, assist in regulating eating, and identify food or nonfood triggers for binge eating and compensatory behaviors.

Considerations for Individuals with Binge Eating Disorder

Considerations for Individuals with Co-occurring Binge Eating Disorder and Obesity

Stunkard (1959), a well-known obesity clinician and researcher, was the first to report the episodic overeating behavior of a minority of his patients with obesity and to formalize this as binge eating or eating without satiation. Since then, it has been widely recognized as an important contributor to both the EDs and weight management areas. Although it is thought that 2% of community samples may have BED, up to 30% of people seeking treatment for obesity are likely to meet criteria (De Zwaan 2001). Binge eating disorder has been linked to chronic nutrition-related physical conditions such as weight gain and obesity, type 2 diabetes, metabolic syndrome, hypertension, dyslipidemias, and sleep disorders (Olguin et al. 2017). Comorbidity with other mental health conditions such as depression and anxiety is also well established (Sheehan and Herman 2015; Keski-Rahkonen 2021).

Research has shown that binge eating behaviors are growing more rapidly than any other disordered eating behavior (Hay et al. 2008). Binge eating disorder presents a unique paradigm that overlaps between EDs and weight management, meaning that these individuals may present to a range of clinical settings (Bertoli et al. 2016), including dietetic services. This highlights the importance of dietitians being equipped to manage people affected by BED. Treating people who are living with both obesity and BED is challenging for both the clinician and individual. In the weight management setting, binge eating may not be identified unless asked directly and even then may not be admitted to. Additionally, weight management dietitians may not ask about binge eating due to a lack of confidence in their ability to deal with

an ED. In clinical practice, it is often noticed that even when binges are reduced and food is in greater control, weight loss is unlikely to meet expectations, leading individuals (and potentially clinicians) to be disappointed.

Clinical trial data such as the US Look AHEAD study have reported that participants with obesity who consistently reported binge eating lost half as much weight by year 4 of the study as those whose binge eating remitted early or those who didn't binge eat at any time (Chao et al. 2017). Similarly, veterans with overweight or obesity in the ASPIRE low-intensity weight management trial differed in success according to their binge eating. Those with binge eating lost half the weight (1.4% of body weight) compared with those without binge eating (2.7%) (Masheb et al. 2015). The small minority with high-frequency binge eating gained 1.4% body weight over the 12-month trial. In addition, binge eating affects the longevity of weight loss. In a weight loss maintenance trial, those with binge eating regained weight at 1.5 times the rate of those without binge eating (Masheb et al. 2015).

In people with high BMIs, very low-energy diets or severely energy-restricted diets that use meal replacement therapy have been shown to be a highly effective treatment (Maston et al. 2019). These treatments are often criticized due to their restrictive nature and potential to be a major contributor to binge eating and lead to the development of EDs. However, some studies that involved highly restricted diets such as very low-energy diets have shown that binge eating generally is stable or improved post intervention (Raymond et al. 2002; Svendsen et al. 2008; Wadden et al. 1994; Pekkarinen et al. 1996). One small study showed that 57% of those with diagnosed BED at baseline had improvements in their BED with 30% no longer meeting criteria for BED or subclinical BED 1 year post intervention (Raymond et al. 2002). However, it should be noted that 10% who did not meet criteria for BED or subclinical BED at baseline developed BED and 14% developed subclinical BED by 1 year. Other studies have shown that it is not dietary restriction or restraint that impacts on the disordered eating but the individual's level of disinhibition (Svendsen et al. 2008; Fogelholm et al. 1999; Yanovski and Sebring 1994).

Despite BED and high BMIs commonly coexisting, treatment for individuals with BED living with obesity is problematic because the approaches used for weight loss generally do not focus on the presence of binge eating and its related psychological symptoms. Additionally, psychological treatments for EDs are generally ineffective in promoting weight loss (Palavras et al. 2021). Traditionally it has been recommended that BED be treated first as dieting or restricting intake may trigger more binge eating events, thus perpetuating the ED and making weight loss harder. Despite this recommendation, people living with concurrent BED and obesity are more likely to seek weight loss treatment than treatment for their ED (Star et al. 2015).

Cognitive behavioral therapy has the strongest evidence for treatment of adults with BED, while evidence for adolescents is more limited (Hay et al. 2014). Behavioral weight loss has also been shown to be effective in the short term (Hay et al. 2009), but not in the longer term (Wilson et al. 2010). Dietitian-delivered guided self-help has also been shown to be effective for individuals with binge eating

(Traviss-Turner et al. 2018). In a review that compared CBT and weight loss behavioral therapy on binge eating pathology and weight loss in those with coexisting BED and high BMI, found CBT was favored for short-term binge eating reduction, but this was not sustained at 12 months. Furthermore, there was insufficient evidence to suggest that one type of intervention was superior to the other for weight loss, binge eating remission, or reduction of binge eating frequency (Palavras et al. 2017). Recently there has been research that has focused on treating the two together, e.g., HAPIFED trial (Palavras et al. 2021; Da Luz et al. 2017). The program has been found to be equally effective as CBT-E in reducing ED symptoms but superior in inducing weight loss. However, more research is required.

Encouraging people living with both BED and obesity to seek psychological support if not offered as part of the weight loss intervention is recommended. Providing a nonjudgmental, non-stigmatizing approach may help the individual confide in the clinician. Acknowledging their desire and reasons for weight loss is important; however, addressing how this could be perpetuating the binge eating should also be acknowledged. There are many strategies that cross both weight management and ED interventions which may offer some hope, although it should be stated upfront that weight loss is not the aim of the initial treatment, and without understanding the drivers that maintain the binge eating, long-term solutions are unlikely.

Strategies that cross both treatment areas include:

- Monitoring intake, behavior, and reasons for eating/restriction.
- Ensuring a balanced diet with regular meals that is nutritionally complete and enjoyable, including a meal plan, discussing food groups, portion sizes, food swaps, and flexibility around food choice.
- Reducing grazing.
- Making the environment suit the way the individual wants to eat.
- Acknowledging body image and stigmatization and its role in thoughts and actions.
- Managing and identifying physical hunger and internal and external cues to eating.
- Ensuring weighing no more than once per week and discussing a nonjudgmental attitude to the number on the scales.
- Removing food labels (e.g., good vs bad foods and dieting rules) and avoiding calorie counting.
- Using cognitive behavioral techniques to change thoughts or emotions and subsequently actions including stimulus control, problem-solving, and distraction techniques. Other behavior techniques include goal setting, urge surfing, and mindfulness.
- Planning for the future and acknowledging that relapses are likely.
- Ongoing collaboration with a mental health clinician.

In addition to the components above, specific additional information gathered as part of the treatment of BED should include family weight history, dieting attempts

and reasons for weight gain, feelings and perceptions of their weight triggers to eating if known, and feelings of loss of control. More research is required to understand how best to treat the people living concurrently with BED and obesity as well as better collaboration between weight management and ED dietitians to improve clinical outcomes.

Application to Other Eating Disorders

This chapter has provided an overview of the principles of dietetic treatment for individuals with EDs with diagnoses of AN, BN, and BED as well as specific considerations for dietetic intervention in an outpatient or inpatient setting. Most nutritional issues and approaches discussed are also relevant to other ED diagnosis including other specified feeding and eating disorders (OSFED) such as atypical anorexia nervosa and avoidant/restrictive food intake disorder (ARFID). Individuals with ARFID, however, tend to restrict the amount of type of particular foods or good groups based on factors such as the appearance, texture, smell, or temperature of a food or due to past negative experiences such as trauma associated with a food experience such as choking. Current research recommends a CBT approach which involves gradually exposing the individual to feared foods, relaxation training, and support to change eating behaviors. Similar to treatment recommendations provided in this chapter, treatment for ARFID should be multidisciplinary involving psychological, nutritional, and medical input.

Mini-Dictionary of Terms

Food insecurity: The disruption of food intake or eating patterns because of lack of money and other resources.

Food literacy: The ability to plan and manage, select, prepare, and eat meals.

Nutrition assessment: A systematic approach to collect, classify, and synthesize important and relevant nutritional data from patients.

Nutrition Care Process: A systematic method that nutrition and dietetics practitioners use to provide nutrition care.

Nutrition intervention: A planned intervention aimed at changing a nutrition-related behavior, risk factor, environmental condition, or aspect of health status.

Nutrition counselling: A two-way interaction between a patient and dietitian to discuss results of a nutrition assessment; identify nutritional issues, needs, and goals; discuss and plan appropriate nutrition intervention; and determine frequency of nutrition monitoring and evaluation.

Refeeding syndrome: A potentially fatal condition comprising metabolic and biochemical complications that can arise when malnourished individuals begin consuming an increased energy intake.

Key Facts

Key Facts Regarding the Role of Dietitians in Eating Disorder Treatment

- Dietitians are highly educated at university in human physiology, biochemistry, nutritional science, and eating behavior.
- Dietitians play a crucial role in helping individuals with EDs understand the interaction between food, nutrition, and well-being and supporting them to achieve nutrition-related treatment and recovery goals.
- Dietitians encourage active learning opportunities to help teach new behaviors and acceptance of food-related tasks, e.g., activities such as cooking, shopping, or modeling normal eating behavior in a meal supervision format or as part of practical eating activities.
- Practice standards for dietitians working in EDs have recently been published to ensure effective, safe, and timely care for individuals with an ED in addition to consistent treatment approaches.
- Consistent and standardized dietetic practice may not only enhance the legitimacy and credibility of dietitians as part of the multidisciplinary team, but may also lead to improvements in clinical care for individuals with EDs.
- It is important that dietitians advocate for people with EDs to have access to relevant, accurate, and evidence-based nutrition information that contributes to their recovery.

Summary Points

- Dietitians are responsible for managing the Nutrition Care Process defined by a comprehensive nutritional assessment, a nutritional diagnosis, implementation of a nutritional intervention, and monitoring progress toward treatment goals.
- Dietitians are likely to encounter individuals with EDs or disordered eating behaviors in their clinical work, even if it is not their specific area of practice. As a result, all dietitians can be considered as "first responders" and have an important role in the identification of EDs, contributing to early intervention and access to treatment.
- People with EDs engage in eating behaviors and dietary patterns with the aim of energy restriction for weight loss. Underpinning these behaviors are disordered cognitions and beliefs relating to food and eating.
- Eating adequately and regularly are core principles of treatment across all eating disorder diagnoses, and provide the basis of nutritional rehabilitation, to facilitate weight restoration and recovery from an eating disorder.
- There are a number of nutrition frameworks available that can be used to deliver nutrition intervention for EDs, including RAVES, the rule of threes, plate-by-plate approach, and the REAL Food Guide.

- Refeeding syndrome describes a potentially fatal condition comprising metabolic and biochemical complications that can arise when malnourished individuals begin consuming an increased energy intake.
- While oral nutrition is most beneficial for people with EDs, continuous nasogastric feeds have key benefits for medically compromised inpatients.
- It is important for the dietitian to liaise with a medical practitioner regarding specific medical complications associated with an ED.

Abstract

Physical activity (PA) is complex and difficult to characterize within eating disorder (ED) populations, due to the presence of both adaptive and maladaptive PA. To better understand PA in ED populations, it's important to consider both the psychological and objective factors of PA in EDs. Within ED research, PA has been most commonly measured using self-report, ecological momentary

assessment, and clinician assessment of PA. While these forms of measurement capture many psychological factors of PA like exercise motivation, these measures are subjective methods prone to biases and are reliant on an individual's recall. In addition to self-report measurement, emerging research has begun to utilize objective measurement tools, such as wearable sensors, to assess the objective components of PA in EDs. Sensor technologies are automatic and continuous methods of measuring PA that do not rely on subjective reporting and instead offer real-time data collection. The following chapter reviews the current measurement tools available to assess both the psychological and objective components of PA in ED populations and proposes future use of a multimodal method of investigating PA in ED populations.

Introduction

Physical activity (PA) is traditionally characterized as a healthy, adaptive behavior due to its physical and mental health benefits (Penedo and Dahn 2005; Catalan-Matamoros et al. 2016); however, among those with eating disorders (EDs), PA is commonly utilized as a maladaptive strategy to control an individual's shape and weight. Research classifies maladaptive PA as (1) PA intended to compensate for calories consumed during binge eating episodes and (2) PA that is driven (i.e., having a compulsive quality) and motivated by shape and weight concerns (Holland et al. 2014; Cook and Hausenblas 2008). Maladaptive PA is acknowledged in the field as a prominent factor in the etiology, development, and maintenance of symptoms across ED diagnoses (Meyer et al. 2011), and it is associated with several negative physical and psychological consequences (Lichtenstein et al. 2017). For example, individuals who engage in maladaptive PA may engage in PA to the point of injury, follow a rigid PA structure that interferes with other commitments (i.e., work, social events), or experience intense guilt or anxiety when unable to engage in PA. Maladaptive PA has also been associated with lower body mass index (BMI), higher levels of anxiety, and perfectionistic qualities (Shroff et al. 2006). Given the profound impact maladaptive PA has on individuals with EDs, it has increasingly become a focus of research as the field aims to gain further insight on how to prevent and treat maladaptive PA in the context of EDs.

While extant literature highlights the prevalence and importance of understanding maladaptive PA among ED populations, a growing body of research indicates that not all PA occurring among individuals with an ED is maladaptive. Rather, some individuals may engage in adaptive PA, which is characterized as PA that is non-compensatory, not solely intended to control shape or weight, and is non-driven. For instance, preliminary research using ecological momentary data revealed that 43% of individuals with binge-spectrum eating report both maladaptive and adaptive PA episodes (Lampe et al. 2021). Further, many individuals with EDs across diagnoses report engaging in only adaptive PA episodes (Wons et al. 2021; Lampe et al. 2021; Kerrigan et al. 2019). As the field continues exploring PA among ED populations, both maladaptive and adaptive PA should be considered when studying PA in EDs, as understanding both types of PA may enhance our understanding of the etiology, development, and maintenance of ED symptomology.

When studying PA in EDs, it is important to consider both (1) objective components of PA (e.g., frequency, duration, and intensity of PA) and (2) psychological components of PA (e.g., motivation to exercise, function of the exercise). To capture the objective and psychological components of PA in EDs, researchers must consider using rather complex multimodal assessment paradigms to fully capture both the objective and psychological components of PA in EDs.

Given the complex nature of assessing the psychological and objective components of PA in EDs, the following chapter aims to provide guidance around best practices for measuring the psychological and objective components of PA. The following sections will review (1) current assessment tools available to assess the psychological and objective components of PA in EDs and their purpose

and (2) the strengths and weaknesses of current assessment tools that assess psychological and objective components of PA in EDs. The chapter will end by providing guidance on multimodal assessment and future directions in the measurement of psychological and objective components of PA in EDs.

Assessment Tools for Measuring Objective and Psychological Components of PA in EDs

The main aim of the following subsections is to review current assessment tools, what psychological components of PA in EDs they assess, and the strengths and weaknesses of self-report measurements, EMA, and semi-structured interviews.

Self-Report Measurement of PA in EDs

Self-report tools are a common way to measure the psychological and objective components of PA among individuals with EDs. To date, self-reported PA has been primarily measured via surveys that assess the overall amount of PA engagement, including maladaptive qualities such as its driven or compensatory nature. Extant measures of self-reported psychological components of PA used in ED populations typically fall into one of three categories: (1) measures of general PA motivations (e.g., health improvement, enjoyment), (2) the compensatory nature of PA, and (3) the driven nature of PA engagement. See Table 1 for a complete list of self-report measures of PA in EDs.

Self-Report Measures of Objective Components of PA

Seven-Day Physical Activity Recall (PAR). The PAR (Blair et al. 1985) asks participants to recall morning, afternoon, and evening activities for the previous day until a full 7 days of information on minutes spent engaged in vigorous-intensity and moderate-intensity activities and sleep has been obtained. Cues are used to prompt classifications of activity into their respective intensities (i.e., light, moderate, and vigorous). While the PAR has not been validated in an ED population, it has demonstrated good validity in adult and young adult populations (Washburn et al. 2003; Lamb and Brodie 1990).

International Physical Activity Questionnaire (IPAQ). There are two versions of the IPAQ (Craig et al. 2003) that both assess PA engagement over the last 7 days. The short version (9 items) collects information from participants on the time spent walking, in vigorous- and moderate-intensity activity, and sedentary activity. The long version (31 items) collects detailed information within the domains of household and yard work activities, occupational activity, self-powered transport, and leisure-time physical activity, as well as sedentary activity. An additional question asks about the pace of walking and cycling. While the IPAQ has not been validated in ED samples, it has demonstrated adequate reliability across diverse populations (Craig et al. 2003; Lee et al. 2011; Bauman et al. 2009).

Table 1 Overview of measures of self-reported PA in EDs

Category	Measure name	Main construct assessed	Assessment period	Reliability in ED samples
Objective PA components	Seven-Day Physical Activity Recall (PAR)	Amount of time spent in "moderate," "hard," and "very hard" activity	Last 7 days	$r = 0.87$ with 7-day PA diary
	International Physical Activity Questionnaire (IPAQ)	Amount of time spent being active, sitting, walking, and engaging in moderate and in vigorous activity	"A typical week"	–
	Godin Leisure-Time Exercise Questionnaire (GLTEQ)	Frequency of engaging in bouts of at least 15 min of mild (e.g., "yoga, easy walking"), moderate (e.g., "fast walking, easy bicycling"), and strenuous (e.g., "jogging, vigorous swimming") activity during a typical week	"A typical week"	–
	Paffenbarger Physical Activity Questionnaire (PPAQ)	Number of flights of stairs climbed (i.e., 10 stairs per flight) and city blocks walked in a typical day and duration of weekly sports and recreational activities	"A typical day/week"	–
General PA motives	Reasons for Exercise Inventory (REI)	Exercise for: weight control, fitness, health, improving body tone, improving physical attractiveness, improving mood, and for enjoyment	In general	$\alpha =$ 0.67–0.81 across subscales
	Exercise Motivations Inventory-2 (EMI-2)	Exercise for: stress management, revitalization, enjoyment, challenge, social recognition, affiliation, competition, health pressures, ill-health avoidance, positive health, weight management, appearance, strength and endurance, and nimbleness	In general	$\alpha =$ 0.75–0.96 across subscales
Maladaptive PA	Eating Disorders Examination Questionnaire (EDE-Q)	Frequency of "hard exercise for weight/shape control"	Past 28 days	–
	Diagnostic Survey for Eating Disorders (DSED)	Frequency and duration of exercise for weight control	In general	–

(continued)

Table 1 (continued)

Category	Measure name	Main construct assessed	Assessment period	Reliability in ED samples
	Eating Disorders Inventory-Symptom Checklist (EDI-SC)	Percentage of exercise that is aimed at controlling weight	In general	$\alpha =$ 0.90–0.97
	Commitment to Exercise Scale (CES)	Obligatory aspects of exercising (e.g., feelings of guilt when an exercise session is missed and the feeling that general well-being is dependent on not missing an exercise session, the need to continue to exercise in the face of illness or injury)	In general	$\alpha = 0.96$
	Compulsive Exercise Test (CET)	Avoidance and rule-driven exercise; weight control exercise; exercise for mood improvement; lack of exercise enjoyment; and exercise rigidity	In general	$\alpha =$ 0.85–0.94 across studies
	[Modified] Obligatory Running Questionnaire (ORQ)	*Exercise behaviors*: Frequency and duration of exercise, solitary/secret exercise, the association between eating and exercise and hyperactivity *Exercise cognitions*: Motives for exercise, perceived adequacy and importance of exercise, feelings after exercise or failure to exercise	In general	–
	Obligatory Exercise Questionnaire (OEQ)	Emotional element of exercise; exercise frequency and intensity; and exercise preoccupation	In general	$r =$ 0.01–0.26 with EDI subscales
	Exercise Addiction Inventory (EAI)	Exercise salience, exercise for mood modification, conflict around exercise, exercise tolerance, withdrawal from exercise, exercise relapse	In general	$\alpha = 0.84$

Godin Leisure-Time Exercise Questionnaire (GLTEQ). The GLTEQ (Amireault and Godin 2015) assesses engagement in various types of PA over an average seven-day period. The questionnaire asks participants about the number of times they do

each activity for more than 15 min during their free time. Activities assessed are strenuous exercise (e.g., running, swimming), moderate exercise (e.g., fast walking, volleyball), and mild exercise (e.g., yoga, easy walking). The GLTEQ also asks participants how often they engage in any regular activity "long enough to work up a sweat" during a seven-day period. Participants can respond "often," "sometimes," or "never/rarely." While the GLTEQ has not been validated in ED samples, it has demonstrated adequate reliability in both adults and adolescents (Amireault and Godin 2015; Zelener and Schneider 2016; Godin et al. 1986; Jacobs Jr et al. 1993).

Paffenbarger Physical Activity Questionnaire (PPAQ). The PPAQ (Simpson 2011) asks respondents to report the number of city blocks they walk and the number of flights of stairs they climb on a typical day, as well as the frequency and type of any sports or recreational activities they participated in over the past year. Using subject responses to these questions, researchers can estimate energy expenditure by calculating a physical activity index (Paffenbarger Jr et al. 1978). Several additional questions assess the frequency and intensity of PA the respondent participates in. While the PPAQ has not been validated in ED samples, it has demonstrated adequate reliability among adults (Simpson 2011; Simpson et al. 2015).

Self-Report Measures of General PA Motivations

Reasons for Exercise Inventory (REI). The REI (Silberstein et al. 1988) assesses PA for the reasons of weight control, physical fitness, health improvement, improving body tone, improving physical attractiveness, improving mood, and enjoyment. The REI asks individuals to indicate whether each PA motive statement is an important reason that they have for exercising. Responses on the REI are made on a 7-point Likert scale ranging from "not at all important" to "extremely important." Additionally, the REI has demonstrated adequate validity in healthy adults (Courneya and McAuley 1995) and adults with anorexia nervosa (AN) (Young et al. 2017) across subscales.

Exercise Motivations Inventory-2 (EMI-2). While the EMI-2 (Markland and Ingledew 1997) also assesses PA for the reasons of enjoyment, health improvement, weight management, appearance, and physical fitness, it also assesses PA engagement for stress management, revitalization, challenge, social recognition, affiliation, competition, health pressures, ill-health avoidance, and nimbleness. The EMI-2 asks individuals to indicate whether each statement of PA motive was true for them personally or would be true for them if they did PA. Responses on the EMI-2 are made on a 6-point Likert scale ranging from "not at all true for me" to "very true for me." Additionally, the EMI-2 has demonstrated adequate validity among healthy adults (Markland and Ingledew 1997), though this instrument has not been validated in ED populations.

Self-Report Measures of Maladaptive PA

Diagnostic Survey for Eating Disorders (DSED). The DSED (Johnson 1987) assesses PA intended to "work off" calories consumed throughout the day. Specifically, the DSED assesses the general frequency and duration of PA for the purposes

of burning calories. DSED assessment of compensatory PA has not been independently validated.

Eating Disorders Examination Questionnaire (EDE-Q). The EDE-Q (Fairburn and Beglin 1994) focuses on the assessment of strenuous PA intended to control one's weight or shape. The EDE-Q assesses the number of times individuals "exercised hard as a means of controlling their shape or weight" over the past 28 days. EDE-Q assessment of PA has shown good reliability among adults with AN, though it has not been independently validated in other ED populations (Young et al. 2017).

Eating Disorders Inventory-Symptom Checklist (EDI-SC). Similar to the EDE-Q, the EDI-SC (Garner and Olmsted 1986) assesses the proportion of individuals' PA that is aimed at controlling their weight or shape. EDI-SC assessment of driven PA has not been independently validated.

Commitment to Exercise Scale (CES). The CES (Davis et al. 1993) measures obligatory or rigid aspects of PA (e.g., feelings of guilt when a PA session is missed and the feeling that general well-being is dependent on not missing a PA session, the need to continue PA in the face of illness or injury). The CES asks individuals to rate the extent to which each statement is generally true for them on a visual analog scale from "never" to "always." The CES has demonstrated good validity within ED populations (Davis et al. 1995; Young et al. 2017).

Compulsive Exercise Test (CET). The CET (Taranis et al. 2011) also measures obligatory or rigid aspects of PA. The CET asks individuals to rate the extent to which each statement is generally true for them on a 6-point Likert scale from "never true" to "always true." The CET has demonstrated good validity within adults with AN, though it has not been validated in other ED populations (Young et al. 2017).

Obligatory Exercise Questionnaire (OEQ). This measure assesses PA frequency and intensity, as well as preoccupation with PA and the emotional element of PA (Steffen and Brehm 1999). The OEQ has shown god validity in healthy adult populations (Duncan et al. 2012), and one study found small-to-moderate correlations between the OEQ and the EDI ($r = 0.01–0.26$ across EDI subscales; Steffen and Brehm 1999).

Exercise Addiction Inventory (EAI). Similar to the OEQ, the EAI (Griffiths et al. 2005) has also been utilized to assess driven PA in EDs. The EAI assesses PA salience, PA for mood modification, conflict around PA, PA tolerance, withdrawal from PA, and PA relapse. The EAI has demonstrated adequate reliability among a general adult population (Griffiths et al. 2005); however, it has not been validated among individuals with EDs.

Modified Obligatory Running Questionnaire (ORQ). A modified version of the ORQ for EDs has also been used to assess the obligatory nature of PA in ED populations (i.e., PA including, but not limited to, running; Blumenthal et al. 1984). This modified ORQ assesses both PA behavior (i.e., PA frequency, duration, secret PA, associations of PA with eating) and PA cognitions (i.e., motives for PA, perceived adequacy and importance of PA, feelings after PA, or failure to engage in PA). Validity information for the modified version of the ORQ is not available.

Strengths and Weaknesses of Self-Report Measures of PA

One benefit of self-report measures of PA in EDs (compared to objective measures of PA) is their ability to capture the compensatory or driven nature of PA, which is subjective and cannot be easily measured via objective measurement tools. Additionally, self-report measures can assess a broader range of constructs such as motivations for PA, compared to objective measures of PA. However, self-report measures of PA in EDs are also subject to several weaknesses. First, self-report measures rely on retrospective recall, which is subject to several biases as well as inaccurate reporting, and recent research has suggested that self-reported frequency of PA engagement is highly inaccurate (Mâsse and Judith 2012). Specifically, Mâsse and colleagues concluded that it is difficult to obtain valid estimates of objective PA components from self-report, as the minutes of PA obtained with self-report measures are biased (e.g., overestimating or underestimating PA). Additionally, we might expect that individuals with EDs would be at a higher risk for under-/overreporting PA engagement due to their increased concern with shape and weight (Dalle Grave et al. 2020). Second, many self-report measures of PA used in ED populations measure PA behavior and/or cognitions "on average" rather than on a specific timescale (e.g., within the last month), which makes reporting inaccuracies more likely. Only the Seven-Day PAR and EDE-Q assess recent objective components of PA engagement (ranging from the last 7 to 28 days). Finally, many measures of PA used in ED populations are not validated in those subpopulations. While many of the measures may apply to both general populations and ED populations, there may be differences in the presentation of PA behaviors among individuals with EDs that necessitate the revalidation of these measures in this group.

Ecological Momentary Assessment of PA in EDs

Several studies have used daily diary or EMA to measure both objective and psychological components of PA in ED samples. While EMA is still based on self-report, it offers the advantage to researchers of being able to capture PA behavior in real-time and in real-world settings through repeated administrations of surveys delivered to participants' smartphones or other handheld devices. See Table 2 for further details on EMA questions assessing PA in EDs.

EMA of Objective Components of PA

EMA of objective components of PA has broadly used a yes/no answer format to assess for engagement in PA over the preceding hours (Lampe et al. 2021; Pirke et al. 1991; Lavender et al. 2013, 2016; Ma and Kelly 2020; Davis et al. 1995). EMA questions have asked about the type of activity that participants engaged in (e.g., swimming, running) and the duration of PA engagement. No studies to date have independently assessed the intensity of PA using EMA. EMA assessment of PA frequency has demonstrated adequate validity among individuals with

Table 2 EMA measures of exercise used in ED samples

Category	Main construct assessed	Item wording (if available)	Reliability
Objective PA components	Exercise engagement (yes/no scale)	*Have you exercised since the last survey*?	–
	Activity type (e.g., running, swimming)	–	–
	Duration of exercise engagement	–	–
General PA motives	Exercise for: health improvement, emotion regulation, routine, enjoyment, shape/weight control, obligation or guilt	*Did you exercise for any of the following reasons?* ☐ *Because it was part of my routine* ☐ *Because I would feel guilty if I didn't* ☐ *To cope with a difficult emotion* ☐ *So that I could eat more later* ☐ *To improve my health* ☐ *Because I enjoy the activity* ☐ *To control my shape or weight* ☐ *Other (specify)*	$\alpha = 0.91$
Maladaptive PA	Frequency of thoughts about exercising to control weight and/or shape or burn calories	*Have you thought about exercising as a means of controlling your weight, altering your shape or amount of fat, or burning off calories*?	–
	Frequency of exercising to control one's weight and/or shape or burn calories	*Did you actually exercise to influence your shape or weight since the last time you were signaled*?	–
	Extent of exercising to control one's weight and/or shape or burn calories at each episode (assessed via 5-point Likert scale from "Not at all" to "Extremely")	*To what extent did you exercise to compensate for eating?*	$\alpha = 0.79$
	Frequency of urges to "over-exercise"	–	–
	Frequency of engagement in "excessive exercise" (measured via Likert scale from 1 "Not at all" to 6 "Extremely" or "A lot")	–	–
	Intensity of feeling driven or compelled to exercise during each episode (measured via Likert scale from 1 "Not at all" to 5 "Extremely")	*To what extent did you feel driven or compelled to exercise*?	$\alpha = 0.79$

binge-spectrum EDs (Lampe et al. 2021); however, it has not been validated in other populations.

EMA of General PA Motivations

One study has used EMA to assess general PA motivations. This study included assessment of PA for health improvement, mood improvement, as part of one's routine, enjoyment, weight control, and due to obligation or guilt (Lampe et al. 2021). Of note, these EMA items were based on the REI and EMI-2 questions and are thus very similar in nature. Additionally, EMA items assessing PA motives demonstrated a high reliability among individuals with binge-spectrum EDs (Lampe et al. 2021).

EMA Maladaptive PA

EMA has also been used to assess PA for the purpose of "working off" calories consumed throughout the day (Lampe et al. 2021; Fitzsimmons-Craft 2017; Stein and Corte 2003). One study used EMA to measure the frequency of thoughts about engaging in compensatory PA (Fitzsimmons-Craft 2017). EMA questions have also assessed both the frequency (Fitzsimmons-Craft 2017; Stein and Corte 2003) and extent (Lampe et al. 2021) to which each bout of PA was designed to compensate for eating. Questions asking about the extent of the compensatory nature of PA have used a 5-point Likert scale ranging from "not at all" to "extremely." One study by Stein and colleagues reported that PA items were derived from commonly used ED behavior questionnaires including the Eating Disorders Examination (Fairburn et al. 1993) and the Questionnaire on Eating and Weight Patterns-Revised (Yanovski et al. 2015). In one study, EMA assessment of compensatory PA demonstrated adequate reliability among individuals with binge-spectrum EDs (Lampe et al. 2021); however, it has not been validated in other populations.

Only one study to date has assessed the driven nature of PA via EMA (Lampe et al. 2021). This study used a question designed to capture the extent to which the individual pushed themselves, or felt compelled to exercise, during each bout of PA using a 5-point Likert scale ranging from "not at all" to "extremely." EMA questions assessing driven PA in EDs have demonstrated adequate reliability among individuals with binge-spectrum EDs (Lampe et al. 2021).

To date, three studies have used EMA to measure excessive PA engagement among individuals with EDs (Levinson et al. 2018; Sala et al. 2019; Vanzhula et al. 2020). One study measured the frequency of urges to "over-exercise" (Levinson et al. 2018), while two studies measured the frequency of actual engagement in self-reported "excessive exercise" (Sala et al. 2019; Vanzhula et al. 2020). No studies provided an operational definition of "excessive" nor reported reliability statistics within their sample. Additionally, EMA measurement of excessive exercise has not been validated.

Strengths and Weaknesses of EMA Measures of PA

EMA offers several notable methodological advantages over traditional self-report for the measurement of PA in EDs. First, information is collected in real time, which

minimizes the risk of recall bias. Second, information is collected within a real-world context, maximizing researchers' ability to observe behaviors outside the lab in an ecologically valid way. Finally, because EMA involves repeated administrations of short surveys, it is possible to establish temporal sequencing of events. This allows researchers to examine precipitants and consequences of PA engagement and associated psychological components.

However, EMA of PA in EDs has several weaknesses. First, EMA is a self-report measure and is thus subject to several biases such as social desirability bias. Further, to date, no study has validated reporting of objective components of PA engagement in ED populations, which may be affected by social desirability bias. Second, many studies using EMA to assess PA in this population do not include information on their definition of PA. For example, several studies reported that "ED behaviors were assessed, including exercise" (Lavender et al. 2013, 2016). In addition, one study reportedly measured "exercise episodes" in anorexia nervosa, using EMA, but the authors did not describe how they assessed PA (Ma and Kelly 2020), and several studies failed to define "excessive exercise" for readers or participants (Levinson et al. 2018; Vanzhula et al. 2020; Sala et al. 2019). Only two studies report training participants on how to recognize maladaptive forms of PA (Lampe et al. 2021; Fitzsimmons-Craft et al. 2016), which is important as ambiguity in this area could result in biased participant responses to EMA questions. Finally, only two studies reported that their items were derived from validated self-report measures of PA and ED behaviors (Stein and Corte 2003; Lampe et al. 2021).

Semi-structured Interviews of PA in EDs

Semi-structured interview tools are another common way to measure psychological and objective components of PA among individuals with EDs. To date, semi-structured interviews of PA are clinician-assessed and reliant on participant's recall. While the entire assessment may be lengthy, the questions regarding PA in a clinician assessment tool are often one to two questions with potential follow-up questions. Extant semi-structured interviews of PA focus on only maladaptive forms of exercise (i.e., driven exercise).

Semi-structured Interviews of Maladaptive PA

Eating Disorders Examination Interview (EDE). The EDE is a semi-structured interview that focuses on assessing driven PA that is intended to control one's shape and weight (Cooper and Fairburn 1987). The EDE assesses the number of days an individual has "felt driven or compelled to exercise" and "exercised as a means of controlling weight, altering shape or amount of fat, or burning off calories" over the past 3 months (Fairburn et al. 1993). Research supports that the EDE is reliable for use across EDs (Grilo et al. 2004; Rizvi et al. 2000). To date, no study has assessed the inter-rater reliability of the EDE exercise items (Berg et al. 2012). The current version of the EDE does not assess compensatory PA or adaptive PA;

Table 3 Semi-structured interview measures of exercise used in ED samples

Category	Main construct assessed	Item wording (if available)	Reliability
Maladaptive PA components	Driven exercise engagement (yes/no scale)	Required questions: 1. Over the past four weeks, have you exercised as a means of controlling your weight, altering your shape or amount of fat, or burning off calories? 2. Have you felt driven or compelled to exercise? Follow-up questions: 1. Typically, what form of exercise have you taken? How hard have you exercised? Have you pushed yourself? 2. Have you exercised even when it might interfere with other commitments or do you harm? 3. Have there been times when you have been unable to exercise for any reason? How has this made you feel?	–
	Frequency of driven exercise engagement	–	–
	Average duration of driven exercise engagement	–	–

however, some researchers have added items assessing compensatory and adaptive PA (Wons et al. 2021), but these items have not been independently validated. See Table 3 for further details on EMA questions assessing PA in EDs.

Strengths and Weaknesses of Semi-structured Interviews of PA

Semi-structured interviews allow the opportunity for probing and follow-up questions, which can lead to opportunities for more thoughtful and descriptive responses. In addition, clinicians are trained to assess different forms of PA, which may allow for a more accurate appraisal of maladaptive and adaptive PA than what a patient may report via self-report of EMA. However, semi-structured interviews of PA in EDs also demonstrate several weaknesses. First, like self-report measures, semi-structured interviews rely on the individual's retrospective recall, which can potentially result in inaccurate reporting and bias. Despite the EDE being reliable, studies have challenged the validity of the measure, given that responses rely on participant recall and self-report (Grilo et al. 2004). Second, the EDE does not capture the compensatory nature of exercise, adaptive exercise, or overall PA engagement. Given that semi-structured interviews are heavily reliant on participant recall, many of the weaknesses reviewed for self-report measures of PA apply to semi-structured interviews of PA.

Assessment Tools for Measuring Objective Components of PA in EDs

Despite self-report measures of PA being the most common way to measure PA in EDs, self-report measures have several weaknesses, including their inability to measure objective components of PA in EDs. This weakness has raised concerns around the accuracy of PA reported across ED samples (Bezzina et al. 2019; Mathisen et al. 2018) and in the general adult population (Prince et al. 2008). Such concerns within the ED field have led researchers to explore PA measurement through alternative techniques, including objective measurements of PA. Many objective measurements of PA used in EDs involve using different types of wearable sensor technology such as wearable portable motion sensors (e.g., accelerometers and pedometers) or wearable physiological sensors (e.g., heart rate sensors, carbon dioxide sensors) (Arnardottir et al. 2012; Chen et al. 2012; Maramis et al. 2014). The use of wearable sensors allows for objective, real-time measurements of PA that are not dependent on memory recall.

The term sensor is used to describe devices that translate physical measurement (e.g., heart rate) into a signal that can be interpreted by an apparatus or an observer (e.g., minutes of PA) (Chen et al. 2012). The sensor technologies most regularly used to objectively measure PA include the following wearable sensors: accelerometers, pedometers, heart rate sensors, and combination devices (Chen et al. 2012; Bratland-Sanda et al. 2011; Warren et al. 2010; Silfee et al. 2018).

Objective Measurement: Types of Sensor Technology

See Table 4 for a brief review of the types of sensor technology and the main PA constructs they assess.

Accelerometers. To date, accelerometers are the most widely used sensors for measuring objective components of PA in free-living settings, clinical settings, and within the ED field (Chen et al. 2012; Bratland-Sanda et al. 2011; Warren et al. 2010). Accelerometers are noninvasive and can be worn in various forms including as an armband, a wrist-worn device, and a hip-worn device. Accelerometers sense vibrations to obtain measurements of body movements and use an algorithm to process and differentiate between a locomotive and non-locomotive movement (Choi et al. 2011; Kozey et al. 2010; Nagayoshi et al. 2019). Further, as research

Table 4 Types of sensors and the main constructs assessed to measure objective components of PA

Type of sensor	Main constructs assessed
Accelerometers	Intensity, duration, frequency, and type of PA
Pedometers	Step count
Heart rate sensors	Intensity, duration, and frequency of PA
Combination devices	Step count, distance, sleep, and intensity, duration, frequency, and type of PA

has advanced, accelerometers can detect specific characteristics of PA such as the intensity, duration, frequency, and type of PA (i.e., playing basketball versus running) (Choi et al. 2011). For example, most accelerometers capture metabolic equivalents (METs), which can be coded through the sensor, or by hand, into minutes of light, moderate, and vigorous PA (Wons et al. 2021; Kozey et al. 2010). The standard MET cutoff points for determining the intensity of PA are the following: <3 METs light PA, 3–5.99 METs moderate PA, and ≥6 METs vigorous PA (Kozey et al. 2010). Accelerometers often export data that contains a MET reading per minute, which can be converted into minutes of light, moderate, or vigorous PA. Some accelerometers also have advanced multi-sensor technology that allows them to collect step count and heart rate data (Silfee et al. 2018), which is beneficial as it reduces the number of sensors a participant would need to wear to capture comprehensive and objective PA data.

Pedometers. Separate from accelerometer sensors are pedometer sensors, which solely measure step count. Since pedometers are specific to measuring step count, they aim to measure overall PA routine because they cannot detect specific types of PA (i.e., playing basketball versus running) (Palavras et al. 2015; McNamara et al. 2010). Although pedometers are not widely used within ED research, accelerometers with step-counting features are often used in ED research to determine overall how physically active an individual is on a daily, weekly, or more long-term basis (Silfee et al. 2018). Step count can provide information on overall PA levels for an individual and whether an individual's step count is compliant with recommended step counts (e.g., Centers for Disease Control (CDC) recommendations, treatment recommendations, weight loss recommendations).

Heart rate sensors. In addition to accelerometers and pedometers, heart rate sensors are also used to objectively measure PA in EDs. Using heart rate data is becoming a popular way to measure PA in EDs because similar to using METs, researchers can convert minute-by-minute heart rate data into minutes of light, moderate, and vigorous PA (Faust et al. 2019). Further, minutes of moderate-to-vigorous physical activity (MVPA) tend to be most often used when reporting objective components of PA because they indicate whether an individual is meeting the PA guidelines promoted by the American Heart Association's PA recommendation of at least 150 min of moderate PA weekly or 75 min of vigorous PA (Alharbi et al. 2016). Further, extant research demonstrates the use of developed frameworks to extract minutes of PA data from minute-by-minute heart rate data. For example, the Physical Activity Trend eXtraction (PATX) framework is commonly used, and it extracts minutes of MVPA data while considering an individual's age and heart rate zones, which are calculated and based on the CDC and American College of Sports Medicine (ACSM) heart rate zone recommendations (Faust et al. 2019). Calculations for determining heart rate zones are outlined in Table 5. Overall, using heart rate data is valuable for understanding the objective components of PA in EDs as it provides researchers with a better understanding of the duration, frequency, and intensity of PA in individuals with EDs.

Combination devices. Although accelerometers, pedometers, and heart rate monitors have utility in objectively measuring PA in EDs on their own, wearable fitness

Table 5 Target heart rate zone calculations as developed by PATX, CDC, and ACSM

Steps	Calculations
Step 1	Calculate age-predicted maximal heart rate (APMHR) APHMR = 220-age
Step 2	Calculate *moderate*-intensity physical activity target heart rate for the 64% and 76% maximal heart rate level 64% level = APMHR × 0.64 76% level = APMHR × 0.76
Step 3	Calculate *vigorous*-intensity physical activity target heart rate for the 77% and 95% maximal heart rate level 77% level = APMHR × 0.77 95% level = APMHR × 0.95

Note: *APHMR* age-predicted maximal heart rate

trackers that include some combination of these objective measurements are becoming more common. Current wearable fitness trackers in objective PA research include products like Apple, Garmin, Fitbit, Mi Band, Samsung, Jawbone watches, and more (Kaewkannate and Kim 2016; Liang et al. 2018). Wearable fitness trackers with multiple-sensor technology reduce the need for an individual to wear multiple sensors to capture all forms of objectively measured PA. Across the wearable fitness trackers listed, all include accelerometer sensor technology and include features like step count, an activity timer, distance recording functions, and sleep tracking (Liang et al. 2018). Apple, Samsung, Jawbone, Mi Band, and Fitbit wearable fitness tracker devices also include heart rate monitoring (Liang et al. 2018; Paradiso et al. 2020). The noninvasive nature and all-inclusivity of objective technology make combination devices sought after for measuring objective components of PA in EDs.

Objective Measurement Outcome Variables

To date, most extant research using objective measurements to capture the objective components of PA in EDs report on step count or minutes of PA and MVPA. As objective measurement techniques have become increasingly popular in the ED field, debate has arisen around whether step count or minutes of PA and MVPA is a better objective measurement of PA in EDs. While step count captures the overall movement and PA of an individual, it does not directly translate into an interpretable value that indicates the duration or intensity of an individual's PA. Work by Faust et al. (2019) suggests that minutes of MVPA is the best indicator for accurate PA levels and that heart rate is superior to step count in measuring MVPA because they found that greater time spent in MVPA based on target heart rate zone resulted in greater steps on average, but steps did not always result in greater MVPA. Further, heart rate is also often preferred over step count to measure minutes of MVPA because many factors can influence steps over time (i.e., dynamic environments where daily routines are subject to change), and step count cannot guarantee an individual is meeting the intensity or bout length guidelines necessary to for

Table 6 Objective measure outcome variables

Outcome variables	Main constructs assessed	Measurement route
Step count	Overall levels of PA	Pedometers, combination devices
Overall minutes of PA	Duration of overall PA	Accelerometers, heart rate sensors, combination devices
Minutes of MVPA	Duration of moderate-to-vigorous-intensity PA	Accelerometers, heart rate sensors, combination devices
Number of PA episodes	Frequency of PA engagement	Accelerometers, heart rate sensors, combination devices

classification as MVPA (Faust et al. 2019). Overall, step count is reliable for measuring how physically active an individual is overall, but minutes of MVPA should be used to determine the duration and intensity of PA in individuals with EDs.

Of note, it is important to take into consideration how to report step count and minutes of MVPA. A majority of work to date report step counts as a daily average. Many researchers collect step count data over 1 to 7 days to determine an individual's daily step count average (Del Giudice et al. 2021; Mathisen et al. 2018; Norris et al. 2017; O'Brien et al. 2018; Yao et al. 2021). For minutes of MVPA, many researchers report on total minutes of MVPA over the course of 1 week. When measuring MVPA it is important to keep in mind that historically, MVPA was counted if it occurred in a bout of at least 10 min. However, recent work suggests that minutes of MVPA that are not at least 10 min in duration are associated with a variety of positive health outcomes and should be counted when measuring total minutes of MVPA (Jakicic et al. 2019). See Table 6 for a brief review of the objective outcome variables from objective measurement of PA.

Strengths and Weaknesses of Objective PA Measurement

Objectively measuring PA in those with EDs allows researchers to assess PA in real time and does not depend on factors like an individual's recall, the accuracy of the reporting, and social desirability biases. As a result, objective measurement removes concern around the accuracy of patients reporting their overall PA. Preliminary research in the ED field demonstrates that objective techniques, such as using wearable fitness trackers to measure step count and minutes of MPVA, more accurately measure the amount of PA and increase the credibility and validity of the findings (Mathisen et al. 2018; Grosser et al. 2020). Further, unlike most self-report measures, objective measurements can accurately assess multiple dimensions of PA (e.g., frequency, intensity, duration, type), as well as increase our understanding of free-living, everyday activity (Silfee et al. 2018).

Although there are several strengths to using objective measures of PA in EDs, there are also weaknesses to consider. Some researchers have raised concerns about wearable fitness trackers potentially having a negative impact on the development and maintenance of ED symptoms (Simpson and Mazzeo 2017). More specifically,

there is concern that wearable fitness trackers with watch faces may display PA measurements and influence ED symptoms and behaviors. For example, an individual may look at their watch, perceive their step count for the day as low, become worried about gaining weight because they haven't been very active, and then engage in driven exercise to increase activity level and their step count. Additionally, objective measures of PA cannot separately measure maladaptive PA from overall PA, and they cannot measure psychopathology associated with the PA (i.e., maladaptive motivations for PA). Lastly, it can be costly to objectively measure PA in EDs as sensors and wearable fitness trackers vary greatly in price, costing up to $200 per device.

Future Directions of Assessment of Psychological and Objective Components of PA in EDs

Collectively, there are a variety of assessment tools that measure the psychological and objective components of PA in EDS. As a field, objective measurements tend to be underused. This is often because maladaptive PA is prevalent across EDs, and many of the psychological components associated with maladaptive PA are cognitive in nature (e.g., a sense of being compelled or driven to continue exercising) and thus cannot be assessed via wearable fitness trackers. However, by not using objective measures of PA as often as self-report, EMA, and semi-structured interviews to measure PA, the ED field is missing out on the valuable and reliable objective PA data that can come from objective measurement. Accordingly, more research using a multimodal approach, including self-report, EMA, semi-structured interviews, and objective measurements, is needed to assess the psychological and objective components of PA behavior in individuals with an ED, as it is not currently possible to dismantle adaptive from maladaptive PA based solely on the amount of overall PA alone, PA motivators, or intensity of PA. Understanding the psychological and objective components of PA in EDs continues to be complex, and ultimately, it will not fully be understood PA within the ED field until more studies use multimodal assessment to explore both the psychological and objective components of PA in EDs. To expand on this area of research, multimodal assessment is necessary across experimental and treatment studies that measure psychological and objective components of PA in individuals with EDs. Additionally, given that wearable sensors are still relatively new to measuring objective components of PA in EDs, exploratory research on the impact that wearable fitness trackers have on ED symptomatology and PA is necessary. Overall, using a multimodal approach to assess the psychological and objective components of PA in EDs will address the weaknesses of self-report, EMA, semi-structured interviews, and objective measurement tools as well as advance the ED field in our understanding of the role of PA in the etiology, development, maintenance, and treatment of EDs.

Mini-Dictionary of Terms

- **Adaptive physical activity**: Exercise that is not compensatory or driven in nature and is motivated by non-pathological physical benefits and mental health improvements.
- **Binge-spectrum eating disorders**: Eating disorders where participants experience binge eating episodes (e.g., binge eating disorder, bulimia nervosa).
- **Compensatory physical activity**: Exercise that is done in response to a binge eating episode to compensate for the calories consumed, with the ultimate goal of impacting one's shape or weight.
- **Driven physical activity**: Exercise that is compulsive and prioritized by an individual above all else, often within a rigid routine and leading to negative consequences, guilt, or anxiety.
- **Ecological momentary assessment**: A method of data collection that involves repeated measurement of behaviors, symptoms, thoughts, or emotions in real time within a participant's naturalistic environment.
- **Excessive exercise**: Exercise that is characterized as high in frequency, intensity, and duration, which may lead to injury.
- **Maladaptive physical activity**: Exercise that is intended to compensate for calories consumed, is driven and excessive in nature, and is motivated by shape and weight concern.
- **Metabolic equivalents**: A commonly used method for expressing the energy cost of physical activities as a multiple of the individual's resting metabolic rate.
- **Moderate to vigorous physical activity**: Physical activity that is characterized by significant increases in breath or heart rate (i.e., brisk walking, jogging, dancing, or cycling).
- **Objective measures**: A quantifiable and impartial method of data collection that is measured consistently (e.g., wearable sensor technology).
- **Physical Activity Trend eXtraction framework**: A specific procedure for preprocessing wearable fitness sensor data to impute missing data, personalize target zones, and extract physical activity trends.
- **Recall bias**: A cognitive error that may occur when an individual misremembers a previous event, which may result in the omission of details and inaccurate reporting when completing self-report measures.
- **Self-report measures**: A method of data collection that relies on an individual's report of their behaviors, symptoms, thoughts, or emotions.
- **Sensors**: Any objective piece of technology (often automatic, passive, and wearable) that uses sensors to measure a feature continuously, in real time, and translates this data into a readable signal.
- **Shape and weight concern**: An individual's concern related to the number on the scale and their physical appearance (i.e., size of their body, their figure).

Key Facts

- Physical activity in eating disorder populations can be both maladaptive and adaptive in nature.
- Maladaptive exercise is exercise that is intended to compensate for calories consumed, is driven and excessive in nature, and is motivated by shape and weight concern.
- Maladaptive PA is acknowledged in the field as a prominent factor in the etiology, development, and maintenance of symptoms across ED diagnoses.
- Adaptive exercise is exercise that is not compensatory or driven in nature and is motivated by non-pathological physical benefits and mental health improvements.
- Multimodal assessment is necessary to capture both the psychological and objective components of adaptive and maladaptive PA in EDs.

Summary Points

- Physical activity is complex and difficult to characterize within eating disorder population because physical activity can be both adaptive and maladaptive.
- Both psychological and objective components of PA need to be taken into account when measuring PA overall or adaptive and maladaptive PA in ED research.
- Physical activity among eating disorder populations can be measured using self-report questionnaires, semi-structured interviews, and objective measurement tools.
- While self-report and semi-structured interview measures can capture an individual's motivations for physical activity, they are subjective methods which are prone to biases or inaccurate reporting.
- Ecological momentary assessments allow for physical activity measurements to be collected in a naturalistic environment in real time, though this data is self-reported and may be subject to social desirability biases.
- Sensor technologies are objective, automatic, and continuous methods of measuring physical activity that do not rely on subjective reporting and instead offer real-time data collection.
- The authors propose a multimodal method of investigating physical activity in eating disorder populations that uses clinician-assessed, self-report, and objective measurements to fully capture both objective and psychological features.

Body Mass Index and Body Fat in Anorexia Nervosa

22

Marwan El Ghoch

Contents

Abstract

Anthropometry is considered one of the main methods of nutritional assessment in individuals with anorexia nervosa (AN). In this chapter, we will focus on body mass index (BMI) and total body fat (BF). We introduce the reliable and validated techniques for their assessment during underweight, weight gain and after complete weight restoration, and their changes during the course of the disease. The chapter also discusses the association/relationship between BMI and BF and the most important treatment clinical outcomes in this population: (i) relapse, remission, and/or recovery; (ii) reduction and normalization in bone mineral density (BMD); and (iii) amenorrhea, resumption of menstrual cycle, and reproductive function.

DXA	Dual-energy X-ray absorptiometry
MRI	Magnetic resonance imaging
ST	Skinfold thickness

Introduction

Nutritional assessment in any population is represented by an evaluation of objective and subjective data to determine the individual's nutritional status or growth patterns (Reber et al. 2019). Accurate assessment is vital and essential in different settings (i.e., in the general population and in the clinical setting). Its aim is to identify persons at risk of malnutrition, determine the nature of nutritional intervention, and monitor the effects of the intervention (Reber et al. 2019). Assessment has four main components, the anthropometric, biochemical, clinical, and dietary components (de Almeida et al. 1999).

Anthropometry is the measurement of the physical dimensions and macro-composition of the body (Gorstein and Akre 1988). It is the most used method in clinical settings for the assessment of nutritional status, especially when using approaches that do not rely on sophisticated instruments and are less expensive. Of these approaches, body mass index (BMI) and body fat (BF) are particularly noteworthy. In this chapter, we will first discuss the importance of the assessment of BMI and BF in patients with anorexia nervosa (AN) during underweight to establish the disease gravity and severity and also its use after treatment for eating disorders. Second, we will identify the best instrument for this aim in the clinical setting. Finally, we will discuss the association/relationship between BMI and BF as good predictors of the main three clinical outcomes (relapse and remission, amenorrhea and resumption of menses, and osteoporosis and bone mineral density [BMD] restoration).

Definitions of BMI and BF

BMI

The concept of BMI was first developed by the Belgian mathematician and statistician Adolphe Quetelet in 1832 (Eknoyan 2008). In his studies on the anthropometric data of human growth, he concluded that weight grows with the square of height and introduced the Quetelet index to describe the relationship between the two variables (Eknoyan 2008). Over a century later, the Quetelet index was used in obesity studies, and the term BMI was then introduced by physiologist Ancel Keys in 1972 (Keys et al. 1984). During that period and based on the data from the Seven Countries Study, researchers noticed that BMI appeared to be a good proxy for adiposity and overweight-related comorbidities (Keys et al. 1984).

BMI is defined as an individual's weight expressed in kilograms divided by the square of height in meters (Kg/m^2). It is very easy to measure and calculate and is therefore the most commonly used index to correlate risk of health problems with weight at a population level. However, as with many other measurements, BMI has certain limitations. Since it only relies on height and weight, it does not take into consideration different levels of adiposity based on age, physical activity levels, and gender. Therefore, it is expected that it over- or underestimates adiposity. The cutoff points of BMI in the general population, according to the World Health Organization (WHO) and Asian classification, as well as the DSM-5 severity specifiers based on thinness for adults with AN, are shown in Table 1.

BF

BF in humans is defined as the mass of fat in the total body mass usually expressed in kilograms. It includes both essential and storage BF. The former is necessary to maintain life and reproductive functions, and for this reason it is greater in females than males, because of the demands of childbearing and other hormonal functions. The latter consists of fat accumulation in adipose tissue, part of which protects internal organs. Age- and gender-specific cutoff percentage points were suggested by Gallagher and colleagues for underweight, normal weight, overweight, and obesity in African American, Asian, and White populations (Table 2) (Gallagher et al. 2000).

Methods of Assessment in AN Clinical Settings

Weight, Height, and Standard for BMI Determination

The determination of BMI in patients with AN is a usual procedure, following the standard formula of body weight in kilograms divided by the square of the height in meters. An individual is usually weighed in a barefoot position and wearing light

Table 1 *Nutrition status based on BMI* according to WHO and Asian classification; DSM-5 severity specifiers based on thinness for adults with AN

Population	BMI status
Adolescents	Underweight: BMI < 5th percentile Normal weight: BMI = 5th–85th percentile Overweight: BMI = 85th–95th percentile Obesity: BMI > 95th percentile
Adults (WHO) Adults (Asian)	Underweight: BMI < 18.5 Kg/m^2 Normal weight: BMI = 18.5–24.9 Kg/m^2 Overweight: BMI = 25.0–29.9 Kg/m^2 Obesity: BMI ≥ 30 Kg/m^2 Underweight: BMI < 18.5 Kg/m^2 Normal weight: BMI = 18.5–22.9 Kg/m^2 Overweight: BMI = 23.0–24.9 Kg/m^2 Obesity: BMI ≥ 25 Kg/m^2
DSM-5 severity specifiers based on thinness for adults with AN	Mild underweight: 17.0–18.5 Kg/m^2 Moderate underweight: 16.0–16.99 Kg/m^2 Severe underweight: 15.0–15.99 Kg/m^2 Extreme underweight: <15.0 Kg/m^2

Table 2 *BF* estimation for BMI status (underweight, normal weight, overweight, and obesity) in males and females in three suggested populations (African American, Asian, and White), as reported by Gallagher and colleagues (Gallagher et al. 2000)

Females				Males		
Age and BMI	African American	Asian	White	African American	Asian	White
20–39 years						
BMI < 18.5 Kg/m^2	20	25	21	8	13	8
BMI ≥ 25 Kg/m^2	32	35	33	20	23	21
BMI ≥ 30 Kg/m^2	38	40	40	26	28	26
40–59 years						
BMI < 18.5 Kg/m^2	21	25	23	9	13	11
BMI ≥ 25 Kg/m^2	34	36	35	22	24	23
BMI ≥ 30 Kg/m^2	39	41	41	27	29	29
60–79 years						
BMI < 18.5 Kg/m^2	23	26	25	11	14	13
BMI ≥ 25 Kg/m^2	35	36	38	23	24	25
BMI ≥ 30 Kg/m^2	41	41	43	29	29	31

indoor clothing to the nearest 0.1 Kg using an electronic weighing scale or 0.5 Kg with analogical scale. Height is measured to the nearest 0.5 cm using a stadiometer.

BF Estimation and Measurement

Several methods are available for determining BF, such as measurement with calipers or through the use of bioelectrical impedance analysis (BIA), dual-energy X-ray absorptiometry (DXA), hydrostatic underwater weighing, computed tomography (CT) scan, and magnetic resonance imaging (MRI) (Duren et al. 2008). In this section, we will describe the most common methods available in clinical settings for patients with AN.

Skinfold Thickness (ST)

ST is considered to be a simple and cheap anthropometric measurement to predict BF in relation to body density (BD). The most widely used method is that of (Durnin and Womersley 1974), which uses the log sum of four ST measurements to develop regression equations for males and females of different age groups.

ST is usually measured in triplicate to the nearest 0.2 mm by means of a plicometer at the biceps, triceps, subscapular, and supra-iliac sites. These measurements are used to estimate the BD using the age- and sex-specific predictive equations of Durnin and Womersley (Durnin and Womersley 1974). Consequently, BF% is then calculated by using determined equations. Table 3 shows the equations most commonly used in clinical setting studies to predict BF via ST in patients with AN (El Ghoch et al. 2012), as well as some examples of formulae used to calculate BD in different age ranges.

Body composition (i.e., BF) in patients with AN has been evaluated in numerous studies and using different approaches, but the few available studies comparing validated methods (e.g., DXA) with the ST method have produced inconsistent findings (El Ghoch et al. 2012). Some studies found that DXA gives a mean lower BF% than ST measurement in underweight patients with AN, while another study found the opposite result. After weight restoration, some studies found the ST measurement method led to a BF over- or underestimation (El Ghoch et al. 2012). The reasons for these discrepancies have not yet been clarified, but one possible

Table 3 *BF* estimation for BD as reported by (Durnin and Womersley 1974)

Examples of formulae to calculate BD in different age ranges in females:	
BD	16–19 years BD = 1.1549–0.0678 × log (biceps + triceps + subscapular + supra-iliac) 20–29 years BD = 1.1599–0.0717 × log (biceps + triceps + subscapular + supra-iliac) 30–39 years BD = 1.1423–0.0632 × log (biceps + triceps + subscapular + supra-iliac) 40–49 years BD = 1.1333–0.0612 × log (biceps + triceps + subscapular + supra-iliac)
Equations for the estimation of BF from BD:	
BF %	Siri equation = (495/BD) – 450 Brozek equation = (457/BD) – 414 Heyward equation = (526/BD) – 483

explanation is the use of inappropriate predictive formulae for patients with AN (El Ghoch et al. 2012). Therefore, the use of ST measurements does not appear to be an alternative to valid methods in estimating BF% before and after weight gain in patients with AN. Results derived from this method should be interpreted with caution (El Ghoch et al. 2012).

BIA

BIA is a noninvasive method based on the electrical current conductance properties of tissues. It is a commonly used technique for estimating body composition, based on a two-component body composition model (BF and fat-free mass [FFM]). BIA determines the resistance (impedance) to small electrical currents as they pass through the body's water pool. It measures changes in electrical conductivity via electrodes placed on the extremities. The lowest resistance values are used to estimate total body water (TBW), from which total body FFM is calculated.

Single-frequency BIA (SF-BIA) is the most commonly used, although this technique is limited in its ability to distinguish between intracellular and extracellular water and may be affected by hydration status or electrolyte imbalances. These two conditions are known to occur in patients with AN, i.e., in severely underweight patients (dehydration), caused by binge purging behaviors (electrolyte imbalances), and during refeeding (overhydration and electrolyte imbalances). A recent consensus paper by the Society on Sarcopenia, Cachexia and Wasting Disorders has discouraged the use of SF-BIA for the assessment of sarcopenia. Specifically, in AN patients with a BMI <16 Kg/m^2, BIA results are affected by variable tissue hydration and should be interpreted with caution during early refeeding. Despite ease and low cost in access to and operation of BIA, its suitability of BIA in the context of AN remains questionable, and its validity is influenced by sex, age, and disease state (Abbaspour et al. 2021).

DXA

The DXA method is rapid and cheap and only relies on a low amount of ionizing radiation. Moreover, it enables the assessment of regional composition measurements, which provides a distinct advantage compared with other approaches such as BIA or hydrodensitometry (Bredella et al. 2010). In addition, no special preparation is required, with the exception that subject needs to wear underwear and not wear any metal accessories. DXA uses a source that generates X-rays, a detector, and an interface with a computer system for imaging the scanned areas of interest. The effective radiation doses involved are small, making the technique widely applicable (Bredella et al. 2010).

The concept of DXA technology is that photon attenuation in vivo is a function of tissue composition. Rectilinear scanning of the supine body divides the body into a series of pixels, and, within each, the photon attenuation is measured at two different energies. The DXA body composition approach assumes that the body consists of three components distinguishable by their X-ray attenuation properties: fat mass

(FM), FFM, and bone mineral. DXA poses a problem if repeated frequently in young females, because of an accumulation of radiation exposure (Bredella et al. 2010).

Several studies have provided evidence that DXA shows high accuracy in estimating body composition with respect to the four-component model in young adults. Moreover, DXA measurements are highly reproducible, and the validity of DXA for measurement of BF in different samples has been previously proved. DXA is still debated as a gold standard technique for BF measurement, but it exhibits a high level of precision in adolescents and adults with AN. There is a strong correlation between DXA and CT independent from level of hydration; therefore, DXA can be used to assess body composition in patients with AN in clinical settings (Bredella et al. 2010).

Changes in BMI and BF Before and After Weight Gain and Normalization

A significant reduction in BMI and BF during AN is seen in adolescents and adults of both genders; however, there is a difference in how patients lose BF based on age. For instance, adolescent females with AN seem to lose more central (trunk, visceral) than peripheral (subcutaneous, extremity) BF (El Ghoch et al. 2015). On the other hand, young adult females and adolescent and young adult males with AN seem to display a preferential loss of BF from the extremities rather than the trunk (El Ghoch et al. 2017). The reasons for these discrepancies are unclear. However, short-term weight restoration treatments (i.e., 20 weeks) can determine a complete weight normalization of BMI ($\geq$19 Kg/m^2 in females and $\geq$20 Kg/m^2 in males) and a complete total restoration of BF in all patients with AN (adolescents and adults of both genders) (El Ghoch et al. 2015, 2017) with preferential accumulation of fat in the trunk (El Ghoch et al. 2015, 2017). The underlying mechanism behind this central adipose deposition (i.e., hormonal weight gain, rate and velocity, etc.) has not yet been clarified.

Despite this, it appears that the central fat deposition achieved immediately after weight restoration does not have any adverse effect on general and eating disorder psychopathology, either by causing any psychological distress or leading to higher rate of relapse (El Ghoch et al. 2014, 2016b). However, the cardio-metabolic effects of this abnormal BF distribution have not been tested in patient with AN after a complete weight restoration; only one study conducted in young adult females has reported that minimum short-term weight restoration showed a preferential redistribution of BF in the trunk region with respect to controls and that such a distribution was associated with insulin resistance status (Prioletta et al. 2011).

Further underlining this result, two studies conducted in young adult females with AN found that the abnormal BF distribution in central regions exhibited after short-term complete weight restoration tends to normalize within a 1- to 2-year period of normal weight maintenance (Dellava et al. 2011; Mayer et al. 2009).

Relationship Between BMI, BF, and Clinical Outcomes

Remission, Recovery, and Risk of Relapse

One of the most important clinical outcomes during the treatment of AN is relapse prevention with successful long-term normal weight maintenance (i.e., BMI $\geq$ 18.5 Kg/m^2 $>$ 1-year follow-up). The identification of factors in the early period after weight restoration that can predict relapse in longer follow-up is vital. The most consistent and robust early data have been provided by a multisite relapse prevention trial (Walsh et al. 2006) which reported that the only factors associated with long-term relapse were BMI at the end of treatment and the rate of weight loss in the first 4 weeks following hospitalization. However, more recently, two further studies in adults with AN reported a relationship between poor long-term outcome (i.e., relapse) and lower BF% in weight-restored inpatients (Mayer et al. 2007; Bodell and Mayer 2011), but recent studies have failed to replicate this finding in both adolescent and young adult females (Aguera et al. 2015; El Ghoch et al. 2016a, b). Future work should pay attention to this issue more closely.

Resumption of Menses and Reproductive Functions

There is a clear positive relationship between a higher BF% achieved after weight normalization and the resumption of menses in adolescent and young adult females with AN. A recent systematic review and meta-analysis published in 2019 showed that patients with AN who resume their menstrual cycle had a significantly higher mean BF% than those who did not (Traboulsi et al. 2019). Moreover, BF% was found to be an independent predictor of menstrual cycle resumption in this population; an increase of only one unit of BF% can increase the odds of menstruation by ≈15–20% (Traboulsi et al. 2019). There is a cutoff point of BF% ≈21 which is suggested as the minimum needed for resumption of the menstrual cycle (Traboulsi et al. 2019).

In the same direction, another recent systematic review published in 2020 only included only studies of completely weight-restored females who had recovered from AN over a follow-up period of between 6 and 18 years. This review revealed that appropriate treatment of AN leads to the normalization of reproductive functions, especially in terms of fertility, pregnancy, and childbirth rates. The meta-analysis confirmed this finding, where the pooled odds of childbirth rates between the AN group and the general population were not statistically significant (Chaer et al. 2020). The authors concluded that if patients with AN undergo appropriate eating disorder treatment and weight restoration, it appears to be unlikely that their reproductive health is affected (Chaer et al. 2020). However, since this finding is derived from only a few studies, it requires replication and confirmation.

Osteoporosis and Restoration of BMD

Reduced BMD (osteopenia or osteoporosis) is one of the most frequent medical complications of AN across adolescent and adult males and females and increases the risk of spontaneous fractures with respect to healthy controls (Tannir et al. 2020). Several factors have been identified to play a role in BMD reduction in AN. These include the underweight status, however expressed (i.e., BMI < 18.5 Kg/m^2 or $<$ 10th centile), associated with depleted BF (Tannir et al. 2020).

A recent systematic review regarding the effect of body weight and fat restoration and BMD in adolescent and young adults resulted in a number of findings (El Ghoch et al. 2016c). First, weight normalization is associated with the stabilization of BMD during the first year of follow-up in adolescent and young adult patients with AN (El Ghoch et al. 2016c). Second, weight restoration begins to determine an increase in BMD after approximately 16 months. This indicates that BMD gain is a slow process in adolescent and young adults with AN and that longer durations of weight maintenance are required to detect improvements in bone status (El Ghoch et al. 2016c). To reinforce these findings, one study found that in female adolescents with AN, normalization of total body and lumbar spine BMD occurs within nearly 30 months of complete weight restoration. Therefore, weight restoration should be considered the most effective strategy to determine improvement or restoration in BMD in adolescent and young adult patients with AN (El Ghoch et al. 2016c). However, this process seems to be slow and requires a certain period of time.

Summary

- BMI and BF are two important anthropometric indices of nutritional status in humans, and their assessment is crucial, especially in clinical settings
- During AN, significant reduction in BMI and BF is observed. BMI can be calculated through the standard formula. The DXA scan is usually available and widely used in clinical practice and has been extensively validated in comparison to gold standards in the precise measurement of total and regional BF in AN
- Adolescent females with AN lose more central (trunk, visceral) than peripheral (subcutaneous, extremity) BF. Adolescent males and adults of both genders with AN seem to have a preferential loss of BF from the extremities rather than the trunk
- BF is completely restored in all patients with AN after short-term weight normalization (BMI $\geq$ 19–20 Kg/m^2); with the occurrence of a central adiposity phenotype, it seems to normalize after 1 to 2 years of normal weight maintenance
- This central adiposity phenotype seems not to negatively influence treatment outcomes (i.e., relapse, eating disorder psychopathology, or psychological distress)

- Strong evidence indicates that the BMI (not the BF) achieved after short-term weight restoration predicted 1-year normal weight maintenance in females with AN
- The BF% is an independent predictor of the return of menses in patients with AN. Higher total BF% (at least 21%) is associated with the resumption of menses
- Appropriate eating disorder treatment for AN, which determines body weight and BF restoration, appears to lead to the normalization of reproductive functions, especially in terms of fertility, pregnancy, and childbirth rates
- During AN, underweight and BF depletion are important factors that lead to an impairment of bone metabolism and a significant reduction in BMD in adolescents and adults of both genders
- Weight restoration (BMI $\geq$ 18.5–19 Kg/m^2 or BMI $\geq$ 10th centile) in patients with AN is the most effective strategy that leads to the stabilization, improvement, and normalization of BMD after approximately 12,16, and 30 months, respectively

Contents

Abstract

Although the pathophysiology underlying anorexia nervosa (AN) has not been fully elucidated, inflammation appears to be a critical component of its course and progression. Eicosanoids (eiCs) are bioactive signaling lipids primarily derived from arachidonic acid which have gained considerable biological relevance for their involvement in central and peripheral inflammatory processes. They were first described as pro-inflammatory mediators, and only afterward their anti-inflammatory and pro-resolution activities were also highlighted. Recent findings suggest that alterations in eiCs signaling could contribute to the dysregulated

inflammatory status observed in AN. In this chapter we will first overview the most important immunological functions of the eiCs, including the regulation of neuroinflammatory processes, and then we will summarize the current knowledge on their possible implication in the pathophysiology of AN, with a focus on animal models.

