HDR brachytherapy has numerous clinical advantages. Most importantly, HDR brachytherapy has been shown to be highly effective, with high rates of local control and relatively low rates of significant late toxicity in prospective trials across multiple disease sites.[2–5] Its high therapeutic ratio has allowed HDR brachytherapy to become the universally accepted clinical standard-of-care for malignancies, including the adjuvant treatment of high-intermediate-risk, early-stage endometrial cancer[2] and the definitive treatment of locally advanced cervical cancer.[4] HDR brachytherapy is convenient because single or multiple treatments can be delivered with relatively short treatment delivery times, often in an outpatient setting. HDR brachytherapy can be used to create highly conformal treatment plans that can account for variations in both anatomy and applicator placement. This is possible due to the ability to fine-tune dwell positions at submillimeter step sizes along multiple catheters. HDR brachytherapy can incorporate contemporary three-dimensional (3D) imaging modalities (eg, computed tomography [CT], magnetic resonance imaging [MRI], and high-resolution ultrasound) into the treatment planning process. In addition, since radiation is delivered within a shielded room via a remote afterloader, there is no personnel exposure to radiation.

However, the safe and effective practice of brachytherapy requires processes and workflows that are quite unique to radiation oncology departments accustomed to delivering external beam radiation therapy (EBRT). An interdisciplinary team of radiation oncologists, medical physicists, radiation therapists, registered nurses, and surgical technicians must function efficiently in real time for the patient to receive the treatment in a safe and timely manner. Furthermore, for treatments requiring sedation, this team must collaborate with members outside the radiation oncology department, such as anesthesiologists, surgical oncologists, recovery nurses, and the admitting inpatient team. With the widespread adoption of 3D treatment planning as well as adaptive image-guided radiation therapy (IGRT),[6,7] patients undergoing brachytherapy may require CT and/or MRI scans in the perioperative period. Due to the extremely high doses delivered, a rigorous quality assurance program is needed to ensure that the treatment is delivered in a safe and effective manner. Additional time may be needed for assessing brachytherapy candidacy, obtaining patient education/consent, acquiring preoperative clearance, and ensuring patient comfort during and after the brachytherapy treatment process.

Over the past decade, multiinstitutional prospective and even randomized controlled trials have greatly enhanced the understanding of the benefits and risks of HDR brachytherapy. The purpose of this chapter is to review the clinical role of HDR brachytherapy across multiple disease sites. At the end of the chapter, practical aspects of an HDR quality management program are provided.

CERVICAL CANCER

Clinical Indications

Brachytherapy is a critical component in the standard-of-care management of locally advanced cervical cancer. Large national database studies have suggested that the addition of brachytherapy boost has been associated with improved survival for patients who received definitive pelvic EBRT and concurrent chemotherapy.[8,9] Furthermore, the multiinstitutional prospective study EMBRACE-I recently reported high local control rates across all tumor stages and low severe single-organ toxicity rates at 5 years.[4] Many patients with locally advanced cervical cancer would lose the chance for cure without the incorporation of HDR brachytherapy boost.

The success of HDR brachytherapy for cervical cancer has resulted in part from three critical advances over the past two decades. The first advance is the transition from two-dimensional (2D) to 3D treatment planning. With 2D

treatment planning, the dose was prescribed to point A, which is located 2 cm superior to the ovoid and 2 cm lateral to the tandem, on x-ray imaging. The same dose was prescribed regardless of differences in tumor size or OAR proximity. With 3D treatment planning on CT and/or MRI, dose can be prescribed to a specific treatment volume but can be minimized to surrounding OARs, based on patient-specific anatomy. Studies have reported that 3D BT exhibits improved local control[10] and reduced toxicity compared to 2D BT.[11]

The second advance is standardized target volume and dose reporting recommendations from Groupe Européen de Curiethérapie and the European Society for Radiation Oncology (GEC-ESTRO).[6,7] These recommendations defined the high-risk clinical target volume (HR-CTV), which includes the cervix and any gross residual disease on MRI after chemoradiation therapy. These volumes account for potential dose response (ie, tumor regression) from previous chemoradiation therapy at the time of brachytherapy. Target volume delineation from an MRI with applicator in place is recommended due to the optimal soft tissue contrast.[12] However, since MRI at the time of brachytherapy may not be available in many centers around the world, consensus recommendations from the Indian Brachytherapy Society (IBS)-GEC-ESTRO-American Brachytherapy Society (ABS) have been recently published for CT-based planning.[13]

The third advance is the utilization of hybrid intracavitary/interstitial applicators. These hybrid applicators allow for the insertion of interstitial needles in parallel to the intrauterine tandem.[14] Such implants have been associated with improved dosimetric coverage for and local control of larger tumors, but without added toxicity.[15] With all three components, marked dose escalation to the target volume can be achieved without exceeding OAR constraints.

For nonsurgical treatment of cervical cancer, the overall treatment workflow involves upfront chemoradiation therapy followed by HDR brachytherapy boost. The chemoradiation portion typically spans 5 weeks. A typical dosing regimen is 45 Gy in 25 fractions of EBRT to the pelvis. The para-aortic (PA) lymph nodes can be included if the patient has gross PA nodal disease or is at high risk of having PA nodal spread (eg, gross common iliac lymph nodes). The patient can also undergo a simultaneous integrated boost of ~55 Gy to suspicious gross pelvic lymph nodes and up to 60 Gy for the PA nodes. During EBRT, the patient also receives chemotherapy, in the form of cisplatin 40 mg/m^2, once weekly for 5 to 6 weeks. Following this, the patient undergoes HDR brachytherapy boost. An example of a dosing regimen involves delivery of 7 Gy over 4 fractions in two implants, with two fractions per implant (Table 24.1). The overall goal for treatment is to achieve an HR-CTV D90 (minimum dose to 90% of the target volume) dose of at least 85 Gy in equivalent dose in 2 Gy fractions (EQD2α/β=10.). The overall treatment time should span less than 50 days, in order to maximize the chance for achieving high local control.[16] It has been estimated that an additional 5 Gy dose to the HR-CTV would be needed to compensate for an increase in overall treatment time by 1 week.

TABLE 24.1 SAMPLE SCHEDULE OF NUMBER OF MULTIMODALITY TREATMENTS FOR CERVICAL CANCER BY WEEK

Week	External Beam	Chemotherapy	Brachytherapy
1	5	1	
2	5	1	
3	5	1	
4	5	1	
5	5	1	
6			2
7			2

Regarding eligibility criteria, patients should undergo a comprehensive history and physical exam, with a bimanual exam to fully understand the clinical extent of spread (eg, parametrial invasion and vaginal extension). Disease extent can be captured in a comprehensive manner with standardized schematic diagrams.[6] Patients must have biopsy-proven disease and should undergo comprehensive staging with a positron emission tomography (PET) and an MRI scan. Patients with 2018 International Federation of Gynecology and Obstetrics (FIGO) IB-IVA disease who choose to undergo primary chemoradiation therapy with curative intent would be eligible. Patients with prior pelvic or abdominal radiotherapy or prior hysterectomy may not be eligible for this treatment regimen.

Outcomes

The clinical outcomes of HDR brachytherapy are best encapsulated in relatively recent multiinstitutional experiences of MRI-guided adaptive brachytherapy. The multiinstitutional, retrospective, retroEMBRACE study included 731 patients treated with definitive radiation therapy followed by brachytherapy across 12 centers.[17] In total, 77.4% received concurrent chemotherapy and 23.0% of patients had combined intracavitary/interstitial implants. The mean HR-CTV D90 was 87 ± 15 Gy $EQD2_{10}$. Respective D2cc values for the bladder, rectum, sigmoid, and bowel in EQD_3 were 81 ± 22 Gy, 64 ± 9 Gy, 66 ± 10 Gy, and 64 ± 9 Gy. Five-year local control was 89%, with lower control rates for more advanced stages (98% for IB, 91% for IIB, and 75% for IIIB). Actuarial grade 3 to 5 morbidity rates were 5%, 7%, and 5% for the bladder, gastrointestinal tract, and vagina, respectively.

In the multiinstitutional prospective EMBRACE-1 study, 1,416 patients with 2009 FIGO stage IB-IVA disease or IVB with PA nodal disease below the L1-L2 interspace were registered across 24 international centers.[4] Patients were treated with chemoradiation therapy, involving five to six cycles of weekly cisplatin 40 mg/m^2 and 45-Gy to 50-Gy of EBRT. PA nodal fields and pelvic sidewall boosts were allowed. Patients then underwent MRI-based image-guided adaptive brachytherapy, with target volume delineation and dose reporting performed per GEC-ESTRO recommendations.[6,7] MRI-based treatment planning with applicator in place was mandatory for the first treatment. Brachytherapy dose prescription was given per institutional guidelines.

The median D90 to the HR-CTV was 90 Gy (interquartile range [IQR] 85-94 Gy) $EQD2_{10}$, with 43.0% patients with combined intracavitary/interstitial implants. Respective median D2cc values for the bladder, rectum, sigmoid, and bowel were 76 Gy (interquartile range [IQR]: 69-83), 62 Gy (57-68), 64 Gy (59-69), and 58 Gy (49-67). At a median follow-up of 51 months, the 5-year local control was 92% (95% CI 90-93), with rates similar across all stages (P =.13). The 5-year nodal control was 87% (95% CI 85-89), with values of 93% (90-95) for N0 versus 81% (77-84) for N1 patients. Two-thirds of nodal failures for node-positive patients occurred in the para-aortic region.[18] The 5-year disease-free survival and overall survival rates were 68% (65-70) and 74% (72-77), respectively. Rates for both indices varied by stage (P <.0001). The cumulative incidences for grade 3 to 5 morbidity per Common Terminology Criteria for Adverse Events version 3.0 were 6.8% (5.8-8.6) for genitourinary events, 8.5% (6.9-10.6) for gastrointestinal events, 5.7% (4.3-7.6) for vaginal events, and 3.5% for fistula. Rates of fistula and ureteric strictures were greater for patients with stage IIIA to IIIB cancer compared with those with IB1 to IIB cancer, likely reflecting increased tumor involvement at diagnosis.

A recent follow-up study reported 5-year Radiation Therapy Oncology Group (RTOG)/European Organisation for Research and Treatment of Cancer grade 3+ events of 26.6% (23.8%-29.6%), with organ-related events reported as 18.4%.[19] Though these results in aggregate are high, organ-specific morbidities (eg, severe GI, fistula, and vaginal) compared favorably with those of prior prospective series based on 2D planning, with no clear trend for GU morbidity.

Technique

A preimplant anesthesia evaluation before brachytherapy is important because most patients will still be experiencing the side effects from the proceeding chemoradiation therapy. Special medical considerations may be necessary for patients on anticoagulation or with low blood counts (eg, absolute neutrophil count <500 mm^3) due to recent chemotherapy, given the goal of completing treatment within 50 days. Furthermore, the physician needs to select an applicator based on the patient's tumor response after chemoradiation therapy. This information can be obtained from a repeat gynecologic exam and prebrachytherapy MRI.

The operative procedure involves the insertion of an intracavitary applicator under anesthesia (eg, general, spinal, or conscious sedation).[20] The applicator most often includes a tandem placed within the uterus, as well as an ovoid or ring pushed against the uterine cervix. Interstitial needles can also be inserted into the tumor, either through the ring/ovoid (eg, hybrid applicator[14,21]) or a perineal template, to ensure adequate dosimetric coverage for larger tumors. Regarding the actual procedure, the patient is induced under anesthesia and placed in dorsal lithotomy position. The patient is prepped and draped. The Foley catheter is inserted under sterile conditions, and the balloon is inflated. A uterine sound can then be inserted, potentially under ultrasound guidance (eg, transabdominal or transrectal), and the cervix is dilated. After this, the applicator is inserted (eg, tandem, ring/ovoid, or interstitial needles) and fixed with packing, balloons, or sutures. The patient is then removed from the dorsal lithotomy position. After the acquisition of CT and/or MRI scans, treatment planning can commence.

Treatment Planning

In the contemporary era, HDR brachytherapy is performed with 3D-treatment planning under MRI or CT guidance with the applicator in place. OAR contours for the bladder, rectum, sigmoid, and bowel loops are delineated. The following target volumes are delineated, per GEC-ESTRO and ICRU 89 guidelines:[6,22]

Residual Gross Tumor Volume (GTV) (GTV_{res}): This consists of gross residual disease, as noted on MRI.

High-risk clinical target volume (HR-CTV): This consists of the entire cervix, the gross residual tumor on MRI, as well as presumed residual microscopic tissue within the initial based on imaging (eg, MRI gray zones) and clinical examination. The HR-CTV can be remarkably smaller than the initial tumor volume, especially if there is a pronounced tumor response.

Intermediate-risk CTV (IR-CTV): This includes the HR-CTV as well as the GTV at the time of diagnosis, plus a safety margin (eg, GEC-ESTRO recommends 10 mm lateral and craniocaudal; 5 mm anterior/posterior). The margins should not extend into any OAR, except for the bladder or rectal wall for FIGO stage IVA disease. The margins, however, can extend into the vagina.

For centers without an MRI available at the time of brachytherapy, target delineation should be performed using CT with applicator in place according to recent guidelines from IBS-GEC-ESTRO-ABS.[13] These guidelines introduce four brachytherapy target remission categories based on imaging response after EBRT and provide recommendations for HR-CTV delineation based on the type of imaging available at the time of diagnosis (CT, MRI) and brachytherapy (CT with or without prebrachytherapy MRI). The guidelines also introduce the concept of "near minimum distance," which measures the lateral extension from the cervical os for each (right and left) parametrium.

Treatment planning is then performed. Dose is prescribed to the HR-CTV. Target volume planning aims include an HR-CTV D90 between 90 and 95 Gy, a GTV_{res} D98 > 95 Gy, and an IR-CTV D90 > 60 Gy, each in $EQD2_{10}$. OAR planning aims include bladder D2cc < 80 Gy, rectum D2cc < 65 Gy, sigmoid D2cc < 70 Gy, and bowel D2cc < 70 Gy, each in $EQD2_3$. In addition, the rectovaginal point dose, defined as 5 mm posterior to the vaginal mucosa in the axial plane, should have a dose <65 Gy $EQD2_3$. Planning aims from the ongoing EMBRACE-II[23] trial are shown in Table 24.2. An example treatment plan is provided in Figure 24.1.

TABLE 24.2 PLANNING AIMS FOR TARGET ORGANS AND OAR RISK FOR HDR BRACHYTHERAPY FOR CERVICAL CANCER FROM EMBRACE-II

Target	Planning Aims	Limits for Prescribed Dose
D90 HR-CTV $EQD2_{10}$	90-95 Gy	>85 Gy
D98 HR-CTV $EQD2_{10}$	>75 Gy	
D98 GTV_{res} $EQD2_{10}$	>95 Gy	>90 Gy
D98 IR-CTV $EQD2_{10}$	>60 Gy	
Point A $EQD2_{10}$	>65 Gy	
Bladder D2cc $EQD2_3$	<80 Gy	<90 Gy
Rectum D2cc $EQD2_3$	<65 Gy	<75 Gy
Rectovaginal point $EQD2_3$	<65 Gy	<75 Gy
Sigmoid D2cc $EQD2_3$	<70 Gy	<75 Gy
Bowel D2cc $EQD2_3$	<70 Gy	<75 Gy

Adapted from Pötter R, Tanderup K, Kirisits C, et al. The EMBRACE II study: the outcome and prospect of two decades of evolution within the GEC-ESTRO GYN working group and the EMBRACE studies. *Clin Transl Radiat Oncol*. 2018;9:48-60. With permission.

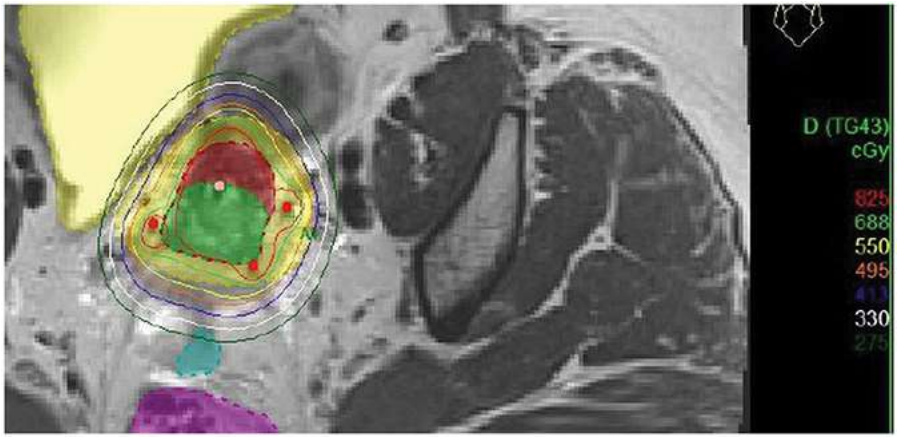

FIGURE 24.1 Axial view of MR-guided HDR brachytherapy (27.5 Gy/5 fractions) for FIGO IIIC2 (T2bN2) cervical squamous cell carcinoma, treated with chemoradiation therapy (45 Gy/25 fractions). The patient had an intracavitary hybrid applicator placed with six interstitial needles. Contours: GTV_{res}, green HR-CTV—red; IR-CTV—yellow; sigmoid—cyan; bladder—yellow; rectum—purple. Target volume dosimetry metrics in $EQD2_{10}$ were HR-CTV D90 97.4 Gy, GTV_{res} D98 95.0 Gy, IR-CTV D98 69.4 Gy. OAR dosimetry metrics in EQD_3 were rectum D2cc 52.9 Gy, bladder D2cc 81.6 Gy, sigmoid D2cc 75.3, and bowel D2cc 49.4 Gy.

Follow-Up

Following brachytherapy, patients should have a repeat pelvic exam with pap smear, with consideration of PET/CT[24] in 3 months. If concerning findings are noted, further evaluation, including MRI and colposcopy, is recommended. Otherwise, the patient should undergo follow-up with routine pelvic exams and pap smears every 3 to 6 months for the first 5 years, and yearly thereafter. Utilization of a vaginal dilator is recommended. Patients with persistent symptoms should be followed closely. Many symptoms (eg, gastrointestinal bleeding or cystitis) will resolve or improve, whereas others (vaginal stenosis) may persist.[19]

ENDOMETRIAL CANCER

HDR brachytherapy is a critical treatment modality for endometrial cancer. Many radiation oncology centers offer HDR brachytherapy for the sole purpose of treating patients with localized endometrial cancer, using vaginal cuff brachytherapy (VBT) after hysterectomy. More specialized centers offer HDR brachytherapy for the definitive treatment of vaginal cuff recurrences after hysterectomy, as well as medically inoperable disease.

Adjuvant Vaginal Cuff Brachytherapy

Clinical Indications

The PORTEC-2 trial established VBT as the standard-of-care adjuvant treatment for localized disease with adverse risk factors. This trial randomized 427 patients with high–intermediate-risk disease (predominantly 2009 FIGO stage IA grade 3 or stage IB grade 1 or 2 endometrioid carcinoma) to pelvic EBRT (46 Gy in 23 fractions) versus VBT (predominantly 7 Gy over three fractions to 5 mm depth). At 5 years, VBT demonstrated noninferior vaginal recurrence compared with EBRT (1.8% vs 1.6%; HR 0.78 [0.17, 3.49]; P =.74), along with significantly less acute grade 1 to 2 gastrointestinal toxicity (12.6% vs 53.8%).[25] Vaginal cuff recurrences at 10 years remained low (3.4% vs 2.4%; P =.55), although pelvic recurrences were more frequent in the VBT group (6.3% vs 0.9%; P = 0.004).[2]

The indications of VBT in patients who have undergone hysterectomy based on 2009 FIGO staging are listed in Table 24.3. These recommendations do not account for the recently released 2023 FIGO staging requiring molecular classification.[26] VBT in the adjuvant setting is recommended for 2009 FIGO stage IA grade 3 endometrioid carcinoma and stage IB grade 1 or 2 endometrioid carcinoma without substantial lymphovascular space invasion (LVSI). Patients with substantial LVSI should undergo EBRT, particularly if a pathologic lymph node assessment was not performed.[27] For FIGO stage IA grade 1 or 2 endometrioid endometrial carcinoma, VBT should only be considered if there are risk factors for recurrence (age ≥ 60 years, focal LVSI, or substantial LVSI).[28]

TABLE 24.3 CLINICAL INDICATIONS OF ADJUVANT VAGINAL CUFF BRACHYTHERAPY AFTER HYSTERECTOMY IN PATIENTS WITH ENDOMETRIAL CARCINOMA BASED ON 2009 FIGO STAGING

Stage IA grade 1 or 2 endometrioid carcinoma with risk factors for recurrence (age > 60, LVSI)
Stage IA grade 3 endometrioid carcinoma, without substantial LVSI
Stage IB grade 1 or 2 endometrioid carcinoma, without substantial LVSI
Stage IB grade 3 endometrioid carcinoma, without LVSI and negative SLNBx
Stage II grade 1 or 2 endometrioid endometrial carcinoma, with microscopic stromal invasion and negative SLNBx
Myoinvasive stage IA serous carcinoma, clear cell carcinoma, or carcinosarcoma, with intended chemotherapy

LVSI, lymphovascular space invasion; SLNBx, sentinel lymph node biopsy.

For IB grade 3 disease, EBRT remains the standard modality, as these patients were not eligible for PORTEC-2. The Gynecologic Oncology Group (GOG)-249 showed equivalent oncologic outcomes between pelvic EBRT ± VBT versus VBT plus three cycles of carboplatin/paclitaxel, for patients with FIGO high-intermediate-risk stage I endometrioid, FIGO stage II endometrioid, and FIGO stage I to II serous/clear cell carcinomas.[29] However, VBT alone could be considered for select patients with IB, grade 3 endometrioid disease, without LVSI and negative pelvic lymph nodes.[28]

For stage II disease, EBRT ± VBT is considered the standard-of-care.[30] However, a multiinstitutional analysis suggested that VBT monotherapy alone could be sufficient for patients with stage II, grade 1 or 2 disease and microscopic cervical stromal invasion who underwent pelvic lymphadenectomy, given the low 5-year vaginal (2.6%) and pelvic (4.2%) failure rates.[31]

Regarding high-risk histologies, vaginal brachytherapy with chemotherapy could be considered for patients with myoinvasive FIGO stage IA serous carcinoma,[32] clear cell carcinoma,[33] or carcinosarcomas.[34,35] Vaginal brachytherapy without chemotherapy could be considered in patients with small polyp-confined serous or clear cell carcinoma.[36]

Technique

It is imperative to perform a speculum examination to ensure adequate healing of the vaginal cuff in order to avoid inadvertent perforation. VBT should be performed between 4 and 8 after hysterectomy. During the speculum exam, fiducial markers could be inserted into the vaginal apex if fluoroscopy is used for conformation of vaginal cylinder placement.

Following this, a vaginal cylinder can be inserted into the vagina. Vaginal cylinders are most often single-channel and span 2 to 4 cm in diameter. The largest cylinder that can fit snugly against the vaginal cuff should be utilized to minimize dose inhomogeneity. Oral pain medications and/or topical anesthesia may be needed to reduce discomfort during the insertion process. The position of the cylinder is then fixed with an external immobilization device. The patient can then undergo imaging. If fiducial markers were inserted, fluoroscopic imaging should show the cylinder near the fiducial markers, provided that the markers did not migrate. If a CT simulation is utilized, the cylinder should fit closely against the vaginal cuff without air gaps.

Treatment Planning

The most commonly used dose fractionation regimen for VBT is 7 Gy × 3 fractions to 5 mm depth, as prescribed from the PORTEC-2 trial.[25] For most patients, the upper 3 to 5 cm of the vaginal length can be treated. However, the whole vaginal length can be treated if pathology demonstrates high-risk histology, grade 3 disease, or LVSI. 2D-treatment planning can be utilized for patients undergoing fluoroscopy. For patients undergoing CT, both 2D or 3D treatment planning can be used. Further details can be found in guidelines from the ABS.[37]

Follow-up

Patients should be counseled regarding the use of vaginal dilators and resumption of sexual activity to prevent vaginal stenosis. Pelvic examination should be conducted every 3 to 6 months for up to 5 years, then annually. Common toxicities of VBT include fatigue, urinary symptoms, vaginal stenosis, and sexual dysfunction.

Vaginal Cuff Recurrences

Clinical Indications

HDR brachytherapy can be utilized in combination with EBRT for the definitive treatment of vaginal recurrences after hysterectomy. Eligible patients should have biopsy-proven recurrence and disease localized to the vagina without or with pelvic lymph nodes on staging imaging (ie, PET and MRI). Patients with a prior history of radiation therapy may be eligible if a definitive dose can be given to the target volume while accounting for previous dose to OARs.[38,39] Recent studies of image-guided brachytherapy have reported 2- to 3-year local control rates surpassing 90%.[40–42]

EBRT consists of treating pelvic lymph nodes and the vaginal cuff (40-45 Gy), while chemotherapy could be considered if patients have large (>4 cm) cuff recurrences or pelvic nodal disease. A repeat MRI, preferably with vaginal jelly, should be performed toward the end of EBRT. Nonbulky recurrences with a residual thickness <0.5 cm can be considered for intracavitary brachytherapy boost, preferably with a multichannel cylinder.[43] All other cases should be treated with interstitial brachytherapy under anesthesia, per guidelines from the ABS.[38]

Technique

Patients who are candidates for a multichannel cylinder can typically be treated on an outpatient basis. After applicator insertion, a CT simulation scan is required. MR simulation could also be considered to better define the location of the tumor with respect to the multichannel cylinder. Treatment planning then commences.

Patients who require an interstitial applicator typically undergo anesthesia. First, a careful exam under anesthesia is performed to better define the radial and proximal-distal extent of disease within the vaginal cuff. A urinary catheter is also inserted. A template-based applicator, most commonly a Syed applicator, is then inserted. A central obturator is inserted through the template and into the vaginal cuff. Following this, needles are inserted into the holes at predefined spaces around the central obturator. Care should be taken to ensure that the inserted needles can allow for adequate coverage of the disease. Finally, the template is sutured to the perineum. Once the applicator is placed, the patient can undergo planning scans with CT without or with MRI.

Treatment Planning

Recent ABS guidelines recommend prescription doses of EBRT with brachytherapy between 75 and 79 Gy.[38] These doses can be achieved with an EBRT dose of 45 Gy in 25 fractions and a brachytherapy dose of 25 Gy in five fractions. Target volume delineation guidelines are now available from the GEC-ESTRO, ABS, and the Canadian Brachytherapy Group (CBG) for image-guided adaptive brachytherapy in the setting of vaginal recurrences.[44] On the treatment planning scan, the GTV is the residual disease noted on treatment planning imaging. The HR-CTV is the GTV plus areas on imaging and examination that are concerning for harboring microscopic disease. The IR-CTV, which represents all potentially significant microscopic disease, is defined as the GTV at diagnosis plus the HR-CTV plus an expansion of 0.5 cm. The normal remaining vagina outside the target volume should be contoured as an OAR. OAR dose constraints can be adopted from cervical cancer (D2cc < 65 Gy for rectum, D2cc < 70 Gy for sigmoid, and D2cc < 80 Gy for bladder). An example treatment plan is provided in Figure 24.2.

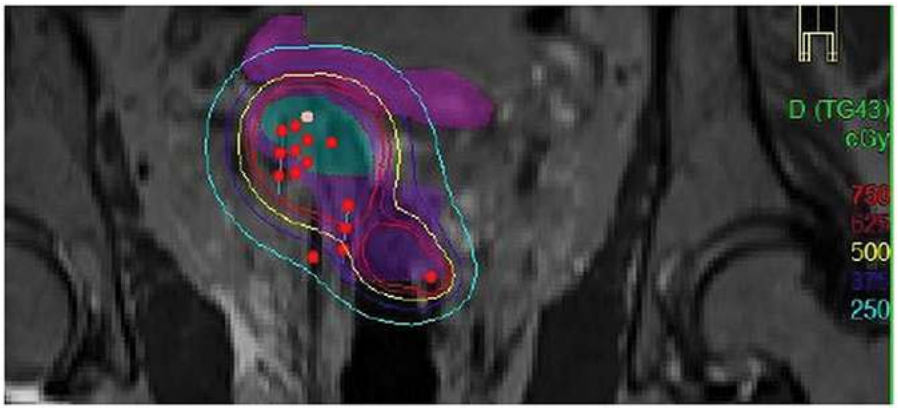

FIGURE 24.2 Coronal view of MR-guided HDR brachytherapy (25 Gy/5 fx) for recurrent endometrial cancer, treated with chemoradiation therapy (45 Gy/25 fractions). The patient had a template-based interstitial applicator placed with a central obturator and 14 interstitial needles. Contours: HR-CTV—cyan; IR-CTV—dark purple; sigmoid—light purple. Target volume dosimetry metrics in $EQD2_{10}$ were HR-CTV D90 96.4 Gy and IR-CTV D98 65.0 Gy. OAR dosimetry metrics in EQD_3 were rectum D2cc 55.1 Gy, bladder D2cc 82.8 Gy, sigmoid D2cc 71.0, and bowel D2cc 44.5 Gy.

Follow-up

Similar to VBT, patients who undergo treatment for vaginal cuff recurrences should undergo a pelvic examination every 3 to 6 months for 5 years, and then annually. This patient population is at a higher risk of developing bowel and bladder toxicities and, as such, requires close follow-up.

Inoperable Endometrial Carcinoma

Clinical Indications

About 5% to 10% of patients with endometrial carcinoma cannot undergo staging hysterectomy due to medical comorbidities.[45] Such patients could be candidates for HDR brachytherapy. Numerous retrospective series have demonstrated favorable outcomes with HDR brachytherapy alone or in combination with EBRT.[46-48] Such patients should undergo a biopsy to determine tumor grade. Staging with PET for detecting distant disease plus MRI for characterizing the depth of myometrial invasion is recommended.

Per ABS guidelines, patients with FIGO stage I, grade 1 or 2, disease with minimal myometrial invasion on MRI are candidates for HDR brachytherapy alone. Patients with FIGO stage I disease, who have deep myometrial invasion (>50%) on MRI or grade 3 pathology, or stage II disease, should undergo a combination of EBRT and BT.[49]

Technique

During the procedure, the patient is placed in dorsal lithotomy position and examined under anesthesia. A Foley catheter is inserted, and the cervix can be serially dilated, potentially under ultrasound guidance. A variety of applicators are available, including single tandem with ovoids, modified Heyman capsules,[50] double tandem applicators,[51] and triple tandem applicators.[52] Once the applicator is inserted, the vagina is packed, and the applicator is fixed in place.

Treatment Planning

The GTV encompasses the T2 weighted abnormality. The CTV encompasses the entire uterus, cervix, and upper 1 to 2 cm of the vagina. OARs include the sigmoid, rectum, bladder, bowel, and uninvolved lower third of the vagina. Both CT and MRI-based treatment planning can be done. Prescription dose targets include a CTV D90 of 48 (6 Gy × 6) to 62.5 (5 Gy × 10) Gy for the monotherapy setting and a CTV D90 of 65 to 75 Gy in total $EQD2_{10}$ for the combination setting.

Follow-up

Pelvic examination should be done every 3 to 6 months for 2 to 3 years, every 6 to 12 months for up to 5 years, and then annually.

PROSTATE CANCER

Clinical Indications

HDR prostate brachytherapy is a suitable option for the definitive treatment of prostate cancer. For low-risk and favorable intermediate-risk (FIR) disease, HDR brachytherapy can be delivered over two fractions as monotherapy. For unfavorable intermediate-risk (UIR) or high-risk disease, HDR brachytherapy can be delivered over one or two fractions in combination with EBRT.[53] There has also been increasing literature on the utilization of HDR brachytherapy as a salvage therapy for radiorecurrent prostate cancer in which there is persistent or recurrent prostate cancer after prior radiotherapy (RT).[54]

HDR brachytherapy involves the insertion of hollow catheters into the prostate gland under transrectal ultrasound (TRUS) guidance, most often with general or spinal anesthesia. A scan of the prostate with needles-in-place is then obtained using CT, TRUS, or MRI. The prostate and OARs (ie, urethra and rectum) are contoured. A treatment plan ensuring adequate prescription dose to the entire prostate while also satisfying OAR constraints is created. After quality assurance, the radiation is then delivered by a remote afterloader, in a shielded room. After treatment, the applicator is removed. The patient will not retain any radioactivity after the procedure.

HDR brachytherapy has certain dosimetric advantages compared with alternative radiotherapeutic techniques. Compared with low-dose-rate (LDR) brachytherapy, HDR brachytherapy provides more consistent dosimetry and treatment plans, due to the ability to optimize individual dwell positions along the implanted catheters.[55] Compared with EBRT/stereotactic body radiation therapy (SBRT) techniques, HDR brachytherapy may provide higher intraprostatic doses while still meeting rigid rectal dose constraints due to the rapid dose falloff with the lower energy Ir-192 source (average energy 380 keV). A phase 2 study involving TRUS/MR fusion at the time of HDR brachytherapy demonstrated that marked dose escalation to the dominant intra-prostatic lesion (DIL) (D90 142.7%; range 131.4%-151.7%) could be achieved while still achieving OAR constraints.[56] This degree of dose escalation likely surpasses the dose escalation that could be achieved with focal EBRT or SBRT boosts.[57-59]

Table 24.4 lists key eligibility criteria for prostate HDR brachytherapy. In general, patients should have sufficient life expectancy (≥10 years for intermediate risk and >5 years for high risk). Patients should have adequate urinary function, often reflected as an International Prostate Symptom Score (IPSS) ≤ 15. Special consideration should be made for patients with large prostate glands (≥60), due to concern for pubic arch inteference,[60] as well as large trans-urethral resection of prostate (TURP) defects.[61] For the latter, careful attention to dosimetry, particularly at interfaces between the remnant prostate and adjacent OAR (eg, urethra and bladder neck), may be necessary. Absolute contraindications for HDR prostate brachytherapy include inability to tolerate general or spinal anesthesia in the dorsal lithotomy position, absence of a rectum, active inflammatory bowel disease, or unacceptable operative risks.

TABLE 24.4 KEY ELIGIBILITY CRITERIA FOR PROSTATE HDR BRACHYTHERAPY

Key Eligibility Criteria
Sufficient life expectancy (>5 y)
IPSS ≤ 15
Prostate gland size ≤ 60 cm^3
No prior TURP
Amenable to undergo general anesthesia

Before brachytherapy, a comprehensive preanesthesia work-up is necessary to minimize the risk of unexpected medical events during the procedure. Screening colonoscopy could be considered for patients who have not had a colonoscopy within 3 years before the prostate cancer diagnosis in order to detect asymptomatic colorectal cancer and minimize the risk of unnecessary biopsies, which could lead to severe rectal complications in the years immediately after brachytherapy.[62]

Specific indications of HDR brachytherapy in favorable, unfavorable, and radiorecurrent disease settings will be reviewed in the following sections.

Outcomes

Favorable Disease

HDR brachytherapy is a standard-of-care treatment option for low-risk and FIR disease. HDR brachytherapy can be performed as monotherapy without the addition of androgen deprivation therapy (ADT). Historically, HDR brachytherapy involved the delivery of multiple fractions over a few days. Previously published regimens included the delivery of 6 to 6.5 Gy × 7 to 9 fractions over one implant,[63] 9.5 Gy × 4 fractions over two implants,[64] 7 Gy × 6 fractions over three implants,[65] and 10.5 to 11.5 Gy × 3 fractions.[66,67] However, over the past decade, the contemporary practice of HDR brachytherapy has drifted toward fewer fractions, with many practicing 13.5 Gy × 2 fractions over two implants.[68] Table 24.5 shows the outcomes from select HDR monotherapy series.

ADT, androgen deprivation therapy; bPFS, biochemical progression-free survival; CI, cumulative incidence; GI, gastrointestinal; GU, genitourinary.

There are no randomized trials comparing HDR brachytherapy monotherapy with alternative modalities. However, a single-institution randomized trial from the Sunnybrook Odette Cancer Centre randomized 170 patients with low (19%), favorable intermediate (51%), or UIR (30%) disease to either two-fraction (13.5 Gy × 2) or single-fraction (19 Gy × 1) HDR monotherapy without ADT. The 5-year biochemical disease-free survival was 95% versus 73.5% (P =.001) for the two-fraction versus single-fraction arms. Respective cumulative incidences of

local failure were 2.8% and 29.4.[68] A follow-up study reported respective 5-year cumulative incidences of grade 2+ GU toxicity (47% vs 62%), grade 3 GU toxicity (0% vs 2%), and grade 2 GI toxicity (9% vs 12%). There was no difference in mean urinary or bowel health related quality of life (HRQOL) at 2 to 5 years from baseline in the two-fraction arm, although differences were noted for sexual QOL.[69] This trial demonstrated high-intermediate-term oncologic control for the two-fraction arm. This trial also showed that single-fraction HDR brachytherapy yielded poor biochemical control results that were consistent with other single-arm prospective series, some of which utilized dose escalation beyond 19 Gy.[70–73]

Unfavorable Disease

HDR brachytherapy is also a standard-of-care treatment option for UIR and HR disease. For this scenario, HDR brachytherapy is typically performed in combination with pelvic or prostate-only EBRT as well as ADT. Contemporary fractionation schemes for HDR brachytherapy include 9.5 to 10 Gy × 2 fractions over one implant[3] as well as 15 Gy × 1[74] fraction. Acceptable EBRT doses are 45 to 50.4 Gy over 25 to 28 fractions or 37.5 Gy over 15 fractions. Standard ADT durations include 6 months for UIR disease and 18 months for high-risk disease.[75] Table 24.6 shows the outcomes from select HDR boost series.

ADT, androgen deprivation therapy; bPFS, biochemical progression-free survival; CI, cumulative incidence; DP, distant progression; FFBF, freedom from biochemical failure; FIR, favorable intermediate risk; GI, gastrointestinal; GU, genitourinary; LP, local progression; UIR, unfavorable intermediate risk.

One randomized trial from Mount Vernon Hospital in the United Kingdom compared combination EBRT + HDR brachytherapy boost against EBRT alone. In this trial, 218 patients, mostly with intermediate- or high-risk disease, were randomized to EBRT (55 Gy in 20 fractions) versus combination EBRT (35.75 Gy in 13 fractions), followed by HDR brachytherapy boost (8.5 Gy × 2 fractions). The 12-year relapse-free survival estimates were 55% and 27%, respectively. There were no differences in severe genitourinary, gastrointestinal, or urethral strictures between arms. Of note, doses for the EBRT alone and EBRT + HDR brachytherapy boost arms were lower than contemporary doses.[76]

Radiation Therapy Oncology Group (RTOG) 0321 was a multi-institutional prospective single-arm trial of 129 patients who underwent EBRT (45 Gy in 25 fractions) followed by HDR brachytherapy boost (19 Gy in two fractions). All patients had intermediate- or high-risk disease, and 43% received ADT. At a median follow-up of 10 years, biochemical, local, and distant failure rates at 10 years were 23%, 2%, and 8%, respectively. The 10-year rate of late grade 3 GI and GU adverse events was 4% and 5%. This trial demonstrated the feasibility of combination therapy in a cooperative group setting.[3]

There has also been a trend toward single-fraction HDR brachytherapy boost regimens. A single-arm prospective trial from the Sunnybrook Odette Cancer Centre enrolled 123 men with predominantly intermediate-risk disease who received HDR brachytherapy (15 Gy in one fraction), followed by hypofractionated EBRT (37.5 Gy in 15 fraction). The 5-year bPFS of 97.4% was comparable with the 92.7% rate observed in a historical series of 61 men who received a 2-fraction HDR boost (10 Gy × 2 fraction) followed by EBRT (45 Gy in 25 fractions).[74] In a follow-up analysis of the single-fraction regimen, rates of late GU grade 2 and grade 3 toxicities were 59% and 4%, respectively. Corresponding rates of late GI toxicities were 19% and 0%. Larger prostate volume was associated with late GU 2+ urinary toxicity.[77]

Pelvic radiation therapy could be considered for patients with high-risk disease undergoing combination HDR brachytherapy boost. In a study of 812 patients who received 15 Gy × 1 HDR brachytherapy boost from Mt Vernon Hospital, 5-year bPFS was 89% for patients who received whole pelvic RT versus 81% for prostate-only RT, with the benefit of whole pelvic RT observed only in the high-risk subgroup (84% vs 77%; P =.001). The prevalence of grade 3+ toxicity was no greater than 1.5% across all time points.[79]

The optimal duration of ADT for patients undergoing combination HDR brachytherapy remains unknown. However, there may still be a benefit of prolonged ADT for such patients. The TROG 03.04 RADAR trial randomized patients with locally advanced prostate cancer to 6 versus 18 months of ADT. Patients were stratified by RT regimen, which included 66 Gy, 70 Gy, or 74 Gy EBRT, or 46 Gy EBRT plus HDR boost (19.5 Gy in three fractions). The trial demonstrated that 18 months of ADT reduced distant progression independently of radiation dose for all patients (sub-distribution hazard ratio [sHR] 0.70; 95% CI 0.50-0.87; P =.002), including the HDR brachytherapy subgroup (sHR 0.61; 0.38-0.97; P =.036). Reported cumulative incidences of 10-year local progression/distant progression were 2.2%/19.7% for HDR boost, compared with 7.3%/24.9% for 74 Gy,

7.5%/26.7% for 70 Gy, and 12.3%/26.1% for 66 Gy EBRT.[75] Of note, patients who received HDR brachytherapy boost were more likely to have stage T3 or T4 (64.1% vs 24.8%-31.7%) and grade group 4 to 5 (51.1% vs 27.2%-34.3%) tumors, compared with the EBRT dose groups.

Radiorecurrent Disease

The role of salvage HDR brachytherapy for the treatment of radiorecurrent prostate cancer continues to evolve. Most evidence involves single-institutional prospective series with short-term or intermediate-term oncologic follow-up. Furthermore, these institutional series varied with respect to fractionation regimens (6 Gy × 6,[80] 8 Gy × 4,[81] 10 Gy × 3,[82] 10.5 Gy × 2,[83] 19 Gy × 1[84]), treatment volumes (whole-gland vs focal[83,84]), and initial staging, with more recent series[84] incorporating prostate-specific membrane antigen (PSMA) PET imaging. A recent meta-analysis reported that HDR brachytherapy was associated with less severe genitourinary toxicity (9.6% vs 20.0%; P <.001) and gastrointestinal toxicity (0 vs 1.8%; P <.01), but similar oncologic efficacy (59.7% vs 53.9%) at 5 years, compared with salvage radical prostatectomy.[85]

More stringent eligibility criteria should be applied in the salvage setting. Patients should have a prostate size ≤45 cc, an IPSS score ≤15, a >30-month interval since prior RT, as well as resolution of grade 2+ GI or GU toxicity per RTOG 0526, a multiinstitutional phase 2 study of salvage LDR brachytherapy.[86] Ideal candidates should have isolated disease localized only within the prostate on PSMA-PET staging because this modality is more sensitive than conventional and even 18F-fluciclovine PET for the detection of metastases.[87,88] Post-RT biopsies documenting pathologic evidence of radiorecurrent disease are warranted, given the small potential for significant GI/GU toxicity with salvage HDR brachytherapy.

Technique

For HDR brachytherapy, the needle insertion procedure is performed under general or spinal anesthesia with the patient in dorsal lithotomy position. Needles are inserted into the prostate gland under TRUS guidance. For whole-gland treatments, approximately 16 needles can be placed (12 peripherally, four centrally) to allow for comprehensive dosimetric coverage of the entire prostate gland.[53] Additional needles can be placed into the dominant intraprostatic GTV if focal boost is performed. TRUS/MR fusion may help in identifying the GTV on TRUS imaging.[89]

Treatment Planning

CT-based treatment planning is widely available in most radiation oncology departments. A key advantage of CT-based planning is that multiple fractions can be delivered, typically 6 hours apart, after the CT simulation scan. In fact, two-fraction HDR monotherapy delivered in 1 day after a single implant has been reported as safe and efficacious.[90] Key disadvantages of this monotherapy are as follows: First, catheters may migrate caudally after the patient is moved out of the dorsal lithotomy position. Cystoscopy while the patient is in the supine position or catheter manipulations at the time of CT simulation could help ensure that catheters reach the prostate base. Second, the prostate may be difficult to contour due to a lack of contrast between the prostate and surrounding tissues. Fiducial markers placed within the prostate could aid in identifying the prostate base and apex. MRI, if available, could assist in prostate delineation due to superior soft-tissue contrast. Third, catheter migration, typically caudal, may occur between CT simulation and treatment delivery.[91,92] Pretreatment imaging verification utilizing x-rays, cone-beam CTs,[93] or CT[94] is recommended. Catheter or treatment plan adjustments could then be made.

Ultrasound-based treatment planning is typically performed at institutions with access to an operating room appropriately shielded for HDR brachytherapy. A key advantage of ultrasound-based brachytherapy is that treatment planning and delivery can be performed in the dorsal lithotomy position. Moving the patient out of the lithotomy position, which is required for CT- or MR-based planning, could lead to the caudal displacement of catheters.[95] Furthermore, time to treatment delivery can be minimized without patient movement. However, only one treatment can be delivered with ultrasound-based treatment planning, such that patients who require two fractions need to undergo a repeat ultrasound-guided implant or repeat treatment planning in the supine position with CT or MRI. Furthermore, prostate contouring and needle digitization can be challenging in the presence of needle artifacts.

Treatment planning should be performed to maximize coverage of the prostate while minimizing OAR doses. Sample OAR constraints are listed in Table 24.7. An example of a TRUS-based treatment plan is provided in Figure 24.3.

TABLE 24.7 TARGET VOLUME AND OAR CONSTRAINTS FOR HDR BRACHYTHERAPY

FIGURE 24.3 Axial view of ultrasound-based HDR brachytherapy (15 Gy/1 fx) for high-volume unfavorable intermediate-risk prostate cancer (Gleason 4+3, 9/12 cores), treated with ADT and pelvic EBRT (45 Gy/25 fractions). The patient had a template-based interstitial applicator placed with 23 interstitial needles for a 40.4 cc gland. Contours: Prostate—red; DIL—blue; urethra—yellow; rectum—brown. Target volume metrics included prostate V100 95.7%, prostate V150 29.9%, prostate V200 6.2%, urethra D0.1 cc 113.75%, bladder D2cc 63.2%, and rectum D0.1 cc 84.2%. The D90 to the DIL was 145.9%.

Follow-up

Patients treated with HDR brachytherapy in any setting should undergo regularly scheduled follow-up to monitor treatment response with serial prostate specific antigen (PSA) values and manage potential acute and late toxicities. Follow-up exams should be performed every 6 months for the first 5 years, and yearly thereafter. Prompt urology referral should be considered if the patient has urologic symptoms, despite alpha-adrenergic antagonists, and negative urinalysis/urine culture. Gastroenterologists who perform a colonoscopy after brachytherapy should be informed that the patient had prior brachytherapy, in order to decrease the risk of unnecessary biopsies that could lead to severe rectal complications.

BREAST CANCER

Clinical Indications

Many patients with early-stage breast cancer are candidates for breast conservation therapy, which consists of lumpectomy followed by RT rather than mastectomy. The most common method of RT involves whole breast irradiation (WBI) using EBRT. Typical WBI regimens include conventionally fractionated regimens (5-6 weeks), moderately hypofractionated regimens (3-4 weeks),[97] and more recently ultrahypofractionated regimens (1 week).[98]

However, over the past two decades, there has been increasing interest in accelerated partial breast irradiation (APBI) for patients with very favorable risk disease. APBI consists of delivering a similar biologically equivalent radiation dose as WBI, but to a much smaller volume consisting of the lumpectomy cavity plus 1 to 2 cm margin over 1 week.[99]

Patients with favorable risk disease are ideal candidates for APBI. The ABS recommends consideration of APBI in patients who are at least 45 years old, with invasive histology or ductal carcinoma in situ (DCIS).[99] Additional criteria include tumor size ≤3 cm, negative nodes, any estrogen receptor (ER) status, negative human epidermal growth factor receptor (Her)-2 status, and no extensive LVSI. Patients should have no tumor on ink for invasive disease and ≥2 mm margins for DCIS. Eligibility recommendations from the ABS, American Society of Radiation Oncology, and GEC-ESTRO are provided in Table 24.8.

TABLE 24.8 OPTIMAL ELIGIBILITY CANDIDACY FOR APBI MONOTHERAPY PUBLISHED BY VARIOUS MEDICAL SOCIETIES

ABS, American Brachytherapy Society; APBI, accelerated partial breast irradiation; ASTRO, American Society of Radiation Oncology; DCIS, ductal carcinoma in situ; LCIS, lobular carcinoma in situ; GEC-ESTRO, Groupe Européen de Curiethérapie European Society for Radiation Oncology; NS, not specified.

APBI has been associated with low rates of risk of in-breast tumor recurrence (IBTR) (<5% at 10 years)[5,102-105] that are comparable to WBI in randomized trials. Furthermore, APBI has been associated with improved late toxicity[5] and cosmesis[105-107] compared with WBI. APBI arms have included multiple forms of RT, including EBRT (3D conformal radiation therapy [3DCRT][103,108] and intensity-modulated radiation therapy [IMRT][102,104,105]), intraoperative radiotherapy (IORT)[107,109] and HDR brachytherapy (BT).[5,103,106] HDR-BT is an attractive modality for APBI, due to the ability to obtain a highly conformal dose distribution around the lumpectomy cavity with less scatter dose to surrounding structures.

The two main forms of HDR-BT include intracavitary and interstitial brachytherapy. Intracavitary brachytherapy involves the insertion of a device into the lumpectomy cavity through a single point of entry. These applicators include balloon (eg, single-lumen or multilumen) and hybrid (eg, strut-based) systems. Although single-lumen balloon systems only allow for relatively spherical dose distributions, multilumen balloon and hybrid intracavitary systems allow for increased dose modulation for sparing surrounding OARs, such as the skin and ribs.[110,111] Interstitial brachytherapy, on the other hand, involves the insertion of multiple catheters across the

lumpectomy cavity. Although interstitial brachytherapy can provide conformal dosimetric coverage across nonspherical geometries, these implants are technically challenging.[112,113] Both forms of HDR brachytherapy are discussed below.

Outcomes

Three randomized trials comparing WBI and APBI have included HDR brachytherapy on the APBI arms (Table 24.9). Two trials have involved interstitial brachytherapy. The GEC-ESTRO group randomized 1,328 patients between 2004 and 2009 to WBI (50 Gy/25 fractions + 10 Gy boost) versus APBI (30.1 Gy/7 fractions or 32 Gy/8 fractions HDR over 5 days, or 50 Gy pulse dose rate). APBI was deemed noninferior to WBI with respect to 5-year local recurrence (1.44% vs 0.92%; P =.42).[114] The 10-year in-breast tumor recurrence rates (IBTR) were 3.51% for APBI versus 1.58% for WBI (P =.074). APBI was associated with lower late grade 3+ side effects (1% vs 4%; P =.021).[5]

APBI, accelerated partial breast irradiation; EBRT, external beam radiation therapy; IC, intracavitary; IS, interstitial; WB, whole breast; WBI, whole breast irradiation.

The National Institute of Oncology from Hungary randomized 258 patients between 1998 and 2004 to APBI (interstitial: 88; electrons: 40) versus WBI (50 Gy). The prescription dose was 36.4 Gy in seven fractions, twice daily. The 20-year IBTR was 9.6% for APBI versus 7.9% for WBI (P =.59). More patients with APBI had excellent or good cosmetic results (79.2% vs 59.5%; P =.0007).[106]

NSABP-B39/RTOG 0413 randomized 4,216 patients to WBI (50 Gy/5 weeks) versus APBI. APBI consisted of 3D-CRT (21%; 38.5 Gy in 10 fx twice a day), intracavitary (21%; 34 Gy in 10 fx twice a day), and interstitial (6%; 34 Gy in 10 fx twice a day). The 10-year IBTR was 3.9% for WBI versus 4.6% for APBI. Although the HR for IBTR of 1.22 (90% CI: 0.94-1.58) favored WBI, the difference in 10-year IBTR between both modalities was less than 1%. Rates of grade 3 toxicity were 10% for APBI and 7% for WBI. The trial was not designed to evaluate clinical outcomes among different APBI techniques.

Two large registry trials have been conducted for intracavitary HDR-BT applicators. In the American Society of Breast Surgeons MammoSite Breast Brachytherapy Registry Trial, 1,449 patients (87% invasive; 13% DCIS) were treated with the single-lumen balloon intracavitary device at a dose of 34 Gy in 10 fractions twice daily. The 5-year actuarial rate of IBTR was 3.8%. The percentage of patients with excellent/good cosmetic results at 5 years was 91.3%.[115] In the strut-based registry trial, 250 patients were treated with a strut-based hybrid intracavitary device at a dose of 34 Gy in 10 fractions, twice daily. The 4-year IBTR was 3.6%. 85.9% of patients had excellent/good cosmesis at 5 years.[116]

Technique

Intracavitary

Intracavitary applicators are inserted into the lumpectomy cavity, either during the time of the lumpectomy surgery or during a separate procedure under ultrasound guidance. Once the applicator is placed, a treatment-planning CT scan is obtained with the applicator expanded. The radiation oncologist must ensure that the applicator conforms well to the cavity, ideally with adequate distance (~5 mm for single- lumen balloon; less for multilumen balloon) between the balloon and skin.

Interstitial

The ABS and GEC-ESTRO guidelines provide detailed guidelines for using this technique.[112,113] The implant can be performed either intraoperatively or postoperatively (nearly 4-12 weeks after lumpectomy) with the use of template-guided or free-hand needles under appropriate anesthesia. A preplan based on ultrasound or CT could aid in defining the optimal needle configuration and orientation prior to the implant. Once the applicator is placed, a treatment-planning CT scan is performed.

Treatment Planning

Treatment planning is most often performed with a CT scan with an applicator in place. The CTV often consists of the lumpectomy cavity plus a 1- to 2-cm margin. OARs may include the skin, ribs, contralateral breast, lung, and heart. Tables 24.10 and 24.11 show the recommended target volumes and OAR constraints for intracavitary and interstitial applicators, based on the NSABP B39/RTOG 0413 protocol.[103] Prescription doses could include 34 Gy in 10 fractions, twice daily, as used in NSABP B39/RTOG 0413, or either 32 Gy in eight fractions or 30.1 Gy in seven fractions, as used in the GEC-ESTRO trial.[5]

TABLE 24.10 PLANNING VOLUMES AND CONSTRAINTS FOR INTRACAVITARY BRACHYTHERAPY, BASED ON NSABP B-39/RTOG 0413 (PRESCRIPTION DOSE 34 GY IN 10 FRACTIONS, TWICE DAILY)

Target volumes	• CTV: resection cavity and device surface with a 10-mm expansion • PTV: equal to CTV • PTV_EVAL: equal to CTV but cropped 5 mm from the skin and by the posterior extent of the breast
Parameters and constraints	• Dose prescribed at a depth of 1 cm from the device surface • ≥90% of dose covering ≥90% of PTV_EVAL • V150 ≤50 cc and V200 ≤10 cc • Uninvolved breast: <60% of WB receiving ≥50% of prescribed dose • Maximum skin dose ≤145% of prescription dose • Minimum skin thickness of 5 mm

TABLE 24.11 PLANNING VOLUMES AND CONSTRAINTS FOR INTERSTITIAL BRACHYTHERAPY, BASED ON NSABP B-39/RTOG 0413 (PRESCRIPTION DOSE 34 GY IN 10 FRACTIONS, TWICE DAILY)

Target volumes	• CTV: resection cavity with a 15-mm expansion • PTV: equal to CTV • PTV_EVAL: equal to CTV but cropped 5 mm from the skin and by the posterior extent of the breast
Parameters and constraints	• ≥90% of dose covering ≥90% of PTV_EVAL • V150 ≤70 cc and V200 ≤20 cc • Dose homogeneity index (DHI) = (1 − V150/V100) ≥ 0.75 • Uninvolved breast: <60% of WB receiving ≥50% of prescribed dose

Follow-up

It is recommended that patients who undergo brachytherapy for APBI be seen in follow-up from every 3 months for the first 2 years, every 6 months for the next 3 years, and yearly thereafter.[5] More frequent early follow-ups are warranted, in order to monitor for hematoma or infectious complications.

RECTAL CANCER

Clinical Indications

HDR brachytherapy can be considered for the definitive treatment of locally advanced rectal cancers. The standard of care for locally advanced rectal cancer over the past two decades has involved long-course preoperative

chemoradiation therapy followed by surgery with total mesorectal excision.[117] HDR brachytherapy boost can provide profound dose escalation far beyond than what is possible with conventional IMRT techniques.[118] This profound dose escalation may lead to improved pathologic complete response (pCR) rates. In a recent systemic review, preoperative chemoradiotherapy regimens involving HDR brachytherapy boost were associated with a greater pathologic complete response (pCR) rate (weighted mean, 22.2%)[119] than that observed with chemoradiation alone (weighted mean 11.8%).[120] An association between pCR and survival has been observed in a large pooled analysis of individual patient data.[121]

Over the past decade, there has been increasing interest in the nonoperative management of locally advanced rectal cancer. After initial treatment involving chemoradiation therapy[122] or total neoadjuvant regimens involving high-dose preoperative systemic therapy,[123] patients with complete clinical responses undergo watchful waiting rather than total mesorectal excision. Profound dose escalation with brachytherapy may improve the chance of complete clinical response and organ preservation, as suggested by the recently reported organ preservation in early cT2–cT3 rectal adenocarcinoma (OPERA) trial. In this trial, 148 patients were randomized to contact brachytherapy boost (90 Gy in three weekly fractions) versus EBRT boost (9 Gy in five fractions) after chemoradiation therapy (45 Gy/25 fractions). Contact brachytherapy boost improved greater complete response rates (81% vs 58%; P =.0006). Furthermore, this treatment improved 3-year organ preservation rates (81% vs 59%; P =.0026). Respective rates for tumors <3 cm were 97% and 63%.[124] However, contact brachytherapy was associated with increased late-grade 1 to 2 rectal bleeding (63% vs 12%).

Endoluminal HDR brachytherapy involves delivering radiation to the tumor through a single-channel or multichannel endoluminal applicator placed in the rectum. Compared with contact brachytherapy, this form of treatment may be able to treat larger (≥3 cm at the time of brachytherapy) as well as deeper tumors (prescription depth of ~1 cm). HDR brachytherapy boost after EBRT has been investigated by multiple groups.[125–127] In a registry study of 94 medically inoperable patients who received pelvic EBRT (40 Gy in 15 fractions) followed by weekly adaptive HDR brachytherapy (30 Gy in three weekly fractions to 1 cm depth), the complete clinical response rate was 86.2%.[127] The 2-year local control among all patients was 71.5%, with only 12.8% reporting late grade 3 bleeding.

Technique

Brachytherapy can be considered about 3 weeks after EBRT in order to allow for resolution of proctitis. After completion of EBRT, a gastroenterologist can examine the tumor with a flexible rectosigmoidoscope in order to confirm adequate response and place radio-opaque clips at the proximal and distal extents of the residual tumor. Then, a single-channel or multichannel applicator is inserted into the rectum. Applicators with shielding and/or a double-balloon system could help shield the uninvolved rectum from high-dose radiation. A CT simulation of the applicator in place is obtained. Care must be taken to ensure that there is no material between the tumor and the applicator. Furthermore, the thickness of the tumor should be at most 1 cm.[127]

Treatment Planning

The CTV is defined as residual macroscopic tumor. Surrounding OARs should be contoured. Dose can be prescribed up to 1-cm depth to limit mucosal dose to 200%. The dose to the uninvolved rectum should be minimized. Weekly adaptive treatment planning could be considered to account for tumor regression in-between fractions and to minimize dose to OAR.[127]

Follow-up

In the non-operative setting, endoscopic evaluation should be performed at 6 to 8 weeks after brachytherapy to document response. Following this, clinical examinations with endoscopies should be considered every 3 months for the first 2 years, every 6 months between years 2 and 5, and yearly thereafter. Imaging with pelvic MRI or staging CT scans could be considered on a semi-annual or annual basis.

SKIN CANCER

Clinical Indications

HDR brachytherapy is a suitable treatment modality for the nonoperative management of skin cancers, such as squamous cell carcinoma and basal cell carcinoma.[128] This is a particularly useful form of treatment for patients who decline surgery, are nonoperative candidates, or may have poor cosmetic or functional outcomes after surgery. Numerous single-institutional studies have reported on the oncologic and cosmetic outcomes of HDR brachytherapy.[129-131] Recently, a meta-analysis compared HDR brachytherapy against EBRT, Mohs micrographic surgery, and conventional excision for T1-T2N0 skin cancers (≤4 cm). Brachytherapy and Mohs surgery had improved cosmesis compared to EBRT and conventional excision. Furthermore, 1-year local recurrence rates were low across all modalities.[132]

HDR brachytherapy is ideally suited for patients with localized, well-defined, clinical T1-T2N0M0 cancers with limited predisposition for spread (no perineural or lymphovascular invasion). HDR brachytherapy may not be ideal for treating cancers that are large (>4 cm), poorly defined, locally invasive (eg, perineural invasion and deep extension beyond cutaneous fat), or associated with chronic immunosuppression. Other contraindications include poorly controlled connective tissue disorders or conditions associated with increased radiosensitivity (eg, Li-Fraumeni syndrome, nevoid basal cell carcinoma, and ataxia telangiectasia). Of note, HDR brachytherapy has also been effective in other types of skin conditions, including Merkel cell carcinoma,[133] keloid scars,[134] cutaneous T-cell lymphoma,[135,136] and angiosarcoma.[137]

A careful physical exam is required for all skin cancers treated with HDR brachytherapy. The tumor should be carefully measured and photographed, in order to select the ideal applicator and assess treatment response. Cross-sectional imaging should only be considered for tumors at higher risk of regional or nodal spread.

Technique

HDR brachytherapy can be delivered using rigid applicators, flaps/custom molds, or interstitial techniques.

Rigid Applicators

Rigid conical and nonconical applicators are ideal for contact-based treatment of small, superficial skin lesions. These applicators are small, fixed-geometry, shielded devices with a dwell position for the HDR source at its vertex. Applicators vary with respect to size (most often 20 mm or 30 mm), as well as the presence or absence of a flattening filter. The dosimetry of these applicators has been well characterized.[138,139] A proper-sized applicator should be selected and secured, while ensuring full contact with the skin.

Custom Surface Flaps/Molds

Custom surface flaps or molds are ideal for superficial cutaneous lesions on curved or irregular surfaces (eg, extremities, waist, and face). Flaps consist of customizable silicone-based sheets or beads with embedded catheters.[131] Molds, on the other hand, are made of synthetic materials (wax, rubber, 3D printed) that can be attached to catheters.[129,130] Both are placed on the target volume and immobilized utilizing tape, bandages, or towels. Detailed descriptive and image documentation of the clinical setup is of utmost importance to ensure reproducibility during subsequent treatments.

Interstitial Brachytherapy

Interstitial brachytherapy is ideal for deeper lesions (>0.5 cm) not amenable to other techniques, such as those around the lip[140] or eyelid.[141] While the patient is under anesthesia, trocars with attached catheters are inserted through the skin, approximately 1 cm apart, to cover the extent of the lesion. Catheters ideally are inserted 5 mm from the skin surface in order to limit skin toxicity.

Treatment Planning

For all applicators, a CTV and PTV can be delineated by inking around the tumor. A 1-cm CTV margin can often be used but may be adjusted to 0.5 cm for more indolent tumors (eg, low-risk basal cell carcinoma) or 2 cm for more aggressive tumors (larger tumors, moderate/poor differentiation). PTV margins range from 0 to 5 mm in diameter and up to 1 mm in depth.[128]

For rigid applicators, treatment optimization is not possible due to the single dwell position. For surface molds, flaps, and interstitial brachytherapy, CT simulation is necessary for dosimetric optimization. Prior to CT simulation, a radio-opaque wire should be placed on the PTV. During treatment planning, the 100% isodose line

should encompass the PTV and the surface dose should be limited to <140% of the prescription dose. With the exception of interstitial brachytherapy, the maximal prescription depth is about 3 to 4 mm. Figure 24.4 demonstrates an example of an RT plan using a custom surface flap.

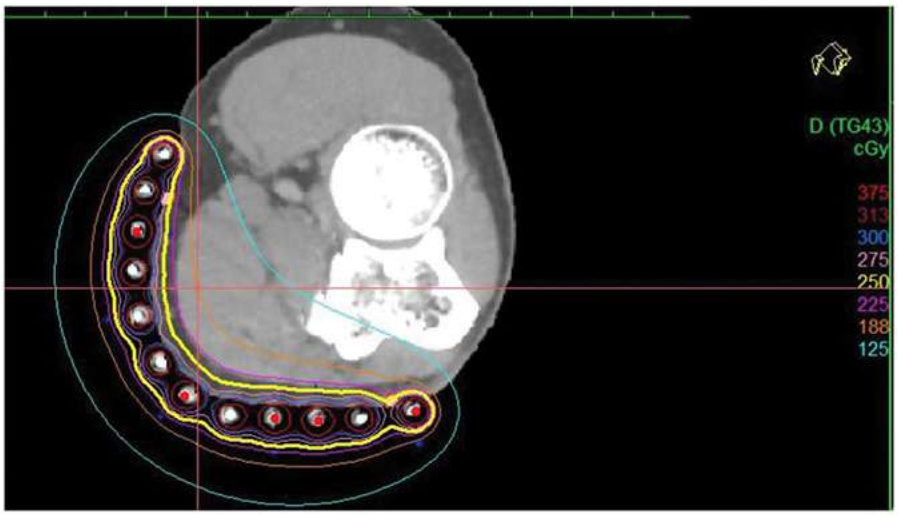

FIGURE 24.4 CT-based treatment plan of surface applicator brachytherapy (20 Gy/8 fractions) for patient with primary cutaneous marginal B-cell lymphoma of the elbow.

Both conventional and hypofractionated regimens can be utilized. Hypofractionated regimens have been associated with good cosmesis at a similar biologically equivalent dose in a recent meta-analysis,[142] and are recommended due to patient convenience. Recommended regimens in ABS guidelines include 42 Gy in six fractions, delivered every other day; 42 Gy in seven fractions, delivered every other day; or 40 Gy in eight fractions, delivered every other day or twice weekly. More sensitive areas or larger tumors could be treated using more conventional fractionation schemes, such as 55 Gy in 20 fractions or 60 to 70 Gy in 30 to 35 fractions.[128]

Follow-up

Follow-up regular examinations can be performed every 3 to 12 months for the first 3 years and then annually thereafter. More frequent follow-ups should be performed for tumors at higher risk of recurrence.

OTHER CANCERS

The roles of HDR brachytherapy for the definitive treatment of endobronchial, esophageal, biliary, soft tissue sarcoma, and head and neck cancers have evolved, given recent advances in intensity-modulated radiation therapy/SBRT, surgical techniques, systemic therapy (eg, immunotherapy), as well as combination regimens. However, HDR brachytherapy remains a treatment option for specific scenarios.

For endobronchial tumors, HDR brachytherapy is predominantly used for the palliation of symptoms, particularly in patients who are not good candidates for additional EBRT due to poor lung function or receipt of prior radiation doses. Endobronchial brachytherapy has been associated with improvements in both symptoms and tumor regression on bronchoscopy.[143-145] This form of brachytherapy involves the insertion of a brachytherapy catheter through a bronchoscope. The catheter should be inserted until it passes by the endobronchial tumor and is lodged within smaller bronchi. The other end of the catheter is then taped to the nose and marked in order to monitor for displacement. CT-based planning is recommended to maximize dose to the target volume while minimizing dose to OARs. Dose fractionation regimens recommended for palliation per ABS guidelines include 10 Gy in one fraction, 15 Gy in one fraction, 14.2 to 20 Gy in two fractions, 22.5 Gy in three fractions, 24 Gy in four fractions, and 30 Gy in five fractions.[146] A randomized controlled trial revealed improved tumor response with 14.4 Gy in two fractions compared with 15.2 Gy in four fractions.[145] A Cochrane analysis concluded that there was insufficient evidence to recommend the addition of a brachytherapy boost to EBRT alone for symptom palliation.[147]

For esophageal carcinoma, HDR brachytherapy is used for palliation of tumors causing symptoms (eg, dysphagia), particularly in patients who are not good candidates for EBRT (eg, poor lung function or prior EBRT dose). This form of treatment has been associated with good symptom palliation in the majority of patients. Esophageal brachytherapy involves the insertion of a catheter or esophageal applicator either intraorally or intranasally under endoscopy. The applicator should pass the tumor. The proximal end of the catheter is then taped to the nose or the mouth and marked, in order to monitor for displacement. CT-based planning is recommended to maximize the dose to the target volume while minimizing the dose to OARs. Dose fractionation regimens include 16 Gy in two fractions and 18 Gy in three fractions based on equivalent rates of symptom palliation in a randomized trial.[148] Another randomized trial did not show the benefit of the addition of EBRT to HDR brachytherapy alone for symptom palliation.[149] Of note, HDR brachytherapy boost has not been incorporated in the definitive management of esophageal cancer, given the high risk of esophageal fistula (12%) observed after chemoradiation therapy (50 Gy RT; cisplatin 75/5-FU 1,000 mg/m^2 every 3 weeks × 4) and HDR brachytherapy boost (15 Gy in three fractions or 10 Gy in second fractions) in RTOG 9207.[150]

For biliary cancers, HDR brachytherapy is predominantly used for addressing biliary tract obstruction from unresectable hepatobiliary tumors. Although biliary tract obstruction is most often managed through decompression using stents and/or drains, multiple decompression procedures may be needed due to occlusion or stent migration. A recent systemic review reported that the delivery of intraluminal HDR brachytherapy was associated with a longer duration of stent patency (10 months) compared to its absence (4-6 months).[151] Briefly, a biliary drainage catheter is placed either through transhepatic cholangiogram or through endoscopic retrograde techniques. The HDR brachytherapy catheter is inserted through this drainage catheter. After CT simulation is performed with the catheter affixed, HDR brachytherapy is performed. Potential dose- fractionation schemes for HDR monotherapy include 25 Gy in five fractions and 30 Gy in six fractions.

For head and neck cancers, HDR brachytherapy can be considered in the definitive or palliative settings. The type of brachytherapy that is performed depends on the subsite. For example, oropharyngeal cancers are typically treated with interstitial brachytherapy. A recent randomized trial reported that HDR brachytherapy boost (21 Gy in seven fractions) after radiation therapy (50 Gy in 25 fractions) was associated with reduced xerostomia on salivary scintigraphy (14% vs 44%) compared with EBRT boost (20 Gy in 10 fractions) in patients with T1-T2N0M0 oropharyngeal cancers. There was no difference in 3-year local control between arms.[152] Interstitial brachytherapy could also be used to treat deeper tumors of the oral cavity. On the other hand, intracavitary applicators or molds could be used for more superficial tumors of the oral cavity, sinuses, or nasopharynx.

For soft tissue sarcoma, preoperative EBRT is now the preferred standard-of-care, given that a randomized trial of preoperative versus postoperative EBRT reported reduced late-onset fibrosis in the preoperative arm.[153,154] Furthermore, a single-institutional study reported improved local control rates observed with IMRT compared with low-dose rate brachytherapy.[155] However, sarcoma brachytherapy in the postoperative setting can be considered for the definitive treatment of sarcomas in patients who are not good candidates for preoperative EBRT due to prior EBRT or OAR considerations. Briefly, the patient undergoes an oncologic resection of the sarcoma tumor. Clips can be placed in the resection bed to mark the appropriate resection margins. Catheters are then inserted through the skin and laid across the resection bed in a parallel, equally spaced manner. After allowing a few days for wound healing (4-7 days), the patient undergoes CT simulation. Target volumes and OARs are delineated, followed by treatment planning. Potential prescription doses include 30 to 54 Gy, given over 4 to 7 days with twice-daily fractions for HDR monotherapy, or 12 to 20 Gy, given over 2 to 3 days with twice-daily fractions for HDR combination therapy followed by EBRT (45-50 Gy) boost.[156]

QUALITY MANAGEMENT PROGRAM

Design of the modern HDR brachytherapy program includes development of step-by-step treatment procedures, specification and qualification of personnel, technical solutions for treatment planning and treatment delivery equipment, implementation of the patient and personnel safety standards, and development of the comprehensive quality assurance program.

To implement the most effective HDR brachytherapy program while minimizing treatment delivery errors and other safety hazards, each institution should develop a comprehensive HDR brachytherapy quality management program (BQMP). The main components of this BQMP are (a) quality assurance (QA) as a set of written policies and procedures that are designed to maintain the standard of quality over a time period, (b) quality control that describes the measurement aspects of the QA program, and (c) continuous quality improvement in order to

improve outcome on a continuing basis. More specifically, QA in HDR brachytherapy involves performing the following documentation: quality management plan, acceptance QA procedures, annual QA procedures, monthly QA procedures, daily QA procedures, treatment plan QA, pretreatment QA, emergency procedure, and chart QA (end of treatment checks). The procedures for implementing all aspects of QA are described in the American Association of Physicists in Medicine (AAPM) Task group reports 40 and 59.[157,158]

Roles and responsibilities in the comprehensive BQMP are defined for radiation oncologists, medical physicists, medical dosimetrists, and radiation therapists. Such programs become exceedingly important in HDR brachytherapy because the planning and the treatments tend to happen very quickly, thus increasing the likelihood of accidents and mistakes. QA is performed at various intervals: some for each patient, some once each treatment day, and others with each source change. Moreover, for HDR machines, the Nuclear Regulatory Commission or the State mandates that users meet certain standards, including education and training on operating the machine, emergency procedures, radiation monitoring, pretreatment safety checks, safe and accurate delivery of the treatment, and monthly/initial calibration of the source. The latest practice guidelines in HDR brachytherapy are given in the AAPM Practice Guideline 13.[159]

Practical Aspects of High-Dose-Rate Quality Management Program

Treatment Planning Preparation

An authorized user (physician) must date and sign a written directive for a specific patient before administration of the radioisotope. The directive must include the radioisotope, treatment site, total dose, dose per fraction, and the overall treatment period. Any modification to the treatment requires a modification before the following treatment. The authorized user and licensed therapist (operator) shall verify the patient's identity by two means: (a) verbal response by the patient and (b) photo identification in the radiation oncology (electronic) chart. For patients who cannot meet one of these requirements, an alternative second means such as hospital wristband identification or hospital card can be used. A radiation oncologist must obtain a signed, dated informed consent from the patient prior to the administration of any treatment.

A radiation oncologist will place the applicator and verify the dummy source locations with appropriate CT/MRI scans or radiographs before commencing any treatments unless the implants use fixed geometries and that all physical parameters of the applicator are known for dosimetry purposes. The radiographs or 3D images will be reviewed by both the authorized physicist and the authorized user. Prior to the administration of the treatment, an independent check of the computer-generated dose calculations will be performed by a physicist and radiation oncologist. The checks shall include computer input data, computer output data, and data transferred from the treatment planning computer to the treatment unit. The data will include the prescription, treatment length/distance, the number of dwell positions, dwell times, total treatment time, channel numbers, and source activity. The person checking the computer data will initial the data printout from the control console. The treatment plan must have a signature approval from an authorized medical physicist, as indicated in the institutional HDR daily pretreatment procedures. The pretreatment record will be filed in the patient's chart and saved in the electronic record. Prior to the administration of the treatment, the authorized user shall check, sign, and date a copy of both the treatment data printout and isodose plan.

Treatment Delivery

When the source is not in use, it is normally stored in the locked radioisotope room. The operator and/or the physicist will perform the appropriate QA tests listed as follows. The operator must follow the written and/or verbal instructions provided. No treatment procedure will be conducted if a decoupled or jammed source cannot be removed expeditiously from the patient and placed in a shielded container. If the daily check of interlocks for the remote afterloading device indicates that the interlock is not operating properly, the physicist must be informed, and no treatment will be carried out until the problems are resolved.

Only the patient will be in the treatment room during activation of the device. Both the authorized user and the authorized medical physicist must be physically present in the console area during all patient treatments. The door to the treatment room will be interlocked, and a sign restricting access to the treatment area will be posted to minimize the risk of inadvertent exposure to personnel not directly involved in a possible emergency source recovery. The patient will be surveyed immediately after the treatment and before removal from the treatment room to ensure that the source has been withdrawn from the patient. Immediately implement the appropriate emergency procedures if the survey indicates that the source is not fully retracted to a shielded position. The

authorized user and the medical physicist will immediately be notified of any problem requiring implementation of emergency procedures. Upon administration of the treatment, the authorized user will sign and date the patient's chart to verify that the correct prescription was administered. The radiation oncologist will also note the loading sequence of the applicator/applicators and the treatment length in the patient's chart for each procedure. A survey of the device will be performed immediately after each use of the device, including the connectors and applicators apparatus, the full catheter guide tube length, and the device's external surface. The device and the console will be locked, and the source will be moved back to the storage room by the physicist or operator.

Emergency Procedures

Based on the existing statistics, the likelihood of major emergencies in HDR brachytherapy is low. This is greatly due to the regulatory requirements—for example, well-developed emergency procedures, training of the personnel, and proper maintenance of the equipment via implementation of the comprehensive BQMP. A routine emergency check should be performed in the department. An emergency kit containing surgical clamps, long forceps, emergency containers, and additional medical supplies should be readily available. In the event the radioactive source fails to retract after termination or interruption after the emergency off switch is pushed or after the stepper motor is cranked manually, the immediate priority is to remove the source from the patient. The emergency procedures should be regularly reviewed and approved by an authorized user. Copies of these emergency procedures should be provided to all device operators, authorized users, medical physicists, and other personnel as necessary. A copy should be posted at the treatment console.

Quality Assurance

Users will be trained to perform each QA test using written and oral instructions.

Daily Quality Assurance Checks or at the Beginning of Each Use

The permanent radiation monitor will be checked for proper operation with a dedicated check source prior to use. The viewing and intercom systems will be verified for proper operation. Treatment Control System or console function tests, including verification of the proper operation of indicator lamps and other status/operational displays, will be performed. A printer test will be performed if the procedure requires it; this test is optional in the paperless procedures. Source status indicators will be tested utilizing a dedicated check source. The mechanical integrity of the applicator(s) (including the placement of internal shields), source guide tubes, and connectors shall be determined by a visual and/or radiographic inspection before use. Treatment room door interlocks will be tested for proper operation.

Monthly Quality Assurance Checks

Monthly QA checks include (a) accuracy of the source activity using a calibrated well chamber, (b) timer accuracy and linearity, and (c) accuracy of sources positioning to within ±1 mm of the programmed position utilizing a radiograph. Records of this test will include the date of the test, the programmed position, the actual position, and the initials of the individual who performed the test. The authorized user will be notified if the test fails to meet the ±1-mm specification. Other checks include (d) measurement of the source transfer tubes to confirm that the total length is within ±1 mm of the specified length, and (e) backup battery test to verify the emergency source retraction upon power failure during each Preventive Maintenance Inspection.

Other Periodic Checks

Calibration of the remote afterloading device will be performed following installation of a new source prior to any patient treatment. This test can be performed more frequently, such as monthly, to be in accordance with the institutional procedures developed by the authorized physicist. A comparison with the manufacturers' stated activity, correcting for decay should be performed. The expected and actual measured values shall be within ±5.0%, according to the Nuclear Regulatory Commission. If the deviation exceeds ±5.0%, the results shall be reviewed by a board-certified physicist prior to any further patient treatments. Each institution can develop a policy with a tighter constraint on HDR source activity. Calibration will be performed by an authorized physicist using a well chamber and an electrometer calibrated by a laboratory accredited by the National Institute of Standards and Technology or AAPM within the previous 2 years and after any servicing that may have affected the dosimetry system. The system is specifically calibrated for several isotopes, including iridium. The calibration will

be countersigned by a second authorized physicist. To confirm source homogeneity, an autoradiograph of the source shall be performed after source installation and prior to resumption of patient treatments. Acceptance testing and computer dose calculation checks for each new treatment planning computer system will be performed by a qualified physicist.

Periodic Reviews

HDR brachytherapy patient charts will be reviewed by other radiation oncologists at least once per month. Annually, a sample of HDR administrations will be reviewed by the Radiation Safety Committee to monitor the effectiveness of the qualified medical physicist (QMP). The sample size will be at least 10% of HDR patients. The results of the review will be reported to the Radiation Safety Committee bi-monthly. In the event of a misadministration, the lot size will be increased by 10% for a year. If any of the QMP monitors are found to be deficient by the Radiation Safety Committee, the monitor deficiencies will be analyzed, and procedures to improve their performance will be initiated.

Inventory Control

The institutional Radiation Safety Office (RSO) tracks the incoming and outgoing of the iridium sources for the HDR program. Except for the purpose of a source exchange, only a limited number of sources should be kept in the department per the institution licenses. The possession of this iridium source will be checked by the RSO office at intervals of not more than 3 months. This physical inventory check will be conducted by the RSO (or a health physics representative) and the authorized physicist. The inventory records shall contain the model number of each source and the serial number, the activity of the iridium source, the location of the iridium source when not in use, the date of the inventory, and the signature of the individual performing the inventory.

Record Keeping

Patient records, including the written prescription, record of the administered dose, and treatment plan, will be stored in the department record room for a minimum of 3 years. Survey records of the device and the patient will be maintained for 3 years and will include the survey date, patient identification, and the initials of the individual performing the survey. Records of all survey meter calibrations will be maintained, and the calibration due dates will be checked daily. Those survey meters that are not calibrated within 1 year will be removed from the clinic and will be sent for calibration. All radioactive sources that are received for the afterloader will be entered in the brachytherapy source inventory and will be summarized quarterly. All inventory records will be kept for a period of 3 years. All QA records (calibration, periodic checks) will be kept in the department for a period of 3 years.

SUMMARY

Over the past two decades, multiple prospective and retrospective analyses have highlighted the clinical value of brachytherapy across multiple disease sites. High local control rates along with low toxicity rates have been reported for cervical cancer,[4,17] prostate cancer,[3,75] endometrial cancer,[2,40,41] and breast cancer[5,106] treated with contemporary HDR brachytherapy techniques. These excellent outcomes were obtained by well-trained brachytherapy practitioners who were devoted to maximizing clinical outcomes for their patients. Unfortunately, the utilization of brachytherapy has been declining due to its time-intensive nature with respect to current reimbursement levels,[160] along with advances in external beam technologies. As a result, graduating radiation oncology residents have reported a lack of confidence in practicing brachytherapy due to insufficient training volume.[161] Continuing education initiatives through workshops[162,163] and externships[164] are essential in ensuring that interested early-career radiation oncologists can gain the training, confidence, and mentorship to practice high-quality brachytherapy. Only through these efforts can the clinical value of HDR brachytherapy be sustained well into the future.

CHAPTER 25

Beyond the Beam: Radiopharmaceutical Therapy

Freddy E. Escorcia, Ravi B. Patel, Teresa Fisher, and Katherine A. Vallis

HISTORY AND OVERVIEW

Radiopharmaceutical therapy (RPT) is the delivery of radionuclides that can localize to and treat patients with cancer. While this approach dates to the 1940s, modern advances and positive prospective clinical trials have recently put this modality on the map and raised the interest of keen radiation oncologists.

In this chapter, we present a brief origin story of RPT, frame it in the context of other early radiation therapy approaches, and review radiation emissions and their biologic implications, including biomedical applications. In addition, we discuss tumor-targeting approaches using biomolecules and how these influence the pharmacokinetics and biodistribution of a given radiopharmaceutical agent. Pivotal trials of currently approved agents and their indications as well as late-stage clinical trials that readers may wish to follow are highlighted. As this field is experiencing a renaissance, we recommend readers to periodically reassess the RPT agent landscape to remain up to date. Importantly, because there are differences in medical training and which specialties administer and manage patients receiving RPTs, when relevant, our focus here is on implementation in the United States.

Birth of Radiation Medicine

Not long after Wilhelm Röntgen first described x-rays out of the University of Wurzburg in Germany in 1895, Henri Becquerel, Marie Curie, and Pierre Curie discovered similar emissions from uranium, radium, and polonium in 1896 and 1898. These groundbreaking discoveries earned Röntgen the inaugural Nobel Prize in Physics in 1901. Becquerel and the Curies earned the honor in 1903.

The properties of these radionuclides were almost immediately applied toward the treatment of cancers. In fact, as early as 1903, the idea of introducing radioactive elements in close proximity to tumors that are deep in the body—that is, brachytherapy—was suggested by an esteemed reader of *Nature*, Dr Alexander Graham Bell.[1] Others used x-rays to successfully treat cancers, including a young

girl with lymphoma treated in 1905 described in the 1923 textbook *La Radiothérapie Profonde*.[2] In the 1930s and 1940s, work by John Lawrence, brother to Ernest of cyclotron fame, used radioactive phosphorous to treat leukemias, first preclinically and then in patients, after learning that leukemic cells took up the radioisotope.[3] Contemporaneously, Saul Hertz and Sam Seidlin used radioiodine to treat hyperthyroidism and thyroid cancers, leveraging the recent discovery of iodine within the thyroid gland by Eugen Baumann.[4-6] RPT was born.

Because both therapeutic and diagnostic radiation evolved in parallel, it is, perhaps, unsurprising that the portmanteaux *theranostics* and *radiotheranostics* emerged consequently—some will often retain the "g" to yield *theragnostics*. Initially, the terms tended to specifically refer to the concept that a tumor-targeted ligand could be transformed from a molecular imaging agent to a therapeutic one by switching from a radionuclide with emissions conducive for imaging (eg, positron and γ emitters) to radioisotopes with therapeutic radiation emissions (eg, β, α, Auger). More recently, the terms could expanded to include the use of molecular imaging agents to be predict responses to other molecularly targeted therapies (eg, biologics, antibody-drug conjugates, chimeric antigen receptor T cells) in addition to RPT. Table 25.1 is an overview of RPT-related terms.

TABLE 25.1 DEFINITION OF TERMS

Term	Definition
Active targeting	Using a biomolecule specific to a tumor or tumor microenvironment target to guide delivery of a radionuclide
Biologic half-life	Biologic half-life ($t_{½b}$) of a radiopharmaceutical is the time taken for the concentration of the agent to be reduced by 50% of its maximum concentration in tissue, organ, or whole body, not considering radioactive decay.
Biomolecule	These are any of the numerous substances that are produced by cells and living organisms. The four major types of biomolecules are carbohydrates, lipids, nucleic acids, and proteins.
Chelate/chelator	A class of coordination or complex compounds consisting of a central metal atom attached to a large molecule, called a ligand, in a cyclic or ring structure
Effective half-life	The effective half-life ($t_{½e}$) is the half-life of a radiopharmaceutical in each tissue, organ, or whole body and is determined by a relationship including both the physical half-life and the biologic half-life. The effective half-life is important in calculation of the optimal dose of radiopharmaceutical to be administered and in monitoring the amount of radiation exposure. It can be calculated from the formula:

Term	Definition
	$t_{½e} = \frac{(t_{½b} \times t_{½p})}{(t_{½b} + t_{½p})}$
Ligand	Any molecule that binds to another molecule (eg, [^{177}Lu] Lu-DOTATATE is a ligand that binds to somatostatin receptors)
Molecular radiotherapy	See radiopharmaceutical therapy.
Passive targeting	Leveraging the natural accumulation of a radionuclide to a given organ system to achieve localization to tumors (eg, $^{223}RaCl_2$ localizing to areas of bone metastases, or ^{131}I localizing to thyroid cancers)
Peptide receptor radionuclide therapy (PRRT)	It is a form of targeted radiopharmaceutical therapy currently approved to treat neuroendocrine tumors ([^{177}Lu] Lu-DOTATATE). A radioactive chemical is linked to a peptide that targets cancer cells. When this radioactive peptide is injected into the body, it binds to a specific receptor found in neuroendocrine cancer cells.
Personalized dosimetry	This is a measurement of patient-specific biophysical parameters to individualize treatment to optimize the antitumor effect while minimizing toxicity.
Pharmacodynamics	Pharmacodynamics is the quantitative study of the relationship between drug exposure (concentrations or dose) and pharmacologic or toxicologic responses. It entails a drug's molecular, biochemical, and physiologic effects or actions.
Pharmacokinetics	Pharmacokinetics is the study of dynamic movements of foreign chemicals during their passage through the body. It illustrates the sequence of its absorption, bioavailability, distribution, metabolism, and excretion over time.
Physical half-life	The physical half-life of a radionuclide ($t_{½p}$) is the time in which the amount of radioactivity decreases to one half of its original value.
Radioconjugate	A biochemical or immunologic conjugate that includes a radionuclide
Radioimmunotherapy	Radioimmunotherapy entails combining a small amount of radioactive material (radionuclide) with a molecule engineered in a laboratory (monoclonal antibody). Monoclonal antibodies can recognize and bind to specific features of cells, such as antigens and cell receptors. (Note: Some investigators use this term to refer to radiotherapy combined with immunotherapy such as immune checkpoint inhibition.)
Radioligand therapy (RLT)	See radiopharmaceutical therapy.
Radionuclide	A radionuclide, or radioisotope, is an unstable element that releases radiation in the form of positron, electron or β particle, α particle,

Term	Definition
	Auger, or γ ray emissions.
Radiopharmaceuticals	Radiopharmaceuticals are unique medicinal formulations containing radioisotopes, which are used in major clinical areas for diagnosis and/or therapy.
Radiopharmaceutical Therapy (RPT)	Radiopharmaceutical therapy is defined as the targeted delivery of radionuclides to tumor cells or to the tumor microenvironment.
Radiotheranostics	See theranostics.
Theranostics	It is a portmanteau of therapeutics and diagnostics. Generally, it involves the use of a target-specific imaging agent to select patients for a corresponding radiopharmaceutical therapy agent specific to the same target (eg, ^{68}Ga-DOTATATE and [^{177}Lu] Lu-DOTATATE).
Tracer	A compound that is labeled by a radioactive or nonradioactive isotope to assist in the study of its transport or metabolism. Tracer dosing involves the administration of a very low mass of agent that can be detected (eg, ^{18}FDG PET imaging).

^{18}FDG, ^{18}F-conjugated fluorodeoxyglucose; PET, photon-emission tomography.
Adapted from Salerno KE, Roy S, Ribaudo C, et al. A primer on radiopharmaceutical therapy. *Int J Radiat Oncol Biol Phys*. 2023;115(1):48-59. With permission.

Types of Radiation and Radiobiologic Implications

The positron-emitting ^{18}F-conjugated fluorodeoxyglucose (^{18}FDG) and positron emission tomography (PET) imaging have been routinely used to diagnose, assess treatment response, and surveille patients with cancer for decades. Other routinely used imaging approaches include scintigraphy and single-photon emission computed tomography (SPECT), which use γ emissions from radionuclides for planar or three-dimensional imaging, respectively. It is critical to emphasize the tracer principle here, which underscores the orders of magnitude differences between the activities administered for imaging purposes (<0.37 GBq, <10 mCi) and those administered with therapeutic intent (>3.7 GBq, >100 mCi). These differences have obvious implications when it comes to radiation safety and the tension between administering activities that are "as low as reasonably achievable" and yet high enough to exert a clinically meaningful therapeutic effect.

As detailed elsewhere in this text, ionizing radiation kills cells through direct or indirect induction of DNA damage, including single- and DNA double-strand breaks (SSB, DSB). Because DNA DSBs are more challenging to repair, accumulation of such damage can become irreparable and result in cell death.[7]

The specific properties of different types of ionizing radiation emissions result in varying degrees of cellular and DNA damage (Figure 25.1). As with external beam radiotherapy (EBRT), RPT also exhibits dose rate and linear energy transfer (LET) considerations when it comes to the type and extent of damage caused. Canonically, lower LET emissions, such as β particles, are less energetic, less densely ionizing, and have a longer pathlength (0.1-10 mm), or range traveled. In contrast, high LET emissions have high energy, are more ionizing, and travel shorter distances. For example, α particles and Auger electrons have pathlength ranges of <100 and <1 μm, respectively. These properties inform how radionuclides are harnessed for therapeutic ends. It is generally accepted, for instance, that internalization of an Auger-emitting radiopharmaceutical agent is required to exert its cytotoxic effect because it needs to be near the nucleus to cause sufficient DNA damage.[8] That said, preclinical data suggest that plasma membrane irradiation can be cytotoxic, suggesting that damage to subcellular structures beyond the nucleus contributes to cell death.[9] We go into further detail in the next section.

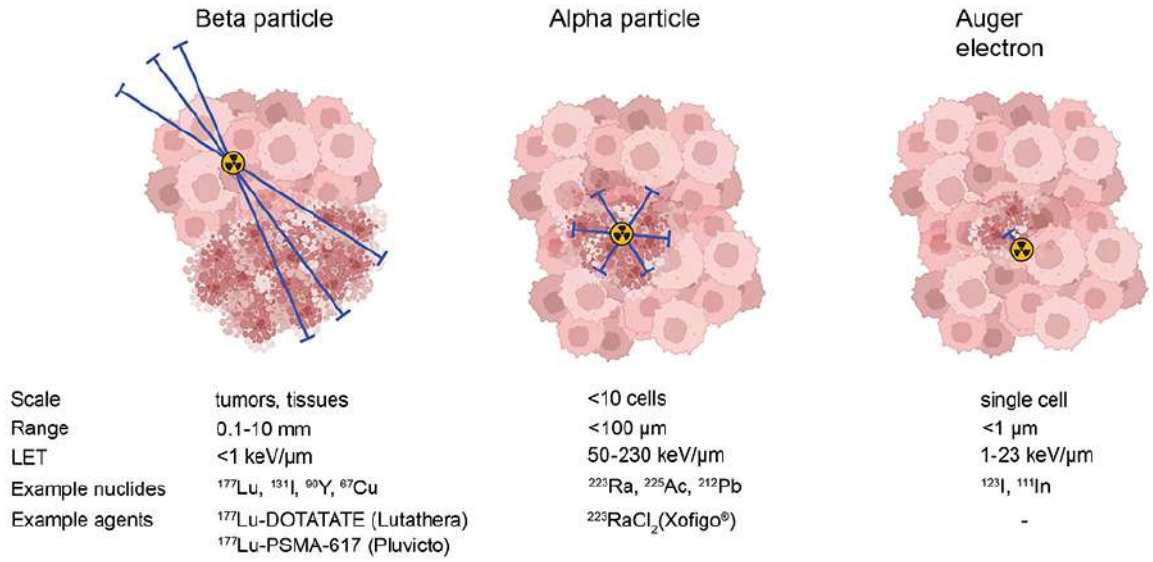

FIGURE 25.1 Types and properties of radiation emissions used for radiopharmaceutical therapy. LET, linear energy transfer. (Adapted from Salerno KE, Roy S, Ribaudo C, et al. A primer on radiopharmaceutical therapy. *Int J Radiat Oncol Biol Phys*. 2023;115[1]:48-59. With permission.)

Radiobiology

Dose Rate and Absorbed Dose Distribution Considerations

EBRT and RPT share the same primary anticancer mechanism: They cause deleterious ionization events in DNA either through direct interactions or through

the hydrolysis of water and production of reactive oxygen species, which cause "indirect" DNA damage. There are, however, important differences in the type, generation rate, and kinetics of repair of DNA lesions that result from exposure to the two modalities.[10] This is partly explained by their profoundly different dose rates. The absorbed dose rate for EBRT, typically about 1 Gy/min, is one to two orders of magnitude faster than that of RPT, which is about 0.01 Gy/min. While the dose rate of EBRT is constant during delivery, that of RPT diminishes exponentially over time. Furthermore, in the case of RPT, DNA repair responses are invoked even as further damage accumulates due to ongoing radioactive decay.

The spatial distribution of DNA lesions can influence the fate of the irradiated cell. α particles have high LET and cause clustered damage, defined as two or more modifications per helix turn, which is often repair resistant. In contrast, β particles maybe include protons as low LET, and most high-energy photon sources used for EBRT have low LET, causing more sparsely distributed lesions.[11]

The pattern of energy deposition in tissues is another important difference between EBRT and RPT, and this also contributes to their divergent radiobiologic effects. RPT is associated with heterogeneously distributed absorbed dose because, as for any systemically administered drug, local physiologic factors such as vascularity or interstitial pressure determine where drug accumulates within a tumor or tissue. Furthermore, the molecular target to which the RPT binds may be unevenly expressed throughout a tumor, being abundant in some cells, yet sparse in others, again leading to variation in the distribution of RPT agent, subsequent absorbed dose, DNA damage, and treatment outcome.[12,13] Another reason for uneven dose distribution is the isotropic nature of radionuclide decay, causing dose to fall rapidly with distance from the source, according to the inverse square law. In contrast, EBRT is unaffected by these variables and delivers a relatively uniform dose throughout a target volume.

The differences in the spatiotemporal pattern of DNA damage that RPT and EBRT cause trigger divergent effects on many cellular processes, including the intratumoral and systemic immune responses, cell cycle, signaling pathways, and mode of cell death.

Immune Effects

It is well established that EBRT can induce an antitumor immune response, and there is now strong evidence that RPT is also able to promote such a response. However, differences in dose rate, LET, and duration of exposure may affect the immune response in diverse ways. Importantly, the systemic nature of RPT may be advantageous as it has been shown that simultaneous treatment of all tumor

lesions enhances induction of an immune response[14] and that even low-dose RPT, when combined with an immune checkpoint inhibitor, can result in the eradication of tumors wherever they are located.[15] There are several explanations for this, including the expression of different tumor-associated antigens (TAAs) in individual lesions. Activated T cells will be directed against the specific TAAs released from an irradiated tumor, whereas, if they differ, TAAs from other sites will not be targeted. It is possible that the immunosuppressive effects of the tumor microenvironment may only be alleviated by radiation locally, and thus while activated antitumor T cells may enter the circulation, their effect may be limited in nonirradiated tumors. RPT results in lower total absorbed dose compared to EBRT, which likely influences the nature of the immune response, as there is accumulating evidence that high doses tend to be immunosuppressive whereas low-dose effects are immune modulatory.[16] RPT has been shown to be capable of inducing proimmunogenic changes such as immunogenic cell death[17] and the cyclic guanosine monophosphate-adenosine monophosphate synthase pathway (cGAMP), which canonically recognizes double-strand DNA as part of antiviral host immune response.[18] Currently, it is not clear how RPT impacts immunosuppressive factors such as macrophage polarization and myeloid-derived suppressor cell recruitment. A deeper understanding of the immunomodulatory effects of RPT will inform the selection of RPT-immunotherapy combinations going forward.

Low Dose-Rate Effects: Hypersensitivity, Cell Cycle, and Cell Death

Experimental investigation of the specific radiobiologic consequences of the low dose-rate (LDR) exposure associated with RPT is challenging, with current knowledge mainly extrapolated from studies in which continuous LDR EBRT was applied to biologic models.[19] An inverse dose-rate effect has been reported whereby, at dose rates in the RPT range (below 0.1 Gy/min), cells exhibit hypersensitivity to radiation, and this is hypothesized to be due to the existence of a dose threshold below which DNA repair processes remain uninduced.[20] This phenomenon appears to be cell line specific, with some investigators observing changes in cell cycle progression in response to LDR exposure with increases in survival, and accumulation of cells in G2 phase with delayed DNA synthesis.[20] Unrepaired DNA damage following exposure to radiation results in cell death of various types.[21] Recent work has highlighted differences in the mode of cell death caused by RPT compared to high dose-rate radiation. In particular, protracted LDR exposure may not cause immediate cell death, but instead triggers long-term growth arrest, or senescence.[22]

There is much to be learned regarding the radiobiology of RPT on tumors and the tumor microenvironment. As our understanding improves, investigators are keen on identifying RPT combinations with other treatments that can improve therapeutic outcomes for patients.

Passive Versus Active Targeting

As previously introduced, some radionuclides have an intrinsic tropism for certain tissues, which can be exploited to treat specific cancers. Because the thyroid gland requires iodine to synthesize thyroid hormones, it will also take up the β particle–emitting iodine-131. Accordingly, radioiodine has been used to treat papillary and follicular thyroid cancers, which exhibit iodine uptake as does their tissue of origin. Similarly, strontium-89, samarium-153, and radium-223 naturally localize to areas of bone turnover and are approved to treat cancers that have metastasized to bone. On the imaging side, technetium-99m methylene diphosphate (^{99m}Tc-MDP) and sodium fluoride-18 (Na^{18}F) also localize to bone metastases and are used for bone scintigraphy (a.k.a. bone scans) and PET of these lesions, respectively (Figure 25.2; Table 25.3).

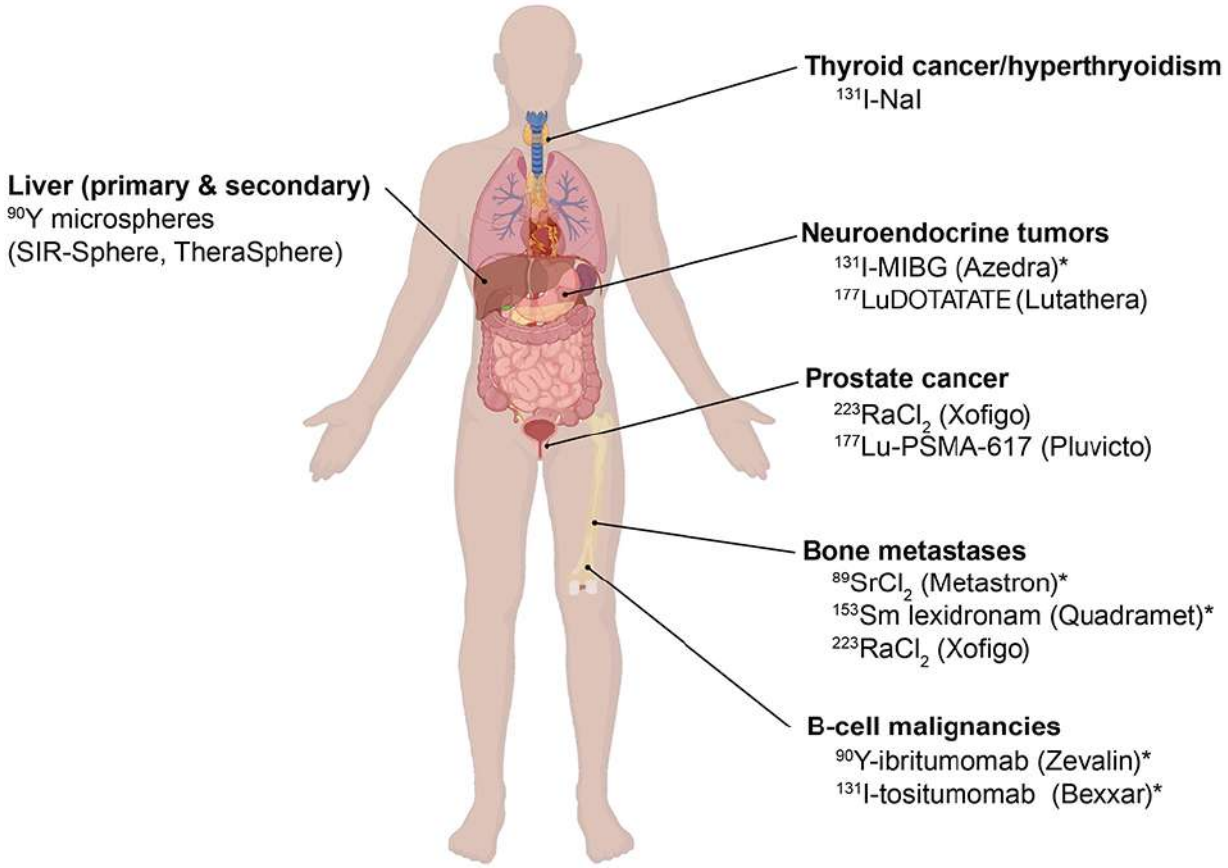

FIGURE 25.2 Food and Drug Administration–approved radiopharmaceutical therapy agents. *Agent no longer commercially available. (Created in part with Biorender.com. Adapted from Salerno KE, Roy S, Ribaudo C, et al. A primer on radiopharmaceutical therapy. *Int J Radiat Oncol Biol Phys*. 2023;115[1]:48-59. With permission.)

Leveraging the natural biodistribution of radionuclides, while successful, limits the spectrum of biomedical applications and the types of tumors clinicians could treat. Active targeting uses biomolecules (eg, peptides, antibodies) that can bind to tumor- or tumor microenvironment–specific targets to deliver radionuclides either by covalently attaching the desired radionuclide directly or by using a chelator, which can tightly bind to a radiometal (Figure 25.3).

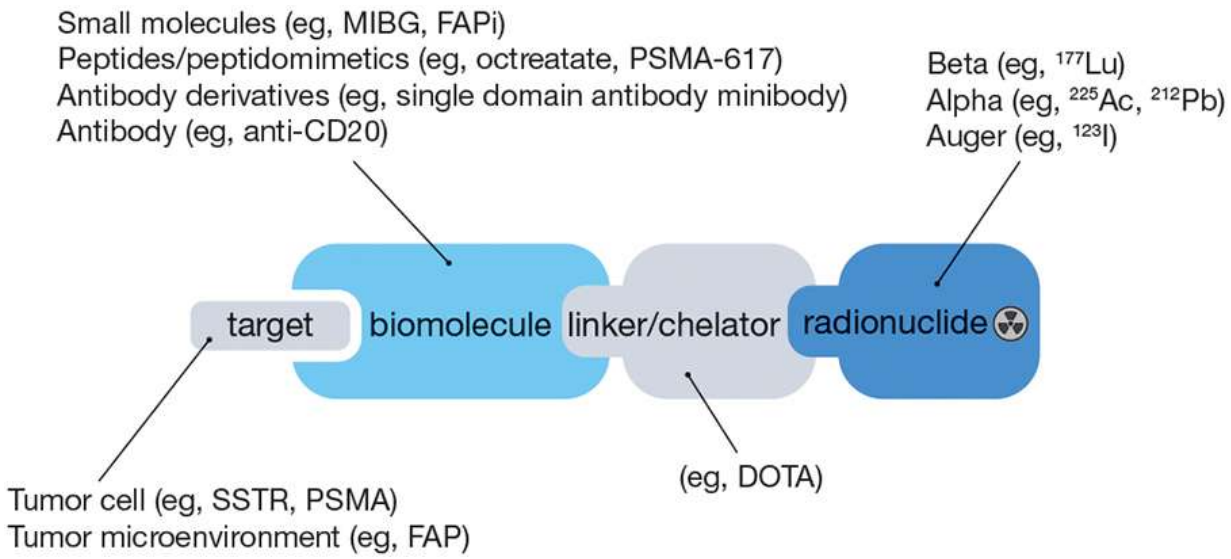

FIGURE 25.3 Generalized structure of a tumor or tumor microenvironment–selective radiopharmaceutical therapeutic agent. FAPi, fibroblast-activating protein inhibitor; PSMA, prostate-specific membrane antigen; SSTR, somatostatin receptor. (Adapted from Salerno KE, Roy S, Ribaudo C, et al. A primer on radiopharmaceutical therapy. *Int J Radiat Oncol Biol Phys*. 2023;115[1]:48-59. With permission.)

The choice of radionuclide depends on both the intended application, namely, imaging or therapy, and the *type* of imaging—that is, PET, SPECT, or the therapy desired, including with β or α particles, or Auger electrons.

Biomolecular Scaffolds and Pharmacokinetic Implications

The choice of molecular scaffold for use in RPT has been historically limited by ones already available to tumor- or tumor microenvironment–selective targets. Advances in phage and yeast display technology, however, have made de novo discovery or peptides or antibody fragments much easier and more economical. Paired with powerful in silico modeling of ligand-target binding, including artificial intelligence–based developments, these tools could allow for not only discovery but also optimization of these molecules with respect to binding affinity and pharmacokinetic performance.

Pharmacokinetics, or how the body interacts with a given drug, is a critical feature of any systemically administered agent, and radiopharmaceuticals are no exception. The molecular weight of the drug in question is directly proportional to the biologic half-life, that is, the lower the molecular weight, the faster the drug is typically cleared from the blood (Figure 25.4). The elimination route of the drug also depends on the molecular weight, where smaller molecules (<50 kDa) are

typically cleared by the kidney and larger molecules (>50 kDa) are cleared by the reticuloendothelial system (liver and spleen), or through the gastrointestinal tract.

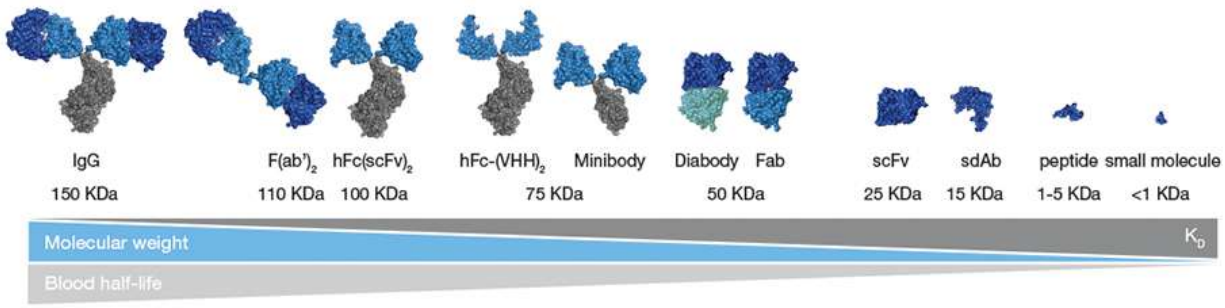

FIGURE 25.4 Incomplete list of biomolecules being explored as scaffolds for radiopharmaceutical imaging and therapy ranging from full-length antibody (immunoglobulin G or IgG), through antibody fragments, to peptides and small molecules.

Several scaffolds have been explored in the preceding decades and are too numerous to include here. Antibody-based scaffolds include full-length antibodies (150 kDa); engineered antibodies including minibodies (80 kDa) or diabodies (60 kDa); antibody fragments including F(ab) (50 kDa), $F(ab')_2$ (110 kDa), and single-chain variable fragments (25 kDa); and, more recently, single-domain antibodies (15 kDa). Typically, bivalent antibodies, that is, antibodies that contain two target-binding sites, allow for much better target-binding affinity due to avidity effects. Because of their high affinity and relative ease of production, antibody-based agents have been part of research and development since the advent of recombinant monoclonal antibody production.[23]

Additional molecules, including designed ankyrin repeat proteins, can similarly be selected for specificity to the desired antigens and have been tested in humans, and there are plans to explore this scaffold for radiopharmaceuticals in clinical trials.[24] Aptamers, single-stranded DNA or RNA molecules that can be selected for specificity against targets of interest, are also being explored, however, to date, have been limited to preclinical studies. Affibodies (6 kDa) are proprietary proteins that have been designed to have high specificity to HER2 as a radiotheranostic as well,[25] and a PET imaging agent has been shown to predict for early metabolic response in patients with breast cancer.[26] More recently, peptides and peptidomimetics, which comprise the most recent cohort of Food and Drug Administration (FDA)-approved RPT agents (Table 25.1; Figure 25.1), have sparked significant enthusiasm in RPTs and their applications in cancer.

Which biomolecular scaffolds are used for imaging, therapy, or both depends nearly entirely on their in vivo performance, that is, their ability to successfully

engage its putative target in preclinical and clinical settings, its broader biodistribution, or where the agents may differentially accumulate in the body, as well as the mode of clearance and the kinetics of that clearance. Charge, molecular weight, and shape influence the biodistribution and clearance of the agent in vivo. Low-molecular-weight proteins (<50 kDa) are generally excreted and sometimes resorbed in the proximal tubule of the kidney. Positively charged proteins tend to get preferentially resorbed. This property is exploited by using positively charged amino acids (eg, arginine and lysine) prior to, during, and following administration of the somatostatin receptor (SSTR)-targeted [^{177}Lu] Lu-DOTATATE used to mitigate nephrotoxicity when treating well-differentiated gastroenteropancreatic neuroendocrine tumors (GEP-NETs). For other agents, including the prostate-specific membrane antigen (PSMA)-targeting peptidomimetics (eg, [^{177}Lu]Lu-PSMA-617), the fact that endogenous PSMA expression is present in the kidney, as well as the lacrimal and salivary glands, can help clinicians predict and mitigate normal tissue toxicities.

These pharmacokinetic considerations are especially critical when choosing with which radionuclide to pair with a particular biomolecule. For RPT, the effective half-life of the radiopharmaceutical as determined by the biologic half-life of the carrier and the physical half-life of the radioisotope needs to be considered and is denoted as follows:

$$t_{½e} = \frac{(t_{½b} \times t_{½p})}{(t_{½b} + t_{½p})} \quad (1)$$

Here, $t_{½e}$, $t_{½b}$, and $t_{½p}$ represent effective, biologic, and physical half-live, respectively. Canonically, the biologic half-life of the biomolecule and the physical half-life of the radionuclide should be similar. Otherwise, if, for example, a peptide with a fast blood clearance and, therefore, a short biologic half-life, is coupled to a long-lived radionuclide, a significant proportion of the resulting radioconjugate will be excreted entirely intact in the urine, without much decay within the tumor. The converse is true of a short-lived radionuclide being coupled to a long-lived biomolecule, where most of the decay would likely occur in the blood before much of the biomolecule accumulates within the tumor. That said, there is evidence, however, that pairings of long-lived radionuclides (days) with short biologic half-life ligands (minutes to hours) can still result in favorable therapeutic effect clinically as is presented later.

CLINICALLY APPROVED RADIOPHARMACEUTICAL THERAPY AGENTS

We have covered some approved and experimental radiopharmaceutical agents in earlier sections of this chapter while describing the components and features of these drugs. For completeness, we include RPT agents that are FDA approved, including those that are not commercially available at the time of this writing (Table 25.1 and Figure 25.1).

Although the oral formulation of radioiodine (sodium iodide I-131, $Na^{131}I$) was approved by the FDA in 1971 to treat hyperthyroidism and thyroid carcinomas, it had been in use for these indications since the 1940s. For patients with intact thyroid carcinoma, therapeutic doses range from 3.70-5.55 GBq (100-150 mCi). For postoperative residual disease, the dose is typically 1.85 GBq (50 mCi).[27] Treatment planning can involve the use of diagnostic oral capsule formulation of radioiodine ($Na^{131}I$ or $Na^{123}I$), using trace activities ranging from 0.185 to 3.7 MBq (5-100 μCi) or 3.7 to 14.8 MBq (100-400 μCi), respectively, to confirm uptake of the radioiodine prior to administering the therapeutic doses.

Modern agents that leverage radionuclide tropism has focused on bone turnover, as happens in regions with metastatic disease. Samarium-153 (^{153}Sm) lexidronam (Quadramet)[28] and strontium-89 (^{89}Sr, Metastron)[29] were evaluated and subsequently approved to treat painful bone metastases, though, at the time of this writing, neither were being provided by their respective manufacturers. More recently, the phase 3 ALSYMPCA trial compared radium-223 dichloride ($^{223}RaCl_2$, Xofigo) versus placebo in patients with metastatic castration-resistant prostate cancer (mCRPC) with bone metastases and no known visceral metastases. The trial showed overall survival (OS) benefit (14.0 vs 11.2 months, hazard ratio [HR] 0.70, 95% confidence interval [CI] 0.55-0.88, $P = .002$) and longer time-to-first symptomatic skeletal event (eg, symptomatic fracture, EBRT for skeletal symptoms).[30] Importantly, when $^{223}RaCl_2$ was combined with abiraterone acetate and steroids in patients with mCRPC, it showed neither improved OS benefit nor improved time-to-first symptomatic skeletal event and was associated with increased fracture risk compared to placebo in the ERA 223 phase 3 clinical trial.[31] Theoretically, any of these bone-seeking radioisotopes should be able to deliver therapeutic radiation to metastases to the bone of other, non–prostate cancer histologies and may demonstrate benefit in patients with bone-only or bone-dominant disease. This question was tackled by a pooled analysis of two phase 2 randomized controlled trials (RCTs) of patients with metastatic breast cancer assessing the effectiveness of ^{223}Ra versus placebo in delaying symptomatic skeletal event-free survival and radiologic progression-free survival (rPFS) and

showed no differences in these primary end points.[32] While the original studies terminated early and the results do not support the use of ^{223}Ra in these patients, authors mentioned that the presence of visceral metastases, which $^{223}RaCl_2$ cannot treat, may have affected the outcomes. Without a reliable way to chelate ^{223}Ra and link it to tumor-targeted biomolecules to address soft tissue disease, therapy with ^{223}Ra will be limited. Preclinical efforts to this end have been reported, though have yet to yield a tumor-targeted ^{223}Ra-based conjugate to date.[33]

The first active targeted agents that were FDA approved leveraged the excitement surrounding recombinant antibody engineering and focused on the B-cell–specific marker CD20. The CD20-specific full-length antibody-based agents, ^{90}Y-ibritumomab tiuxetan (Zevalin), which used a chelating group that binds the β particle–emitting ^{90}Y, and ^{131}I-tositumomab (Bexxar), which used covalent radioiodination with the β particle–emitting ^{131}I, received FDA approvals in 2002 and 2003, respectively. Both agents had indications for patients with relapsed or refractory, low-grade, or follicular B-cell non-Hodgkin lymphoma, which express CD20. Notably, ^{131}I-tositumomab did include a "dosimetric dose" of 0.185 GBq (5 mCi), with 35 mg of antibody followed by γ camera counts and imaging at three separate time points postinjection (1 hour; day 2, 3, or 4; day 6 or 7). Data from these time points could then be used to calculate the therapeutic dose for each patient. Still, this attempt at personalized dosimetry was a logistical challenge in the context of other logistical challenges in a disease that had alternative approved therapies that more easily fit within existing clinical oncology workflows (eg, rituximab). At the time of this writing, neither agent is commercially available as their use has been largely supplanted by other systemic therapies.[34,35]

Following the commercial failure of these antibody-based agents, interest in RPT development waned. Although a few of the modern targeted agents appeared to demonstrate therapeutic benefit when given to patients based on bioplausibility, because these agents were not studied in RCTs, interest was limited to specialty centers in Europe. Notably, these modern RPT agents typically also have a diagnostic agent with which they are paired and often precede the development of the therapeutic partner.

The first phase 3 RCT that demonstrated improved clinical outcomes in patients with tumors harboring a tumor- selective target was the NETTER-1 trial. This was a phase 3 trial of patients with SSTR-positive GEP-NETs randomized to receive standard of care somatostatin (a.k.a. octreotide)-based therapy versus somatostatin combined with [^{177}Lu] Lu-DOTATATE delivered in 7.4 GBq (200 mCi) doses every 8 weeks for a total of four doses. Intravenous amino acid infusion is required prior to, during, and following [^{177}Lu] Lu-DOTATATE infusion. The

primary end point for NETTER-1 was PFS, and secondary end points were objective response rates (ORRs), overall survival (OS), safety, and side-effect profiles. The interim report published in 2017 showed superior 20-month PFS in the RPT arm (65.2%, 95% CI 50.0-76.8) over the control arm (10.8%, 95% CI 3.5-23.0). ORRs and OS were also significantly improved in the [^{177}Lu] Lu-DOTATATE arm.[36] These results led to FDA approval in 2018. Importantly, while the OS benefit seen in the interim analysis did not hold up in the final report (median OS of 48.0 months in the [^{177}Lu] Lu-DOTATATE group versus 36.3 months in the control group, HR 0.84, 95% CI 0.60-1.17, P = .30), both PFS and the quality of life of patients in the RPT group were superior to the control arm.[37,38] Authors posit that the loss of the OS signal may be due to 36% of patients in the control arm receiving postprotocol SSTR-targeted RPT at progression in the form of [^{177}Lu] Lu-DOTATATE, ^{177}Lu-DOTANOC, ^{90}Y-DOTANOC, ^{90}Y-DOTATOC (edotreotide), or ^{90}Y-DOTATATE. These similar agents, if tested prospectively for efficacy, may join [^{177}Lu] Lu-DOTATATE (Lu-177 oxodotreotide, Lutathera) for similar indications.

Pheochromocytomas and paragangliomas, types of NETs associated with hypertension due to increased catecholamine production, have also been the focus of targeted RPT. Iodine-131 iobenguane (^{131}I-MIBG, Azedra) is a small molecule similar in structure to the neurotransmitter norepinephrine and binds to the norepinephrine receptor overexpressed in pheochromocytomas and paragangliomas. This agent was FDA approved in 2018 following a multicenter phase 2 single-arm study, showing that patients who received at least 18.5 GBq (500 mCi) demonstrated durable reduction in antihypertensive medications compared to baseline and 92% of patients exhibited partial response or stable disease.[39,40] Like ^{131}I-tositumomab, ^{131}I-MIBG also used a dosimetry dose to tailor the administered activity for each patient. At the time of this writing, however, this agent is not commercially available and the manufacturer has discontinued its production.

The gene encoding PSMA, also known as folate hydrolase 1 and glutamate carboxypeptidase II, was first cloned in 1993. In the intervening years, first antibodies and later small molecules specific to the target were developed with both diagnostic and therapeutic intent.[41] Diagnostically, because prostate adenocarcinomas do not typically take up the standard PET tracer ^{18}FDG, FDG was not routinely used to help with staging, treatment response monitoring, and surveillance of patients with prostate cancer. Instead, computed tomography (CT) and bone scintigraphy, or bone scans, with ^{99m}Tc-MDP were the main imaging modalities for staging. With the recent testing and subsequent approvals of PSMA-selective PET imaging agents, including ^{68}Ga-PSMA-11 (Ga-68 gozetotide,

Locametz and Illuccix), ^{18}F-DCFPyL (piflufolastat F-18), and ^{18}F-rhPSMA-7.3 (flotufolastat F-18, Posluma), allowed for more precise patient selection for the PSMA-targeted β particle–emitting RPT [^{177}Lu]Lu-PSMA-617 (Lu-177 vipivotide tetraxetan, Pluvicto). These imaging agents are already being used to change treatment recommendations for patients, although improved outcomes for patients as a consequence of this change remain to be determined.[42]

The first prospective RCT of PSMA-targeted RPT was first reported in the TheraP phase 2 trial that enrolled patients with mCRPC who progressed after first-line taxane (docetaxel) and randomized patients to treatment with [^{177}Lu]Lu-PSMA-617 or cabazitaxel.[43] The trial required patients to be imaged with both FDG and PSMA PET (^{68}Ga-PSMA-11), having stringent imaging criteria requiring both PSMA-positive disease and no sites of metastatic disease with discordant FDG-positive and PSMA-negative findings. The primary end point was prostate-specific antigen (PSA) response defined by reduction of at least 50% from baseline. In the intention-to-treat analysis, authors showed 66% versus 37% PSA response in the experimental arm compared to cabazitaxel. In addition, there were fewer grade 3 or 4 adverse events in the experimental arm. OS was no different between patients treated with [^{177}Lu]Lu-PSMA-617 versus those treated with cabazitaxel.[44] These findings showed that RPT could be an effective alternative to chemotherapy with more favorable toxicity profiles in patients.

On the heels of TheraP, the phase 3 VISION study enrolled patients with mCRPC, who had progressed after first-line taxane and/or were not eligible to receive second-line taxane therapy, and randomized them to [^{177}Lu]Lu-PSMA-617 (7.4 GBq, 200 mCi every 6 weeks for four to six cycles) or to protocol- defined standard of care. Notably, the protocol-defined standard of care permitted hormonal treatments, bisphosphonates, radiation, denosumab, and glucocorticoids, but not cytotoxic chemotherapy, ^{223}Ra, immunotherapy, or other investigational drugs. This definition of standard of care raised criticism regarding the use of a substandard control arm. In response, authors have highlighted the idea that clinicians would be much more willing to offer [^{177}Lu]Lu-PSMA-617 to patients who might be too fragile for chemotherapy. Eligible patients underwent ^{68}Ga-PSMA-11 imaging and had one or more PSMA-positive lesions. Primary end points were imaging-based PFS and OS. With a median follow-up of 20.9 months, [^{177}Lu]Lu-PSMA-617 demonstrated prolonged imaging-based PFS (median 8.7 vs 3.4; HR 0.40, 99.2% CI 0.29-0.57, $P < .001$) and OS (median 15.3 vs 11.3 months; HR 0.62, 95% CI 0.52-0.74, $P < .001$).[45] Importantly, health-related quality of life and pain outcomes were superior in patients who received [^{177}Lu]Lu-PSMA-617.[46] Following the results of VISION, the FDA approved [^{177}Lu]Lu-PSMA-617 (lutetium Lu-177 vipivotide tetraxetan, Pluvicto) in 2022.

There are several trials looking to test [^{177}Lu] Lu-DOTATATE and [^{177}Lu]Lu-PSMA-617/[^{177}Lu]Lu-PSMA-I&T earlier in the course of disease, as well as in combination with surgery, external radiotherapy, immune checkpoint blockade, or DNA damage repair inhibitors. These are discussed in detail in Future Directions.

Before closing this section, we wanted to touch on transarterial radioembolization (TARE, a.k.a. radiation segmentectomy, and selective internal radiotherapy), which uses β particle–emitting yttrium-90 (^{90}Y) glass (TheraSphere) or resin (SIR-spheres) microspheres for transarterial therapy of primary and/or secondary liver cancers, respectively. These agents are distinct from the others discussed so far in that they exploit the fact that primary and secondary liver tumors are primarily perfused arterially, whereas non–tumor-bearing liver is perfused mostly by the portal circulation. Assuming that the lung shunt fraction is low, by use of ^{99m}Tc-labeled macroaggregated albumin as a surrogate for the biodistribution of the microspheres, the radioactive microspheres will preferentially accumulate in tumors.[47] While randomized controlled studies assessing the ability of this approach to improve OS were negative,[48-50] TARE can achieve excellent local control and can be used in multifocal hepatocellular carcinoma (HCC).[51]

In contrast to RPT, microspheres can remain localized within tumors, allowing for more reliable tumor-absorbed dose estimates, and recent prospective data suggest that dose escalation in this setting results in improved patient ORRs.[52] Recently, the American Association for the Study of Liver Diseases guidelines recommended TARE along with stereotactic body radiotherapy to treat patients with unresectable liver HCC tumors >3 cm.[53]

Managing Adverse Events of Radiopharmaceutical Therapy Agents

Toxicities for the approved agents are well described and correspond with the biodistribution of the associated agents. For example, [^{177}Lu]Lu-PSMA-617 has known renal, bone marrow, and salivary gland toxicity. Accordingly, threshold laboratory values for serum creatinine/estimated glomerular filtration rate, hemoglobin, white blood cell count, and platelets included in the relevant studies have been reported.[54] The European Association of Nuclear Medicine (EANM) and Society of Nuclear Medicine and Molecular Imaging (SNMMI) published their guidelines for the use of [^{177}Lu]Lu-PSMA radioligand therapy and expanded on the management of adverse events of this agent.[55] Hematologic toxicity (eg, anemia, leukopenia, thrombocytopenia), nephrotoxicity, xerostomia, nausea/vomiting, and fatigue are among the common acute adverse events expected in patients receiving [^{177}Lu]Lu-PSMA radioligand therapy.

Generally, for grade ≥2 toxicities, postponing the subsequent cycle or reduction of administered activity (eg, by 20%) to allow recovery is recommended. As with other cytotoxic systemic agents, growth factors (eg, granulocyte colony-stimulating factor) can be used to support treatment-induced neutropenia, and red blood cells or platelet transfusions can be used to address clinically meaningful anemia or thrombocytopenia.

To address xerostomia, which is anticipated for the approved [^{177}Lu]Lu-PSMA-617 as well as other investigational peptidomimetic PSMA-targeted agents (eg, [^{225}Ac]Ac-PSMA-617, [^{177}Lu]Lu-PSMA-I&T, [^{225}Ac]Ac-PSMA-I&T), recommendations range from proper hydration, use of humidifiers at home, to use of gum and lozenges, salivary substitutes, and pharmacotherapy with pilocarpine or cevimeline. Experimental approaches aiming at the prevention of xerostomia involve the use of cooling of glands prior to therapy, or administering a nonradioactive PSMA-targeting molecule to block uptake in salivary glands either systemically or directly into the ducts in preclinical studies.[56-58] Others have shown decreased uptake of [^{225}Ac]Ac-PSMA-617 by pretreating with intraglandular injection of botulinum toxin; however, this approach raises concerns regarding the effects of the toxin itself on the health of the gland.[59]

In addition to xerostomia, because there is a renal tubular expression of PSMA and [^{177}Lu]Lu-PSMA–targeted ligands are excreted renally, nephrotoxicity is of concern. Investigators have reported mean absorbed doses of 20 and 31 Gy for four to six cycles of [^{177}Lu]Lu-PSMA-617 or [^{177}Lu]Lu-PSMA-I&T and that, unsurprisingly, the number of cycles administered correlates with toxicity.[60-62] To date, 23 Gy, which is extrapolated from the external beam, has been used as an albeit imperfect limit for late renal toxicities following treatment with RPT. We have already touched on the need to administer amino acids as part of [^{177}Lu] Lu-DOTATATE therapy, which helps to mitigate renal failure to <2%.[63]

Other late toxicities can include myelodysplasia, leukemias, or chronic cytopenias; although, described for patients receiving [^{177}Lu] Lu-DOTATATE, these toxicities are reported to be in the range of 2% to 7% and skew higher if patients also receive alkylating agents.[63,64] Perhaps because patients receiving [^{177}Lu]Lu-PSMA targeted ligands tend to have a shorter survival time, these therapy-related myeloid neoplasms have not yet had the time to declare themselves in patients with prostate cancer who received this treatment. That said, given the growing interest in moving peptidomimetic PSMA-targeted RPT (eg., PSMA-617 and PSMA-I&T) to earlier lines of therapy, these late toxicities become a much more salient competing risk.

NUTS AND BOLTS OF A RADIOPHARMACEUTICAL THERAPY PROGRAM

Implementation

Following [^{177}Lu]Lu-PSMA-617 approval by the FDA, challenges in securing sufficient radioisotope and additional supply chain issues caused significant delays in having this agent, and [^{177}Lu] Lu-DOTATATE, available for eligible patients. These growing pains resulting in treatment interruptions for many patients, though, should resolve over time as more production facilities come online.

Among the first challenges in implementation is ensuring that standard operating procedures (SOPs) for the receipt of, handling, ensuring quality, and administration of the relevant RPTs are established. These SOPs will require close collaboration with the drug manufacturers, who can share wisdom gained from implementing programs globally. In addition, dose calibrators, shielded areas for dose handling, and dedicated spaces for patient administration are needed to perform quality assurance testing of RPT agents. While not all agents will require significant space and shielding, investments required to establish and maintain this infrastructure and trained personnel represent a rate-limiting step in the broader implementation of RPT. In the United States, other challenges with respect to billing and reimbursement are being addressed, but are still in flux.[65,66]

Multisociety white papers including the American College of Radiology, the American College of Nuclear Medicine, the American Radium Society, the American Society for Radiation Oncology, and SNMMI Practice Parameter are a good place to start when first learning about the agents and how to administer them in clinic.[67] International collaborations such as the white paper published by the EANM, SNMMI, and the International Atomic Energy Agency (IAEA) offer additional guidance in launching a theranostics center.[68] Because regulations differ depending on local regulations, close collaboration with radiation safety officers to ensure compliance is critical.

Early considerations when launching a theranostics clinical service are identifying which agents will be used and ensuring the facilities are able to adequately accommodate these agents with respect to shielded rooms, dedicated bathrooms, and ability to quickly address any acute medical issues. Long-lived contaminants that may be present based on the manufacturing methods used to make radionuclides need to be considered as well. For example, ^{177}Lu, when made via direct neutron irradiation of ^{176}Lu targets, ^{177m}Lu ($t_{1/2}$ = 161 d) is also generated and items need to be stored and allowed to decay to acceptable levels for disposal per local regulatory requirements.

Zoberi et al published a comprehensive report on getting a[^{177}Lu]Lu-PSMA-617 therapy program up and running, echoing many of the important considerations laid out by the EANM/SNMMI/IAEA guide.[69] The same group also published on their experience launching a [^{177}Lu] Lu-DOTATATE program.[70] While both agents use the same radionuclide, the workflow for administration differs. Specifically, unlike [^{177}Lu]Lu-PSMA radioligand therapy, [^{177}Lu] Lu-DOTATATE therapy requires infusion of amino acids prior to, during, and after RPT delivery lasting ~4 hours, which needs to be considered as part of clinical workflows. Both publications offer excellent step-by-step guidance for departments and institutions interested in incorporating RPT as part of comprehensive cancer care.

Workforce

Training and Certification

To ensure that approved RPT agents are available for the patients who need them, it is critical to have a workforce who understands how to use the approved RPT agents, their indications and contraindications, how to administer them safely and appropriately, and how to manage adverse events. A formalized curriculum would be helpful for standardization and competency. Nuclear medicine physicians and radiation oncologists are all eligible for Clinical Authorized User (AU) status and will lead the way shaping how this modality is used along with multidisciplinary teams. Nuclear medicine technologists, medical physicists, and nurses trained to work with radiopharmaceuticals will also be needed to round out the clinical care team.

Historically, the extent of training in RPT within radiation oncology residencies varies widely from program to program. The ASTRO RPT Workgroup proposed a framework to ensure that radiation oncology trainees have both the prerequisite didactics and hands-on exposure as part of a standard residency curriculum.[71]

Demonstrating sufficient knowledge and skills in radiation protection practices and procedures is necessary for qualifying individuals who want to be approved as an AU physician. The United States Nuclear Regulatory Commission (NRC) has established training and experience requirements they deem essential for the use of therapeutic radiopharmaceuticals in 10 CFR 35.390.[72] These requirements include completion of 700 hours of training and experience, including a minimum of 200 hours of classroom and laboratory training in basic radionuclide handling techniques applicable to the medical use of therapeutic radiopharmaceuticals (Table 25.2). The requirements in this section are understandably skewed toward physicians specializing in nuclear medicine.

TABLE 25.2 SUMMARY OF FDA-APPROVED RADIOPHARMACEUTICAL AGENTS

Agent	Disease	Type of Emission	Known Adverse Events	Contraindications
^{131}I (radioiodine)	Well-differentiated thyroid cancer Toxic adenoma Toxic multinodular goiter Nontoxic multinodular goiter	β	Early Xerostomia Nausea and vomiting Transient myelosuppression Radiation thyroiditis Nasolacrimal duct obstruction Transient thyrotoxicosis Late Second malignancy Pulmonary fibrosis Hypothyroidism Permanent myelosuppression	Lactation and pregnancy Moderate to severe Graves ophthalmopathy Severe thyrotoxicosis Thyroid cancer with no iodine uptake
^{153}Sm lexidronam (Quadramet)	Painful multifocal osteoblastic skeletal metastases from prostate, breast, and lung cancer, and osteosarcoma	β	Myelosuppression Nausea and vomiting Constipation Asthenia Fever Anorexia Spinal cord compression Pain flare UTI	Absolute Severe myelosuppression Severe renal dysfunction Relative Solitary or limited bone metastasis Osteolytic lesion Lesions with poor uptake on bone scan
$^{89}SrCl_2$ (Metastron)	Painful multifocal osteoblastic skeletal metastases from prostate, breast, and lung cancer mCRPC	β	Pain flare Myelosuppression Hot flush	Absolute None Relative Bone marrow infiltration Bone marrow dysfunction Pregnancy
$^{223}RaCl_2$ (Xofigo)	mCRPC with symptomatic ≥2 bone metastases and no visceral metastasis	α	Bone pain Anemia Spinal cord compression Myelosuppression Constipation Nausea and vomiting	Visceral metastasis Imminent or established spinal cord compression Malignant lymphadenopathy Concurrent use of abiraterone and

Agent	Disease	Type of Emission	Known Adverse Events	Contraindications
			Asthenia	$^{223}RaCl_2$
[^{177}Lu]Lu-PSMA-617 (Pluvicto)	mCRPC (pretreated with docetaxel)	β	Myelosuppression Fatigue Xerostomia Nausea and vomiting	Absolute None Relative Urinary tract obstruction
[^{90}Y]Y-ibritumomab (Zevalin)	CD20$^+$ antigen-expressing relapsed or refractory, low-grade, follicular, or transformed NHL, including patients with rituximab-refractory NHL	β	Myelosuppression Diarrhea Nausea and vomiting Asthenia Arthralgia URTI Colitis Sepsis UTI	Absolute Pregnancy Lactation Hypersensitivity to murine antibodies Myelosuppression >25% marrow involvement or treated with radiation therapy Prior autologous SCT Elevated HAMA titers with biodistribution
[^{131}I]I-tositumomab (Bexxar)[a]	CD20$^+$ antigen-expressing relapsed or refractory, low-grade, follicular, or transformed NHL, including patients with rituximab-refractory NHL	β	Myelosuppression Diarrhea Nausea and vomiting Asthenia Arthralgia URTI Colitis Sepsis UTI	Absolute Pregnancy Lactation Hypersensitivity to murine antibodies Myelosuppression >25% marrow involvement or treated with radiation therapy Prior autologous SCT Elevated HAMA titers with biodistribution Iodine allergy Creatinine >1.5 Relative Urinary incontinence
[^{131}I]I-MIBG (Azedra)[a]	Neuroblastoma[b] Unresectable, locally advanced, or metastatic	β	Myelosuppression Fatigue Increased INR Nausea and vomiting	Absolute None Relative Pregnancy Lactation

Agent	Disease	Type of Emission	Known Adverse Events	Contraindications
	pheochromocytoma and paraganglioma		Hypertension Dizziness Hypothyroidism Second malignancy Infertility	Renal failure
[^{177}Lu]Lu-DOTATATE	Advanced SSTR^{+} gastroenteropancreatic neuroendocrine tumors	β	Myelosuppression Nausea and vomiting Diarrhea Asthenia Anorexia Musculoskeletal pain Flushing Alopecia Myelodysplastic syndrome	None
^{90}Y-labeled glass microspheres (TheraSphere)	Solitary 1-8 cm of HCC and Child-Pugh class A cirrhosis Colorectal liver metastasis (progressed on first-line chemotherapy)	β	Myelosuppression Nausea and vomiting Fatigue Fever Gallbladder obstruction Hyperbilirubinemia Cerebrovascular accident	^{99m}Tc-MAA hepatic arterial perfusion scintigraphy showing any deposition to the gastrointestinal tract that may not be corrected by angiographic techniques Shunting of blood to the lungs that could result in delivery of greater than 16.5 mCi of Y-90 to the lungs Contraindications to hepatic artery catheterization Pulmonary insufficiency (Pa_{O_2} <60 and Sa_{O_2} <80) Severe liver dysfunction, hepatic encephalopathy, clinically evident ascites

Agent	Disease	Type of Emission	Known Adverse Events	Contraindications
				Tumor replacing >70% of liver Portal vein thrombosis with type 4 involvement Pregnancy
^{90}Y-labeled resin microspheres (SIR-spheres)	Unresectable secondary liver cancer from colorectal primary with adjuvant intrahepatic artery chemotherapy of floxuridine	β	Myelosuppression Diarrhea Fatigue Peripheral neuropathy Nausea and vomiting Radiation hepatitis Gastric/duodenal ulcer Hypoalbuminemia	Prior external beam radiation therapy to the liver Clinically evident ascites or are in clinical liver failure Markedly abnormal synthetic and excretory liver function tests >20% lung shunting of the hepatic artery blood flow determined by ^{99m}Tc-MAA scan Preassessment angiogram demonstrating abnormal vascular anatomy that would result in significant reflux of hepatic arterial blood to the stomach, pancreas, or bowel Disseminated extrahepatic malignant disease Prior treatment with capecitabine within the 2 previous months, or planned to be treated with capecitabine at any time following treatment with SIR-spheres

Agent	Disease	Type of Emission	Known Adverse Events	Contraindications
				Portal vein thrombosis

^{99m}Tc-MAA, technetium-99m macroaggregated human albumin; DLBCL, diffuse large B-cell lymphoma; EBRT, external beam radiation therapy; FDA, Food and Drug Administration; HAMA, human anti-mouse antibody; HCC, hepatocellular carcinoma; INR, international normalized ratio; mCRPC, metastatic castrate-resistant prostate cancer; NHL, non-Hodgkin lymphoma; PSA, prostate-specific antigen; SCT, stem cell transplant; URTI, upper respiratory tract infection; UTI, urinary tract infection.

[a]No longer commercially available.

[b]Not FDA approved for this indication.

The NRC has similar requirements for physicians specializing in radiation oncology. Requirements for the authorization of radiation oncology uses can be found in 10 CFR 35.490 for manual brachytherapy sources and 10 CFR 35.690 for remote afterloaders, teletherapy units, and γ stereotactic radiosurgery units.[73,74]

Most of the required didactic subject matter overlaps between nuclear medicine and radiation oncology, including radiation physics and instrumentation, radiation protection, and radiation biology. However, while nuclear medicine training includes information regarding the chemistry of byproduct material for medical use as a topic, radiation oncology typically does not.

The authorization requirements for the two specialties also diverge in the required areas of supervised work experience. Where the nuclear medicine resident must log experience in ordering, receiving, and unpacking radioactive materials, quality control for instruments used to assay doses, determining patient dosages, and spill response, a radiation oncology resident must instead log experience in reviewing calibration measurements and periodic spot-checks, treatment planning for sealed sources, implanting and removal of brachytherapy sources, and emergency procedures during abnormal operation of devices. Most, if not all the required training and experience, is accrued during a residency program. However, a resident in a radiation oncology program may only be able to accrue the training and experience specific to therapeutic radiopharmaceuticals during dedicated nuclear medicine rotations. That said, accruing enough work experience hours to meet the requirements in 10 CFR 35.390 may be onerous.

Until December 2023, the American Board of Radiology (ABR) offered an "AU-Eligible" designation on board certifications of candidates submitting training and experience documentation to the ABR.[75] Due to this change, it will

now be necessary for a physician seeking authorization for more typical radiation oncology uses (manual brachytherapy sources, teletherapy units, remote afterloader units, γ stereotactic radiosurgery units) to submit training and experience documentation to the NRC or the Institutional Radiation Safety Committee overseeing the radioactive materials license on which the physician intends to practice. In addition to this documentation, a written attestation from a preceptor or residency program director that the candidate has completed all requirements and is independently able to fulfill radiation safety-related duties will be required.

To add authorization for the use of therapeutic radiopharmaceuticals, additional training and experience documentation will be necessary. If a physician is already approved on a radioactive materials license under 10 CFR 35.490 and/or 10 CFR 35.690, the NRC regulations provide an option for expanding that authorization to therapeutic radiopharmaceutical uses. These requirements can be found in 10 CFR 35.394 (oral administration of $Na^{131}I$) and 10 CFR 35.396 (parenteral administrations).[76,77] By pursuing this pathway, the 200 hours of classroom and laboratory training required by 10 CFR 35.390 is reduced to 80 hours. Supervised work experience in specific areas is needed under these regulations, but there is no longer a required number of hours. A written attestation from a preceptor approved for RPTs is still required.

Ideally, residency program directors could work with the radiation safety officers and have senior residents to apply for authorization for radiation oncology uses on their home institution license as soon as they meet all requirements in 10 CFR 35.490 and/or 10 CFR 35.690. If this is not possible, the resident should ensure they have acquired any necessary written attestations and training and work experience documentation for their records so they are prepared to apply for authorization as soon as they are able. These records should include those associated with RPTs, such as participation in at least three cases of oral administrations of $Na^{131}I$ and three cases of parenteral administrations; additional training in materials ordering, receipt, and surveying; training in spill response; and a written attestation from a preceptor approved for RPT uses. Once the radiation oncology authorization is acquired, the pathway for approval to administer RPTs is available by meeting the requirements in 10 CFR 35.396. Time is of the essence when applying for authorizations. The NRC requires that the training and experience applied toward the authorization process be completed within 7 years preceding the date of application (10 CFR 35.59).[76] For a summary of these requirements, see Table 25.3. Readers are encouraged to speak with the radiation safety officers at their institutions who will be able to offer up-to-date guidance.

TABLE 25.3 SUMMARY OF US NUCLEAR REGULATORY COMMISSION REQUIREMENTS FOR RADIONUCLIDES

Classroom and Laboratory (200 h)	Work Experience (500 h)	Additional Requirements
Radiation physics and instrumentation	Ordering, receiving, and unpacking radioactive materials safely and performing the related radiation surveys	Involvement in a minimum of three cases in each of the following categories: • Oral administration of ≤1.22 GBq (33 mCi) of sodium iodide I-131 requiring a written directive • Oral administration of >1.22 GBq (33 mCi) of sodium iodide I-131 • Parenteral administration of any radioactive drug that contains a radionuclide that is primarily used for its electron emission, β characteristics, α radiation characteristics, or photon energy of less than 150 keV requiring a written directive
Radiation protection	Performing quality control procedures on instruments used to determine the activity of dosages, and performing checks for proper operation of survey meters	
Mathematics pertaining to the use and measurement of radioactivity	Calculating, measuring, and safely preparing patient or human research subject dosages	
Chemistry of byproduct material for medical use	Using administrative controls to prevent a medical event involving the use of unsealed byproduct material	
Radiation biology	Using procedures to contain spilled byproduct material safely and using proper decontamination procedures	Written attestation from a preceptor-authorized user or residency program director to the satisfactory completion of these requirements

Beyond the Basics

To launch an independent and sustainable RPT clinical program, our radiation oncology programs must recognize that we need to provide a more comprehensive educational experience for our trainees. While the ASTRO RPT Committee framework represents a step in the right direction, it is insufficient for radiation oncologists who wish to start their own independent program from scratch. Alternative training paradigms that include cross-pollination between nuclear medicine and radiation oncology residency programs could simultaneously offer more rigorous oncology training to nuclear medicine residents and more hands-on training in delivery of RPT and interpretation of PET and SPECT images for radiation oncology residents.

More formalized options for residents of both specialties could include an in-depth nuclear medicine rotation or even extend to dual board certification in

nuclear medicine and radiation oncology, a pathway that already exists in the ABR Diagnostic Radiology certification and has been explored by radiation oncology residency programs.

For interested radiation oncology faculty, well-established RPT programs are considering intensive courses along with certification programs for those who wish to obtain the needed training and credentials (eg, NRC requirements). Similarly, physicists and therapists with dual training in external radiation and RPT may be needed. Dosimetry calculations between external beam and RPT differ significantly, though, brachytherapy specialists may be able to extend upon their foundational knowledge.

At the program level, metrics to ensure best practices and quality assurance should be considered. The SNMMI launched Centers of Excellence designation, and ASTRO's Accreditation Program for Excellence could include RPT accreditation as well. Whether any, one, or both accreditations should be mandatory remains to be determined.

FUTURE DIRECTIONS

It is always a risky proposition to make predictions regarding a dynamic field. That said, there are some natural lines of inquiry to be pursued when it comes to RPT, which is touched on below. Where relevant, we touch on some open clinical trials; however, the list is not intended to be comprehensive.

Optimization of Existing Agents

Personalized Dosimetry

With the notable exception of ^{131}I-MIBG and ^{131}I-tositumomab, administration of RPTs does not currently consider patient tumor burden. Instead, RPT agents are administered as flat or weight-based activity per session akin to many systemic chemotherapy regimens, with dose adjustments based on observed toxicities. Accounting for tumor burden could significantly improve antitumor effect and mitigate toxicity. A patient with low burden of disease may quickly saturate targets with a standard flat dose of an RPT agent, resulting in high excess radioligand circulating in nontarget tissues, only contributing to toxicity and radiation safety concerns. Conversely, a patient with high burden of disease may require a higher administered activity to effectively saturate targets on tumors and might have been undertreated with use of the standard activity approach. In addition, such patients could benefit from receiving more than the number of treatments studied in the corresponding clinical trials. Tumor burden may also change over time. For instance, a patient with good response may have very little tumor burden and

hence uptake by the last treatment and may not require the same injected activity by the final treatment fraction as they did earlier in their course. Such dose-based optimizations may yield improved patient outcomes but need to be evaluated prospectively.

While radiation oncologists take it as a given that dose matters when it comes to both tumor control and organ-level toxicity, because there are limited prospective data demonstrating benefit of personalized dosimetry for RPT, it remains a point of debate. Bodei et al made the case for individualized dosimetry to tailor radiation-absorbed dose to maximize the efficacy of tumor treatment and minimize toxicity to organs at risk.[78] Strosberg et al, in contrast, recommended waiting for clinical trials to demonstrate a clinical benefit before fully endorsing the endeavor and associated time and costs.[79] Of course, one has to perform high-quality dosimetry studies with RPT agents as part of systematic investigations to definitively determine dose-response effects.[80]

A persistent logistical challenge for personalized dosimetry is that, ideally, SPECT images over several days are needed to accurately estimate the absorbed doses in patients. This approach adds more visits for patients and presents a challenge as to who should pay for these scans. Furthermore, typical SPECT scanners would subject patients to at least an hour of scanning for each time point, though, modern scanners can significantly decrease these times.[81] Appreciating these barriers, some investigators have successfully devised single time point–based dosimetry.[82,83]

A recent dosimetric analysis of the VISION trial estimated that the observed and predicted absorbed dose to the kidneys were comparable (15 ± 5 and 19 ± 7 Gy, respectively), both of which were below the historically established limit of 23 Gy based on external beam, suggesting that, at least with respect to renal toxicity, it is theoretically possible to administer more cumulative activity per patient.[62] Importantly, because PSMA is endogenously expressed in the lacrimal and salivary glands, PSMA-targeted RPT will specifically localize to these tissues. The observed absorbed dose to the lacrimal and salivary glands were significant, with a mean of 77 Gy (53-115 Gy) and 30 Gy (11-58 Gy), resulting in any grade dry eye and mouth of 3% and 39%, respectively.[45] These findings support the importance of organ-level dosimetry and assessing tissue-specific radiosensitivity differences with RPT agents.

The LUMEN phase 2 single-arm study used multimodality imaging in patients with GEP-NETs to predict outcomes with [^{177}Lu] Lu-DOTATATE therapy. Investigators used ^{68}Ga-DOTATATE and ^{18}F-FDG PET/CT imaging and SPECT/CT imaging at three time points for each of the four 7.4-GBq cycles. The

results showed that both the absorbed dose of ≥35 Gy in all targets and ≥10% tumor volume decrease following cycle 1 correlated with longer PFS.[84]

Methods for Radiopharmaceutical Therapy Dosimetry

While clinical use of RPT largely relies on weight- or toxicity-based activity, administration efforts for personalized dosimetry have been an area of significant interest. Personalized dosimetry methods for RPT have long been developed by researchers, yet they have not been routinely implemented in the clinical setting due to many barriers, including challenges in performing post-treatment imaging, having dedicated expertise and software tools for RPT dosimetry, and reimbursement-related issues. ASTRO, AAPM, and SNMMI have recognized the importance of patient-specific dosimetry for RPT and have been actively working on resolving these barriers. The SNMMI committee on medical internal radiation dose (MIRD) has released the MIRDfit and MIRDcalc software products for providing dosimetry calculation tools for the community and hosted a dosimetry challenge in 2021, with the goal of advancing personalized RPT dosimetry.[85,86] ASTRO has also been actively working on increasing the utilization of personalized RPT dosimetry, including by developing a working group to develop reimbursable RPT dosimetry codes and hosting a think tank to connect differing groups within the RPT space.[66] In addition, in 2023, AAPM hosted its summer school on Radiopharmaceutical Therapy and Dosimetry to improve training for personalized RPT dosimetry within the clinical medical physics community.

Various mathematical methods for personalized dosimetry have been developed, yet many, even current solutions, rely on the MIRD schema, which was developed in the 1960s.[87] The MIRD equation estimates the mean absorbed dose to a volume (or organ) depending on the time integral of activity; the mean energy of radiation type, which is dependent on the type of radionuclide; absorbed dose fraction; and mass of target volume. While the MIRD schema has been validated for RPT dosimetry applications, it does take several assumptions into account including static and homogeneous size, shape, position, composition, and density of each region (tumor/normal tissue organ) as well as assumptions regarding the residence time of various source regions within a region of interest.[88] To overcome these limitations, more recent RPT software packages have incorporated Monte Carlo, MIRD voxel S-values, or point kernel convolution methods and multi-time point post-treatment SPECT/CT imaging to generate a more accurate representation of changes in source activity position and tumor/organ position, composition, and density.[89,90] The general workflow of RPT dosimetry includes recording the time of administration, then performing post-treatment imaging with SPECT/CT,

preferably at multiple time points, contouring regions of interest such as normal tissues and areas of tumor, and then performing organ- or voxel-based, radionuclide-specific dosimetric calculations of the absorbed dose to these tissues (Figure 25.5). Several commercially available software packages are available for RPT dosimetry, and others are currently in development.[91] Understandably, the ease with which methods to calculate the absorbed doses to tumors and organs at risk can be incorporated into existing clinical workflows as well as whether the work will be reimbursed will influence adoption.

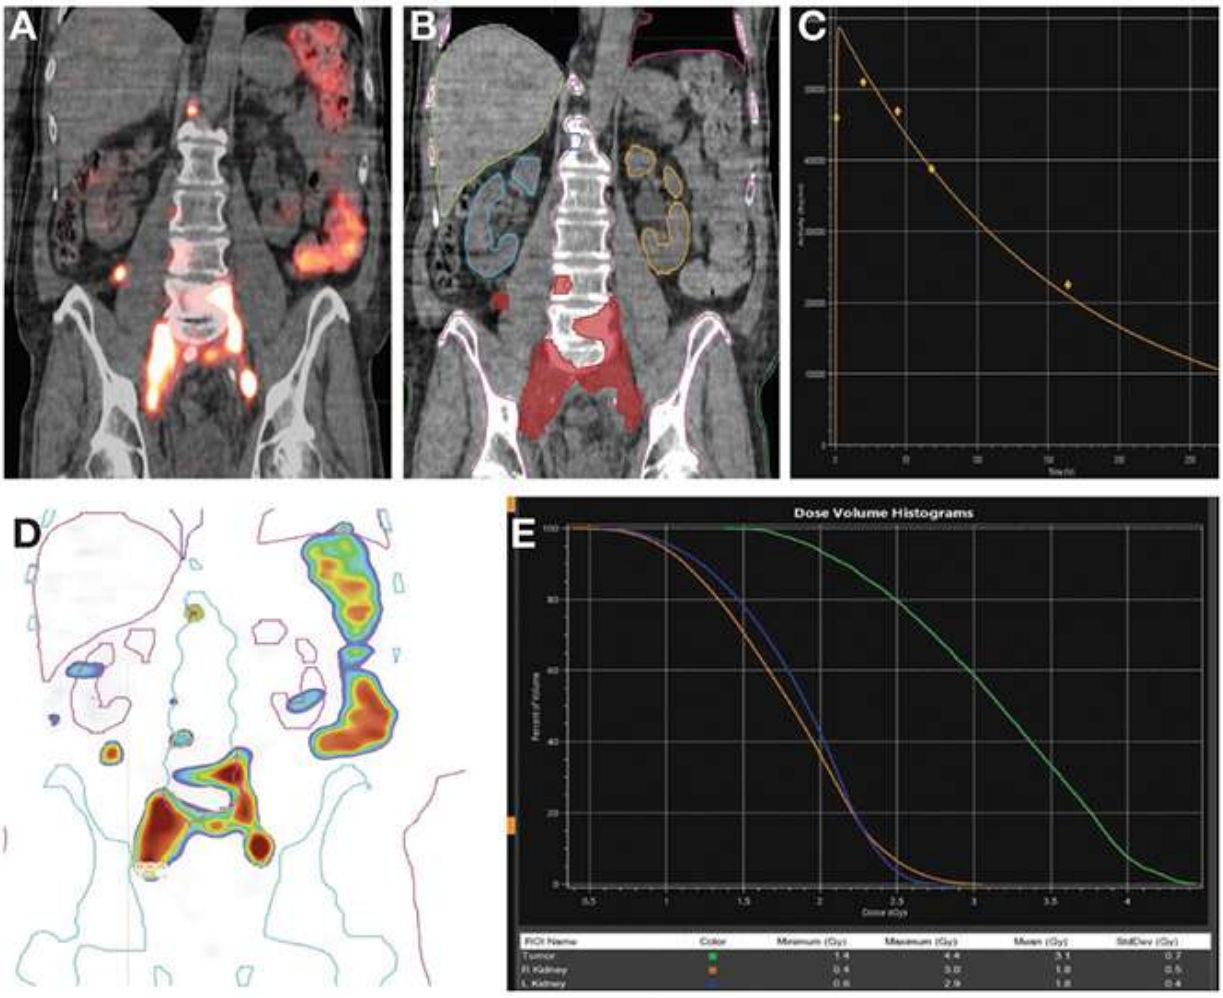

FIGURE 25.5 Workflow for radiopharmaceutical therapy (RPT) dosimetry. Post-treatment single-photon computed tomography/computed tomography imaging is obtained (preferably at multiple time points) (A), and normal and target tissue (red) contours are segmented (B). After imaging and segmentation, time activity curves of RPT agent in tumors and organs at risk are obtained (C), dose is calculated (MIRD Voxel S-Values, Monte Carlo, point kernel convolution); (D), and dose-volume histogram curve can be obtained for a three-dimensional dose plan (E).

While we can calculate the absorbed dose to tumor and normal tissues with currently available solutions, another significant barrier to implementation of RPT dosimetry is the lack of radiobiologic correlates.[92] Currently, most RPT dose constraints rely on values from conventionally fractionated EBRT; however, these are unlikely to be accurate for β particle–emitting radioisotopes with long half-lives (days) or high LET α particle–emitting radioisotopes. In addition, accounting for redistribution of daughter radionuclides (eg, Ac-225, Ra-223) adds more uncertainty in dose predictions. That said, biologically effective dose calculations to harmonize external beam and radiopharmaceutical absorbed dose response with respect to nephrotoxicity[93] and tumors[94] could allow more facile interpretation of how EBRT and RPT doses interface.

In summary, the current evidence supporting rigorous absorbed dose estimates for tumors and organs at risk, or personalized dosimetry, is sparse, though growing. Much work to streamline and standardize the process is needed, which can help inform the prospective clinical studies to provide the definitive answers on its utility. For a discussion on the debates surrounding the matter and a more in-depth dive on how to calculate the absorbed dose for RPT, we encourage readers to review Blaickner and Carter and Kesner, respectively.[80,95]

New Indications

Expansion of RPT use in additional clinical indications is under active investigation. Several ongoing studies are moving toward the use of RPT agents earlier in the course of disease. For example, LuTectomy (NCT04430192), a phase 1/2 trial assessing the effect of either one or two cycles (5 GBq each) of neoadjuvant [^{177}Lu]Lu-PSMA-617 prior to surgery for high-risk prostate cancer. Authors reported on the primary outcome of the absorbed dose and calculated a median tumor-absorbed dose of 35.5Gy,[96] and 19 of 20 patients having ≥10 Gy, which has been previously reported as associated with ≥50% reduction in PSA for trials in patients with more advanced disease.[97]

The PSMAddition (NCT04343885) phase 3 RCT is enrolling patients with metastatic hormone-sensitive prostate cancer and will compare standard of care (androgen deprivation therapy and androgen receptor pathway inhibitor [ARPi]) to standard of care plus [^{177}Lu]Lu-PSMA-617.[98]

PSMAfore, a phase 3 RCT trial of taxane-naïve patients with mCRPC randomized to [^{177}Lu]Lu-PSMA-617 (7.4 GBq every 6 weeks for six cycles) or switch of ARPi, reported results in abstract form after 15.9 months of follow-up. The results demonstrate promising radiographic PFS benefit of 12.0 months (95% CI 9.30-14.4) versus 5.59 months (95% CI 4.17-5.95) that was statistically

significant (HR 0.43, 95% CI 0.33-0.54, $P > .0001$).[99] Critics of the study argue that a taxane, and not ARPi switch, should be the appropriate control arm. Similarly, the SPLASH trial compares another PSMA-targeted agent ^{177}Lu-PNT2002 (ie, PSMA-I&T, 6.8 GBq every 8 weeks for four cycles) versus ARPi switch in patients with mCRPC. Like in PSMAfore, the primary end point in SPLASH was rPFS in favor of RPT 9.5 versus 6 months (HR 0.71, $P = .0088$). For both studies, the OS was not a primary end point, but did not differ when compared with control arms at the time of reports of either trial. Adverse events were comparable between the experimental and control arms for both. The ECLIPSE phase 3 trial (NCT05204927) is evaluating patients with mCRPC and randomizing them to either [^{177}Lu]Lu-PSMA-I&T (7.4 GBq for six cycles) or abiraterone or enzalutamide. Of note, this control arm has been called into question, given that patients have already developed mCRPC and could be eligible for taxane therapy.

Of particular interest to radiation oncologists, the PSMA-DC phase 3 RCT will randomize patients with oligometastatic prostate cancer to stereotactic radiotherapy followed by either [^{177}Lu]Lu-PSMA-617 (7.4 GBq every 6 weeks for four cycles) or placebo (NCT05939414). The primary end point is metastasis-free survival. RPT, in this setting, is thought to be able to target and treat micrometastatic disease below the limits of detection of clinical scanners.

[^{177}Lu] Lu-DOTATATE (7.4 GBq for four cycles) combined with long-acting octreotide is also being compared to long-acting octreotide alone as first-line therapy in a phase 3 clinical trial for patients with grade 2 and 3 well-differentiated GEP-NETs (NETTER-2, NCT03972488). Of note, NETTER-1 enrolled patients with grade 1 or 2 well-differentiated GEP-NETs. The primary end point is PFS, and this end point has been called into question for systemic agents.[100] Late toxicities, including nephrotoxicity[101] associated become of particular importance in this setting given a longer anticipated survival time of patients with earlier stage disease. Interim analysis was reported in January 2024, which demonstrated superior median PFS in the experimental arm (22.8 months, 95% CI 19.4—not estimable) versus the control arm (8.5 months, 95% CI 7.6-13.8) with a stratified HR of 0.276 (95% CI: 0.182-0.418, $P < .0001$).

LUTIA phase 2 study randomized patients to treatment of either the right or left hepatic lobes with intra-arterial [^{177}Lu] Lu-DOTATATE in patients with GEP-NET liver metastases in addition to systemically administered [^{177}Lu] Lu-DOTATATE. Investigators found no differences in tumor uptake of the RPT agent as measured by planar scintigraphy and/or SPECT between the experimental and control arms, concluding their data do not support the intra-arterial administration of this RPT agent.

As these agents are tested and approved for patients earlier in their disease course and who are more likely to survive for many years, late toxicities become much more relevant and need to be considered when choosing treatment options.

α Versus β

At the interface between existing RPT agents and novel ones, are agents that share the same targeting ligand, but are instead "armed" with α particle–emitting radionuclides such as [^{225}Ac]Ac or ^{212}Pb, in lieu of β-emitting ^{177}Lu. Given that the higher LET of α compared to β emissions, it is thought that tumors refractory to the β-emitting agents may still respond to the α-emitting agents.[102] PSMA and SSTR-targeting ligands are being actively investigated and have demonstrated promising activity thus far.[103-105]

In the multicenter retrospective WARMTH Act study, Sathekge et al evaluated [^{225}Ac]Ac-PSMA radioligand therapy— authors did not specify which ligand, PSMA-617 or PSMA-I&T, was used—in patients with mCRPC (n = 488). The study confirmed good antitumor effect in patients with prior treatments including with docetaxel (66%), [^{177}Lu]Lu-PSMA RLT (32%), or radium-223 (4%). Unsurprisingly, xerostomia was reported in 68% of patients after the first cycle, and all patients who had more than seven cycles eventually developed this side effect.[106]

The ACTION prospective phase 3 RCT is randomizing patients who progressed following ^{177}Lu-based SSTR-targeted RPT to [^{225}Ac]Ac-DOTATATE (RYZ101) versus best standard of care including everolimus, sunitinib, octreotide, or lanreotide (NCT05477576).[107] TATCIST is a single-arm phase 2 trial evaluating the efficacy of [^{225}Ac]Ac-PSMA-I&T in patients with mCRPC, allowing inclusion of patients with prior treatments with ^{177}Lu-based PSMA-targeted RPT (NCT05219500).

We note that, against conventional wisdom, the physical half-life of [^{225}Ac]Ac (~10 days) is much longer than the biologic half-life of the peptidomimetic PSMA-targeting or SSTR- targeted peptide ligands (minutes to hours). Still, these agents have demonstrated some activity in prior clinical studies including of patients who had disease refractory to ^{177}Lu-based RPT.[105,108] More canonical pairings using the theranostic pairs ^{203}Pb and ^{212}Pb for imaging and therapy, respectively, coupled to novel SSTR-targeting ligands for patients with NETs are also being investigated[104] (NCT05636618, NCT05153772).

Same Agents, Different Diseases

Approved agents could be tested for use in patients with other malignancies. As referenced earlier, ^{223}Ra was evaluated in patients with metastatic breast cancer; however, that trial did not demonstrate benefit.[32] Other RPT agents may be more promising. For example, while PSMA is overexpressed on prostate cancer cells, it is also expressed in the neovasculature of renal cell carcinoma[109] and HCC,[110,111] opening the potential utility of PSMA-targeting RPT for these indications. Similarly, SSTRs are also present in pituitary tumors[112] and meningiomas,[113] and therapeutic DOTATATE or DOTATOC (edotreotide) RPT agents may have utility in these diseases. ^{131}I-MIBG, which is used off-label for neuroblastoma, is being compared with a kinase inhibitor (lorlatinib) in pediatric patients with ganglioneuroblastoma and neuroblastomas undergoing intensive standard of care therapy as part of a phase 3 RCT (NCT03126916).

It should go without saying that before these agents can be routinely repurposed for other uses, prospective clinical studies should be performed. One could envision the pursuit of disease-agnostic indications based on the presence of the clinically relevant target as evinced by the diagnostic imaging agent serving as a noninvasive biomarker predictive of response to the therapeutic agent—radiotheranostics in action. Similar histology agnostic approvals exist for patients with tumors harboring mismatch repair deficiency, microsatellite instability high, and neurotrophin tropomyosin receptor kinase rearrangements, for example.[114]

Combination Therapy

Because monotherapy with RPT is not curative, rational combinations with EBRT (Ra-223 with SABR, RaVENS NCT04037358[115]; SABR with [^{177}Lu]Lu-PSMA for oligometastatic prostate cancer, NCT05079698), or systemic therapies ([^{177}Lu] Lu-DOTATATE with cabozantinib, NCT05249114) such as immunotherapy ([^{177}Lu]Lu-PSMA with ipilimumab/nivolumab NCT05150236; [^{177}Lu]Lu-PSMA with pembrolizumab NCT03805594[116]) or inhibitors of DNA damage repair pathways ([^{177}Lu]Lu-PSMA with olaparib, NCT03874884; [^{177}Lu] Lu-DOTATATE with olaparib, NCT04086485; [^{177}Lu] Lu-DOTATATE with DNA-PK inhibitor, NCT04750954) are active areas of exploration in clinical trials. Additional studies with rational combinations will surely emerge over time as we learn more about the interplay between the biology of these cancers and these therapeutic agents.

New Agents, Same Targets

A good place to preview what targets and agents are coming down the line as RPTs is to consider the novel molecular imaging agents that are being developed. For example, the peptidomimetic imaging agents, including the ^{18}F-rh-PSMA7.3

agent, which was FDA approved in 2023,[117] and its therapeutic counterpart ^{177}Lu-rhPSMA-10.1 is being evaluated in clinical trials (NCT05413850).[118] Chemistry-oriented readers will note that this ligand can chelate either a β-emitting ^{177}Lu or nonradioactive natural lutetium and that the fluorine can be either the positron-emitting ^{18}F or stable nonradioactive ^{19}F. Therefore, both the imaging, ^{nat}Lu/^{18}F-rhPSMA, and therapeutic, ^{177}Lu/ ^{19}F-rhPSMA, are elementally identical and would have the same biodistribution.[119] This contrasts with currently approved theranostic pairs and could facilitate prospective personalized dosimetry. Interestingly, while we have more or less treated all peptidomimetic PSMA-targeting ligands (ie, PSMA-617, PSMA-I&T, rhPSMA-10.1), each has distinct pharmacokinetics and biodistribution, which influence the subsequent absorbed dose to tumors and organs at risk. For example, a case report of a patient with mCRPC, whose disease progressed on [^{177}Lu]Lu-PSMA-I&T by PSA and PSMA PET, demonstrated a response to ^{177}Lu-rhPSMA-10.1.[120] While this does not make evidence, it is clear that there is more to be explored on how these differences in chemical composition affect therapeutic outcomes.[120]

Radioconjugates of the PSMA-specific human antibody J591 are being tested in prospective clinical trials. ^{177}Lu-J591 (TLX591, rosopatamab) is being tested in a phase 3 RCT as second-line therapy for patients with mCRPC who have progressed on modern hormone therapy and randomizes them to standard of care or standard of care plus the RPT agent (2.8 GBq for two cycles separated by 14 days) (NCT04876651). The results of the phase 1 dose-escalation study of [^{225}Ac]Ac-J591 in patients with mCRPC (NCT03276572), including some who received prior [^{177}Lu]Lu-PSMA-617 RPT, recently reported that the maximal tolerated dose was not reached, and the recommended phase 2 dose was the highest dose level of 93.3 KBq/kg[121] and fractionated dosing is being evaluated in another phase 1/2 study (NCT04506567). It is important to emphasize that these full-length antibodies exhibit dramatically different biodistributions when compared with the peptidomimetic RPT agents. Namely, antibodies have longer circulations times (days to weeks vs minutes to hours), are not renally cleared, and are not seen to bind to the PSMA expressed in the lacrimal and salivary glands. Notably, while grade 1 xerostomia is <2% in patients in trials of ^{177}Lu-J591, Tagawa reports 34% grade 1 and 3% grade 2 xerostomia in patients treated with [^{225}Ac]Ac-J591, suggesting a potency difference due to the LET differences between β and α particles.[121]

Leveraging the avidity effects of having two groups specific to a given target can be used to extend the potential utility and efficacy of existing targeting ligands. For example, the novel theranostic pairs, [^{64}Cu]Cu-SAR-bisPSMA and [^{67}Cu]Cu-SAR-bisPSMA, each of which contains two PSMA-binding ligands

along with a chelator cage aims to improve tumor binding and anticipated improvements in imaging and therapy, respectively, are being tested in clinical studies (NCT04868604). Somewhat related are investigators using heterodimers, or ligands that are specific to two targets. It is well known that tumors exhibit heterogeneity in expression of these therapeutic targets and investigators could couple two (or more) ligands specific to different tumor- or tumor microenvironment–selective targets as part of one molecule to increase tumor-binding ability.[122,123]

Novel variations of existing agents that have extended blood half-lives have been developed to alter the pharmacokinetics and biodistribution of agents targeting SSTR and PSMA. The rationale is that because the intrinsic blood half-life of peptide and peptidomimetic agents is short, a significant proportion of the activity administered will be excreted and not contribute to therapy. By coupling these molecules to albumin-binding domains, for example, the blood half-lives can be extended by days and potentially allow for more absorbed dose to tumors[124-126] (NCT03478358). On the other hand, however, this also allows for blood pool irradiation, which can cause hematopoietic toxicities seen in other longer lived agents, such as full-length antibody-based radioconjugates. Whether these agents supplant or become part of the therapeutic repertoire remains to be seen.

Emerging Targets and Applications

Long-standing research in radiopharmaceutical imaging and RPT has yielded many promising targets beyond PSMA and SSTR. To some extent, antibody-drug conjugates, other antibody-based cancer therapies (eg, bispecific antibodies, T-cell engagers), and cellular therapies share the same targets of interest for theranostics as well. Efforts to systematize novel target and biomolecule discovery for theranostics development are challenging but are worth the investment, especially in the context of decreasing costs for the pursuit.

There are many targets and targeting biomolecules being investigated at varying stages of development—too many to list here, there are two general categories of agents: ones that are selective to a target that is generally present on a few tumor types and others that are more broadly applicable by targeting either a molecule expressed on several tumor types or the tumor microenvironment.

Small molecules including those targeting fibroblast- activating protein (FAP) with FAP inhibitors, which can selectively bind to cancer-associated fibroblasts[127] as a pan-cancer agent, are also being investigated in clinical trials for both imaging and therapy. Other targets, including C-X-C motif chemokine receptor 4, which is expressed in several solid tumors and hematologic malignancies and being

targeted by the diagnostic agent ^{68}Ga-pentixafor[128] and therapeutic agents ^{177}Lu-pentixather[129] and ^{212}Pb-pentixather (NCT05557708), are actively being evaluated in early-phase clinical trials. Integrins, nectin-4, melanocortin 1 receptor (NCT05655312), B7-H3, carbonic anhydrase IX, fibroblast growth factor (NCT05363605), and gastrin-releasing peptide receptor are among the expanding number of targets actively being explored.[130-135]

Beyond the traditional applications for RPT, some groups have explored nontraditional uses. For example, the anti-CD45 antibody (^{131}I-apamistamab, Iomab-B, NCT02665065) has been creatively applied as part of the bone marrow conditioning regimen for hematopoietic stem cell transplant. Others have employed a topical β particle–emitting rhenium-188 for nonmelanoma skin cancers (NCT05135052).[136]

New Technologies

New technologies could complement RPTs in the clinic. For example, total body PET, which has much higher sensitivity when compared with conventional PET, could be used to better define the pharmacokinetics of a PET agent. This information could be used to prospectively calculate the administered activity needed to deliver a desired absorbed radiation dose from the RPT partner (eg, personalized dosimetry). Similarly, the latest generation of SPECT scanner is now able to achieve comparable imaging quality as PET in much shorter time frames, allowing for easier post-treatment absorbed dose estimates that may guide the subsequent cycle of administered activities.[81]

In addition, the novel combined PET/linear accelerator technology could theoretically use the 511-keV photons from the positron-electron annihilation event to guide therapeutic photon delivery.[137] Because many RPTs are first evaluated as imaging agents, this technology could expand the utility of such positron-emitting agents from diagnostic agents to beacons for EBRT delivery. Importantly, the workflow, including having user-friendly treatment planning software and speed with which treatments are completed, needs to be optimized for adoption beyond specialty centers. Automation of some of these processes could extend expertise more broadly.

FURTHER READING

Entire books could be and have been written to cover this rapidly evolving topic. This book chapter aimed to present the fundamentals and offer a framework upon which interested radiation oncologists can build. For additional depth, we encourage interested readers to consider *Radiopharmaceutical Therapy*, edited by

Bodei, Lewis, and Zeglis, as well as *Beyond Becquerel and Biology to Precision Radiomolecular Oncology* edited by Prasad.[138,139] Another useful resource is a contemporaneous issue in Seminars in Radiation Oncology on RPT that covers many of the topics presented in this text in additional detail.[140] Readers should be cautioned that, while the fundamentals will not change, any allusions to novel agents and future perspectives are but a snapshot in time and likely out of date as soon as published. Accordingly, to remain up to date, we encourage those interested to regularly visit www.clinicaltrials.gov to identify any new trials of both radiopharmaceutical imaging and RPT agents.

CONCLUSIONS

The renaissance of RPTs hinges on novel agents that have demonstrated improvements in survival and quality of life in patients eligible for treatment with this modality. Despite this success, there is significant room for optimization even in already FDA approved agents.

As investments in both academic and industry settings yield dividends in the form of new agents and new indications, we will require clinicians who understand the fundamentals of RPTs and how they are best used in the context of the broader cancer therapy spectrum. In the United States, radiation oncologists and nuclear medicine physicians both have the expertise needed to appropriately offer RPTs to patients. In fact, both specialties will need to be ready to ensure sufficient workforce to be able to meet the anticipated demand for RPTs, especially in patients with mCRPC, as clinically authorized users. Many radiation oncologists are early movers, and already serving patients in this way.[141,142] Multidisciplinary Theranostics Centers with participation from all clinical stakeholders could serve as a model for collaboration across disciplines.

Radiation oncology departments should continue to invest in basic and translational science in general and in RPTs specifically, to expand our understanding on how to best use this modality in the context of existing treatments. It is only through such investments that novel, previously unforeseen opportunities arise. Departments could help promote research from de novo design, synthesis, and testing, through mechanistic studies of unique radiobiology in preclinical studies, to clinical trials of next-generation molecular imaging for image-guided radiotherapy and RPT combinations with external beam and systemic therapies.

There are many exciting avenues yet to be explored and others yet to be defined. As we move forward, we should take the words of esteemed computer

scientist and Turing award winner, Alan Kay to heart: “The best way to predict the future is to create it.”

CHAPTER 26

Radiation Therapy and the Immune System

Ahsen Ahmed, Charles X. Wang, Michael Gough, and Arta M. Monjazeb

The immune system's primary function is to maintain tissue integrity by protecting against foreign pathogens and by removing damaged or malignant cells. As with most physiologic systems, the immune system functions on a principle of homeostasis. Inappropriate activation, magnitude, or duration of the immune response can lead to inflammatory and autoimmune conditions. Conversely, a feeble immune response can lead to infections and malignancy. The immune system must precisely recognize and eradicate harmful entities while maintaining self-tolerance. This requires a delicate balance between immune stimulatory and immune-suppressive mechanisms to protect normal tissues from both harmful foreign agents and the immune system itself. Due to the precision and power of the immune system, understanding the mechanisms governing inflammation and immune suppression, and learning how to manipulate the cells and molecules of the immune system for therapeutic benefit, remains a promising frontier of medicine in general and oncology in particular.

Radiation therapy (RT) has been a mainstay of cancer treatment for over a century. The primary mechanisms of cancer cell killing or growth arrest through irreparable DNA damage are well studied, but there is a growing understanding that RT also heavily relies on the immune system for anticancer effects.[1] The possible role of RT in stimulating the immune system and antitumor immunity has been long known and studied. There are case reports dating back to the 1950s detailing out-of-field treatment responses at distant metastatic sites after localized RT. This is known as the abscopal effect and is an immune-mediated phenomenon.[2-5] Studies demonstrate that the immune-modulating effects of RT are not a potential alternative mechanism of action only relevant in certain circumstances but are central and requisite for the antitumor effects of RT. Studies in immune

cell (T cells and dendritic cells [DCs]) depleted mice have repeatedly demonstrated that depletion of immune function significantly and almost completely diminishes the antitumor efficacy of RT.[6,7] Likewise, clinical data suggest that immune-compromised patients respond poorly to RT and have inferior outcomes.[8-10] Thus, not only can RT modulate immune function, but immune function is also essential for RT efficacy.

The advances in molecular techniques over the past few decades and subsequent studies have helped further elucidate the interplay between RT and the immune system and shed light on the underlying mechanisms. Due to the growing power of manipulating the immune system, understanding the immune-modulatory effects of RT and how best to use these effects for therapeutic benefit, either alone or in conjunction with other immune-modulating agents, has become one of the most dynamic fields of study in radiation oncology. Since clinical trials in this field are rapidly evolving, the goal of this text is not to provide a comprehensive overview of ongoing and completed clinical trials. The specific disease site chapters will review some of these data. Rather, the goal of this chapter is to provide a foundation for approaching this field of study, to highlight some of the critical understandings in the field, and to outline some of the key gaps in knowledge that limit progress.

IMMUNE FUNCTION

The function of the immune system is highly complex with numerous cell types (and subtypes) and molecules involved. The pace of discovery in the field is daunting with regular discovery of new cell subclasses or novel molecular pathways. A thorough introduction to immunology is beyond the scope of this textbook, and we refer the reader to other available texts on the topic. However, any discussion of RT and the immune system requires a basic foundation of immune function and tumor immunology for context. Thus, at the risk of oversimplification, we briefly highlight a few key concepts in this section and the next on tumor immunology, as a refresher for the nonimmunologist reader, that provides context for the rest of the chapter and can serve as a springboard into deeper study of immunology-specific texts.

In a nutshell, the immune system functions to sense damage or pathogens, signal the danger (and amplify that signal), take effect to neutralize the danger, and then resolve the immune response. The sensing and effector systems of the immune system are broadly categorized into innate and adaptive immunity. The effector systems of the immune system are also broadly categorized into humoral and cellular immunity. These systems are described in more detail below. It is important to keep in mind that the lines between these categories are quite blurred as cell types and molecules can actively participate in both and the systems are intimately dependent on one another. It is also important to keep in mind that the immune system is plastic and that a molecule or cell type may play different roles depending on tissue and context.

The immune system can be conceived as an offshoot of a wound repair system that serves to eliminate organisms that have penetrated the organism due to a barrier breach. If we were to design an immune system from the first principles, we would have to address how to provide fully functional immune readiness at all potential sites of entry. The ancestral immune system still found in horseshoe crabs employs amebocytes, which function to identify invading pathogens via innate receptors for molecular patterns (known as pathogen-associated molecular patterns or PAMPs) consistently and specifically expressed by bacteria (or other infectious agents), such as lipopolysaccharide (LPS). Amebocyte activation triggers a clotting cascade to repair the damage and releases innate antibacterial peptides to control the infection.[11] In this example, the entire immune response is localized to the infection site with integrated sensing and response pathways.

Though more complex, our immune system is built upon these evolutionarily conserved sensing and response pathways. We inherit this immune sensing system, which is broadly unchanging through our lifetime; thus, it is described as innate immunity. In addition, over the past 500 million years, we have evolved an additional immune system that changes in response to our unique history of infections[12] and is, therefore, described as adaptive immunity. The principle adaptive immune cells are known as B and T cells based on tissue of origin (bone marrow and thymus, respectively). These are the dominant focus of immunology research due to the ability of B cells to produce antibodies (Abs) that can bind almost any molecular shape, or the ability of T cells to directly recognize the infected

or mutated cells. An adaptive immune response against a specific virus can result in viral antigen–specific B cells and T cells that remain throughout life.[13] A similar response to tumor antigens is a goal for cancer immunity.

The development and selection of B and T cells is fundamental to immunology but is beyond the scope of this chapter. However, it is critical to understand a series of facts. The first fact is that these cells are highly diverse in target recognition. The B-cell receptor is theoretically unique on each new B cell, can be refined through immune responses, and may result in up to 10^{18} potential structures.[14] T cells have a similarly diverse potential structure in their T-cell receptor (TCR), with children producing more than 10^9 unique T cells each day.[15] The diversity of TCR declines with age, in part as a result of decreased output of new T cells, but of the approximately 10^{12} to 10^{13} T cells in a human, there may be as high as 10^8 to 10^9 unique TCR in a young adult.[16] The targets of B-cell receptor and TCR are called antigens and represent a molecular shape directly recognized by either the Ab surface of the B-cell receptor or the TCR when a fragment is bound to the surface of a major histocompatibility complex (MHC) molecule. The second fact is that these B or T cells have the potential to recognize our own cells, but any "autoreactive" cells are (almost entirely) eliminated during the development process by negative selection. This results in a B- and T-cell repertoire that theoretically recognizes nothing in the individual. On infection, new molecular shapes, which are different that self, are introduced by the infectious agent and some B and T cells are able to recognize them, as they were not part of the negative selection. This is the essence of self versus nonself recognition that forms the basis for adaptive immunity. Importantly, mutation of our genes can create novel molecular shapes that have the potential to be recognized by our own immune cells as nonself, permitting anticancer immunity. The final critical fact in adaptive immunity is expansion and memory. Again, the details of this process are beyond the scope of the review, but newly emerged B and T cells are known as naïve cells and have a finite lifespan. Following antigen recognition, these cells rapidly expand, and while most of these cells differentiate into an effector population specialized to control the acute phase of the infection, a portion of the cells differentiate into memory cells that can last for the lifetime of the individual.[13] These clonally expanded memory cells

represent the adaptive immunity that develops in response to each person's unique infectious history.

B cells, once activated and expanded, can secrete Ab for the duration of the animal's lifespan,[13] and the Ab can permeate the body. T cells, in contrast, must come into physical proximity to a cell-presenting antigen (nonself molecular shape) on their cell surface MHC molecule to control infections. For this reason, T cells are very dynamic in their movement, and they enter and exit secondary lymphoid organs and pass into and out of tissues as they scan for their targets.[17,18] Innate sensors serve not only to activate innate immunity but also as a recruitment tool to mobilize T-cell responses to a location of infection. For any new infection, the innate response will occur first and provide the first line of defense. It also triggers adaptive immunity and guides adaptive immune cells back to the infection site to provide a second layer of response. These phases are highly integrated and not yet fully understood. However, the field has identified critical trigger points for productive immunity that can be manipulated to artificially guide immune responses against infectious agents and, recently, cancer.

The core pathways of innate immunity are structured to detect viral and bacterial infection. The best studied innate sensors are the Toll-like receptors (TLRs),[19] a family of molecules that activate inflammatory mechanisms following recognition of their specific ligands (which are generally molecular patterns ubiquitously and specifically expressed by infectious agents, but not by self during normal circumstances known as PAMPs). These ligands include LPS from bacterial cell walls that signals through TLR4 and unmethylated CpG dinucleotides from nonmammalian cells that signal through TLR9 (reviewed in Yin et al[20] and Iwasaki and Medzhitov[21]). In general, TLRs are on the cell surface membrane or located on intracellular cell membranes (endoplasmic reticulum, etc) and share a common cytoplasmic signaling domain, thought to oligomerize and recruit adaptor proteins, which include critical signaling molecules such as MyD88, TRIF, and TRAM.[22] In addition, there are cytoplasmic sensors of infection, such as RIG-I and cGAS, that signal through MAVS and STING, respectively, which like MyD88, TRIF, and TRAM link nucleic acid sensing to innate signaling pathways. MAVS links the cytoplasmic sensors of viral RNA (RIG-I, MDA5, and LGP2) to downstream signaling.[23-25]

STING links signals from the cytoplasmic DNA sensor, cGAS, to downstream signaling[26] following viral or bacterial infection.[27,28] STING can also be directly activated by cyclic dinucleotides produced by bacteria.[29] In each case, following sensing and activation of the adaptor protein, downstream signaling results in inflammation focused around interferon (IFN) gene transcription (reviewed in Honda et al[30]). Finally, there is a complex system of pattern recognition receptors centered around the inflammasome. Inflammasome activation is often part of a two-step activation process where innate sensing through TLRs initially causes upregulation of nod-like receptors (NLRs) as well as transcription of interleukin (IL)-1b and IL-18 in their pro-form. The second step causes inflammasome sensors to recruit apoptosis-associated speck-like protein containing a CARD that serves as an adapter protein for the oligomerization of the inflammasome complex.[31] A series of homotypic interactions and autocatalytic activations result in activation of caspase 1.[31] Caspase 1 is then able to process IL-1b and IL-18 to their mature forms, resulting in potent inflammation. The inflammasome is particularly sensitive to molecular patterns that are absent from our cells but present following infection, which includes not only specific bacterial toxins,[32] but also more general features of abnormal behavior such as lysosomal disruption, protein aggregates, or crystals (reviewed in Broz and Dixit[33]).

Many of the mechanisms that the innate immune system employs to identify infection can also recognize abnormal responses in our own cells in the absence of infection. These innate sensing mechanisms can not only discriminate PAMPs but can also respond to damage-associated molecular patterns (DAMPs), which result from abnormal processes in our own cells. For example, while LPS is uniquely a PAMP, the same TLR4 signaling pathway can be activated by high mobility group box 1 (HMGB1), which can be released from dying cells.[34,35] Dying cells can similarly provide DAMPs via heat shock proteins,[36-38] such as calreticulin,[39] and lysis can activate innate sensors via uric acid.[40,41] Innate signaling is critical to immunity; for this reason, when we discuss anticancer immunity and the impact of radiation, we show how DAMPs play a critical role in immune mechanisms following radiation.[42,43]

Large, complex organisms, such as ourselves, may simultaneously have multiple ongoing immune responses at different sites. However, we would

not necessarily want to mobilize the entire immune system to respond to one location since most immune cells would not be specific for this particular pathogen. Instead, our immune system employs selective sensors, which provide an initial indication of the type of immune response required, to mobilize suitable cells. For example, intracellular sensors for nucleic acids that might detect a viral infection, such as TLR3, RIG-I–like receptors, and cGAS/STING, can generate a different pattern of cytokine responses as compared with extracellular sensors for bacterial components, such as TLR2 and TLR4.[21,44] The various sensors are not uniformly shared across cell types, so specific immune cells can specialize in detecting specific infections[21] or types of damage.[43] In this way, the immune response is prewarned of the nature of the infection, and the appropriate adaptive response is activated and recruited.

The DC is the essential link between innate sensing of infection and adaptive T-cell responses. DCs are able to move antigen from peripheral sites to lymph nodes,[45] which is one of the few locations where naïve T cells can meet antigen. DCs are the highest expressors of TLR3,[46] which is focused on sensing the kind of intracellular infectious agents that demand T cells for effective immune control.[47,48] In addition, DCs are uniquely able to cross present antigens phagocytosed from other cells or extracellular locations on their MHC class I[49] (as opposed to the canonical pathway where these antigens would be presented on MHC class II). These features ensure that DCs have all of the required tools to sense infection, carry antigen to T cells, and present that antigen to initiate T-cell immune responses. As we have recently reviewed, these features of DCs are also critical for immune responses to RT.[50] Also critical is the array of co-stimulatory molecules expressed by DCs to support T-cell activation. While the TCR on T cells recognizes the specific MHC-peptide combinations being presented by the DC, this signal alone is insufficient for T-cell activation. Effective signal transduction in the T cell is supported by co-stimulation (signal 2) through CD80 and CD86 on DCs engaging CD28 on T cells. Naïve cells are particularly dependent on co-stimulation for initial activation, as compared to reactivation of memory cells.[51] Adhesion molecules regulate a strong interaction with the DC for a strong and prolonged TCR signal that can result in T-cell activation and proliferation,[52] and an array of additional co-stimulatory as well as co-inhibitory receptors

that are regulated on T cells and DCs in response to initial activation regulate the scale of the T-cell response to its target antigen.[53-58] It is here that most of the current immunotherapy (IT) targets are found, regulating the interactions between T cells and antigen-presenting cells (APCs) or similarly regulating the interactions between T cells and their targets. These include autocrine or paracrine cytokines such as IL-2 that support TCR signals for effective T-cell proliferation.[59]

While T-cell effector functions are discussed more in relation to cancer IT, one additional feature of the transition to adaptive immunity is critical to understanding the immunobiology of cancer. The initial innate sensing of infection results in secretion of a range of cytokines that accompany DCs to the lymph node and remain present in the infectious site. The specific cytokines present during T-cell activation (signal 3) can guide their differentiation, such that a T cell specific for a single antigen could become a cell that secretes IFN-γ on activation, or instead one that secretes IL-4 on activation.[60] In infectious diseases, T cells that produce these cytokines represent important patterns of response to intracellular infections, such as viruses versus parasites. There are a range of other differentiation patterns that T cells can undergo, and the resulting cell types are particularly notable for CD4 T cells. Each differentiation choice can be guided by cytokines,[60,61] and one critical pattern is the differentiation of CD4 T cells into suppressive regulatory T cells (Tregs). T-regulatory cells are defined by differentiation in the presence of transforming growth factor β (TGF-β)[62] and can suppress adaptive immune responses by other T cells with special relevance in cancer and radiation. Thus, the innate response to infection guides T-cell differentiation via cytokines, which has direct implications for cancer. This multilayered integration of innate and adaptive immunity is critical to our ability to generate a diversity of immune responses, and as we discuss, the dysregulation of these responses plays an important role in the success and failure of antitumor immunity.

IMMUNO-ONCOLOGY

The tumor is a dynamic, continuously evolving environment encompassing the cancer cells and normal cells and consists of a diverse array of resident and infiltrating cells. These include immune cells, fibroblasts, stroma, and

vasculature, with all their accompanying secreted factors and signaling pathways. Some portion of this environment is entirely populated by normal cells—the tumor stroma—and cells in the tumor stroma may not directly interact with cancer cells. In the immediate vicinity of the cancer cells is the tumor microenvironment (TME), which may have a distinct set of cells and molecules due to the dominant impact of the cancer. The TME has a decisive role in tumor growth and progression.[63] Immune cells within the TME can include innate cells such as APCs and other myeloid-derived cells, as well as lymphocytes and others. The interactions between the host immune system and malignancy, which occur within the TME but can have systemic ramifications, are the basis of immuno-oncology.

Immune Recognition of Tumors

As with most immune responses, the antitumor immune response begins with innate immunity. Conditions within the TME, such as hypoxia and nutrient exhaustion, can give rise to unique metabolic features that can lead to cellular stress and extensive death of cancer cells and other cells in the midst of a growing tumor.[64-67] These processes cause intracellular release, extracellular release, or cell surface expression of a range of stress ligands, cytokines, chemokines, and DAMPs that are associated with the TME and less prevalent in normal tissues. As outlined above, these can not only initiate an immune response but also impact the infiltration and activation of immune cells in the TME. The generated innate immune response can have direct antitumor effects and also trigger an adaptive immune response against tumors.

Regarding recognition by the adaptive immune system, cancer cells straddle the line between “self” and “nonself.” Cancer cells are derived from host cells and are, therefore, considered “self.” Yet, by definition, cancer cells have developed DNA mutations that can give rise to mutated proteins, which are not found in normal cells. These altered proteins can be recognized as foreign by adaptive immune cells since they were not present during the negative selection process that eliminates autoreactive immune cells. In addition, alternative splicing, translation, and post-translational modifications in cancer cells also produce novel antigens not found in normal healthy cells. Tumor cells express these novel antigens, termed

neoantigens, which arise from tumor-specific alterations and mutations and permit the immune system to distinguish cancer cells from normal "self" cells.[68,69] The immune system can form an antitumor response against these neoantigens, also known as tumor-specific antigens (TSAs). The immune system can also recognize aberrantly expressed self-proteins, known as tumor-associated antigens (TAAs), which are self-proteins but inappropriately expressed in terms of time, tissue, or quantity (eg, carcinoembryonic antigen or CEA, expressed during embryogenesis, but not in normal adult tissues).[70] The immune response generated against epitopes from these tumor antigens can potentially eliminate cancers and precancerous cells. In fact, it is possible that mutated cells with malignant potential arise often but are eliminated by the immune system, in a process termed *immune surveillance*.[71] Only those mutated cells that evolve a mechanism to escape immune surveillance or that arise in a niche where immune surveillance is suppressed can progress to clinically relevant malignancies.

As outlined above, the main principle of T-cell–mediated adaptive immunity is the recognition of peptide antigens presented on cell surface MHC molecules by TCRs. To generate T-cell immunity against tumors, the epitopes from tumor antigens must first be presented to T cells in a manner that can prime them (ie, in the context of MHC on APCs, which can provide co-stimulatory signals). This generally occurs as there is some extent of necrosis in the TME and APCs infiltrate the TME and phagocytose the debris from dying cancer cells. The APCs can then migrate to the draining lymph nodes. Phagocytosed antigens from the debris are digested, and the peptides are presented on the cell surface in the context of MHC. The APCs involved are most often mononuclear phagocytes, such as macrophages and DCs. DCs play a critical role in this biology since they are the most effective APC for T-cell priming. In addition, some DC subsets have the capacity for cross-presentation, which allows them to present exogenous extracellular peptides on MHC class I rather than only on MHC class II, which is the canonical pathway for phagocytosed antigens. Thus, both CD4+ and CD8+ T cells can be primed against tumor antigens in the draining lymph nodes. These cells then clonally expand and migrate into tissues carrying out effector functions, including direct killing of tumor cells. Tumor killing is triggered by activated CD8+ cytotoxic TCR

recognition of tumor antigen presented on MHC class I on the surface of cancer cells.

Mechanisms of Escaping Immune Surveillance

As outlined the section "Immune Recognition of Tumors," an active antitumor immune response culminates in the infiltration of the TME with effector cells, primarily cytotoxic T-lymphocytes (CTLs), which target the tumor. In a hypothesis termed *immune surveillance*, this process may eradicate many malignancies early in their development before they are clinically detectable, akin to how our immune system eradicates innumerable infectious pathogens that we are exposed to on a daily basis before they have the opportunity to cause illness. This hypothesis is supported by the increased rates of malignancy in immune-compromised patients.[72-74] Once a malignancy has become clinically detectable, it is rarely eradicated by the immune system alone, primarily because it must have evolved mechanisms to escape immune surveillance to get to this stage. The immune system has tightly regulated suppressive mechanisms to limit overactivation and resolve inflammation since uncontrolled immune activity can be highly pathogenic. Malignant tumors often hijack and exploit these natural homeostatic pathways to attain immune evasion through mutations, cellular changes, and alterations in the TME and local tissue architecture.[75,76] These mechanisms can prevent the initiation or TME access of the antitumor immune response yielding immunologically "cold" tumors characterized by a lack of TME T cells. Other mechanisms can disrupt the immune response within the TME yielding tumors that are "hot" or "T-cell inflamed." Understanding these broad categories is important because it may dictate the best application of RT and IT to bolster antitumor immunity. A complete discussion of mechanisms of immune surveillance escape is beyond the scope of this chapter; however, a basic understanding is required as many current IT approaches seek to address these mechanisms. A cursory outline of some mechanisms is presented below.

Decreased Tumor Immunogenicity

Immune surveillance eradicates tumor clones expressing strongly immunogenic neoantigens. Thus, the tumor evolves under selective pressure

from the immune system, and clones, which express fewer or less immunogenic antigens, survive. In addition, cancer cells often have deficiencies in antigen processing and presentation machinery, such as downregulation of class I MHC molecules, enabling them to evade recognition by T cells.[77]

Exclusion of Immune Cells

Immune cells, particularly T cells, can be excluded from the TME via immune based or mechanical means yielding cold tumors. Tumor cells and stroma can downregulate CXCR3 ligands, which CTLs require for migration into the TME.[78] Factors such as vascular endothelial growth factor (VEGF) can alter tumor endothelial cells to limit the expression of adhesion molecules necessary for T-cell extravasation and migration. Finally, suppressive immune cells and fibroblasts in the TME can produce a desmoplastic reaction and dense extracellular matrix (ECM) acting as a physical barrier to T-cell infiltration.

Upregulation of Immune-Suppressive Cells and Molecules

The TME recruits/induces immune-suppressive cells that can limit the efficacy of an antitumor immune response. Many suppressive immune cell types can be found within the TME, but myeloid-derived suppressor cells (MDSCs), M2-polarized macrophages, and Tregs are the best described. MDSCs can generate immunosuppressive factors, including arginase, inducible nitric oxide synthase (iNOS), and TGF-β. M2-polarized macrophages produce IL-10 and other suppressive cytokines and factors. Tregs can not only produce immune-suppressive cytokines (IL-10, IL-35, TGF-β) but can also be directly cytotoxic to other immune cells including CTLs. Within the TME, many cells also express immune-suppressive cell surface molecules including co-inhibitory ligands for TCRs (or checkpoints). For example, MDSCs and cancer cells can express programmed death-ligand 1 (PD-L1), which binds programmed cell death protein 1 (PD-1) on T cells, and Tregs can express cytotoxic T-lymphocyte associated protein 4 (CTLA-4), which binds CD28 on T cells. T cells also express other checkpoint molecules including Tim-3, TIGIT, and LAG-3 whose ligands can be expressed by tumor cells or immune cells in the TME.

Overall, signaling via these co-inhibitory receptors leads to decreased functionality and exhaustion of T cells.

Poor Priming of T-Cell Responses

The various immune-suppressive cytokines and cells listed above can limit the maturation of DCs and decrease the expression of co-stimulatory molecules by APCs from the TME, thereby limiting their ability to prime T-cell responses.

Metabolic Immune Suppression

Rapid growth of tumors, dense ECM, and altered metabolism of cancer cells can lead to a TME that is hypoxic and acidic. Furthermore, the TME is also starved of essential nutrients, which T cells require for activation and functionality. There is direct competition with cancer cells for nutrients. Furthermore, immune-suppressive enzymes such as arginase, mentioned above, and indolamine-2,3-dioxygenase (IDO), described by Munn and Mellor,[79] can be expressed by immune cells and cancer cells in the TME. These enzymes can catabolize essential nutrients (arginine and tryptophan) required for immune cell activity and produce catabolites, which are immune suppressive. Overall, the TME can be very hostile to T cells and other immune cells, limiting their ability to carry out effector functions.

Modern Immunotherapy Approaches

Immuno-oncology aims to direct, expand, and engineer immune responses against tumors capable of eradicating local and systemic disease. As outlined above, understanding the normal function of the immune system and the mechanisms that limit effective immune responses during malignancy are critical to designing therapies that can initiate a new or reinvigorate an existing antitumor immune response. For this discussion of IT, we focus on the most salient ITs that have reached clinical approval rather than the wide array of ITs in preclinical development or failed in the clinic. Later, in discussion of RT, we discuss more preclinical work and clinical pipelines to consider the near future of cancer IT in the context of radiation.

Cellular Therapies

As discussed above, most antigens presented by cancer cells are the normal self-antigens that are not generally recognized by T cells. Yet cancer cells have DNA mutations, some of which generate mutated proteins that are not found in normal cells and were not part of the selection process that generated the T-cell repertoire. These are referred to as neoantigens and are an important target for patient-specific immunity.[68,69] Most mutations are random and, therefore, unique to each patient, requiring that T cells targeting such mutations to be generated for each individual.[80] However, there are specific mutations in key genes that drive malignant transformation that may be shared between individuals. An example would be activating mutations in Kras that are widely shared. These "driver" mutations are particularly attractive in that they are central to the malignant program of these cells and cannot be readily silenced to acquire resistance to therapy. Tumor-specific T-cell therapies have been developed to target these mutations but require that patients share both the correct mutation and the correct MHC allele to present the mutated peptide.[81,82]

A range of other potential antigens can also be recognized by T cells.[70,83-85] These include self-antigens that have not been effectively eliminated from the T-cell repertoire and generated by alternative modes of translation and post-translational modifications in cancer cells, for example, CEA or MAGE.[86] The immune response generated against epitopes from these tumor antigens can potentially eliminate cancers and precancerous cells in a similar manner to neoantigens, but with some risk of on-target effects in other tissues that may also express that protein. In general, there are likely to be similar mechanisms by which T cells are directed against neoantigens and TAAs and similar mechanisms of resistance.

An alternative to approaches that require preknowledge of tumor antigens is the isolation and ex vivo expansion of tumor-infiltrating T cells (tumor-infiltrating lymphocytes [TILs]) for adoptive transfer back into the patient as pioneered by Rosenberg at the National Cancer Institute. Logically, the tumor represents the richest source of tumor-specific T cells, and multiple decades of research have refined the procedure for expanding T cells from tumors, enriching for tumor specificity, and reinfusion into patients.[80] One of the most important developments has been the procedure to support these

cells in vivo after infusion back into the patient. Following ex vivo stimulation, the T-cell product is dominated by effector T cells, which have good effector capacity but limited long-term survival capacity. Using a combination of pretransfusion lymphopenia and support with IL-2, T cells can alter into memory phenotypes during homeostatic expansion,[87,88] resulting in both long-term persistence and increased effector function. Like vaccines (as discussed in the next section), the development of improved genomic profiling has allowed investigators to guide the expansion of patient's T cells using patient-specific, tumor-specific neoantigens.[89,90] These include shared neoantigens such as mutated Kras.[82] Importantly, investigators have started to clone the TCRs that recognize these mutated neoantigens,[80] and there is the potential to build a library of TCRs to cover each MHC haplotype to expand such responses to all patients. These developments have permitted TCR gene therapy, with adoptive transfer of T cells genetically engineered to express TCR specific for shared antigens in patients with an appropriate combination of antigen and MHC.[81,91] This is an active area of development in a well- established but not widely applied IT. One important point in adoptive T-cell therapy is that while this changes the proportion of tumor-specific T cells in the patient, these cells are subject to the same resistance mechanisms that were faced by the original T cells. The hope is that ex vivo expansion and infusion of an overwhelming number of T cells can overcome resistance sufficiently to control tumors, but immune evasion still remains a problem. For example, where the neoantigen is nonessential, cancer clones that delete or repress the mutated gene have a selective advantage. Where the gene is essential, as with Kras, cancer cell clones with MHC loss have emerged following adoptive therapy.[82] In addition, the suppressive features of the tumor and TME may still suppress adoptively transferred T cells. For example, expression of PD-L1 can limit the efficacy of adoptively transferred T cells, and there is the opportunity to combine adoptive transfer with deletion of PD-1 in the T cells.[92] We discuss approaches targeting the TME more below.

An alternative to adoptive transfer of TILs and TCR therapy is T cells engineered to express chimeric antigen receptors (CARs). In this approach, Abs provide the recognition component and the recognition domain is linked to an engineered receptor incorporating features of the TCR and co-receptor signaling domains.[93] The limitation of CAR-T approaches is that

there needs to be a unique structure on the surface of the target cell since the TCR has been replaced with an Ab. Surface- expressed proteins are a small proportion of our protein repertoire, and while there are cancer-selective modifications, selectivity has been a difficulty in CAR-T approaches, resulting in toxicity.[94] Where CAR-T has been effective in hematopoietic malignancies, it has been possible to eliminate an entire lineage based on surface receptor expression, such as CD19+ B cells for B-cell lymphoma.[95-97] Nevertheless, CAR-T is now a mainstay of cancer IT, and solutions to expand their use to solid tumors are in active investigation. While CAR engineering can incorporate a potentially unlimited array of regulatory features in CAR-T, as above, the features of the TME that limit T-cell efficacy can also limit CAR-T effectiveness.[92]

Vaccines

The presence of TAAs raises the prospect of using vaccines to generate or bolster tumor-directed immune responses against antigens expressed in common across patients. A number of different vaccine approaches such as DCs, bacteria, yeast, virus, DNA plasmids, and messenger RNA have been tested. Oncolytic viruses are vectors that both carry the vaccination targets and have direct cytolytic effects against the cancer cells. While there has been some success of vaccine approaches for cancer therapy, the clinical impact has been modest. Clinical trials using vaccines against TAAs, such as CEA, MUC-1, PSA, and HPV, have been completed, showing moderate levels of efficacy and promise. For example, PANVAC, a poxvirus-based vaccine encoding the tumor antigens CEA and MUC-1, along with three T-cell co-stimulatory molecules (TRICOM), demonstrated high progression-free survival (PFS) in clinical trials compared to control groups.[98] The first Food and Drug Administration (FDA)-approved cancer vaccine is sipuleucel-T, which is an autologous DC vaccine loaded ex vivo with a recombinant fusion protein consisting of the tumor antigen prostatic acid phosphatase linked to granulocyte-macrophage colony-stimulating factor (GM-CSF), for patients with metastatic castration-resistant prostate cancer.[99,100] However, significant time and cost constraints associated with this approach as well as the modest clinical benefit have limited widespread adoption of this vaccine approach. General shortcomings of targeting TAAs

are that since these are self-antigens that are inappropriately expressed, it is possible that they are poorly immunogenic and/or they present the possibility of injury to other normal tissues that might express the antigen.

Since many patients have T cells that can recognize TSAs (neoantigens), another vaccine approach is to generate or expand these T cells in vivo. This is the basis of personalized vaccine approaches, and a variety of personalized vaccine approaches have been attempted. Personalized vaccine strategies, like general cancer vaccine strategies, have had limited success,[101] partly because neoantigens are broadly unique to each patient, requiring patient-specific vaccines, and shared nonmutated antigens (TAAs) are not entirely cancer specific. The rapid development of genomic sequencing has increased the feasibility of patient-specific neoantigen vaccines, and this is an area of active investigation.[102] As with cellular therapies described above, vaccines against shared commonly mutated TSAs such as Kras may overcome some of these roadblocks of personalized vaccines and are in clinical development.[103] As discussed later, there is also the possibility of using the patient's own tumor in situ as the source of antigens for vaccination, allowing the generation of antitumor immunity without the need to sequence or know the individual antigens.

Many novel vaccine approaches are being developed, and it is likely that vaccines will be a more important part of our cancer IT arsenal in the future.

Antibody Therapies

Abs can not only be engineered as targeting mechanisms for CAR-T cells but also be directly used as therapies. For example, while anti–B-cell Abs are the target recognition component of CAR-T, they were long preceded by infusion of free anti–B-cell Abs.[104,105] In selecting Abs as therapeutics, it is essential to consider the mechanism of action as this will determine the design.[106] For example, with B cell targeting Ab for B-cell lymphomas, as discussed above, the aim is to cause death of B cells via immune mechanisms. While the binding domains of Ab provide target recognition, the Fc domain provides function. Cells coated with Ab can be killed via an array of mechanisms, including complement activation, opsonized phagocytosis, and Fc-mediated cellular cytotoxicity. This latter method

results in effector cells such as NK cells binding the Fc portion and killing cells recognized by the binding domain. This is an endogenous version of what CAR-T tries to achieve and can be extremely potent. However, some Ab therapeutics are not intended to cause cytotoxicity. For example, anti-epidermal growth factor receptor (EGFR) Abs are intended to block the increased EGFR signaling in EGFR overexpressing cancer cells.[107] However, the Fc-mediated activation of immune responses was found to play a critical role in patient responses.[108] Fc engineering is, therefore, critical in the design of therapeutic Abs.[106]

Abs can also serve as therapeutic or diagnostic radionuclide delivery systems.[109] These design criteria can take advantage of the stability of Abs as a platform, with the pharmacodynamics of Abs having half-lives measured in weeks, permitting stable systemic engagement. However, isotopes used in diagnosis and therapy have much shorter half-lives for a range of reasons, including safety. This impacts design decisions for the combination.[110] The use of radionuclide Abs in radiation and IT is discussed elsewhere in this text.

Immune-Modulating Antibodies (Checkpoint Inhibitors)

T cells (and other immune cells) can express a variety of co-receptors, which help modulate their activity. Some of these co-receptors can be inhibitory and are known as checkpoints (or co-inhibitory), and some of these can be activating and are known as co-stimulatory. Sometimes, a T cell may receive multiple suppressive and stimulatory signals at once, and it is the synthesis of these various signals that determines the activity of the T cells. In the past two decades, Abs targeting immune checkpoints dominated the landscape of cancer IT and revolutionized the clinical care of patients with cancer. For the first time, curing patients with metastatic cancers such as melanoma and non–small cell lung cancer (NSCLC) is possible, albeit only achieved in a small fraction of patients.

One of the main challenges in cancer IT is the tumor's inherent ability to evade immune responses. Unlike infectious immunity, tumor immunity must remain active over a prolonged period, which often leads to exhaustion of tumor- specific CD4+ and CD8+ T cells. Exhaustion is driven by negative inhibitory interactions, in which either inhibitory receptors, like

CTLA-4 binding to co-stimulatory ligands B7-1/B7-2, or specific inhibitory ligands, such as PD-L1/PD-L2 binding to PD-1, B7-H3 to Lag3, or galectin to TIM3, mediate the suppression.[111] To address this, monoclonal antibodies (mAbs) can be used to target and block these interactions. These are also known as immune checkpoint inhibitors (ICIs), since they overcome a regulatory checkpoint to permit full function of T cells. Abs targeting CTLA-4 and the PD-1/PD-L1 interaction have been clinically approved,[112] with various versions blocking PD-1/PD-L1 making a dramatic impact across diverse malignancies.[113-116] Blocking CTLA-4 and PD-1 with specific mAbs limits CTL exhaustion and enhances T-cell proliferation and function in the early phases of the response.[117] The clinically approved Abs block either the PD-1-PD-L1 interaction or the CTLA-4-CD80/86 interaction, which play important regulatory roles in limiting T-cell function. PD-1 is upregulated on T cells following activation and is likely most important during the effector phase of T-cell function. When PD-1 is engaged by its ligand, PD-L1, this limits TCR-CD28 co-receptor activation.[118] PD-L1 is upregulated on cells following exposure to IFNs, as well as other stimuli, and provides negative feedback to T cells. Expression of PD-L1 by cancer cells and suppressive immune cells in the TME limits T-cell control of tumors. Chronic engagement of PD-1 on T cells by PD-L1, as often occurs in the TME, can induce exhaustion characterized by decreased proliferative and effector function of T cells. CTLA-4 is rapidly upregulated on T cells during activation and displaces CD28 (signal 2) in binding the CD80/86 co-stimulatory molecules.[119,120] Again, the consequence is that TCR-CD28 co-receptor activation is limited. This dampens and modulates T-cell activation during the initial priming phase. Therapeutic Abs block these interactions and allow T cells to overcome this regulatory suppression. Notably, the Fc portion of these Abs again plays an important function. In the preclinical models used to develop these therapies,[121] the Fc portion plays a critical role, and Fc receptor binding is essential.[122] In preclinical models, the anti–CTLA-4 Ab results in the depletion of T-regulatory cells, which are high expressors of CTLA-4.[123] Thus, in using Abs as a therapeutic, actions beyond target binding are often critical. To date, many Abs blocking immune checkpoints have been FDA approved for the treatment of cancer. Ipilimumab and tremelimumab are anti–CTLA-4 Abs. PD-1 inhibiting Abs include pembrolizumab, nivolumab, cemiplimab, and dostarlimab. PD-L1

blocking Abs include atezolizumab, durvalumab, and avelumab. PD-1/PD-L1 and CTLA-4 are not the only immune checkpoint molecules, and strategies targeting other immune checkpoints associated with T-cell exhaustion, including Lag3, Tim3, and TIGIT, are actively moving forward.[124] Recently, the FDA approved a Lag3 inhibiting Ab (relatlimab) to be used in combination with nivolumab for advanced melanoma.[125,126] While ICIs may provide significant initial benefit, resistance to them may eventually develop. For example, resistance to CTLA-4 inhibition can arise from the upregulation of PD-L1 on melanoma cells, leading to T-cell exhaustion.[127] Persistent type I and II IFN signaling can also contribute to resistance, resulting in PD-L1–dependent and PD-L1–independent adaptive resistance to immune checkpoint blockade.[128] Strategies to overcome this adaptive resistance include incorporating multiple checkpoint inhibitors or inhibiting chronic IFN signaling, among many others. For instance, combining anti–CTLA-4 and anti–PD-L1 therapies has shown promise in melanoma and NSCLC.[129]

Many of the co-receptors that are upregulated on T cells, such as OX40, 4-1BB, and GITR, serve to provide further co-stimulation to T cells rather than inhibition.[124] Abs targeting these pathways aim to be agonistic, which activate the receptor rather than blocking it, as is the aim of Abs targeting the checkpoint molecules. This area of research has seen a number of failures in clinical translation, despite often dramatic preclinical efficacy, suggesting that there is much left to learn in the application of immunoregulatory Abs for cancer therapy. Critically, radiation has proven to be a dramatically effective partner for immunoregulatory Abs in preclinical models, as further discussed.

Innate Immunotherapy

Another major subclass of immuno-oncology relates to more general manipulation of the antitumor immune response using innate immune mechanisms. For the purposes of this discussion, we can also consider cytokines in this context (although addressed under the next subheading), since while they may be produced by or act on adaptive immune cells, they are normally regulated as part of more general inflammatory responses and accompanied by many other cytokines, rather than induced alone.

If the immune system most commonly functions as a series of stimuli resulting from infection and causing elimination of the infectious agent, the logical solution to generate immunity in a tumor is to introduce an infectious agent. While this may not direct immunity to the cancer cells, it can provide the authentic innate signals to generate and support immunity in the vicinity of the tumor, which can extend to tumor antigens as the immune cells infiltrating to clear infection will also take up debris from dying tumor. If TAAs are not successfully generating immunity, inflammatory signals from infectious agents may turn this around. The archetype for this is Coley toxins, an intratumoral administration of infectious agents with the intent to clear cancer either through direct infection and destruction of the cancer cells or via immune mechanisms, though the latter were not appreciated at the time.[130] This has been the mechanistic basis of Bacillus Calmette-Guérin instillation in bladder cancer,[131] as well as similar intralesional injections in other cancer types.[132] More recently, engineered selectively replication-competent viruses have been approved for the treatment of melanoma.[133] As with Coley toxin, a combination of mechanisms can influence the response. The agents are designed to directly infect cancer cells and can cause the death of the infected cells. In addition, innate sensing mechanisms can recognize the infectious virus and locally activate inflammatory cytokine secretion that can induce cancer cell death, such as tumor necrosis factor α (TNF-α), or additionally remodel the TME. Finally, these various components can result in an in situ vaccine effect yielding adaptive immune responses against the tumor. Despite the theoretical potential of this approach, it is clear that injection of an infectious agent is not universally effective. The inflammatory signals may not be sufficient to induce in situ vaccination against tumors, and bacterial or viral clearance does not necessarily result in epitope spreading and generation of an immune response against the unrelated tumor antigens. Also, clearance of the infectious agent may result in inflammatory resolution and allow the tumor to restore a suppressive TME. For this reason, it may be important to combine innate initiators of response with additional therapies such as anti–PD-1 to support ongoing antitumor immunity[134] or additional inflammatory agents such as RT.

As an alternative to infectious agents, synthetic triggers of innate immunity have been widely tested in cancer. In particular, a range studies

have shown that ligands for nucleic acid sensors have particular therapeutic efficacy in preclinical models (reviewed in Medler et al[42]). Innate triggers have been shown to synergize well with radiation in preclinical models[43] as discussed later. However, these have not translated into approved clinical therapies thus far. This has been particular disappointing for agents targeting STING, which are dramatically effective in preclinical models,[135,136] synergize well with radiation,[137] but have not shown similar efficacy in patients.[138,139] However, this is an area of active research, and novel targets and agents are in development.

Cytokine Immunotherapy

Cytokine therapies are among the earliest employed ITs in the modern era. In the 1990s, the FDA approved two cytokine ITs: IL-2 for melanoma and renal cell cancers and IFN-α (type I IFN) for melanoma. Many of the innate pathways discussed above result in the production of cytokines in the form of either type I IFN or TNF-α. Both have been applied as cancer therapies. Type I IFN is induced downstream of many of the innate immune activators mentioned above. Type I IFN has been studied as a therapy for melanoma and can improve recurrence-free survival[140,141] but does not impact overall survival (OS).[142] However, the toxicities of type I IFN have limited its broader use. For example, in patients receiving type I IFN along with adjuvant chemoradiation (chemo-RT), efficacy was observed in early-stage studies[143]; however, multicenter studies also reported improved outcomes but resulted in grade III or IV toxicity in 90% of patients.[144] A range of delivery approaches have been proposed and tested to overcome systemic toxicities. It is important to note that RT locally induces type I IFN for immune activation[145] and does not induce the toxicities seen with systemic IFN therapy. TNF-α has shown a similar clinical trajectory to type I IFN. TNF-α has long been identified as the active factor, resulting in necrosis of tumors following infection.[146,147] However, TNF-α is the main factor contributing to systemic shock, and extensive systemic toxicities limit clinical use. Again, local delivery has been attempted through a range of strategies, and TNF-α has been effectively combined with RT clinically and preclinically.[148,149] At present, TNF-α is not an independent cancer therapy

but may play a role in radiation efficacy and toxicity, so it is an ongoing topic of investigation.

High-dose IL-2 is a cytokine therapy approved for the treatment of metastatic melanoma and renal cell carcinoma.[150] Despite developments in immunoregulatory Abs, IL-2 remains a viable and effective therapy for these patients.[151,152] As discussed above, IL-2 is a backbone of adoptive transfer therapy,[153] and novel molecules targeting IL-2 receptor signaling are in late-phase clinical trials.[154] This development is important since toxicity management is critical in delivery of high-dose IL-2, so agents with a similar efficacy but decreased toxicity have high value. This is relevant to RT since high-dose IL-2 has shown evidence of increased responses in combination with radiation in early-phase studies.[155,156] There is potential for IL-2 support of T-cell responses generated following RT,[157] given an increasing understanding of the impact of IL-2 timing on T-cell responses.[158] Numerous other inflammatory cytokine therapies are being developed as cancer therapy, including GM-CSF, IL-7, IL-12, IL-15, IL-18, and IL-21. Additional work is ongoing on therapies to neutralize suppressive cytokines, such as IL-10 and TGF-β.

Current Directions in Immuno-Oncology

The recent status of the field was that we had more candidate therapies than the capacity to test them. However, the high failure rate of ITs on clinical translation has narrowed the field significantly. Likely, many potentially efficacious candidates have been discarded as a result of poorly designed clinical trials or an as-of-yet incomplete understanding of mechanisms of action. A critical ongoing endeavor is identification of biomarkers of response to focus therapies on those likely to respond and reveal mechanisms governing failures. However, to date, few biomarkers are so strongly predictive of poor response that treatments are *not* given to patients. The current status of the field is dominated by combination treatments. In these, the common denominator is generally anti–PD-1/PD-L1, given the widespread efficacy across malignancies and clinical scenarios, albeit in a subgroup of patients. It is in this setting that radiation finds its strongest role. Radiation alone is very rarely able to impact immunity to tumors outside the treatment field,[159] but preclinical studies and

clinical anecdotes have shown that in combination with IT, radiation is an effective partner for local and distant tumor control.[160,161] Clinical translation of preclinical therapies that include radiation has also not been simple.[127] but as we will discuss, there is enormous potential.

RADIATION IMMUNE MODULATION

The principle of RT traditionally involves delivery of ionizing radiation to a focal tumor while minimizing dose and damage to the surrounding healthy tissues with the goal of producing local effects on the target volume. Advances in our understanding of the immune-modulating effects of ionizing radiation have increased focus on RT's ability to stimulate the immune system, locally and systemically, to induce antitumor effects manifesting as regression in distant, unirradiated sites, known as the abscopal effect.[162] The phenomenon underlying the abscopal effect has been mechanistically referred to as in situ vaccination, where the irradiated local tumor acts as a vaccine activating the immune system to produce systemic antitumor effects targeted against nonself, TSAs. However, the immunomodulatory effects of RT are generated by multiple radiation-induced effects on the tumor, TME, and immune system[1] and likely extend beyond in situ vaccination and antigen-specific responses. RT induces a complex interplay of immune responses involving cytokines, DNA sensing pathways, and the activation of pattern recognition receptors. Understanding these interactions is crucial for harnessing the immune-modulatory properties of RT and developing effective combination strategies with IT.

In Situ Vaccination

An idealized and simplified overview of RT-induced in situ vaccination is presented in Figure 26.1 and summarized below. The subsequent sections present more detail on each of these processes. RT is primarily a local modality, and the effects of radiation on the immune system begin directly at the site of the tumor irradiation (and draining lymph nodes). RT can affect the TME, which consists of various immune cells, an intricate network of fibroblasts, blood vessels, lymphatics, and the cancer cells themselves. These components of the TME are enclosed within a dense

stroma formed by collagen and elastin fibers, collectively known as the ECM. The TME has been acknowledged as a vital factor influencing the signaling pathways and tumor characteristics that promote or suppress antitumor immunity and disease progression.[63] RT can alter the stroma and TME structure to increase the diapedesis of immune cells. Infiltrating APCs, such as DCs, can take up antigens from dying tumor cells and present them to T cells to activate the adaptive immune response against the tumor.[163] Thus, the first local action of RT is to alter the stroma and TME to allow an influx of immune cells.