Keywords

Anorexia nervosa · Activity-based anorexia · Inflammation · Neuroinflammation · Polyunsaturated fatty acid · Arachidonic acid · Eicosanoids · Prostaglandins · Thromboxanes · Leukotrienes · Cyclooxygenases · Lipoxygenases · Cytochrome P450 epoxygenases

Abbreviations

2-AG	2-arachidonoylglycerol
5(S)-HETE	5(S)-hydroxyeicosatetraenoic acid
8(S)-HETE	8(S)-hydroxyeicosatetraenoic acid
12(S)-HETE	12(S)-hydroxyeicosatetraenoic acid
15(S)-HETE	15(S)-hydroxyeicosatetraenoic acid
20-HETE	20-hydroxyeicosatetraenoic acid
AA	arachidonic acid
ABA	activity-based anorexia
AEA	anandamide
ALA	α-linolenic acid
AN	anorexia nervosa
CB1R	cannabinoid type 1 receptor
CNS	central nervous system
COX	cyclooxygenase
CYP	cytochrome P450 monooxygenase
CysLT	cysteinyl-leukotriene receptors
DGLA	di-homo-γ-linolenic acid
DP	prostaglandin D receptor
EET	epoxyeicosatrienoic acid
eiCs	eicosanoids
EP	E-prostanoid receptor
FAAH	fatty acid amide hydrolase
FP	PGF2α receptor
GPCRs	G protein-coupled receptors
HETE	hydroxyeicosatetraenoic acid
HPETE	hydroperoxyeicosatetraenoic acids
IL	interleukin
IP	prostacyclin receptor
LOX	lipoxygenase
LTs	leukotrienes
LXs	lipoxins

MAGL	monoacylglycerol lipase
NSAIDs	nonsteroidal anti-inflammatory drugs
OEA	oleoylethanolamide
PBMC	peripheral blood mononuclear cell
PEA	palmitoylethanolamide
PGD2	prostaglandin D2
PGE2	prostaglandin E2
PGF2α	prostaglandin F2α
PGG2	prostaglandin G2
PGH2	prostaglandin H2
PGI2	prostacyclin I2
PGs	prostaglandins
PLA2	phospholipase A2
PPARs	peroxisome proliferator-activated receptors
PUFA	polyunsaturated fatty acid
TNFα	tumor necrosis factor-alpha
TP	thromboxane receptor
Tx	thromboxane

Introduction

Although the pathogenesis of anorexia nervosa (AN) has not yet been elucidated, it is widely acknowledged that biological factors contribute to its course and progression. For instance, alterations in neuroendocrine functions, including hypothalamic-pituitary axis dysregulation as well as changes in the levels of several appetite-regulating hormones (e.g., leptin, ghrelin), have been observed in anorexic patients (Schorr and Miller 2017). Also, altered neuronal bases of reward processes were suggested to contribute to the behavioral pathology of AN (Berner et al. 2019). Moreover, expanding evidence demonstrated that AN could be also related to a dysregulated inflammatory status that drives toward a pro-inflammatory profile (Butler et al. 2021). In this regard, increased serum levels of several pro-inflammatory cytokines, such as interleukin (IL)-1 beta (IL-1β), IL-1, and IL-6 and tumor necrosis factor-alpha (TNF-α), were found in anorexic patients (Solmi et al. 2015; Dalton et al. 2018). In addition, a recent proteomic study investigating a wide group of inflammatory-related proteins, including IL-6 and TNF-related proteins, shows that the pro-inflammatory profile appears to be associated with the acute stage of the disease (Nilsson et al. 2020). In agreement, two different studies showed an increased spontaneous release of pro-inflammatory cytokines from peripheral blood mononuclear cells (PBMCs) isolated from patients with AN that normalized upon refeeding (Vaisman and Hahn, 1991; Allende et al. 1998). Eicosanoids (eiCs) are bioactive signaling lipids derived primarily from omega-6 arachidonic acid (AA), one of the most abundant long-chain polyunsaturated fatty acids (PUFAs) in the brain (Bazinet and Layé 2014). Other eiCs precursors include omega-3 eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Fig. 1). In recent

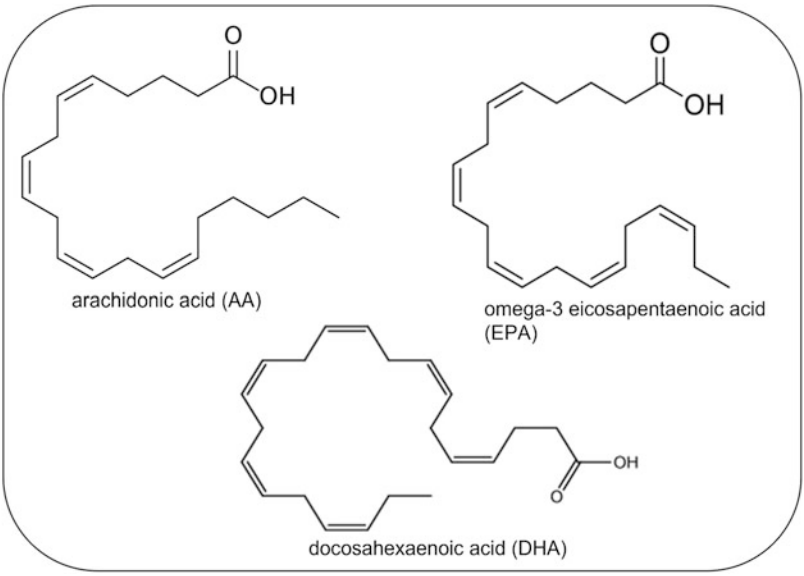

Fig. 1 Precursors of eicosanoids. Polyunsaturated fatty acids (PUFAs) omega-6 arachidonic acid (AA), omega-3 eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA)

years, eiCs have gained considerable biological relevance in relation to their involvement in a huge spectrum of physiological and pathological processes in the brain and throughout the rest of the body, including the regulation of important aspects of immunity and inflammatory responses (Leuti et al. 2020). Indeed, several eiCs and their associated receptors were shown to participate in the initiation, coordination, and resolution of inflammation (Tilley et al. 2001; Serhan et al. 2014). Recent findings suggest that alterations in the AA metabolic pathways, both in the periphery and in the brain, lead to an imbalanced production of eiCs that may contribute to the dysregulated inflammatory status observed in AN (Shih 2019; Collu et al. 2020; Caso et al. 2020). For example, protein expression of COX-2 was found increased in PBMCs of female adolescent patients with AN (Caso et al. 2020). Moreover, eiCs seem to be implicated in not only the risk of AN, but also in its comorbid psychopathology (Shih et al. 2016). On the other hand, several studies reported abnormal plasma levels of PUFAs in individuals with eating disorders, including AN (Langan and Farrell 1985; Satogami et al. 2019; Ayton 2004). Finally, the clinical importance of resolution of inflammation by PUFA treatments for weight and appetite restoration in AN, key clinical goals for patients, was also highlighted (Yehuda and Rabinovitz 2016; Shih et al. 2017). In this chapter, we will describe the most important immunological functions of the eiCs, including the regulation of neuroinflammatory processes, and we will overview the current knowledge on their possible implication in the pathophysiology of AN, with a focus on animal models.

AA-Derived eiCs Pathways

The major source of eiCs derives from the oxidation of AA which is released from the phospholipid pool in cellular membranes by enzymes of the phospholipase A2 (PLA2) superfamily in response to various physiological and pathological stimuli including inflammation (Harizi et al. 2008). An alternative source of AA involves the degradation of endogenous cannabinoids such as N-arachidonoylethanolamine, also known as anandamide (AEA), and 2-arachidonoylglycerol (2-AG), which are a group of lipid mediators playing a key role in critical pathophysiological functions that over the last decades have received growing amount of attention in regard to their involvement in inflammatory processes (Cabral and Griffin-thomas 2009). More specifically, the fatty acid amide hydrolase (FAAH) enzyme catalyzes the metabolism of AEA to AA and ethanolamine, whereas the monoacylglycerol lipase (MAGL) enzyme converts 2-AG to AA and glycerol (Ahn et al. 2008; Nomura et al. 2011) (Fig. 2). Once available, free AA can be metabolized by three different enzyme systems, namely, cyclooxygenases (COXs), lipoxygenases (LOXs), and cytochrome P450 monooxygenases (CYP). Activation of the COX pathway gives rise to the production of prostanoids, which represent the most abundant group of eiCs, and even though they are often synthesized and released during inflammation, acting as both pro- and anti-inflammatory mediators, they are also involved in the maintenance of physiological cell homeostasis. COXs catalyze the first step of prostanoids formation, in which AA is converted to prostaglandin (PG)-H2 via PGG2 reduction. PGH2 represents the common substrate for the enzymatic synthesis

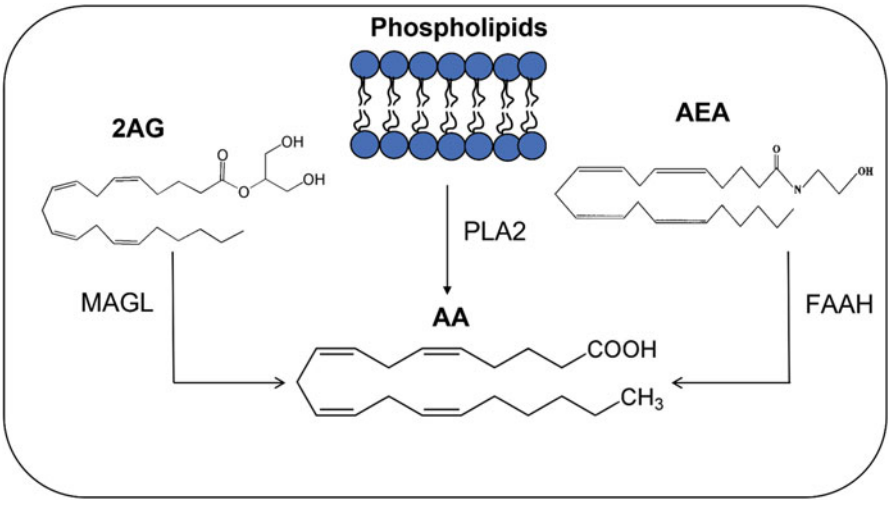

Fig. 2 Production of free arachidonic acid (AA). Free arachidonic acid (AA) derives from various intracellular sources: AA present in phospholipids membrane is released by phospholipase A2 (PLA2) in response to various stimuli; anandamide (AEA) is primarily hydrolyzed by FAAH to ethanolamine and AA; 2-arachidonoylglycerol (2-AG) is primarily hydrolyzed by MAGL to glycerol and AA

of PGD2, PGE2, PGF2α, prostacyclin (PGI2), and thromboxane A2 (TXA2). COXs exist in two distinct isoforms: the COX-1, which is constitutively expressed in several tissues and mainly involved in homeostatic functions, and the COX-2, which is typically induced in response to inflammatory stimuli (e.g., pro-inflammatory cytokine production, growth factors, hormones) and plays a major part in inflammatory processes (Harizi et al. 2008). LOXs are a family of lipid-peroxidizing enzymes (e.g., 5-LOX, 12-LOX, and 15-LOX) that metabolize AA into several hydroperoxyeicosatetraenoic acids (HPETEs, e.g., 5-HPETE, 12-HPETE, 15-HPETE), which are then reduced to hydroxyeicosatetraenoic acids (HETEs, e.g., 5-HETE, 12-HETE, 15-HETE), leukotriene A4 (LTA4), lipoxins A4 and B4 (LXA4 and LXB4). Moreover, LTA4 is rapidly metabolized to LTB4 or to cysteinyl leukotrienes (e.g., LTC4, LTD4, and LTE4) which are potent pro-inflammatory mediators. LTA4 could be also degraded to LXA4 and LXB4. In contrast to LTs and PGs, LXA4 and LXB4 are anti-inflammatory molecules (Wang et al. 2021). Finally, under the control of hormones, growth and transcription factors, AA can also be metabolized by many CYP including ω-hydroxylases, which generate HETEs (e.g., 6-HETE, 17-HETE, 18-HETE, 19-HETE, and 20-HETE) and epoxygenases whose activity results in the production of epoxyeicosatrienoic acids (EETs, e.g., 5,6-EET, 8,9-EET, 11,12-EET, and 14,15-EET) studied in conjunction with their involvement in inflammatory responses. All the pathways forming AA-derived eiCs are identified as the "arachidonate cascade" (Fig. 3).

eiCs Receptors

Upon release from the cell, eiCs affect cell function by binding to different G protein-coupled receptors (GPCRs), although some are also ligands for peroxisome proliferator-activated receptors (PPARs) (Murakami et al. 1999; Bishop-Bailey and Wray 2003). To date, nine membrane receptors for prostanoids have been identified and include four subtypes of the PGE receptor (EP1, EP2, EP3, and EP4), the PGD receptor (DP1 and DP2), the PGF receptor (FP), the PGI receptor (IP), and the TXA receptor (TP) (Narumiya et al. 1999). LTs receptors fall into two groups: BLT receptors (BLT1 and BLT2) and cysteinyl-leukotriene receptors (CysLT1 and CysLT2) (Yokomizo et al. 2018). Finally, the ALX receptors are related to the biological activity of LXs (Chiang et al. 2006). After receptor binding and activation, eiCs can modulate the generation rate of cytosolic second messengers (e.g., cAMP or Ca^{2+}), induce alterations in membrane potential, or activate specific protein kinases (Harizi et al. 2008) (Table 1). eiCs receptors are expressed in many cell types in the central nervous system (CNS) and are involved in various neural processes and pathways including neuroinflammation (Herbst-Robinson et al. 2015). Accordingly, eiCs production is remarkably increased during this pathological condition, and they cooperate with other inflammatory mediators (e.g., cytokines and chemokines) to mediate or debilitate this response (Phillis et al. 2006; Tassoni et al. 2008). Indeed, eiCs exert both pro-inflammatory (e.g., PGD2, PGE2, PGF2α, LTB4, TxA2, and TxB2) and anti-inflammatory (e.g., PGD2, PGE2, PGI2, LxA4, LxB4) effects

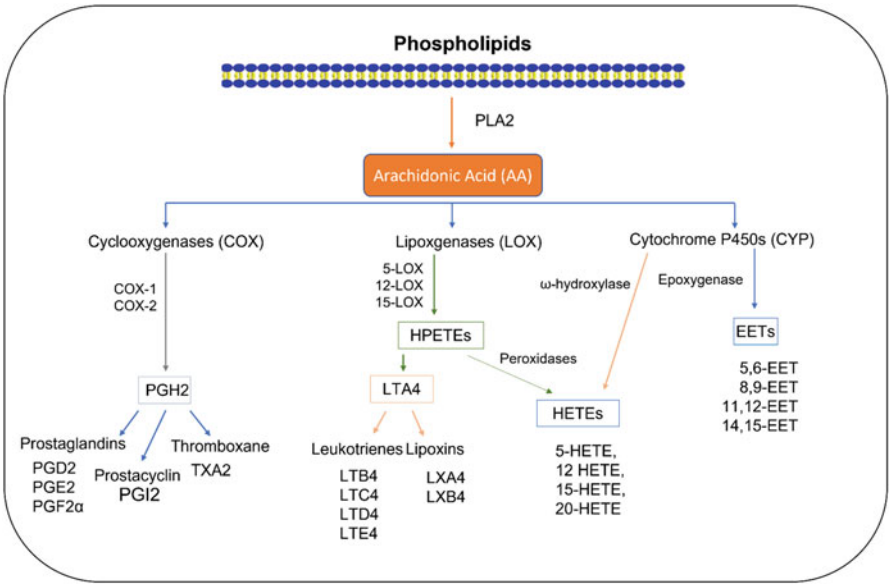

Fig. 3 Pathways of eicosanoids biosynthesis. Free arachidonic acid (AA) can be metabolized by three different enzyme systems: cyclooxygenases (COXs), lipoxygenases (LOXs), and cytochrome P450 monooxygenase (CYP). COX pathways produce prostaglandins (PGD2, PGE2, and PGF2α), prostacyclin (PGI2), and thromboxane A2 (TXA2). LOXs pathways produce leukotrienes (LTB4, LTC4, LTD4, and LTE4), lipoxins (LXA4 and LXB4), and hydroxyeicosatetraenoic acids (HETEs). CYP pathways produce HETEs and epoxyeicosatrienoic acids (EETs)

depending on the cellular context, the specific receptor expression profile, and the signal transduction pathways activated (Serhan et al. 2008).

eiCs and Neuroinflammation

Neuroinflammation is a protective mechanism against injury and disease that aims at preserving brain homeostasis by protecting the neural tissue integrity and function (Shabab et al. 2017). It involves the activation of several molecular and cellular events that take place to initially potentiate and then to regulate the inflammatory response. Neuroinflammation is triggered and sustained by the activation of different cells of the CNS including neurons, astrocytes, microglia, and oligodendrocytes. Among all these, microglial cells are responsible for initiating the inflammatory response (Gomez-Nicola and Perry 2015). Once activated, these resident immune cells induce the release of various inflammatory mediators, including cytokines and chemokines, which in turn stimulate the induction of inflammatory-related enzymes and receptors. Therefore, increased levels of these compounds play a significant role in the recruitment of immune cells in the brain. Indeed, cytokines and chemokines are able to stimulate the activity of PLA2 and, consequently, the release of free AA

Table 1 Eicosanoids receptors and their signaling pathways. Eicosanoids (eiCs) affect cell function by binding to different G protein-coupled receptors (GPCRs). Upon binding and receptor activation, eiCs can modulate the rate of cytosolic second messenger generation (cAMP or Ca^{2+}); ↑ increase, ↓ decrease

Receptor	Ligand	G protein	Transduction
EP_1	PGE_2 (PGI_2)	G_q/G_{11}	↑ Ca^{2+} mobilization
EP_2	PGE_2	G_s	↑ intracellular cAMP
EP_3	PGE_2	G_i/G_o - G_s - G_q	↑↓ intracellular cAMP ↑ Ca^{2+} mobilization
EP_4	PGE_2	G_s	↑ intracellular cAMP
DP1	PGD2	Gs	↑ intracellular cAMP
DP2/CHRT2	PGD2 (15d-PGJ2)	Gi/Go	↑ Ca^{2+} mobilization
$FP_{A,\ B}$	$PGF_{2\alpha}$	G_q	↑ Ca^{2+} mobilization
IP	PGI_2 (PGE_2)	G_s	↑ intracellular cAMP
$TP_{\alpha,\ \beta}$	TxA_2	G_q - G_i - $G_{12/13}$ - G_{16}	↑↓ intracellular cAMP ↑ Ca^{2+} mobilization
BLT_1	LTB_4	G_{16} - G_i/G_o - G_q/G_{11}	↓ intracellular cAMP ↑ Ca^{2+} mobilization
BLT_2	LTB_4 [12(S)-HETE 12(R)-HETE]	Simil- G_q - G_i - G_z	↓ intracellular cAMP ↑ Ca^{2+} mobilization
$CysLT_1$	LTD_4, LTC_2, LTE_4	G_q	↑ Ca^{2+} mobilization
$CysLT_2$	LTC_4, LTD_4, LTE_4	G_q	↑ Ca^{2+} mobilization

from neural membrane phospholipids (Lin et al. 2004; Farooqui et al. 2007). They also induce the expression of COX and LOX enzymes so that the released AA can be metabolized to give rise to the production of pro-inflammatory PGs (PGE2 and PGD2) and LTs, thus amplifying the initial inflammatory response (Mark et al. 2001; Phillis et al. 2006). In the brain, unlike other tissues, both COX-1 and COX-2 are expressed under physiological conditions (Bosetti 2007; López and Ballaz 2020). More specifically, both isoforms are constitutively expressed in neurons contributing to physiological brain functions, and COX-1 is also expressed in microglial cells (Maihofner et al. 2003). However, the expression of COX-2 can be rapidly induced in microglial cells under pathophysiological conditions including neuroinflammation (Akundi et al. 2005). Recent evidence suggests that COX-1 can also be upregulated in reactive microglia and may play a prominent role in the brain during neuroinflammation (Ghazanfari et al. 2021), and its activity appears to be necessary for COX-2 induction (Dargahi et al. 2011). Thus, it is important to point out that both isoforms may contribute to the release of pro-inflammatory PGs. Although PGE2 and PGD2 are potent pro-inflammatory molecules, they also have anti-inflammatory activity, and, as mentioned before, this depends on the type of cell and on the receptors that are activated. For instance, several studies have reported that PGE2 can significantly increase neurotoxicity by activating EP2 receptors, whereas PGE2-induced neuroprotection is mediated by the activation of both EP2 and EP4 receptors (Pooler et al. 2004; Echeverria et al. 2005). Similar to COXs,

5-LOX is expressed in neuronal and glial cells, and LTs signaling contributes to microglial and astroglial cells activation (Ciccarelli et al. 2004; Yu et al. 2014). Both COX and LOX enzymatic pathways are involved in the production of LXs that possesses anti-inflammatory and pro-resolution properties mediated by different mechanism including the inhibition of pro-inflammatory cytokine production (McMahon and Godson 2004).

Animal Models of AN

Various pathophysiological factors are involved in the onset and development of AN, and animal models greatly facilitated the progress of preclinical studies and the investigation of the mechanisms underlying the pathogenesis of the disease. The activity-based anorexia (ABA) model is so far the most used paradigm to mimic AN in rodents (Scharner and Stengel 2021). The combination of a scheduled time-restricted access to food (usually few hours per day) with the free access to a running wheel rapidly leads to a series of behavioral, neuroendocrine, and mood alterations that best represent the human pathological condition in rodents. A phenotype characterized by dramatic weight loss (up to 25% of initial body weight) and physical hyperactivity (increased running wheel activity) clearly distinguishes ABA animals from those exposed to exercise and food restriction only, and it's centrally associated with alterations of key neurotransmitter systems (e.g., endocannabinoid, dopaminergic, serotoninergic systems) and appetite-regulating hormones (e.g., leptin, ghrelin, corticosterone) involved in the modulation of both homeostatic and hedonic feeding processes (Collu et al. 2019) and in neuroinflammation (Collu et al. 2020). Other environmental models of AN have been developed and are based on the modification of the feeding patterns (dietary restriction models) or on the effect of stressful events (stress models) that are able to induce the development of key anorectic-like traits (Scherma et al. 2019). Among the genetic models, the anx/anx represents the most commonly used model for AN in mice (Nilsson 2019). This model is based on the spontaneous anx/anx mutation and was first identified by Maltais and collaborators in 1984. Mice carrying this mutation are characterized by poor appetite, reduced stomach size, inability to regulate food intake, lower body weight, and an emaciated appearance (Maltais et al. 1984). Interestingly, mutant anx/anx mice display alterations in different hypothalamic neurotransmitters and neuropeptidergic signals involved in the regulation of feeding and energy expenditure. However, the main limitation of using these mice as model of AN is the high rate of premature death due to critical health conditions (Nilsson 2019). Other genetic models consist of gene knockout approaches aiming at studying the specific contribution of candidate genes implicated in eating behavior or energy regulation. Some of these include the knockout models for genes encoding for the brain-derived neurotrophic factor, serotoninergic receptors, corticotropin-releasing factor, tyrosine hydroxylase, and muscarinic receptors (Kim 2012). Collectively, these models represent useful tools to investigate pharmacological, environmental, and genetic determinants that contribute to the development and

maintenance of the disease, as well as for the identification of new therapeutic targets for the pharmacological management of AN.

Neuroinflammation in Animal Models of AN

In agreement with the results obtained in clinical studies, preclinical evidence also support the notion of an impaired inflammatory status in AN. For example, ABA induction in mice resulted in increased mRNA levels of TNF-α and IL-1β in colonic mucosa as well as of IL-1β and interleukin-1 receptor type 1 in the hypothalamus suggesting intestinal and hypothalamic inflammation in these animals (Belmonte et al. 2016). Moreover, the expression of the anti-inflammatory cytokine IL-10 in colonic mucosa was also significantly increased during initial weight loss. The same study also showed an increased expression of the Toll-like receptor 4 in colonic epithelial cells and macrophages in ABA mice, and it is known that these receptors play a key role in the innate immune response by activating inflammatory processes that leads to the secretion of pro-inflammatory mediators (Barton and Medzhitov 2002). Also, the dehydration-induced model of AN increases microglial cells density and the expression of TNF-α, IL-6, and IL-1β in the hippocampus of young female rats, further supporting the hypothesis that AN may result in hippocampal neuroinflammation (Ragu-Varman et al. 2019). On the other hand, Barbarich-Marsteller and collaborators (2013) reported reduced hippocampal cell proliferation following ABA induction (Barbarich-Marsteller et al. 2013). Accordingly, evidence showed that caloric restriction alters both hippocampal neurogenesis and hippocampus-dependent forms of learning (Cardoso et al. 2016). Neuroinflammation has also been observed in the anorectic anx/anx mouse model of AN. In this animal model, microglial cells are selectively activated in the hypothalamus, and overexpression of genes involved in inflammatory process also occurred in this brain region (Nilsson 2019; Lachuer et al. 2005). Of importance, it has been suggested that inflammatory mediators can have profound effects on the brain function relevant to feeding behavior (Wong and Pinkney 2004). For example, pro-inflammatory cytokines (e.g., IL-1β and TNF-α) or stimulants of the release of cytokines such as lipopolysaccharide have been found to reduce food intake in animals (Gautron and Layé 2010).

eiCs in the ABA Model

The neuroinflammatory processes mediated by AA-derived eiCs in the ABA model were also investigated. Central administration of AA was found to affect feeding behavior by increasing the activity of the COX enzymatic pathway as well as the levels of TNF-α, IL-1β, and IL-6 raising an inflammatory response in the hypothalamus (Cheng et al. 2015). Increasing studies suggest that eiCs may also act downstream of cytokines during cachexia (Ross and Fearon 2002). Moreover, central administration of PGE2 was shown to induce neural activation in brain areas

involved in feeding and energy metabolism (e.g., hypothalamus) (Scammell et al. 1996; Lacroix et al. 1996). Recent findings revealed that under the ABA condition an array of eiC-mediated responses is observed in the brain of ABA rats. In particular, induction of and recovery from ABA were correlated with impairments of the COX, LOX, and CYP pathways with altered inflammatory eiCs profile and dysregulated expression of key metabolic enzymes in specific brain areas implicated in the development of the typical anorexic-like phenotype, e.g., in the prefrontal cortex, cerebral cortex, nucleus accumbens, caudate putamen, amygdala, hippocampus, and hypothalamus (Collu et al. 2020). Specifically, significantly altered levels of the main eiCs precursor AA, and of COX-derived prostaglandins (e.g., PGE2, PGD2, PGF2α) and thromboxane (e.g., TxB2), as well as of LOX- and CYP-derived hydroxyeicosatetraenoic acids (e.g., 5(S)-, 8(S)-, 12(S)-, 15(S)-HETE and 20-HETE) were detected in the brain of ABA rats. Of importance, the complex inflammatory response mediated by distinct routes of eiC signaling seems to suggest a selective influence of food restriction and exercise, the two key variables combined in the ABA paradigm. Interestingly, brain inflammation in ABA rats was shown to persist even after recovery, suggesting a long-term inflammatory effect that may serve as a substrate for relapse conditions (Collu et al. 2020). Of note, impaired levels of the two major endocannabinoids, AEA and 2-AG, and of the endocannabinoid-related acylethanolamides, oleoylethanolamide (OEA) and palmitoylethanolamide (PEA), were also observed in ABA rats (Collu et al. 2019). More specifically, at the end of the ABA induction phase, 2-AG was significantly decreased in different brain areas including the prefrontal cortex, cerebral cortex, nucleus accumbens, amygdala, hippocampus, and hypothalamus. In contrast, no changes were detected in AEA levels in any region, whereas the levels of OEA and PEA were decreased in the hippocampus and hypothalamus. Furthermore, cannabinoid type 1 receptor (CB1R) density was decreased in the dentate gyrus of the hippocampus and in the lateral hypothalamus. Both 2-AG levels and CB1R density were partially reverted toward control levels after recovery from ABA condition, whereas AEA levels became markedly reduced. Moreover, the pharmacological modulation of the endocannabinoid system was shown to effectively improve the anorexic-like ABA phenotype in rats by reducing body weight loss and running wheel activity and by normalizing levels of appetite-regulating hormones such as leptin and corticosterone (Scherma et al. 2017). The endocannabinoid system, including the aforementioned endocannabinoids AEA and 2-AG, together with the cannabinoid receptors (e.g., CB1R, CB2R) and their metabolic/biosynthetic enzymes, was shown to modulate neuroinflammation (Walter and Stella 2004). More specifically, endocannabinoids were shown to mediate anti-inflammatory responses by modulating immune cell functions. On the other hand, rat microglia primary cultures express CB1 and CB2 receptors (Walter and Stella 2004), and both 2-AG and AEA prevented the release of TNF-α when cells were activated by LPS (Facchinetti et al. 2003). Moreover, as mentioned before, the degradation of AEA and 2-AG by FAAH and MAGL enzymes can serve as an additional source of AA which can in turn be metabolized to eiCs (Ahn et al. 2008; Nomura et al. 2011). Of note, AEA and 2-AG can also be metabolized by COX-2, several LOXs, and CYP

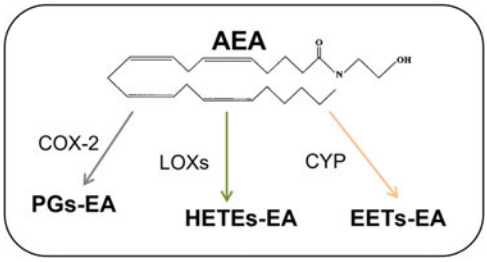

Fig. 4 Metabolism of anandamide (AEA) by eicosanoid biosynthetic enzymes. AEA can be subjected to oxygenation by COX-2, LOX, and CYP to form PGs-EA, HETEs-EA, and EETs-EA

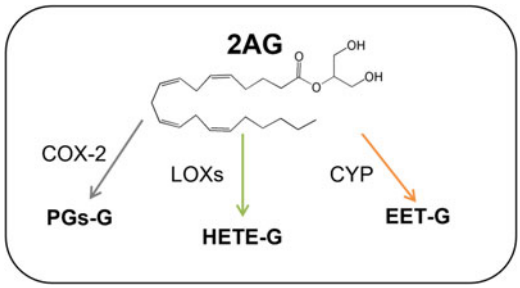

Fig. 5 Metabolism of 2-arachidonoylglycerol (2-AG) by eicosanoid biosynthetic enzymes. 2-AG can be subjected to oxygenation by COX-2, LOX, and CYP to form PGs-G, HETEs-G, and EETs-G

generating a plethora of bioactive lipids like prostaglandin-ethanolamides (PGs-EA) (e.g., PGG2-EA, PGH2-EA, PGD2-EA, PGE2-EA, PGF2a-EA, PGI2-EA) and prostaglandin-glycerols (PGs-G) (e.g., PGG2-, PGH2-, PGD2-, PGE2-, PGF2a-, PGI2-G), hydroxyeicosatetraenoyl-ethanolamides (HETEs-EA) (e.g., 11- and 15-HETE-EA) and hydroxyeicosatetraenoyl-glycerols (HETEs-G) (e.g., 15-HETE-G), and epoxyeicosatrienoyl-ethanolamides (EETs-EA) (e.g., 5,6-, 8,9-, 11,12-, and 14,15-EET-EA) and epoxyeicosatrienoyl-glycerols (EETs-G) (e.g., 11,12- and 14,15-EET-G) (Turcotte et al. 2015) (Figs. 4 and 5). Accordingly, specific genetic deletion of MAGL in astrocytes increases brain 2-AG levels and reduces the availability of AA for PGs synthesis and thereby attenuates LPS-induced neuroinflammation (Grabner et al. 2016). In agreement, brain levels of AA and several downstream AA-derived eiCs, including PGE2, PGD2, PGF2, and TXB2, were decreased in mice lacking the gene that encodes for MAGL (Nomura et al. 2011). Altogether these findings suggest that endocannabinoids degradation generates brain eiCs (e.g., PGs, HETEs) that promote neuro-inflammation. All these endocannabinoid-derived metabolites appear to be involved in the regulation of inflammatory processes by acting on specific receptors (Turcotte et al. 2015).

Conclusion

In light of the multiple functions exerted and based on the extent of neuroinflammatory processes mediated by AA-derived eiCs, this class of inflammatory lipids represents a key signaling system within the brain circuits involved in the regulation of neurobehavioral responses in AN. Therefore, further understanding on potential therapeutic approaches targeting different AA metabolic pathways or eiCs receptors is of particular interest. So far, studies have primarily focused on the pathways activated by lipids produced by the COX enzymes. In particular, the COX pathway is the target for nonsteroidal anti-inflammatory drugs (NSAIDs), which represent the most popular drugs for the treatment of inflammation, pain, and fever. Clearly, additional work is needed to deeply investigate the potential application within the scenario of AN condition and comorbidities pharmacological management. Overall, the evidence presented here highlight the important role that different eiCs pathways might have for future understanding of the neurobiology as well as for studying new pharmacological targets and approaches for the treatment of inflammatory-related processes in AN.

Applications to Other Eating Disorders

In this chapter we have reviewed the emerging role of a class of bioactive lipids derived from AA, the eiCs, in a broad range of pro- and anti-inflammatory processes related to physiopathological conditions. In particular, we have focused our attention on the potential involvement of the eiCs in brain neuroinflammatory processes in AN, a dramatic eating disorder with unclear etiology. In this regard, we have described how eiCs activity and their interaction with other well-known mediators of inflammation, such as cytokines and chemokines, influence a wide range of processes. Indeed, the complex signaling network of different inflammatory mediators, like eiCs and cytokines, was also described in the pathogenesis of obesity, further supporting neuroinflammation as a key factor in the onset and progression of eating disorders. As we all know, obesity is a growing worldwide health issue and together with high-fat feeding is associated with a systemic inflammatory status that leads to neuroinflammation, thus affecting not only the physiological activity of satiety signals but also influencing the development of central comorbidities such as depression and cognitive decline (Miller and Spencer 2014). In light of the repercussions for some cerebral functions, obesity-derived neuroinflammation represents a keen area of research to investigate the neurobiology of altered feeding disorders. A link between obesity and the eiCs-derived neuroinflammation has been observed in mice where increased microglia activation and altered eiCs profile were found and related to disrupted blood-brain barrier and impaired cognitive functions (Valcarcel-Ares et al. 2019). Considering the variegate roles of these mediators of inflammation in appetite, mood, and cognitive functions, these may serve as trait or biomarkers for AN and other eating disorders, as well as candidate targets for therapeutic approaches.

Mini-Dictionary of Terms

- **Anorexia nervosa**. Complex psychiatric disorder characterized by dramatic fear and control over body weight and altered image perception, extreme diet restriction, and intense physical activity.
- **Activity-based anorexia**. Rodent model of anorexia nervosa based on the combination of scheduled food restriction with access to physical exercise.
- **Neuroinflammation**. Activation of molecular and cellular processes of the brain's innate immune system as a protection against detrimental inflammatory response to physical or functional changes of the neural tissue.
- **PUFA**. Polyunsaturated fatty acids are cell components and precursors of various regulators of inflammation and immunity. Docosahexaenoic acid (C22:6 ω-3) and arachidonic acid (C20:4 ω-6) are the main PUFAs in the mammalian brain.
- **Arachidonic acid**. Represents around 20% of the total amount of the neuronal fatty acids and is mainly esterified in membrane phospholipids. Free arachidonic acid is released by phospholipases A2 and enzymatically converted into different eicosanoids.
- **Arachidonate cascade**. Includes all the pathways leading to the production and action of a wide range of inflammatory arachidonic acid-derived lipids called eicosanoids. Cyclooxygenases, lipoxygenases, and cytochrome P450 epoxygenases are the main enzymes of the arachidonic acid metabolism.
- **Eicosanoids**. Bioactive lipids derived by the metabolism of arachidonic acid and involved in the initiation, intensity, and resolution of inflammatory response.
- **Cytokines**. Small, secreted proteins with pro- and anti-inflammatory activity released by cells and involved in the initiation and persistence of the inflammatory response.
- **Microglia**. The primary immune cells of the central nervous system comprising up to 20% of the glial cell population. They are critically involved in the innate and adaptive immune responses.

Key Facts of Anorexia Nervosa

- Anorexia nervosa is the eating disorder with the highest mortality rate among all psychiatric disorders.
- It is characterized by food deprivation, dramatic body weight loss, and fear of gaining weight.
- Extreme physical exercise is often used as a strategy to control body weight.
- Anorexia typically emerges during adolescence and tends to have a chronic progression with frequent relapses.
- Mood and cognitive dysfunctions are typical co-occurrences in the disease.

Summary Points

- Eicosanoids are bioactive lipids derived from the metabolism of arachidonic acid by COX, LOX, and CYP enzymatic pathways.
- Eicosanoids act as both pro- and anti-inflammatory mediators of inflammation.
- Neuroinflammation plays a key role in the pathophysiology of anorexia nervosa.
- Rodents exposed to the activity-based model of anorexia nervosa (ABA) display significantly impaired brain inflammatory eicosanoids levels.
- Expression levels of PLA2, ALOX-5, and ALOX-15 enzymes of the eicosanoids biosynthesis pathways are altered in the brain of ABA rats.
- Diet restriction plays a key role in the neuroinflammation displayed by ABA rats.

Anorexia Nervosa and Impact After Three Decades

24

Mortality and Beyond

Elisabet Wentz

Contents

Abstract

There are currently only two outcome studies of anorexia nervosa (AN) with a follow-up period of 30 years or more. Both of them have been carried out in Sweden, but apart from that there are few similarities. One of the studies was published in the mid-1980s and the other one 35 years later. The former reported high mortality rates, and the latter had not experienced any deaths during the 30-year follow-up. Can the development of specialized eating disorder services during the last decades of the twentieth century explain the difference regarding a fatal or nonfatal outcome between the studies? The truth is probably much more complex. The two studies will be described, and similarities and differences will be discussed in this chapter.

Introduction

Follow-up studies of anorexia nervosa (AN) have been conducted since the 1950s. The outcome studies that were performed during the second half of the twentieth century have been reviewed by Steinhausen and included 119 patient series and approximately 5600 AN cases (Steinhausen 2002, 2009). Steinhausen's review concluded that half of all individuals with AN had recovered, one third had improved, one fifth were considered as chronic AN cases, and the mortality rate was 5%. The studies included in the review were heterogeneous in many respects. They were therefore divided into subgroups based on the duration of the follow-up periods: less than 4 years, between 4 and 10 years, and more than 10 years. Another categorization was based on whether the sample with AN had the onset of AN only in adolescence or whether the sample had a variable onset of AN, including onset in adulthood. In general, the outcome was better in the studies with only adolescent-onset AN cases. The highest mortality rates were seen in studies with variable AN onset and a follow-up period of more than 10 years. The two AN samples that will be introduced in the present chapter were included in the review by Steinhausen. A study by Theander (see below) (Theander 1985) excelled in terms of the unique follow-up period of 33 years and a mortality rate of 18%. The Gothenburg AN study (see below), which at the time had published 10-year follow-up data (Nilsson et al. 1999), represented a sample with only adolescent-onset cases of AN. The outcome in terms of mortality was encouraging, as no individuals had died. The Gothenburg AN study has continued to follow the AN sample including a matched control group, and a 30-year follow-up was published in 2020 (Dobrescu et al. 2020). Theander's study and the Gothenburg AN study are the only two AN outcome studies with a follow-up period of 30 years or more. In this chapter, the two studies will be presented and compared with each other, and similarities and differences between the two will be discussed.

Sten Theander's Study in the Southern Part of Sweden

Sten Theander, a psychiatrist and researcher at Lund University, Sweden, published his thesis, "Anorexia nervosa: a psychiatric investigation of 94 female patients," in 1970 (Theander 1970). He had aimed at conducting a retrospective study by tracing all female inpatients with AN in a defined area of southern Sweden. His search included medical records from departments of internal medicine, gynecology, pediatrics, child psychiatry, and psychiatry in the defined part of Sweden. The women had been admitted to hospital between 1931 and 1960. The mean observation time was 15 years. At the time of the first study, which took place in 1966, 94 women had been found in the records. Seventy-nine of the former AN patients underwent a personal interview with the researcher. The remaining 15 women had either died ($n = 10$), lived too far away to take part in the study ($n = 3$), or refused to participate ($n = 2$). The causes of death were either suicide ($n = 3$) or AN/undernutrition

($n = 7$). In the majority of the women ($n = 59$), the AN onset occurred before the age of 19 and included five women with an early onset, at age 11 and 12.

The women were divided into three groups depending on in which decade they had been hospitalized for the first time, 1931–1940, 1941–1950, and 1951–1960. The majority of the participants had been hospitalized during the last two decades. The women were also classified into three degrees based on the severity of the AN at first admission. The degrees were based on "the general state of health," and the most severe group was termed "cachectic," with grave undernutrition indicating "a vital risk." The cachectic condition was characterized by one or more symptoms including bradycardia, edema, and/or hypothermia (low body temperature). The cachectic group included 37 of the 94 women. Nine of the 11 women who had been admitted to hospital for AN between 1931 and 1940 were classified as cachectic. During the following two decades, the proportion of cachectic patients was less dominant, with 32% and 34%, respectively. All women who had died of undernutrition belonged to the cachectic group. Theander suggested that the decreased proportion of inpatients classified as cachectic over time was due to the fact that only the most severe cases were admitted to hospital in the 1930s, and most of these women had had a longer history of AN before being hospitalized.

In his thesis, Theander considered 63% to be recovered and defined the outcome as "completely free from anorectic symptoms," including having normal weight and normal menstruations and no weight phobia or bulimic symptoms (Theander 1985, 1970).

A second follow-up was conducted between 1982 and 1984 (Theander 1985, 1983) with a mean observation time of 33 years from the time of the original admission to hospital. The observation period showed great variation and varied from 24 to more than 50 years. Only one third of the former AN inpatients had ever been admitted to a psychiatric ward. Another seven women had died since the first study was conducted; two of them had committed suicide. In three cases, death was caused by AN, and another two had died from cancer. The subgroup with a fatal outcome corresponded to a mortality rate of 18%. A more encouraging finding in the 33-year follow-up was that 71 former AN patients (76%) were considered recovered and did not fulfill the criteria for AN or bulimia nervosa anymore. Only 6% were classified as having a poor outcome, i.e., the individual still suffered from AN or had had a "crossover" and now fulfilled the criteria for bulimia nervosa. Theander found that recovery rarely occurred after 12 years had elapsed since the onset of AN (Theander 1985).

The Gothenburg Anorexia Nervosa Study

Background and Methods

This prospective study originally aimed at performing an epidemiological study of adolescent-onset AN in Gothenburg by inviting all students born in 1970 ($n = 4291$), attending eighth grade, and living in Gothenburg in 1985. School health nurses in all

junior high schools were informed to weigh and measure the students. The adolescents completed a short self-report questionnaire pertaining to eating disorder-related symptoms. Maria Råstam, one of the initiators of the study, scrutinized all the students' grow charts in order to discover growth deviances (Rastam et al. 1989). The researchers found 25 individuals with AN. One of them, a girl, refused an in-depth examination, leaving 24 adolescents, 22 girls and two boys, all born in 1970, to form a population-based group. The school health nurses involved in the study also reported other adolescent cases with AN. These individuals were not born in 1970 but in adjacent years, in most cases between 1971 and 1974. This group, consisting of 27 young people, was compared with the population-based group regarding a considerable number of background variables, and almost total agreement between the groups was observed. The population-based group had, however, received treatment to a lesser extent. Based on the similar structure of the two groups, the researchers decided to pool them together to form the "AN group," which consisted of 51 individuals, 48 girls and three boys.

As a part of the study, the school health nurses were also asked to select comparison cases who matched the AN cases regarding age, sex, and schooling. This group was labeled the "COMP group" and also included 51 individuals, 48 girls and three boys. The young people in the COMP group had no history of AN or any other eating disorder.

The epidemiological study showed that the prevalence of AN before age 18 was 1.08% in females and 0.09% in males (Rastam et al. 1989).

The 51 AN and 51 COMP cases all agreed to an in-depth assessment including a physical examination and personal interview at the time of the original study. The mothers were interviewed regarding the child's early development, physical and psychiatric symptoms, and personality. Medical records including pregnancy, delivery, and the perinatal period were scrutinized by the researchers.

In total, the AN and COMP groups have been examined on five occasions. Table 1 shows the mean ages of the participants at the time of the five examinations (AN study 1, AN study 2, AN study 3, AN study 4, and AN study 5), beginning at age 16, the original study, until the 30-year follow-up. In the first four studies, there were no dropouts, i.e., all the 51 individuals in the AN and COMP group, respectively, agreed to participate. The project is characterized by studying a community-based (partly population-based) sample using a prospective case-control design.

At the 30-year follow-up, the participants were in their mid-40s (Table 1). All the individuals in the AN and COMP group had been traced. All the 51 COMP cases and 47 of the 51 AN cases agreed to participate. The reasons why four individuals in the AN group abstained were either due to living abroad and having a busy schedule at work ($n = 1$), being very disabled due to psychiatric morbidity ($n = 1$), or not feeling comfortable taking part in the study ($n = 2$) (Rydberg Dobrescu et al. 2020). The majority, 36 AN and 42 COMP cases, were interviewed face-to-face, and the rest were interviewed via online video conferences or telephone.

Table 2 shows all the assessments that were used in the 30-year follow-up. One of the outcome measures, the Morgan-Russell assessment schedule (Morgan and Russell 1975; Morgan and Hayward 1988), which has been used in all four follow-up studies,

Table 1 The Gothenburg anorexia nervosa study. Mean ages at examinations

	AN onset	AN study 1; original study	AN study 2; 6-year follow-up	AN study 3; 10-year follow-up	AN study 4; 18-year follow-up	AN study 5; 30-year follow-up
AN group	14.3	16.1 ($n = 51$)	21.0 ($n = 51$)	24.5 ($n = 51$)	32.4 ($n = 51$[a])	44.4 ($n = 47$[b])
COMP group	NA	16.0 ($n = 51$)	20.8 ($n = 51$)	24.2 ($n = 51$)	32.4 ($n = 51$)	44.2 ($n = 51$)

AN anorexia nervosa, *COMP* comparison, *NA* not applicable
[a]The mother of one participant was interviewed instead of the proband, since the proband considered herself too ill to take part
[b]All 51 individuals were traced and were alive, but four of them declined to participate in the study

deserves to be mentioned in more detail. The instrument supplies information, based on the individuals' BMI and menstrual status, on whether the outcome should be classified as good (normal weight + normal menstruations), intermediate (either normal weight or normal menstruations but not both), or poor (low weight, i.e., <18.5 kg/m^2, and no or scanty menstruations). A modified categorization suggests that all individuals with an ongoing eating disorder, irrespective of whether BMI and menstruations have normalized, should belong to the poor outcome category (Ratnasuriya et al. 1991). In addition, the Morgan-Russell assessment schedule includes five scales covering different areas that may be affected in individuals with a current or previous diagnosis of AN. The domains encompass food intake, menstrual pattern, and psychiatric, psychosexual, and socioeconomic status. A composite score, the Morgan-Russell averaged scale score, is calculated based on the five scales.

Two other outcome measures were used in the 30-year follow-up: the Global Assessment of Functioning Scale (GAF) (APA 1994), which measures both the degree of psychiatric symptoms and social/occupational functioning, and the 36-item Short Form Health Survey (SF-36) (Sullivan et al. 2002). The former scale has a span from 0 (severely impaired) to 100 (no impairment/very high functioning). The SF-36 (Sullivan et al. 2002) is a well-established and widely used instrument to measure health-related quality of life. It is the most frequently used health-related quality of life instrument in the field of eating disorder research (Treasure et al. 2015). It is a self-report questionnaire divided into four physical and four mental subscales. A composite score can be calculated for the physical (physical composite score, PCS) and the mental (mental composite sore, MCS) subscales.

Neurofilament Light Chain Protein in Serum

Blood samples were collected to investigate serum levels of biomarkers for neuronal injury seen in dementia and other neurodegenerative disorders. Neurofilament light chain protein (NfL) is a biomarker that can detect increased rates of axonal degeneration (Teunissen et al. 2005), including Alzheimer's disease (Mattsson et al. 2017) and traumatic brain injury (Rubin et al. 2019). An in-house single-molecule array (Simoa) assay (Quanterix®, Billerica, MA) was applied to measure serum NfL concentrations in the 30-year follow-up. The method delivers an approximately

Table 2 Assessments at the 30-year follow-up in the Gothenburg anorexia nervosa study

Assessment	Purpose
Weight and height	Assess outcome regarding anthropometric data
MINI International Neuropsychiatric Interview (MINI 6.0)	Assign psychiatric disorders
Structured Clinical Interview for DSM-IV (SCID-I) eating disorder module	Assign eating disorders
DSM-5 checklist for feeding and eating disorders	Assign eating disorders according to the DSM-5
The Short Form Health Survey (SF-36)	Assess outcome regarding health-related quality of life
Global Assessment of Functioning Scale (GAF)	Assess outcome regarding psychosocial functioning
The Morgan-Russell scales	Assess outcome regarding eating disorder symptoms, mental health, and psychosexual and socioeconomic state
Serum neurofilament light chain protein	Detect neuronal injury
Facial emotion recognition task	Assess capacity of facial emotion recognition
Instruments pertaining to physical and psychiatric status in offspring[a]	Detect symptoms of somatic and psychiatric disorders (including eating disorders) in offspring
Register search[a]	Attain information on offspring from the Medical Birth Registry to identify all births including delivery and perinatal status
Register search[a]	Attain information on inpatient hospitalizations and outpatient specialist consultation for psychiatric and somatic settings, pharmacological consumption, social assistance, disability pension, and sick leave to conduct health economic analyses

[a]Data not yet published

1000-fold increase in sensitivity (Rohrer et al. 2016). The correlation between cerebrospinal NfL and serum NfL has been shown to be robust (Lewczuk et al. 2018). The participants were asked whether they or any of their first-degree relatives suffered from dementia. The Swedish National Patient Register for in- and outpatient treatment was scrutinized regarding potential diagnoses of dementia, according to the ICD-9 and the ICD-10, among the participants. The data presented are limited to female participants, since male cerebrospinal NfL concentrations tend to be higher than female concentrations (Goossens et al. 2018). Blood samples were collected from 34 women in the AN and 38 women in the COMP group.

Facial Emotion Recognition Task

Twenty-six women who had recovered from eating disorders in the AN group and 31 women in the COMP group completed a facial emotion recognition task using the Tobii Studio 3.03 software. The participants were shown photos of faces expressing the emotions anger, fear, and happiness. The facial expressions varied between 0% (neutral), 40%, 60%, 80%, and 100% of the expression. A photo with the morphed

emotion (0%, 40%, 60%, or 80% of the full emotion) was presented to the left on a screen, and four faces expressing 100% of the different emotions (neutral, anger, fear, and happiness) were shown to the right on the same screen. The participant had to match the photo with the morphed expression to the left with one of the photos to the right showing the correct full expression. The task, which is entirely nonverbal, consists of 104 pictures, starting with 24 images as a training set. The number of correct answers, reaction time, and visual scanning behavior were registered and analyzed. Six of the participants in the AN group had shown diagnostic stability in previous studies regarding autism spectrum disorder (ASD), i.e., they had been assigned an ASD diagnosis in at least three of the four previous examinations by a blinded rater (Anckarsater et al. 2012). In the facial emotion recognition study, these six participants constituted a subgroup (recovered AN with ASD), and their data were compared with the remaining individuals in the AN group. It was considered important to analyze the subgroup with ASD separately, since individuals with ASD are known, in general, to pay less attention to eyes compared with typically developed individuals (Klin et al. 2002). In addition, facial emotion recognition is usually more challenging for individuals with ASD (Baron-Cohen et al. 2001). For further details regarding the methods, see Dinkler et al. (2019).

Definition of Full Eating Disorder Recovery

All follow-up studies based on the Gothenburg AN study have used the same definition for full eating disorder recovery. The criteria for recovery were fulfilled if the individual had not met any criterion for an eating disorder, exhibited BMI within the normal range, had had normal menstruations, and reported no dieting or preoccupation with body weight and shape during the last 6 months. The definition is in accordance with the proposal by Strober and colleagues (Strober et al. 1997); however, Strober's group only claimed a 2-month duration of recovery, compared with 6 months in the Gothenburg AN study.

The present chapter will focus on data from the three papers from the 30-year follow-up that have been published so far. The findings include general outcome, psychiatric morbidity including eating disorders, facial emotion recognition, and serum concentrations of neurofilament light chain protein signaling neural injury (Rydberg Dobrescu et al. 2020; Dinkler et al. 2019; Wentz et al. 2021).

Results

General Outcome

No participants had died, neither in the AN group nor in the COMP group, in the 30-year follow-up or in previous follow-up studies. Based on the modified Morgan-Russell outcome categorization, 72.3% ($n = 34$) had a good outcome, 8.5% ($n = 4$) had an intermediate outcome, and 19.1% ($n = 9$) had a poor outcome in the AN group. All individuals in the intermediate group had a low BMI, and all in the poor outcome group had a current eating disorder.

The AN group scored significantly lower on the GAF scale compared with the COMP group (AN: 60.72 (SD: 17.23); COMP: 80.20 (SD: 14.78); $p < 0.0001$). Regarding the health-related quality of life outcome, the AN group scored significantly lower on the mental composite score (MCS) of the SF-36, and on the mental subscale, "mental health," than the COMP group. In the AN group, those with a current eating disorder did not score lower than those without a current eating disorder on the SF-36.

Eating Disorder Outcome

Nine (19%) of the 47 individuals in the AN group had an eating disorder at the 30-year follow-up. Three of them had current AN, of whom two were "in partial remission." The most common eating disorder diagnosis was "other specified feeding and eating disorders" (OSFED), which affected five individuals. This diagnosis is assigned when the individual has "atypical AN" (weight loss criterion for AN not fully met) or almost fulfills the criteria for bulimia nervosa (low frequency of bingeing or purging and/or limited duration) or binge-eating disorder (low frequency of bingeing and/or limited duration). There are two additional OSFED subtypes: purging disorder and night-eating syndrome. In the AN group, two of the individuals with OSFED were categorized as atypical AN, and one each was classified as bulimia nervosa, binge-eating disorder, and the purging type. One individual in the AN group had binge-eating disorder. One woman in the COMP group had the OSFED-type night-eating syndrome. No further eating disorders were diagnosed in that group.

Over the 30 years, the mean duration of AN, if all AN episodes were included, was 4.9 years (SD 5.1), and the mean duration of all eating disorder episodes, including AN, was 10.2 years (SD 8.1). During the past 12 years, since the previous follow-up, 18 years after the onset of AN, 32% ($n = 15$) had at some time experienced an eating disorder including AN. Seventeen percent ($n = 8$) reported that they had suffered from AN at some point between the two latest follow-ups. Figure 1 illustrates the number and type of eating disorders that occurred in AN study 4 and AN study 5 and during the 12-year period between the two follow-up studies.

Psychiatric Morbidity

At the 30-year follow-up, 29% in the AN group suffered from anxiety disorders (COMP: 10%; $p < 0.05$), which constituted the most common psychiatric cluster at the time. Eighteen percent in the AN group had a current affective disorder, and 38% had at least one psychiatric disorder, excluding ongoing eating disorders (COMP: 12%; $p < 0.01$).

Neurodegenerative Findings

No individuals in the AN or COMP group had been assigned a diagnosis of dementia according to the Swedish National Patient Register. Figure 2 illustrates serum NfL concentrations in the women in the AN and COMP groups. The AN group exhibited significantly higher serum NfL concentrations than the COMP group (AN:

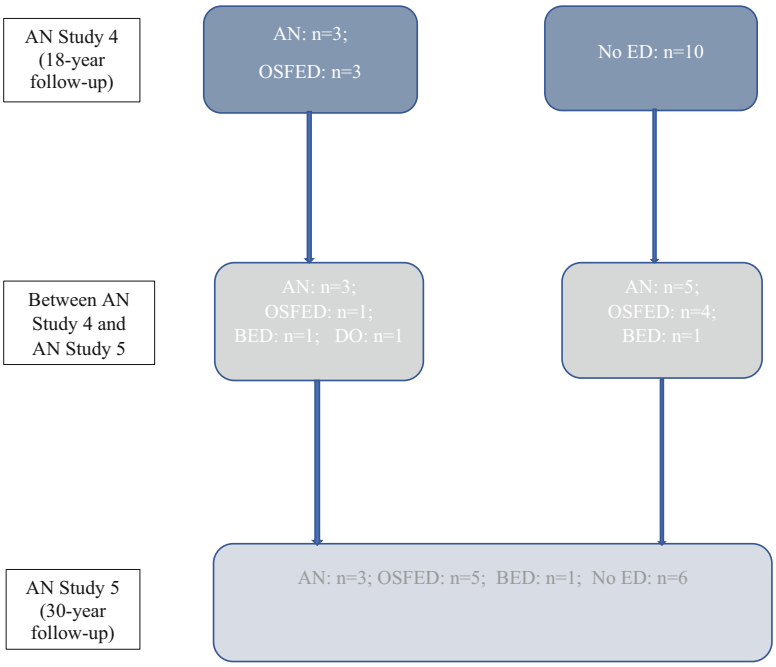

Fig. 1 Eating disorders in AN study 4 and AN study 5 and between the two follow-up studies**.** In AN study 4, six individuals had an eating disorder (ED). Ten individuals without an ED in AN study 4 had an ED relapse between AN study 4 and AN study 5. Altogether, 15 individuals (32%) had an ED between the two follow-up studies. In AN study 5, there were nine (17%) individuals with an ED. Six individuals with an ED between the two follow-up studies no longer met the criteria for an ED in AN study 5. AN, anorexia nervosa; BED, binge-eating disorder; OSFED, other specified feeding and eating disorders; No ED, no eating disorder; DO, dropout

27.7 pg/ml; SD: 22.0; COMP: 19.0 pg/ml; SD: 12.1; $p = 0.041$). Among the women in the AN group who no longer suffered from an eating disorder (28 of the 34 women who agreed to the collection of blood samples), an increased, albeit statistically nonsignificant ($p = 0.054$), serum NfL concentration was seen in relation to the serum NfL concentration in the COMP group. There was a statistically significant negative correlation between the serum NfL concentration and the current BMI in the AN group ($r = -0.44$), i.e., the lower the BMI, the higher the serum NfL concentration. This correlation appeared exclusively in the AN group. No significant correlation was seen between the total duration of AN during the 30 years and the serum NfL concentration in the AN group ($r = 0.15$).

Facial Emotion Recognition Task

The recovered AN women without ASD ($n = 20$) performed similarly to the women in the COMP group regarding accuracy, reaction time, and visual scanning behavior. The recovered AN women with ASD ($n = 6$) showed significantly higher accuracy than the recovered AN women without ASD regarding low expression intensity

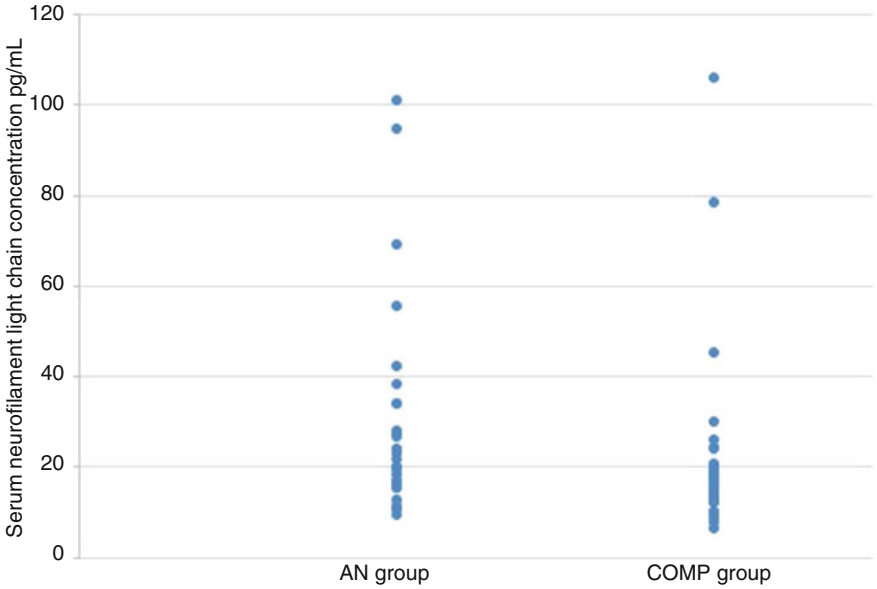

Fig. 2 The distribution of serum neurofilament light chain protein in women in the AN and the COMP group**.** AN, anorexia nervosa; COMP, comparison group

(40% of the facial expression) but not regarding the facial expressions with higher intensity (60% and 80%).

Comparisons Between Theander's Study and the Gothenburg AN Study

Table 3 compares the study designs, samples, and outcome of the two Swedish studies with a follow-up period of 30 years or more. Theander's study reported high mortality rates, while the Gothenburg AN study reported no deaths. On the other hand, Theander found that as much as 76% of his sample had recovered, and only 6% had an eating disorder 33 years after first admission to hospital. The corresponding data in the Gothenburg AN study showed poorer results: 64% had recovered, and 19% had a current eating disorder.

Discussion

The two studies presented in this chapter are very different in many respects, which makes it difficult to compare the outcomes. One study represents females admitted to hospital due to AN, mainly during the first half of the twentieth century, and the other study is based on a sample of individuals with adolescent-onset AN born in the

Table 3 Characteristics and outcome of the two studies with a follow-up period of at least 30 years

	Theander's study	The Gothenburg AN study
Characteristics		
Sample characteristics	Hospitalized AN patients	Adolescents recruited from the community including a total birth cohort
Study design	Initially retrospective; second assessment prospective	Prospective, case-control
Location	Southern Sweden	Gothenburg, Sweden (southwest Sweden)
Females/males	94/0	48/3
Control group	No	Yes; 51 individuals (48 females/3 males) matched for age, sex, and school and without a history of eating disorders
Observational time (years)	33 (on average 15 years between admission to inpatient treatment and first assessment; second assessment 18 years later)	30 (mean age at onset of AN: 14.3 years; fifth assessment after 30 years, at mean age 44)
Number of examinations	2 (1 retrospective, 1 follow-up study)	5 (1 baseline, 4 follow-up studies)
Outcome		
Recovered; n (%)	71 (76%)	30 (64%)[a]
Number of individuals with an eating disorder; n (%)	6 (6%)	9 (19%)[a]
Type of eating disorders	4 AN, 2 BN	3 AN, 1 BED, 5 OSFED
Deaths; n (%)	17 (18%)	0
Death caused by suicide; n (%)	5 (5%)	0

N number, *AN* anorexia nervosa, *BN* bulimia nervosa, *BED* binge-eating disorder, *OSFED* other specified feeding and eating disorders

[a]47 of the 51 in the AN group agreed to participate at the 30-year follow-up

second half of the same century and recruited from the community. Both studies originate in Sweden but were performed during different time periods, which probably had implications for the outcome.

Mortality only occurred in the study by Theander. How can that be explained? The most obvious explanation is the different selection of participants in the two studies. Theander's study included inpatients only, and the Gothenburg AN study was community-based. Half of the participants in the Gothenburg AN study constituted a total age cohort (born in 1970), and the majority of individuals in this population-based group had not received treatment for AN at the time of the original study (Gillberg et al. 1994). It can therefore be assumed that individuals who have a history of inpatient care due to AN belong to a more severe group than a community-

based sample. In his thesis, Theander classified the participants based on the severity of AN during the inpatient treatment. The most severe cases were labeled the cachectic group, and, in the thesis, all participants who had died due to undernutrition belonged to that category. The Gothenburg AN study did not include data regarding the number of participants who had received inpatient treatment for AN over the 30-year follow-up period. However, a study based on the 6-year follow-up, at mean age 21 years, reported that 13 of the 51 individuals (25%) had been treated in intensive care or in specialized AN inpatient units (Gillberg et al. 1994). At the 30-year follow-up, 23% stated that they had never received any treatment for AN or any other eating disorder (Rydberg Dobrescu et al. 2020). Another notable discrepancy between the studies that may have influenced mortality rates is the different time periods when the two studies took place: Theander's study, in which all individuals were born (and usually treated for AN) during the first half of the twentieth century, and the Gothenburg AN study, where the participants were born in the 1970s and had an onset of AN in the 1980s. Specialized eating disorder services had not yet been developed in Sweden in the 1980s, but health care in general had made huge progress compared with the first half of the 1900s. The more homogeneous sample in the Gothenburg AN study, consisting solely of cases with adolescent-onset AN, may also have contributed to the zero mortality, since the outcome is known to be better when the onset of AN happens in adolescence than later (Steinhausen 2009). Late onset of AN has been observed as a risk factor for premature death (Fichter and Quadflieg 2016). A meta-analysis of mortality in eating disorders published in 2011 found a standardized mortality rate (SMR) of 6 for AN, i.e., a sixfold increase in the risk of premature death among individuals with previous or current AN (Arcelus et al. 2011). The SMR was not calculated in Theander's study, but a mortality rate of 18% is remarkably high compared with a systematic review, based on outcome studies of AN during the second half of the nineteenth century, with a mortality rate of 5% (Steinhausen 2009). On the other hand, the Gothenburg AN study had an unforeseen low mortality rate, reporting no deaths. The FinnTwin study, a population-based project studying individuals with AN, reported zero mortality at 10-year follow-up (Mustelin et al. 2015), a result that is in line with that in the Gothenburg AN study.

In Theander's study, the eating disorder recovery rate is higher than in the Gothenburg AN study. The definition of recovery by Theander was not as detailed and strict as the one in the Gothenburg AN study. Theander did not specify the time frame of having been "completely free from anorectic symptoms," while the Gothenburg AN study required a duration of at least 6 months. Further, Theander did not require the absence of dieting, a criterion that was included in the full recovery definition in the Gothenburg AN study. In summary, the different definitions across studies may imply that the proportion of recovered women has been overestimated in the study by Theander compared with the Gothenburg AN study. There is, however, still no consensus regarding the characteristics of full recovery from an eating disorder (Khalsa et al. 2017).

The eating disorder prevalence was relatively low, 6%, in the 33-year follow-up by Theander and lower than the prevalence in the Gothenburg AN study where 19%

had an eating disorder at the 30-year follow-up. This is a "surprising" finding considering that the cases in Theander's original study in general exhibited a more severe variant of AN, including several patients who had been cachectic. The diagnostic criteria for eating disorders have changed considerably since Theander's work in the beginning of the 1980s. According to the criteria for AN in the DSM-III, published in 1980 (APA 1980), refusal to maintain weight over a minimal normal weight for age/height, and a weight loss of 25%, had to be met. In the DSM-III-R (APA 1987), published in 1987, the weight criterion had been modified and was now specified as "body weight 15% below that expected," and the weight loss criterion had been removed. According to the DSM-5 (APA 2013), amenorrhea, a criterion that was included in the DSM-III, the DSM-III-R, and the DSM-IV (APA 1994), is no longer a symptom that has to be present, and the weight criterion is fulfilled if BMI is below 18.5 kg/m^2 in adult cases with AN. To sum up, assigning an eating disorder diagnosis in the 1980s required a more severe condition than in 2013 when the DSM-5 was published. More eating disorder diagnoses have been established since the 1980s, including binge-eating disorder in the DSM-5. At the 33-year follow-up, Theander reported that two of the six women with an eating disorder had bulimia nervosa and the rest had AN. No one in the Gothenburg AN study, neither at the 18-year nor at the 30-year follow-up, met the criteria for bulimia nervosa. Based on the findings in the Gothenburg AN study, one could assume that individuals with a history of AN rarely cling to a diagnosis of bulimia nervosa two to three decades after the onset of AN. However, Theander's study implies another outcome; bulimia nervosa can still appear 33 years after the first hospitalization due to AN.

Theander stated that recovery was rare beyond 12 years after the onset of AN. The Gothenburg AN study could not completely corroborate Theander's findings. In the 18-year follow-up, there were six cases with eating disorders, including three with AN. The individuals with AN were all free from an eating disorder in the 30-year follow-up, i.e., they had recovered from AN more than 18 years after the onset of AN. In the 18-year follow-up study, two of the three individuals with another eating disorder did, however, not recover; one exhibited a crossover to AN, and one continued having another eating disorder. For that individual with another eating disorder in the 18-year follow-up study dropped out in AN study 5, why no information could be collected regarding the eating disorder outcome. Eddy and co-workers performed a 22-year follow-up study of patients with AN and bulimia nervosa who had been admitted to an eating disorder service (Eddy et al. 2017). The research group had previously conducted a 9-year follow-up and reported that 31.4% of the patients with AN were recovered after 9 years, and 62.8% were recovered 22 years after admission. There were, however, four of the original 121 AN patients who had been classified as recovered at the 9-year follow-up but later had a relapse and fulfilled the criteria for AN at the time of the 22-year follow-up. The findings are in accordance with the results in the 30-year follow-up study, namely, that an AN relapse may appear decades after the individuals had been classified as having recovered from AN.