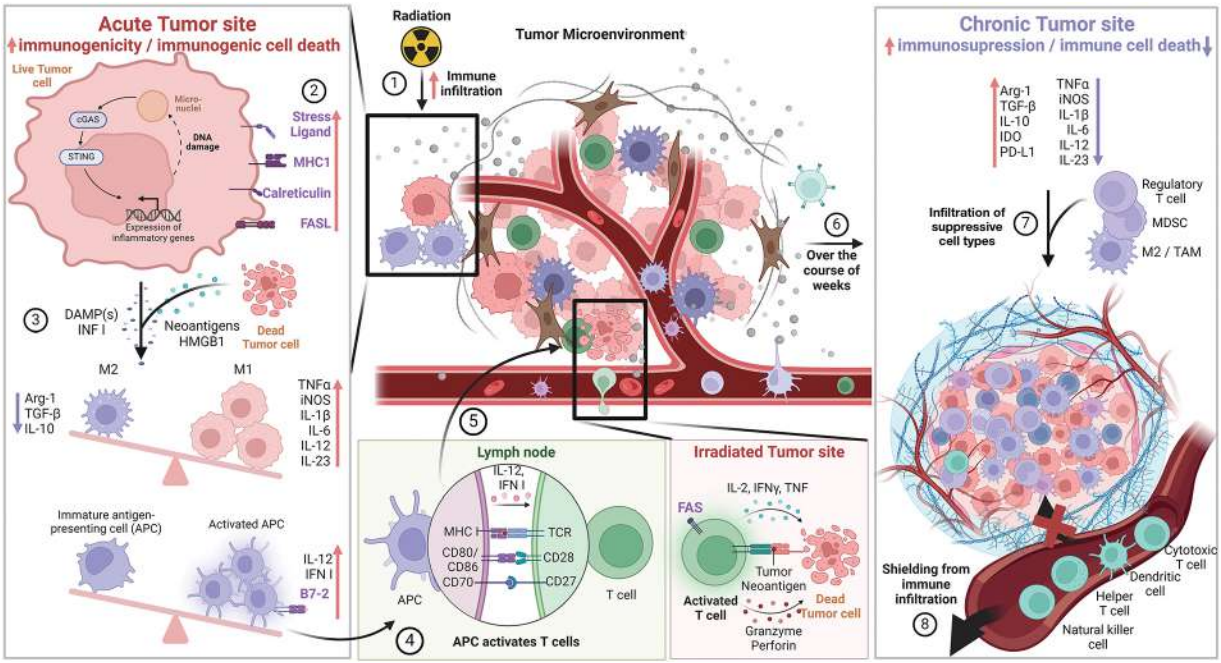

FIGURE 26.1 Simplified overview of radiotherapy-induced in situ vaccination. 1. Radiation alters the stroma and vasculature to increase the diapedesis of immune cells, thereby changing the TME's endogenous composition and dynamic features. 2. Radiation also induces DNA damage that ignites nucleic acid spillage into the cytoplasm, thereby triggering the endogenous viral detection systems to initiate a sequence of events, including increased presentation of intracellular contents and self-tagging for destruction, all leading to immunogenic cell death. 3. Immunogenic cell death releases the intracellular contents as DAMPs and neoantigens to repolarize the M2 to M1 macrophages and activate APCs that phagocytose neoantigens. 4. These newly loaded APCs then migrate to draining lymph nodes and cross-present to activate T cells. 5. The activated T cells then return to the primary tumor site or any other site (abscopal effect) and trigger tumor cell death, which may also be immunogenic and potentially self-propagating. 6. However, tolerance takes hold if the signal becomes chronic, increasing immunosuppression and decreasing immunogenic cell death. 7. Over time, immune suppressive cells infiltrate or develop within the TME, promoted by various signal changes. 8. The ECM/stroma around the tumor regenerates, reducing the number of functional immune cells infiltrating into the TME and functionally evading immunosurveillance. NK cell and B-cell mechanisms are intentionally excluded from this scheme for simplicity. APC, antigen-presenting cell, DAMPs, damage-associated molecular patterns; ECM, extracellular matrix; IDO, indolamine-2,3-dioxygenase; IL-10, interleukin-10; INF, interferon; iNOS, inducible nitric oxide synthase; MDSC, myeloid-derived suppressor cell; MHC, major histocompatibility complex; NK, natural killer; PD-L1, programmed death-ligand 1; TCR, T-cell receptor; TGF, transforming growth factor; TME, tumor microenvironment; TNF, tumor necrosis factor. (Created with BioRender.com.)

Irradiated cancer cells undergo immunogenic cell death (ICD), resulting in more efficient uptake and presentation of TSAs from dying cancer cells by APCs. Thus, RT can increase the influx of APCs and also increase their

functionality. The dying cancer cells release DAMPs, resulting in the upregulation of IFNs, which feed into this process and activate the inflammatory cascade.[164] RT augments type I IFN and TLR signaling.[145] These effects can increase the functionality of APCs to more efficiently present tumor neoantigens and can upregulate antigen presentation machinery on cancer cells. Due to DNA and RNA alterations and protein misfolding, cancer cells may also generate new nonself antigens, referred to as neoantigens, which the immune system can identify as foreign.[165] The increased antigen presentation can generate new and bolster preexisting antitumor T-cell responses. The chemokine and cytokine changes in the TME can help support T-cell functionality, and increased expression of MHC and stress ligands on tumor cells can sensitize them to T-cell killing. Thus, RT augments existing T-cell responses as well as stimulates new T-cell responses. RT increases the infiltration of T cells into the TME and also sensitizes tumor cells to killing by CTLs and other immune cells through increased expression of MHC I and upregulation of stress ligands including Fas.[162,164,166] Only when T cells are generated with sufficient function and numbers to enter, the systemic circulation and eradicate distant tumors in a clinically meaningful way can this be considered a true in situ vaccination, resulting in an abscopal response.

Stroma and Vascular Changes

RT induces a number of changes that facilitate trafficking of immune cells into the TME. Changes in chemokines and cytokines attract immune cell infiltrates into the TME and are discussed below. RT can also effect changes in the tumor stroma and vasculature, which result from RT effects directly on fibroblasts and endothelial cells or can result from the effects of RT-driven signaling molecules on these cells. Hammerling and colleagues[167] at the German Cancer Research Center described RT effects on tumor vasculature in two elegant reports 11 years apart. They demonstrate that RT induces remodeling and normalization of the structure of tumor vasculature, which facilitates immune cell infiltration into the TME. Furthermore, they indicate that RT-induced changes in macrophage polarization can induce activation of endothelial cells by iNOS. This results in normalization of vasculature and secretion of T-cell recruiting Th1 chemokines increasing

TILs.[168] This process is critical to the success of adoptive T-cell IT in their models. Numerous preclinical and clinical studies demonstrate that radiation also upregulates adhesion molecules on both immune cells and the vasculature and stroma, which increases homing and extravasation of immune cells into the TME. Initial preclinical studies demonstrated increased levels of vascular cell adhesion molecule 1 (VCAM-1) on endothelial cells after RT.[169] Clinical data from patients with irradiated head and neck cancer report RT-induced increases in β-2 integrin on leukocytes and intercellular adhesion molecule 1 (ICAM-1) on endothelial cells.[170] Taken together, these effects indicate that RT can induce the trafficking of immune cells into the TME, which is now a well-accepted immune-modulatory effect of RT. Clinical data from UC Davis in a cohort of patients with sarcoma treated with neoadjuvant RT clearly demonstrate a significant increase in TILs post-RT.[171] In the clinic, it is difficult to distinguish between an influx of immune cells into the TME and the proliferation of immune cells within the TME.

Immunogenic Cell Death and Radiation-Induced Danger-Associated Molecular Patterns

Several studies demonstrate that tumor cells undergoing radiation-induced cell death release a milieu of DAMPs (also known as alarmins), which interact with pattern recognition receptors on immune cells and other cells in the TME to help activate the immune system. This is referred to as ICD and is different than the traditional apoptotic cell death pathway, which is considered to be immunologically silent. Landmark studies by Zitvogel, Kroemer, and colleagues[172,173] reported that irradiated tumor cells (as well as cells killed by certain chemotherapeutic agents such as anthracyclines) die in a manner that increases phagocytosis, processing, and display of their antigens by DCs. Preapoptotic cancer cells undergoing radiation-induced cell death translocate calreticulin from the endoplasmic reticulum to the cell surface. Cell surface calreticulin on the tumor cells can interact with receptors, including CD91, expressed on the surfaces of DCs and other APCs, which act as an “eat me” signal upregulating phagocytosis of the dying tumor cells. Furthermore, these dying tumor cells release the nuclear protein HMGB1, which interacts with TLR4 on DCs to increase the

processing and cross-presentation of antigens from phagocytized dying tumor cells.[34] Likewise, the release of adenosine triphosphate from these dying cancer cells can also help recruit DCs to the TME.[174] Studies by Formenti, DeMaria, and colleagues[175] built on this concept of RT-induced ICD by identifying another mechanism whereby dying irradiated cancer cells induce recruitment and activation of TME DCs. RT induces the release of double-strand DNA into the cytosol, which acts as a DAMP that is sensed by cGAS. cGAS, via its downstream effector STING, induces transcription factors such as IRF3 and NF-κB for the production of type I IFNs, which recruit and activate DCs and have various other immunologic effects. Other danger signals, such as heat shock proteins, also play a role in these processes. Together, these processes can increase the maturation and activation of DCs and increase their ability to take up and cross present tumor antigens to the adaptive immune system. Furthermore, these activated DCs will upregulate co-stimulatory molecules such as CD80/86 and inflammatory cytokines such as IL-1β, IL-6, and TNF-α, thereby also providing signals two and three required for T-cell priming (Figure 26.1, panels 3-5). Thus, the induction of ICD is key for in situ vaccination.

Radiation Effects on Surviving Tumor Cells

RT may not consistently achieve the death of every tumor cell. The inherent sensitivity variations of tumor cells to radiation and limitations in dose delivery due to surrounding normal tissue structures often allow some tumor clonogens to survive. Numerous studies have demonstrated that RT-induced cell stress in surviving cancer cells triggers a range of phenotypic changes, collectively increasing their vulnerability to being targeted and killed by the immune system.[176] After RT, the surviving fraction of tumor cells upregulates cell surface stress ligands and death receptors, intercellular adhesion molecules, proapoptotic TNF family member receptors, and various co-stimulatory molecules. Conversely, there is downregulation of antiapoptotic and prosurvival genes, as well as an overall increase in the presentation of tumor antigens.[177] Thus, while ICD helps induce an in situ vaccination bolstering the antitumor immune response, the surviving fraction of irradiated tumor cells is not left unscathed and becomes sensitized to targeting and killing by the generated immune response. In

clinical practice, it is likely that RT relies not only on direct cancer cell cytotoxicity but also on the immune system to clear surviving clones.

Stress ligands are upregulated on tumor cells in response to RT-induced DNA damage. Natural killer cell group 2D (NKG2D) ligands are upregulated on the cancer cell surface in response to DNA damage[178] and RT.[179] The NKG2D receptor is expressed on several potent effector cells including NK cells, NKT cells, γΔT cells, and CTLs, and recognition of the ligand on the surface of irradiated tumor cells can lead to cell killing in an antigen-nonspecific manner. Coleman, Hodge, and colleagues[180] demonstrate that irradiated cancer cells upregulate the Fas/CD95 death receptor, which renders them more susceptible to antigen-specific killing by CTLs expressing Fas ligand. They also demonstrate upregulation of TRAIL death receptor sensitizing cells to antigen-specific killing by TRAIL expressing effector cells.[181] Studies from UC Davis demonstrate RT-induced upregulation of Fas and MICA/B (NKG2D ligands) on stressed radiation-resistant cancer cells, which renders them susceptible to killing by NK cells in an antigen-nonspecific manner.[179]

In addition to stress ligands that can target irradiated cancer cells for immune-mediated cytotoxicity, there is also increased expression of adhesion molecules like ICAM-1/CD54 and lymphocyte function-associated antigen 3 (LFA-3/CD58), which enable immune cells to form a stable immunologic synapse for interaction with the stress ligands and MHC molecules on these cancer cells. RT also upregulates cell surface expression of co-stimulatory ligands on tumor cells, including B7-1, B7-2, OX40L, and 41BBL, which are critical for overcoming tumor-specific anergy and sustaining effective CTL responses.[182-184] Some of these co-stimulatory molecules have also been associated with reduced levels of Tregs, which may further help counteract immunosuppression.[184] Critically, RT also upregulates the machinery involved in antigen processing and presentation on cancer cells. RT increases the pool of antigens presented on cell surface MHC by cancer cells by increasing translation, degradation, and processing of peptides, resulting in increased and novel intracellular peptides available for presentation by MHC I.[185] Furthermore, RT increases the cell surface expression of MHC I, facilitating recognition and killing of cancer cells by CTLs.[185] Gough, Crittenden, and colleagues[186] demonstrated that RT-induced upregulation of MHC I on surviving cancer cells via

NLRC5 is a critical mechanism whereby RT contributes to a successful antitumor immune response.

Radiation-Induced Cytokines and Chemokines

Much of the work examining RT-induced cytokines has focused on examining their contribution to RT-induced toxicity. However, cytokine and chemokine induction are essential for an RT-generated immune response. One of the critical immunogenic properties of RT-induced ICD is induction of type I IFNs (ie, IFN-α, IFN-β) by cancer cells, which can help recruit and activate DCs. Numerous cytokines and chemokines are upregulated by cancer cells, immune cells, and/or stromal cells in response to RT. Many of the immune-modulatory effects of RT described in the preceding sections are signaled or effected, at least in part, through cytokine and chemokine signaling. For example, type II IFNs (ie, IFN-γ) are also critical mediators of the RT-induced immune response generating several changes within the TME. RT-induced IFN-γ in the TME upregulates VCAM-1 on endothelial cells and MHC I on tumor cells, augmenting the TME to one that is conducive to infiltration and tumor cell recognition by T cells.[187] DCs activated by the processes outlined in the above sections secrete numerous cytokines, including IL-6, IL-1b, TNF-α, and IFN-γ, which are critical for the induction and activation of antitumor T cells. RT-induced chemokines such as CCL2 and CCL5 recruit T cells and macrophages to the irradiated TME, and CCL20 recruits DCs. Likewise, the production of CXCL16 (a chemokine that binds to the chemokine receptor CXCR6 on activated T cells) by irradiated breast cancer cells was shown to be critical to RT-induced T-cell infiltration of the TME and the efficacy of combining RT with ICI IT.[188] The upregulation of RT-induced TLR signaling in macrophages has been associated with increased macrophage secretion of the immune-activating cytokines IL-12 and IL-18.[189]

Radiation Therapy Modulation of Effector Cells

RT modulates immune effector cell function primarily in an indirect manner via induced changes in the TME, including changes in tumor cells, cytokines/chemokines, APCs, and tumor vasculature, which are described in the preceding sections (Figure 26.1). Much of the focus of RT studies has

been on adaptive T-cell responses and CTLs as effectors, but there is also an important role for B cells and innate effector cells in the RT-induced antitumor immune response.

RT induces a wide array of changes in the TME, which support existing and generate new T-cell responses. RT augments existing T-cell responses via numerous mechanisms described in the preceding sections. RT sensitizes tumor cells to T-cell cytotoxicity by increasing expression of MHC I, Fas, Trail, and other ligands. Upregulation of inflammatory cytokines including IL-1b, TNF-α, and IL-6 supports the function, expansion, and differentiation of antigen-experienced T cells. The concept of increasing TILs to transform the TME from "cold" to "T-cell inflamed" is a common rationale for combining RT with IT. As outlined above, RT induces changes in vasculature, adhesion molecules, chemokines, and cytokines that increase the homing and infiltration of T cells into the TME. In addition to inducing infiltration of T cells, RT also induces the proliferation of T cells (Ki-67+ T cells) within the TME and draining lymph nodes. Studies of clinical specimens from resected oral squamous cell carcinomas and renal cell carcinomas demonstrated an increase in proliferating CD8+ T cells post-RT.[190,191] RT can also generate new T-cell responses by increasing antigen expression by cancer cells, increasing the uptake and presentation of those antigens by DCs, and increasing the activation of DCs (which increases expression of co-stimulatory molecules and cytokines), all of which can serve to prime a T-cell response by providing signals 1, 2, and 3. Studies using TCR sequencing to interrogate how RT alters T-cell clonality demonstrated RT increases the diversity as well as expansion of new and preexisting T-cell clones, supporting the idea that RT immune modulation supports existing and generates new T-cell responses.[127,192,193] All of these processes serve to increase the number of T cells in the TME post-RT.

RT has also been shown to induce changes in B cells. In the TME of mouse NSCLC models, RT is reported to increase tertiary lymphoid structures, which have germinal centers with proliferating B cells.[194] However, other studies have suggested that RT can transiently deplete tertiary lymphoid structures.[195] The presence of tertiary lymphoid structures in tumors has been linked with positive clinical outcomes in general and in response to IT. Many studies have also focused on increased T-cell

infiltrates in the TME after RT, but it appears that infiltrating B lymphocytes are also increased. The aforementioned examination of soft tissue sarcomas also demonstrates increased B-cell infiltrate in the TME after standard neoadjuvant RT.[171] Likewise, Sharabi and colleagues[196] demonstrate that RT increased B-cell infiltrates and B-cell activation marker expression in the TME of their preclinical models.

As outlined in the above section, RT can induce upregulation of many stress ligands on cancer cells, which serve to target them for killing in an antigen-nonspecific manner by innate effector cells. As demonstrated by Minn and colleagues,[197] these innate effector pathways may be particularly important when tumors have developed strategies, such as downregulating MHC, to reduce their antigenicity. Historically, interest in the innate immune system was focused on its role in activating and managing the adaptive immune reactions, but there is a growing interest in the effect of RT on innate immune cells such as the NK cells and their direct role in tumor cell killing in solid tumors. While NK cells have been known for their involvement in hematologic malignancies, mounting evidence suggests that they also play a role in solid tumors. Several preclinical studies have shown that RT upregulates NK cell ligands and induces NK cell migration into tumors.[171,198-201] Moreover, radiation-induced DNA damage pathways can activate NK cells to eliminate tumor cells through upregulation of specific molecules that promote the efficient killing of tumor cells by NK cells.[178] RT upregulates NK cell ligands and induces NK cell migration into tumors. NK cell activity is mediated through receptors such as NKG2D (activating) and killer cell immunoglobulin-like receptors (activating and inhibitory).[202] Radiation-induced DNA damage pathways, mediated by the ataxia telangiectasia–mutated protein and p53, can activate NK cells. These pathways lead to the upregulation of NK cell ligands (MIC-A, MIC-B, and ULBP) on irradiated tumor cells that interact with the activating NK cell receptor NKG2D, promoting the efficient killing of tumor cells by NK cells.[178,179] Restoring p53 expression in tumors lacking it can trigger complete tumor regression. This occurs through p53-mediated cellular senescence, followed by increased production of inflammatory cytokines and the initiation of tumor-directed innate immune responses, rather than through RT-induced apoptosis.[111,179] Preclinical studies indicate that RT increases NK cell killing of several murine solid tumor cell lines as

well as human cancer cell lines and primary cultured human cancer cells that are co-cultured with NK cells.[171,198-201]

RADIATION IMMUNE SUPPRESSION

Inflammation is a double-edged sword. As with other physiologic processes, the inflammatory cascade is under tight regulatory and counterregulatory mechanisms function to maintain homeostasis. RT can have positive immune- modulating effects, but it can also induce immune suppression. RT induces immune suppression via regulatory pathways, which are activated to limit the degree and duration of inflammation, as well as through direct cytotoxic effects on immune cells. While data clearly support the radiation-induced immune events outlined in Figure 26.1, the full story is more complex, as the TME consists of a milieu of supportive and suppressive immune cells. RT can be directly cytotoxic to immune cells and can also increase the release of immunosuppressive cytokines, such as VEGF, TGF-β, and IL-10. These cytokines can promote suppressive immune cell function in the TME and reduce the overall lymphocyte count in systemic circulation.[171,203] RT can also upregulate other immune-suppressive factors such as PD-L1 and the enzyme IDO.[204,205] These effects are time dependent. While the exact kinetics are model dependent and not wholly deciphered, it generally appears that RT introduces a window of pro-inflammatory opportunity before counterregulatory immune-suppressive networks set in.

Radiation Therapy–Induced Immune Cell Cytotoxicity

Conventional RT induces some degree of immune suppression due to the loss of radiosensitive immune cells within the irradiated field.[111,206] The impact of RT on lymphocyte populations has been long recognized.[207] Studies in numerous cancers including high-grade glioma, squamous head and neck cancer, pancreatic adenocarcinoma, and NSCLC treated with RT or chemo-RT demonstrate treatment-induced lymphopenia and correlate severe lymphopenia with poor clinical outcomes.[208-213] Focusing solely on blood counts might underestimate the effects of cytotoxic therapies on the immune system. Schuler et al[214] studied lymphocyte subtypes in patients with head and neck cancer undergoing chemo-RT and found that chemo-RT

led to a decrease in overall circulating CD4 helper cells, but increased CD4+ CD39+ Tregs, which dampen the immune response. Moreover, they found that this increase in Tregs persisted years after treatment conclusion. Radiation-induced lymphopenia is further exacerbated by the fact that it is often accompanied by tumor-driven granulocytosis that drives an elevation in the neutrophil-to-lymphocyte ratio—a factor that has been validated in numerous studies as an independent predictor for OS in various cancer clinical trials.[215]

Yet, it is unclear precisely which lymphocyte populations are affected. While circulating and naïve lymphocytes are very radiation sensitive, Weichselbaum et al[216] have demonstrated that tissue-resident and TME T cells are more radioresistant. Sharabi et al[196] also demonstrated that activated and class-switched B cells are more radiation resistant than their naïve counterparts. Likewise, it has been shown that tissue-resident macrophages and DCs are more radiation resistant than the circulating monocytes from which they derive.[217] The impact of RT on peripheral blood counts is often attributed to bone marrow irradiation, where normal stem cells are particularly sensitive to DNA damage, but the data above suggest that dose to the circulating blood pool may be most critical. Yovino and Grossman[208] suggest that lymphopenia arises from apoptosis of lymphocytes passing through the radiation field. They estimate that during a fractionated course of partial brain irradiation, about 99% of lymphocytes received at least 0.5 Gy, with an average circulating lymphocyte dose of 2 Gy—doses sufficient to induce apoptosis in circulating lymphocytes. Their simulations also predict that a single fraction of RT would deliver 0.5 Gy to only 5% of circulating lymphocytes. It, therefore, appears that highly critical variables in RT-induced cytotoxicity of immune cells are the field size and number of fractions that determine the volume of irradiated blood pool since this is where the most radiosensitive immune cells are present. For a more detailed review of this topic, we refer the reader to two thorough and expertly written reviews by Gough and Crittenden[161] and Paganetti.[218]

Rebound Immune Suppression

The immune system is a homeostatic system with built-in regulatory pathways to limit the magnitude and duration of the inflammatory response.

Inflammation is meant to be short-lived and resolved once the infection or offending agent has been cleared. Chronic inflammation, as can occur with certain infections and cancers, can ultimately be immunosuppressive as multiple regulatory pathways are activated to control the inflammatory response that has not resolved. Likewise, RT can induce chronic inflammatory changes, which lead to upregulation of immune-suppressive pathways, a process we coin "rebound immune suppression."[205] Thus, while acute inflammation can be beneficial and RT can initially stimulate the immune system during the acute inflammatory phase, this can give way to chronic inflammation and rebound immune suppression as the immune system attempts to reestablish homeostasis. RT-induced hypoxia-inducible factor-1α (HIF-1α) and chronic IFN-γ may be the master signals governing this immune suppression. Several immune-suppressive cell types including Tregs, M2-polarized tumor-associated macrophages (TAMs), and MDSCs have also been reported to be involved in this process. Further long-term changes to the stroma and vasculature also affect the TME and the ability of the immune system to eradicate tumor.[205,219-221]

Over time, RT-induced inflammation gives rise to pathways used for the resolution of immune responses in which bone marrow–derived myeloid cells and vasculogenesis play a key role. RT upregulates HIF-1α and, in turn, CXCL12, CCL2, CSF1, and VEGF, which recruit bone marrow–derived MDSCs and TAMs to the TME and increase their immunosuppressive functions.[222-225] Of note, the HIF-1–dependent chemokine CXCL12 and its receptor CXCR4 have been strongly implicated in recruiting immune-suppressive myeloid cells to the TME.[223] Inhibiting CXCR4 has shown to inhibit tumor regrowth and lung metastasis while enhancing the effectiveness of anti–PD-L1 IT in mouse cancer models.[226] HIF-1α and IFN-γ signaling also induce the expression of PD-L1 on MDSCs, TAMs, and tumor cells, which increases their suppression of the antitumor immune response.[227] TAMs and MDSCs also upregulate anti-inflammatory cytokines such as TGF-β and IL-10 and enzymes such of arginase-1.[228] While these effects can occur days to weeks after RT, acutely RT reduces circulating myeloid cell numbers, suggesting that RT may create a therapeutic window for IT at the time of minimal myeloid-induced immunosuppression.[229] Likewise, preventing this myeloid induction may prolong the beneficial immune modulatory effects of RT. Preclinical studies

from Shiao et al[228,230] demonstrate that depleting myeloid-derived cells enhances RT efficacy.

RT-induced IFN signaling, while critical for many of the antitumor and immune-modulatory effects of RT, can also upregulate resistance pathways. Minn and colleagues[197] report that chronic IFN signaling can drive tumor cell resistance to immune attack. IFN signaling is also known to upregulate IDO, an enzyme implicated as a master regulator of immune suppression and known to potently induce Tregs. Studies demonstrate that RT can induce IDO expression in the TME and limit the efficacy of RT + IT, while blocking IDO decreases Tregs and improves the efficacy of therapy.[205] Welsh and colleagues further demonstrated that RT-induced IDO is linked to increased MDSCs in the TME.[231]

OPTIMIZING RADIATION THERAPY VARIABLES FOR IMMUNE MODULATION

The immune-modulatory effects of RT, as described above, are diverse, and the effects are highly dependent on factors of RT delivery, such as dose, fractionation, quality, timing, and the volume and type of tissue being irradiated. In this setting, RT should not be considered a single treatment modality but rather as many different drugs with varying immune-modulatory effects depending on how it is employed. The best RT approach will thus depend on the desired immune-modulatory effects. This will likely also depend heavily on the type of cancer and the existing TME, as well as the type of IT that RT is being partnered with if a combinatorial strategy is undertaken. This is an area of study where large gaps in knowledge remain and highly systematic preclinical and clinical studies testing these variables are required.

Radiation Therapy Dose and Fractionation

The variable with the largest consequences for RT immune modulation is likely dose and fractionation. A recent review has expertly discussed many of the issues, which we summarize below.[232] External beam RT (EBRT) can be administered in different ways, such as standard fractionation (1.8-2.0 Gy daily for several weeks) or with larger doses in fewer fractions

(hypofractionation).[177] For the purpose of this discussion, we consider four approaches (the distinction between which is arbitrary and hazy):

1. Low-dose RT is considered a small fraction number + small dose per fraction (<2 Gy), which would not be considered sufficient for tumor control.
2. Standard fractionated RT is considered 1.8 to 2 Gy per fraction to a sufficient dose to obtain tumor control (generally several weeks).
3. Hypofractionated RT is generally considered subablative doses delivered in a limited number of fractions.
4. Ablative RT is considered high dose (>10 Gy) delivered in one to five fractions.

Low-Dose Radiation Therapy

Low doses of RT may be insufficient to kill all tumor cells but, as discussed above in the section on RT effects on the surviving fraction of tumor cells, may be sufficient to stress cells and alter the TME. Studies have shown that RT induces the upregulation of MHC class I expression in a dose-dependent manner starting at doses as low as 1 Gy or less, leading to increased presentation of tumor antigens on the tumor cell surface. Nonlethal radiation has also been shown to activate the mammalian target of rapamycin, facilitating increased protein synthesis and availability of peptides for MHC class I loading.[177] These effects lead to elevated antigen presentation on the surface of the tumor. In addition, very low doses of radiation (0.5 Gy × 4) have been found to reprogram macrophages and stimulate effective T-cell immunity against tumors, offering a novel approach to modulating the TME.[168,233] In these preclinical studies, this low dose is sufficient to induce vascular remodeling of tumors. Two randomized clinical studies organized by the National Cancer Institute's Experimental Therapeutics Clinical Trials Network (ETCTN) and led by Schoenfeld, Monjazeb, and Hodi[129,234] tested a low-dose RT approach in combination with dual ICI for colorectal cancer and NSCLC but failed to show a clinical benefit over dual ICI alone. Preclinical studies and clinical reports from Welsh and colleagues suggest that RT + IT strategies using low-dose RT may be most useful when combined with high-dose RT to at least one lesion

to induce in situ vaccination at the high-dose lesion but take advantage of RT immune modulation at other sites of disease treated with low dose.[235,236] This concept is discussed further below when considering spatially fractionated RT.

Standard Fractionated Radiation Therapy

Traditionally, radiation oncology has equated increased dose with improved tumor control based on clonogenic cell survival assays.[237] The survival curves imply an intimate connection between radiation dose and cell kill. In the clinic, fractionation enables higher radiation doses to achieve local control but allows for sparing effects on normal tissues. A certain minimum dose is likely required for disease control, but escalating doses further has not yielded additional improvements in outcomes across various cancer types, including esophageal, low-grade glioma, glioblastoma, and NSCLC.[238,239] These principles were developed based on in vitro systems and fail to consider RT effects on the immune system and TME, including the cytotoxic effects on local and circulating immune cells discussed in preceding sections. Standard fractionated RT also generally utilizes larger field sizes, which treat not only the gross tumor but also areas at high risk for subclinical disease, often including draining lymph node basins. Thus, due to increased field size and fraction number, standard fractionation RT irradiates more normal tissue and blood pool, causing more local and systemic immune suppression. Crittenden, Gough, and colleagues[240] tackled this issue by examining the impact of neoadjuvant standard fractionated and hypofractionated chemo-RT on immune cells among patients with locally advanced and borderline resectable pancreatic adenocarcinoma. They report that standard fractionated chemo-RT caused a substantial and prolonged reduction in lymphocytes, not attributed to deficiencies in homeostatic cytokines or cytokine responses. Conversely, hypofractionated RT avoided the lymphocyte loss associated with conventional fractionation. It is difficult to separate the effects of standard fractionation from those of larger field size, and this topic is discussed more below.

Hypofractionated Radiation Therapy and Ablative Radiation Therapy

Ablative and hypofractionated RT employ larger doses per fraction. The line between hypofractionated and ablative RT is quite blurred, but most radiation oncologists would classify 8 Gy × 3 or 6 Gy × 5 as hypofractionated, whereas regimens such as 20 Gy × 1 or 10 Gy × 5 would be considered ablative. Larger fractional doses may induce higher levels of ICD, generating a more intense radiation-induced antitumor immune response.[7,206] In addition, tumor cells that survive may be more immunogenic, rendering them more susceptible to attack. Furthermore, these approaches, particularly ablative RT, often treat more limited field sizes and thus avoid the detrimental effects of multiple fractions and large field sizes discussed above. Larger doses have demonstrated promise in combination with tumor vaccines[181] and immune checkpoint blockade.[241]

Ablative RT is usually delivered in one to five fractions and yields very high rates of local tumor control. The use of ablative RT has demonstrated high control rates for tumors that are resistant to fractionated RT, and there is a suggestion that tumor control is dependent on both direct cell kill and endothelial cell injury.[242,243] These effects are most prominent above a single dose of 12 Gy and increase with increasing doses above this threshold.[70] Hypofractionated RT often has lower rates of tumor control likely due to a delivery of a lower BED. Seminal work by Demaria, Formenti, and colleagues studied the role of dose fractionation, particularly single-fraction versus hypofractionated RT, for RT combined with anti–CTLA-4 immune checkpoint blockade, in mediating abscopal effects in murine models of breast and colon cancer.[241] They found that hypofractionated RT (eg, 8 Gy × 3 or 6 Gy × 5 fractions on consecutive days) induced an abscopal effect when combined with anti–CTLA-4 therapy, but single high doses of RT (eg, 20 Gy × 1) failed to do so. Their follow-up studies indicated that ablative RT doses (>12-18 Gy), compared to hypofractionated doses, were less effective and immunogenic, inducing less cGAS/STING pathway activation due to the breakdown of intratumoral cytosolic DNA by an exonuclease called Trex1, which is induced by higher RT doses.[175] As previously discussed, sensing of RT-induced cytosolic DNA by cGAS/STING resulting in IFN signaling is among the most important RT immune-modulatory effects. The expression of Trex after RT may be an important biomarker to guide the selection of RT dose and fractionation for IT. Despite these findings, it is important to note that the impact of fractionation schedules on

RT immune modulation should be considered an unresolved issue and that the use of ablative doses for immune modulation cannot be discounted. Clinical success combining RT and IT has been reported for both ablative and hypofractionated RT approaches. Two recent studies evaluating ablative RT + ICI in early-stage NSCLC by Monjazeb, Daly, and colleagues[244] and Heymach and colleagues[245] suggest a benefit of this approach. Another, similar recent study in early-stage NSCLC by Formenti and colleagues[246] used instead hypofractionated RT + ICI and also noted a benefit to this approach. None of these trials was phase III, and none of them compared ablative versus hypofractionated RT.

In summary, different RT fractionations can be seen as various immunomodulatory drugs, with functions ranging from immunogenic ablation and immune modulation of tumor cells to modulation of the TME's stromal cells.

Field Size and Irradiated Target

An issue that goes hand in hand with dose and fractionation is field size, as described above. Standard fractionation approaches often employ larger field sizes and may also target draining lymph node regions, whereas hypofractionated and ablative RT fields are often more tightly defined. As outlined in sections above, larger field sizes and increased fraction numbers will irradiate more blood pool and induce more cytotoxicity of circulating immune cells. Thus, strategies with large field sizes and many fractions may not be the optimal approach for maximizing the immune-modulatory effects of RT. In prostate cancer, an unexpected and unexplained interaction between RT field size (whole-pelvic radiation vs targeting the prostate only) and androgen deprivation was observed in RTOG 9413.[247] This interaction was confirmed in a large meta-analysis that also hypothesized that the field size interaction could be immune related.[248] The effects of field size may also explain the disparate outcomes between PACIFIC-1[249] and PACIFIC-2, which is discussed in the section "Sequencing."

An important concept is not just the volume of tissue being irradiated but also the nature of the tissue. As noted above in the introductory section on immune function, priming and activation of T cells occur primarily in the draining lymph nodes. Thus, elective nodal irradiation (ENI), which is

commonly employed in many standard fractionation approaches, may have unintended detrimental effects on RT immune modulation. This is an active field of study. Preclinical studies by Drake and colleagues[250] found that irradiation of draining lymph nodes limits adaptive immune responses by altering RT-induced chemokines and CD8+ T-cell trafficking and is detrimental to combining RT with IT. This was confirmed in preclinical studies by Karam and colleagues[251] in head and neck cancer models, which found that ENI limited the RT-induced immune response and the success of combining RT + IT. ENI decreased the systemic immune response including antigen-specific T cells and epitope spreading leading to increased local and systemic tumor growth. However, eliminating ENI increased regional nodal recurrence, serving as a clear caution that more study is needed to determine if and when ENI should be omitted.

Another point of consideration is that the irradiated site may also play a role in dictating the induction of immune-modulatory effects. For example, the liver is thought to be inherently immune suppressive and liver metastases have been reported to be less sensitive to IT than metastases at other sites.[252] A study at UC Davis by McGee et al[253] demonstrates differential immune effects of stereotactic body RT (SBRT) depending on the irradiated site. Irradiation of parenchymal sites significantly increased circulating levels of activated memory T cells, which was not observed with irradiation of nonparenchymal sites (bone, brain, etc).

Overall, these data suggest that in theory, standard fractionated RT may have the least favorable immune-modulatory effects and be the least well suited to combine with IT. However, before discounting standard fractionated RT as a viable partner for IT, it is important to note that in clinical practice perhaps, the most impactful application of RT + IT has been in the setting of standard fractionated chemo-RT for locally advanced NSCLC (PACIFIC-1).[249]

Sequencing

Similar to dose and fractionation, there is no established consensus as to the optimal sequencing of RT in combination with IT. Most likely, the optimal sequencing will be multifactorial depending on the IT strategy employed, the type of RT, and patient and TME factors. For example, preclinical

reports suggest that optimal sequencing of RT with IT may differ for Abs that block checkpoint molecules versus those that activate co-stimulatory molecules. In a report from Young et al[254] combining 20 Gy with either an inhibitor of CTLA-4 or an agonist of OX40 (CD134), the optimal timing depended on the mechanism of action of the IT agent. Anti–CTLA-4 was the most effective delivered prior to RT due to depletion of Tregs and anti-OX40 agonist Ab was the most effective sequentially 1 day following RT during the period of increased antigen presentation. Dovedi et al report that anti–PD-L1 Abs are the most effective delivered concurrently with RT. Clinical studies employ IT before, after, and concurrent with RT treatment without a strong rationale for the sequencing. Data and evidence examining how the sequencing of therapies influences the synergy of RT and IT agents represent a clear area of unmet need.

Recently, it has been reported that the PACIFIC-2 trial failed to meet its end points. Like PACIFIC-1, PACIFIC-2 tested standard fractionated chemo-RT + ICI for locally advanced NSCLC. While PACIFIC-1 enrolled patients and started ICI after completion of chemo-RT, PACIFIC-2 sought to test concurrent use of chemo-RT + ICI. The reason for the disparate outcomes between PACIFIC-1,[249] which was a strongly positive landmark trial, and PACIFIC-2 is not yet clear. It could be due to patient selection since PACIFIC-1 enrolled patients who did not progress on chemo-RT and who tolerated chemo-RT. Thus, patients destined to progress on or with poor tolerance of chemo-RT were enrolled in PACIFIC-2 and not on PACIFIC-1. However, beyond patient selection, there may be a genuine biologic difference between the approaches of these two trials. It is possible that chemo-RT given prior to ICI primes the immune system for response to ICI. It is also possible that chemo-RT given concurrently with ICI inhibits the efficacy of ICI. Since this is standard fractionated RT with large field sizes, it is possible that the very T cells being reinvigorated by ICI were being depleted by chemo-RT. These possibilities help illustrate the complexity and nuisance of the field.

Spatially Fractionated Radiation Therapy

A central principle of traditional RT is “Don’t miss the target.” Using a traditional cell-kill mentality, missed tumor is the untreated tumor and is

bound to recur. However, when thinking about radiation immune modulation, it is unknown if treating the entire tumor volume is necessary or beneficial for inducing immune modulation, since untreated tumor may be eradicated by the immune system. This consideration is particularly relevant as sometimes treating the entire tumor with the prescribed radiation dose is not possible due to the tumor's heterogeneous nature or potential harm to surrounding healthy tissue. To address this, spatially fractionated GRID RT (SFGRT) was developed.[255] This technique involves delivering the prescribed radiation dose to only a portion of the tumor volume, aiming to reduce local tumor burden and trigger a systemic immune response.[177] Originally, this approach utilized two-dimensional (2D) grid fields with orthovoltage beams to achieve spatially alternating dose distribution. Successful clinical responses were observed, particularly in the treatment of large bulky tumors. Preclinical studies using SFGRT have also shown abscopal effects, indicating that the treated tumors may have prompted immune cells to produce inhibitory factors, hindering tumor growth.[177] More recent preclinical studies have advanced SFGRT by modifying it into 3D GRID, allowing for a comparison between the effects of high-dose RT targeting the entire tumor volume versus only partial tumor volumes. This is because the irradiation of partial tumor volumes can induce the secretion of immune-related cytokines and activate the ceramide pathway, which affects both the nonirradiated intratumoral environment and distant metastases.[256] In a recent study, patients with bulky tumors were treated with partial tumor irradiation using SBRT to target hypoxic areas. Bystander response rate was 96%, while abscopal response rate in distant nontargeted tumors was 52%.[257] These studies demonstrated that irradiating partial tumor volumes with focused high-dose beams using lattice RT (3D SFGRT) might lead to immune stimulation. One consideration of this approach is that tumor areas in the dose peaks can receive high doses capable of inducing ICD whereas the areas in the dose valleys may still receive immune- modulating doses of RT.

FLASH Radiation Therapy

FLASH radiation therapy (FLASH-RT) involves the delivery of RT at very high dose rates compared to conventional RT. Generally, dose rates >40

Gy/s have been considered for FLASH-RT, but there is no single universally accepted cutoff. FLASH-RT has shown remarkable normal tissue-sparing properties, which enhances the differential effects of RT on tumor in relation normal tissues, and thus has shown great potential for significant increase in the therapeutic ratio. FLASH-RT is not a new concept. Initial published studies were completed as far back as the 1960s and 1970s[258,259]; however, given the technological advances over the past few decades and the significant potential for a paradigm shift from pursuing FLASH-RT, it is again attracting significant interest.[260] The underlying mechanism for FLASH-RT is still being studied. Proposed causes of the differential response between FLASH-RT and conventional RT include oxygen depletion and immune sparing. The oxygen depletion hypothesis is based on the idea that oxygen depletion in normal tissues protects them from damage due to reactive oxygen species while tumors are comparatively more hypoxic and thus less affected.[261] In contrast, the immune hypothesis posits that conventional RT results in greater irradiation of radiation-sensitive, circulating lymphocytes (larger total blood volume irradiated) in contrast to FLASH-RT, which provides greater immune sparing.[261] This strong immune-sparing effect was noted in a computation study that models the effects of FLASH-RT and found that the killing of circulating immune cells was reduced from 90% to 100% in conventional RT to 5% to 10% with FLASH-RT. It was also found that this sparing effect increased and reaches a plateau at doses/fraction of 30 to 50 Gy/fraction and almost completely vanished at lower doses of 2 Gy/fraction.[262] One study of proton FLASH-RT in mice found significantly smaller tumors in mice treated with proton FLASH-RT compared to conventional proton therapy as well as increased recruitment of CD8+ T lymphocytes while simultaneously reducing the percentage of immune-suppressive Treg among lymphocytes in the TME in tumors treated with FLASH-RT.[263] The early studies of FLASH-RT and its potential for immune sparing are promising. Further studies are needed to improve understanding of the underlying mechanisms and to also specifically exploit its immune-sparing effects, in combination with ITs and potentially with other immune-sparing techniques, such as spatially fractionated RT.[264]

Radiation Therapy Quality

EBRT most commonly employs photons, which are massless particles or waves. Photon radiation is characterized by its high penetration capability, which increases with energy, but dose deposition starts promptly upon entering the tissue.[265] Particle therapy involves depositing lower energy upon entry into tissue and generating Bragg peak radiation, which allows for more specific dose deposition into the target volume.[266] In addition to differences in the physics of dose deposition, particle therapy may have different biologic effects, which could also manifest as different or more pronounced immune-modulatory effects. For example, carbon ion RT (CIRT) has high linear energy transfer and a focused dose with reduced beam scattering, resulting in more precise dose distribution. Compared to traditional photon therapy, CIRT shows less sensitivity to cell cycles, making it a promising candidate for future combination treatment strategies.[267,268] Preclinical studies have demonstrated the potential of CIRT in inducing systemic antitumoral immunity in mouse models.[269-271] Preclinical studies by Drake and colleagues[272] and Zhou, Wang, and colleagues[273] suggest improved synergy of CIRT versus photon RT in combination with ICI. They also demonstrate in murine melanoma models that compared to photon RT, carbon ion induces a greater influx of lymphocytes into the TME, greater functionality of those lymphocytes, and also reduces MDSCs to a greater extent.[274]

RADIOTHERAPY PLUS IMMUNOTHERAPY

The antitumor immune response induced by RT is rarely strong enough to induce clinically meaningful regression of systemic disease (abscopal effect). While altering methods of RT delivery to improve its immunogenic effects may help to some degree, combinations strategies with IT are likely needed to amplify RT's immunogenic properties. Strategies combining RT and IT make mechanistic sense in that each therapy can benefit the other. RT's cytotoxic and immune-modulatory properties can enhance IT by debulking tumors, boosting the tumor's antigenic properties, inducing T-cell activation and influx, and making surviving tumor cells more vulnerable to immune-mediated elimination. IT can reciprocally assist RT by activating

the immune system to eradicate lingering disease both within and beyond the radiation field.

Significant progress has been made in our understanding of the interactions between RT and the immune system, and preclinical studies have demonstrated that RT can stimulate antitumor immunity and synergize with IT.[39,275] With multiple completed randomized trials, there is limited clinical evidence of the expected synergy between RT and IT,[129,276-280] but most of the focus has been on combining RT with ICI. Additional preclinical and clinical studies are required to further elucidate optimal strategies for combining RT and IT.

Devising an optimized methodology for combining RT with IT can be explored in the context of the cancer immunity cycle.[281] This cycle involves several steps: (1) RT-induced release of cancer antigens, (2) antigen presentation by DCs and other APCs, (3) T-cell priming and activation in draining lymph nodes, (4) trafficking of activated T cells from draining lymph nodes to the bloodstream, (5) infiltration of T cells into tumors, and (6) recognition and killing of cancer cells. RT can be combined with various tumor vaccines and immune adjuvants such as TLR agonists, STING ligands, and agonist anti-CD40 for the first two steps. For step 3, agonistic Abs that enhance T-cell activation (eg, anti-OX40, anti-CD27, and anti-CD137), cytokines (eg, IL-2 and IL-12), and immune checkpoint blockade (eg, anti–CTLA-4) can be used during the immune priming phase. To improve T-cell infiltration into tumors (steps 4 and 5), low-dose regimens of RT and anti-VEGF therapy can be employed. Finally, to enhance cancer cell recognition and killing by tumor-infiltrating CTLs (step 6), epigenetic modulation can be utilized to increase RT-induced antigen presentation and class I MHC expression in tumor cells. Immune checkpoint blockade with agents targeting anti–PD-1, anti–PD-L1, anti-Tim3, and anti-LAG3 can then counter tumor-evading strategies and reinvigorate exhausted T cells, sustaining a robust antitumoral immune response.

Cellular Therapies

As outlined in the section “Radiation Immune Modulation,” RT can both induce influx of effector cells into the TME and sensitize cancer cells to killing by effector cells. For these reasons, combining RT with adoptive

transfer of effector cells in the form of ex vivo expanded TILs, TCR transgenic T cells, CAR-T cells, or CAR-NK cells is a rational approach with a strong preclinical foundation. Preclinical studies demonstrate that adoptive transfer of T cells[167,168] or NK cells[179] is more effective when combined with RT due to increased immune-attracting chemokines, vascular normalization increasing tumor infiltration of immune cells, and increased sensitization of the tumor cells to killing by effector immune cells. Likewise, a translational study from a pancreatic clinical trial incorporating chemo-RT demonstrated that RT increased CXCL8 and NK cells systemically and, in the TME, the magnitude of which was associated with improved clinical outcomes.[282] Several preclinical studies also demonstrate synergy of combining CAR-T cells with RT. A preclinical study using EGFR targeting CAR-T cells in triple negative breast cancer demonstrated that RT increased lymphocyte infiltration into tumors and enhanced the efficacy of CAR-T therapy.[283] Clinical studies in hematologic malignancies have reported that bridging strategies using RT prior to CAR-T therapy appear to be safe and effective. Analysis of a Chinese clinical trial using CAR-T for patients with relapsed/refractory diffuse large B-cell lymphoma (DLBCL) reveals that pretransplant conditioning with RT (vs chemotherapy) increased response rates.[284] Likewise, a multicenter retrospective analysis of DLBCL treated with CAR-T demonstrates that patients who received bridging or salvage RT had no increased toxicity but had improved clinical outcomes.[285] While there is an abundance of preclinical data and circumstantial evidence to support this combination, conclusive clinical evidence is still needed and many studies are underway.[286]

Antibody Therapies

As outlined in the section on immuno-oncology, numerous Ab therapy approaches exist. For the purpose of this discussion, we focus on Ab therapies that seek to inhibit T-cell signaling through suppressive T-cell co-receptors (ie, ICIs or ICI) and those that seek to agonize stimulatory T-cell co-receptors.

Immune Checkpoint Inhibitors

ICI therapy has spear headed the cancer IT revolution. Likewise, the greatest abundance of preclinical and clinical studies in combining RT + IT has focused on ICI. Numerous preclinical studies demonstrate a strong synergy between RT and ICI. We will not attempt to review the body of preclinical data here. These preclinical studies in conjunction with clinical case reports that demonstrated the abscopal effect of RT + ICI (eg, Postow et al[287] and Hiniker et al[288]) sparked unprecedented interest in the field and a frenzy of clinical trials followed. However, replicating the results of preclinical studies and case reports with RT + ICI has been challenging, indicating that the design of clinical trials may play a crucial role in testing these combinations. In retrospect, it is reasonable to conclude that the pace of development was too fast, based on too little science, incorporated too little collaboration with seemingly every academic cancer center having their own iteration of an RT + ICI trial, and ultimately was harmful to the development of the field. The abundance of studies is such that they cannot be encompassed here, but salient studies are highlighted to outline the progress made and lessons learned.

The most experience and greatest body of clinical data for combining RT + IT exists in the setting of NSCLC. Retrospective data and some clinical trials have shown that the combination of RT and checkpoint inhibitors offers significant benefits in several disease sites. The phase 1 KEYNOTE-001 trial assessed the safety, side-effect profile, and antitumor activity of pembrolizumab. A secondary analysis compared patients who had received prior RT with those who had not. The OS with pembrolizumab was significantly longer in patients who had received any form of prior RT compared to those without previous RT. The same trend was observed for patients who had received extracranial RT compared to those without previous extracranial RT. However, patients who had previously received thoracic RT also experienced higher rates of pulmonary toxicity. Overall, the study suggests that prior treatment with RT in patients with advanced NSCLC resulted in longer PFS and OS with pembrolizumab treatment, while maintaining an acceptable safety profile.[289]

The groundbreaking PACIFIC trial established the role of IT as standard of care in the definitive treatment of locally advanced NSCLC. In this phase 3 study, durvalumab, an anti–PD-L1 Ab, was compared with placebo as consolidation therapy after chemo-RT in patients with stage III NSCLC

who had not experienced disease progression after two or more cycles of platinum-based chemo-RT. The results were impressive, with durvalumab attaining significant improvement in median PFS (17.2 vs 5.6 months) and OS (2 year OS of 66.3% vs 55.6%) when compared to placebo. In addition, durvalumab showed higher response rates and longer duration of response without significant increase in toxicity.[249,290] These exciting results led to the subsequent stage III PACIFIC-2 trial evaluating the addition of concurrent durvalumab with chemo-RT. Unfortunately, the results show that concurrent durvalumab does not significantly improve PFS. While there were several differences between the trials, the discrepancy in results may indicate that the timing of IT in relation to RT is a critical factor in unleashing the full synergistic effect of both treatments. As outlined previously, combining IT concurrently with large field fractionated RT may be counterproductive due to the volume of irradiated blood pool.

RT + ICI is also being studied for early-stage NSCLC. Studies evaluating ablative RT with ICI patients with in medically inoperable NSCLC who are rarely offered systemic therapy demonstrated the safety and suggest a benefit with this approach.[244,245] Similarly, the use of hypofractionated RT with ICI has also been evaluated, also showing a benefit with this approach.[246] These early trials have led to several prospective randomized stage III trials evaluating the role of IT in combination with RT in early-stage NSCLC. This includes the phase III PACIFIC-4 trial[291] of adjuvant durvalumab with SBRT; the phase III SWOG 1914 trial[292] of induction, concurrent, and adjuvant atezolizumab with SBRT; and the phase III KEYNOTE-867 trial of concurrent and adjuvant pembrolizumab with SBRT,[293] all for early-stage NSCLC. These trials are not only studying different ICI regimens/durations but also employing different timing of the IT in relation to RT, which may provide additional insights.

Clinical successes are not limited to NSCLC. The randomized, double-blind, placebo-controlled phase 3 CheckMate 577 trial testing nivolumab as adjuvant therapy in patients with locally advanced esophageal or gastroesophageal junction cancers with pathologic residual disease after neoadjuvant chemo-RT and surgery was practice changing. The results showed that the addition of adjuvant nivolumab significantly improved disease-free survival (DFS) from 11 to 22.4 months.[294] Another recent trial with positive results is the phase 3 KEYNOTE-A18/GOG-3047 trial

evaluating the addition of concurrent and adjuvant pembrolizumab to concurrent chemo-RT followed by brachytherapy in patients with high-risk locally advanced cervical cancer. After a median follow-up of 17.9 months, there was a statistically significant improvement in 2-year PFS to 67.8% with the addition of pembrolizumab compared to 57.3% with placebo.[295] While there have been significant successes and the practice-changing studies are quite encouraging, there have also been multiple completed randomized trials with limited clinical evidence of the expected synergy between RT and IT.[129,276-280] For example, the GI002 trial, which evaluated the addition of pembrolizumab to neoadjuvant chemo-RT in locally advanced rectal cancer, did not show an improvement in DFS.[296] Similarly, the JAVELIN Head and Neck phase 3 trial, which evaluated the addition of avelumab to definitive concurrent chemo-RT followed by maintenance of avelumab in locally advanced head and neck squamous cell carcinomas, failed to show a benefit in PFS.[297] Importantly, these studies, whether showing a clinical benefit, have generally demonstrated the safety of combining ICI with RT in various types of cancers (including cervix, head and neck, lung, and brain[298] cancers and more). When used alongside RT, single-agent PD-1/PD-L1 or CTLA-4 inhibitors seem to have minimal added toxicity and more recent studies also show little added toxicity of adding RT to dual-checkpoint blockade.[129,234]

What has been particularly disappointing is not the number of negative trials, but the lack of data demonstrating synergy between RT and ICI. While there have been positive randomized trials, these trials generally demonstrate the benefit of adding ICI to standard-of-care RT or chemo-RT, which could be the result of independent additive effects of each therapy as opposed to a true synergism relying on RT immune modulation. Studies trying to demonstrate a true synergy by demonstrating that RT can induce a systemic response to ICI in patients with primary or acquired resistance to ICI or in histologies otherwise unresponsive to ICI have been negative. For example, both of these scenarios were tested by Schoenfeld and colleagues[129,234] through the ETCTN by combining RT with dual-checkpoint inhibition in patients with metastatic NSCLC resistant to ICI and in metastatic microsatellite stable colorectal cancer, both of which failed to show a benefit to RT + dual ICI.

Co-stimulatory Molecules

It is possible that RT alone does not provide enough T-cell activation and in situ vaccine effect to produce meaningful antitumor immunity. Combining RT with immune stimulants may help address this issue. The activation of antigen-specific T-cell responses necessitates the presentation of antigens and the presence of co-stimulatory molecules (B7-1/2, OX40L, CD40, or 41BBL) on DCs to interact with their respective ligands/receptors on T cells.[111] Preclinical trials have indicated that exposing human prostate cancer cells to ionizing radiation enhances the expression of co-stimulatory ligands (OX40L and 41BBL) while decreasing PD-L1 levels, resulting in improved CTL function.[182] This led to the idea that localized expression of co-stimulatory molecules and cytokines within the TME could enhance the activation of effector T cells. Preclinical studies have shown that introducing co-stimulatory ligands into the tumor can bolster antitumor immune responses.[299] The OX40 (TNF-receptor family member) on activated T cells stimulates T-cell proliferation, effector differentiation, and expansion of effector memory T-cell populations while suppressing Treg function. In a murine sarcoma model, combining RT with agonistic Abs for OX40 demonstrates promising results with increased tumor control and OS.[300] Several preclinical studies also suggest a benefit of combining RT with CD40 agonists. CD40 is expressed on DCs, B cells, and macrophages and upregulates the activity of these cell types when engaged by its ligand CD40L, which is primarily expressed on activated T cells. RT was combined with an agonist anti-CD40 Ab to treat B-cell lymphoma, leading to improved long-term survival.[301] Another study by Vonderheide and colleagues[302] demonstrated that adding CD40 agonist Ab to RT + ICI in a pancreatic cancer model was able to eradicate irradiated and unirradiated tumors. A recent clinical trial tested combinations of ICI, 41BB agonist, OX40 agonist, and RT in advanced gynecologic malignancies and observed a response rate of 3%.[303] Patients were accrued in a nonrandomized manner, there were only 35 evaluable patients across 6 arms, and very few patients were treated on the arms incorporating RT, limiting interpretation of the results.

Innate Agonists

One of the critical steps in generating an immune response is the activation of innate immunity by DAMPs and PAMPs, which is key to the eventual production of adaptive immunity. Many of the immune-modulatory effects of RT and the induction of ICD are thought to be mediated by the generation of DAMPs. However, since RT rarely induces abscopal effects alone, it stands to reason that combining RT with agonists of the innate receptors that recognize DAMPs and PAMPs may increase its vaccine effect. While this area has received relatively little attention compared to ICI, perhaps the best clinical data for synergy of RT and IT employ innate agonists as outlined in our prior review.[43]

The TLRs are among the best studied of all pattern recognition receptors. Exciting preclinical data exist for combining RT with various TLRs, including TLR4 and TLR7.[43] We focus our discussion on TLR3 and TLR9 since these have been tested clinically in combination with RT. TLR3 senses double-stranded RNA and can be activated by the synthetic ligand poly(I:C). No randomized studies employing RT and TLR3 agonists have been reported, but two phase II studies demonstrated improved survival compared to historical controls in patients with glioblastoma.[43] Brody and colleagues[304] further reported abscopal responses and complete remission in patients with indolent non-Hodgkin lymphoma treated with RT, TLR3 agonist, and Fms-like tyrosine kinase receptor 3 ligand (FLT3L). TLR9, like TLR3, has a broad expression profile, in B cells, DCs, and macrophages. TLR9 is a receptor for unmethylated CpG oligonucleotide DNA sequences that are present in pathogens, but not for mammalian DNA. It also recognizes endogenous DAMPs, such as chromatin DNA complexes and ribonucleoproteins. Synthetic CpG oligonucleotides are used therapeutically and can be administered systemically but, in the setting of cancer therapy, are most often administered intralesional. Clinical studies combining RT + TLR9 agonists demonstrate that this combination is safe and effective. A series of clinical trials by Levy and colleagues in low-grade lymphomas demonstrate a genuine synergy of this approach by inducing abscopal responses outside the irradiated and injected lesion in about 20% of patients with heavily pretreated systemic[305] or cutaneous[306] indolent lymphoma. Many of the responses were durable and lasted for months or years. This is particularly exciting, given that CpG is not known to have single-agent activity and RT rarely induces abscopal effects alone; thus, the systemic

response rates in these trials likely demonstrate a true synergy between these agents. Building on these findings, Monjazeb and colleagues[205] tested combining this approach with IDO inhibition to prevent rebound immune suppression triggered by the strong inflammation induced by RT + CpG. They report promising systemic efficacy and abscopal response of this approach in solid tumors when tested in mice and in a canine clinical trial in pet dogs with spontaneous cancers. This has since been translated into a human clinical trial with preliminary reports suggesting activity in solid tumors and lymphomas (NCT03322384 presented at ASTRO 2020). However, two similar trials using this approach with a different CpG agent and incorporating ICI instead of IDO inhibition reported limited activity of this approach.[307,308]

Other innate agonist pathways such as RIG-I–like receptors, FLT3, and STING have also shown great promise in preclinical studies.[43] STING agonists are being tested in clinical trials, but there are no reports publishing the outcomes of STING + RT in clinical trials. Likewise, there are no clinical reports of RIG-I agonists + RT. However, it is important to note that the TLR3 agonist poly(I:C) likely also exerts some effects through agonism of RIG-I. FLT3 is a receptor, which, like CD40, is expressed on a variety of APCs (B cells, macrophages, DCs) and, when triggered, can lead to the expansion and maturation of APCs. FLT3L is a cytokine that activates FLT3, and various agents targeting this pathway are being tested in clinical trials. Preclinical studies from Guha and colleagues[309,310] in murine models of metastatic lung cancer and hepatocellular carcinoma demonstrate a systemic effect of RT + FLT3L mediated by DC expansion. Combining RT of the primary tumor with the administration of FLT3L not only controlled the primary tumor but also suppressed the spread of metastasis and resulted in a cure.[309] Numerous clinical trials are testing various combinations, including FLT3L and RT or radiopharmaceuticals. Also, the published study mentioned above when discussing TLR3 agonists shows promising outcomes when combining FLT3L, RT, and poly(I:C).[304]

Cytokines

Among the first ITs was administration of IL-2 or IFN. IL-2 is a strongly immune-stimulating cytokine that is critical to T-cell activity. The high-

affinity receptor for it is expressed on activated T cells (but also on suppressive Tregs), and it may synergize with RT but support an RT-induced T-cell response. Combining local tumor irradiation with systemic IL-2 therapy or intratumoral injection of an immunocytokine has shown positive results in reducing tumor burden and enhancing Ab-dependent cell-mediated cytotoxicity and tumor-specific memory T-cell responses in preclinical mouse models of cancer.[311-313] Two clinical studies from the Earl Chiles Research Institute in metastatic melanoma and renal cell cancer have demonstrated the promise of this approach and suggest that combining IL-2 with ablative RT can increase systemic response rates beyond IL-2 alone.[155,156] Given the toxicity of high-dose systemic IL-2, there are also trials underway testing RT in combination with intralesional IL-2 and with engineered formulations of IL-2, which are less toxic. The CapRI regimen incorporating chemo-RT with type I IFN garnered significant attention for pancreatic cancer based on work out of Virginia Mason, which showed 42% 5-year survival for patients after pancreaticoduodenectomy.[314] The toxicity of this approach as well as the negative results of a larger trial from Germany has dampened enthusiasm for this approach, but ongoing trials are still exploring type I IFN + RT. Preclinical studies have also suggested a potential benefit for combining RT with various other immune-stimulatory cytokines, including IL-12 and IL-15.

Vaccines

There is a strong mechanistic rationale for combining RT with vaccine approaches. A vaccine aims to generate T cells directed against cancer antigens. RT can enhance the effectiveness of cancer vaccines via cytotoxic and immunomodulatory effects on the TME. RT can increase cancer cell antigen presentation and stress ligand expression, yielding them easier to detect and kill by vaccine-generated T cells. RT also alters the TME vasculature and cytokines, increasing the trafficking and homing of T cells to the TME. RT debulking effects improve oxygen and nutrient delivery in the TME, providing a less hostile environment for T-cell function. Clinical trials have demonstrated increased tumor immunity when combining DC vaccines with RT. For instance, one phase I study involving 14 patients with advanced-stage/metastatic hepatoma showed improved tumor-specific

immune responses in 7 out of 10 assessable patients when RT was combined with the injection of autologous immature DCs.[315] Another recent trial with 40 patients having recurrent, metastatic, or locally advanced tumors of the head and neck, pancreas, lung, esophagus, or uterus, treated with an autologous DC-based vaccine in combination with conformal RT also showed promising clinical responses.[316] However, to date, despite many clinical trials, there are no practice-changing or widely clinically used RT + vaccine approaches. As the development of personalized neoantigen vaccines continues, the potential of this combination may become realized.

CONCLUSION

After decades of research, the promise of cancer IT is now changing the lives of patients. Yet, we are just at the nascent stages of understanding how cancers evade immune attack and how to best harness the immune response to fight cancer. It is likely only through the perspective of the coming decades that we will understand the full scale of the revolution we are witnessing. Likewise, we are just beginning to understand the potential effects of RT in modulating the immune system. The complexity of radiation responses and the complexity of the immune system itself indicate that the optimal strategies to capitalize on the immune modulatory effects of RT and to combine RT with IT are likely to be complex as well. While we have made remarkable advances, we must also take the time to learn from our many failures and mistakes. As a field, we must have the humility to acknowledge that the path forward requires improved understanding and renewed commitment and that investment in scientific endeavor is needed. Unquestionably, our path forward will continue to be fraught with many failures and mistakes, but the potential reward for our patients is why we make the journey.

CHAPTER 27

Hyperthermia

Mark Hurwitz, Mark Dewhirst, and Johannes Crezee

Hyperthermia (HT), the therapeutic application of heat, has potential and in several scenarios established benefit in treatment of malignancies. While ablative temperatures can result in direct tumor kill, application of moderate temperature elevation in the range of 39 to 45 °C can enhance the effectiveness of radiation, chemotherapy (CT), and potentially immunotherapy. Since the introduction of HT into the clinic in the 1980s, similar to radiation therapy, significant advancements have been made. These advancements include better appreciation of how to exploit the underlying biology, treatment device development to meet clinical needs, establishment of quality assurance guidelines, and successful completion of randomized trials.

THE BIOLOGY OF HYPERTHERMIA

Definition of Hyperthermia

When cells or tumor tissues are subjected to elevated temperatures, several effects occur that have important biologic consequences for cancer therapy: (1) HT is cytotoxic and sensitizes tumor cells to radiotherapy (RT) and CT. (2) Thermally induced reoxygenation improves tumor responses to RT and CT.[1] (3) HT inhibits RT and CT-induced DNA damage repair.[2] (4) HT increases tumor microvessel permeability and pore size, increasing macromolecular and nanoparticle drug delivery, respectively.[3] (5) HT augments host immune responses against tumor cells in ways complementary to immune effects of RT and CT.[4]

Effects of Hyperthermia Alone on Cell Survival

HT kills cells in a log-linear fashion depending on the time at a defined temperature (Figure 27.1A). At *T* of less than 43 °C, a resistant tail may appear; the tail is caused by induction of thermotolerance that increases resistance to further HT damage.[5] Thermotolerance is not observed during HT above 43 °C but is observed for varying lengths of time (hours to several days) after HT[5] depending upon the temperature and length of heating. HT kills hypoxic cells as efficiently as aerobic cells. However, cells that are nutrient deprived, as might occur in chronically hypoxic tumor regions, are more heat sensitive than aerobic cells.

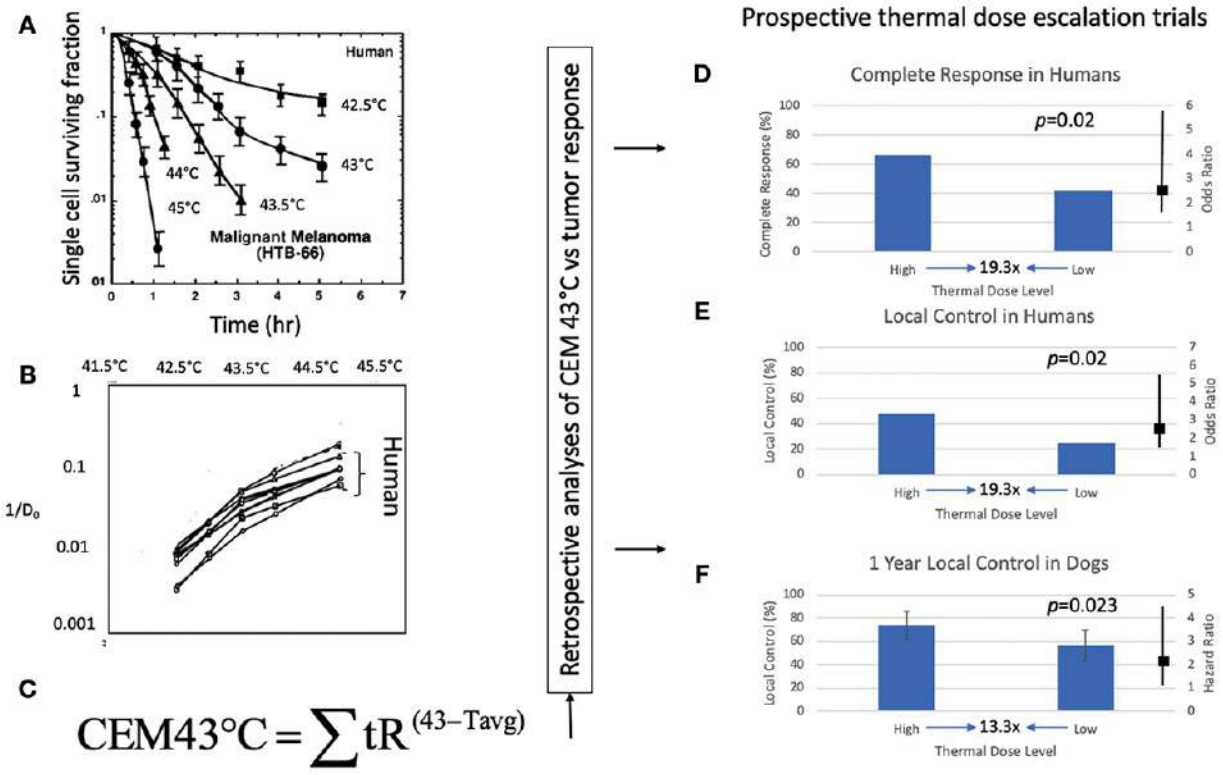

FIGURE 27.1 Summary of key principles of thermal dosimetry. A. The fundamental basis for thermal dosimetry is based upon characteristics of in vitro cell survival curves. The rate of cell killing is temperature dependent. The change in slope during heating for *T* 43 °C or less is caused by induction of thermotolerance. Thermotolerance is an adaptive response to thermal stress and leads to transient resistance to hyperthermia (HT). B. Arrhenius analysis of cell-killing rate versus temperature. A cluster of human cell lines is highlighted by the bracket to the right of the plot. A break point (change in slope) is observed between *T* of less than 43 °C versus more than 43 °C. Above the break point, the rate of cell killing doubles for each 1 °C temperature elevation, whereas below the break point, the rate of cell killing drops by a factor of 4 to 8 for each 1 °C temperature drop. C. The characteristics of the Arrhenius relationship enable straightforward conversion of any time-temperature history to cumulative equivalent number of minutes at 43 °C (CEM43°C) using the equation depicted here. *t*, time of heating; *R*, coefficient related to change in slope of the Arrhenius plot. Typically for *T* more than 43 °C, *R* = 0.5, for *T* less than 43 °C, *R* = 0.25; T_{avg} is the average temperature during the time interval *t*. For a complex time-temperature history, the heating profile is broken into intervals of time (*t*) length, where temperature remains relatively constant. CEM43°C is calculated using the average *T* (T_{avg}) for each interval, and the resultant data are summed to give a final CEM43°C for the entire heating regimen. Because multiple locations are measured in each tumor, descriptors of the temperature distribution are used. Examples include T_{50} = median and T_{90} = 10th percentile of the distribution. Retrospective analysis of thermal data from several clinical trials showed relationships between thermal dose and outcome. To further test the value of thermal dose to influence HT + RT (radiotherapy) outcome, two prospective randomized clinical trials were conducted. In the human and canine trials, the delivered thermal dose (CEM43°C T_{90}) varied by factors of 19 and 13 between low and high thermal dose groups, respectively. D

and E. Key results from the human trial with superficial tumors treated with HT + RT. The higher thermal dose group (N = 56; 19.3× higher than low thermal dose group N = 52) was associated with significantly higher response rate and longer duration of local control. Odds ratios are shown on the right side of each panel. The relative difference in CEM43°C T_{90} for the low and high thermal dose groups is indicated on the X-axis. F. Key results from a study of companion dogs with soft tissue sarcomas treated with HT + RT. The higher thermal dose group (N = 58) had a 13.3× higher thermal dose than the low thermal dose group (N = 64; P < .0001). The high thermal dose group exhibited significant prolongation of local tumor control compared with the low dose group. The hazard ratio is shown on the right side of the panel. The relative difference in CEM43°C T_{90} for the low and high thermal dose groups is indicated on the X-axis. These trials were provocative, but much more work is required to verify the validity of this approach for thermoradiotherapy. Further, thermal dosimetry has not been tested in trials involving chemotherapy.

Thermal Isoeffect Dose: The Arrhenius Relationship

The temperature dependence of cell-killing rate by HT has been studied using Arrhenius analysis.[5] The log of the slope ($1/D_o$) of cell survival curves versus temperature (Figure 27.1B) shows a biphasic curve. The temperature at which the slope changes is referred to as a "break point." The break point is near 43 °C for rodent cells but closer to 43.5 to 44 °C for human cells. Above the break point, an increase in temperature of 1 °C doubles cell-killing rate. Below the break point, the cell-killing rate drops by a factor of 4 to 8 for every temperature drop of 1 °C. Sapareto and Dewey[6] proposed normalizing thermal data by converting any time-temperature data to a cumulative equivalent number of minutes at 43 °C (CEM43°C) (Figure 27.1C). HT creates nonuniform temperatures within tumors, so multiple measurements are made. Descriptors of the temperature distribution are used to describe aspects of the spatial variation, such as the median (T_{50}), or the 10th percentile (T_{90}). CEM43°C T_{90} and T_{50} represent the lower end and average of the temperature distribution, respectively. Both CEM43°C T_{90} and T_{50} have been frequently associated with treatment outcomes in retrospective analysis of thermoradiotherapy trials.[7,8] Two prospective clinical trials showed therapeutic benefit of deliberately creating a 10- to 15-fold difference in CEM43°C T_{90} between low and high HT dose groups[1] (Figure 27.1D, E). Thermal analyses of some trials have not shown a thermal dose effect, which is likely due to inadequate thermometry.[9]

Standardization of treatment, thermometry, and reporting are needed for future studies.[7,10-14]

Mechanisms of Hyperthermic Cytotoxicity

Cellular and Tissue Responses to Hyperthermia: Targets for Hyperthermic Cytotoxicity

Proteins are the predominant molecular targets for hyperthermic cell killing.[15] When cells are exposed to HT, proteins are denatured at rates paralleling those for cell killing. Further, synthesis of nearly all proteins is stopped with the exception of heat shock proteins, the synthesis of which is upregulated.[16] One of the primary functions of heat shock proteins is to refold other proteins that have been denatured or damaged.[17]

The cytoskeleton of cells is particularly heat sensitive.[18] Cytoskeletal collapse disrupts cytoskeletal-dependent signal transduction pathways.[19] Enzymes in the respiratory chain are more heat sensitive than enzymes in the glycolytic pathway.[1] Most DNA repair proteins responsible for repairing RT and CT damage are relatively heat sensitive.[2]

Thermotolerance and Clinical Trial Design

Thermotolerance is a transient adaptation to thermal stress that renders surviving heated cells more resistant to additional heat stress. Whether or not a cell dies as a result of thermal insult is dependent on the net balance between how much protein is damaged and how much is protected and repaired via upregulated heat shock proteins. Thermotolerance develops either during or after heat stress and can persist for several days. The time of peak thermal resistance and the time of thermotolerance decay are related to the severity of the heat shock.[5] Concerns over the persistence of thermotolerance after HT impacted the design of many HT + RT clinical trials. In most trials, a minimum of 48 hours between HT fractions has been used to avoid reheating when cells are thermotolerant. The potential for thermotolerance after HT gave pause to the concept of delivering HT daily in conjunction with daily RT.

It has been argued that one should take advantage of HT-radiosensitization by giving HT multiple times per week. The degree of HT-

mediated cytotoxicity is low because temperatures are largely below that needed for direct cell killing. Further, HT-radiosensitization is relatively unaffected by thermotolerance.[20] A canine clinical trial was conducted using patients with soft tissue sarcomas. HT was given either once or 4 times a week in combination with fractionated RT.[21] By design, total CEM43°C T_{90} was equivalent between the two arms, meaning that the CEM43°C per fraction was higher in the arm that had a lower number of HT treatments. Treatment outcome was better for one fraction per week arm. These results suggest that thermotolerance induction in the more fractionated HT schedule inhibited direct HT cell killing, which blunted the HT + RT response. In other words, direct HT cytotoxicity is an important component governing HT + RT treatment outcome.

Immunologic Implications of the Heat Shock Response

Like RT, HT augments immunologic responses toward tumors.[4] Examples of effects that are known to occur after HT include: (1) increased immunogenicity, (2) increased T cell, natural killer cell, and dendritic cell maturation and activity, and (3) enhanced IL6-mediated trafficking of immune effector cells into tumors and lymphatic organs. These effects have been shown to be complementary to immune stimulation by RT.[22]

Hyperthermia and Physiology

As temperatures are elevated, tissue perfusion increases, but at higher temperatures, vascular stasis, hemorrhage, and hypoxia develop.[23] The change in normal tissue perfusion in response to HT is greater than one sees in tumors. Muscle and skin perfusion increase by about 10-fold, whereas tumor perfusion may increase by 1.5- to 2-fold. The difference in vascular response between tumor and normal tissue may be clinically advantageous since it can contribute to preferential tumor heating.

Effects of Hyperthermia on Tumor Metabolism and Oxygenation

Aerobic metabolic enzymes (respiration) are more heat sensitive than enzymes driving anaerobic metabolism.[1] About 43 to 44 °C HT for 30 to 60 minutes reduce adenosine triphosphate concentrations, which reflects

reduced mitochondrial activity. Decreases in mitochondrial activity reduce oxygen consumption rates in murine and human tumor lines.[1] A reduction in respiration rate decreases oxygen consumption rate, which contributes to improved tumor oxygenation. Oleson[24] suggested that clinical benefits of HT may result from improvements in oxygenation. It must be kept in mind, however, that higher HT exposure causes vascular damage (eg, median $T >$ 44 °C, 60 minutes) and decreases tumor oxygenation.[23]

The combination of reduced oxygen consumption rate and improved perfusion after HT improves tumor oxygenation in a majority of canine (sarcoma) and human tumors (sarcoma and locally advanced breast cancer).[1] HT-induced reoxygenation is complimentary to RT-induced reoxygenation. Further study is needed to fully understand whether there is a consistent link between HT-mediated reoxygenation and HT + RT treatment outcome.

Physiologic Approaches to Enhance Thermal Cytotoxicity: pH Modification

Chronically acidic cells are not more sensitive to HT than normal cells, but acute reduction in intracellular pH (pH_i) of such cells can greatly enhance their HT sensitivity.[25] The enhancement in killing is substantial if the pH_i drop is greater than 0.2 pH units. Hyperglycemia pushes tumors toward glycolysis and increases lactic acid production. In humans, the drop in extracellular pH after induction of hyperglycemia is about 0.17 pH units, which is not sufficient to reduce pH_i and create thermal sensitization.[26] One could further drop pH_i by using pharmacologic agents that block hydrogen ion extrusion from cells, which is normally accomplished via membrane-bound pumps. Although promising, this approach has not been tested in clinical trials.

Blood Flow Manipulation

Pharmacologic tumor perfusion reduction leads to increased tumor temperatures. Preclinically, vasoactive agents (hydralazine, nitroprusside, and angiotensin II) reduce tumor blood flow and enhance antitumor effects of HT. Clinically, however, drug-induced changes in blood pressure limit

doses of vasoactive drugs. Accordingly, tumor temperatures were not changed in either human or canine patients treated with HT and vasoactive drugs.[27,28]

Radiation and Hyperthermia

Rationale for Combining Hyperthermia + Radiotherapy

When RT is combined with HT, complementary effects occur. Cells in cell cycle S phase are relatively radioresistant, but these cells are most sensitive to HT. Hypoxic cells are 3 times more resistant to RT, compared with aerobic cells. In contrast, there is no difference in HT sensitivity between aerobic and acutely hypoxic cells, but chronically hypoxic, nutrient-deprived cells are more HT sensitive than aerobic cells.

The interaction between RT and HT is described by the "thermal enhancement ratio" (TER), defined as the ratio of doses of RT to achieve an isoeffect for RT + HT versus RT alone. TERs for local tumor control have been estimated for several human tumors.[29] In most tumor types examined, TERs were greater than 1.5 to 2 indicating that HT enhanced local tumor control compared with RT alone. TERs for normal tissue damage have been less than those for tumors in the same patient populations, suggesting potential for therapeutic gain for RT + HT. Prospective randomized trials in dogs with spontaneous tumors have shown improved local tumor control with RT + HT versus RT alone[30] with no observable increase in the frequency of clinically relevant late normal tissue complications. In summary, most available data from preclinical and clinical studies indicate that therapeutic gain is achievable for HT + RT.

Hyperthermia and Chemotherapy

Rationale for Using Hyperthermia With Chemotherapy

Many chemotherapeutic agents exhibit synergistic cell kill with HT including cisplatin, melphalan, cyclophosphamide, nitrogen mustards, anthracyclines, nitrosoureas, bleomycin, mitomycin C (MMC), and hypoxic cell sensitizers.[31] The mechanisms include (a) increased cellular drug uptake, (b) increased oxygen free radical production, (c) increased DNA damage and inhibition of DNA damage repair.[2] For drugs listed earlier, the

optimal sequence is to simultaneously administer HT + drug or to give the drug immediately before the onset of heating. The degree of interaction between drugs and HT is temperature and cell line dependent.[31] HT can reverse, at least partially, drug resistance for cisplatin, melphalan, and nitrosoureas.

For some drugs, in vitro results show no HT-induced synergism with CT, whereas there is a strong in vivo effect. Paclitaxel and MMC, for example, show little in vitro activity with HT + RT or CT, but clinical results for these combinations have been encouraging.[32] Stimulation of antitumor immunity toward stem cells is likely important for in vivo effects.[22]

Most antimetabolites do not interact with HT when given simultaneously.[31] 5-Fluorouracil (5FU) given simultaneously with HT yields only additive effects.[31] However, 39 to 41 °C HT enhances conversion of 5FU to active metabolites, thereby increasing drug cytotoxicity. Continuous infusion with 5FU leads to a cell cycle block in S phase, a relatively sensitive part of the cell cycle to HT. HT + etoposide yields unpredictable results; the current consensus is that synergistic interactions with etoposide are unlikely.[31] There is no evidence for synergistic interactions between vinca alkaloids and HT.

HT inhibits repair of both sublethal and potentially lethal damage by inactivating double-strand break DNA repair pathways.[2] Importantly, HT induces BRCA2 (BRCA2, DNA repair associated) degradation, providing rationale for combining HT with poly[ADP-ribose] polymerase-1 (PARP-1) inhibition. Enhancement of cytotoxicity to cisplatin and doxorubicin has been reported with the combination of HT and PARP-1 inhibitors.[33]

HT increases nanoscale drug delivery. These effects occur by selectively increasing microvessel pore size, thereby permitting enhanced transvascular delivery of nanoparticles, such as liposomes.[3] Further, enhancement of small drug delivery and efficacy can occur via the use of thermosensitive liposomes, which rapidly release drugs intravascularly, driving the drug into the interstitial space down an enhanced concentration gradient.[3]

Summary

In this brief review, we have shown multiple means by which HT augments RT and CT efficacy. For the most part, we have not emphasized the

temperature dependence of the different effects described in the text. Temperature dependence of primary effects is summarized in Figure 27.2.

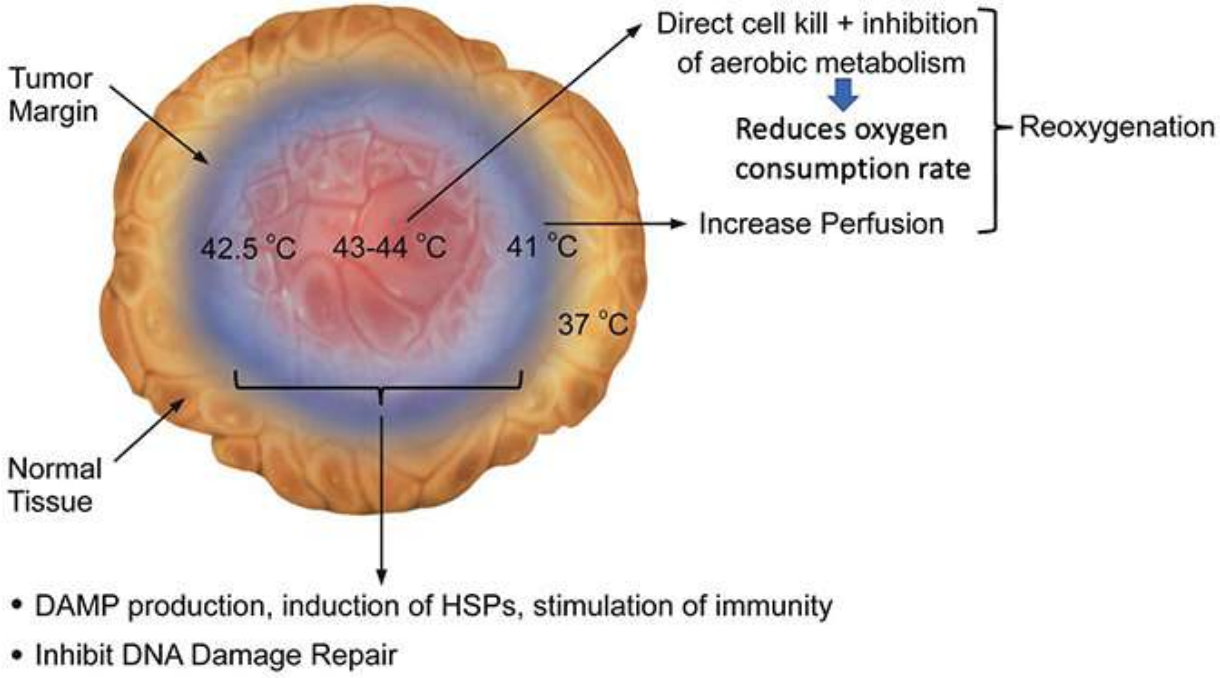

FIGURE 27.2 Key biologic effects of hyperthermia (HT) that contribute to enhanced HT + RT (radiotherapy) and HT + CT (chemotherapy) tumor response. Typical temperature distributions in heated tumors show a peaked profile, with higher temperatures in the center and lower temperatures toward the edge. Heating at temperatures of 41.5 °C and greater stimulates immunity and inhibits repair of DNA damage. Higher temperatures of 43 to 44 °C decrease oxygen consumption rates by killing some cells and by inhibiting respiration in remaining surviving cells. Hypoxic, nutrient-deprived cells are sensitized to HT killing. Reduction in oxygen consumption rate, combined with increases in tumor perfusion associated with milder temperatures, leads to reoxygenation. Reoxygenation has been associated with better treatment outcomes in several clinical trials. The important concept here is that the effects depicted occur simultaneously in different parts of a tumor either during or after heating. DAMP, damage associated molecular patterns; HSP, heat shock proteins. (Adapted from Dewhirst MW, Oleson JR, Kirkpatrick J, Secomb TW. Accurate three-dimensional thermal dosimetry and assessment of physiologic response are essential for optimizing thermoradiotherapy. *Cancers (Basel)*. 2022;14[7]:1701. https://creativecommons.org/licenses/by/4.0/.)

For typical peaked temperature distributions, the beneficial effects described occur simultaneously in different parts of a tumor.[34] In the future, HT prescriptions may focus on key characteristics of the tumor temperature distribution, which can simultaneously induce a plethora of beneficial HT

effects, including reoxygenation, inhibition of DNA damage repair, and stimulation of antitumor immunity. It is likely that therapeutically beneficial temperature distributions are already achieved in many tumors, which likely contribute to the success of the reported positive randomized trials.[35] Alternatively, uniform temperature distributions, which are not currently clinically achievable, are likely counterproductive. Uniform temperature distributions may not efficiently decrease oxygen consumption rate while reliably improving perfusion. Ultimately, thoughtful application of HT based on sound biologic principles holds great promise for enhancing clinical outcomes.

HYPERTHERMIA PHYSICS AND APPLICATION

Since the 1980s many different devices have been developed for inducing HT at 40 to 43 °C for 1 hour, aiming at tumor-selective sensitization for RT and CT. This section and Figure 27.3 outline the heating techniques used for different tumor sites.[34,36-38]

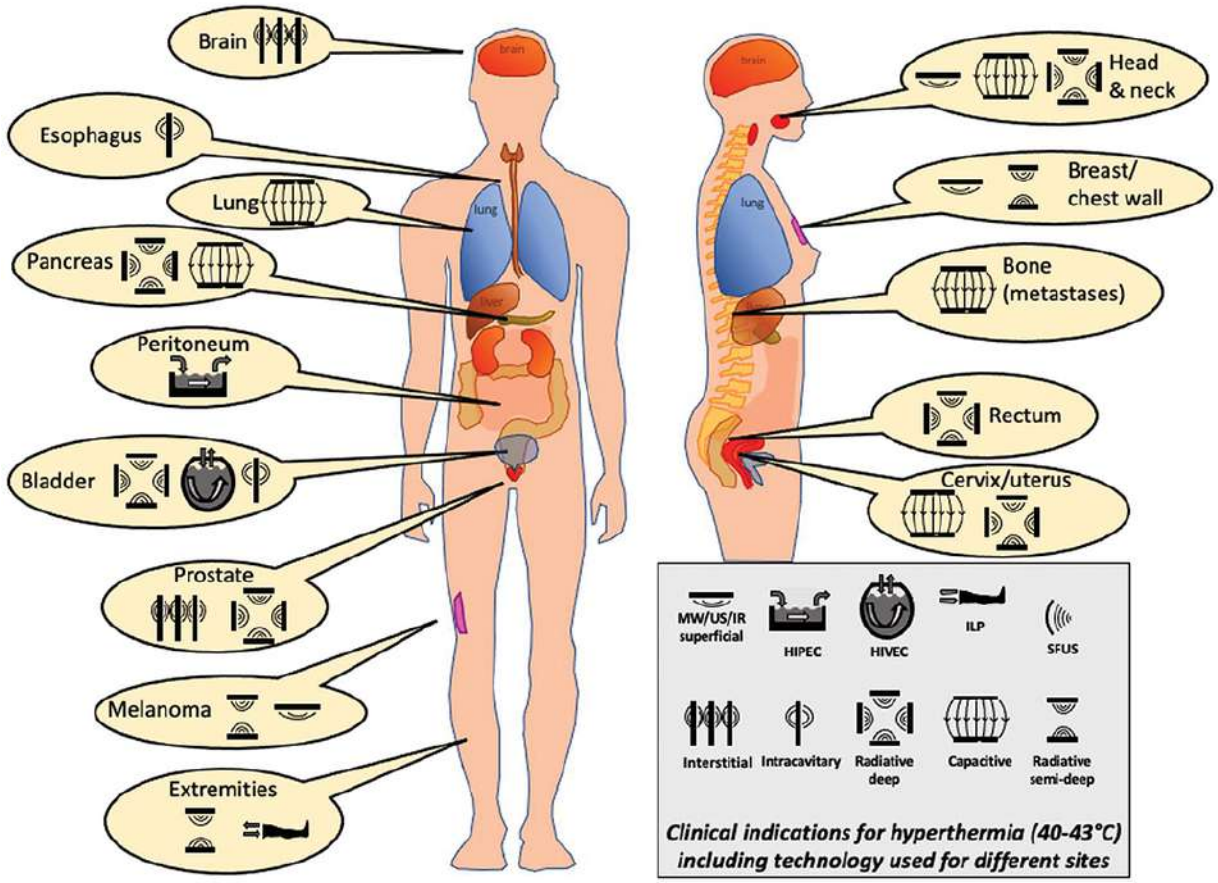

FIGURE 27.3 Overview of clinically used moderate hyperthermia techniques used for various indications and tumor locations. All techniques shown are or have been clinically applied for moderate hyperthermia at 40 to 43 °C in combination with radiotherapy and/or chemotherapy. The different categories of devices are indicated with symbols and discussed in the physics section.[34] HIPEC, hyperthermic intraperitoneal chemotherapy; HIVEC, hyperthermic intravesical chemotherapy; ILP, isolated limb perfusion; MW/US/IR, microwave/ultrasound/infrared; SFUS, scanned focused ultrasound. (Reprinted from Kok HP, Cressman ENK, Ceelen W, et al. Heating technology for malignant tumors: a review. *Int J Hyperthermia*. 2020;37(1):711-741. http://creativecommons.org/licenses/by/4.0/.)

Local and Locoregional Hyperthermia Approaches

Techniques that focus on localized tumor heating employ external applicators for superficial lesions, while invasive interstitial or intracavitary approaches are used for treating deeper sites. Superficial heating targets tumors located up to 4 cm below the skin, using applicators outside the patient. Proven clinical applications include (recurrent) breast, melanoma, and head and neck cancer.[12,13,34,36-38] Interstitial and intracavitary strategies are used for brain, prostate, head and neck, cervix, bladder, breast, and

cervix tumors.[14,34,36,39] Interstitial heating mainly aims to achieve higher temperatures for thermal tumor ablation; temperatures of 40 to 43 °C are less commonly used due to the intrinsically heterogeneous temperature distributions in interstitial HT.[34] Intracavitary heating uses applicators in natural body cavities like bladder, rectum, vagina, cervix, esophagus, urethra. Locoregional approaches use external applicators to heat deep-seated tumors and surrounding tissue. Inclusion of normal tissue is acceptable as temperatures of less than 45 °C induce tumor-selective radiosensitization. Tumors treated include cervix, rectum, bladder, prostate, pancreas, and soft tissue sarcoma.[34]

In all approaches, heating is induced using nonionizing electromagnetic (EM) or ultrasound (US) energy deposition, perfusion with heated fluids, or conductive heating. Energy deposition is quantified by the specific absorption rate (SAR) in W/kg. The resulting temperature increase depends on the energy deposition and on heat removal by thermal conduction, perfusion by small vessels, and convection by large vessels. Perfusion is important in heat transfer and can strongly increase in response to elevated temperatures.[40] EM devices apply radiofrequency (RF) and microwave (MW) radiation, capacitively coupled RF currents, or infrared (IR) radiation. RF and MW exposure causes dielectric tissue heating, which can lead to heterogeneous temperature distributions due to significant differences in electrical conductivity and permittivity between tissue types.[41] This may lead to excessive, treatment-limiting temperatures (hot spots) at tissue interfaces.[34]

Radiative Electromagnetic Heating

Radiative RF/MW devices are used for the majority of tumor sites and are responsible for gaining clinical evidence. The operating frequency determines tissue penetration depth (PD), with a descending PD for ascending frequency, moving from RF, MW, and IR to laser heating. Radiative RF/MW heating requires the use of a temperature-controlled conformal water bolus between skin and antennas to guide energy into the skin without reflections, for skin cooling when treating deep-seated tumors, and to provide skin heating for surface tumor locations. Radiative superficial systems aim at a PD of less than 4 cm and operate at MW

frequencies, mostly at industrial, scientific, and medical (ISM) frequencies (434, 915 MHz). Clinically proven radiative devices are available and include 915 MHz rectangular waveguides and circular spiral antennas (BSD-500, Pyrexar Medical) and 434 MHz microstrip applicators consisting of two coplanar active electrodes and a shield electrode mounted on a fluoroplastic substrate (ALBA ON 4000, ALBA Hyperthermia; Yahta-4, SRPC "Istok").[34] An example of a clinically proven intracavitary MW heating device is a 915 MHz antenna used in a Foley bladder catheter combined with MMC instillation for non-muscle invasive bladder cancer (Synergo, Medical Enterprises).[34,42] Radiative locoregional systems for deep-seated tumors operate at 60 to 150 MHz, non-ISM RF frequencies which need shielded rooms in a metal Faraday cage. These systems use phased arrays of multiple antennas with a dominant E-field in the cranial-caudal direction, creating a 10- to 15-cm focal region through constructive interference.[34] Steering the focal region to the tumor location and suppressing treatment-limiting hot spots in normal tissue are achieved by phase and amplitude steering,[43] with antenna settings based on HT treatment planning.[44] Commercially available phased-array systems use one or more circular, elliptical (BSD-2000, Pyrexar Medical) or adaptable shape (ALBA 4D, ALBA Hyperthermia) rings of independent antennas around the patient. Phase steering of individual antennas allows 2D spatial power steering within a single ring of antennas, while three rings permit 3D power steering.[34] Temperature monitoring is invasive or noninvasive and described in the next section. A new site-specific device is the Hypercollar phased array of 434 MHz antennas for treatment of deep-seated head and neck tumors.[34]

IR radiation at frequencies greater than 300 GHz is another approach. IR is strongly absorbed in tissue with a PD of less than 1 cm. The Hydrosun TWH1500 system (Hydrosun medizintechnik GmbH) is used for HT of superficial tumor lesions with water-filtered IR-A radiation (215-430 THz) lamps to increase PD to 1.5 to 2 cm and avoid skin overheating and dehydration.[34] No water bolus is used, and IR thermography gives real-time noninvasive temperature feedback.

Capacitive Electromagnetic Heating

Capacitive heating uses current fields between electrodes placed on the body on either side of the target region operating at 8 to 30 MHz.[34] The RF currents enter the body through water bolus bags for skin cooling and to prevent hot spots in superficial fat. Energy deposition is spatially steered by using different-sized electrodes, concentrating heat deposition under the smallest electrode. The technique is clinically used for superficial and semi-deep tumors; heating of deep-seated tumors can be challenging: The main EM field component is perpendicular to the skin and may result in excessive heating in skin fat layers, thus limiting power at depth.[34] Capacitive heating is primarily used in patients with thin fat layers, where skin hot spots can be prevented by strong surface cooling using a saline water bolus, for example, using the Thermotron RF-8 (Yamamoto Vinita). Successfully treated tumors include cervix, head and neck, and bone metastases.[34]

Ultrasound Heating

US techniques employ acoustic energy at 0.5 to 10 MHz to induce tumor heating with a PD up to 8 cm.[34,38,45] Clinical US devices have been developed for sequential and concomitant use in combination with RT for treatment of groin/trunk, axilla, breast, chest wall, head and neck tumors. The Sonotherm 1000 device (Labthermics Technologies Inc) provides multisector applicators in a non-focused planar array with a variable PD depending on the selected frequency. Another approach is high intensity focused ultrasound, which focuses pressure waves in small focal zones of a few millimeters in diameter, up to approximately 1 cm long. Scanned focused ultrasound (SFUS) is widely used for thermal ablation by scanning a focused US beam through the tumor region guided by noninvasive US or magnetic resonance (MR) thermometry to achieve conformal tumor treatment. Techniques are also under development to use SFUS for inducing moderate HT elevations under guidance of noninvasive MR thermometry.[46] Studies also aim at targeted drug delivery by combining heat with temperature-sensitive liposomes.[46-48] Advantage of SFUS-based HT is superior SAR focusing and noninvasive MR thermometry guidance. The disadvantages are that (1) limited target volumes can be heated uniformly during HT treatment and (2) the need for selecting acoustic entrance

windows to avoid overheating at bone or air cavities. These limitations reduce the number of suitable tumor sites.

Conductive Heating

Heating can also be induced by thermal conduction, for instance by implanting hot sources into the tumor. Perfusional heating is currently the most clinically relevant conductive technique; it uses circulating heated fluids containing chemotherapeutic agents to augment local drug delivery in areas such as the peritoneal or thoracic cavities. Hyperthermic intraperitoneal chemotherapy (HIPEC) is widely used to circulate chemotherapeutic solutions heated to approximately 42 °C in the peritoneal cavity to eradicate microscopic lesions, prophylactically or after surgical removal of larger peritoneal metastases of various origins, with good results.[49] CT vapors are applied in pressurized intraperitoneal aerosolized chemotherapy. Hyperthermic intrathoracic chemotherapy is used for intrathoracic lesions. Hyperthermic intravesical chemotherapy is a treatment of non-muscle invasive bladder cancer by circulating a hyperthermic MMC solution in the bladder, serving as a potential alternative to RF/MW-based bladder heating.[42] Hyperthermic isolated limb perfusion refers to infusion of heated perfusate into the vascular system of isolated limbs and used in some centers. Conductive heating has limited thermal PD and is thus only used in case of limited tumor depth, as one sees for HIPEC after resection of macroscopic disease.

Magnetic nanoparticles (MNPs) are a highly targeted conductive heating strategy for challenging tumor sites. MNPs are composed of magnetic materials, typically around 100 nm in size, and are injected into the tumor suspended in a biocompatible fluid.[50] MNPs are then magnetized by exposure to an external magnetic field of approximately 0.1 to 0.2 MHz, generating heat via magnetic hysteresis. An advantage is the option to coat MNPs with biomaterials and extend MNPs to a theranostics platform. A disadvantage is the challenge of obtaining uniform MNPs throughout the treatment volume, as temperature distributions depend on the injected MNP distribution. Clinical use for glioblastoma and prostate cancer is approved for NanoTherm AS1 (MagForce Nanotechnologies AG) for use in Europe and the United States.[34] Other technologies are in development.[51]

Monitoring Temperature and Thermal Dose

Achieving clinically effective tumor temperatures of greater than 40 °C is crucial for an optimal therapeutic gain in view of the temperature dose-effect relationship,[8,52] at the same time normal tissue temperatures of greater than 44 °C must be avoided to prevent vascular damage and other side effects.[5,23,53] Good temperature control is needed during treatment, requiring good SAR control and reliable pretreatment prediction of SAR and resulting temperature. This is challenging due to uncertainty in the patient-dependent tissue and perfusion values during treatment. Measured temperature data are thus crucial but often sparse. An alternative is to combine measured temperature data with treatment planning data to reconstruct the real 3D temperature distribution. Thermometry and treatment planning are thus both important tools for achieving good treatment control.

International HT quality assurance guidelines prescribe the use of validated devices, temperature monitoring guided by sufficient thermometry, trained staff, and documentation of relevant treatment parameters.[10-14,39,45,54-57] As described in the biology section, measured temperature distributions are reported using temperature descriptors T_{90}, T_{50}, T_{10}. Guidelines also recommend the use of the thermal dose parameter CEM43°C T_{50} and T_{90} to convert the time-temperature exposure during treatment to an equivalent exposure time at 43 °C.[6,9,15]

Thermometry is performed with single- or multisensor probes in or near the target volume. Probe locations are the skin and minimally invasive sites in natural body cavities such as the bladder, rectum, vagina, and urethra. If needed, invasive thermometry can be performed using thermometers inserted into catheters that are placed in the target region. For pelvic tumors, probes are placed in all available cavities to monitor both tumor and region heating. High-resolution skin thermometry is needed to avoid toxicity when heating superficial lesions.[58] Probe types include thermistors, thermocouples, and fiber-optic sensors, depending on compatibility with the HT method. High-resistance lead thermistor probes are relatively insensitive to EM fields; thermal mapping can be used to extend the monitoring trajectory of these single-sensor probes. Thermocouple probes have the advantage of multisensor probes giving continuous read-out along

their active length, but their metal wires need to be aligned perpendicular to the direction of the EM field to prevent interference with the EM field. Fiber-optic probes are nearly insensitive to EM interference but may be disturbed by US or laser-based HT. Regular calibration of thermometry is obligatory to ensure safe treatment delivery. Invasive thermometry is challenging for some tumor locations and as a result, noninvasive thermometry has been under development for the past two decades. Magnetic resonance imaging thermometry based on the proton resonance frequency shift method is routinely used for guiding thermal ablation procedures, and MR thermometry is also in use in locoregional HT.[58] The Sigma-30 and Sigma-Eye system can be integrated in 1.5 T MR scanners for noninvasive MR thermometry,[37] but reliability and accuracy are challenged by motion artifacts.[59] Current use is limited to select tumor locations and is always accompanied by (minimally) invasive thermometry probes.[10] Work is ongoing to improve reliability of MR thermometry.[59]

Hyperthermia Treatment Planning

The large number of independent antennas in phased-array systems makes hyperthermia treatment planning (HTP) indispensable for optimization of the antenna phase and amplitude settings.[44] HT simulation software has been developed[60] and integrated into HTP systems to compute and optimize SAR and temperature distributions in patients.[44,61] The clinical application of HTP has been validated for EM-based HT by comparing the quality of HTP-guided and experience-based steering.[62-64] HTP is now being integrated into the clinical workflow for EM-based HT.[44,61] Quantitative accuracy of HTP is limited by uncertainties in patient models, tissue properties, and dynamic changes in perfusion,[44] but HTP is qualitatively sufficiently accurate[63] and proven useful in clinical applications, such as evaluation of heating potential, applicator selection, effect of different treatment strategies, and real-time treatment control.[44]

Adaptive HTP is used to adapt antenna phase/amplitude settings in real time during treatment, enhancing tumor heating and suppressing treatment-limiting hot spots in normal tissue. The clinical benefit of adaptive HTP has been shown.[63] A next step is biologic planning to quantify and optimize the radiosensitizing effect of HT in terms of equivalent radiation dose, that is,

the radiation dose yielding the same biologic effect as the combination of RT and HT. The effect of adding HT to RT can be expressed in RT dose escalations expressed in Gy.[65] Biologic modeling can be useful in answering clinically relevant questions, such as the optimal scheduling between RT and HT and how to orient the heating field to maximize cell killing. Thermoradiotherapy planning is feasible and a next step for further optimizing combined HT and RT treatments in individual patients.[65]

Summary of Hyperthermia Physics

This review has shown that devices are available for routine HT delivery at 40 to 43 °C for a wide range of tumor sites, and with clinical benefit proven in randomized trials. High-quality treatment delivery must be safeguarded by adherence to quality assurance and temperature monitoring protocols. Treatment planning is an increasingly important tool for real-time treatment guidance. Novel site-specific devices, heat-induced targeted drug delivery, and noninvasive temperature monitoring are under development for even more effective HT treatments.

CLINICAL STUDIES

Numerous trials including randomized phase II and III studies have demonstrated clinical benefit across a wide range of malignancies and clinical settings to the use of HT in combination with radiation or CT (Figure 27.4).[35] Taken as a whole, research to date has defined specific indications for the use of HT and several other promising therapeutic approaches for which further investigation is warranted.

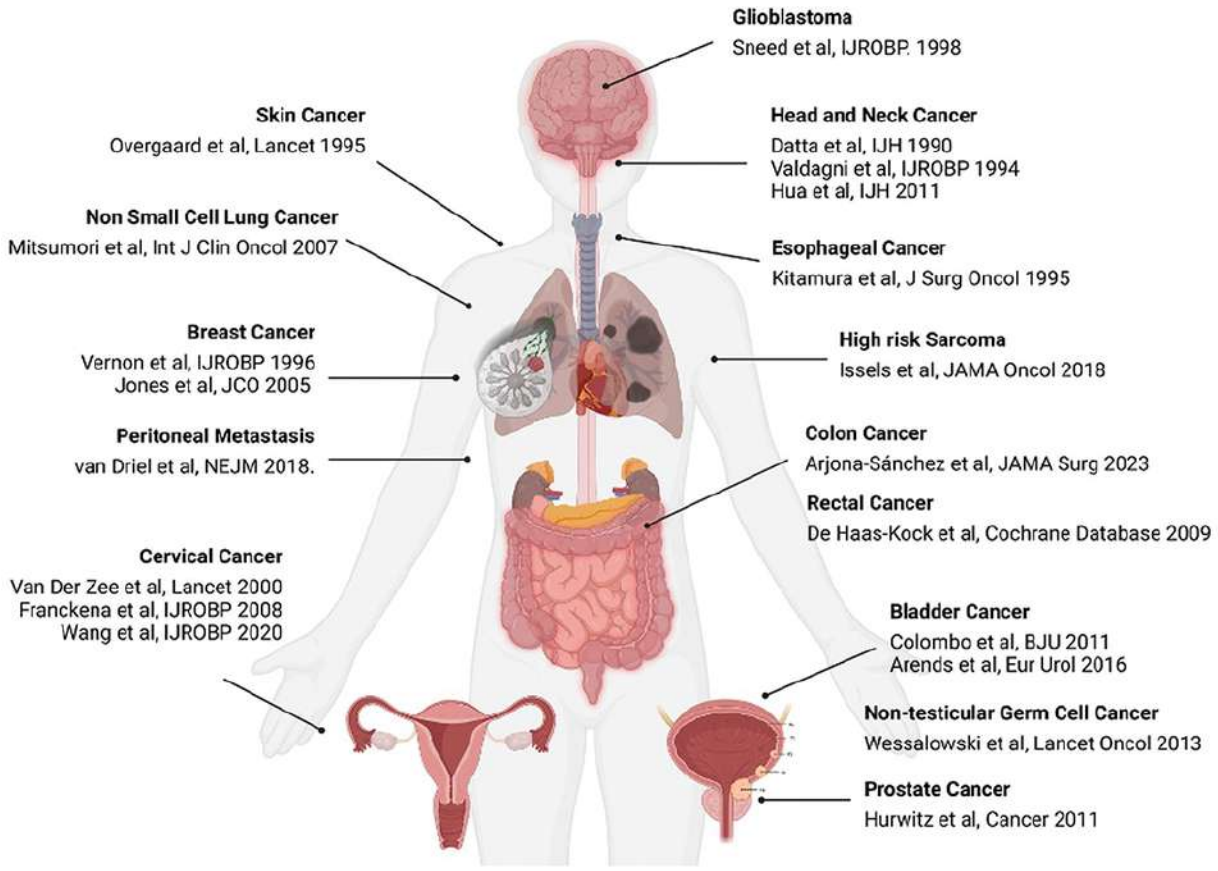

FIGURE 27.4 Overview of key hyperthermia clinical trials for various indications and tumor locations. (Created with BioRender.com. Figure adapted from BioRender. Diseased human body. 2023.)

Radiation and Hyperthermia: Key Randomized Trials

Early Cooperative Group Studies

The rapidly evolving understanding of the biologic rationale for combining HT and radiation in the 1980s led to the initiation of several phase III clinical trials, including two Radiation Therapy Oncology Group (RTOG) studies to assess the role of HT in superficial and deep regional disease. Unfortunately, HT technology, meaningful therapeutic goals, and quality guidelines necessary for successful treatment lagged in development. RTOG-8104 compared RT with or without HT for a variety of superficial malignancies. There was no difference in complete response between groups; however, benefit was noted for tumors smaller than 3 cm, suggesting that if tumors could be effectively heated, meaningful clinical responses could be achieved.[66] RTOG-8419 was intended to assess

interstitial radiation alone or with HT for persistent or recurrent tumors after previous RT or surgery. No differences were noted; however, only 1 of 173 evaluable patients met protocol-defined minimum accepted criteria for adequate HT, and there were quality concerns with brachytherapy as well. Therefore, the authors concluded that the study lacked the ability to assess the question of benefit in this clinical setting.[67] Despite challenges identified in the RTOG trials, several early randomized studies revealed benefits with the addition of HT to RT. Subsequent development of quality assurance guidelines, clinically meaningful thermal dose parameters, and improvements in treatment technology have helped to move the field forward.

Superficial Hyperthermia

HT has been shown to be beneficial for several superficial disease presentations including for breast, head and neck, melanoma, and skin cancers. MW devices that treat up to a depth of 3 cm are most commonly used. US with soft tissue penetration up to 6 to 8 cm and occasionally other modalities are also employed in the treatment of superficial malignancies.

Breast Cancer

HT can improve complete response and local control for women with breast cancer, particularly in the setting of recurrent chest wall disease. Vernon et al[68] reported combined results of five randomized breast cancer trials including locally advanced primary or recurrent disease with or without prior RT. The primary end point in each trial was local tumor response. Due to slow accrual, a combined analysis was developed including a prospective statistical plan to allow for the assessment of the initial objectives. Three hundred and six eligible patients were enrolled. Treated lesions included chest wall (71%) and intact breast tissue (26%). Forty-eight percent of cases had multiple lesions. There were more patients who had received prior CT and lesion size was greater in the HT plus radiation treatment arm. A highly significant difference in complete response was noted for combined RT and HT, 59%, versus radiation alone, 41%. Further analysis determined that this difference was driven by benefits in patients undergoing reirradiation for whom RT doses were limited. There was nearly a doubling in complete

response with HT and RT of 59% versus 31% with radiation alone. Patients achieving a complete response with HT had a reduced risk of recurrence with a hazard ratio (HR) of 0.67 compared to patients who received RT alone. Treatment with HT was well tolerated. Apart from the acute occurrence of skin blistering 11% with versus 2% without HT, no other differences in acute or late toxicity were noted.

Treating a range of superficial malignancies, Jones et al[69] confirmed a dose-response relationship for HT in a randomized trial in which patients with superficial tumors at a depth of 3 cm or less received either "low" versus "high" dose HT combined with RT. Sixty-five percent of patients had breast cancer, 13% head and neck cancer, 11% melanoma, and the remainder had various other malignancies. Prior studies had shown a thermal dose of CEM43°C T_{90} (the number of cumulative equivalent minutes at 43 °C exceeded by 90% of monitored points within the tumor) equated with improved treatment outcome. HT was prescribed to achieve either CEM43°C T_{90} of less than 1 or greater. Eighty-nine percent were determined at the time of first HT treatment to have heatable tumors. These 109 patients were randomized to no additional HT or twice weekly HT over their course of RT up to 10 treatments. Patients were stratified by whether they had received prior RT and by disease site. Median CEM43°C T_{90} in the low- and high-dose HT groups was 0.74 and 14.3, respectively. Thirty-six percent of patients had received prior RT. Median RT dose was 4,100 cGy in previously treated patients versus 6,000 cGy for those not previously irradiated. Complete response rate in the high-dose arm was 66% versus 42% in the low-dose arm. The odds ratio for complete response was 2.7. This improvement in complete response translated into improved local control, with rates of 48% versus 25% at the time of death or the last follow-up. Previously irradiated patients had the greatest incremental gain in complete response, with rates of 68% versus 23% in the high- versus low-dose arms as compared to 65% versus 51% for patients without prior RT. The study demonstrated that thermal dose can be prospectively prescribed and delivered, correlating with treatment outcome.