In addition to the findings regarding full recovery rate, the proportion of individuals with a remaining eating disorder, and survival data, some other major findings in the 30-year follow-up also require attention. Psychiatric morbidity, excluding eating disorders, was surprisingly common; about a third of the individuals in the AN group had a psychiatric disorder, of which anxiety and affective disorders were the most frequent. Both anxiety and depression are almost ubiquitous in individuals with current AN. Depressed mood is usually secondary to starvation in individuals with AN. However, the overrepresentation of anxiety and affective disorders 30 years after the onset of AN implies that the individuals may have a susceptibility for these psychiatric disorders in addition to an eating disorder. An extensive genetic study using GWAS and involving almost 17,000 AN cases showed a relationship between AN and anxiety and affective disorders (Watson et al. 2019), a finding that corroborates the data in the 30-year follow-up study.

Another major finding in the 30-year follow-up was the elevated serum concentration of the brain injury marker NfL in the AN group. There was no significant difference between the serum NfL concentration among those with a current eating disorder and those without an eating disorder. The results may imply that brain tissue is more likely to show signs of damage in individuals with a history of AN compared with matched individuals without a history of an eating disorder. Interestingly, the duration of AN was not related to a higher serum NfL concentration.

The facial emotion recognition study is the first of its kind assessing women recovered from AN and investigating whether coexistent ASD has an impact on the results. Recovered women and women in the COMP group showed similar results regarding accuracy, reaction time, and visual scanning behavior. These findings indicate that no facial emotion recognition deficits should be expected in women recovered from AN. In the AN group, the subgroup of women with coexistent ASD performed better than the women without ASD regarding interpretation of facial expressions with low intensity. This result demonstrates an ability to detect glimpses of a facial appearance among the women with coexistent ASD. The discovery could be a symptom of "attention to detail," a finding which is usually present in individuals with ASD (Baron-Cohen et al. 2001).

Conclusions

Two Swedish outcome studies of AN with a follow-up period of 30 years or more were published in the 1980s and in the 2020s, respectively. The study published in the 1980s consisted of a sample with a more severe form of AN. All the patients had originally been hospitalized due to AN, while the other outcome study consisted of a community-based sample with adolescent-onset AN cases. The mortality rates were surprisingly high in the former study, while zero deaths had occurred in the latter study. The two studies reported better recovery rates from eating disorders than the recovery rate of 47% found in an extensive review of AN outcome studies published by Steinhausen in 2002 (Steinhausen 2002). The study from the 1980s found a lower prevalence of eating disorders after 33 years than the more recent outcome study

where as many as one in five still suffered from an eating disorder 30 years after the onset of AN. A comparison between the two studies implies that mortality due to AN seems to have decreased over the years, and the development of a better health-care system may have contributed to this finding. However, when comparing the two studies with regard to full eating disorder recovery rates and the prevalence of persisting eating disorders, there is no indication of a better outcome in the study published in 2020.

Key Facts

- AN has one of the highest mortality rates among psychiatric disorders
- Mortality rates in AN seem to have decreased compared with data based on studies from the twentieth century
- Recovery from AN after 12 years is rare but does occur
- Individuals who are admitted to inpatient treatment due to AN have a poorer prognosis regarding premature death

Summary Points

- A 33-year follow-up study of female inpatients with AN was performed in the 1980s. The study reported a mortality rate of 18%
- Of the women, 76% had recovered at the 33-year follow-up
- After 33 years, 6% still had an eating disorder, in most cases chronic AN
- A 30-year follow-up study of AN with adolescent onset was conducted during the second decade of the twenty-first century. No deaths had occurred in the study
- Sixty-four percent were considered fully recovered from AN at the 30-year follow-up
- Nineteen percent still had an eating disorder 30 years after the onset of AN
- Psychiatric disorders other than eating disorders were still common among the participants in the 30-year follow-up of AN
- The mean duration of AN (including all episodes) was 5 years in the 30-year follow-up

potential of modifying the gut microbiota as an adjunct to standard nutritional treatment protocols for AN patients. Recently, the gut microbiota has been increasingly recognized as an important factor contributing to various diseases, including psychiatric disorders. Gut microbiota communicates with the central nervous system on the gut-brain axis and potentially affects mental health. In patients with AN, the microbial composition and related microbial products differ from healthy individuals. The microbiota in the gastrointestinal tract is a very important antigenic source for the host immune system. Evidence is now emerging for an association between specific psychiatric disorders and altered immune reactions, some of which have been described in patients with AN. Some immune components have the potential to regulate brain functions and may underlie the pathology of anorexia nervosa.

Keywords

Microbiota · Microbiome · Anorexia nervosa · Microbiota-gut-brain axis · Dysbiosis · SCFA · Neurotransmitter · Fecal microbiota transplantation · Probiotics · Prebiotics · Autoimmunity

Abbreviations

ABA	Activity-based anorexia
AN	Anorexia nervosa
ATB	Antibiotic
BCAA	Branched-chain amino acid
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
ClpB	Caseinolytic protease B
CNS	Central nervous system
DNA	Deoxyribonucleic acid
FMT	Fecal microbiota transplantation
fT4	Free thyroxine
GABA	Gamma-aminobutyric acid
GF	Germ-free
HPA axis	Hypothalamic-pituitary-adrenal axis
IBD	Inflammatory bowel disease
IBS	Irritable bowel syndrome
IgG	Immunoglobulin G
IL-17	Interleukin 17
IL-6	Interleukin 6
MC	Melanocortin
NPY/AGRP	Neuropeptide Y/agouti-related peptide
OTU	Operational taxonomic unit

PANDAS	Pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections
POMC/CART	Pro-opiomelanocortin/cocaine- and amphetamine-regulated transcript
SAM	*S*-Adenosyl-L-methionine
SCFA	Short-chain fatty acid
TNF-α	Tumor necrosis factor alpha
TSH	Thyroid-stimulating hormone
α-MSH	Alpha-melanocyte-stimulating hormone

Introduction

The human gut is home to an enormous community of resident microorganisms called the microbiota, including bacteria, viruses, fungi, archaea, and protozoa. Among these, bacteria represent the best-studied group, with the estimated number in the adult "reference man" being approximately 3.8×10^{13} (Sender et al. 2016). The frequently used term microbiome refers to the collective genomes of the microorganisms in a particular environment. The gut microbiota composition varies throughout life. It is very dynamic in childhood and relatively stable during adulthood, but it declines and changes in the elderly. The human gut harbors from 200 to more than 1000 bacterial species. Everyone has a personalized gut microbiota containing a unique taxonomic composition, with only a small number of species being found in all humans, which is known as the core gut microbiota (Turnbaugh et al. 2009). Approximately a third of resident intestinal microbes are common to all individuals; the remaining part is unique for each host. The variable part is affected by various factors, like age, disease, diet, lifestyle, host genotype, medications, hygiene, geographical location, etc. It has been shown that some bacteria occur mainly in healthy people and have beneficial effects, while other commensal microbes may be pathogenic under certain conditions (the so-called pathobionts). However, it appears that a core "healthy" microbiota common to all individuals does not exist.

Moreover, it is sometimes difficult to distinguish whether a particular commensal microbe is harmful or beneficial, depending on the specific strain or location in the body. A compositional and functional alteration in the microbiota is called "dysbiosis" and is associated with many diseases, including neurological and psychiatric disorders (Liang et al. 2018). Microbiota dysbiosis is characterized by an increase in pathobionts, a decrease in commensals, or a decrease in microbial diversity, or it may be a combination of all three (Levy et al. 2017). The gut microbiota depends on ingested nutrients, which means that both short- and long-term dietary changes can affect the composition of microorganisms inhabiting the intestines (David et al. 2014). This chapter will discuss the importance of the gut microbiota relative to human behavior and describe how the gut microbiota is linked to anorexia nervosa.

The Microbiota-Gut-Brain Axis

The bidirectional neural communication between the brain and gut is well established. However, much of the earlier work regarding gut-brain communication concentrated on digestive functions and satiety. Neural signaling is supported by sophisticated interactions with the endocrine and immune systems. More and more evidence indicates that gut microbiota plays an essential role in this communication process. Microbial products can act either directly on enterocytes, gut-resident immune cells, and enteric nerve cells or indirectly on the central nervous system (CNS) via neuroendocrine and metabolic pathways. Therefore, we often use the "microbiota-gut-brain axis" to describe these interactions (Fig. 1).

Animal models are frequently used to understand the microbiota-host relationship. Perhaps the most important models use germ-free (GF) animals that have never been exposed to microorganisms. These animals can be colonized, for example, by the fecal microbiota of patients, and the effect of this transfer can be observed. Conventional animal models can be used to evaluate antibiotic or probiotic treatments relative to the microbiota. Many of these studies have consistently shown that the microbiota influences behavior (Table 1).

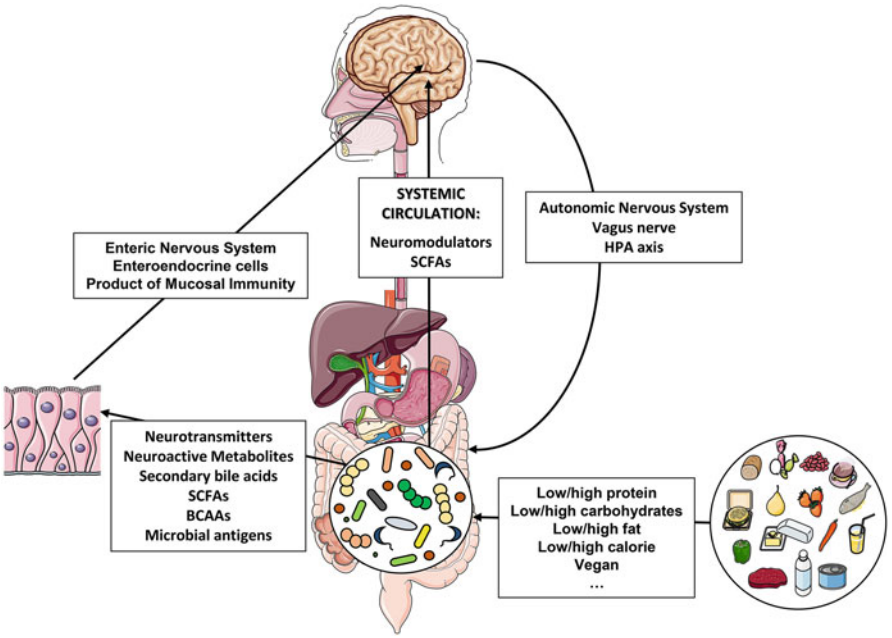

Fig. 1 Bidirectional communication between the gut microbiota and the brain. Diet affects the microbiota composition and, in turn, affects the whole cascade of molecules that may affect the central nervous system and human behavior. *SCFAs*, short-chain fatty acids; *BCAAs*, branched-chain amino acids; *HPA axis*, hypothalamic-pituitary-adrenal axis

Various bacterial species produce metabolites able to influence host appetite and eating behavior by directly affecting nutrient sensing and appetite as well as affecting appetite- and satiety-regulating systems (van de Wouw et al. 2017). Altered gut microbiota has been described in patients with anorexia nervosa (Morita et al. 2015; Borgo et al. 2017; Prochazkova et al. 2021), in certain forms of malnutrition (Genton et al. 2015), and also in obese individuals (Crovesy et al. 2020).

The gut microbiota also affects the permeability of the gastrointestinal barrier. Excessive intestinal permeability, referred to as "leaky gut," results in increased translocation of microbial products across the gut wall and the development of low-grade inflammation. Increased intestinal permeability has been described in obese patients (Teixeira et al. 2012) and patients suffering from various psychiatric disorders (Safadi et al. 2021). One study in AN patients showed a decrease in intestinal permeability related to lactulose/mannitol absorption (Monteleone et al. 2004). In contrast, increased gut permeability was observed in the activity-based anorexia (ABA) mice model (Jesus et al. 2014). Some evidence suggests that anorexia nervosa and other eating disorders are associated with inflammatory

bowel disease, with AN being mostly associated with Crohn's disease (Ilzarbe et al. 2017). We can hypothesize that an increase in gut permeability, with subsequent translocation of microbial products, results in an inflammatory reaction that causes changes in the anatomy and physiology of intestinal tissue; this would explain both reduced gut permeability in later stages of AN and a higher risk of Crohn's disease.

As mentioned above, the intestinal microbiota modulates the CNS through neuroimmune and neuroendocrine mechanisms. Microorganisms produce and secrete hormones (serotonin, dopamine, norepinephrine, and gamma-aminobutyric acid (GABA)), respond to host hormones, and regulate the expression of host hormones (Neuman et al. 2015). Serotonin is linked to most of the behavioral characteristics seen in patients with AN. Tryptophan, the precursor of serotonin, is an essential amino acid, which is only available from the diet. Diet restrictions can result in a reduction in serotonin synthesis, thereby reducing the role of serotonin in neurotransmission at postsynaptic sites. This reduction can lead to depression, anxiety, hyperactivity, and behavioral impulsivity (Haleem 2012). Some evidence suggests that elevated dopamine levels initially trigger the reward system during food restriction and exercise. However, AN patients can become dependent on the reward, not unlike drug addiction (Sodersten et al. 2016). In addition, altered GABA levels play a role in various neuropsychiatry disorders such as anxiety and depression (Cryan and Kaupmann 2005). Prochazkova et al. found significantly reduced levels of dopamine and GABA and slightly reduced serotonin levels in the stool samples from patients with AN compared to healthy controls. A significant increase in the abundance of *Alistipes finegoldii* and *A. onderdonkii* was found in the gut microbiome of patients with AN. The *Alistipes* genus can hydrolyze tryptophan to indole and thus decreases serotonin availability and thus affects the microbiome-gut-brain axis (Prochazkova et al. 2021). However, the effect of altered intestinal neurotransmitter levels on the CNS is not well understood, and we can only speculate on the significance of these changes in patients with AN.

Gut Microbiota Link to AN

Diet and feeding behaviors are the most influential external factors for gut microbiota composition, and since AN is accompanied by starvation, it is evident that AN can induce changes in gut microbiota. Food and habitual diet shape the composition of the gut microbiota; the microbiota then provides nutrient signals to the host. The food composition and diversity determine which intestinal microbes will colonize, proliferate, persist, or vanish (Shanahan et al. 2017).

Interestingly, disturbances during microbiota development in infancy can contribute to the risk of immune and metabolic disease in later life. Additionally, the loss of microbes and their diversity in the elderly due to monotonous diets is associated with unhealthy aging and weakness. Moreover, loss of microbiota diversity is associated with a risk of inflammation and infections (Claesson et al. 2012). However, the effect of a dietary intervention varies extensively among individuals,

whereas factors determining an individual's responsiveness to dietary interventions are not known.

Currently, there are several studies on the gut microbiota in patients with AN, all performed on stool samples (summarized in Table 2). The outcomes of these studies are varied and inconsistent in terms of abundance, diversity, and microbial composition. Reduced alpha diversity (i.e., richness, abundance, and frequencies of species in a microbial ecosystem) in one analyzed index, which reflects the microbial variance within a particular sample compared to controls, was reported in three studies (Kleiman et al. 2015; Morkl et al. 2017; Hanachi et al. 2019), while in four other studies, no difference in alpha diversity was found (Mack et al. 2016; Borgo et al. 2017; Prochazkova et al. 2021; Schulz et al. 2021). Since the results vary between studies, it is difficult to unequivocally interpret the changes in alpha diversity in AN.

However, all studies found significant differences between microbiota composition of patients with AN and healthy controls. There are some indications that AN is associated with a distinct microbiota signature. One potentially important species is the archaeon *Methanobrevibacter smithii*, which showed increased abundance in several AN studies (Armougom et al. 2009; Million et al. 2013; Borgo et al. 2017). These archaea feed on waste products of polysaccharide decomposition and increase the transformation of nutrients into calories. Another possible signature of the AN microbiota is the decreased abundance of butyrate-producing bacteria, e.g., *Roseburia*, *Clostridium*, *Anaerostipes*, and *Faecalibacterium*, which was confirmed by almost all existing AN studies (Kleiman et al. 2015; Morita et al. 2015; Mack et al. 2016; Borgo et al. 2017; Hanachi et al. 2019; Prochazkova et al. 2021).

Similar to the altered microbiota in patients with AN (Prochazkova et al. 2021), overexpressed *Alistipes* and decreased *Faecalibacterium* numbers were found in patients with depression, which is a common AN comorbidity (Jiang et al. 2015). *Faecalibacterium* levels are reduced in many human diseases and disorders, and it is suggested that its greater abundance is associated with a healthier state and has been proposed as a potential therapeutic.

Another potential AN signature is the overrepresentation of the heritable *Christensenellaceae* family. Such an overrepresentation was found in the microbiome of AN patients as well as in those with lower body mass indexes (BMI) (Goodrich et al. 2014; Prochazkova et al. 2021).

Patients with AN exhibited increased interindividual variation in gut bacteriome composition compared to healthy individuals, manifesting as core microbiota depletion (Prochazkova et al. 2021). Greater interindividual variation of patients with AN can be elucidated by the so-called Anna Karenina principle, explaining that dysbiotic individuals vary more in microbial community composition than healthy individuals due to a stochastic microbiota response to disequilibrium states induced by stressors. Such effects on the microbiome are a common and vital response of animal microbiomes to stressors, and they are often associated with host health impairment (Zaneveld et al. 2017). It was shown that approximately half of microbiome-associated diseases follow this Anna Karenina principle and are caused mainly by highly dominant microbial species (Fig. 2; Ma 2020).

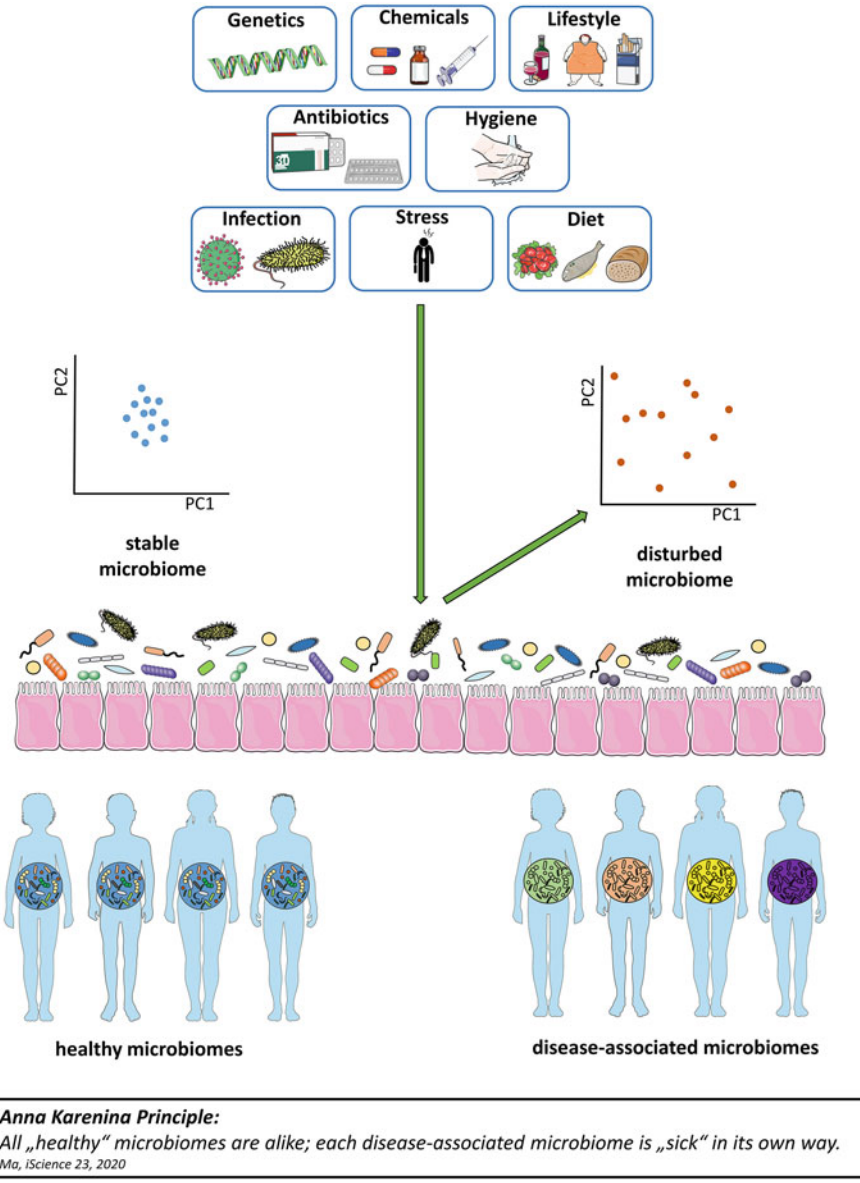

Fig. 2 Anna Karenina principle in human microbiomes associated with diseases. Many external factors influence the human gut microbiome. These can alter the microbiome by disrupting its stability and producing more dispersed microbiomes (right plot). Stable ("healthy") microbiomes form tight clusters on the ordination graph (left plot). Microbiome stability is an important sign of healthy host physiology. Dysbiotic (unstable) microbiomes are often associated with various diseases and are more heterogeneous. The Anna Karenina principle suggests that some stressors have stochastic rather than deterministic effects on community composition. Consequently, "healthy microbiomes are similar, but each dysbiotic microbiome is dysbiotic in its own way"

Four longitudinal studies compared fecal microbiota before and after weight restoration. A study with a small number of patients described a trend toward a healthier microbiota during treatment (Kleiman et al. 2015). The other three studies have consistently shown that patient renourishment led to only minor bacterial composition changes, and the bacteriome of patients after weight gain was still more similar to the bacteriome of patients at hospital admission than to the bacterial composition of healthy controls (Mack et al. 2016; Prochazkova et al. 2021; Schulz et al. 2021), which could be potentially linked to only partial weight recovery. These data suggest that alterations in the gut microbiome may be connected to AN causality rather than a consequence of low body weight or starvation.

Except for composition changes, variations in predicted metabolic pathways associated with AN were described by Prochazkova et al. (2021). For instance, an underrepresented *S*-adenosyl-L-methionine (SAM) cycle I pathway was detected in samples of patients with AN. Cellular L-methionine is converted to SAM, which is the principal methyl donor. Deficiency in SAM production and subsequent DNA methylation, an important epigenetic mechanism, is associated with severe neuropsychiatric diseases (Gao et al. 2018). Additionally, SAM is also essential for synthesizing various neurotransmitters, such as serotonin, dopamine, and norepinephrine. Interestingly, SAM was used as a dietary treatment leading to modulation of patient methionine metabolism via altered nutrient availability; the treatment showed promising results in depression disorders (De Berardis et al. 2016).

The composition of the microbiota does not answer the question of which bacterial species contribute to the pathophysiology of AN. Different strains of bacteria can have unique physiological roles associated with different diseases and disorders. In addition, bacteria of the same genus and even from the same species can have substantially divergent metabolic capabilities. Also, various bacterial species can duplicate the same metabolic functions and can deputize each other.

Intestinal Microbial Metabolites in AN

Some of the leading roles of the intestinal microbiota are associated with the breakdown of indigestible polysaccharides (human lacks the relevant enzymes), production of short-chain fatty acids (SCFA), production of specific vitamins, activation of genes regulating the absorption of nutritional components, epithelial differentiation, formation of the mucosal barrier, and immunological defense.

SCFAs are produced mainly by bacterial fermentation of dietary non-digestible carbohydrates. The three most abundant SCFAs, each with a different role in the human body, are acetate, butyrate, and propionate. The most abundant SCFA, acetate, is an essential metabolite for bacterial growth in the colon and is utilized in cholesterol metabolism and lipogenesis in peripheral tissues. Moreover, acetate crosses the blood-brain barrier and induces an anorectic signal via increased POMC/CART neurotransmission at glutamatergic neurons and via decreased NPY/AGRP neurotransmission at GABAergic neurons in the hypothalamic arcuate nucleus (De Vadder et al. 2014; Frost et al. 2014; Chambers et al. 2015). Butyrate is the

Table 3 Reported differences in bacterial SCFA abundance in feces of patients with AN compared to healthy controls

	Population	Acetate	Butyrate	Propionate
Morita et al. (2015)	AN = 25 C = 21	↓	↔	↓
Mack et al. (2016)	AN = 55 C = 55	↔	↓	↔
Borgo et al. (2017)	AN = 15 C = 15	↔	↓	↓
Speranza et al. (2018)	AN = 10 C = 8	↔	↓	↓
Prochazkova et al. (2021)	AN = 59 C = 67	↓	↓	↔

AN, anorexia nervosa; *C*, healthy persons
↓ lower than in healthy persons, ↔ not different from healthy persons

most important SCFA for human health since it is the main energy source for human colonocytes. It can induce apoptosis of colon cancer cells and activate intestinal gluconeogenesis. Moreover, butyrate has a well-characterized anti-inflammatory effect, both on intestinal epithelial and immune cells (Couto et al. 2020). Propionate is an energy source for epithelial cells. The liver regulates gluconeogenesis and satiety signaling through its interaction with the gut fatty acid receptors.

Acetate is produced by various bacterial species, whereas pathways for propionate and butyrate are more conserved and substrate-specific. The main butyrate-producing bacteria are anaerobes, and the low oxygen concentrations in the colon provide them with a favorable environment. The main butyrate-producing bacteria in the human gut are *Faecalibacterium prausnitzii* and *Clostridium leptum* from the family *Ruminococcaceae* and *Eubacterium rectale* and *Roseburia* spp. of the family *Lachnospiraceae*. Other bacteria, like *Eubacterium hallii* and *Anaerostipes* spp. can produce butyrate from lactate and acetate (Louis and Flint 2017).

An abundance of SCFA is inconsistently reported in AN studies (Table 3). While one study showed reduced acetate and propionate concentrations (Morita et al. 2015), another found decreased butyrate and propionate (Borgo et al. 2017). Longitudinal studies by Mack et al. (2016) observed slightly decreased butyrate levels, and Prochazkova et al. (2021) observed slightly decreased butyrate and acetate levels in patients with AN, but without change after weight gain. Although therapeutic renourishment in both studies led to increased BMI and improved psychometric parameters, SCFA did not change substantially during the hospitalization period, which could be associated with only a partial weight recovery.

Non-targeted metabolomic studies revealed metabolic changes in patients with AN, implying severe system disruptions, such as the development of inflammation and oxidative stress, altered free thyroxine (fT4) and thyroid-stimulating hormone (TSH) levels, vitamin deficits, muscle mass breakdown, and a decrease in ketone bodies (which are essential sources of energy for the brain and heart). Renourishment led to very slight improvements in the abundance of these

metabolites (Tomasova et al. 2021). Different metabolomic profiles were described between restricting and binge-purging AN, which are caused by the different eating and purging behaviors of these two types of patients with AN (Monteleone et al. 2021).

Gut Microbiota Adaptation to Diet

Gut microbiota is known to reflect the diet of the host. Data show that various dietary patterns, e.g., Western, Mediterranean, vegetarian, vegan, or keto diets, are associated with specific microbial communities (Singh et al. 2017). Each bacterial species uses a wide variety of strategies to adapt to the gut environment, mainly through the acquisition of available nutrients. Consistent findings show a greater *Firmicutes/Bacteroidetes* ratio in obese individuals compared to normal-weight people (Crovesy et al. 2020). Moreover, a growing body of evidence shows that obese individuals have more efficient energy extraction from a diet compared to lean people due to alterations in gut microbiota (Lee et al. 2020). Germ-free mice transplanted with "obese microbiota" had an increased capacity to harvest energy from the diet, which was reflected by the significantly greater increase in total body fat compared to mice colonized with "lean microbiota" (Turnbaugh et al. 2006).

On the other hand, recent studies have found a link between gut microbiota and severe acute malnutrition; there is a depletion in oxygen-sensitive prokaryotes and an increase in some potentially pathogenic bacterial species (Tidjani Alou et al. 2017). Mortality linked to severe acute malnutrition was related to diarrhea, low fecal butyrate and propionate concentrations, and high systemic inflammation. These conditions were not linked to specific pathogens, which suggests the absence of gut protective factors (Attia et al. 2016), such as a healthy mature gut microbiota. Fecal microbiota transplantation from undernourished children to germ-free mice-fed donor-like diets provided clinical evidence for a causal role of gut microbiota in disease pathogenesis (Blanton et al. 2016).

In patients with AN, an increased abundance of methane-producing archaeon *Methanobrevibacter smithii* was detected in studies by Armougom et al. (2009), Mack et al. (2016), and Borgo et al. (2017). Moreover, its abundance negatively correlates with body mass index (Million et al. 2013). This archaeon removes the end product H_2 from bacterial fermentation of polysaccharides, metabolizes it to methane, and thus increases energy extraction from the diet. Its increased abundance may result in the optimization of food transformation from very-low-calorie diets. It can be considered an adaptive response in energy-depleted organisms. An abundance of *M. smithii* could also be related to constipation (Ghoshal et al. 2016), a frequent gastrointestinal complaint of patients with AN, which discourages food intake by slowing down colonic transit.

Starvation-induced changes in the gut microbiome were detected in acute and chronic starvation using the activity-based anorexia (ABA) rodent model that mimics the key symptoms of anorexia nervosa, such as food restriction, weight loss, and hyperactivity. This model was established to better understand AN's

underlying pathophysiology. After a 20% loss of weight, decreased thickness of the colon layer and increased colon permeability were detected in these mice (Jesus et al. 2014). The gut microbiota that has adapted to a low-energy gut environment can play an important role in sustaining anorexia nervosa, possibly by directly affecting weight loss and behavior; this is supported by evidence from experiments with ABA mice after fecal microbiota transplantation (see below).

Manipulating the Gut Microbiota

Human gut microbiota manipulation as a disease treatment has become a very hot topic. There are several ways to manipulate the microbiota, e.g., the use of antibiotics (ATB); consumption of fermented food; use of probiotics, prebiotics, or even synbiotics; or fecal microbiota transplantation (FMT). These approaches are mainly used to treat gastrointestinal disorders, such as inflammatory bowel disease (IBD) or irritable bowel syndrome (IBS). Many of these treatments have also been tested with a variety of neuropsychiatric and mental health disorders. In anorexia nervosa, most of these modifications have been tested on mice, with few studies on patients with AN. An abundance of *Lactobacillus* and *Bifidobacterium* species, which is associated with deregulation of the appetite-regulating hormones leptin and ghrelin, has been consistently described in patients with AN (Queipo-Ortuno et al. 2013). It seems likely that targeting the gut microbiota could be an effective adjuvant to standard AN therapies.

Antibiotics

Antibiotics are considered very beneficial drugs for treating bacterial diseases. On the other hand, these drugs are potentially harmful. Their abuse is linked with microbiota impairment and disorders such as *Clostridium difficile* infection. Additionally, antibiotics are often used to assess the role of gut microbiota in various disorders.

No relevant studies have been conducted with AN patients, and few studies have described the effect of ATB treatment on the ABA rodent model. In ABA mice, an increased abundance of *Clostridium cocleatum* and several *Lactobacillus* species and a decreased abundance of *Burkholderiales* were found compared to control mice. Most of the observed alterations were caused by food restriction and were not affected by physical activity (Breton et al. 2021). Loss of body weight was less pronounced in antibiotic-treated ABA male and female mice than untreated mice, although food intake was similar. Similarly, increased fat mass and decreased lean mass were observed in ATB-treated mice. Furthermore, physical activity was reduced after antibiotic administration in male but not female ABA mice. ATB-treated male ABA mice showed altered anxiety-like behavior at the end of the experiment, which was associated with changes in the hypothalamic corticotropin-releasing hormone, hippocampal dopamine, and serotonin receptor

expression (Tirelle et al. 2021). Similarly, many studies have found that gut microbiota plays a role in the pathogenesis of anxiety and depression based on ATB treatment (Lurie et al. 2015).

Probiotics, Prebiotics, and Psychobiotics

A growing body of evidence shows that probiotics can modulate cognitive and emotional processes via the gut-brain axis in animal models (Valcarce et al. 2020; Yang et al. 2020). To our knowledge, no studies have described the effect of probiotics on anorexia nervosa in humans or ABA rodents; however, many studies have focused on their use in anxiety and depressive disorders, both of which are frequent concomitant psychological illnesses of patients with AN. Besides, probiotics (live microorganisms that, when administered in adequate amounts, confer a health benefit to the host), prebiotics (a substrate that is selectively utilized by host microorganisms conferring a health benefit), and synbiotics (contain both components) have been described to exert beneficial effects in both anxiety and depression (Liu et al. 2019; Haghighat et al. 2021). Recently, the term "psychobiotics" was coined targeting microbiota interventions that support good mental health. One promising psychobiotics is butyrate-producing *Faecalibacterium prausnitzii*, which can induce an anxiolytic and antidepressant-like phenotype in rats, probably via increased SCFA in the cecum and shifting the immune response in an anti-inflammatory direction (Hao et al. 2019). Reduced *Faecalibacterium* abundance was correlated with increased severity of depressive symptoms in patients with major depressive disorder (Jiang et al. 2015). In AN patients, *Faecalibacterium* levels were observed to be significantly decreased compared to healthy individuals (Prochazkova et al. 2021), while increased *Faecalibacterium* levels were associated with improved mental health, reduced depressive symptoms, and better sleep in patients suffering from bipolar disorder (Evans et al. 2017).

Fermented Food

Fermented foods contain three primary functional components – probiotics, prebiotics, and bioactive components, biogenics. These components influence the gut microbiota composition and function. Besides affecting macronutrient breakdown and absorption, they can change intestinal permeability and shift the immune response in the gut in an anti-inflammatory direction (Aslam et al. 2020). Moreover, fermented foods have been described to have beneficial effects on mental health parameters (Mohammadi et al. 2016). The functional properties of these foods may affect psychiatric disorders through the synthesis of neuroactive substances and modulation of the hypothalamic-pituitary-adrenal axis and the stress response (Aslam et al. 2020).

Based on all the evidence showing the impact of fermented foods on neuronal mechanisms, they can be considered a potential preventative or treatment for some

psychiatric disorders. Because anorexia nervosa is highly comorbid with mood, gastrointestinal, and immune disturbances, fermented foods could be added to standard nutritional treatment protocols as energy- and nutrient-rich components with very beneficial effects on the physical and mental health of patients with AN (Rocks et al. 2021).

Fecal Microbiota Transplantation

A recent case study of a patient with AN who underwent fecal microbiota transplantation showed a 13.8% weight gain over 36 weeks. The fecal microbiota donor was an unrelated healthy female with a BMI of 25. The gut bacterial composition of the patient's stools showed an increase in weighted phylogenic diversity at 6 and 12 weeks after FMT, especially in the phylum *Verrucomicrobia*. After treatment, the gut microbiota gradually reverted to its initial state. Additionally, FMT led to a significant increase in the fecal SCFAs, acetate and butyrate (de Clercq et al. 2019). In another FMT case study, a patient with severe chronic AN suffering from small intestinal bacterial overgrowth syndrome had increased richness and evenness of bacterial species and decreased fungal diversity after FMT. As with a previous study, total SCFA levels gradually increased after FMT. The metabolomic analysis detected various neurotransmitters and a downward trend in serotonin levels post-FMT. However, despite the improvement in gut microbiota composition, the patient did not show any signs of clinical improvement (Prochazkova et al. 2019). It seems apparent that choosing a suitable donor is a key parameter for a successful therapeutic transfer of gut microbiota. In anorexia nervosa, disease duration and severity are also important factors that must be considered during all types of therapy.

In various studies, gut microbiota transfer from lean or obese mice to GF or ATB-treated mice resulted in an altered capacity for energy harvest (Turnbaugh et al. 2006; Ellekilde et al. 2014). Similarly, the lean or obese phenotype was transferred with the human gut microbiota to GF mice (Ridaura et al. 2013). These findings show the close interconnection between intestinal microbiota and host energy balance.

Immunity Involvement

Extensive research into the composition and function of the microbiota is caused by the rapid development of culture-independent "omics" techniques, such as next-generation sequencing, shotgun metagenomics, metaproteomics, metabolomics, and metatranscriptomics. This research has revealed that the microbiota can affect multiple host functions, including immunity, metabolism, endocrine and nervous system, and nutritional responses (Gilbert et al. 2018). Perturbations in the gut microbiota composition can contribute to the activation of the immune system and the production of various neuroactive compounds, which can affect the development of anorexia nervosa (Roubalova et al. 2020). Various stressful situations can affect

bidirectional communication between the immune system and brain, contributing to psychopathologies, such as major depressive disorder, bipolar disorder, and schizophrenia (Muller 2017). The CNS communicates with the immune system via direct nerve connections with both primary and secondary lymphoid tissues.

Furthermore, cytokines produced by immune cells can cross the blood-brain barrier and affect the function of the CNS. The so-called sickness behavior is an example of such a behavioral alteration. Pro-inflammatory cytokines released in response to infectious agents result in loss of appetite, reduction of activity and social interactions, depressed mood, and loss of libido (Maier and Watkins 1998). It is a physiological process resulting in energy conservation, which is essential for the organism to fight the infection. Increased levels of pro-inflammatory cytokines, such as TNF-α, IL-17, and IL-6, have been detected in patients with AN (Roubalova et al. 2021). These cytokines can cause appetite reduction and thus participate in the development of this disease. Also, elevated levels of pro-inflammatory cytokines may be caused by greater permeability of a gut as described above. However, studies of "leaky gut" syndrome are quite contradictory, and more evidence is needed for such conclusions (see section "The Microbiota-Gut-Brain Axis").

The gut microbiota represents an antigenic source recognized by the mucosal immune system. Some of these molecules can structurally mimic host neuropeptides and neurohormones and thus trigger the production of antibodies that can cross-react with host compounds (Roubalova et al. 2020; Smitka et al. 2021; more in section "Potential Mechanisms in AN Development").

Malnutrition often causes immunodeficiency, comprising both cell-mediated and humoral immunities. In the case of anorexia nervosa, the immune impairments are usually less severe, probably because in malnutrition there is a lack of vitamins and proteins, while patients with AN predominantly suffer from a lack of carbohydrates and fats (Marcos et al. 2003). Another frequent immune-mediated disorder associated with anorexia nervosa is inflammatory bowel disease, specifically Crohn's disease. These disorders are widely studied for their interconnection with gut microbiota dysbiosis (Ni et al. 2017). We can assume that the altered microbiota in patients suffering from both IBD and AN is partly responsible for the development of both pathological conditions.

Potential Mechanisms in AN Development

The etiology of anorexia nervosa is believed to be multifactorial. The participation of the gut microbiota and related immune reactions may contribute to the development of the disease. Clinical and research evidence also suggests an association between pediatric autoimmune neuropsychiatric disorders linked to streptococcal infections (PANDAS) and anorexia nervosa. Conventional AN treatment in combination with antibiotics was effective in four children with acute onset of AN symptoms soon after an infectious disease (Sokol 2000).

The gastrointestinal tract, CNS, and gut microbiota produce many neuroactive compounds with orexigenic (appetite-stimulating) and anorexigenic (appetite-

suppressing) effects (Smitka et al. 2021). The balance between these factors regulates healthy food intake. Patients with AN cannot adapt their eating behavior to their energy requirements, which can be caused by dysregulation of appetite-regulating hormones (Estour et al. 2010). One of these neuroactive peptides, which has been consistently described to be reduced in patients with anorexia nervosa, is anorexigenic/anxiogenic alpha-melanocyte-stimulating hormone (α-MSH) which is produced by the anterior pituitary (Galusca et al. 2015; Roubalova et al. 2021). Interestingly, most patients with AN produce antibodies against this molecule (Fetissov et al. 2002; Roubalova et al. 2021). Caseinolytic protease B (ClpB), a bacterial heat shock chaperone protein produced by some *Enterobacteriaceae* family representatives, induces the production of antibodies that cross-react with α-MSH (Tennoune et al. 2014). Anti-α-MSH IgG antibodies can form immunocomplexes with this peptide and chronically activate the melanocortin (MC) system, which helps regulate feeding behaviors (Fetissov et al. 2008). α-MSH signals via the MC type 4 receptor, which is a key molecular pathway regulating appetite (Lucas et al. 2019). This interaction represents a potential pathophysiological trigger for the development of AN. Furthermore, some evidence suggests that increased diversity among gut bacterial species may result in a decreased abundance of species expressing ClpB with the α-MSH-like motif, which triggers the production of α-MSH cross-reactive IgA antibodies in the gut (Roubalova et al. 2021). Recently, one study showed the presence of IgA-secreting plasma cells educated in the gut positioned adjacent to the dural venous sinuses in human and mouse brains. These cells were almost undetectable in germ-free mice and substantially reduced in mouse brains after 6 weeks of antibiotic treatment (Fitzpatrick et al. 2020). These data suggest that the presence of meningeal IgA-secreting cells is dependent on the gut microbiome. We can assume that such antibodies directed against microbial structures and cross-reacting with appetite-regulating peptides could be important players in anorexia nervosa development.

An analysis of gut microbiota showed a shift toward increased mucin-degrading *Firmicutes* and *Verrucomicrobia* (mainly *Akkermansia muciniphila*) and away from carbohydrate-degrading species such as *Bacteroidetes* in patients with AN (Kleiman et al. 2015; Mack et al. 2016). This shift could increase digestion of protective intestinal wall mucus and further weaken the intestinal wall barrier in the colon, allowing greater translocation of bacterial products and components (Jesus et al. 2014; Mack et al. 2016), which could trigger immune and inflammatory responses and promote the development or increase the severity of anorexia nervosa.

Applications to Other Eating Disorders

In this chapter, we have reviewed studies dealing with the role of microbiota in the pathophysiology of AN. It has been shown that fecal metabolomic and microbiome profiles can distinguish between the restricting and binge-purging types of acute patients with AN (Monteleone et al. 2021). There have been no microbiome studies on how changes in gut microbiota affect eating disorders other than AN. However,

microbiota changes were proposed to modulate appetite regulation mechanisms in bulimia nervosa (BN). ClpB mimicking α-MSH was elevated in patients with BN, which triggered an autoimmune response (Fetissov and Hokfelt 2019). Similar to AN, autoantibodies against α-MSH that formed immunocomplexes with this peptide were also found in patients suffering from BN, but they differ in their affinity (Lucas et al. 2019). Increased levels of high-affinity anti-α-MSH or anti-ClpB autoantibodies can induce bulimia binge eating. In contrast, increased levels of low-affinity anti-α-MSH autoantibodies can induce anorexia (satiety effect) due to an epitope switch of the IgG forming immunocomplexes (Fetissov and Hokfelt 2019).

There are no microbiome studies on binge eating disorder (BED). However, BED is often accompanied by obesity, which is well-described in relation to the gut microbiota. The microbiota of obese individuals differs mainly with regard to nutritional behaviors, i.e., consumption of a high-calorie food leads to an increased abundance of carbohydrate-fermenting bacteria, which leads to elevated SCFA levels that provide an additional source of energy for the host that can be stored as lipids or glycogen. FMT studies showed the transferability of the obese phenotype together with the "obese" microbiota (Turnbaugh et al. 2006).

Considering the relationship between diet, microbiota, and eating disorders, more effort should be made to elucidate the effects of gut microbiota on the pathogenesis of these diseases. Specific signs of gut microbiota alterations could serve as biomarkers and improve the identification, prevention, and treatment of a range of eating disorders.

Mini-dictionary of Terms

- **Activity-based anorexia model**. A rodent model that reproduces the AN symptoms of body weight loss, hyperactivity, and self-starving by opting to run during limited food access.
- **Alpha diversity**. Microbiome diversity within each sample.
- **Anna Karenina principle**. A hypothesis applied to microbiome studies explaining the rise of heterogeneity/stochasticity in animal microbiomes associated with dysbiosis.
- **Beta diversity**. A measure of similarity or dissimilarity between two or more communities.
- **Dysbiosis**. Disrupted functional and compositional microbiota homeostasis.
- **Fecal microbiota transplantation**. Transfer of stool from a healthy donor into the gastrointestinal tract of patients.
- **Leaky gut**. Intestinal hyperpermeability, which allows bacteria and toxins to pass from the gut into the bloodstream.
- **Microbiome**. Collective genomes of microbiota in a particular environment.
- **Microbiota**. A community of microorganisms in a particular environment, i.e., bacteria, viruses, fungi, archaea, and protozoa.

- **Microbiota-gut-brain axis**. Bidirectional communication between the gut-brain axis (the central and enteric nervous system) and microbiota through neural, endocrine, immune, and humoral pathways.
- **Probiotics**. Live microorganisms that, when administered in adequate amounts, confer a health benefit to the host.
- **Prebiotics**. A substrate that is selectively utilized by host microorganisms conferring a health benefit.
- **Psychobiotics**. Probiotics that, when ingested, confer mental health benefits through interactions with commensal gut bacteria.

Key Facts of Human Microbiota

- A complex system of microorganisms populates all the epithelial surfaces of the human body.
- The gut microbiota is the largest microbial community in the body.
- The human gut microbiota ecosystem harbors approximately 3.8×10^{13} resident bacteria.
- Human-associated microbial communities vary predominantly during the postnatal and early stage of life.
- A healthy human gut microbiota is dominated by bacteria from two phyla, *Firmicutes* and *Bacteroidetes*.
- Gut microbiota communicates with the central nervous system via the microbiota-gut-brain axis.
- The gut microbiota is diverse, dynamic, and responsive to external influences, enhancing its potential as a target for therapeutic intervention.
- Microbial dysbiosis has been observed in a variety of diseases, including AN.

Key Facts of Microbiota in Patients with AN

- There are significant differences between the composition of the gut microbiota in patients with AN and healthy individuals.
- Increased abundance of *Methanobrevibacter smithii* and decreased abundance of butyrate-producing bacteria have been reported in patients with AN.
- Patients with AN exert core microbiota depletion signs and exhibit greater interindividual variation in the gut bacteriome, as well as in metagenome content compared to controls, suggesting altered bacteriome functions.
- The amount of short-chain fatty acids is reduced in the gut of patients with AN compared to healthy individuals.
- In patients with AN, reduced dopamine, GABA, and serotonin levels have been detected compared to healthy individuals.
- In patients with AN, antibodies are produced against bacterial structures that can cross-react with appetite-regulating hormones.

- In patients with AN, the permeability of the gastrointestinal tract appears impaired, enabling increased translocation of microbial compounds across the mucosal barrier.

Key Facts of Gut Microbiota Modifications

- The gut microbiota can be modulated using ATB, probiotics, prebiotics, fermented food, and FMT.
- Germ-free animals are an ideal model for the observation of gut microbiota function.
- Few studies have dealt with gut microbiota modifications in patients with anorexia nervosa.
- The lean vs. obese phenotype can be transferred via the gut microbiota.
- Microbiota modifications can affect anxiety and depressive disorders.
- Microbiota manipulation is a potential therapeutic strategy for the prevention and treatment of various neuropsychiatric diseases.
- Consumption of fermented food may help to restore a healthy gut microbiota in patients with AN.

Summary Points

- The gut microbiota is an important player in mental health, affecting the central nervous system via the gut-brain axis.
- Patients with AN have a significantly different gut microbiota compared to healthy individuals.
- Altered gut microbiota is accompanied by changes in microbial metabolic activity, such as reduction of certain SCFA and neuroactive compounds in patients with AN.
- Dysbiosis of the gut microbiota can trigger the production of antibodies that cross-react with certain appetite-regulating hormones.
- The gut microbiota plays a role in the development and severity of anorexia nervosa.
- Modifying the gut microbiota through the consumption of fermented foods could be a valuable adjunct to standard nutritional treatment protocols for patients with AN.

Gender Aspects of Anorexia Nervosa: the Male

26

The Male

Hiral Kotadia

Contents

Abstract

Anorexia nervosa (AN) is considered to be a disorder of females. However, the prevalence (proportion of population having disorder) of AN in males is rising. One of the contributing factors for this could be a better understanding of AN in males and its early recognition. AN varies in males and females in parameters of the age of onset, types of symptoms, ideal body image concerns, age of presentation, and treatment. This chapter focuses on the above aspects of AN in males. The goal of the chapter is to sensitize the readers (current and future clinicians,

nutritionists, dieticians, or any other professionals dealing with AN along with other eating disorders) regarding the prevalence and presentation of AN in male population. This may help them to be vigilant and recognize AN in males in the early phase so that early and appropriate intervention could be offered.

Introduction

According to the Diagnostic and Statistical Manual version 5 (DSM-5), anorexia nervosa (AN) can be characterized through three essential features: (1) persistent energy intake restriction leading to significantly low body weight; (2) intense fear of gaining weight or of becoming fat, or persistent behaviour that interferes with weight gain; and (3) a disturbance in self-perceived weight or shape (American Psychiatric Association 2013).

Prevalence

The lifetime prevalence (proportion of a population who, at some point in life, has ever had the illness) of AN in males ranges from 0.16% to 0.3%, while the incidence (number of individuals who develop an illness or during a particular time period such as a month or a year) is 15.7 per 100,000 people per year (Raevuori et al. 2009). The belief that AN occurs predominantly in females may lead to underestimation of the prevalence of AN in males, and the true prevalence rates could be much higher (Smink et al. 2014). The prevalence of AN in males is

increasing over a period of time. The male-to-female ratio of prevalence of AN is 1:10 (Swanson et al. 2011).

Risk Factors, Symptom Onset, and Age of Presentation

The following are risk factors for the development of AN in males:

(A) *Genetic factors*:
1. The role of genetic factors in males who develop AN is more as compared to females who develop AN. Multiple genes play a role in the etiology of AN (Nakabayashi et al. 2009).
2. Various genes that play a role in the functioning of various neurotransmitters (chemical molecules used by the nervous system to transmit messages between nerve cells) like serotoninergic, opioid, dopaminergic, and cholinergic system may lead to the causation of AN in males (Scherag et al. 2010).
3. Male individuals having first-degree relatives with eating disorders are more susceptible to developing AN in late adolescence to adulthood (Raevuori et al. 2008).
4. Males with female twins have a higher risk of developing AN as compared to males with a male twin (Procopio and Marriott 2007).

(B) *Hormonal factors*:
1. Estrogen (female sex hormone) is a causative factor for developing AN, while testosterone (male sex hormone) acts as a protective factor against the development of AN. This might be the reason that the prevalence of AN in males is much lower than in females (Klump and Culbert 2007; Ostlund et al. 2003).
2. The genetic risk for developing AN in males remains the same prepuberty as well as after the onset of puberty (puberty is the period during which adolescents reach sexual maturity and become capable of reproduction). But in females the genetic risk for developing AN increases from 0% to 50% after the onset of puberty. This also highlights the role of estrogen in causing or developing AN (Culbert et al. 2013; Klump et al. 2006).

(C) *Environmental (societal and cultural) risk factors*:
1. Premorbid (prior to illness) weight is also a significant factor in males contributing to AN in the future. Bullying and critical comments about the weight and body shape by peers may lead to overexercising and dietary restrictions. There is also some hormonal contribution in the development of AN in premorbid overweight/obese males (Raevuori et al. 2009).
2. Sexual orientation is also a contributory factor in the development of AN in males as compared to females. The standards and expectations regarding body shape and weight in homosexual males set by peer groups along with

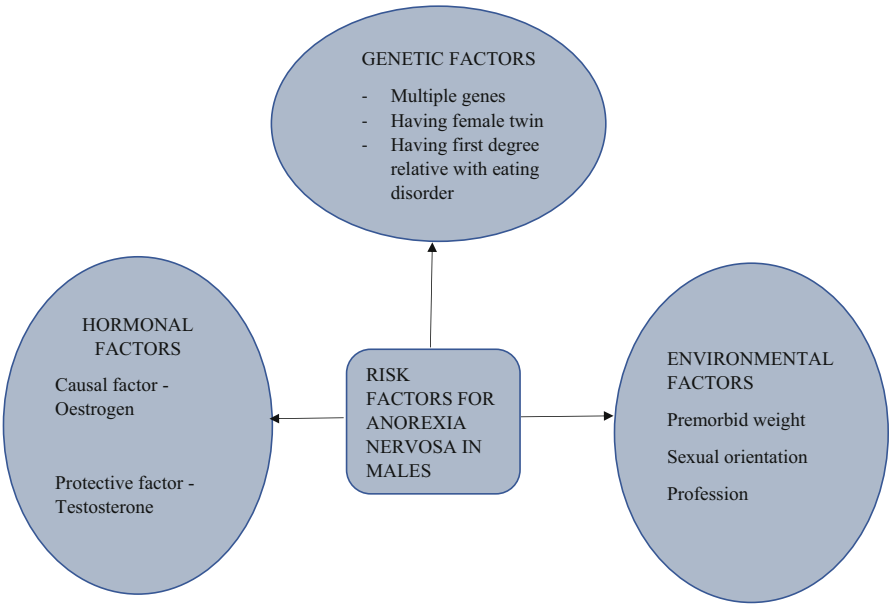

Fig. 1 Risk factors for the development of AN in males

the increased pressure to maintain a certain body type to attract a male partner play a significant role in the development of AN in later stages (Ming et al. 2013).

3. Professions like sports, athletics, and modeling also play a role in the causation of AN in males. The demands of the professional environment may directly or indirectly lead the male to indulge in dietary restrictions and more importantly in exercise regime which leads to an increase in muscularity. This may reinforce the body image concerns, and thus the symptoms of AN may persist for a long period of time (Nagata et al. 2019; Gorrell et al. 2021) (Fig. 1).

The onset of AN in males is generally in late adolescence (17–19 years of age) or early adulthood (the early 20s) as compared to females who generally have onset in early adolescent years (12–14 years of age) (Gueguen et al. 2012; Nagata et al. 2019). This data about the age of onset may not actually represent true information as males having AN are identified in later age and present to a hospital setting for treatment later as compared to females (Dalgliesh and Nutt 2013).

The common age of consultation seeking for symptoms of AN in males is late teenage years to early 20s. The delayed treatment-seeking in males could be due to the belief that AN occurs exclusively or predominantly in females, stigma, and poor awareness about eating disorders in males (Grillot and Keel 2018). The assessment interviewing technique and various structured scales currently used for assessing the

presence of AN is more female-centric, because of which AN in males could be commonly missed (Grillot and Keel 2018).

Symptoms and Comorbidities

Males having AN have a significant body image distortion and a consequent drive for thinness, similar to females. However, there are certain differences in terms of ideal body shape, methods used to reduce the body weight, premorbid (prior to illness) body weight, symptom presentation at first contact, medical complications, and psychiatric comorbidities.

Males with AN are more concerned about being lean and muscular rather than just being thinner. They are more inclined toward having a "six-pack" rather than a flat stomach. The body shape (muscularity) is more important to them rather than the body weight. Males with AN have to focus on the shape of their shoulders and the size of their chest in addition to their belly and thighs. This is different from females with AN who have a desire for thinness and low body weight (Darcy and Lin 2012; Murray et al. 2017a, b).

The methods used by males to achieve this ideal body shape are also different from the methods used by females to achieve a thin body. Males focus more on exercise to get this shape rather than restriction of dietary intake or use of laxatives which is more commonly used by females to achieve a thin body and low body weight. Males may tend to exercise more often due to cultural and social expectations (men need to be muscular and women are expected to be lean) (Holliday et al. 2005).

As mentioned earlier, premorbid weight is a risk factor in developing AN in males in late adolescence to early 20s. The more the premorbid weight, the more are chances of having AN later (Gueguen et al. 2012; Nunez-Navarro et al. 2012). As per the diagnostic criteria (DSM-5), the severity of AN is measured in terms of body mass index (BMI) which is an indicator of whether the person is overweight, underweight, or having normal weight. BMI is defined as the weight of the person (in kilograms) divided by the square of the height of the person (in centimeters).

Males who have higher premorbid weight have much higher BMI so, when they lose weight, they may still have normal or low normal BMI despite having AN. Clinically if we consider BMI as the only criteria to diagnose AN, many males having AN might remain undiagnosed and thus not receive the needed medical care and treatment. Hence, in males, the premorbid weight and the amount of weight loss over a period should be considered as an important factor to diagnose AN rather than only BMI at the time of presentation.

The symptom presentation of males with AN on first contact with a physician is slightly different from females in the following parameters:

1. Age of presentation – it is late as compared to females mainly due to two reasons. Firstly, the age of onset of AN is late in males, and, secondly, the time duration

between onset and visit to a physician is more in males with AN (it is on an average 1 year). The belief of the society that eating disorders including AN are present only in females and the stigma associated with it play a major role in poor awareness, identification, and acceptance of AN in males (Griffiths et al. 2015; Welch et al. 2015; Forman-Hoffman et al. 2008).

2. Weight and BMI at the presentation – as mentioned earlier, males with AN may present with normal weight and normal BMI despite the severity of AN. The reasons for this are high premorbid weight and an increase in muscle mass (mainly composed of protein) due to exercise and weight training but at a cost of significant loss in fat deposition which is harmful to the body.
3. The DSM-IV (American Psychiatric Association 1994) criteria used to diagnose AN were more female-centric (included amenorrhea which is an absence of menstrual periods which may be temporary or permanent and low BMI at presentation as a cutoff to diagnose AN). The DSM-5 criteria (implemented since 2013) on the other hand have tried to address the above aspects. However, the structured assessment tools for AN currently used are still female-centric leading to underdiagnosis and late diagnosis of AN in males.
4. Presentation with medical complications – males with AN present with more severe medical complications as compared to females with AN. The longer duration between the age of onset of symptoms and age at presentation to the physician in males as compared to females with AN is a significant factor contributing to the presence of severe medical complications at the time of presentation (Strother et al. 2012).

Males with AN have more psychiatric comorbidities (presence of other diseases) as compared to females with AN. The various psychiatric comorbidities in males with AN predominantly include mood disorders and substance use disorders. The most common associated psychiatric comorbidity is major depressive disorder (Manzato et al. 2017). The presence of comorbidities leads to an increase in the severity of AN, poor course of illness, increased need for treatment, and poor compliance to treatment. That is why it is necessary to evaluate the presence of psychiatric comorbidities in AN as addressing them may lead to significant and early improvement.

The following table (Table 1) lists the differences in males and females having AN in terms of the above parameters.

Images: Photographs of a 12-year-old male with AN

The images have been printed after taking consent from parents and assent of the patient

Images 1–4:	**At time of presentation**
	Weight – 20.3 kgs
	BMI – 10.36 kg/m^2

Table 1 Differences between males with AN and females with AN in terms of age of onset, age at presentation, ideal body shape, methods used, medical complications, and comorbidities

Various parameters in AN	Males with AN	Females with AN
Age of onset (years)	*Late teenage years (17–19 years)*	Early teenage years (12–14 years)
Age of treatment-seeking (years)	*Late teenage years to early 20s*	The mid- to late 20s
Ideal body image	*Muscular*	Thin and lean
Methods used to achieve an ideal body shape	*Excessive exercise and calorie control*	Dietary restriction and use of purgatives and laxatives
Medical complications	More and severe during the presentation	Less and mild at presentation
Psychiatric comorbidities	More frequent	Less frequent

Abbreviations: *AN* anorexia nervosa

Notice the loss of buccal fat.

Notice the loss of gluteal fat.

The loss of fat on the upper chest.
Notice that ribs are visible.

Medical Complications

Out of all the eating disorders, AN is the most severe due to significant malnutrition and higher chances of medical complications. These complications potentially affect all organs and systems. The severity of medical complications depends on the type of methods used to achieve weight loss (the restrictive methods have severe complications), the duration of illness, the rapidity of weight loss, weight at the time of presentation, and degree of malnutrition.

The loss of weight and malnutrition lead to compensatory mechanisms by reducing the energy expenditure which leads to various complications of the cardiovascular system, gastrointestinal system, and bone growth (Mehler and Brown 2015).

Carbohydrate is the main source of energy in the body. In AN, as the oral intake or purging is more, there is a significant decrease in carbohydrate intake and storage. Fat is the next source of energy. At the end of puberty, fat mass (that portion of the human body which is composed strictly of fat as opposed to fat-free mass) is around

12% in males as compared to 25% in females. In AN, there is significant fat loss. As the baseline fat mass in males is low, the loss of fat in AN is significant in males. Due to significant fat loss, there is an increase in ketones (a breakdown product of fat) leading to a pathological condition called ketosis which may lead to low blood pressure, kidney stones, constipation, nutrient deficiencies, and an increased risk of heart disease (Raevuori et al. 2009; Mehler and Brown 2015).

Pubertal development is longer in males. So, the growth spurt in males is late as compared to females. Their bones have greater linear growth and a greater bone mass compared with females. So, if males are affected in the early to mid-teens, the bone growth is significantly impaired which may lead to growth reduction and a final low stature. This may also lead to osteopenia (a medical condition in which the protein and mineral content of bone tissue is reduced) or osteoporosis (a medical condition in which the bones become brittle and fragile from loss of tissue) (Misra 2008; Misra et al. 2008; Modan-Moses et al. 2003).

Due to reduced energy expenditure, the cardiac activity for pumping blood decreases. Also due to loss of fluid in the body, hypotension (systolic blood pressure <90 mm Hg and diastolic pressure <60 mm Hg) may occur which may cause dizziness, blurring of vision, fainting, and fatigue. The reduced cardiac pumping activity leads to a decrease in heart rate known as bradycardia (heart rate <60/min). It may also lead to irregular heart rate and conduction abnormalities (a conduction disorder is a problem with the electrical system of the heart which controls the rate and rhythm of heart rate) known as arrhythmias which are life-threatening in nature (Misra et al. 2004; Niemeijer et al. 2015). An important cardiac structural change like reduction in cardiac muscular mass may be seen in restricting-type AN. Cardiovascular complications are important to evaluate as they are a cause of death in patients with AN in more than 50% of cases.

Complications of AN also include endocrinological complications (hormonal changes). There is a lowering of thyroid hormone levels in the body (Vo et al. 2016). One of the main functions of thyroid hormone is to maintain basal metabolic rate (BMR – a measurement of the number of calories needed to perform body's most basic (basal) functions, like breathing, circulation, and cell production). Because of the decrease in thyroid hormone levels, there is a decrease in energy expenditure needed for maintaining basic functions. The lowering of thyroid also causes a reduction in heart rate (Manzato et al. 2017).

The reduced food intake leads to a delay in gastric emptying which causes post meal fullness, bloating, and pain which further perpetuate the patient's desire to avoid food. At times it may lead to rupture of the esophagus or stomach which is a surgical emergency (Benini et al. 2004; Olausson et al. 2014).

The reduction in food intake or purging associated with AN leads to significant disturbances in serum electrolytes (various ions like sodium, potassium, or chloride which regulate the electric charge and flow of water molecules across the cell membrane and are essential for metabolism, for proper nerve and muscle functioning, and for maintenance of proper water balance and proper blood pH (acid-base balance)). This may lead to conditions like seizures, loss of consciousness, and arrhythmias (Berend et al. 2014).

Table 2 Various medical complications of AN in males

Medical complications (systems affected)	Signs and symptoms
Body fat loss	Ketosis (nutrient deficiency, low blood pressure, kidney stone, increased risk for cardiac disease)
Bone growth	Growth reduction, osteopenia, osteoporosis
Cardiovascular complications	Bradycardia, hypotension, arrhythmias, decrease mass of cardiac muscle
Endocrine complications	Hypothyroidism (decrease in BMR, low heart rate)
Gastrointestinal complications	Reduced gastric motility, bloating, esophageal rupture
Life-threatening complications	Cardiac arrhythmias, esophageal rupture, electrolyte disturbances

Abbreviations: *BMR* basal metabolic rate

The following Table 2 lists the various body systems affected due to AN in males.

Course and Prognosis

AN is generally a long-standing illness in both females and males. However, the chronicity in males is more due to delayed diagnosis and delay in treatment-seeking. The course of AN is almost the same in males and females if both are diagnosed and treated in the initial part of the illness and have a 60–70% chance of improvement and remission in AN if identified and treated early. Though males with AN seek treatment at a later stage, the duration of their admission stay and time taken to remission is much shorter as compared to females with AN. Also, they show better improvement as compared to females in parameters of weight and BMI in follow-up. However, due to delays in treatment-seeking in males, the course is more deteriorating as compared to females. Also due to the chronicity of illness, males have significant medical complications at the time of presentation. Of male patients with AN, 20–25% have a poor prognosis and suffer from the chronicity of the illness (Strobel et al. 2019; Quadflieg et al. 2019; Bardone-Cone et al. 2019).

The following are poor prognostic factors in males with AN (Hoang et al. 2014; Kask et al. 2017; Crisp et al. 2006):

1. Later age of presentation for seeking treatment
2. Lower BMI at presentation (<15 kg/m^2)
3. AN restrictive subtype

(AN is of two subtypes – restrictive subtype and binge eating/purging subtype. In the restrictive subtype, the weight loss is primarily achieved by fasting, dieting, and/or excessive exercise. There are minimal or no episodes of binge eating or purging, i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas. However, in binge eating/purging subtypes, there are frequent episodes of binge eating and/or

purging. Because of no or minimal binge eating and significant dietary restriction, the restrictive subtype has more chances of BMI to be significantly low and hence leads to more complications and poor prognosis.)

4. Later age of onset of illness
5. Longer duration of AN
6. Higher percentage of weight loss
7. Lack of interest in exercise during illness
8. More psychiatric comorbidities
9. Previous treatment, disturbed childhood family relationships
10. An absence of premorbid sexual activity, masturbation habits, or sexual fantasies

Treatment

Apart from the societal belief that AN is a disorder of females and the reluctance of males in acceptance regarding the disorder, the other factor playing a role in delayed diagnosis and treatment setting is the lack of understanding in clinicians about the disorder, its occurrence in males, and the difference in presenting symptoms as compared to females. This delay in treatment-seeking leads to more medical complications and a poorer prognosis of the illness. The goals of treatment aims are (Hay et al. 2014):

1. Restoring a healthy weight (falling in the range of normal BMI percentile, normal sexual drive)
2. Addressing medical complications and psychiatric comorbidities
3. Educating the patient and family regarding illness and motivating the patient to increase oral intake and participate in treatment
4. Addressing patient's belief regarding the body image and societal concerns using medicinal treatment or psychological intervention
5. Working on prevention of recurrence of the illness

The following chart provides the treatment algorithm for treatment of AN (Fig. 2) (Table 3).

Role of the Dietitian

Dietitian plays a significant role in the treatment of AN specifically in the early phase for the purpose of nutritional refeeding. This includes the calculation of calories and enlisting the available food items for meeting this calorie intake. The dietitian should also involve the patient in making and implementing of diet chart. The role of a dietitian is equally important in inpatient and outpatient treatment of males with AN.

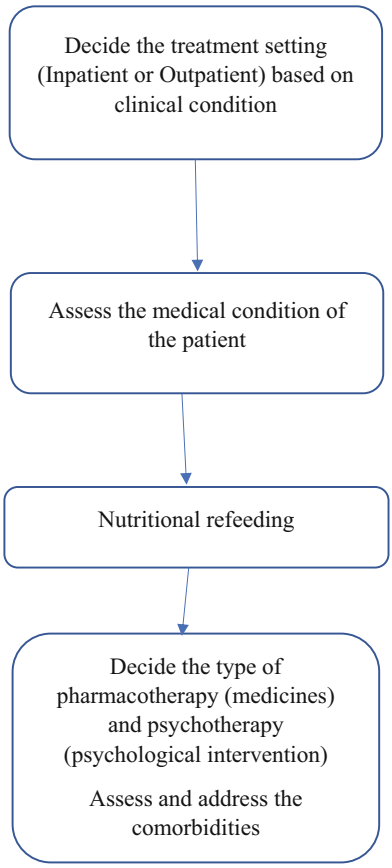

Fig. 2 Treatment algorithm for AN. The type of therapy may vary in individuals

Table 3 Guidelines for treatment of AN

Treatment of AN	General guidelines	Salient features for treatment in males having AN
Assessment	Interview, examination, and structured questionnaires like the Eating Disorder Examination Questionnaire (EDE-Q) to be used (Thomas et al. 2014)	The difference in ideal body image (more muscularity), high BMI at presentation, and BMI percentile (for males) is to be considered
Indications for inpatient treatment	BMI <15 kg/m^2 Rapid or continuing weight loss (>20% over 6 months) Weight <85%; acute weight decline with food refusal even if not <85% Of healthy body weight High physical risk Severe comorbid conditions Heart rate <50/min Blood pressure <80/50 mm Hg Severe electrolyte disturbances	The BMI in males at presentation can be high. So even BMI >15 kg/m^2 can be considered for admission based on other factors Separate settings for males are required as treatment in the same setting with females leads to more reluctance and feminization of disorder (Dearden and Mulgrew 2013; Räisänen and Hunt 2014)
Target weight	Restoring normal activity (resumption of menstrual cycles in females)	Measuring restoration of normal activity is difficult as there is no evident measure as compared to the resumption of menstrual cycles in females Return to normal sex drive is considered as a return to normal activity, but the definition of normal sex drive is very subjective (varies from patient to patient)
Nutritional refeeding	Start with 20–30 kcal/kg (1000–1500 kcal/day) and gradually increase or begin with 200–300 calories above the patient's usual caloric intake Recommended weight gain – 0.5 to 1 kg/week Prevent and treat refeeding complications (low potassium, low phosphorous, low calcium, refeeding edema – swelling caused by excess fluid trapped in body's tissues, cardiac arrhythmias)	Males may require higher initial calorie refeeding (3000–3500 kcal/day) as they have higher lean body mass and lower fat mass compared with female patients (Hay et al. 2014)
Pharmacotherapy	Fluoxetine – selective serotonin reuptake inhibitor (helps to deal with distressing thoughts regarding body image) Olanzapine, mirtazapine – helps in increasing appetite and thus gaining weight	Might require higher doses of medicines (Murray et al. 2017a, b)

(continued)

Table 3 (continued)

Treatment of AN	General guidelines	Salient features for treatment in males having AN
Psychological intervention (psychotherapy)	Family-based treatment (FBT) – involvement of family in initiating refeeding and restoration of weight in the patient (younger age of onset – family can be more involved as the patient is of younger age) Cognitive behavioural treatment (CBT) The core features of AN (food restriction and avoidance) are based on a schema (beliefs and ideas people have about themselves) which helps to form and maintain self-esteem; over a period of time, acting on schema becomes a habit CBT deals in restructuring this schema by structured methods and thus reducing patients' distress	An appropriate and comfortable environment is to be provided (men support group and male therapists) Males have late-onset and late presentation of illness with family involvement and family control. This might lead to FBT being less effective in males In males, individual therapy may be more helpful (Peterson et al. 2016) CBT in males has to focus more on schema regarding ideal male muscular image rather than focusing on drive for being lean and thin (Dalgliesh and Nutt 2013)

Abbreviations: *BMI* body mass index, *Kcal* kilocalories, *Kg* kilogram

Notice the improvement in fat deposition on the upper chest and the buccal fat.

Future Directions and Need for Awareness

There seems to be a common belief in physicians that eating disorders like AN are exclusively seen in females which leads to a dismissive attitude of physicians toward the male patients. This further contributes to the already existing stigma regarding eating disorders in males which leads to worsening of illness and delay in treatment-seeking and intervention. It is thus imperative to bring to attention the prevalence, symptom presentation, and management of male patients suffering from AN. There is also a need of sensitizing the physicians regarding the need of being vigilant about the symptoms of AN in males and psychoeducate the patient and family regarding the illness and need for treatment. The existing instruments (scales and questionnaires) are more female-centric and are insensitive toward muscularity-oriented

disordered eating. These need to be modified accordingly. This chapter tries to address these issues by sensitizing the readers.

Application to Other Eating Disorders

This chapter highlights the gender bias in the community and clinicians regarding the prevalence and diagnosis of AN. It focuses on creating awareness about symptom presentation, course, complications, and treatment of AN in males as compared to females. Similarly, the gender differences in the above aspects need to be considered in other eating disorders. Further studies are required to focus on various eating disorders in males to differentiate them from females. Male-centric assessment tools are required to evaluate for other eating disorders. The attitude toward the female centricity of eating disorders needs rectification to bring gender neutrality. Understanding the cognitive and behavioural aspects of other eating disorders in males may help in designing male-specific interventions like different models of cognitive and behaviour therapies. The DSM-5 has tried to make the diagnostic criteria of AN to be more gender-neutral by removing the criteria of the presence of amenorrhea and substituting the criteria of self-reporting of fear to gain weight with either reporting or observable behaviour about fear of gaining weight. This chapter suggests the need for consideration of a change in diagnostic criteria of other eating disorders and an inclination toward more gender neutrality.

Mini-dictionary of Terms

Acid-base balance: It is the balance between input (intake and production) and output (elimination) of hydrogen ion. This decides the level of alkalinity and acidity in your body. A balance between these is required to maintain regular functioning of the body.

Diagnostic and Statistical Manual version 5 (DSM-5): It is a classificatory system for mental health (psychiatry disorders) with diagnostic criteria to maintain uniformity in diagnosis. It includes eating disorders.

Eating Disorder Examination Questionnaire (EDE-Q): It is a self-reported questionnaire used to assess various parameters of eating disorders.

Estrogen: The main sexual hormone in females that is required for the development and regulation of sexual secondary characteristics such as pubic hair and breast along with the female reproductive system.

Psychotherapy: Various psychological interventions that help a person change thoughts and behaviors to deal with various stressors.

Sexual orientation: Who you are attracted to (male, female, both) and want to have a relation with. Same-sex orientation is homosexuality. The opposite sex orientation is heterosexuality. Orientation toward both sexes is bisexuality.

Testosterone: The main sexual hormone in males that is required for the development and regulation of sexual secondary characteristics such as body hair as well as the development of muscle mass and bone growth.

Key Facts

Key Facts of DSM (Diagnostic and Statistical Manual of Mental Disorders)

- First edition of DSM was published in 1844 (by American Psychiatric Association) for institutionalized patients with mental illness.
- The purpose was to develop a universal classification of mental health disorders to improve communication regarding the needs for proper care of the patients.
- Since then, four other editions of DSM have been released, the recent one being DSM-5 released in 2013.
- *DSM* contains descriptions, symptoms, and other criteria for diagnosing mental disorders to establish consistent and reliable diagnoses that can be used in the research as well as clinical management of mental disorders.

Key Facts of BMI

- BMI is defined as a person's weight in kilograms divided by the square of the person's height in meters (kg/m^2).
- It is a measure of nutritional status.
- The ranges of BMI are based on the effect that body fat has on the physical condition of the body.
- It is also a risk indicator of disease.
- The BMI ranges are based on the level of body fat.
- The more obese the person, the more the BMI.
- This increases the risk of various conditions like cardiovascular diseases, high blood pressure, osteoarthritis, some cancers, and diabetes.

Summary Points

- There is a common belief that AN is a disorder of females. However, this is not true and even males are vulnerable to this disorder.
- The lifetime prevalence of AN in males ranges from 0.16% to 0.3%, while the incidence is 15.7 per 100,000 people per year. The prevalence of AN in males is increasing over a period of time.
- The ratio of male to the female prevalence of AN is 1:10.
- The age of onset in males is around late teenage years to early 20s.

- The average time between symptom onset and consultation with a physician is much higher as compared to females.
- The symptom presentation in males is different from females – high premorbid weight, high BMI at presentation, and need for a muscular body as compared to the thin body in females.
- Exercise is a common mode used by males with AN to reduce weight and get a muscular body.
- The course of illness in males is similar to females if diagnosed and treated early.
- AN may lead to severe medical complications if not treated early and adequately.
- Psychotherapy along with pharmacotherapy is the mainstay for the treatment.

The Biology of Anorexia Nervosa

27

A New Narrative Overview

Kamil Skowron, Magdalena Kurnik-Łucka, and Krzysztof Gil

Contents

Abstract

Anorexia nervosa, one of the most deadly mental disorders, is a pathophysiologically complex mosaic of numerous extensively investigated pathways, and the current state of knowledge cannot provide us with one definite answer regarding its etiopathogenesis. Although classified as a psychiatric disorder, traditionally viewed as a consequence of the psychological features, the model explaining the onset and development of anorexia is multifactorial with growing interest in its metabolic origin. The clinical presentation varies in severity, but ultimately every organ in the diseased body is affected. There are many biological alterations that simply act in accordance with severe malnutrition and weight loss; nevertheless, there is an evident dysfunction in the course of adaptive pathways that induce or at least potentiate those changes. Based on human and animal studies, the most relevant streams in AN pathophysiology seem to point toward a relatively adequate peripheral response that fails to properly stimulate

feeding-related neurohormonal brain circuits. This metabolic origin of AN is supported by molecular identifications of specific genetic polymorphisms. Endocrine adaptations involve among others hyperghrelinemia, hypoleptinemia, hypogonadotropic hypogonadism, and CRH hypersecretion. Those hormonal shifts interact not only with appetite-regulating brain regions but also affect energy expenditure, physical activity, behavior, cognition, as well as rewarding/motivational drive. This narrative review aims to present emerging biological concepts underlying anorexia nervosa.

T3	Triiodothyronine
T4	Thyroxine

Introduction

Anorexia nervosa (AN), according to DSM-V criteria, is classified as a feeding or eating disorder characterized by restriction of energy intake leading to dramatically low body weight, intense fear of gaining weight or behavior preventing weight gain as well as a disturbance of body image, and/or lack of understanding of the danger of low body weight. The severity of weight loss is based on body mass index (BMI) derived from the World Health Organization categories for thinness in adults or corresponding percentiles in children and adolescents: BMI greater than or equal to 17 kg/m^2 (mild), BMI 16–16.99 kg/m^2 (moderate), BMI 15–15.99 kg/m^2 (severe),

and BMI less than 15 kg/m^2 (extreme) (American Psychiatric Association 2013). AN presents with various short- and long-term complications, depending on the severity of the disease, placing it at the top of the statistics when it comes to the all-cause mortality rate and suicide risk among all psychiatric disorders (Chesney et al. 2014). The recovery rate fluctuates from 0 to 92% (Steinhausen 2002; Auger et al. 2021). The lifetime prevalence of AN ranges from 0.3% to 1.5% and 0.1% to 0.5% for females and males, respectively, based on international data (Keski-Rahkonen et al. 2018), yet the risk of mortality in male patients was estimated to be more than twice that of female patients (Edakubo and Fushimi 2020). The average age of onset of AN is 16–17 years and has been considerably decreasing (Keski-Rahkonen et al. 2018).

Food restriction and subsequent malnutrition in AN may lead to severe multi-organ complications, such as cardiovascular, dermatologic, endocrine, gastrointestinal, hematologic, musculoskeletal, neurologic, ophthalmic, and pulmonary (Mehler and Brown 2015). Most of them are usually controllable after renourishment, symptomatic treatment, and psychotherapy (Westmoreland et al. 2016). Those complications resemble simple starvation (semistarvation) from the pathobiological point of view, but complete AN etiopathogenesis remains far from being understood (Skowron et al. 2020b). AN is primarily a psychiatric disease; still, there is only minimal to moderate evidence that available psychiatric medications are effective (Westmoreland et al. 2016; Flament et al. 2012; Kaye 2008; Claudino et al. 2006), which further supports the need for the in-depth understanding of biological factors relevant for AN.

Clinical Presentation of Anorexia Nervosa

A reduction of food intake and/or loss of appetite and hyperactivity with increasing anxiety are the core features of AN. Thus, as a direct consequence of malnutrition, AN patients present with a range of systemic symptoms (Table 1), from mild to life-threatening depending on the nutrition status and severity of weight loss (Mehler and Brown 2015; Rome and Ammerman 2015). The body's total energy expenditure relies on the resting energy expenditure (energy required for the essential physiological functions), the energy expended for muscular work (known as the thermic effect of exercise), and the thermic effect of food (metabolic costs of processing a meal). And on the cellular level, mitochondrial proton leak, Na+/K+ ATPase activity, and protein turnover are responsible for up to 75% of resting energy expenditure. Thus, weight loss achieved by food restriction is less than that calculated from the caloric deficit, and furthermore, weight loss declines with time due to continuous changes in the body's composition, its maintenance energy requirements, and hormonal mechanisms decreasing the metabolic activity at the cellular level (Abdel-Hamid 2002; Kinney 1995). Starvation-induced protein and fat catabolism accounts for the loss of cellular volume and function and ultimately atrophy of the liver, lymphoid tissue, gastrointestinal tract, muscles, kidneys, heart, and brain (Mehler and Brown 2015). Under physiological conditions, exercising contributes

Table 1 Clinical manifestations of anorexia nervosa together with their possible pathogenesis

Symptoms	Possible pathogenesis/ pathomechanisms	Symptoms	Possible pathogenesis/ pathomechanisms
Cardiovascular		**Hematologic**

Table 1 (continued)

Symptoms	Possible pathogenesis/ pathomechanisms	Symptoms	Possible pathogenesis/ pathomechanisms
Thyroid abnormalities (↓T3, T4, TSH within normal range)	Dietary restriction and weight loss		
Gastrointestinal			
Bradygastria and delayed gastric emptying	Dysregulated microbiome-gut-brain axis, motor and sensory gastroduodenal dysfunction, impaired mucosal integrity, local low-grade immune activation, autonomic nervous system dysfunction, visceral hypersensitivity, altered regional brain activation		
Constipation			
Dysphagia			
Hepatitis			
Hausea, vomiting			

Abbreviations: *CRH* corticotropin-releasing hormon, *FSH* follicle-stimulating hormone, *GH* growth hormone, *GnRH* gonadotropin-releasing hormone, *IGF* insulin-like growth factor, *LH* luteinizing hormone, *T3* triiodothyronine, *T4* thyroxine

to the total energy expenditure through the cost of the exercise itself and the compensation of a diet-induced depression in metabolic energy (Abdel-Hamid 2002). Protein synthesis (and muscle size) should increase during exercise, thus protecting against the loss of fat-free mass (McArdle et al. 1996). Starvation-induced protein breakdown, which may be further potentiated by increased physical activity in case of AN, possesses a serious threat to life's maintenance. However, in contrast to marasmus, severe hypoproteinemia and hypovitaminosis rarely occur in AN patients, whose hypocaloric diets are relatively rich in protein and vitamins (Hebebrand et al. 1997). Yet, only around half of the women with AN recover after therapy, around 30% recover incompletely, and the rest either experience recurrent periods of remission and relapse or suffer from chronic disease even after re-nutrition and weight restoration (Schorr and Miller 2017).

AN may manifest with a range of gastrointestinal symptoms, which can be the very first physical signs of the disease. Frequently, detailed attention is paid to diet, body weight, and food-related gastrointestinal symptoms that may further result in a chronic dietary restriction (Sato and Fukudo 2015). However, cardiac complications are thought to be the most common cause of death in AN (Sachs et al. 2016; Olivares et al. 2005). Yet, foremostly, AN is characterized by broad endocrine manifestations due to hypothalamic-pituitary axis dysfunction and alterations in appetite-regulating hormonal pathways (Schorr and Miller 2017). These endocrine disturbances are not only an adaptation to the low energy state, but they can also exert detrimental effects on the host as they may maintain and intensify the disease with enduring

consequences (Støving 2019). Currently, their etiologic role cannot be excluded based on the available data. Those complex metabolic adaptations enable AN patients to survive with a BMI of around 10 kg/m^2, with only a few cases described with BMI below 9 kg/m^2 (Frolich et al. 2016). Weight loss is accompanied by an adaptive decline in serum concentrations of triiodothyronine (T3), thyroxine (T4), and thyroid-binding globulin to downgrade the metabolic rate and resting energy expenditure. Reverse T3 is elevated from increased peripheral deiodination of T4. The thyroid gland is atrophic even at normal levels of TSH in AN. Hypercortisolemia, which is also a consequence of the stress of chronic nutritional deprivation (together with hyperactivity), maintains euglycemia but also exerts a noxious effect on muscle mass and inhibits the hypothalamic-pituitary-gonadal axis. Corticotropin-releasing hormone hypersecretion directly contributes to weight loss and might be stimulated by increased ghrelin levels or be compensatory for cortisol resistance. The degree of hypercortisolemia correlates inversely with BMI, fat mass, and bone mineral density as well as directly with the severity of depression, anxiety, and hippocampal atrophy (Støving 2019; Schorr and Miller 2017). It should be also stressed that hypothalamic-pituitary-adrenal axis dysregulation was reported to persist after weight gain; however, its etiologic role cannot be fully confirmed (Schmalbach et al. 2020). The low energy availability in female patients may also result in hypothalamic amenorrhea. In addition to low estrogen levels, hypothalamic amenorrhea results in low androgen levels in AN (Schorr and Miller 2017). Increased ghrelin and cortisol levels during starvation also suppress gonadotropin secretion (Støving 2019). The recent DSM-V diagnostic criteria excluded amenorrhea as a criterion. Yet only a minority of females with AN continue to menstruate despite extreme weight loss and malnutrition, and thus the resumption of menses is an important indicator of recovery (Dempfle et al. 2013). Menstrual resumption in weight-recovered patients may be further restricted due to anxiety or physical hyperactivity (Jacoangeli et al. 2006). Also, adolescent boys with AN present with lower fat and lean body mass, lower testosterone and estradiol concentrations, as well as reduced bone mineral density compared to normal-weight controls (Schorr and Miller 2017; Misra et al. 2008). However, existing literature concerning endocrinopathies in male patients is limited. Still, estrogen and testosterone have well-established roles in maintaining muscle, mucous membrane, and bone mass (Misra et al. 2016) and pose a risk for permanent adverse effects in both sexes. It is also possible that deficiency in sex hormones aggravates anxiety and depression in AN independent of body weight (Miller et al. 2007).

Neurohormonal Regulation of Appetite and Metabolism

Over the past two decades, the health crisis of obesity and the multifaceted damage it causes have been a particularly important stimulus for scientists to expand research into the complex systems of regulating human metabolism. The acquired knowledge has enriched the set of tools that we can use to explain the basis of diseases characterized by disturbed energy homeostasis. Since AN is associated with the

lack of appetite as a complex interaction of hormonal and neuronal signals, it is understandable to search for its biological basis. A potential fundamental role of those appetite-driving biological mechanisms in AN has gained interest with the incorporation of advanced molecular and neuroimaging techniques into the investigation of AN etiopathogenesis. The analysis of genetic factors in the family context, including twin and adopted siblings, showed an estimated genetic contribution at the level of 50–60% (Bulik et al. 2015). The genetic variants determining low BMI were shown to be associated with AN through a two-way correlation (Watson et al. 2019).

On this basis, a neurobiological concept of susceptibility to AN began to emerge. The neurochemical basis of those concepts includes two major theoretical currents that revolve around dysfunction in the reward system and/or appetite-regulating neuropeptides. These pathways appear to integrate with the hypothalamus, the center of the body's metabolic balance. In patients suffering from AN, hypothalamic reactivity is blunted, and connectivity with brain regions involved in reward processing is decreased compared to healthy people (Simon et al. 2020).

Brain Centers of Energy Homeostasis

At the central level, regulation integrates signals from peripheral tissues and reacts to information from reward/motivation centers, creating a synthetic response of the body in the form of hunger or satiety that physiologically would reflect its metabolic demand. Although its clinical presentation resembles a set of adaptive physiological changes to the state of fasting, AN exhibits many neurobiological characteristics that significantly distinguish those two states. The hypothalamic control of appetite starts within the arcuate nucleus (ARC) where two distinct populations of neurons basically either stimulate (neuropeptide Y and Agouti-related protein) or inhibit (cocaine- and amphetamine-related transcript and proopiomelanocortin) food intake. Functional MRI of AN patients revealed that the number of neuronal fibers in the ARC is reduced, while the connectivity of the lateral hypothalamic area (LHA) increases (Florent et al. 2020). At the neurotransmitter level, glutamatergic signaling in ARC appears to behave oppositely to that in healthy control, as reflected in higher fasting concentrations and a paradoxical decline after feeding. ARC orexigenic neurons are stimulated by ghrelin, when the body is food-deprived, resulting in the release of neuropeptide Y (NPY) and Agouti-related protein (AgRP). Despite the physiologically increased secretion of ghrelin in AN, numerous reports indicated a lack of the expected accompanying upregulation in the NPY expression (Galusca et al. 2015). In this context, the impact of anorexigenic peripheral hormones on the functioning of the hypothalamus also seems to be important, taking into account that leptin inhibits AgRP/NPY neurons. However, the concentration of leptin in AN is significantly reduced. On the other hand, proopiomelanocortin (POMC) mRNA expression seems to adequately correspond with the nutritional status of AN patients, and so far no epigenetic changes typical of AN have been demonstrated (Candler et al. 2019).

The ARC neurons send multiple projections that form neuronal pathways between hypothalamic nuclei and with extrahypothalamic regions. Genes associated with AN were identified by their marked expression in two brainstem regions, the lateral parabrachial nucleus and the ventral tegmental area (VTA) (Howard et al. 2020). VTA, the center of the mesocorticolimbic dopamine system, projects into the ventral striatum, which in turn potentially could overcome hypothalamic hunger due to inverted effective connectivity between those areas. However, VTA of AN patients was shown to be hypoactive in reaction to food odors (Jiang et al. 2019). Physiologically, the hypothalamus, by activating LHA-derived GABAergic projections into the VTA, is believed to induce feeding behavior (Barbano et al. 2016). Moreover, LHA receives inputs from the ARC and expresses the orexigenic neuropeptides (orexins and melanin-concentrating hormone) which may evoke an excitatory effect on VTA dopaminergic neurons (Teegala et al. 2020). Activation of orexin receptors in the VTA was shown to increase food intake, while experimental LHA damage drastically reduced the amount of food consumption (Terrill et al. 2016).

Hypoleptinemia in Anorexia Nervosa: A Chicken or an Egg?

Energy expenditure can be further modulated by adipokines, with leptin being undoubtedly the most studied one in various contexts, including eating disorders. Leptin (from Greek λεπτός leptos, "thin") is a 167-amino acid peptide secreted in a pulsatile manner in proportion to the amount of body fat and exerts its action through binding to specific receptors located throughout the central nervous system (Park and Ahima 2015) as well as peripherally (Muoio and Lynis Dohm 2002). Higher leptin levels in women compared to men have been explained by the fact that subcutaneous fat produces more leptin than visceral adipose tissue and by a direct influence of sex hormones on leptin secretion (Hebebrand et al. 2007; Montague et al. 1997). Leptin affects the arcuate nucleus of the hypothalamus by binding to specific receptors, thereby inhibiting NPY/AgRP-expressing neurons and activating POMC and cocaine- and amphetamine-regulated transcript (CART) neurons. Leptin also directly reaches the nucleus of the solitary tract to amplify the short-term satiety signals from the gastrointestinal tract that are processed there (Morton et al. 2006). Key factors stimulating circulating leptin levels are excess energy, overfeeding, glucose, insulin, estrogen, and pro-inflammatory cytokines, while low energy states and fasting (as, e.g., in AN), as well as physical activity, cold exposure, thyroid hormones, and testosterone, decrease those levels. Leptin, displaying a circadian rhythm with the lowest levels at mid-afternoon and the highest levels at midnight, on the one hand, stimulates glucose uptake and fatty acid oxidation in the skeletal muscle, and on the other hand, it inhibits glucose production in the liver as well as glucagon and insulin secretion in the pancreas (Park and Ahima 2015).

The fundamental role of leptin in the regulation of metabolism and appetite is indisputable, with reduced levels in AN (Støving et al. 1998). Leptin levels in the cerebrospinal fluid were also decreased, although the cerebrospinal fluid to plasma

leptin ratio was higher in AN patients than in controls (Mantzoros et al. 1997). Successful re-feeding and weight recovery in AN are associated with an increase in free and bound plasma leptin levels (Ruscica et al. 2016). However, studies with more frequent measurements of leptin levels in adolescents with AN revealed that during weight gain, peak levels higher than the reference range were reached (Ballauff et al. 1999; Hebebrand et al. 1997). Thus, two questions should be asked – what factors particularly associated with AN might influence leptin levels (possibly bidirectionally?) and foremostly if there is any causal relationship between AN development and hypoleptinemia?

Firstly, it should be clarified that alterations in circulating leptin levels are dependent on splicing of leptin receptor mRNA, hypothalamic leptin receptors (long/signaling form of the leptin receptor, ObRb), and soluble leptin receptors (sObR or ObRe) binding most of the circulating leptin. The soluble receptor is upregulated in patients with acute AN, and consequently, the levels of free leptin are further reduced, while weight gain reduces the number of sObR receptors (Hebebrand et al. 2007). Recently, Mendelian randomization analysis of data sets from genome-wide and exome-wide association studies indeed demonstrated a causal effect of lower leptin levels on a higher risk of AN development, yet in females only (due to insufficient data from the male population) (Peters et al. 2021). Previously conducted genome-wide association studies of AN reported significant genetic correlations with both psychiatric phenotypes and metabolic traits, independent of the effects of common variants associated with BMI (Watson et al. 2019; Duncan et al. 2017). Genetic variation (rs12706832) in the leptin gene (LEP) was related to dissimilar dopamine release from the mesolimbic system in response to pain stress challenges. A positive relationship between plasma leptin levels and dopamine release was also observed (Burghardt et al. 2012), and leptin signaling pathways act as key modulators of post-absorptive signals on central dopamine release (de Araujo et al. 2012).

In mice, leptin signaling directly influenced gastrointestinal microbial composition, independently of food intake and body weight, and regulated antimicrobial peptide-encoding genes in the gut epithelium. The gut microbiome of intestinal epithelial leptin receptor knockouts demonstrated a significantly increased ratio of *Firmicutes* to *Bacteroidetes*, analogous to ad libitum-fed obese leptin-deficient mice (Rajala et al. 2014). Still, in AN patients, inconsistent results were observed between studies regarding the *Firmicutes*/*Bacteroidetes* ratio or the identity of altered levels of bacterial taxa (Skowron et al. 2020b). Most importantly, gastrointestinal microbiota may serve as a source of molecules of similar sequence and conformational homology with appetite-regulating peptides, including leptin or biogenic amines, for example, that can, directly and indirectly, modulate gut-brain axis (Clarke et al. 2014). The sequence homology with those peptides was identified among commensal and pathogenic microorganisms including *Lactobacillus*, *Bacteroides*, *Helicobacter pylori*, *Escherichia coli*, and *Candida* species. At the same time, IgG and IgA autoantibodies directed against leptin and other appetite-regulating peptides were present in human sera, which could further alter appetite regulation (Fetissov and Hökfelt 2019; Fetissov et al. 2008). Fetissov et al. reported that levels and

affinities of autoantibodies against those peptides correlated with psychopathological traits in AN patients (Fetissov et al. 2005). What is more, the levels of total short-chain fatty acids (acetate, propionate, and butyrate), resulting from non-digestible carbohydrate fermentation and supplying up to 10% of the host's daily caloric intake, have been changeably reported in AN studies, while branched-chain fatty acids (especially valerate and isobutyrate), resulting from protein fermentation, were increased in AN patients at the time of hospital admission (Skowron et al. 2020b). In mice, the activation of SCFA receptors localized in adipose tissue, namely, FFA2, FFA3, and HCA1, was found to increase the secretion of leptin (Zaibi et al. 2010). In humans, propionic acid stimulated leptin mRNA expression and secretion by omental and subcutaneous adipose tissue (Al-Lahham et al. 2010).

Furthermore, leptin influences emotions, cognition, and motivational drives related to hunger and may be bidirectionally influenced by stress (Appelhans 2010; Burghardt et al. 2012; Peters et al. 2021). Leptin receptors are found in brain areas that are involved in emotion recognition (Adolphs 2002), and leptin appears to enhance cognitive functioning and neuroplasticity (Paz-Filho et al. 2010). Human adipocytes express CRH-Rs, and CRH downregulates leptin production by mature adipocytes (Gioldasi et al. 2019). Interestingly, the relationship between leptin and vulnerability for depression in AN might depend on symptom severity and weight loss. During inpatient treatment and renourishment, higher leptin levels were associated with either greater feelings of depression, anxiety, and stress in patients with very low BMI and higher chronicity or lower psychological symptoms in patients with less severe symptoms (Stroe-Kunold et al. 2016).

Interaction of Metabolic State and Gonadal Function

To conserve the energy necessary for survival, the malnourished organism promotes the retention of energy-consuming reproductive functions. Thus, another key issue in AN is the extreme effect the central signaling that regulates food consumption imposes on the proper functioning of the hypothalamic-pituitary-gonadal (HPG) axis. It is worth noting that these interactions may steer in the opposite direction, which is reflected by the influence of the reproductive hormones on the energy balance such as an anorectic effect of estradiol (Eckel 2011). The HPG hormonal cascade is initiated with the activation of GnRH neurons potently stimulated by a neuropeptide called kisspeptin (KISS1) in response to metabolic signals. Hypothalamic kisspeptin-containing neurons are located mainly in the ARC and the rostral periventricular area of the third ventricle (RP3V) being responsible for pulsatile release of GnRH as well as preovulatory surge, respectively. KISS1 exerts its effects through a G-protein-coupled receptor 54 (GPR54 or KISS1r), the antagonism of which leads to the development of hypogonadotropic hypogonadism similar to the state of malnutrition (de Roux et al. 2003). The central regulation of KISS1 neuronal output is under the control of insulin, leptin, and ghrelin; however, circulating nutrients like glucose or amino acids through a set of protein kinases in kisspeptin neurons also directly modulate their activity. Fasting has been shown to reduce

kisspeptin expression in the hypothalamus as a potential result of hypoleptinemia (Castellano et al. 2005). The KISS1 serum concentration in AN appears to vary to a similar range as in healthy controls but is positively correlated with BMI and negatively with physical activity (Hofmann et al. 2017). In addition, subcutaneous administration of KISS1 has been shown to increase food intake and partially restore hypothalamus signaling in an animal model of anorexia (Skowron et al. 2020a).

Analysis of the HPG axis in anorexia took another big step with the discovery of a hypothalamic neuropeptide called phoenixin (PNX). It was found that through the GPR173 receptor, it increases the secretion of GnRH and LH in rats and thus impacts the reproductive cycle. In subsequent experiments, it was established that the infusion of PNX into the lateral ventricles of the rat brain increases food consumption, probably due to the opposite effect to co-expressed nesfatin-1 involved in the regulation of food intake, energy expenditure, and glucose homeostasis. Despite the sparse data on direct regulators, it has been suggested that PNX neurons sense and react to nutritional signals (McIlwraith et al. 2018). Malnourished patients with AN present a significantly decreased concentration of PNX.

Conclusions

The pathogenesis of AN is undoubtedly a multifactorial integration of interacting psychological and biological changes, and thus the disease is no longer considered as a psychiatric entity only. Peripheral and central dysregulation in the pathways directly and indirectly associated with appetite-regulating hormones seems to be critical for the disease initiation and perpetuation (Skowron et al. 2020b). There is much evidence gathered by molecular and neuroimaging studies that point out the underestimated relevance of AN organic origin, but it is still difficult to determine the extent of the changes that precede the clinical development of the disease. In fact, an ample amount of evidence regarding AN etiopathogenesis comes from animal studies. An activity-based rodent model of anorexia (ABA) is not only highly similar to AN, but it is also considered the best animal model of any psychiatric disorder. A reduction of food intake and/or loss of appetite and hyperactivity together with increasing anxiety as observed in human AN are at the same time the core features of the ABA model (Skowron et al. 2018, 2020b, 2021; Kurnik-Łucka et al. 2020). Although many of the symptoms are simply the consequences of severe malnutrition and weight loss, there is an evident dysfunction in the course of adaptive pathways that gradually complement the complex causes of AN. Thus, ABA, supplemented with human studies, provides us with an in-depth picture of AN that allows the introduction of targeted therapeutic interventions into clinical studies. All in all, based on the heterogeneity of the disease, its complex clinical presentation, and increasing prevalence in adolescents of both sexes, anorexia nervosa should be of interest to all clinical specialties.

Applications to Other Eating Disorders

In this chapter, we review studies that relate to the pathobiology of AN. A complex interaction of hormonal and neuronal signals results in the lack of appetite and quite often physical hyperactivity (Mehler and Brown 2015; Rome and Ammerman 2015). Hypothalamic reactivity is blunted, and connectivity with brain regions involved in reward processing is decreased in AN compared to healthy people (Simon et al. 2020). Interestingly, while hypoleptinemia, among other hormonal disturbances, is characteristic for anorexia nervosa (Støving et al. 1998), not hyperleptinemia but predominantly leptin resistance (together with physical inactivity) defines obesity (Considine et al. 1996; Brownson et al. 2005; Myers et al. 2008). What is more, the cerebrospinal fluid/blood leptin ratio was higher in AN (Mantzoros et al. 1997) and lower in obese humans (Caro et al. 1996; Schwartz et al. 1996) in comparison to control subjects. Physiologically, leptin serum levels were reported to be significantly and positively correlated with body weight, body mass index, abdominal circumference, and insulin and significantly and negatively correlated with peak oxygen uptake in both sexes. Peak oxygen uptake in men and physical activity in women were reported to be determinant factors for circulating leptin levels after adjusting for confounding factors (Miyatake et al. 2014). Foremostly, leptin maintains overall energy homeostasis (Izquierdo et al. 2019). Leptin also influences emotions and motivational drives related to hunger (Appelhans 2010; Burghardt et al. 2012; Peters et al. 2021) and may enhance cognitive function and neuroplasticity (Paz-Filho et al. 2010). However, recombinant human leptin (metreleptin) has little effect in patients with multifactorial obesity. Yet, it has been successfully used for the treatment of rare congenital leptin deficiency presenting with obesity and starvation-like symptoms including hypothalamic amenorrhea in females. Recently, metreleptin was also approved for the treatment of extremely hyperactive patients with AN off-label (Hebebrand et al. 2019).

Mini-Dictionary of Terms

- **The arcuate nucleus (ARC or ARH or infundibular nucleus).** An aggregation of neurons in the mediobasal hypothalamus that includes diverse populations of neurons maintaining several neuroendocrine and physiological functions, such as food intake, metabolism, and fertility
- **NPY/AgRP neurons.** Medial neurons in the arcuate nucleus involved in the neuroendocrine regulation of feeding and appetite stimulation
- **POMC/CART neurons.** Lateral neurons in the arcuate nucleus centrally involved in the neuroendocrine regulation of feeding and appetite suppression
- **Kisspeptin.** A protein hormone that, through its G-protein-coupled receptor (GPR54), is able to directly activate hypothalamic GnRH neurons, which is essential for successful reproduction

- **Phoenixin.** A ligand of the G-protein-coupled receptor 173 (GPR173) which is present in numerous hypothalamic neurons
- **Leptin.** A peptide secreted in a pulsatile manner proportional to the amount of body fat that exerts its effects by binding to specific receptors (ObR) located throughout the central nervous system

Key Facts of Anorexia Nervosa

AN represents a disorder with the highest mortality rate among all psychiatric diseases.

The average age of onset of AN is decreasing.

Detailed attention paid to diet and body weight may further result in a chronic dietary restriction typical for AN.

AN may manifest with a range of gastrointestinal symptoms, which can be the very first physical signs of the disease.

Food restriction and subsequent malnutrition in AN may lead to severe multi-organ complications.

A minority of females with AN continue to menstruate despite extreme weight loss and malnutrition, and thus the resumption of menses is an important indicator of recovery.

Renourishment and psychotherapy remain the cornerstones of treatment for most AN patients.

Summary Points

- Genetic studies demonstrated a causal effect of lower leptin levels on a higher risk of AN development
- Successful re-feeding and weight recovery in AN are associated with an increase in free and bound plasma leptin levels
- The relationship between leptin and vulnerability for depression in AN might depend on symptom severity and weight loss
- Kisspeptin signaling acts as a potential link between nutritional status and reproductive function of the organism
- Hypothalamic expression of kisspeptin is downregulated in AN
- Hypothalamic response to increased levels of ghrelin is blunted
- Susceptibility to developing AN may be associated with genetic alterations in the ventral tegmental area responsible for reward processing

Contents

Abstract

The hippocampus is an anatomically complex structure that is peculiarly involved in the neurobiology of different brain disorders. At present, different studies evidence a role for this structure in the neurobiology of anorexia nervosa, but findings are rather inconsistent and heterogeneous both from a functional and structural point of view.

Activity-based anorexia models provided important insights into the possible functional, structural, and molecular involvement of the hippocampus in disordered eating behaviors and in excessive physical activity. Moreover, neuroimaging studies pointed out both structural and functional hippocampal alterations in the acute phases of the disorder.

The aim of this chapter is to summarize the main findings concerning hippocampal structure and function in anorexia nervosa.

Introduction

Several studies to date have evidenced the presence of both structural and functional brain alterations in patients with anorexia nervosa (AN). These alterations were observed both at the whole-brain level and at the level of some specific cortical and subcortical areas. However, the results of these studies are quite conflicting and inconclusive, due to methodological differences and some heterogeneity in sample selection (Collantoni et al. 2022; Meneguzzo et al. 2019).

A brain region that has attracted an important interest in the field of neurological and psychiatric disorders, including eating disorders, is the hippocampus.

From an anatomical point of view, the hippocampal formation is a complex structure located in the medial surface of the temporal lobe, inside the inferior temporal horn of the lateral ventricle, and it is composed of three distinct zones: the dentate gyrus, the hippocampus proper, and the subiculum (Anand and Dhikav 2012).

From a functional point of view, ever since the case report of patient H.M., who lost the ability to form new declarative memories after bilateral medial temporal lobectomy (Scoville and Milner 1957), the hippocampus has been associated with memory formation, consolidation, and retrieval. A few years later, the discovery of "place cells" in the rodent hippocampus revealed its involvement also in spatial representation and navigation, a result that has been later confirmed in human studies (Ekstrom et al. 2003; O'Keefe and Nadel 1978). However, in more recent years, several studies showed that the hippocampus subserves many cognitive functions other than memory consolidation and spatial navigation. A role of the hippocampal formation has been, indeed, demonstrated in decision-making, food intake regulation, reward, stress resilience, emotion regulation, and other cognitive functions (Kanoski and Grill 2017; Palombo et al. 2015).

The involvement of the hippocampus in such a variety of functions is supported by its high level of connections with both cortical and subcortical structures, making this structure an important hub for connective pathways (Maller et al. 2019). Moreover, according to the most recent literature, the hippocampus is functionally divided into two distinct regions: a "cold" dorsal one that primarily serves cognitive functions and a "hot" ventral one that is mostly related to mood, stress, emotion regulation, and social behaviors.

An important aspect of the hippocampus is that it is the only brain region, together with the subventricular zone in the lateral ventricles, in which neurogenesis persists throughout life. Neurogenesis, which primarily occurs in the subrganular zone of the dentate gyrus, is thought to play a crucial role in hippocampal functioning, in particular for memory consolidation, learning, and mood regulation

(Christian et al. 2014). The degree of neurogenesis, however, differs between individuals and seems to be influenced by several environmental factors. While some factors, like physical activity and intense navigation, tend to promote neurogenesis, other factors are usually associated with a decrease in neurogenesis (Van Praag et al. 2005). It has been shown, for example, that both acute and chronic stress suppress hippocampal neurogenesis in rodents by increasing the level of circulating adrenal steroids (Gould and Tanapat 1999). Another factor that seems to negatively affect neurogenesis, independently from stress and adrenal hormones, is sleep deprivation (Meerlo et al. 2009). Particularly interesting for the research on eating disorders is the evidence that the degree of neurogenesis is also influenced by an individual's diet and nutritional status. Reductions in neurogenesis have been mainly observed as a consequence of unhealthy and high-fat diets; however, evidence shows that a deficiency in some specific nutrients can also lead to a reduction in cell proliferation (Stangl and Thuret 2009).

The role of the hippocampus in the neurobiology of different psychiatric disorders has been extensively investigated.

Reduced hippocampal volume has been observed in several psychiatric disorders and is one of the most replicated findings in the study of major depressive disorder (MDD), with patients with prolonged illness duration presenting smaller hippocampi than patients at the first episode (McKinnon et al. 2009).

MDD seems also to be associated with reduced hippocampal neurogenesis, while an increase in hippocampal cell proliferation has been observed following pharmacological antidepressant treatments (Dranovsky and Hen 2006). A deficit in hippocampal neurogenesis during adulthood has been proposed to characterize the neurobiology of many other psychiatric disorders, including anxiety disorders, posttraumatic stress disorders, addictions, and schizophrenia. However, it is not yet fully clarified whether dysfunctional neurogenesis occurs as part of the disorder's pathophysiology or, alternatively, as an adaptive response that compensates for pathological conditions caused by environmental stressors.

Some studies, adopting both task-related and resting-state fMRI paradigms, also evidenced functional alterations of the hippocampus in different psychiatric disorders.

Patients with chronic MDD, for example, showed reduced activation of the right hippocampus, compared to healthy controls, when performing a recollection memory task, while they showed increased hippocampal activation when processing negative information (Jaworska et al. 2015; Milne et al. 2012). Task-related functional alterations have also been observed in patients with schizophrenia, who presented reduced hippocampal activation in tasks of emotional processing, navigation, and memory (Gur et al. 2002; Ledoux et al. 2013).

As regards resting-state studies, a meta-analysis conducted on 567 patients with schizophrenia and 470 patients with MDD reported decreased activation of the left hippocampus in patients with schizophrenia compared to controls and no differences between patients with MDD and controls (Kühn and Gallinat 2013).

The observation that various psychiatric disorders are associated with volumetric and functional alterations of the hippocampus, as well as with a reduction in hippocampal neurogenesis, has strongly highlighted the need to carefully investigate

the mechanisms affecting this structure in both psychiatric and neurological conditions.

Investigating the hippocampus in AN is of great interest for several reasons. Firstly, some evidence suggests that patients with AN present alterations in some hippocampal-related functions, such as episodic memory, decision-making, and food intake regulation (Tenconi et al. 2016, 2021). AN is also characterized by some of those environmental factors that are thought to influence cell proliferation in the hippocampus, including chronic stress, altered nutritional status, and hyperactivity. Furthermore, AN is characterized by alterations in both neurodevelopmental and neuroprogressive processes, thus offering the potential to investigate the role that different pathogenetic conditions may have on this structure (Collantoni et al. 2019).

Hippocampus in Animal Model of AN

Activity-based anorexia (ABA) is a translational rodent model of AN originally proposed in 1967 by Rottenberg and Kuznesof (1967). In this model, adolescent rodents are exposed to food restriction while having access to a running wheel, and it was observed that they further reduce food intake, leading to self-starvation, and increase physical activity. This model allows some of the disorder's key features, such as reduction of food intake, hyperactivity, and weight loss, to be observed in an animal model. Moreover, by varying the degree of food deprivation and physical exercise, it is possible to determine the specific contribution of hyperactivity and low food intake to maintaining the AN phenotype.

In recent years, ABA has been shown to be a particularly useful model for studying some specific neurobiological, molecular, and structural bases of AN, and alterations have also been observed at the level of the hippocampus.

Some studies focused on the expression level of the brain-derived neurotrophic factor (BDNF), a protein that promotes hippocampal neurogenesis, in ABA rodents. Gelegen et al. (2008) observed that rodents that were exposed to a restricted feeding schedule and unlimited access to running wheels presented a reduction in BDNF expression localized in the mice hippocampus. On the contrary, in a more recent observation, Ho et al. (2016) evidenced an increase in BDNF mRNA (but not BDNF protein) expression in the hippocampus of rodents exposed to food restriction, while physical activity seemed to have no effect. Overall, these results suggest that BDNF expression might be altered in ABA rodents. However, the results are quite inconsistent, and further studies are needed to better clarify the involvement of BDNF expression in the neurobiology of ABA, even in light of the variable results observed in human AN (Brandys et al. 2013).

In a study using a rodent model to investigate the effect of ABA on hippocampal neurogenesis, Barbarich-Marsteller et al. (2013) evidenced a significantly reduced cell proliferation in the hilus region of the dentate gyrus and in the dorsal hippocampus after 3 days of ABA, and they also observed a positive correlation between the level of cell proliferation, body weight, and food intake. Interestingly, since proliferating cells in the hilus primarily give rise to glial cells rather than neurons, the effect of ABA on rodents was suggested to be mainly on gliogenesis rather than on

neurogenesis. However, this result was not replicated by Farinetti and colleagues (2020), who reported no differences between ABA and control rats in the degree of dentate gyrus neurogenesis.

In a study conducted to assess structural changes in the ABA hippocampus, Chowdhury et al. (2014a) observed a reduction in dendritic branching and a decrease in total dendritic length in the dorsal hippocampus of ABA rats compared to control rats, while in the ventral hippocampus, they observed that ABA was associated with an increased branching of the stratum radiatum. Since the ventral hippocampus is suggested to mediate anxiety symptoms while the dorsal hippocampus is mainly associated with spatial learning and cognition, the authors suggested that ABA may induce alterations leading to both increased anxiety and reduced behavioral flexibility through changes that occur at different neuroanatomical levels.

Interestingly, by differentiating the experimental groups so that one was specifically characterized by excessive exercise and the other by low-calorie intake, the authors observed that food restriction and hyperactivity were likely to influence different regions of the hippocampus. In particular, excessive exercise was suggested to be mostly associated with changes in the rostral-dorsal stratum radiatum, while food restriction was evidenced to be associated with decreased branching in the stratum lacunosum-moleculare in the dorsal and ventral regions of CA1 (Chowdhury et al. 2014a).

Chowdhury and colleagues (2014b) also investigated possible age-dependent effects of ABA on hippocampal structure, and they observed that while inducing ABA during adolescence was associated with increased branching of pyramidal cells in the ventral hippocampus, ABA induced during adulthood had no effect on dendritic branching.

To date, only one study has assessed changes in hippocampal volume following ABA induction, but it failed to observe any difference between ABA and control rats (Farinetti et al. 2020).

Structural Studies

Several studies have evaluated hippocampal alterations in AN from a structural point of view and using different methodologies. Some of them focused on overall hippocampal volume, while others investigated differences in specific subregions by using different segmentation systems.

However, given the high methodological heterogeneity among studies, results are quite inconsistent, and difficult to compare each other.

As regards alterations in whole hippocampal volume, some studies observed a reduction in gray-matter volume in patients with acute AN compared to healthy controls (Collantoni et al. 2021; Connan et al. 2006; Miles et al. 2018). Other authors, however, reported either no differences between patients and healthy controls (Burkert et al. 2015) or even an increase in whole hippocampal volume in patients with AN (Beadle et al. 2015).

In this regard, though, it is important to note that even if alterations in the whole hippocampal volume have not been consistently pointed out, differences in some of its subregions are likely to be present.

Burkert et al. (2015), for example, observed, in a sample of 21 female patients with acute AN, a reduced volume of the fimbria and an enlargement of the hippocampal fissure compared to healthy controls. Two studies found a reduction in bilateral parahippocampal gyri in patients with acute AN, and Brooks and colleagues (2011) also observed that parahippocampal gyri volume was lower in restrictive-type patients compared to binge-purging ones.

The fact that in some psychiatric disorders, such as MDD, the volume of the hippocampus is negatively associated with the duration of the disease has raised the hypothesis that it might be structurally involved in some neuroprogressive processes concerning the pathophysiology of AN. However, studies testing the hypothesis of a reduction in hippocampal volume alongside AN progression did not find any relationship between volume and duration of the disorder. The only partial exception is represented by a study conducted by Giordano and colleagues (2001), who found a trend-level negative correlation between the duration of the disease and the volume of the hippocampus-amygdala formation. In a recent study, Collantoni and colleagues (2022) evaluated hippocampal volumes in three groups of patients with AN: one with a recent onset (less than 1 year), one with a longer illness duration (more than 1 year), and one of fully recovered patients, with the aim of characterizing the potential role of the hippocampus in the neurobiological trajectories of AN. Although this study showed the presence of significantly reduced hippocampal volume in patients with AN compared to the control group, no significant association was detected between hippocampal volume and the duration of the disorder. Furthermore, a comparison between patients with a duration of the disorder shorter than 1 year and patients with a duration of the disorder longer than 1 year showed no differences between the two groups (Table 1).

As regards other associations between clinical variables and hippocampal volume, one study observed a trend-level negative association between total hippocampal volume and stress in patients with AN, meaning that smaller volumes were related to higher stress levels (Burkert et al. 2015). Age of onset might also determine different structural alterations in patients with AN. Studies conducted on adolescent patients with AN have indeed reported more extensive hippocampal volumetric alterations than research conducted on adult samples. This evidence suggests that one of the factors that may contribute to altering hippocampal morphology in AN may be related to its onset in periods in which brain development is particularly intense, such as in adolescence and early adulthood. Lastly, one of the studies that reported increased hippocampal volume in patients with AN observed that this increase was present only in patients who exercised excessively, suggesting that hyperactivity may compensate for the effects of malnutrition on this structure (Beadle et al. 2015).

At present, four studies have adopted a longitudinal design in order to assess the effects of weight recovery on the hippocampal structure. In the acute phase of the disorder, three of these studies observed a reduced volume of the hippocampus in patients with AN (Bernardoni et al. 2016; Mainz et al. 2012; Martin Monzon et al. 2017), while the other found that patients with AN who exercised excessively presented a larger hippocampus than healthy controls (Beadle et al. 2015). Bernardoni and colleagues (2016) conducted a study on an adolescent sample of patients with AN

Table 1 Hippocampal volumes in patients with short (≤1 year) or long duration of anorexia nervosa (Adapted from Collantoni et al. (2021))

	Short duration (<1 year) (27 AN vs. 24 HW)		Long duration (>1 year) (31 AN vs. 30 HW)	
	F (p)	Effect size d	F (p)	Effect size d
Whole left hippocampus	**7.30 (0.010)**	0.75	**5.65 (0.021)**	0.62
Whole right hippocampus	4.23 (0.045)	0.59	**6.15 (0.016)**	0.65
Left tail	**6.78 (0.012)**	0.54	**8.45 (0.005)**	0.76
Right tail	3.34 (0.074)	0.31	**10.95 (0.002)**	0.86
Left subiculum	4.02 (0.051)	0.64	0.62 (0.436)	0.19
Right subiculum	1.15 (0.289)	0.28	2.74 (0.103)	0.41

Right fimbria	1.70 (0.198)	0.46	**12.55 (0.001)**	0.92
Left CA1_2	3.61 (0.06)	0.56	**5.40 (0.024)**	0.61
Right CA1_2	2.69 (0.108)	0.56	2.17 (0.147)	0.40

AN anorexia nervosa, *HW* healthy women
Statistics adjusted for age and site: threshold of significance according to FDR correction $p < 0.025$

and pointed out a complete normalization of hippocampal volume after a 3-month inpatient treatment program and partial weight normalization. The research conducted by Martin Monzon et al. (2017), instead, found that only the left hippocampus was restored after weight gain, with the right one being persistently reduced in volume. Although Mainz and colleagues did not explicitly assess differences in hippocampal volume between baseline and follow-up, they observed an association between recovery of sex hormones (FSH) and GM increase in the right hippocampus. Lastly, Beadle and colleagues (2015), who, at baseline, reported an increased hippocampal size in patients who exercised excessively, observed that after weight restoration, hippocampal volume was significantly lower than at baseline.

These findings indicate that weight restoration can normalize hippocampal structure in patients with AN, thus suggesting the role of malnutrition as a pathogenetic mechanism modifying the hippocampus' morphology. Moreover, although more longitudinal studies are needed to better clarify the changes occurring in the hippocampal structure during AN progression, the absence of a correlation between the volume of the hippocampus and the duration of the disorder leads to the hypothesis that the hippocampus may be structurally sensitive to disorder-specific alterations without being a useful marker for neuroprogression in AN.

Functional Studies

Most studies that employed functional neuroimaging methodologies to investigate hippocampus activation in patients with AN aimed at examining the role of this structure in the processing of food signals. The findings of these studies, which involve relatively low sample sizes and whose results should therefore be taken with

caution, are quite heterogeneous, mainly due to differences in task designs and methodologies.

Holsen et al. (2012) found lower left hippocampal activation in patients with AN, compared to healthy controls, when viewing high-calorie food images in a hungry state. These results, however, were not confirmed in another study conducted by Sanders and colleagues (2015), who found higher activation in the left hippocampus in both acute and recovered patients with AN than in controls in response to food cues. However, in this study, the comparison was made only for food versus nonfood cues, without specifying responses to high- or low-calorie food separately.

Lastly, Brooks and colleagues (2012) observed a left-sided parahippocampal hyperactivation in response to food images in patients with restrictive AN compared to patients with binge-purge AN, while no differences in hippocampal activation were observed between patients and healthy controls.

Other studies that examined hippocampal activation during specific tasks focused on the neural responses elicited during a set-shifting task and an emotional conflict task.

Sato and colleagues (2013) measured brain activity while participants were performing the Wisconsin Card Sorting Test, a task requiring cognitive flexibility and set-shifting abilities. The authors observed that patients with AN showed lower activation than healthy controls in the bilateral parahippocampal cortices. Furthermore, left parahippocampal activation during task execution has been shown to be negatively correlated with age in the experimental sample.

Bang and colleagues (2016) assessed brain activity in a sample of 22 patients who recovered from AN while performing an emotional conflict task. The task required participants to categorize affective faces while ignoring affective words. Face and word stimuli were either congruent (non-conflict) or incongruent (conflict). Their results during congruent trials evidenced a lower activation of the hippocampus (bilaterally) in patients who recovered from AN than in healthy controls.

A resting-state fMRI study conducted on a sample of 74 patients with acute AN found a higher fractional amplitude of low-frequency fluctuation in the bilateral hippocampus of patients with AN compared to healthy controls, suggesting the presence of a higher spontaneous fluctuation in neuronal activity in patients with acute AN in this area. These results were later confirmed in a recent study conducted on a smaller sample of seven patients with AN (Lai et al. 2020).

To date, two studies have used PET methodology in patients with AN to assess possible alterations in neurotransmitters that affect the hippocampus. A study conducted by Frank and colleagues (2002) found a reduced level of [18F] altanserin binding, a serotonin 2A receptor antagonist, in the amygdala and in the hippocampus of patients who recovered from AN, thus indicating an alteration of serotonin transmission that persists also after weight restoration.

Another study, conducted by Yoshizawa et al. (2009) evidenced an increased binding of [^{11}C]doxepin, which is a radioligand for the histamine H1 receptor, in the hippocampus of female participants as compared to males. However, no differences were observed between patients with AN and healthy women.

Hippocampus in Other Eating Disorders

The studies investigating the functioning of the hippocampus in bulimia nervosa (BN) are few and heterogeneous, as regards both methodology and findings. However, they deserve to be described given that they are of possible interest for future research.

As regards structural alterations, a study conducted using voxel-based morphometry (VBM) in order to characterize brain abnormalities in patients with BN failed to observe any significant difference between patients and healthy controls in hippocampal gray matter volume (Amianto et al. 2013).

The role of the hippocampus in the neurobiology of BN was also investigated by Wang et al. (2017), who explored brain networks in 44 patients with the disorder and in 44 healthy controls using graph theory tools. Interestingly, when analyzing nodal strength, the authors evidenced a decrease in nodal strength in patients with BN in different subcortical regions: in the medial orbitofrontal gyrus, in the left hippocampus, and in the bilateral parahippocampal gyri. Also, the hippocampus and the amygdala showed reduced connectivity in the experimental group compared to the healthy control one. Given the involvement of these regions of reduced strength and connectivity in reward functions, the authors suggest that these results may support the reward hyposensitivity hypothesis in patients with BN.

Reduced integrity of brain networks involved in reward processing was confirmed by a diffusion tensor imaging (DTI) study (Mettler et al. 2013). This study evidenced lower fractional anisotropy in the bilateral corona radiata, corpus callosum, right subinsular white matter, and right fornix in patients with BN compared to healthy controls. Interestingly, the results of this study highlighted that trait anxiety was negatively correlated with the fractional anisotropy of the fornix, corpus callosum, and left corona radiata in healthy women but not in patients with BN.

Another study by Mueller et al. (2017) investigated the neural substrate of catecholaminergic dysfunction in bulimia nervosa and its relationship with symptom relapse. In this investigation, the authors induced catecholamine depletion through the oral administration of alpha-methylparatyrosine (AMPT) for 24 h in 18 women with remitted BN and 22 healthy female participants using a randomized, double-blind, and crossover study design. A continuous arterial spin labeling sequence was used to measure cerebral blood flow. Furthermore, the presence of bulimic symptoms relapse was assessed by means of a follow-up telephone interview. Interestingly, bulimic relapse was found to be associated with a reduction in the cerebral blood flow in the hippocampus and in the parahippocampal gyrus following catecholamine depletion. On the contrary, staying in remission was associated with an AMPT-induced increase in cerebral blood flow in the hippocampus/parahippocampal gyrus.

One study conducted by Cyr and colleagues (2016) used a virtual reality-based paradigm to investigate the neural correlates of reward-based learning in a sample of 27 adolescents with BN and 27 age-matched healthy control participants. While acquiring fMRI data, participants had to navigate a virtual maze and collect monetary rewards. In the learning condition, they could learn the structure of the maze,

while in the control condition, learning was experimentally prevented, and thus reward stimuli were unexpected. The authors observed that patients with BN deactivated the right anterior hippocampus in the learning condition (when receiving expected rewards) and activated it in the control condition (when receiving unexpected rewards). In healthy controls, instead, activation of the hippocampus was greater in the learning condition than in the control condition.

In addition, activation of the right anterior hippocampus in response to unexpected rewards was greater in individuals who reported more bulimic behaviors in the 28 days prior to scanning.

Applications to Other Areas

The involvement of the hippocampus in food-intake regulation, reward-related mechanisms, and memory consolidation, among many other cognitive functions, made the study of this area of particular interest in the context of eating disorders and other psychiatric conditions.

In anorexia nervosa, both functional and structural neuroimaging studies suggested a possible involvement of this area in the neurobiology of the disorder. The findings, however, are inconclusive to date, mainly due to the small size of the experimental samples and to some methodological heterogeneities. Furthermore, only a few assessments of hippocampal structure and function in weight-recovered patients are present, and no longitudinal studies have been conducted to date. Therefore, it is currently not possible to properly evaluate whether the alterations affecting this structure are trait- or state-related phenomena or whether they may represent sequelae of the disorder. Further investigations are needed to better address these research points.

Mini-Dictionary of Terms

Activity-based anorexia nervosa: bio-behavioral phenomenon described in rodents that models the key symptoms of anorexia nervosa.

Diffusion tensor imaging: an imaging technique that provides information about the white matter microstructure.

Voxel-based morphometry: a computational approach that can be applied to MRI data. Employing a voxel-wise comparison of multiple brain images can measure differences in local concentrations of the brain tissue.

Neurogenesis: Process by which new neurons are produced.

Key Facts of Hippocampus in Anorexia Nervosa

Studies evaluating the hippocampus structure and function in eating disorders are still limited and not fully conclusive to date.

Some hippocampal structural and functional alterations have been pointed out in the acute phases of anorexia nervosa.

With weight recovery, the structural alterations affecting this structure seem to improve in patients with anorexia nervosa.

Summary Points

- The hippocampus is an anatomically complex structure that is peculiarly involved in the neurobiology of different brain disorders.
- Different studies have evidenced a role for this structure in the neurobiology of anorexia nervosa, but findings are rather inconsistent and heterogeneous both from a functional and structural point of view.
- Activity-based anorexia models provided important insights into the possible functional, structural, and molecular involvement of the hippocampus in disordered eating behaviors and in excessive physical activity.
- Neuroimaging studies pointed out both structural and functional hippocampal alterations in the acute phases of the disorder.

Endocrine Disturbances in Anorexia Nervosa

29

Resistance to Hedonic Feeding Hormone Ghrelin

Magnus Sjögren

Contents

Abstract

Anorexia nervosa (AN) is a devastating psychiatric condition associated with a high mortality and chronicity and for which the etiology is unknown. Recent genomic-wide association studies suggest that AN is a psychometabolic disorder, having identified several genes that link AN to both psychiatric disorders and metabolic states. One of the metabolic factors that have since long been of interest in eating disorder pathophysiology is ghrelin, an orexigenic hormone produced by the gut. Ghrelin increases before food intake and stimulates appetite, reducing insulin, and is linked to increase in norepinephrine and growth hormone. Ghrelin exists in different forms in humans, i.e., as acyl-ghrelin, the activated form, and desacyl-ghrelin, a previously presumed inactive form, that may counteract the effects of acyl-ghrelin. Both have consistently been found to be increased in AN

both in the acute stage and after weight restoration therapy, in spite of a lack of increase in appetite. Some findings indicate that individuals with long-standing AN develop resistance to the increased ghrelin levels, a process where exercise may be involved. This review present some of the most recent findings in the field of ghrelin research, as relevant for the understanding of the pathophysiology of AN.

Keywords

Anorexia nervosa · Ghrelin · Desacyl-ghrelin · Acyl-ghrelin · Eating disorders · Ghrelin resistance · Exercise · Disease model

Abbreviations

AG	Acyl-ghrelin
AgRP	Agouti-related peptide
AN	Anorexia nervosa
BBB	Blood–brain barrier
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
CNS	Central nervous system
D2R	Dopamine 2 receptor
DA	Dopamine
DAG	Desacyl-ghrelin
ED	Eating Disorder
fMRI	Functional magnetic resonance imaging
GH	Growth hormone
GHRL gene	Ghrelin gene
GHSR1a	Growth hormone secretagogues receptor 1a
GOAT	Ghrelin-o-acetylase enzyme
Gαi	Gi protein alpha subunit
Gαq	Gq protein alpha subunit
HC	Healthy controls
IGF-1	Insulin-like growth factor 1
Leu	Leucine
ME	Median eminence
Met	Methionine
NAc	Nucleus accumbens
NPY	Neuropeptide Y
POMC	Proopiomelanocortin
PROLED	PROspective Longitudinal all-comer inclusion study in Eating Disorders
SNP	Single-nucleotide polymorphism
VTA	Ventral tegmental area

Introduction

Anorexia nervosa (AN) is a devastating psychiatric disorder, often having an onset during adolescence, characterized by extreme weight loss or failure to gain weight appropriately for age, associated with an intense fear of weight gain, and a distorted body image (Association 2013). Recent reconceptualization of AN, as of both psychiatric and metabolic etiology, suggests that metabolic circuits linked to hunger may be a critical nexus linking metabolic dysfunction to mood disturbances. During the acute stage of AN, patients display multiple endocrine abnormalities that are commonly associated with starvation, including elevated stress hormones, hypogonadotropic hypogonadism, and adipocytokine disturbances (Singhal et al. 2014; Levine 2002). Upon weight restoration, many of these abnormalities normalize (Brown and Mehler 2015). Of particular interest to AN is ghrelin, a centrally active, unique orexigenic hormone, being peripherally produced, and involved in gut–brain signaling for appetite control and energy balance (Kojima et al. 1999).

Ghrelin is secreted from oxyntic glands in the gastric fundus (Kojima et al. 1999) and primarily acts via the growth hormone secretagogues receptor 1a (GHSR1a), stimulating the release of growth hormone (GH) from the pituitary, which in turn releases insulin-like growth factor 1 (IGF-1) as a response (Warzecha et al. 2006). In addition, ghrelin exerts pleiotropic effects both peripherally and centrally, including the modulation of the dopaminergic reward system (Mequinion et al. 2013).

The GHRL gene is located on the short arm of chromosome 3 (3p25–26), and translation mRNA gives rise to five products of similar structure and function: (a) The first is the 117-amino acid *preproghrelin*, which is homologous to promotilin, both of which are members of the motilin family. Preproghrelin is cleaved to produce (b) *proghrelin* which is cleaved in the next step to produce the 28-amino acid (c) *ghrelin* (unacylated; desacyl-ghrelin) and *C-ghrelin* (acylated) and (d) *obestatin*, which is presumed to be cleaved from C-ghrelin (Seim et al. 2010).

In order for ghrelin to pass the blood–brain barrier and activate the GHSR1a receptor and trigger the release of GH from the pituitary, it must be modified posttranslationally. This is done by the ghrelin-o-acetylase enzyme (GOAT; (Yang et al. 2008)), which forms acyl-ghrelin (AG). In contrast, desacyl-ghrelin (DAG), which is the more abundant form, does not activate the ghrelin receptor (Giovambattista et al. 2007).

The GHSR1a receptor is expressed across the brain (Schellekens et al. 2010; Stengel and Tache 2012) and especially in the arcuate nucleus, in neurons that also express agouti-related peptide (AgRP) and neuropeptide Y (NPY), both of which are involved in regulating food intake (Tschop et al. 2000). AgRP neuron involvement includes regulating a broad range of behaviors that become activated in response to the presence or absence of food availability. These behaviors include motivation, locomotor activity, negative reinforcement, anxiety, and obsession (Mequinion et al. 2019). When AG activates GHSR1a, this stimulates food intake, reduces insulin secretion leading to hyperglycaemia (Gauna et al. 2005), and stimulates gastric motility (Tack et al. 2006). DAG is more abundant in plasma and accounts for 80–90% of total ghrelin (Kojima and Kangawa 2005) and has been described as

anorexigenic and may counterbalance acyl-ghrelin (Inhoff et al. 2008; Fernandez et al. 2016), probably acting as an agonist at the supraphysiological levels (Gauna et al. 2007; Heppner et al. 2014).

Recently, the first meta-analysis of all forms of ghrelin in AN, including analyses of longitudinal changes, confirmed elevated fasting blood levels in acute AN compared to HCs for all forms of ghrelin (Seidel et al. 2021). In addition, although the previous studies have indicated subgroup differences, some finding higher levels in binge/purge AN vs restrictive AN (Tanaka et al. 2003), whereas others have not (Stoving et al. 2007; Westwater et al. 2020), the results did not reveal an effect of AN subtype on ghrelin levels (Seidel et al. 2021). Furthermore, in longitudinal studies, total ghrelin levels in AN showed a significant decrease during treatment, although the levels were still significantly elevated compared to the levels in HC at the same follow-up time points. Since the levels of total ghrelin have been found to be decreased in BMI-matched lean individuals compared to AN (Tolle et al. 2003; Korek et al. 2013; Germain et al. 2007), likely, there are other factors that underlie the elevated ghrelin levels in AN than a low BMI and undernourished state. Instead, explanations to the differences may need to be sought in behavioral and physiologic changes. For example, lean individuals do not exhibit clinical features such as persistent efforts to reduce energy intake, amenorrhea, distorted body image, or fear of weight gain, and lean individuals display an equilibrated energy metabolism similar to that of healthy controls, which might result in normalized ghrelin levels (Korek et al. 2013; Germain et al. 2007).

Physiological Functions of Ghrelin

Ghrelin is known to have many physiological effects such as increasing food intake which historically has been presumed to be via modulating both the homeostatic and hedonic systems. In addition, ghrelin increases gut motility, is involved in stress and reward-oriented behaviors including anxiety, and also influences locomotion (Muller et al. 2015; Perello and Dickson 2015). Studies of ghrelin function in AN have been less conclusive.

In order to map the physiological functions of ghrelin in AN, infusions of ghrelin have been adopted. In one study in AN, intravenous ghrelin infusions during 5 h led to no clear changes in food intake but instead increased sleepiness (Miljic et al. 2006). In another study, a slight sense of hunger was experienced in six of nine patients with AN after a bolus intravenous injection of 1 mg/kg ghrelin (Broglio et al. 2004), at a similar level as in HC (five of seven responders). Yet another study found that administration of ghrelin (3 mg/kg) twice a day led to a decrease in gastrointestinal symptoms and an increase in the sense of hunger, which also led to an increase in daily energy intake (12–36%) in five AN patients (Hotta et al. 2009). Albeit these studies suffer from being experimental and lack statistical power, as well as lack proper controls, and fail to properly evaluate the motivation aspect of AN, namely, to eat (Ueno et al. 2010), they still provide some support for the involvement

of ghrelin in appetite and food intake in AN. Whether this is homeostatic or hedonic is however unsettled by these studies.

Other studies stress that ghrelin influences hedonic food intake rather than homeostatic. For example, in mice with total ghrelin deficiency or selective AG deficiency, food intake is not reduced (Sun et al. 2003, 2004; Zigman et al. 2005; Zhao et al. 2010; Pfluger et al. 2008), which does not support a key role of AG in homeostatic eating. However, suppressed intake of rewarding food in a free choice food paradigm, lack of cue-potentiated feeding, and suppressed motivation for food in an operant responding model rather support a role of the endogenous peptide(s) in hedonic eating (Uchida et al. 2013).

Ghrelin and Reward Signaling in AN

Several findings provide support for the involvement of ghrelin in hedonic eating in AN, for example, as evidenced by research on reward signaling. Using a sucrose taste classic conditioning paradigm, with fMRI to investigate dynamic effective connectivity during expected sweet taste receipt, and where violations of learned associations between conditioned visual and unconditioned taste stimuli evoked dopamine-related prediction error, Frank et al. found an elevated prediction error response in AN compared with HC, BN, and binge eating disorder (BED). Furthermore, this altered reward response in AN was inversely associated with BMI. In addition, they found changed signaling in reward and food intake brain circuits in AN patients compared to healthy controls (Frank et al. 2021).

In another study, using a reward prediction error construct, i.e., a computational model for reward receipt and omission related to motivation and neural dopamine responsiveness, brain function was tested using functional MRI (fMRI) before and after treatment. This study found an increased brain activity of the DA-mediated reward system in AN patients compared to HC when exposing the subjects to situations that require reward-related learning (deGuzman et al. 2017), especially when underweight. After weight restoration, an elevated prediction error response in the striatum and insula was still found, although normalized as compared to before treatment. This replicates another study that also found underweight to be associated with increased dopamine-related reward system responsiveness, which only partially recovered with weight restoration (Carr 2002). In the study by DeGuzman et al. (2017), they especially found elevated brain reward circuits in the nucleus caudate and insula during reward learning, with the caudate being known to respond to salient stimuli and encode prediction error signals during stimulus reward learning (Zink et al. 2004), which thereby may reflect an altered dopamine function in AN, and the insula containing the primary taste cortex and being involved in cognitive control (Cauda et al. 2011; Klein et al. 2013). Prediction error signaling in insula has been associated with flexible behavioral control, and thereby, an increased signaling in insula may indicate altered reversal learning in AN, which may be associated with therapy resistance.

To further support the role of ghrelin as a potential modulator of reward-related behaviors, a study on cognitive functioning such as reward-based decision-making found that high levels of ghrelin were associated with better cognitive performance on the Iowa gambling task (reward sensitivity) (Paslakis et al. 2019) and with decreased delay discounting in AN (patients with high ghrelin more often chose the delayed reward) (Bernardoni et al. 2020).

The role of ghrelin in reward processing is thought to occur via its strong connections to the mesolimbic dopamine system (Stievenard et al. 2017). For example, ghrelin injection was associated with increased dopamine in the nucleus accumbens (Jerlhag et al. 2007) as well as heightened activation in key regions associated with pleasure and reward (Malik et al. 2008). It is via this pathway that ghrelin is able to increase the incentive value of food (Kroemer et al. 2013) and, in the same fashion, also in other reward-motivated behaviors such as alcohol consumption and drug use (Wittekind and Kluge 2015; Dickson et al. 2011).

Another central structure where ghrelin exerts its actions is the ventral tegmental area (VTA), a structure involved in the reward/locomotion behavior, and hypothalamus to modulate appetite, respectively (Jiang et al. 2006; Kern et al. 2012; Sharpe et al. 2016).

A recent fMRI study in women with AN demonstrated that the VTA activity, measured with the blood flow to the VTA, was reduced compared to individuals suffering from bulimic nervosa when exposed to food odors, which may indicate potential dysregulation of VTA activity in AN patients (Jiang et al. 2019). Additionally, a retrograde viral injected, chemogenetic induction of intracellular ghrelin (Gαq) pathway activity, in projections from the VTA to NAc, increased food intake and food anticipatory behavior of activity-based anorexia (ABA) rats, an animal model of AN, mainly as a result of activated dopaminergic neurons (Foldi et al. 2017). The interpretation of these findings suggests that a decreased activation of the dopaminergic projections from VTA to the NAc, which have been consistently found to be activated by ghrelin in the presence of food, may be involved in the etiology of AN. A modulation of these dopaminergic projections may influence and even reduce the development of AN (Kawahara et al. 2009).

On the other hand, others have associated high ghrelin levels not only with increased impulsivity (Anderberg et al. 2016) but also with increased reward sensitivity (Farokhnia et al. 2018; Ralevski et al. 2018) or reduced activity in areas associated with regulatory control (dorsolateral prefrontal cortex, (Bogdanov et al. 2020) in other populations.

There are additional evidence to support an involvement of the DA system in mediating the effects of ghrelin in AN, e.g., from fMRI studies in which individuals with AN showed a high rate of self-control and are less sensitive to rewards and more sensitive to punishment, e.g., during odor-cued food task (Jiang et al. 2019) or increased blood flow oxygenation in the left anterior insula in response to food images (Kim et al. 2012), and in behavioral studies, as an increased activity level (Dalle Grave et al. 2008).