Skin Cancer

HT has also demonstrated efficacy in treatment of skin cancers including melanoma. A European Society of Hyperthermic Oncology phase III trial, performed in the 1990s, randomized 134 metastatic or recurrent melanoma lesions to receive 3 fractions of 800 or 900 cGy over 8 days with or without HT. Local control was significantly increased from 28% to 46% with the addition of HT. Overall 5-year survival in this study predating immunotherapy was 19% with note made of 38% overall survival for subjects for whom all known disease was controlled demonstrating the importance of local control.[70,71]

Head and Neck Cancer

Two early studies from the 1980s, prior to the use of CT, demonstrated the potential for improved outcomes with the addition of HT to radiation therapy. Datta et al[72] randomized 65 subjects to RT with or without HT twice weekly. Total RT doses were 6,000 to 6,500 cGy. For 50 patients with stage III or IV disease, complete response was 20% for radiation alone versus 58% with addition of HT. Valdagni and Amichetti[73] performed a randomized study to assess the impact of HT on local control and acute toxicity for patients with cervical adenopathy. A planned interim analysis after 41 patients were accrued revealed a highly significant improvement in the complete response of 85% with HT translating into 5-year local control of 69% versus 24%. Five-year overall survival was notably 53% versus 0%. Hua et al[74] randomized 180 nasopharynx patients to 7,000 cGy with cisplatin/5FU with or without HT with statistically significant improved overall survival with HT of 73% versus 63%.

Deep Regional Hyperthermia

The refinement of systems for deeply penetrating HT, primarily with use of RF, has led to successful clinical trials for a wide range of deep-seated malignancies. Additional techniques including HIPEC, interstitial or intraluminal HT also have been employed. Phase II and III studies have demonstrated benefits for cancers of the cervix, rectum, bladder, esophagus, lung, and sarcoma among others.

Cervical Cancer

A Dutch multicenter phase III trial assessed the benefit of HT in addition to RT for the treatment of locally advanced pelvic tumors. Three hundred and sixty-three patients with bulky stage IIB, III, or IVA cervical, T3 or T4 bladder or unresectable or recurrent rectal cancers were stratified based on primary disease site. Local control at 2 years with RT and HT versus radiation alone was 56% versus 39%. A highly significant improvement for patients with cervical cancer in 3-year overall survival of 51% versus 27% was noted.[75] This benefit was sustained at 12 years with overall survival of 37% versus 20%.[76] A HT dose effect was noted.[52] A Cochrane review of six randomized controlled trials assessing RT with or without HT for locally advanced cervical cancer found HT resulted in a significantly higher complete response rate (HR 0.56); significantly reduced local recurrence rate (HR 0.48); and significantly better overall survival (HR 0.67). No increase in short- or long-term toxicity was observed. Several limitations were noted including the limited number of patients available for analysis, methodologic flaws in some studies, and a significant overrepresentation of patients with International Federation of Gynecology and Obstetrics (FIGO) stage IIIB (74%), which prohibited drawing definite conclusions. Nevertheless, reviewers noted that available data do suggest addition of HT improves local tumor control and overall survival in patients with locally advanced cervix carcinoma, without affecting treatment-related grade 3 to 4 acute or late toxicity.[77] Concurrent with the publication of the Dutch Deep Hyperthermia trial results, five studies were reported that demonstrated similar benefits with the addition of cisplatin to RT. Subsequent studies have sought to evaluate the benefit of HT in addition to RT and CT including a phase III trial reported by Wang et al.[78] Three hundred and seventy-three patients with FIGO stage 1B-IV disease were randomized to radiochemotherapy versus radical hysterectomy alone. Significantly improved 5-year overall survival was noted with the addition of HT 82% versus 72% with no differences in toxicity.

Rectal Cancer

A Cochrane review identified six randomized controlled trials including 520 patients. Significantly higher complete rates were observed (HR 2.8). Overall survival was significantly improved with addition of HT at 2 years

(HR 2.1); however, this benefit was not sustained with longer follow-up. No significant differences were noted in acute toxicity. While promising, the authors concluded that additional high-quality phase III randomized studies are needed to definitively define the role of HT in rectal cancer.[79]

Glioblastoma

A randomized trial at University of California, San Francisco showed a remarkable improvement in overall survival for patients with glioblastoma multiforme with the addition of interstitial HT to brachytherapy boost in 79 patients following standard external beam radiation and CT. Time to progression and overall survival were significantly increased with the addition of HT. Two-year overall survival was 31% with versus 15% without HT. A multivariate analysis adjusting for age and Karnofsky performance status showed that improved survival was significantly associated with randomization to HT with a HR of 0.51.[80]

Esophageal Cancer

A Japanese randomized study including 66 patients with resectable squamous cell carcinoma of the thoracic esophagus compared standard neoadjuvant chemoradiotherapy with or without HT. Complete response was significantly improved with HT, 25% versus 5% as was 3-year survival, 50% versus 24%.[81]

Chemotherapy and Hyperthermia: Key Randomized Trials

HT has also been shown in randomized trials to improve outcomes with CT using a range of delivery strategies. The European Organisation for Research and Treatment of Cancer conducted a phase III randomized study to assess the use of HT in the treatment of localized high-risk sarcoma. All patients received standard surgery, RT, and neoadjuvant CT with or without RF deep regional HT. A total of 341 patients were enrolled. The primary end point was local progression-free survival and secondary end points included overall and disease-free survival. With a median follow-up of over 11 years, adding regional HT improved local progression-free survival (HR 0.65). Survival was also improved with the addition of HT (HR 0.73) with a 10-year survival of 53% versus 43%.[82] Colombo et al[83] reported notable

improvement in progression-free survival with combined intravesical HT and MMC as opposed to mitomycin alone for treatment of superficial bladder cancer following transurethral resection of bladder tumor. Eighty-three patients were randomized. The primary end point of recurrence-free survival at 10 years was 53% with HT versus 15% with CT alone. These results were consistent with findings of a subsequent study comparing intravesical BCG with intravesical MMC and HT.[84] HIPEC has shown efficacy in treatment of peritoneal metastases in phase III trials. A Dutch multicenter trial with 245 enrolled patients revealed the benefits of cisplatin-based HIPEC compared to systemic CT alone after interval cytoreductive surgery (CRS) in the treatment of stage III epithelial ovarian cancer, with no added toxicity. Two hundred and forty-five patients were enrolled. Disease recurrence or death was reduced in the HIPEC arm, 81% versus 89% (HR 0.66). Median overall survival was 46 versus 34 months.[85] A Spanish multicenter randomized trial of HIPEC for locally advanced colon cancer revealed the primary end point of 3-year locoregional control was improved with CRS followed by MMC-based HIPEC: 98% versus 88% (HR 0.22).[86]

Other Notable Studies

HT has shown promise across widely ranging malignancies and clinical scenarios apart from randomized trials. A German series reported the benefits of using deep regional HT in conjunction with standard CT for the salvage treatment of children with refractory or recurrent non-testicular germ cell tumors. Among 35 evaluable patients, 86% had an objective response with 5-year event-free and overall survival of 62% and 72%, respectively. These results were notable for nearly approximating outcomes with first-line CT alone.[87]

Several trials have shown promise for HT in the treatment of prostate cancer including Dana Farber 94-13, a phase II trial of trans-rectal US HT in combination with standard RT and androgen deprivation in treatment of unfavorable intermediate- to high-risk locally advanced disease. Thirty-seven subjects were matched both in regard to known prognostic factors and treatment approach to historical controls from RTOG-9202. The primary end point was absolute 2-year disease-free survival which was 84%

versus 64% in the control group. With a median follow-up of 70 months, overall survival was 94% and 61% remained failure-free.[88] HT has also demonstrated the potential for better outcomes for lung cancer. An International Atomic Energy Agency sponsored, multi- institutional prospective randomized trial including 80 patients assessed if the combination of HT and radiation improves the response rate of locally advanced non–small cell lung cancer compared with radiation alone. No significant differences between the two arms in local response rate or overall survival rate were noted. However, local progression-free survival was significantly better with the addition of HT. Toxicity as typical of most HT trials was generally mild and limited.[89]

FUTURE DIRECTIONS

HT has been shown to have clinical benefits for many patients with cancer. Realization of the full potential of this cancer treatment modality, however, remains to be achieved. Barriers to widespread adoption need to be fully addressed. The ability to reliably prescribe and deliver HT remains challenging at times. The added complexity of treatment which requires real-time attention to physiology in addition to physics necessitates added clinical effort for treatment delivery. New user and patient-friendly technology, such as noninvasive thermometry, will further increase utilization. While the rationale of thermal biology is robust, incorporation of biology and heat for the betterment of patients with cancer has yet to be fully exploited in the clinic.

Targeted use of HT with other established cancer therapies holds tremendous potential. In regard to CT, both enhanced delivery with temperature-sensitive liposomes and mechanistic synergy as per combination of HT with agents such as cisplatin and PARP inhibitors have yet to be fully exploited.[90] Systems for simultaneous treatment with RT with the potential to greatly enhance TER are in development.[51,91] Noting the impact of HT on the sphingomyelin/ceramide pathway, clinical studies combining HT with stereotactic body radiation therapy may impact a great number of patients.[92] HT also has great potential to improve results with immunotherapy through a wide range of mechanisms. Tumor-specific immune responses generated by heat might also be generated by partial

tumor heating abrogating the demands of whole tumor heating.[1] Should HT prove beneficial when added to immunotherapy, as opposed to the limitations of repeated use of ionizing radiation, HT can be administered repeatedly in combination with immunotherapeutic agents.[93] While HT has been shown in several scenarios to have clinical benefit, the full potential of this cancer treatment modality has yet to be fully realized for patients.

ACKNOWLEDGMENTS

The authors appreciate the assistance of Drs Greg Palmer and Sooyun Caroline Tavolacci in preparing the figures.

CHAPTER 28

Reirradiation

Carsten Nieder and Anthony E. Dragun

A second course of radiotherapy (RT) to a previously treated, overlapping anatomic region poses considerable challenges if a high cumulative total dose is attempted. In palliative clinical scenarios, for example, painful bone metastases, such treatment is well established.[1,2] Occasional patients might even benefit from a third course. Reirradiation has been prescribed for local/regional relapse or second primary tumors, the latter often after very long time intervals, as well as benign diseases. The history of head and neck and other reirradiation dates back many decades.[3] First in 2022, a collaborative effort by the European Society for Radiotherapy and Oncology (ESTRO) and European Organisation for Research and Treatment of Cancer (EORTC) led to a consensus report on definition, reporting, and clinical decision-making.[4] In this report, reirradiation is defined as a new course of RT, either to a previously irradiated volume (irrespective of concerns of toxicity) or where the cumulative dose raises concerns of toxicity. Type 1 is a new course of RT that has geometrical overlap with the irradiated volume of previous courses, and type 2 is a new course with concerns of toxicity from the cumulative doses but in which there is no overlap with the irradiated volume of previous courses, for example, in the lungs. Repeat organ irradiation is a new course of RT to a previously irradiated organ but without overlap of the irradiated volumes and without concerns for toxicity from cumulative doses. Despite a long-standing legacy, few prospective randomized clinical studies have provided high-level evidence clarifying the optimal approach toward previously irradiated tumors.[5] Phase II studies often included a single arm only.[6-9] Therefore, the clinical practice of reirradiation, prescribed as either monotherapy or combined with other modalities, is highly variable. Recent guidelines endorse repeat RT in selected patients,[10-12] and international recommendations inform clinical strategies.[13-16] Workflow solutions have also been suggested.[17]

TISSUE TOLERANCE AND RECOVERY

General Aspects

Animal studies and clinical data on reirradiation of head and neck tumors, breast cancer, lung cancer, and others showed that acute skin and mucosal reactions after reirradiation were well within the range observed after the first course of RT.[18-20] If the previous treatment has caused persistent severe mucosal damage, reirradiation might be poorly tolerated. Clinical data related to many cancer types revealed that late complications were more frequent than anticipated after reirradiation to high cumulative doses. The majority of data is derived from head and neck cancer retreatment. Lee et al[21] reported that the major determinant of postretreatment complications was the severity of damage during the initial course. Severe toxicity occurred also after intensity-modulated radiotherapy (IMRT), but no prospective randomized head-to-head comparison of salvage IMRT versus three-dimensional (3D) conformal RT is available.[22] In the IMRT study reported by Duprez et al,[23] 84 patients were reirradiated to a median cumulative total dose of 130 Gy (median time interval 49.5 months, median reirradiation dose 69 Gy). Late toxicity was scored in 52 patients, with at least 6 months of follow-up. Eight patients developed grade 3 or 4 late dysphagia, and three developed osteoradionecrosis. Overall, 30 different grade 3 or 4 late complications were recorded. Updated results from the University of Texas MD Anderson Cancer Center (n = 206, IMRT) revealed actuarial rates of grade ≥3 toxicity of 48% at 5 years, most often dysphagia and odynophagia.[24] Increased toxicity was associated with retreatment volume >50 mL. Stereotactic body (SBRT) reirradiation for recurrent head and neck cancer resulted in higher late toxicity rates if the larynx or hypopharynx were treated.[25] It is unrealistic to expect zero risk of any severe late toxicity after IMRT or other highly conformal techniques, since certain parts of the mucosal and/or connective tissues will always be part of the planning target volume and receive high cumulative doses. With proton therapy, grade ≥3 toxicities were seen in 15% acutely and 25% in the late setting, including treatment-related deaths.[26] Overall, the available literature indicates that mesenchymal tissues recover from radiation injury less than rapidly reacting tissues like the epidermis and mucosa, at least in the head and neck region.

Large Arteries

Recent reports of high-dose reirradiation have also identified the large arteries as critical organs at risk (OARs). Evans et al[27] analyzed the end point of grade 5 aortic toxicity in 35 patients with lung cancer. The median prescribed dose was 54 Gy in 1.8-Gy fractions and 60 Gy in 2-Gy fractions. The median interval between the two courses was 32 months. The median raw composite dose to 1 mL of the aorta was 110 Gy. Toxicity developed in 25% of patients who received ≥120 Gy, but not in

patients irradiated to lower cumulative doses. A dose constraint of 120 Gy has also been suggested for the carotid arteries.[28] The issue of carotid blowout syndrome (CBOS) has been studied by Yamazaki et al.[29] They pooled data from seven Japanese Cyber Knife institutions and analyzed 381 patients. Of these, 32 (8.4%) developed CBOS after a median of 5 months from reirradiation. Twenty-two (69%) patients died. Later, a predictive model (CBOS index) was developed, which includes carotid invasion of >180°, presence of ulceration, and lymph node area irradiation (0-3 points).[30]

Lung/Thorax

In animal experiments, the lungs recover at least partially from occult injury, as reviewed by Nieder et al.[18] Experimental data on trachea, bronchi, or esophagus are lacking. Most clinical series did not describe particular problems with these critical structures, except for stereotactic treatment of central lesions and recurrent disease with infiltration or likely infiltration, where it is often difficult to determine the cause of fistula or hemoptysis (tumor progression vs treatment toxicity).[31] Table 28.1 shows different treatment regimens.

Spinal Cord

The spinal cord has been studied in several experimental settings. Clinically applicable data were generated in adult rhesus monkeys by Ang et al.[32] The cervical spinal cord of these primates was irradiated with 2.2 Gy per fraction after an identical initial course of 44 Gy. Reirradiation dose was 57.2 Gy, given after 1-year (n = 16) or 2-year (n = 20) intervals, or 66 Gy, given after 2-year (n = 4) or 3-year (n = 14) intervals. Of the 45 monkeys that completed the required observation period of up to 2.5 years, four developed myelopathy. Fitting the data with a model, assuming that all (single course and reirradiation) dose-response curves were parallel, yielded recovery estimates of 33.6 Gy (76%), 37.6 Gy (85%), and 44.6 Gy (101%) of the initial dose, after 1, 2, and 3 years, respectively, at the 5% incidence level. Another way to look at these results is to estimate the total cumulative dose that can be tolerated, expressed in EQD_2 that is equivalent dose in 2-Gy fractions calculated using the linear-quadratic approach. For a time interval of 1, 2, and 3 years between the treatment courses, cumulative doses of 150%, 156%, and 167% of the first-line setting's tolerance dose appear possible. If true in humans, an initial exposure equivalent to 46 Gy in 2-Gy fractions (arbitrarily selected to represent 100% of the tolerance dose at the 5% myelopathy risk level because many institutions limit the spinal cord dose to lower levels than true tolerance) might be followed by an additional 23 to 24 Gy in 2-Gy fractions (50% of the tolerance dose) 1 or 2 years later. Clinical data from different institutions supporting this interpretation have been published.[33] Nieder et al[34] have published a risk prediction model, based on time interval, cumulative dose, and the presence or absence of any treatment course, resulting in quite high spinal cord exposure. Besides cumulative dose, interval <6 months and total dose equivalent to >50 Gy in 2-Gy fractions in one of the two courses increase the risk of myelopathy. The introduction of SBRT has resulted in new challenges. Rather than irradiating complete spinal cord cross sections with homogeneous doses, small areas are exposed and steep dose gradients achieved. Medin et al[35] developed a swine model where a 10-cm length of the spinal cord (C3-T1) was uniformly irradiated to 30 Gy in 10 fractions and reirradiated 1 year later with a single radiosurgery dose centered within the previously irradiated segment. Follow-up after reirradiation was 1 year. Summarized briefly, pigs receiving radiosurgery 1 year following 30 Gy in 10 fractions were not at significantly higher risk of developing motor deficits than pigs that received radiosurgery alone. Sahgal et al[36] provided a recommendation of presumably safe stereotactic reirradiation doses after initial conventional RT (interval at least 5 months). A thecal sac point maximum P(max) EQD_2 of 20 to 25 Gy appeared to be safe, provided the total P(max) EQD_2 does not

exceed approximately 70 Gy, and the SBRT thecal sac *P*(max) EQD_2 comprises no more than approximately 50% of the total normalized biologically equivalent dose. The feasibility of salvaging spinal metastases initially irradiated with SBRT, who subsequently progressed with imaging-confirmed local tumor progression, with a second SBRT course to the same level has also been confirmed.[37]

Brain

In contrast to the spinal cord, no animal experiments on reirradiation of the brain are available. Clinical data mainly relate to temporal lobe injury after treatment of recurrent nasopharynx cancer[38] or reirradiation of glioma, meningioma, and brain metastases. Shepherd et al[39] retreated glioma with fractionated SBRT (five fractions per week, 5 Gy per fraction) after a median initial dose of 55 Gy (Table 28.2). All patients treated with more than 40 Gy developed late toxicity, whereas only 25% of those who received 30 to 40 Gy developed such adverse events. Several institutions have used reirradiation doses of 30 to 40 Gy with fraction sizes below 4 Gy with acceptable rates of toxicity, and prospective trials such as NRG Oncology/RTOG1205 are in line with these findings. An interstudy comparison between retrospective series is difficult because the literature is confounded by a lack of standardized recording of RT and outcome variables. In addition, some patients were treated at first and others at second or third progression. Recent prospective data from a multicenter study in 92 patients with recurrent high-grade gliomas suggest that reirradiation has no negative impact on health-related quality of life, comparable to other options such as surgery and chemotherapy.[48] Currently, there is no standard recommendation on what imaging modality has to be incorporated and what specific margins should be applied. The minimal consensus may be summarized as to confine gross tumor volume definition to gadolinium-enhancing regions. The GLIAA (NOA 10) study (NCT01252459), an ongoing multicenter, prospective randomized, phase II clinical trial, evaluates the impact of [18F]-fluoro-ethyl-l-tyrosine-positron emission tomography versus T1Gd magnetic resonance imaging (MRI) target volume delineation on the outcome of patients with recurrent glioblastoma treated with high-precision radiation therapy (39 Gy, 3 Gy per fraction). As evident from the review of treated volumes with different modalities, such as single-dose and fractionated stereotactic irradiation, some institutions preferred hypofractionation for recurrences that others treated with a single dose. This finding reflects the lack of universally agreed dose constraints for reirradiation. In the randomized phase II NRG Oncology/RTOG1205 study of systemically administered bevacizumab with or without reirradiation, 35 Gy in 10 fractions was prescribed.[47] The maximum tumor diameter was 6 cm, and the

minimum time interval from previous RT was 6 months. The brainstem, optic nerves, and chiasm were expanded by 3 mm to create planning organ at risk volume (PRV). The maximum per protocol dose of 0.03-mL PRV was 24 Gy (brainstem) and 20 Gy (optic nerves and chiasm), respectively. Acceptable variations included 30 and 25 Gy, respectively. According to a Swiss study, reirradiation appeared both safe and effective in patients with recurrent primary or secondary brain tumors with doses to the brain up to 120 Gy_2 EQD_2, doses below 100 Gy_2 EQD_2 for brainstem, and doses below 75 Gy_2 EQD_2 to chiasm and optic nerves.[49] Figure 28.1 shows a clinical example of a patient treated with conventionally fractionated reirradiation.

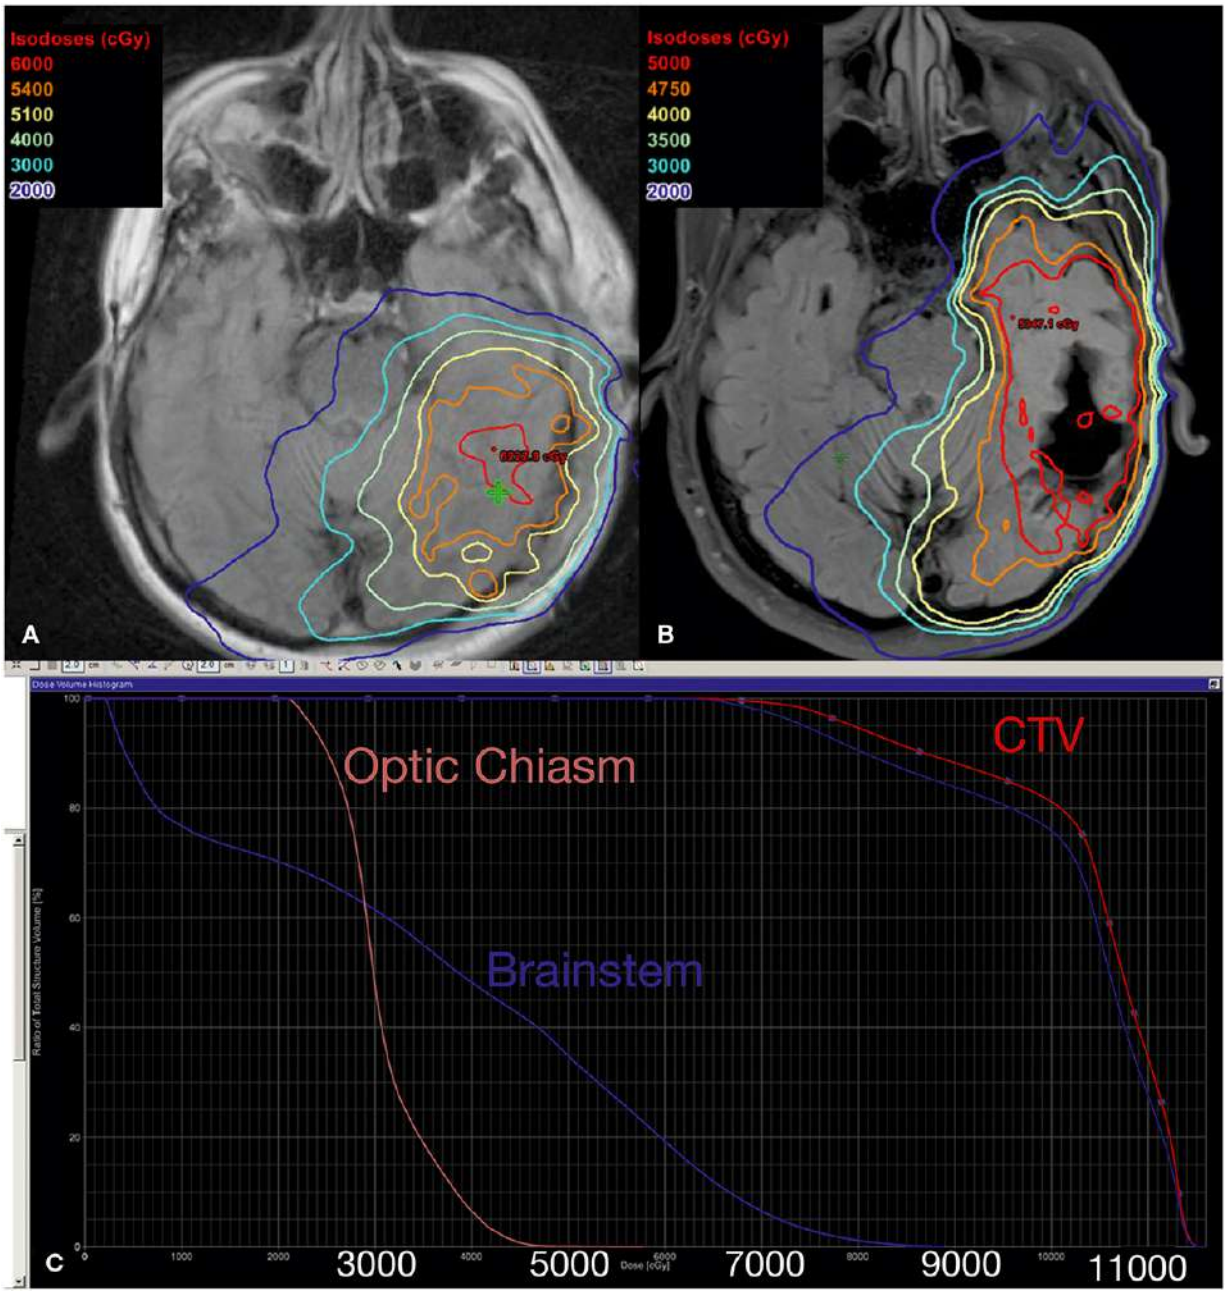

FIGURE 28.1 A. Representative axial slices from a T2-weighted fluid attenuation inversion recovery magnetic resonance image of a 66-year-old man with a left temporoparietal glioblastoma originally treated after surgical resection to 60 Gy in 30 fractions with concurrent temozolomide. B. He subsequently had an in-field recurrence 4 years after the completion of his original treatment and was treated to 50 Gy in 25 fractions. C. A dose-volume histogram. Cumulative brainstem dose to 0.3 cm^3 was limited to 80 Gy. Treatment was successfully delivered without serious toxicity. (Courtesy of Mark Amsbaugh, MD, University of Louisville School of Medicine.)

Radiosurgery was systematically studied by the Radiation Therapy Oncology Group (RTOG).[50] Adults with cerebral or cerebellar solitary nonbrainstem tumors

≤40 mm in maximum diameter were eligible. Initial radiosurgical doses were 18 Gy for tumors ≤20 mm, 15 Gy for that 21 to 30 mm, and 12 Gy for that 31 to 40 mm in maximum diameter. Dose was prescribed to the 50% to 90% isodose line. Doses were escalated in 3-Gy increments, providing the incidence of irreversible grade 3 or any grade 4 or 5 RTOG central nervous system toxicity was <20% within 3 months of radiosurgery. Between 1990 and 1994, 156 analyzable patients were entered, 36% of whom had recurrent primary brain tumors (median prior dose 60 Gy) and 64% recurrent brain metastases (median prior dose 30 Gy). The median interval was 11 months, minimum 3 months. The maximum tolerated doses were 24, 18, and 15 Gy for tumors ≤20, 21 to 30, and 31 to 40 mm in maximum diameter, respectively. However, for tumors ≤20 mm, investigators' reluctance to escalate to 27 Gy, rather than excessive toxicity, determined the maximum tolerated dose. The actuarial incidence of radionecrosis was 5%, 8%, 9%, and 11% at 6, 12, 18, and 24 months following radiosurgery, respectively. Unacceptable toxicity was more likely in patients with larger tumors. Sneed et al[51] reported that radiosurgery followed by a second radiosurgery for recurrent brain metastases resulted in a 20% 1-year cumulative incidence of symptomatic adverse radiation effect (median reirradiation dose 18 Gy, n = 72, crude risk 14%). Compared to patients who had not received prior radiosurgery to the same lesion, the hazard ratio (HR) for any adverse radiation effect was 5.05 (95% confidence interval [CI] 1.9-13.2). Another study of 46 retreated lesions reported symptomatic radiation necrosis in 24% (actuarial 1-year rate 29%), while local control at 1 year was 79%.[52]

Heart

Wondergem et al[53] assessed the reirradiation tolerance of the heart at intervals of up to 9 months in a rat model by measuring cardiac function ex vivo 6 months after reirradiation. The cardiac tolerance dose was arbitrarily defined as the dose causing at least 50% function loss in one half of the treated animals (ED_{50}). Up to a 6-month interval, the reirradiation ED_{50} was close to the single course ED_{50} but dropped significantly when the interval was longer than 6 months. The reirradiation tolerance also decreased with an increasing priming dose. A slow progression of damage induced by the priming dose is a plausible explanation for the decrease in tolerance with increasing time from the initial course. Systematic clinical data are not available.

Kidney and Bladder

Experimental data caution also against whole-bladder reirradiation.[54] With respect to late bladder damage in mice (end point defined as >50% reduction in bladder volume, increased urination frequency at ≥27 weeks after reirradiation), no long-term recovery was observed in up to a 9-month interval. Unfortunately, neither experimental data for partial organ reirradiation nor larger clinical studies on bladder reexposure are available, despite considerable evidence for prostate cancer reirradiation feasibility.[14] Studies on mouse, rat, and pig kidney suggested that radiation-induced toxicity progresses rather than recovers with time.[55,56]

SELECTED HEAD AND NECK CANCER STUDIES

The randomized Chinese phase II trial by Tian et al[19] that included 117 patients evaluated de-escalation of the biologically equivalent dose for late-responding normal tissues, while maintaining the same EQD_2 for nasopharynx cancer cells. This was accomplished by selecting a slightly hypofractionated experimental regimen (60 Gy in 27 fractions, IMRT), which was compared to a conventional regimen with 2-Gy fractions (total dose 68 Gy, IMRT) and longer overall treatment time. It was assumed that normal tissue sparing would result in less life-threatening toxicity and thus better overall survival, that is, a better therapeutic ratio. In principle, the results confirmed this hypothesis, with a 5-year overall survival rate of 44% versus 30%, but the difference was not statistically significant ($P = .06$). A subsequent randomized trial compared 60 Gy in 27 fractions to a regimen with further de-escalated EQD_2, employing hyperfractionation (65 Gy in 54 fractions twice daily [bid]) with identical overall treatment time.[57] The rate of severe late complications was significantly lower in the hyperfractionation arm, while overall survival improved. Serious toxicity was not uncommon, and therefore, continued research efforts are necessary.

The Groupe d'Oncologie Radiothérapie Tête et Cou/Groupe d'Étude des Tumeurs de la Tête et du Cou reported on a prospective study in which 130 patients who underwent salvage surgery were randomly assigned to receive full-dose reirradiation (60 Gy) combined with concomitant chemotherapy (5-fluorouracil and hydroxyurea) versus no adjuvant treatment.[58] All patients underwent a macroscopic complete resection, and in the majority, the surgical margins were sufficient. A significant improvement with regard to the primary end point of locoregional tumor control (HR 2.7; 95% CI 1.7-4.5; $P < .001$) and disease-free survival (HR 1.7; 95% CI 1.1-2.5; $P = .01$) was observed in those patients who were assigned to receive postoperative chemo-reirradiation compared to those who underwent surgery alone. However, this benefit in disease-free survival did not translate into a significant improvement in overall survival, which

may be due to the higher incidence of distant metastases in the chemo-reirradiation arm. The gain in locoregional tumor control and disease-free survival was achieved at the cost of significantly higher rates of grade 3 and 4 late side effects (39% vs 10% at 2 years). It should be noted that participants allocated to the wait-and-see arm could receive salvage chemo-reirradiation at the time of locoregional recurrence after salvage surgery, which was the case in 25% of patients. This type of crossover reduces the likelihood of improved overall survival. Postoperative chemo-reirradiation should be considered in selected cases, in particular given the very low locoregional control rate after salvage surgery alone, which was only 20% at 2 years. However, in light of the high rate of late toxicity, the optimal postoperative regimen in the reirradiation setting has yet to be defined. Based on the results of this study, a wait-and-see policy could also be considered, in particular when patients suffer from severe late toxicities from the first course of treatment. Ho et al[59] in a retrospective comparison of primary closure to flap reconstruction (n = 59 and 37, respectively) reported that nonflap patients experienced a significantly greater incidence of severe late toxicities (47.5% vs 21.6%, P = .02), while acute toxicities and 5-year survival were comparable.

As shown in Figure 28.2, median survival is limited,[6,23,24,60-64] but a proportion of patients experience long-term survival after reirradiation, a finding that has already been described in historical studies. Patients with new primary tumors fared better than those with local relapse. Target volumes should be kept tight, and elective nodal irradiation should be avoided in order to minimize severe toxicity.[13,67]

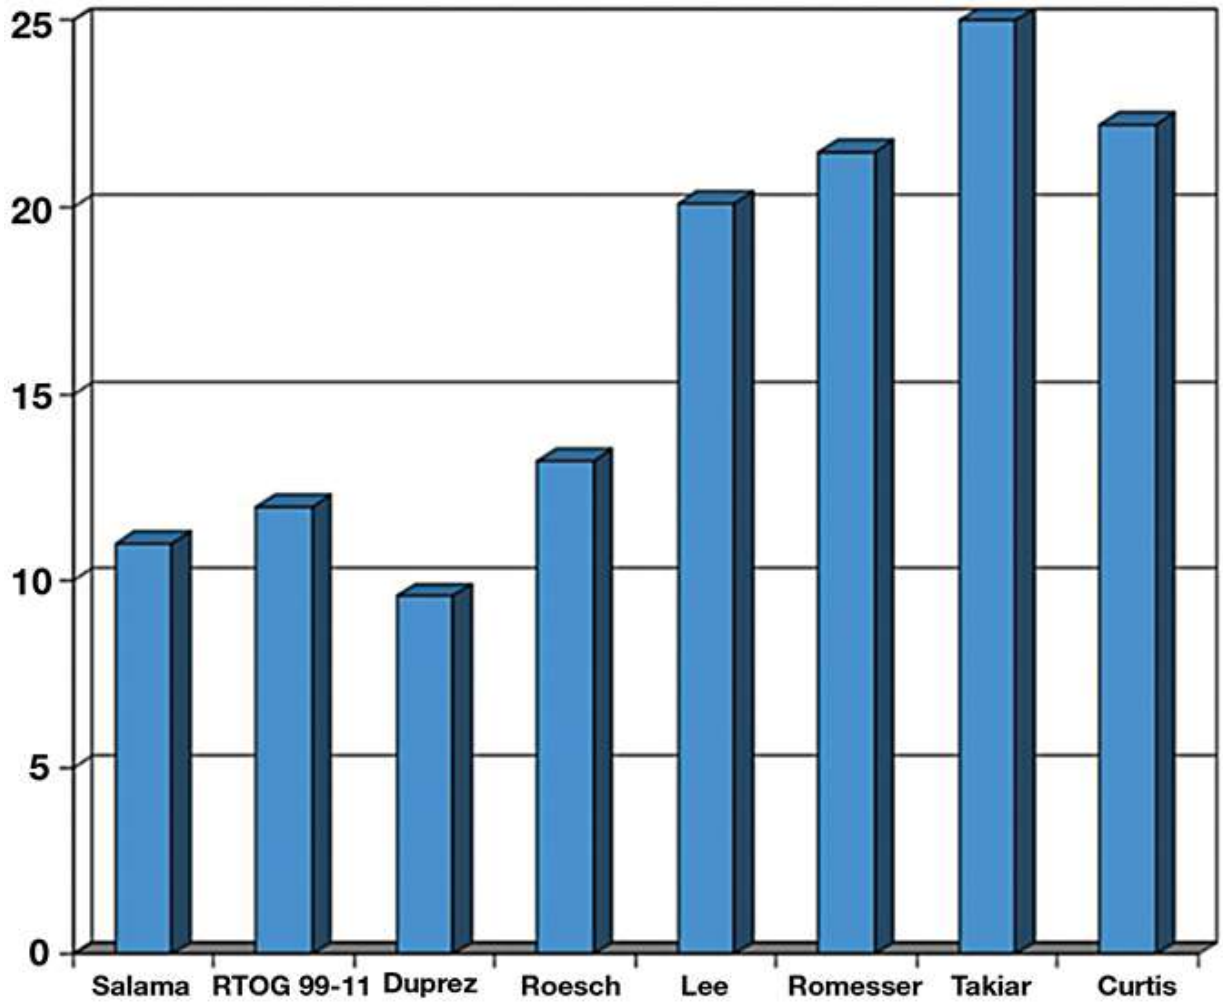

FIGURE 28.2 Median overall survival in months after reirradiation of head and neck cancers (selected studies[6,23,24,60-64]). The studies by Takiar et al,[24] Lee et al,[62] Romesser et al,[63] and Curtis et al[64] included mixed populations, that is, patients treated after salvage surgery or without resection. Limited recurrence treated with stereotactic body at an experienced center was associated with a median survival of 44 months.[65] In a pooled analysis of 500 patients, the risk of progression or death was approximately 4 times the risk of radiation-related severe late toxicity.[66]

BREAST CANCER

In-Breast Tumor Recurrence After Prior Breast-Conserving Surgery and Whole-Breast Radiation Therapy

It is generally accepted that in-breast tumor recurrence (IBTR) is expected to occur in approximately 5% to 10% of patients within 10 years after initial breast-conserving surgery (BCS) plus whole-breast radiation therapy (WBRT), equating to a cumulative risk of 0.5% to 1% per annum. The most often recommended treatment for IBTR is salvage mastectomy, which imparts excellent local regional control and 5-year survival rates.[68] Given the fact that there are subgroups of

patients who refuse mastectomy after IBTR, a number of series have described the approach of repeat BCS alone, without additional reirradiation. In these studies, local regional recurrence is unacceptably high, with rates approaching 40%,[69] as opposed to 10% following mastectomy.[68] Even so, radiation oncologists have generally shown a reluctance to offer reirradiation in the treatment of locally recurrent breast cancer.[70] However, with an increase in technological sophistication of radiation therapy techniques over the past two decades, a number of studies have investigated the feasibility and efficacy of adding reirradiation to BCS for IBTR.

Table 28.3 shows a summary of the modern series (published since 2010) of repeat BCS and reirradiation in the setting of IBTR. The overwhelming majority of the data exists for partial breast irradiation (PBI) using interstitial, multicatheter brachytherapy with low-dose rate, pulsed-dose rate, or high-dose rate source techniques.[71-81] Pooled data from European experience using all three of the aforementioned methods represent the largest study of this approach published to date.[73] In a total of 217 patients, this collaborative multi-institutional analysis from high-volume centers in Europe found that interstitial brachytherapy was very well tolerated with local control rates much more comparable to salvage mastectomy (93%) as well as good to excellent cosmetic outcome in the overwhelming majority of patients (85%). Simplified interstitial techniques using single- catheter balloon brachytherapy have been described with similar outcomes.[74]

Published since 2010 with >3-year median follow-up.
bid, twice daily; EBRT, external beam radiotherapy; eIORT, electron-based intraoperative radiotherapy; HDR, high-dose rate; IBTR, in-breast tumor recurrence; LDR, low-dose rate; PDR, pulsed-dose rate; qd, once daily; xIORT, 50-kV x-ray–based intraoperative radiotherapy.

An emerging modality to address the challenge of reirradiation after the second BCS for IBTR is intraoperative radiation therapy (IORT) at the time of salvage lumpectomy, using either electron[75] or "soft" x-rays.[76] IORT is delivered using a single dose of approximately 18 or 20 Gy with intraoperative electrons or 50 kV x-rays. In these two small studies of approximately 20 patients each, IORT was associated with local control of >90% at 4 years, with higher grade 3 toxicity reported for electron (21%) than for x-rays (0%). Cosmetic outcome was also somewhat disappointing compared to other techniques, with only 51% of patients treated with electron-based IORT reporting satisfactory results.

In terms of breast reirradiation using external beam radiation therapy (EBRT), the data are more scant, but growing. A modern study of its kind from Europe included 83 patients treated with once-daily conventionally fractionated RT (45 Gy in 1.8 Gy/fx) directed at the tumor bed after repeat BCS.[77] At a median follow-up of 3 years, the therapy was generally well tolerated with local control rates at 85% and no grade 3 or higher toxicity. In the United States, a multi-institutional phase II

trial (NRG Oncology/RTOG1014) evaluated the safety and efficacy of repeat PBI using bid accelerated hyperfractionated 3D conformal RT (45 Gy in 1.5 Gy/fx) over 3 treatment weeks.[81] In this study, 58 patients with small invasive or preinvasive lesions completely excised with negative surgical margins completed reirradiation and were assessed at over 5-year median follow-up. This regimen was well tolerated with excellent rates of local control (95%) and very few grade 3 toxicities.[75] Data from these trials serve to increase the use and availability of breast reirradiation among centers that do not offer interstitial brachytherapy or IORT.

As more data accumulate, there are two modern published consensus guidelines from Germany (DEGRO) and Italy to inform clinicians in routine practice of how to approach these challenging and heterogeneous populations.[12,82] Although the panels both recognize that mastectomy is generally regarded as a standard of care for patients with IBRT, but that a subset of patients may be appropriately offered reirradiation after a second BCS. Since the largest experience to date exists for a multicatheter brachytherapy, other techniques such as EBRT or IORT should preferentially be performed on a clinical trial.

Management of Local Regional Recurrence After Prior Mastectomy and Postmastectomy Radiation Therapy

The Early Breast Cancer Trialists' Collaborative Group estimated that the addition of RT significantly reduced the 10-year risk of isolated local recurrence from approximately 25% to 7%.[83] The addition of modern systemic therapy has fortunately made this type of event even more rare. That does not diminish the clinical challenge that is experienced by physicians in cases of isolated chest wall or regional nodal recurrences in patients who have had prior postmastectomy radiation therapy. Published series that address this issue tend to be single institution and small experiences with heterogeneous mix of patients, including those who have undergone prior mastectomy or breast conservation, as well as some who have unresectable gross disease present at the time of therapy.[84-92] These situations favor external beam approaches, rather than brachytherapy or IORT, including (more recently) proton beam radiotherapy (PBRT).

A selection of the most modern published series in the reirradiation for chest wall and regional recurrences is presented in Table 28.4. Historically, the majority of investigators use concurrent hyperthermia (HT) combined with EBRT that is typically conventionally fractionated or hypofractionated.[85-89] Although HT is not available at a majority of RT centers, it does have a proven benefit in the treatment of advanced superficial local recurrences such as these. Two of the largest studies,

both published by Linthorst et al, used large fraction external beam doses along with HT to produce reasonable local control rates (40%-78%) and relatively low rates of grade 3 toxicity (<15%). A recent small series combining PBRT with HT (62%) for a cohort of 19 patients mainly treated to the chest wall only with reirradiation to a total median dose of 50 CGyE showed outstanding local control at 19 months (100%) at the cost of >30% grade 3 toxicity.[89]

TABLE 28.4 COMPARATIVE OUTCOMES AMONG PUBLISHED SERIES OF CHEST WALL AND/OR REGIONAL NODAL REIRRADIATION FOLLOWING LOCOREGIONAL RECURRENCE AFTER INITIAL MASTECTOMY AND PMRT

Study (year)	Type of Reirradiation	*N*	Reirradiation Dose (median, Gy or CGyE)	Concurrent Treatment	Median Follow-Up (mo)	Toxicity (% ≥G3)	Local Control (%)

Some trials included breast-conservation patients as well.

CT, cytotoxic chemotherapy; EBRT, external beam radiotherapy; HT, hyperthermia; PBRT, proton beam radiotherapy; PMRT, postmastectomy radiotherapy.

Series that omit HT generally include fewer, more favorable patients treated for high-risk, microscopic disease post limited resection treated with conventionally fractionated photons[84,87] or PBRT[90-92] with or without concurrent chemotherapy. Local disease control rates are favorable (63%-100%), with lower rates of toxicity compared to combined HT. There is a great deal of enthusiasm for the emerging experience of PBRT to maximize normal tissue avoidance as well as dose escalate.[90-92] Although these relatively large series of PBRT show excellent rates of local control (>93%) with a low toxicity profile (<20% grade 3), the rates of distant disease failure remain very high, even in the setting of concurrent or sequential chemotherapy. The aforementioned DEGRO expert panel currently recommends the use of reirradiation both in cases of unresectable recurrences and after surgical resection in high-risk patients.[12] This group recommends reirradiation with doses between 45 and 50 Gy in conventional fractionation, not exceeding cumulative doses of 100 to 110 Gy, and notes that HT can further improve tumor control in this population.

Isolated Regional Nodal Recurrences After Prior Radiotherapy

Isolated supraclavicular and/or axillary recurrences are very uncommon in breast cancer, especially after appropriate adjuvant radiation therapy in the up-front setting. These clinical scenarios, however, pose the most significant clinical challenges for physicians and patients alike, due to the difficulty in early diagnosis and high-risk surgical management. In these situations, the risk of injury to clinical OARs such as the brachial plexus from repeat RT must be weighed against the certain involvement of these structures due to direct invasion of progressive disease.

In the largest series of its kind, a multi-institutional study from the Netherlands, 42 patients with isolated supraclavicular recurrence treated with a combination of systemic and local regional RT were examined.[93] The 5-year overall survival and disease-free survival rates were significantly worse than are seen with chest wall recurrences (38% and 22%, respectively). What is more striking is that outcomes were even worse for patients who did not receive RT as a component of their salvage treatment. Given the grim prognosis, there are small emerging series that address isolated nodal recurrences with a combination of either concurrent or sequential chemotherapy and reirradiation[89-95] using photon and PBRT techniques to median doses of 50 Gy. Even in these most conformal techniques, point doses to the brachial plexus are well above historically cited tolerance with cumulative doses in excess of 100 Gy. Since overall survival in these patients is less than half

that of patients with chest wall recurrences,[93] clinicians must weigh the risks of a tumor-induced plexopathy versus iatrogenic injury in each particular case.

Patients with isolated axillary recurrences tend to fare somewhat better due to the fact that they lend themselves more often to surgical excision and reirradiation without compromising the brachial plexus. In a series of axillary recurrences from the MD Anderson Cancer Center, the authors found that durable control was able to be achieved in 31 (70%) of 44 patients.[96] Success was most often seen in patients who were able to undergo up-front surgery and multimodality therapy. Twenty percent of these patients had prior axillary RT, and the addition of reirradiation to the axilla significantly improved local disease control (81% vs 56%). As of now, the DEGRO expert panel acknowledges that in cases of isolated nodal recurrences, approximately half to two-thirds of patients will eventually develop distant metastatic disease. Durable local regional control is more often achieved in patients with axillary nodal involvement only, and reirradiation improves local control and should be applied wherever feasible.[12] Newer technologies such as PBRT, MR-guided adaptive RT, and novel concurrent radiosensitizing systemic agents are likely to lead the next generation of reirradiation techniques for locoregionally recurrent breast cancer.

DISCUSSION

Reirradiation should only be considered if the radiation tolerance of critical tissues or organs has not been exceeded during the first treatment, that is, after an in-depth review of the initial plan and dose distribution, and assessment of organ status and side effects after the first treatment.[4] Moreover, reasonable performance status; the absence of other, less toxic treatment alternatives; and careful dose summation are prerequisites. It is important to weigh the expected benefits against morbidity and compromised quality of life. Several studies, especially on lung and head and neck cancers, demonstrated that reirradiation can either cause or prevent a fatal outcome. In many scenarios, including, but not limited to, pelvic tumors, the ability of reirradiation to palliate pain and other symptoms has repeatedly been confirmed[7,97,98] (Figure 28.3). For many tissues, organs, and indications, an increasing body of clinical data is now emerging. These include settings with much higher single-course equivalent doses than previously prescribed, for example, SBRT for early-stage lung cancer.[99] Nevertheless, limited knowledge exists for a number of end points, such as neurocognitive function and damage to endocrine organs or second reirradiation tolerance.[100] Acutely responding tissues, in general, recover radiation changes practically completely within a few months and, therefore, can tolerate a repeat treatment course.

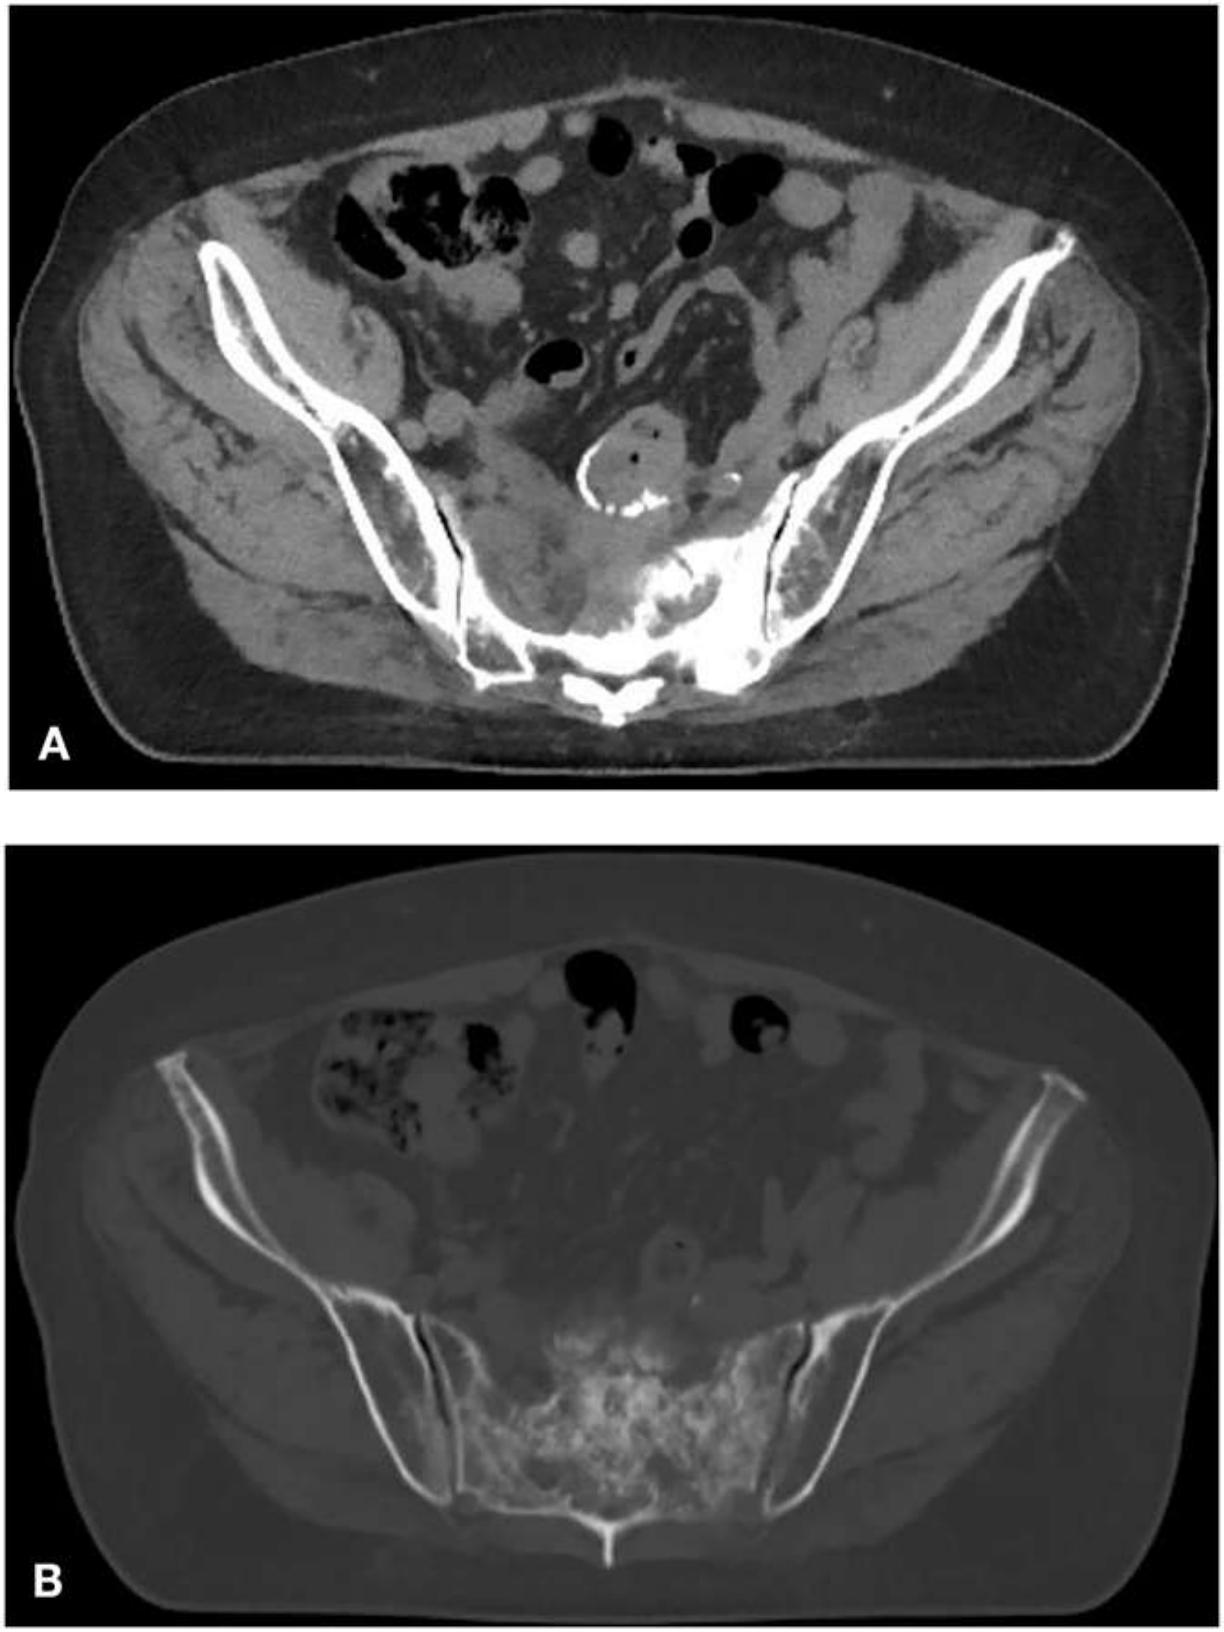

FIGURE 28.3 Representative axial slices from planning computed tomography images (soft tissue [A] and bone [B] window) of a 64-year-old female patient initially treated surgically for cancer in the

sigmoid colon in 2013. She relapsed in the sacral bone in 2014 and received long-course chemoradiation (50 Gy in 25 fractions with concomitant capecitabine) without surgery. Due to local progression chemotherapy with an oxaliplatin/5-fluorouracil regimen was initiated in 2016. Due to increasing pain, reirradiation was offered in June 2016. A hyperfractionated regimen was chosen (1.25 Gy bid, total dose 40 Gy) concomitant to capecitabine. Symptom improvement was achieved without high-grade treatment-related toxicity.

Clinical evidence dating back many decades[101] suggests that fibrosis, impaired blood perfusion, and, in general, late normal tissue injury in humans continue to progress for many years. These findings have triggered a trend toward highly sophisticated, conformal image-guided reirradiation approaches aiming at better normal tissue sparing. Brachytherapy (including intraoperative administration), stereotactic techniques, proton, and carbon ion beams are under clinical investigation.[9,102-110] However, severe dysphagia and fatal bleeding might still occur after proton beam reirradiation for head and neck cancer. It is hoped that models that predict the risk of serious complications might contribute to optimized patient selection. Proton beam reirradiation of non–small cell lung cancer was associated with six grade 5 toxicities in a multi-institutional study of 57 patients.[105] Increased overlap with the central airways, mean esophagus and heart dose, and simultaneous chemotherapy were risk factors for grade ≥3 toxicity.

While small target volumes can be treated with fraction sizes above 2 Gy, radiobiologic principles and clinical data suggest that large-volume reirradiation might be less toxic if hyperfractionation is employed.[7,57,111,112] Despite strong rationales, this logistically difficult approach has only been studied in a single randomized head-to-head comparison to once-daily reirradiation (nasopharynx cancer). Many institutions consider reirradiation for primary and secondary brain tumors; bone and lymph node metastases; head and neck, lung (Figure 28.4), breast, prostate, gynecologic, and rectal cancer; lymphoma; and soft tissue sarcoma. Fewer reports were published regarding hepatic, pancreatic, and esophageal tumors.[112-116] The EORTC/ESTRO ReCare multicenter study will gather real-world data on patients treated with high-dose reirradiation for local recurrence and new primary or secondary cancer in line with recently published reporting recommendations and definitions.[4]

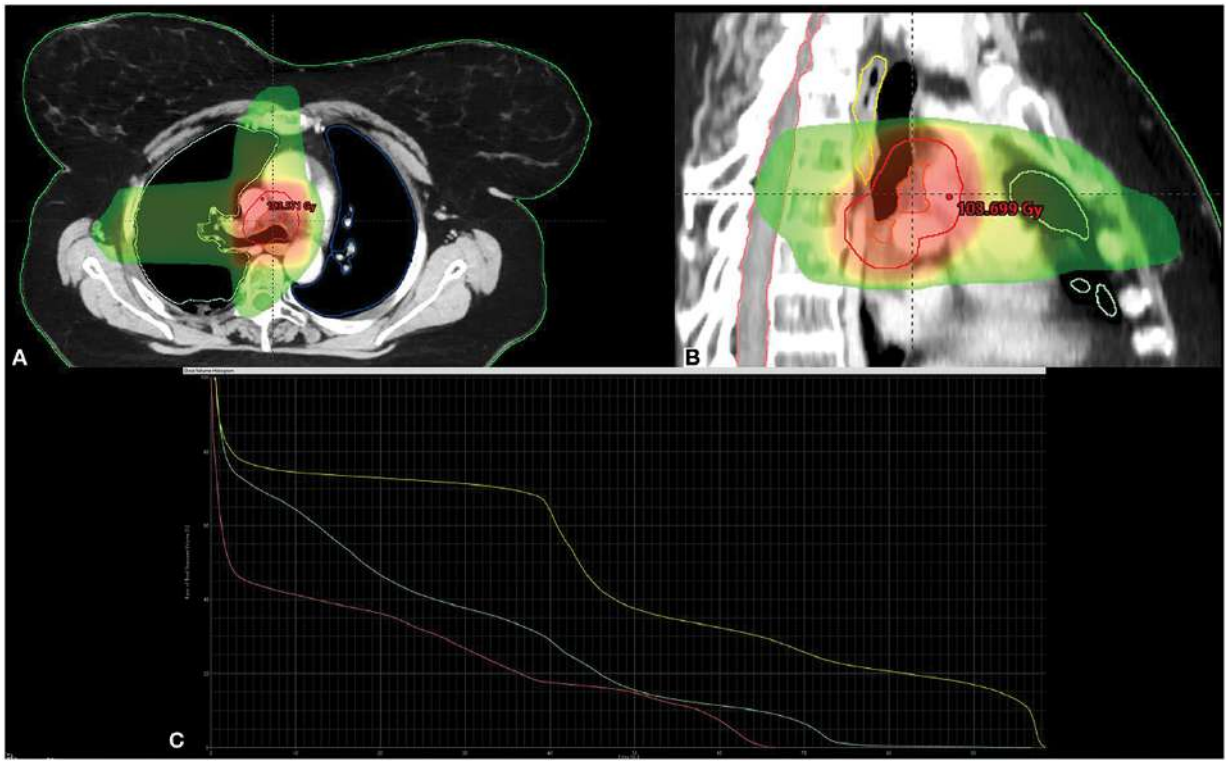

FIGURE 28.4 Representative axial slices from planning computed tomography images (A) and sagittal (B) from computed tomography images of a 59-year-old female patient initially treated in November 2015 for right-sided small cell lung cancer (chemoradiation with cisplatin/etoposide and bid radiation to 45 Gy in two daily fractions of 1.5 Gy). In February 2017, mediastinal in-field relapse was confirmed. The patient again received chemoradiation, however to an escalated dose of 57 Gy, two daily fractions of 1.5 Gy. In February 2022, surgery was performed for a left-sided second primary lung cancer (squamous cell, stage I). Severe late toxicity from reirradiation was not observed. C. The cumulative dose-volume histogram shows a D_{max} of 98.6 Gy in the esophagus (yellow curve) and 66.6 Gy in the spinal canal (brown curve). Mean lung dose was 25 Gy (green curve).

CHAPTER 29

Chemical Modifiers of Radiation Response

Yvonne Marie Mowery, Ashlyn G. Rickard, and David M. Brizel

Chemical agents have been administered in conjunction with radiation therapy (RT) for both the enhancement of antitumor therapeutic efficacy and the amelioration of treatment-induced toxicity. Two concepts are fundamental to understanding the rationale for chemical modification of radiation response and to interpreting the studies that have addressed this issue. The first is the therapeutic ratio (TR), which is defined as the TCP/NTCP where TCP is the tumor control probability and NTCP is the normal tissue complication probability. Both parameters have sigmoid dose-response curves (Figure 29.1). The horizontal separation between these two curves for any given treatment will often determine its overall utility. As the separation between these curves increases, the likelihood becomes greater that the treatment will be effective without causing an unacceptable level of morbidity. Conversely, when the two curves are closer together, the treatment may be less effective while causing an unacceptable level of morbidity.

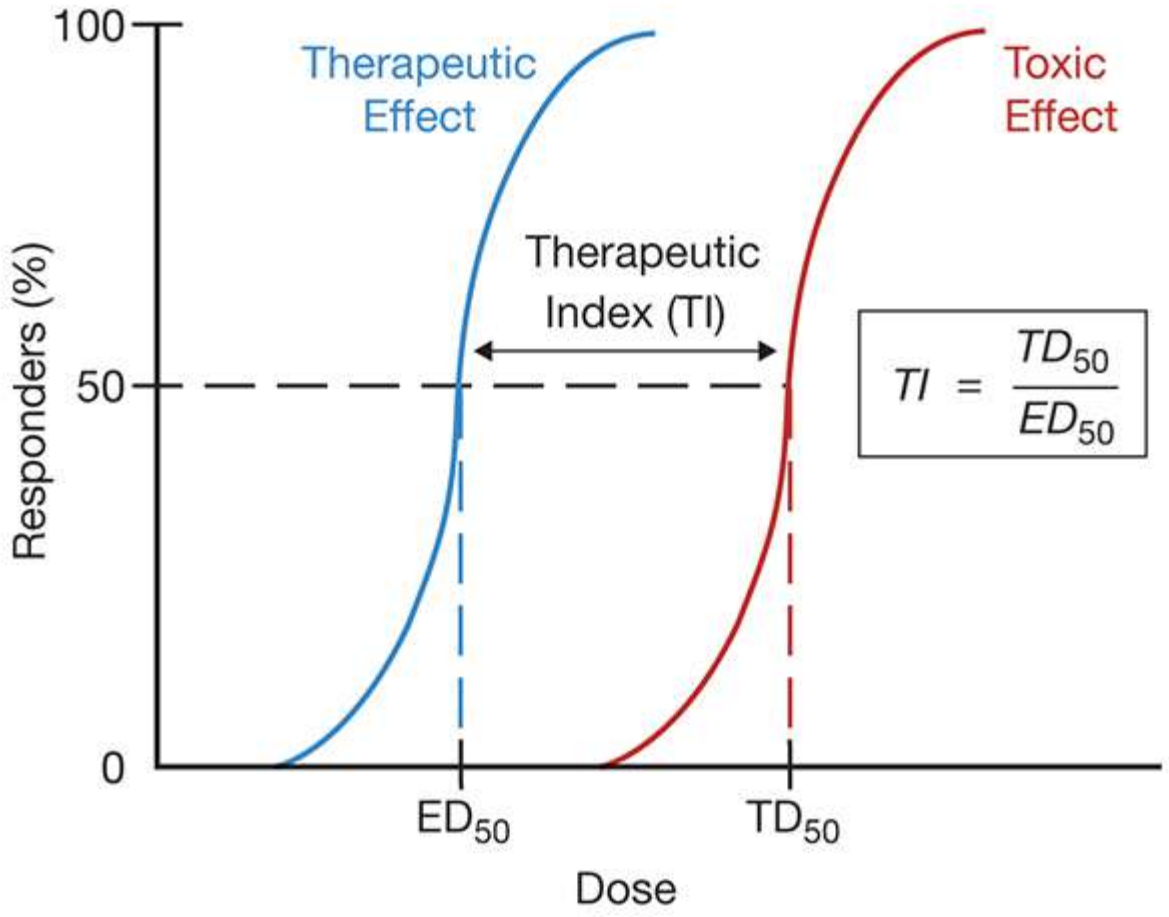

FIGURE 29.1 A graphic representation of the therapeutic index (TI). The tumor control probability (TCP) is to the left of the normal tissue complication probability (NTCP), and both are displayed as sigmoid dose-response curves. Larger separations are indicative of higher TIs. Ideally, normal tissue protection strategies would move the NTCP curve to the right without compromising TCP (moving the TCP curve to the right). Ideal therapeutic intensification strategies would move the TCP curve to the left without worsening NTCP (moving the NTCP curve to the left).

The second concept is the efficacy/toxicity profile of the putative chemical modifier, which can directly affect the TR. A radiosensitizing agent that exacerbates toxicity to the same extent that it improves efficacy (shifting both NTCP and TCP curves to the left) may leave the TR unchanged or worsened and, therefore, not be clinically practical. Conversely, a radioprotective agent that also reduces RT efficacy against the tumor (shifting both NTCP and TCP curves to the right) may not affect or even reduce the TR. The intrinsic toxicity of a radioprotector must also be

considered when reduction of NTCP is the primary goal of a given chemical modification strategy. A compound that causes significant side effects may render it unsuitable, even if it can reduce the treatment-induced toxicity in question. This chapter explores chemical radiosensitization and radioprotective strategies. The primary focus is on treatments that have been clinically tested in head and neck cancer to amplify these concepts.

CHEMICAL RADIOSENSITIZATION

The Oxygen Effect

Tumor cell killing is produced by direct ionizations within critical cellular targets, as well as by the indirect effect of energy deposited in other cellular molecules like water. Ionizing radiation generates free radicals, which can lead to cellular death by inducing single- and double-strand DNA breaks. This damage can be fixed or repaired by the chemical processes of oxidation and reduction, respectively.[1] The addition of molecular oxygen to target free radicals produces altered chemical structures that are potentially lethal. When a tumor is hypoxic, reduced availability of molecular oxygen leads to fewer reactive oxygen species induced by radiation, thus decreasing radiosensitivity in vitro and in vivo.[2,3] Well-oxygenated tumors (partial pressure of oxygen or pO_2 >10 mm Hg) are at least 2.5 times more sensitive to a given dose of ionizing radiation than their hypoxic counterparts.

Clinical data clearly demonstrate the existence of tumor hypoxia in head and neck cancer,[4,5] and there are extremely strong correlations between hypoxia and both infield treatment failure and overall survival.[6,7] This effect is independent of the disease stage at diagnosis.[7] Tumor hypoxia has also been correlated with local and distant recurrence in cervical carcinoma treated with surgery[8,9] or RT[10] and with distant failure in soft tissue sarcomas treated with surgery and adjuvant RT.[11]

Augmentation of Tumor Oxygenation

Therapeutic attempts to overcome the deleterious effect of tumor hypoxia have followed three general lines of investigation: increased delivery of oxygen to tumor, preferential sensitization of hypoxic cells with oxygen-mimetic agents, or cytotoxic agents that selectively target hypoxic tumor

cells. Hemoglobin concentration is the major determinant of the oxygen delivery capability of blood to tissue. Hemoglobin oxygen saturation exceeds 90% when the arterial pO_2 is >70 mm Hg. Still, oxygen is relatively insoluble in plasma under normobaric conditions. Under hyperbaric conditions, considerable quantities of oxygen can be dissolved into plasma and thus be potentially available for delivery to hypoxic tissues.

Clinical trials of hyperbaric oxygen (HBO) and RT were conducted from the 1950s to the 1970s. Trials conducted in patients with cancers of the central nervous system,[12] lung,[13] bladder,[14] and skin[15] showed no benefit from the addition of HBO to RT. However, randomized controlled trials in carcinoma of the cervix[16] and head and neck[17,18] did show improvements in locoregional control and overall survival. The cumbersome logistics associated with HBO delivery in conjunction with RT necessitated the utilization of nonconventional hypofractionated treatment regimens, which has prevented HBO from being incorporated into routine clinical use.

Carbogen (95% oxygen [O_2]/5% carbon dioxide [CO_2]) breathing, with or without concurrent nicotinamide administration, has also been utilized in attempts to improve tumor oxygenation and enhance RT response. CO_2 addition in the gas-breathing mixture induces a mild acidosis that shifts the oxyhemoglobin association curve to the right, facilitating more unloading of oxygen into hypoxic tissues. The rationale for adding nicotinamide, a vitamin B derivative, is based on preclinical studies showing enhancement of tumor blood flow.[19,20] Polarographic electrode assessments in cervical and head and neck cancer have demonstrated that carbogen breathing and nicotinamide administration improve tumor oxygenation in some patients.[21-23]

A randomized trial of hyperfractionated RT with or without carbogen was conducted at the University of Florida from 1996 to 2002.[24] The study included patients with cT2-T4 squamous cell carcinoma (SCC) of the oropharynx, larynx, and hypopharynx. It was designed to detect a 20% improvement in a 2-year local control in the carbogen arm relative to the RT-alone arm, with a 15% improvement in a 4-year cause-specific survival. Virtually all enrolled patients in both arms completed their prescribed courses of treatment. The addition of carbogen to RT did not appear to improve any of the planned end points of this trial. However, while the

design of this trial called for enrollment of 675 patients, only 101 were accrued over a 5-year period. The trial was, therefore, significantly underpowered to detect the hypothesized treatment effects. The inability to accrue patients also called into question the overall viability of strategies utilizing carbogen.

The use of accelerated RT with carbogen inhalation and nicotinamide (ARCON) was tested in a phase II trial of 215 patients with head and neck cancer.[25] Ninety-seven percent had stage III or IV disease, and the primary tumor site was larynx in 46%, hypopharynx in 23%, and oropharynx in 23%. Full compliance with carbogen breathing during RT occurred in 88% of patients. Nicotinamide was administered 1 to 1.5 hours prior to RT at 60 to 80 mg/kg. Nicotinamide-induced nausea and vomiting necessitated discontinuation of the drug in 10% of patients receiving the lower dose and 31% of patients receiving the higher dose. Five-year locoregional control rates were 48% for hypopharynx, 77% for larynx, and 72% for oropharynx primaries.[26] A subsequent phase III trial randomized 345 patients with cT2-T4 laryngeal SCC to ARCON versus accelerated RT.[27] Local tumor control did not differ between treatment arms, but 5-year regional control was significantly higher with ARCON compared to accelerated RT alone (93% vs 86%; $P = .04$). A subgroup analysis indicated that this beneficial effect of ARCON is limited to patients with tumors having a high hypoxic fraction.

Allosteric modifiers of hemoglobin structure have been identified that can shift the oxyhemoglobin dissociation curve to the right and increase O_2 delivery to hypoxic tissues.[28] One such compound, RSR13 (efaproxiral), has been shown to improve tumor oxygenation[29] and enhance the effectiveness of RT in preclinical models.[30] A phase III open-label trial of whole-brain RT and oxygen breathing with or without daily infusion of efaproxiral was conducted in 538 patients with brain metastases.[31] Fifty-four percent of patients had metastatic non–small cell lung cancer, and 20% had metastatic breast cancer. Overall, no improvement in survival was detected. A planned subset analysis suggested significant improvement in median survival in patients with breast cancer with sufficient efaproxiral levels in their erythrocytes.[32] However, the phase III ENRICH trial, which examined efaproxiral and supplemental oxygen with whole-brain RT (30 Gy in 10

fractions) in 368 patients with breast cancer with brain metastases, showed no significant difference in overall survival.[33]

Sensitization of Hypoxic Cells

Electron-affinity compounds can oxidize radiation-induced free radical damage in the cell to produce increased kill.[34] The use of these agents would be particularly attractive in the hypoxic tumor microenvironment, where low oxygen concentrations impair RT efficacy. The 2-nitroimidazoles are one such class of compounds that are metabolized into their active form under hypoxic conditions. Misonidazole, the prototype 2-nitroimidazole, was tested in two randomized trials. The Danish Head and Neck Cancer Study 2 (DAHANCA-2) performed a double-blind randomized trial evaluating the effect of misonidazole given in two drug schedules with split-course irradiation in the treatment of carcinoma of the larynx and pharynx.[35] Patients (n = 626) were stratified according to tumor site (larynx vs pharynx), nodal status, and institution. The total misonidazole dose was 11 g/m^2. Overall, the misonidazole group did not have significantly better local tumor control than the placebo group. Serious peripheral neuropathy, the dose-limiting toxicity of all nitroimidazole compounds, occurred in 26% of misonidazole-treated patients. The European Organisation for Research and Treatment of Cancer conducted a randomized study of conventional fractionation RT versus modified fractionation RT (three fractions per day) with or without misonidazole in 523 patients with advanced head and neck cancer. No differences were seen in treatment outcome.[36]

Etanidazole (SR2508) is a misonidazole analog with lower lipid solubility and less neurotoxicity in phase II studies in head and neck cancer.[37] A Radiation Therapy Oncology Group (RTOG) phase III study randomized 521 patients with stage III or IV head and neck cancer to receive conventionally fractionated (CF) irradiation with or without etanidazole 2 mg/m^2 delivered 3 times per week.[38] Of those on the etanidazole arm, 77% received at least 14 doses of the drug. No grade 3 or 4 central nervous system or peripheral neuropathy was observed. The 2-year actuarial local tumor control was 40% in each arm, and survival was 41% and 43% in the irradiation alone and irradiation plus etanidazole arms, respectively. A similar study of 374 patients performed in Europe showed

increased neurotoxicity and no improvement in outcomes in patients who received etanidazole.[39]

Nimorazole is a 5-nitroimidazole of the same structural class as metronidazole.[40] Its dose-limiting toxicity is nausea and vomiting; however, the drug can be administered with each radiation treatment. DAHANCA conducted a phase III trial of nimorazole (1.2 g/m^2 vs placebo) for SCC of the supraglottic larynx and pharynx.[41] There was a statistically significant improvement in locoregional tumor control (49% vs 33% at 5 years; P = .002), but not in survival, which is consistent with the DAHANCA misonidazole trial. The use of nimorazole administered 60 to 120 minutes prior to each radiation fraction has become the standard of care (SOC) for head and neck SCC in Denmark, but it has not been adopted in other countries. An international multicenter phase II randomized trial of nimorazole with accelerated RT for stage I to IV head and neck SCC (excluding nasopharynx and stage I to II larynx) failed to meet accrual goals, enrolling only 104 of a planned 600 patients.[42] Although premature closure resulted in this trial being underpowered, there was a trend toward reduced 18-month locoregional failure with nimorazole (33% vs 51% in control group, P = .1). The difference in overall death (19%; 95% CI, −3% to 42%; P = .1) also favored nimorazole but did not meet statistical significance. NIMRAD (NCT01950689) was a randomized, placebo-controlled phase III trial in the United Kingdom assessing nimorazole (1.2 g/m^2 daily prior to RT vs placebo) with a 6-week course of intensity-modulated radiation therapy (IMRT: 65 Gy in 30 fractions) for patients with locally advanced head and neck cancer not suitable for concurrent cetuximab or platinum chemotherapy.[43] In 338 patients with median follow-up of 3.1 years, there were no significant improvements in locoregional control or overall survival in the nimorazole group compared to placebo. Similarly, a subgroup of 139 patients with hypoxic tumors did not benefit significantly from the addition of nimorazole in terms of locoregional control (adjusted hazard ratio [HR] 0.72; 95% confidence interval [CI] 0.36-1.44; P = .35) or overall survival (adjusted HR 0.96; 0.53-1.72; P = .88). In addition, patients receiving nimorazole reported higher rates of acute nausea compared to the placebo group.[44]

Pharmacologic Targeting of Hypoxic Cells

Mitomycin C (MMC) is an alkylating agent metabolized in regions of low oxygen concentration and preferentially cytotoxic to hypoxic cells. MMC plays an integral role in conjunction with RT and 5-fluorouracil (5-FU) in the definitive nonsurgical management of anal SCC.[45] Yale University investigators examined the concurrent use of MMC in 195 patients with head and neck cancer treated on two randomized trials.[46] Their treatment program consisted of 68 Gy with or without MMC on days 1 and 43 of RT. Locoregional recurrence-free survival was improved with the addition of MMC from 54% to 76% ($P = .003$). Overall survival improved from 42% to 48%, but this was not statistically significant. The majority of patients in these trials received postoperative or preoperative irradiation. Only 74 (38%) received definitive primary RT, and the benefit from the addition of MMC in this subset is unclear.

A three-armed randomized trial conducted at the University of Vienna compared CF RT (2 Gy daily to 70 Gy) against continuous hyperfractionated accelerated RT with or without MMC (V-CHART + MMC and V-CHART, respectively).[47] RT was given as an initial 2.5 Gy fraction followed by 1.65 Gy twice a day to a total dose of 55.3 Gy in 17 days. MMC was given as a 20 mg/m^2 bolus on day 5 of RT. Of the 239 patients enrolled, 85% had T3 or T4 primaries and 79% had nodal involvement. Three-year actuarial locoregional control was 48% for V-CHART + MMC versus 32% for V-CHART and 31% for CF ($P = .05$ and .03, respectively). Overall survival was also significantly higher in the V-CHART + MMC arm at 41%, compared to 31% for V-CHART and 24% for CF ($P = .03$). The incidence of confluent mucositis was 90% in both experimental arms as compared with 33% in the CF arm. The median time to complete resolution of mucositis was 6 to 7 weeks in all three arms. Grade 3 or 4 hematologic toxicity, primarily thrombocytopenia, occurred in 18% of the V-CHART + MMC patients.

Porfiromycin, a derivative of MMC, provides greater differential cytotoxicity between hypoxic and oxygenated cells in vitro.[48] The Yale investigators also conducted a phase III study that compared patients treated with CF RT + MMC versus RT + porfiromycin.[49] Hematologic and nonhematologic toxicities were equivalent in the two treatment arms. With

a median follow-up >6 years, MMC was superior to porfiromycin with respect to 5-year local relapse-free survival (91.6% vs 72.7%; P = .01), locoregional relapse-free survival (82% vs 65.3%; P = .05), and disease-free survival (72.8% vs 52.9%; P = .03). There were no significant differences between the two arms with respect to overall survival (49% vs 54%) or distant metastasis- free survival (80% vs 76%). Their data supported the continued use of MMC as an adjunct to RT in advanced head and neck cancer; however, this regimen is no longer used on a routine basis.

Tirapazamine (also known as SR-4233; WIN 59075; 3-amino-1,2,4-benzotriazine 1,4-dioxide) is a bioreductive agent preferentially cytotoxic to hypoxic cells in vitro. Twenty-five to 200 times more drug is required to produce the same level of cell killing in aerobic compared to anaerobic conditions.[50,51] Under hypoxic conditions, a free radical one- electron reduction product rapidly forms and is believed to be the toxic species, causing oxidative damage to pyrimidines and inducing DNA strand breaks.[52] Analysis of DNA and chromosomal breaks following hypoxic exposure to tirapazamine suggests that DNA double-strand breaks are the primary lesions involved in cell death.

This bioreductive agent differs from oxygen-mimetic sensitizers, such as the nitroimidazoles, in that it is itself cytotoxic to hypoxic tissues. Therefore, unlike the oxygen-mimetic sensitizers, tirapazamine-mediated therapeutic enhancement occurs whether the drug is given before or after irradiation.[53,54] In fractionated RT of murine tumors, tirapazamine is as effective as, if not superior to, etanidazole.[55] The efficacy of this radiation modifier depends on the number of “effective doses” that can be administered during a course of RT and the presence of hypoxic tumor cells.[56] Tirapazamine can also enhance the cytotoxicity of cisplatin.[57]

Rischin et al. investigated the use of concurrent tirapazamine, cisplatin, and RT in advanced head and neck cancer in a series of trials. A phase I trial established the dosing schedule for tirapazamine given with RT and cisplatin.[58] A randomized phase II study compared RT with cisplatin/tirapazamine versus RT with cisplatin/5-FU and suggested a benefit in the tirapazamine treatment arm (3-year locoregional failure-free survival 84% vs 66%; P = .07).[59] Tumor hypoxia imaging was performed with 18-fluorodeoxyglucose-misonidazole positron emission tomography scanning in 45 patients in these studies.[60] Hypoxia was identified in primary

or nodal sites in 71% of these patients. Eight (62%) of 13 patients with hypoxic tumors who received cisplatin/5-FU experienced subsequent locoregional failure compared to only one (5%) of 19 patients with hypoxic tumors who received tirapazamine (HR = 15; P = .001). Only one of 10 patients with nonhypoxic tumors who received cisplatin/5-FU had a locoregional failure. These findings strongly suggested that the benefit of tirapazamine resulted from improved treatment efficacy against tumor hypoxia.

Two phase III trials were initiated to validate the use of tirapazamine in head and neck cancer. The HeadSTART study enrolled 861 patients and compared standard fractionation RT (70 Gy) with concurrent cisplatin/tirapazamine versus concurrent cisplatin alone.[61] The primary end point was overall survival, with 2-year rates of 65.7% in the cisplatin-alone arm and 66.2% in the cisplatin/tirapazamine cohort. No differences were seen in failure-free survival, time to locoregional failure, or quality of life. Of note, patients in this study were not selected based on the presence of tumor hypoxia. Moreover, 12% had major RT planning deficiencies, with those patients having significantly worse locoregional control and overall survival compared to those in protocol compliance.[62] A second trial with a planned enrollment of 550 patients was closed prior to completion of accrual because of an excess number of early deaths in the cisplatin/tirapazamine arm.[63]

Hyperthermia

Hyperthermia (HT) involves elevation of tissue temperature, typically 40 °C to 45 °C, for a therapeutic effect.[64] Although HT monotherapy can result in some cells being killed, it has been more widely used for its radiosensitizing effect in tumors. Physiologic changes induced by HT include increased perfusion, causing tissue reoxygenation and altered metabolism associated with reduced oxygen consumption. This improved oxygenation confers increased tumor radiation sensitivity and is correlated with pathologic complete response in patients with soft tissue sarcoma undergoing preoperative irradiation and HT.[65] In addition, cells are particularly sensitive to HT under conditions associated with radioresistance, including hypoxia, low pH, and the presence in S phase of

the cell cycle. Heat may also interfere with repair of radiation-induced DNA damage.[66,67] The thermal enhancement ratio (TER) quantifies the synergistic effect of HT and RT. TER is defined as the ratio of RT dose without HT to the isoeffective RT dose with HT:TER = RT dose without HT/RT dose for equivalent effect with HT. TER is >1 for most tumor types when HT is administered within 2 hours of RT.[68]

Several randomized clinical trials have assessed RT with HT compared to RT alone. Results have been mixed, but a meta-analysis suggests overall improved tumor response with combined RT and HT for multiple tumor types.[68,69] Combined RT and HT have been most widely studied for head and neck cancer and cervical cancer, largely because of the association between tumor hypoxia and poor clinical outcomes in these diseases as discussed above. The Dutch Deep Hyperthermia group performed the largest randomized controlled trial comparing RT alone to RT with HT in 358 patients with locally advanced bladder, cervical, or rectal cancer. HT was administered once weekly within 1 to 4 hours of RT for five total treatments. Complete response rates were significantly higher with RT and HT compared to RT alone (55% vs 39%; $P < .001$), and local control duration was longer with combined therapy. On multivariate analysis adjusting for age, tumor site, and tumor size/stage, RT combined with HT was also associated with reduced death (relative HR, 0.74; 95% CI, 0.57-0.97; $P = .03$). Acute and late radiation toxicity did not differ by treatment group.[70] Although results with combined HT and RT have been promising, enthusiasm for HT has waned due in large part to technical challenges in uniformly heating tumors, particularly at deep-seated locations.[71]

Chemotherapy

Chemotherapeutic agents are often utilized in conjunction with RT for their radiosensitizing effect.[72,73] Concurrent chemoradiation with platinum agents, particularly cisplatin, improves survival in numerous malignancies, including head and neck cancer,[74,75] cervical cancer,[76,77] and lung cancer.[78] Multiple potential mechanisms for platinum-induced radiosensitization have been proposed, including blocking DNA repair and inducing cell cycle arrest.[72,79] Several clinical trials are investigating the addition of new agents to cisplatin-based chemoradiation. For example, the ribonucleotide

reductase inhibitor triapine showed promise in a phase II clinical trial for cervical cancer,[80] and a randomized phase III trial is ongoing (NCT02466971). Taxanes are also widely employed with RT for the treatment of head and neck cancer, lung cancer, and esophageal cancer. These drugs facilitate radiation-induced cell killing by synchronizing cell cycle and causing cell cycle arrest in the radiosensitive G2/M phase.[81-83] Fluoropyrimidines such as 5-FU are commonly administered concurrently with RT for gastrointestinal malignancies because of their radiosensitizing effect. Slowed repair of radiation-induced double-strand DNA breaks and alteration of cell cycle progression by fluoropyrimidines likely result in radiosensitization.[84] Although mechanistic understanding of the interactions between RT and chemotherapy remains poorly understood, combined chemoradiation has dramatically improved outcomes for multiple malignancies.[74]

Biologic Modifiers of Radiation Response

Overexpression of the epidermal growth factor receptor 1 (EGFR-1) is associated with adverse outcomes in head and neck SCC.[85] Cetuximab (C225) is a chimeric monoclonal antibody to EGFR. Preclinical studies have demonstrated that cetuximab sensitizes cells to the cytotoxic effects of ionizing irradiation.[86-88] An open-label phase III trial compared outcomes for RT alone versus RT with weekly cetuximab after a loading dose.[89] Most patients received accelerated fractionation with concomitant boost, although hyperfractionation and standard fractionation schemes were also permitted. Oral cavity primary tumors were ineligible for enrollment. Two-year locoregional control was 56% with RT and cetuximab versus 48% with RT alone ($P = .02$). The incidence of distant metastatic recurrence was the same in both treatment arms. The initial survival advantage seen with the addition of cetuximab to RT has persisted, with updated 5-year overall survival rates of 45.6% versus 36.4% ($P = .018$).[90]

This trial provided an important proof of principle that adding a biologically targeted agent to a physically targeted modality can improve therapeutic outcome and that enhanced locoregional control can lead to enhanced survival. However, one-third of enrolled patients had stage III disease and thus had less advanced disease with more favorable prognoses

than a significant proportion of patients who typically undergo chemoradiotherapy (CRT). A more favorable prognosis and improved treatment response has also been seen in patients with oropharyngeal SCC associated with the human papillomavirus (HPV).[91] Whether RT with cetuximab is as effective or less toxic than RT with cisplatin in this select population was recently evaluated in the phase III RTOG 1016 study and De-ESCALaTE trial. With a median follow-up of 4.5 years for RTOG 1016 (NCT01302834), 5-year overall survival was 77.9% for cetuximab and 84.5% for cisplatin. This did not meet prespecified noninferiority criteria. In addition, 5-year progression-free survival was significantly lower in the cetuximab group compared to cisplatin in the cisplatin group (67.3% vs 78.4%; P = .0002). Acute and late toxicities were similar in both groups. The authors concluded that concurrent cisplatin with RT is the SOC for patients with HPV-positive oropharyngeal carcinoma without contraindications to cisplatin.[92] Similarly, concurrent cetuximab was inferior to cisplatin with RT for HPV-related oropharyngeal SCC in the De-ESCALaTE trial (NCT01874171). The 2-year overall survival and recurrence rates were significantly worse in the cetuximab group (P = .0001 and P = .0007, respectively), and toxicity rates were similar for both groups.[93] A phase II Italian trial comparing cetuximab to weekly cisplatin (40 mg/m^2) for stages III to IVB head and neck SCC was closed early because of slow accrual (n = 70 of planned 130 patients). Unlike the other trials, serious adverse events were more common among patients receiving cetuximab compared to cisplatin (19% vs 3%, P = .044). Two-year overall survival rates were similar in both arms (68% for cetuximab and 78% for cisplatin).[94]

A separate phase III study, RTOG 0522, randomized patients with locally advanced head and neck cancer to receive RT and concurrent cisplatin with or without cetuximab.[95] Treatment intensification with the addition of cetuximab to CRT did not improve 2-year progression-free or overall survival. Patients with p16-positive oropharyngeal cancer had better progression-free and overall survival than those with p16-negative oropharyngeal cancer. No significant interaction was present between p16 status and treatment, although there was a trend toward worse overall survival for p16- positive patients receiving cetuximab (HR 1.42, P = .13). Toxicity was more pronounced in patients who received cisplatin and

cetuximab. Still, EGFR inhibition remains a very active area of investigation in head and neck cancer. Agents currently in clinical trials include fully humanized monoclonal antibodies and orally administered small molecule inhibitors of the tyrosine kinase domains of the EGFR family of receptors.

A relatively new drug class with radiosensitizing potential is second mitochondria-derived activator of caspase (SMAC) mimetics, which trigger apoptosis and reduce prosurvival signaling by inhibiting the activity of proteins in the inhibitor of apoptosis family. Circumventing apoptosis is a key mechanism for causing radioresistance, particularly in glioblastoma multiforme (GBM).[96] In a preclinical study utilizing two heterotopic xenograft GBM models (U-251 and U-87) and an orthotopic intracranial xenograft model (U-251), the SMAC mimetic birinapant combined with RT significant delayed tumor growth compared to RT alone (P = .01).[97] Currently, there is an active phase I clinical trial combining birinapant with intensity- modulated reirradiation therapy in patients with locally recurrent head and neck SCC (NCT02567422). Study completion is anticipated in July 2024.

Targeting DNA damage response pathways is another approach to radiosensitizing tumors that is under active investigation. RT combined with inhibitors of DNA damage sensors, such as ataxia-telangiectasia mutated (ATM) or ATM- and rad3-related (ATR), forces cells to replicate with unrepaired DNA damage, eventually culminating in cell death. Preclinically, increased radiosensitivity with ATR inhibitors has been reported in hepatocellular carcinoma,[98] colorectal cancer,[99,100] head and neck SCC,[101] and pancreatic cancer.[102] Most ongoing clinical trials evaluating RT combinations with ATR inhibitors are focused on evaluating safety and determining the maximum tolerated dose. In a phase I dose-escalation trial, the ATR inhibitor berzosertib (M6620) was combined with chemoradiation for esophageal cancer (NCT03641547). Initial results reported no dose-limiting toxicities when combined with RT (35 Gy/15 fractions in 3 weeks).[103] A phase I trial evaluating berzosertib with weekly cisplatin and RT for locally advanced head and neck SCC was initiated in 2016, with anticipated completion in late 2023 (NCT02567422). Another ongoing phase I trial is evaluating the ATR inhibitor elimusertib (BAY 1895344) with stereotactic body radiation therapy (SBRT) and pembrolizumab in

patients with recurrent or metachronous primary head and neck SCC within a previously irradiated field (NCT04576091).

Nanoparticles

Nanoparticles are emerging as a promising method for enhancing radiosensitivity. Because radiation-mediated damage is dependent on the atomic number (Z) of the target, higher Z materials generally correlate with increased radiobiologic effects at megavoltage energies. Nanoparticle technology facilitates the accumulation of high-Z atoms within a solid tumor, increasing direct and indirect DNA damage. NBTXR3, a hafnium oxide (HfO_2, Z = 72) nanoparticle, was tested in this capacity in a phase II/III randomized trial of patients undergoing preoperative RT for locally advanced soft tissue sarcoma (NCT02379845). One hundred and eighty patients were randomized to receive RT + NBTXR3 or RT alone. In both groups, 50 Gy of external beam RT was delivered over 25 fractions. In the RT + NBTXR3 group, NBTXR3 (53.3 g/L) was delivered intratumorally pre-RT. In the RT + NBTXR3 group, 16% of patients demonstrated a pathologic complete response compared to 8% in the RT group (P = .044). While there were no treatment-related deaths, grade 3 to 4 adverse events were noted, with the most common being postoperative wound complications (9% in both groups).[104] NBTXR3 was also studied in a phase I clinical trial for hepatocellular carcinoma (NCT02721056). No grade 4 to 5 adverse events were observed, and efficacy appears promising with five complete responses, five partial responses, one patient with stable disease, and two nonevaluable patients.[105] There are additional active clinical trials investigating NBTXR3 with RT in pancreatic cancer (NCT04484909), inoperable recurrent non–small cell lung cancer (NCT04505267), recurrent and metastatic head and neck SCC (NCT04862455), esophageal cancer (NCT04615013), and locally advanced SCC of the oral cavity or oropharynx (NCT01946867). Combinations with RT, NBTXR3, and immunotherapies are also gaining interest.

CHEMICAL RADIOPROTECTION

The protection of normal tissues from the deleterious effects of radiation is a critical component in the development of a comprehensive treatment plan. Strategies for accomplishing this aim include the physical manipulation of the beam, modification of the fractionation schedule, and pharmacologic manipulation of the radiation response. Physical radiation protection rests on the principle of exclusion of normal tissue from the high-dose region and may be accomplished by contouring the shape of the radiation beam, the use of multiple treatment fields, the use of different beam energies, modulation of the dose delivery from each beam with IMRT, and utilizing particle therapy (eg, proton or carbon ion therapy). Modified fractionation typically uses multiple fractions of RT per day as opposed to the conventional once-daily paradigm to exploit the differing radiation repair capabilities of normal tissues as opposed to tumors. Physical modification of the treatment beam and altered fractionation are discussed elsewhere.

Protection

Pharmacologic radioprotection itself can be classified into three categories: protection, mitigation, and treatment. The direct cytotoxicity of ionizing irradiation results from the generation of free radicals that cause DNA strand breaks and lead to mitotic cell death. Amifostine (WR2721; Ethyol, Medimmune, Inc, Gaithersburg, MD) is the prototype pharmacologic radioprotector that functions via free radical scavenging. Amifostine is a thiol-containing prodrug that preferentially accumulates in the kidneys and salivary glands where it is metabolized to its active moiety, WR1065.[106]

An open-label phase III randomized trial was conducted from 1995 to 1997 to assess the ability of this drug to reduce the incidence of grade 2 or higher acute and late xerostomia and grade 3 or higher acute mucositis.[107] Patients enrolled in this trial received curative intent or adjuvant postoperative irradiation without concurrent chemotherapy. All treatment was delivered with conventional once-daily fractionation of 1.8 to 2.0 Gy. Definitive RT consisted of 66 to 70 Gy total dose, and postoperative irradiation was delivered at 50 to 60 Gy total dose depending on the patient's assessed risk for recurrence. IMRT was not utilized, and inclusion of >75% of both parotid glands was required for inclusion in the study. Patients randomized to receive amifostine received a daily dose of 200

mg/m^2 intravenously for 15 to 30 minutes every day prior to each fraction of RT.

Three hundred and three patients were enrolled in this trial, and the minimum follow-up was 2 years. Amifostine did not reduce the incidence of grade 3 mucositis but did significantly reduce the incidence of acute and long-term grade >2 xerostomia (34% in the amifostine group vs 56% for patients in the control arm; $P = .002$). Unstimulated saliva production >0.1 g was also more common in patients who had received amifostine (72% vs 49%; $P = .003$). Two years post-RT, amifostine use was still associated with a significantly lower incidence of xerostomia, although the magnitude of benefit was lower (19% vs 36%; $P = .05$). The lower incidences in both groups of patients also suggest some late recovery of salivary function. Reinforcing this idea of late recovery of salivary function is the fact that the percentage of patients in the control group who could exceed the >0.1 g of unstimulated saliva threshold had increased to 57%.[108]

Severe toxicity (CTCAE grade >3) attributable to amifostine occurred in <10% of patients in this trial and consisted of nausea and vomiting and transient hypotension. Nearly two-thirds of the patients had less severe grades of these side effects. Drug-related toxicity caused approximately 20% of patients to discontinue amifostine prior to completing RT. Subcutaneous administration of the drug causes less nausea, vomiting, and hypotension than intravenous dosing but is associated with increased risk of cutaneous toxicity, leading to 15% to 20% of patients discontinuing amifostine prior to RT completion.[109] The incidence of severe cutaneous toxicity, including erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis, is 6 to 9 in 100,000.[110]

A criticism of this trial is that it was underpowered to detect a very small compromise in survival caused by amifostine (tumor protection).[111] This argument is correct but overlooks the reality that absolute refutation of a small compromise of antitumor efficacy attributable to amifostine would have required an equivalence trial. Demonstration that amifostine reduced survival from a hypothetical 45% to 40% ($P = .05$; 80% power) would have necessitated >1,200 patients per study arm.[112] Such large studies have rarely been performed in head and neck cancer, because patient resources are too scarce. The largest randomized head and neck trial ever conducted, RTOG 9003, required 8 years to enroll 1,113 patients into four treatment arms.[113] A

meta-analysis of amifostine that used individual patient data from 12 trials and 1,119 patients examined the impact of this drug on survival in patients treated with RT or CRT. The majority of patients (65%) had head and neck cancer, with 33% lung cancers and 2% pelvic carcinomas. The HR of death was 0.98 (95% CI, 0.84-1.14; $P = .78$).[114]

The potential of amifostine as a protector against radiation- induced esophagitis during the treatment of non–small cell lung cancer was studied in a randomized trial conducted by the RTOG.[115,116] No reduction in the incidence of grade 3 esophagitis was observed, although less swallowing dysfunction occurred in the patients who received amifostine. Part of the explanation for this absence may be attributable to the study design, which utilized a hyperfractionated radiation schedule 5 days per week (69.6 Gy total dose) and concurrent carboplatin/paclitaxel. Amifostine 500 mg intravenous was delivered 4 days per week prior to the afternoon fraction only. Moreover, 28% of the patients did not complete the full course of the drug either because of toxicity or refusal. Consequently, approximately 50% of the RT was delivered in the absence of the radioprotective drug among patients randomized to receive amifostine. Preclinical studies of amifostine delivered daily in conjunction with fractionated lung and esophageal irradiation have demonstrated morphologic and immunohistochemical evidence of radioprotection.[117-119]

Amifostine is approved by the U.S. Food and Drug Administration (FDA) for xerostomia in the setting of RT alone. The majority of both curative-intent and adjuvant RT for head and neck cancers, with large target volumes that put the parotid glands at risk, are now delivered in conjunction with concurrent chemotherapy. Small phase II and III trials suggest that amifostine has a cytoprotective benefit in the chemoradiation setting, but level 1 evidence is lacking.[120,121] Moreover, the widespread adoption of IMRT with its ability to spare one or both parotid glands and reduce the incidence of xerostomia compared to conventional, non-IMRT techniques has further reduced the role for this drug.[122] The utility of amifostine in conjunction with IMRT has been investigated in small settings with inconclusive results.[123]

Superoxide dismutase (SOD) mimetics represent a new class of radioprotectors that are currently under active investigation. These drugs convert the radiation-induced toxic reactive oxygen species superoxide

anion (O^{-}_{2}) to hydrogen peroxide and molecular oxygen to mitigate radiation-induced toxicity. Similarly, these drugs interact with other potentially damaging reactive oxygen and reactive nitrogen species. A phase Ib/IIa clinical trial of the SOD mimetic avasopasem (GC4419) in patients with oral cavity or oropharyngeal cancer showed delayed development of oral mucositis, as well as reduced severity, incidence, and duration.[124] In a subsequent double-blind phase IIb trial, patients receiving an intravenous infusion of avasopasem prior to each fraction of RT for locally advanced oral cavity or oropharyngeal cancer exhibited significantly reduced severe oral mucositis incidence and severity compared to patients receiving placebo.[125] At 2 years post-treatment, there was no significant difference in overall survival, progression-free survival, locoregional control, or distant metastasis-free survival.[125] In the randomized phase III ROMAN trial, patients with locally advanced head and neck cancer receiving avasopasem prior to RT had a 10% absolute decrease in grades 3 to 4 mucositis compared to placebo (64% vs 54%, $P = .045$) and reduced median days of severe mucositis (18 vs 8 days, $P = .002$).[126] However, the FDA rejected the New Drug Application for avasopasem in 2023, citing insufficient evidence of its efficacy in reducing radiation-induced severe oral mucositis in patients undergoing RT for head and neck cancer. The recently completed single-arm phase 2 open-label study of avasopasem prior to RT in patients undergoing chemoradiation for nonmetastatic lung cancer showed low rates of grade 3 esophagitis in an unscheduled interim analysis, but no follow-up studies in lung cancer are ongoing.[127] Preliminary results from a randomized, double-blinded, placebo-controlled trial in locally advanced pancreatic cancer showed improved locoregional tumor control, progression-free survival, and overall survival for patients receiving avasopasem compared to placebo prior to RT with a 5- fraction SBRT regimen.[128]

Another SOD mimetic, Mn(III)meso-tetrakis (*N*-*n*-butoxyethylpyridinium-2-yl)porphyrin (MnBuOE), has been shown to mitigate oral mucositis, xerostomia, and salivary gland fibrosis in preclinical models.[129,130] Mice treated subcutaneously with MnBuOE twice daily or 3 times per week for 1 week prior to single-fraction RT to the oral cavity and ventral neck, followed by continued MnBuOE dosing after RT,

exhibited significantly decreased incidence and severity of oral mucositis. This was demonstrated by fluorescence molecular tomography assessing cathepsin activity as a marker of mucositis.[90] Stimulated saliva production was also significantly greater in mice treated with MnBuOE compared to saline control at 2 to 4 and 11 weeks post-RT. At 6 and 12 weeks post-RT, significantly decreased salivary gland fibrosis was observed in MnBuOE-treated mice.[129,130] Importantly, MnBuOE does not appear to protect tumor cells from RT. In FaDu flank models of head and neck cancer, MnBuOE with RT resulted in further slowing of tumor growth[129] or no change in radiation-induced tumor growth delay.[130] Analogs of MnBuOE have also been shown to reduce radiation-induced erectile dysfunction[131] and pulmonary injury in mice.[132-134] A recent phase I/II single-arm clinical trial investigated the effect of MnBuOE (also known as BMX-001) on mucositis and xerostomia in 29 patients with locally advanced head and neck cancer (NCT02990468). Early results indicate that BMX-001 is well tolerated, with only three serious adverse events (hypotension, fever with pancytopenia, and hyponatremia). In addition, severe oral mucositis had resolved by 5 weeks postchemoradiation in 83.3% of patients. Grade >2 xerostomia incidence was 18% at 1 month postchemoradiation and decreased to 8% and 9% at 6 and 12 months postchemoradiation, respectively.[135] Based on these promising results, a placebo-controlled randomized phase II trial in patients undergoing definitive chemoradiation for head and neck cancer is in development. An ongoing phase I/II trial is also assessing MnBuOE in patients with high-grade glioma receiving concurrent RT and temozolomide to determine the maximum tolerated dose and assess median overall survival compared to historical controls (NCT02655601).

Mitigation

Administration of compounds that mitigate damage caused by previous radiation exposure constitutes a different approach to the management of radiation-induced toxicity. This strategy contrasts to the classic free radical scavenging radioprotective mechanism of drugs, such as amifostine. The leading drug under development in this category is palifermin. Palifermin is a recombinant human keratinocyte growth factor that belongs to the

fibroblast growth factor family of cytokines. It stimulates cellular proliferation and differentiation in a variety of epithelial tissues, including mucosa throughout the alimentary tract, salivary glands, and type II pneumocytes. Palifermin also regulates intrinsic glutathione-mediated cytoprotective mechanisms. Administration of palifermin in preclinical rodent models leads to a significant thickening of oral tongue mucosa.[136] Preclinical studies of fractionated RT have revealed that the administration of palifermin leads to increase in the dose of RT necessary to induce ulcerative mucositis and to reduction in the duration of this ulceration when it does occur.[137,138] Parotid gland production of saliva is also preserved when palifermin is administered in the setting of RT in preclinical systems. Preclinical evaluation of palifermin in a rodent model has also demonstrated that administration of a single dose of this drug after completion of a course of fractionated thoracic irradiation significantly reduces the severity and duration of pneumonitis and the severity of pulmonary fibrosis.[139]

The ability of palifermin to reduce mucositis in a clinical setting has been tested in a pivotal phase III double-blind placebo- controlled trial of patients with non-Hodgkin lymphoma undergoing bone marrow transplantation.[140] The bone marrow ablative regimen consisted of 12 Gy of total body irradiation (TBI) given at 1.5 Gy twice a day. Thereafter, etoposide (VP-16) and cyclophosphamide were administered. Palifermin was delivered prior to the initiation of TBI and again after the completion of chemotherapy, which also corresponded to 5 days after the completion of TBI. The dose schedule of palifermin was 60 μg/kg/d 3 times for both administrations. This trial enrolled 212 patients who were equally divided between the placebo and palifermin arms. The World Health Organization (WHO) scoring system was used. The incidence of grade 3 or 4 mucositis approached 90% in the placebo arm as opposed to approximately 60% in the palifermin arm. For those patients who developed this level of toxicity, the duration was significantly reduced from 10.4 days in the placebo arm to 3.7 days in the palifermin arm ($P < .001$). Grade 3 mucositis developed in 62% of the placebo arm patients and only 20% of the palifermin arm patients ($P < .001$). The mean duration of grade 4 mucositis was reduced from 6.2 to 3.3 days with the use of this drug ($P < .001$).

A phase II study examined the safety and efficacy of palifermin in patients with locally advanced head and neck cancer.[141] Patients were randomized 2 to 1 between palifermin and placebo. Palifermin was delivered at a dose of 60 μg/kg. Institutions had the discretion to deliver RT via conventional once-daily 2-Gy fractions or with an accelerated hyperfractionated regimen of 1.25 Gy twice daily. One hundred patients were enrolled, of whom 34 received accelerated hyperfractionation and the remainder received standard fractionation. The first dose was delivered prior to the initiation of CRT and then every Friday afternoon after the last fraction of radiation. Two additional doses of palifermin were given 1 and 2 weeks after the completion of RT for a total of 10 doses of the drug. Palifermin did not reduce the incidence or duration of mucosal or salivary gland toxicity. The subset of patients receiving hyperfractionated radiation, however, showed significant improvements in the duration and severity of mucositis (Figure 29.2). They also had improved swallowing function and less salivary gland toxicity relative to patients who received placebo.

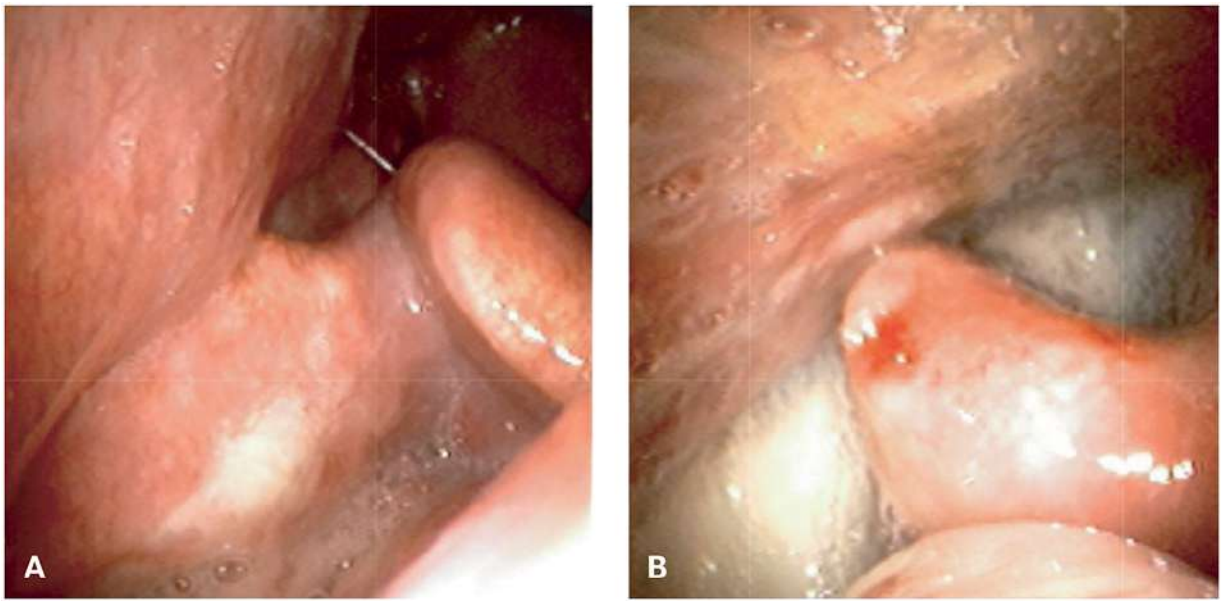

FIGURE 29.2 Confluent mucositis induced by concurrent chemoradiation in the base of tongue and supraglottic larynx regions. A. Normal mucosa prior to the initiation of treatment. B. The pseudomembranous exudate, hemorrhage, and edema that are characteristic of this confluent mucositis.

A subsequent randomized phase III study examined a higher dose of palifermin at 180 μg/kg to reduce oral mucositis in 188 patients with locally advanced head and neck cancer treated with CRT.[142] Palifermin was administered prior to starting CRT and once weekly for 7 weeks. The incidence of severe oral mucositis, the primary endpoint, was significantly lower in the palifermin arm compared to placebo (54% vs 69%; $P = .041$). Both overall survival and progression-free survival were similar as well. However, no statistically significant differences emerged in secondary efficacy end points, such as narcotic doses and duration of treatment breaks. A similar randomized phase III study examined palifermin at 120 μg/kg in 186 patients with head and neck cancer treated with postoperative CRT.[143] Palifermin again reduced the time to development and duration of WHO grade 3 or 4 oral mucositis without differences in patient-reported pain scores, treatment breaks, or efficacy. The precise role of palifermin in the management of head and neck cancer remains to be established.

SUMMARY

The chemical modification of radiation response for both enhancing treatment efficacy and reducing therapy-induced toxicity remains an area of active investigation. Promising candidates identified in preclinical and early-phase trials have been less successful in randomized phase III settings. Attempts to improve treatment efficacy by augmenting tumor oxygen delivery have a mixed record of success. The use of drugs that are preferentially cytotoxic to hypoxic cells holds promise, although improved tools to identify those patients most likely to benefit from targeted therapy are needed. Proof of principle for chemical radioprotection has been established in salivary glands but not elsewhere and is associated with significant toxicity. Growth factor utilization appears to protect against treatment-induced mucositis, but not to an extent to change clinical practice. As RT regimens evolve and new technological advances continue to improve treatment delivery, investigators will continue to seek agents that optimize the TR.

CHAPTER 30

Oncologic Imaging and Oncologic Anatomy

Edina Wang, Pooja Karukonda, Christopher R. Kelsey, Bryan O'Sullivan-Murphy, Travis Henry, and Junzo P. Chino

This chapter addresses two topics central to the management of patients with cancer: oncologic anatomy and oncologic imaging. Although these topics are relevant for all specialties involved in the treatment of cancer, they are particularly germane for radiation oncologists. A sound understanding of anatomy, especially pertaining to malignant processes, facilitates interpretation of imaging studies. Likewise, understanding the advantages and limitations of individual imaging modalities assists in defining rational clinical target volumes (CTVs) that maximize the therapeutic ratio.