Another evidence of the involvement of reward and dopamine in AN stems from studies on drug use, which have indicated a rather high usage, especially of

amphetamine and cocaine, in this population (Herzog et al. 2006; Aguinaga et al. 2019). Anecdotal reports from my own interviews with patients in the PROspective Longitudinal all-comer inclusion study in Eating Disorders (PROLED; for more info see (Fjeldstad et al. 2021)) suggest that the usage of dopaminergic stimulating drugs helps to suppress hunger signals in AN. Hypothetically, the hedonic reward from the CNS stimulant overrides the drive for feeding. Supporting this is both the clinical experience of refusal to accept medication with antipsychotic drugs (D2R antagonists), i.e., drugs that potentially may drive feeding behavior, and the results of clinical trials which suggest no overall positive effect from treatment with anti-dopaminergic drugs; see meta-analysis (Blanchet et al. 2019). Many of these studies used second-generation antipsychotics, which are known to increase body weight, at least in patients with schizophrenia and bipolar disorders, which raises questions on the compliance in these clinical studies in AN but also whether these drugs influence ghrelin-related hedonic food intake in the way required for changing the course of AN. However, the D2 blockade may also be affecting the dopaminergic system insufficiently or be too crude a mechanism to promote feeding behavior in AN (see below on biased signaling).

Clinical Evidence of Ghrelin Resistance

One potential explanation for the lack of effects of ghrelin infusions on food intake in AN concerns potential ghrelin resistance. Overall, there are a couple of disparate findings that support this:

(a) A reduced ability of ghrelin to be transported to central targets within the hypothalamus (Schaeffer et al. 2013); the transport mechanisms of ghrelin, through the blood–brain barrier (BBB) and into the nucleus arcuatus, is yet vaguely understood, and the current knowledge implies that it may be either via diffusion across fenestrated capillaries in the median eminence (ME) or via saturable receptor-mediated transport across the BBB. One study has demonstrated that ghrelin is able to pass the fenestrated capillaries in ME and that hypothalamic neuronal monitoring of this is possible together with rapid adaptations of the passage of ghrelin (Schaeffer et al. 2013).
(b) A reduced GHSR1a sensitivity or function; this could be related to a dysregulation of hypothalamic NPY/AgRP and POMC neurons, which function as direct or indirect targets of ghrelin effects, thereby leading to opposing actions on food intake (Denis et al. 2014). Overall, GHSR1a signaling is highly complex as reflected in the available four different intracellular pathways that may be triggered as a result of GHSR1a activation: Gαq, Gαi/o, Gα12/13, and the recruitment of β-arrestin. Thus, a biased signaling may enable a partial or complete activation or inhibit one or a subset of intracellular pathways of this pleiotropic receptor (Khelifa et al. 2021).
(c) An alteration in the ghrelin signaling on dopaminergic neurons, in the ventral tegmental area (VTA) (Abizaid et al. 2006). See more below.

Ghrelin Resistance: Antagonism by Other Ghrelin-Derived Peptides?

With regard to altered ghrelin signaling on DA neurons, this may be the effect of other ghrelin-derived peptides, such as those that may modulate the actions of AG. One potential modulator is DAG, which may exert its actions on appetite by counteracting the effects of AG. Evidence of such a counteracting mechanism stems from studies on central and peripheral injections of DAG (Asakawa et al. 2005; Inhoff et al. 2008), where DAG suppresses ghrelin-induced food intake by reducing the ghrelin-induced increase in neuronal activity in the arcuate nucleus. In addition, transgenic mice overexpressing DAG present with a reduced body weight, reduced food intake and reduced body fat mass, and decreased linear growth (Asakawa et al. 2005). Furthermore, DAG exerts several biological actions, independent of the GHSR1a pathway, including regulation of glucose homeostasis and fat metabolism (Delhanty et al. 2012, 2013). Another candidate for opposing the effects of AG is obestatin (Chartrel et al. 2007). For example, in individuals suffering from restrictive subtype of AN, obestatin and the ghrelin/obestatin ratio were found decreased in comparison to constitutionally thin women, who had a normal ratio (Germain et al. 2010). Such changes may participate in the eating restriction despite the hyper-ghrelinemia observed in these patients.

Physical Activity: The Patients' Option to Induce Ghrelin Resistance?

Patients suffering from AN frequently engage in increased physical activities to burn calories and thereby counteract any risk of weight gain. This often becomes a habit in AN, and many patients report several hours of physical activity per day for extended periods of time. The effects of physical activity on ghrelin levels in AN are yet to be fully elucidated, but speaking in favor of an effect on inducing resistance is a systematic review of physical activity that found ghrelin levels are suppressed after acute and increased after chronic physical exercise (Ouerghi et al. 2021).

Genetic Factors Involved in Ghrelin Resistance

Genetic factors may be yet another reason for altered ghrelin levels in AN as proposed by Dardennes et al. (2007), who studied 114 trios (studies in individuals with AN including both of their parents). Transmission disequilibrium was observed for the Leu72Met single-nucleotide polymorphism (SNP) in the preproghrelin gene, which was primarily transmitted in trios in the binge eating/purging subtype of AN (Muller et al. 2011). Studies on a general population have found that Met72GHREL carriers have the lowest BMI and the lowest fat mass including less visceral fat and a lower fasting respiratory quotient, indicating a greater utilization of fat as an energy substrate (Ukkola and Poykko 2002).

Chronicity and Ghrelin Levels in AN

A yet unknown aspect is how ghrelin levels change over time, for example, with development of severe and enduring AN. The development of ghrelin resistance in AN may be part of this treatment-resistant state. Some findings indicate that some individuals with AN suffer progressive disorder, similar to that in schizophrenia and bipolar disorder. This neuroprogressive state changes the clinical features of AN in terms of psychological and clinical symptoms and signs. However, it is unknown how ghrelin resistance may influence or be part of the pathophysiology of this state (Fig. 1).

Application to Other Eating Disorders

In other disorders such as BN, ghrelin levels have mostly been found to be at normal levels (Westwater et al. 2020; Troisi et al. 2005; Monteleone et al. 2008) and increased before food intake and decreased after (Kojima et al. 2005). In addition, acute stress increased ghrelin in AN but not in BN (Westwater et al. 2020). In BED, ghrelin levels in blood are usually comparable to that of healthy controls (Munsch et al. 2009). In addition, while the GHRL gene may be involved in AN and BN, no such association has been found for BED (Palmeira et al. 2019).

Summary Points

Ghrelin is a unique orexigenic hormone, being produced in the periphery, and is involved in feeding behavior. All forms of ghrelin have been found to be increased in blood in AN and still being increased after weight gain. No clear evidence links

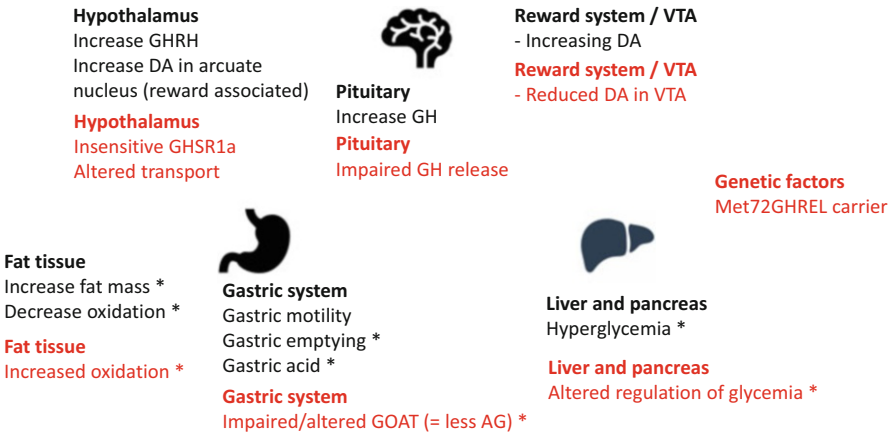

Fig. 1 Ghrelin physiological effects (in black) and signs of resistance to ghrelin (in red)

ghrelin levels in blood to any specific behavior in AN, and in general, most evidence point at ghrelin being involved in hedonic feeding behavior, linked to reward. The actions of the active form of ghrelin, AG, may be counteracted by its sisterpart, DAG, and potentially also by other hormones such as obestatin. The concept of ghrelin resistance has been presented. This is supported by the increased ghrelin levels in AN, while normal in lean individuals, and a lack of effect of ghrelin on feeding in AN. Both genetic factors and physical activity may be involved in ghrelin resistance. No clear evidence of an involvement of ghrelin in other ED exists.

Mini-Dictionary

- **Ghrelin:** A peripherally produced orexigenic hormone involved in feeding behavior.
- **Acyl-ghrelin:** The active form of ghrelin stimulating primarily hedonic feeding behavior.
- **Desacyl-ghrelin:** The previously presumed inactive form, while current concept suggests it is counteracting the effects of AG.
- **Reward system:** Neuroanatomically and neurochemically defined system involved in behaviors linked to a sensation of reward.
- **Reward sensitivity:** Being prone to react to rewarding stimuli.
- **Anorexia nervosa:** An ED characterized by extreme weight loss or failure to gain weight appropriately for age, associated with an intense fear of weight gain, and a distorted body image.

Anorexia Nervosa and Eye Movements

30

Andrea Phillipou

Contents

Abstract

Eye movement tasks have been used widely in psychiatric and neurological illnesses to gain a better understanding of cognitive processes and the neurobiology involved in these conditions. A range of different eye movement tasks have been employed, most of which have focused on saccadic eye movements – the fast, "jerky" eye movement humans typically use to view their surroundings. This chapter will provide an overview of the eye movement literature in anorexia

nervosa (AN) to date and will describe the value of gaining a better understanding of eye movements to inform improved diagnosis, treatment, and prevention of AN.

Keywords

Anorexia nervosa · Eye movements · Saccade · Fixation · Square wave jerk · Prosaccade · Antisaccade · Memory-guided saccade · Self-paced saccade · Smooth pursuit · Scan path · Visual attention · Cognition · Body · Food

Abbreviations

AN	Anorexia nervosa
BMI	Body mass index
DLPFC	Dorsolateral prefrontal cortex
FEF	Frontal eye fields
GABA	gamma-Aminobutyric acid
HC	Healthy control
LIP	Lateral intraparietal lobule
SD	Standard deviation
SEF	Supplementary eye fields

Introduction

The visual system is a complex biological system that processes information gathered from visible light to build a representation of our surrounding environment. Light enters our eyes via the cornea and through the pupil, onto the retina situated at the back of our eyes. The retina is connected to the optic nerve which sends neural signals to our brains. Our eyes move to locate stimuli of interest onto the region of the retina with the greatest visual resolution – the fovea – using four different types of eye movements: saccadic, smooth pursuit, vergence, and slow stabilizing eye movements. Slow stabilizing eye movements – namely, the vestibular-ocular reflex and optokinetic reflex – are reflexive eye movements which help us hold gaze stationary. Vergence describes when our eyes converge or diverge when a target moves toward or away from us, respectively. Smooth pursuit refers to slow eye movements ($<100°/s$) that we use to track moving targets. Saccadic eye movements – or saccades – are the fast jerky eye movements, typically followed by a period of fixation, that redirect gaze. As humans, we use a "saccade and fixate" strategy when viewing our surroundings, making approximately three to four saccades every second of our waking lives. Given that saccades are by far the predominant type of eye movements that we use in everyday life, they are also the most researched. But why would we research saccadic eye movements, and what do differences or deficits in their execution tell us?

Saccadic eye movements are stereotypical and tend to have a characteristic profile, and when saccades do not look like how we would expect, it can suggest neurocognitive or neurobiological deficits. Saccadic eye movements can tell us about higher level processing such as inhibition and memory, as well as visual attention. Examining different characteristics of saccadic eye movements can also tell us about neurological mechanisms that may underlie different conditions, such as anorexia nervosa (AN). As brain regions involved in eye movement production overlap with regions thought to be involved in various psychiatric conditions, deficits in eye movement production have been researched in mental health populations since the early 1900s, providing increased understanding of the neurobiology underlying these conditions.

Neurobiology of Saccadic Eye Movements

Each eye is controlled by six extraocular muscles, with horizontal eye movements controlled by the medial and lateral rectus muscles, and vertical eye movements controlled by the superior and inferior rectus muscles, and superior and inferior oblique muscles. Saccadic eye movements are generated in the brainstem with horizontal saccades generated by neurons in the paramedian pontine reticular formation (Keller 1974) and vertical saccades generated by neurons in the mesencephalic reticular formation (Buttner et al. 1977; Buttner-Ennever and Buttner 1978). A number of other subcortical and cortical brain areas are involved in the production of saccades – which are best understood for horizontal saccades – including the superior colliculus, basal ganglia, thalamus, and parietal and frontal cortices.

The superior colliculus is a midbrain region that plays an important role in the generation of saccades, with caudal regions involved in driving saccades and more rostral regions involved in maintaining fixation between eye movements (Munoz and Wurtz 1993a, b, 1995). Neurons in the intermediate superior colliculus discharge in relation to saccades of different amplitudes, with larger saccades generated in caudal regions and smaller saccades generated in rostral areas (Robinson 1972; Schiller and Stryker 1972). The intermediate superior colliculus receives projections from cortical areas – including the frontal eye field (FEF) (Bruce et al. 1985; Sommer and Wurtz 2000), supplementary eye fields (SEF) (Shook et al. 1990), dorsolateral prefrontal cortex (DLPFC) (Selemon and Goldman-Rakic 1988), and the lateral intraparietal lobule (area LIP) (Clower et al. 2001; Lynch et al. 1985) – as well as subcortical regions – such as the brainstem and basal ganglia, as well as the cerebellum (Edwards et al. 1979; Hikosaka et al. 2000). The superior colliculus itself projects to areas involved in premotor circuitry of eye movements – the paramedian pontine reticular formation and the rostral interstitial nucleus of the medial longitudinal fasciculus (Sparks 2002) – as well as to the FEF, providing a warning of an impending eye movement (Sommer and Wurtz 2008).

Saccade Characteristics

In normal viewing, saccades generally do not exceed an amplitude of 15° (Bahill et al. 1975), with targets further in the periphery usually involving moving the head to redirect the image onto the fovea (Bahill et al. 1975). Saccades can be made in less than 100 ms, with both eyes moving in the same direction with the same amplitude. Saccades begin when the eye is stable, quickly accelerating to a peak velocity followed by a rapid deceleration which then quickly returns to a stable position. In laboratory-based experiments, a number of saccade characteristics are typically examined including the gain, latency, and peak velocity of the saccadic eye movement (see Fig. 1). Gain refers to the accuracy of a saccade onto a target and is calculated by dividing the saccadic amplitude by the amplitude of the target. Latency describes the time from stimulus onset to the initiation of a saccade (saccadic reaction time), whereas peak velocity refers to the fastest point of a saccade, quoted in degrees per second (Liversedge et al. 2011).

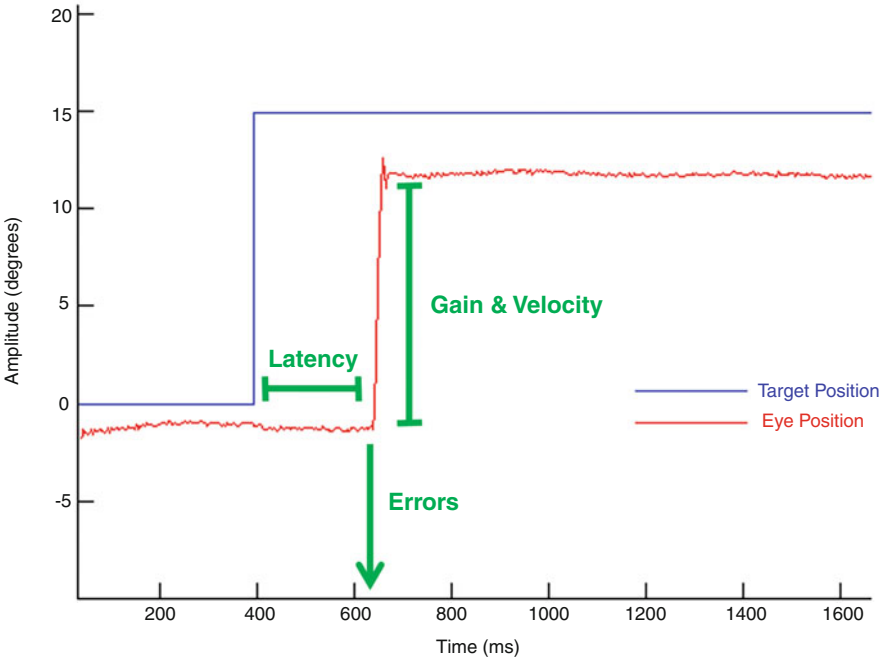

Fig. 1 Saccadic eye movement characteristics typically measured in laboratory-based experiments. Visual representation of eye movement data to a 15° target. The blue line represents the target position, and the red line, the eye position. In this example, a correct prosaccade is shown. An error on this task would result in a saccade made in the opposite direction of the target. Latency refers to the time from the onset of the target to the onset of the saccadic eye movement. Gain refers to the accuracy of the saccade onto a target, calculated by dividing the saccadic amplitude by the amplitude of the target. Peak velocity refers to the fastest point of the saccade, quoted in degrees per second

In laboratory-based experiments, saccades are typically researched in terms of the direction in which they are made, i.e., vertical or horizontal. In everyday life, horizontal saccades are more frequently used and are therefore more frequently researched, and consequently their neurobiology is better understood.

Saccade Tasks

A range of tasks based in the laboratory are typically carried out to examine the various saccade characteristics in different populations. Included among these tasks are the "basic saccade tasks" such as fixation, prosaccade, antisaccade, go/no-go, memory-guided and self-paced saccade tasks, and other types of paradigms in which gaze is examined. Examining performance on these types of tasks has been of increasing interest in the study of AN and has provided valuable insights into possible neurocognitive and neurobiological deficits in this population.

The first study on eye movements in AN did not specifically employ a saccadic eye movement task but a smooth pursuit task (Pallanti et al. 1998). In this study, participants who were weight-restored from AN were required to track a moving dot with their eyes. Unpredictable step-ramp stimuli were utilized, and patients were found to have lower mean peak velocity gains, increased anticipatory saccades, and lower target matching than healthy controls (HC). The authors also reported that 3 of 28 wr-AN participants also exhibited square wave jerks during the smooth pursuit task. The authors suggested that these impairments may represent alterations in cortical-subcortical neuronal circuits that control oculomotor activity and saccadic eye movements. Since this early pioneering study, all the research in AN to date has focused specifically on saccadic eye movements.

Fixation Task

The fixation task is perhaps the simplest of all eye movement tasks to perform but is also perhaps the most interesting in terms of AN. In a fixation task, participants are required to remain fixated on a central stimulus for the entire duration of the task (usually for around 1 min). Performance on this task is determined by the ability to remain fixated on the central stimulus. Intrusive saccades, however, occur at a low rate during fixation. In particular, a type of small, involuntary eye movement – called a square wave jerk – is frequently seen in individuals with AN (see Fig. 2). Square wave jerks involve a pair of small (typically 0.5–5°), involuntary, and unconscious horizontal saccadic eye movements that very briefly (~200 ms) move the eye away from and back to the target, appearing as an eye movement "twitch" (Abadi and Gowen 2004; Abadi et al. 2003). It is typical to make square wave jerks at a low rate during fixation; however, individuals with AN have been reported to make a very large number of these atypical eye movements (Phillipou et al. 2014, 2022). In the first study to identify an increased rate of square wave jerks during fixation in AN, Phillipou et al. (2014) found that individuals with AN made an average of 11.8

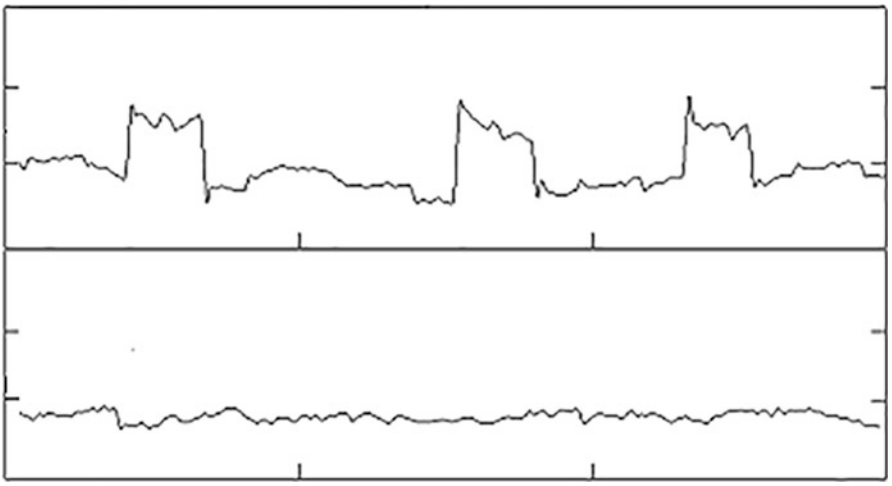

Fig. 2 An example of square wave jerks in an individual with AN (top panel) and stable fixation in a HC (bottom panel) during a fixation task. Visual representation of eye movement data over a three-second period. The vertical axis represents 1° increments

(SD = 12.2) square wave jerks in a 1 min eye tracking recording, compared to an average of only 2.95 (SD = 2.8) in HCs. This study also reported a significant negative correlation between square wave jerk rate and levels of anxiety in the AN group. Square wave jerk rate and anxiety levels, together, were also able to discriminate AN from HCs with exceptionally high accuracy (91.25%), providing a potential biomarker for identifying people with AN. A follow-up study by the same authors replicated this finding in individuals currently with AN compared to HCs (with 92.5% accuracy) and also extended the findings to individuals who were weight-restored from AN and sisters of individuals with AN who could each be discriminated from HCs with 77.5% accuracy, respectively (Phillipou et al. 2022).

In addition to the finding of a new potential biomarker for AN that could potentially be used for diagnosis or as a screening tool for prevention, the presence of these intrusive saccades and their relationship to anxiety levels provide support for the hypothesis that the superior colliculus and gamma-Aminobutyric acid (GABA) may play a role in AN. GABA levels in the superior colliculus have been linked to intrusive saccades (Munoz and Wurtz 1993b), and levels of anxiety are closely related to GABA activity (Tallman et al. 1980). Importantly, the superior colliculus is also involved in multisensory integration, and deficits in this area may be related to the integration of visual and tactile information that contributes to body image disturbances in AN (McFadyen et al. 2020; Meredith and Stein 1986). As this biomarker was also present in individuals who were weight-restored from AN, this suggests that this marker may represent an AN trait. Further to this, as sisters of individuals with AN were also found to show this marker, it indicates that not only may this eye movement suggest an underlying neurobiological trait, but it may also

represent a hereditary endophenotype, suggesting that certain individuals may be predisposed to developing AN.

Prosaccade Task

The prosaccade task – also known as the reflexive saccade task – is a simple task in which a stimulus, such as a black dot on a white background, is simply presented and a participant is required to make a saccade toward this target (Hallett and Lightstone 1976). While minimal effort is required to perform a prosaccade task, performance on this task requires some attention, and the brain mechanisms involved in attentive processes overlap with brain regions involved in eye movements including FEF, SEF, inferior parietal lobule, and cerebellum, among other areas (Beauchamp et al. 2001; Nobre et al. 2000; Corbetta et al. 1998; Perry and Zeki 2000). Gain, latency, and peak velocity of prosaccades are typically examined and are rarely reported to be disrupted in psychiatric conditions. To date, two studies have investigated prosaccades in AN, the earlier of which found significantly shorter latencies in AN relative to HC (Phillipou et al. 2016b) and the latter not reporting a difference in any prosaccade characteristic between AN, weight-restored AN, and sisters of individuals with AN and HC (Phillipou et al. 2020). The lack of consistency in these two studies may be as a consequence of different methods of trial presentation. The earlier study examined prosaccades within a paradigm that also contained antisaccade and no-go trials following a cue period and may have resulted in attention being disengaged before the presentation of the target, enabling faster saccades. This earlier finding of faster initiation of prosaccades also provides support for the potential role of the superior colliculus in AN given the region's involvement in the initiation of eye movements, as well as the potential role of the neurotransmitter GABA in this brain region. However, given the lack of group difference in the latter study, further research into prosaccade task performance is required.

Antisaccade Task

The antisaccade task is a somewhat more complicated task than the prosaccade task. In this task, the participant is asked to fixate on a central stimulus. Similarly to the prosaccade task, a target is presented in the periphery. However, unlike the prosaccade task, the participant is required to suppress making a saccade to the stimulus and instead make a saccade to its mirror image – in other words, they need to make a saccade of the same distance from the center but in the opposite direction – a "correct antisaccade" (Hallett 1978). The antisaccade task is frequently used in psychiatric conditions to assess neurocognitive function because it can provide information on a number of different cognitive processes, including inhibition, attentional focus, working memory, and spatial representation. Correct antisaccades require the participant to inhibit making a prosaccade to the presented stimulus, a process which requires focused attention as well as working memory. While correct antisaccades

tend to by hypometric – meaning that participants tend to "undershoot" the target by making a saccade that is not quite as large as necessary to be a "mirror image" of the target (i.e., have smaller gains) – being excessively hypometric or hypermetric can indicate difficulties with transforming coordinates to spatial representations (Krappmann 1998). The latency of correct antisaccades is also typically longer than that of prosaccades due to the increased cognitive processes required to inhibit the automatic response to make a prosaccade to the target (Everling and Fischer 1998; Hutton and Ettinger 2006; Munoz and Everling 2004; Olk and Kingstone 2003). Errors on the task are common, with two types of errors typically recorded – corrected and uncorrected antisaccade errors. Corrected errors occur when a saccade is made toward the presented target and immediately corrected to make a saccade in the opposite direction, whereas this correction is not made with uncorrected errors. Both types of errors are thought to result because of deficits or lack of maturation of the frontal lobe, particularly the DLPFC (Ford et al. 2005; Curtis and D'esposito 2003; Bowling et al. 2012), but uncorrected antisaccades are rare and are typically only seen in populations with neurological diseases such as Alzheimer's disease and frontal lobe damage (Crawford et al. 2005; Guitton et al. 1985; Abel et al. 2002) and are not typically found in individuals with mental health conditions. Corrected antisaccade errors, however, are common in individuals with mental health conditions, particularly in individuals with schizophrenia where no study to date has failed to find an increased rate of antisaccade errors in this population (Hutton and Ettinger 2006; Myles et al. 2017). In relation to AN, two studies have investigated antisaccade task performance, one using an interleaved design (interleaved with prosaccade and no-go saccade trials) and the other using a block design of just antisaccade trials. The study using an interleaved design failed to find a difference in any antisaccade variable between AN and HC groups (Phillipou et al. 2016b). The blocked design study, however, reported that individuals with AN and sisters of individuals with AN showed higher gains than both HC and individuals who were weight-restored from AN who tended to "undershoot" the target, suggesting discrepancies in visual representations (Phillipou et al. 2020). Furthermore, in the group currently with AN, gain negatively correlated with body mass index (BMI), suggesting that starvation effects may contribute to visual representation difficulties.

Go/No-Go Saccade Task

In the go/no-go saccade task, participants are required to fixate on a central stimulus which will change to indicate whether a saccade should be made to a peripherally presented stimulus (the "go" response/prosaccade) or to remain fixated in the center when the peripherally presented stimulus appears (the "no-go" response/fixation) (Van'T Ent and Apkarian 1999). Similarly to the antisaccade task, the no-go response requires an inhibitory response when the stimulus appears, but unlike the antisaccade task, it does not require the volitional action of generating a saccade (Brown et al. 2006), thereby allowing for the investigation of inhibitory processes regardless of the ability to perform a volitional saccade. In terms of investigations in

AN, only one study to date has examined performance on this task and found no differences in no-go error rate, relative to HC (Phillipou et al. 2016b).

Memory-Guided Saccade Task

The memory-guided saccade task – also known as the oculomotor delayed response task – requires a participant to fixate on a central stimulus while a target is briefly presented in the periphery. The participant is required to maintain fixation on the central stimulus and to not look at the stimulus that has just flashed in their periphery. Only when the central stimulus disappears following a short delay are they required to make a saccade to where the target was briefly presented (Pierrot-Deseilligny et al. 1991). While the memory-guided saccade task assesses short-term memory, it also taps into other cognitive processes, including inhibition and attentional control. Inhibitory errors on this task can result due to a failure to suppress an unwanted reflexive saccade to the briefly presented stimulus or a failure to inhibit a planned saccade to the remembered location during the delay period. Similarly to the antisaccade task, correct memory-guided saccades have longer latencies than prosaccades, indicating increased cognitive demand during this task (Özyurt et al. 2006; Mitchell et al. 2002). Similarly to antisaccades, memory-guided saccades also tend to be hypometric (Gnadt 1991; Krappmann 1998).

In relation to AN, two studies have examined performance on the memory-guided saccade task. The first of these studies presented AN and HC participants with stimulus targets at 5° and 10° (Phillipou et al. 2016b). Group differences were not observed for gain, latency, peak velocity, or directional error rate. The AN group were, however, found to show an increased rate of inhibitory errors, specifically to stimulus targets at 10°. The latter of these studies employed a similar paradigm but also presented stimulus targets at 15° (Phillipou et al. 2020). Interestingly, the only group difference found again was on inhibitory errors to 10° targets. Individuals with a current diagnosis of AN showed increased inhibitory errors to stimuli presented at 10° in comparison to HC, as well as in comparison to individuals weight-restored from AN. The current AN group also showed a trend toward making more inhibitory errors to 10° targets than first-degree relatives (i.e., sisters) of people with AN.

This finding of increased inhibitory errors to a specific target amplitude in AN provides further evidence for the potential role of the superior colliculus in the disorder. Cells producing saccades are topographically mapped on the superior colliculus – with smaller amplitude saccades being initiated by more rostral areas and larger saccades by more caudal areas (Sparks 2002). Hence, there may be dysfunction in a very specific region of the superior colliculus in individuals with AN given that deficits were only present at 10°. As these findings do not appear to extend to individuals who were weight-restored from the illness, it suggests that this dysfunction may represent a state effect that is restored with the restoration of body weight or improved psychological symptoms.

Self-Paced Saccade Task

The self-paced saccade task is considered an almost entirely volitional task in which the participant is required to self-initiate refixations back-and-forth between two stimuli for the entire duration of the task (usually for around 30 s) (Abel and Douglas 2007). Findings from aging and neurodegenerative studies suggest a role of frontal functioning in the production of self-paced saccades (Abel and Douglas 2007; Abel 2009), while traumatic brain injury studies suggest that performance on this task represents an inability to disengage attention and speed of information processing (Heitger et al. 2009; Williams et al. 1997). Only one study to date has examined performance on this task in AN and found no difference to HC on saccade rate, gain, intersaccadic interval or peak velocity (Phillipou et al. 2016b).

Visual Scan Path Tasks

In everyday life, saccades do not occur in isolation but are preceded and followed by a period of fixation, resulting in a continuous sequence of saccade, fixation, saccade, fixation, etc. This sequence is typically referred to as a visual scan path and describes the gaze or pattern of eye movements used to view visual scenes and our surroundings. Visual scan paths are generally controlled by top-down processing – i.e., we make saccades towards locations that provide information for the task at hand. Bottom-up processing is, however, also involved and describes visual attention that is driven by salient stimuli. In terms of scan paths, there are a number of aspects that can be examined. The simplest is examining visual attention to specific elements of a visual scene, such as how long someone spends looking at a face within a scene or how many fixations are made to that face. The other aspect of visual scan paths that is investigated is the scanning behavior – e.g., whether they show a disorganized scan path or tend to hyper- or hypo-scan, reflecting lots of fixations with short duration or few fixations with long durations, respectively.

In terms of AN, several studies have examined scan path behaviors. Individuals currently with AN have been reported to show hyperscanning behaviors to both faces (Phillipou et al. 2015) and bodies (Phillipou et al. 2016a). Hyperscanning behaviors are closely linked with anxiety (Horley et al. 2003), with these results suggestive of anxiety toward social (i.e., faces) and disorder-relevant (i.e., bodies) stimuli. Further, the presence of hyperscanning provides additional support for the presence of saccadic inhibition deficits in people with AN, similarly to the findings in basic saccade and fixation tasks, and provides further evidence for the potential role of brain regions and neurotransmitter systems that underlie saccadic disinhibition in the development of AN (i.e., the superior colliculus and GABA). Research in scanning behaviors is, however, limited, with other studies reporting a lack of hyperscanning when looking at faces in a recovered AN group (Dinkler et al. 2019), as well as in a mixed ED group (Fujiwara et al. 2017). Current AN, weight-restored AN, and sisters of individuals with AN and HC were also found to not differ in scanning behaviors to disorder-irrelevant stimuli (i.e., landscapes and

geometric shapes) (Phillipou et al. 2016b), suggesting that if hyperscanning behaviors are present, they may be specific to stimuli relevant to AN pathology.

Eye movement tasks utilizing disorder-relevant stimuli have been of particular interest to identify differences in attentional biases in individuals with AN, such as areas of a stimulus that are given more or less visual attention, indexed by more frequent and/or longer fixations. Examining these types of attentional biases can provide important information about how visual information is processed in AN, which may contribute to their symptomatology. Of particular interest has been the investigation of where AN patients focus on when presented with stimuli of bodies. Individuals with AN tend to show longer fixation durations to areas of their own body that they perceive to be unattractive or they are dissatisfied with (Bauer et al. 2017a, b; Svaldi et al. 2016; Freeman et al. 1991; Von Wietersheim et al. 2012). When looking at other individuals' bodies, the findings are more mixed, and it is unclear where attentional biases may exist. In a study by Tuschen-Caffier et al. (2015), individuals with AN made more fixations with longer durations to areas of other peoples' bodies that they were more dissatisfied with in themselves and thought were more unattractive. When completing a task which required participants to estimate the body size of stimuli, individuals who were recovering or in recovery from AN showed more attention to the face and torso of stimuli, relative to HC (Cornelissen et al. 2016). In a different study where participants rated bodies on both body size and attractiveness, HC participants made fixations mostly to the stomach, whereas AN participants made more widespread fixations from the breast and collar bone down to the hips and groin (George et al. 2011). Individuals with AN have also been reported to make more fixations and have longer fixation times to thin bodies (Pinhas et al. 2014) but to not differ to HC in the amount of time fixating on overweight bodies (Hartmann et al. 2020). Other studies have, however, failed to find a difference in the number of or durations of fixations to different body areas when presented with different body weights, ranging from very thin to very heavy (Horndasch et al. 2012; Phillipou et al. 2016a). Interestingly, when body stimuli are presented with faces being visible, individuals weight-restored from AN have been reported to be less likely to look at faces, compared to HC (Watson et al. 2010). The same study also reported that when presented with just faces, wr-AN spent less time looking at the eyes than HC (Watson et al. 2010).

AN patients have also been shown to spend less time looking at faces while viewing a naturalistic scene than recovered AN and HC; when looking at faces specifically though, attention to different facial features did not differ between AN and HC in this study (Kerr-Gaffney et al. 2021). Kerr-Gaffney et al. (2020) also reported a lack of group difference between AN, recovered AN, and HC during a facial emotion recognition task in terms of the time spent looking at faces. Similarly, Phillipou et al. (2015) found no difference in the number of or duration of fixations to salient facial features (i.e., eyes, nose, and mouth), compared to HC during an emotion discrimination task. When looking at one's own face, however, the same study reported that HC made more fixations of longer duration to salient features of their own faces, whereas AN did not differ in the amount of attention shown to their own salient and non-salient features. This finding suggests that individuals with AN

may avoid fixating on salient features of their own face as they find looking at these important features of their face anxiety-provoking.

Individuals with AN are frequently reported to have high levels of social anxiety and difficulties with social situations (Kaye et al. 2004). A key aspect of social interactions in Western societies is the level of eye contact held with someone. An early study reported that adolescents with AN made less eye contact with a psychologist than HC, which the authors suggested may be related to social difficulties, depression, or anxiety in AN (Cipolli et al. 1989). In a more recent study, individuals with AN made fewer fixations and spent less time looking at the eyes of static and moving social stimuli and during a real-life social interaction than HC, whereas a recovered AN group demonstrated greater eye contact in the same paradigms than AN but less so than HC (Harrison et al. 2018).

Attentional Bias Tasks

While examining scan paths can tell us about differences in visual attention, other cognitive tasks can also employ eye movements to assess attentional biases. During a visual-probe or a "dot-probe" task, for example, while the participant is fixating on a central fixation cross, they are presented with two images simultaneously to the left and right and are required to make a saccade as quickly as possible to the target stimulus (e.g., circled in red). In these tasks, disorder-relevant (e.g., bodies, food) and disorder-irrelevant stimuli are often presented simultaneously, and examining saccadic latencies to targets can indicate attentional biases to disorder-relevant stimuli. When presented with images of their own body and another individuals' body, people with AN have been shown to have shorter latencies to images of themselves when it was the target than images of others, whereas HC showed similar latencies to self- and other target images (Blechert et al. 2010). This suggests that individuals with AN may have an attentional bias for images of their own bodies. Other studies have used similar paradigms where two stimuli are presented simultaneously, such as image pairs of people undertaking physical activity and people being physically inactive. While both AN and HC have been shown to orient their attention to physically active stimuli first, individuals with AN have been found to gaze longer at images containing physical activity (Giel et al. 2013). Individuals weight-restored from AN, however, have been reported to show less visual attention to images of physical activity than current AN and HC, which may indicate an avoidance of illness-related information during recovery (Giel et al. 2020). The same study also reported that individuals with a current diagnosis of AN spent less time looking at food stimuli than HC and the weight-restored group "fell in between," not significantly differing to either group. This finding of increased visual attention to stimuli of food in AN has been replicated several times (Werthmann et al. 2019; Giel et al. 2011). Increased visual attention has also been shown specifically to high- over low-calorie foods in AN, however, only when stimuli are presented on their own rather than simultaneously (Godier et al. 2016; Horndasch et al. 2020), suggesting

that there may be conflicting mechanisms of attention toward food depending on whether there is another stimulus competing for the viewer's attention.

Conclusions and Implications

Gaining a better understanding of how eye movements differ in individuals with AN has a number of significant implications. While the area of research is still very much in its infancy, the findings to date provide us with a better understanding of the cognitive and neurobiological differences which may underlie the disorder, which consequently provide potential targets for treatment. For example, attentional biases in terms of body regions that are focused excessively on by individuals with AN may be targeted with visual retraining or other cognitive-based therapies (Beilharz et al. 2018). Further, neurobiological deficits, including brain regions and neurotransmitter systems, implicated in AN through saccadic eye movement tasks could be targeted with brain stimulation and pharmacotherapy, respectively (Phillipou et al. 2019). In addition, the identification of a potential biomarker or endophenotype of AN (square wave jerks during fixation) is significant as this type of eye movement may provide an objective diagnostic tool, as well as a tool that could potentially be used for early identification and prevention of AN.

Applications to Other Eating Disorders

In this chapter, we reviewed the literature pertaining to eye movements in AN. The great majority of the eating disorder research in eye movements to date has focused on AN, with little research directed to the other eating disorders. The eye movement literature in AN is still very small but growing. It is still unclear whether many of the findings will replicate in future research and whether we will find similar or different results in other eating disorders. Undertaking similar paradigms in individuals with other eating disorders will be of great value to identify overlapping neurobiological and cognitive processes that may be similar across different eating disorders.

Mini-Dictionary of Terms

- **GABA**: Inhibitory neurotransmitter involved in anxiety and the initiation of saccades.
- **Gain:** The accuracy of a saccade onto a target, calculated by dividing the saccadic amplitude by the amplitude of the target.
- **Latency**: The time from stimulus onset to the initiation of a saccade.
- **Peak velocity**: The fastest point of a saccade, quoted in degrees per second.
- **Saccade:** Fast, jerky eye movement humans frequently use to observe their surroundings.
- **Scan path:** The sequence of saccades and fixations when viewing an image.

- **Square wave jerks:** Small, involuntary, and unconscious eye movement pairs that briefly take the eye away from and return it to fixation.
- **Superior colliculus:** AN area of the midbrain involved in saccade inhibition/disinhibition.

Key Facts of Eye Movements in AN

- Differences in eye movements are found in individuals with AN.
- Key differences include an increased rate of square wave jerks during fixation and increased inhibitory errors to 10° targets on the memory-guided saccade task.
- Eye movement differences in individuals with AN suggest saccadic inhibition deficits.
- Findings also implicate specific neurobiological differences in individuals with AN including brain regions such as the superior colliculus and neurotransmitter systems such as GABA.
- Individuals with AN also show attentional biases to disorder-relevant stimuli such as bodies and food.

Summary Points

- Saccadic eye movement deficits are present in individuals with AN.
- An increased rate of inhibitory errors on the memory-guided saccade task, and an increased rate of square waver jerks, is present in individuals with AN.
- The specific eye movement deficits suggest neurobiological dysfunction which may contribute to the illness.
- The rate of square wave jerks during fixation, together with anxiety, has been proposed as a promising biomarker to identify individuals with AN.
- Individuals with AN show attentional biases to disorder-relevant stimuli which may contribute to illness pathophysiology.

Abstract

Anorexia nervosa (AN) mainly affects girls and women in adolescence and early adulthood, making it of particular importance to understand the impact of the disease on reproductive function, pregnancy, and postpartum period *and* how children to mothers with eating disorders are affected. Anorexia nervosa is associated with extensive endocrine abnormalities resulting in impaired fertility, which is commonly normalized with weight and nutritional restoration. Although rare, spontaneous pregnancy can occur among women with ongoing AN, and there are no major limitations for women recovered from AN to conceive. Nevertheless, pregnancy constitutes a vulnerable time period and may affect the disease course among women with ongoing disease and possess a relapse risk for women with previous disease. Consequently, it is important to identify women with ongoing or a history of AN in antenatal maternal health care in order to provide adequate support and management to prevent adverse outcomes. Maternal AN is associated with several adverse pregnancy-related outcomes, including anemia, hyperemesis gravidarum, antepartum hemorrhage and preterm delivery, and restricted fetal growth. The children to mothers with AN seem to suffer from an increased risk of developing specific conditions throughout childhood. This chapter reviews available evidence on the impact of maternal anorexia nervosa on fertility, pregnancy, and postpartum period and childhood health.

Keywords

Anorexia nervosa · Undernutrition · Reproduction · Pregnancy · Postpartum · Perinatal · Amenorrhea · Fertility · Functional hypothalamic amenorrhea · Neonatal · Child health · Anemia · Antepartum hemorrhage · Preterm delivery · Small for gestational age

Abbreviations

AN	Anorexia nervosa
BMD	Bone mineral density
CRH	Corticotropin-releasing hormone
CVD	Cardiovascular disease
DXA	Dual-energy X-ray absorptiometry
FHA	Functional hypothalamic amenorrhea
FSH	Follicle-stimulating hormone
GH	Growth hormone
GnRH	Gonadotropin-releasing hormone
hCG	Human chorionic gonadotropin
HG	Hyperemesis gravidarum
ID	Iron deficiency
IGF-1	Insulin-like growth factor 1
LDL	Low-density lipoprotein
LH	Luteinizing hormone

PPROM	Premature rupture of membrane
SGA	Small for gestational age
SHBG	Sex hormone-binding globulin
T3	Triiodothyronine
TSH	Thyroid-stimulating hormone

Introduction

Anorexia nervosa (AN) impacts multiple aspects of the reproductive health. The fertility is impaired among women with AN due to the extensive hormonal aberrations, induced by energy deficit. Pregnancy in women with ongoing AN is rare but can occur sporadically, and women with a history of AN have no major obstacles to conceive in general. Pregnant women with ongoing or previous AN suffer from an increased risk of multiple pregnancy complications and are likewise at an increased risk of impaired outcomes in the postpartum period. Early identification of women with AN in antenatal maternal health care is essential in order to provide adequate and intensified support throughout the pregnancy and postpartum period.

Anorexia Nervosa and Fertility

The reproductive health is compromised in women with AN, mainly as a consequence of functional hypothalamic amenorrhea (FHA). Depending on age at disease onset, AN is associated with either primary amenorrhea (defined as spontaneous menstruation that has never occurred) or secondary amenorrhea (absence of menstruation for at least three consecutive months after menarche). Sporadically, AN is associated with infrequent menstruation with increased menstrual intervals (>35 days) or five to nine periods within the last year (oligomenorrhea).

Functional Hypothalamic Amenorrhea

The specific pathophysiology of FHA is complex. In brief, energy deficit caused by starvation and weight loss, the hallmark of anorexia nervosa, induces an aberration in multiple hormone levels, including increased levels of corticotropin-releasing hormone (CRH), reduced levels of insulin and insulin-like growth factor 1 (IGF-1), and altered levels of appetite-regulating hormones such as leptin and ghrelin, leading to an impairment of the pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus (Allaway et al. 2016). In turn, the altered GnRH pulsatility leads to disrupted secretion of the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH) resulting in reduced ovarian production of estradiol, progesterone, and testosterone and consequently amenorrhea and anovulation (Gordon 2010; Misra and Klibanski 2014). In addition to a suppressed hypothalamic-pituitary-ovarian axis, an overactive hypothalamic-pituitary-adrenal axis and an altered

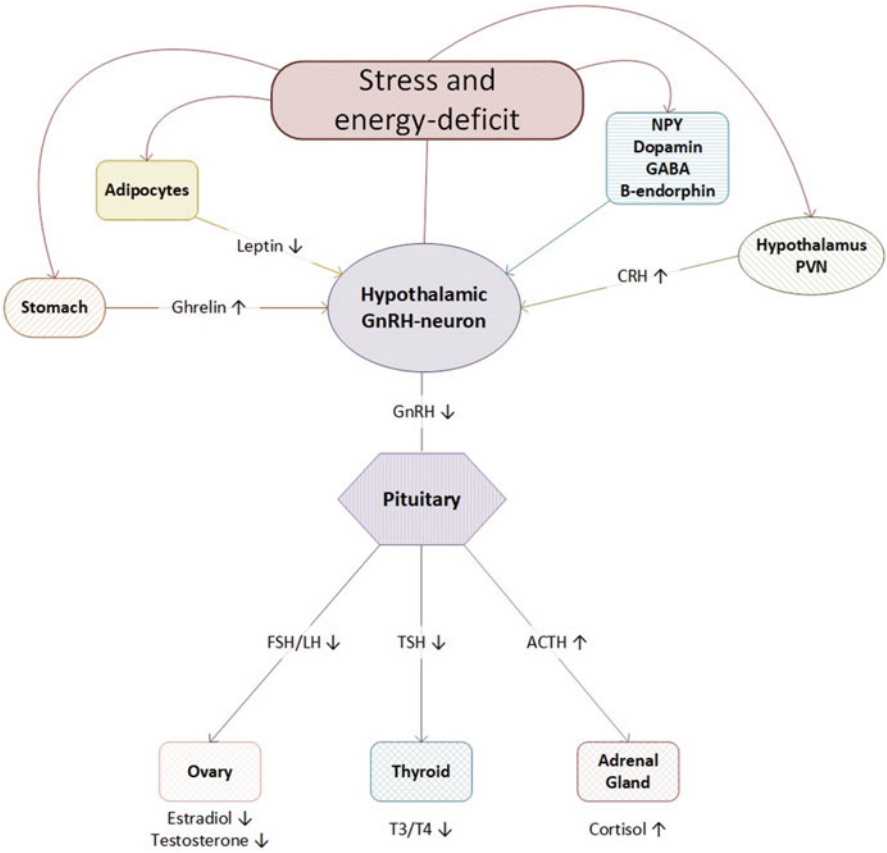

Fig. 1 Overview of hormonal changes in functional hypothalamic amenorrhea. In addition to a suppressed hypothalamic-pituitary-ovarian axis, functional hypothalamic amenorrhea is characterized by an overactive hypothalamic-pituitary-adrenal axis and an altered thyroid hormone regulation. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, gamma-aminobutyric acid; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PVN, paraventricular nucleus; TSH, thyroid-stimulating hormone; T4, thyroxine; T3, triiodothyronine

regulation of thyroid hormones are commonly seen in patients with FHA (Misra and Klibanski 2014) (Fig. 1).

Besides impaired reproductive function, AN/FHA has a detrimental effect on bone health by interfering with the bone turnover. The multiple deranged hormonal axes have partially different effect on the complex osteoblast-osteoclast interaction depending on the patient's age. Estrogen is involved in the normal bone formation homeostasis by inhibiting osteoclastic bone resorption, and reduced levels of estrogen accordingly lead to an increased osteoclastic bone resorption (Almeida et al. 2017; Snow et al. 2000). However, estrogen deficiency alone does not explain the overall bone effect in anorectic patients, which is likely to be multifactorial and

involve multiple, presumably interlinked, mechanisms (Legroux and Cortet 2019). Hypercortisolism amplifies the osteoclast activity and bone resorption and additionally impairs the calcium absorption (Tauchmanova et al. 2007). Moreover, the reduced levels of the anabolic growth hormone (GH) and IGF-1 lead to decreased bone formation (Snow et al. 2000). As a consequence of the disrupted bone metabolism, the bone mineral density (BMD) is reduced and bone microarchitecture altered, resulting in an increased prevalence of osteoporosis and increased fracture risk among girls and women with AN (Faje et al. 2014; Legroux-Gerot et al. 2005). The increased risk of fractures in AN persist many years after diagnosis (Vestergaard et al. 2002) and is highest among girls and women with active disease.

Management and Treatment of Functional Hypothalamic Amenorrhea

Regardless of amenorrhea no longer being one of the diagnostic criteria of AN, it is a cardinal feature (Treasure et al. 2020). However, despite amenorrhea being an expected clinical finding among girls and women with AN, it should always be carefully evaluated in order to rule out alternative or concomitant conditions. Importantly, the prevalence of an AN diagnosis is not always known when assessing amenorrhea since some patients with AN may be reluctant to inform health-care professional about the disease, whereas other patients may be in denial of having an eating disorder (Schorr and Miller 2017). Hence, evaluation of amenorrhea should include a careful assessment of comorbidities, including eating disorders, and detailed laboratory assessment of hormone levels, liver function tests, complete blood count, electrolytes, and specific nutritional markers should be performed (Gordon et al. 2017). As expected, suppressed levels of LH, FSH, estradiol, testosterone, and T3 and increased levels of sex hormone-binding globulin (SHBG) are characteristic of FHA (Allaway et al. 2016; Gordon 2010) (Table 1). If nothing points toward alternative conditions requiring physical examination, gynecological

↑ indicates increased levels, ↓ indicates decreased levels, and ↔ indicates no change in levels

examination is not indicated. In order to address the associated risk of bone loss, bone mass should be evaluated in adult patients, using dual-energy X-ray absorptiometry (DXA).

FHA is a functional condition without underlying organic pathology, and with weight and nutritional restoration, the menstrual function usually normalizes. Therefore, treatment of AN and restoring the energy balance should be prioritized. Not surprisingly, the prevalence of eating disorders among women receiving infertility treatment with GnRH pulsatility pharmacotherapy is high (Barbosa-Magalhaes et al. 2021). However, encouraging fertility treatment among women with active AN should be avoided, partially due to the increased risk of impaired pregnancy and neonatal outcomes (Gordon et al. 2017).

In long-term amenorrhea (>1 year), the effects of hypoestrogenism should be evaluated, primarily in relation to the risk of osteoporosis, but also regarding multiple other potential consequences of estrogen deficiency, including urogenital symptoms, adverse lipid profile, and endothelial dysfunction. Estrogen affects the endothelium, including the vascular endothelium, via several mechanisms, by promoting endothelial homeostasis and preventing atherosclerosis. Estrogen deficiency is associated with a deteriorated vascular function as well as a shift toward an atherogenic lipid profile (increased levels of low-density lipoproteins [LDL] and total cholesterol). Consequently, conditions associated with low levels of estrogens, e.g., premature menopause, have been associated with an increased risk of cardiovascular disease (CVD) (Wellons et al. 2012). However, except for a few number of case reports on coronary heart disease in women with AN, no association between AN and long-term risk of CVD has been reported (Birmingham et al. 2003). Weight restoration is central to increase the bone mass and should be prioritized (Legroux and Cortet 2019). Transdermal estrogen in combination with cyclic progesterone, shown to improve bone mass in girls with AN, could be used (Misra et al. 2011). Oral estrogen lowers the levels of IGF-1 and hence amplifies the negative effects on bone formation and should therefore be avoided (Snow et al. 2000). Likewise, the knowledge of the long-term efficacy of bisphosphonates among women with eating disorders of reproductive age is limited, wherefore their use is not recommended (Fig. 2).

Long-Term Effect on Fertility

As the menstrual function commonly normalizes with weight and nutritional restoration, the fertility naturally improves. Girls with FHA prior to, or in relation to, puberty might suffer from delayed menarche, disrupted puberty, and underdevelopment of sex characteristics. In adult women, long-lasting FHA might induce atrophic changes in urogenital mucosa and uterine muscle atrophy, which could reduce reproductive function (Meczekalski et al. 2014). One meta-analysis, investigating the reproduction after recovery from AN, that included five small studies, whereof three uncontrolled, concluded that the birth rate did not differ in women having recovered from AN compared with the general population and that long-term

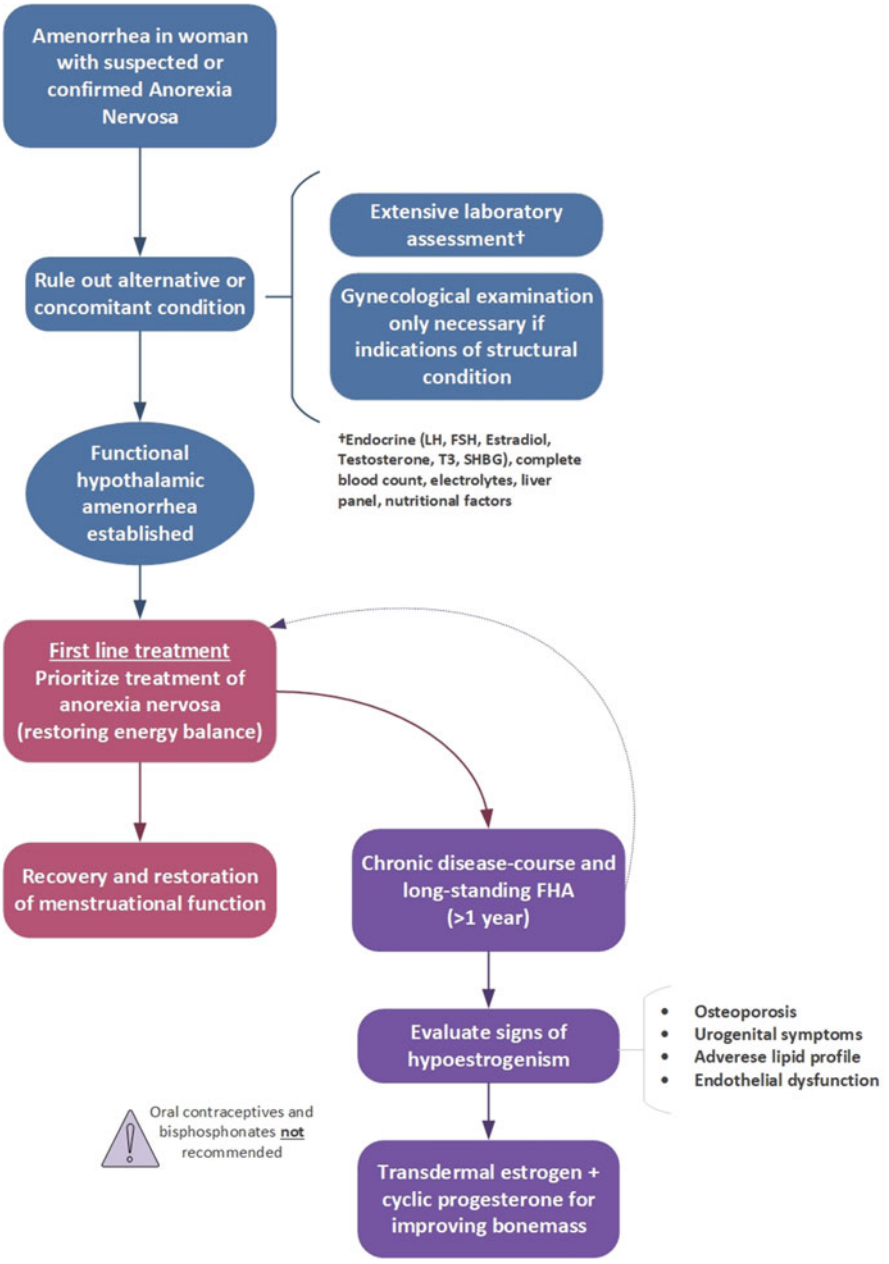

Fig. 2 Evaluation and management of functional hypothalamic amenorrhea in women with anorexia nervosa. FHA, functional hypothalamic amenorrhea; FSH, follicle-stimulating hormone; LH, luteinizing hormone; SHBG, sex hormone-binding globulin; TSH, thyroid-stimulating hormone; T3, triiodothyronine

fertility is unlikely to be affected (Chaer et al. 2020). Yet, other studies have found that adolescents with AN had a lower prevalence of medical abortions compared with adolescents with other eating disorders (Lindeman et al. 2021) and that women with a history of AN are more likely to see a fertility doctor, delayed first birth, and lower parity (Linna et al. 2013).

The Prevalence of Anorexia Nervosa in Pregnancy

The vast majority of individuals affected by AN are girls or women. The reported incidence of AN in women varies considerably depending on study setting and case definition. In a recent meta-analysis, the pooled incidence of AN among women was higher in outpatient care settings (8.8/100,000 person-years [95% CI 7.83–9.80]) compared with the pooled incidence of hospital admissions (5.0/100,000 person-years [95% CI 4.87–5.05]) (Martinez-Gonzalez et al. 2020).

Not surprisingly, the prevalence of AN is much lower among pregnant women than in the general female population. However, ovulation can occur in irregular menstrual cycle, and although rare, spontaneous pregnancy do occur in women with ongoing AN. In fact, AN has been associated with an increased frequency of unplanned pregnancies (Bulik et al. 2010), which could be a consequence of mistaken assumption of reduced reproductive function. Additionally, despite the potential effect of AN history on long-term fertility, naturally there are no major obstacles for women with previous AN to conceive.

In similarity with incidence and prevalence reports based on the general female population, there is extensive variability in the reported prevalence of AN among pregnant women, depending on the case definition. Based on studies on pregnancy-related outcomes in women with AN, where the exposure was self-reported using interviews or questionnaires, the prevalence of a self-reported history of AN was reported between 0.9 and 2.0% (Easter et al. 2014; Micali et al. 2016; Popovic et al. 2018). Studies using a similar case definition have reported a prevalence of ongoing AN between 0.1 and 0.3% (Bye et al. 2020; Micali et al. 2016; Popovic et al. 2018). In general, register-based studies identifying exposure (AN) using registered diagnoses have reported lower AN prevalence compared with self-reported exposure. Based on such studies, a prevalence of previous AN between 0.1 and 0.5% and a substantially lower prevalence of ongoing AN (<0.03%) have been reported (Ante et al. 2020; Eik-Nes et al. 2018; Mantel et al. 2020; Perrin et al. 2015).

Despite controversies regarding temporal changes in the AN incidence in the last decades, there are in fact several indices of an increasing incidence of AN (Martinez-Gonzalez et al. 2020). Whether this reflects an actual increase in disease incidence or rather altered diagnostic criteria, improved diagnostic awareness, and/or expansion of health-care resources to identify cases is not known. There are, up to date, no reports on the temporal variation of anorexia nervosa prevalence among pregnant women, but considering the point prevalence of AN being the highest in adolescence and early adulthood, it is likely to follow the trend of the general female population.

Disease Course in Pregnancy

The recovery from AN is gradual and the long-term disease course heterogeneous. Longitudinal studies suggest that the disease course is chronic for one of five women and that it takes no less than 20 years from disease onset to recover for 60% of all women with AN. Many women experience residual symptoms, and one of four women relapse into disease after treatment (Mitchell and Peterson 2020).

The pregnancy and postpartum period constitute a particularly vulnerable time period, characterized by physiological, psychological, and hormonal changes, which could affect the AN disease course. There seem to be large variations in the inter-individual response to pregnancy, which has been reported to have a protective as well as possessing a risk for relapse, among women with AN. An improvement of eating disorder symptoms, including decreased weight and shape concern, during pregnancy among women with ongoing or recent AN has been described in some studies (Blais et al. 2000; Crow et al. 2008; Micali et al. 2007). Psychological, social, and biological factors have been suggested to mediate the improvement of eating disorder symptoms during pregnancy among women with ongoing or recent AN. Psychologically, a sense of maternal responsibility of recovery and altered body perception have been reported by women with AN as factors influencing improvement during pregnancy. Improved and intensified support from partner and health-care services (Madsen et al. 2009) and placental-induced neuroendocrinal changes are other suggested potential explanations for symptom relief during pregnancy. Importantly, several other studies report an increased frequency of eating disorder symptoms and risk of relapse of AN during pregnancy, in particular among women with a history of AN (Easter et al. 2015; Koubaa et al. 2005; Makino et al. 2020; Micali et al. 2007).

Considering the complexity of the disease course, the frequently persisting symptoms over a long period of time, and the increased relapse risk among women with previous AN, it is important to acknowledge pregnant women with AN in their medical history (in addition to women with ongoing anorexia nervosa) when screening women for psychiatric comorbidities in antenatal maternal health care in order to provide adequate support and management throughout the pregnancy period (Fig. 3).

Anorexia Nervosa and Pregnancy Complications

Recently, several population-based studies have strengthened the evidence on impaired outcomes in women with AN, by adding information on the subject to the previously reported observations from clinical studies. In addition to being a frequent finding among girls and women with AN in general, anemia in pregnancy is a more common finding among pregnant women with ongoing or previous AN compared with pregnant women without eating disorders (Bansil et al. 2008; Koubaa et al. 2005; Linna et al. 2014; Mantel et al. 2020). The underlying pathophysiology of anemia in AN has mainly been attributed to morphological alterations of the bone

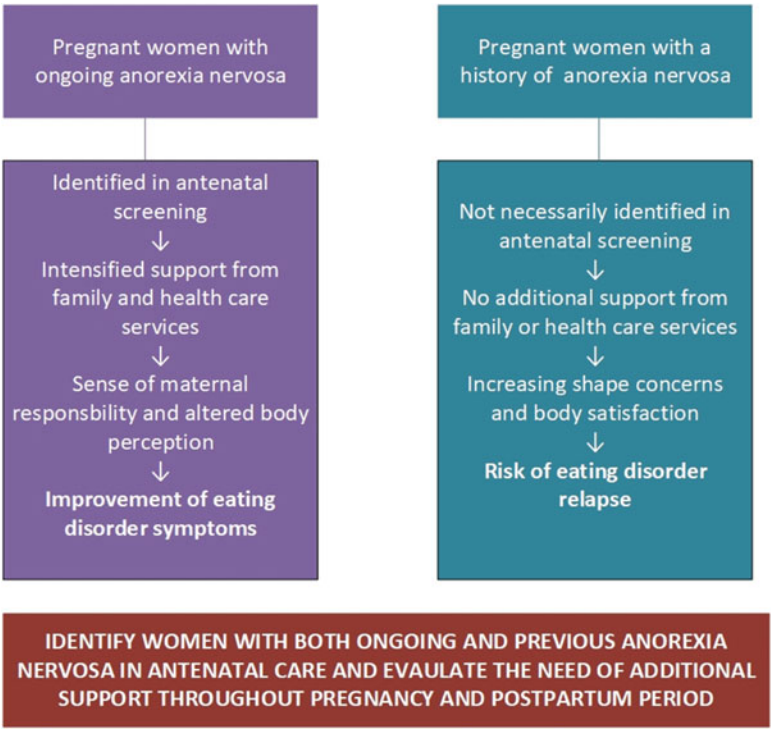

Fig. 3 Schematic flow chart of the pregnancy disease course of ongoing vs. previous anorexia nervosa. Highlighting the importance of recognizing women with both ongoing and previous anorexia nervosa in antenatal care in order to provide adequate support and measurements to improve eating disorder symptoms and decrease the relapse risk

marrow, and laboratory findings are various (Walsh et al. 2020). The most common type of anemia seen among pregnant women in general is iron deficiency (ID) anemia due to an increased iron demand necessary to support the fetoplacental development (Breymann 2015), and one study found lower levels of ferritin in pregnant women with AN (Koubaa et al. 2015). However, unpregnant women with AN commonly have normal iron status and often increased levels of ferritin (biomarker of iron storage), which could be a consequence of increased intake of iron supplements and decreased loss due to amenorrhea or stress-induced inflammation and liver damage (Hutter et al. 2009).

Women with AN are at an increased risk of developing hyperemesis gravidarum (HG), a severe form of nausea and vomiting in pregnancy resulting in dehydration, weight loss, and electrolyte disturbances, often requiring hospital admission (Austin et al. 2019). The etiology of HG is not completely understood but has, inter alia, been associated with low early pregnancy BMI and transient gestational thyrotoxicosis (Nurmi et al. 2020) which presumably could mediate the increased risk of HG among women with AN. The increasing levels of human chorionic gonadotropin

Table 2 Overview of adverse pregnancy and perinatal outcomes in women with anorexia nervosa

Infections and sepsis →	Admission to NICU ↑
Delivery mode →	Birth trauma →
	Congenital anomalies →

↑ indicates increased risk of outcome in women with anorexia nervosa (or their neonate), and → indicates no difference in outcome in women with anorexia nervosa compared to women without eating disorder

(hCG) in the first trimester stimulate the TSH receptor inducing increased levels of thyroxine and triiodothyronine resulting in transient biochemical hyperthyroidism, observed in approximately one of 10 pregnant women. Importantly, TSH and thyroxine values normalize in mid-pregnancy, and anti-thyroid pharmacotherapies are not warranted. HG is a clinical diagnosis and is managed by supportive care, including usage of antiemetic drugs and monitoring of fluid balance.

Moreover, AN is associated with an increased risk of antepartum hemorrhage (Ante et al. 2020; Mantel et al. 2020) and in particular an increased risk of abruptio placentae (Ante et al. 2020). The mechanism mediating this association is not known, but abruptio placentae is associated with low BMI and specific vitamin and mineral deficiencies, which might explain some of the association. Anorexia nervosa has also been associated with an increased risk of acute liver failure during pregnancy and admission to intensive care unit (ICU). Prolonged starvation in severe AN has been suggested as a potential explanation of the increased risk of acute liver failure (Ante et al. 2020). Most studies have not observed a difference in delivery mode in women with AN compared with women without eating disorders, and likewise, women with AN are not at an increased risk of postpartum hemorrhage (Table 2) (Ante et al. 2020; Mantel et al. 2020).

Anorexia Nervosa and Adverse Perinatal Outcomes

In addition to being associated with several adverse pregnancy outcomes, AN prior to or during pregnancy is also associated with an increased risk of multiple adverse perinatal outcomes. Pregnant women with AN are at an increased risk of delivering prematurely (before 37 gestational weeks) (Ante et al. 2020; Mantel et al. 2020), and this increased risk is similar for moderate preterm birth (between 32 and 37 gestational weeks) and very preterm birth (between 28 and 32 gestational weeks) (Mantel et al. 2020).

The etiology of the increased frequency of preterm births in AN has not been specified but is likely to be diverse since women with AN seem to be at an increased

risk of both premature rupture of membrane (pPROM) and precipitous labor (Ante et al. 2020). Furthermore, the risk of both spontaneous preterm delivery and medically induced preterm delivery is increased among women with AN. Multiple studies have consistently reported a negative impact of maternal AN on neonatal growth outcomes. AN has been associated with an increased risk of stillbirth (Ante et al. 2020) or delivering low birthweight (<2500 grams) (Ante et al. 2020) or small-for-gestational-age neonates (SGA, <2 SDS below median birthweight for gestational age) and neonates with microcephaly (head circumference < 2 SDS of median head circumference for gestational age) (Koubaa et al. 2005; Linna et al. 2014; Mantel et al. 2020; Micali et al. 2016; Watson et al. 2017). As a consequence, neonates to mothers with AN have a lower Apgar scores and are intubated and admitted to neonatal intensive care (NICU) more frequently than neonates to mothers without eating disorders (Ante et al. 2020; Mantel et al. 2020). The prevalence of birth trauma or congenital anomalies is not different in neonates to mothers with AN compared with neonates to healthy mothers (Ante et al. 2020). The risks of adverse neonatal outcomes have been reported to be higher among women with ongoing or recent AN during pregnancy compared with previous AN (Ante et al. 2020; Mantel et al. 2020). Importantly though, the risks of a majority of adverse neonatal outcome are still significantly increased among women with a history of AN.

The rationale for the association between maternal AN and increased risk of adverse neonatal outcomes is not known. Presumably, the key factors poor nutrition, low BMI, and stress can explain some of the association. In fact, one study found that low maternal pre-pregnancy BMI and weight gain mediated a majority of the association between maternal AN and low birthweight neonates (Watson et al. 2017), which is indicative of a nutritional impact. The level of cortisol is increased in women with AN, and increased levels of cortisol have been associated with preterm birth and with microcephaly in children to mothers with AN (Koubaa et al. 2015). Undernutrition and specific vitamin deficiencies are doubtlessly leading to fetal growth restriction due to compromised nutritional transfer to the fetus (Table 2).

The Postpartum Period

Depressive and anxiety symptoms are common among all women during the postpartum period, which in similarity with the pregnancy period is characterized by physiological and psychological changes. Women with AN report a higher frequency of depressive and anxiety symptoms during the postpartum period (as compared with women without a history of eating disorder), which is related to problems of maternal adjustment (Koubaa et al. 2008). An eating disorder history independently predicts the risk of postpartum depression (Johansen et al. 2020; Makino et al. 2020).

Moreover, women with AN have been reported to have a more rapid weight loss compared with healthy mothers within the first postpartum months, and, in contrast to the improvement of eating disorder symptoms during pregnancy, many women

with eating disorders experience eating disorder exacerbation during the postpartum period (Micali et al. 2007).

Several studies with inconsistent results have investigated breastfeeding pattern in women with eating disorder. One large population-based study reported no difference in initiating breastfeeding among women with AN compared with women without eating disorders, but earlier breastfeeding cessation (Micali et al. 2009). Insufficient milk production and concerns about the baby being hungry or not completely satisfied have been suggested to explain the difference in breastfeeding pattern among women with AN.