There has been great progress in the past decade with the development of consensus guidelines for target and critical organ delineation in most disease sites (Table 30.1). While some of the volume definitions may be conceived primarily based on expert opinion, they facilitate the rational demarcation of nodal stations at risk, reporting of patterns of spread and failure, and communication with surgical colleagues. These guidelines and atlases should be seen as living works, refined and revised on a regular basis. These should complement, and not replace, the judgment of the treating physician, since anatomic variations, prior surgery, and unusual patterns of disease spread can invalidate the applicability of an atlas to an individual patient.

IMAGING MODALITIES

Radiography

In conventional radiography, a two-dimensional grayscale image is produced from the differential attenuation of x-rays passing through soft tissues and osseous structures of varying density. Tissues that are very dense, such as bone, will attenuate more x-rays than tissues that are less dense, such as lung. The loss of source x-rays identified by the x-ray detector is directly proportional to tissue density, resulting in a processed image where highly dense objects appear bright (radiopaque) and less dense objects are dark (radiolucent). Radiographs are, therefore, best suited to

detect pathology when a lesion differs greatly in density from adjacent structures, such as a soft tissue mass surrounded by aerated lung or a lytic lesion surrounded by dense bone. Radiographs have excellent spatial resolution, however, and are suboptimal when there are only subtle differences in tissue density, and even large lesions may not be distinguished if they are of similar density to surrounding structures. Further, determining spatial relationships to adjacent structures is limited due to the two-dimensional geometry. Radiographs may help identify an abnormality, but additional imaging modalities are often required for further characterization.

Cross-Sectional Imaging

Computed Tomography

Computed tomography (CT) generates cross-sectional images from the transmission of radiation through tissue. A patient is positioned on the scanner table that moves through a gantry housing an x-ray generator opposite multiple rows of detectors, hence the term *multidetector CT* (MDCT). As the gantry rotates, the detectors measure x-ray transmission through the rotation, or slice. The patient is moved through the scanner as the gantry rotates, resulting in a helical or spiral course at very thin-slice thickness, typically 0.625 mm. The spatial and temporal data from multiple projections are then processed by a Fourier transform mechanism generating two-dimensional axial images. The thin-slice volume data set is isotropic, meaning that images can be reconstructed in orthogonal and oblique planes without a loss in image quality.

CT images are displayed within a matrix composed of voxels, each representing a volume of tissue density. These densities are quantified by a linear attenuation value called a Hounsfield unit (HU). Densities are standardized into HU, which are obtained by a linear transformation of the measured attenuation coefficient. By convention, air is the least dense material with an HU value of −1,000, while water has an HU value of 0. Soft tissues have a range of attenuation with typical HU values as follows: fat (−120 HU), blood (30 HU), muscle (40 HU), and bone (>300 HU). HU analysis is more accurate than visual assessment of tissue composition and is particularly useful in characterizing enhancement of tissues following intravascular contrast administration.

Both intravenous (IV) and oral contrast agents may be utilized to improve spatial resolution. Oral contrast agents are routinely used for abdominal and pelvic imaging to distinguish bowel from adjacent organs, lymph nodes, and tumors. The use of an intravascular contrast agent during CT depends on the study indication, target organ, and patient status. IV contrast agents contain variable concentrations of iodinated compounds that attenuate x-rays, improving the distinction of vascular structures. Administration of IV contrast media is required for thorough assessment of vessels (eg, aorta, pulmonary arteries) and solid organs (eg, liver, kidneys) and characterization of lesion vascularity. Contrast-enhanced CT is often necessary to detect solid organ metastases (eg, liver, adrenal gland, brain). Contrast is usually not necessary for routine pulmonary imaging due to the inherent contrast of solid lesions in a background of aerated lung, although it does improve the characterization of hilar lymph nodes.

Given that the administration of contrast media can alter tissue attenuation, the HU value of a lesion or tissue may differ depending on whether the study was performed with or without contrast and based on the timing of image acquisition (eg, arterial vs portal venous phase). HUs are used during radiation treatment planning dose calculations; therefore, both IV and bowel contrast can affect these calculations. If indicated, the HU within a structure enhanced by contrast (eg, the bladder when planning for prostate cancer treatment) can be set to an alternate value prior to dose calculations. A similar phenomenon often occurs when materials with a high atomic number are within the scanned volume. These materials (eg, dental fillings, hip prostheses) can cause artifacts that can make it challenging to accurately segment the image and affect dose calculations. The latter can also be corrected by setting the HU within the affected area to the desired value. Metal artifact reduction algorithms have also been developed to improve image quality and recover anatomic information otherwise obscured.

IV contrast agents are excreted through the kidneys and are not typically administered to patients with impaired renal function (glomerular filtration rate [GFR] <60, creatine [Cr] <2.0, though institutional policies vary) unless on dialysis or emergently necessary. IV contrast media should also not be given to patients with a known contrast allergy resulting in anaphylaxis or laryngeal edema. Minor reactions, such as pruritus, are not absolute

contraindications, and IV contrast may be administered following a proper steroid pretreatment protocol. Alternative imaging modalities should be considered if a contrast-enhanced study is required in the setting of a severe contrast allergy. An allergy to shellfish is not considered a contraindication to iodinated contrast administration.

CT utilizes ionizing radiation, and although dose modulation and optimal scanning parameters can significantly reduce patient radiation exposure, the cumulative effects of CT radiation may be of clinical concern. Photon-counting CT, which can quantify single-photon incident on detectors, may further reduce patient exposure and image noise, improve image resolution, and allow for novel spectral applications.[1] However, alternative imaging modalities should always be considered and performed in lieu of CT when appropriate.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) generates cross-sectional images without ionizing radiation. MRI utilizes strong magnets to generate images, typically 1.5 or 3.0 T for clinical applications. A 3.0-T magnet is 60,000 times greater than the earth's magnetic field. The magnetic field uniformly aligns the nuclei of hydrogen protons within tissue. Applying a radiofrequency (RF) pulse sequence and gradient to the magnetic field disrupts this alignment and equilibrium. When the RF pulse is removed, the protons realign, or relax, within the field and emit a measurable resonance radio signal. The detected radio signals, referred to as *echoes* or *spin echoes* (SEs), are then used to generate an image. The most important tissue properties for image generation are the proton density, the spin-lattice relaxation time (T1), and the spin-spin relaxation time (T2). Different tissues have different proton density and relaxation times, absorbing and releasing radiowave energy at different rates, which, in part, accounts for the high tissue contrast obtained by MRI.

Different RF pulse sequences can accentuate different tissue characteristics by varying parameters such as the repetition time (TR)—the time between RF pulses in the sequence, which determines how much time protons have to realign within the magnetic field—and the echo time (TE)—the time between the RF pulse and the peak returning signal. TR and TE dramatically affect image contrast and determine which tissue properties are

selected. T1-weighted images, in which fluid is dark and fat is bright, are generally good at depicting anatomy; T1-weighted images are generated by selecting short TR (typically ≤800 ms) and short TE values (≤30 ms). T2-weighted images, in which fluid is bright and fat is dark, are fluid sensitive and can depict areas of pathology; T2-weighted images are generated by selecting long TR (≥2,000 ms) and long TE values (≥60 ms) (Table 30.2). Scan sequences are composed of variations in RF pulses and TR and TE settings. Although these vary by MRI scanner manufacturer using proprietary names, the underlying principles are similar. Common sequence techniques include:

TABLE 30.2 MAGNETIC RESONANCE IMAGING SIGNAL INTENSITIES (SPIN-ECHO IMAGING)

	T1WI	T2WI	FLAIR
Cerebrospinal fluid	Dark	Bright	Dark
Fat[a]	Bright	Dark	Bright
Solid mass (tumor)	Dark	Bright	Bright
Edema	Dark	Bright	Bright
Cyst	Dark	Bright	Dark

bright, hyperintense; dark, hypointense; FLAIR, fluid-attenuation inversion recovery; T1WI, T1-weighted image; T2WI, T2-weighted image.

[a]Fat is bright on T2 fast spin-echo or gradient echo sequences.

Spin Echo (SE) sequences produce standard T1- and T2-weighted images.

Multiple spin-echo (MSE) sequences allow for faster image acquisition and are also referred to as turbo SE, fast SE, or rapid-acquisition relaxation-enhanced imaging. The signal intensity and image quality are less than those of conventional SE sequences. Furthermore, fat is bright on MSE T2-weighted images, which can limit sensitivity for detecting pathology. Fat suppression techniques can be used to offset this limitation. Fast low-angle acquisition with relaxation enhancement and half Fourier acquisition single-shot turbo SE sequences are MSE variations.

Inversion recovery (IR) pulse sequences emphasize differences in T1 properties of tissues. A time of inversion (TI) is added to the sequence that can be set to target specific tissue properties. Short TI recovery

sequences suppress tissues with short T1 relaxation times, such as fat, and enhance tissues with high T2 properties, such as fluid, resulting in added tissue contrast. The opposite effect may be achieved with fluid-attenuation inversion recovery (FLAIR) sequences. In addition to IR, tissue suppression may be achieved with fat or fluid saturation and opposed-imaging techniques.

Gradient-recalled echo (GRE) pulse sequences are used for rapid image acquisition, which minimizes motion artifact associated with breathing, the cardiac cycle, vessel pulsation, and bowel peristalsis. GRE sequences have low tissue contrast, with the exception of flowing blood, which is bright in signal, and are, therefore, ideal for cardiac and vascular applications. Fast low-angle shot and true fast imaging with steady-state precession are examples of this technique.

Although the inherent tissue contrast with MRI is excellent, the administration of contrast media can further improve the detection of pathology and subtle differences in tissue properties. Gadolinium chelates are the most used MRI contrast agents, which, like the iodinated CT equivalents, are confined to the vasculature and do not cross an intact blood-brain barrier. Hepatobiliary contrast agents and intravascular superparamagnetic iron oxides are also sometimes used for specific imaging.

Gadolinium is a heavy metal ion with paramagnetic effects that shorten T1 and T2 relaxation times. Although there are flow-related techniques for vascular imaging that do not require contrast media (eg, time-of-flight imaging), the use of a contrast agent is essential for characterizing tissue perfusion. The use of gadolinium-based contrast agents is associated with nephrogenic systemic fibrosis (NSF), a debilitating and potentially fatal condition of fibrin deposition within the skin and other organs in patients with impaired renal function.[2] Although the precise mechanism is not understood, patients with severe renal dysfunction (GFR <30) are at increased risk of developing NSF, with additional contributing factors including an underlying inflammatory state, higher doses of gadolinium, or repeated dosing over short intervals. Careful patient evaluation, including a risk/benefit analysis, should be performed before administering gadolinium-based contrast agents in patients with impaired renal function.

MRI techniques allow for tissue diffusion and perfusion imaging, quantification of blood flow by velocity phase encoding, and magnetic resonance proton spectroscopy, which provides biochemical quantification of tissues. Dynamic contrast-enhanced (DCE)-MRI uses sequential images after contrast administration to calculate the volume transfer constant k^{trans}, providing information on the microvascular leakiness and rate of exchange. In a variety of malignancies, including brain, head and neck, esophageal, and breast cancers, k^{trans} correlates with tumor stage and response to treatment.[3-5] DCE-MRI–derived k^{trans} may also help distinguish recurrent glioma from radiation necrosis.[6] However, k^{trans} values cannot be generally applied to all malignancies and may be specific to different tumor types and their distinct microenvironment.

Diffusion-weighted imaging (DW or DWI) measures Brownian motion within the cellular microenvironment and calculates an apparent diffusion coefficient (ADC) map. A region of low intensity in an ADC map represents restricted diffusion, a state that may correlated with increased cellularity, as seen with malignancy or fibrosis. This may improve the specificity of breast MRIs for differentiating malignancy from benign processes, and even predicting the grade of the lesion.[7] DWI has also improved the detection rate of hepatic lesions and differentiation between benign and malignant processes.[8] Conversely, high pretreatment ADC in cervical cancers may be associated with poorer eventual disease-free survival, again reflecting how functional imaging may be revealing a complex interaction in the tumor microenvironment.[9]

As with other imaging techniques, MRI has modality-specific artifacts that can limit image quality. Motion artifact can be problematic with MRI due to long scan times and breath holding required with some sequences. Chemical shift artifact results in a loss of signal at the interface of tissues with highly variable contrast properties. MRI is also sensitive to magnetic field distortions that can produce artifacts. Susceptibility artifact is one of the most common problems with MRI and is frequently attributable to objects that alter the magnetic field such as metallic hardware or devices, resulting in signal voids or distortion of MRI. The magnetization of such objects also presents a safety hazard as items can overheat or become displaced, resulting in injury. Patients must be carefully screened to ensure that any medical devices or surgical hardware is MRI compliant.

Ultrasonography

Ultrasonography (US) is an imaging modality that uses high-frequency sound waves with pulse-echo techniques rather than radiation to produce an image and characterize tissues. The US transducer converts electrical energy into a high-frequency pulse that is transmitted through tissues. The pulse interacts at tissue interfaces, generating a reflected echo signal that is detected by the transducer. The returning sound waves are transformed into grayscale images in real time. Image quality is, in large part, determined by the pulse frequency. High-frequency transducers (5-12 MHz) produce high-resolution images but have limited ability to penetrate tissue. Therefore, they are best suited to imaging superficial structures, such as the breast or thyroid. Low-frequency transducers (1-3.5 MHz) generate lower quality images but have better tissue penetration and are most often used for imaging abdominal and pelvic organs. The degree to which tissues are visualized by US is called *echogenicity*. Fat is highly echogenic (bright), whereas fluid-containing structures, such as simple cysts, are anechoic (dark).

The quality of US images is highly dependent upon the technical skill of the operator and affects the reproducibility and interpretation of US examinations. US is also prone to artifacts. Bone almost completely absorbs sound waves, resulting in acoustic shadowing that completely obscures tissues located beyond the bone. Air is also problematic as it almost completely reflects sound waves, leaving little pulse energy to penetrate tissues deep to the air. Artifacts secondary to air markedly limit the evaluation of lesions near the lung or bowel. In contrast, fluid readily transmits sound and makes an excellent “acoustic window” for imaging. Thus, a water-soluble gel between the transducer and the patient’s skin eliminates air at the skin surface and improves the transmission of the US beam. Patients are encouraged to drink plenty of fluids prior to a pelvic US examination—so that the bladder is fully distended.

Color Doppler US is an important adjunct to conventional grayscale sonography. The Doppler effect is a change in the frequency of returning sound waves reflected by a moving object, such as flowing blood. If blood flows away from the transducer, the echo frequency decreases; whereas if blood flows toward the transducer, the echo frequency increases. The change in frequency is directly proportional to the flow velocity and

produces a color overlay in areas of flow on the standard grayscale US image. Color Doppler US is useful in characterizing blood flow within lesions and assisting in image-guided procedures.

Endoscopic ultrasound (EUS) was introduced in the early 1980s and has become an important tool in oncologic staging. It allows for high-resolution images of internal structures not typically accessible by high-frequency transducers by passing the probe through bowel or airways. It is most widely applied in the setting of gastrointestinal (GI) malignancies, especially esophageal and rectal carcinomas. A 5- to 12-MHz transducer can readily identify five of the layers of the GI tract (Table 30.3 and Figure 30.1). Higher frequency transducers can identify additional layers, such as the muscularis mucosa and lamina propria of the esophagus, which has important staging implications. EUS is also utilized for characterization and image-guided sampling of regional lymph nodes in GI or bronchopulmonary disease. The ability of EUS to predict the tumor (T) stage is generally superior to its ability to predict the node (N) stage, although some imaging patterns of nodal involvement are recognized. Normal lymph nodes are usually ovoid, <10 mm in short axis, and have a homogeneous but variable echogenic appearance that may be isoechoic, hyperechoic, or hypoechoic to surrounding tissues. An echogenic (bright) center is common and represents the normal fatty hilum. Suspicious lymph nodes are typically round, >10 mm in short axis, have distinct margins, and are often hypoechoic. If all four features are present, the likelihood of malignancy is 80% to 100%.[10] There is, however, considerable overlap between benign and malignant features of lymph nodes on EUS in addition to wide interobserver variability. Tissue sampling is, therefore, recommended for accurate staging. When describing clinical T and N staging by EUS, the prefix *u* should be utilized (eg, uT3N1).

TABLE 30.3 ENDOSCOPIC ULTRASOUND WALL LAYERS OF THE ESOPHAGUS

Nuclear Imaging

Although radiographic and cross-sectional studies provide important anatomic information regarding pathologic processes, nuclear radiology provides physiologic information based on the distribution of an injected or ingested radiopharmaceutical. Radiopharmaceuticals consist of a radioactive substrate (radionuclide, radioisotope, or radiotracer) that is coupled with a physiologically active compound or analog. For example, technetium-99m (^{99m}Tc) may be coupled to pertechnetate, a water-soluble ion salt that distributes similar to iodine, such that it is specific for imaging of the thyroid, bladder, stomach, and colon, among other organs. The timing of

imaging depends on the kinetics of absorption, metabolism, and half-life of the radionuclide. Gamma rays emitted by nuclear decay of the radionuclide are detected using a γ-camera corresponding to radiotracer activity that is described in terms of uptake.

There are numerous available nuclear imaging studies that take advantage of differing radiopharmaceuticals for oncologic imaging. Many of these play a primary role in the management of oncology patients with specific malignancies. However, the primary nuclear imaging studies relevant to general oncologic imaging are positron-emission tomography (PET) and bone scintigraphy. These studies have broad applications for many malignant processes in the diagnosis, staging, and surveillance of disease.

Positron-Emission Tomography

Although several radionuclides for PET are available, the most common is 18-fluorodeoxyglucose (FDG). FDG is a glucose analog that concentrates in areas of high metabolic activity. Tumor cells are often highly metabolic, with rapid cell division and an increased number of glucose transporters. However, FDG uptake is not specific for malignancy and accumulates in any cell with increased metabolic activity, including myocardium, gastric mucosa, brain tissue, thyroid, and salivary glands, which limits PET evaluation of these organs. Furthermore, FDG tracer is excreted within the urinary system; therefore, activity within the kidneys, collecting system, and bladder can obscure the malignancy of these structures. Notwithstanding these limitations, PET-CT has become the preferred imaging modality for clinical staging in many malignancies, facilitating the characterization of benign versus malignant pathology, detecting sites of unsuspected disease, identifying optimal sites for tissue sampling, assessing treatment response, and monitoring for recurrence.

PET is now routinely obtained in conjunction with CT. PET-CT combines the physiologic assessment of PET with the anatomic assessment of CT, resulting in improved diagnostic accuracy.[11] PET and CT may be obtained independently on the same day but are more commonly performed on a combined PET-CT scanner, which more precisely aligns the two imaging data sets for fusion such that the patient does not have to move between examinations. Patients must fast for 4 to 6 hours prior to scanning in order to limit metabolic activity within the GI tract. Blood glucose levels should

be well controlled (<150 mg/dL) to limit glucose receptor competition with FDG, as high glucose levels can result in a false-negative scan. Speech and motion should be restricted to minimize muscle uptake, which could obscure pathology. Approximately 1 hour following FDG administration, a CT scan is performed immediately followed by PET imaging, which can take up to 60 minutes. CT and PET data sets are then reconstructed in separate axial, coronal, and sagittal series as well as fused PET-CT images.

FDG uptake is quantified by the standard uptake value (SUV). Most malignant tumors have a maximum SUV >2.5, while physiologic uptake is typically <2.5. SUVs are not absolute and can be affected by the timing of imaging, improper attenuation correction, partial volume effects, patient weight, FDG dose, and other factors affecting FDG uptake. It is, therefore, difficult to accurately compare SUVs between scans. However, if care is taken to ensure that variables between studies are similar, such as performing the examination on the same scanner with similar patient preparation, FDG dosing, and image timing, comparing SUVs between studies may be reliable. Clinical studies to date have documented that under such uniform conditions, changes in SUV have prognostic value, indicating that most tumors responding to therapy show a 20% to 40% decrease in SUV early in the course of treatment.[12-14]

The registration of CT and PET has led to novel ways of quantifying the burden of disease. Total lesion glycolysis, for example, is calculated by multiplying the mean SUV in a segmented lesion by its volume. This metric essentially weights the volume of disease by its metabolic activity in an attempt to reflect the true burden and has been associated with worse prognosis in non–small cell lung cancer (NSCLC).[15] Metabolic tumor volume (MTV), on the other hand, is a measure of tumor volume only counting voxels above a certain SUV threshold, either relative (such as a percentage of SUVmax) or an absolute SUV value. Higher pretreatment MTV is associated with poorer eventual outcome in head and neck cancers.[16]

Other radionuclides with potential application to oncologists include ^{18}F-fluoromisondazole, ^{18}F-fluoroazaomycin arabinoside, and copper-64 diacetyl-bis-N4-methylthiosemicarbazone, all of which have different mechanisms of co-locating to intratumoral hypoxic regions.[17] As hypoxia is a driver of both prosurvival factors such as hypoxia-inducible factor 1α, and

resistance to radiotherapy (RT), these agents are of considerable research interest, though not yet of routine clinical utility. Recent advances in radiopharmaceuticals include gallium-68 (^{68}Ga) or lutetium-177 (^{177}Lu) bound to the somatostatin analog DOTATATE for imaging and therapy of neuroendocrine tumors, respectively. Newer specific agents for prostate cancer include ^{18}F-fluciclovine and ^{68}Ga prostate-specific membrane antigen (^{68}Ga-PSMA).[18]

PET-MRI is an emerging hybrid technique combining the functional information of PET with anatomic and soft tissue definition of MRI. Benefits of this multimodality imaging over PET-CT include offering lower ionizing radiation and superior soft tissue contrast and image resolution. Coupled with the previously described DCE-MRI and DWI, simultaneous assessment of tumor properties such as perfusion and cellularity in addition to metabolism may be obtained. PET-MRI is of particular interest for repeated longitudinal studies and for pediatric imaging.[19]

Bone Scintigraphy

Normal bone undergoes continuous remodeling, maintaining a balance between osteoblastic and osteoclastic activity. Most bone metastases originate as intramedullary lesions, having gained access to the bone through the vasculature. As the lesions enlarge, reactive osteoblastic and osteoclastic activity results in characteristic radiographic changes indicative of bone metastases (sclerotic, lytic, or mixed lesions). Rapidly growing metastases tend to produce lytic lesions, while more slowly growing metastases typically produce sclerotic (or blastic) lesions. Metastases from multiple myeloma, thyroid cancer, and renal cell carcinoma are predominantly lytic, while blastic lesions are associated with breast and prostate cancers.

Bone scintigraphy or bone scan imaging utilizes radiopharmaceuticals composed of bisphosphonates; the most common of which is the radionuclide technetium-99m methylene diphosphonate (^{99m}Tc-MDP). ^{99m}Tc-MDP localizes to areas of new bone mineralization, which occurs in a wide array of bone pathology and is, therefore, highly sensitive to osseous disease, but not specific. Bone scans are relatively inexpensive, convenient, and visualize the entire skeleton, including sites that are difficult to assess on plain films (eg, ribs, sternum, scapula, sacrum). Reported sensitivities

range from 62% to 100% with similar specificity rates (78%-100%).[20] Recently, advances in bone imaging incorporate the positron emitter ^{18}F-NaF with PET/CT. Research into this agent shows increased specificity and sensitivity compared to ^{99m}Tc-MDP and marked improved resolution of osseous metastatic disease.[21]

Two primary patterns of radiotracer activity can be associated with malignancy: increased or decreased activity. Increased uptake occurs in areas of increased blood flow and osteoblastic activity; this is a common finding in metabolically active tumors and small sclerotic metastatic foci. Decreased radiotracer activity occurs as a "cold" area on bone scan and is associated with lytic bone disease and aggressive tumors that outgrow their blood supply. Rapidly progressing and purely lytic diseases are the main causes of false-negative findings on bone scintigraphy, while false-positive findings can be related to trauma, healing, benign bone tumors, or arthritic changes. The false-positive rate of planar bone scintigraphy can be reduced by the use of single-photon emission CT (SPECT), which can be obtained in conjunction with conventional CT or MRI for more precise localization of disease.[22,23]

New developments in cancer response criteria (RECIST 1.1) have stressed the importance of reporting the response of bone metastases such that bone metastases with soft tissue components >10 mm are now considered measurable disease.[24] A number of facts need to be considered when interpreting the degree of uptake in follow-up bone imaging studies: First, tumor treatment response may cause a "flare phenomenon," resulting in increased bone scan uptake secondary to new osteoblastic activity concomitant with new bone formation. This may be falsely attributed to progressive disease. Similarly, lytic lesions that were previously "cold" on bone scan can transform into "hot" spots (areas of uptake) after treatment. Second, rapidly progressive disease with overwhelming bone destruction without new bone formation can be misinterpreted as stable or responding disease on bone scan.

Radiomics

Radiomics is a burgeoning field, combining large databases of radiographic data extracted from clinical imaging (usually of CT, MRI, or PET origin) with high-throughput computing capabilities to detect emergent patterns of

data associated with clinically relevant outcomes.[25] It borrows its name and much of its terminology from genomics and proteomics, employing similar computational techniques to detect signatures within the data that may correlate to underlying tumor biology. An example of this is texture analysis, which derives several features of the intensity of not only a single voxel but also its relationship to all neighboring voxels, which may potentially derive quantifiable measures of tumor heterogeneity, necrosis, and hypoxia.[26] However, it is worth noting that radiomics is susceptible to multiple comparisons and testing. Given the increasing interest in radiomics, it is incumbent for research in this area to understand its limitations, and that findings are confirmed in independent data sets prior to clinical application.

BRAIN AND SPINE

Oncologic Anatomy

The Brain

The central nervous system (CNS) consists of the brain and spinal cord, which are covered with three meningeal layers—the dura mater, arachnoid mater, and pia mater. Meningiomas are the most common tumors arising from the meninges. They arise from arachnoid cells but are usually affixed to the underside of the dura mater. They are well-circumscribed tumors that do not typically invade the underlying brain parenchyma. The arachnoid mater and pia mater are considered the leptomeninges, with the intervening space (subarachnoid space) filled with cerebrospinal fluid (CSF). Cancer can breach the CSF space through several routes, including hematogenous spread or by direct extension. Once cancer breaches the subarachnoid space, the entire craniospinal axis is at risk, and tumor deposits can lead to increased intracranial pressure, cranial nerve (CN) deficits, radiculopathies, and seizures. Leptomeningeal involvement occurs most frequently with pediatric brain tumors (eg, medulloblastoma), acute lymphoblastic leukemia, and some solid cancers (eg, breast cancer, melanoma, and lung cancer in particular).[27]

The major units of the brain include the cerebral hemispheres, diencephalon, cerebellum, and brainstem. The cerebral hemispheres consist of the frontal, parietal, temporal, and occipital lobes; basal ganglia; and lateral ventricles. The diencephalon includes the thalamus, hypothalamus,

and third ventricle. The brainstem consists of the midbrain, the pons, and the medulla oblongata. The fourth ventricle lies between the pons and the cerebellum. Although more than half of pediatric brain tumors arise in the posterior fossa (cerebellum and brainstem), most primary brain tumors in adults arise in the cerebral hemispheres or diencephalon.

The hippocampus is a portion of the limbic system located in the deep medial temporal lobes. It plays an important part in the development and maintenance of memory. It is also seldom a site of metastasis and, therefore, may be spared under select circumstances to improve the therapeutic ratio of whole-brain radiotherapy (WBRT). After WBRT, dose-dependent hippocampal atrophy and neurocognitive decline have been demonstrated.[28] Multiple trials have since found decreased cognitive decline in subjects treated with hippocampal-sparing WBRT.[29,30]

Cranial Nerves

The CNs consist of 12 paired nerves whose nuclei (except CN I) are in the brainstem and upper spinal cord. They are termed *cranial nerves* because they exit the cranium through foramina in the base of skull and are encased by sheaths formed from the meninges (Table 30.4). Although spinal motor neurons are innervated by the corticospinal tracts, many of the lower motor neurons in the brainstem are innervated by the corticobulbar tracts. These upper motor neurons innervate the cranial motor nuclei bilaterally (with some exceptions), in contrast to the nerves within the corticospinal tracts, which largely cross in the medulla, leading to contralateral innervation.

TABLE 30.4 MAJOR FORAMINA AND OTHER APERTURES IN THE CRANIAL FOSSAE AND THEIR PRIMARY CONTENTS

Foramina/Opening	Contents
Anterior cranial fossa	
Foramina in cribriform plate	Axons of olfactory cells (CN I)
Middle cranial fossa	
Optic canal	Optic nerve (CN II)
	Ophthalmic artery
Superior orbital fissure	Oculomotor nerve (CN III)

Foramina/Opening	Contents
	Trochlear nerve (CN IV)
	Abducens nerve (CN VI)
	Ophthalmic nerve (CN V_1)
Foramen rotundum	Maxillary nerve (CN V_2)
Foramen ovale	Mandibular nerve (CN V_3)
Foramen spinosum	Meningeal branch of CN V_3
	Middle meningeal artery/vein
Foramen lacerum	Internal carotid artery[a]
Petrous portion of the temporal bone	
Internal acoustic meatus	Facial nerve (CN VII)[b]
	Vestibulocochlear nerve (CN VIII)
	Labyrinthine artery
Posterior cranial fossa	
Jugular foramen	Glossopharyngeal nerve (CN IX)
	Vagus nerve (CN X)
	Spinal accessory nerve (CN XI)
	Internal jugular vein (superior bulb)
Foramen magnum	Spinal roots of spinal accessory nerve (CN XI)
	Medulla
	Vertebral artery
	Anterior/posterior spinal artery
Hypoglossal canal	Hypoglossal nerve (CN XII)

CN, cranial nerve.

[a]After entering the skull through the carotid canal.

[b]The facial nerve exits the skull through the stylomastoid foramen.

Multiple tumors, both benign and malignant, commonly involve the CNs, leading to focal neurologic deficits. Some of the more common include meningiomas involving the optic nerves (CN II), vestibular schwannomas

(CN VIII) (Figure 30.2), parotid gland tumors (CN VII), nasopharyngeal carcinoma (NPC) (multiple), and brainstem gliomas (multiple).

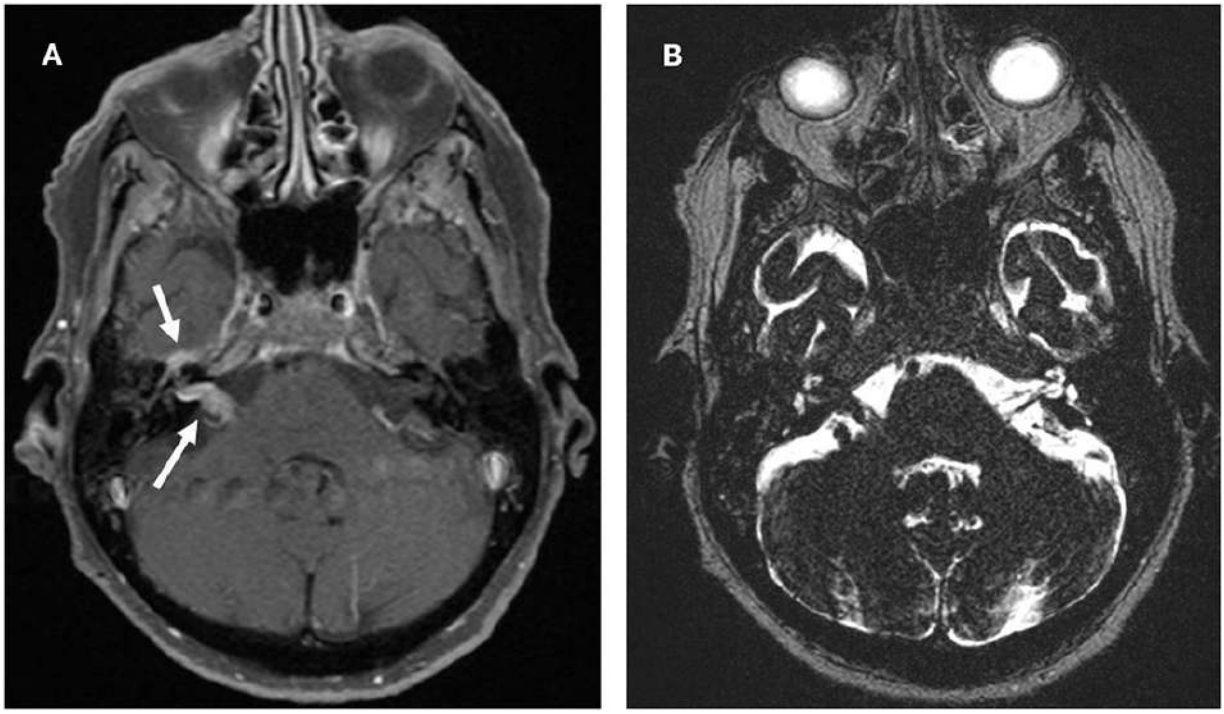

FIGURE 30.2 Magnetic resonance imaging (MRI) sequences demonstrating an enhancing lesion concerning for vestibular schwannoma in the right seventh/eighth cranial nerve complex as it originates from the right cerebellopontine angle bulging into the prepontine cistern. There is perineural spread with involvement of the geniculate ganglion and tympanic segment of the facial nerve. A. Representative axial slice on T1 weighted postcontrast. B. Representative axial slice on steady-state free precession (a type of gradient echo MRI pulse sequence).

The classic presenting symptoms of diffuse pontine gliomas illustrate the intricate anatomy of the pons. A unilateral lesion in the ventral pons with involvement of the pyramidal tracts (upper motor neurons) can cause contralateral motor weakness in the arms or legs. In addition, CNs within the pons might also be affected unilaterally, without complete resulting paralysis, because of bilateral innervation of the CNs by fibers in the corticobulbar tracts. Ataxia, denoting impairment of coordination without weakness, can be caused by involvement of fibers projecting from the pons to the cerebellum within the middle cerebellar peduncle. Through this pathway, the cerebellum receives a copy of the information for muscle

movement that the corticospinal tracts relay to lower motor neurons, facilitating the complicated act of coordination.

The CNs should also be carefully examined when evaluating a patient with NPC. One-fifth of patients with NPC present with symptoms of CN involvement. The most involved CNs are the abducens nerve (CN VI) and the trigeminal nerve (CN V). CN VI originates in the ventral aspect of the brainstem, ascends on the clivus, and crosses the internal carotid artery near the superior aspect of foramen lacerum before entering the cavernous sinus. It then exits the skull through the superior orbital fissure. The motor and sensory nerve roots of CN V exit the pons and pass underneath the free edge of the tentorium cerebelli into Meckel cave, forming the trigeminal (Gasserian) ganglion. From the ganglion, V_1 and V_2 enter the cavernous sinus and subsequently exit the skull through the superior orbital fissure and foramen rotundum, respectively. V_3 exits the skull through the foramen ovale.

The nasopharynx is near the foramina lacerum, rotundum, and ovale, hence the frequent tumor involvement of CN V and CN VI. Invasion superiorly to the foramen lacerum and involvement of the trigeminal ganglion could lead to dysfunction in all three branches of CN V. In fact, most patients with NPC and CN V involvement have isolated deficits of V_2 or V_3. This occurs due to extension into the foramen rotundum and ovale, respectively. After gaining access to the middle cranial fossa, NPC may extend superiorly into the cavernous sinus. The nerves of the cavernous sinus include CN III, CN IV, CN V_1, CN V_2, CN VI, and the sympathetic plexus around the internal carotid artery. Within the sinus, CN III is located most superiorly, while CN V_2 is located most inferiorly. CNs located more superiorly in the cavernous sinus are less frequently involved than those located closer to the base of skull. Lower CN involvement can occur without intracranial extension. The fossa of Rosenmüller (the posterolateral pharyngeal recess) is the most common site of origin of NPC. The lateral border of the fossa of Rosenmüller is the pharyngeal space. Direct tumor extension laterally into the parapharyngeal space or lymphatic metastases to high parapharyngeal lymph nodes can affect the CNs exiting the jugular foramen (CN IX, CN X, and CN XI) and hypoglossal canal (CN XII). This may result in loss of the gag reflex (CN IX), hoarseness or dysphagia (CN

X), atrophy or paralysis of trapezius and sternocleidomastoid (SCM) (CN XI), as well as tongue deviation (CN XII).

Spine

The vertebral column typically consists of 33 bones (7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal). Although all individuals have seven cervical vertebral bodies, variations in the number of the other vertebral levels are occasionally observed. The spinal cord is housed within the spinal canal and encased by the meninges. Spinal cord levels do not correspond with levels of the vertebral column. In adults, the spinal cord typically ends at the L1-2 interspace (termed the *conus medullaris*). In an infant, the spinal cord typically terminates at L2 or L3. However, the spinal nerves continue to descend within the spinal canal (termed the *cauda equina*). The subarachnoid space, containing CSF, typically extends to the second sacral vertebral body. At this level, the meninges fuse together and extend caudally as the filum terminale, which anchors the spinal cord to the coccyx. These anatomic distinctions have implications when evaluating a patient with spinal cord compression, designing craniospinal fields, and when setting up palliative spine fields.

Oncologic Imaging

Intracranial Metastases

Approximately 50% of adult intracranial neoplasms are metastatic, with lung, breast, and melanoma being the most common primaries, in order of decreasing frequency.[31] Most metastases gain access to the brain through the vasculature and typically arise at the junction of the gray and white matter, presumably because the caliber of blood vessels decreases at this point, acting as a trap for tumor emboli.[32] Approximately 80% of brain metastases are found in the cerebral hemispheres, with less frequent involvement of the cerebellum (15%) and brainstem (5%), reflecting their smaller volume and blood flow.[33]

The preferred imaging modality for the diagnosis of intracranial metastasis is contrast-enhanced MRI.[33] Brain metastases are typically well circumscribed and avidly contrast enhancing. They are also typically associated with a disproportionate amount of surrounding edema, best

visualized on T2-weighted sequences. The detection of multiple lesions helps to distinguish metastases from primary brain tumors, which are more commonly solitary.

Primary Brain Tumors

Primary brain tumors account for approximately 50% of adult intracranial masses, of which half are malignant. The most common malignant primary brain tumor in adults is glioblastoma (GBM). As with brain metastases, MRI is more accurate than CT in delineating the local gross extent of disease, given its superior soft tissue resolution.

GBM most commonly develops along white matter tracts and does not typically involve the dura or skull. GBM and primary CNS lymphoma have the potential to spread into the contralateral cerebral hemisphere via tracts of the corpus callosum. Other potential routes of spread, including subependymal extension with CSF contamination or hematogenous dissemination, are possible but unusual. GBMs are typically expansile masses that are isointense to hypointense to surrounding tissue on T1-weighted images, with central necrosis and peripheral ring enhancement postcontrast administration. T2-weighted imaging shows a heterogeneous mass with surrounding T2-signal abnormality corresponding to vasogenic edema, in which malignant cells are known to frequently reside. Central areas of low signal reflect a combination of blood products, necrosis, and vascular flow voids.[34]

Low-grade gliomas generally appear as non–contrast enhancing, T2/FLAIR-hyperintense lesions without associated vasogenic edema, while primary CNS lymphomas appear T2 hypointense and enhance with contrast. Meningiomas are the most common benign brain tumor in adults, and many small meningiomas are found incidentally. On CT imaging, most meningiomas are hyperdense or isodense compared to cortex. About 20% to 25% have associated calcification or adjacent bone hyperostosis. On MRI, most meningiomas are isointense to gray matter and fairly homogeneously contrast enhancing (Figure 30.3). A CSF cleft can often be seen between the tumor and the brain parenchyma. Many meningiomas will have a linear area of enhancement on MRI, extending from the tumor along the dura. This so-called dural tail is generally not felt to represent direct extension of tumor

but rather vascular congestion within the dura, leading to the characteristic enhancement.[35]

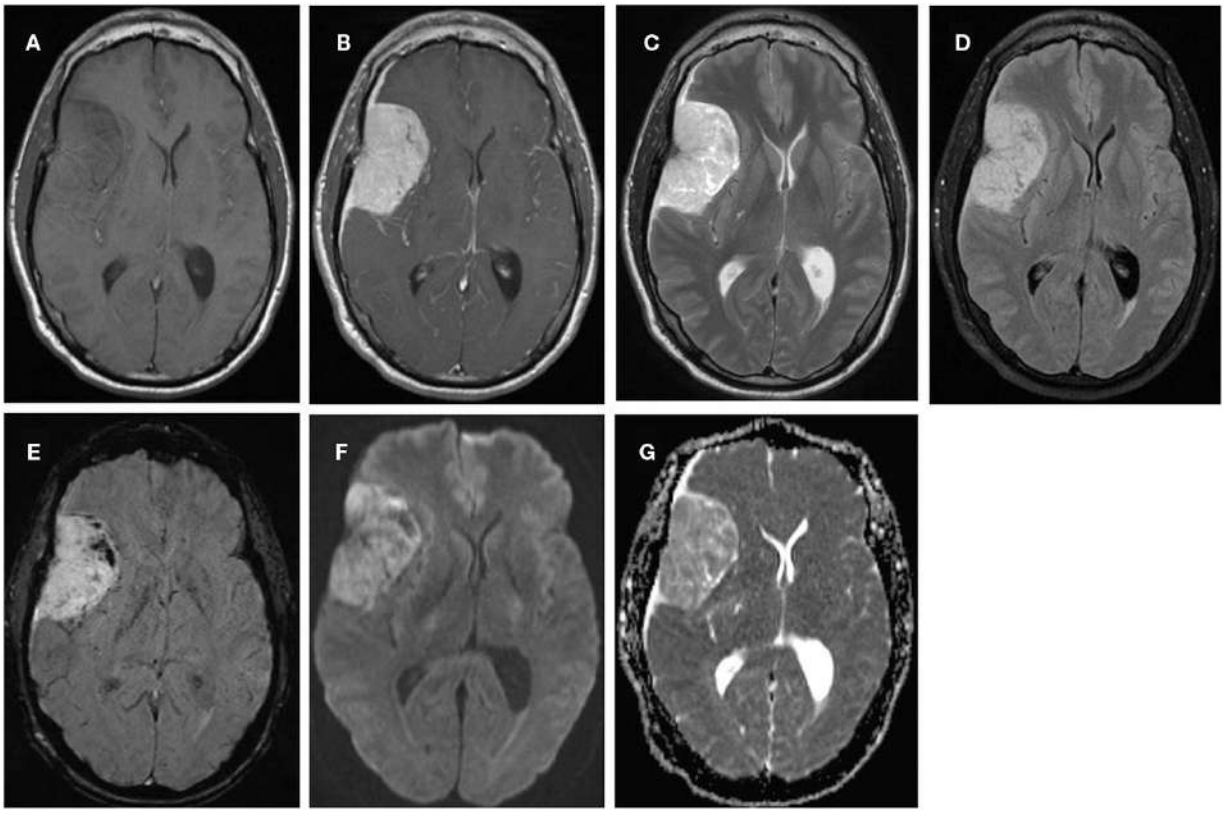

FIGURE 30.3 Magnetic resonance imaging sequences demonstrating meningioma. A. T1 weighted noncontrast. B. T1 weighted postcontrast. C. T2 weighted. D. T2 fluid-attenuation inversion recovery. E. Susceptibility-weighted imaging. F. Diffusion-weighted imaging. G. Apparent diffusion coefficient.

Pituitary adenomas are common benign neuroendocrine brain tumors. They are broadly classified into pituitary microadenomas (<10 mm in size) and pituitary macroadenomas (>10 mm in size). Pituitary macroadenomas are the most common suprasellar mass in adults. MRI is the preferred imaging modality to delineate both pituitary microadenoma and pituitary macroadenoma. On imaging, macroadenomas usually present as a solid tumor that is isointense to gray matter both on T1- and T2-weighted MRI (Figure 30.4). Imaging characteristics can vary depending on tumor components (eg, hemorrhage, cystic transformation).

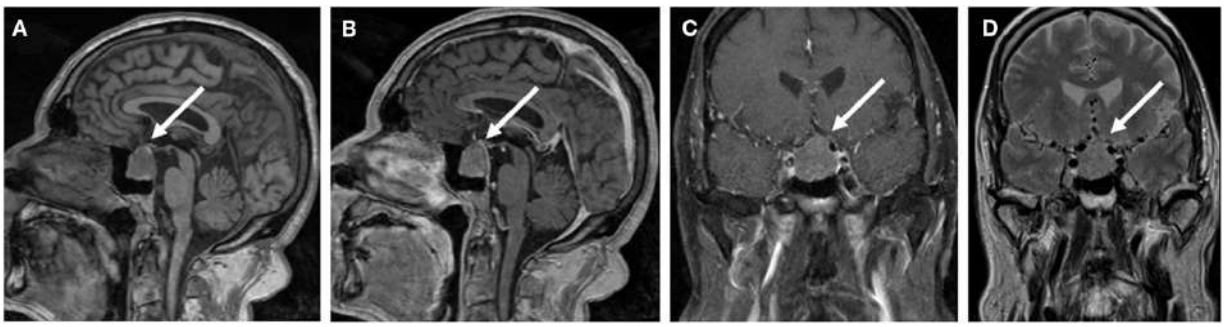

FIGURE 30.4 Magnetic resonance imaging sequences demonstrating pituitary macroadenoma (indicated by arrow). A. Representative sagittal slice on T1 weighted noncontrast. B. Representative sagittal slice on T1 weighted postcontrast. C. Representative coronal slice on T1 weighted postcontrast. D. Representative coronal slice on T2 weighted.

Advanced imaging techniques are also beneficial in characterizing intracranial malignancy. Magnetic resonance spectroscopy (MRS) provides metabolic and biochemical information about tumors in relation to normal brain tissue by quantifying five metabolite peaks: choline (Cho)-containing compounds, Cr, *N*-acetylaspartate (NAA), lactate, and lipid. The Cho peak reflects cell membrane turnover, while Cr is a surrogate for energy synthesis, and NAA is a marker exclusive to neuronal cells. Lactate is detected in necrotic tumors and infarcted tissue, a byproduct of anaerobic metabolism. Lipid peaks result from cellular and myelin breakdown products. The hallmark spectroscopic pattern of brain tumors is an increase in Cho-containing compounds and a decrease in NAA relative to normal brain tissue. MRS can also aid in the evaluation of tumor type and grade. High-grade gliomas tend to exhibit higher Cho:Cr and Cho:NAA ratios and also typically have higher lipid and lactate peaks as a result of necrosis. MRS can additionally distinguish metastatic disease from high-grade gliomas, particularly when combined with perfusion MRI.[36] Differentiating radiation necrosis from recurrent or progressive tumor remains a significant challenge in imaging, though delayed contrast extravasation (DCE) MRI has shown early promise in differentiating between active tumor (fast extravasation) and benign processes (slow extravasation).[37]

Conventional PET-CT has limited utility in the assessment of brain neoplasms due to the high metabolic rate of normal brain tissue. However, delayed-phase PET performed approximately 3.5 hours following FDG injection, allowing for washout of FDG from normal brain cells, while

abnormal tissue retains FDG. Delayed-phase PET has been shown to be beneficial in detecting both primary and metastatic brain lesions as well as differentiating between residual or recurrent tumor and radiation necrosis following treatment.[38] The development of new radioisotopes for neurologic applications, such as ^{11}C-methionine for targeting gliomas, has demonstrated clinical utility and advantages over FDG and might have similar utility in metastases. Many of these new tracers target different cellular processes, such as apoptosis, angiogenesis, and hypoxia; the latter being of particular prognostic importance as hypoxic tissue is less sensitive to chemotherapies.[39] The utility of delayed-phase PET may be further enhanced through fusion with MRI.[40]

Spinal Metastases

Osseous metastases are common in many malignancies, and the vertebral bodies are frequently involved due to the extensive vascular distribution to the spine. MRI is more sensitive than both radiographs and CT at detecting early vertebral body metastases, as it can detect changes within the marrow space before cortical destruction occurs. Given, however, that PET has similar sensitivity as MRI for osseous metastatic disease, is performed as part of routine staging, and can image the entire body, MRI is reserved for more specific characterization, such as determining the extent of tumor invasion into adjacent tissues. One notable exception is the use of urgent MRI for the identification of cord compression in the setting of acute neurologic compromise. In this situation, it is often the T2-weighted sequences that are most useful: the high signal CSF provides contrast to identify disease encroaching into the spinal canal. Spinal cord edema can also be identified. Screening the entire spine is often indicated when evaluating for cord compression due to the possibility of additional disease above or below the index lesion.

HEAD AND NECK

Oncologic Anatomy

Lymphatic Drainage of the Head and Neck

The lymphatics in the head and neck region largely proceed in an orderly manner from sites in the upper aerodigestive tract into the common jugular

chains, which eventually empty into systemic circulation near the junction of the internal jugular and subclavian veins.

The lymphatic basins of the neck are divided into multiple distinct levels. Level I is defined as both the submental basins (level IA) and the submandibular basins (level IB) and receive drainage from the oral cavity, although this basin may also be at risk from other sites in the setting of advanced nodal disease (N2b or greater). Level II contains the upper jugular nodes, extending from the C1 vertebral body to the hyoid bone, including the contents of the carotid sheath and the space deep to the SCM muscle. Level II is subdivided into anterior (level IIA) and posterior (level IIB) regions, as defined by the posterior border of the jugular vein. Level II contains the jugulodigastric node at the level of the jugular vein as it crosses the posterior belly of the digastric muscle and is a common lymphatic pathway for the majority of the upper aerodigestive tract. Level III follows the carotid sheath and space posterior to the SCM from the hyoid bone to the cricoid and receives efferent lymph drainage from level II. Level IV continues to follow the same jugular chain to the level of the clavicle. Level V contains the posterior triangle of the neck, boarded by the trapezius posteriorly, the SCM anteriorly, and the clavicle inferiorly. Level VI are the prelaryngeal lymph nodes (Delphian nodes), which extend from the inferior edge of the thyroid cartilage to the sternal notch, bounded laterally by the sternal heads of the SCM. Level VI is at risk in laryngeal cancers with subglottic or transglottic extension and for hypopharyngeal cancers with esophageal extension.[41]

There are two regions not included in this level classification. Just superior to level II, following the carotid sheath to the skull base are the junctional or retrostyloid nodes, which may be at risk when there is ipsilateral nodal disease. Medial to these nodes and to level II lie the retropharyngeal nodes (nodes of Rouvière), which lie in the regions anterior to the prevertebral fascia, which, in turn, surrounds the longus capitis and longus colli muscles. The retropharyngeal nodes extend superiorly to the skull base and inferiorly to the hyoid bone and are at risk of cancers of the nasopharynx, posterior pharyngeal wall, and the pyriform sinus.

The Oral Cavity

Oral cavity cancer sites include the lip, floor of the mouth, oral tongue (anterior two-thirds of the tongue), lower alveolar ridge, upper alveolar ridge, retromolar trigone, hard palate, and buccal mucosa. Carcinomas originating from the oral tongue have the potential to spread locally through the intrinsic and extrinsic muscles of the tongue, inferiorly to the floor of mouth, and posteriorly to the anterior tonsillar pillar. For the floor of mouth, the genioglossus, geniohyoid, and root muscles of the tongue are at risk for local disease spread, as well as levels IA and IB of the neck, laterally to the alveolar ridge and mandible. Tumors of the buccal mucosa may extend superiorly to the infratemporal fossa, inferiorly to the submandibular region, anteriorly to the lip commissure, and posteriorly to the retromolar trigone.

Nasopharynx

The nasopharynx is bounded superiorly and posteriorly by the sphenoid sinus, clivus, and the prevertebral fascia of C1 and C2. The parapharyngeal space lies laterally to the nasopharynx, which, in turn, is bounded laterally by the medial pterygoid muscle. The parapharyngeal space offers few anatomic barriers for the direct invasion of tumors superiorly and laterally to the base of skull, resulting in CN deficits as noted above. The eustachian tube empties into the nasopharynx at the torus tubarius; just posterior to the torus is the pharyngeal recess (or fossa of Rosenmüller), a fold of mucosa that is a frequent site for primary malignancies of this region.

Oropharynx

The oropharynx is bounded anteriorly by the base of tongue, laterally by the tonsils, superiorly by the soft palate, and posteriorly by the posterior pharynx. Tumors arising from the base of tongue are often difficult to assess for extent of disease. PET/CT or MRI may aid in delineation of the gross tumor volume for this site.

The pharyngeal constrictor muscles (PCMs) lie along the posterior aspect of the nasopharynx and oropharynx, bounded by the parapharyngeal space. The PCM may be further divided into (1) the superior PCM starting at the occipital condyle to the hyoid; (2) the middle PCM, starting 0.5 cm superior to the hyoid and ending at the inferior edge of the hyoid; and (3) the inferior PCM, which continues from the inferior aspect of the hyoid to the

esophagus. The middle PCM was initially investigated as an organ at risk, with dose-volume metrics associated with late swallowing problems.[42] Dose to other swallowing structures, including the genioglossus, mylohyoid/geniohyoid complex, and anterior digastric muscle has also been implicated in addition to the superior PCM and the middle PCM.[43]

Hypopharynx

The hypopharynx is divided into three anatomic subsites: the pyriform sinus, the posterior pharyngeal wall, and the postcricoid space. Cancers arising from the pyriform sinus account for approximately 65% to 85% of hypopharyngeal cancers. The posterior pharyngeal wall is formed by the constrictor muscles covered with a mucosal lining and is the origin of approximately 10% to 20% of cancers. Cancers arising from the postcricoid space account for the remaining 5% to 15% of hypopharyngeal tumors.

Larynx

The larynx is subdivided into three anatomic regions: the supraglottis (containing the epiglottis, the arytenoid and aryepiglottic folds, and the ventricular bands or false cords), the glottis (a 1-cm plane extending inferiorly from the lateral margin of the ventricle, including the true vocal cords and commissures), and the subglottis (from the inferior border of the glottis to the inferior aspect of the cricoid). The true cords have essentially no lymphatic drainage, allowing for focal treatment of a limited primary tumor without elective nodal treatment. In contrast, the supraglottic larynx has a rich and bilateral lymphatic system, requiring either dissection or elective nodal RT for even early tumors. The subglottis is a rare site of primary tumors and may invade locally into soft tissue as well as metastasize to laryngeal and tracheal lymphatics.

Oncologic Imaging

For cancer of the head and neck, staging relies on careful physical examination, fiberoptic and direct laryngoscopy, directed biopsies, and integration of imaging modalities. Contrast- enhanced CT is the standard imaging modality for carcinomas of the head and neck region (Figure 30.5). MRI may be a superior imaging modality for evaluating the extent of

primary tumors of the oral cavity, oropharynx, and nasopharynx. DW MRI may provide information about the cellularity of a tumor mass or involved lymph node; an increase in the ADC (corresponding to a decrease in cellularity) during chemoradiation has been correlated with improved 2-year local control in one series.[44]

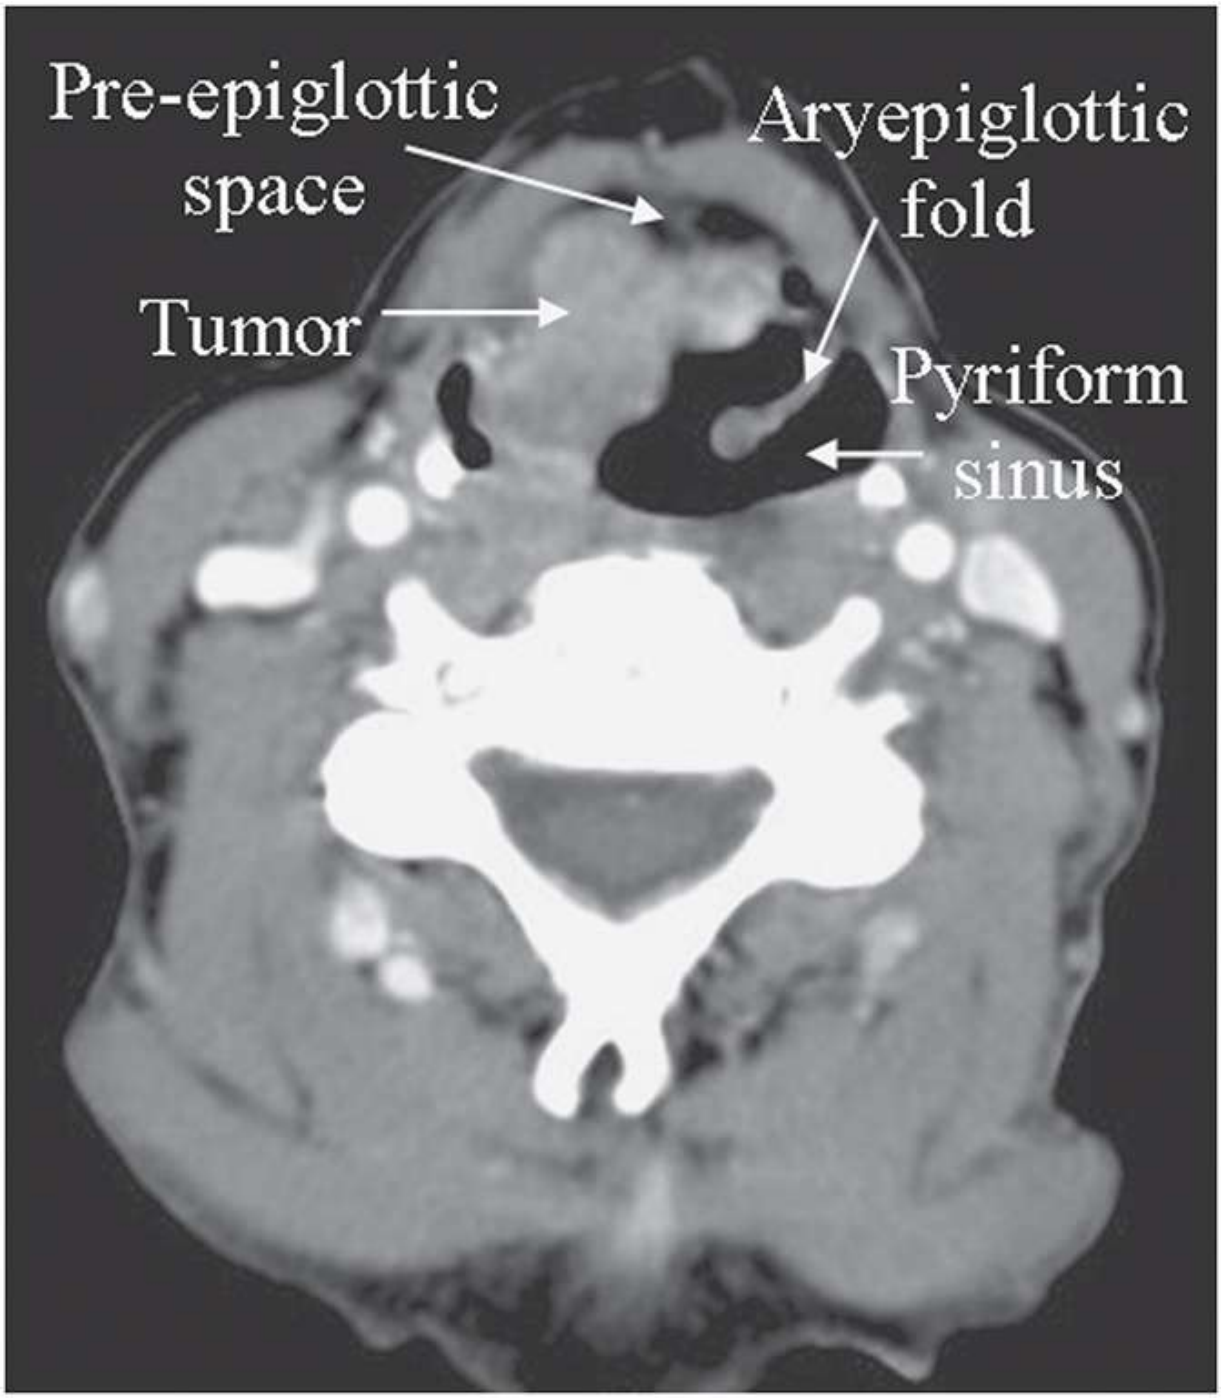

FIGURE 30.5 Axial computed tomography image demonstrating a squamous cell carcinoma involving the right aryepiglottic fold with anterior extension into the pre-epiglottic space.

FDG-PET imaging for head and neck cancer is a useful as an adjunct to CT, particularly in clarifying the significance of intermediate lesions (Figure 30.6). In one series, the addition of FDG-PET imaging improved the

accuracy of tumor delineation from 40% to 70% with MRI or CT alone to 97% to 100%, altering the management of 23% of the patient under study.[45] Another series found FDG-PET to have a sensitivity of 88% in determining the primary tumor and a sensitivity of 82% and specificity of 100% for lymph node metastases.[46] However, in initial staging, no noninvasive imaging modality has a high enough negative predictive value to forgo appropriate dissection or elective nodal irradiation when the characteristics of the primary tumor suggest a significant risk of spread. This contrasts with the value of FDG-PET after chemoradiation for the detection of residual nodal disease. The sensitivity for the detection of persistent disease was 96% with a specificity of 72% in a post-treatment series, with a negative predictive value in some series as high as 99%, allowing for the abandonment of routine post-treatment neck dissections in patients with a complete clinical and PET response.[47,48]

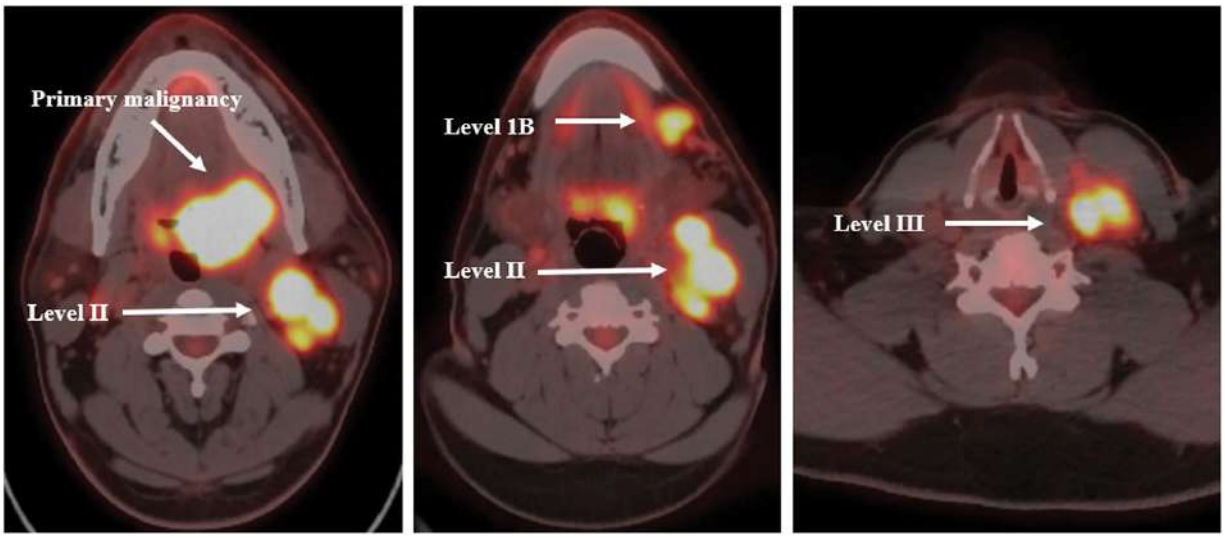

FIGURE 30.6 Positron-emission tomography computed tomography images demonstrating a large hypermetabolic mass centered in the left palatine tonsil and crossing midline. There are multiple level IB-IV cervical lymph nodes. Pathology showed squamous cell carcinoma.

THE BRACHIAL PLEXUS

Oncologic Anatomy

The brachial plexus originates from the primary rami of the C5 through T1 vertebral levels and joins to form three nerve trunks (superior, middle, and inferior) in the neck. These trunks divide as they course beneath the clavicle

forming three cords (lateral, medial, and posterior) in close approximation to the axillary artery, posterior to the pectoralis minor. The cords then form the three primary terminal nerves for the arm (the median, ulnar, and radial nerves) as well as the musculocutaneous and axillary nerves.

The brachial plexus is a critical organ at risk due to the significant morbidity associated with injury, either from direct tumor invasion or from treatment-related toxicity. As the plexus traverses the neck, crosses over the apex of the lung, and continues into the axilla, it is of relevance when treating tumors of the head and neck, upper thorax, and breast.

Oncologic Imaging

Identifying the brachial plexus is difficult on CT imaging and is most directly visualized using MRI. However, one may accurately contour the position of the brachial plexus on CT imaging using bony, muscular, and vascular landmarks.[49] The method put forward by Hall et al begins by contouring at the origination of the vertebral foramina of C5 through T1 (Figure 30.7). The brachial plexus trunks pass between the anterior and middle scalene muscles. The middle scalene will end at the superior aspect of the first rib just as the divisions of the plexus will be joining with the subclavian vasculature as a neurovascular bundle. The posterior aspect of the subclavian vasculature can be followed laterally as a surrogate for the remainder of the cords into the arm.

Brachial plexus coursing between anterior (pink) and middle (green) scalene muscles at C7. C. T1 ventral ramus and brachial plexus coursing behind subclavian neurovascular bundle.

THE THORAX

Oncologic Anatomy

The thoracic cavity contains several important structures, including the lungs, esophagus, thymus, pleura, and heart. Common malignancies arising in the thorax include lung cancer, esophageal cancer, thymic malignancies, malignant pleural mesothelioma, and Hodgkin (HL) and non-Hodgkin lymphomas (NHL). Primary tumors of the heart are extremely rare.

There are many clinically relevant anatomic issues when evaluating patients with cancers of the thorax, particularly lung cancer. These include lobe-specific patterns of lymphatic spread, the complex anatomy surrounding the lung apex, the extent of the pleural space, esophageal landmarks, thymic architecture, and cardiac anatomy.

Patterns of Lymphatic Spread

Lung cancers frequently metastasize to regional lymph nodes. The mediastinal nodes are a complex system, and it is challenging to predict where lymph node metastases will develop. However, these basic patterns provide a framework for customizing local treatment approaches (ie, surgery and RT).[49-51]

Bronchogenic tumors frequently spread directly into mediastinal lymph nodes, bypassing intrapulmonary and hilar lymph nodes. This phenomenon appears to occur more frequently for upper lobe tumors. For right-sided

tumors, these pathways most frequently lead to ipsilateral paratracheal and subcarinal lymph node stations. For left upper lobe tumors, direct spread to para-aortic and aortopulmonary window stations predominates. While right lung segments drain predominantly into the ipsilateral mediastinum, left lung tumors commonly spread to both sides of the mediastinum, especially left lower lobe tumors. Direct passageways to the supraclavicular fossa exist but are rare. Clinically, supraclavicular lymph node involvement is almost always associated with involvement of upper paratracheal lymph node stations. Subcarinal lymph nodes are frequently involved by both upper and lower lobe tumors.

The Superior Sulcus

The superior sulcus of the lung is surrounded by multiple critical structures. The subclavian artery and vein pass anterior to the lung apex, the brachial plexus and its branches cross over the apex of the lung toward the arm, and the stellate ganglia lies posteriorly alongside the exiting nerve roots of the lower cervical and upper thoracic spine. Other structures that can be involved by superior sulcus tumors include the ribs, vertebral bodies, trachea, and esophagus. Patients with superior sulcus tumors present with a variety of presentations (arm edema, hand weakness, sensory deficits, and/or Horner syndrome) related to the local extent of their disease.

The Pleura

The lungs are enclosed within a pleural sac. The visceral pleura is adherent to all of the surfaces of the lung, including the individual lobes where the pleura extends into the fissures. The parietal pleura is adherent to the thoracic wall, mediastinum, and diaphragm. The pleural recesses are potential spaces where portions of opposed parietal pleura are in contact during quiet respiration (Figure 30.8). The inferior extension of the costodiaphragmatic recess can be easily underestimated, as can the medial extent of the costomediastinal recess. The inferior aspect of the costodiaphragmatic recess often extends to the level of the mid-kidney. The posteromedial extent of the pleura often wraps anteriorly over the descending aorta. These considerations are important when managing pleural mesothelioma or drop metastases from thymic malignancies.

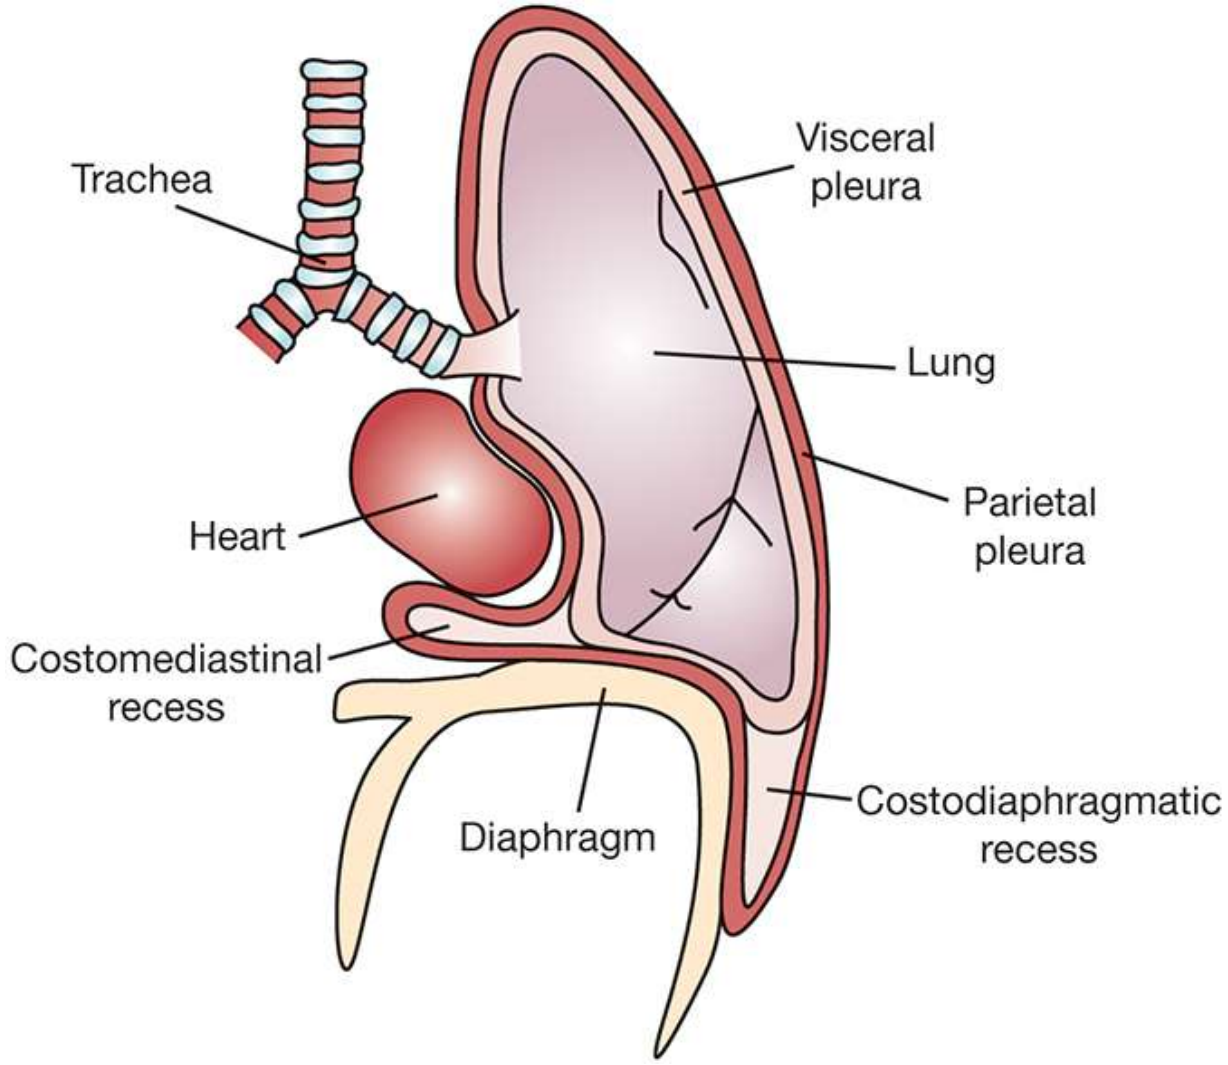

FIGURE 30.8 The extent of the pleura is illustrated. Note the inferior extension of the costodiaphragmatic recess and the medial extension of the costomediastinal recesses. (Courtesy of the University of Bristol, Department of Anatomy.)

Esophageal Anatomy

The esophagus extends from the cricopharyngeus muscle at the level of the cricoid cartilage to the gastroesophageal junction in the abdomen. The cervical esophagus extends from the cricopharyngeus muscle (approximately 15 cm from the incisors) to the level of the thoracic inlet (approximately 18 cm from the incisors). The thoracic esophagus extends from the thoracic inlet to the diaphragm and is sometimes divided into upper, middle, and lower sections. The carina is located at approximately 25 cm from the incisors, and the gastroesophageal junction is located at

approximately 40 cm. These general numbers are helpful when planning radiation fields based on staging studies that include endoscopy, EUS, and PET-CT.

Thymus Architecture

The thymus is an encapsulated, bilobed gland situated in the superior anterior mediastinum and is involved in adaptive immunity. Although prominent in size during infancy and early childhood, it begins to involute during adolescence. Thymic neoplasms are a common cause of anterior mediastinal masses. The thymus gland is composed of both lymphocytes and epithelial cells. Thymomas and thymic carcinomas arise from epithelial elements within the thymus. Primary mediastinal (thymic) large B-cell lymphoma arises from B cells within the thymus, and T-cell lymphoblastic lymphomas arise from T cells within the thymus.

Thymic malignancies are the second most common primary mediastinal neoplasm in adults following lymphoma and are classified on a histologic spectrum from thymoma to thymic carcinoma. Once a thymic malignancy extends through the capsule, it can invade other regional structures including the lungs and great vessels, sometimes rendering it inoperable. The thymus gland lies within the pleural envelope. For thymomas, the most common pattern of spread is within the pleural and pericardial spaces. Lymphatic and hematogenous metastases are rare.

Cardiac Anatomy

The heart is composed of several subunits, including the valves, coronary arteries, pericardium, and individual chambers. There is an increasing awareness that radiation dose to the individual subunits is correlated with toxicity though many uncertainties exist. One component of the heart that has garnered recent attention is the left anterior descending artery (LAD). The LAD is the largest coronary artery. The left coronary artery branches to create the LAD and the circumflex. The LAD runs along the interventricular septum, supplying blood to the anterior and left sides of the heart (Figure 30.9). Studies have shown that dose to the LAD (V15 Gy >10%) is associated with a higher risk of major cardiac events and all-cause mortality.[52,53]

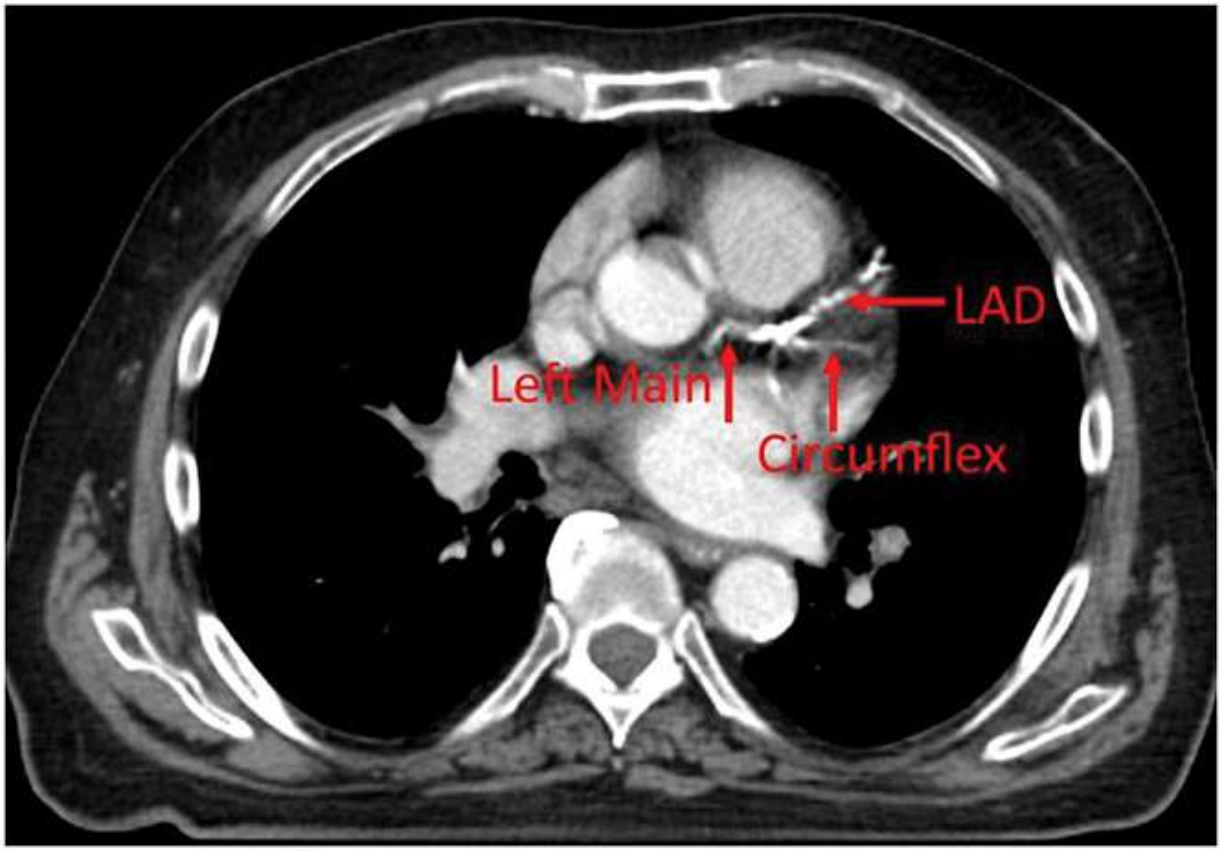

FIGURE 30.9 On a representative axial computed tomography image, the left anterior descending artery (LAD) is shown in the interventricular septal region. The left main coronary artery and circumflex are also delineated.

Oncologic Imaging

Non–Small Cell Lung Cancer

Treatment decisions are often predicated on the status of the mediastinum in patients with NSCLC. Patients with operable disease, without mediastinal lymph node involvement, generally proceed directly to resection. Patients with operable disease but involved ipsilateral mediastinal lymph nodes (N2) typically receive induction therapy or definitive chemoradiotherapy. Patients with contralateral mediastinal or supraclavicular disease (N3) are not considered appropriate surgical candidates.

PET-CT is superior to CT in staging the mediastinum and is the standard noninvasive staging tool for NSCLC. The sensitivity of PET-CT in detecting mediastinal lymph node involvement is generally about 80% to 85% with a specificity of 80% to 90%.[54] However, PET-CT is not sensitive enough to

replace pathologic staging. Thus, mediastinoscopy or endobronchial ultrasound is often utilized to pathologically stage the mediastinum.[55]

Localization of the esophagus is important during treatment planning of lung cancer. The esophagus is often well visualized on CT. However, its course can be tortuous and its exact location is often uncertain, especially in the subcarinal region. Having the patient swallow dilute contrast during the planning CT can be helpful. IV contrast helps delineate several important cardiac substructures such as the coronary arteries and aortic valve, but more advanced cardiac imaging is necessary to visualize others. Motion of the heart and lungs degrades resolution of the heart on standard planning CT scans.

Esophageal Carcinoma

The most used staging tools for esophageal carcinoma are barium swallow, EUS, CT, and PET-CT. EUS, as previously discussed, is the most accurate modality to assess depth of invasion (T stage) but is slightly less accurate in assessing nodal involvement (N stage) (Figure 30.10). The ability to perform fine-needle aspiration biopsies of suspicious nodes has significantly increased the accuracy of EUS staging of regional nodes.[56] The reported accuracy of EUS for esophageal staging is approximately 90%, especially for experienced gastroenterologists.[57] PET-CT is primarily used to evaluate for metastatic disease and is superior to CT.[58] PET-CT may also be helpful in identifying patients who have achieved a complete response to neoadjuvant chemoradiotherapy, potentially sparing them from the morbidity of surgery. This is most relevant for patients with squamous cell carcinomas.

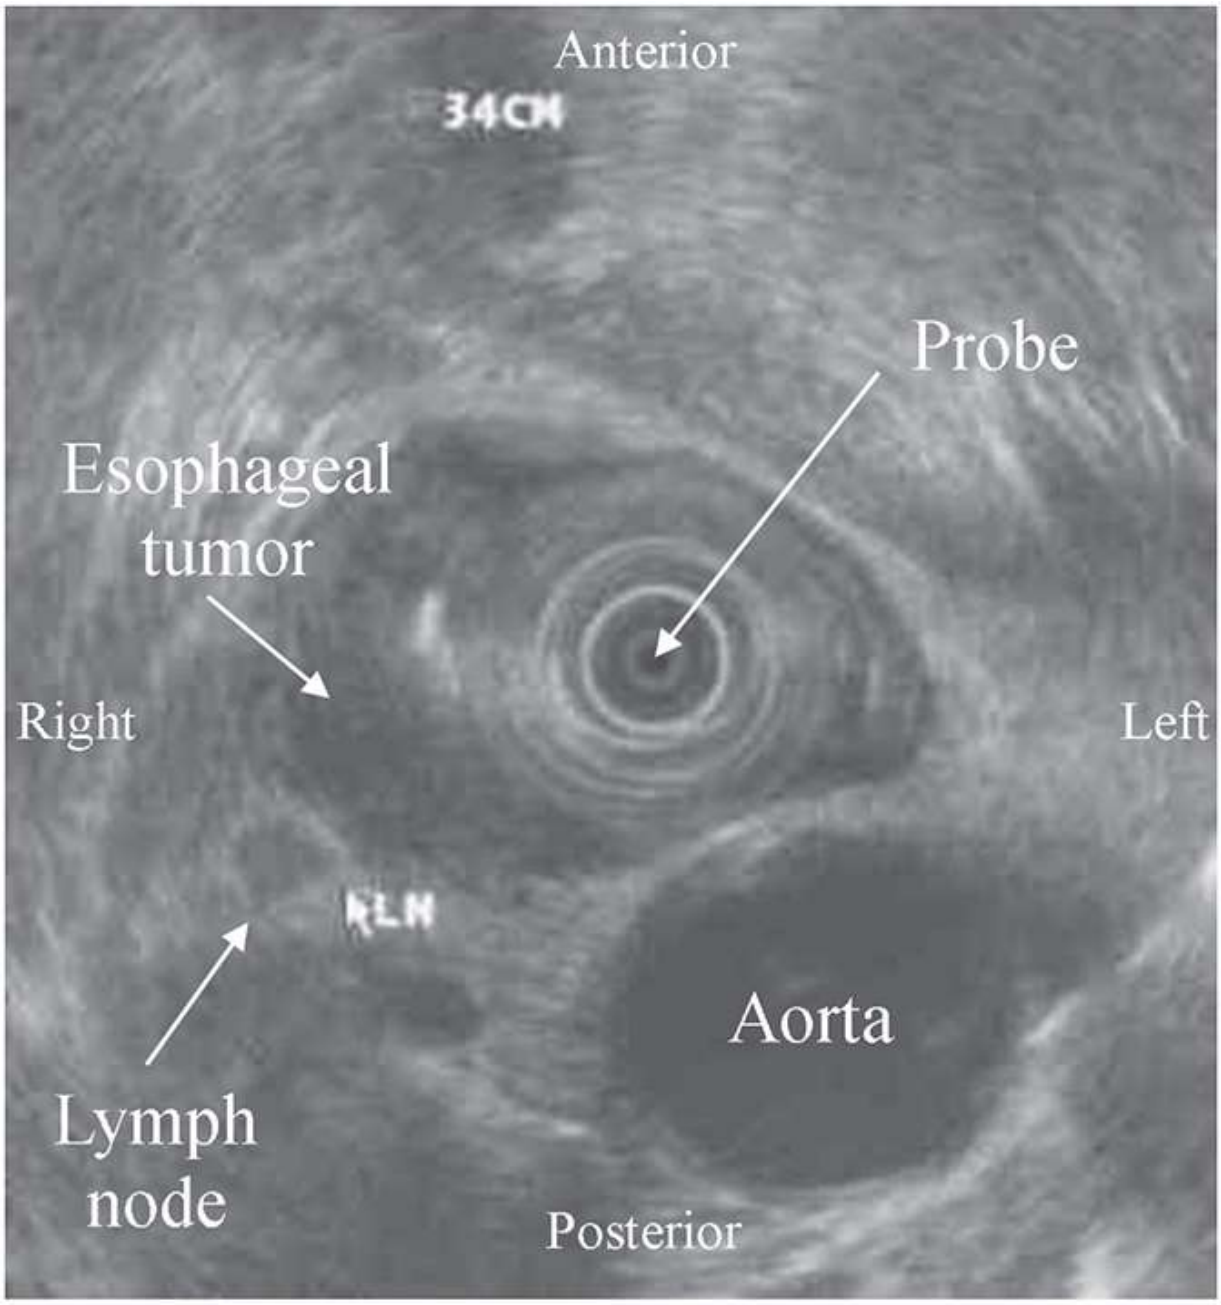

FIGURE 30.10 Endoscopic ultrasound image demonstrating a T3 esophageal tumor with an abnormal peritumoral lymph node. (Courtesy of Dr Frank Gress.)

Mesothelioma

The characteristic CT appearance of pleural mesothelioma is focal or diffuse nodular pleural thickening, which demonstrates enhancement postcontrast administration. MRI is not routinely used in the diagnosis of mesothelioma but can be helpful in special circumstances (eg, evaluating cardiac invasion).

PET-CT is often performed for staging to detect distant and nodal metastases. However, it can also be helpful in establishing the initial diagnosis when CT findings are subtle, as even small foci of disease are typically highly FDG avid.

Superior Sulcus

Superior sulcus tumors are NSCLCs that arise in the apex of the lungs and invade surrounding structures, such as the chest wall, vertebral bodies, and/or brachial plexus. CT is best to define the primary tumor and detect rib or vertebral body invasion. Contrast-enhanced MRI using T1-weighted sequences is best for determining resectability by assessing the brachial plexus and surrounding vascular structures.[59] The primary role of PET-CT is to identify distant and nodal metastases.

Thymic Malignancy

Thymic neoplasms develop in the anterior mediastinum (Figure 30.11) and are often discovered incidentally when imaging is obtained of the chest. They are rarely symptomatic unless they become quite large or if a paraneoplastic process develops. Contrast-enhanced CT is best for characterizing thymomas and assessing for local invasion into the lung, great vessels, and/or pericardium. A preserved fat plane between tumor and adjacent structures is a negative predictor of invasion. However, mere contiguity of tumor with a structure or loss of normal anatomic planes is not sufficient to rule out surgical resection. CT features that have been correlated with stage III or greater disease include primary tumor size 7 cm or larger, lobulated margins, and infiltrative changes of the mediastinal fat surrounding the mass.[60] PET-CT is useful to detect distant disease, including pleural or pericardial drop metastases.

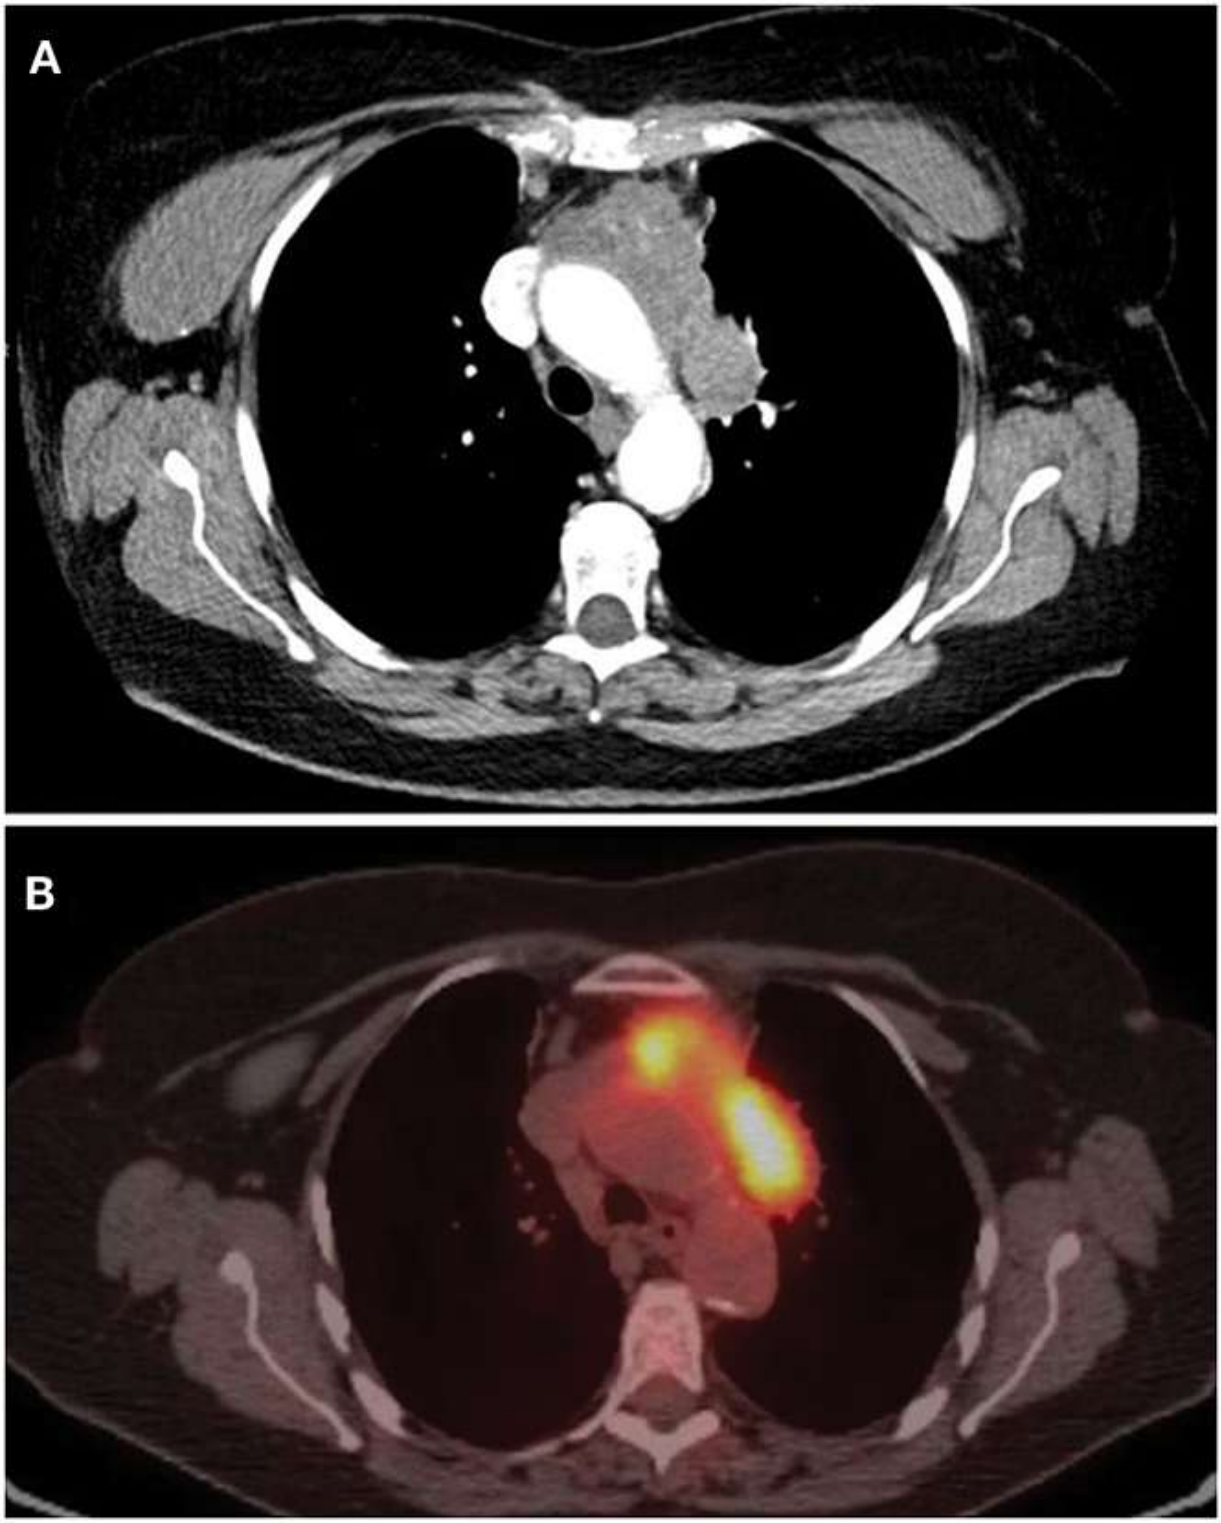

FIGURE 30.11 A. Lobulated anterior mediastinal mass originating in the anterior mediastinum. B. The mass is hypermetabolic on positron-emission tomography computed tomography. Pathology showed a thymic carcinoma.

THE BREAST

Oncologic Anatomy

Breast tissue consists of lactiferous ducts that each drain 15 to 20 mammary gland lobules. The majority of noninvasive (in situ) and invasive ductal carcinomas originate within these ducts. Both males and females have breast tissue, although, with the onset of puberty, it is only well developed in females. Male breast tissue generally contains few ducts, which nonetheless can rarely develop into malignancy, particularly in the context of *BRCA2* mutations.[61] The breast originates from a roughly circular base or bed, with longitudinal extent from the lateral border of the sternum to the midaxillary line, and craniocaudal (CC) extent generally from the second through the sixth ribs. The upper outer quadrant extends along the pectoralis major toward the axilla, forming the axillary tail of Spence. Primary breast cancers are most prevalent in the upper outer quadrant (~40%), likely due to the additional breast tissue associated with the tail. The retromammary space consists of loose connective tissue, allowing for movement of the breast on the chest wall. Two-thirds of the breast rests on the deep pectoral fascia, which overlies the pectoralis major; the remainder rests on the fascia of the serratus anterior. The breast is then anchored to the skin by suspensory ligaments (or Cooper ligaments) and interspersed with fat lobules. These ligamentous attachments to the skin become more prominent with breast edema or congestion due to tumor involvement of the dermal lymphatics, resulting in the characteristic appearance of *peau d'orange*.

The lymphatic drainage of the breast is primarily to the axilla, although the upper outer quadrant in particular may drain to the intermediary intrapectoral nodes (Rotter nodes) lying between the pectoralis major and pectoralis minor muscles. The inner quadrants in particular may drain to the internal mammary nodes (IMNs). The axilla is divided into three sections, designated relative to the pectoralis minor muscle. The nodes inferolateral to the muscle are termed level I, while those beneath the muscle are termed level II, and those medial to the muscle are level III. Level I and II nodes are generally removed in a standard axillary dissection, while level III as well as infraclavicular and supraclavicular nodes are generally considered unresectable.

In surgical series in which the IMNs were routinely dissected, the incidence of isolated IMN involvement was limited to 4% to 16%.[62-64] The risk of pathologic involvement increased when the axilla was also involved and was dependent on the axillary disease burden and of the involved breast quadrant (Table 30.5). When IMNs are involved, the majority (>85%) tend to be located in the first three intercostal interspaces. Elective irradiation of the IMN nodes remains controversial, though recent randomized data have shown a modest benefit in terms of recurrence rates and cancer-specific survival when IMN and medial supraclavicular fields are treated, particularly in patients with medially or centrally located tumors.[65-67]

TABLE 30.5 RISK OF INTERNAL MAMMARY LYMPH NODE INVOLVEMENT BASED ON STATUS OF AXILLA AND LOCATION WITHIN THE BREAST

Scenario	Livingston and Arlen[62] (%)	Urban and Marjani[63] (%)	Huang et al[64] (%)
Negative axilla	8	16	4
Outer quadrant primary	5	13	3
Medial/central primary	14	20	7
Positive axilla	32	52	28
Outer quadrant primary	23	42	24
Medial/central primary	59	65	36
1-3 + axillary nodes	ns	ns	19
≥4 + axillary nodes	ns	ns	43

ns, not stated.

Oncologic Imaging

Mammography remains the preferred imaging modality for the diagnosis and follow-up of both invasive and noninvasive diseases. Multiple randomized trials have shown that screening mammography reduces the risk of breast cancer mortality by 20% to 35% in women aged 40 to 70 years. Screening mammography includes two standard views of each breast: CC

and mediolateral oblique (MLO). The CC view is oriented in the long axis of the patient, and the MLO view is oriented in the medial-superior/lateral-inferior direction. The MLO view increases visualization of the upper outer quadrant and tail of the breast, while the CC view ensures adequate visualization of the inferior and medial aspects of the breast. Most women (approximately 95%) with abnormalities on a screening mammogram do not have breast cancer, rendering the positive predictive value (PPV) low. Overall, the sensitivity of screening mammography is approximately 75%, with 25% of women diagnosed with breast cancer have a normal mammogram 12 to 24 months prior to diagnosis. Sensitivity and specificity vary significantly based on breast density. For fatty versus dense fibroglandular breasts, reported sensitivities are 87% versus 63%, while specificities are 92% versus 68%.

The Breast Imaging Reporting and Data System was developed to standardize reporting and quality assurance of screening mammography within the United States (Table 30.6).[68] Mammographic features concerning for malignancy include focal masses, irregular borders, and microcalcifications. Spiculation can be due to invasion into or reactive changes within the surrounding breast parenchyma. Spiculated masses, however, can also be secondary to fat necrosis, postoperative scarring, or other nonmalignant processes. Calcifications associated with ductal carcinoma in situ or invasive carcinoma are typically pleomorphic (heterogeneous) in appearance and clustered in a localized area (Figure 30.12). Linear, branching calcifications are suggestive of intraductal carcinoma. Round, well-circumscribed lesions, with or without coarse calcifications, are often benign.

TABLE 30.6 BREAST IMAGING REPORTING AND DATA SYSTEM (BI-RADS) CATEGORIES USED FOR MAMMOGRAPHY EXAMINATIONS AND RISK OF MALIGNANCY

Assessment Category	Assessment	Risk of Malignancy (%)
0	Need additional imaging evaluation	na
1	Negative	<0.1
2	Benign finding	<0.1

Assessment Category	Assessment	Risk of Malignancy (%)
3	Probably benign finding—short-interval follow-up suggested	<2
4	Suspicious abnormality—biopsy should be considered	2-95
5	Highly suggestive of malignancy	>95
6	Known biopsy-proven malignancy	100

na, not available.

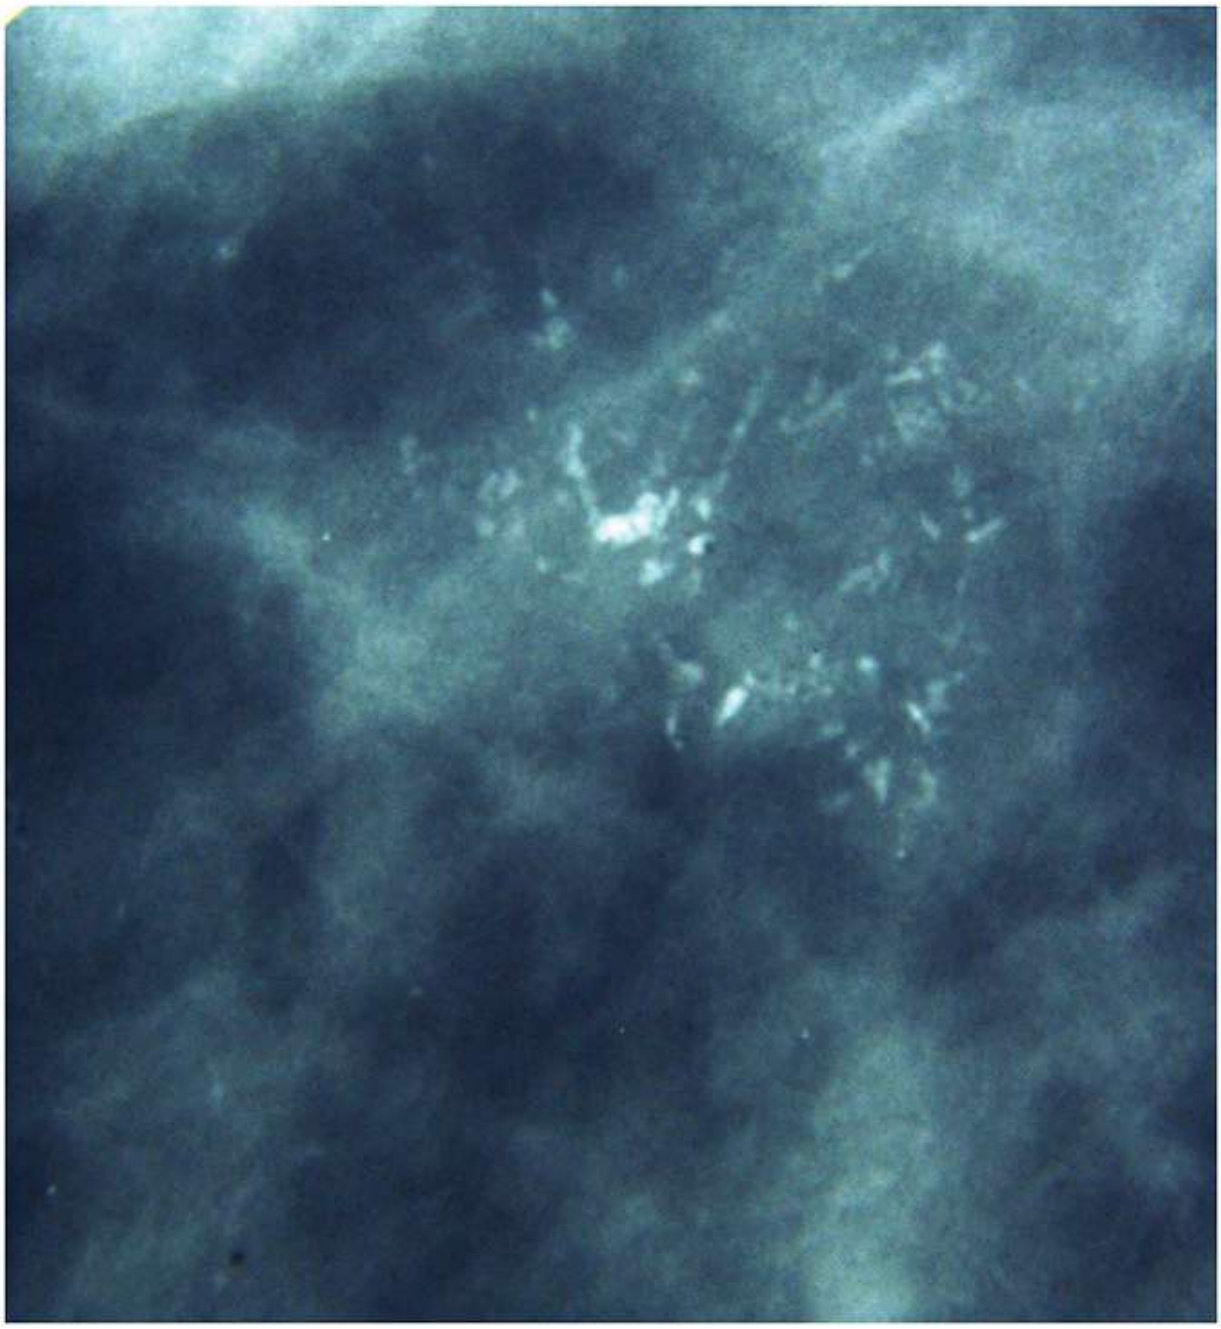

FIGURE 30.12 Clustered, pleomorphic calcifications visualized on mammography. The patient was found to have ductal carcinoma in situ.

Patients with abnormal clinical examinations, specific breast symptoms, and/or abnormalities on screening mammogram are generally evaluated with a diagnostic mammogram. In addition to CC and MLO views, supplemental compression and magnified views may be obtained to detect and characterize microcalcifications (Figure 30.13). Breast US is also often

performed to further characterize suspicious lesions, guide core biopsy, and assess regional lymph nodes. It is most helpful in differentiating fluid-filled cysts from solid tumors.

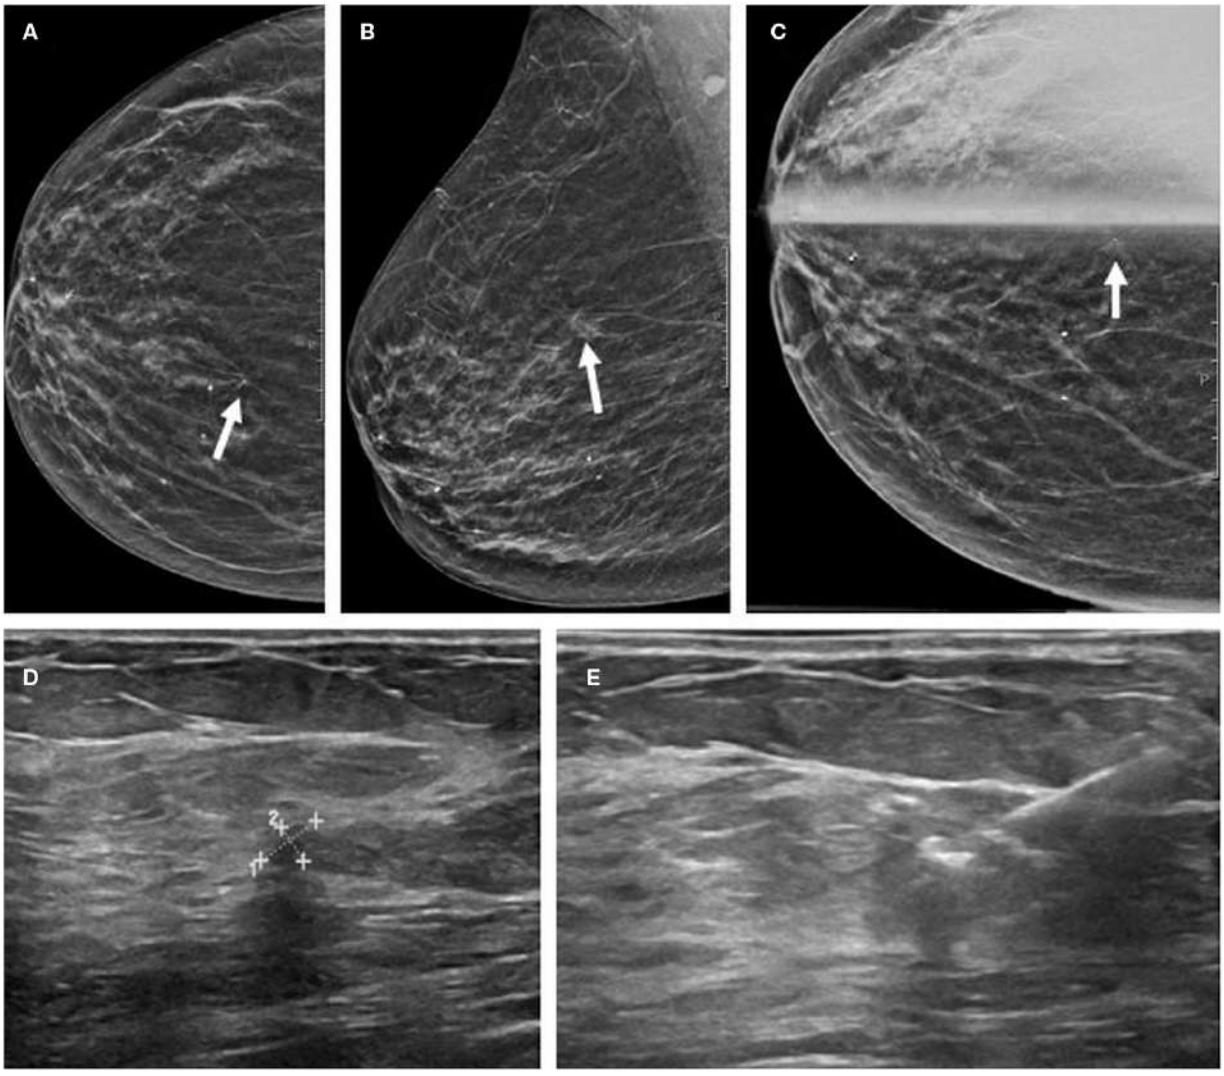

FIGURE 30.13 Invasive ductal carcinoma (indicated by arrow) on mammogram and ultrasound. A. Craniocaudal view (CC view). B. Mediolateral oblique view. C. Spot compression CC view. D. Area of concern demarcated on breast ultrasound. E. Ultrasound-guided breast biopsy.

MRI is not routinely recommended for upfront screening, except in patients at very high risk for primary breast malignancy, including those with *BRCA* mutations, a strong family history of breast cancer, or those who received chest RT at a young age (typically <30 years old).[69] The utility of

routine preoperative MRI in patients with biopsy-proven malignancy has also been studied. One trial found that preoperative MRI resulted in additional contralateral breast biopsies in 12% of patients, with resultant malignant pathology in only 3% of patients. Preoperative MRI was also not shown to reduce the requirement for reoperation in a randomized UK trial.[70] In addition, the routine use of preoperative MRI is associated with an increase in the percentage of women undergoing mastectomy, as opposed to breast conservation, with unclear oncologic benefit.[71] While preoperative MRI may be useful in select circumstances, given its limited specificity, routine usage is not recommended.

Digital breast tomosynthesis (DBT) is a method of generating three-dimensional (3D) breast imaging from several planar x-ray images taken at differing angles. As with conventional two-dimensional mammography, the images are not taken in axial sections, and only a limited rotational angle is utilized. Generally, DBT appears to result in higher cancer detection rates with fewer false positives, as it allows for distinguishing overlapping lesions that may confound planar imaging.[72] As such, it is beginning to supplement screening for high-risk individuals, particularly in follow-up after radiation treatment.[73]

THE ABDOMEN

Oncologic Anatomy

Gastric Cancer: Patterns of Lymphatic Spread

The stomach is divided into four subsites: the gastroesophageal junction (cardia), fundus, body, and pylorus (antrum). The incidence of epithelial malignancies of the distal stomach has declined in Western countries over the past century, while the incidence of malignancies involving the gastroesophageal junction has increased.[74] Lymph node involvement is common in gastric cancer, likely due to the extensive submucosal and subserosal lymphatic networks. This rich lymphatic network places all lymph node regions within the abdomen at risk of harboring regional metastases, irrespective of the location of the gastric tumor. Some general patterns have been observed, however, which can guide radiation treatment planning. The perigastric region located along the greater and lesser curvatures of the stomach is typically the initial draining lymph node basin;

this region is typically addressed by a D1 lymph node dissection and is covered in radiation treatment plans. The other primary lymph node basins lie along the three arterial branches of the celiac axis (common hepatic, left gastric, splenic) and are typically explored in a D2 dissection. These nodal basins should also be covered in most radiation treatment plans, though coverage of the splenic artery/hilum can potentially be limited when treating more distal tumors. Secondary and tertiary drainage sites include lymph nodes in the hepatoduodenal, peripancreatic, para-aortic, mesenteric, and middle colic basins. Detailed guidelines have been published outlining proposed radiation fields for gastric cancer based on the extent of surgery and site of involvement within the stomach.[75]

Pancreas

The pancreas is an elongated digestive gland located posterior to the stomach. It is classically divided into four parts: the head, neck, body, and tail. Most pancreatic carcinomas arise within the pancreatic head, which is nestled within the curve of the duodenum. The pancreas has a rich lymphatic network and is in close proximity to multiple other abdominal organs and structures, making surgical resection challenging, which can subsequently negatively impact long-term survival. Surgery offers a chance of cure for pancreatic carcinomas, but most tumors are not resectable at diagnosis.

Biliary Tree

Hepatocytes within the liver secrete bile into bile canaliculi, the initial branches of the intrahepatic duct system. These canaliculi drain bile into larger channels that eventually form the left and right hepatic ducts, draining bile from the respective lobes of the liver. These ducts exit the liver via the porta hepatis and join to form the common hepatic duct. The cystic duct joins the common hepatic duct to form the common bile duct and empties into the duodenum (Figure 30.14).

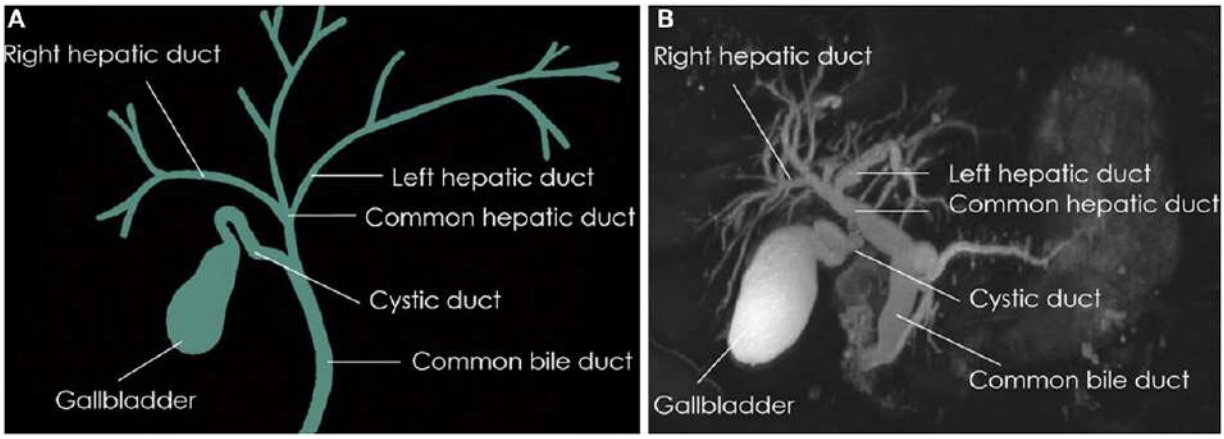

FIGURE 30.14 Anatomy of the biliary tract in an illustrated schematic (A) and on magnetic resonance cholangiopancreatography imaging (B).

Biliary tract cancers include cholangiocarcinomas of the gallbladder and bile ducts. These include intrahepatic, perihilar, and extrahepatic biliary malignancies. Klatskin tumors are perihilar tumors that involve the bifurcation of the common hepatic duct. Distally located biliary tumors tend to have improved resectability and prognosis.

Oncologic Imaging

Pancreatic Cancer

The pancreas can be imaged with US, CT, and MRI. The clinical stage of pancreatic cancers can be determined with accurate pretreatment CT imaging. MDCT with IV contrast and thin-section reconstructions optimize pancreatic tissue characterization and allow for detection of small tumors as well as vascular and ductal invasion. CT with thin-section reconstructions and IV contrast enhancement is important for assessing whether a tumor is resectable, borderline resectable, locally advanced, or metastatic. On CT, pancreatic adenocarcinoma usually appears hypodense mass relative to the normal pancreatic tissue. Encasement of the superior mesenteric artery (SMA) or celiac trunk defines an unresectable T4 tumor. Conversely, the presence of a fat plane around the celiac trunk and SMA, along with a patent superior mesenteric (SMV) or portal vein, indicated potentially resectable disease. Borderline cases include those with tumor abutment of the SMA, severe unilateral SMV or portal vein impingement, or adjacent organ invasion (Figure 30.15). CT does not, however, sensitively detect small

volume peritoneal or surface liver metastases; these can be identified with laparoscopy as indicated. MRI may also be performed when CT findings are equivocal or there is a contraindication to administering iodinated contrast; however, there is no diagnostic advantage of MRI over contrast-enhanced CT (sensitivity of 84% vs 86%).[76] The role of FDG-PET for pancreatic cancer diagnosis and staging remains uncertain and is not routinely performed.

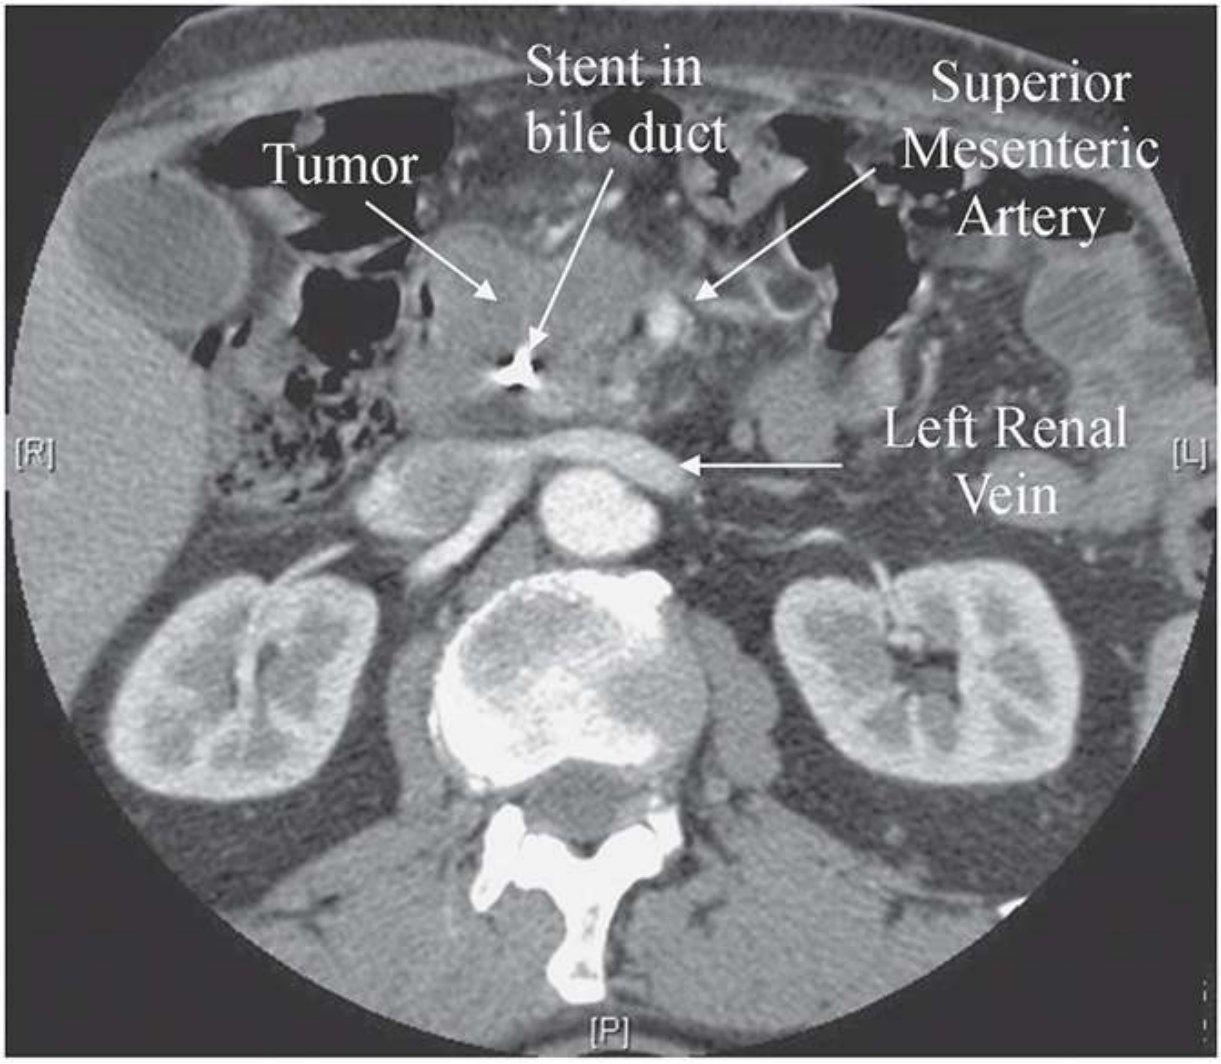

FIGURE 30.15 Axial computed tomography image demonstrating an adenocarcinoma of the pancreatic head, with tumor abutting the superior mesenteric artery.

Hepatic Imaging

Multiphase CT and MRI with IV contrast allow for morphologic characterization of the liver and biliary system. The administration of IV contrast is essential as many hepatic tumors are of similar attenuation as normal liver parenchyma and are not identifiable until central necrosis is present. Imaging is performed in the arterial, portal venous, and delayed phases of enhancement. This allows for detection of both early- and late-enhancing lesions, as well as characterization of enhancement patterns that can differentiate between benign and malignant disease. For example, hepatic hemangiomas, which are the most common benign vascular liver lesions, classically exhibit low attenuation on noncontrast CT images, have peripheral enhancement on the arterial phase and demonstrate central filling on the portal venous phase. Hepatocellular carcinoma (HCC) is the most common primary hepatic malignancy and is characteristically hypervascular with pronounced enhancement throughout the solid tumor components on arterial phase images and diminished enhancement on portal venous phase images. Contrast-enhanced imaging can also identify invasion of tumor into the portal and hepatic veins, which is frequently associated with portal vein thrombosis. Liver Imaging Reporting and Data System (LI-RADS) is a standardized method of categorizing liver lesions in patients at risk for developing HCC and applies to imaging with ultrasound (LI-RADS US) and CT/MRI (LI-RADS CT/MRI). CT and MRI have similar sensitivity and specificity for evaluation of focal, larger lesions.[77,78]

The liver is also one of the most common sites for metastatic disease. Contrast-enhanced CT is fairly sensitive (74%) and specific (77%) for detecting hepatic metastases. CT of the liver to assess for metastatic disease is typically performed with biphasic technique. Although most metastases are identified on the portal venous phase, some hypervascular tumors (eg, melanoma, renal cell carcinoma) may only be identified on arterial phase imaging. MRI has superior diagnostic sensitivity of up to 95% and outperforms CT imaging in this regard, particularly in the detection of small liver metastases.

Biliary Imaging

US is typically the initial imaging study for patients with suspected biliary or pancreatic disease. The primary goals of evaluation include assessing for abnormal biliary and pancreatic ductal dilatation (>3 mm), identifying

calculi, characterizing the gallbladder wall, and excluding a pancreatic head mass. US does not, however, image the entire pancreatic and biliary ductal system. In the presence of an US abnormality, further imaging is required.

Endoscopic retrograde cholangiopancreatography (ERCP) is a minimally invasive procedure that involves passing an endoscope into the duodenum and cannulating the main bile duct at the ampulla of Vater. Contrast is then infused to image both the biliary and pancreatic ductal system. Though it is minimally invasive, ERCP can induce pancreatitis in 1.3% to 8.6% of patients.[79] Any evidence of biliary obstruction in the absence of calculi typically prompts further evaluation with cross- sectional imaging to exclude malignancy. ERCP can itself, however, directly visualize ampullary carcinomas and permit tissue diagnosis using needle aspiration, brush cytology, or forceps biopsy. ERCP may also provide palliation via stent placement in the setting of known obstructive biliary malignancy.

Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive method of imaging the intrahepatic and extrahepatic biliary and pancreatic ductal system. MRCP does not require IV contrast: Imaging relies on heavily T2-weighted sequences and high-resolution techniques, resulting in the pancreatic and biliary ducts appearing hyperintense in contrast to surrounding soft tissues. MRCP can be a useful adjunctive tool in terms of defining the anatomic extent of potential malignant biliary obstruction.

THE PELVIC LYMPH NODES

Oncologic Anatomy

The lymphatic drainage of pelvic organs follows the iliac vessels throughout their branching within the pelvis. Most superiorly within the pelvis, the common iliac chains receive the majority of lymph drainage from intrapelvic organs, which then empty to the para-aortic chains superiorly. The gonadal veins and arteries are notable exceptions to this orderly flow of lymph from the pelvis and are discussed separately below. Also of note, the rectum, sigmoid, and distal colon have a separate path for lymphatic metastasis via the inferior mesenteric chain to the preaortic basin.

The common iliac pathway receives lymphatic drainage from three primary routes: the external iliac chain, the internal iliac chain, and the presacral chain. The external iliac pathway begins at the point where the

femoral vessels cross the inguinal ligament to become the external iliac chains, which courses more proximally to the common bifurcation. The internal iliac chain (also termed the *hypogastric chain*) is a more complex plexus, flowing back from the distal elaborations of the same artery. Just as these branches of the internal iliac vessels provide blood supply for the pelvic organs, the corresponding lymph node chains provide the majority of lymph drainage. The obturator nodes are part of the internal iliac system and may be found at the point in which the obturator vessels perforate the obturator internus muscle. Radiographically, these nodes lay medial to the femoral head, just superior to the bony obturator foramen. The presacral chain is located just anterior to the sacrum and receives lymphatic drainage from the rectum, the cervix, and posterior vagina and the prostate.[80,81]

The testicles have lymphatic drainage that differs with laterality, mirroring the differences in venous drainage. On the right, the testicle drains into the para-aortic nodes along the lower portion of the inferior vena cava at about the level of L3-L4 following the left testicular vein. On the left, the testicle drains to the renal hilar nodes following the left testicular vein.

Oncologic Imaging

CT is the preferred means of identifying vessels within the pelvis and is an acceptable method of delineating the pelvic lymph node basins for elective RT. A 7-mm margin may be applied to the internal and external iliac vessels to arrive at a nodal CTV, with uninvolved bone, muscle (such as the psoas), and bowel excluded from the volume. The 7-mm margin was determined as the minimum margin on CT visible vessels needed to cover 95% of all nodes identified using ultrasmall iron oxide particles as an MRI contrast agent.[82,83] Special care, however, should be taken to include visualized lymph nodes, even if they lie outside this margin.

Symmetric expansion margins on vessels are not adequate in the para-aortic or inguinal regions. In the para-aortic region, the most common location for nodal involvement includes the region to the left of the aorta, a basin that extends to the medial margin of the psoas muscle.[84] This region is often inadequately covered by a symmetric expansion. Similarly, in the inguinal region, nodes lie medial to the femoral neurovascular bundle, often

at a distance ≥2 cm. In this region, the space bounded by the regional musculature is the preferred CTV.[85]

One centimeter of soft tissue anterior to the sacrum, bridging between the common and internal nodal CTVs, should be added when presacral coverage is required. The Radiation Therapy Oncology Group (now part of the NRG) developed several atlases to aid the clinician in the contouring of pelvic CTVs. With 3D CT imaging, bony landmarks are no longer the ideal determinant of block or multileaf collimator shapes when treating the pelvis.[86]

THE RECTUM

Oncologic Anatomy

The rectum is the final, straight portion of the large intestine, beginning at the transition of the sigmoid colon with the fusion of the taenia coli into the circumferential longitudinal muscle. It terminates with the rectal ampulla, leading to the anal canal and dentate (or pectinate) line. Posteriorly, the rectum is extraperitoneal, whereas anteriorly, the peritoneal reflection occurs at approximately 7 to 9 cm from the anal verge at the posterior aspect of the bladder in males (superior to the prostate), and 5 to 8 cm from the verge in females, forming the rectouterine pouch, or pouch of Douglas. Below this point, the distal third of the rectum is extraperitoneal.

The mesorectum is the supportive mesentery of the rectum, located in the extraperitoneal space between the rectum anteriorly and the sacrum posteriorly. It is at risk for both direct and lymphatic spread of rectal cancers. High-quality total mesorectal excision with sharp dissection has been associated with excellent local control when compared to blunt dissections for rectal cancers. However, this has not obviated the need for perioperative RT, as demonstrated by an increase in local recurrences with omission.[87,88]

Oncologic Imaging

Colonoscopy is the most accurate diagnostic test for colorectal cancer. Biopsies can be performed with endoscopically visible lesions. A complete colonoscopy can also assess synchronous second primary colorectal cancers. For suspected rectal cancer, pelvic MRI is the recommended imaging

modality for initial tumor and nodal staging as well as post-therapy restaging. MRI not only allows for high accuracy clinical staging (~90% concordance with pathologic T staging) but can also further stratify patients for appropriate therapies based on the presence of various high-risk features, such as extramural venous invasion and close circumferential resection margins (Figure 30.16).[89,90] Recommendations for standardized MRI evaluation and reporting have been published.[91] Transrectal endoscopic ultrasound (TEUS) is an alternative imaging modality for tumor and nodal staging, particularly for early-stage tumors. The accuracy of TEUS may be limited by the inability to adequately image bulky or proximal tumors.[92] TEUS can, however, still be utilized when there is a contraindication to pelvic MRI and may provide complementary information in some cases. Contrast-enhanced CT is the preferred imaging modality to detect distant metastatic disease, particularly synchronous liver metastases, which can occur in up to 20% of patients.[93]

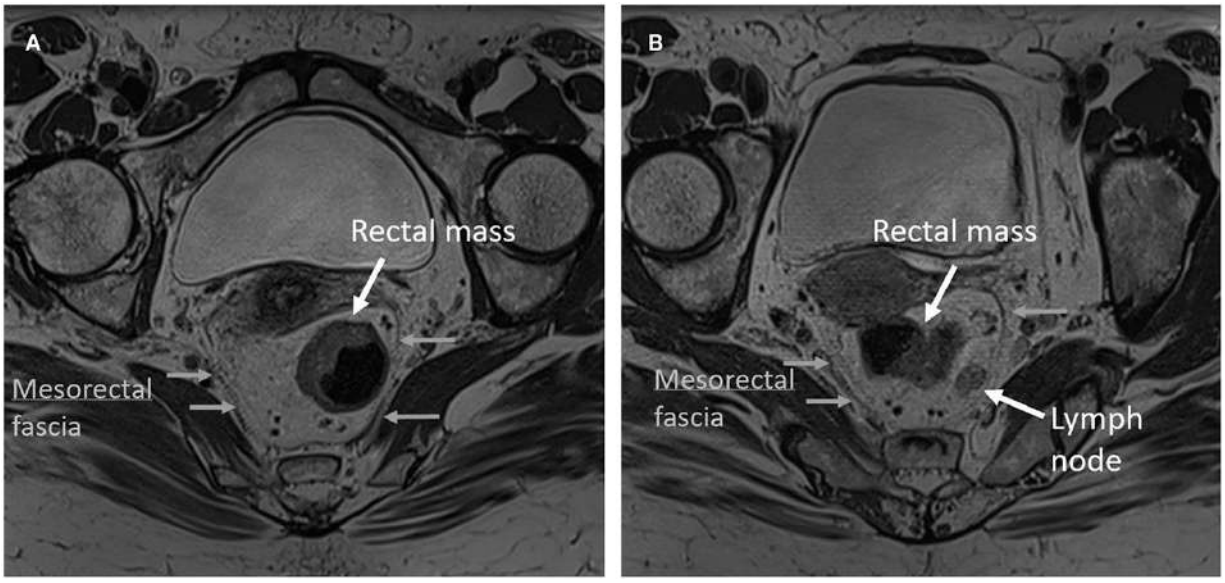

FIGURE 30.16 Rectal carcinoma on magnetic resonance imaging (MRI). A. Representative axial slice on a T2-weighted MRI. B. Representative axial slice on a T2-weighted MRI.

THE BLADDER AND URETHRA

Oncologic Anatomy

The bladder is an expansile muscular organ, which may be contained completely within the pelvis when empty and may extend far into the

abdominal cavity when distended. The trigone is the posterior and inferior portion of the bladder, defined by the two ureteral orifices and the internal urethral meatus. The trigone remains fixed at the base, while the superior portion of the bladder expands to accommodate urine. Due to this distensibility, the bladder is surrounded by loose connective tissue and fat. Anteriorly, this connective tissue is termed the *space of Retzius*, or the *retropubic space*.

The urethra traverses a short distance to the introitus in females, measuring approximately 4 to 5 cm in length. In males, it is approximately 20 cm in length and traverses the prostate and penis to reach the meatus.

The base and posterior wall of the bladder preferentially drain to the obturator and internal iliac lymphatic basins via anterior pathways. In contrast, the external iliac chain receives primary drainage from the lateral and superior bladder wall. Cancer arising from the bladder neck may also metastasize to the presacral nodal basins. Bladder cancer is the most common malignancy involving the urinary system, though direct spread from other pelvic malignancies should be considered (prostate or cervix).

Oncologic Imaging

Cystoscopy with biopsy is considered the gold standard for the initial diagnosis of bladder cancer. CT or MRI can be used to assess the extent of local invasion of primary muscle-invasive bladder tumors, though sensitivity and specificity for detection of lymph node metastases are low.[94] CT urography (CT of the abdomen and pelvis with IV contrast and excretory imaging) is useful for the diagnosis of superficial bladder tumors and for imaging of the upper urinary tract, but cannot differentiate the depth of bladder wall invasion (Figure 30.17). MR urography may be appropriate in patients with poor renal function or iodinated contrast allergy. FDG-PET has limited utility in tumor staging due to obscuration with urinary excretion of FDG. Chest radiographs are often used for the initial evaluation of metastatic disease, but CT chest may be preferred in some scenarios, such as muscle-invasive bladder cancer.

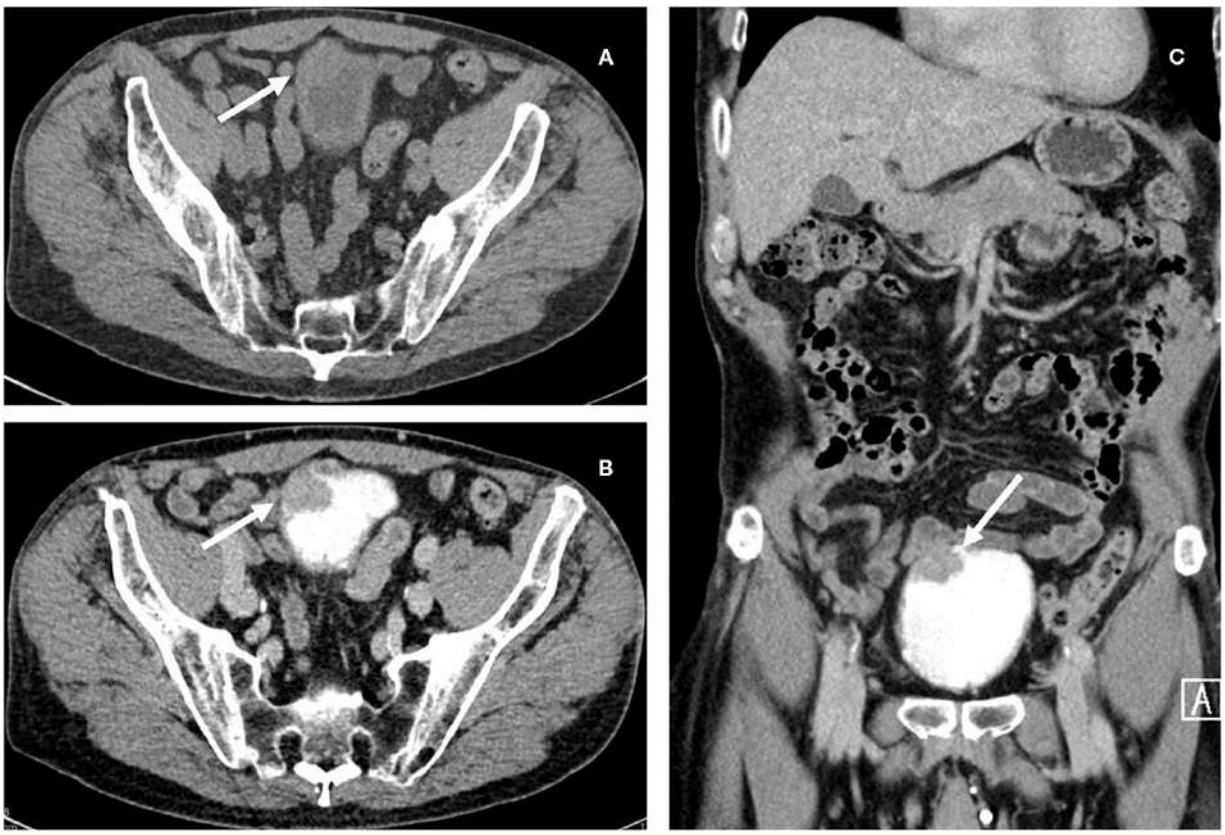

FIGURE 30.17 High-grade urothelial carcinoma (indicated by arrow) on computed tomography (CT) and CT urogram. A. Representative axial slice on pelvic CT scan. B. Representative axial slice on CT urogram. C. Representative coronal slice on CT urogram.

CERVIX, UTERUS, AND OVARIES

Oncologic Anatomy

The uterus lies between the bladder anteriorly and the rectum posteriorly, covered by a layer of peritoneum. Laterally lie the fallopian tubes and ovaries, which are anchored medially by the ovarian ligament (or utero-ovarian ligament) and laterally by the suspensory ligament of the ovary (or infundibulopelvic [IP] ligament). The ovarian arteries originate from the abdominal aorta, just inferior to the renal vessels, following a course anterior to the psoas on the left and crossing anterior to the inferior vena cava to the psoas on the right, both sides crossing anterior to the ureter and then crossing medially with the IP ligament to the ovaries. The fold of the peritoneum over the uterus continues laterally over these structures, forming the broad ligament. Similar to the testes, the right ovarian vein drains to the inferior vena cava, while the left ovary drains to the left renal vein.

The uterine corpus or body is the cephalad two-thirds of the organ and is lined internally by the endometrium, which varies in thickness by the menstrual cycle and by menopausal status. The middle muscular layer, the myometrium, is primarily smooth muscle. The final outer layer is the serosa or perimetrium and is continuous with the peritoneum. The caudal one-third of the organ is the uterine cervix, which consists of firm connective tissue, approximately one-half of which extends into the vagina. The intravaginal portion is lined by nonkeratinized squamous epithelium (the ectocervix), whereas the cervical canal is lined by columnar epithelium (the endocervix).

Lateral to the uterine cervix and corpus is the parametrium, consisting of the paracervical tissue, including the cardinal ligament, uterine artery and vein, and the ureter as it courses anteriorly to the bladder. This caudal portion of the parametrium is of importance for evaluation of lateral spread of cervical cancer and can best appreciated on physical examination by a rectovaginal examination, where the examining rectal finger can palpate these structures. Cephalad to this, the parametrium continues as the broad ligament, terminating at the suspensory ligament of the ovary. Posteriorly the cervix is anchored to the sacrum via the uterosacral ligament, which classically attaches at the third sacral foramen, although MRI studies would suggest a fair amount of individual variation.[95]

Oncologic Imaging

MRI of the pelvis is the most useful modality outside the physical examination to determine the extent of disease within the uterus and cervix with an accuracy of approximately 85% (Figure 30.18).[96,97] For endometrial carcinoma, T2- and postcontrast T1-weighted sequences are beneficial in staging, such as identifying the primary tumor, extent of invasion, and involvement of regional pelvic lymph nodes. In the setting of cervical cancer, T2-weighted sequences are often the most useful in determining the extent of disease and are preferred for MRI-guided brachytherapy.[98] Either CT or MRI may be used for image-guided brachytherapy to potentially improve central disease control and reduce toxicity. However, CT systematically provides larger estimates of target size compared to MRI, particularly in the lateral extent.[99,100] US (either via a transabdominal or through transrectal approach) can be useful during intracavitary

brachytherapy to ensure the proper placement of a uterine tandem and prevent uterine perforation.

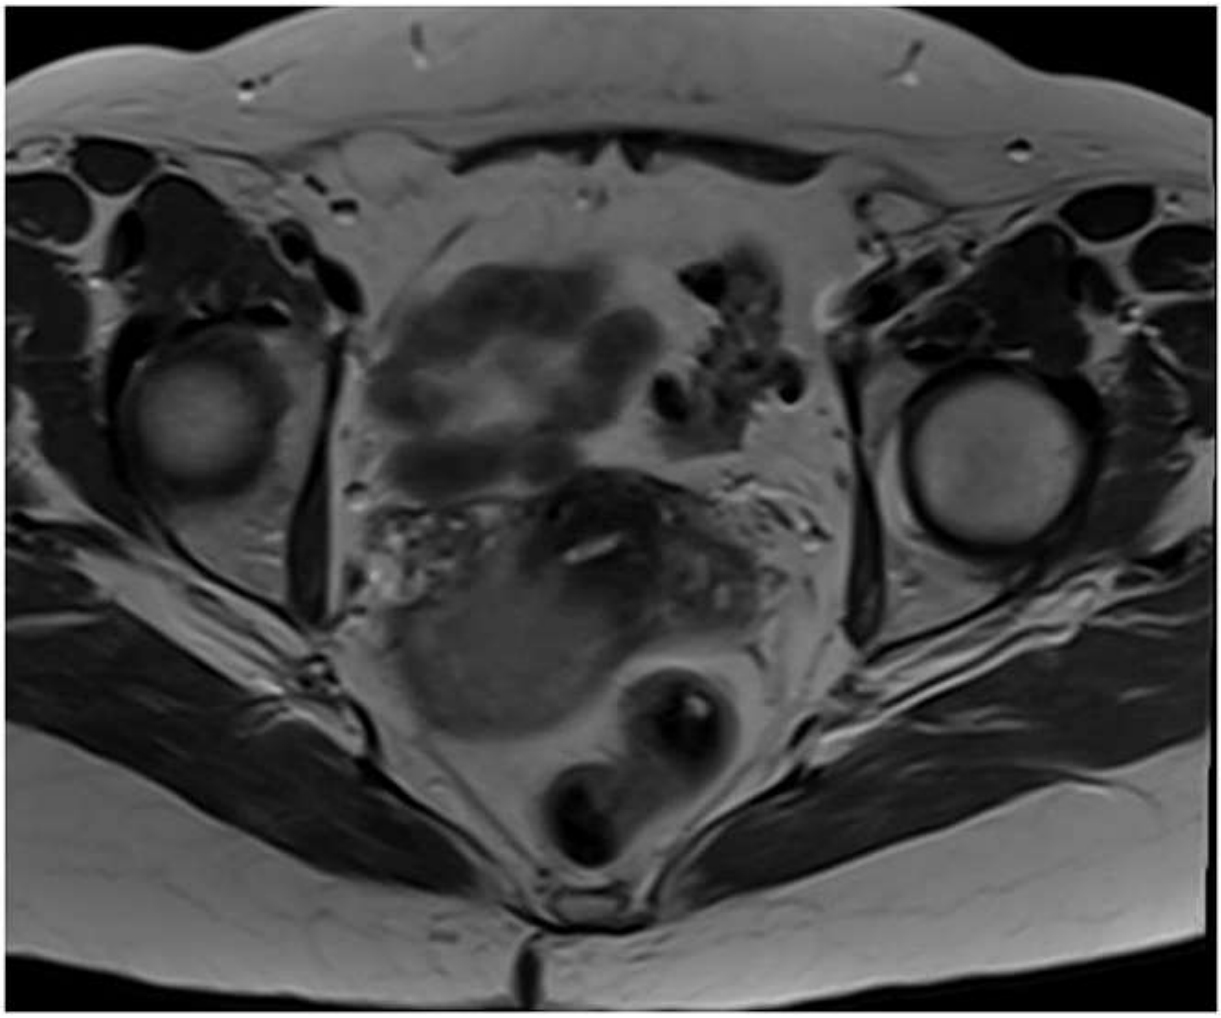

FIGURE 30.18 T2-weighted magnetic resonance imaging of a patient with cervical cancer showing right-sided sidewall extension (FIGO IIIB). The normal stromal cervix is dark on T2-weighted imaging, while tumor extension appears gray.

PET-CT has been proven to be sensitive and specific in the evaluation of lymph nodes within the pelvic and para-aortic chains with squamous cell carcinoma of the cervix (sensitivity approximately 85% and specificity 95% for para-aortic nodes), although it is less well studied in endometrial and other primary gynecologic sites[101] (Figure 30.19). Investigators from Washington University have extensively studied FDG-PET in cervical cancer, showing that the initial maximum SUV of the primary tumor is

predictive of response to treatment.[102] In addition, they found that a complete metabolic response to treatment was predictive of progression-free survival (PFS); at 3 years, with complete response, PFS was 78% versus 33% in partial responders and 0% with PET progression, findings that have been independently confirmed.[103,104]

FIGURE 30.19 Positron-emission tomography imaging of a patient with cervical cancer showing an 18-fluorodeoxyglucose–avid left internal iliac lymph node.

PROSTATE

Oncologic Anatomy

The prostate lies centrally within the male pelvis, with its widest portion, the base, closely approximating the bladder neck superiorly and narrowing to the apex inferiorly with support from the urogenital diaphragm (UGD).

The prostate consists of the peripheral zone, the central zone, the transitional zone, and the anterior fibromuscular stroma. The peripheral zone constitutes the majority of the gland and is the location of the majority of prostate cancers (60%-70%). The central zone accounts for an additional

25% of glandular tissue and lies near the origin of the seminal vesicles; it is the location of approximately 10% of prostate cancers. The transitional zone surrounds the urethra cephalad to the insertion of the ejaculatory duct, may hypertrophy with age, and is the origin of the remaining 10% to 20% of prostate cancers. The neurovascular bundles are posterolateral to the prostate capsule bilaterally and are a potential site of extraprostatic extension. The seminal vesicles are located superiorly and posteriorly to the prostate and extend laterally and can also be involved by tumor (ie, seminal vesicle invasion or SVI).

The Batson venous plexus is a series of valveless veins located anterior to the vertebral bodies that receives drainage from the deep pelvic veins and prostate gland. It has been postulated that the lack of valves facilitates a pathway for metastatic spread, providing anatomic rationale for the propensity of prostate cancer to involve the lumbosacral vertebral bodies.[105]

The T staging of prostate cancer is based primarily on digital rectal examination. It is important to palpate the lateral sulci of the gland, as evidence of effacement is highly suggestive of extraprostatic extension of disease. However, it may not always be possible to detect prostate cancer or determine extraprostatic extension from the digital rectal examination.

Oncologic Imaging

Transrectal US is invaluable for guiding biopsies for the diagnosis of prostatic disease; however, it has limited specificity and sensitivity (approximately 40%-50%) for the determination of seminal vesicle involvement and extraprostatic extension.

While it can detect gross extraprostatic extension, as well as nodal and distant metastatic disease, CT imaging has limitations, as the prostate gland has similar attenuation characteristics as the anterior and lateral venous plexus, the UGD inferiorly, and the bladder wall superiorly. MRI is an increasingly used imaging modality for the evaluation of the prostate and aids treatment planning. T1-weighted images are used to help determine the presence of hemorrhage and delineate the outline of the prostate gland. T2-weighted imaging can be used to distinguish the zonal anatomy of the prostate, and the prostatic apex can be clearly distinguished from the UGD and other neighboring structures (Figure 30.20). The joint maximum

sensitivity and specificity of detecting extraprostatic extension on MRI is approximately 70%, although this may be improved with endorectal coils.[106,107]

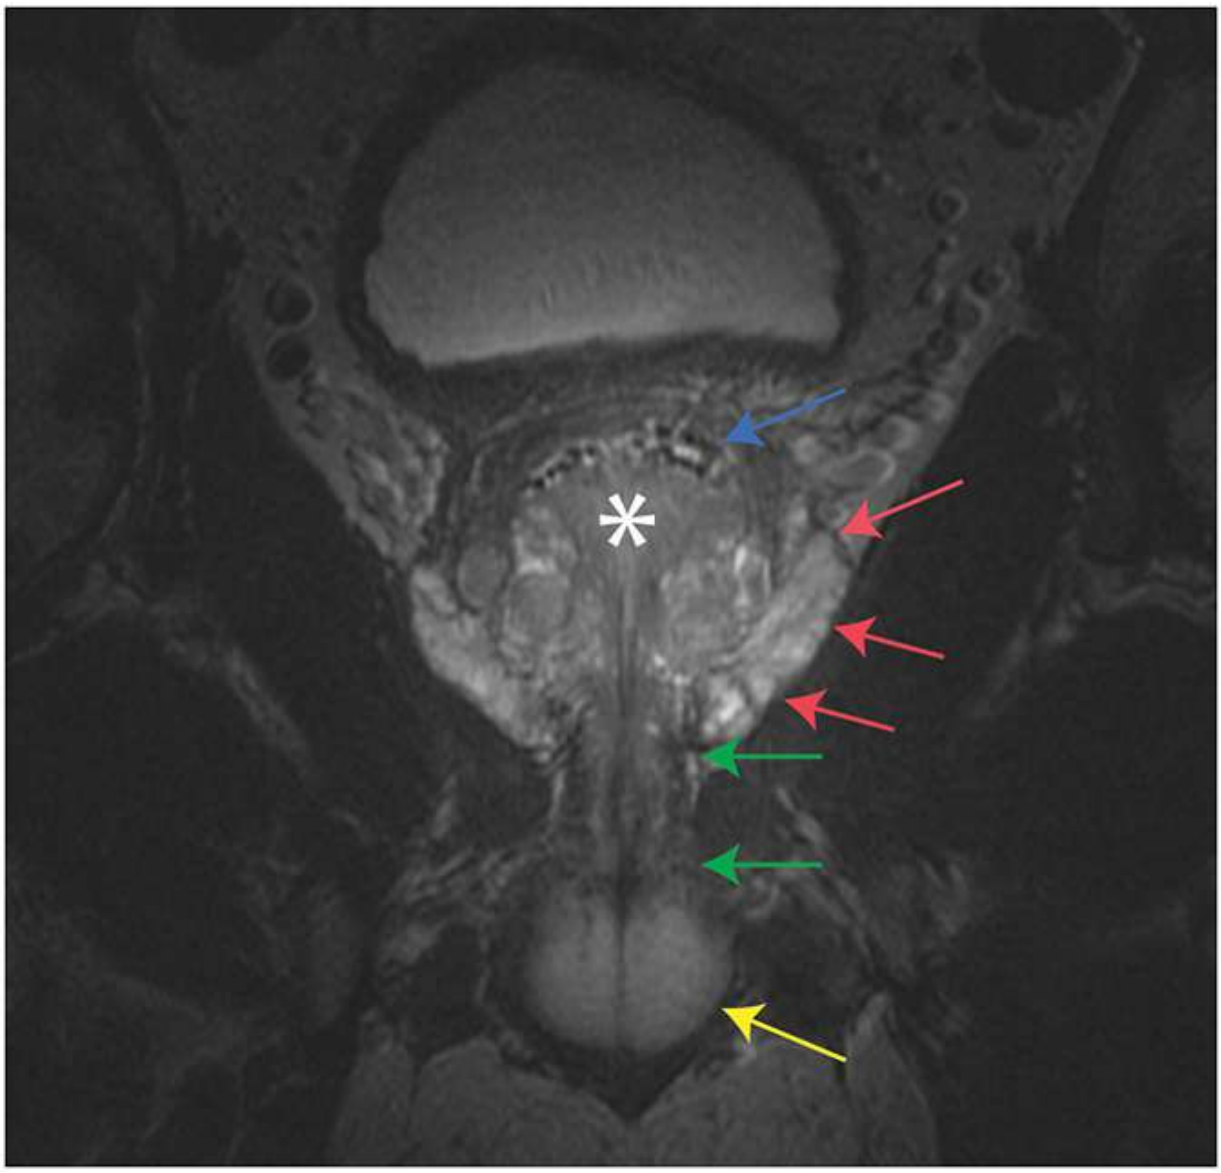

FIGURE 30.20 A coronal T2-weighted magnetic resonance imaging demonstrating the anatomy of the prostate. The regional anatomy is labeled as follows: the asterisk (*) is the central gland—a combination of the central zone and transitional zone; red arrows indicate the peripheral zone; blue arrow indicates the seminal vesicles and their insertion in the base; green arrow indicates the urogenital diaphragm; and yellow arrows indicate the penile bulb.

Multiparametric MRI (mpMRI) consists of different sequences, including T1-weighted imaging, T2-weighted imaging, DWI, and DCE. Combining

the unique characteristics of each of these sequences (discussed in section "Magnetic Resonance Imaging") has led to an increased specificity (>90%) of lesion localization within prostate and in the detection of extraprostatic extension.[108,109] Since prostate cancer has increased cell density, there may be focally restricted free water diffusion on DWI, hypointense on ADC maps (Figure 30.21). The Prostate Imaging Reporting and Data System (PI-RADS) has been developed to serve as a standardized system for reporting findings of mpMRI in the evaluation of suspected prostate cancers.[110] PI-RADS categorizes prostate lesions based on the likelihood of cancer according to a five-point scale (Table 30.7).

TABLE 30.7 PROSTATE IMAGING REPORTING AND DATA SYSTEM (PI-RADS) FOR MULTIPARAMETRIC PROSTATE MRI IN THE EVALUATION OF SUSPECTED PROSTATE CANCER

Assessment Category	Definition
1	Clinically significant cancer is highly unlikely to be present.
2	Clinically significant cancer is unlikely to be present.
3	The presence of clinically significant cancer is equivocal.
4	Clinically significant cancer is likely to be present.
5	Clinically significant cancer is highly likely to be present.

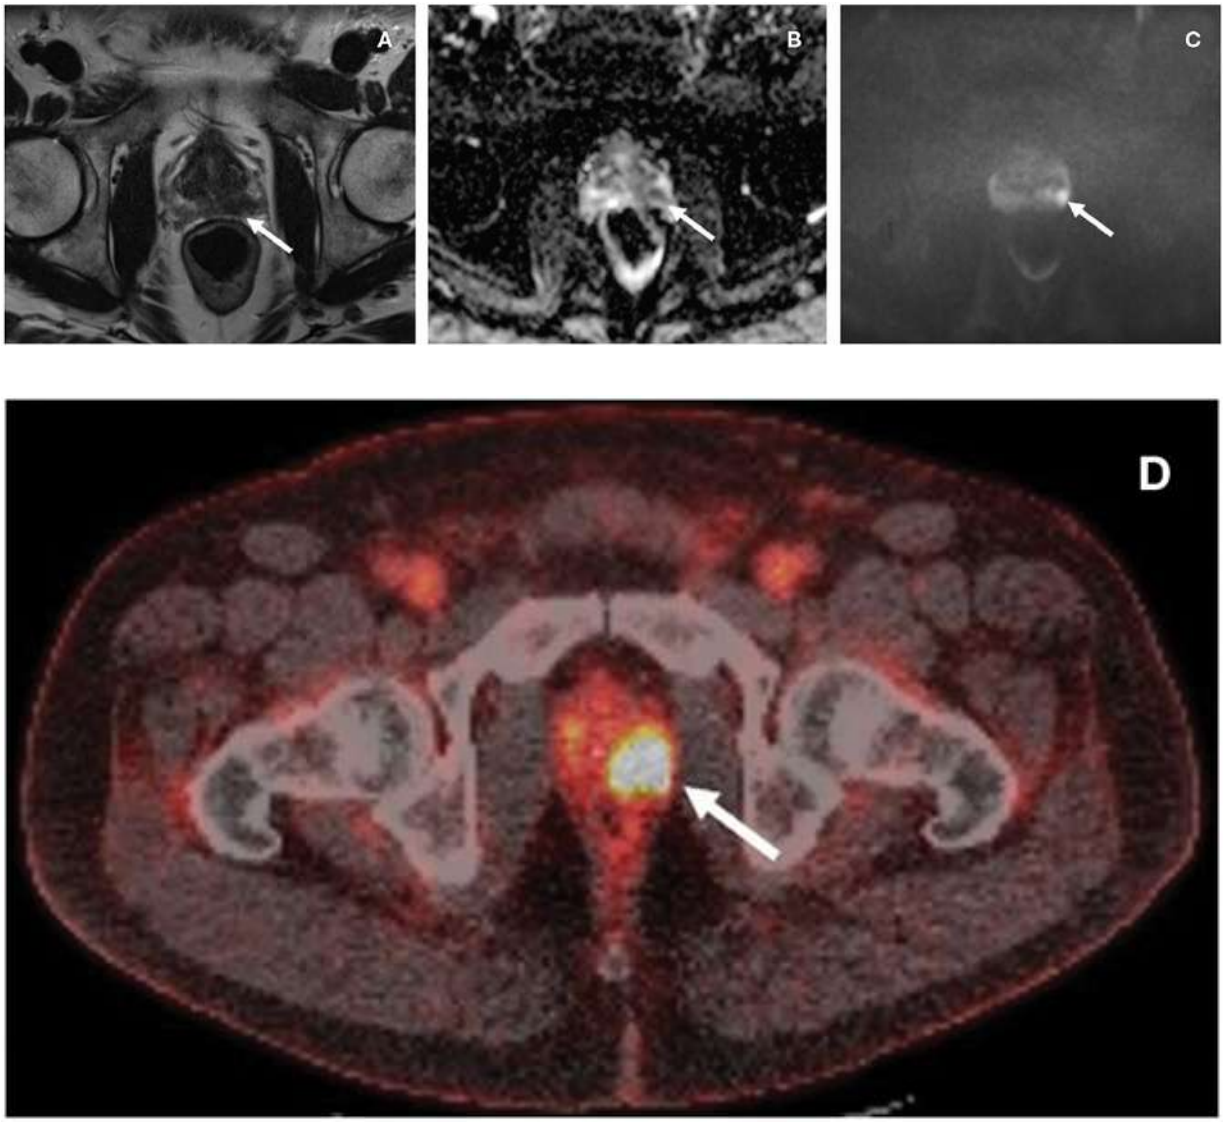

FIGURE 30.21 Prostate carcinoma (indicated by arrow) on T2-weighted magnetic resonance imaging (MRI) (A), apparent diffusion coefficient MRI, (B) diffusion-weighted imaging MRI (C), and prostate-specific membrane antigen positron-emission tomography (D).

In addition to transrectal ultrasound-guided biopsy, mpMRI has become useful for directing targeted prostate biopsies. Prostate MRI can also be useful for the identification of appropriate RT coverage of the prostate apex, areas of extraprostatic extension, and SVI.[111] Compared with CT, MRI better depicts the prostate apex, thus allowing dose reduction to the genitourinary diaphragm, which contains the external urethral sphincter. Prostate MRI can be used to identify areas of dominant intraprostatic lesions and thus direct delivery of a heterogeneous RT dose to the prostate gland.[112] It is important

to keep in mind that prostate imaging and pathologic analyses can be somewhat discordant. The lesions seen with improved imaging techniques can appear focal. However, prostate cancer is mainly a multifocal disease with prostatectomy specimens usually demonstrating the microscopic presence of cancer in multiple regions of the gland. Thus, delivery of heterogeneous RT dose to the prostate gland based on imaging findings is still an area of study in prospective trials.

For evaluation of osseous disease, ^{99m}Tc-MDP bone scintigraphy is the most used modality to detect osteoblastic activity from prostate cancer metastases. However, in recent years, there have been many new sensitive radiotracers. There are Food and Drug Administration-approved prostate-specific PET tracers: Cho ^{11}C, fluciclovine ^{18}F, sodium fluoride ^{18}F, piflufolastat ^{18}F, and ^{68}Ga-PSMA-11. All of these tracers have been approved for the evaluation of patients with biochemical recurrent prostate cancer. Studies have shown that PSMA tracers (^{68}Ga-PSMA-11 and piflufolastat ^{18}F) may have higher sensitivity for disease detection than other modalities, particularly in patients with lower PSA values (PPV 92%).[113,114]

PSMA-PET is now additionally considered an alternative to standard bone and soft tissue imaging for initial staging of patients at high risk for metastatic disease, with sensitivity and specificity of 31% to 42%, and 95% to 99%, respectively.[115] PSMA-PET has been shown to frequently alter radiation treatment planning in patients with high risk or biochemically recurrent prostate cancer, though whether these changes impact survival outcomes is yet unknown.[116,117]

THE LYMPHATIC SYSTEM

Oncologic Anatomy

The lymphatic system is a component of the circulatory system, and wherever arteries and veins pass, lymphatic vessels are also present (with the notable exceptions of the placenta and CNS). In the CNS, lymph is carried within perivascular lymph sheaths as opposed to distinct lymphatic vessels. The lymphatic system includes lymphatic vessels, lymph nodes, lymphatic organs such as the spleen, and the lymphocytes themselves. It is loosely organized but generally follows somewhat predictable paths. Small lymphatic vessels form within the tissues of the body, drain into one or more

lymph nodes, and eventually drain into larger lymph trunks. These unite to form either the thoracic duct or right lymphatic duct, which empties into the venous system at the subclavian vein-internal jugular vein junction. The lymphatics are primarily involved in returning plasma from the interstitial space to the venous system, although they are also involved in the absorption and transport of fat and in defense mechanisms. Site-specific lymphatic spread has been reviewed in prior sections.

Oncologic Imaging

Lymphoma

Lymphomas can arise virtually anywhere in the body, including both nodal and extranodal sites. Consequently, comprehensive imaging with PET-CT plays an integral role in the staging and management of both HL and many NHLs (Figure 30.22). Current guidelines recommend that PET-CT be employed for initial staging of all lymphomas that are FDG avid.[118] CT alone is appropriate for the minority that are not, such as chronic lymphocytic leukemia/small lymphocytic lymphoma. Postchemotherapy response assessment with PET-CT is also standard and should utilize the Deauville criteria (Table 30.8).[119] These criteria are under revision to better define Deauville 4 and 5 responses, which, under various circumstances, can represent either a partial response, stable disease, or progressive disease. A negative (Deauville 1-3) PET-CT scan after chemotherapy does not necessarily mean that all disease has been eradicated, simply that an excellent response was achieved. This point has been confirmed in randomized trials of HL, where patients were randomized to observation or consolidation RT after achieving a complete response by PET-CT after chemotherapy. Even in the setting of a negative post-chemo PET, consolidation RT still decreased the risk of recurrence.[120]

TABLE 30.8 PET-CT RESPONSE ASSESSMENT FOR LYMPHOMAS

Deauville Criteria (Five-Point Scale)	Degree of FDG Avidity	Clinical Interpretation[a]
1	No uptake (below background)	Complete response
2	Above background but equal to or below mediastinal blood pool	Complete response

Deauville Criteria (Five-Point Scale)	Degree of FDG Avidity	Clinical Interpretation[a]
3	Above mediastinal blood pool but below or equal to liver	Complete response
4	Slightly to moderately higher than liver	Partial response, stable disease, or progressive disease
5	Markedly increased uptake than liver or new lesion(s)	Partial response, stable disease, or progressive disease

CT, computed tomography; FDG, 18-fluorodeoxyglucose; PET, positron-emission tomography.

[a]Some clinical trials have defined a “negative” PET-CT as Deauville 1-2 and positive PET-CT as Deauville 3-5.

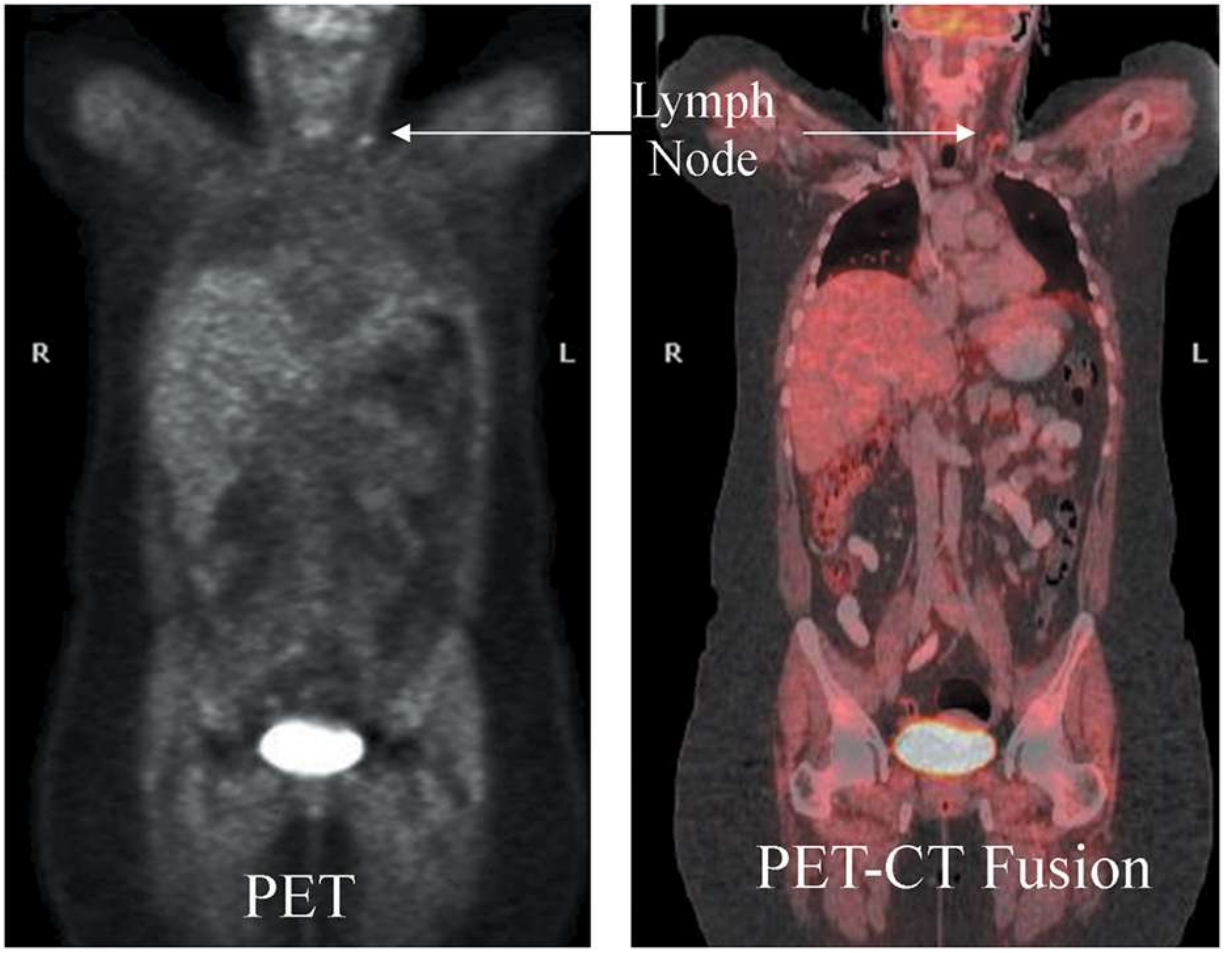

FIGURE 30.22 Postchemotherapy coronal positron-emission tomography (PET) scan images of a patient with stage IVa Hodgkin disease demonstrating a hypermetabolic left supraclavicular lymph node. The lymph node was <1 cm on computed tomography (CT) and would not be considered suspicious. Biopsy confirmed persistent disease. Left: PET image. Right: PET-CT fusion image. CHAPTER 31

Basic Concepts of Chemotherapy and Irradiation Interaction

Sean C. All, D. Nathan Kim, and Christopher D. Willey

For decades, radiation therapy (RT) has been a major treatment modality for locally or regionally confined cancers. The rate of treatment failure is still high, particularly for large tumors or advanced disease. Technological improvements in RT have continuously been made that allow delivery of higher radiation doses to the tumor while simultaneously allowing for better dose sparing to normal tissues. In addition, the implementation of strategies that modulate the biologic response of tumors or normal tissues to radiation has been employed, including altered fractionation scheduling including extreme hypofractionation (eg, stereotactic body RT, stereotactic radiosurgery), combined modality treatments using chemical or biologic agents, and, more recently, targeting molecular processes and signaling pathways that have become dysregulated in cancer cells.

The combination of chemotherapeutic drugs with radiation has perhaps had one of the strongest impacts on current cancer RT practice. This is particularly true for concurrent chemoradiation therapy, which has now been shown in multiple practice-changing clinical trials to be superior to RT alone in controlling locoregional disease and improving patient survival. Combining chemotherapeutic drugs with RT has a strong biologic rationale. Such agents reduce the number of cells in tumors undergoing RT by their independent cytotoxic action and by rendering tumor cells more susceptible to killing by ionizing radiation. An additional benefit of combined treatment is that chemotherapeutic drugs, by virtue of their systemic activity, may also act on potential microscopic distant metastatic disease. Most drugs have been chosen for combination with RT based on their known clinical activity in particular disease sites. Alternatively, agents that are effective in overcoming resistance mechanisms associated with RT could be chosen.

There have been clinical successes with concurrent chemoradiation therapy using traditional drugs, such as cisplatin and 5-fluorouracil (5-FU), and these studies have led to extensive research on exploring newer chemotherapeutic agents for their interactions with radiation. A number of potent chemotherapeutic agents, subsequently, have entered clinical trials or practice. There are also molecular targeting strategies aimed at improving the efficacy of RT. In this era, there is a significant explosion of activity revolving around the exciting and emerging data suggesting the potential benefit to combining immunotherapy agents with RT. This chapter reviews the biologic rationale and principles fundamental to the use of chemotherapy in conjunction with radiation treatments and discusses mechanistic interactions between drugs and radiation, the knowledge of which is essential in developing the optimal treatment strategies and designing appropriate clinical trials.[1-11]

THERAPEUTIC INDEX

Both radiation and chemotherapeutic drugs are cytotoxic to tumor and normal tissue cells. This lack of specificity is a major limitation in their use when applied either as individual treatments or in combination. Radiation inflicts damage to tumor and normal tissues in the radiation treatment field, whereas drugs, because of their systemic action, can affect any tissue in the body. Damage is often accentuated when the two agents are combined and when they affect the same tissue. In general, both the antitumor effectiveness and the severity of normal tissue damage produced by either radiation or drugs are increased as their dose is increased. This dose-effect relationship is sigmoidal and enables estimation of the therapeutic index (ratio), which is defined as the ratio between the doses (radiation, drug) that produce the same level (probability) of antitumor efficacy and normal tissue damage. To be therapeutically beneficial, the therapeutic ratio must be positive (>1); that is, individual agents or their combination must be more effective against tumors than normal tissues. To define therapeutic benefit in clinical settings, many factors must be taken into account, such as whether the treatment is curative or palliative, which tissues are dose limiting (critical tissues), and what degree of tissue damage is acceptable. The balance between a given level of antitumor efficacy and acceptable

normal tissue complications gives a measure of the therapeutic ratio of a treatment.

EXPLOITABLE STRATEGIES IN CHEMORADIATION THERAPY

The goals of combining chemotherapeutic drugs with RT are to increase patient survival by improving locoregional tumor control, decrease or eliminate distant metastases, or both while preserving organ and tissue integrity and function. Combined modality treatment can further improve positive therapeutic outcome of individual treatments through a number of specific strategies, which Steel and Peckham classified into four groups: "spatial cooperation," independent toxicity, enhancement of tumor response, and protection of normal tissues.[12]

Spatial cooperation was the initial rationale for combining chemotherapy with RT, in which the action of radiation and chemotherapeutic drugs is directed toward different anatomic sites. Localized tumors would be the domain of RT because large doses of radiation can be given. On the other hand, chemotherapeutic drugs are likely to be more effective in eliminating disseminated micrometastases than in eradicating larger primary tumors. Thus, the cooperation between radiation and chemotherapy is achieved through the independent action of two agents. Spatial cooperation is the basis for adjuvant chemoradiation therapy, in which radiation is given first to control the primary tumor and chemotherapy is given later to cope with micrometastases. The concept of spatial cooperation is also applied in the treatment of hematologic malignancies that have spread to "sanctuary" sites, such as the brain. These sites are poorly accessible to chemotherapeutic agents, and thus, they are more appropriately treated with RT.

Independent toxicity is another important strategy for increasing the therapeutic ratio of chemoradiation therapy. Normal tissue toxicity is the main dose-limiting factor for both chemotherapy and RT. Therefore, combinations of radiation and drugs would be better tolerated if drugs were selected such that toxicities to specific cell types and tissues do not overlap with, or minimally add to, radiation-induced toxicities. This strategy requires a thorough knowledge of drug toxicity, underlying mechanisms, and drug pharmacokinetics. Another strategy in chemoradiation therapy is

to exploit the ability of chemotherapeutic agents to *enhance tumor radioresponse*. The enhancement denotes the existence of some type of interaction between drugs and radiation at the molecular, cellular, or pathophysiologic (microenvironmental, metabolic) level, resulting in an antitumor effect greater than would be expected on the basis of additive actions. Many mechanisms may be involved in drug-radiation interactions leading to tumor radio enhancement, and some of them are elaborated on further in the text. The enhancement must be selective or preferential to tumors compared with critical normal tissues to achieve therapeutic gain. The ability of chemotherapeutic agents to enhance tumor radioresponse by counteracting determinants associated with tumor radioresistance is a major rationale for concurrent RT.

An additional strategy is to *protect normal tissues* so that higher doses of radiation can be delivered to the tumor. This can be achieved through technical improvements in radiation delivery or administration of chemical or biologic agents that selectively or preferentially protect normal tissues against the damage by radiation or drugs.

ASSESSMENT OF DRUG-RADIATION INTERACTION

Any drug considered for use in combination with RT needs to undergo preclinical evaluation for its interaction with radiation both in in vitro cell culture systems and in vivo, with the aim of assessing antitumor activity and normal tissue toxicity. The interaction between two agents is more easily defined and quantified in vitro because complete cell survival curves are readily obtained. The in vitro cell survival assay measures the ability of cells to produce colonies of a defined minimum size. The cell survival curve after irradiation characteristically has a “shoulder” of varying width that denotes the capacity of cells to repair radiation damage. The curves that describe survival after chemotherapeutic agents show much more variation both in absolute sensitivity to drugs and their shape than those after radiation, all depending on the drug tested. Some curves possess shoulders, some lack them, and some show resistant “tails” at higher drug doses. The tails denote the existence of cell subpopulations resistant to chemotherapeutic agents.

To assess the effect of the drug on cell radiosensitivity, the combined drug-radiation curve is commonly plotted after the cytotoxicity produced by the drug alone is excluded ("normalized"). The radiation cell survival curve is not changed if the drug does not influence cell radiosensitivity, regardless of whether the drug is cytotoxic on its own. In this case, the cytotoxicity of the drug contributes only to the overall cell killing by the combined treatment (*additive effect*) of both agents. Chemotherapeutic agents may interact with radiation by altering cell radiosensitivity such that the combination results in a *supra-additive* or *subadditive effect*, depending on whether the cell killing is greater or smaller than the sum of cell killings produced by individual agents. Drugs may eliminate the shoulder on the radiation survival curve, implying that drugs can inhibit cell repair from radiation damage, or they may change the slope of the exponential portion of the survival curve. A steeper slope indicates increased sensitization to radiation, whereas a shallower slope indicates protection.

Because of non–linear dose-related characteristics in cell killing by both chemotherapeutic agents and radiation, the effects of the combined treatment are best assessed using the "isobologram," an isoeffect plot for the dose response to the combination of two agents (Figure 31.1).[12] Dose-response curves are determined for each agent to generate the isobologram, an envelope of additivity, which denotes the expected additive response over a range of doses of the agents used. If the interaction between drugs and radiation is supra-additive or synergistic (ie, the effect is caused by lower doses of the two agents than the envelope of additivity would predict), the effect is shown on the left side of the envelope. In contrast, the effect of the subadditive or antagonistic interaction is shown to the right of the envelope: The effect required higher doses of the two agents than predicted. The width of the envelope of additivity depends on the degree of the nonlinearity in the dose response to individual agents. The envelope is wider as the degree of nonlinearity increases. In the case of a linear dose-response relationship for each agent, which is rare, the isobologram is also linear, represented by a single straight line.

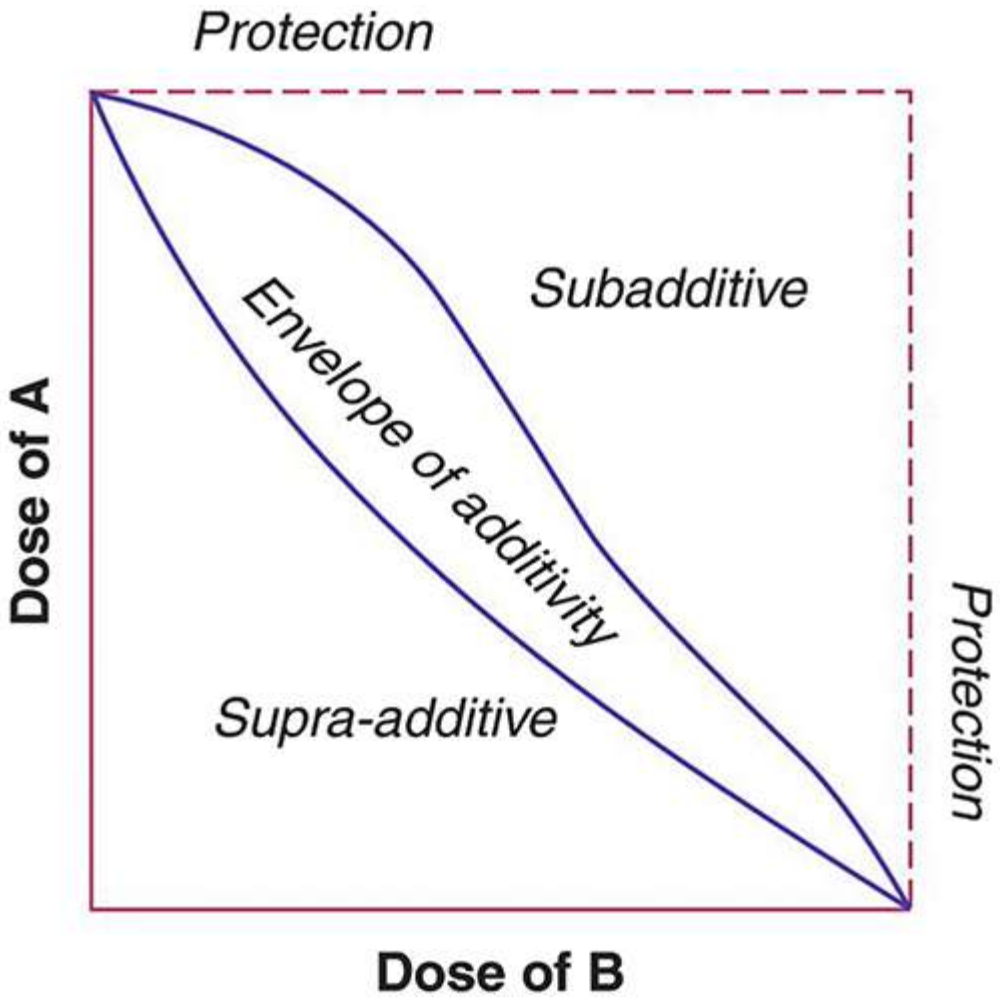

FIGURE 31.1 An isobologram for two agents when their dose-response curves are nonlinear. The isobologram shows the envelope of additivity and regions of supra-additivity and subadditivity. (Reprinted from Steel GG, Peckham MJ. Exploitable mechanisms in combined radiotherapy-chemotherapy: the concept of additivity. *Int J Radiat Oncol Biol Phys*. 1979;5[1]:85-91. Copyright © 1979 Elsevier. With permission.)

In vitro testing is often followed by in vivo exploration of drug-radiation interactions, which allows assessment of the combined treatment on both tumors and normal tissues. This is essential for the determination of therapeutic gain, as discussed earlier in this chapter. Syngeneic animal tumors or human tumor xenografts in nude mice are most often used for this purpose. The efficacy of the treatment is determined by the extent of tumor growth delay or the rate of tumor cure. In normal tissues, the effect of chemotherapeutic drugs on radiation response of acutely and late-responding tissues can be assessed using a variety of available assays. Some

of these assays are clonogenic, such as the jejunal crypt assay, where the endpoint depends directly on the reproductive integrity of individual cells. More frequently, however, dose-response relationships for normal tissues are based on functional endpoints (such as breathing rate in lung damage and paralysis in spinal cord damage). These end points tend to reflect the minimum number of functional cells remaining in tissues or organs and not the proportion of cells retaining reproductive integrity.

MECHANISTIC CONSIDERATIONS IN DRUG-RADIATION INTERACTIONS

Increasing Initial Radiation Damage

Radiation induces many different lesions in the DNA molecule, which is the critical target for radiation damage. The lesions consist of single-strand breaks (SSBs), double-strand breaks (DSBs), base damage, DNA-DNA and DNA-protein cross-links, and so forth. DSBs and chromosome aberrations that occur in association with or as a consequence of DSBs are usually considered to be the principal damage that results in cell death.[13] Any agent that makes DNA more susceptible to radiation damage may enhance cell killing. Certain drugs, such as halogenated pyrimidines, incorporate into DNA and make it more susceptible to radiation damage.[14]

Inhibition of Cellular Repair

Both sublethal and potentially lethal damage inflicted by radiation can be repaired.[15-17] Although sublethal damage repair (SLDR) denotes the increase in cell survival when the radiation dose is split into two fractions of radiation separated by a time interval, potentially lethal damage repair (PLDR) designates the increase in cell survival as the result of postirradiation environmental conditions. SLDR is rapid, with a half-time of approximately 1 hour, and is complete within 4 to 6 hours after irradiation. This time between two radiation fractions allows radiation-induced DSBs in DNA to rejoin and repair. SLDR is expressed as the restitution of the shoulder on the cell survival curve for the second dose. PLDR occurs when environmental conditions prevent cells from dividing for several hours, such as keeping in vitro growing cells in plateau phase after irradiation.

Preventing cells from division allows the completion of repair of DNA lesions that would have been lethal had DNA undergone replication within several hours after irradiation. PLDR is considered to be a major determinant responsible for radioresistance in some tumor types, such as melanomas. The repair can be achieved through restoration of damaged molecules by reducing species that donate electrons to oxidized substrates or through involvement of enzymes mediating homologous and nonhomologous recombination repair of DNA DSBs, base excision repair of base damage, and nucleotide excision repair of DNA-protein cross-links.

Many chemotherapeutic agents used in chemoradiation therapy interact with cellular repair mechanisms and inhibit repair and hence may enhance cell or tissue response to radiation. The aforementioned halogenated pyrimidines enhance cell radiosensitivity, not only through increasing initial radiation damage but also by inhibiting cellular repair.[14,18] Nucleoside analogs, such as gemcitabine, are a class of chemotherapeutic agents potent in inhibiting the repair of radiation-induced DNA and chromosome damage.[19,20] They have been shown strongly to enhance tumor radioresponse in preclinical studies and have been, and are continuing to be, extensively investigated for such activity in patients with cancer.[21,22]

Cell Cycle Redistribution

Both chemotherapeutic agents and radiation are more effective against proliferating than nonproliferating cells. Their cytotoxic action further depends on the position of cells in the cell cycle. Cell cycle dependency in response to radiation was first described almost 40 years ago.[23] Terasima and Tolmach reported that the sensitivity of the cell response to radiation varied widely depending on which phase of the cell cycle the cells were in at the time of irradiation and that cells in the G_2 and M cell cycle phases were approximately 3 times more sensitive than cells in the S phase.[23] The exact reason for this variability is still unknown.

The influence of the cell cycle on cell response to cytotoxic agents can be therapeutically exploited in chemoradiation therapy using cell cycle redistribution strategies. For example, some chemotherapeutic drugs, such as taxanes, can block transition of cells through mitosis, with the result that cells accumulate in the radiosensitive G_2 and M phases of the cell cycle.

Radiation delivered at the time of significant accumulation of cells in both the G_2 and M phases results in enhanced radioresponse of cells in vitro and of tumors in vivo.[24-27] However, this cell cycle mechanism of taxane-induced enhancement of tumor radioresponse is dominant only in tumors that are resistant to paclitaxel or docetaxel as a single treatment. Although tumor growth in taxane-resistant tumors is not substantially affected by the drug, tumors do exhibit significant transient accumulation of cells in mitosis 6 to 12 hours after the treatment.[27] Taxanes also enhance the radioresponse of tumors that respond by significant tumor growth delay to taxanes given as a single treatment modality, but a major mechanism for radio enhancement in such tumors is reoxygenation of radioresistant hypoxic cells, as discussed later.[26]

Elimination of the radioresistant S-phase cells by the chemotherapeutic agents may be another cell cycle redistribution strategy in chemoradiation therapy. Nucleoside analogs, such as fludarabine or gemcitabine, are good examples of the agents that become incorporated into S-phase cells and eliminate them by inducing apoptosis.[19,21] In addition to purging S-phase cells, the analogs induce the surviving cells to undergo parasynchronous movement to accumulate in the G_2 and M phases of the cell cycle between 1 and 2 days after drug administration, a time when the highest enhancement of tumor radioresponse was observed.[21] Tumors with a high cell growth fraction are likely to respond better to the cell cycle redistribution strategy in chemoradiation therapy than tumors with a low cell growth fraction.

Counteracting Hypoxia-Associated Tumor Radioresistance

Solid malignant tumors are usually characterized by defective vascularization, both in the number of blood vessels and vessel function. Because of this, blood supply to tumor cells is inadequate, cells lack oxygen and nutrients, and multiple tumor microregions become hypoxic, acidic, and, eventually, necrotic. Hypoxia occurs at distances from blood vessels larger than 100 to 150 μm. The hypoxic cell content in tumors varies widely and can be more than 50%. The presence of hypoxia makes tumors more aggressive (hypoxia is conducive to the emergence of more virulent tumor cell variants) and stimulates metastatic spread and more resistant to radiation as well as most chemotherapeutic agents.[28,29] Hypoxic cells are 2.5

to 3 times more resistant to radiation than well-oxygenated cells. The fact that hypoxia may be a cure-limiting factor in RT, at least in some clinical situations, is suggested by the findings that reduced hemoglobin levels and low tumor pO_2, are associated with higher treatment failure rates.[30-32] Also, there are reports showing that local tumor control by RT can be improved by the use of hypoxic cell radiosensitizers or hyperbaric oxygen.[33-35] With respect to the effects of chemotherapy, hypoxic regions are less accessible to chemotherapeutic drugs; in addition, hypoxic tumor cells are either nonproliferating or proliferate poorly and as such do not respond well to drugs.

Combining chemotherapeutic agents with RT can reduce or eliminate hypoxia or its negative influence on tumor radioresponse. Most chemotherapeutic drugs preferentially kill proliferating cells, primarily found in well-oxygenated regions of the tumor. Because these regions are located close to blood vessels, they are easily accessible to chemotherapeutic agents. Destruction of tumor cells in these areas leads to an increased oxygen supply to hypoxic regions and hence reoxygenates hypoxic tumor cells. Massive loss of cells after chemotherapy lowers the interstitial pressure, which then allows the reopening of previously closed capillaries and the reestablishment of blood supply. It also causes tumor shrinkage so that previously hypoxic areas are closer to capillaries and thus accessible to oxygen. Finally, by eliminating oxygenated cells, more oxygen becomes available to cells that survived chemotherapy. It was recently shown that tumor reoxygenation is a major mechanism underlying the enhancement of tumor radioresponse induced by taxanes in tumors sensitive to these drugs.[26]

Another approach to counteract the negative impact of hypoxia is selective killing of hypoxic cells through bioreductive drugs, such as tirapazamine, which undergo reductive activation in a hypoxic milieu, rendering them cytotoxic.[28] A related possibility is to exploit the acidic state (low pH) of tumors, which develops as a result of hypoxia-driven anaerobic metabolism that produces lactic acid, through the use of drugs that selectively accumulate in acidic environments or become activated by a low pH.[36,37]

The use of agents that selectively radiosensitize hypoxic cells to reduce their negative impact has been considered and tested in clinical trials. These drugs increase radiation damage by mimicking the effect of oxygen. Many clinical trials have tested these drugs, particularly misonidazole, in combination with RT, but few of them have shown an improved treatment outcome. The exception is nimorazole, which also does not elicit the neurotoxicity commonly associated with hypoxic cell sensitizers that prevented the delivery of clinically effective doses of these agents.[38]

Inhibition of Tumor Cell Repopulation

The constant balance between cell production and cell loss maintains the integrity of normal tissues. When this balance is perturbed by cytotoxic action of chemotherapeutic drugs or radiation, the integrity of tissues is reestablished by an increased rate of cell production. The cell loss after each fraction of radiation during RT induces compensatory cell regeneration (repopulation), the extent of which determines tissue tolerance to RT. In contrast to normal tissues, malignant tumors are characterized by an imbalance between cell production and cell loss in favor of cell production. As with normal tissues, tumors also respond to radiation- or drug-induced cell loss with a compensatory regenerative response. Preclinical studies provided ample evidence demonstrating that the rate of cell proliferation in tumors treated by radiation or chemotherapeutic drugs is higher than that in untreated tumors.[39-41] This increased rate of treatment-induced cell proliferation is commonly termed *accelerated repopulation*. Accelerated repopulation of tumor clonogens has been shown to occur during clinical RT as well. Withers et al showed that the total dose of radiation needed to control 50% of head and neck carcinomas progressively increased with time whenever RT treatment was prolonged beyond 1 month.[42] This increase in radiation dose required to achieve tumor control was greater than what would be anticipated based on the pretreatment tumor volume doubling time of approximately 60 days for head and neck tumors. The increase was attributed to accelerated repopulation, and it was estimated to average approximately 0.6 Gy/d but may be as high as 1 Gy/d.[42,43]

Although accelerated cell proliferation is beneficial for normal tissues because it spares them from radiation damage, it has an adverse impact on

tumor control by RT or chemotherapy. Chemotherapeutic drugs, because of their cytotoxic or cytostatic activity, can reduce the rate of proliferation when given concurrently with RT and hence increase the effectiveness of the treatment. Caution must be taken to select drugs that preferentially affect rapidly proliferating cells and preferentially localize in malignant tumors. However, the main limitation of concurrent chemoradiation therapy is the enhanced toxicity of rapidly dividing normal tissues because most available chemotherapeutic agents show poor tumor selectivity. Moreover, accelerated repopulation induced by chemotherapeutic drugs may have a negative influence on the outcome of tumor response to radiation when drugs are used in induction or neoadjuvant chemotherapy protocols. In this strategy, chemotherapy precedes RT. Treatment outcomes after induction chemotherapy followed by RT have not been overly encouraging in terms of both local tumor control and patient survival, even if a large proportion of tumors initially responded with total or partial clinical regression by the time of RT implementation. Some experimental evidence suggests that the drug-induced accelerated cell repopulation can actually make the tumor more difficult to control with radiation.[39,40]

TIMING OF DRUG ADMINISTRATION IN RELATION TO RADIATION THERAPY

Most clinical chemoradiation therapy regimens evolved empirically: increasingly, information from preclinical studies is being considered in planning the optimal timing of drug administration in relation to RT. Depending on the principal aim of the therapy, drugs are administered before (*induction* or *neoadjuvant chemotherapy*), during (*concurrent* or *concomitant chemotherapy*), or after (*adjuvant chemotherapy*) the course of RT. The advantages and disadvantages of each approach are summarized in Table 31.1.

TABLE 31.1 ADVANTAGES AND DISADVANTAGES OF DIFFERENT CHEMORADIATION SEQUENCING STRATEGIES

Strategy	Advantages	Disadvantages
Sequential chemoradiation	• Least toxic	• Increased treatment time • Lack of local synergy

Strategy	Advantages	Disadvantages
	• Maximizes systemic therapy • Smaller radiation fields if induction shrinks tumor	
Concurrent chemoradiation	• Shorter treatment time • Radiation enhancement	• Compromised systemic therapy • Increased toxicity • No cytoreduction of tumor
Concurrent chemoradiation and adjuvant chemotherapy	• Maximizes systemic therapy • Radiation enhancement • Both local and distant therapy delivered up front	• Increased toxicity • Increased treatment time • Difficult to complete chemotherapy after chemoradiation
Induction chemotherapy and concurrent chemoradiation	• Maximizes systemic therapy • Radiation enhancement	• Increased toxicity • Increased treatment time • Difficult to complete chemoradiation after induction therapy

In regard to the primary tumor, induction chemotherapy may reduce the number of clonogenic cells and cause the reoxygenation of the surviving hypoxic cells, both of which render tumors more controllable by radiation. In addition, chemotherapy-induced tumor shrinkage may allow the use of smaller radiation fields, in which case less normal tissue is exposed and damaged by radiation. This treatment approach is often used in the therapy of solid tumors in children and of lymphomas. Induction chemotherapy precedes RT for a few weeks to a few months, which improves tolerability of the combined treatment.

Induction chemotherapy has resulted in therapeutic improvement in several clinical trials compared with RT, but in general, the therapeutic benefits are below expectations. A number of factors could account for this, including accelerated proliferation of tumor cell clonogens and selection or induction of drug-resistant cells that are cross-resistant to radiation. The preclinical findings provide solid evidence for the existence of accelerated

repopulation in tumors treated with chemotherapeutic agents. On the other hand, although development of drug resistance is a significant problem in chemotherapy, the evidence that cells that acquire drug resistance are also resistant to radiation is not convincing.

When chemotherapy is given during a course of RT, it is referred to as *concurrent chemotherapy*. This form of treatment is intended to cope with both disseminated lesions and the primary tumor, but it takes advantage of drug-radiation interactions to maximize tumor radioresponse. The drug scheduling in relation to individual radiation fractions is highly important, and the selection of optimal timing of drug administration must be based on mechanisms of tumor radio enhancement by a given drug, the drug's normal tissue toxicity, and the conditions under which the highest enhancement is achieved. The data from preclinical studies can greatly contribute to the selection of the most optimal schedules. For example, it has been demonstrated that murine tumors sensitive to taxanes show enhanced radioresponse, but the best effect is achieved if drug treatment precedes radiation by 1 to 3 days.[26] A major mechanism for tumor radio enhancement was reoxygenation of hypoxic cells. Based on this preclinical information, one would anticipate that in clinical protocols such tumors would best respond to a bolus of a taxane given once or twice weekly during RT. In contrast, tumors resistant to taxanes on their own would call for daily administration of a taxane because they show accumulation of radiosensitive G_2- and M-phase cells 6 to 12 hours after drug administration. If the objective is to counteract rapid repopulation of tumor cell clonogens induced by radiation, then administration of cell cycle–specific chemotherapeutic agents during the second half of RT, when accelerated repopulation is more expressed, might be more effective. At present, the enhancement in normal tissue complications remains the major limitation of concurrently combining chemotherapy with RT. Nevertheless, as is made evident later in the text, concurrent chemoradiation therapy has provided better clinical results in terms of both local tumor control and patient survival than have other modes of chemoradiation therapy combinations.[44,45]

Adjuvant chemotherapy designates a treatment modality in which chemotherapeutic drugs are given some time after completion of RT. The

primary objective is to eradicate disseminated disease; however, the control of the primary tumor may also be improved by the ability of drugs to deal with tumor cells that survived radiation.

INTERACTION OF SPECIFIC CHEMOTHERAPIES AND RADIATION IN THE TREATMENT OF CANCER

This section provides an overview of the evidence that exists for combining particular chemotherapies with radiation. In many cases, the level of support that exists for combined therapy mirrors the age of the drug. However, as would be expected, newer drugs have generally been subject to more rigorous preclinical assessment of their efficacy before their introduction into the clinical setting (Table 31.2).

TABLE 31.2 MECHANISMS OF CHEMOTHERAPY-INDUCED RADIATION SENSITIZATION

Class of Compound	Mechanism of Radiosensitization	References
Platinum-based compounds	Inhibition of DNA synthesis Inhibition of transcription elongation by DNA interstrand cross-links Inhibition of repair of radiation-induced DNA damage	46-49
Taxanes	Cellular arrest in the G_2M phase of the cell cycle	26,27,50,51
	Induction of apoptosis	
	Reoxygenation of tumor cells	
Topoisomerase I inhibitors	Inhibition of repair of radiation-induced DNA strand breaks	52-54
	Redistribution into G_2 phase of the cell cycle	
	Conversion of radiation-induced SSBs into DSBs	
Hypoxic cell cytotoxins	Complementary cytotoxicity with radiation on euoxic and hypoxic tumor cells	55,56
Antimetabolites	Nucleotide pool perturbation	19,20,57,58
	Lowering apoptotic threshold	
	Cell cycle redistribution	
	Tumor cell reoxygenation	

Class of Compound	Mechanism of Radiosensitization	References
Temozolomide	DNA repair inhibition (radiosensitization effect may be subject to MGMT status)	59,60

DSBs, double-strand DNA breaks; MGMT, O^6-methylguanine-DNA methyltransferase; SSBs, single-strand DNA breaks.

Platinum-Based Drugs

This group of compounds, distinguished from most others by its metallic element base, has come to be recognized as one of the most potent chemotherapies available to date. Cisplatin (*cis*-diamminedichloroplatinum II), which is the prototype drug, has been acknowledged to be a potent radiosensitizer for many years and has a significant role in clinical practice to date. Preclinical work done using murine models by Rosenberg et al in the late 1960s showed that cisplatin is an effective antitumor chemotherapy. Subsequent efforts have shown that its primary mechanism of inhibition of tumor growth appears to involve the inhibition of DNA synthesis by formation of DNA cross-links.[61-63] Another secondary mechanism includes the inhibition of transcription elongation by DNA interstrand cross-links.[64]

Cisplatin-free radical–mediated sensitization may involve the ability to scavenge free electrons formed by the interaction between radiation and DNA. The reduction of the platinum moiety may serve to stabilize DNA damage that would otherwise be repairable.[65] Greater than additive effects of cisplatin and radiation are seen in tumor models most reliably when the drug is administered with fractionated radiation, explained by its inhibition of SLDR.[65] Bladder cancer, head and neck cancer, lung cancer, esophageal cancer, and cervix cancer are some of the disease sites where cisplatinum is approved for use in combination with RT.

Carboplatin, a second-generation platinum compound with a different toxicity profile, has also been studied as a radiosensitizer.[48,49] Mechanism of action also involves interfering with function of DNA by producing interstrand DNA cross-links. Carboplatin tends to have less nephrotoxic or neurotoxic effects compared to cisplatin, but hematologic toxicity is slightly increased. Its potential efficacy as a radiosensitizer has allowed for its incorporation into regimens used in several randomized trials including, but not limited to, landmark trials that allowed for its indication for use in

esophageal cancer, head and neck cancer, and lung cancer. Oxaliplatin, although sharing a similar mode of action as other platinum compounds, has been shown to have activity in cisplatin- resistant systems in vitro.[4] One potential explanation for this is that oxaliplatin is not affected by loss of mismatch repair, which leads to cisplatin resistance in vitro, and there are those that postulate that adducts formed by oxaliplatin are less well recognized by DNA repair systems.[66,67] Whether oxaliplatin is truly active against cisplatin-resistant cancer clinically is an area of active investigation.[68] Despite encouraging findings in phase I to II rectal cancer studies, phase III studies integrating neoadjuvant oxaliplatin with 5-FU or capecitabine with RT, with the exception of the CAO/ARO/AIO-04 study, have yielded negative findings (STAR-01, ACCORD 12, NSABP R04, PETACC-6).[69] In esophageal cancer, oxaliplatin-based chemoradiation therapy, although did not demonstrate improvement in efficacy over cisplatinum/5-FU–based regimen, was suggested to be a more convenient regimen and was not found to be more toxic.[70] Oxaliplatin-based regimens with RT are being further studied in additional randomized phase II studies in comparison to carboplatin-based regimen (NEOSCOPE and PROTECT-1402).[69,71]

Antimicrotubules: Taxanes

The radiosensitizing properties of plant-derived chemotherapeutic agents, the taxanes, have been studied extensively in both preclinical models and clinical trials. Paclitaxel (Taxol) and docetaxel (Taxotere) act as mitotic spindle inhibitors through their promotion of microtubule assembly and inhibition of disaggregation.[72] Both taxanes bind to the *N*-terminal 31-amino-acid sequence of the β-tubulin subunit of cellular tubulin polymers, stabilizing the polymers by shifting the dynamic equilibrium that exists between tubulin dimers and microtubules in favor of the polymerized state.[73,74] Although there is preclinical evidence that docetaxel has both a higher affinity for the tubulin-binding site and greater in vitro cytotoxicity than paclitaxel, this has not necessarily translated into greater clinical efficacy because the toxicity profiles of the two drugs also differ.[75,76]

The administration of a taxane leads to cellular arrest in the G_2/M phase of the cell cycle, which is the precise point associated with increased

sensitivity to the lethal effects of ionizing radiation.[77] Early laboratory studies with a human lung cancer cell line and human astrocytoma cells bore out the prospect of significant radiosensitization, with relative enhancement ratios in the 1.48 to 1.8 range when paclitaxel was administered before irradiation.[24,25]

The exact conditions used in various studies appear to determine the strength of the interaction between radiation and paclitaxel because subadditive effects have been seen in addition to the more widely reported additive and supra-additive effects.[27] In general, enhancement of radiation effects is seen when proliferating cells have been incubated with moderate concentrations of paclitaxel for 24 hours before irradiation. Conditions leading to a less than optimal response include paclitaxel-mediated G_1 arrest, wherein a more resistant cell subpopulation counteracts the effects of a G_2/M block; paclitaxel-induced cell cycle effects such as the G_2/M block in cells destined to die before irradiation; and incubation conditions insufficient to exert cellular effects. The fact that nonproliferating cells are also sensitized to the effects of radiation by the use of paclitaxel suggests that mechanisms other than the cell cycle arrest in the G_2/M phase underlie paclitaxel's sensitizing abilities.

Paclitaxel also acts to induce programmed cell death; work from the MD Anderson Cancer Center has examined the relationship between mitotic arrest, apoptosis, and the antineoplastic activity of paclitaxel in 16 murine tumors.[27] Single-dose paclitaxel (40 mg/kg) induced mitotic arrest to varying degrees in all tumors; however, apoptosis was induced in only 50% of tumors. This study also revealed that pretreatment levels of apoptosis correlated with both paclitaxel-induced apoptosis and tumor growth delay. Therefore, both the pretreatment apoptotic rate and the paclitaxel-induced apoptotic rate could potentially act as predictors of the response to paclitaxel.

Milas et al summarized observations that showed that (1) there was massive loss of tumor cells though the apoptotic pathway was restricted to the perivascular region and (2) radio enhancement occurring during this period of cell loss became even more impressive when apoptotic cells were removed from the tumor.[27] Experiments in which tumor xenografts were treated with paclitaxel and exposed to radiation under hypoxic or air-

ambient conditions were pursued.[26] It was found that the creation of hypoxic conditions greatly reduced the efficacy of paclitaxel in its enhancement of radioresponse. It appears that a combination of cell cycle effects, drug-induced reoxygenation, and drug-induced apoptosis underlies paclitaxel's radiosensitizing abilities.

Docetaxel has also been found to be a respectable radiosensitizer in both in vitro and in vivo models.[50,51] Radiation response in the presence of docetaxel was examined in three different cell lines that have widely different responses to radiation alone.[78] Their findings suggest that the p53 status of tumor cells may have a profound effect on the radiosensitizing effects of a taxane. Other novel taxanes and analogs that continue to attract the interest of investigators for their potential to enhance radiation effects include Abraxane, paclitaxel poliglumex, larotaxel, cabazitaxel, and orally available taxanes.[79-81]

Antimetabolites

5-Fluorouracil

The radiosensitizing properties of 5-FU has been known for years.[82] Several mechanisms have been proposed for the cytotoxicity of this drug:

- Its incorporation into ribonucleic acid (RNA), which leads to a disruption of RNA function
- Inhibition of thymidylate synthase function and subsequently of DNA synthesis
- Direct incorporation of the drug into DNA

It is believed that a combination of these effects underlies its radiosensitizing properties.[83] Optimization of its schedule of delivery is crucial to obtaining an effect with this combination, and it is accepted that cytotoxic doses of 5-FU are needed to obtain a radiosensitizing effect. In general, it is thought that a continuous infusion of the drug is needed to obtain the desired drug levels after irradiation.[84] Long-standing clinical experience with this drug bears out much of the laboratory studies of its effectiveness as a radiation sensitizer. Gastrointestinal tract cancers, bladder cancer, and head and neck cancers are some of the disease sites where 5-

FU–based combined modality therapy with radiation is used as standard of care.

Capecitabine

Capecitabine is an oral prodrug of 5-FU. It is converted to its cytotoxic form in three enzymatic steps, the last of which is mediated by thymidine phosphorylase. One of the potential advantages of this mechanism for increasing tumor cytotoxicity is that thymidine phosphorylase is overexpressed in tumor tissues. Interestingly, radiation has been shown to stimulate expression of thymidine phosphorylase, which provides a further rationale for considering combined therapy with radiation treatments.[85] Capecitabine was shown to be safe to replace 5-FU in chemoradiotherapy regimen for rectal cancer.[86] It is being used in the combined modality setting as standard therapy, and in clinical trials, for many tumor types (including, but not limited to, rectal cancer, gastric cancer, esophageal cancer) requiring fluorouracil-based chemoradiation.

Gemcitabine

Gemcitabine is another nucleoside analog that acts as a very potent radiosensitizer. The biologic action of gemcitabine is due almost completely to its effects on DNA metabolism. Early studies of this drug in leukemic cell lines found that notable decreases in cellular deoxynucleotide triphosphates occurred with the use of the drug.[87]

Direct incorporation of the drug into DNA and drug-induced apoptosis are also thought to underlie its cytotoxicity.[87] The metabolism of gemcitabine in the cell is complex, and it is able to potentiate its cytotoxicity as a sole therapy.[87] Depending on the conditions, relative enhancement ratios in the range of 1.1 to 2.5 have been reported.

Gemcitabine is S phase specific and as such should be selectively toxic to proliferating cells, decreasing the amount of proliferation that can occur during fractionated RT.[88] In addition, cell cycle redistribution induced by these agents may improve cell kill by allowing more cells to be treated in the more sensitive parts of the cell cycle.[89] As DNA synthesis inhibitors, these drugs may act to inhibit the repair of radiation-induced DNA

damage.[19] Finally, as DNA chain terminators, they may serve to trigger the apoptotic response.[20]

Milas et al found the largest enhancement of growth delay when gemcitabine was delivered 24 to 60 hours before irradiation in a murine sarcoma tumor model.[21] The use of gemcitabine with radiation also decreased the risk for the development of lung metastases in those mice that attained durable local control (73% in the radiation-alone group vs 40% in the combined modality group), which was confirmed in a second study with a larger number of mice.[58] This preclinical work is supportive of the principles of combined modality therapy in that better local control translated into decreased systemic spread of tumor cells. The same authors also report a dose-dependent increase in the apoptotic rate after the administration of gemcitabine, which they believe correlates with the elimination of the more radioresistant S-phase population of cells and a redistribution of the remaining cells into more radiosensitive parts of the cell cycle.[21] They also report that reoxygenation of the resistant hypoxic fraction of tumor cells is a mechanism for the radiosensitizing action of gemcitabine.[58]

In summary, the preclinical evidence suggests that gemcitabine acts through several mechanisms (nucleotide pool perturbation, lowering of the apoptotic threshold, cell cycle redistribution, and tumor cell reoxygenation) to enhance the effect of ionizing radiation on tumors. Clinical experience has shown that this drug is indeed a potent sensitizer with the potential for significant toxicity as well as improvement in tumor control when combined with radiation.[90-96]

Pemetrexed

Pemetrexed is a novel multitargeted agent, exerting its effect via simultaneous inhibition of multiple folate-requiring enzymes, including thymidylate synthase, dihydrofolate reductase, and glycinamide ribonucleotide formyl-transferase.[97] Pemetrexed has shown synergistic activity with radiation treatments, likely because of interference with DNA synthesis.[98] There are indications that radiosensitization by pemetrexed is not cell cycle phase specific in vitro.[99] Others have suggested that a combination of RT and pemetrexed results in supra-additive effects, which

may be in part because of apoptosis induction.[100] Phase III study in non–small cell lung cancer (NSCLC) has demonstrated nonsuperiority for pemetrexed-cisplatin with radiation, compared to cisplatin-etoposide and radiation, and although trial closed early because of futility, it is considered to be a potential alternative regimen.[101]

Topoisomerase I Inhibitors

Camptothecin is a plant alkaloid obtained from the *Camptotheca acuminata* tree. Its initial clinical evaluation in the 1960s and 1970s was abandoned because of severe and unpredictable hemorrhagic cystitis.[102,103] Camptothecin and its derivatives (eg, irinotecan, topotecan, 9-aminocamptothecin, SN-38) target DNA topoisomerase I.[104-106] This enzyme relaxes both positively and negatively supercoiled DNA and allows for diverse essential cellular processes, including replication and transcription, to proceed. In the presence of camptothecin, a camptothecin-topoisomerase I-DNA complex becomes stabilized with the 5′-phosphoryl terminus of the enzyme-catalyzed DNA SSB bound covalently to a tyrosine residue of topoisomerase I. These stabilized cleavable complexes interact with the advancing replication fork during the S phase or during unscheduled DNA replication after genomic stress and cause the conversion of SSBs into irreversible DNA DSBs, resulting in cell death.[106]

Several investigators have reported that camptothecin enhances the cytotoxic effect of radiation in vitro and in vivo.[52-54] Chen et al showed that cells exposed to 20(S)-10,11 methylenedioxy-camptothecin before or during radiation had sensitization ratios of 1.6, whereas those treated with the drug after radiation had substantially less enhancement of radiation-induced DNA damage.[53] There are several hypotheses regarding the mechanism of interaction between radiation and irinotecan: (1) inhibition of topoisomerase I by irinotecan leads to inhibition of repair of radiation-induced DNA strand breaks; (2) irinotecan causes a redistribution of the cells into the more radiosensitive G_2 phase of the cell cycle; and (3) topoisomerase I-DNA adducts are trapped by irinotecan at the sites of radiation-induced SSBs, leading to their conversion into DSBs.[107] Although there is currently insufficient evidence to identify the underlying mechanism with certainty, the primary mechanism involved with

radiosensitization may depend on which camptothecin derivative is being used.

Data from in vivo experiments demonstrate that combination 9-aminocamptothecin and irradiation is more effective when fractionated, compared with single doses.[108] There is also evidence for circadian-dependent cytotoxicity and radiation sensitization when camptothecin derivatives like 9-aminocamptothecin are used as radiation sensitizers.[108] The integration of this group of drugs into clinical treatments with RT has been explored in NSCLC and brain tumors.[109-112]

Alkylating Agents: Temozolomide

Temozolomide is a second-generation alkylating agent, which is orally administered, is readily bioavailable, and demonstrates broad-spectrum activity in a variety of difficult-to-treat malignancies, including glioma and melanoma.[113] It is unique in its ability to cross the blood-brain barrier (about 30%-40% of plasma concentration found in cerebrospinal fluid). In vitro studies demonstrate increased inhibition of cell growth in combination with RT.[114] Radiosensitization appears to occur via inhibition of DNA repair, leading to an increase in mitotic catastrophe.[59] It has proven efficacy as a first-line therapy for patients with glioblastoma multiforme (GBM) in conjunction with RT based on a randomized phase III clinical study demonstrating survival benefit.[115] Temozolomide spontaneously converts to the reactive methylating agent 5-(3-methyl-1-triazeno)imidazole-4-carboxamide and transfers methyl groups to DNA, the most important one being at the O6 position of guanine, an important site for DNA alkylation.[116] The MGMT gene encodes a DNA repair protein that removes the alkyl group from the O6 position of guanine, and high MGMT activity levels abrogate the effectiveness of alkylating agents. In vitro, temozolomide enhances the radiation response most effectively in MGMT-negative glioblastomas, and likely because of decreased double-strand DNA repair capacity and increased DNA DSB damage, which occurs when the combination of temozolomide and RT was administered.[60] Analysis of a randomized study by the European Organization for Research and Treatment of Cancer (EORTC) and National Cancer Institute of Canada demonstrated that loss of MGMT expression by promoter methylation is

correlated with a better outcome after treatment with radiation and temozolomide.[117] Temozolomide and radiation combination is considered the backbone standard therapy for newly diagnosed GBM, upon which combination of additional new investigational agents are being studied.

Other Agents

Mitomycin-C

Mitomycin-C is a quinone, whose mechanisms of action include inhibition of DNA and RNA synthesis.[118] When combined with radiation, the rationale for the use of mitomycin-C is based on its ability to target hypoxic cells that are known to be relatively radiation resistant.[119] There is preclinical evidence to suggest that mitomycin-C administered before irradiation leads to a supra-additive interaction.[55,120] The postulated mechanisms of action for supra-additivity include prevention of repopulation and hypoxic cell sensitization, although the definitive action is not fully elucidated. Given that normal tissues are not hypoxic, the selective targeting of this cell population with mitomycin-C has the potential to improve cures without compromising normal tissue complication rates. The use of mitomycin-C is limited by its hematologic toxicities. Mitomycin-C combined with RT remains the standard-of-care therapy for anal carcinoma based on multiple clinical studies.[121]

Hypoxic Sensitizers

Tirapazamine

Investigators have pursued a similar strategy as outlined previously with the development of tirapazamine, a hypoxic cell cytotoxin.[28,56] Brown has discovered that tirapazamine, which is a benzotriazine di-*N*-oxide, is toxic to hypoxic cells at concentrations much lower than what is needed to radiosensitize cells.[56] It has the greatest differential toxicity known between hypoxic and well-oxygenated cells. Essentially, this drug functions through its intracellular reduction to form a highly reactive radical capable of causing both SSBs and DSBs.[122] In the presence of oxygen, a free electron is absorbed, and the compound is back-oxidized to the parent compound with the concomitant release of a superoxide radical, which is much less cytotoxic than the tirapazamine radical. Clinical trials are ongoing or have

been completed in multiple tumor sites, including cervix, head and neck, GBM, and lung malignancies (small cell lung cancer).[123-135] Although most studies have demonstrated a reasonable toxicity profile, several studies have suggested caution in the appropriate selection of a dose and delivery regimen when combining tirapazamine to a standard chemoradiation regimen.[127,130,136]

Fairly promising earlier phase trials led to phase III studies in head and neck and cervical cancer. A phase III study by the Trans-Tasman Group (TROG 02.02) suggested no significant improvement in survival outcome in patients with locally advanced head and neck cancer, unselected for hypoxia, with the addition of tirapazamine to a standard platinum-based chemoradiation regimen.[133] A subset analysis of the phase II study from the Trans-Tasman Group suggested that tumors with a hypoxic component as assessed by ^{18}F-fluoromisonidazole positron emission tomography imaging had a higher likelihood of locoregional failure, whereas an improvement in local control was identified for those treated with the addition of tirapazamine, suggesting that it specifically targets hypoxic tumor cells.[129] Similarly, GOG phase III trial studying the role of addition of tirapazamine to platinum-based RT in cervical cancer was closed early and demonstrated no improvement in survival outcomes with the addition of tirapazamine.[136] Study was closed early because of the lack of available study drug and limits future development of this drug.[136-138]

Nimorazole

Nimorazole is another hypoxic cell radiosensitizer belonging to a class of chemical known as 5-nitroimidazoles, with less neuropathic toxicity than misonidazole; it has demonstrated improved tumor control outcome and tolerability with RT, in supraglottic laryngeal and pharyngeal tumors in the DAHANCA 5 study.[38] A randomized multicenter study, IAEA- HypoX study with nimorazole and concomitant accelerated RT in head and neck squamous cell carcinoma, was attempted but closed prematurely in 2014 because of poor recruitment (100 of the intended 600 patients were accrued).[137] Although closed early, it suggested an improvement in locoregional tumor control with the addition of nimorazole. Additional ongoing trials include NIMRAD, a phase III study of addition of

nimorazole to RT in patients with locally advanced head and neck cancer not suitable for chemotherapy or cetuximab.[138] EORTC has opened a phase III multicenter study of radiation with or without nimorazole using a 15-gene signature for hypoxia in the treatment of head and neck squamous cell carcinoma. DAHANCA 30, a randomized noninferiority study of hypoxia-profile guided selection of patients who are predicted to be nonresponders to chemoradiotherapy with or without nimorazole, is recruiting patients.

EMERGING STRATEGIES FOR IMPROVEMENT OF CHEMORADIATION THERAPY

In spite of increasing therapeutic achievements of chemoradiation therapy, the use of this form of therapy is still very much restricted by its narrow therapeutic index. The available agents are either insufficiently effective on their own or in combination with radiation against tumors, or normal tissue toxicity prevents the use of effective doses of drugs or radiation. Significant research efforts, both preclinical and clinical, have been undertaken to improve chemoradiation therapy. They include developing more selective and more effective chemotherapeutic agents, incorporating additional agents into chemoradiation therapy that protect normal tissues from injury by drugs or radiation, and improving the technique of RT delivery to minimize treatment of adjacent normal tissue while maximizing tumor dose delivery.

Increasing Antitumor Efficacy of Chemotherapeutic Drugs

A number of newer chemotherapeutic agents are being developed with the goal of enhancing antitumor effects by improving on the selective targeting of tumor cells via strategies such as chemical modification of known compounds including agents currently in use with RT because of their radiosensitizing properties.

Approaches for improvement of drug safety, convenience, or efficacy could include chemical modifications or modifications of the formulation of a known drug. One example is that of Abraxane (nab-paclitaxel, ABI-007). Abraxane is a 130-nM particle form of paclitaxel that is bound to albumin and is solvent free. This avoids the need for Cremophor-based vehicles and lowers the risk of hypersensitivity reactions.[79] Such vehicles have the

potential for altered pharmacokinetics by drug entrapment, leading to decreased drug clearance, decreased volume of distribution, and, ultimately, nonlinear pharmacokinetics. Interestingly, Abraxane has been demonstrated to have higher antitumor activity compared to Taxol in preclinical studies. This is in part mediated via utilization of albumin receptor–mediated endothelial transport, which leads to higher intracellular accumulation compared to standard paclitaxel.[139] Clinically, Abraxane has demonstrated efficacy in metastatic breast cancer in a phase III study.[140] Phase I/II studies in advanced NSCLC, melanoma, bladder cancer, high-risk prostate cancer, and gynecologic malignancy have been reported.[140-151] Preclinical studies have demonstrated Abraxane to have radiosensitizing properties.[152] Therefore, there is significant interest in determining the potential efficacy of Abraxane in disease sites where combined therapy with taxanes and radiation has demonstrated therapeutic advantage. Phase I and phase I/II study of nab-paclitaxel with radiation in lung cancer and head and neck cancer have been completed and reported demonstrating tolerability.[153,154]

Another approach to make current chemotherapeutic drugs more effective against tumors and at the same time less toxic to normal tissues is compound modification via conjugation with water-soluble polymeric drugs, such as polyglutamic acid. These conjugates accumulate in tumors and release the active drug into the tumor in high concentrations and for a longer time. The enhancement in uptake by and prolongation of drug release in tumors are thought to be due to the enhanced permeability and retention effect of macromolecular compounds in solid tumors.[155,156] The abnormal vasculature in tumors is porous to macromolecules, but high concentrations of drug can build up in tumors owing to inadequate lymphatic drainage, whereas polymer-drug conjugates are confined to the bloodstream in normal tissue.[155] This leads to improved spatial localization of the cytotoxic drug within tumor. A promising polyglutamic acid-paclitaxel conjugate (paclitaxel poliglumex) was developed. It is less toxic, more effective against tumors, and more enhancing of tumor radioresponse in preclinical studies than unconjugated paclitaxel.[156,157] Furthermore, there are in vivo laboratory data suggesting that radiation adds to the accumulation of drug within tumors by modification of tumor vasculature.[158] Therefore, multiple mechanisms for spatial localization and cooperation, including inherent drug properties, radiation modification of

vasculature, and radiation-based targeting of sites within the body, could make this an attractive strategy for combining this agent with radiation treatments. Clinical trials in esophageal cancer (phase II), gastric cancer (phase I), and glioblastoma without MGMT methylation (phase II) have been reported in combination with radiation treatments.[159-161]

Normal Tissue Protection

Because normal tissue toxicity represents a major limitation of concurrent chemoradiation therapy, every effort must be taken to prevent or minimize complications. This could be achieved through the incorporation into the treatment of radioprotective or chemoprotective agents or through improvements of radiation delivery. A number of chemical and biologic compounds are available that exhibited either selective or preferential protection of normal tissues in preclinical in vivo testing.[162-166] In addition, there are many candidate compounds, particularly extracts from plants used in traditional medicine settings, that are undergoing in vitro evaluation.[167-169] The most commonly tested radioprotectors are thiol compounds, such as WR-2721 (amifostine), a prodrug that must be converted in vivo to its active metabolite WR-1065. Amifostine is currently the only Food and Drug Administration–approved radioprotector. The principal mechanisms of protection by these agents include scavenging of free radicals generated by ionizing radiation and some chemotherapy agents, such as alkylating agents, and donating hydrogen atoms to facilitate direct chemical repair of DNA damage. However, amifostine modulates transcriptional regulation of genes involved in apoptosis, cell cycle regulation, and DNA repair as well.[170] The protector is taken up preferentially by normal tissues, where the entry into cells is accomplished by active transport. In contrast, the drug diffuses passively into tumors, where its availability is also reduced by deficient tumor vasculature. Amifostine has been shown to reduce normal tissue toxicity in a number of clinical settings, including protection of salivary glands in head and neck RT, prevention of acute and late normal tissue toxicities from chemoradiation in cancers of the head and neck, and the esophagus in chemoradiation therapy of lung cancer, without adversely affecting tumor response to treatment.[171-175] The drug significantly protects against cisplatin-induced nephrotoxicity, ototoxicity, and neuropathy.

Technology-Based Strategies to Improve Radiation Therapy

Several technological strategies to improve the efficacy and decrease the toxicity of RT have been developed. These advances include improvements in RT delivery, such as three- dimensional (3D) treatment planning, conformational radiation therapy (CRT), intensity-modulated radiation therapy (IMRT), and image-guided radiation therapy (IGRT). Use of heavy particles, such as protons or carbons, which have a more favorable beam profile, is another approach likely to minimize the toxicity, and combining such treatments with chemotherapy may lead to enhancement of the effectiveness of not only RT but also chemoradiation treatments. The principle primarily exploited with this would be that of maximizing spatial localization, with technological advances and/or heavy particles being used to maximize RT's spatial localization. Further advances in imaging, with the advent of molecular-based imaging applications in oncology, will lead to further refinement of IGRT techniques. Because there are significant discussions of 3DCRT, IMRT, IGRT, and heavy particles detailed in other chapters, we refer readers to those chapters for more in-depth discussion.

Altering Fractionation Schemes to Improve Therapeutic Ratio for Chemoradiation Treatments

Accelerated fractionation regimens are designed to counteract tumor repopulation, and accelerated fractionation with concomitant boost technique has shown superiority in terms of local control to the standard fractionation regimen in a large randomized study for patients with head and neck cancer.[176] Head and neck cancer remains one of the best paradigms for effectiveness of accelerated fractionation methods in clinical use. However, when combined with chemotherapy, a benefit to accelerated fractionation over standard fractionation was not demonstrated.[177]

Hyperfractionation is another strategy aimed at increasing the tumoricidal dose by delivering smaller doses/fractions, which allows a higher total dose to be administered as smaller doses/fractions lead to improved tolerance of late-responding normal tissues.[77] The efficacy of hyperfractionation over standard fractionation has been demonstrated in several disease sites, including lung and head and neck cancer.[176,178,179] In head and neck cancer, hyperfractionated RT with chemotherapy has yielded

superior outcomes compared to hyperfractionated RT alone; however, there has been no trial to demonstrate superiority of hyperfractionated RT and chemotherapy compared to conventional RT and chemotherapy.[180] Perhaps, given the limited success of concurrent therapy, methods of combining systemic agents sequentially either before or after radiation treatments with altered fractionation can be considered.

CLINICAL EXPERIENCE WITH CHEMORADIATION IN CANCER THERAPY

The level of clinical experience with the combination of radiation and chemotherapy has increased dramatically during the years. In many tumor types, the sequencing and method of administration of the combination have been very important in attaining improved outcomes seen in randomized trials. Improved local control and better overall survival rates have resulted from combination therapy in several diseases, including rectal cancer, limited-stage small cell lung cancer, locally advanced NSCLC, esophageal cancer, gastric cancer, cervical cancer, glioblastoma, and rhabdomyosarcomas. Equally important are the successes seen in the realm of organ preservation in sarcomas of the extremity, bladder cancers, carcinomas of the anal canal, head and neck cancers, and breast cancer.

As the role for combined modality therapy and studies leading to such for each of the tumor types are well represented in individual chapters addressing the disease site, readers will be referred to individual disease site chapters in the text for details. Briefly summarized in Table 31.3, however, are some representative disease sites in adult malignancies, where combined modality therapy with chemotherapy and/or targeted biologic agents and RT is accepted as the standard of care. The table also summarizes the commonly used systemic agent for these different disease sites. The list, while not comprehensive, is certainly extensive and impressive, and the clinical impact that combined modality therapy has had in each of these disease sites cannot be understated.