Children to Mothers with Eating Disorders

Understanding the risk of adverse outcomes in children to mothers with AN and to identify factors mediating these risks are of importance to provide sufficient resources and to identify potential key preventive interventions. There are indications of an increased risk of various adverse health outcomes among children to mothers with AN. A recent systematic review has compiled existing studies on maternal eating disorder and childhood development. Children to mothers with AN seem to have a higher degree of early developmental difficulties, including motor and cognitive development, compared with children to mothers without eating disorder. In contrast, studies on later cognitive development have indicated higher IQ and better working memory capacity in children to mothers with AN. Moreover, studies have shown that children to mothers with AN have an increased risk of emotional difficulties already visible at an early age (3.5 years). Likewise, maternal AN predicts emotional and anxiety disorders in children between 7 and 13 years of age (Martini et al. 2020). A recent large population-based cohort study reported that maternal AN was associated with an increased risk of offspring neuropsychiatric diseases, which could not be explained by coexisting parental comorbidities (Mantel et al. 2022). The mechanism behind the impact of maternal AN on childhood development has been suggested to consist of a complex interplay between genetic and environmental factors.

One study has investigated the impact of maternal AN on childhood respiratory morbidity and found that maternal AN is associated with an increased risk of early childhood wheezing (Popovic et al. 2018).

Additional studies on long-term consequences on childhood health are lacking but warranted.

Management of Pregnant Women with Anorexia Nervosa

Given the complex interplay between AN and reproductive function, the influence of pregnancy on AN disease course, and vice versa the impact of AN on adverse pregnancy and perinatal outcomes, early identification of eating disorders in fertility planning and antenatal maternal health care is fundamental.

Among women with infertility planning to conceive with prevalent eating disorder, focusing on treatment of the eating disorder is essential due to the associated risks in pregnancy. Advice and education on the importance of an adequate weight and nutritional intake and well-being prior to attempting to conceive are recommended to increase the likelihood of conception and promote a healthy pregnancy (NICE 2020).

In many countries, a routine inquiry of ongoing and previous mental illness, including eating disorder, is recommended for all women enrolling in antenatal maternity health care. It is important to acknowledge that women with eating disorder may be reluctant to share their ongoing or previous eating disorder to health professionals. The stigma surrounding eating disorders and feelings of shame are patient-related factors known to impede health-seeking for eating disorders in general (Ali et al. 2017). Additionally, among health professionals in maternal health care, lacking of confidence, due to insufficient professional training, has been reported to hamper the identification of pregnant women with eating disorders (Bye et al. 2018). Keeping the many barriers for acknowledging pregnant women with eating disorders in mind, a focus on a non-judgmental and delicate inquiry when screening for eating disorders is important (Bye et al. 2018).

Women, who disclose an ongoing or previous eating disorder, should be regarded as a risk population during pregnancy and postpartum period and be offered intensified support throughout the pregnancy. An early pregnancy appointment with an obstetrician for assessment of the patient's physical and mental health is recommended. Depending on whether the eating disorder is ongoing or past, the co-occurrence of other psychiatric diseases, the severity of the disease, and the patient's individual need and wish, a tailored follow-up scheme should be developed. A low threshold for referral to specialized eating disorder unit (or perinatal specialist mental health service if not available) is preferable during the pregnancy and postnatal period. Referral to a curator or psychologist, specialized in management of eating disorders, is another alternative. In order to provide information on the importance of adequate nutrition and nutritional support, and pregnancy-adjusted exercise during pregnancy, referral to nutritionist and physiotherapist should also be considered. Intensified frequency of antenatal visits to midwife with a focus on continuity of care in order to facilitate identification of altered patient well-being throughout pregnancy is preferable. In agreement with the patient, frequent weight measurements are recommended in conjunction with the antenatal visits. Underweight patients (BMI <18.5) and patients with insufficient weight gain or patients with weight and shape change preoccupation are alarming signs of relapsing or uncontrolled disease and hence reasons for concern. Due to the association between AN and low fetal gestational weight, extra fetal growth scan is indicated, in particular among women with poor gestational weight gain (Fig. 4). Clearly, women with severe eating disorder presentation during pregnancy should be managed by a multidisciplinary team involving specialized obstetric, internal medicine, and psychiatric care.

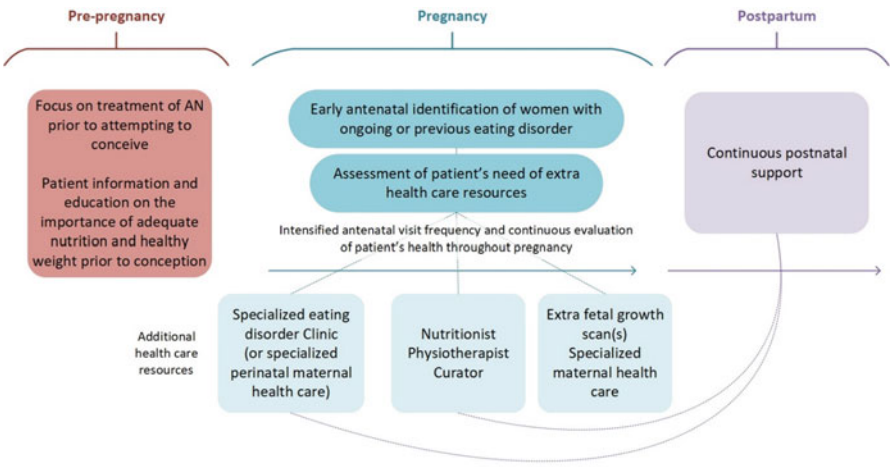

Fig. 4 Overview of clinical management of women with anorexia nervosa prior to pregnancy and during the pregnancy and postpartum period. AN, anorexia nervosa

In light of the increased risk of deteriorated eating disorder symptoms, disease relapse, depression, and anxiety and attachment difficulties postnatally, the intensified support should continue for up to 1 year postpartum (NICE 2020).

Applications to Other Eating Disorders

In this chapter, we have reviewed the impact of anorexia nervosa (AN) on fertility, pregnancy, postpartum period, as well as neonatal and child health. There is a separate chapter reviewing the impact of bulimia nervosa (BN) on fertility, pregnancy, postpartum period, and child health. In brief, the prevalence of amenorrhea and infertility among women with BN is higher compared with the general population but lower compared with women with AN. Periods of starvation in BN could induce functional hypothalamic amenorrhea by similar mechanism as among women with AN, but BN is additionally associated with polycystic ovary syndrome, which similarly is characterized by oligomenorrhea/amenorrhea and infertility. Women with BN are at an increased risk of several adverse pregnancy and perinatal outcomes but in general not to the same extent as women with AN. Moreover, there is evidence of separate distinct neurocognitive phenotypes in AN vs. BN, which is likely to partly explain some of the differences in childhood developmental outcomes. Hence, the information within this chapter can only partly be transferable to women with BN. Moreover, a majority of studies have focused on women with specific eating disorders such AN or BN, wherefore it is difficult to extrapolate results to women with unspecified eating disorders. There are, however, indications of similar rates of adverse pregnancy and perinatal outcomes among women with unspecified eating disorder as women with AN.

Mini-Dictionary of Terms

- **Apgar score** is a structured evaluation of the health of the newborn according to five criteria (tone, pulse, grimace, appearance, and respiration) at 1, 5, and 10 min after birth.

Key Facts

Key Facts of Amenorrhea in Anorexia Nervosa

- Amenorrhea is a cardinal feature in women with anorexia nervosa and is commonlycaused by functional hypothalamic amenorrhea (FHA).
- In FHA, stress and energy deficit induces an aberration in the hormonal regulation of the menstrual cycle, by interfering with the release of regulating hormones from the hypothalamus and pituitary, leading to amenorrhea and consequently infertility.
- First-line treatment of FHA consists of treating underlying eating disorder and restoring the energy balance, which normalized the menstruation and restores fertility.

Key Facts of Pregnancy and Perinatal Outcomes in Women with Anorexia Nervosa

- Women with anorexia nervosa might experience improved or deteriorated eating disorder symptoms throughout pregnancy.
- Anemia, hyperemesis, and antepartum hemorrhage are more common among pregnant women with anorexia nervosa compared with healthy pregnant women.
- Pregnant women with anorexia nervosa are at an increased risk of preterm delivery.
- Neonates born to mothers with anorexia nervosa have lower Apgar score and lower birthweight and more often require intubation and admission to neonatal intensive care units.

Key Facts of Management of Pregnant Women with Anorexia Nervosa

- Among pregnant women, the prevalence of ongoing, recent, or previous anorexia nervosa should be identified and acknowledged early in antenatal screening.
- Given the association between anorexia nervosa and increased risk of adverse pregnancy, neonatal, postpartum, and child outcomes, pregnant women with anorexia nervosa should be considered a high-risk population.

- Individually tailored follow-up schemes for pregnant women with ongoing or previous anorexia nervosa are recommended and may include psychologist or psychiatrist contact, nutritional support, and intensified antenatal visit frequency follow-up, including extra growth ultrasound in the third trimester and earlier postpartum follow-up.

Summary Points

- Amenorrhea is a cardinal feature of anorexia nervosa (AN) and commonly attributed to functional hypothalamic amenorrhea (FHA).
- FHA is diagnosed by careful endocrine evaluation in order to rule out other causes of menstrual dysfunction.
- First-line treatment of FHA consists of restoring energy balance, leading to normalized menstruation and fertility.
- Some women with AN experience improvement of eating disorder symptoms during pregnancy, whereas others experience deterioration of eating disorder symptoms throughout the pregnancy.
- Pregnant women with anorexia nervosa are at an increased risk of several pregnancy complications, including anemia, hyperemesis, antepartum hemorrhage, and acute liver failure.
- Maternal anorexia nervosa is associated with adverse perinatal outcomes, including preterm delivery, delivering small-for-gestational-age or low birthweight neonate.
- Neonates born to mothers with anorexia nervosa have lower Apgar scores at birth and are at an increased risk of being intubated or admitted to neonatal intensive care units.
- Depressive and anxiety symptoms are more common among women with anorexia nervosa in the postpartum period.
- Feeding difficulties are more common in children to mothers with anorexia nervosa, and they have lower weight-for-length growth during the first year of life.
- Children to mothers with anorexia nervosa are at an increased risk of impaired neuropsychiatric and cognitive development and more likely to seek health care for childhood wheezing.
- Pregnant women with recent or previous anorexia nervosa should be recognized as a high-risk population in antenatal screening and offered intensified support and extra health-care resources throughout pregnancy and postpartum period.

Contents

Abstract

Inpatient treatment for Anorexia Nervosa (AN) is the most intensive level of care, often aimed at emergency renutrition. As per international guidelines, vital signs alterations, psychiatric symptoms, Body Mass Index (BMI) thresholds

(extreme when <15 kg/m^2), and severe rate of weight loss (>1 kg/week) should all be used as indicators of severity when considering hospitalization. Hospital care must be multidisciplinary and integrated, and caregivers should be involved in the treatment decision whenever possible. Weight gain (0.5–1.4 kg/week) aiming at weight restoration is the main goal of nutritional rehabilitation and is achieved mainly through oral diet, nutritional supplements, and tube feeding, alone or combined. Caloric prescriptions (starting from 5–20 kcal/kg and increasing every 2–4 days) must be balanced to avoid both refeeding and underfeeding syndromes. Psychological treatments during hospitalization are useful in sustaining weight recovery, and clinicians should value therapeutic alliance and interventions fostering patient motivation. The use of psychoactive drugs can be useful in treating psychiatric comorbidities, however not in pursuing weight gain. Clinicians should be aware that rehospitalization is common, mostly due to symptoms' persistence after discharge. On this line, inpatient and outpatient services should collaborate to promote continuity of care.

Introduction

Although outpatient care is recommended for most patients with EDs, individuals with anorexia nervosa (AN) can require hospital treatment during the course of the illness due to the sometimes rapid worsening of their medical and psychopathological conditions. Quite often, acute hospitalization is needed for reverting severe weight loss and accompanying complications that are no more manageable in the outpatient setting, since renutrition requires specialized care when malnutrition is established. On this line, current evidence agrees on the centrality of weight gain in allowing good treatment outcomes, and in recent years several authors have argued that clinicians should not be overcautious in caloric prescription when closely monitoring the clinical conditions of malnourished patients. It should be borne in mind that patient's motivation to treatment is key to obtaining and maintaining clinical results, and psychological interventions provided in the inpatient setting should foster the patient's will to change.

The present chapter moves from presenting the conditions requiring hospital admission, to describing current refeeding practices and the other components of the integrated treatment provided in inpatient units. Inpatient treatment outcomes are then discussed as well as the factors both related to the patient and to the service organization that are currently recognized as pivotal in enabling longer-term recovery beyond medical stabilization.

Hospitalization Criteria

Inpatient treatment is the most intensive level of care and is usually reserved for those patients who are medically unstable or who fail to benefit from outpatient care (National Institute for Health and Care Excellence (NICE) 2017). International guidelines (listed in Table 1) depict the situations in which hospitalization is most appropriate; however, no stringent criteria are available and clinical expertise is often of great use. Table 2 presents a summary of clinical severity signs and criteria for hospitalization. The decision is also influenced by contingent factors such as the type of treatment facilities available in the region (Royal College of Psychiatrists 2014).

Hospital admission becomes necessary when there are vital signs alterations that can become life-threatening (such as bradycardia below 40 bpm, severe hypotension, hypothermia). Even though body mass index (BMI) <15 kg/m^2 in adults and $<70\%$ mBMI (median BMI) in children and adolescents are used to define the extreme level of malnourishment (American Psychiatric Association 2013), BMI alone should not be used as an indicator of severity in deciding for the hospital admission. For instance, a rate of weight loss exceeding 1 kg/week may warrant hospitalization even at non-extreme BMI, while some patients with a severe enduring course of illness can be safely managed at the outpatient level even at very low BMI (Robinson and Jones 2018). The clinician evaluating the patient's risk and need for hospitalization should carefully assess psychiatric symptoms, both about eating pathology (e.g., frequency of binge purging behaviors, time spent doing compulsive exercise) as well as to non-eating psychopathology (e.g., acute suicidality, self-harm ideation). Resort to compulsory admission for patients with AN is debated in the literature (Elzakkers et al. 2014) and differently regulated based on country legislation; however, involuntary hospitalization needs to be considered when patients with AN refuse treatment while being in life-threatening conditions that can only be managed in the inpatient setting (Atti et al. 2021).

Besides emergency medical and psychiatric care, inpatient treatment in the specialized eating disorders units provide a structured environment that can foster treatment adherence when it becomes difficult for the patient to follow treatment plan at the outpatient level. As stated by NICE guidelines, following admission, inpatient and outpatient services should collaborate in the care management. Whenever possible,

Table 1 Main guidelines with recommendations regarding inpatient treatment for AN

Guideline	Year of publication
National Institute for Health and Clinical Excellence (NICE)	2017
MARSIPAN: Management of Really Sick Patients with Anorexia Nervosa	2014
Royal Australian and New Zealand College of Psychiatrists clinical practice (RANZCP) guidelines for the treatment of eating disorders 2014	2014
Junior MARSIPAN: Management of Really Sick Patients under 18 with Anorexia Nervosa	2012
American Psychiatric Association (APA)	2006

Table 2 AN risk assessment and signs warranting inpatient treatment

Area of assessment	Indices of severity	Comment
BMI (kg/m^2)	Medium risk 13–15 High risk <13	Do not use only BMI thresholds but consider also if the rate of weight loss can be safely managed in a day patient service
Weight loss	Rate of weight loss of more than 1 kg a week	
Blood tests	Hypokalemia: high risk <3.0 mmol/l	Consider vomiting or laxative abuse, especially in case of hypochloremic metabolic alkalosis or metabolic acidosis
	Hyponatremia: high risk <130 mmol/l	Can be due to severe malnutrition, water loading, diuretics abuse, inappropriate antidiuretic hormone secretion associated to occult infection
	Hypoglycemia: blood glucose <3 mmol/l	Especially severe if symptomatic. With low albumin or raised C-reactive protein can be associated with occult infection
	Raised creatinine or urea	Impairment in glomerular filtration rate increases the risks of refeeding syndrome. Reduced protein intake and low muscle mass can however hinder detection of this alterations
	Raised transaminases	Common in severe AN, probably due to hepatocellular autophagy
ECG	Bradycardia Prolonged QTc interval (>450 ms) Hypokalemia-induced alterations T-wave changes	Can lead to atrial and ventricular arrythmias
Physical examination	Low pulse (< 40 beats per minute) Blood pressure < 90/60 mmHg Low body temperature (<35°C) Reduced muscle strength	Due to autonomic nervous systems alteration Severe if associated with postural symptoms
Mental state examination	Suicide ideation Serious comorbid psychiatric illness	In case of acute mental health risk, consider psychiatric crisis or psychiatric inpatient care

Freely modified from NICE and MARSIPAN guidelines

carers should be included in the decision process and kept informed on the treatment plan (National Institute for Health and Care Excellence (NICE) 2017).

Integrated Treatment

It is well established that the treatment of AN requires a multidisciplinary team in which specific professional figures collaborate on the different aspects of the pathology while keeping in sight the individuality of each patient. Even though

the team's composition can differ between centers, specialized eating disorders units generally comprise psychiatrists, dieticians, nurses, clinical psychologists, and internal medicine physicians among others (Braude et al. 2020). It is advised that local protocols are developed and that the professionals meet regularly to discuss advances in the treatment plan and recalibrate the care provided according to the patient's need (Hay et al. 2014). Furthermore, the care of patients with AN is often emotionally demanding and team meetings and supervision are important moments to share difficulties and shortcomings in the therapeutic relationships with patients.

Tenets of inpatient treatment are nutritional rehabilitation and medical management, as well as the delivery of psychological interventions (Cuerda et al. 2019). Psychotropic drugs are often used to treat psychiatric comorbidities. The main aims of the treatment usually are to ameliorate clinical life-threatening conditions, restore weight, foster patient's motivation to engage in subsequent treatment steps, work with the patient to understand and modify their altered cognitions, and the factors that maintain the disorder and lead to its exacerbation (Marzola et al. 2021b). The treating team should be prepared to manage the commonly encountered behavioral problems that can hinder treatment during the inpatient stay.

Nutritional Rehabilitation

The core component of the treatment of inpatients with AN is refeeding with the goal of weight restoration. Weight gain during hospitalization is of pivotal importance for AN recovery and is associated with positive post-discharge outcomes (Baran et al. 1995; Lock and Litt 2003; Lund et al. 2009).

Notwithstanding the centrality of renutrition, current refeeding practices are still based mainly on clinical expertise rather than on randomized control trials (Hale and Logomarsino 2019; Chatelet et al. 2020), resulting in variability among treatment protocols. An important factor in this variability is the need for obtaining an adequate rate of weight gain while at the same time avoiding the refeeding syndrome (RS), which could entail severe and potentially fatal medical complications (Garber et al. 2016). On the other side, the so-called "underfeeding syndrome" (Royal College of Psychiatrists 2014), which coincides with sub-optimal weight gain during hospitalization is also growing in consideration (Cuntz et al. 2021). Table 3 displays the main clinical findings in RS and the measure to put in place to prevent its development. More detailed recommendations on RS prevention and treatment can be found in the recently published consensus paper by the American Society for Parenteral and Enteral Nutrition (da Silva et al. 2020).

According to guidelines, a rate of weight gain of 0.5–1.4 kg/week is considered appropriate in balancing clinical benefits against the risk of RS in hospitalized patients (Yager et al. 2010; Bargiacchi et al. 2019). Regarding caloric prescription, it is currently debated in the literature whether more aggressive procedures ("start higher, advance faster") should be preferred over cautious approaches ("start low and go slow") (Cuerda et al. 2019). Generally, slower rates of refeeding are favored for severely malnourished patients with extreme BMI, even though some groups

Table 3 Characteristics of refeeding syndrome

Biochemical characteristics	Potential clinical consequences	How to prevent it
Hypophosphatemia Hypomagnesemia Hypokalemia Glucose intolerance Sodium retention/fluid overload Thiamine deficiency Hematologic signs: hemolysis, anemia, thrombocytopenia, leukocyte dysfunction, uremia	**Cardiac**: arrhythmias, contraction changes, congestive heart failure **Neurological**: delirium, ataxia, seizures, paresthesias, skeletal-muscle weakness, Wernicke's encephalopathy, coma **Pulmonary**: dyspnea, respiratory failure, pulmonary edema **Gastrointestinal**: Nausea, vomiting, diarrhea or constipation **Others**: Peripheral edema, hypotension, shock, metabolic acidosis	Determine levels of phosphorus, magnesium, potassium, and calcium before initiation of renutrition, every day for the rest of the week and every other day in subsequent weeks Replete low electrolytes (P, K, Mg) Supplement thiamine Gradually increase calories every 1–2 days. In patient at high risk for RS and low levels of electrolyte, consider holding increase of calories until electrolytes are supplemented Monitor ECG and vital signs

advocate for a faster rate of refeeding under close medical surveillance, adequate supplementation, and rapid treatment of complications even for these patients (Cuntz et al. 2021). A recent systematic review (Garber et al. 2016) reached the following evidence-based conclusions on refeeding practices:

- Lower-calorie refeeding is too conservative for mild and moderately malnourished patients (i.e., respectively with 80–90% and 70–79% mBMI according to CDC data).
- Higher calorie refeeding is not associated with increased risk for refeeding syndrome under close medical monitoring with electrolyte correction.
- There is insufficient evidence to change the current standard of care for refeeding in severely malnourished inpatients (i.e., BMI <15 in adults or mBMI <70% in adolescents).
- Total parenteral nutrition is not recommended unless no other form of refeeding is possible.
- Meals and liquid formulas with nutrient compositions within recommended ranges are appropriate for refeeding.
- The impact of approaches to refeeding on long-term outcomes is unknown.

Refeeding Process

Oral diet is the first option for refeeding. Even though some authors advocate for standardization over personalization of caloric prescription (Haynos et al. 2016), in most cases is advisable for each patient to receive a personalized dietary plan which

should take into account the patient's nutritional requirements and be structured following a healthy diet model (Cuerda et al. 2019).

Caloric Prescription

As mentioned above, starting caloric prescription varies among centers and countries (e.g., varying from 1200 kcal/day in the United States to as low as 200 kcal/day in some centers in Europe) (Garber et al. 2016). NICE and MARSIPAN guidelines suggest a range between 5 and 20 kcal/kg at the beginning of treatment. Despite differences in starting prescriptions, the caloric intake needs to be increased gradually over time to sustain weight gain. Indeed, it should be considered that individuals with AN appear to be in a hypermetabolic state during renutrition (Marzola et al. 2013), and require a higher amount of calories compared to healthy individuals to gain 1 kg/week in the refeeding process (Mehler et al. 2010; Gentile 2012). Furthermore, some authors suggested in the past that patients with restricting AN need more calories than patients with binge-purging AN (Kaye et al. 1986). Rather obviously, the number of excess calories needed for weight gain can greatly vary based on the amount of physical exercise that the patient engages in. During refeeding, weight should be monitored with appropriate frequency (e.g., weekly) since daily fluctuations are not necessarily representative of weight gain over time. Table 4 presents theoretical values needed for weight maintenance and weight gain in a 30 kg woman.

Nutrient Quality and Nutrient Supplementation

Little is still known regarding whether specific food products are to be preferred in replenishing essential nutrients (Marzola et al. 2013), and there is no evidence in the literature indicating specific diet type requirement (e.g., diet enriched in polyunsaturated fatty acids or deprived in sodium) (Cuerda et al. 2019).

Oral nutritional supplements (medical foods) are usually introduced when the patient cannot eat enough food to meet caloric prescription but can also be utilized to provide an adequate amount of vitamins and minerals (Marzola et al. 2013). Moreover, since gastric emptying of solid but not of liquid content tends to be delayed in AN (Zipfel et al. 2006), liquid meals can result in more tolerability to patients with AN. On the same line, energy-dense supplements can potentially entail less abdominal bloating compared to regular food, which is relevant since patients with AN often report unpleasant gastroenteric sensations as limiting factors in feeding

Table 4 Example of theorical formula for caloric prescription in a 30 kg woman

Calories needed for weight maintenance	Calories needed for weight gain	
900 kcal/day[a]	+ 500 kcal/day	+ 200–400 kcal/day every 2–4 days

[a] International guidelines suggest starting caloric prescription around 5–20 kcal/kg a day in case of malnourishment

(Kessler et al. 2020). Interestingly, in a study comparing the administration of the same volume of liquid nutritional supplements and fruit juice, patients with AN reported comparable hedonic evaluation for the two conditions, suggesting that liquid supplements could be useful in providing significant energy intake with reduced volumes of food (Marzola et al. 2020a).

Nasogastric Feeding and Parenteral Nutrition

For severely malnourished patients who refuse to eat, a nasogastric tube can be adopted to administer specific formulas. An infusion pump helps in formula delivery allowing for a progressive increase in the rate of administration and avoiding manipulation from the patient. Some authors note that, even if historically the precocious use of tube feeding in the nutritional treatment of AN has been associated with an increased sense of lack of personal control (Hebert and Weingarten 1991; Rizzo et al. 2019), there are studies that show that this treatment modality can be accepted and even recognized as helpful by patients (Halse et al. 2005). A recent systematic review on the subject (Rizzo et al. 2019) analyzed ten studies on nasogastric nutrition in AN and found that this treatment was well tolerated and produced an average weight gain exceeding 1 kg/week without an increase in adverse effects in comparison to enteral nutrition.

Other modalities of renutrition, like parenteral nutrition and percutaneous endoscopic gastrostomy, are used much less frequently (Cuerda et al. 2019), requiring even more specialized care than the other modalities and, for parenteral nutrition, being associated with potentially more severe complications than oral and tube feeding.

Psychological Treatment

Different psychological therapies that were originally developed for the outpatient setting have been adapted to the hospital context (Hay 2020). For children and adolescents, family-based treatment remains the gold standard also when patients are hospitalized (Halvorsen and Rø 2019). For adults, Cognitive Behavioral Therapy is the most recent iteration for EDs, Enhanced Cognitive Behavioral Therapy is currently used in the inpatient setting with good outcomes (Dalle Grave et al. 2016). Other types of manualized psychotherapies are heterogeneously applied in different centers. All these treatments, however, share the psychoeducation and support to the nutritional rehabilitation provided in the inpatient setting.

Different novel treatments are currently under study. For instance, initial studies evaluated interventions focused on emotional difficulties with promising results (Money et al. 2011; Preis et al. 2020). Cognitive remediation therapy (CRT) aims to improve cognitive flexibility and can be seen as a form of treatment that enables further psychological work (Harrison et al. 2018). Studies on inpatients have been

conducted; however, the results appear to be inconsistent (Zuchova et al. 2013; Giombini et al. 2021).

Psychopharmacological Treatment

No medication is approved for AN treatment. Psychopharmacological agents are generally regarded as useful in the treatment of psychiatric comorbidities of AN (preferably after weight restoration); however, clinicians also often use them "off-label" to target symptoms of depression, anxiety, or hyperactivity in the course of weight restoration. There are very few studies conducted on the subject, and the evidence is still mixed. For instance, a 2015 study on the combined use of atypical antipsychotic agents and antidepressants in inpatients with AN found encouraging results regarding the use of aripiprazole in the reduction of eating-related preoccupations and rituals (Marzola et al. 2015). However, a recent metanalysis with a total sample of 99 patients with AN who received pharmacological treatment concluded that there is currently no evidence to support its use neither to treat AN-specific psychopathology nor to pursue weight gain (Cassioli et al. 2020). Furthermore, the scarcity of pharmacological trials in AN should warrant caution when prescribing psychopharmacological agents to severely emaciated inpatients. For instance, a Japanese case report described the onset of extreme hypoglycemia in a woman with AN short after the beginning of the treatment with olanzapine (Haruta et al. 2014).

Behavioral Management

AN being an ego-syntonic disorder, even when hospitalization is accepted by the patient, often treatment sabotaging and behavioral problems occur requiring careful monitoring and management by the hospital team. MARSIPAN guidelines describe the commonly encountered problems in a ward dedicated to AN, which include, but are not limited to, drinking water to falsify weight measurement, emptying nasogastric feed container and hiding food, vomiting in the toilet, wearing little clothing to induce shivering, engaging in excessive walking, or even trying to escape from the ward. As in other psychiatric disorders, also a more common way of self-harm should be assessed, and measures should be put in place to prevent them. The management of these problems is not trivial since they directly impact the clinical treatment, challenge the therapeutic relationship with the patients, and may disrupt the cohesion of the treating staff.

To deal with these problems, often a "contract" is individually agreed with the patient at the beginning of the treatment, specifying treatment goals and modalities and usually involving the patient's family in the discussion (Strik Lievers et al. 2009). Furthermore, specific rules are applied in the specialized eating disorder ward (e.g., locking toilets for some time after meals). Advancement in treatment should be periodically monitored in the staff meeting. Recently, some studies have evaluated

the integration of treatment aiming specifically at the reduction of compulsive exercise into CBT and showed promising results during inpatient treatment and after discharge (Dittmer et al. 2020).

Motivation to Treatment

Motivation to change is increasingly recognized as crucial in the treatment of AN. The transtheoretical model provides a framework for the assessment of motivation in AN, and motivational interviewing techniques are utilized to foster a patient's will to change (Dray and Wade 2012; Mander et al. 2013).

This translates into the importance of planning hospitalization with the patient when it is needed, ideally as a moment in the integrated care that is actively sought and recognized as useful by the patient. Indeed, per international guidelines, inpatient treatment should be considered before the occurrence of serious medical complications; however, in many cases, patients with AN reach clinical attention only when seriously ill and severely malnourished, therefore requiring urgent hospitalization (Fassino and Abbate-Daga 2013).

Kawai and collaborators (2014) compared treatment outcome and psychopathological scores in patients with AN who were urgently hospitalized to patients who underwent a planned inpatient treatment, finding that the first group had a poorer outcome and still after 2 years showed significantly low BMI and poor psychosocial functioning.

Different studies have shown motivational stages to predict inpatient treatment outcome, and motivation to change has been retrospectively pinpointed by remitted patients who underwent hospitalization as a key factor in their recovery (Long et al. 2012). Interestingly, studies like the one by Mander and collaborators show that the stage of contemplation significantly predicts therapeutic alliance in adult inpatients (Mander et al. 2013). Therefore, even though the directionality of this association is not clear, the therapeutic alliance should be highly valued in the course of inpatient treatment (Marzola et al. 2019).

Treatment Outcomes

Renutrition

Outcomes of refeeding programs are first of all weight gain, degree of medical complications, and mortality. The efficacy of inpatient treatment on weight gain is well established (Schlegl et al. 2014) and weight gain during treatment has emerged as a predictor of medium and long-term recovery (Lock et al. 2013). Indeed, some analyses evidence that the greater the weight gained during hospitalization, the better the outcome after discharge. This sometimes leads to longer hospitalization time, especially in the case of patients starting from extreme BMI (Guinhut et al. 2021). Even in centers that predominantly treat extreme cases, the mean length of stay

greatly varies, for example, ranging from 36 (Guinhut et al. 2021) to 72 (Chatelet et al. 2020), and up to 150 days (Born et al. 2015). In the studies reviewed by Cuerda et al. (2019), BMI increased from 1 to 6 points during hospitalization. Regarding medical complications, the incidence of hypophosphatemia has been reported to vary from 0 to 40%; the degree of malnutrition, rather than the rate of refeeding, seems to be a better predictor of the occurrence of this alteration (Garber et al. 2016). Vital signs have different times needed for renormalization, for example, heart rate reverts to normal range faster than others such as hypotension (Garber et al. 2016). The recent review by Cass and collaborators (2020) analyzes in more detail the rate and management of medical complications in the hospital setting.

Even though AN is recognized to be the psychiatric disorder with the highest mortality, studies conducted in specialized eating disorder units underreport mortality rates (Cuerda et al. 2019). It is to be noted however that mortality in intensive care units can be as high as 10%. A nationwide retrospective study conducted in Japan found male sex, age at first hospital admission, the ratio of actual weight to ideal body weight, psychiatric comorbidities, hypotension, and being treated in non-university hospitals as greater predictors of in-hospital mortality (Edakubo and Fushimi 2020).

Psychopathology

Besides weight gain, several studies report amelioration of eating psychopathology during inpatient treatment (Calugi et al. 2018; Waples et al. 2021; Marzola et al. 2021b). However, it is noteworthy that most patients still show clinical range values in eating disorders measures when discharged from inpatient treatment (Goddard et al. 2013), and even in the longer run (Eielsen et al. 2021). To deepen the understanding of psychopathological factors that influence hospitalization outcomes, the role of nonspecific ED psychopathology and its connections to core AN symptoms are increasingly studied also in the inpatient setting (Martini et al. 2021). For instance, Olatunji and collaborators (2018) have shown that the most relevant symptoms at admission to inpatient treatment were interoceptive awareness and feeling of ineffectiveness, while body dissatisfaction and drive for thinness were less central to the network of psychopathological symptoms. In the same sample, ineffectiveness at admission predicted discharge BMI and depression.

Comorbidity with depressive and anxiety disorders is relevant in the scope of inpatient treatment. A recent study (Panero et al. 2021) comparing AN inpatients with and without major depressive disorder highlighted that even though both groups were similar in terms of clinical severity and eating psychopathology at admission, the diagnosis of depressive disorder impacted hospitalization length and response to treatment (i.e., being associated with a lower increase in caloric intake and lower BMI at discharge in comparison to patients without major depression). Inpatient treatment has shown effective in improving body shape concerns despite baseline clinical severity (Marzola et al. 2020b).

Quality of Life

Quality of life measured with an instrument such as the EuroQol in patients with AN at admission to inpatient treatment is comparable with or even worse than that of other debilitating psychiatric and medical diseases, even in the light of a purported poor perception of psychosomatic distress, which poses some challenges in the comparison between ED inpatients and outpatients (Baiano et al. 2014). Nevertheless, hospitalization can result in improvement in both physical (i.e., mobility, pain) and psychological (i.e., anxiety, depression) dimensions (Abbate-Daga et al. 2014). These changes can set the stage for durable results in the outpatient setting. Therapeutic alliance during hospitalization has been shown to correlate to quality-of-life improvement upon discharge (Marzola et al. 2019). Patients with AN (both restrictive and binge-purging phenotypes) can establish acceptable levels of the therapeutic alliance (Marzola et al. 2019). It should be borne in mind, that this remains true even for a patient with a severe and enduring form of the disorder, who can benefit from inpatient treatment like patients with more recent disease onset (Marzola et al. 2021b).

Rehospitalization

Many patients with AN undergo more than one single hospitalization in the course of their illness, and some of them enter a cycle of frequent admission to inpatient treatment which has been indicated as "revolving door" (Marzola et al. 2021a). The determinants of these patterns are to be sought first of all in the high relapse rate, between 30 and 50% for adult patients in the European context (Bryan et al. 2021), which Treasure and collaborators (2021) motivate with the fact that most patients remain symptomatic when discharged from intensive care. Furthermore, it is now established that BMI at discharge is the strongest predictor of readmission in adult AN (el Ghoch et al. 2016). Low BMI at discharge, besides being associated with more severe psychopathology in the year after inpatient treatment, also correlates with an increased rate of hospitalization (Baran et al. 1995; Lund et al. 2009).

A recent analysis on the predictors of rehospitalization in a cohort of extremely severe inpatients confirmed improvement in BMI during the first admission to predict time to readmission (Marzola et al. 2021a). Furthermore, this study found drive for thinness as measured by the Eating Disorders Inventory 2 (EDI-2) to predict early readmission even controlling for all the other clinical and comorbidity-related conditions taken into consideration. The authors argue that if high levels of drive for thinness are still present at discharge, even the BMI improvement achieved during the inpatient treatment could not be sufficient to prevent further hospitalizations.

In children and adolescents, 1-year rehospitalization rate is recognized to be around 20% (Peebles et al. 2017), and an RCT found no difference in rehospitalization rate in adolescent patients treated with family-based therapy

when the first hospitalization was either aimed at medical stabilization (i.e., relatively short) or weight restoration (i.e., longer duration) (Madden et al. 2015).

Discharge and Follow-up

As per NICE guidelines, the care plan developed for each patient should specify how the patient will be discharged and reenter community-based care. In comparison to other medical illnesses, this transition is so much important for AN due to the clinical level of symptomatology still displayed after intensive treatment. Indeed, the goal of inpatient treatment is not to replace outpatient care but rather to make it possible (Giel et al. 2021). Unfortunately, the end of inpatient treatment still too often coincides with discontinuity of care. Very recently, prominent authors in the field of EDs have stressed the importance of favoring the transition from inpatient to outpatient services to provide continuity of care (Treasure et al. 2021). Psychological interventions to support this transition are under study (Treasure et al. 2021). A recent review on the subject found a small trend for better weight maintenance in patients allocated at the time of discharge to intervention adopting guided self-help and social support through the involvement of carers (Bryan et al. 2021), even though these interventions did not seem to improve eating and mood symptomatology.

Applications to Other Eating Disorders

Due to the complications associated with low weight and malnourishment described in this chapter, Anorexia Nervosa is the diagnosis most commonly encountered in inpatients units. However, also patients with other EDs can require acute hospitalization, due to medical and psychiatric emergency conditions. For instance, patients with Bulimia Nervosa (BN) and frequent compensatory episodes can encounter severe electrolytes alterations requiring urgent correction, and hospitalization can serve to break the binge/purge cycle (Atti et al. 2021). Furthermore, regarding urgent psychiatric symptoms, a recent retrospective study analyzing data from hospital admission over a 10-year time span in patients with an ED diagnosis found that among patients diagnosed with AN, BN, or Eating Disorder Otherwise Specified (EDNOS) 331 (6.7% of the total sample) required hospitalization due to a suicide attempt (Cliffe et al. 2020). Some authors report that BN can be treated in the inpatient setting with good outcomes and without engendering excessive weight gain (Hessler et al. 2018). Avoidant Restrictive Food Intake Disorder (ARFID) most often affects young patients and can be associated with weight loss and malnutrition which sometimes are not different from those encountered in patients with Anorexia Nervosa (Brigham et al. 2018). Patients with ARFID can be more compliant to nutritional modalities such as tube feeding also in the outpatient setting; however, sometimes hospitalization is required for medical stabilization and to provide a safe setting to reintroduce feared foods (Brigham et al. 2018).

Mini Dictionary of Terms

Caloric prescription: The amount of energy from food established for individual's requirements during refeeding, commonly expressed in kilocalories per day (kcal/day)

Refeeding: The process of reintroducing nutrition in malnourished individuals

Refeeding syndrome: A severe medical condition associated to shift in electrolytes that can occur during too rapid renutrition of severely malnourished individuals

Nasogastric feeding: A modality of renutrition that involves the positioning of a tube through the nose to reach the stomach allowing for controlled delivery of liquid food

Medical foods: Specific formulations of nutrients used in clinical settings

Summary Points

- Inpatient treatment is the most intensive level of care for AN, often aimed at emergency renutrition.
- Vital signs alterations, psychiatric symptoms, Body Mass Index thresholds (<15 kg/m^2 extreme), and rate of weight loss >1 kg/week should all be used as indicators of severity.
- Hospital care must be multidisciplinary and integrated.
- Weight gain (0.5–1.4 kg/week) aiming at weight restoration is the main goal of nutritional rehabilitation.
- Caloric prescriptions (starting from 5–20 kcal/kg and increasing every 2–4 days) must be balanced to avoid both refeeding and underfeeding syndromes.
- Oral diet, nutritional supplements, and tube feeding, alone or combined, are the main modalities of refeeding.
- Psychological treatments are useful in sustaining weight recovery; motivation to treatment and therapeutic alliance during hospitalization are predictors of good outcomes.
- Psychopharmacological treatment can be useful in treating psychiatric comorbidities, not to achieving weight gain.
- Rehospitalization is common due to symptoms' persistence.
- Discharge from inpatient treatment should be planned to favor the transition to outpatient services.
- Caregivers should receive information and participate in the decision regarding treatment whenever possible.

Anorexia Nervosa and Comorbidities

33

Linking Autism

Antonia Parmeggiani and Jacopo Pruccoli

Contents

Abstract

Anorexia Nervosa (AN) and Autism Spectrum Disorder (ASD) are two mental health conditions sharing a series of clinical features. Epidemiological studies have documented that subjects with AN may present ASD and ASD traits more frequently than the general population. Specific studies have discussed the use of psychodiagnostics tools to investigate ASD traits in individuals with AN. Recent

research has reported common neuropsychological (i.e., deficits in "Theory of Mind") and psychopathological (i.e., alexithymia) traits between the two conditions. Finally, ASD traits may impact the interventions to treat AN. This chapter examines the recent literature reporting on the link between AN and ASD, and discusses the implications of this link for the development of new screening and treatment protocols.

Introduction

Feeding and Eating Disorders

Eating behavior represents a fundamental regulating factor in normal childhood development. The achievement of adequate eating functions relies on the proper integration of a range of physical and psychological competencies. While transitory feeding problems in infancy are common and considered paraphysiological, 1–5% of infants develop severe feeding and eating disorders (Rybak 2015). A peak in incidence regarding specific eating disorders (ED) is evident in late childhood and especially teenage years (Jagielska and Kacperska 2017). The conceptualization and increased incidence of ED in the past decade have called for standardized research on the topic and the development of specific treatment programs. According to the

Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) (APA 2013) Feeding and ED are classified as: Pica, Rumination Disorder, avoidant/restrictive food intake disorder (ARFID), Anorexia Nervosa, Bulimia Nervosa, and Binge-Eating Disorder, Other Specified Feeding or ED, and Unspecified Feeding or ED. Current understanding suggests that both genetic and environmental factors are involved, but the biological mechanisms underlying ED are still not understood compared with other psychiatric disorders. An extensive co-occurrence of other psychiatric disorders is often observed in all ED, which intersect with weight and appetite regulation.

Anorexia Nervosa

Among ED, Anorexia Nervosa (AN) represents one of the most challenging conditions for clinicians and health policymakers worldwide. According to the DSM-5 (APA 2013), AN is defined by A) a restricted-energy intake, resulting in significantly low body weight for the individual's age, gender, development, and medical health; B) intense fear of gaining weight, or behaviors precluding weight gain, despite a significantly low weight; C) a disturbed experience of body weight or shape, and/or an excessive influence of body weight/shape on self-evaluation, or an insufficient recognition of low body weight. The prevalence of AN has been estimated to be as high as 1.4% in women and 0.2% in men in a systematic literature review (Galmiche et al. 2019).

Mental Health Comorbidities in Individuals with AN

A considerable lifetime prevalence of psychiatric comorbidities has been documented among individuals with AN, ranging from 45% to 97% (Herpertz-Dahlmann 2015). Specifically, researchers have documented relevant comorbidity between AN and mood disorders, anxiety disorders, obsessive-compulsive disorder (OCD), and personality disorders (Herpertz-Dahlmann 2015; Mairs and Nicholls 2016). These associations may be due to the specific neurodevelopmental features of the individuals with AN, since they may present a familial liability (transmitted propensity) for generalized anxiety, OCD, separation anxiety disorder, social phobia, panic disorder, and obsessive-compulsive personality disorder (Strober et al. 2007). In addition to the reported evidence of comorbidity between AN and psychopathological conditions, researchers have documented a specific link between AN and neurodevelopmental disorders (NDD).

NDD are a group of mental health conditions affecting the nervous system during early development. These disorders may involve different brain functions, manifest themselves clinically during childhood, and affect the personal, social, academic and occupational life of an individual (Thapar and Rutter 2015). Unlike the frequently remitting and relapsing course of many psychiatric conditions, the core symptoms of NDD are usually stable across the life of an individual, despite undergoing

Table 1 Neurodevelopmental disorders according to DSM-5 criteria

Group	Conditions
Intellectual disability	Intellectual Disability, Global Developmental Delay, Unspecified Intellectual Disability
Communication disorders	Language Disorder, Speech Sound Disorder, Social (Pragmatic) Communication Disorder, Childhood-Onset Fluency Disorder (Stuttering), Unspecified Communication Disorder
Autism spectrum disorder	Autism Spectrum Disorder

Specific learning disorder	Specific Learning Disorder
Motor disorders	Developmental Coordination Disorder, Stereotypic Movement Disorder, Tic Disorders, Other Specified Tic Disorder, Unspecified Tic Disorder
Other neurodevelopmental disorders	Other Specified Neurodevelopmental Disorder, Unspecified Neurodevelopmental Disorder

continuous modifications at different developmental stages (Thapar et al. 2017). The DSM-5 recognizes seven groups of NDD, namely Intellectual Disability, Communication Disorders, Autism Spectrum Disorder (ASD), Attention-Deficit/Hyperactivity Disorder (ADHD), Specific Learning Disorders, Motor Disorders, Other NDD (APA 2013). Among those conditions, ASD seems to be associated with AN through major direct and indirect developmental, neuropsychological, and psychopathological links. The NDD recognized by the DSM-5 are reported in Table 1.

Autism Spectrum Disorder

The core features of ASD are represented by A) persistent deficits in social communication and social interaction; B) restricted, repetitive patterns of behavior, interests, or activities; C) symptoms must be present in the early developmental period (but may not become fully manifested until social demands exceed limited capacities, or may be masked by learned strategies in later life); D) symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning (APA 2013). Patients with ASD usually show deficits in nonverbal communication, social reciprocity, and skills in developing, maintaining, and understanding relationships (Chiang and Carter 2008). Restrictive and repetitive behaviors and interests (RRB) constitute a further key clinical feature of ASD, pertaining to the field of neuropsychology and requiring the diagnosis and treatment of affected individuals (Lanzarini et al. 2021). These behaviors may include stereotyped or repetitive motor movements and use of objects or speech; insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behaviors; highly restricted interests, with abnormal intensity or focus; excessive or reduced reactivity to sensory input or unusual interest in sensory elements (APA 2013). The severity of ASD is

recorded as the level of support needed for each of the two reported major psychopathological domains (D'Cruz et al. 2013).

The reported prevalence of ASD in the USA is 24.7 every 1000 children (age 3–17 years) with a reported gender ratio of 3 males to 1 female (Xu et al. 2018). More recent data published by the Center for Disease Control and Prevention (CDC) in the United States indicate a prevalence of 18.5 per 1.000 (one in 54) children aged 8 years (Maenner et al. 2020). The reported male to female ratio does not appear to be constant among different research studies. Classic studies indicate a gender ratio of 2 males to 1 female (Baron-Cohen et al. 2011; Lai et al. 2014). The previously cited CDC data report a diagnosis of ASD 4.3 times more prevalent among boys than among girls (Maenner et al. 2020). It is likely that females affected by ASD with normal high intelligence quotient (IQ) are more difficult to diagnose; biological, psychopathological, and diagnostic factors have been accounted for these gender differences (Baron-Cohen et al. 2011). Moreover, researchers have documented relevant comorbidities between ASD and other mental health conditions such as anxiety disorders (Simonoff et al. 2008) and ADHD (Taurines et al. 2012).

Problematic feeding behaviors have been documented to have a high prevalence in children with ASD, ranging from 46% to 89% (Ledford and Gast 2006, Parmeggiani 2014; Parmeggiani and Pruccoli 2022). The most frequently reported feeding issue is food selectivity, affecting nearly 70% of individuals with ASD. With regard to feeding disorders, the literature has documented a possible comorbidity between ARFID and ASD. It has also been recognized that the differential diagnosis may at times be difficult when considering ARFID and Pervasive Refusal Syndrome (Perrone et al. 2020). Although ARFID and Pervasive Refusal Syndrome are not connected with body weight or shape, recent research has specifically documented a comorbidity between ASD and AN (Adamson et al. 2020).

This chapter will focus on the neuropsychological, clinical, and treatment connections between AN and ASD.

AN and ASD

General Considerations

Gillberg and colleagues were the first to hypothesize the possible existence of an association between AN and ASD (Gillberg 1983). In a seminal clinical study that the group subsequently conducted, the documented prevalence of ASD and autistic traits in a population of adolescents affected by AN was 15% (Gillberg and Rastam 1992). Following this research, different authors have proposed new models to explain the documented clinical associations between AN and ASD. Some have formulated the possibility that undiagnosed ASD females with a high IQ could develop an ED during their lives, manifesting clear ED symptoms which, however, would conceal neurodevelopmental and communicative altered traits (Head et al. 2014; Lai et al. 2014). Others have suggested that occurrences of malnutrition in individuals with AN may induce specific psychopathological features, including

mental rigidity, obsessive behaviors, and RRB; these features resemble core ASD symptoms, but would improve upon restoration of a normal nutritional status (Mandy and Tchanturia 2015). In recent years, consideration of AN and ASD common neuropsychological features has led researchers to examine potential links existing between these conditions in the fields of psychology and psychiatry (Westwood and Tchanturia 2017).

Epidemiology

Little literature exists concerning the epidemiology of individuals with ASD and AN, and the data available is extremely variable. Possible reasons for this variability include inhomogeneous patient samples, evolving diagnostic criteria for the two conditions, and different diagnostic tools to investigate ASD traits in individuals with AN. Huke et al. (2013) have published a systematic review and metanalysis of the prevalence of ASD among individuals with AN. The authors found an average prevalence of 22.9%, but stressed that most of the included studies were conducted by a single research group on the same sample (Huke et al. 2013). These findings have been partially confirmed by more recent reviews (westwood and tchanturia 2017; Nickel et al. 2019). A relevant nationwide study on this topic was conducted by Kock and colleagues in Denmark (Koch et al. 2015). This research documented that individuals with AN present an increased risk of comorbid ASD; moreover, an increased risk for ASD was also documented in individuals with a family history for AN. It should be pointed out that, in this study, individuals with a diagnosis or a family history of any other psychiatric condition showed an increased risk for AN (Koch et al. 2015). The prevalence of ASD traits in individuals with AN, as detected by the autism quotient (AQ) questionnaire (Baron-Cohen et al. 2001) was compared to healthy controls was assessed by a metanalysis of Westwood et al. (2016). The authors documented individuals with AN, who presented higher AQ scores than healthy controls, even though the mean scores did not reach the cutoff values suitable for a diagnosis of ASD. All the reviews consulted for this article appear to agree on a higher prevalence of ASD traits in individuals with AN than in the general population.

Psychodiagnostics

Among the diagnostic instruments to assess ASD traits in individuals with AN which have been reported in literature, we have considered for this study: a) the Autism spectrum Quotient (AQ) (Baron-Cohen et al. 2001), b) the Autism Diagnostic Observation Schedule-2nd Edition (ADOS-2) (Lord et al. 2012), c) the Adult Autism Subthreshold Spectrum (AdAS) (Dell'Osso et al. 2017), and d) the 3-developmental, dimensional and diagnostic interview short version (3di-sv) (Santosh et al. 2009). The AQ is a test exploring five different domains: social skills, attention shifting, attention to detail, communication, and imagination. The AdAS is

a questionnaire tailored to investigate subthreshold ASD in adults. This test shows high internal consistency, and test-retest reliability and strong convergent validity with alternative dimensional measures of ASD (Dell'Osso et al. 2017). The AQ and the AdAS scores of patients affected by AN are significantly more elevated compared to those of control groups, even when they do not reach the threshold for diagnosis of autistic traits (Westwood et al. 2016; Dell'Osso et al. 2018). The 3di represents an accurate tool to assess, in dimensional terms, ASD symptoms in both clinical and nonclinical individuals (Skuse et al. 2004). The ADOS-2 is a key diagnostic tool for the recognition of individuals with ASD (National Institute for Health and Clinical Excellence 2011). Module 4 of the ADOS-2 investigates adolescents and adults with no language impairment by examining language and communication, reciprocal social interaction, imagination, creativity, stereotyped behavior, and restricted interests. The scores obtained in the language and communication and reciprocal social interaction domains produce a final score, possibly leading to a diagnosis of "Autism," "Autistic Spectrum" or "Non-Spectrum" (Lord et al. 2012). In a study by Westwood et al. (2018) 3di-sv, clinical observation and ADOS-2 were used to investigate ASD traits in AN individuals. In 51.2% of the enrolled patients over-threshold ADOS-2 scores were documented, while only 10.0% of them could be clinically diagnosed with ASD. Nevertheless, this result is significantly higher than data referring to the general population (Westwood et al. 2018). (Sedgewick and colleagues 2019a) show that the recently revised ADOS-2 diagnostic algorithm for adults permits to identify ASD cases above the cutoff value established in the previous edition. This result was confirmed in both individuals with active AN and in individuals who have recovered from AN, which suggests that ASD traits are more highly represented in AN, independent of the effect of malnutrition (Sedgewick et al. 2019a).

As for the studies conducted on pediatric samples, a research by Postorino et al. (2017) compared individuals with severe AN (age range 10–17 years) to ASD and healthy controls. The enrolled individuals were tested using ADOS-2 and AQ. In the AN sample, only three individuals (10%) obtained a score above thresholds for ASD. AQ scores did not significantly differ between individuals with AN and controls. However, AN individuals presented obsessive-compulsive, theory of mind and affect recognition scores similar to those obtained by members of the ASD group (Postorino et al. 2017). In a recent study, our group investigated possible associations among ED psychopathology, ASD traits and body-mass index (BMI) in a sample of young individuals with AN, using the EDI-3 (Eating Disorder Inventory-3) test and gold-standard tests for ASD. Twenty-three inpatients were enrolled. ASD traits were assessed administering ADOS-2 and AQ, investigating both present and past autistic traits using different versions of AQ. We found a high frequency of ASD traits in young inpatients with AN. These traits were significantly correlated to four specific EDI-3 subscales and independent of BMI (Pruccoli et al. 2021a). An example of the existing psychodiagnostic tools used to assess ASD traits in individuals with AN is reported in Table 2. Figure 1 reports the potential diagnostic issues in detecting comorbidities between ASD and AN.

Table 2 An example of psychodiagnostic tools used to assess ASD traits in individuals with AN

Psychodiagnostic tools	Description
Autism spectrum Quotient (AQ) (Baron-Cohen et al. 2001)	Questionnaire exploring social skills, attention shifting, attention to detail, communication, and imagination
Adult Autism Subthreshold Spectrum (AdAS) (Dell'Osso et al. 2017)	Questionnaire exploring ASD-related domains: childhood/adolescence, verbal communication, nonverbal communication, empathy, inflexibility and adherence to routine, restricted interests and rumination, hyper-hypo reactivity to sensory input
Autism Diagnostic Observation Schedule-2nd Edition (ADOS-2) (Lord et al. 2012)	Direct observation, assessing the domains of language and communication, reciprocal social interaction, imagination, creativity, stereotyped behavior, and restricted interests
3-developmental, dimensional and diagnostic interview short version (3di-sv) (Santosh et al. 2009)	Parental interview, assessing the domains of reciprocal social interaction, communication, and repetitive and stereotyped behavior

Abbreviations: ASD: Autism Spectrum Disorder

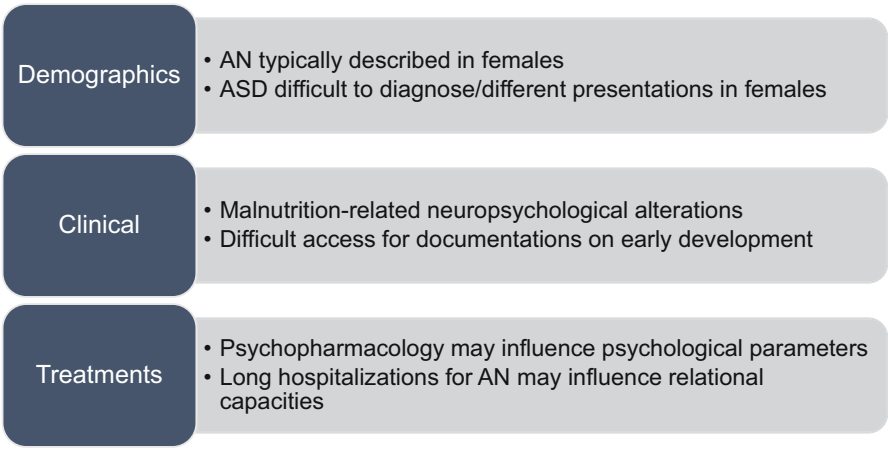

Fig. 1 Potential diagnostic issues in detecting ASD traits in AN individuals. (Abbreviations: AN: Anorexia Nervosa; ASD: Autism Spectrum Disorder)

Clinical Traits and Theories

A series of clinical traits have been documented in individuals with AN and ASD. Alexithymia is defined as a marked impairment in emotional awareness, social attachment, and interpersonal relating. Westwood and colleagues (2017a) have reported that individuals with ASD may present alexithymia in 33–66% of the cases, while this condition can be documented with a prevalence of 74–83% in patients with AN. Empathy and empathy-related measures in subjects with ED may present profiles comparable to individuals with ASD (Kerr-Gaffney et al. 2019). Similarities between ASD and AN were identified for measures related to the theory

Table 3 Main neuropsychological domains linking Anorexia Nervosa and Autism Spectrum Disorder

Domain	Description	Considerations
Alexithymia	Impairment in emotional awareness, social attachment, and interpersonal relating	Documented in 33–66% of subjects with ASD and 74–83% patients with AN.
Theory of Mind (TOM)	Ability to understand the mental states of others	Both individuals with ASD and AN have widely shown poor performances in TOM
Set-shifting	Capacity to change and adapt current thoughts of actions to meet environmental demands	Impaired set shifting in patients with ASD; compromised set shifting after childhood in individuals with ED

Abbreviations: AN: Anorexia Nervosa; ASD: Autism Spectrum Disorder; ED: Eating Disorders; TOM: Theory of Mind

of mind (TOM). TOM represents the ability to understand the mental states of other individuals (Baron-Cohen et al. 1985). Poor performances have been widely documented both in cases with AN and in cases with ASD, while emotional theory of mind seems to be more significantly compromised in individuals with ASD than in those with AN, as documented by a recent metanalytic review (Leppanen et al. 2018). Set shifting, defined as the ability to change and adapt current thoughts of actions to meet environmental demands, has been compared between cases affected by ASD and ED by Westwood et al. (2016). The authors found impaired set shifting in ASD patients, while those affected by ED showed normal set-shifting profiles during childhood but a compromised ability later in their lives (Westwood et al. 2016). Moreover, AN patients with over-threshold ADOS-2 scores may present a significant impairment in set shifting (Westwood et al. 2017b). Other authors, who have used the AQ questionnaire, report nonsignificant differences concerning set shifting between AN subjects with and without ASD features (Sedgewick et al. 2019b). Table 3 reports the main neuropsychological domains linking AN and ASD.

Treatments and Outcomes

AN has the highest mortality rate among mental health conditions (Smink et al. 2012). Clinical interventions typically aim to restore body weight and address social and emotional issues preventing recovery (Treasure and Schmidt 2013). Family-based treatment represents the mainstay of the treatment of children and adolescents with AN in a series of different settings. As for psychopharmacological interventions, selective serotonin reuptake inhibitors and atypical antipsychotics have been widely used in the management of patients with AN. However, medications should not be prescribed as the sole treatment for AN (NICE 2017). Contradictory evidence is available concerning the possible impact of ASD traits on the treatment and outcomes of AN. Individuals with ED and overlapping ASD traits may experience a greater impairment of cognitive flexibility, ritualistic behaviors, mood disorders, and social impairment, but these features do not seem to directly correlate with malnutrition or BMI (Nielsen et al. 2015; Stewart et al. 2017; Tchanturia et al. 2019).

In a recent study, we directly assessed the impact of ASD traits on the treatment of a group of adolescents with AN. Enrolled patients were assessed with ADOS-2 and AQ tests, and outcomes were measured as changes in psychopathology and body weight. When compared to other patients, AN individuals with diagnostic scores for ASD showed overlapping types of treatments, as well as psychopathological and weight outcomes (Pruccoli et al. 2021b). Currently, no specific protocol addresses the management of individuals with AN and comorbid ASD, and new studies on this topic are needed by clinicians (Kinnaird et al. 2017; Kinnaird et al. 2019).

Conclusions

Psychiatric comorbidities are frequent in ED; they may be premorbid, comorbid, or even present after recovery. Thus, the assessment of individuals with ED requires a thorough psychiatric history, and psychodiagnostic testing to define a psychological profile. Obtaining this information is key to programming early interventions in developmental age. AN is a severe ED with many complications and a high mortality. According to an epidemiologic survey (2018–2020) conducted by the Italian Ministry of Health, a 30% increase in the mortality rate for individuals with AN was observed following the COVID-19 pandemic. A considerable lifetime prevalence of psychiatric comorbidities has been documented among individuals with AN; a particularly interesting yet potentially undetectable case is the comorbidity of AN with ASD when considering females with a normal IQ. Patients with comorbid AN and ASD may present specific neuropsychological and clinical features. Clinical evolution of patients with AN, who have not been properly diagnosed with ASD traits, could affect a clinical improvement or facilitate the emergence of other psychopathologies. In the literature, current studies have failed to clearly identify the specific interventions needed to address this particular population. A special effort should be made to deal with the specific diagnostic challenges in order to properly identify ASD traits in girls with AN, given the relevant differences in the clinical expression of ASD between males and females. We believe further research should systematically investigate the biological and hormonal factors that may distinguish this clinical population, in order to propose new interventions and establish new health policy protocols.

Applications to Other Eating Disorders

In this chapter, we have reviewed the available evidence on the links between Anorexia Nervosa (AN) and Autism Spectrum Disorder (ASD), documenting a number of relevant links between these two conditions. However, ASD and ASD traits may also impact other Eating Disorders (ED). Numata and colleagues have evaluated a group of patients with different ED for the presence of ASD traits (Numata et al. 2021). Individuals without self-induced vomiting presented more evident ASD traits than those with self-induced vomiting, while subjects with BED had the most evident ASD traits (Numata et al. 2021). Moreover, in a recent

study by Demartini and colleagues, individuals with ASD showed higher scores than neurotypical controls for the two scales that assessed eating disturbances (EAT-26 and SWEAA), with a higher frequency of both eating disturbances typical of ASDs and ED symptoms, such as a distortion of the body image, a tendency toward bulimic behaviors, and self-control of eating (Demartini et al. 2021). The recognition of this evidence may help researchers to expand the existing body of literature concerning the links between ASD and ED, and to systematically investigate the presence of disorders of eating behaviors and body image in individuals with ASD.

Mini Dictionary of Terms

- ***Autism Spectrum Disorder****: A condition characterized by an altered brain development, with resulting problems in relationship development and communication.*
- ***Alexithymia****: The inability to identify and describe one's feelings, and to distinguish emotional states from physiological perceptions.*
- ***Empathy****: The ability to understand the mood, behavior, and emotions of others.*
- ***Theory of mind****: The capacity to represent one's own and others' mental states.*
- ***Set shifting****: The ability to subconsciously shift attention between different tasks.*

Key Facts of Anorexia Nervosa and Comorbidities: Linking Autism

- The suggestion of a link between Anorexia Nervosa (AN) and Autism Spectrum Disorder (ASD) was first advanced by Gillberg in Gillberg 1983.
- The first systematic review and metanalysis of the prevalence of ASD among individuals with AN found an average prevalence of 22.9%.
- A series of psychodiagnostic tools have been used to identify ASD traits in individuals with AN.
- Alexithymia, defined as difficulty in identifying and describing one's feelings, has been documented in 33–66% of the individuals with ASD, and 74–83% of the patients with AN.
- Individuals with ED and overlapping ASD traits may exhibit greater impairment of cognitive flexibility, ritualistic behaviors, mood disorders, and social impairment.

Summary Points

- *Recent systematic reviews and metanalyses have documented that individuals with Anorexia Nervosa (AN) may present a comorbid Autism Spectrum Disorder (ASD) or ASD traits more frequently than the general population.*
- *The Autism spectrum Quotient (AQ), the Autism Diagnostic Observation Schedule-2nd Edition (ADOS-2), the Adult Autism Subthreshold Spectrum*

(AdAS), and the 3-developmental, dimensional, and diagnostic interview short version (3di-sv) have been used to assess ASD traits in individuals with AN.

- *Psychopathological features, such as alexithymia, have been reported with a high frequency both in individuals with ASD and AN.*
- *Neuropsychological impairments, such as deficits in the Theory of Mind, may link the development and persistence of both AN and ASD symptoms.*
- *No specific treatment protocols have been developed so far to address individuals with AN and comorbid ASD.*

Abstract

The electrocardiogram (ECG) provides important information regarding the heart rate and heart rhythm in patients with anorexia nervosa (AN). Up to one third of deaths in AN are due to cardiac causes, with a subset of those due to arrhythmia. The ECG is an inexpensive, minimally invasive, and widely accessible screening tool to assess the heart's electrical activity. Bradycardia occurs widely in AN, with severity correlating to degree of malnutrition and/or low BMI, attributed to impaired autonomic regulation. Changes in the QT interval and other repolarization parameters are less ubiquitous in patients with AN, and their prognostic and therapeutic implications are less clear. However, a growing field of research supports serial ECG monitoring, especially in acutely unwell patients with AN, for both risk assessment and to monitor regression to normal with treatment.

Keywords

Eating disorders · Anorexia nervosa · Electrocardiogram · Heart rhythm · Arrhythmia · Bradycardia · Heart rate variability · QT interval · T-wave · Sudden unexpected death

Abbreviations

AN	Anorexia nervosa
BN	Bulimia nervosa
BPM	Beats per minute
ECG	Electrocardiogram
HR	Heart rate
HRV	Heart rate variability
QTc	Corrected QT interval
SSRI	Selective serotonin reuptake inhibitor
SUD	Sudden unexpected death

Introduction

Background

Anorexia nervosa (AN) is a complex eating disorder that has the highest mortality of all psychiatric disorders (Arcelus et al. 2011). Up to one third of deaths are due to cardiac manifestations of disease; as such, identifying at-risk patients prior to adverse events is of great importance (Papadopoulos et al. 2009). The most harrowing of these cardiac deaths are sudden unexpected deaths (SUD), which are

precipitated by sudden-onset arrhythmia. In other cardiac conditions, clinical warning signs of arrhythmia and SUD have been identified and are an important risk-assessment and prognostic tool. These warning signs include symptoms such as syncope (fainting) and palpitations or changes seen on cardiac testing of the heart rhythm. While SUD secondary to arrhythmia represents a subset of cardiac deaths, and therefore a fraction of all-cause mortality in AN, arrhythmias remain an important area of clinical concern.

Principles from other known causes of SUD, such as inherited arrhythmia conditions, have helped inform how best to screen and identify patients with AN who may be at risk for arrhythmia and SUD. A mainstay of cardiac screening is the electrocardiogram (ECG), a widely used, quick, and cost-effective test which can provide detailed information regarding the heart rate (HR) and heart rhythm. The utility of the ECG in the setting of AN will be explored in this chapter.

Heart Rate and Heart Rhythm

Each heartbeat is initiated by an electrical signal that travels through the heart to create coordinated, effective muscle contractions which are related to two clinically important variables: heart rate (HR) and heart rhythm. HR is measured as the number of heartbeats per minute (bpm), while heart rhythm is the origin and nature of the cardiac impulse that subsequently leads to electrical and mechanical activation across the heart. Both parameters are measured on the electrocardiogram (ECG).

Both heart rate and heart rhythm are dependent on intracellular and extracellular electrolyte gradients and as such are sensitive to changes in body electrolyte levels. Serum electrolyte imbalances are almost universally observed in AN, including hypokalemia, hyponatremia, hypocalcaemia, and hypomagnesemia (Abed et al. 2014). These imbalances are seen in most subtypes of AN, with both starvation and purging behaviors impacting serum electrolyte levels. As such, deranged serum electrolytes can impact the ECG in ways which will be explored throughout this chapter. Clinical evaluation of serum electrolytes is also indicated during AN treatment, as the nutritional changes associated with refeeding syndrome can increase the risk of cardiac arrhythmia (Hofer et al. 2014; Boateng et al. 2010; Abed et al. 2014). HR is also tightly regulated by the autonomic nervous system, wherein parasympathetic stimulation slows HR. While most studies conclude that parasympathetic predominance is observed in AN, this finding has not been completely reproducible, nor has an ideal measure of autonomic nervous system activity been identified (Mazurak et al. 2011; Jenkins et al. 2021; Farasat et al. 2020).

The Electrocardiogram

The electrocardiogram (ECG) measures the electrical signal of the heart through the placement of skin electrodes. The electrical impulses are then transcribed and recorded to produce the 12-lead ECG (Fig. 1). The ECG recording provides both

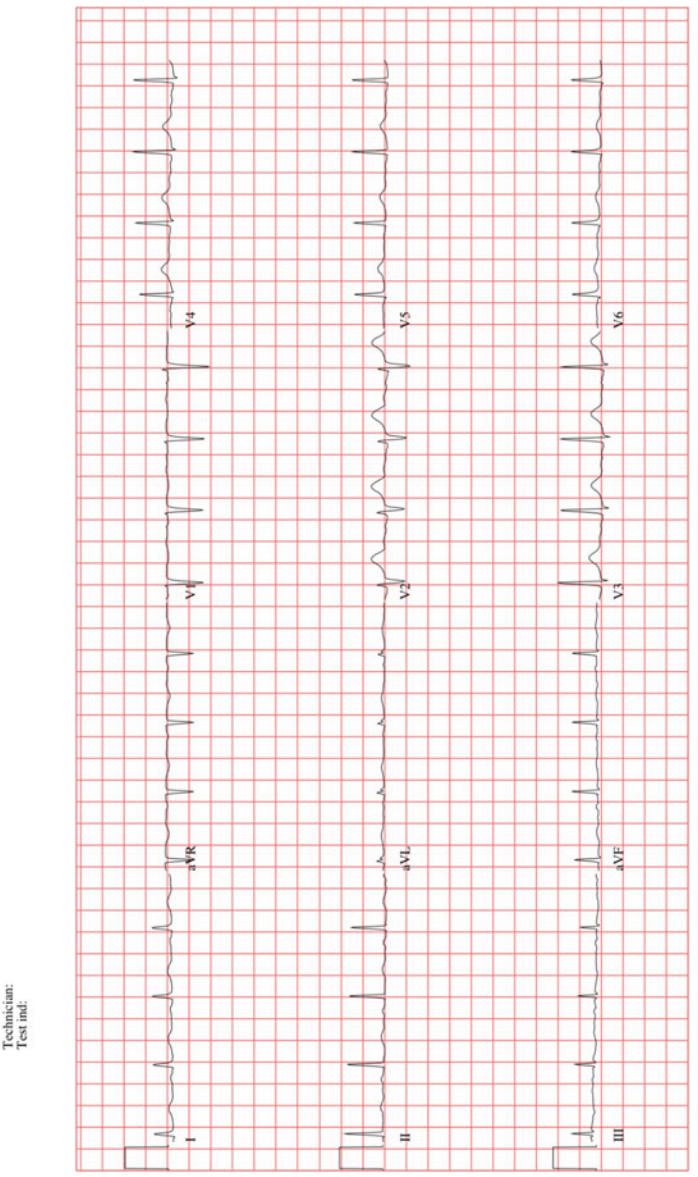

Fig. 1 A normal ECG including computer-generated parameters and interpretation

Table 1 Normal electrocardiogram values

Parameter	Normal range and units	Notes
RR interval	0.6–1.2 s	Heart rate is calculated as 1/(RR/60) [normal value 60–100 bpm]
PR interval	0.12–0.20 s	
QRS duration	0.06–0.10 s	
ST segment	0.08 s	Normally on the isoelectric line
QTc interval	Lower limit: 350 ms Borderline: 450–470 ms (male) 460–480 ms (female) Prolonged: >470 ms (male) >480 ms (female)	The absolute QT interval is corrected for heart rate (QTc)

spatial and temporal information, as waves are plotted with time (seconds) on the x-axis and amplitude (millivolts) on the y-axis. Each waveform corresponds to a specific portion of the cardiac cycle with clinically accepted normal values (Table 1). Of note, the QT interval represents the entire cycle of ventricular depolarization and repolarization and is used clinically to assess ventricular abnormalities as explored below. This "raw" QT interval is also adjusted to a baseline HR of 60 bpm to calculate the corrected QT (QTc) interval. As HR increases, the duration of each cardiac cycle shortens, and the raw QT interval decreases. By adjusting the QT interval for HR (i.e., the QTc interval or value), clinicians are able to accurately compare QTc intervals both within and between patients.