TABLE 31.3 CHEMORADIATION THERAPY AS STANDARD OF CARE BY SELECTED DISEASE SITES

Disease Site	Commonly Used Chemotherapeutic Agents	Sequencing and Intent of Therapy	Benefit of Combined Modality Approach
Locally advanced head and neck cancer	Cisplatin, 5-FU, hydroxyurea, carboplatin, cetuximab	• Definitive concurrent • Postoperative concurrent	Definitive: organ preservation/survival benefit Postoperative: DFS/LRC benefit; OS benefit in subset of patients
Glioblastoma multiforme	Temozolomide	• Postoperative concurrent • Definitive concurrent in unresectable cases	OS
Locally advanced/unresectable non–small cell lung cancer	Cisplatin, carboplatin, paclitaxel, etoposide, vinblastine	• Definitive concurrent • Sequential	OS
Limited-stage small cell lung cancer	Cisplatin/etoposide	Definitive concurrent	OS
Esophageal cancer	Cisplatin/5-FU	• Preoperative concurrent • Definitive concurrent	Local control, OS
Gastric cancer	5-FU, leucovorin	Postoperative concurrent	OS
Pancreatic cancer	5-FU, gemcitabine	• Postoperative concurrent • Definitive concurrent in unresectable patients	LRC, possibly survival
Locally advanced rectal cancer	5-FU, Xeloda	Preoperative concurrent	Improved sphincter preservation, improved DFS
Anal cancer	5-FU, mitomycin-C	Definitive concurrent	Improved colostomy free survival

Disease Site	Commonly Used Chemotherapeutic Agents	Sequencing and Intent of Therapy	Benefit of Combined Modality Approach
Cervical cancer	Cisplatin, 5-FU, hydroxyurea	Definitive concurrent	OS benefit
Bladder cancer	Cisplatin, 5-FU, mitomycin-C	Definitive concurrent	Bladder preservation

DFS, disease-free survival; LRC, locoregional control; OS, overall survival; 5-FU, 5-fluorouracil.

As outcomes in each of the solid tumors improve with concurrent therapy, we need to become cognizant of the potential for significant long-term toxicity from combination chemoradiation and do our best to minimize the risks that these side effects pose to patient survival and quality of life. Several well-documented chemoradiation-imposed late effects are summarized in Table 31.4.

TABLE 31.4 REPRESENTATIVE LONG-TERM TOXICITY OF COMBINED CHEMORADIATION THERAPY

Agent	Toxicity	Mechanism	References
Bleomycin	Pneumonitis/pulmonary fibrosis	Undefined but related to total drug dose and effects on pulmonary macrophages, type I and II alveolar cells; effects/lethality exacerbated by the administration of radiation	181-183
Actinomycin-D	Hepatopathy	Altered liver function postradiation leads to decreased metabolism of agents, including actinomycin, which in turn worsens the hepatopathy.	184,185
Doxorubicin	Cardiomyopathy	There is an additive interaction between doxorubicin and radiation with recall of radiation effects occurring. Primary radiation effect is on the endothelial cell, whereas doxorubicin affects the connective tissue stroma of the myocardium.	186-189

Agent	Toxicity	Mechanism	References
Methotrexate	Leukoencephalopathy	Methotrexate may cause this syndrome on its own. Radiation effects on the blood-brain barrier and the choroid plexus can alter methotrexate clearance, leading to higher levels in the brain. Effects are increased when both modalities are used.	190-192
Cisplatin	Sensorineural hearing loss	Although cisplatinum alone can cause this, reports suggests radiation therapy concurrently with cisplatin may contribute to sensorineural hearing loss.	193-196

CONCLUSION

The combination of chemotherapy and RT has become a common strategic practice in the therapy of locally advanced cancers, with emphasis on the concurrent delivery of both modalities. Improvements in treatment outcome in terms of both local control and patient survival have been achieved with traditional chemotherapeutic agents such as cisplatin and 5-FU. However, there is considerable room for improvement of the combined treatment strategies. Selection of the most effective drug or the optimal treatment approach remains a significant challenge.

Newer chemotherapies are becoming available at an increasing rate. These agents have high potential for increasing the therapeutic effectiveness when used in conjunction with RT, and therefore, their evaluation—both in the laboratory and in the clinic, in combination with RT—is essential for improvement of cancer treatment.

Biomarkers, molecular therapeutics, immunotherapy advances, advanced imaging technology, and advances in understanding of effective chemotherapy/immunotherapy and radiation treatment integration have led to an era where personalized medicine for cancer therapy is becoming a reality. There are certainly challenges that we can anticipate along the way toward an era of personalized medicine.

Finally, despite significant improvements rendered to cancer therapy in the past decades, it is sobering to realize that cancer, particularly when

advanced, remains a deadly disease for many. As we continue to engage in novel ideas to further strengthen our arsenal, it will be essential to design well-thought-out and effective combined modality therapy clinical trials to further improve the odds in the battle against cancer.

CHAPTER 32

Artificial Intelligence and Data Science as Applied to Radiation Oncology

Tafadzwa L. Chaunzwa, Danielle S. Bitterman, Christian Guthier, Carl F. Haugg, Benjamin H. Kann, and Raymond H. Mak

As artificial intelligence (AI) technologies are increasingly integrated into both research and clinical facets of oncology, radiation oncologists will need to understand the nuances of AI and its applications. This chapter delves into the foundational principles of AI, its integration within radiation oncology workflows, medical image acquisition, reconstruction and analysis, natural language processing (NLP), advanced modeling of oncology data, and the challenges (ethical or otherwise) and prospects AI presents in radiation oncology. While this chapter provides a comprehensive overview for clinical radiation oncologists and resident physicians, it does not delve into the depth suited for data scientists, engineers/developers, or AI technologists. Advanced readers are encouraged to consult the data science and AI-focused literature for a more nuanced examination of AI methodologies and technologies.

ARTIFICIAL INTELLIGENCE, MACHINE LEARNING TECHNIQUES, AND APPLICATIONS TO RADIATION ONCOLOGY WORKFLOW

Artificial Intelligence Methods and Applications to Radiation Oncology in Perspective

Radiation oncology is undergoing transformative changes. The integration of AI systems, advanced pattern recognition and predictive modeling software, and automation tools into clinical workflows is ushering in a new era of streamlined patient care, adaptive and personalized radiotherapy (RT), and unparalleled innovation and advancement (Table 32.1).

TABLE 32.1 NONEXHAUSTIVE LIST OF COMMONLY USED MACHINE LEARNING AND ARTIFICIAL INTELLIGENCE METHODS AND EXAMPLES OF CLINICAL APPLICATION IN ONCOLOGY

Method	Description	Clinical Application Example
Conventional Machine Learning		
Linear regression	Predicts a continuous variable by fitting a line through data points	Predicting tumor growth rates over time[110]
Logistic regression	Used for classification, predicting the likelihood of an input belonging to a class based on a threshold	Predicting likelihood of cancer recurrence after radiation[111]
Decision trees	Tree-like structures for classification and regression, recursively dividing data based on input features	Selecting the most relevant prognostic factors for accurately predicting breast cancer relapse to assist clinicians in choosing appropriate adjuvant treatments[112]
Support vector machines	Used for classification and regression by determining a hyperplane to separate or predict data	Classifying tissue samples as malignant or benign based on histopathologic features[113]
Random forests	An ensemble of decision trees, mainly for classification and regression	Identifying key biomarkers associated with cancer prognosis[114]
K-means	Unsupervised learning to identify data clusters or patterns	Clustering patients based on gene expression profiles[115]
Deep Learning		
Convolutional neural networks (CNNs)	Analyze visual data like images by applying filters to identify patterns and features	• Auto-segmentation of OARs and tumor targets[68] • Extracting features from images to predict outcomes[49] • Image classification, such as determining tumor histology from digital pathology slide or CT[37]
Recurrent neural networks (RNNs)	Analyze sequential data by capturing and conveying information stepwise, although	Outcome prediction from a time series such as serial follow-up CT scans[48]

Method	Description	Clinical Application Example
	susceptible to the “vanishing gradient” issue in long sequences	
Transformers	Process sequential data using a self-attention mechanism to evaluate element importance, overcoming RNN’s long-range dependency limitations	Extracting various types of clinical concepts from medical text to facilitate downstream natural language processing tasks in the medical domain[116]
Generative adversarial networks (GANs)	Generate synthetic data samples resembling a training data set, using a cyclic process between a generator and a discriminator	Generating realistic synthetic EHRs to overcome limited access to real EHR data and accelerate research in medical informatics[117]
Deep reinforcement learning	Learning through trial and error to make decisions with unstructured data	Image enhancement such as CT reconstruction[56]
Foundation models	Adaptable AI models proficient in handling tasks related to text, audio, and images, capable of learning from labeled and unlabeled data to serve as a base for specialized applications	Integrating textual patient history with medical imaging data for comprehensive diagnostic decision-making[109]
Multimodal models	AI models designed to process and integrate multiple types of data inputs, such as text, images, and audio, for more comprehensive analysis and decision-making	Personalizing prostate cancer therapy by predicting long-term, clinically relevant outcomes using a combination of clinical data and digital histopathology from prostate biopsies[47]
Generative AI	AI algorithms designed to generate new data that mimic the properties of the training data, useful for simulation and augmentation tasks	Creation of personalized patient clinic letters with limited clinical input using LLMs providing high-quality, understandable, and human-like outputs adapted to clinical communication scenarios[118]
Large language models	AI models specifically trained on large amounts of text data to understand and generate human-like text	Utilization LLM to communicate clinical advice or reports to patients[118]

AI, artificial intelligence; CT, computed tomography; EHR, electronic health records; LLM, language learning model

While the term "AI" is used somewhat liberally in the modern literature, the definition and boundaries of AI have been dynamic, shifting as technological advancements were achieved and by preference in the popular media. Current systems mostly fall within a "narrow AI" definition, where models focus on a specific, singular, or limited task, such as image recognition or outcomes prediction but lack self-awareness, consciousness, or the ability to think independently. These models are often trained on vast amounts of data in a supervised, unsupervised, semisupervised, or self-supervised manner, allowing them to accomplish specific tasks on data sets within the same domain (eg, health care or finance) and data modality (eg, natural images or language). "General AI," by contrast, refers to systems that can handle a range of cognitive tasks with little supervision and have the capacity for creativity, novel insight, adapting to new situations to exhibit competence on multiple tasks. These systems would theoretically pass the Turing test for independent human-level intelligent behavior.[1] Current systems do not pass the litmus test for "general AI," and some developers question if this form of artificial general intelligence (AGI) can indeed be realized (Table 32.2).

TABLE 32.2 GLOSSARY OF ARTIFICIAL INTELLIGENCE/MACHINE LEARNING-RELATED TERMS

Term	Definition
API	Application Programming Interfaces that allow different software applications to communicate with each other, commonly used to integrate ML models into software systems
Artificial general intelligence	Hypothetical AI with the ability to understand, learn, and apply knowledge in multiple domains, resembling human cognitive functions
Autoencoder	Unsupervised AI algorithms that learn to encode the important features of data and then decode it, often used for dimensionality reduction or anomaly detection
Back-propagation	Optimization technique to minimize an objective function in a web of nonlinear mappings by calculating the gradient of the loss function in a neural network

Term	Definition
Black box	A model or system where the internal mechanisms or logic is not directly observable or understandable. Often used to describe complex ML models like deep learning (DL) networks
Contrastive learning	An unsupervised learning approach that trains models to differentiate between similar data points, thereby learning useful feature representations from the data
Data augmentation	Techniques used to increase the size and diversity of training data sets through transformations such as rotation, scaling, and flipping, aimed at improving model generalization
Data curation	The process of collecting, organizing, and validating data for use in ML models
Developed from scratch	Refers to developing an AI algorithm without using pre-existing code or frameworks
Digital twins	Virtual replicas of physical systems or processes that are used for simulation, analysis, and control
Dimensionality reduction	Techniques to reduce the number of variables in a data set while preserving its essential features, often used for visualization or to improve model performance
Deep learning	DL is a subfield of ML where algorithms model and process hierarchical complex patterns in data using multiple layers of nonlinear transformations, popularized as “neurons.”
Explainability	The capacity for the logic or reasoning behind an AI model’s decisions to be easily understood by its users
Interpretability	The quality of an AI model that allows users to understand the underlying factors leading to its predictions
Few-shot learning	An ML paradigm that aims to train models to perform well with only a small number of labeled examples for each class, often used in situations where data are scarce
Fine-tuning	The process of adapting a pretrained model to a specific task or data set
Fully connected	In neural networks, a fully connected layer is one where each neuron is connected to every neuron in the previous and next layer.
Generalizability	The ability of an AI model to make accurate predictions when applied to diverse conditions or data sets
Hallucinations	The term is borrowed from psychiatric vernacular to denote model errors related to overconfident incorrect responses or fixed false beliefs by LLMs.

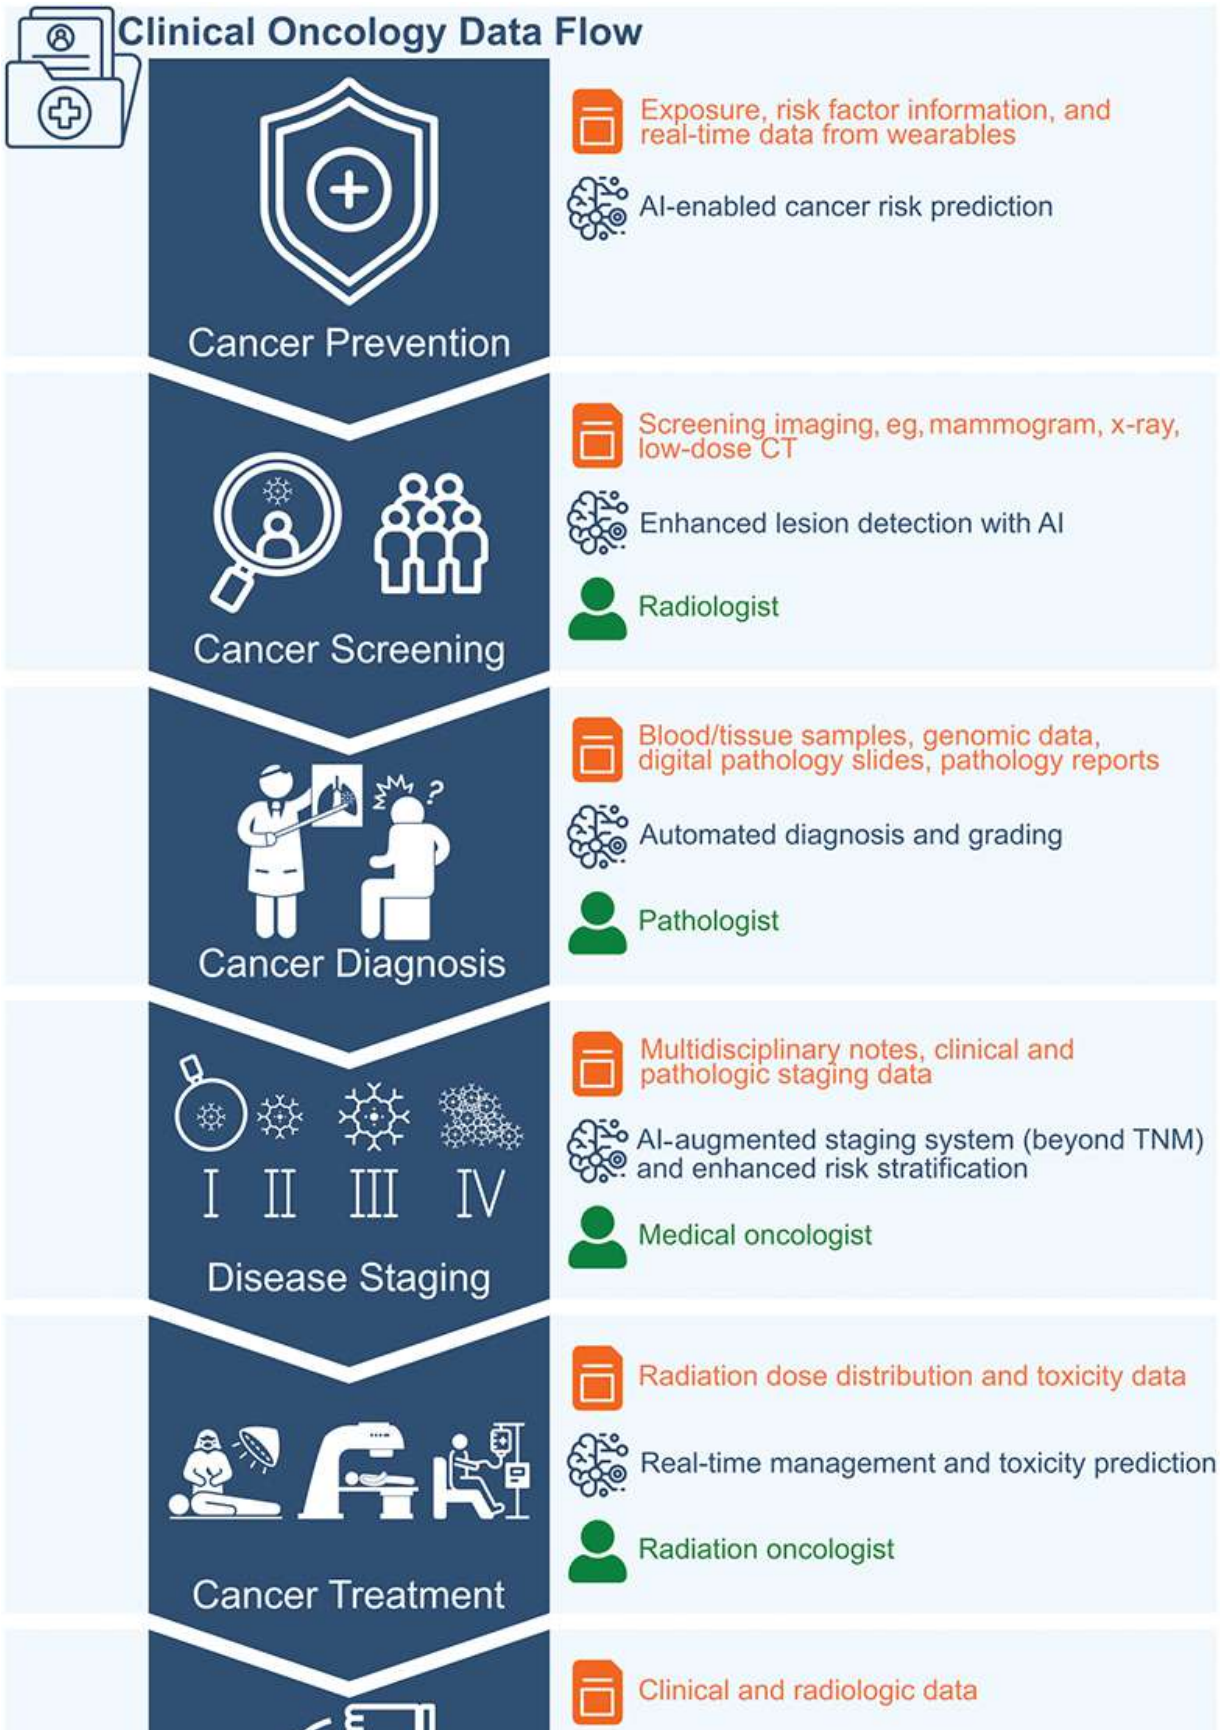
Term	Definition
Multi-GPU multinode data parallelism	A distributed computing setup that leverages multiple GPUs across multiple nodes to parallelize data processing and model training, enhancing computational power and efficiency
Parameters	In ML, parameters are internal variables that the model learns through training. They define the transformations that the model applies to its input data to make predictions or decisions.
Pretraining	Initial training phase where a model learns from a general data set before being fine-tuned for a specific task
Principal components analysis	A statistical procedure that uses orthogonal transformation to convert correlated variables into a set of linearly uncorrelated variables called principal components; often used for dimensionality reduction
Prompts	Short questions or cues used to guide the behavior of language models, often employed to narrow down the focus or topic that the model will generate text about
PyTorch	An open-source ML framework developed on the Python interface and utilized for computer vision tasks
Radiomics	The extraction of a large number of advanced quantitative features from medical images, often used for predicting patient outcomes or treatment responses
Radiogenomics	The study of the relationship between radiologic imaging data and genomic data to predict disease characteristics or patient outcomes
Reproducibility	The ability of a clinical AI model to achieve the same results when applied to new data of the same type
Saliency maps	Visual tools used to highlight regions in an input (like an image) that are most important for a model's prediction, aiding in interpretability
Softmax	A function that takes an unnormalized vector and normalizes it into a probability distribution, typically used in the output layer of a classification neural network to represent probabilities
Supervised learning	A specific type of ML where a model is trained on labeled data. The model makes predictions or decisions based on input data and is corrected when its predictions are incorrect.
Survival models	Analyze time-to-event data with known covariates, predicting survival probabilities or hazard ratios

Term	Definition
T-distributed stochastic neighbor embedding	An ML algorithm used for dimensionality reduction and data visualization; it is often used for embedding high-dimensional data into a space of two or three dimensions.
Transparency	The degree to which the inner workings or decision-making processes of an AI model are open and understandable
Turing test	A test, proposed by Alan Turing in his seminal 1950 paper to evaluate a machine's ability to exhibit human-like intelligence
Unsupervised learning	A specific type of ML that involves modeling with data sets that contain input data without labeled responses. The system tries to learn the patterns and structure from the data without any supervision.
Visual representation learning	A subset of ML focused on training models to understand and generate visual features from raw data, commonly used in image recognition and computer vision tasks

AI, artificial intelligence; CT, computed tomography; EHR, electronic health record; LLMs, language learning models; ML, machine learning; OARs, organs at risk.

Nevertheless, existing methods in narrow AI are seeing widespread adoption in many facets of society and within oncology, accelerating the pace of discovery and automation in clinical workflows (Figure 32.1). Early iterations of these systems, such as, early computer-aided diagnosis systems,[2] were rule based, with programs that followed specific steps handcrafted by experts (often hard-coded) or by engineers with guidance from those with the respective domain expertise (eg, internists or radiologists). While these systems were functional, they had limitations and struggled when encountering situations or data that did not fit their prespecified rules. More advanced techniques for pattern recognition based on neural networks and their foundational architecture were popularized in the late 1980s and early 1990s, with the advent of early models such as the Le-Net.[3] These models consisted of multilayer nonlinear transformations trained with back-propagation, and they vastly outperformed existing techniques at the time. However, early adoption was limited by a paucity of computational power in contemporary processors. This changed in the 2010s with the computing performance offered by graphical processing units (GPUs). Initially designed to enhance three-dimensional (3D) graphics rendering in video games, GPUs evolved to become more flexible and

programmable, paving the way for leaps in machine learning (ML) and opening new possibilities for advanced numerical methods and scientific computing. This facilitated a resurgence in the popularity of convolutional neural networks (CNNs), with these models gaining significant attention and becoming a mainstay in deep learning (DL), especially for image-processing tasks.



Clinical Oncology Data Flow
Cancer Prevention
Exposure, risk factor information, and real-time data from wearables
AI-enabled cancer risk prediction
Cancer Screening
Screening imaging, eg, mammogram, x-ray, low-dose CT
Enhanced lesion detection with AI
Radiologist
Cancer Diagnosis
Blood/tissue samples, genomic data, digital pathology slides, pathology reports
Automated diagnosis and grading
Pathologist
I II III IV
Disease Staging
Multidisciplinary notes, clinical and pathologic staging data
AI-augmented staging system (beyond TNM) and enhanced risk stratification
Medical oncologist
Cancer Treatment
Radiation dose distribution and toxicity data
Real-time management and toxicity prediction
Radiation oncologist
Clinical and radiologic data

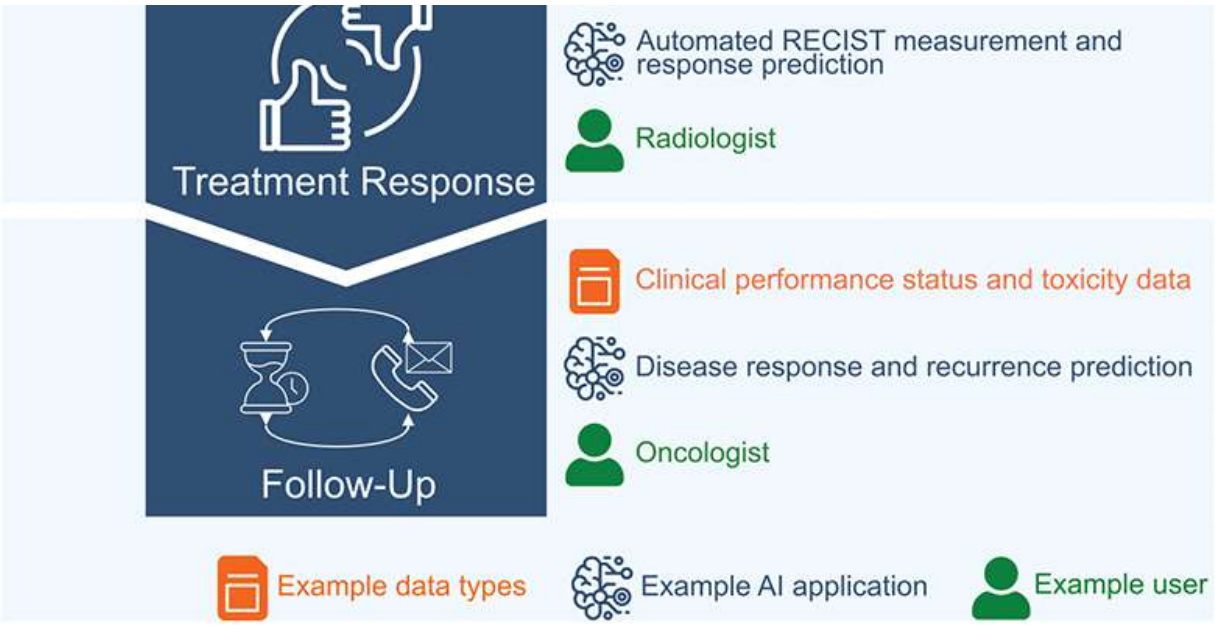


FIGURE 32.1 Clinical oncology data flow. This figure illustrates a prototypical pathway for care of a patient with cancer with an escalating flow of data. It captures a series of critical touchpoints, starting from preventive care, cancer screening, initial cancer diagnosis, disease assessment and staging, primary oncologic treatment, response assessment, and follow-up care. At each step, example data types that are collected, either routinely or as part of advanced care, are listed, along with potential AI applications and example users. The figure illustrates the interface between AI technology and the clinical environment in the delivery of personalized management of oncology patients through their cancer care journey. AI, artificial intelligence; CT, computed tomography; RECIST, Response Evaluation Criteria in Solid Tumors.

The rise of more sophisticated architectures and the availability of large digital data sets (made possible in large part by the internet), coupled with the increased computational power of GPUs over the ensuing decade, accelerated advances in this field. In the domain of NLP, this included the groundbreaking introduction of transformer architectures[4] with the self-attention mechanism. Subsequent iterations, including Generative Pre-trained Transformer (GPT) and GPT-like models, gained widespread adoption and perhaps shifted public perceptions and attitudes toward AI, given seemingly coherent outputs that mimic human language and could mask potential limitations, for example, in oncology domain-specific predictions.[5] The current generation of AI, therefore, presents both exciting opportunities and potential pitfalls with new modes of failure that will require the radiation oncologist to be well versed on their inner workings to

take full advantage of these technologies in the streamlined delivery of cancer care and RT, while effectively minimizing the risk for harm to patients (Table 32.1).

Machine Learning Paradigms in Oncology Data Analysis

ML is a subset of the broader AI domain that offers various methodologies to decipher patterns and make predictions based on data. This field has evolved from simplistic models, such as logistic regression assuming independent input variables, to more advanced algorithms, such as random forest, which can weigh and characterize input variable interrelationships, enabling them to fit more complex data. Current methodologies vary based on the nature and structure of the data, as well as the objective of the analysis. Within different learning paradigms, multiple specific model types can be employed, each relying on different approaches for training and discerning patterns from the data.

In "supervised learning," models are trained on labeled data to predict future instances based on learned features from the data. This approach excels in tasks such as image classification and clinical outcomes prediction. Common examples include regression models to project survival rates from labeled data sets or support vector machines (SVMs) for identifying optimal hyperplanes that separate data classes, for example, in tumor histopathologic subtyping. By contrast, unsupervised learning identifies inherent patterns within unlabeled data, grouping similar instances without explicit guidance. A typical application is in identifying distinct, previously unknown, tumor subtypes using genomic data. Frequently used methods for unsupervised learning include dimensionality reduction algorithms such as autoencoders—a generalized form of principal component analysis (PCA)—and t-distributed stochastic neighbor embedding used widely for visualization of high-dimensional data in the two or three dimensions that are readily understandable to the human observer. "Semisupervised learning" blends supervised and unsupervised approaches, leveraging labeled and unlabeled data for enhanced accuracy. Initially, it utilizes labels to hone a classifier, which subsequently aids in labeling more data, potentially reducing the demand for human annotations.

"Self-supervised learning" operates on unstructured data by automatically generating labels. It might train a model to predict missing sections of an image or masked words in a sentence, honing its capability to learn generalizable features about that data type that can be employed to improve performance on downstream tasks, such as segmentation or classification. Variations or augmentations are often introduced to unlabeled data, teaching the models to identify inherent features from the data. In recent years, unsupervised algorithms, for example, for visual representation learning, have shown better performance and improved robustness to perturbation than supervised approaches.[6] This has been largely driven by the paradigm of contrastive learning, where representations are learned by contrasting negative and positive examples. Contrastive learning has shown great promise in extracting high-level features from volumetric tumor information.[7] Finally, "reinforcement learning" employs an iterative feedback system where a model learns optimal actions through rewards and penalties, analogous to a cat refining its jump based on previous experience. These algorithms shape strategies that yield the most advantageous outcomes, finding applications in domains ranging from gaming to potentially streamlining radiation treatment planning.

Overall, each ML paradigm serves specific needs, guiding the choice of method for various tasks. Of note, a recent shift in the ML community toward creating large general-purpose models that can be fine-tuned for specific tasks rather than training separate models for each task has led to the concept of "foundation models." These models are pretrained on vast amounts of data in a self-supervised, task-agnostic manner to capture a broad understanding of language, images, and other data types and can be adapted to specific tasks with relatively small amounts of task-specific data. Foundation models open exciting new avenues for biomarker discovery in cancer imaging[8] and other applications. However, questions on whether ML models generalize even with such broad training remain.

Advances in oncology research, increased data generation in clinical practice, and computational innovations have shifted the way patient data are represented from a low-dimensional to a high-dimensional framework. Historically, due to data and computational constraints, patient data, such as diagnostic imaging and pathology, were simplified into digestible measures,

such as the American Joint Committee on Cancer TNM cancer staging system for decision management in clinical oncology. However, the introduction of electronic medical records (EMR), The Cancer Imaging Archive, The Cancer Genome Atlas, and others have enabled the development of more complex risk stratification models. These models, combined with the expanding data streams through EMR mining, allow for detailed profiling of patients as they progress through the cancer care pathway (Figure 32.1). With expanding data availability in oncology, ML algorithms can be employed for the advanced modeling of oncology data to identify patterns that could help guide treatment decision-making for specific patient groups or individual patients. This convergence of comprehensive data and precision in care underscores the potential of AI and ML techniques in revolutionizing oncology, although their full promise remains to be realized.

Artificial Intelligence and Machine Learning Applications to Radiation Oncology

As an inherently technology-driven specialty, with frequent use of radiologic imaging, repetitive protocol-driven tasks such as target delineation and treatment planning, and the generation of vast amounts of digital, quantitative, and multimodal data, radiation oncology is a field ripe for AI applications (Figure 32.2). However, current AI tools in radiation oncology are predominantly designed for singular tasks like segmentation. This presents integration challenges in clinical workflows. Holistic approaches, embedding these AI solutions within existing systems, can enhance workflow efficacy and user acceptance.

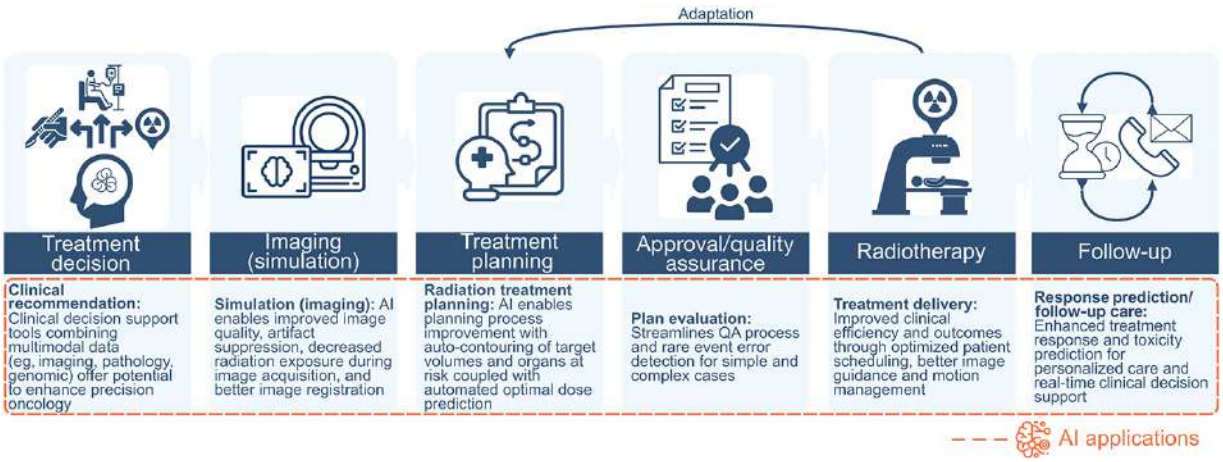

FIGURE 32.2 Integration of AI in radiation therapy workflow. This figure shows the stages of the radiation therapy workflows and highlights corresponding areas where AI can be integrated to enhance each step. The process starts with a treatment decision where a clinical recommendation regarding radiation therapy is made, leading to simulation where patient anatomy and imaging data are acquired for treatment planning. Following the generation of a tailored treatment plan, meticulous plan review and QA protocols are followed prior to the delivery of radiation. Follow-up care includes response assessment and toxicity management. AI applications can potentially augment operational efficiency for radiation oncology care team, improve the precision and quality of radiation treatments, and enhance predictive and prognostic modeling to inform and refine decision-making. AI, artificial intelligence; QA, quality assurance.

AI in radiation oncology already offers potential efficiency improvements, notably in auto-segmentation and auto-planning (Figure 32.3). However, its role in direct clinical decision-making is still limited. To bridge this gap, radiation oncologist training in AI is essential to promote collaboration between clinicians and data scientists, build trust in these technologies as they evolve, and optimize several steps within the radiation oncology workflow.

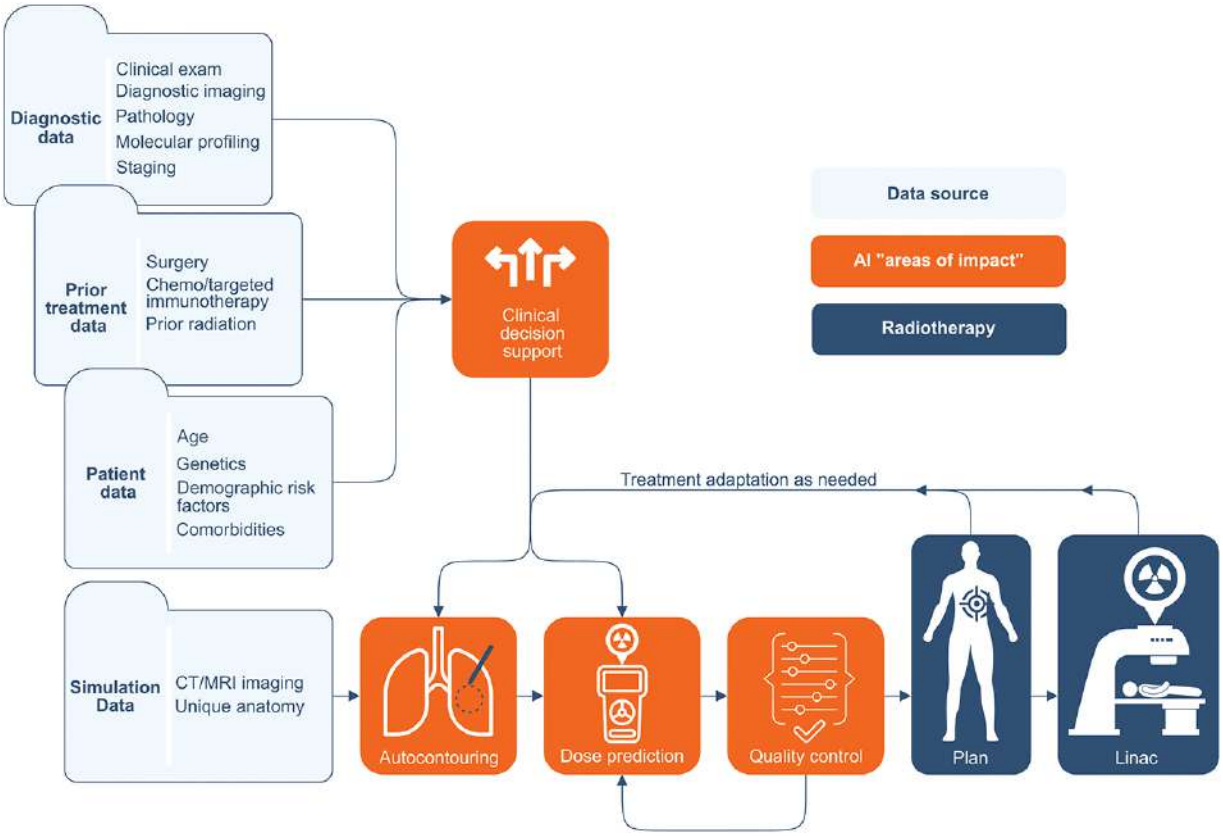

FIGURE 32.3 Utilizing artificial intelligence (AI) in radiation therapy planning and delivery. This figure shows the multiple data sources utilized in radiation therapy decision-making, planning, and treatment delivery, highlighting areas where AI can be meaningfully integrated. The key data sources include diagnostic data, prior treatment information, patient-specific data, and simulation data. Simulation data are typically collected in the later stages of the process. AI assists in tasks like treatment decision, auto-contouring and dose prediction, and quality control. A radiation treatment plan is then formulated and delivered. The plan can be adapted as needed over the course of a patient's treatment. AI can assist in real-time treatment adaptation to enhance efficiency and precision. CT, computed tomography; MRI, magnetic resonance imaging.

The RT workflow can be parsed into several key steps: initial treatment decision, treatment planning, quality assurance (QA), the delivery of RT with on-treatment monitoring, and post-treatment follow-up care (Figure 32.3). The following subsections provide an in-depth exploration of each step, highlighting the key tasks, stakeholders, and innovative ways in which AI can enhance these processes.

CLINICAL INFORMATICS, NATURAL LANGUAGE PROCESSING, AND LARGE LANGUAGE MODEL APPLICATIONS

NLP is a subdomain of AI that seeks to transform human language into formats that computers can analyze, offering a method to extract valuable information from text (Figure 32.4). Current iterations of this technology can improve our comprehension of multiple data sources, including information stored in the EMR. In radiation oncology, NLP algorithms offer a promising avenue for enhancing several aspects of care and research, for example, by refining patient data management and presentation, automating radiation oncology data integration into cancer registries, and uncovering new insights into cancer treatment and outcomes.[9] However, several hurdles exist to realizing NLP's full potential in radiation oncology. This includes inconsistent naming conventions in radiation oncology (eg, in contoured treatment planning structure sets, requiring efforts to standardize naming conventions and generate radiation oncology ontologies that map, integrate, and query radiation oncology data from various sources[10,11]), specialized radiation oncology terminology or jargon that pretrained models may not be able to handle, the scarcity of publicly available labeled radiation oncology– specific data sets for model training, and integration challenges across data systems, particularly given the prevalence of radiation oncology data silos across health systems.

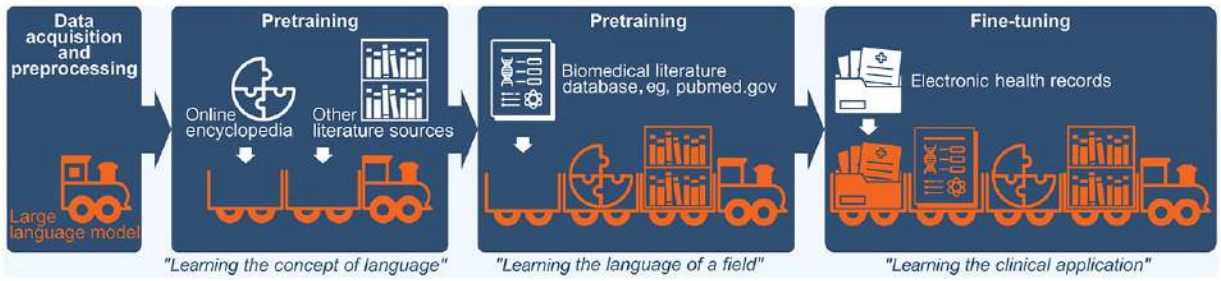

FIGURE 32.4 Language learning model (LLM) training for clinical applications. This figure illustrates the stages of training an LLM, each represented as a train stop on the model's journey through training. The first stop is Pretraining on general literature sources such as online encyclopedias to help the model learn the concept of language. The models then go through a second Pretraining phase focused on biomedical literature databases, such as PubMed, to enable it to learn clinical domain-specific language. Finally, the model goes through Fine-tuning, where it is fed clinical text from electronic health records to adapt to a specific clinical application. Each phase enhances the model's abilities, from understanding language fundamentals to becoming adept at specialized clinical tasks.

NLP pipeline evaluation and implementation in radiation oncology remains limited, although some applications are beginning to emerge. An open-source NLP platform, Apache Clinical Text Analysis Knowledge Extraction System, demonstrated an ability to extract toxicity data from unstructured notes from RT on-treatment visits, outperforming human interrater variability for positive symptoms.[12] The pipeline, however, underperformed against humans in negative instances. Some small studies have investigated using NLP to standardize planning structure naming from inconsistent physician-assigned labels of prostate and lung organs at risk (OARs) with TG-263 standardized terms.[13,14] The model attained high F1 scores on both internal validation and external test sets for each organ.

More recently, emerging work shows the potential of fine-tuning neural language models with transformer architectures to support RT (Figure 32.4). An end-to-end pipeline of fine-tuned pretrained language models demonstrated strong performance in extracting comprehensive details of patients' radiation treatments from clinical notes.[15] Similarly, fine-tuned language models showed excellent performance in extracting radiation esophagitis toxicity severity in patients with lung cancer.[16] However, performance dropped when applied to patients with esophageal cancer, highlighting the common challenge of domain transfer with language models. These early studies demonstrate the potential of neural language models to support real-world databases and electronic health record (EHR) mining.

Increases in computational power and pretraining data set size have led to the development of current state-of-the-art large language models (eg, those based on DL transformer architectures and trained on extremely extensive data from the internet). Language learning models (LLMs) are generally over 6 to 13B parameters in size, and the most state-of-the-art LLM, such as OpenAI's GPT-3.5, is 137B parameters in size. There is growing interest in LLMs, including expanding use by the general public. While earlier generations of language models required fine-tuning on task-specific data to carry out NLP tasks, LLMs exhibit emergent abilities to process and understand language without additional fine-tuning. This is especially exciting for the medical domain, where labeled data sets of clinic notes are scarce, and data and model sharing are limited by patient privacy concerns. In fact, LLMs appear to learn a representation of biomedical and clinical

knowledge during their pretraining and have been shown to pass the USMLE.[17] The fact that LLMs can provide coherent responses with no updates to their parameters has created a new emphasis on prompt engineering, which is designing optimal methods to elicit the correct response from LLMs. For example, providing examples of correct input/output along with the query (few-shot) can improve performance in some cases. More consistently, instructing the LLM to lay out its reasoning via Chain-of-Thought prompting, that is, "think step by step," boosts LLM performance.[18] Automated prompt refinement is an actively evolving field. It is important to note that prompt engineering, which is the process of developing and refining how to prompt the LLM to provide a response, is not trivial and can be time-, compute-, and data-intensive.

Given the rapid adoption of LLMs, work evaluating the models' utility in oncology is of high priority for both oncology practitioners and patients. Limitations, particularly in oncology domain-specific knowledge, can pose a risk for radiation oncology patients seeking information about their disease and treatment options.[5] Moreover, the propensity for "hallucinations" in model outputs can potentially undermine oncologist recommendations and also limit the models' clinical utility if clinicians cannot ascertain the accuracy of the outputs and recommendations. However, there have been attempts to tailor LLMs with oncology-specific knowledge to construct models that can be more reliably used in clinical practice. One such attempt, RadOnc-GPT, aimed to demonstrate potential in three primary areas: formulating RT treatment plans, deciding the best radiation treatment approaches, and assigning diagnostic descriptions and *International Classification of Diseases* codes based on patient information.[19] Other exploratory clinical language model examples include GatorTron,[20] which was developed from scratch using clinical text and showed a more than 9% improvement at tasks such as medical question answering; ClinicalBERT;[21] and OncoBERT,[22] which is tailored for oncology applications. OncoBERT was designed to predict cancer outcomes by analyzing unstructured clinical notes about three distinct cancer types: brain, prostate, and breast. Compared to general language models, the fine-tuned model outputs were clearer, more specific, and more likely to be clinically pertinent. These examples highlight the

transformative potential of domain-specialized language models in clinical oncology.

Health disparities persist, and research into the etiologies of these disparities in cancer care is often limited by the challenge of analyzing unstructured clinical data that are often asymmetrically recorded, particularly with regard to sociodemographic factors. NLP can transform human language into analyzable formats, unlocking insights from such data. Analysis of unstructured clinical notes using NLP may help uncover Social Determinants of Health (SDoH) that contributes to disparities in cancer care and outcomes.[23,24] The development of NLP tools also promises enhanced access to clinical trials for marginalized populations and improved communication in health care settings.[25]

NLP systems are poised to become increasingly integrated into the EMR, offering several potential benefits to clinical practice. If fully realized, these technologies could streamline the radiation oncology workflow by automatically generating oncologic histories, standardizing radiation oncology naming conventions, enhancing QA in treatment planning, and facilitating research via EHR mining for real-world evidence. In addition, as NLP evolves, it may play a direct role in patient care through interactive generative LLMs (eg, OpenAI's ChatGPT) that provide guidance, assist with minor toxicity management, and even match patients to suitable clinical trials.

However, rigorous and nuanced interrogation of NLP systems will be crucial before the clinical integration of the models. The models must be appropriately evaluated for their specific patient populations and end-use to avoid inaccuracies and resultant medical errors. For instance, misinformation in public sources, particularly in critical domains like breast oncology,[26] can adversely influence the outputs of language models. It is, therefore, vital that language models capture accurate information in the training phase to be reliable sources of oncology recommendations and mitigate the propagation of any biases from the training data that could disproportionately impact marginalized groups and potentially cause harm. Moreover, radiation oncology is continually evolving, and the knowledge or guidelines from any given period may diverge from future accepted practices. Accounting for these potential shifts in clinical knowledge may pose an intractable challenge in model training, fine-tuning, and evaluation

processes. Outputs from locked language models trained on older data, even within a year, may not reflect accepted practices in contemporary clinical scenarios. As such, there will be a need for an iterative and continuous process to train and fine-tune state-of-the-art language models on fresh data to produce outputs mirroring the latest insights and recommendations. In this context, continuously learning AI systems may seem ideal; however, these systems would also present their own set of challenges, particularly with regard to regulatory oversight, for example, Food and Drug Administration (FDA) approval (if interfacing with patients or leading to clinically meaningful interventions). More work is needed to understand the extent of biomedical knowledge represented in LLMs and how to elicit correct clinical responses.

Going forward, research studies on NLP will need to provide clarity on metrics or evaluation criteria used to quantify errors, elaborating on the benchmarks or standards determining clinical reliability to aid the broad clinical and data science community in contextualizing conclusions about the models' clinical utility. Studies must have a robust methodology that accounts for factors such as potential temporal disparities in information. To the extent possible while protecting patient privacy, it would be ideal for clinically applied NLP models to be available open source so that the clinical AI/computer science community can access model parameters and have the capacity to thoroughly evaluate and fine-tune models.

RADIOMICS AND IMAGING-BASED RISK PREDICTIONS

Traditionally, radiation oncology clinical workflows and oncology research have relied on human visual interpretation for clinical imaging studies, which is often subjective. However, advances in medical image analysis have introduced concepts such as radiomics, which uses mathematical formulas applied to image pixel (or voxel) intensity values to quantitatively analyze images, extract features, and uncover patterns not discernible to the human observer.[27] Radiomic features can then be coupled with statistical and ML models to predict a number of outputs, including disease outcome, survival, toxicity, or, in the case of radiogenomics, underlying tumor genomics. These modern techniques provide objective and precise

quantitative imaging descriptors, holding potential as noninvasive biomarkers and clinical decision-making tools across various cancer types.

Radiomic investigations in radiation oncology ideally follow a systematic approach to ensure the validity and utility of the developed models. First, researchers identify the clinical question and hypothesis, asking if the problem is suitable for radiomics and if radiomics is essential for the specific clinical problem. Key steps during this phase include defining the study end points, setting the benchmark for current standards, and understanding how the model's implementation will impact clinical decisions. This is followed by meticulous data collection and curation, including choosing the best imaging modality, labeling and annotating the data, and performing quality checks. Image preprocessing can include suppressing unwanted artifacts, enhancing essential features, and ensuring consistent imaging data across all samples. Knowledge of scanner models, pixel resolution, postacquisition algorithms, and other parameters is required for image preprocessing. Feature selection then allows researchers to decide which radiomic features to use (from a range of shape, first order, and texture features), considering their consistency and stability across various test scenarios. Dimensionality reduction methods such as PCA and least absolute shrinkage and selection operator are often employed for this step. When features are selected, the best ML technique is chosen, taking into account data set size, outcome variable type, feature number, and available computational resources. The model is then trained, validated, and benchmarked to evaluate its performance against the standard of care. Postvalidation assessment is vital, emphasizing feature importance, model generalizability across different patient groups, stability testing, and analysis of model failures. This rigorous roadmap ensures that radiomic models are accurate, reliable, and clinically valuable. These methods have been implemented to decode imaging phenotypes noninvasively using images.[27] A generalized summary of DL/ML model development is shown in Figure 32.5.

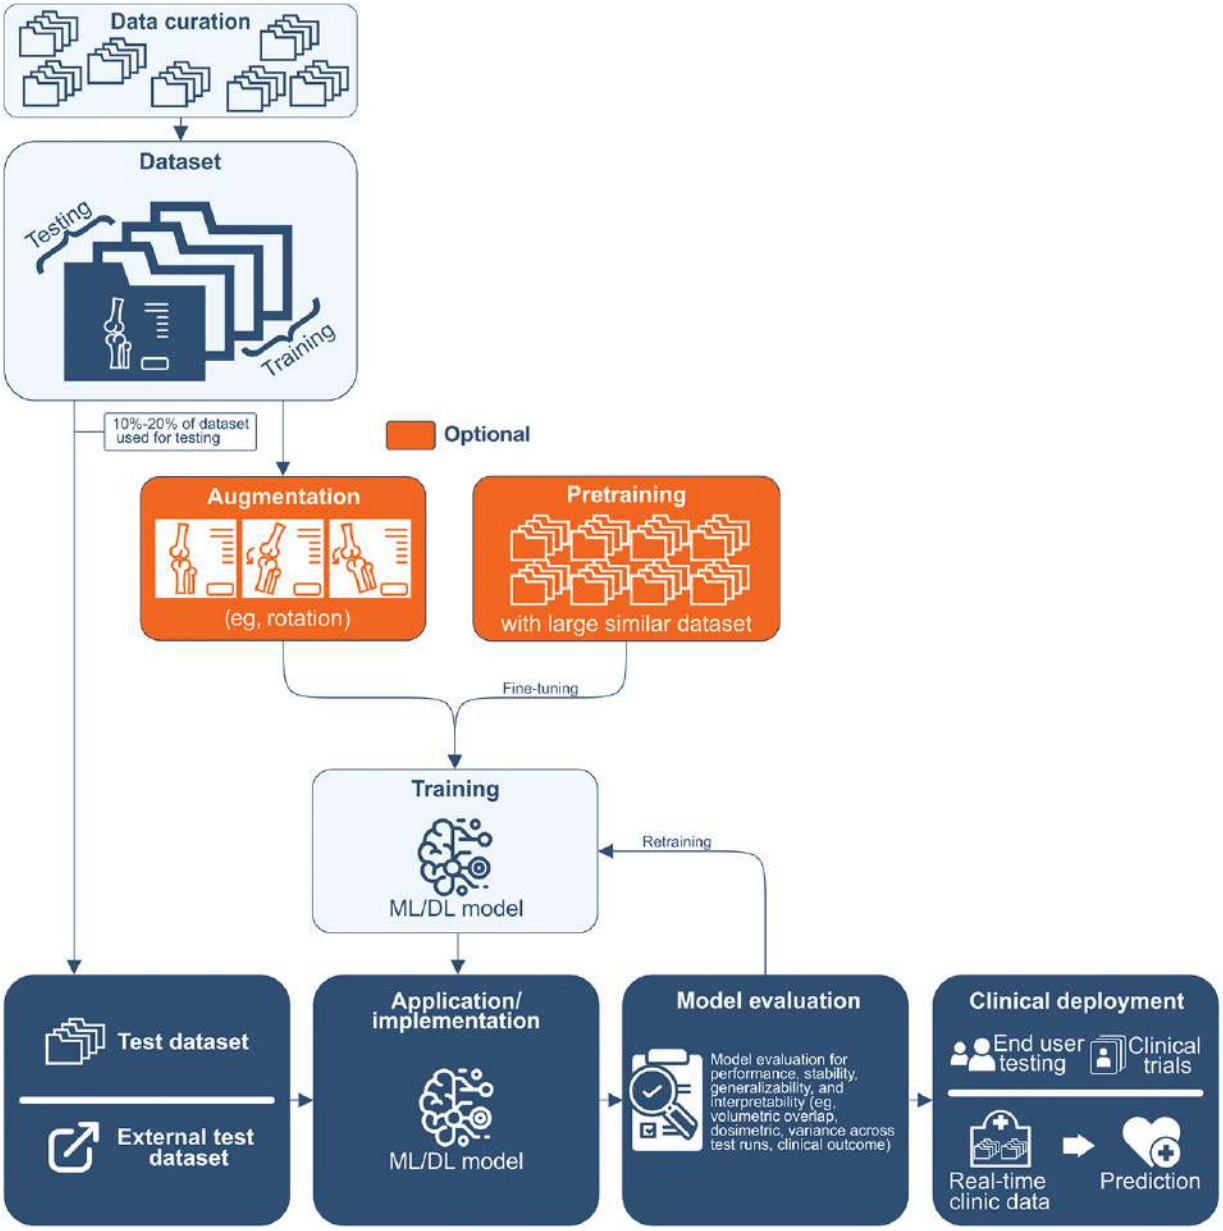

FIGURE 32.5 Comprehensive DL/ML model development and development for clinical applications: This figure presents a detailed schematic for the DL/ML model development pipeline, highlighting key phases from initial data handling to final clinical application. The process begins with a "train-test split," in which the data set is divided into training and validation subsets, ensuring the model can be tested against previously unseen data. An optional "data augmentation" step follows, where the training set may be artificially expanded to improve model robustness. The "pretraining phase" is illustrated as an initial step to initialize the model weights, which can be particularly beneficial for DL models. The core of the pipeline is the "model training" phase where the algorithm learns to identify patterns within the data. Following training, the model is evaluated using a "held-out" test data set as well as any external test samples to assess generalizability. This evaluation may initiate a feedback look of "retraining" and "fine-tuning" to refine the model based on performance metrics Once the model achieves satisfactory performance, it can then the

deployed for clinical use, for example, in trials. End user testing ensures usability and effectiveness in a clinical environment. DL, deep learning; ML, machine learning.

Dosiomics is a recent advancement within the radiomics field, focusing on the radiomic analysis of 3D dose distribution data from radiation treatment plans. Unlike traditional models, which rely on dose-volume histograms (DVHs) and normal tissue complication probability, dosiomics offers a more reliable and granular voxel-level method to predict radiation treatment-related toxicity and prognosis. This is achieved by integrating spatial and statistical data from the 3D dose distribution, capturing spatial relationships between doses at the voxel level.[28] Methods utilizing dosiomic features were first used to predict gastrointestinal (GI) and genitourinary (GU) toxicity following RT for prostate cancer with improved predictive capacity compared to conventional methods (eg, DVH and clinical parameters), particularly with regard to GI toxicity.[29] Subsequent studies demonstrated the utility of dosiomic analyses in predicting radiation pneumonitis in patients with non–small cell lung cancer (NSCLC) receiving stereotactic ablative radiotherapy (SART) and xerostomia in patients with head and neck cancer treated with radiation.[30,31] This predictive value was noted to be driven by texture-based radiomics features. Dosiomics has also been implemented to predict weight loss in patients with NSCLC treated with RT[32] and as a prognostic indicator in radiation oncology patients. Dosiomic features from CT enhance the capability to stratify risk for biochemical recurrence in prostate cancer treated with intensity-modulated radiation therapy (IMRT), outperforming traditional models.[33] Models combining dosiomic features with positron-emission tomography (PET) and CT characteristics outperformed conventional radiomics at predicting local recurrence in patients with head and neck cancer receiving radiation.[34] Dosiomic signatures emerged as a reliable predictor for local control in rare tumors such as skull-base chordomas treated with heavy ion therapy.[35] Moreover, a combination of dosiomic features and treatment plan parameters using ML methods was shown to improve prediction for the γ passing rate in a large sample of patients undergoing complex treatment using volumetric modulated arc therapy.[36]

While image analyses have historically relied on manual annotation and explicit extraction of hand-crafted features based on predefined

mathematical representations from imaging data, recent studies have shifted toward learned features obtained automatically from raw imaging data using DL models, such as CNNs.[37] For example, autoencoders—unsupervised CNN variants—can compress image content into a concise yet representative feature vector using a series of single-layer neural networks trained to detect image structures pertinent to classification problems. The extracted abstract features can be used for classification either within the neural network (fully connected, softmax) or processed using conventional ML classifiers like decision trees, SVM, or regression models. These techniques can overcome challenges associated with the often-demanding workflows, the need for manual or semiautomatic lesion annotations, insufficient feature standards, and multicenter validation. For example, conventional radiomic approaches (eg, using the PyRadiomics platform) would require volumetric segmentations for feature extraction, while DL-based methods may only need a single click seedpoint to localize to the structure of interest[37] or operate on unsegmentated data entirely. By obviating the need for manual segmentation in imaging analyses, DL approaches may be more practical, generalizable, and clinically useful than their traditional radiomic counterparts. DL/ML-based techniques are increasingly utilized for radiomic analyses and automated image segmentation tasks relevant to radiation oncology. Several studies have demonstrated the utility of DL-based approaches to automatically localize and contour primary and metastatic intracranial tumors for RT planning using advanced multisequence magnetic resonance imaging (MRI).[38,39] Moreover, DL-based dosiomics has also shown promise and can outperform the conventional approach.[40]

Beyond abstract feature analysis, AI methods also have the capacity to accelerate the analysis of images in various lines of investigation related to radiation oncology and help uncover new insights into disease prognosis based on clinical imaging data to inform treatment decision-making. Automated sarcopenia assessment using AI pipelines, for example, for patients with head and neck squamous cell carcinoma receiving primary RT, can inform treatment decisions and triage of patients receiving RT.[41] AI-derived body composition from CT data can also predict outcomes and toxicity in patients treated with immunotherapy, which is increasingly offered to patients receiving radiation treatment.[42] Computer vision methods

have also been used for automated patient data cleaning by standardizing RT organ labeling for patients with prostate or head and neck cancer.[43]

CURRENT CHALLENGES IN COMPUTER VISION MODEL DEVELOPMENT

Most DL models implemented for computer vision and clinical tasks are often trained in a supervised manner. While supervised learning has proven valuable in numerous applications, it comes with inherent limitations. One of the primary challenges is the extensive manual annotations required, which can be both time-consuming and costly. Linear algebra principles would dictate that as model complexity increases, more data are necessary to train it effectively and prevent overfitting. Annotation quality can vary significantly, with instances where the designated "ground truth" might even be inaccurate. Furthermore, training on specific data types can introduce bias, making the models more apt to a particular annotator's style, acquisition method, or domain, resulting in overfitting with diminished generalization capabilities. Certain data types, like thick slice images, are often challenging for manual annotation. Anatomic changes, such as the growth of a lesion, may be difficult to annotate accurately, even when using high-quality data sources. Moreover, supervised models often lack robustness, becoming overly sensitive to minor changes or perturbations in the input data, compromising their accuracy and dependability. Imbalanced data sets, where one class far outnumbers another, can be problematic for supervised models. Such imbalances can lead to predictions that are biased toward the majority class. Furthermore, conducting longitudinal assessments using these models poses its own set of challenges. An approach that offers a possible solution to these challenges is self-supervised learning. In self-supervised learning, a model is trained without explicit labels. Instead, it predicts parts of its input based on other parts of the same input. This method leverages unlabeled data, which are often more readily available than labeled data. Foundation models for medical image analysis and visual representation learning pretrain on large-scale medical imaging data sets in a task-agnostic manner to capture generic visual patterns. They are then fine-tuned on a specific task, allowing for more

robust and accurate predictions even with limited task-specific labeled data (Figure 32.5).

With the growth in clinical AI applications to medical imaging, there is a need for standardization in model development and evaluation. There is also a need for community collaboration to ensure solutions meet real-world demands, have flexibility and portability, and are scalable. Medical Open Network for AI (MONAI) is one such open-source framework tailored for DL applications in biomedical imaging. It aims to establish a collaborative platform for academic/clinical researchers and industry and is built on PyTorch (an open-source ML framework developed on the Python interface and utilized for computer vision tasks). The framework offers flexible preprocessing for multidimensional medical imaging data, compositional and portable application programming interfaces, domain-specific implementations for networks, and evaluation metrics. In addition, MONAI supports a customizable design suitable for various user expertise levels and provides multi-GPU multinode data parallelism capabilities. The MONAI Model Zoo is a repository where researchers and data scientists can access and contribute cutting-edge models. The use of the MONAI Bundle format simplifies the integration of these models into MONAI-based workflows. Another platform that seeks to enable data scientists and clinical AI researchers to develop and share generalizable and portable AI model implementations is Modelhub.ai. This is a National Cancer Institute/National Cancer Institute-supported repository of DL models sourced from contributions by the scientific community and highlights current trends in DL, focusing on reproducible AI.

PATIENT JOURNEY

Workup and Treatment Decision-Making

Intake and comprehensive patient evaluation are the initial steps in the RT workflow. Traditionally, the radiation oncologist evaluates the patient's symptoms and clinical history, performs a physical examination, and evaluates a wide range of clinical data and diagnostic tests, including pathology, radiology, genomic data, and potential risks associated with RT. After aggregating and synthesizing this broad range of data, a treatment plan is proposed by the clinician. However, the rapid accumulation of

medical data coupled with the growth in patient volume presents a mounting challenge for radiation oncologists. AI can be a powerful tool for automatically interpreting clinically relevant data to provide real-time clinical decision support at initial consultation. AI-driven methods for medical image analysis and NLP tools for processing large amounts of data from the EMR have shown promise in this domain. For instance, utilizing AI to identify the presence of extranodal extension on pretreatment imaging can guide decisions regarding adjuvant treatment escalation in patients with head and neck cancers.[44] Similarly, quantitative methods have been used to predict response in patients undergoing chemoradiotherapy for NSCLC with the potential to reshape therapeutic strategies.[45] Moreover, AI tools for noninvasive pathology prediction may help guide clinical decision-making in cases where tissue sampling may be clinically contraindicated.[37]

AI applications to digital pathology have emerged as well,[46] and AI algorithms have been developed to quantify relevant histopathologic features and automate risk prediction. A multimodal DL-based prognostic biomarker, ArteraAI Prostate Test, predicts long-term outcomes for localized prostate cancer using digital pathology and patient clinical data.[47] The model was developed and validated using a large sample of phase III randomized data (including the RTOG 9202, 9408, 9413, 9910, 0126, 0521 trials) and outperforms current national consensus guidelines risk groups at risk-stratifying localized patients with prostate cancer using multiple end points, such as distant metastasis, biochemical failure, prostate cancer–specific mortality, and overall survival (OS). It is currently implemented as a clinical decision aid, specifically guiding decisions regarding the use of androgen deprivation therapy in patients with localized prostate cancer.

In addition, AI models could enhance cancer prognostication and help predict radiation treatment response[48] and outcomes.[49] In addition to risk stratification based on tumor features, AI can also assist clinicians with quantitative assessment of baseline patient health to better inform treatment selection.[50] For example, DL-based, automated body composition measures can identify patients with sarcopenia who may be at higher risk for toxicity[41] or automated cardiac health assessments via DL-based quantification of coronary artery calcium can identify individuals who may be at higher risk for cardiac toxicity.[51] Furthermore, innovative analyses, including analysis of natural images of the face acquired before radiation

treatment in patients with advanced cancer, could provide invaluable insights into oncology patient baseline health and prognosis, to inform clinical decision-making with regard to palliative treatments.[52]

Shared decision-making in cancer care relies on the patient and physician reviewing the best available evidence with the patient supported to make informed preferences. AI can enable shared decision-making in radiation oncology practice by assisting in synthesizing vast amounts of medical literature, clinical studies, and patient data to provide up-to-date and relevant evidence to all stakeholders, offering personalized recommendations pertinent to the patient's unique risk profile and biology, and bias mitigation through the generation of objective and data-driven insights. Although their seamless integration into standard clinical practice has not yet been fully realized, AI models promise to advance different facets of clinical decision-making in radiation oncology.

Radiation Treatment Prescription

Before finalizing the treatment strategy, the radiation oncologist determines the radiation dose targeting the tumor and sets constraints for adjacent OARs, grounding their decisions in national standards and clinical trial outcomes. However, significant variations in tumor biology influence radiation sensitivity, even within the same cancer type or patient. The spatial location of the tumor in relation to OARs can also pose challenges, often rendering the desired treatment dose unattainable. Compounding the problem, these limitations are often realized late in the planning process. Al can be leveraged to address this challenge by both predicting a tumor's sensitivity to radiation and determining an achievable optimal dose based on tumor characteristics and OARs.[53,54] Both applications facilitate a shift toward personalized RT.

Radiotherapy Simulation

AI has the potential to transform the simulation process, which in the modern era, often includes complex immobilization and multimodality (eg, CT, MRI) image acquisition followed by image reconstruction, processing, and registration. The simulation process can be complex depending on patient- and body site–specific factors and anatomy, requiring significant

collaboration between radiation oncologists, radiation therapists, and medical physics. For example, collision between the patient or immobilization devices and treatment machines could occur if special consideration is not paid to patient-specific parameters such as any unique anatomy and how this might interact with the intended treatment beam angles. There is the potential for AI to anticipate these issues during the treatment simulation phase based on preexisting anatomic knowledge sourced from diagnostic imaging or other ancillary data.[54,55] This could expedite and optimize the planning process.

Optimal image quality for tumor targeting is also paramount, and AI algorithms based on deep reinforcement learning have been used in CT image reconstruction (as a parameter tuning policy network) and achieved image quality similar to or better than images reconstructed using manually tuned parameters.[56] Further examples of AI applications for image enhancement include the reduction of noise and metal artifacts.[57]

Postsimulation Image Processing

After acquisition of scans during simulation, postprocessing will include registration of simulation scans and diagnostic imaging if needed. Historically, CT scans are most commonly utilized, given the need for electron density information for dose calculations. Scans are typically acquired in the treatment position for CT simulation. Other modalities, such as MRI and PET scans, are also obtained for enhanced tumor delineation, and these ancillary imaging modalities are still most currently obtained in diagnostic imaging studies (eg, diagnostic MRIs for central nervous system [CNS] cases or PET scans for lung cancer delineation), which may have been obtained with the patient in different orientations. This introduces uncertainty when attempting to co-register these studies for target delineation.

AI can generate synthetic CT images from MRI from several sites, including the pelvis or the CNS, with modest deviation from ground truth CT electron density.[58,59] This suggests the potential utility of AI-derived synthetic CT in treatment plan generation. Another creative application has been to generate synthetic CT from non–attenuation-corrected PET with results that qualitatively and quantitatively resemble CT.[60] These methods

could effectively reduce uncertainty introduced by acquiring and registering multiple different scans, streamline clinical operations by reducing the number of imaging appointments for patients, and minimize patient radiation exposure from CT scans.

Another potential AI application is to improve image registration. Automatic image registration is crucial in radiation oncology; however, conventional methods can be slow and lack precision. Standard commercial algorithms for image registration have predominantly been designed to perform well only for modality-specific registration tasks. One considerable limitation of these algorithms is their sensitivity to image artifacts, which can compromise their accuracy and often necessitate manual corrections to achieve clinically acceptable registration. This demands additional labor and potentially introduces human error, making the registration process less efficient.

A salient feature of AI-based registration tools is their adaptability across different imaging modalities—a departure from the traditional modality-specific algorithms. Improved generalizability also allows for more reliable implementation across data types within different systems, which may make them more desirable for standardizing the registration process in the setting of multi-institutional trials. Moreover, AI tools have been shown to mitigate the impact of both motion and image artifacts on registration. For instance, AI tools have been shown to reduce distortion and registration inaccuracies that may be introduced in x-ray images of the spine that contain metal artifacts.[61] These methods have been implemented for image registration across various modalities, including MRI, x-ray, CT-MRI, and MRI-PET. While many of these algorithms were not developed initially with RT in mind, they address issues that are similarly encountered in this domain. Consequently, there is potential for these algorithms to enhance the workflow within RT.

Recent years have seen the integration of what was previously thought to be fundamentally incompatible technologies in combining MRI scanners with linear accelerators to achieve MR-guided Linac systems. Fundamental challenges were presented by the magnetic field's interference with radiation beams and the linear accelerator's potential to induce magnetic artifacts. Moreover, diagnostic quality MRI requires extended times for high-resolution low noise image and sequence acquisition, which would

take from the practicality of this modality in efficient treatment planning and delivery. As some of the measures implemented to circumvent these challenges, low-field strength magnets, typically ranging from 0.35 to 1.5 T have been utilized, with undersampling to improve on the image acquisition time. This results in a compromise in image quality relative to traditional high-field strength MRI systems. AI can be leveraged for the reconstruction of high-resolution MRI from undersampled data[62] and generate images, resembling results from data acquired with a higher strength magnetic field, which would be advantageous for enhancing tumor visualization throughout treatment.

Automation of Contouring

Manual contouring of target volumes and OARs has been a mainstay of the RT workflow in the modern era. This typically requires meticulous manual assessment of both diagnostic and planning imaging data and other clinical data (including pathology and surgical reports) by the radiation oncologist, which can be time-consuming and labor-intensive. Accurate delineation is crucial for optimizing therapeutic outcomes and minimizing toxicity, but there is significant interobserver variation in contouring both target and OARs volumes among clinicians, even when comparing experienced radiation oncologists. Such variations can result in disparities in treatment plan quality, potentially influencing oncologic outcomes, and efforts to standardize contours and provide training through consensus guidelines and contouring atlases can be effective. Previous iterations of semiautomated contouring tools utilized prior data from reference images, like segmentation atlases, were unreliable (often-demanding significant manual corrections) and remained out of reach for most radiation oncologists, given prohibitive costs.[63] In recent years, AI-driven auto-contouring tools have been developed that generate results that parallel human expert contours with efficiency gains in a range of settings.[64]

With the increased adoption of auto-contouring tools, clinicians only need to evaluate and approve automatically generated contours (particularly when it comes to OARs), but clinical integration should still be cautiously approached by both developers and radiation oncologists, as potential risks for harm with inaccurate contours can be significant. First, the performance

of a given auto-segmentation algorithm will be driven by the underlying training data, and thus, it is important for clinicians to understand these details, including whether the algorithm is based on real-world, clinical data with its underlying inherent variation or from contours specifically generated from atlases for a given use case. Since contouring standards may differ from clinician to clinician, institution to institution, and indication by indication, the end user should have an understanding of the intended use of a given algorithm before utilizing its output, but currently, there has not been widespread adoption of algorithmic transparency (eg, through presentation of AI "labels" that provide algorithmic training, failure modes, and intended use, similar to FDA medication labels).[65]

In addition, end users will need to understand and benchmark AI performance, and standard methods for evaluating the quality of auto-contouring tools include geometric overlap measures, such as the Dice similarity coefficient.[66] This method compares autogenerated segmentations to contours manually generated by experts. However, a notable drawback is that such metrics often do not align with crucial considerations, for example, when the agreement is with an inaccurate clinician-generated ground truth, which may not be clinically acceptable, or the impact of patient variation, the potential influence of ancillary data such as the clinical exam, pathology reports, endoscopic examination, or other imaging modalities (eg, PET or MRI). As such, DICE values do not necessarily signify a superior contour, and a variety of other overlap metrics might be valuable to assess depending on the clinical context,[66] but more importantly, functional auto-segmentation validation through verification of prediction of dosimetric values and clinically relevant end points against gold standard contours is critical.[67,68] It is also essential to recognize the significance of clinical data that are not captured by imaging (eg, physical examination findings), which may greatly inform radiation oncology contouring and planning decisions. Prospective studies directly evaluating the efficiency, precision, and consistency of these AI tools compared to the established gold standard methods in RT will be valuable.

As commercial AI solutions for auto-segmentation are increasingly integrated into clinical and treatment planning systems, there' is a heightened need for QA mechanisms to detect inaccuracies. Manual QA for auto-segmentations is notably resource-intensive and time-consuming. This

creates an opportunity for AI-based QA tools, potentially minimizing the time and resources required with current methods.[69] Future iterations of target delineation algorithms could leverage multimodal data embedding to integrate other clinical information, such as pathology, radiology reports, and surgical procedural notes, to accurately delineate the clinical target volumes (CTVs) or areas at risk for microscopic disease in the postoperative setting.

AI solutions being rolled out to the clinic for contouring tasks have shown great promise at contouring various OARs, but many radiation oncology–specific applications are restricted to contouring commonly constrained organs and conforming to existing contouring atlases. It is possible to implement even more advanced and granular OAR delineation systems with current solutions for total body segmentation (eg, looking at lobar-level segmentations in the lung or other substructures).[70] Total Segmentator is one such platform based on the nn-U-NET architecture. It can automatically segment more than 100 anatomic structures (including 27 organs, 59 bones, 10 muscles, and 8 vessels) on full-body CT images.[70] Wasserthal et al trained the model on 1,204 CT scans with 117 anatomic structures segmented from a range of use cases, including RT planning CTs. It is available as open source and provides an alternative to commercially available products.

Previously, time constraints made it such that only so many OARs could be contoured. This often meant the radiation oncologist had to exercise clinical judgment in deciding which OARs to focus on. However, that did not necessarily mean that some structures that were not contoured were not clinically relevant, with the potential to impact clinical outcomes. With AI, radiation oncologists may be able to contour many substructures that were not previously part of routine practice, optimizing the dose to these structures using modulated RT or protons to improve patient outcomes. Examples include cardiac substructures such as the left anterior descending artery, which may be clinically important.

Beyond OAR contouring, AI algorithms are beginning to show promise in auto-contouring of gross tumor volume[68] and malignant nodal segmentation and CTV.[71] Target volume segmentation poses a tougher challenge to AI than OARs in that a higher level of expertise and knowledge is required, contours often rely on data outside available

imaging (eg, biopsy findings), and there is inherent institutional and practitioner-level variability. Despite these challenges, with steady improvements in methodology and data, AI-enabled target contouring may help improve contour standardization, efficiency, and quality.[68]

Automation of Treatment Planning

Historically, medical dosimetrists meticulously design the plan and dose distribution, making modifications through a trial-and-error approach to align with the objectives of the radiation oncologist's treatment intent. The quality of such radiation plans hinges on various human-influenced factors, such as selecting radiation beam angles and setting optimization parameters. As such, there can be significant variation in treatment plan quality, within and between institutions. Conventional methods aimed at standardizing and improving the efficiency of treatment planning lean on automating repetitive tasks based on predefined, hard-coded rules, refining plan parameters based on set objectives using statistical techniques.[72] Automating treatment planning follows a two-step process. First, predicting the optimal dose distribution and then finding the best machine parameters necessary to realize that ideal dose distribution. Early approaches of applying ML techniques to treatment planning aimed to identify hand-crafted features for predicting dose metrics that were fed into the optimization engine, allowing a semiautomated planning approach. More recently, DL approaches are used to predict the entire clinical dose distribution in 3D. To allow evaluating the trade-off space for a given patient, Pareto optimal dose prediction algorithms have been proposed. These prior knowledge-based approaches are generally designed for specific anatomic sites and have a restricted capacity for adjusting to the nuances and range of complexity in modern plans or adapting to individualized patient-specific considerations. Several studies have shown the proficiency of DL models in predicting the optimal dose distributions tailored to individual patients, factoring in their unique anatomy. Moreover, these algorithms have shown promise in cutting the time required for dose calculations.[73] Once the optimal dose distribution is found, beam orientation and machine parameters need to be selected and optimized. Traditionally, beam orientation follows standardized clinical protocol, which may, on a

patient-to-patient basis, lead to suboptimal configurations. Converting a dose distribution to a deliverable treatment plan is an inverse optimization problem that has to fine-tune the radiation machine-specific parameters. Since the underlying problem is highly complex, one optimization cycle can take several minutes. To speed this up, AI-based methods are used to predict fluence maps and machine parameters, given an optimal dose distribution. DL-based approaches try to solve these problems with various techniques, reducing the required optimization times from minutes of calculation to a subseconds timescale. All discussed methods are still in an early stage and have not been clinically implemented.

For proton therapy, accurate dose calculation is essential. While pencil beam calculations are quick, they lack precision, especially in inhomogeneous regions, whereas Monte Carlo methods are accurate but slow. A DL model, based on the U-Net architecture, was developed to enhance pencil beam accuracy to Monte Carlo level, using patient CT images and pencil beam doses. This model improved dose accuracy and can be integrated into clinical proton therapy planning, adaptable to various tumor types and data sets via transfer learning.[74] Other AI models have been used for 3D dose prediction for IMRT,[75] beam orientation optimization,[76] intelligent inverse planning in high dose-rate cervical brachytherapy,[77] dose prediction in prostate cancer and lung cancer RT, improving DVH parameter predictions to within 1.6%,[78,79] and patient anatomy–specific dose distributions.[54]

For AI-driven treatment planning algorithms to produce high-quality plans, complex decision-making processes must be embedded in the underlying models. This approach mirrors the strategies employed in AI algorithms proficient at playing games like Atari or the board game Go.[77] The underlying reinforcement learning technique has the potential for solving sequential-type clinical problems. Thus, treatment planning with time-intensive and repetitive tasks, often based on a trial-and-error method, could potentially benefit from large-scale application of these methods. The gamification concepts for auto-treatment plan generation have been explored in retrospective studies generating radiation dose adaptation schemas in NSCLC and controlling treatment planning parameters for external RT as well as brachytherapy, outperforming human planners.[77]

Peer Review

Early, prospective (before treatment starts) peer review of contours and plans has been identified as a critical component of high-quality RT, but manual detection of errors remains a challenge.[80] AI-supported peer review might include deployment of auto-segmentation and auto-planning algorithms to deploy automatically in the background and detect outliers in the clinical workflow by comparing clinical contours/plans with AI-generated "digital twins,"[81] or conversely development of AI/ML algorithms that directly detect outliers based on historical data or learned features. Conversely, as AI automation technologies proliferate in radiation oncology clinics, novel QA frameworks to ensure human expertise is integrated to detect AI-based errors will be critical.

Preradiation Treatment Verification and Quality Assurance

Once the treatment plan receives approval from the radiation oncologist, the medical physicist conducts plan evaluation and QA verification. This ensures that every technical element for treatment delivery is operational and accurately configured to safely deliver the specified dose to the patient, which includes patient- and machine-specific QA. Patient-specific QA focuses on detecting issues that could impact the patient's treatment. This includes a thorough assessment of the accuracy and suitability of the plan and treatment parameters and verifying the consistency between the planned dose and prescription. Solutions for automation are tools that check treatment plans based on a heuristic approach, which uses hand-crafted rules to check a patients' chart. More recently, AI tools have demonstrated the capability to accelerate this process and identify rare errors.[82] In addition, it is a regulatory requirement to verify that a given treatment plan can be delivered and that the resulting dose distribution matches the planned dose distribution. This requires physical measurements of the delivered dose using a dosimeter-containing phantom. To reduce the amount of measurements and focus on plans that are more likely to fail a measurement, AI algorithms have been developed to predict QA passing rates by analyzing the treatment plan itself, obviating the need for physical dose measurements.[83] The integration of these AI tools has the potential to enhance the efficiency of the QA process, thereby enabling medical

physicists to invest more time in other important tasks, but currently, those methods are still in a developmental phase and only tested by few institutions.

Machine QA assessment involves a broad range of verifications and evaluations of treatment machine function, precision, and accuracy. The wealth of data generated during these assessments has provided avenues to develop AI systems capable of predicting trends, such as in cone-beam computed tomography (CBCT) image quality degradation, identifying errors like treatment beam asymmetry and positional errors in the multileaf collimators.[84,85] Since patient- and machine-specific QA have always been well documented and data have been collected over years, there will be ample opportunity to harness AI's power to analyze these data as they are increasingly collected to improve RT delivery.

Treatment Setup and Delivery

Scheduling

Radiation oncology patients typically present for multiple appointments over the course of their radiation treatment. Prolonged waiting times can impact the clinic's operational efficiency, contribute to patient anxiety, and negatively affect patient satisfaction. AI can help identify key factors influencing patient waiting times within a department's daily operations, such as the time of day, number of fractions, historical average treatment duration, and number of treatment fields. Using AI to predict waiting times can optimize clinic workflows and efficiency.[86] Appointment scheduling can be refined and optimized using AI to organize the patient sequence based on anatomic treatment site and the specific immobilization and treatment techniques employed. This approach can reduce room turnover times between patients and increase capacity to efficiently accommodate more patients.

AI systems can also be readily combined with sensors to track patients in real time over the course of their visit, allowing the radiation oncology care team to keep track of how the patient is progressing through their visit. These AI-enabled real-time locating systems allow the care team to localize the patient and keep track of treatment and appointment durations, therefore

minimizing wait times and the risk for errors and ultimately optimizing the scheduling of treatments and patient experience.

Image Guidance and Motion Management

Precisely setting up a patient in the same position as at the time of simulation is critical for the safe and effective delivery of RT. Current methods for on-treatment patient positioning include utilizing CBCT mounted on the treatment machine. However, CBCT image quality is usually lower than the higher resolution planning CT images. AI has been implemented to enhance CBCT image quality, enabling more precise patient positioning for treatment.[87] AI algorithms are also adept at automatically detecting imaging artifacts, such as scatter artifacts,[88] and can be implemented to improve CBCT image quality to support target verification and online adaptive RT.[89] Other imaging modalities, including ultrasound, onboard MRI, and optical surface imaging, are increasingly utilized in image-guided RT. These present a unique opportunity for AI-driven methods to enhance or synthesize complex data in real time during treatment appointments.

Patient or organ motion may necessitate motion management techniques to mitigate, capture, and monitor motion stemming from physiologic processes, such as breathing or digestion. However, there is significant variation in the degree of motion (magnitude or frequency) between individuals, and even for any given individual, the movement of organs relative to each other may vary between fractions. This variability poses challenges when attempting to construct predictive models for tumor motion. AI can help address these variations by creating patient-specific dynamic motion management models that can adapt to shifts in motion patterns to enhance tracking of the target volume during treatment. Research in this domain has focused on predicting respiratory motion, utilizing data obtained from external surrogate positional markers as predictive model inputs.[90] These algorithms can automatically adapt to complex respiratory patterns in real time, ensuring precise tumor motion tracking and predicting the tumor's position up to 0.8 seconds in advance.[90]

Adaptive Radiotherapy

Significant changes in patient anatomy reflecting tumor growth or shrinkage, or due to internal organ motion (eg, from physiologic movement of gas or liquid in the GI or GU tracts), can occur in the days to weeks between simulation/planning and actual treatment delivery. These changes can result in significant alterations in the dose received by the treatment target and normal tissues, and potentially necessitating adaptive replanning, but the clinical criteria for adapting a new plan are currently not standardized and often require the radiation oncologist to make subjective judgments regarding the clinical significance of the anatomic changes. AI can help predict which patients require treatment replanning and the optimal timing for adaptation. AI models have been used to identify the need for replanning in lung cancer to reduce the risk for radiation pneumonitis.[91,92] Similar methods have been used to predict geometric changes in patients with head and neck cancers throughout treatment and identified the fourth week as the ideal time for the adaptation of treatment.[93]

Post-Treatment Evaluation and Continuation of Care

The Response Evaluation Criteria in Solid Tumors (RECIST) is the most commonly used system for evaluating solid tumor response to treatment-based on tumor size changes. However, with the introduction and increased adoption of immunotherapy and targeted agents in clinical practice, the RECIST method for response assessment has become inadequate (eg, due to phenomena such as pseudoprogression),[94] and even revised criteria do not accurately capture nuances, especially in immunotherapy patients. AI algorithms show promise in automating such assessments and can provide more comprehensive insights into tumor response over the course of RT. This includes capturing changes in tumor phenotype using advanced visual representations and learning of imaging characteristics, potentially enabling superior assessments of treatment response and more accurate outcome prediction than tumor size alone. For example, AI has been evaluated for early assessment of lung cancer response to different therapies, predicting cancer-specific outcomes, such as disease progression, locoregional or distant recurrence, and OS.[48,53] In particular, Xu et al demonstrated that tumor tracking using AI for serial image analysis looking at follow-up CT scans at 1, 3, and 6 months after RT for lung cancer predicted oncologic

outcomes and tumor pathologic response in those receiving trimodality therapy. This model worked without the need for manual contours and was robust to radiation-related changes. Furthermore, AI-generated volumetric RECIST measurement was shown to be better at risk-stratifying patients with lung cancer than manually generated annotations.[95] Similarly, AI has been used to estimate RECIST in patients receiving immunotherapy (which is increasingly given with RT either sequentially or concurrently as is currently evaluated on clinical trials for future treatment paradigms).[96] Radiation-related tissue damage undermines the precision of manual RECIST measurements and complicates disease recurrence identification. AI algorithms can identify early and easy-to-overlook alterations in the lung that may be associated with local recurrence (often mistaken for radiation-induced fibrosis).[97] This information can facilitate early intervention to improve patient outcomes.

Toxicity Prediction and Management

The management of acute and late radiation-related toxicities is complicated by their difficult-to-predict nature and variable severity. Although preemptive/proactive management of these adverse effects would be ideal, the unpredictability of both stochastic and deterministic effects makes this a complex issue to navigate. Predictive models for radiation-induced toxicities can nonetheless be developed based on risk factors, such as germline genomic variations (eg, radiation sensitivity related to ataxia telangiectasia mutated [*ATM*] gene mutations), comorbidities, other treatments (eg, radiation recall pneumonitis in patients receiving immunotherapy), radiation dose distribution, and imaging characteristics. These models can be implemented to guide treatment planning. Existing methodologies have predominantly focused on subsets of these modalities of information and, in some instances, relied on the extrapolation of radiobiologic models from observational and preclinical studies.[98]

AI can enhance the processing of these multimodal data to develop robust predictive models that seamlessly incorporate factors such as clinical characteristics, radiation dose, and imaging data acquired before treatment to aid in clinical decision support for the prevention of radiation-related toxicities and preemptive management. Examples include AI-driven

probability models designed to predict the severity of acute dysphagia, xerostomia, and oral mucositis in patients with malignancies of the head and neck.[31,99,100] Prediction models for radiation-induced pneumonitis, esophagitis, rectal toxicities, and even seizure risk have been successfully developed using AI.[101] A study focusing on late-stage cervical cancer RT used an AI model to analyze rectum dose distribution and predict toxicity. The results showed the feasibility of the prediction model, with saliency maps highlighting regions indicating potential locations for rectal toxicity.[102]

In addition, there have been promising real-time monitoring approaches, such as prospective testing of an ML algorithm trained on clinical data to predict acute toxicities that could result in emergency department visits or hospital admissions for patients receiving RT or chemoradiotherapy with high sensitivity and specificity.[103] These applications underscore the potential of AI to integrate multiple clinical data streams to develop real-time, actionable clinical decision support for advanced prediction of adverse events during radiation treatment.

REGULATORY/ETHICS

The FDA and international regulatory bodies (eg, The International Medical Device Regulators Forum) categorize AI and ML technologies as "Software as a medical device" (SaMD).[104] SaMD refers to software designed for a medical function, such as treating, diagnosing, or preventing disease, without being integrated into or forming a component of a hardware-based medical device.[105] Most AI technologies applied to radiation oncology are subject to these regulatory guidelines. For example, software for treatment planning decision support has been distinctly labeled as SaMD.[104] Despite a surge in AI-related medical publications, the implementation of AI tools in radiation oncology (and medicine more broadly) has been relatively limited aside from auto-segmentation algorithms. However, there has been a significant uptick in approvals from a few dozen FDA-approved AI algorithms in 2019 to a total of 500 by the end of 2022, of which over 75% were medical imaging applications. Nevertheless, the adoption of AI remains measured, as many AI models do not progress beyond the proof-of-concept stage due to various limitations, such as deficiencies in clinical

utility, reproducibility or transparency, generalizability, explainability, or trust.

The regulatory sphere has focused on reevaluation schedules for new devices and the requirements for locked versus continuously learning AI systems. More clear standards are needed to govern the clinical evaluation of these tools. Clinical AI implementation has potentially significant implications for patient outcomes, which can only be evaluated in comprehensive prospective studies or retrospective data collected in representative cohorts. While randomized clinical trials are the benchmark for evaluating anticancer therapies, they may not always be feasible or necessary for every AI device. However, prospective evaluation should still be considered for any system that has the potential to impact patient outcomes, cost of care, and efficiency of the cancer care delivery workflow. In the context of AI, protocols that assess various technologies within a single category across multiple cancer types could help make prospective evaluation more practical and efficient.[106] For low-risk tools that operate under continuous monitoring by health care professionals, phase I/II studies may suffice. Conversely, high-risk devices, especially those used without routine expert human or clinician supervision, demand rigorous phase III studies.

Postmarketing monitoring is needed to gauge the value of AI-based RT tools. Such scrutiny is essential, given that these tools' functionality could be influenced by their interaction with other software and hardware systems and broader user adoption (ie, human-AI interactions). High-quality, risk-assessed clinical validation is the cornerstone to determining the value of and instilling confidence in AI technologies. Given their potentially profound impact on cancer care, this trust becomes especially important for these "black box" systems. It is imperative to establish safety measures due to the potential risks associated with AI applications. While image registration and auto-segmentation AI platforms allow human expert review, possible errors from AI tools in radiation treatment QA require robust safeguards. Proposed solutions include AI models that predict errors in QA algorithms. Current practice holds clinicians accountable for errors, and regulatory entities are formulating guidelines addressing AI's legal implications.

It is also worth noting that AI systems are increasingly used in clinical trials, many of which do not require informed consent due to their classification as minimal risk, potentially leaving patients unaware of their participation.[107] Given the unique challenges in AI system risk assessment, including the unknown impact of human-AI interactions and data limitations, patients need to be informed when AI influences their clinical decisions. To uphold ethical standards, AI clinical trials should disclose to patients when their data are used, ensuring patients retain the right to determine their health care decisions.[107]

AI model development often requires extensive, multi- institutional data sets that may contain sensitive personal information. Providing data security and preventing leakage is critical, but achieving complete anonymization can be challenging, particularly with genetic, textual, or radiologic data that might inadvertently identify individuals. Federated learning has been introduced as a potential solution, allowing for decentralized data usage where only model weights, not actual data, are shared between institutions. However, even with this approach, there is a risk that models might inadvertently reveal personal health information through back-engineering of parameter weights, posing privacy concerns.

ARTIFICIAL INTELLIGENCE IN RADIATION ONCOLOGY RESEARCH

Research is a cornerstone of radiation oncology. It drives the understanding of patient-specific risk factors, refines our ability to predict outcomes following RT, and provides evidence-based guidance on escalating or de-escalating treatment. Therein, clinical trials offer controlled environments to test the efficacy and safety of interventions, typically following strict protocols and patient selection criteria. While the highest level of evidence within oncology continues to be randomized phase III studies, robust analyses of real-world data may offer valuable insights in instances where the barriers to conducting a clinical trial are intractable (eg, problems with accrual in studies of rare malignancies such as sarcoma or comparing SART to surgery in early-stage lung cancer) or when navigating new “data-free zones” in clinical practice as new evidence emerges (eg, management of some locally advanced NSCLC cases in the immunotherapy era). Real-

world data capture the diverse experiences of patients in routine clinical settings, reflecting a broader range of outcomes and variables not typically seen in the controlled clinical trial setting, while enabling detection of very rare events that may never occur in a smaller trial cohort. Advanced modeling of these data using robust statistical learning methods and AI algorithms can help shift the balance toward more use and trust of insights from real-world data analyses.

Several key distinctions arise in comparing AI methods to conventional statistical methods for research applications. Traditional statistics often require the specification of a hypothesis a priori and use parametric and nonparametric comparisons between groups with methods such as linear regression and survival models with linear projectors. They offer stability by adhering to predetermined statistical plans. Their strength lies in handling data with fewer predictors, statistical inference, and hypothesis testing. Reproducibility in conventional statistics is ideally external, with clear interpretability due to explicit features and parameters. Their less flexible and more explicit nature allows for more straightforward equity checks when data are available. On the other hand, AI approaches tend to be agnostic to a priori hypothesis and can be more general. They utilize techniques like random forests, XGBoost, and neural networks and are more prone to instability based on domain and user choices. Their primary applications include image analysis and large data set processing, focusing on pattern discovery and prediction. Reproducibility in AI is often internal (due to robustness limitations in the supervised training methods that are widely implemented to date, and additional barriers include the rise of proprietary algorithms and a lack of transparency). AI methods can also be a “black box,” leading to challenges in interpretability. They might magnify biases in data sets, potentially exacerbating inequities. Overall, AI’s strength is in pattern discovery, dimensionality reduction, and automatic feature selection, compared to the statistical inference and quantification of uncertainty in conventional methods.

In radiation oncology research, statistical models based on expert radiation oncologist judgment, manual data curation, and selection of features and measurements that predict outcomes with RT are a mainstay. They have offered a reliable method to test hypotheses and assess the impact of radiation treatments, resulting in reproducible study conclusions.

However, it is difficult to scale these analyses to large data sets combining multiple data streams. Statistical learning and AI models can automatically search and extract abstract features that predict outcomes or perform other tasks at scale. They can handle vast multimodal data sets and derive useful —potentially orthogonal—information from the high-dimensional data sets. A trade-off is that these systems can be opaque, and reproducibility challenges may persist despite model optimization.[108]

FUTURE DIRECTIONS

AI is a rapidly evolving field. Innovations continue to emerge with the promise to revolutionize cancer care, particularly in the technology-driven discipline of radiation oncology. Several advances and challenges will warrant close attention in the near future.

Multimodal Models

Effectively consolidating various patient data streams, including imaging and genetic markers, will help generate new insights and a more comprehensive view of patient health. This is particularly invaluable in oncology, where individual patient treatment pathways will demand increasingly nuanced personalized approaches.

Foundation and Generalist Medical Artificial Intelligence Models

Foundation models serve as broad-based systems trained on massive data sets, often in a task-agnostic manner, to develop strong baseline performance within an application domain. These adaptable frameworks can be subsequently tailored for specific tasks with few data points needed for fine-tuning to achieve optimal performance at the particular task. Generalist models extend these foundations across diverse medical tasks, for example, analyzing the EMR and providing treatment recommendations.[109] Both promise flexibility, adaptability, and potentially better generalizability.

Generative Artificial Intelligence

Generative AI is characterized by its capacity to produce new content—be it text or image generation or medical report formulation—in response to specific prompts. This is achieved by systematically training AI models on existing data sets, enabling them to identify and replicate patterns in order to subsequently generate new and pertinent content. Popular generative models included large language models such as ChatGPT. Within oncology, there is potential for generative AI to create medical images, which can be invaluable for data augmentation during the training phase of AI model development. The models may also help generate medical reports, clinical annotations, and comprehensive patient summaries, although clinical integration should be approached with caution pending further research.[5,9]

CHALLENGES

Data Availability and Quality

High-quality data sets for training and validation are critical in this domain. The unmet need for standardized definitions and consistency across various data types in radiation oncology impedes seamless data sharing and AI model development.

Proprietary Software Limitations

Treatment planning software often remains proprietary, limiting knowledge and integration capabilities. However, vendors are beginning to offer interfaces for research endeavors.

Clinical Relevance

Early AI analyses have tended to focus on readily measurable patient outcomes such as OS, or on performance metrics compared to a gold standard. There will need to be a shift toward other outcomes that are directly relevant to RT, including radiation-induced toxicity, which can be more challenging to measure and study but provide more direct evidence on the benefit of the specific AI system. Demonstrating benefit on patient-centered outcomes will be essential for uptake by patients, providers, and payers.

Clinical Implementation

Many AI tools remain experimental and lack external validation. Achieving trust is crucial, given the "black box" nature of most algorithms. The legal landscape regarding clinical liability and responsibilities may change with increased AI utilization and buy-in from all stakeholders.

Transparency and Ethics

Despite improvements in AI interpretability, the lack of transparency makes it difficult for developers, end users, and regulators alike to comprehend the mode outputs and predictions. This also makes it challenging to uncover any potential systematic biases that are trained into the models from imbalanced data sets, which may impact underrepresented groups in those training sets, resulting in the propagation of cancer disparities. Ethical concerns, from racial biases to potential misuse for financial gains, are also an important consideration.

CONCLUSION

In the era of AI, radiation oncologists need to be well versed with these tools and the AI landscape. While AI promises to be a powerful ally in patient care, it also requires rigorous oversight, understanding, ethical deployment, and constant collaboration among various stakeholders to truly benefit patients and radiation oncology practitioners.

Integrating AI into radiation oncology will inevitably transform the roles and responsibilities of the workforce. The radiation oncologist will see their role move away from manual tasks such as contouring and pivoting toward ensuring the quality of AI-generated parameters and spending more time on direct patient interactions. This shift will place a premium on human-centric activities, such as patient counseling, education, clinical management, and providing emotional support. AI will also lead to more standardization in tumor contouring and treatment planning, minimizing disparities, particularly in health care settings with limited resources. Moreover, clinical radiation oncology training will likely shift away from the rote learning of clinical trial data and extended apprenticeship to master manual contouring and treatment planning. Instead, training programs of the future will be

tailored to equip radiation oncology residents with skills that will help them to navigate, assimilate, and derive insights from expansive data sets, fortifying their clinical decision-making capabilities in an AI-enabled clinical landscape.

SECTION III

Policy, Economics, Education, Ethics, and Technology Assessment

CHAPTER 33

Technology Assessment, Outcome Analysis Research, Comparative Effectiveness, and Evidence-Based Radiation Oncology

James B. Yu and Ronald C. Chen

Radiation oncology (RO) is a technologically intensive discipline. Innovations in computing, radiation technology, genetics, cancer biology, diagnostic imaging, and artificial intelligence (AI) all have the potential to impact the field. Because RO teams treat multiple cancer types and medical conditions, the practical application of these new technologies and innovations across multiple clinical situations can occur almost immediately. As a result, given the rapid and continuous pace of technological innovation, it is important for all radiation oncologists and their teams to understand how new technologies disseminate, are evaluated, and are compared to older technologies. As well, it is critical for radiation oncologists and researchers to apply radiation in an evidence-based manner.

This chapter provides a review of technology assessment, assessment of health outcomes from radiotherapy, comparative effectiveness research (CER), and how evidence is generated for radiotherapy.

ASSESSMENT OF TECHNOLOGY

In 2015, the Institute of Medicine National Cancer Policy Forum Board on Health Care Services convened a workshop to discuss the appropriate use of advanced technologies for radiation therapy and surgery.[1] The goal of the workshop was to discuss how to ensure appropriate use and evaluation of technologies such as proton beam radiation, as well as how these new technologies disseminate. The workshop highlighted the importance of evidence generation as new technologies are adopted and identified several potential areas of research and improvement. The workshop centered

around the themes of regulatory oversight, training and monitoring of performance, generation of evidence assessing medical technology, optimal payment strategies, and recommendations for utilization and clinical guidance. A key recommendation included the encouragement of "coverage with evidence development," which means that evidence is generated during the adoption of the technology by linking practice and provider reimbursement for the new technology in question with participation in prospective clinical data and evidence generation.

Though much of the 2015 workshop focused on proton beam radiation, many other new radiation technologies have been introduced or continued to disseminate over the past decade. The list of new or disseminating technology includes intensity-modulated proton beam therapy (distinct from "three-dimensional conformal" proton beam therapy), magnetic resonance imaging–guided linear accelerators, new radiopharmaceutical therapy, positron emission tomography (PET)-guided linear accelerators, the so-called adaptive radiotherapy, as well as incremental innovations in imaging technology, patient body surface tracking, patient positioning and immobilization, innovations in brachytherapy delivery (both high- and low-dose rate), intraoperative radiotherapy, and new systems to improve the frameless delivery of intracranial stereotactic radiosurgery. This list is growing constantly.

Traditionally, as discussed in the section on evidence generation, innovations in medical care are best evaluated in well-designed prospective randomized trials. However, these studies can be prohibitively expensive, and cancers with long natural histories often require a prolonged response assessment (such as prostate cancer). By the time randomized trials have completed and are ready for analysis, newer technologies have been invented and are already in the market. Furthermore, it is often impossible to test a technology in all areas of potential application (all cancers where the technology will be used) simultaneously. Therefore, how to ensure that technology is applied based on evidence but without depriving patients of new innovations is at times an intractable problem.

Governmental Assessment

One potential path for evaluating new technology is through the U.S. Food and Drug Administration (FDA). The FDA is responsible for regulating medical devices used in the United States, including radiation devices that do not use nuclear decay, such as linear accelerators. New radiation technologies are typically evaluated using the 510(k) pathway.[2] This pathway assumes that the new radiation therapy technology is still fundamentally similar to other applications of radiotherapy in its use of therapeutic doses of radiation. The 510(k) pathway, therefore, evaluates safety and similarity, rather than treatment efficacy. A device is considered substantially equivalent as the preceding device if it has the same intended use and the same technological characteristics. If the new device has different technological characteristics, it must not raise different questions of safety and effectiveness. Another pathway is to receive "de novo" approval for a device that is not substantially equivalent to prior devices. A recent example of this type of approval is the RefleXion Medical PET-guided platform.[3]

Once a technology is FDA approved, how rapidly the technology disseminates often depends greatly on the reimbursement that a physician or health system receives for its use. At the governmental level, reimbursement for RO services is set by the Center for Medicare & Medicaid Services (CMS) based on recommendations of a committee of medical professionals and others nominated by professional societies known as the Relative Value Scale Update Committee (RUC).[4] The American Society for Radiology Oncology (ASTRO) participates in the RUC committee, though there is no radiation oncologist on the committee. New Current Procedural Terminology (CPT) codes for new radiation treatment are set by the CPT Editorial Panel of the American Medical Association.

Medicare coverage decisions regarding medical services are made at the national and regional levels. The national determination of treatment coverage is done in consultation with the Medicare Evidence Development & Coverage Advisory Committee.[5] In the absence of a national determination, regional coverage decisions (known as a *local coverage determination*, or LCD) are made by the Medicare administrative contractor (MAC) administering the claims within a region. There are 12 MAC jurisdictions nationwide.[6] These LCDs also often rely on RO society

practice guidelines as well as review and consultation with experts, with a period of public comment and an open meeting. Requests for an LCD or revision of an existing LCD can be made as further evidence accumulates.[7]

Other government institutions perform their own assessment of new technologies. For example, the U.S. Veterans Administration (VA) launched a system of health technology assessment in 2022 called the Value-Driven Framework.[8] The framework evaluates a technology based on measures of value, access, effectiveness, and equity. As well, the VA evidence-based synthesis program has performed past evaluations of radiation technology, including proton therapy.[9] Overseas, the National Health Service of England's Health Technology Assessment (HTA) Programme performs a similar function on a broad array of radiotherapy technologies. Evaluation by the HTA typically involves a systematic review and cost- effectiveness evaluation via a cost-utility decision-analytic model.

Insurance Company Assessment

Outside government approval of new technology, health insurance companies provide their own assessment of new technology. Differences in insurance coverage for stereotactic body radiotherapy (SBRT) and proton beam radiation can be illustrative of how insurance companies evaluate technology.[10,11] Insurance companies and benefits managers can vary widely in what they consider to be "medically necessary."[12] Given the complexity of radiation treatment and application, as well as the perceived high cost of radiation, radiation oncologists face the highest burden in terms of prior authorization administration compared to other specialties.[13] Prior authorization requirements were estimated to be over $40 million nationwide, using data from 2017 to 2018.

How an insurance company decides on coverage may depend on a combination of clinical evidence and cost- effectiveness. However, insurance denials occurred for 17% of in-network claims in nationwide data released by CMS for 2021[14] and varied by insurer from less than 10% to nearly half, suggesting that other factors beyond clinical evidence were being brought to bear.

Outcomes Assessment

Before discussing how evidence is generated (in later sections of this chapter) via CER, it is useful to discuss how and what types of outcomes and end points are assessed.

Standard outcomes for clinical trials include overall survival (how long a patient lives) and cause-specific survival (how long a patient lives before dying of a specific cause, usually the cancer that was treated by radiotherapy). Other types of "survival" can include how long a patient lives before the disease progresses after treatment, how long before metastasis, or how long before experiencing toxicity from treatment. How an investigator chooses the type of survival to investigate is a deliberate choice that can impact the success of an investigation. For example, comparing the overall survival between two technologies may not be as informative as measuring disease-specific survival if patients are more likely to die from comorbid illnesses.

Survival is usually compared using estimation methods such as the Kaplan-Meier method that aggregates group data into data that provide a proportion of patients surviving over time.[15] These results can be graphically represented as "survival curves." In this method, patients who are lost to follow up are censored as noninformative at the time of last contact. Survival curves can be compared using statistical tests, such as log-rank testing. Alternately, if assumptions regarding proportional hazards and noninformative censoring are met, there are statistical techniques to compare the "hazard" of nonsurvival between groups using techniques such as Cox proportional hazards regression.[16] If there are risks that compete with the outcome in question (such as the competing risk of noncancer death in older patients undergoing treatment for prostate cancer), a competing risks regression can be performed, showing the risk of an outcome taking into account a competing risk that may preclude the outcome in question.[17]

Regardless of the statistical technique used, finding an improvement in overall or cancer-specific survival is the highest hurdle for most new radiation technologies. Often, improvements in survival due to radiotherapy (compared to no radiotherapy) have to be tested or validated in randomized studies that are not radiation platform or vendor specific, especially if the studies are funded by the National Cancer Institute (NCI's) National Clinical Trials Network cooperative groups. These studies often require

large patient cohorts. As a result, most initial claims of improvement on behalf of new technology innovators (compared to older radiation technology or techniques) are for improved safety or quality of life.

Measures of Cancer Response Outcomes

Given the rapid pace of desired technology change and adoption, and the long-term follow-up required to detect improvements in overall survival and cancer-specific survival, there is considerable interest in finding surrogate clinical end points that can be assessed sooner. Radiographic development of metastatic disease is often used as a measurement of treatment success or failure, given the importance of metastatic disease for cancer mortality. Radiographic assessment has also been used to define patients who require further treatment with radiation (eg, patients with early-stage Hodgkin lymphoma with persistent PET after two cycles of chemotherapy).[18] Further, assessment of treatment response with imaging is also performed. Commonly used in response assessment is the Response Evaluation Criteria in Solid Tumors criteria.[19] Radiomics, the science of using all available radiographic signals and features including those not readily identifiable to the human eye, has been used for head and neck and lung cancers to assess outcomes and remains an active area of investigation.[20]

Other potential surrogates include the use of tumor markers such as CA19-9, CEA, and prostrate-specific antigen (PSA).[21,22] Many other tumor markers exist.[23] Circulating tumor cells, circulating tumor DNA, and other sophisticated markers of tumor burden are also being considered.[24,25] These promising tests may provide early signals on treatment response and tumor progression.

With all these potential measures of cancer response, rigorous comparison to actual outcomes is needed. For example, for potentially indolent cancers such as prostate cancer, an intermediate clinical end point would allow for clinical trials to report findings earlier, but it is important to consider whether these earlier end points are clinically meaningful. Though PSA end points have been validated in patients with prostate cancer treated with radiotherapy,[26] one meta-analysis was only able to validate metastasis-free survival as being a consistent surrogate for overall survival.[27]

Nonetheless, PSA remains an important end point, given its association with salvage treatment and clinical decision-making.[28]

Measuring Quality of Life and Treatment-Related Toxicity

Toxicity assessment commonly takes two forms: physician- or provider-assessed toxicity, and patient-reported symptoms or quality of life.

Physician- or provider-assessed toxicity commonly uses a standardized scale, such as the Common Terminology Criteria for Adverse Events (CTCAE), at discrete time points. For example, clinical trial protocols may recommend the assessment of skin toxicity from breast radiotherapy at specific time points after radiation. Some studies use insurance claims data (eg, Medicare data), looking for billing codes that represent diagnoses of certain toxicities (eg, hematuria) or procedures that are consistent with treatment-related complications. For example, the incidence of laser coagulation procedures for rectal bleeding after radiation therapy for prostate cancer can be used as a surrogate for treatment-related toxicity.

Alternately, patient-reported outcomes can be collected before, during, and after radiation treatment. Patient-reported outcomes can range from specific questions about episodic toxicity such as the PRO-CTCAE (patient-reported outcomes version of the CTCAE),[29] to survey instruments that assess a diverse range of patient experiences from global physical and mental health, to organ-specific symptoms, to financial toxicity.[30]

Survey instrument creation requires methodological rigor to ensure appropriateness, reliability, validity, discrimination, and interpretability, while minimizing question burden.[31,32] Appropriateness means how well the domain of interest is related to the conceptual framework that will be used to build a survey instrument. This connection between domain of interest and framework should be assessed through qualitative patient interviews and focus groups. Reliability of a survey instrument refers to the internal consistency (the degree to which questions within the survey are inter-related and nonconflicting) and test-retest reliability (the ability of an instrument to produce consistent scores from the same population). Validity is the extent to which the survey instrument actually measures the concept it purports to measure. The discriminatory ability of the survey instrument measures the ability to detect differences between individuals and health

states. The interpretability of an instrument is its ability to be translated into relevant clinical outcomes or states. Typically, one estimates a minimal clinically important difference to interpret the minimal difference in a survey domain that leads to differences in clinical experience. Finally, question burden is minimized by reducing redundant questions with answers that are shown to be highly correlated in a survey sample, via an iterative process.

Cost-Effectiveness as a Cancer Outcome

The cost of new radiation technology is often (but not always) more expensive than the technology that it is replacing or improving upon. Since the choice of a radiation treatment does not take place in a vacuum, but within a health care environment that is limited in resources and access, weighing the cost of a new technology against its improvement in outcomes is critical.