Typical ECG reports include automated measurements of common parameters, such as HR, QRS duration, and QT interval. Algorithms are relatively accurate for most measurements except the QT interval. This is particularly the case when the T-wave has abnormal shape, making it more difficult to measure, which is often the case in AN (Janzen et al. 2019). As such, manual measurement of the QT interval is encouraged to ensure accurate values.

The ECG is an inexpensive, noninvasive, and widely accessible screening tool used to assess for and risk-stratify a multitude of cardiac abnormalities. Specifically, its utility in AN is becoming increasingly better understood as research progresses, with particular interest in the HR and QTc interval.

The Electrocardiogram in Anorexia Nervosa

As AN is a complex and multifactorial disease, clinical presentation and systemic manifestations can vary widely. The underlying etiologies of the binge/purge compared to restrictive subtypes of AN result in drastically different biochemical profiles. Further, refeeding and psychopharmacotherapy can impact the ECG and play a dynamic role in AN treatment and remission. This results in heterogeneity of the ECG, perhaps with the exception of bradycardia (Garber et al. 2021). Nevertheless, the ECG provides important insight into the cardiac status of patients and is commonly used in the clinical setting, especially as part of inpatient care.

The ECG can also be used to identify at-risk markers for SUD. The most widely used is prolongation of the corrected QT (QTc) interval (Table 1). The implication of QTc interval prolongation in SUD in AN was first described in a case report published in 1985, which prompted a flurry of research and clinical interest (Isner et al. 1985). Since this report, many studies have analyzed the QT interval in AN, but a consensus has not been reached regarding resting QT interval prolongation or a definitive link to the increased risk of SUD (Janzen et al. 2018). The most recent evidence does not support a clear link between widespread QTc prolongation and risk of SUD in the AN population. The utility of the QT interval in AN is an incompletely understood, yet important, topic and will be explored in depth later in this chapter.

Specific ECG changes have not been identified globally in the AN population aside from bradycardia, but the ECG remains an important mainstay of care. As this chapter will explore, a myriad of factors may affect the ECG and become important on a patient-level basis.

The ECG in Anorexia Nervosa

Specific ECG parameters of interest include bradycardia, heart rate (HR) variability, and the QTc interval. The ECG can be highly variable, and special considerations in monitoring should be taken in the settings of refeeding, exercise, and psychopharmacotherapy.

Bradycardia

Bradycardia is a slowed heart rate, with definitions varying slightly from HR $<$60 bpm or $<$50 bpm. It is the most consistent ECG change seen in patients with AN, with HR $<$50 bpm reported in up to 80% of acutely unwell patients and likely to be seen in those with more extensive weight loss (Garber et al. 2021; Yahalom et al. 2013; Sachs et al. 2016; Assalone et al. 2021). Figure 2 shows an example of an ECG with sinus (regular) bradycardia. The mechanism underlying this reduction in HR is incompletely understood and likely multifactorial with disease, environmental, and genetic contributors. However, a relatively well-supported overarching hypothesis of the underlying cause of bradycardia in AN is dysregulation of autonomic tone with parasympathetic dominance (Jenkins et al. 2021). Importantly, autonomic dysregulation has not been shown to account for all HR changes, suggesting other, minor factors are at play (Buchhorn et al. 2021). The degree of AN exacerbation, as measured by low BMI, correlates with more extensive bradycardia, supporting the notion that the underlying mechanisms are in part a reflection of the systemic severity of AN. Further, compulsive exercise may be a manifestation of anorexia nervosa. As athletes are known to have a slower resting HR, this may predispose some patients with AN to exhibiting more profound bradycardia. Similarly, genetic

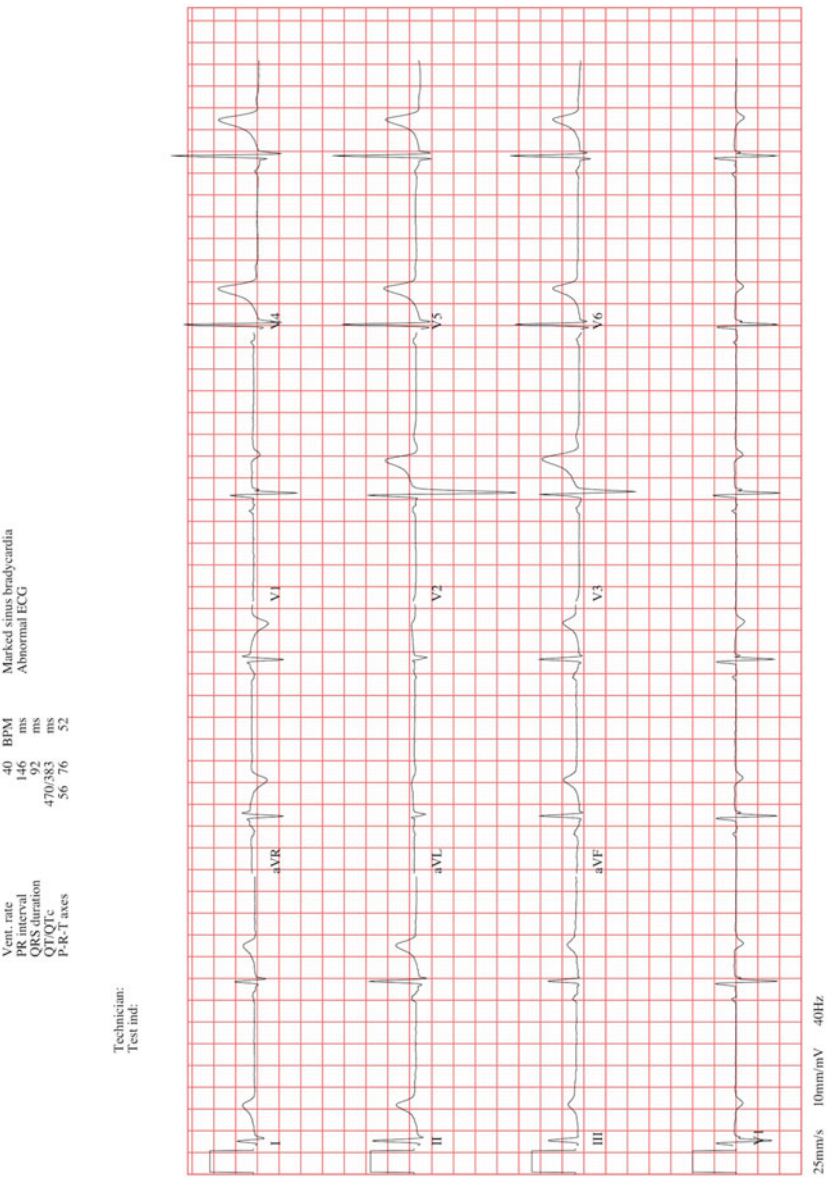

Fig. 2 An ECG showing sinus bradycardia including computer-generated parameters and interpretation

variants likely play a role in nonneural bradycardia in AN, although this is a new area of research awaiting robust studies (Buchhorn et al. 2021).

Although there are no current national guidelines for admission to hospital, physician surveys suggest that most centers implement a bradycardic threshold of HR ≤40–45 bpm to prompt admission (van Son et al. 2014; Schwartz et al. 2008). Local jurisdictions and care centers often follow admission criteria based on clinical experience in the absence of formal evidence-based guidelines. For example, in British Columbia, Canada, emergency room guidelines for admission of adults with AN are risk-stratified by BMI with specific advice regarding prolonged QTc interval and T-wave inversion or flattening on ECG. Similarly, local pediatric guidelines indicate to consider admission for patients with HR <45 bpm, QTc interval < 450 ms, or any heart rhythm disturbance. The complete clinical picture should be taken into account when considering hospital admission for treatment for acute AN, but in the absence of other factors, profound bradycardia is a reasonable indication for admission. Patients with HR <50 bpm should also be placed on a cardiac monitor where available. Heart rates have been reported as slow as 30 bpm on admission, although restoration to normal (60–100 bpm) is often seen with even modest weight gain in the early refeeding period (Farasat et al. 2020; Assalone et al. 2021; Jenkins et al. 2021). As such, the return of HR to normal range is often used as a marker of clinical recovery and stability. Although related to more severe AN, the evidence does not suggest that bradycardia is an independent predictor of death or adverse outcomes in this population (Edakubo and Fushimi 2020). Of note, while periodic heart rate surveillance during admission is effective in monitoring the progression and normalization of bradycardia, cardiac monitoring, including ECG, is not regularly performed.

Heart Rate Variability

With the reproducibility of bradycardia in AN, researchers sought to quantify and better understand the contribution of the autonomic nervous system. HR variability (HRV) is the beat-to-beat variability in HR measured over 24-hour continuous monitoring. Increased HRV reflects parasympathetic nervous system predominance as demonstrated in the general population (Draghici and Taylor 2016). In theory, parasympathetic-mediated bradycardia would also be reflected as increased HRV which may provide further information regarding the underlying systemic changes seen in AN. However, increased HRV has not been consistently reported in AN, suggesting parasympathetic predominance is not the only factor responsible for bradycardia in patients with AN (Mazurak et al. 2011). Sympathovagal balance may also play a role, wherein decreased sympathetic tone synergistically potentiates the impact of increased parasympathetic tone on bradycardia. Reduced sympathetic tone may be a form of evolutionary conservation. Further, even if HRV is only present in a subset of patients with AN, its clinical utility is not clear (Peyser et al. 2021). HRV is cumbersome to record and is not widely used as a clinical tool in the care of patients with AN.

QTc Interval

The QT interval is a measurement of ventricular depolarization and repolarization and is highly dependent on HR. As HR increases, repolarization time and the absolute QT interval decrease to allow effective propagation of the next heartbeat. To adjust for HR changes and create normalized QT interval values, various formulae to calculate the corrected QT (QTc) interval have been developed (also called the QTc value by some). Bazett's formula is by far the most widely used of these formulae ($QTc = QT/\sqrt{RR}$). Most ECG programs utilize a computer algorithm to measure the absolute QT interval, which is then mathematically converted to the QTc interval. However, these algorithms are not particularly accurate, especially in the context of concurrent ECG abnormalities; as such, QT interval measurements should be validated by trained personnel.

The QTc interval has been a point of interest on the ECG of patients with AN since 1985, when Isner et al. recorded QTc interval prolongation in the days preceding the sudden unexpected death of three patients with AN (Isner et al. 1985). While QTc interval prolongation has been definitively linked to fatal arrhythmias in other populations, current evidence for its relevance in AN is inconsistent. While a 2008 meta-analysis reported QTc interval prolongation in patients with AN compared to healthy controls, the majority of subjects had QTc intervals within normal range (Lesinskiene et al. 2008). Conversely, an updated 2018 meta-analysis reported no significant difference between patients with AN and healthy controls but did find significant publication bias in the field (Janzen et al. 2018).

In the setting of bradycardia, Bazett's formula underestimates the QTc interval producing lower than accurate values (Johnson and Ackerman 2009). Given the high prevalence of bradycardia in AN, it was hypothesized that QTc intervals are lower than accurate values in this population, masking prolonged QTc intervals and arrhythmic risk. However, this was not seen in studies which used other QT interval correction formulae and reported no difference between the QTc intervals of AN patients and healthy controls (Janzen et al. 2019; Walter et al. 2015).

In cases where dramatic QTc interval prolongation at rest has been reported, multiple factors are often at play such as severe hypokalemia, extremely low BMI, and/or the presence of QT prolonging drugs (Sachs et al. 2016). However, the individual impact of each confounder is also inconsistent, suggesting perhaps a subset of patients with AN may be more susceptible to QTc interval prolongation than others.

Current evidence suggests the impact of AN on cardiac repolarization and the QTc interval is complex, multifactorial, and incompletely understood. Further, in the vast majority of studies, even if QTc intervals were significantly prolonged compared to healthy controls, mean values were within normal range, and thus any prolongation was likely of negligible clinical impact. It is possible with future research that the QTc interval will play a larger prognostic role in AN as a whole, but the specific subpopulations in which this may be a factor have not yet been identified. While it remains advised to perform ECG on patients with AN, current evidence suggests that the initial perceived clinical importance of the resting QTc interval in AN was overemphasized.

T-Wave Changes

The T-wave measures ventricular repolarization, and its morphology can relay important information regarding the underlying cardiac tissue. For example, in genetic forms of long QT syndrome, flat, notched, or otherwise abnormal T-waves are observed concurrently with or independently of prolonged QT intervals (Porta-Sánchez et al. 2017). Evaluation of the T-wave in patients with AN is an emerging field of research, but flattening of the T-wave appears to occur during both acute and weight-restored AN (Stahi et al. 2020; Janzen et al. 2019). The significance of this finding is uncertain but may play into the multifactorial hypothesis of cardiac risk in the AN population and as such remains a field of active research.

Special Circumstances

Impact of Refeeding

Prompt initiation of refeeding is a hallmark of treatment for acute exacerbations of AN. A sudden influx in caloric intake can result in abrupt changes in serum electrolytes, which as discussed play an important role in the heart rhythm. In a minority of cases, this sudden shift can lead to refeeding syndrome and increase the risk of arrhythmias (Giovinazzo et al. 2019). However, with careful medical monitoring and appropriate electrolyte adjustment, adverse outcomes can be avoided and are not increased with more aggressive refeeding protocols (Garber et al. 2016, 2021).

Importantly, refeeding most often reverses ECG abnormalities seen in acute AN exacerbations (Ulger et al. 2006). As discussed above, the underlying pathophysiology of such abnormalities is often not well understood, but the reproducible finding of normalization with weight gain suggests that low BMI plays an important role. Any risk associated with observed ECG abnormalities is also assumed to normalize with the ECG. From a clinical perspective, this further supports the incentive to pursue aggressive refeeding and treatment as both cardiac stabilization and medical stabilization are achievable.

The Electrocardiogram during Exercise

Many patients with AN have a complex relationship with exercise; this simultaneously supports the importance of understanding any ECG changes with exertion while complicating the ethical and practical aspects of clinical research. However, other conditions with ECG abnormalities, specifically QTc interval prolongation, show changes during exercise which can be imperative to quantifying the clinical risk of arrhythmia. Recent research has demonstrated impaired QTc interval dynamics during exercise in both adults and adolescents with AN (Padfield et al. 2016; Janzen et al. 2020). The repolarization reserve is a marker of the heart rhythm's

ability to appropriately respond to changes in HR; a reduction in reserve is observed in patients with AN and may correspond to an increased risk of arrhythmia at faster HR, in contrast to rest. This field of research is relatively new, and future studies will be important in better understanding the absolute risk conferred by impaired QT interval dynamics during exercise in this population. At present, exercise evaluation is not recommended in AN. Similarly, continuous cardiac monitoring (e.g., 24-hour Holter monitor) is utilized in other states with abnormal cardiac repolarization, but its clinical utility in AN is currently unclear.

Psychopharmacotherapy and the Electrocardiogram

Many patients with AN are concurrently prescribed psychopharmacotherapy such as selective serotonin reuptake inhibitors (SSRIs) and anxiolytic medications, even though evidence does not support their efficacy in treating AN (CROW 2019). Outside of AN, these drugs are well known to prolong the QT interval and predispose patients to ventricular arrhythmias. As such, the risk implications in patients with AN are of interest. Current evidence does not support a link between psychopharmacotherapy use and QT interval prolongation; however, observational studies are difficult given dose and agent alterations throughout treatment (Janzen et al. 2019). A convenient resource for clinicians to determine if drugs prolong the QT interval is available at www.QTDrugs.org, with a user-friendly smartphone app for both major platforms (CredibleMeds Mobile). Figure 3 outlines the

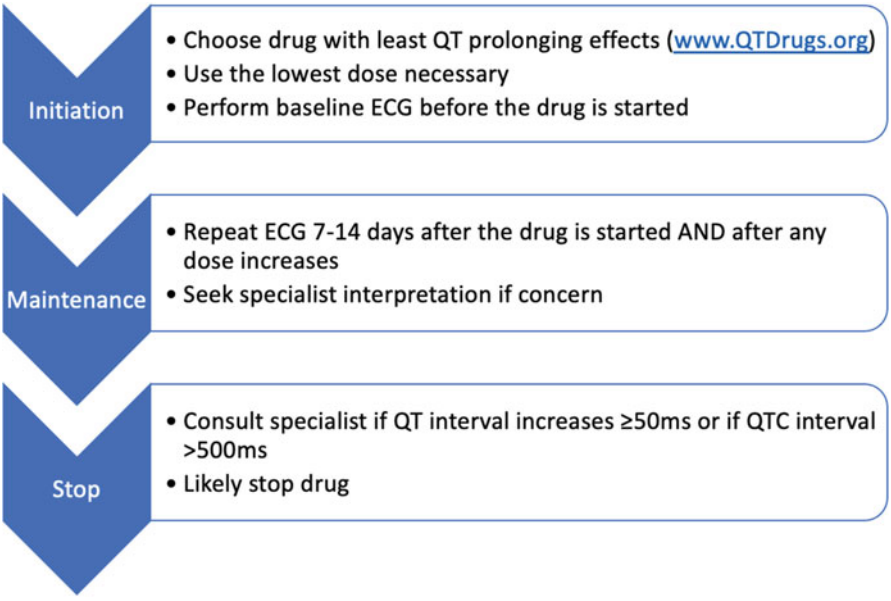

Fig. 3 Approach to prescribing QT-prolonging medications in AN

recommended steps to assess patients at risk of QT prolongation with the initiation and maintenance of QT-prolonging drugs. Once again, it is likely that any additional QT interval prolongation risk conferred by psychopharmacotherapy is dependent on a multitude of factors in patients with AN, from drug dose to current degree of disease exacerbation to underlying genetic predisposition. Nevertheless, it remains best practice to regularly evaluate the indication for these drugs throughout treatment, especially in light of evidence refuting their efficacy in AN.

Sudden Unexpected Death

The first evidence for an arrhythmic cause of sudden unexpected death (SUD) in the AN population was reported in 1985, in a case report of three patients with recorded QT interval prolongation in the days preceding SUD (Isner et al. 1985). Prolongation of the QT interval has been widely implicated in other SUD conditions, perhaps most prominently in the inherited long QT syndrome (Schwartz et al. 1993). As discussed above, QTc interval changes in patients with AN are variable and often within normal range, complicating the clinical implications. So, although this link was logical, in the over 35 years since its publication, a definitive consensus regarding the cause of SUD in AN has not been reached. If the QTc interval was primarily and independently involved in SUD risk, the evidence would reflect this. It is also plausible that inherited long QT, which is present in 1:2000 person, was present in those rare cases on SUD, and AN was a triggering factor in individuals otherwise at risk (Schwartz et al. 2009).

More recently, significant bradyarrhythmias such as sinus pause have been postulated as an etiology of SUD in AN (Farasat et al. 2020). This is a divergence from previous belief that ventricular tachyarrhythmias were the culprit as seen in other conditions, where SUD risk is increased. Nevertheless, given the high prevalence of bradycardia in AN, bradyarrhythmias are an important consideration, and this new hypothesis further supports the pursuit of prompt refeeding to normalize HR and reduce risk.

Clinical Use of the ECG in AN

Guidelines recommend routine ECG monitoring at diagnosis, throughout treatment, and annually in recovery as outlined in Table 2 (National Institute for Health and Care Excellence (NICE) 2017; Royal Colleges of Psychaitrists 2014). Patients with electrolyte imbalances or taking medications that may alter the HR or QTc interval should receive more regular monitoring, especially during acute exacerbations of AN. The ECG is best utilized and evaluated on a patient-specific level, taking all relevant clinical findings into consideration. For example, a prolonged QTc interval in a patient with concurrent hypokalemia would support more urgent electrolyte replenishment compared to a patient with mild hypokalemia without QTc interval prolongation.

For many centers, resolution or improvement of bradycardia is used as a marker of medical improvement during treatment for AN. For this reason alone, serial ECG monitoring is implicated. While a prolonged QTc interval may not be seen consistently

Table 2 Summary of indications to include ECG in clinical care of patients with AN. *Adapted from the 2017 NICE Guidelines and 2014 MARSIPAN Report.*

Primary care	
Baseline physical assessment	*Indicated if any of the following:* Rapid weight loss Excessive exercise Severe purging behavior Bradycardia Hypotension Excessive caffeine Muscular weakness Electrolyte imbalance Previous abnormal heart rhythm Medications that may compromise cardiac function (electrolyte imbalance, bradycardia, hypokalemia, QT prolongation)
Follow-up	Annual ECG recommended if purging behavior and/or significant weight change since last visit
Secondary/tertiary care (inpatient or day patient)	
Admission	All patients
Throughout treatment	*Daily ECG indicated if any of the following:* Bradycardia (HR <40 bpm) QTc interval prolongation (QTc > 450 ms [male] or > 460 ms [female]) Nonspecific T-wave changes Hypokalemia-associated changes
Follow-up	Monthly ECG recommended for seriously ill patients until clinical stability and/or absence of ECG abnormality

Table 3 Summary of ECG abnormalities seen in patients with AN

Parameter	Abnormality	Prevalence	Clinical implications/indications
Heart rate	Bradycardia (HR <50 bpm)	Very common	Monitor as outpatient depending on rest of clinical picture
	Severe bradycardia (HR <40 bpm)	Less common; likely more severe disease	Hospital admission supported
Heart rate variability	Decreased	Inconsistent	Monitor as outpatient depending on rest of clinical picture
QTc interval	Prolonged	Inconsistent	Review potential underlying causes of QT prolongation (e.g., drugs, electrolyte imbalance) and correct where possible
T-wave	Morphology changes	Unclear	Unclear, likely not independent risk factor

in patients with AN, it is important to monitor the ECG throughout treatment given the abundance of confounding factors present which may exacerbate QTc interval abnormalities. Importantly, routine ECG may identify a small, yet high-risk, subset of patients predisposed to ventricular arrhythmia. Common ECG abnormalities should be noted (Table 3), and more nuanced abnormalities such as T-wave morphology

changes may require consultation with experienced personnel, which should be sought with a low threshold of suspected abnormal ECG. In the authors' experiences, cardiology and/or electrophysiology specialists should be urgently consulted when the QTc interval $\geq$ 500 ms, especially in the absence of QT-prolonging factors.

Conclusion

The increased risk of SUD and potentially profound ECG changes, from severe bradycardia to prolonged QTc interval in a subset of patients with AN, have prompted a clinical interest in ECG monitoring. Bradycardia is reported in the majority of patients in part due to autonomic dysregulation, but with no apparent associated direct risk of arrhythmia or adverse events. As the current evidence stands, other definitive and consistent ECG changes have not been identified in the AN population. Nevertheless, the ECG remains an important and useful tool in monitoring individuals on a patient level, and the impact of common patient-specific confounders such as psychopharmacotherapy and electrolyte imbalances should be considered.

Applications to Other Eating Disorders

In this chapter we review the utility and changes seen on the electrocardiogram (ECG) in patients with anorexia nervosa (AN). Aside from bradycardia, the ECG changes described are likely multifactorial and impact only a subset of patients. As such, the underlying pathophysiology is not yet fully understood. Nevertheless, the ECG remains an important tool in the setting of AN to identify the subset of patients who may be at increased risk of adverse cardiac events and sudden death. It is likely that abnormal serum electrolytes and low BMI are significant contributors to the cardiac manifestations of AN. As such, we would expect to observe these complex findings in other eating disorders with similar etiology to anorexia nervosa.

In bulimia nervosa (BN), binge-purge cycles often exacerbate serum electrolyte disturbances. As a result, it was similarly hypothesized that QTc interval prolongation would be observed on the ECG of patients with BN. However, similar to AN, the impact on QTc interval prolongation is likely multifactorial as studies have found contrasting results in the BN population (Krantz et al. 2020; Frederiksen et al. 2018). Interestingly, in the subset of patients with BN who did show changes on their ECGs, these were not associated with worse long-term outcomes.

Mini-Dictionary of Terms

- Electrocardiogram: A minimally invasive test to measure the heart rate and heart rhythm.
- Heart rate: The number of heartbeats per minute.
- Heart rhythm: The pattern of how each heartbeat activates the heart.

- Bradycardia: A heart rate slower than 60 beats per minute.
- QTc interval: A measurement of cardiac repolarization on the electrocardiogram.

Key Facts of the Electrocardiogram in Anorexia Nervosa

- The electrocardiogram measures heart rate and heart rhythm.
- Certain heart rhythm abnormalities predispose patients to cardiac arrest and sudden death.
- Bradycardia is a slow heart rate, often seen in patients with anorexia nervosa.
- Other variations in the electrocardiogram in patients with anorexia nervosa are multifactorial and not fully understood.
- Electrocardiogram abnormalities usually revert to normal with weight restoration.

Summary Points

- Bradycardia (HR <60) is commonly seen in patients with anorexia nervosa.
- Resting QTc interval prolongation is not a reliable marker for cardiac risk in patients with anorexia nervosa.
- Electrocardiogram abnormalities generally return to normal with weight restoration.
- The mechanism underlying increased risk of sudden unexpected death in anorexia nervosa is not fully understood.
- Refeeding and weight restoration normalize ECG changes.

Gennaro Catone

Contents

Abstract

Psychiatric comorbidity indicates the possibility of diagnosing more than one disorder in the same individual. Anorexia nervosa presents a high psychiatric comorbidity with implications both on a theoretical and clinical level.

Population-based and clinical-based studies provided lifetime and concurrent rate of the main psychiatric comorbidities in anorexia nervosa. In the community sample, anorexia nervosa presented a prevalence of approximately at least one psychiatric comorbidity ranging from 20% to 50%. In the clinical sample, results were oriented toward the search for the most frequent comorbid disorders. They are depressive and bipolar disorders, anxiety disorders, obsessive-compulsive disorders, psychosis, substance abuse disorder, and personality disorders. Concomitant psychiatric comorbidity has strong impact on the onset, course, clinical manifestations, prognosis, and treatment of AN; therefore, it should be carefully assessed and treated. Psychiatric comorbidity can impact on symptom severity, hinder functional recovery, substantially worsen outcome, and be a risk factor for mortality.

Introduction

Comorbidity is a term originally used in the divisions of internal medicine in order to indicate "any distinct additional clinical entity that has existed or that may occur during the clinical course of a patient who has the index disease under study" (Feinstein 1970). Originally related to epidemiological medicine and biomedical research, the term has progressively gained interest in psychiatry in correspondence with a paradigm shift in psychopathology. Klerman supports the thesis that the progressive introduction of the concept of multiple and discrete mental disorders, operational criteria, structured interviews, diagnostic algorithms, validity, and reliability progressively produced the effect to introduce the topic of comorbidity into psychiatric language (Klerman 1990). This psychopathological paradigm shift coincided with a renewed interest in nosology and diagnosis determined by the increasing demand of objectivity and reliability expressed by mental health professionals and researchers and by the progressive development of psychopharmacology and psychotherapeutic and psychosocial approaches.

In psychiatry, the definition of comorbidity is to be considered extensive; it depends on various factors. Burke introduced the temporal element and defined comorbidity as the presence of two or more disturbances in a given period of time; in a broader sense, this can be transposed to the lifetime, and therefore the temporal element becomes continuous rather than discrete (Burke et al. 1990). In epidemiological psychiatry, the comorbidity relates to the greater or lesser risk of developing a certain disorder or symptoms if you already have one. In a clinical perspective, the comorbidity construct indicates the possibility of diagnosing more than one disorder in the same individual or the coexistence of a disorder and a constellation of symptoms of another category(ies), which, however, do not meet the criteria defined for the diagnosis(es) (Maser and Cloninger 1990).

The increase in comorbid diagnoses began with the publication of the DSM III (1980) and more in detail of the DSM III R (1987). In fact the introduction of the multiaxial system and the subsequent change in hierarchical diagnostic rules allowed multiple diagnoses of comorbid states (Klerman 1990). DSM IV (1990) and DSM IV TR (1994) seem to encourage the coding of multiple diagnoses, underlying a principle that the collection of as much descriptive information as possible responds best to the complexity of clinical presentations. Furthermore, in the clinical setting, the patient with a complex clinical picture can receive specific treatments for each of the problems presented, while in the field of epidemiological research the high amount of information described allows to define more precisely population studies (Pincus et al. 2004).

In DSM 5 (2013), it is possible to grasp a new conceptual framework; the premise of this transition is the idea that an excessively rigid diagnostic classification system

cannot correctly represent the complexity of clinical experience and scientific research data. As a consequence, it has become clear that the boundaries between many categories of disorders are plastic, and therefore many symptoms can be found in more than one disorder, and this was also evident from studies on psychiatric comorbidity. Therefore, the DSM 5 introduces a dimensional approach to mental disorders that interfaces with the categorical one already in use (American Psychiatric Association, DSM-5 Task Force 2013).

Large epidemiological studies revealed that among patients who suffered from a mental disorder, 35% to 45% satisfied the criteria for two or even more psychiatric disorders (Van Loo et al. 2013).

Obviously, there is no lack of elements of critical judgment regarding the rapid expansion of psychiatric comorbidity, especially in the clinical and psychopathological fields.

Pincus et al. stressed that the uncertainty in the question whether the coexistence of symptoms indicates in a patient the presence of two separate clinical entities or on the contrary manifestations of a single disorder derives from the scarce knowledge we have accumulated on the etiology and pathophysiology of mental disorders (Pincus et al. 2004).

Vella et al. raised the issue relating to the problems that may arise in the transposition of the term comorbidity from medicine to psychiatry. They stated that "comorbidity should be the epidemiological descriptive starting point to build hypotheses that must be clear and rigorously defined, with specified usefulness and limits" with the possibility to test these hypotheses with appropriate methodologies (Vella et al. 2000).

Other critical issues that are raised refer to the low sample size, different definitions of time limits attributed to the comorbidity, and the presence of different methodological biases in the studies that have assessed psychiatric comorbidity. These epidemiological studies often suffer from selection bias (patients vs. general population, different clinical characteristics, rejection rates) or the absence of control groups (Siracusano et al. 2003).

Maj in a refined dissertation argues for the thesis that "the use of the term comorbidity to indicate the concomitance of two or more psychiatric diagnoses appears incorrect . . . and the usage of the term 'comorbidity' should probably be avoided." Obviously, the greatest criticism on the idea of psychiatric comorbidity occurs when the concept is handled from a psychopathological perspective, in fact the author affirmed that: "splitting a complex clinical condition into several pieces may prevent a holistic approach to the individual, he also added what is currently conceptualised as the co-occurrence of multiple disorders could be better reformulated as the complexity of many psychiatric conditions" (Maj 2005).

Lilenfield et al. (1994) argued that the term comorbidity is not appropriate to the psychopathological lexicon as it would express a level of knowledge of the categories, etiology, and pathophysiology of mental disorders that is currently lacking. They proposed the term co-occurrence (Lilienfeld et al. 1994).

Krueger and Markon (2006) proposed a conceptual framework to cope with these difficulties. They introduced a liability spectrum model of comorbidity in which

mental disorders are interpreted as the result of latent liability factors. This makes the concept of comorbidity predictable in light of the role of these factors on the onset of specific mental disorders (Krueger and Markon 2006).

Comorbidity has theoretical, research, and clinical implications for those involved in mental health. Rutter proposed that it could have a strong impact on research on current diagnostic constructs (Rutter 1994). Moreover, the concept is applicable to both general population and clinical studies. The accurate evaluation of comorbidity patterns could improve classification systems and answer a series of questions: "Are mental illnesses discrete entities? Are the diagnostic criteria used valid and reliable? What do we know about the course of the disease and the family aggregation of syndromes and symptoms? How do environmental and genetic factors interact with each other?" From a clinical perspective, it is possible to state that the issue of comorbidity has an impact on diagnosis, prognosis, and the choice of appropriate treatments (Maser and Cloninger 1990).

Leaving aside the implications of a psychopathological nature, in this chapter, the concept of comorbidity has primarily a statistical-quantitative significance linked to the methodology of research in epidemiology. The enlightenments of concurrent comorbidity in AN resume what the authors of the studies considered in this review have tried to interpret in an explanatory key based on the data presented. Comorbidities with neurodevelopmental disorders (i.e., autism spectrum disorder, ADHD) are not presented which, although they represent an emerging area of study, deserve a separate discussion.

Psychiatric Comorbidity in Anorexia Nervosa

Early clinical descriptions of AN had highlighted the association with other psychiatric manifestations such as anxiety and depression. Population-based and clinical-based epidemiological studies confirmed these observations.

Population-Based Studies

Hudson et al. examined a subsample ($n = 2980$, aged 18+) of the NCR-S. They found that the 56.2% of respondents who meet DSM IV criteria for AN had at least another DSM IV disorder assessed in the survey. In detail, 8.4% had exactly one disorder, and 14.1% had exactly two disorders, while 33.8% had three or more. The significant comorbidities were those with specific phobia (26.5%, OR = 2.1), MDD and dysthymia (39.1%, OR = 2.7, and 12.8%, OR = 4.5, respectively), and alcohol and/or drug misuse and/or dependence (24.5%, OR = 2.9, and 17.7%, OR = 3.4, respectively) (Hudson et al. 2007).

In the NCR-S adolescent supplement ($n = 10{,}123$, aged 13–18), the data on general comorbidity were quite similar; in fact, 55.2% of respondents with DSM IV criteria for AN showed at least another DSM IV disorder. Of these, the 28.4 had exactly one disorder, and 10.4% had exactly two disorders, while 5.5% had three or more. They diverged in relation to the type of concomitant disorder, as oppositional defiant disorder

was the most frequent and significant one in association with AN (30.4%, OR = 5.1). From these results, it is possible to affirm that the type of concurrent psychiatric comorbidity in the course of AN is age dependent and also in the adolescent range the single comorbidity is more frequent, while in the adult range the opposite occurs because multiple comorbidities are more represented (Swanson et al. 2011).

In a matched Denmark nationwide cohort study of individuals with diagnosis of AN (n = 9985 patients vs. 49,351 controls) with a follow-up analysis, the risk of developing any other psychiatric disorder was about 25% in the first 2 years and 55% in the two decades after the inclusion in the study protocol. Authors found a hazard ratio of seven to receive a concurrent psychiatric comorbidity in the first year after the diagnosis, and this risk was higher for patients aged 8–13 at the diagnosis. The comorbidities most frequent were affective, autism spectrum, personality, and obsessive-compulsive disorders. Interestingly, the rate of psychiatric morbidity tends to decrease over the years, but the risk of developing a psychiatric disorder after 20 years remains double or more than that of the general population (Steinhausen et al. 2021). In another prospective controlled study, 39% and 38% of subjects with adolescent-onset AN had at least the criteria for another concurrent psychiatric diagnoses (affective, anxiety, or psychotic disorders) at 18- and 30-year outcome, respectively (Wentz et al. 2009; Dobrescu et al. 2020).

Clinical-Based Studies

One of the first studies assessing comorbidity in anorexic patients examined a sample of 229 patients, of whom 41 (11%) had AN and 90 (29%) had anorexia/bulimia nervosa. Affective disorder was the most frequent comorbidity in the groups. Authors found also the co-occurrence of personality disorders, anxiety disorders, and substance use disorder. They concluded that treatment-seeking anorexics display a high rate of concurrent comorbidity and this has clinical implications because these patients entail diverse interventions (Herzog et al. 1992).

A clinical study on psychiatric comorbidity in 62 patients with feeding and eating disorders (48ss, 66.7% diagnosed with AN; 24ss, 33.3% diagnosed with OSFED) focused on the relationship between dimensional and categorical approach to comorbidity diagnosis. In this sample, the assessment was carried out with a clinician-rated questionnaire that investigated the categorical diagnoses (DSM based) and different self-report dimensional scales on depression, social anxiety, obsessive-compulsive symptoms, mania, paranoia, and hyperactivity. With the categorical approach, a quarter of patients had a comorbidity, while about half had two psychiatric comorbidities. The most frequent were social anxiety disorder (38ss, 52%), depressive disorder (31ss, 43.1%), and generalized anxiety disorder (14ss, 19.4%). Through the dimensional evaluation, it was possible to demonstrate that other psychiatric symptoms are distributed along a continuum in the course of AN. Moreover, with regard to the two most frequent comorbidities, the results showed that the participants were able to self-report the social anxiety symptoms, but they had difficulty in self-indicating depressive symptoms. This could indicate a tendency to deny depressive symptoms by those suffering from AN (Catone et al. 2020).

In 22-year follow-up study with 38 adolescents who met criteria for AN, 13 (34%) showed persistence of eating symptoms, whereas 25 (66%) had completely recovered. Of interest is the fact that psychiatric comorbidity mainly concerned the group with still active symptoms (Andres-Pepina et al. 2020).

In a Mexican adolescent sample study, the 78.12% ($n = 25$) of subjects with AN presented another psychiatric comorbidity (mood and anxiety disorders, substance-related and addictive disorders, disruptive and impulse control/conduct disorders, and neurodevelopmental disorders) (Ruiz-Ramos et al. 2021).

Theoretical Implications

The psychiatric comorbidity model in AN has been the subject of studies for a long time, and several authors have attempted to understand the nature of the relationship underlying this association. C. Bulik provided a starting point from which to test a series of hypotheses through clinical and community epidemiological studies. She indicated five plausible models to explain the relationship between eating and affective symptoms (Table 1).

Evidence suggests that there is little evidence for models 1, 3, and 4 as the conditions examined are not always found in comorbidities and the data do not converge on the hypothesis of a single shared factor. Rather, the evidence suggests that eating disorders follow the onset of affective disorders (this is especially true for anxiety disorders and AN), and they support the presence of both shared and specific causal factors (Bulik 2005).

A further study model of concurrent psychiatric comorbidity in AN is that related to the NA approach. In other words, the NA hypothesizes that mental disorders are made up of a constellation of symptoms, which in turn self-maintain each other. Therefore, the concurrent comorbidity corresponds to the situation in which the symptoms of different clusters are activated. The NA included nodes, which represent the selected variables, and edges that indicate the connections between the

Table 1 Bulik hypotheses of the nature of association underlying AN and affective disorders (anxiety, depression)

1	*Anxiety and depression are sequelae of eating disorder. The implications of this model are that affective symptoms do not manifest until after the onset of the eating disorder and they may respond to treatment of the underlying disorder*
2	*Eating disorders are sequelae of anxiety and depression. In this model, eating symptoms can improve following the treatment of affective symptoms*
3	*Eating disorders are expression of an underlying affective disorder. In this model, the causal factors are entirely shared among the two groups of disorders, and eating symptoms may be conceptualized as age and gender particular signs of affective disorders (forme fruste model)*
4	*Eating disorders and affective disorders are different manifestations of the same underlying etiological factors*
5	*Eating disorders and affective disorders may share same causal factors although they are to be understood as separate/distinct categories. In this model, there is no prediction of the succession of the various clinical manifestations*

various nodes. Centrality is a measure of the importance of a node within the network. Studies showed the centrality of general psychiatric symptoms (anxiety, depression) as well as core symptoms (drive to thinness and interoceptive awareness) in AN (Monteleone and Cascino 2021). Monteleone et al. explored the potential of the NA approach in studying comorbidity in 405 adolescent inpatients aged 9–18 with diagnosis of AN (duration of illness <3 years). In this sample, depressive symptoms and personal alienation were the nodes with the highest centrality followed by drive to thinness, asceticism, post-traumatic stress symptoms, anxiety physical symptoms, and low self-esteem. Potential maintaining comorbid symptoms belong to two different clusters: (1) negative affect symptoms/internalizing problems and (2) negative self-appraisal problems. This conceptual approach may suggest focusing the intervention on the symptoms that convey the concurrent comorbidity as well as the AN core symptoms, which are notoriously difficult to treat (Monteleone et al. 2019).

Clinical Implications

Clinically, the importance of concomitant psychiatric comorbidity lies in the impact it has on the onset, course, clinical manifestations, prognosis, and treatment of AN.

Psychiatric comorbidity could impact on AN symptom severity (Saccomani et al. 1998). For example, affective and especially anxiety disorders can worsen cognitive-affective eating disorder symptoms such as fixation on underweight, fear of weight gain, and preoccupation with weight and appearance; also dieting has been found to be linked with anxiety disorders, whereas binge/purging behaviors were associated with substance misuse disorders and cluster B personality disorders in addition to anxiety disorders. These findings derive from a study on a mixed population of 277 subjects with eating disorders, of which 84 (30%) had AN, and they confirmed that concurrent psychiatric comorbidity produces an increased severity of the eating disorder symptoms with recurrent patterns of association (Spindler and Milos 2007).

A further clinical aspect is AN recovery. It is not easy to define recovery in this field; in fact, physical, behavioral, and psychological indices should be considered. A group of patients with complete remission ($n = 20$) was compared with a group of subjects (1) in partial remission ($n = 15$), (2) with active disease ($n = 53$), and (3) with a healthy control group ($n = 67$). The complete remission group did not differentiate from the healthy control group in terms of having other non-eating axis I diagnosis (conversely the partial remission group and active disease group showed three and seven times greater risk, respectively). The subjects belonging to the complete recovery group and the healthy control group showed the same low rate of mood disorder comorbidity. The pattern of comorbidity with anxiety disorders was quite different; in this case, the total and partial remission groups showed comparable results, with a concurrent diagnosis rate of anxiety disorder higher than those in the group of healthy controls but lower than those relating to subjects in the active disease phase. The authors interpreted these results as confirming the hypothesis that anxiety disorders precede AN, while mood disorders are consequences (Bardone-Cone et al. 2010).

Comorbidity affects also outcome (Wentz et al. 2009; Dobrescu et al. 2020; Andres-Pepina et al. 2020). The severity of the clinical expression of AN is influenced by the psychiatric comorbidity (Riquin et al. 2021). In children and adolescent sample with AN, the comorbidity with mood disorders and personality disorders was associated with poorer outcome (Saccomani et al. 1998).

AN presents a higher risk of mortality than the general population and also other psychiatric and nonpsychiatric disorders. Comorbidity was considered a risk factor for mortality for AN in association with demographic and socioeconomic factors (Ulfvebrand et al. 2015). Himmerich et al. confirmed these observations in a retrospective study of 1970 subjects diagnosed with AN from the South London and Maudsley Foundation Trust retrieved through a clinical record interactive search. Indeed, mortality in the sample was moderately associated with concomitant substance use and personality disorders (Himmerich et al. 2019). Suicide is a significant element in AN mortality, and suicidality (suicidal ideation and attempts) is augmented in people with EDs compared to the general population especially when a concurrent psychiatric comorbidity occurs (Milos et al. 2004). There is evidence that AN, depression, and suicide attempts may share a strong common genetic predisposition (Thornton et al. 2016). In a sample of 288 ED patients including 87 anorexic patients (about 30%), a quarter admitted a lifetime suicide attempt, and the same proportion stated existing suicide ideation. Patients with a history of suicide attempt had a higher prevalence of mood disorders and cluster b personality disorders than patients who did not report a lifetime suicide attempt. Moreover, anxiety, depressive disorders, and clusters B and C and negativistic depressive disorders significantly increased the rate of concurrent suicidal ideation with an additive effect among various other associated psychiatric disorders. This effect was particularly pronounced for AN (Milos et al. 2004).

Woodside and Staab in a practical review summarized all the prominent aspects of the management of psychiatric comorbidity in AN. The starting point relates to the fact that the treatment of AN is complex, and therefore the concomitant presence of other psychiatric disorders adds further complexity. Furthermore, clinicians must take into consideration the effects of malnutrition and dysfunctional eating behaviors, which can impact on therapeutic choices and modify responses to treatment. The authors pointed out that the effects on concomitant psychiatric comorbidity are modest if there is no parallel improvement in starvation conditions and reduction of AN core symptoms (Woodside and Staab 2006).

Anorexia Nervosa and Depressive Disorders

Numerous evidences indicate that depression is the main comorbidity in the course of AN. Several authors identify shared etiological factors between the two conditions such as temperament, genetic aspects, altered neurotransmitter and neurometabolic profile, cognitive styles and attachment pattern, childhood trauma, and psychosocial functioning (Fernandez-Aranda et al. 2007). Depressive symptoms are often present in the course of AN, and they must be carefully evaluated to decide whether they delineate a depressive disorder according to the DSM 5 criteria; the main ones are

flattened mood, feelings of guilt, hopelessness and worthlessness, reduced self-esteem, difficulty in managing eating patterns, irritability, insomnia, suicide ideation, and attempts. These symptoms often impact on social, school, and work functioning (Siracusano et al. 2003; Bulik 2005). Fernandez-Aranda et al. in a study of 1371 individuals with EDs investigated the temporal relationship between the two diagnoses and looked for a potential clinical profile in the case depression precedes EDs. They found a great prevalence of MDD among EDs and quite high in binge/purging subtypes. Moreover, in one third of the sample, MDD preceded ED, and in this case patients reported a longer duration of depressive symptoms, greater psychomotor agitation, and increased thoughts about death but not increased suicidality (Fernandez-Aranda et al. 2007). In a 10-year controlled follow-up study of 51 adolescent-onset AN, authors found a high prevalence of depression among patients (84%) with respect to the control group (18%). Findings supported the thesis that depression was concomitant or subsequent AN onset, but depression itself predicted further depressive episode in the longitudinal observation (Ivarsson et al. 2000). The prevalence of depressive disorder in AN varies according to epidemiological studies between 20% and 94% (Ivarsson et al. 2000; Kennedy et al. 1994; Blinder et al. 2006; Godart et al. 2007). These studies differ in the choice of diagnostic instruments used ranging from structured interviews to self-report tools (Srober and Katz 1997); furthermore, samples were different between the various studies (in- and outpatients, volunteers in evaluation or treatment phase, follow-up patients), and there are several general methodological limitations (small sample, difference in the assessment procedure, potential selection bias, lack of control group, difference between concurrent and lifetime prevalence, and changing in diagnostic criteria for anorexia nervosa and depressive disorder). In a descriptive review of *methodological issues and prevalence findings*, Godart et al. examined studies of mood disorder comorbidity among anorexic subjects until 2006 (Godart et al. 2007). MDD was present in a range between 9.5% and 64.7% in the restrictive subtype AN and between 50% and 71.3% in the binge/purging subtype in five referred patient sample studies; moreover, MDD concurrent prevalence was about 2.2–35.3% in a seven follow-up studies of anorexic patients. The concomitant dysthymic disorder in AN has been estimated between 13% and 33% with contrasting results in the AN subtypes with unclear results when compared to control groups.

A further issue relates to the possibility that depressive symptoms are linked to the state of malnutrition with conflicting results deriving from the various studies. Pleple et al. demonstrated a positive relationship between markers of nutritional status (BMI, FMI, FFMI) and anxious and depressive symptoms (Pleple et al. 2021). Voderholzer et al. found different results in a study of 418 women with AN (mean age at hospitalization 26.42 years, range 18–62), of whom 152 (36.4%) suffered from a depressive episode and 165 (39.5%) from recurrent depressive episodes. In their analyses, depressive symptoms and BMI are not correlated, and this negative association was evident both at the time of admission and that of discharge (Voderholzer et al. 2016). It is difficult to establish if depressive symptoms precede AN or some effects of eating psychopathology such as starvation and neurometabolic alteration led to chronic depressive state. Some authors indicate that the AN-depression association is multifactorial and therefore not reducible to

the effects of malnutrition; other authors, on the other hand, indicate that malnutrition and caloric restriction can generate an increase in CRH and a reduction in serotonin functioning, both factors implicated in the onset of depression (O'Brien and Vincent 2003). Concomitant mood disorder is associated with a poorer outcome of the underlying AN pattern with worse response to treatment (Halmi et al. 1973). In a 7-year follow-up study of 34 anorexic inpatients, authors found a positive and significant association between depression and AN outcome; therefore, the persistence of one condition entailed the persistence of the other as well (Herpertz-Dahlmann et al. 1995). Finally, AN and depressive disorder are considered two conditions to be at high risk for suicide, and the risk is higher when there is comorbidity between these disorders. In fact, suicide attempts occurred more frequently in patients with AN and depression than in those with only AN, and furthermore suicide attempts were reported mainly during the exacerbation of depressive symptoms (Bulik et al. 2008). A recent community cross-sectional study (8.746 Chinese students, mean age 15.38 years, SD 1.95 years) pointed out that AN is an indicator of suicidal thoughts and depression associated with AN has a synergistic effect on these thoughts (Lian et al. 2017). Thornton et al. in the Swedish Twin Study of Adults: Genes and Environment provide an indication of the common biological disposition to AN, depression, and suicide which is represented by a genetic liability (Thornton et al. 2016).

Anorexia and Bipolar Disorders

The association between AN and BD received less attention than those with unipolar depressive mood disorders. McElroy et al. summarized the few and scattered contributions on the argument (McElroy et al. 2005). In a community controlled longitudinal study of 810 female of which 19 were classified as full eating syndrome ($n = 7$ AN) and 23 as partial eating syndrome ($n = 9$ AN), there was no difference between eating disorder groups and control group regarding the prevalence of bipolar disorder diagnosis; however, the presence of subthreshold bipolarity was significantly greater in the full eating syndrome group (26.3%) and partial eating syndrome group (21.7%) than in the control group without eating disorders (3.8%). At the follow-up point, bipolar disorder period prevalence rate was 10.5% and 8.3%, respectively, in the two groups and significantly higher than in control groups (Lewinsohn et al. 2000). Clinical studies suggested a range of 2.4–16.1% of AN in bipolar disorder patients. In detail, Halmi et al. found ten BD (two mania, two BD, and six atypical BD in a sample of 62 females with AN) (Halmi et al. 1991). AN and BD share several phenomenological similarities. Both disorders start in adolescence and presented an episodic chronic course. Manic symptoms such as elation, irritability, mood swings, hyperactivity, hypertalkativeness, impulsivity, insomnia, poor insight, delusions, and behavioral agitation may occur during AN. Two recent studies showed interesting results. In the first one, the sample was constituted by 288 patients with EDs (aged 18–24). In the AN subsample ($n = 54$), nine subjects (16.7%) had lifetime occurrence of bipolar disorder, a rate significantly higher than in the control group. Furthermore, the comorbidity of EDs and bipolar disorder also

showed increased psychiatric comorbidities with anxiety disorders, impulsivity, suicidality, and increased intensity of body concerns (Tseng et al. 2016). In the second one, the comorbidity with BD worsened the clinical (psychiatric and nutritional) state of AN, extended the duration of AN, and increased the association with other psychopathological symptoms and syndromes, requiring greater use of psychotropic drugs (Radon et al. 2021). A recent review highlighted that the presence of a bipolar disorder had a negative impact on outcome and quality of life and raised reflections on additional treatment modalities (Craba et al. 2021).

Anorexia Nervosa and Anxiety Disorders

The first observations on AN anxiety comorbidity highlighted a similar phenomenology between the two conditions with respect to clinical presentations, familiarity, and response to treatment. Both conditions share essential psychopathological aspects such as the distress of negative evaluation (social phobia) as well as the fear of gaining weight (weight phobia) which is a nuclear symptom of AN; in this light, anxiety is considered an onset and maintenance factor for AN (Bulik 1995). In most epidemiological studies on EDs, the presence of anxiety disorders in both probands and family members is very high, and both conditions respond to treatment with SSRIs.

Several studies assessed the comorbidity between AN and anxiety disorder (Godart et al. 2002; Swinbourne and Touyz 2007).

Kaye et al. found a prevalence of *at least one anxiety disorder* in 55 of 97 (55%) anorexic subjects, of which 21 (22%) had social phobia. The onset of social phobia, specific phobia, and GAD usually preceded AN, whereas panic disorder and agoraphobia were successive. Further findings indicated that the BMI was higher if there was no concomitant anxiety disorder and that various aspects of the eating disorder (perfectionism, avoidance) worsened in the presence of acute state of eating pathology and concomitant anxiety disorder (Kaye et al. 2004). Swinbourne et al. found approximately the same results in a sample of 50 inpatients (mean age 25.4, SD 8.3) which included 33 anorexics (66%). The percentage of those with *at least one anxiety disorder* was around 70% ($n = 23$), and social phobia had a prevalence of 27.3% ($n = 9$) (Swinbourne et al. 2012).

In a controlled cross-sectional study of 271 women seeking treatment (166 anorexics, 111 restrictive subtype, 55 binge/purging subtype), the presence of at least one concomitant anxiety disorder was high (62.2% restrictive subtype, 63.6% binge purging subtype) and greater than in the control group. The most frequent anxiety disorders were generalized anxiety disorder (48.6% and 45.4% in the two subtypes, respectively) and social phobia (30.6% and 32.7% in the two subtypes, respectively). Separation anxiety history was common in AN (18.2% restrictive subtype and 12.7% binge/purging subtype). Less than half of the comorbid cases showed that the anxiety disorder preceded AN and social phobia most regularly respected this pattern (Godart et al. 2003). Lavender et al. in a refined study on 118 anorexic women demonstrated that eating disorder symptoms and behaviors were associated with different daily patterns of anxiety. For example, binge and

vomiting behaviors early in the day were associated with a decrease in anxiety throughout the day or if they showed up late were consequences of an increase in anxiety during the day. Furthermore, high anxiety during the day was associated with concomitant mood disorder, affective lability, self-harm, oppositive behaviors, and social avoidment (Lavender et al. 2013). Several interpretations suggest a contributing role of anxiety in AN. AN have typically onset in mid-late adolescence, whereas anxiety disorders develop in childhood – early adolescence. Some authors propose that cognitive and behavioral symptoms of AN (restrictive diet, prevalent ideation about food and diet) could reduce preexisting anxious symptoms and thus maintain the eating disorder. Lloyd et al. conducted a systematic review of the longitudinal association between anxiety and AN (Lloyd et al. 2019). There was an association between childhood anxiety and AN in retrospective studies, while the prospective studies failed to clearly demonstrate a functional association between a specific anxiety disorder and AN although the authors concluded that this did not imply the absence of a significant correlation between the two conditions. From the analysis of the retrospective studies, it was possible to state that subjects with AN reported anxiety more frequently than control groups in childhood, but there was no evidence that anxiety could be the only factor that could explain the subsequent development of AN. A study by Taborelli et al. highlighted that separation anxiety was more endorsed in childhood by subjects with AN than healthy sister who represented the control group (Taborelli et al. 2013). A prospective study (23 years) by Maier et al. in a childhood cohort of a large community sample ($n = 1{,}664{,}876$) from Danish population registry found that GAD and social anxiety diagnoses increased the risk of developing AN and the AN – social anxiety association was maintained even after control with confounders (age, sex, family psychiatric history, other psychiatric comorbidities excluding anxiety disorders). However, if the analysis was controlled by including the presence of other anxiety disorders as confounders, the results excluded that a single anxiety disorder could have an independent effect on the onset of AN (Meier et al. 2015). A recent longitudinal study using data from the ALSPAC demonstrated a robust association between the presence of an anxiety disorder at age 10 and subsequent develop on AN at age 24, moreover worry had a fundamental impact on a successive AN onset (Lloyd et al. 2020).

Anorexia and Obsessive-Compulsive Disorder

The overlap between OCD and anorexic symptoms was highlighted from the first observations and clinical descriptions of AN. Properly in AN we observe obsessive concerns on the theme of eating, weight and body shape; ritualized behaviors at mealtimes and compulsive physical activity (Bulik 1995). The prevalence of OCD approximately ranged from 6% to 35% (Kaye et al. 2004; Swinbourne et al. 2012; Godart et al. 2003). In children and adolescents, the percentages were higher (50–60%) (Serpell et al. 2002; Blinder et al. 2006).

The present prevalence of OCD in 58 anorexic inpatients and outpatients (mean age 18.6 years, SD ±4) was 19% ($n = 11$), a significantly higher proportion than in the control group. This study evaluated also difference between AN subtypes:

(1) AN restrictive subtype had a prevalence of 16% (7/44) and (2) AN binge/purging subtype had a prevalence of 29% (4/14). These results were in contrast to other results which showed a higher prevalence of OCD in the restrictive subtype (Deep et al. 1995). Finally, the AN-OCD association presented a clinical profile characterized by a lower BMI than AN without this comorbidity (Speranza et al. 2001). In another study, OCD comorbidity was related with a higher duration of AN illness; in this sample constituted by 84 females with AN, the prevalence of concomitant OCD was 28.6% (Milos et al. 2002). In a recent report, results indicated that subjects diagnosed with OCD had a 17 times greater risk of also having AN and this risk was higher for males. Furthermore, in the longitudinal analyses, the risk of OCD in patients with AN was four times greater than in the control population (mean interval between the two diagnoses = 2.2 years), while the risk of developing OCD in AN subjects was ten times greater than in the control group (mean interval between the two diagnoses = 2.4 years) (Cederlof et al. 2015).

Many studies agree on the observation that obsessive traits were present before the onset of eating symptoms and furthermore starvation can worsen these pre-existing aspects. Furthermore, there could be a similar genetic and neurotransmitter profile between the two conditions as they both respond to SSRI treatment (O'Brien and Vincent 2003; Halmi et al. 1991). Ylmaz et al. reviewed the shared genetic basis of AN and OCD using a GWAS meta-analysis that confirmed the elevated genetic correlation between the two conditions (Yilmaz et al. 2020). Finally, the association between AN and OCD has been linked to a clinical profile characterized by excessive physical activity, exercise, and orthorexia (Davis and Kaptein 2006; Dell'Osso et al. 2016; Young et al. 2013).

Anorexia Nervosa and Psychosis

The association between AN and psychosis was less explored than that with affective disorders. Contributions on the topic mainly concern the association of AN with psychotic symptoms and/or schizophrenia or the use of antipsychotic drugs.

In the association studied contributions are mainly case reports or case series (Miotto et al. 2010; Sarro 2009; Grounds 1982). Others studies highlighted the concomitant of AN and schizophrenia (Lyon and Silber 1989; Kouidrat et al. 2014). Looking at several study designs, Hudson et al. found a prevalence of psychotic symptoms in 17 patients among 130 consecutive anorexic patients (Hudson et al. 1984). McGrath et al. were interested in the temporal relationship between the two conditions and whether the anorexic symptoms preceded the psychotic ones or the opposite. They analyzed the bidirectional relationship concerning the DSM-IV-TR diagnostic categories and psychotic symptoms in 31.261 respondents belonging to an international survey. In their analysis, authors showed a significant temporal relationship between AN and psychotic symptoms (OR 2.8, 95% CI = 1.0–7–8) demonstrating that anorexic symptoms preceded psychotic ones. The inverse relationship (psychotic symptoms – AN) was not significant

(McGrath et al. 2016). A recent study investigated the relationship between AN and paranoia. Data showed that paranoia was dimensionally distributed among 92 adolescents (mean age 14.3 years, SD 1.9 years, age range 11–17.8 years) with diagnoses of AN (66, 71.7%) and OSFED (26, 28.3%). Furthermore, in this population, the presence of paranoia was more explained by the concomitant presence of social anxiety and depression rather than by the core symptoms of eating disorder and by body image concerns (Catone et al. 2021). These results support recent cognitive models that attribute an important role to emotional symptoms in the onset and maintenance of paranoia (Garety et al. 2001).

The role of SGA in the treatment of AN is currently controversial. For example, in several studies, these medications appear to improve anxiety-depressive symptoms and some core symptoms of the eating disorder, but generally findings have failed to demonstrate a general improvement and an increase in BMI compared to placebo control group. Authors conclude that further studies are needed with large sample and improved methodology; moreover, antipsychotics may be useful in some patient subgroups or individual cases (McKnight and Park 2010; Lebow et al. 2013; Dold et al. 2015; Kishi et al. 2012; Brewerton 2012; Hagman et al. 2011). Pisano et al. presented a naturalistic clinical data from five patients with AN in treatment with olanzapine that showed an improvement in 6 months of follow-up (Pisano et al. 2014). Clinical data were focused on the clinical presentation of the AN in order to highlight which clinical features should direct toward a pharmacological treatment with SGA. Eligibility criteria were displayed in Table 2.

In a retrospective study of 106 adolescents, treatment with aripiprazole as part of a specialized intervention on eating disorders was associated with an increase in BMI compared to the control group (Frank et al. 2017).

Anorexia Nervosa and Other Disorders

Several clinical and community studies assessed the comorbidity between AN and substance use. There is a substantial convergence of data in favor of the greater predisposition to the use of substances for the AN binge/purging subtype, especially when alcohol is taken into consideration. Root et al. analyzed this association in two different samples. In the first one ($n = 731$ participants), alcohol abuse dependence was 13.7%, 19%, and 23.9%, respectively, in the AN restrictive subtype ($n = 328$),

Table 2 Eligibility criteria for SGA treatment by Pisano et al.

1	*Patient is nonresponder (weight and food intake continue decreasing) for at least 1 month of psychological and psychoeducational interventions*
2	*Is consuming a mean caloric intake < 800 kcal/day*
3	*Has comorbid bipolar (I, II, or NOS) or disruptive mood dysregulation disorder with overactivity*
4	*Has high functional impairment and clinical severity (CGAS < 51, CGI-S ‡4)*
5	*Has low insight*

AN purging subtype ($n = 184$), and AN binge subtype ($n = 109$); drug use was 23.2%, 29.9%, and 25.7%, respectively, in the AN restrictive subtype, AN purging subtype, and AN binge subtype; and drug dependence was 6.4%, 14.1%, and 17.4%, respectively, in the AN restrictive subtype, AN purging subtype, and AN binge subtype (Root et al. 2010a). In the second sample, they confirmed that alcohol abuse/dependence, diet pills weekly, stimulants ever and polysubstance ever were more likely in the AN binge/purging subtype than in the AN restrictive subtype (Root et al. 2010b). Personality disorders are often comorbid with EDs. In summary, there is a close relationship between binge/purging symptoms and BPD and cluster C personality disorder and restrictive symptoms of AN (O'Brien and Vincent 2003). An extensive review of the literature has shown a frequency of 22% of obsessive-compulsive personality disorder in the restrictive subtype and a frequency of 25% of BPD in the binge/purging subtype. In a clinical analysis, the characteristics of obsessive-compulsive personality disorder are frequently found in the AN restrictive subtype. They are concern for details; the tendency to organize through lists and rules; perfectionism; dedication to the task; hyperconscientiousness and moral inflexibility; rigidity, which are found in the restrictive AN in the form of rigid adherence to diet; counting calories and nutrients contained in food; extreme dedication to weight loss; social isolation; perfectionism; and the desire to achieve a culturally defined ideal of thinness. On the other hand, impulsivity, self-harm, emotional instability, a sense of emptiness, irritability, and unstable relationships are the characteristics of borderline personality disorder which are found in the AN binge/purging subtype in the form of episodes of binge eating and elimination conducts (vomiting, use of laxatives and diuretics) (Sansone and Levitt 2006). Moreover, cluster C disorders and depressive negativistic personality disorder were related to fixation to underweight, fear of weight gain, preoccupation with weight and appearance, and dieting; instead, cluster B disorders were associated with binge eating behaviors and vomiting (Spindler and Milos 2007).

Application to Other Eating Disorders

Bulimia nervosa is more common than AN. Its prevalence is approximately 1–2% in the female population (Keski-Rahkonen and Mustelin 2016). Clinically, BN often presents with other psychiatric comorbidities. Several studies have confirmed the concomitance of anxiety disorders (Bulik 2005), mood disorders (Miniati et al. 2018), substance abuse (Fouladi et al. 2015), personality disorders (Himmerich et al. 2019), self-harm, and suicidal ideation (Anderson et al. 2002). The high prevalence of anxiety disorders in bulimia nervosa and the evidence that bulimic symptoms often follow anxious symptoms led researchers to speculate that binge/purging behaviors may have an effect to reduce subjective anxiety. Social phobia and GAD are the most common anxiety disorders in BN (Bulik 2005). Depressive and bipolar disorders are frequent among subjects with BN (Godart et al. 2015; Tseng et al. 2016). Depressive symptoms are considered to be maintenance factors in bulimic behaviors, and they have been associated with persistence of the disease,

relapse, and negative outcome (Linardon et al. 2017). The concomitance of BN and bipolar disorder displayed poorer outcome, lower quality of life, impulsivity, and further psychiatric comorbidity which in turn expose you to greater suicidal risk (Tseng et al. 2016). The relationship between BN and substance abuse has been studied for a long time. Many results converge on the hypothesis that substance abuse is often the result of the concomitance of BN and other psychiatric disorders, especially personality disorders (O'Brien and Vincent 2003). As already mentioned, the personality disorder most associated with the bulimic profile (binge/purging behavior) is BPD. In a recent study, BN BPD comorbidity showed a significant effect on mortality in a sample of 1501 bulimic subjects (Himmerich et al. 2019). The association of impulsive behaviors, substance abuse, and other psychiatric and personality disorders confers a greater suicidal risk than in patients with BN without psychological comorbidities (Spindler and Milos 2004; Milos et al. 2004). BED is often associated with depressive and bipolar disorders, anxiety disorders, substance abuse disorders, and personality disorders. Obviously negative affect may trigger binge eating and loss of control. Another issue is the obesity responsibility in the onset of psychiatric comorbidity. BED showed elevated suicidal risk when it presents with other psychiatric comorbidities (Welch et al. 2016).

Mini-Dictionary of Terms

- **Hierarchical diagnostic rules:** Rules that regulate the process of diagnosis and that do not allow certain diagnoses to be made when certain conditions coexist
- **Diagnostic and Statistical Manual of Mental Disorders fifth edition (DSM 5)**: It is a classification and categorization tool of the main psychiatric disorders published by the American Psychiatric Association in which experts from all over the world collaborate. It has reached its fifth edition published in 2013
- **Dysthymia**: Also called persistent depressive disorder, it is characterized by depressive symptoms for at least 2 years (in children and adolescents, the duration must be at least 1 year)
- **Major depressive disorder**: In the DSM 5, MDD is described such as the presence of depressive symptoms for at least 2 weeks
- **Personality disorders**: In the DSM 5, personality disorder is defined: "a constant pattern of internal experience and behaviour that is profoundly different from what is expected based on the culture of the individual. It is characterized by stability, pervasiveness and inflexibility. This pattern begins in adolescence or early adulthood and causes discomfort". Personality disorders are classified into three groups: *Cluster A personality disorders*, paranoid personality disorder, schizoid personality disorder, and schizotypal personality disorder; *cluster B personality disorders*, antisocial personality disorder, borderline personality disorder, histrionic personality disorder, and narcissistic personality disorder; and *cluster C personality disorders*, avoidant personality disorder, dependent personality disorder, and obsessive-compulsive disorder

- **Psychopathology**: The definition of Schulze-Lutter et al. was provided: "Psychopathology is the scientific exploration of abnormal mental states that, for more than a century, has provided a Gestalt for psychiatric disorders and guided clinical as well as scientific progress in modern psychiatry" (Schultze-Lutter et al. 2018)
- **Recovery**: Suggested operational recovery criteria by Bardon-Cone used in the text were as follows: (1) no longer encounter diagnostic criteria for AN, (2) absence of binge/purging or fasting behavior in the past 3 months, (3) a body mass index not lower than 18.5 mg/kg, and (4) results within 1 *SD* on all the subscales of the Eating Disorder Examination-Questionnaire (EDE-Q; Fairburn and Beglin 1994)
- **Suicidality:** Dimensional concept that starts from the vague and sporadic suicidal ideation up to the complete suicidal act

Key Facts

Key Facts of Depressive Disorders

In the DSM 5, depressive disorders are disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder (dysthymia), premenstrual dysphoric disorder, depressive disorder due to another medical condition, and depressive disorder with other specification and without specification. Major depressive disorder is characterized by the presence of depressed mood, loss of interest, and irritability to which changes in appetite and weight, sleep, psychomotor activity, anergy, low self-esteem, and difficulty in attention and concentration can be added. Symptoms must be present daily for at least 2 weeks. Suicidal ideation may be present. The DSM 5 recognizes a 12-month prevalence of the disorder of 7% with greater frequency in women and in the 18–29 age group. The course has frequent relapses. Dysthymia presents persistent depressed mood with at least two additional symptoms described above for major depressive disorder. The 12-month prevalence in the United States is between 0.5% and 1.5%. The treatment of depressive disorder is combined in moderate-severe forms and uses psychotherapy and psychopharmacology

Key Facts of Bipolar Disorders

In the DSM 5, bipolar disorders are bipolar disorder I, bipolar disorder II, cyclothymic disorder, and bipolar disorder substance/drug induced, due to another medical condition or unspecified. Bipolar disorder I is characterized by the presence of a manic episode which may be preceded or followed by hypomanic or major depressive episodes. Manic episode presents elevated or irritable mood lasting at least 1 week, increased activity with associated high self-esteem, reduced need for sleep, increased speed of thought and language with hypertalkativeness, and involvement in potentially harmful activities. The 12-month prevalence of bipolar disorder I is

about 0.6%. Bipolar disorder II is characterized by the presence of hypomanic and depressive episode; hypomanic episodes are of a shorter duration and intensity than manic ones. The course of bipolar II disorder is chronic, characterized by the alternation of episodes. The prevalence at 12 months is estimated at around 0.3%. Cyclothymic disorder is constituted by chronic mood alteration (at least 2 years) with alternating symptoms relating to the two depressive-hypomanic polarities without, however, the criteria for depressive/hypomanic episode being met. In the studies presented above on the association between AN and bipolar disorders, authors usually included not only categorical diagnosis of BD but also those contributions/participants related to the broad bipolar spectrum, including subthreshold presentations. This approach appears to be more inclusive and useful in order to obtain information about this particular comorbidity

Key Facts of Anxiety Disorders

In the DSM 5, anxiety disorders are presented with an order relative to the age of onset. They are separation anxiety disorder, selective mutism, specific phobia, social phobia, panic disorder, agoraphobia, and generalized anxiety disorder. The various disorders differ substantially in the content of the threat and in the intensity and duration of cognitive, somatic, and behavioral symptoms. For example, in separation anxiety disorder, the separation from the reference figure represents the stressful event, while in social phobia it is related to the possible judgment by others. Panic disorder has high intensity and short-duration acute symptoms, while generalized anxiety disorder shows low intensity and long duration symptoms. Anxiety disorders are widespread in the general population and require combined psychoeducative, psychotherapeutic, and psychopharmacological treatments

Key Facts of Obsessive-Compulsive Disorders

Obsessions are recurring and persistent thoughts, impulses, and images, experienced as intrusive and unpleasant; compulsions are repetitive attitudes or mental actions that usually follow an obsession. The annual prevalence in the United States of OCD is 1.2%, and the disorder is more frequent in females, but in males the onset is anticipated. The course is chronic if left untreated. OCD responds to drug treatment with SSRIs and TCAs in combination or not with psychotherapeutic treatments

Key Facts of Psychosis

Psychosis is severe type of psychiatric disorder, expression of an alteration of the psychic stability of the individual, with impairment of reality examination, frequent absence of insight, and frequent presence of thought disorders, delusions, and hallucinations. Psychosis is often accompanied by an altered relationship with

reality, impairment of one or more mental functions, disintegration of the personality, lack of insight, very marked regression, primordial and catastrophic anxieties, and defense mechanisms such as scotomization and external projection. Schizophrenia is characterized by the presence of delusions, hallucinations, speech and disorganized behavior, decreased expression of emotions, and abulia with a chronic and worsening course with remissions and exacerbations of active symptoms. The prevalence of schizophrenia is 0.3–0.7%

Summary Points

- The association of two or more mental disorders, properly psychiatric comorbidity, has increased in recent years, and this is due to multiple factors including introduction of the concept of multiple and discrete mental disorder categories, operational criteria, structured interviews, diagnostic algorithms, validity, and reliability of the diagnosis
- AN displays a high level of psychiatric comorbidities, and this has been confirmed by population-based and clinical-based studies
- Several theories have been attempted to explain the frequent association between AN and other psychiatric disorders. Findings suggest that there may be common causative and maintenance factors or that AN may complicate a preexisting affective disorder. Negative affect symptoms and negative self-appraisal are potentially important as well as eating core symptoms
- Clinically, the presence of psychiatric comorbidities in the AN has an impact on the onset, course, severity of clinical manifestations, recovery, outcome, and prognosis with evidence of increased mortality and suicidal risk
- Treatment of AN is complex, and therefore the presence of psychiatric comorbidity adds further complexity. The effects of malnutrition and dysfunctional eating behaviors must be taken into account as well as the evidence that improvements on the psychological state are usually obtained after improvements on the physical level
- The AN-depression association is the most frequent. The two conditions can potentially share numerous causal and maintenance factors. It is not clear whether depression precedes or follows AN, but an area of investigation is the link between malnutrition and depressive symptoms. Comorbidity AN-depression increases suicidal risk
- Some symptoms of the bipolar spectrum are often present in the course of AN such as hyperactivity, hypertalkativeness, impulsivity, insomnia, and poor insight. Comorbidity AN-bipolar disorder was associated with a negative outcome, worse quality of life, and greater treatment complexity
- Anxiety usually precedes AN. Several authors suggest that anorexic symptoms may have the function of reducing underlying anxiety. The most common anxiety disorders are social phobia and GAD
- Anorexia nervosa and OCD appear to share common psychopathological features and several causative and maintenance factors. This comorbidity is very common

- The association between AN and psychosis has been less studied than the other comorbidities. The most promising area of investigation is that relating to the use of SGAs, in particular populations of patients with severe AN
- Substance abuse is more common in the AN binge/purging subtype
- The binge/purging subtype is often associated with cluster B personality disorders
- The restrictive subtype is often associated with obsessive-compulsive personality disorder

Abstract

Anorexia nervosa is a psychiatric disorder characterized by low body weight and serves as a model of chronic human starvation. Humans have evolved hormonal adaptations to survive periods of starvation. One critical response to periods of decreased nutrient intake is growth hormone (GH) resistance. This adaptive response allows for the maintenance of the beneficial counter-regulatory properties of GH during periods of low caloric intake, while minimizing energy expenditure on growth-related processes. This chapter will review the GH-insulin-like growth factor-1 (IGF-1) axis in anorexia nervosa. We will also describe potential mechanisms of GH resistance in this disorder, the effects of GH resistance on bone mass in anorexia nervosa, and the effects of treatment with exogenous GH and IGF-1 in anorexia nervosa.

Keywords

Anorexia nervosa · Growth hormone · IGF-1 · Bone mineral density · Growth hormone resistance · Chronic starvation · Adaptive response · Exogenous GH · rhIGF-1

Abbreviations

AN	Anorexia nervosa
BMD	Bone mineral density
BN	Bulimia nervosa
CREBH	cAMP-responsive element-binding protein H
FGF-21	Fibroblast growth factor-21
GH	Growth hormone
GHSR1a	Growth hormone secretagogue receptor 1a
IGF-1	Insulin-like growth factor-1
kg	Kilograms
mcg	Micrograms
mg	Milligrams
rhGH	Recombinant human growth hormone
rhIGF-1	Recombinant human insulin-like growth factor-1
SIRT1	Sirtuin 1
STAT5	Signal transducer and activator of transcription 5
T3	Triiodothyronine

Introduction

Anorexia nervosa affects up to 2.2% of women (Keski-Rahkonen et al. 2007) and is defined by low body weight due to self-induced starvation. This psychiatric disorder, which affects women more often than men, can serve as a model of chronic starvation in humans. As our evolutionary past was marked by periods of famine, humans have evolved several hormonal adaptations to survive periods of decreased nutrient intake. These responses to undernutrition include functional hypothalamic amenorrhea, an adaption that results in shunting energy away from reproduction, a costly process that is critical for the survival of the species but notably not critical for the survival of an individual (Fazeli and Klibanski 2018). A second crucial adaptive response to a state of chronic undernutrition is growth hormone (GH) resistance (Fazeli and Klibanski 2014).

GH is a hormone secreted by pituitary somatotroph cells and signals the liver to produce insulin-like growth factor (IGF)-1. IGF-1, in turn, mediates many of GH's growth-related processes. GH has other effects, including lipolytic actions (Gahete et al. 2013) and counter-regulatory effects that help maintain euglycemia during periods of fasting (Zhao et al. 2010; Kopchick et al. 2020). Whereas the counter-regulatory effects and lipolytic actions of GH are essential for energy mobilization during periods of low caloric intake, it is not advantageous to utilize energy for growth during such periods (Fazeli and Klibanski 2018). Therefore, a state of GH resistance – robust GH secretion coupled with low or low-normal IGF-1 levels, which would minimize energy expenditure on IGF-1-dependent processes – would be advantageous in states of chronic undernutrition such as anorexia nervosa.

In this chapter, we will review the GH-IGF-1 axis in anorexia nervosa. We will describe potential mechanisms of GH resistance in this disorder, the effects of GH resistance on bone mass in anorexia nervosa, and the effects of treatment with exogenous GH and IGF-1 in anorexia nervosa.

GH and IGF-1 Levels in Anorexia Nervosa

IGF-1, a hormone primarily secreted by the liver in response to GH secretion by the pituitary gland, is also responsive to nutritional status. For example, during an acute fast, IGF-1 levels fall below the normal range (Clemmons et al. 1981) (Fig. 1); IGF-1 levels drop by 40% within 4 days of a fast (Grinspoon et al. 1995), but the decrease in IGF-1 levels are not due to a drop in GH levels (Clemmons et al. 1981). Girls and women with anorexia nervosa, a state of chronic undernutrition, also have lower IGF-1 levels compared to normal-weight girls (Counts et al. 1992). IGF-1 levels in anorexia nervosa are approximately 50% of those of normal-weight individuals (Counts et al. 1992), and these low IGF-1 levels are concomitant with increased GH secretion (Garfinkel et al. 1975; Scacchi et al. 1997; Stoving et al. 1999) and a failure of GH to suppress in the setting of intravenous or oral glucose (Tamai et al. 1991; Misra et al. 2004). Notably, bioactive IGF-1 levels are also decreased compared to normal-weight controls (Støving et al. 2007). The importance of nutritional status on the GH-IGF-1 axis is further underscored by the fact that hyperalimentation

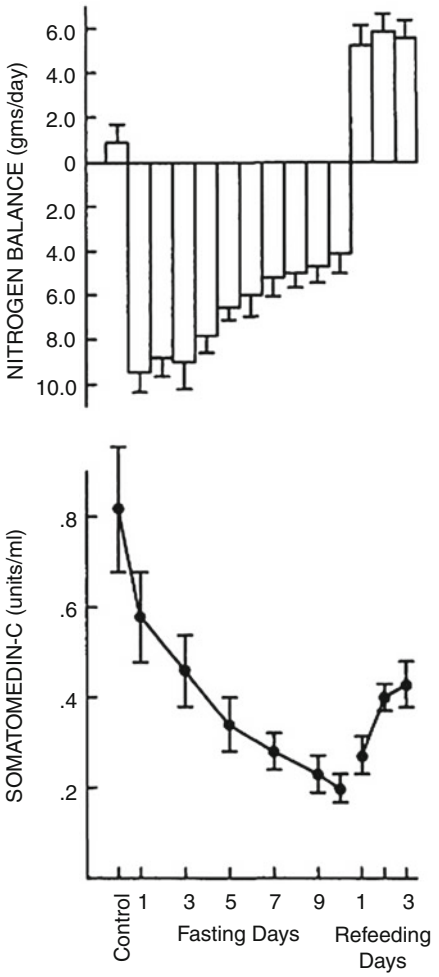

Fig. 1 Plasma somatomedin C [IGF-1] levels decrease during an acute fast. Nitrogen balance and immunoreactive plasma somatomedin C levels in study subjects. Nitrogen balance (top panel) was determined as the nitrogen intake minus daily urinary urea nitrogen plus 2 g nitrogen (2 g nitrogen was estimated to be the loss in stool, skin, and urinary nonurea nitrogen). The mean (±SEM) balance value for all seven subjects is depicted. The mean (±SEM) plasma somatomedin C is depicted in the lower panel. The control day sample represents the mean values for all subjects on 3 consecutive control days. (Reprinted by permission of Oxford University Press on behalf of the Endocrine Society (Clemmons et al. 1981))

therapy in women with anorexia nervosa results in a rapid increase in IGF-1 levels – 3 days of hyperalimentation therapy increases IGF-1 levels by nearly 50% (Hotta et al. 2000). This nutritional regulation of IGF-1 levels in states of fasting and chronic starvation is likely an adaptive response, allowing for decreased energy expenditure on IGF-1-dependent processes, including acquisition and maintenance of bone mass (Dixit et al. 2021) during times of reduced caloric intake. In contrast, given GH's lipolytic and insulin-resistant actions (Kopchick et al. 2020), the robust secretion of GH during periods of decreased caloric intake is also advantageous. Therefore, anorexia nervosa, a state of chronic undernutrition, is biochemically characterized by low IGF-1 levels and normal/elevated GH levels, also known as a state of GH resistance.

Potential Causes and Mechanisms of GH Resistance in Anorexia Nervosa

Although the precise mechanisms of GH resistance in anorexia nervosa have not been elucidated, there are several potential mechanisms (Fig. 2). First, the lack of high IGF-1 levels in the setting of robust secretion of GH suggests either down-regulation of GH receptors in the liver or a post-receptor defect, resulting in a disruption in GH's ability to stimulate IGF-1 production and secretion (Fazeli and Klibanski 2014). Animal studies suggest that GH receptor downregulation may in part contribute to the low IGF-1 levels observed in states of starvation (Baxter et al. 1981; Straus and Takemoto 1990).

Protein Deficiency

Isolated protein deficiency is also associated with GH resistance. This has been shown in studies of children (Olusi et al. 1977; Robinson and Picou 1977; Hintz et al. 1978; Soliman et al. 1986) and adults (Isley et al. 1983). Given the overall inadequate caloric intake in anorexia nervosa, one might hypothesize that protein deficiency contributes to the state of GH resistance in anorexia nervosa also. However, this is not the case, and studies demonstrate that individuals with anorexia nervosa consume similar amounts of protein compared to normal-weight controls (Fernstrom et al. 1994; Misra et al. 2006a, b). Therefore, protein deficiency is not likely to be a primary driver of GH resistance in anorexia nervosa.

Ghrelin

Acylated ghrelin – the active form of the hormone ghrelin, which is an orexigenic hormone secreted by the fundal cells of the stomach – binds to the GH secretagogue

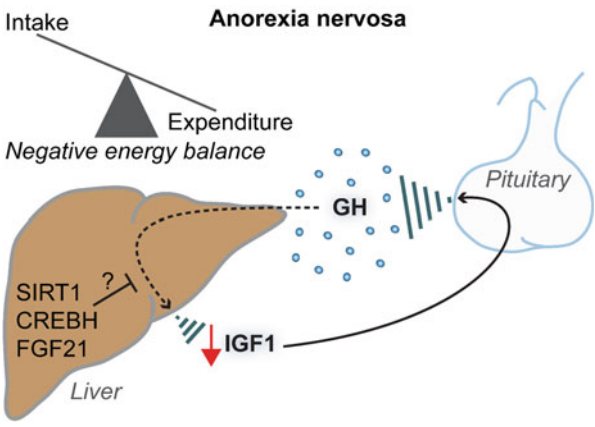

Fig. 2 Possible mediators of growth hormone (GH) resistance in anorexia nervosa include sirtuin 1 (SIRT1), cAMP-responsive element-binding protein H (CREBH), and FGF-21

receptor 1a (GHSR1a). Levels of ghrelin are higher in anorexia nervosa as compared to normal-weight controls (Otto et al. 2001). As ghrelin binds to the GHSR1a and results in GH release, the elevated ghrelin levels likely help maintain GH levels in anorexia nervosa and may be a potential mediator of GH resistance.

Although ghrelin is an orexigenic hormone and levels are higher in anorexia nervosa than normal-weight individuals, levels of hunger are lower in anorexia nervosa than in controls (Halmi et al. 1989). Therefore, women with anorexia nervosa may be resistant to the orexigenic effects of ghrelin. In a randomized, placebo-controlled study investigating the impact of a GHSR1a agonist (a ghrelin agonist) in women with anorexia nervosa, we found a trend in weight gain in women randomized to the GHSR1a agonist as compared to the placebo-treated women (Fazeli et al. 2018). IGF-1 levels also increased significantly in response to 4 weeks of treatment with the GHSR1a agonist even after controlling for changes in weight (Fazeli et al. 2018). This rise in IGF-1 levels was unexpected, given the state of GH resistance in anorexia nervosa and the fact that we would expect a GHSR1a agonist to act on the GH-IGF-1 axis by increasing GH levels. This finding suggests that there may be an alternate means by which a ghrelin agonist increases circulating IGF-1 levels.

Sirtuin 1

Sirtuin 1 (SIRT1) is a deacetylase that promotes gluconeogenesis and fatty acid oxidation in the setting of fasting (Gillum et al. 2010). In murine models, SIRT1 has been shown to be a mediator of GH resistance during starvation (Yamamoto et al. 2013). As compared to controls, mice in whom SIRT1 was knocked down had higher serum levels of IGF-1 after a 48-h fast (Yamamoto et al. 2013), suggesting that SIRT1 may be a mediator of the low IGF-1 levels observed in the setting of starvation (Yamamoto et al. 2013). The proposed mechanism by which SIRT1 reduces IGF-1 levels is through a decrease in STAT5 phosphorylation, a transcription factor that plays a vital role in GH signaling and induction of IGF-1 (Yamamoto et al. 2013).

CREBH

The cAMP-responsive element-binding protein H (CREBH) is a transcription factor induced during fasting. Liver-specific CREBH transgenic mice have a biochemical profile consistent with GH resistance – increased GH levels and decreased IGF-1 levels (Nakagawa et al. 2021). The liver-specific CREBH transgenic mice have reduced liver expression of GH receptor mRNA, suggesting a potential mechanism by which CREBH causes GH resistance (Nakagawa et al. 2021).

Fibroblast Growth Factor (FGF)-21

FGF-21 is a hormone predominantly secreted by the liver during fasting (Badman et al. 2007; Inagaki et al. 2007; Fazeli et al. 2015). FGF-21 is a potential mediator of GH resistance in murine models (Inagaki et al. 2008); FGF-21 transgenic mice have the biochemical profile of GH resistance – compared to wild-type mice, they have higher GH levels and lower IGF-1 levels (Inagaki et al. 2008) (Fig. 3). Similar to SIRT1, the mechanism by which FGF-21 is thought to mediate GH resistance is a reduction in STAT5 phosphorylation (Inagaki et al. 2008). In the human model of chronic starvation, anorexia nervosa, we have also shown that FGF-21 may mediate GH resistance. In a study of adolescent girls with anorexia nervosa, FGF-21 was positively associated with GH area under the curve during 12-h frequent overnight sampling and negatively associated with IGF-1 (Fazeli et al. 2010a). Therefore, FGF-21 may be a potential mediator of GH resistance in anorexia nervosa.

Insulin

GH resistance is observed in type 1 diabetes mellitus – a state of insulin deficiency (Horner et al. 1981; Gutefeldt et al. 2018). In vitro studies and studies in animal models suggest that the GH resistance in insulin-deficient states may be due to a reduction in GH receptors in the liver (Baxter and Turtle 1978; Leung et al. 2000). In conditions of starvation, insulin levels are low due to decreased nutrient intake, and therefore low insulin levels may play a role in mediating GH resistance in anorexia nervosa (Fig. 4).

Triiodothyronine

Anorexia nervosa is characterized by low thyroid hormone levels, including triiodothyronine (T3) (Miyai et al. 1975; Moshang Jr. et al. 1975). In fasted animal

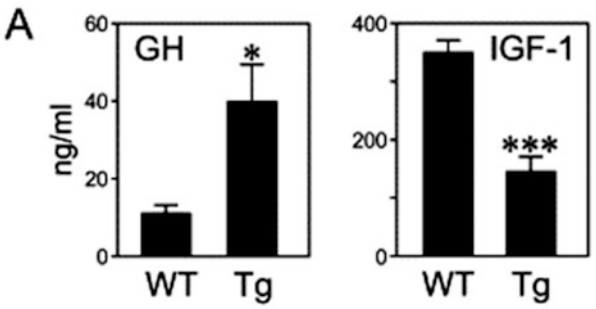

Fig. 3 Levels of GH and IGF-1 in FGF-21 transgenic mice. FGF-21 causes GH resistance. (**a**) GH and IGF-1 concentrations in plasma from wild-type (WT) and *FGF21*-transgenic (Tg) mice. $n = 8$ male mice/WT group, 11 male mice/Tg group. Fig. 4 Relationship between insulin levels and GH binding. GHR biosynthesis. (**a**) Total GH binding. GH binding to total cellular membranes was determined as described in Materials and Methods. The control level was 1676 ± 228 cpm/mg protein. Significance versus control: *, $P < 0.0001$. (**b**) RT-PCR for mRNA of GHR and β-actin. Total RNA was harvested from cultures treated with insulin at the indicated concentrations and used in the RT-PCR for GHR and β-actin mRNA. A representative agarose gel electrophoresis of PCR products stained with ethidium bromide is shown. (**c**) Western blot of GHRs. Immunoprecipitation was performed with a combination of an antiserum (αGHRcyto) and a monoclonal antibody (MAb263) against GHR. The samples were then separated by SDS-PAGE and studied by Western blotting with αGHRcyto. (**d**) Densitometric quantitation of GHR protein from Western analysis. Significance versus control: *, $P = 0.001$; #, $P < 0.005$. (Reprinted by permission of Oxford University Press on behalf of the Endocrine Society (Leung et al. 2000))

models, similar to human models of starvation, IGF-1 and T3 levels are both reduced, but treatment with subcutaneous T3 results in normalization of T3 levels and a significant increase in IGF-I levels (Ikeda et al. 1990). Therefore, the low T3 levels in anorexia nervosa may also mediate GH resistance.

Leptin

Leptin is a hormone secreted predominantly by subcutaneous adipocytes. As subcutaneous adipose tissue stores are reduced in states of chronic starvation such as

anorexia nervosa, leptin levels are also low (Grinspoon et al. 1996a). Low leptin levels are a likely mediator of functional hypothalamic amenorrhea in states of negative energy balance (Welt et al. 2004). In women with functional hypothalamic amenorrhea, treatment with recombinant human methionyl leptin results in normalization of leptin levels and an increase in IGF-1 levels (Chan et al. 2008). Therefore, in addition to being a potential mediator of functional hypothalamic amenorrhea, low leptin levels may also mediate GH resistance in anorexia nervosa.

Estradiol

As a likely result of the low leptin levels, most women with anorexia nervosa have functional hypothalamic amenorrhea (Welt et al. 2004; Miller et al. 2004). To treat the hypoestrogenemia resulting from functional hypothalamic amenorrhea, women with anorexia nervosa are often started on oral contraceptive pills containing oral estrogen, despite multiple prospective, randomized studies which have demonstrated no benefit to oral estrogen compared to placebo with respect to changes in bone mineral density (Klibanski et al. 1995; Golden et al. 2002; Grinspoon et al. 2002). Oral estrogen reduces IGF-1 levels in women in a dose-dependent manner (Kam et al. 2000) and to a greater degree than transdermal estrogen (Weissberger et al. 1991). Therefore, treatment of functional hypothalamic amenorrhea with oral contraceptive pills may lead to a more significant reduction in IGF-1 levels in women with anorexia nervosa than that observed due to GH resistance alone.

Testosterone

Treatment with testosterone increases IGF-1 levels in men (Hobbs et al. 1993; Liu et al. 1987). A similar association is found in women; compared to normal-weight controls, women with anorexia nervosa have lower testosterone levels (van Binsbergen et al. 1990; Miller et al. 2007), and free testosterone levels are positively associated with IGF-I levels (Brick et al. 2010). Therefore, low testosterone levels in anorexia nervosa may also contribute to the low IGF-1 levels observed in this disorder.

Effects of GH Resistance on Bone Mineral Density

Low bone mass is the most prevalent medical complication associated with anorexia nervosa (Miller et al. 2005). More than 85% of women with anorexia nervosa have either osteopenia-range or osteoporosis-range bone mineral density (BMD) values (Miller et al. 2005) and an increased fracture risk, which persists even years after initial diagnosis (Rigotti et al. 1991; Lucas et al. 1999; Vestergaard et al. 2002; Nagata et al. 2017; Frølich et al. 2020). The hormonal adaptations observed in anorexia nervosa, including functional hypothalamic amenorrhea and GH resistance,

are likely integral mediators of this reduction in bone mineral density (Fazeli and Klibanski 2018; Fazeli 2019).

The low IGF-1 levels in anorexia nervosa, which are secondary to GH resistance, are associated with abnormal bone parameters. Low IGF-1 levels are associated with both low markers of bone formation (Hotta et al. 2000; Soyka et al. 1999) and low BMD (Fazeli et al. 2010b; Grinspoon et al. 1999). Low IGF-1 levels are also associated with lower estimates of bone strength in this population (Fazeli et al. 2020).

Effects of GH and IGF-1 Replacement in Anorexia Nervosa (Table 1)

Recombinant Human GH

Treatment with supraphysiologic doses of GH cannot overcome GH resistance in anorexia nervosa (Fazeli et al. 2010c). We randomized 21 women to recombinant human GH or placebo for 12 weeks (Fazeli et al. 2010c). The mean maximum daily dose of recombinant human GH was 1.4 mg/day, which is approximately five times greater than typical doses used to treat adult GH deficiency (Fazeli et al. 2010c). Despite these high doses of recombinant human GH, levels of IGF-1 were similar in the groups receiving recombinant human GH and placebo at the conclusion of the study (Fazeli et al. 2010c). Although IGF-1 levels were similar in both groups after treatment, the study participants with anorexia nervosa who received recombinant human GH had a significant decrease in fat mass compared to the placebo group, demonstrating that the lipolytic effects of GH – a potentially advantageous effect in a state of starvation – remained intact and also suggesting that the lack of a difference in IGF-1 levels between the two groups was not likely due to participant non-compliance with the recombinant human GH treatment (Fazeli et al. 2010c).

Recombinant Human IGF-1

The use of recombinant human IGF-1 has been investigated in both women and adolescent girls with anorexia nervosa. Given the association between low IGF-1 levels and low bone parameters (Hotta et al. 2000; Soyka et al. 1999; Fazeli et al. 2010b, 2020; Grinspoon et al. 1999), the primary outcome for the studies investigating recombinant human IGF-1 in anorexia nervosa is bone parameters including bone turnover markers, bone mineral density, and bone microarchitecture. The results of these studies have differed in adults versus adolescents, with women having a beneficial response with respect to changes in bone mineral density with recombinant human IGF-1 (Grinspoon et al. 2002; Haines et al. 2021), whereas adolescent girls do not have a beneficial response (Singhal et al. 2021).

With respect to adults, there have been three randomized studies investigating the use of recombinant human IGF-1 in women with anorexia nervosa (Grinspoon et al. 1996b, 2002; Haines et al. 2021). In a study looking at short-term use of recombinant

Table 1 Studies assessing the effects of recombinant human growth hormone (rhGH) or recombinant human insulin-like growth factor 1 (rhIGF-1) in anorexia nervosa

Treatment	Design	Participants	Intervention groups	Treatment duration	Results	References
rhIGF-1	Randomized	Women, anorexia nervosa (ages: 18–29 yo)	1. rhIGF-1 30 mcg/kg twice daily 2. rhIGF-1 100 mcg/kg twice daily 3. Placebo	6 days	**rhIGF-1, 30 mcg dose**: Increase in bone formation marker **rhIGF-1, 100 mcg dose**: Increase in bone formation and bone resorption markers	Grinspoon et al. (1996b)
rhIGF-1	Randomized	Women, anorexia nervosa (ages: 18–38 yo)	1. rhIGF-1 2. Oral contraceptive (OCP) 3. rhIGF-1 + OCP 4. Placebo	9 months	**rhIGF-1 + OCP**: 1.8% increase in spine bone mineral density **OCP alone**: No significant change in bone mineral density	Grinspoon et al. (2002)
rhIGF-1	Open-label	Adolescent girls, anorexia nervosa (ages: 12–18 yo)	rhIGF-1 30–40 mcg/kg twice daily	7–9 days	Increase in marker of bone formation No increase in marker of bone resorption	Misra et al. (2009)
rhIGF-1	Randomized	Adolescent girls, anorexia nervosa (ages: 14–22 yo)	1. Transdermal estradiol + rhIGF-1 2. Transdermal estradiol + placebo	12 months	No benefit of IGF-1	Singhal et al. (2021)

(continued)

Table 1 (continued)

Treatment	Design	Participants	Intervention groups	Treatment duration	Results	References
rhIGF-1	Randomized	Women, anorexia nervosa (ages: 18–45 yo)	1. Six months rhIGF-1 followed by 6 months of risedronate 2. 12 months of risedronate 3. Placebo	12 months	**rhIGF-1 followed by risedronate**: 1.9% increase in lumbar spine bone mineral density at 12 months **12 months of risedronate**: 1.7% increase in lumbar spine bone mineral density at 12 months **Placebo**: 0.3% decrease in lumbar spine bone mineral density at 12 months	Haines et al. (2021)
rhGH	Randomized	Women, anorexia nervosa (ages: 18–45 yo)	1. rhGH 2. Placebo	12 weeks	IGF-1 levels similar in rhGH group compared to placebo at 12 weeks Fat mass decreased in rhGH group versus placebo	Fazeli et al. (2010c)

rhIGF-1: recombinant human IGF-1; rhGH: recombinant human growth hormone; yo: years old

human IGF-1 in women with anorexia nervosa, the primary outcome was markers of bone turnover (Grinspoon et al. 1996b). At baseline, women with anorexia nervosa had significantly lower bone formation markers and elevated bone resorption markers compared to women without anorexia nervosa (Grinspoon et al. 1996b). Six days of treatment with 30 mcg/kg twice per day of subcutaneous recombinant human IGF-1 increased bone formation markers, whereas 6 days of treatment with a higher dose (100 mcg/kg twice per day) led to an increase in both bone formation and bone resorption markers in women with anorexia nervosa (Grinspoon et al. 1996b). A subsequent randomized placebo-controlled study investigated the effects of recombinant human IGF-1 on bone mineral density in women with anorexia nervosa and found that those randomized to recombinant human IGF-1 in addition to oral estrogen, in the form of an oral contraceptive pill, had an increase in spine bone mineral density of 1.8% after 9 months of treatment (Grinspoon et al. 2002) (Fig. 5).

In contrast, in a study in adolescents randomized to either subcutaneous recombinant human IGF-1 or placebo in addition to transdermal estradiol, there was no benefit observed with the addition of recombinant IGF-1 to transdermal estradiol after 12 months of treatment with respect to areal or volumetric bone mineral density measures (Singhal et al. 2021). Surprisingly, there was a significantly greater increase in areal bone mineral density at the spine in the adolescent girls randomized to transdermal estradiol alone compared to those randomized to the combination of transdermal estradiol + recombinant human IGF-1 (Singhal et al. 2021). This

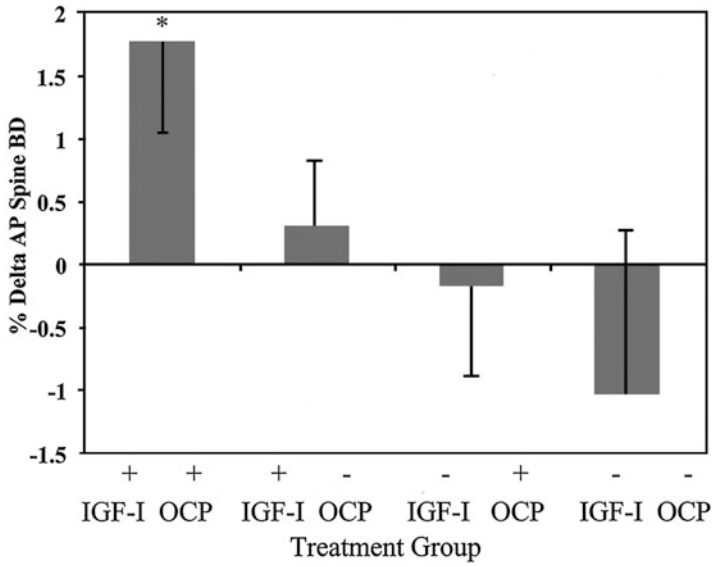

Fig. 5 Spine bone density increases in response to treatment with rhIGF-1 and oral estrogen. Percent change from baseline in AP spinal bone density. *, $P < 0.05$ versus control subjects (group IV). Results are mean ± SEM. (Reprinted by permission of Oxford University Press on behalf of the Endocrine Society (Grinspoon et al. 2002))

difference in the response of adults versus adolescents has been observed in prior treatment studies in anorexia nervosa with respect to treatments for low bone mineral density. For example, when compared to placebo, bisphosphonates increase bone mineral density in adults (Miller et al. 2011) but not in adolescents (Golden et al. 2005). This is likely because bone turnover is distinctly different in adolescents – a time when bone mass is increasing – as compared to adults when peak bone mass has been achieved (Fazeli and Klibanski 2018; Fazeli 2019). These findings underscore the importance of testing therapies to treat low bone mineral density separately in adolescents with anorexia nervosa and adults with the disorder.

Applications to Other Eating Disorders

Anorexia nervosa results in a unique state of GH resistance. Limited conflicting data regarding changes to the GH-IGF-1 axis have been reported in patients with bulimia nervosa (BN), an eating disorder characterized by binge eating and actions to prevent weight gain, such as purging (American Psychiatric Association 2013). Kiriike et al. examined GH levels at baseline and following thyrotropin-releasing hormone stimulation in women with BN and found that 33% of the BN patients had elevated baseline GH levels (Kiriike et al. 1987). Similarly, Levy et al. compared a group of subjects with BN to control subjects and found that IGF-1 levels in BN were comparable to controls despite the fact that the BN group had significantly higher fasting GH levels and the mean GH level after thyrotropin-releasing hormone stimulation was significantly higher in the BN group as compared to controls (Levy and Malarkey 1988). As GH is a counter-regulatory hormone and released in states of physiologic stress, the elevated levels could potentially reflect a stress response, but thus far AN remains the only eating disorder associated with low IGF-1 values in the setting of high GH levels.

Conclusions

Anorexia nervosa is a psychiatric disorder characterized by chronic undernutrition resulting in low body weight. Several hormonal adaptations occur in this state of chronic undernutrition, including functional hypothalamic amenorrhea and GH resistance (Fazeli and Klibanski 2018). The biochemical profile of GH resistance includes normal or elevated GH levels and low IGF-1 levels. This state of GH resistance allows for the lipolytic and insulin-resistant effects of GH (Kopchick et al. 2020) to be maintained while minimizing energy expenditure on costly IGF-1-dependent processes, including the maintenance of bone mass (Dixit et al. 2021). Treatment with supraphysiologic recombinant human GH cannot overcome GH resistance in anorexia nervosa (Fazeli et al. 2010c). Treatment with recombinant human IGF-1, when combined with estrogen, increases bone mineral density in adults with anorexia nervosa (Grinspoon et al. 2002) but not adolescents with anorexia nervosa (Singhal et al. 2021). Further studies are needed to better

understand the mechanisms of GH resistance in states of chronic undernutrition and ways to minimize the negative consequences of long-term GH resistance in anorexia nervosa, namely, loss of bone mass.

Mini-Dictionary of Terms

- *Functional hypothalamic amenorrhea:* A likely adaptive response to states of physiologic stress, including undernutrition and negative energy balance, whereby gonadotropin-releasing hormone secretion from the hypothalamus is disrupted, resulting in amenorrhea.
- *Gluconeogenesis*: A metabolic process that results in the formation of glucose.
- *Lipolysis*: The process by which adipose tissue is broken down into its constituents.
- *Orexigenic*: Hunger-stimulating.
- *Transcription factor:* A protein that binds to specific DNA motifs to regulate gene expression.

Key Facts of the GH/IGF-1 Axis

- The GH/IGF-1 axis is responsible for growth in childhood and is important in the maintenance of bone and muscle mass in adulthood.
- GH-releasing hormone, produced in the hypothalamus, induces secretion of GH from the pituitary gland which stimulates IGF-1 production, primarily from the liver.
- GH deficiency in childhood can result in short stature and can be treated with subcutaneous recombinant human GH.
- In adults, GH deficiency can cause changes in body composition, cardiovascular risk markers, and quality of life.
- Acromegaly is a disorder of pathophysiologic GH excess and elevated IGF-1 levels. Acromegaly is most commonly due to a GH-secreting pituitary tumor. If this pathophysiologic GH excess occurs in a child, before the growth plates are fused, it is called gigantism.

Summary Points

- Anorexia nervosa is a psychiatric disorder that serves as a model of chronic human starvation.
- GH is secreted by the pituitary gland and signals the liver to produce IGF-1, a hormone responsible for most of the growth-mediating effects of GH.
- GH is also a secreted during periods of starvation and may help with the maintenance of euglycemia during periods of decreased caloric intake, in part by mobilizing adipose tissue stores.

- GH resistance, characterized by normal or high GH levels and low IGF-1 levels, is an adaptive response to undernutrition and starvation.
- Potential mediators of GH resistance include FGF-21, SIRT1, and CREBH.
- Treatment with supraphysiologic rhGH does not overcome the state of GH resistance in anorexia nervosa, and IGF-1 levels remain low.
- Bone mineral density is decreased in states of chronic starvation, likely in part due to the hormonal adaptations to undernutrition, including GH resistance.
- Subcutaneous administration of rhIGF-1, when coupled with estrogen, has been shown to improve bone mineral density in adult women with anorexia nervosa but not adolescent girls with this disorder.

and psychological aspect that occur in the young person – adolescent – affect the person's bulimic behavior. The girl or boy who is strongly focused on the body shape and weight is not satisfied with the image of her/his own body, negative thoughts and emotions are present, and they strive for perfection; therefore, the failure to meet the highly set goals is compensated with an increased desire to eat and overeat, which fosters the pathological patterns of food-related behavior, such as bulimia nervosa. The negative self-image leads to low self-esteem, increased level of perfectionism, fear, anxiety, sadness, increased internal pressure and conflict, and body weight; therefore, the adolescent needs professional help and adequate nutritional, pharmacological, and psychological treatment.

Introduction

Eating disorders in infancy and early childhood are different, such as refusal of food or qualitatively increased food intake. The infant's behavior during the eating process is partly an instinctive and partly a scientific process. Mouth activity and turning toward the source of stimulation are the infant's first activities in relation to the outside world. The child responds to stimuli coming from the mother's arms and breast. While eating, the child ingests food, but simultaneously, this process represents love, pleasure, and tenderness and, on the other hand, dissatisfaction, fear, and sadness. Impaired interaction with parents contributes to the emergence of guilt, decreased self-esteem, and behavioral problems in the child (Vidovic 2009). In

infancy and early childhood, an eating disorder known as pica is most common, while in adolescence, such disorders are anorexia (anorexia nervosa) and bulimia (bulimia nervosa).

Eating disorders have been known since ancient civilizations; however, in the world we live in, we are constantly exposed to information that the number of adolescents with eating disorders is constantly increasing. The mental state that can lead a young person toward dissatisfaction with his/her body is still a mystery in modern medicine and psychology. High levels of hatred of one's own body, self-criticism, self-control, and discipline are required to develop a complex disorder, such as bulimia. Due to preoccupation with the physical appearance, this type of eating disorder in adolescents is an obstacle for the successful performance and focus on daily responsibilities. It is associated with impaired self-esteem and self-image, later on followed by withdrawal, loss of contact with others, and difficulty to establish emotional relationships. The young person with a bulimic disorder experiences changes from psychological aspect, but also in terms of the behavior that is associated with increased dissatisfaction with the appearance and increased body weight. For this reason, psychologists, nutritionists, psychiatrists, and doctors try to penetrate the bulimic person, to recognize the first signs and risk factors for the emergence of this type of eating disorder, its psychological implications for the young person, as well as the development of adequate prevention programs focused on adequate treatment and lifestyle changes.

Adolescence: A Risky Period for the Development of Bulimia Nervosa

Adolescence is a period of life between childhood and adulthood. This interspace in life is an important, decisive period in the life of each individual. Biologically, adolescence begins with the development of reproductive abilities and ends with a deceleration of the physical development. Psychologically, an adolescent is a person in a transitional period between a behavior that is typical of a child and one that is typical of an adult. From a social point of view, it is a period focused on choosing a profession, as well as a period of establishing independence from parents.

The hormonal changes that occur at the onset of puberty strongly and rapidly disrupt the peace from the period of latency. The body becomes an important and decisive developmental segment considering that it reaches maturity and formation. The physical experience largely affects the formation and maintenance of the identity. To be yourself in your big body (strong, powerful, and wise), to feel good and to be harmonized with yourself and different from others, is something that is set before every adolescent. The road is thorny, full of ups and downs, fears, concern, or low mood. The progress in one field of functioning is often accompanied by regression in another field. Therefore, in this developmental period, the feeling of disorder, ambiguity, confusion, and incomprehension of changes often occurs. This is present from the very beginning of the acquisition of psychosexual identity in

early adolescence, when a "painful" hypersensitivity occurs, as well as fear associated with the body (mirror phenomenon, dysmorphic or hypochondriac difficulties), when the adolescent feels "very strong," when the person wants everything to be "immediately and now," and when the process of separation-individualization begins. It is a period when the adolescent starts to rebel, although sometimes he/she does not even know why, but he/she knows that he/she must do that. However, this is related to the awareness of the need for changes that occur with age and development.

The inadequate adaptation of the young person to the conflicting developmental tasks of adolescence, the disturbed realization of the personal synthesis of the individual and the social, and the problems with basic and gender identity all contribute to the development of depressive behavior in the young person, whereby the person's ego becomes fragile and vulnerable. Due to this regression, the person develops nonspecific psychological symptoms, signs and forms of behavior, and characteristic defense mechanisms. Simultaneously, a fear arises regarding the person's own somatic health, fear of specific somatic diseases, behavioral changes, school-related difficulties, emotional difficulties, or mental anorexia or bulimia.

Bulimia most frequently occurs in the transition period from early to middle adolescence and during the transition from adolescence to the early developmental period (Fischer and Le Grande 2007; Sullivan et al. 1998). With the very commencement of secondary school, many girls start dieting, which is a problem because it leads to weight fluctuations and overeating, and any such behavior leads to bulimia and health disorders (Gjurovic 2003).

The dissatisfaction with one's appearance, the adherence to different diets, the increased physical activity, and the inadequate attitudes related to the diet all have different oscillations from one person to another. Many factors are present that contribute to the occurrence of such behavior; however, in the literature, there are two basic models that explain the role of pubertal maturation in the development of bulimia nervosa (Ambrosi-Randic 2004).

The first model is focused on the moment when pubertal maturation begins, so the young person, especially girls, can develop early, on time, or late. The stress and fear of early maturation is a major reason for the development of a psychopathology, including bulimia. Researches have shown that girls who mature early have negative attitudes regarding their own body, so they follow a diet or overeat; therefore, they are at an increased risk of developing bulimia nervosa (Pinel 2002; Pokrajac-Bulian and Kandare 2000).

The second model focuses on the simultaneous action of puberty and transient changes in this period. It is considered that cumulative stress negatively affects the psychosocial functioning, self-esteem is reduced, and it leads to overeating, which contributes to weight gain and mental difficulties – dissatisfaction, low mood, and frustration.

Psychodynamics of Bulimia Nervosa

Over the last few decades, the idea of a single factor as the main cause for the emergence of bulimia nervosa has been replaced by the vision of a "multifactorial" disease, although to this day it is still not entirely clear. In 1980, Paula Garfinkel and David Garner proposed the model of the different predisposing and precipitating factors, the combination of which explains the development of bulimia nervosa in the young person during adolescence (Garfinkel and Garner 1987). It is now known that sociocultural, psychological, biological, and genetic factors make up the genesis of development of bulimia nervosa (Polivy and Herman 2002).

Psychologists and psychiatrists who support the psychodynamic theory of development of bulimia believe that a person's mental rigidity, i.e., reduced flexibility, is the main reason for a sadistic attack of one's own body, which is a major characteristic associated with this disorder. A study by Riviere and Douilliez (2017) shows that adolescence is a "fertile period" for the study of the body image and bodily functions, with an emphasis on food as a means of expressing conflict and aggression, as well as intimacy. Body parts, their shape, and size can metaphorically and symbolically help explain conflict and defend against potential problems. Eating can be a major factor in controlling and regulating urges, due to the guilt and shame that the person experienced in one of the stages of psychosexual development. Dieting or overeating is a "magical" way wherewith a young person attempts to prevent changes in the body or to resolve the existing intrapsychic conflict. According to Marcinko (2013), there are four models that explain self-destruction toward one's own body:

- ***Attack of the pleasure principle***
  The act of eating itself is a satisfaction, an intake of energy, something that is good for the body itself. Dissatisfaction is manifested by blocking the primary potentials through which sensory pleasures occur. Usually this condition occurs due to the inadequate relationship with the mother in the early developmental period which is the basis for the development of potentially aggressive attacks in the future (Stavrou 2018).
- ***Attack of the mother related to the pleasure principle***
  In the dynamics of a person with bulimia, a problem emerges in an event of separation from the mother during the person's developmental path, and a pathological connection with the mother is formed; however, each separation from the mother contributes to the emergence of emotional problems in the young person, such as anxiety and depression. These problems during the growth of the personality can be reactivated and lead to an increased desire to eat as a way to resolve the intrapsychic conflict (Smolak 2011). With the increased food intake, the child compensates for the unsatisfied emotional needs, because the food he/she eats has the same value and meaning as the mother's love. At the same time, increased food intake can be a way to reduce aggression, fear, and depression. Vomiting in a bulimic person also occurs due to the denial of the object – the mother who is a symbol of the food.

- ***Attack of one's own femininity***

  As early as in the initial development of the young person, there are roots that affect the person's understanding and acceptance of her own femininity. The reason is considered to be the inadequate relationship between the child and the mother, due to the emotional and physical absence of the mother, her increased anxiety, and inadequate care, which contribute to the child developing resistance to contact the mother, even when it comes to the eating process (Fairburn and Harrison 2003). During adolescence, girls experience an average increase in body weight, which leads to a departure from the perceived ideal of body weight and thus affects their negative emotions that are associated with their own attractiveness and femininity. Simultaneously, the identification with the mother in many situations in life is substantially blocked, so the young girl feels fear and rejection. Believing that the intrapsychic conflict can be resolved by overeating and vomiting, the feeling of femininity is threatened from both physical and psychological aspects. The very act of overeating in bulimia is a defense against the conflict associated with separation/individualization. In this way, the girl expresses her anger and rage, because of the real or imagined feeling of rejection.
- ***Attack of heterosexuality***

  Psychoanalysts consider that problems with heterosexuality and femininity are related to envy and hatred toward the mother; however, they are also reflected on the father. A characteristic is that girls experience the father, i.e., every male person, in a negative emotional context. The young girl is vulnerable; has an increased threshold of frustration, fear, and anxiety; and directs her own sadistic thoughts toward herself; therefore, a "compulsive," i.e., addictive, need for overeating, clearing, or dieting arises (Gila et al. 2004).

Bulimia Nervosa, Adolescence, and Psychological Profile of the Person

Bulimia nervosa is an eating disorder characterized by episodes of uncontrolled overeating followed by various types of compensatory behavior. The person within a short period of time consumes a large amount of food, with high calorific value, with no control over the act of eating. After an episode of overeating, which is followed by severely reduced self-control, an increased sense of guilt and shame emerges. Guilt usually emerges due to the reduced ability to correct the situation, while shame arises from the negative evaluation of the whole self (French et al. 2001). Now the boy or the girl resorts to compensatory behavior in order to correct the mistake and reduce the feeling of guilt. It is usually self-induced vomiting, but the use of laxatives or diuretics, excessive exercise, dieting, and strict regime are also common.

The young bulimic person is strongly focused on the body shape and weight, and a fear of gaining weight is present, as well as a negative self-esteem in relation to the person's body. In addition to the present developmental difficulties, problems in separation, i.e., separation of the self from the object and denial and fear of

separation and sexuality, are expressed; therefore, bulimia is described as a disorder that occurs due to unsuccessful adaptation to the requirements of adolescence.

There are four empirical models providing us better understanding of the relationship between the psychological characteristics of the person and the bulimic disorder (Marcinko 2013):

1. The first one is the "predisposing model" which refers to the increased risk of developing bulimia in relation to personality traits in adolescence. According to this model, the factors for the occurrence of personality pathology and bulimia are independent of each other.
2. The "shared sample model" also assumes that personality traits and bulimia are independent entities; however, they have a common cause such as the developmental factors, family problems, or problems with peers.
3. The "complication model" refers to the thesis that the changes that occur in a person are the result of bulimia. The personality traits according to this model are a consequence of bulimia.
4. The "pathoplastic model" assumes that the present inadequate psychological characteristics and bulimia affect each other during the developmental path of the person.

The bulimic disorder can occur at all levels during the transition of a person from early to middle and late adolescence; therefore, the adolescent is emotionally unstable and introverted, and he/she reacts to any criticism with violent negative emotions, has a feeling of low value, changes his/her mood in relation to external factors, is ambitious, and strives to be the best (Geller et al. 2000; Keel and Forney 2013).

Psychological Problems in Adolescence and Bulimia Nervosa

Adolescence is not only an overall developmental process, nor a universal developmental process, it has its own path and course, and it all depends on the differences that occur in the environment where the young person grows, the different values and norms that are characteristic of each environment, and the differences in the social role of adults, which for the adolescent are a model of shaping and formation. Thus, the social growth of the person emerges gradually, the person becomes increasingly alert and aware and creates social consciousness and starts to acquire an image and an idea of himself/herself, and self-confidence and self-esteem grow in him/her, which become dominant characteristics of the young person.

Adolescence is a period of intensive intellectual development, a period of gaining great cognitive experiences, concepts, and knowledge, all of which affect the process of cognitive and affective rapprochement with the environment. At the same time, this is a period when young people are facing the world of values, when everywhere they measure their ideals with reality, thereby experiencing conflicts and forming their self-confidence. A characteristic is that the adolescent becomes familiar with

his/her own personality and begins to be objective toward himself/herself and his/her shortcomings, which is especially important for the person's moral and emotional development. Integrating different views into a single homogeneous image of oneself is a difficult process, and therefore, a conflict emerges, which is perceived as stressful, and this often leads to tense relationships between parents and adolescent children. Low self-esteem, intertwined with unfavorable relationships at home, low performance at school, and some stressful events in other social domains all lead to unpleasant experiences in the young person.

Therefore, it is considered that the central notion that develops during adolescence is the identity that should answer numerous questions, such as who am I, why am I, what will happen to me, etc. Prerequisites that lead a young person to develop personal identity are sexual maturation and adequate social functioning. The very process of forming a personal identity takes place in two directions: one of them is the experience of reality and the other is the ideal ego. If during the development of the young person these two directions coincide or are closely related, then the young person is satisfied with himself/herself, will be confident, and will be accepted as he/she is, and this is a prerequisite for harmonious living. However, if there is a discrepancy between these two processes, then the adolescent does not accept his/her physical appearance and bodily ego, and this creates a conflict in the person accompanied by certain psychological and mental reactions, such as low self-esteem, reduced efficiency, conflict between identity and autonomy, depressed mood, and eating disorders (Boone and Leadbeater 2006; Dobmeyer and Stein 2003).

The most problematic types of eating disorders are starvation, dieting, overeating, purgatory behavior, induced vomiting, and abuse of laxatives or diuretics, which are followed by strong emotional distress of the individual and his/her environment.

Psychologically, bulimia nervosa occurs as a reaction to the demands of adolescent development for increased independence and social and sexual functioning. Researches have shown that mental and psychological changes that occur in the young adolescent affect his/her bulimic behavior (Mendelson et al. 2002). The person reacts more intensely to negative events and has low self-esteem and increased feelings of anger, fear, rage, or irritation, problems related to autonomy and personality traits.

The Image of One's Own Body as a Predictor for the Development of Bulimia Nervosa in the Period of Adolescence

The image of one's own body is a subjective perception of one's body (the body's appearance and function), the internalized emotional experience of the body and the reaction of the environment to the subject's body, and the standards and expectations that the person has built for his/her body, so this will determine the person's ideal image of the body (Lackovic-Grgin 2014). Actually, the image of one's body has a strong role in increasing the pathology of bulimia, because young people are not satisfied with their body, and they consider that they are obese and fat and have disproportionate dimensions, especially in some parts of the body. A person believes

only in his/her personal assessment, considering that he/she is obese; therefore, the dissatisfaction with the person's own body is related to problematic eating habits and perception and loss of self-control through food intake, dieting, or overeating. The negative image of one's body is particularly pronounced in adolescents with purgative bulimia nervosa (Patalay and Gage 2019; Vohs et al. (2001)).

According to Erceg-Jugovic (2015), there are four approaches to explaining the occurrence of dissatisfaction with one's own body in adolescents:

- **Social adaptation approach** – the young person who compares his/her appearance with other individuals has an increased risk of dissatisfaction with his/her own appearance.
- **Approach of sociocultural pressure** – the media is a source of strong messages about which bodily disorders are acceptable
- and desirable.
- **Developmental approach** – the body dissatisfaction develops during maturation in adolescence.
- **Approach of negative verbal comment** – negative comments that are associated with dissatisfaction with the body, bulimia nervosa, and generally impaired psychological functioning.

According to the same author, 40–60% of the girls at 6–12 years of age are worried that they are overweight, and this concern continues throughout their entire life (Erceg-Jugovic 2015). When a girl becomes insecure in interpersonal relationships or does not believe in her own abilities, then she uses her disturbed weight self-control as a means to ensure success and acceptance.

The bulimic young person has a negative image of oneself, i.e., a distorted mental image of his/her own appearance. Every day the person seeks evidence to support the false mental image within himself/herself. When a person looks in the mirror, he/she focuses only on those parts of the body for which he/she thinks "something is wrong," self-esteem is decreased, inferiority is increased, and this leads to pronounced psychological disorders (Pesa et al. 2000). The person is prone to self-punishment, so one such form is "compulsive eating." The person is preoccupied with obsessive thoughts related to the diet, he/she cannot control them, and they often transform into compulsive activities. The end result is an increased desire for food, especially when the love the person desires is not available. So it is not hunger that bothers him/her but obsessive thoughts that drive him/her to certain activities, such as overeating, and this leads to a distorted image of his/her own body (Pokrajac-Bulian 2000).

Self-Esteem and Bulimia Nervosa

Self-esteem is a good indicator of an individual's mental health. We usually define it on the basis of the formed notion about ourselves, i.e., valuation or evaluation of ourselves either in a positive or negative way. Actually, it is a multifaceted construct

or a construct of specific domains (Vulic-Prtoric and Cifrek-Kolarcic 2011). From that perspective, the facets of self-esteem are placed in a hierarchical structure where global self-esteem is at the top, followed by the academic, social, emotional, and physical domains of self-esteem (Pazzaglia et al. 2020).

According to Pehar (2016), adolescents with high self-esteem apply a positive way in solving life problems. As life stress increases, self-esteem decreases, so often bulimia nervosa develops as a comorbidity with anxiety and depression. Decreased self-esteem is especially expressed in girls who have an inadequate perception of body weight and body satisfaction. Decreased self-esteem in girls is thought to be related to external factors (such as body appearance) rather than an internalized process, so it is an important precipitating factor in the development of bulimia nervosa (Lebedina-Manzoni 2007). Girls with low self-esteem fear that they will be abandoned because they inadequately assess their body; therefore, they have a negative assessment of their abilities and all aspects of their self-image.

Self-esteem is a primary risk factor that may contribute to the development of other risk factors in bulimia nervosa. Specific research studies have shown that the development of bulimia is more frequent in young people with increased perfectionist tendencies and dissatisfaction with the body, who have low self-esteem, while adolescents with high self-esteem do not have these risk factors and therefore do not develop bulimia (Joiner et al. 1997; Vohs et al. 2001). In addition, studies focusing on the relationship between self-esteem and physical dissatisfaction have shown that a positive correlation between these two variables is present (Mendelson et al. 2002). Decreased self-esteem contributes to the development of an inadequate self-image in boys and girls, which is the cause for the development of bulimic symptoms (Gleason et al. 2000).

According to Mora et al. (2017), the young person with bulimia has increased dissatisfaction with his/her body, as well as the weakest explicit and implicit "I." Explicit self-esteem is the conscious sense of self-evaluation, while implicit self-esteem includes unconscious, automatic self-evaluation. Therefore, Smink et al. (2012) suggest that implicit and explicit self-esteem should be examined separately; however, implicit evaluation is related to impulsive processes, while explicit evaluation is related to reflexive processes. In this way, the two types of self-esteem affect bulimic behavior differently. The act of overeating itself is an impulsive process; hence, implicit self-evaluation plays a greater role in assessing self-esteem (Stavrou 2018; Button et al. (1997)).

Perfectionism and Bulimia Nervosa

Perfectionism is a person's aspiration for high achievements, followed by increased self-evaluation and fear of failure. The perfectionist aspires to be perfect in all areas of life. Perfectionism is easily recognized in the adolescent population, through regular completion of schoolwork, meticulousness, dedication, and the desire to be the best student in the class, to win a competition, etc. And when a young person achieves the desired goal, he/she is usually satisfied, happy, and proud. Then new

endeavors and new pleasures come. If that is the course of the story, it is a matter of a desired (adaptive) perfectionism, because it is a healthy pursuit for high achievements followed by a sense of satisfaction (Flett et al. 2001). However, the story may have a different ending. The adolescent may have high aspirations and therefore inadequately assess his/her own abilities in a particular area. And when he/she is successful, non-adaptive perfectionism comes to the fore, so the person feels dissatisfied, anxious, and obsessed with the thought of being the best and manifests neurotic difficulties and sleep or eating disorders (Boone et al. 2014; Frost et al. 1990; Bardone-Cone et al. 2007).

In the context of bulimia, it is interesting how perfectionists think about the way to be placed in the "all or nothing" category, which limits them in accepting the mediocrity and imperfection that pertain to their physical appearance. The young person primarily sets unrealistic standards for the body appearance and strives for perfection in all areas of his/her life, which affects the person's daily functioning and living (Bardone-Cone et al. 2017). The person has high criteria regarding the ideal of their own appearance and body shape and weight; however, the failure to meet high personal goals is satisfied by increasing the desire to eat and overeat, which encourages pathological patterns of food-related behavior, such as bulimia nervosa (Mennati et al. 2013; Bulic et al. (2003).

In their research, Paulson and Rutledge (2014) indicate that adaptive perfectionism leads to a decrease in bulimia, while non-adaptive perfectionism leads to an increase in the symptoms of bulimia. The same authors indicate adaptive perfectionism as a protective factor and non-adaptive perfectionism as a risk factor for the development of bulimia.

Anxiety, Depression, and Bulimia Nervosa

The primary characteristic of bulimia nervosa is the pathological burden of body weight and body shape, especially during personality development. This affects the developmental course of difficult experiences with shape and weight that lead to the development of a distorted image of one's own body, as well as eating disorders. The bulimic person uses his/her appearance and weight as a response to problems of identity, self-esteem, self-control, and regulation of negative affective states (Prefit et al. 2019).

In the acute phase of the disorder, mood swings are characteristic, which result in overeating and clearing, and this affects the psychological stability of the individual. The most pronounced comorbidity with bulimia is depression or anxiety disorders, such as obsessive-compulsive disorder or social anxiety (Garcia et al. 2020). In early adolescence, the young person begins to reorganize his/her body image; becomes preoccupied with their body self and the reaction of others to it, due to weight gain; and hence loses control of food intake, resulting in episodic overeating which secondarily leads to the onset of anxiety and depression. Fear, anxiety, and sadness are expressed, which indicates that low mood, loneliness, and reduced self-esteem are a central characteristic of anxious and depressive experiences during

adolescence. Negative emotions, such as the feeling of shame, guilt, and dissatisfaction, contribute to a young person becoming withdrawn, sad, or angry because of their above-average weight (Penate et al. 2020).

Cognitive distortion followed by dysfunctional thoughts predominates in adolescents with bulimia nervosa (Gjurovic 2003):

- Logical operation: "Just one more spoon, which means a few more kilos."
- Selective abstraction: "I am 'someone' only if I'm skinny, but what can I do?"
- Personalization: "When I see someone who is fat, I immediately fear about my fat appearance, but that's how I am."
- Generalization: "Fat people are not beautiful"; "I am not happy with a normal weight, so I will not be happy by gaining weight, and still, I am happy."

This way of thinking contributes to the young person being upset, worried, and anxious; there is an increased internal restlessness and conflict, which the individual resolves by overeating or attacks of ingesting large amounts of forbidden food, wherewith the person reduces the feeling of anxiety or depression (Hughes et al. 2013). The mechanism by which food affects these emotional states is not entirely familiar; however, it is considered that increased protein and carbohydrate intake affects the synthesis of brain neurotransmitters, particularly serotonin. Overeating in order to reduce anxiety or depression leads to compulsive overeating or weight gain, i.e., disinhibition of eating control (Gilbert and Meyer 2005).

Other Psychological Problems in Adolescence and Bulimia Nervosa

Eating disorders, such as bulimia nervosa, occur at the crossroad between childhood and adulthood, between the mental and the somatic, the individual and the social. According to the multifactorial model, it is a matter of eating disorders that result from complex relationships between biological, developmental, individual, psychological, and sociocultural factors (Baell and Werheim 1992).

The young person with bulimia is extroverted, acts like a person full of oneself, and is well adapted; however, this person is basically overwhelmed with a sense of low self-esteem and self-worth, dissatisfied with his/her appearance, and dissatisfied with his/her body and with himself/herself in general. The studies by Gander et al. (2015) confirm that the bulimic adolescent perceives food as a symbolic substitute for love and that the relationship with the mother is an issue in the background of the disorder. The feelings of insecurity, anxiety, and sadness are strong; therefore, the adolescent tends to increase food intake, followed by self-induced vomiting due to fear of gaining weight.

Ivarsson et al. (2006) in their research emphasize that narcissism is one of the characteristics of the young bulimic person. The characteristics of narcissism include grandeur, reduced sense of vulnerability, and threat by others. A young girl with expressed narcissistic traits tries to compensate for her low self-esteem by achieving

an ideal body weight and body shape, but at the same time, she has low self-control in terms of eating.

At the same time, there are numerous studies that attempt to explain the impact of sexual, physical, and emotional abuse in childhood of the bulimic person. However, the obtained results are inconsistent. On the one hand, Levinson et al. (2013) in their research confirm that sexual, physical, and psychological abuse in childhood is strongly associated with various psychiatric symptoms, including bulimia. On the other hand, another group of researchers does not confirm this fact but, however, still believes that child abuse in childhood affects the occurrence of specific mental disorders, such as bulimia (Fairburn and Harrison 2003).

Moreover, the relationship with the parents is very important for the adolescent. The lack of "good enough" motherhood during the symbiotic phase and birth problems have a frustrating effect on a child's basic need to be loved and to adequately respond to his or her needs (Eckerd 2005). This is especially evident in the period of adolescence when girls have an insecure style of relationship, especially with the father. This relationship has been shown to be a risk factor for bulimia nervosa, prolonged anxiety, and depressed mood (Fisher et al. 2008). The relationship with the father is very important, because it is related to the late psychosocial adaptation, the secure connection in the friendly and romantic relations, the separation from the parents, the individualization, and the acquisition of autonomy.

Bulimic problems in adolescence are associated with an increased propensity to self-harm which is a conscious and an unintentional infliction of self-harm (Bora and Kose 2016). It is assumed that the individual has an inadequate connection between the psyche and the body which integrate at the moment when something bad and painful is done to the body. Overeating, self-induced vomiting, and increased physical activity are all a part of internal self-harming behavior (Trindade and Ferreira 2014).

Our Experience

We will start this part with a sentence that has profound implications for the psychological problems associated with the complex disorder of bulimia nervosa in adolescence "think globally, act locally." We begin by describing a study conducted at a local level that we believe has global applicability.

The research on this topic provides us with an insight into the prevalence, classification, and characteristics of bulimia nervosa in adolescence. Only in this way we can recognize the disorder from the very beginning and react when an inadequate behavior associated with it occurs. At the same time, this approach allows us to plan and implement primary prevention, to prevent its occurrence. It is known that the disorder itself most commonly occurs in the period of adolescence, i.e., in the school period; therefore, it is necessary to implement preventive programs that will be performed in the very school.

The study includes an analysis of a sample of 300 randomly selected students in the first and fourth year in two secondary schools in Skopje during the winter

semester of the academic year of 2019/2020. The inclusion criteria for the study were subjects between 14 and 19 years of age, while the criteria for exclusion from the study were subjects with severe somatic diseases who are on a special diet and subjects with previous surgeries. The initial idea for this study is the assumption that several key factors are responsible for the occurrence and development of bulimia nervosa. In this study, we examined the relationship between the variables bulimia nervosa, self-esteem, perfectionism, anxiety, and depression. The purpose was to collect data from different, complementary sources; therefore, a battery of questionnaires and scales was used, as well as a survey questionnaire to obtain data on gender, age, height, and body weight.

What Questionnaires Did We Use for Evaluation?

For the purposes of this study, we used the following instruments:

- Bulimia Investigatory Test, Edinburgh (BITE)

  The Bulimia Investigatory Test, Edinburgh (Fairburn and Beglin 1994; Henderson and Freeman 1987), is an assessment scale that consists of 33 statements designed to identify the symptoms of bulimia or overeating in respondents. The scale itself consists of two sub-scales: the Scale of Symptoms (BITE-sas), which measures the degree of present symptoms, and the Scale of Severity (BITE-ss), which shows us the overeating and clearing severity index defined with their frequency of emergence. The Cronbach alpha of the questionnaire is 0.78.
- Child-Adolescent Perfectionism Scale (CAPS)

  We used the Child-Adolescent Perfectionism Scale (Flett et al. 2001) to assess perfectionism, which is a self-assessment scale consisting of 22 statements based on the multidimensional conceptualization of perfectionism. It consists of two sub-scales: Self-Oriented Perfectionism with 12 statements and Socially Oriented Perfectionism with 10 statements. Self-Oriented Perfectionism refers to the unrealistic demands of the person striving for perfection, while Socially Oriented Perfectionism refers to the demands of others in the environment who expect the person to be perfect. The range of possible results is from 22 to 110 points where the higher result favors a higher level of perfectionism. The Cronbach alpha of the whole questionnaire is 0.91.
- Rosenberg Self-Esteem Scale (RSE).

  The Rosenberg Self-Esteem Scale is a scale for the assessment of self-esteem (Rosenberg 1965). The scale measures the global value orientation toward oneself. It consists of ten statements, five in a positive and five in a negative direction. The respondents rate their self-esteem on a 4 point Likert-type scale, ranging from 1 (I strongly disagree) to 4 (I strongly agree). A higher score favors higher self-esteem. The Cronbach alpha is 0.87.
- Kutcher Adolescent Depression Scale (KADS)

  The Kutcher Adolescent Depression Scale (KADS) is a scale for self-assessment of depression in adolescents (LeBlanc et al. 2002). It consists of

11 statements, whereby the answers are scored on a 4 degree scale: from 0 (never) to 4 (always). The range of possible results varies from 1 to 33b where a higher score favors a higher level of depression. The Cronbach alpha for the whole scale is 0.94.

- The State-Trait Anxiety Inventory (STAI)

  The State-Trait Anxiety Inventory (STAI) is a scale for measuring anxiety (Spielberger et al. 1970). It consists of 40 statements where the answers are scored on a 3 degree scale: from 1 (never) to 3 (always). There are two sub-scales: Anxiety as a Trait (Trait Anxiety – STAI-T) and Anxiety as a State (State Anxiety – STAI-S). A higher score favors a higher level of anxiety. The Cronbach alpha for the scale is 0.82.
- Body Mass Index (BMI)

  We get the body mass index when we divide the body weight expressed in kilograms by the square of the body height expressed in meters.

  The statistical analysis of the data was performed with the software package SPSS (Statistical Package for the Social Sciences, version 20).

What Do the Obtained Results Show Us?

The study included 300 respondents, 150 (50%) male and 150 (50%) female respondents, from 15 to 19 years of age, first and fourth year high school students. In our sample, most of the respondents, i.e., 129 (43%), had normal BMI (18.50–24.99 kg/m^2), 41 (13.66%) had reduced BMI (15.00–18.49 kg/m^2), 102 (34.01%) had slightly increased BMI (25.00–29.99 kg/m^2), and 28 (9.33%) had significantly increased BMI (30.00–35.00 kg/m^2).

Table 1 and Fig. 1 show the average value of the examined variables. From the presented table, it can be seen that the mean value for bulimia is $M = 29.52$, for self-esteem $M = 15.32$, for perfectionism $M = 64.21$, for anxiety $M = 74.51$, and for depression $M = 2.45$.

Table 2 and Fig. 2 show the interrelationship of the examined variables of self-esteem, perfectionism, anxiety, and depression in relation to bulimia and BMI. The results show that a significant correlation is present between the body mass index and the total score of BITE, BITE-sas, and BITE-ss in relation to STAI, STAI-T, STAI-S, and KADS at the level of $p < 0.05$ and $p < 0.01$.

As can be seen from Table 3, students between 14 and 15 years of age show lower results of the examined variables compared to students between 18 and 19 years of age.

The research conducted on our sample shows that the young population is at an increased risk of developing bulimic disorders, due to age, the developmental period, and the environment. It is thought that this developmental period may provoke or exacerbate pre-existing risk factors associated with the development of this disorder.

Table 1 Descriptive statistics for bulimic symptoms, self-esteem, perfectionism, anxiety and depression

Construct	Scale	N	Mean ± SD	Theoretical range
Bylimia	**BITE**	300	25.52 ± 1.65	1–48
Bylimic symptoms	**BITE–sas**	300	21.22 ± 1.34	1–30
Severity of binging and purging behavior	**BITE–ss**	300	8.31 ± 0.76	1–18
Self–esteem	**RSE**	300	15.32 ± 6.34	10–40

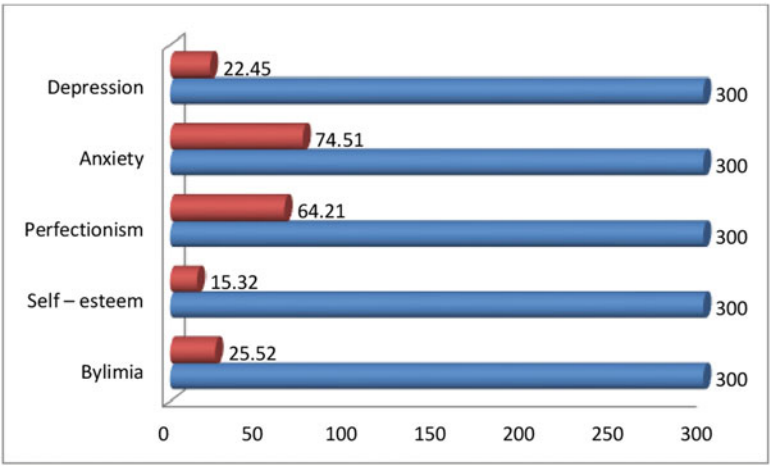

Fig. 1 The level of bylimia, self – esteem, perfectionism, anxiety and depression among adolescents

Through this study, we can see that certain psychological problems in adolescence such as self-esteem, perfectionism, anxiety, and depression play a major role in the development of the bulimic behavior. In accordance with this, it is essential to

confirm or reject the influence of already known predisposing factors but also to discover new ones.

Applications to Other Eating Disorders

In this part, we tried to analyze the relationship between psychological problems that are present in the period of adolescence, such as self-esteem, perfectionism, anxiety, depression, self-image, and suffering caused by the discrepancy between the real and the ideal body weight and eating disorders, including bulimia nervosa. Eating