Economic analysis of new technology is broadly considered "cost-effectiveness research." Practically, this work involves the assessment of a "choice" between two or more treatments and then the probabilistic simulation of potential outcomes from that choice. Therefore, there are several elements to a formal cost-effectiveness study. First, the investigator must decide on the time horizon for the study—how much time will the analysis consider? Often, the time horizon is long enough that a patient's life span can be considered. However, in cases where only acute outcomes are important, the time horizon can be shorter. Second, the investigator must consider what health states a patient may pass through from treatment to the final end point of the study. Each health state should be assigned a "health utility," which is a value between 0 and 1 that places a numerical value on the quality of life in that health state. Health utilities are obtained via a formal process— either through surveys that have been developed with scores that are anchored to health utility values or through asking a representative group of patients to consider existing in the health state and their willingness to "gamble" to exit the state for perfect health. This technique is called the *standard gamble* technique.[33] When the health utility is integrated over the timescale of years, this produces a measure called a *quality-adjusted life year* (QALY). QALYs are commonly used in economic

analysis. Alternatives to the QALY include disability- adjusted life year and life years gained (without "discounting" years lived with disability,[34] which can be problematic). Third, the investigator must estimate the probability the patients will pass between different disease states. These probabilities are ideally obtained from contemporary clinical trial data. Fourth, the investigator must define the cost of treatment choices as well as the cost of existing within each disease state. These costs must be defined from a prespecified point of view, or "payer perspective," such as Medicare.

How much a payer is able or willing to pay for a treatment relative to a benefit is known as a "willingness to pay." Payers with more resources are postulated to have a higher willingness to pay compared to those with lower resources. The willingness of a country or society to pay for treatment that provides incremental gain is known as a "societal willingness to pay."[35] Societal willingness to pay is often reported in cost per QALY and has been hypothesized to range from $50,000 per QALY to $200,000 per QALY and more in the United States.[36,37]

Once this model has been created, the investigators can calculate the cost of each choice via a "decision tree." However, it is often useful to consider how changes in parameters may influence the cost-effectiveness of a treatment choice. For example, it is useful to take into account a range of potential probabilities for transitions between health states, as well as the range of potential values for health utility and cost of care. If one knows (or hypothesizes) about the relative distribution of potential values, one can model the impact of parameter changes as well as the likelihood that a treatment is cost-effective by simulating a cohort of patients. One method of simulation is known as a "Markov analysis" and is a powerful tool for probabilistic analysis of treatment decisions and chance-based outcomes.[38]

The economics of cancer care and new radiation technology is complex and requires a holistic view of structural societal factors, economic inputs, and policy factors as they relate to the cancer control continuum (including treatment) (Figure 33.1). Economic analysis of cancer treatment (including radiotherapy) requires improved data, training, and prospective economic study of cancer treatment. Unfortunately, the NCI Cancer Therapy Evaluation Program and Division of Cancer Prevention do not provide funding for economic research, and proposals to integrate economic data collection are rarely approved. As well, unfortunately, the NCI Biomarker,

Imaging and Quality of Life Studies Funding Program cannot be used to fund comparative effectiveness or cost-focused studies associated with cooperative group clinical trials.[39] Therefore, with these structural barriers, economic data collection currently must utilize passively collected data, such as insurance claims or institutional billing.

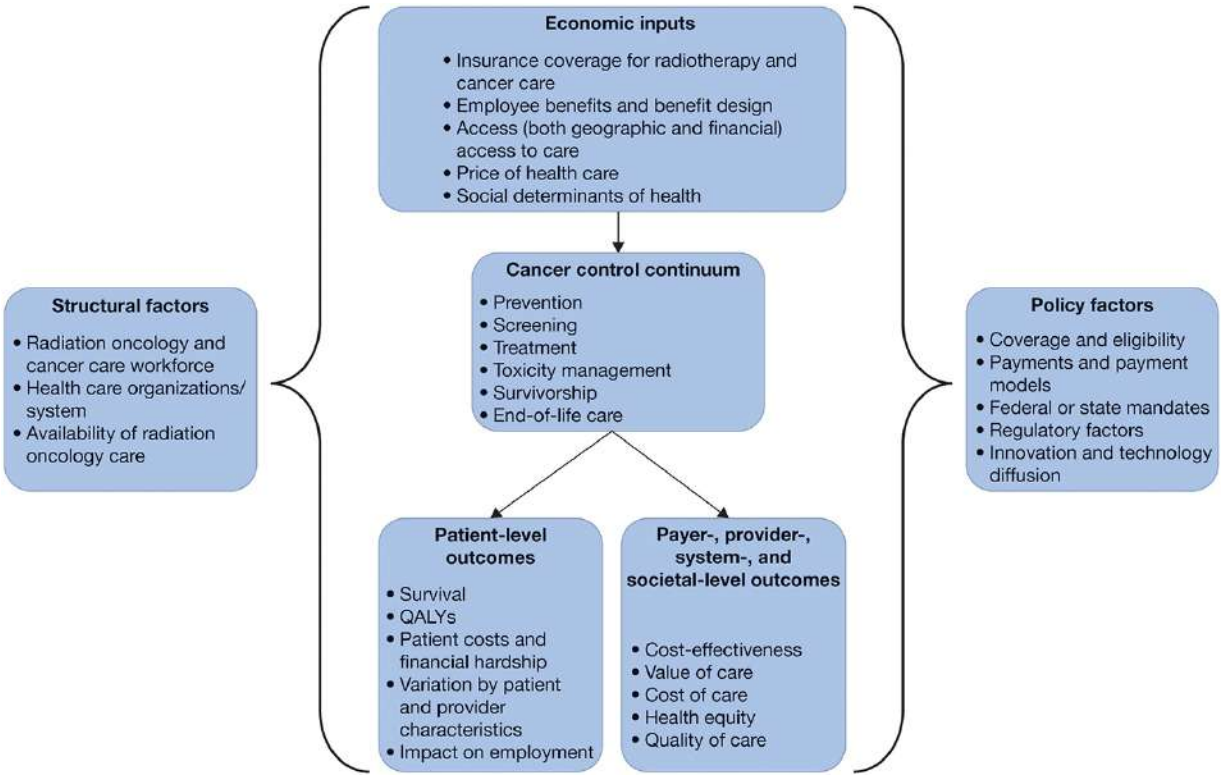

FIGURE 33.1 Interconnectedness between structural factors, economics of cancer care, patient outcomes, and policy. QALY, quality-adjusted life year. (Adapted from Halpern MT, Shih YT, Yabroff KR, et al. A framework for cancer health economics research. *Cancer*. 2021;127[7]:994-996. Copyright © 2020 American Cancer Society. GENERATION OF EVIDENCE

Except in rare cases of obvious benefit, the adoption of a new radiation technology generally requires evidence supporting its improved efficacy, reduction in toxicity, and/or improvement in cost-effectiveness compared to older technology or the absence of treatment. Not all clinical evidence is considered to be equal. Traditionally, the evidence pyramid creates a hierarchy of evidence from lowest to highest quality (Figure 33.2). At the bottom of the hierarchy are case series and expert opinion. Above those

levels are case-control studies, cohort and observational data studies, and randomized controlled studies. Traditionally, evidence that has been synthesized such as systematic reviews and meta-analyses is considered the top of the hierarchy. This hierarchy is also reflected in the levels of evidence used to measure therapeutic studies, with "level 1" evidence defined as randomized clinical trial evidence and levels 4 and 5 as case series or expert opinion.[40]

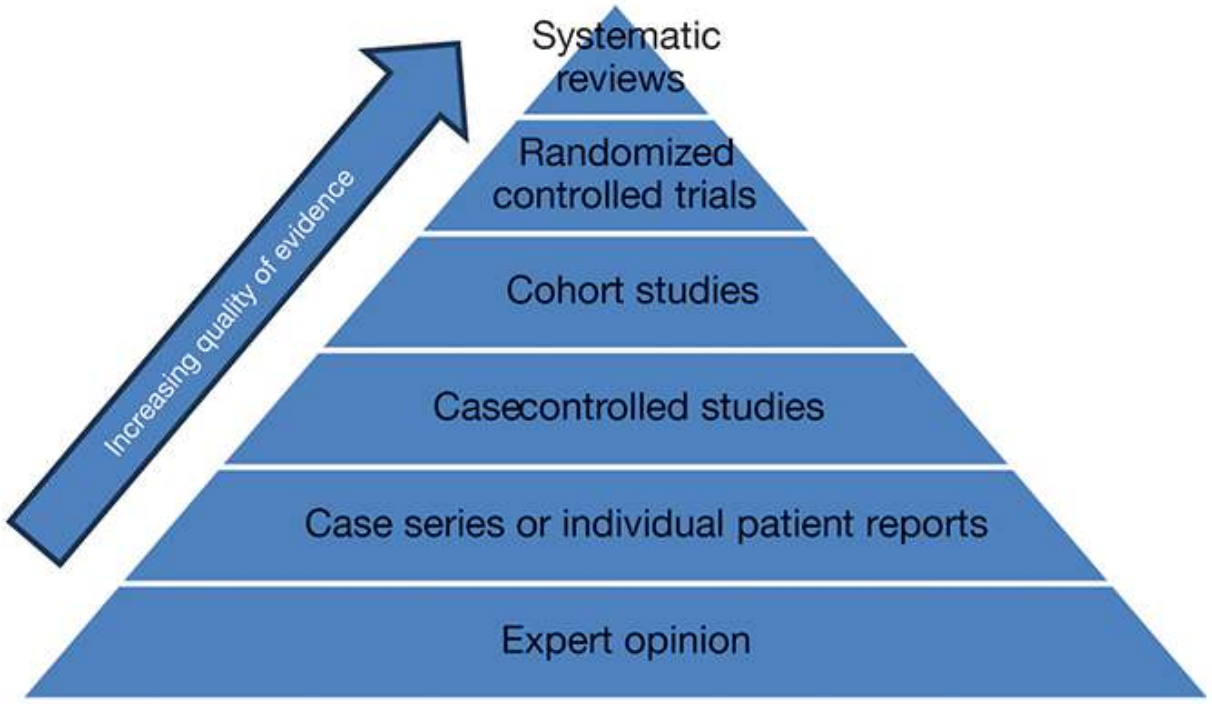

FIGURE 33.2 Pyramid of strength of evidence.

Generally, randomized controlled trials are considered the best source of clinical evidence. Randomized controlled trials often have the benefit of being able to isolate a treatment effect from confounding variables through randomization of intervention. However, randomized controlled trials are not foolproof, as pitfalls may remain. For example, if a randomized new treatment is associated with a higher level of overall clinical care compared to no treatment, the clinical benefit observed with the randomized new treatment may actually be due to enhanced clinical care rather than the supposedly tested intervention. As well, clinical trials have been criticized for being limited in its external validity to patient groups who were not

robustly included in trials with limited representativeness.[41] Finally, clinical trials are expensive, often with long periods between trial conception, activation, accrual, analysis, and completion.[42] Thus, answering every clinical question using a randomized clinical trial is simply not practical.

In light of these issues, alternative forms of evidence generation are needed to compare the *effectiveness* of radiation technologies, in addition to the *efficacy* of the treatment. The efficacy of a treatment is what is tested in a randomized controlled trial—the benefit of a treatment in ideal conditions, with the treatment impact isolated from all other factors. The effectiveness of a treatment is how the treatment impacts outcomes in real-world practice, in normal and not idealized situations. Alternative forms of evidence may also address the "efficacy-effectiveness" gap.[43]

COMPARATIVE EFFECTIVENESS RESEARCH

Though in an ideal world, all treatment decisions would have a supporting prospective randomized clinical trial, this is unrealistic given the rapid pace of change in cancer treatment and radiation technology. CER addresses this need for clinical evidence regarding the effectiveness of a new radiation technology. The Institute of Medicine defines CER as "the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. The purpose of CER is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels."[44] Technically, this also includes clinical trials, but generally has been understood to involve nonprospective trial investigation with studies that use observational registry data, insurance claims, and other large data sets to compare medical practice that would otherwise be difficult to compare.

Examples of CER in RO include comparisons of radiation to surgery, adjuvant radiation to no adjuvant treatment,[45] as well as comparisons of different radiation techniques (extreme hypofractionation to standard fractionation, proton to photon, brachytherapy to external beam radiotherapy, etc). Great care should be taken when attempting to compare radiation to surgery, given the huge inherent bias in patient selection that

favors surgery.[46] It has been shown that bias favoring surgery for prostate cancer cannot be adequately adjusted using standard statistical techniques.

Limitations of CER comparing radiation technologies center around the limitations of retrospective data as well as the potential bias inherent in patients who are selected for new versus older technologies. It is possible that patients treated in more recent years benefit from improved staging, supportive care, and medical care in general. These benefits (and others) cannot be adjusted for with statistical methods if their values are unknown and unmeasured. This unmeasured confounding is a key limitation of retrospective data. Furthermore, as technology matures, its impact may change and indications for use may change in ways not accounted for in retrospective data sets.[45]

To address limitations in the analysis of observational and registry data sets with standard regression models such as logistic regression and Cox proportional hazards analysis, additional analytic methods have been applied. These methods include techniques involving propensity scores, such as inverse propensity weighting and propensity score matching.[47] Instrumental variable analysis attempts to get around the question of unmeasured confounding variables. An instrumental variable is a measured variable that cannot influence the outcome, except through the treatment in question, and at the same time is not related to any other variable, except the treatment variable.

For an instrumental variable to be used to avoid treatment selection bias, the instrumental variable must be related to the outcome of interest without being related to selection bias. For example, if hospital's overall SBRT utilization rate is related to the use of SBRT for lung cancer (vs surgery) and you believe that SBRT utilization can theoretically only affect survival through choice of clinical treatment, it would make a reasonable instrument.[48] However, one could hypothesize that the overall use of SBRT is also related to other factors (eg, overall hospital technology, presence of multidisciplinary tumor boards, academic practice) that could influence patient outcomes. Therefore, though instrumental variable analysis is a compelling technique to avoid unmeasured confounding variables, it is difficult to find the perfect instrumental variable in actual practice.

ASSESSING THE ROLE OF ARTIFICIAL INTELLIGENCE IN RADIATION ONCOLOGY

The term *machine learning* (ML) broadly means computerized algorithms that work without explicit coding but instead by analyzing data that are fed into the algorithm. AI is often considered a broader area of study investigating the ability of a computer to perform tasks that traditionally require human intelligence. In this chapter, we use the two concepts interchangeably. The data fed into the algorithm are generally known as "training data," which can be curated with known outcomes (in the so-called supervised learning) or left to the algorithm to organize into recognizable features (the so-called unsupervised learning). The algorithms themselves can vary from readily understandable multivariable logistic regression models to inscrutable deep learning neural networks that have been compared to a "black box." Furthermore, not only has AI been used to interpret and classify data, but algorithms trained on images and languages are being increasingly used to generate output in response to prompts and questions from the user. This "generative AI" is an area in which AI is going beyond analysis of data to potentially directly impacting patient care.

How to evaluate analytic and generative AI algorithms is a question that is important for regulators tasked with determining the safety of medical technology such as the FDA. To address the question of AI in drug development, the FDA released a discussion paper that characterized the risks of AI-developed drugs, including biased data, and inaccuracies in the completeness of the data.[49] Ultimately, the differences between standard FDA postmarket monitoring for non-AI and AI-informed drugs will likely be similar.

In the United States, AI-based medical devices are largely cleared through the FDA's 510(k) pathway for "substantially equivalent" devices.[50] As with drugs, postmarket surveillance does not substantially differ for AI-utilizing medical devices. Relevant to RO, a recall of a software that utilized AI/ML for treatment planning and analysis of radiation was affected by an error that would have resulted in local underestimation of expected dose (FDA recall number Z-2341-2020). It is not clear whether AI/ML-based machines are more or less likely to be involved in recalls by the FDA.

To address the evaluation of AI/ML-based software, the FDA released an action plan, following a discussion and request for feedback.[51-53] This action plan focused in part on how algorithms are updated as more data are evaluated by an algorithm. As a result, the FDA recommended a "predetermined change control plan" in premarket submissions that required anticipating modifications to an algorithm and how to implement those changes in a controlled manner. As well, the FDA is expecting transparent and real-world monitoring of the AI/ML-based software once approved. This is the goal of the FDA's Digital Health Center of Excellence.[54]

Finally, best practices in AI/ML technology development are needed. Known as *Good Machine Learning Practice*, this includes areas such as data management, training data, unsupervised feature extraction, algorithm interpretability, and documentation.[55] Arguably, whether a technology is developed in adherence to Good Machine Learning Practice could be used to assess its quality. Further, the Minimum Information about Clinical Artificial Intelligence Modeling (MI-CLAIM) checklist has been developed to describe the minimum amount of documentation required for proper interpretability, transparency, and utility of health care AI models.[56] The six parts of the MI-CLAIM process are proper reporting of study design, proper partitioning of data for training and testing of the model, final model selection, performance evaluation, model examination, and evaluation of model-building pipeline reproducibility.

Ultimately, an AI/ML technology will need to be evaluated in the same manner as any medical technology. The same can be said for AI/ML-developed drugs. Is the tool based on a transparent algorithm that uses plausible features and good training data (analogous to the question, "is the mechanism of action explainable")? Is the tool biased? Is the technology reliable and robust? Once approved, the performance of the AI/ML technology will need to be evaluated in a similar manner to any technology. Unique to AI/ML technology is the potential for continuous change as more contemporary data are being fed into the algorithm. Monitoring the algorithm as it changes in response to additional data is an area of intense focus by the FDA.

TOWARD EVIDENCE-BASED RADIATION ONCOLOGY

Evidence-based medicine (EBM) is the conscious use of current best evidence in decision-making in clinical care and health services delivery. Arguably, EBM should provide an underpinning for our understanding of the clinical literature and thus our daily RO clinical practice. EBM involves the clinician using the best evidence available, in consultation with the patient, to decide on a clinical course that suits the patient best.

Synthesizing outcomes data and CER, the American College of Radiology (ACR) began documenting RO national benchmarks with the Patterns of Care Studies (PCS), performed under a grant first awarded by the National Institutes of Health in 1973.[51,52] This move toward EBM followed a discrete move across medicine, led by Canadian researchers.[53]

In many ways, the PCS represented the first nationwide assessment of practice within a medical discipline. These studies described essential requirements of the proper clinical, physics, and administrative aspects of contemporary RO practice. By focusing on this process in the context of specific pretreatment and treatment factors, improvement in the treatment process contributed not simply to better quality of care but ultimately to improved survival of patients with cancer.[51]

In the early 1990s, data from the PCS developed into decision trees. These may be recognized as early versions of clinical pathways. Similarly, practice guidelines involved the use of expert panel review with application of a consensus tool such as the Delphi technique[54] to document appropriate techniques for clinical cancer cases. Clinical pathways and practice guidelines became the mechanisms by which EBM was integrated into active clinical usage in the late 1990s and early 2000s.

In contemporary practice, many radiation oncologists now rely on treatment guidelines published and updated by expert committees from ASTRO, ACR, and other societies or practice groups. Some departments have created their own internal clinical practice guidelines.[57] These national and institutional clinical guidelines have the potential benefit of providing treatment recommendations where evidence is lacking, though caution is required where bias and conflicts of interest exist.[58,59]

CONCLUSION

Given the rapid and continuous pace of technological innovation, it is important for all radiation oncologists and their teams to understand how new technologies understand how new technologies disseminate, are evaluated, and are compared to older technologies. Comparative effectiveness researchers, clinical trial groups, as well as government and health care payers are continuously attempting to measure the efficacy of new technologies against their cost to patients and payers. Because of the rapid pace of change and inherent difficulties in comparing new technologies to old, analytic techniques that attempt to reduce bias and overcome limitations of retrospective data have been developed and are being used. Patient-reported outcomes, physician-measured outcomes, and other outcomes such as financial burden and toxicity are being assessed to obtain the full impact and benefit of the new innovations in radiotherapy. The breadth of research can be considered in clinical guidelines advising physicians in the optimal use of radiation technology, both old and new.

CHAPTER 34

Global Radiation Oncology

Timothy P. Hanna, Melinda Mushonga, Fabio Ynoe de Moraes, and C. Norman Coleman*

Global radiation oncology links the discipline of radiation oncology to global health, where the latter may be defined as "… an area for study, research, and practice that places a priority on improving health and achieving equity in health for all people worldwide."[1] This chapter provides an overview of the unique challenges to providing radiation oncology in low- and middle-income countries (LMICs). It also provides reasons for hope that the global challenge of cancer can be met and provides some innovative models of how cancer care should be considered integral to health care and not an "expensive add-on." Low-income countries have a 2025 per-capita gross national income of US$1,145 or less, and for middle-income countries, the range is US$1,146 to $14,005.[2,3] Nations falling into these income groups are sometimes described as developing countries.

GLOBAL BURDEN OF DISEASE

In 2019, an estimated 17% of all deaths worldwide were due to cancer.[4,5] In comparison to the worldwide burden of cancer, cardiovascular disease and other chronic conditions are responsible for, respectively, 32% and 25% of deaths globally. In total, 74% of mortality worldwide is the result of noncommunicable diseases (NCDs). Seventy-six percent of these deaths occur in LMICs.[4,5] In low-income countries, where deaths from communicable diseases and other related causes are common, deaths due to NCDs are 42% of all deaths.[4,5]

In 2020, 59% of cancers worldwide occurred in LMICs, as did 71% of all cancer deaths.[6-8] In 2020, 55% of all cancer incidence was in Asia and Africa alone, and deaths were 65%.[9] The continual increase in the burden of cancer in LMIC relates to an increasing life expectancy in LMIC, coupled

with a rising incidence of risk factors for chronic diseases.[10,11] For example, an estimated 65% of people 60 years of age or above lived in less developed countries in 2010, and this is expected to rise to 79% by 2050.[4] The growing burden of cancer and other NCDs in LMIC represents a significant epidemiologic transition and a dual challenge for disease control efforts in countries already faced with a high burden of communicable disease.

EPIDEMIOLOGY OF CANCER WORLDWIDE

Worldwide, there were 18.1 million new cases of cancer and 9.9 million cancer deaths in 2020.[6,12] Breast cancer is the most common cancer worldwide (2.3 million new cases in 2020), followed by lung cancer (2.2 million) and colorectal cancer (1.9 million).[6,7] Lung cancer is the most common cause of cancer death, with 1.8 million deaths in 2020, followed by colorectal cancer (0.9 million), liver cancer (0.8 million), and gastric cancer (0.8 million).[6,7] Figure 34.1 illustrates trends in cancer incidence and mortality by country income, comparing high-income (HICs) and upper-middle-income countries. Age-standardized incidence rates of cancer in HICs are more than double the rates in low-income countries, though age-standardized mortality rates are far more similar. These findings reflect a variation in the prevalence and distribution of major risk factors and limitations in early detection and treatment resources in low-income countries.[13]

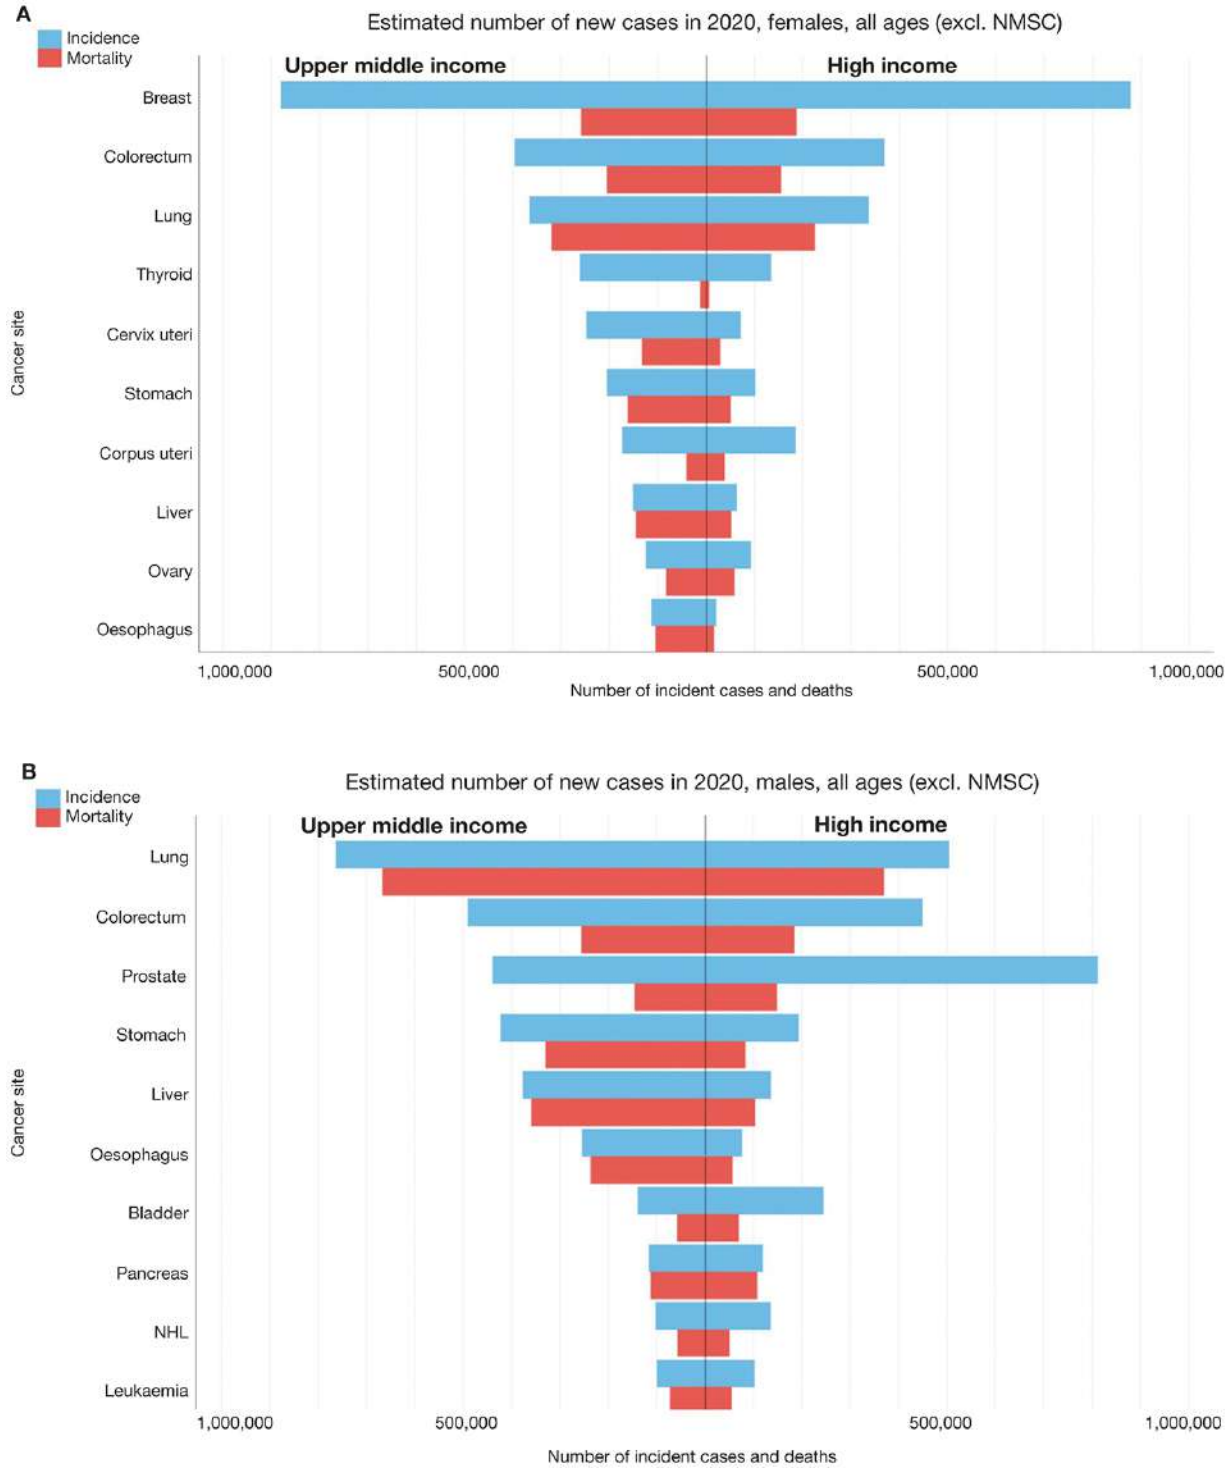

FIGURE 34.1 Estimated number of new cancer cases (incidence) and deaths (mortality) in upper-middle-income countries compared to high-income countries. Data are shown for 10 common cancer sites according to sex, ranked by cancer incidence in upper-middle-income countries. NMSC, non-melanoma skin cancer. (Reprinted with permission from Ferlay J, Ervik M, Lam F, et al. Global cancer observatory: cancer today. International Agency for Research on Cancer; 2020. Accessed September 18, 2023. https://gco.iarc.fr/today.)

Although cervix cancer is the 11th most diagnosed cancer among women in developed countries, it is second only to breast cancer in many developing nations and first in many Sub-Saharan African countries.[7] It is also an extremely common cancer in Latin America and parts of Asia, such as India (Figure 34.2). This suggests the lack of sufficient prevention of cervical cancer in many LMICs or a reflection of yet-to-be-realized human papillomavirus (HPV) vaccination efforts. Gastric cancer and hepatocellular carcinoma are also common in many LMICs, with 43% of all cases of gastric cancer in the world occurring in China alone (Figure 34.2).[7] Esophageal cancer has the highest incidence rates worldwide in some regions of Asia and Africa.[7] Oral cancer has a high incidence in South Asia, particularly among men.[14]

cancer today. International Agency for Research on Cancer; 2020. Accessed September 18, 2023. https://gco.iarc.fr/today.)

Among nine common modifiable risk factors for cancer, tobacco smoking is associated with the largest proportion of attributable risk.[15] There are over one billion people globally who smoke, and 80% live in LMICs.[16] With large populations and high tobacco use in China and India, tobacco is an extremely important risk factor for cancer in Asia.[17] In general, many LMICs have demonstrated increased tobacco use between 1970 and 2004.[18] History has shown a 30- to 40-year delay between the peak in smoking rates in a population and the peak in tobacco-related mortality.[19] Thus, an increasing rate of tobacco-related malignancies is expected in LMIC during the next half century.[20]

Over 26% of cancers in developing countries are attributed to infectious causes.[21] Hepatitis B is a major risk factor for hepatocellular carcinoma in LMIC. Other factors are hepatitis C[22] and aflatoxin produced from *Aspergillus* in certain poorly preserved foods.[23] HPV and *Helicobacter pylori* are important etiologic agents, and there are numerous other infectious agents relevant to cancer in the developing world. These include Epstein-Barr virus, human immunodeficiency virus (HIV), schistosomiasis, human T-cell leukemia virus type, and human herpesvirus 8.[21,24] The prevalence of infectious causes is notable, given the preventability of many of these causes through public health measures (eg, hepatitis B, HPV vaccine). The prevalence of infectious causes helps raise the issue of how to merge the investment of NCDs and infectious diseases, where the latter has generally been the dominant focus of global investment in the developing world. This issue is considered in the “innovation” section.

There are a few other risk factors relevant to current patterns of global cancer incidence. Diet and obesity are recognized risk factors for some cancers.[25,26] This is notable, given increasing trends in the adoption of unhealthy diet and sedentary lifestyle in LMIC.[27] The impact of genetic polymorphisms on patterns of global cancer incidence has not been fully elucidated in LMICs, but there is some suggestion of their relevance.[28,29] Similarly, the role of occupational and environmental exposures to cancer in LMIC requires continued exploration.[30]

In many LMICs, cancer often presents in advanced stages, due to factors such as the lack of comprehensive screening and poor access to diagnostic services.[31] In addition, where there is a lack of access to treatment, case fatality rates are expected to be much higher. For example, Beaulieu et al found the case fatality rates for breast and cervical cancer in low-income countries to be more than double compared to rates in HICs.[32] About half of all cancers in LMICs require radiotherapy.[33,34] Cervical cancer is common in LMIC, and advanced cancer presentations requiring chemoradiation and brachytherapy are common. Therefore, radiation therapy has an extremely important role in LMIC. Accordingly, the World Health Organization (WHO) considers external beam radiation machines, remote afterloading brachytherapy systems, and their supporting technologies as priority medical devices for cancer management.[35] The following sections describe radiation oncology in LMIC in terms of access, quality, and economics.

GLOBAL STATUS OF ACCESS TO RADIATION THERAPY

Access to radiation therapy is a multifactorial issue. Availability of machines and personnel for treatment is a key part of access to care. Other considerations include spatial accessibility, temporal accessibility, acceptability, affordability, accommodation, awareness, and adoption of optimal radiation departmental practices.[36,37] The most pertinent elements of access to radiation therapy in LMIC are discussed here.

Availability of equipment and personnel for radiation therapy are common limiting factors in LMIC. Less than 5% of global medical spending on cancer is in LMIC.[38] This is despite LMIC containing over 80% of the world's population[10] and over 70% of the world's deaths from cancer.[6] Oncology medical training programs are steadily growing; however, more needs to be done to address the lack of key personnel for radiation oncology and refine the curriculums in line with treatment advances in radiation oncology.[39-43] LMICs only have about one-third of the world's 13,136 megavoltage radiation therapy units despite an estimated need for more than double the current number.[44,45] In Africa, as of March 2020, 430 external beam radiotherapy units were available in 28 of 52 countries; however, more than half of these units were in either South Africa or Egypt.[46]

The greatest limitations in machine supply are strongly associated with low national economic status (Figure 34.3).[33] Given the expected rise in cancer incidence in LMIC, these large mismatches between need and availability will widen if current machine supply remains inadequate. In addition to machine availability, other physical resources need to be considered. These include clinical space, bunkers, other equipment (brachytherapy, simulation, immobilization, treatment planning, beam modification, dosimetry, quality assurance), a reliable power supply for linear accelerators, and the availability of parts and technical support for machine maintenance and repair.[47]

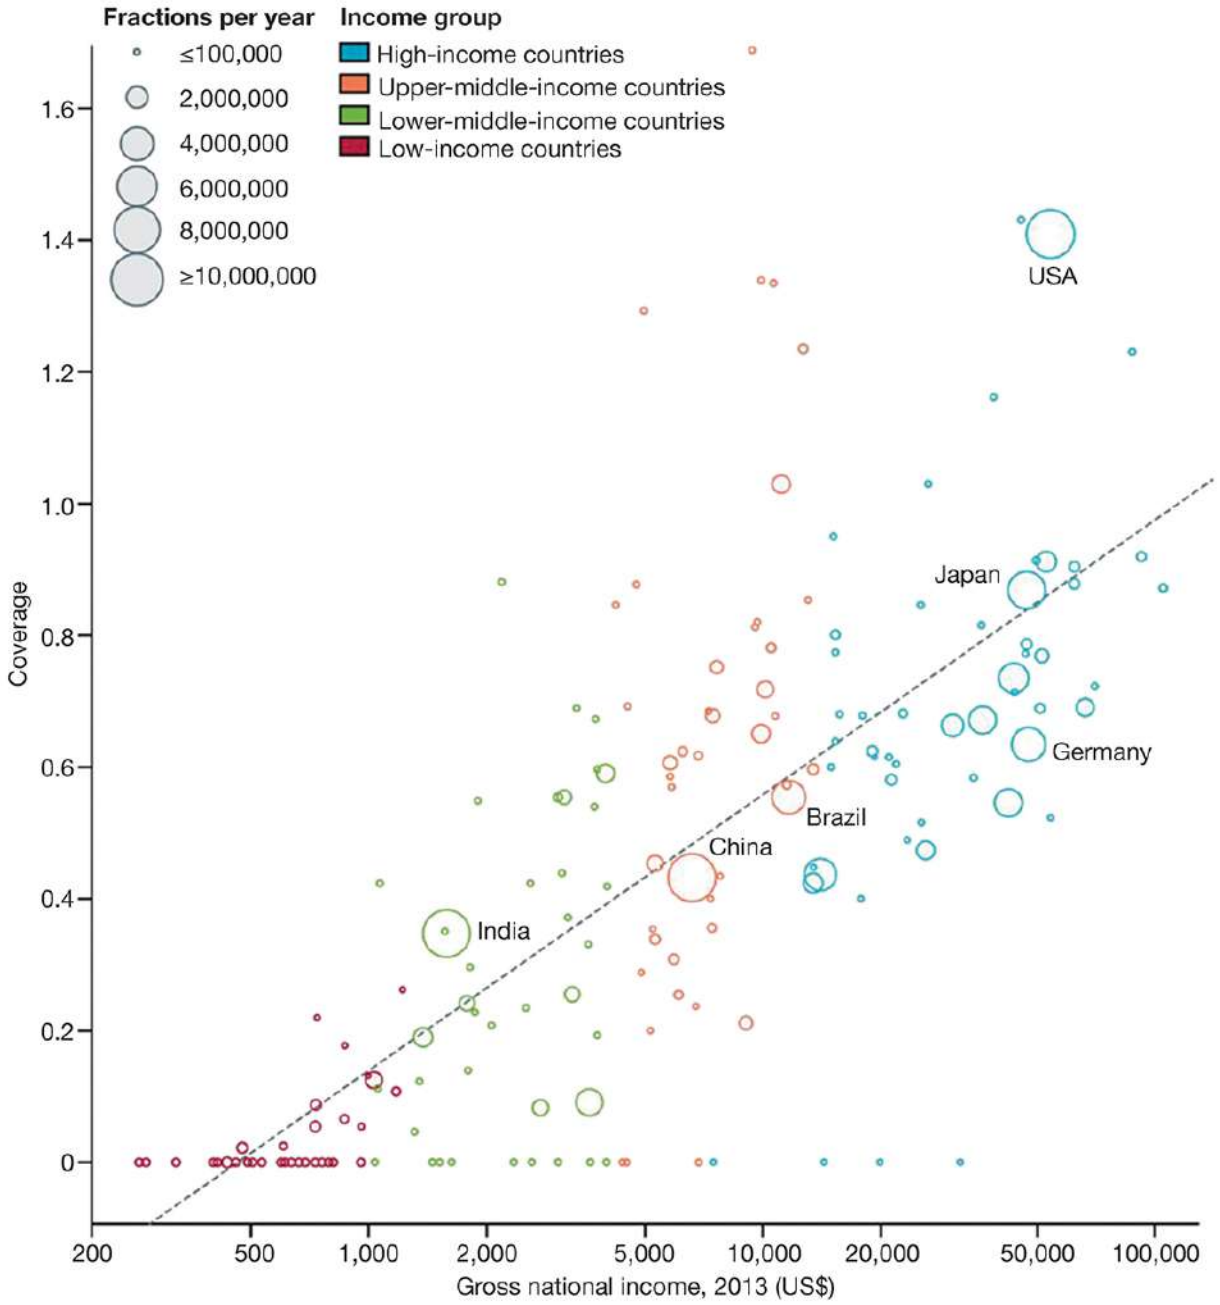

FIGURE 34.3 Radiotherapy coverage according to country gross national income per capita. Each circle represents a single country. The diameter corresponds to the actual annual number of fractions delivered by each country. Color corresponds to country income group. Coverage is reported assuming an 8-hour operating day. (Reprinted from Atun R, Jaffray DA, Barton MB, et al. Expanding global access to radiotherapy. *Lancet Oncol*. 2015;16[10]:1153-1186. Copyright © 2015 Elsevier. With permission.)

The state of radiation therapy resources varies between LMICs and regions.[40,43,48,49] Some selected examples are provided for illustration. In

1999, Levin et al[49] documented the availability and distribution of radiation therapy equipment in Africa. Only 22 of 56 countries in Africa were confidently known to have megavoltage radiation therapy facilities. In total, more than 400 million Africans had effectively no access to radiation therapy. Although machine supply has since increased, there are still dramatic shortfalls in machine supply in Sub-Saharan Africa.[44,45]

In the Asia and Pacific Region, Tatsuzaki and Levin[40] found an 82-fold variation in the number of megavoltage machines per million population in 1999. China's and India's machine supply has increased in recent years, though capacity is still well below what is needed to treat all patients.[8,44,50] Workforce resources vary considerably between countries, and most countries have less than two radiation oncologists per 1,000 incident cancers annually.[8,41,44] Many more physicists and radiation therapists are required to expand global treatment capacity.[33,41,51]

Cancer care is multidisciplinary, and these disciplines triage patients who eventually require radiotherapy. Surgical oncology, medical oncology, oncology nursing, pathology, radiology, rehabilitation, supportive care, and palliative care all have a role to play in effective cancer management.[52] Limitations in pathology and radiology compromise diagnosis and the ability to distinguish curative-intent treatment from palliative cases. Surgical oncology plays a central role in curative treatment of early-stage cancer. The Lancet Oncology Commission on Global Cancer Surgery reported that despite over 80% of cancer cases needing surgery globally, less than 25% of patients with cancer get safe, affordable, or timely surgery.[53] Access to palliative care, including pain control for moderate-to-severe pain, is a major issue. The WHO estimates that 5 billion people live in countries with limited or no access to narcotic analgesics and other controlled substances, with an estimated 5.5 million patients with terminal cancer dying each year without adequate treatment.[54] Therefore, if the disciplines that triage patients who may eventually need radiotherapy are not supported, the number of patients able to access appropriate radiotherapy as part of cancer care will remain low.

Spatial accessibility refers to the geographic accessibility of medical treatments. Available information suggests spatial accessibility is of concern in LMIC as less than 25% of the Sub-Saharan African population is estimated to be within 2 hours of radiation therapy.[44,55,56] With radiation

therapy centers often in large cities, rural populations may face substantial financial challenges when traveling into cities for the duration of radiation treatment. For example, in Ghana, only 47% of the population lived within 100 km of the nearest radiotherapy facility.[57] Notable is that there are "LMIC"-like situations within HICs such that there are both solutions in common among the range of resource rich and limited. This is particularly relevant to geographically isolated regions, often indigenous populations.[58-60] One of our early career leaders in the International Cancer Expert Corps (ICEC) has dubbed this "local-global"[61] an important consideration when seeking investment in global health, discussed in the "Innovation" section.

Temporal accessibility refers to accessing radiotherapy without undue delay. Delays in cancer treatment, including radiotherapy, are in many cases associated with patient anxiety, and with adverse clinical outcomes, including reductions in local control, and potentially worse survival.[62-64] Professional societies and health systems have established benchmarks that set reasonable standards for timely treatment.[65-67] Though data are limited, particularly for low-income countries, available information suggests that despite these wait time targets, waiting for cancer diagnosis and treatment can be lengthy across all country income levels and should be addressed.[68,69]

Acceptability of available care options can impact an individual's willingness to take advantage of services and adhere to recommended therapies. For example, a small study from Cameroon found beliefs, fears, cultural factors, and awareness were among the explanations for the delay in seeking medical attention for cancer.[70] Values surrounding the effects of pelvic radiation treatment on fertility, loss of hair with some chemotherapy, and anatomic changes associated with surgery such as mastectomy are some potential factors in need of further description and quantification in LMIC. Culturally appropriate cancer control plans sensitive to a region's social and political concerns are needed, including initiatives to overcome stigma and improve awareness.[71]

Affordability of radiation therapy and other forms of cancer therapy is a major concern in LMIC.[72] Households in LMICs often have limited or no health insurance coverage.[38,73] Cancer-related publicly funded treatment may be limited or nonexistent.[74] The cost of travel to the nearest cancer center can itself be another major financial obstacle, and the costs of staying for the length of radiation treatment in another location can mean lost

income and more cost to the patient and family.[72] A family may lose additional income due to the caregiver absence from work.[72,75]

Awareness of the basic cancer principles and the value of cancer screening and early detection potentially limit timely access to cancer services for the public in LMIC. A large Union for International Cancer Control (UICC) survey of multiple LMICs found a substantial lack of awareness of common preventable causes of cancer and found that a quarter or more of respondents in Asia and Africa did not think cancer could be cured.[76] Limited awareness of principles of cancer diagnosis among health care workers and poor coordination of care can further compromise access to cancer treatment.[68,77,78] Moreover, a lack of awareness of indications for radiotherapy among the public and referring physicians can further limit access to radiotherapy. For example, there may be a lack of awareness of the role of radiotherapy in hemostasis for cervical cancer or palliation of painful bone metastasis.

Adoption of optimal departmental practices is an important part of improving access to radiotherapy. Increased waiting times to start radiotherapy have been reported in many Sub-Saharan African countries because of the reduced availability of radiotherapy machines.[79,80] Adoption of hypofractionation regimens for breast, prostate, and other cancers can potentially result in reduced machine time for individual patients; hence, many more patients can be treated compared to protracted treatments. There is established evidence in breast cancer treatment for hypofractionation but poor adoption in LMICs, suggesting the need for targeted interventions that aid knowledge translation to clinical practice in LMICs.[81] Moreover, capacity can be further improved with sufficient departmental staffing, longer operating hours, and less machine downtime due to appropriate maintenance and servicing.

Access to and adoption of new techniques requires training. New radiotherapy machines have been commissioned in some countries in Sub-Saharan Africa, and these can be used to deliver stereotactic treatments in keeping with advances in radiation oncology management protocols with the right support. There is no data on the status of advanced radiotherapy techniques to organize support for institutions with potential capability based on the already existing infrastructure. As highlighted, cervical cancer is one of the most common cancers in LMICs, and most patients present

with advanced disease. Interstitial brachytherapy has an established role in the management of locally advanced cervical cancer. There are 101 brachytherapy units in 20 African countries according to the International Atomic Energy Agency (IAEA) data, but limited information on access to interstitial brachytherapy in these countries.[82] There is, therefore, an opportunity for the global oncology community to focus on clinical skills transfer programs onsite to complement the established and traditional observorships, which, in most cases, are not hands-on.

QUALITY OF RADIATION ONCOLOGY IN LOW- AND MIDDLE-INCOME COUNTRIES

Key dimensions of quality are described by the Institute of Medicine as safety, effectiveness, patient centeredness, timeliness, efficiency, and equity.[83] Quality can be assessed through consideration of a health system's structure, process, and outcomes.[84] Elements of structure are physical resources, human resources, and organizational structure. Limitations in physical and human resources in LMIC have already been described. The access issues that relate to late presentation and failure to receive indicated treatment arguably have the greatest impact on outcomes and quality of radiation therapy in LMIC. Quality may be further degraded by the inequitable access of the few available resources between country and city, rich and poor.

The organizational structure of health care in LMIC has historically revolved around communicable disease, nutritional deficiencies, and child and maternal health. The additional burden of NCD in LMIC, commonly cancer, cardiovascular disease, chronic lung disease, and mental illness, imposes a major strain on current resources and health care models. Other issues may include political or social instability, conflict, corruption, and fragmented service provision. Challenges to the structure of cancer control in limited-resource settings may also include insufficient priority of cancer control among some governments and donor agencies with many competing priorities. Cancer infrastructure may be considered expensive. However, health investment is not a zero-sum game. There is a global need for sustainable local health care infrastructure relevant to all conditions, and focusing on cancer can help catalyze its development. Moreover, though

prevention must be part of this, it is emphasized that targets set by WHO for reducing mortality from NCDs by 2025 will not be met by prevention alone.[85] Effective cancer control requires prevention, timely and accurate diagnosis, and access to treatment. The immediate need for cancer care once a diagnosis is made and that cancer is a problem in upper income countries altogether makes it a good focal point for investment in LMIC.

The process of health care refers to what occurs while care is provided. For radiation oncology, this includes technical elements of quality assurance, treatment prescription, treatment planning, and treatment delivery. It includes the integration of multidisciplinary services needed alongside radiation oncology for effective cancer management. A major process issue in some countries is system-related delay in diagnosis.[86,87] This contributes to high rates of advanced disease at presentation. System-related diagnostic delay can relate to weak or nonexistent referral systems or limited resources for diagnosis. It is compounded by patient-related delay in seeking medical attention due to previously described access issues.[88] The additional impact on delay due to waiting times for radiation following radiation oncology consultation may be substantial.[89] Treatment delays for radiation, systemic therapy, and surgery have been associated with worse overall survival in many high-quality studies.[62]

The technical process of radiotherapy is a vital element of quality. For this reason, the IAEA and WHO have maintained a postal dose audit program using thermoluminescent devices (TLDs). A report focusing on measurements from LMIC found acceptable results, with most machines calibrated within the ±5% dose acceptance limit. Sixteen percent of machines registered measurements outside this range in the first round of testing, with 91% measuring dose within 5% of the standard after the second round.[90] Notably, a dosimetric audit in Latin America and the Caribbean suggested an association between on-duty medical physics support and acceptable TLD results.[91] This emphasizes the importance of adequate staffing to a radiation department's quality assurance process as well as the development of robust treatment equipment capable of functioning in challenging environments. An example of efforts underway to develop such equipment is the ICEC STELLA project (Smart Technology to Extend Lives with Linear Accelerators).[92]

There are opportunities for gains in the process of clinical care in LMIC, as there are in HIC. Improving the volume and quality of training programs are clear needs for high-quality national radiation treatment programs. For example, in a survey of 26 African countries, 17 countries identified insufficient staffing/human resources and/or limited training opportunities as one of the main challenges facing their radiotherapy centers.[93] Taking advantage of hypofractionation to increase throughput where there is supportive evidence has not always occurred.[94,95] Implementation of multidisciplinary decision-making among oncologists in LMIC is important, but not always present.[96,97] Treatment refusal or nonadherence by patients can be a major issue in some cases and is an important area for quality improvement where it exists.[55,75,98] Audits of the clinical decision-making and the treatment planning process provide a useful means of ensuring patient safety, improving processes, and creating opportunities for continuing education.[99,100] This is particularly important with the introduction of technology at new locations. For example, initial experience with this approach in a new radiation therapy center in an Asian developing country found suboptimal management in 52% of cases.[99]

Adverse event rates in LMIC treated with radiation are largely unknown. A report examining the risk profile of radiation therapy for the WHO could not identify any detailed reports of adverse events from Africa or Asia.[101] It is important to highlight the need for adverse event recording and reporting for the purpose of patient safety and quality improvement for all countries utilizing radiation therapy.

Importantly, the quality of radiation oncology in LMIC relates to outcomes. Of all cancer outcomes, there is the most information on survival. Generally, overall survival for patients with cancer is lower, and sometimes dramatically so, for populations in LMIC. In a large multinational series from the International Agency for Research on Cancer (IARC), 5-year age-standardized relative survival for cervix cancer was 79% in Seoul, South Korea, but 46% in Mumbai, India; 22% in The Gambia; and only 13% in Kampala, Uganda.[102] Similarly, for breast cancer, survival rates ranged from 90% in Hong Kong SAR to 13% in The Gambia. When absolute survival was stratified by the extent of disease, in many cases, treatment outcomes were still inferior in regions with less developed health services compared to regions with more developed services (eg, local

and regional extent breast cancer and larynx cancer). This may reflect access and quality issues in diagnosis, treatment, and follow-up and/or limitations of the available data.

Finally, corruption is a complex and multifaceted challenge in the global health care sector that significantly undermines the efficiency, equity, and quality of health services.[103] Corruption significantly impacts the quality of health care globally, manifesting through increased wait times, inequitable care, poorer patient treatment, compromised supply chains, unjustified fees, and misallocation of funds. These practices erode trust in both governments and health care systems, leading to poorer care quality and health outcomes.

The spectrum of corrupt practices ranges from smaller scale acts, such as health care professionals demanding bribes for services, to larger scale corruption at the ministerial or administrative level, where funds are misappropriated for personal gain.[104] Annually, the health care sector sees an estimated $455 billion lost to fraud and corruption out of a global expenditure of $7.35 trillion,[105] reflecting a grave issue where around 45% of the global population perceives the health sector as corrupt or very corrupt.[106]

Chronic underfunding by governments, insufficient regulatory oversight, and a lack of transparency in health governance foster an environment ripe for corruption, which, in turn, diminishes the quality of health care delivery. In contrast, environments where good governance prevails demonstrate the importance of transparency and accountability in ensuring that public health expenditures translate into positive health outcomes.[103]

The adverse effects of corruption and bureaucratic states are vividly illustrated through various global instances,[107] through countries including, but not limited to, India, Costa Rica, Cameroon and other parts of Africa, Albania, and through initiatives like Brazil's PER-SUS.[108-110] These examples highlight the direct financial extortion from patients, collusion for personal gain, delays in capacity building and the promotion of unnecessary treatments for profit, showcasing the complex nature of corruption within health care.

To counteract corruption, effective strategies include investing in health care infrastructure and worker salaries, enhancing accountability, public reporting, and strengthening regulatory institutions. Achieving improved governance, accountability, and transparency, while challenging, is crucial

for reducing corruption in health care and enhancing outcomes. Integrity is fundamental to achieving quality health care, emphasizing the need for robust governance structures to protect against corruption, promote ethical practices, and ensure equitable care for all. A concerted, collaborative effort is required to dismantle the systemic corruption that plagues global health care,[110] underscoring the need for a unified approach to foster a more equitable and efficient health care environment worldwide.

ECONOMICS OF RADIATION THERAPY IN LOW- AND MIDDLE-INCOME COUNTRIES

In 2013, the Global Task Force on Radiotherapy for Cancer Control (GTFRCC) was commissioned by the UICC to determine the investment needed to achieve equitable access to radiotherapy in LMIC by 2035.[33] This was a broad collaborative effort, involving radiation oncologists, physicists, industry, economists, and global health experts. GTFRCC published their findings as a Lancet Oncology Commission, as part of the Lancet Cancer Campaign. Dramatic shortfalls in radiotherapy coverage were evident (Figure 34.3). The cost of scaling up radiotherapy services from 2015 to 2035 was estimated to be US$26.6 billion in low-income countries, $62.6 billion in lower-middle-income countries, and $94.8 billion in upper-middle-income countries. By comparison, 1 year of immunotherapy (budgeted at $295,000 per patient) for the current burden of metastatic cancer in the United States would cost an estimated $174 billion.[111]

What could be gained by investment in radiotherapy for LMIC? The GTFRCC estimated that scaling up radiotherapy from observed levels in 2015 to 2035 could save 26.9 million life-years in LMIC over the lifetime of patients receiving treatment. Moreover, the estimated net economic benefit derived from investment in radiotherapy from 2015 to 2035 was found to be substantial. These estimates utilized a full-income method, which is rooted in the societal or individual willingness to pay to avoid a shortened life expectancy. Investment in radiotherapy could produce a net benefit of $265.2 million in low-income countries, $38·5 billion in lower-middle-income countries, and $239·3 billion in upper-middle-income countries. That the analysis of the benefit of radiation therapy for cancer care and the benefit of the overall economy is compelling, yet the progress

in the 8 years, since the report is so limited, is both a source of frustration and evidence of the need for innovative paradigms for cancer care. Not only has the investment in NCDs historically been limited compared to infectious diseases, but the COVID-19 pandemic has further raised the global concern for and investment in the pandemics. In the "Innovation" section, the concept of "flex-competence" is considered (Figure 34.4).[112]

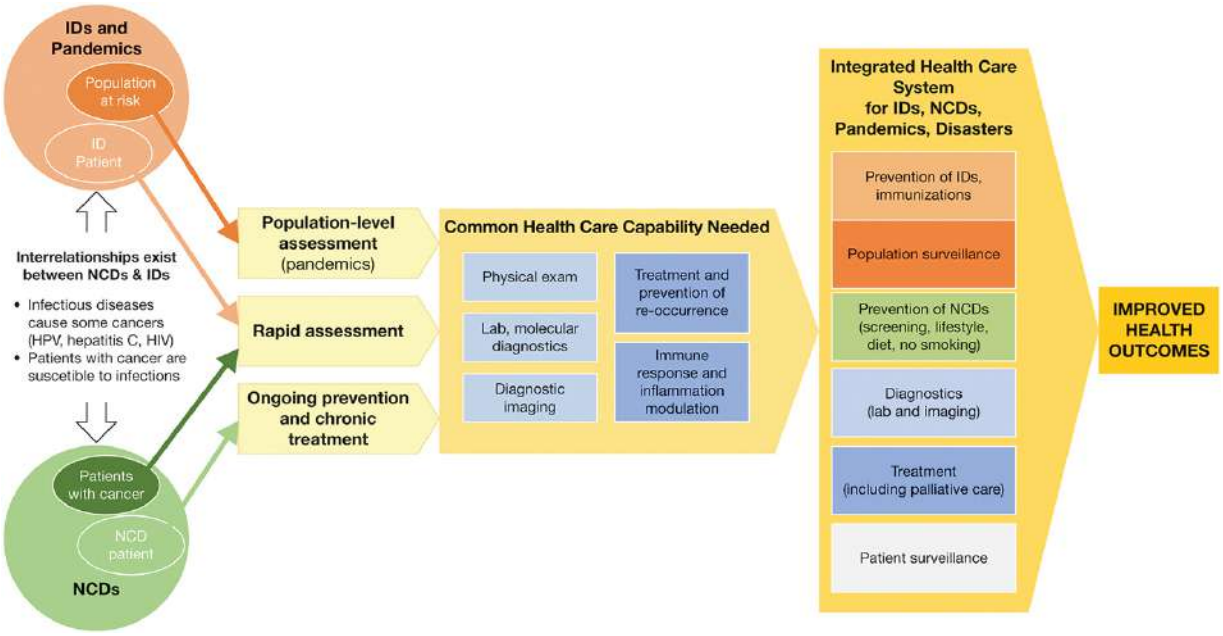

FIGURE 34.4 Flex-competence health care system approach. Approaches to control infectious diseases (IDs) and noncommunicable diseases (NCDs) are similar and often share common etiology. They also often share the same urgency, requiring prompt intervention. There is a common health care capability and capacity needed to control these conditions. HIV, human immunodeficiency virus; Hep C, hepatitis C; HPV, human papillomavirus. (Reproduced from Coleman CN, Mansoura MK, Marinissen MJ, et al. Achieving flexible competence: bridging the investment dichotomy between infectious diseases and cancer. *BMJ Glob Health*. 2020;5[12]:e003252, with permission from BMJ Publishing Group.)

Undoubtedly, applications of various radiation therapy techniques and modern equipment will yield opportunities to maximize the cost-benefit ratio of radiation treatment in LMIC. The GTFRCC found that economic benefits from efficiency gains in radiotherapy delivery could be substantial. These efficiency gains included automation of treatment planning and quality assurance.[33] Hypofractionation yields opportunities to treat more patients with the same supply of equipment.[113] Hypofractionation for

cervical cancer and lung cancer are examples of identified areas for research.[114-116] Investigation of brachytherapy or intraoperative radiation therapy may provide a means of delivering adjuvant treatments rapidly. High-dose rate (HDR) brachytherapy markedly increases patient throughput (eg, for cervical cancer) compared to low-dose rate (LDR) brachytherapy per machine.[117] An IAEA study of accelerated radiation therapy for head and neck cancer in LMIC suggests an opportunity for increasing the effectiveness of treatment without increasing departmental resources, though with increased, but tolerable, acute toxicity.[118] It should be emphasized that prevention and early detection are critical to reducing the number of people diagnosed with cancer and the number of advanced cancers requiring more complex, multimodality treatments.

TRANSLATING KNOWLEDGE INTO ACTION

Recognized priorities for action fall into six categories: advocacy, investment, planning, capacity building, quality, and innovation.[38,119-123] The varying resources, priorities, and disease burden seen in countries at different stages of development mean that there is no single solution that will apply in all cases.[78] In low-income countries with extreme resource limitations, a strategy focusing on cost-effective prevention, raising awareness of cancer within the population, monitoring of process and outcomes, good palliative care, and focused early detection and treatment goals would be a reasonable starting point.[80]

Advocacy

An international coalition to support cancer control and cancer care in LMIC is emerging. The UICC plays an important role as an umbrella organization for advocacy, notably commissioning the GTFRCC, whose efforts have been described earlier. The GTFRCC called for action on five items: population-based cancer control plans, expansion of access to radiotherapy, human resources for radiotherapy, sustainable financing to expand access to radiotherapy, and aligning radiotherapy access with universal health coverage.[33] We elaborate on some of these items in a review of the six priority categories for action covered in this section.

Other groups involved in advocacy range from international agencies (eg, IAEA, WHO, IARC), to national organizations (eg, U.S. National Cancer Institute), to professional groups (eg, American Society for Radiation Oncology, European Society for Radiotherapy and Oncology, American Society of Clinical Oncology, African Organization for Research and Training in Cancer, International Organization for Medical Physics), to nongovernmental organizations (NGOs) (eg, International Network for Cancer Treatment and Research [INCTR], Axios International, AfrOx, American Cancer Society), to academic institutions and hospitals (eg, the Global Task Force on Expanded Access to Cancer Care and Control in Developing Countries [GTF.CCC] convened by Harvard, St Jude Children's Research Hospital). Through the advocacy of the UICC and many other partners (eg, NCD Alliance), the 2011 Political Declaration[124] of the United Nations High-Level Meeting on the Prevention and Control of Non-communicable Diseases was an important acknowledgment by governments of the global problem of cancer and other NCDs. It was also a substantial step toward specific and concerted action by the international community.

Investment

Substantial investment is required, though the potential return on investment is considerable. The GTFRCC called for $46 billion of investment by 2025 to establish radiotherapy infrastructure and training in LMIC.[33] Particularly in middle-income countries, incorporation of cancer care into public health insurance for those living in poverty is an important goal to meet.[38,125] The GTFRCC set a target for 80% of LMICs to include radiotherapy services as part of their universal health coverage by 2020. Given the shortage of national funding for cancer care in poorer countries, international private and public donor support and advocacy for tiered pricing will be notably important in improving access to cancer therapy.

Planning

Development of radiation therapy capacity cannot occur in isolation. Radiation therapy resources must be integrated into a broader context of multidisciplinary cancer control and into a functional health system capable of tackling the double burden of communicable and NCDs afflicting

LMIC.[126] For this reason, the GTFRCC called for population-based cancer control plans, with a target of 80% of countries with cancer plans that include radiotherapy by 2020. A national cancer control plan and collection of cancer registry and health data are central to organizing resources in an equitable and appropriate manner.[127] Notably, the GTF.CCC has published an important resource for planning, advocacy, and priority setting entitled *Closing the Cancer Divide: A Blueprint to Expand Access in Low and Middle Income Countries*.[128] The Global Coalition for Radiotherapy has also developed recommendations on essentials for radiotherapy in cancer control plans for both LMIC and HIC.[129]

Prevention (eg, tobacco control, hepatitis B and HPV vaccination) and early detection are crucial in reducing the burden of advanced cancers in LMIC. When early detection and prevention are combined with timely access to effective cancer therapy, there is great potential for reducing deaths from cancer in LMIC as well as minimizing national costs of cancer therapy.[38]

The IAEA plays a prominent role in quality assurance, safety standards, and dose calibration of radiation therapy equipment internationally. It has also been involved in numerous technical cooperation projects and radiation therapy clinical trials in LMIC. In 2004, the IAEA launched the Program of Action for Cancer Treatment (PACT) to widen the scope of its work in radiation therapy planning and capacity building. Its wide-ranging plan started with the development of sustainable demonstration radiation treatment sites in six countries throughout the developing world (Albania, Nicaragua, Sri Lanka, Tanzania, Vietnam, and Yemen). Recently, IAEA launched Rays of Hope, an initiative to support countries to establish or scale up safe, secure, and effective radiation capabilities in an effort to bridge the major shortfall in equipment and highly skilled personnel common to developing countries.

At a global level, breast cancer guidelines stratified by availability of resources have been developed through groups such as the Breast Health Global Initiative.[130] This is a useful paradigm for developing resource-appropriate and stepwise, scalable goals and guidelines for cancer care that is being adopted for other cancers.[131] A related approach has been used by the IAEA to describe additional resource requirements, benefits, and risks

for specific approaches in lung cancer treatment, including curative and palliative radiation.[132]

Developing innovative means of organizing and funding cancer services is needed. The IAEA's PACT program offers opportunities to identify successful models of service delivery and planning. A model of radiotherapy service provision utilizing geographically dispersed telemedicine-linked sites with varying levels of capacity has also been proposed by an Indian group to maximize available resources.[133] Another concept that is being explored is utilizing community health workers and primary care to expand cancer-related service provision. Proposed activities are cancer prevention, early detection, some treatment (eg, systemic therapy), palliation, and follow-up.[38]

Capacity Building

The importance of improving human resources for radiation oncology and oncology in general cannot be overstated, given the global workforce shortage of trained health care professionals. Some initial efforts have been made in developing curricula and educational approaches specific to the discipline of radiation medicine.[134-136] The IAEA has been notably involved in these efforts. The issue of loss of trained staff from developing to developed countries is especially important to consider in developing educational programs. Urban regions in LMIC may have high-level expertise that can be utilized in developing national training programs. A complementary approach is online training. This is the approach of the Virtual University for Cancer Control and Regional Training Network initiative in Africa. A growing number of cancer centers, regional groups, and specific nations have been involved in twinning projects building capacity for cancer therapy in limited-resource countries. These initiatives have been particularly strong in pediatric oncology, with demonstrated success.[137,138] They provide an appealing means for broad participation in improving cancer control in LMIC.

Surge in Career Interest and Opportunities

Over the past decade, particularly following the United Nations declaration that emphasized the importance of addressing NCDs in 2011,[124] there has

been a surge in interest in radiation and clinical oncology in making global health an integral part of a career. With support from visionary senior leadership, much of the initiative has been undertaken by trainees and early career leaders in defining a career path[139,140] and for establishing resources for idea sharing and opportunities for clinical rotations.[141] The ICEC has established an Early Career Leaders Working Group and Fund[142] to provide support for small grants for global health projects. The hurdle that must be overcome is the issue of how one supports a career in global health because it is not a revenue-generating activity. This can be surmounted with both the appreciation of the need for service as an essential component of a career in health care and the tangible and intangible benefits to institutions and individuals that come from establishing a means of sustainable service to society. New creative paradigms have the potential to bring in interest and investment in global health from a wide range of economic sectors,[143] including science, education, economics, and industry. The data from the GTFRCC[33] indicate that treating cancer provides economic as well as health benefits and is, indeed, a wise investment.

What is obvious is that visionary leaders interested in (1) innovation in career path development, (2) enhancing the capability of existing technology and creating new robust technology and connectivity, and (3) expanding the scope of what is a bona fide medical career are needed to address the gap in global cancer care in both capacity and capability. This will represent a paradigm shift to address an issue of health care inequality that is morally unacceptable, requiring immediate attention with effective action and a sustainable commitment to a problem that will take decades to solve. On the very positive side, the absolute need for radiation therapy for effective global cancer care is an extraordinary opportunity for global contribution and leadership and expanding the reach of radiation oncology.[144-146]

Indigenous Populations in High-Income Countries

Expanding the number of stakeholders in global health will benefit those in need and may enhance the interest and investment from resource-rich countries or HICs, including a recognition that they have similar problems within their own country. Optimism for investment in global health by

radiation oncology over the past few years is the result of remarkable interest by trainees and early career leaders and understanding that this is not simply a problem in the developing world. The level of interest is demonstrated by two reviews, in *Clinical Oncology*[147] and *Seminars in Radiation Oncology*.[148]

Indigenous populations in HICs, particularly people living in geographically isolated or remote regions, have economic, social, and societal issues that are often quite similar to the underserved in LMIC.[59] Similar to LMIC, poor access to screening, presentation with more advanced stages of disease, and poor access to treatment are common. While there is substantial overlap in terms of access and the need for care between indigenous and indigent populations and in the social determinants of health, a distinction is being made between indigent populations in urban centers who are near medical facilities but with limited access often due to other reasons, compared to geographically isolated indigenous people who may be many miles away and for whom physical access to facilities is limited by distance, expense, and the need to be at home to care for families. Success is possible when investment is made, as demonstrated in the Walking Forward Program[149] and the Native Navigators and the Cancer Continuum.[150] Indeed in the National Cancer Institute's Cancer Disparities Research Partnership Program, the program with the Lakota Sioux demonstrated that clinical and translational research can be accomplished.[151,152] The UICC has included an indigenous populations session in its last two World Congress meetings, with participation from Australia, New Zealand, Canada, and the United States.

What is critical to remember is that the health care disparities within geographically remote indigenous populations are experienced by nonindigenous people who are neighbors of the tribes so that they, too, benefit from investment in cancer care. Addressing this common need serves to build a link among the local communities. For those seeking investment from HICs for global health, there is an advantage in including indigenous populations among the needs for LMIC. This approach serves to make the investment more immediate to those in HICs and helps address the frequently raised question as to why invest abroad when problems exist at home.

Quality

Embedded within the themes of investment, planning, and capacity building is the implicit theme of structure-related quality improvement. Process-related initiatives in quality are another very important part of ensuring optimal outcomes. These are often referred to indirectly (eg, safety, effectiveness, patient centeredness, timeliness, efficiency, equity).[83] Quality improvement relating to process and organizational structure is important as it holds the potential for improving some outcomes more rapidly than other drivers of health, such as economic growth.[153] Many aspects of quality improvement have already been discussed in this chapter. One important element of quality for radiation oncology in LMIC is safety, given the potential for unsafe treatment to negate any benefit of available treatment.[154] Safety includes the clinical process, the various elements of technical quality assurance, maintenance, worker safety, public safety, and source security.[155,156] Safety requires investment in appropriate dosimetry equipment, sufficiently trained human resources, and time for quality assurance activities.[156] Internal and external audits, peer review, regulation, accreditation, certification, checklists, adverse event reporting, common protocols, quality improvement, and independent checking are examples of interventions ensuring safety and quality assurance in radiation oncology.[101,157,158]

Innovation

There are many fundamental questions that remain unanswered for cancer in LMIC. It cannot be assumed that evidence-based treatment protocols from specific HIC settings will produce the same results when applied in other countries. Considerations include potential differences in disease burden, malnutrition, rates of chronic infections such as HIV/tuberculosis/hepatitis B, and genetic polymorphisms affecting disease biology and treatment response.[159-163] There are many unknowns in cancer epidemiology and basic science, and, as mentioned, more health services research is emphatically needed into areas such as access, quality, and economics.[127]

International research partnerships are essential in the interconnected and interdependent world we live in.[164] Many LMICs have advanced resources

to sustain research activities; for instance, clinical trials for cervical cancer radiotherapy in India (eg, HDR vs LDR brachytherapy, radiation vs chemoradiation).[165,166] India is also home of the Advanced Center for Treatment, Research and Education in Cancer, part of the Tata Memorial Center. Regional research collaborations are developing, for example, the Forum for Nuclear Cooperation in Asia. In addition, several research/teaching twinning partnerships between developed and LMIC have been formed.[137,138,167] Supporting research on cancer by investigators in the LMIC is important as it can build local research capacity and provide a means of adapting scientific knowledge to local circumstances to meet national health priorities.[164] The U.S. National Cancer Institute has also been involved with numerous international collaborations. Protocol-driven clinical research can also strengthen local treatment capacity. The INCTR has been involved in designing clinical trials relevant to LMIC, as has the IAEA.

Clinical trials are often geared to expensive innovations that require complex and expensive supporting infrastructure to deliver (eg, companion diagnostics or gene panel testing). The IAEA has provided leadership in undertaking clinical trials in radiation oncology relevant to low-resource settings. For example, the HYPNO pragmatic trial investigated hypofractioned (20 fractions in 4 weeks) versus normofractionated accelerated radiation (33 fractions in 5.5 weeks) with or without cisplatin for locally advanced head and neck squamous cell carcinoma, a major problem in LMIC. This trial involved 792 patients from 12 centers in 10 LMIC in 4 continents. They found that the resource-sparing hypofractionated approach was noninferior with respect to late adverse events and locoregional tumor control.[168] Other international agencies and cooperative groups have an opportunity to advance access to radiotherapy by developing innovations sensitive to the context of low and middle income where the majority of the world's cancer is diagnosed and resources are most constrained.

What should be implicit in capacity building is capability of the workforce and of the technology to provide state-of-the-art care. It is debated about what is the best technology for the developing world between the relative simplicity of cobalt-60 and the more sophisticated ability of linear accelerators, which are dependent on effective physical infrastructure.

Logically, a range of technologies is needed,[169] including brachytherapy. However, to fill the enormous gap in global cancer care, it is imperative to look forward toward longer term solutions because while incremental steps and small projects are useful, innovative systems solutions are necessary to reach the necessary capacity and capability. The medical device industry has a responsibility to develop technologies that are accessible to countries with limited physical infrastructure and human capacity. The preponderance of equipment that is costly and complex to maintain effectively excludes low-income countries from scaling up radiotherapy services.

An example of novel partnerships emerged from the White House's Interagency Working Group on Alternatives to High-Activity Radioactive Sources[170] that brought together experts interested in reducing the availability of potentially dangerous radiation sources (including medical radionuclides of cobalt-60 and cesium-137), radiation oncologists and medical physicists, and also groups interested in nuclear nonproliferation. Pomper et al developed a new concept, "Treatment, not terror," which highlights the importance in providing safe alternatives to radionuclides, which, for cobalt-60, require expertise for delivering linear accelerator treatment.[171] The relatively lower initial cost of cobalt-60 is offset by a very high cost of disposal of the source at the end of its useful life, a number that is often not included in the purchase price. Certainly, treatment with both cobalt and linear accelerators is important for cancer care; however, as the huge shortage of capacity is addressed, it is worthwhile to look toward the future with improvements possible in technology, telecommunications, economic models, and efficient use of expert personnel. Recognizing the need for improved infrastructure to support linear accelerators, a workshop was conducted by the ICEC in Geneva at CERN[172] to address this complex topic. This included people with expertise in accelerator design, technology modularization, telemedicine, industrial design, and education/training. Task Groups will address unique solutions for training, education, the use of current technology, and the potential for innovative technology. Feain et al have highlighted new approaches to radiation technology for LMIC, including software, information management, and technological solutions.[173]

Closing the gap in cancer care also includes increasing the opportunities for a career in global health and recruiting, training, and retaining people

willing to serve within the challenging environments. Detailed discussions for issues raised in the sections in this chapter on capacity and capability building are in the radiation oncology reviews mentioned earlier, in *Clinical Oncology*[147] and *Seminars in Radiation Oncology*.[148]

ARTIFICIAL INTELLIGENCE IN GLOBAL ONCOLOGY

Artificial intelligence (AI) has emerged as a potentially transformative force in the field of oncology, aiming to reshape how we detect, diagnose, treat, and manage cancer. By harnessing the capabilities of AI, health care professionals worldwide may be able to make more precise and timely decisions, to improve patient outcomes.[174] AI encompasses the development of computer systems capable of performing tasks traditionally reliant on human intelligence, such as learning, reasoning, and problem-solving.[174]

Machine learning (ML) is a subset of AI that focuses on the development of algorithms and statistical models that enable computers to learn from and make predictions or decisions based on data, without being explicitly programmed. In essence, it is a way to teach machines how to improve their performance on a specific task through experience and data.

In the context of global oncology, AI algorithms can be meticulously crafted to analyze extensive medical data sets, including patient records, diagnostic imaging, genomic profiles, and clinical trial data. These algorithms can uncover patterns, predict outcomes, and assist health care professionals in making well-informed decisions in a timely manner.[175,176]

Applications of Artificial Intelligence in Low- and Middle-Income Countries

Early Detection

AI holds enormous promise in the early detection of cancer. ML algorithms adeptly scrutinize medical images, such as mammograms or computed tomography scans, to identify suspicious lesions or tumors that might otherwise go unnoticed.[177] Early cancer detection in LMICs has a far-reaching impact, potentially improving survival rates, reducing treatment costs, and enhancing the overall quality of life for patients.

Clinical Decision Support Systems

AI-powered clinical decision support systems aid health care professionals in formulating treatment recommendations by methodically analyzing patient data, medical literature, and treatment guidelines. The clinical decision support system could be a valuable tool for enhancing health care delivery and addressing the unique challenges faced by these regions in providing high-quality medical care with limited resources.

Resource Allocation

AI has the capacity to optimize resource allocation within oncology by evaluating data pertaining to patient demographics, disease prevalence, and treatment outcomes. This information could empower health care providers to allocate scarce resources efficiently and equitably, ensuring that patients receive timely and appropriate care, even in resource-constrained settings.

Automating Treatment Planning

A large amount of a radiation oncologist's and dosimetrist's time is spent in preparing radiation treatment plans for patient care. Limited human resources in LMIC could be scaled up to serve a much larger patient population if treatment planning could be automated, thus improving timely access to care. Efforts to harness AI to do this exist, and notably, the Artificial Intelligence Based Radiotherapy Treatment Planning for Cervical, Head and Neck and Prostate Cancer study (ARCHERY) is evaluating the use of AI for contouring and determination of beam geometry across sites in LMIC.[178]

Other Applications

Other aspects of radiation oncology not considered earlier include automation of quality assurance, image guidance, adaptive treatment, prediction and management of side effects, response assessment, and follow-up.[175]

AI in global oncology holds tremendous promise. As technology advances, AI algorithms will become increasingly refined and accessible, resulting in greater accuracy in early detection, enhanced treatment planning, and pioneering new treatments approaches. The integration of AI

with other emerging technologies, such as telemedicine and remote planning, could further enhance the delivery of cancer care on a global scale.[179]

Challenges of Artificial Intelligence in Low- and Middle-Income Countries

Despite encouraging developments, it is crucial to acknowledge the need for robust, long-term evaluations before definitively asserting that these approaches will mitigate late-stage diagnoses or offer other hoped-for benefits. Without rigorous scrutiny, there is a risk of deploying expensive technology that offers little value or, worse, proves detrimental or is more costly without added benefit. It could fail to meet expectations, not enhance the efficacy of care, become financially unsustainable, or impractical to scale, ultimately squandering valuable resources that could be more effectively utilized to enhance patient outcomes.

It is imperative that AI projects prioritize building local capacity for technology usage and testing and establish comprehensive plans for outcome evaluation through clinical trials. To date, comprehensive approaches and prospective or randomized controlled trials involving patients in low- and middle-income countries remain the exception. Without rigorous testing, we cannot assume that AI-based interventions will render complex care pathways more affordable and efficient, ultimately improving individual lives.[179]

While AI presents immense potential in global oncology, it also presents several challenges that demand attention. Ethical considerations, patient privacy, data security, and regulatory frameworks are crucial to ensuring the responsible and equitable use of AI in cancer care.

Ethical Considerations

The ethical implications of AI in oncology are multifaceted. Health care professionals and policymakers must grapple with questions about the fairness of AI-driven health care access, the potential for bias in AI algorithms, and the ethical use of patient data. Ensuring that AI benefits all patients, regardless of socioeconomic factors, age, gender, race, ethnicity, indigeneity, nationality, or disability, is a paramount ethical concern. AI

algorithms can inherit biases present in historical health care data, potentially leading to disparities in diagnosis and treatment among equity-deserving groups. Identifying and mitigating bias in AI systems is an ongoing challenge. Efforts to diversify training data sets and develop fairness-aware algorithms are essential to promote equitable health care outcomes. Development and testing of AI solutions within low-resource settings need particular attention.[179] Similarly, AI algorithms can be complex and difficult to interpret, making it challenging to explain their decisions to patients, decision makers, and health care providers. Ensuring transparency and explainability in AI-driven diagnoses and treatment recommendations is vital for fostering trust and acceptance.

Patient Privacy

The use of AI in health care involves the collection and analysis of vast amounts of patient data, including sensitive medical records and genomic information. Protecting patient privacy is essential. Stringent data anonymization and de-identification techniques, along with robust encryption methods, are necessary to safeguard patient confidentiality.

Data Security

Health care data are a prime target for cyberattacks. AI systems must adhere to stringent data security protocols to protect against breaches and unauthorized access. Regular security audits, encryption, and secure data storage practices are imperative to maintain data integrity.

Regulatory Frameworks

The deployment of AI in health care is subject to varying regulatory landscapes across different countries. Harmonizing regulatory frameworks to ensure AI systems comply with safety, efficacy, and ethical standards is a significant challenge. In addition, global standards on data structure and essential variables for cancer information systems require attention, to allow for national and international benchmarking of quality of care, access to care, and value of care. Developing clear and globally recognized guidelines is crucial for fostering trust in AI-driven oncology.

The intersection of AI and global oncology holds promise and presents challenges that we must address. AI has started to show its potential to transform cancer care by enhancing early detection, optimizing resource allocation, and providing valuable clinical decision support. However, we must remain vigilant in addressing the ethical, privacy, security, and regulatory considerations that come with this transformative technology.

The future of global radiation oncology is intertwined with AI, and by addressing these challenges head-on, we can make it a future of improved patient outcomes and enhanced health care worldwide. As we move forward, collaboration among stakeholders is crucial. Governments, health care institutions, technology developers, ethicists, and patients must work together to create a responsible and equitable AI-driven ecosystem for global cancer care. By doing so, we can ensure that AI benefits all patients, regardless of their geographic location, personal characteristics, or economic status. While challenges lie ahead, the potential rewards are immense. With continued research, innovation, and a commitment to ethical AI implementation, we can revolutionize cancer care and take significant strides toward a world free from the current high burden of cancer.

THE COVID-19 GLOBAL PANDEMIC AND GLOBAL ONCOLOGY

The global COVID-19 pandemic led to lockdowns and restrictions to movement, inevitably impacting overall cancer care globally. It exposed health disparities across the globe, including among indigenous peoples, immigrant populations, and by income, race, gender, and among other equity-deserving groups in LMIC. The impact on vulnerable populations within HICs as well as LMICs confirmed the relevance of global health, and global oncology, regardless of country income group.

In LMIC, families were financially insecure as many wage earners could not work, particularly those who were entrepreneurs in these settings. Health care was no longer a priority as households focused on putting food on the table rather than expensive out-of-pocket costs related to cancer care. Therefore, there were disruptions to care for those who had initiated treatment and delays in seeking care.[180] Due to underreporting, limited health data infrastructure, and limited research in LMICs, we may never

know the full mortality impact on patients with cancer in LMIC during this period.

There were ongoing cancer research projects and those at the implementation stage spearheaded by the global oncology community when the pandemic started. These included research activities, in-person educational sessions for clinical skills transfer, scientific meetings, and radiotherapy machine installations/commissioning, among others. These activities were unexpectedly put to a halt, therefore resulting in further delays in realizing the positive impact of ongoing efforts that had been in motion to support oncology capacity building in LMICs.

On the other hand, the pandemic inspired innovative solutions in clinical care delivery relevant to the broader oncology field, irrespective of country income group. For example, educational seminars were conducted virtually, including major oncology conferences. Clinicians who could not travel due to costs had an opportunity to attend and share ideas. This has accelerated knowledge sharing across regions with potential to improve care. Follow-up clinics and simple consultations, which may not require an in-person visit, have been conducted virtually, potentially reducing the cost of transport to cancer centers. During the pandemic, shorter fractionation regimens in radiation oncology were implemented with the support of several oncology groups as guided by current evidence.[181,182] It remains to be seen whether changes in practice toward hypofractionation will be durable following the pandemic.

Redefining the Problem

The size and scope of the global burden of cancer, with the very limited progress since obvious arguments for the need and benefit for radiotherapy by the GTFRCC,[33] suggests that totally new approaches building on experience are required. The basics of how to provide radiation therapy and how to wisely adapt it have been described above. Two issues that we and colleagues perceive as impediments to progress are first, the dichotomy of investment in infectious diseases and NCDs and the often siloed efforts by institutions, professional groups, NGOs, and philanthropy, and, second, to some extent, the competitive situation of grants. Recognizing the need for idea sharing on a global scale, the ICEC has proposed a model designated

as “flex-competence” wherein the overlap in resources for basic health care, infectious diseases, cancer care, and pandemic response is considered an essential component with the flexibility and competence built into the health care system from the outset so that the day-to-day capacity for routine health care includes the capability to rapidly rebalance efforts in the face of pandemics or other potential natural or human-induced disasters (Figure 34.4).[112] Building on global partnerships for mentorship, ongoing training, and supply lines, such a system can rapidly adapt while maintaining the routine care needs. The COVID-19 pandemic was a good lesson of the need to sustain care for the ongoing health care needs while mustering the pandemic/disaster response. Basic cancer care requires maternal-child care, prevention, diagnostics, imaging, and expertise in infectious diseases. The more “expensive” aspects such as radiation therapy, which build on the imaging and diagnostics for routine care, can be cost-effective early additions rather than later-in-development add-ons, especially with the potential for “smart technology.”[92]

The global impact of patient-centered cancer care includes what was described by GTFRCC and more.[33,183] Broadening career opportunities for radiation oncology for early career leaders has been discussed earlier, but what is required for new programs in resource-limited environments is the expertise of mid-career and senior members of both academia and clinical practice who often have the hands-on experience in cancer treatment that was necessary before the advanced high-technology era over the past few decades. Finally, a resource all-too-often underutilized, which may be available largely on a voluntary basis, is that of the retirees whose experience, wisdom, patience, and time should be incorporated as proposed.[184] From experience over the past decade, this is certainly a win-win situation.

Bringing resources together, often through their power of convening, are global agencies such as the IAEA via their Human Health Division. The recently launched initiative “Rays of Hope” is aimed to help build capacity[185] with an Anchor Centre and network model[186] for which the broad range of radiation oncology professional societies and select NGOs have agreed to work together. It is not possible to list the many academic institutions, NGOs, and efforts from the individual professional societies in this chapter. A key message is that a good deal of the problem and the

necessary solutions is well known. It remains for those working in global oncology, often on their own time and resources, to look for ways to work together to solve a problem far greater than any one group could accomplish. A metric that often draws attention to the scope of the problem is that with the immediate global need now of more than 5,000 linacs, if one well-staffed unit was commissioned per week it would take a century to address the current need. The proposed "century-challenge" is this: How quickly could we work together to accomplish that century?

CONCLUSION

Cancer in the developing world is an urgent problem, reaching critical proportions. Almost 60% of all cancer cases occur in the developing world. Vast numbers of people in LMIC have either limited access or no access to radiation therapy. At a time when new gains in oncology outcomes in the developed world are often incremental, oncologists have the chance to help make some of the largest survival gains in history in the developing world. In addition, the potential for health care gains through cancer prevention and early detection, and the relief of suffering through palliative care is enormous. Global access to quality cancer care is a moral imperative. The challenge will now be to deliver this in a thoughtful and contextually appropriate way.

ACKNOWLEDGMENTS

This chapter is dedicated to Dr C. Norman Coleman (1945-2024). May we all take up the challenge of increasing justice and equity in global radiation oncology, as Norm did with skill, good humor, and gusto. As Norm would say, the world needs *you*.

CHAPTER 35

Radiation Oncology Undergraduate, Graduate, and Continuing Medical Education

Eulanca Y. Liu and Ann C. Raldow

Radiation oncology is a unique specialty that requires a broad knowledge base, as it is one of the few specialties that delivers care to patients from all age groups and all genders and interfaces with a multitude of medical specialties. The radiation oncologist must have the requisite clinical skills necessary to evaluate a new patient at the time of consultation, appropriately stage a tumor,[1] assess treatment planning scans for the extent of tumor to delineate target volumes and organs at risk accurately,[2] and evaluate patients during and after treatment for radiation toxicities and signs of tumor recurrence.[3] A subset of these physicians must also have the surgical skills for brachytherapy implant placement, such as suturing, operating a bedside ultrasound, and performing endoscopies.[4] To do this, radiation oncologists must not only have a solid foundational knowledge of oncology, anatomy, tumor biology, physics, and radiation delivery but also be well versed in a variety of additional areas including communication, collaboration, patient advocacy, and health system management.[5,6] Other professions that work as part of the radiation oncology care team, including medical physics,[7,8] dosimetry,[9] radiation therapy,[10] nursing,[11,12] social work,[13] physical therapy,[14] as well as those who function as part of the brachytherapy surgical team, such as circulating nurses and surgical technicians,[15,16] also have specific skill sets that are acquired during training and continue to develop while working in the radiation oncology department. Although the focus of this chapter is education for radiation oncologists, to provide optimal patient-centered care, the educational process for all of these professions ideally is coordinated in a complementary manner, with each member of the interprofessional and interdisciplinary radiation oncology team optimally trained to deliver high-quality, effective, and compassionate patient care (Figure 35.1).

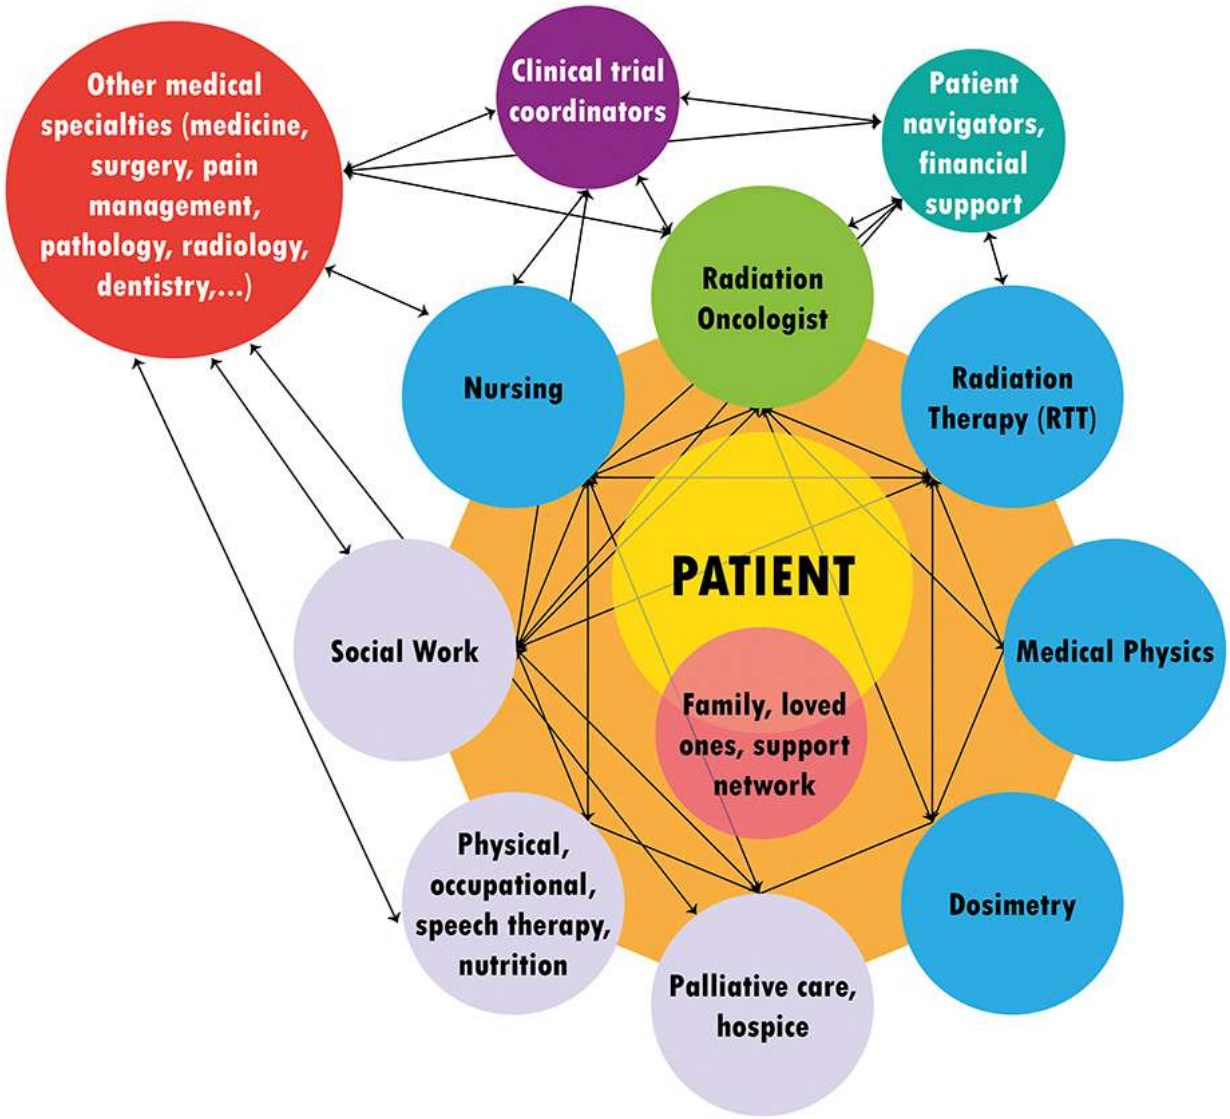

FIGURE 35.1 Interprofessional care of the radiation oncology patient.

Descriptions of radiation oncology educational training programs can be found in the literature dating from the 1950s,[17] and currently, radiation oncology training programs exist worldwide.[18-26] Despite the abundance of established training programs, there is little literature discussing the core aspects of medical education and its application to radiation oncology. The goals of this chapter, therefore, are to describe fundamental educational theory and processes necessary to develop an effective radiation oncology educational curriculum, to review current educational practices in radiation oncology, and to identify potential areas for radiation oncology educational scholarship. Physician training at the undergraduate (medical school), graduate (residency and fellowship), and continuing medical education (CME) (attending physician) levels will be used primarily to frame this discussion, but the concepts, theory, and methods described can be applied to education of other health professions involved in radiation oncology clinical care.

BACKGROUND

The day-to-day practice of medical education in radiation oncology needs to be considered within the broader context of learning theories. It is essential to look beyond the oncology literature, and even outside the medical literature, to understand best practices for medical education and curriculum development.

Learning Theory

Much of the literature surrounding learning has differentiated between "andragogy," or adult learning defined as "the method and practice of teaching adult learners," viewed as unique from "pedagogy," which is defined as "the method and practice of teaching" but which literally means "leading children." There is considerable debate surrounding this differentiation. Rather than present a detailed discussion of the history and controversies in learning theory, concepts of learning theories will be discussed in relation to the range of adult learners in radiation oncology from medical students to practicing radiation oncologists. The basic concepts of most learning theories are based on behavioral change and transformative experiences. The goal of any educational intervention is to effect a behavioral change in the learner through some form of experience. Examples within radiation oncology include improving physician-patient interactions (behavior) through an objective simulated clinical exam (experience),[27] improving brachytherapy technique (behavior) through simulation-based education (experience),[28] and improving contour accuracy (behavior) through a simulated contouring workshop (experience).[2,29]

Learning models can be helpful for understanding the process by which educational interventions can result in changes in behaviors. Kolb's experiential learning model (Figure 35.2) describes a four-step cycle of learning that involves a concrete experience, reflective observation, abstract conceptualization, and active experimentation.[30] Similarly, Merriam et al[31] described three keys to transformational learning—experience, critical reflection, and development. Collins[32] frames adult learning in the context of studying theory and applying it to practice. Others have proposed that the two fundamental components of adult learning are critical thinking and self-directed learning.[33,34] Taken together, educational opportunities that allow for concrete experiences, application, and the opportunity for reflection are best aligned with these principles.

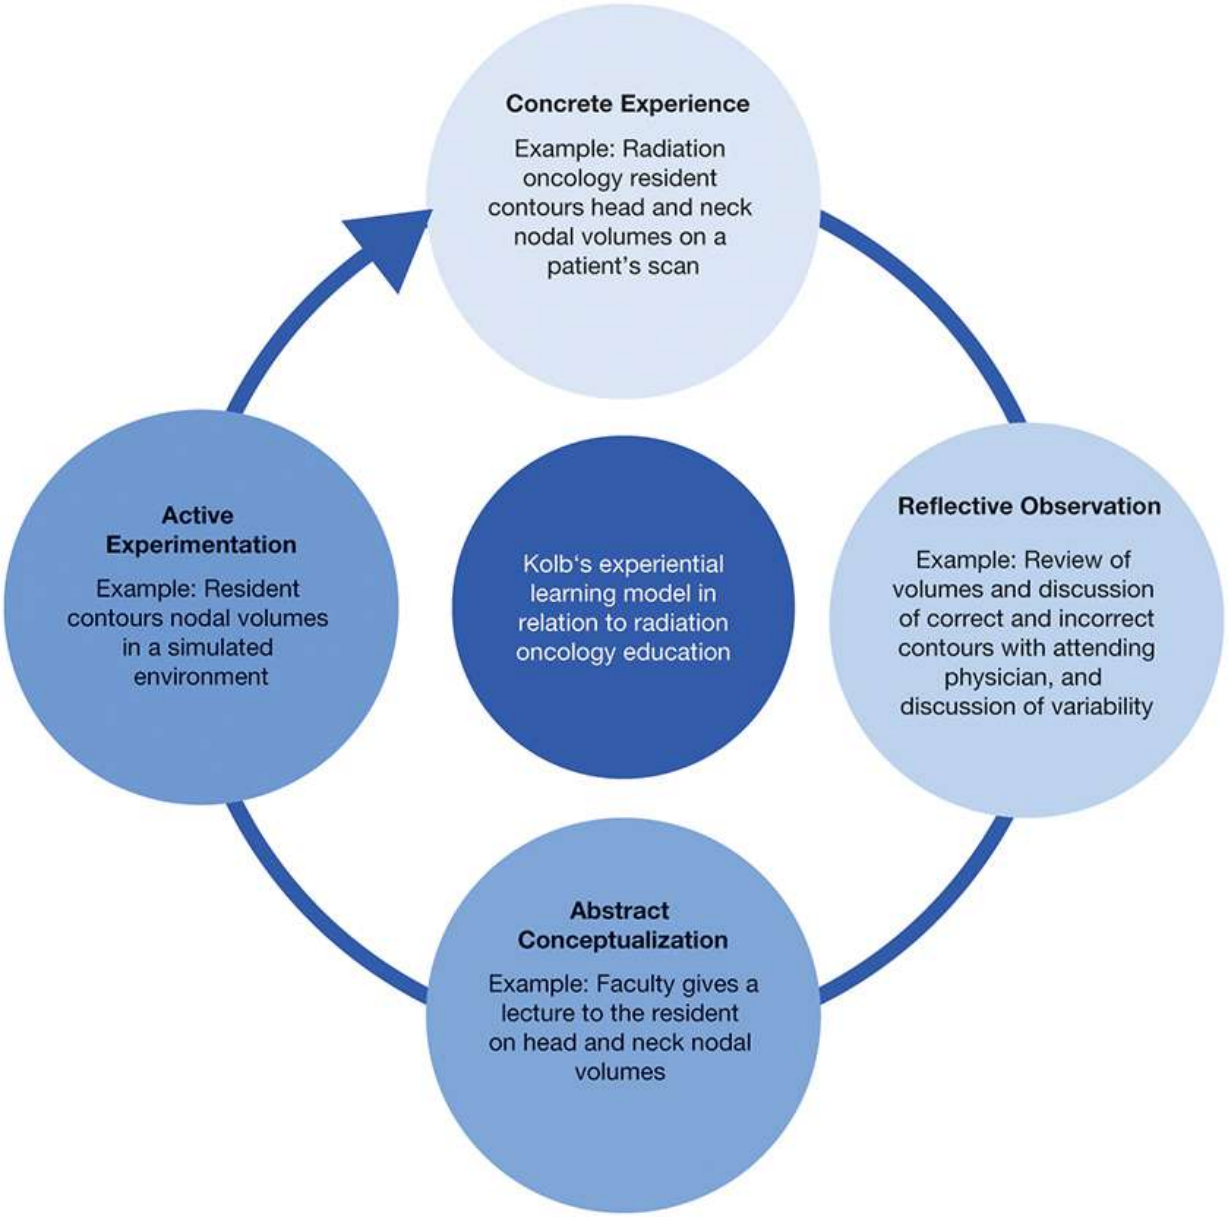

FIGURE 35.2 Kolb's experiential learning model in relation to radiation oncology educational activities. (Adapted from Wijnen-Meijer M, Brandhuber T, Schneider A, Berberat PO. Implementing Kolb's experiential learning cycle by linking real experience, case-based discussion and simulation. *J Med Educ Curric Dev*. 2022;9:23821205221091511. Copyright © 2022 SAGE Publications. Reprinted by permission of SAGE Publications.)

Learning theory can be enhanced by an understanding of the six assumptions regarding characteristics of the adult learner as defined by Knowles et al[35] (Figure 35.3). These six assumptions can be applied to learning in radiation oncology. For example, in the case of a radiation oncology residency training program, the residents must understand why, what, and how they are going to learn their chosen profession. They need to have some autonomy and control over their learning within the structure of the residency training program. Therefore, when the radiation oncology educator is developing an adult learning experience, consideration should be given to Knowles' six assumptions, what behavior the curriculum or educational intervention intends to change, and how the learning experiences will stimulate critical thinking, self-directed learning, and transformation.

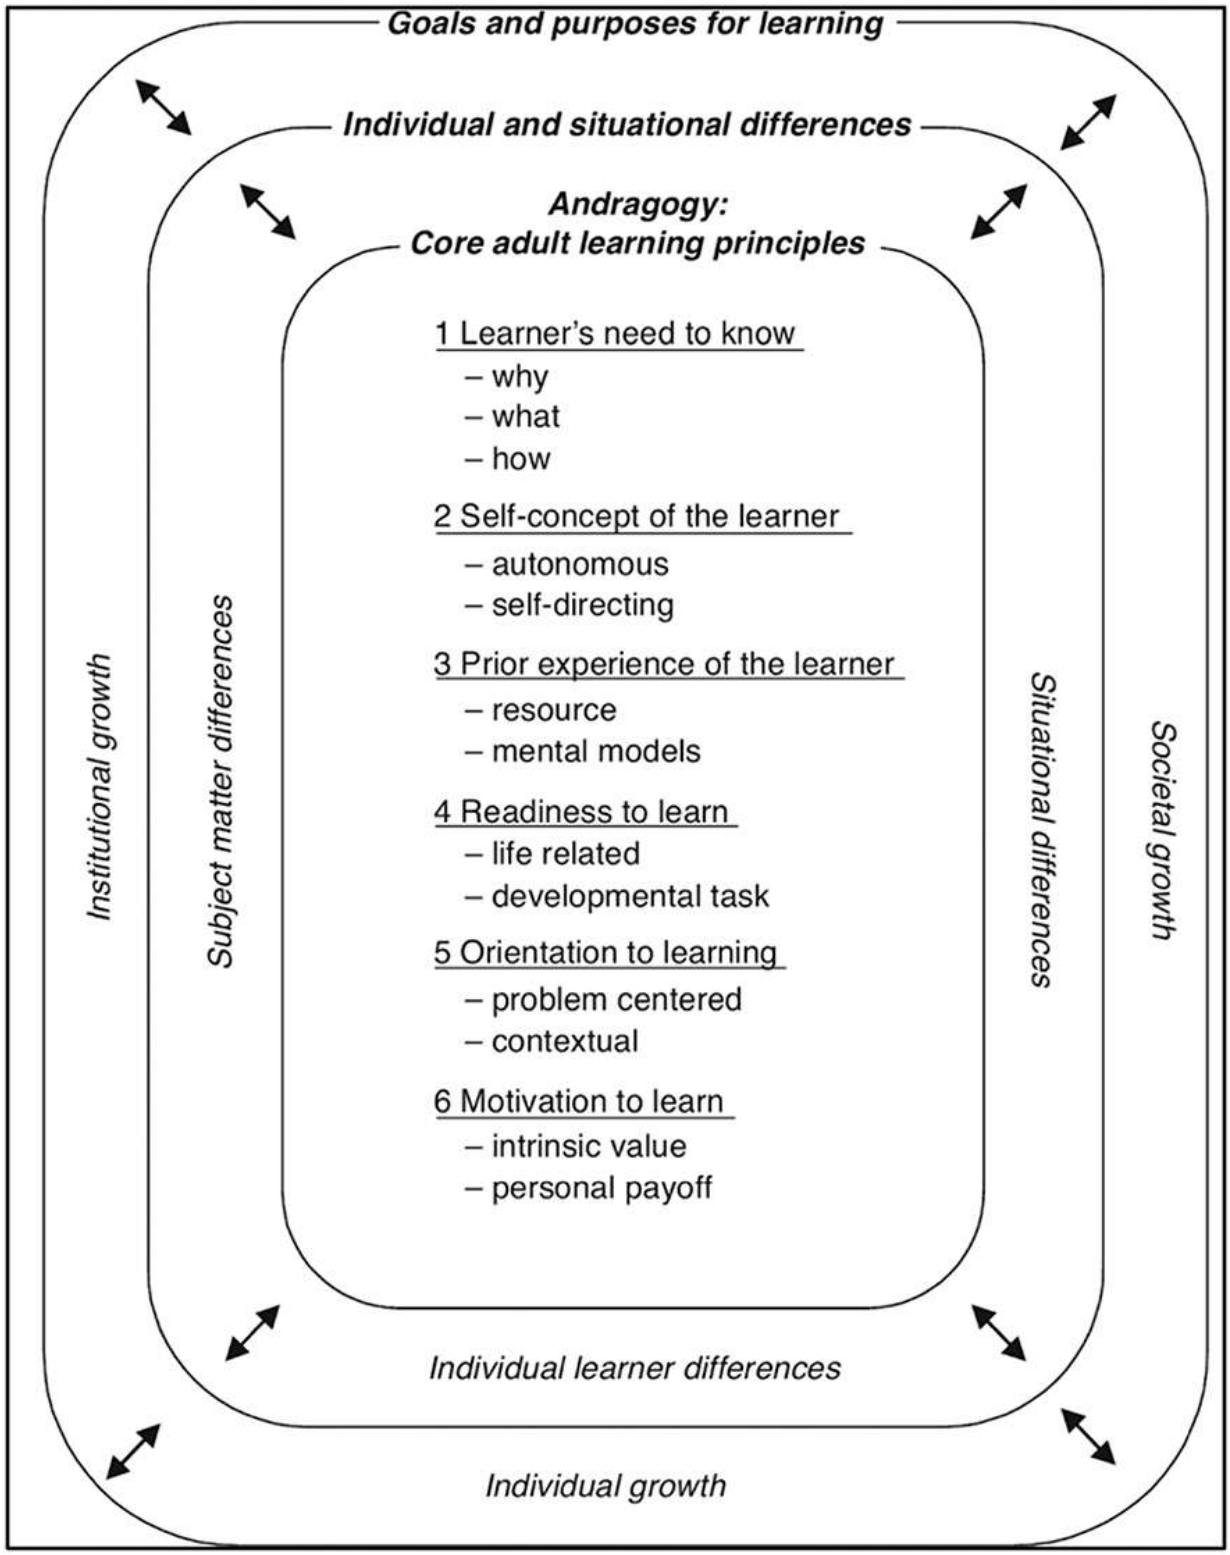

FIGURE 35.3 Knowles and Swanson's six assumptions of adult learning. (Used with permission of Taylor & Francis Informa UK Ltd—Books from Knowles MS, Holton EF III, Swanson RA. *The Adult Learner: The Definitive Classic in Adult Education and Human Resource Development*. 5th ed. Gulf Publishing; 1998; permission conveyed through Copyright Clearance Center.)

Lastly, to optimize learning, it is important for medical educators to consider the learning environment when designing an educational program. The Hebbian version of the Yerkes-Dodson law suggests that learners have an optimal level of arousal, or stress, that will promote optimal learning (Figure 35.4).[36,37] At very low levels of stress and arousal, the learner is not stimulated enough to learn. An example is an early morning resident lecture with no postlecture knowledge assessment. The stakes for the resident learner are low, and the resident may not engage with the presentation to learn. As arousal increases, an optimal point is encountered on the learning curve where stress optimally enhances learning without negatively impacting it. As stress continues to increase, learning begins to decline because of stress impeding higher level cognitive process, such as attention, working memory, and problem-solving. Thus, the radiation oncology educator must consider stressors on the trainees (both positive and negative) and determine if the amount of stress within a given learning environment will facilitate optimal learning. Examples of pertinent stressors include medical student anxiety about securing a residency position, resident anxiety about certification boards, presenting in front of a group versus a single listener, or a multiple-choice test with a minimum score required to obtain credit as a component of a self-Assessment CME (SA-CME) module. Educators should work to minimize undue (negative) stressors while emphasizing the rationale for planned positive stressors, such as postlecture knowledge assessments.

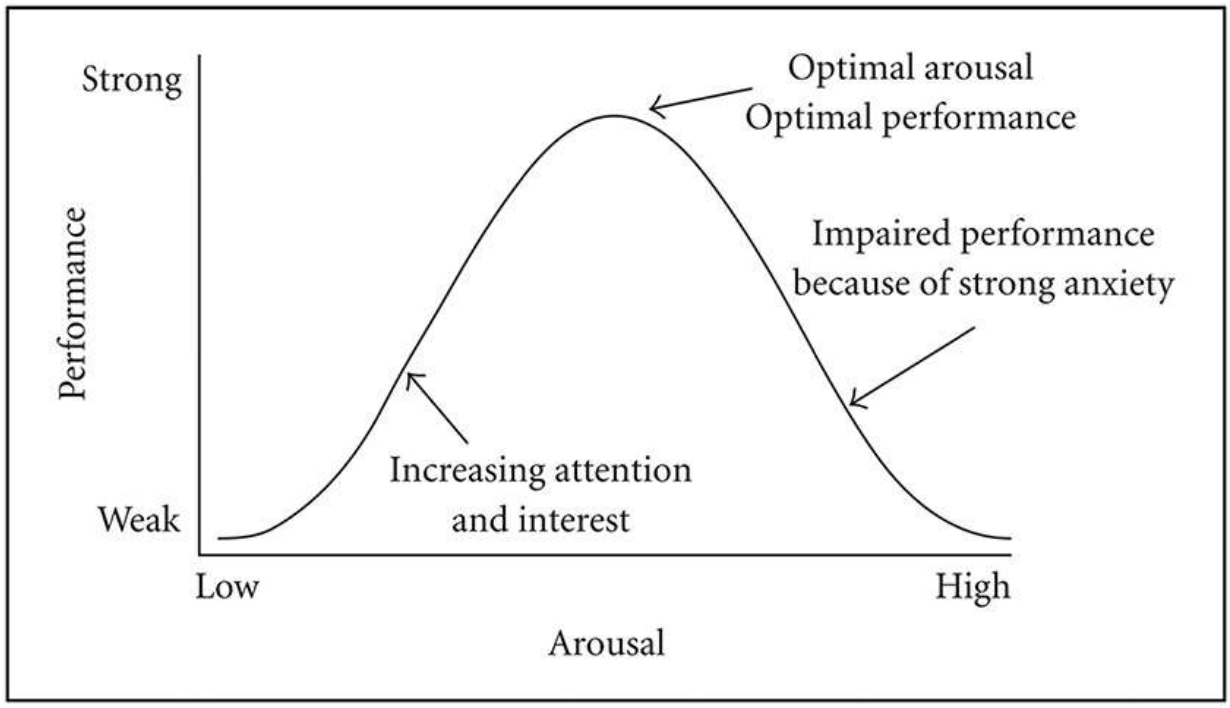

FIGURE 35.4 Hebbian version of the Yerkes-Dodson law correlating arousal with performance.

Recently, investigators have piloted the "flipped classroom curriculum" to promote greater engagement and critical thinking.[38,39] These didactics typically include prerecorded video lectures, key journal articles, and slides containing key points reviewed by residents independently prior to the live didactic session. The live session then consists of case review or live quizzes that review the concepts presented in the presession study materials. Ongoing work is underway to determine the flipped curriculum's efficacy in promoting knowledge comprehension and retention for medical residents.

SCHOLARSHIP OF RADIATION ONCOLOGY EDUCATION

Methods for successful curriculum development and implementation draw from both social sciences and business theory. The research methodology for scholarship of radiation oncology education incorporates qualitative research, an approach that may not be familiar to radiation oncology educators, whose training is focused in the biologic and physical sciences. This section reviews the concepts of scholarship as relevant to radiation oncology education and provides an introduction to qualitative methods and conceptual frameworks useful to radiation oncology educational scholarship.

Scholarship in Medical Education

When undertaking any medical education intervention, careful attention should be given at the outset for opportunities for scholarship.[40] Boyer[41] defines four types of scholarship: the scholarship of discovery, the scholarship of application, the scholarship of integration, and the scholarship of teaching. The scholarship of discovery refers to scholarly activities for the purpose of finding new knowledge and best encompasses our traditional view of research.[41,42] The scholarship of integration refers to scholarship that draws on other research and draws across disciplines or extends research to new areas and beyond boundaries helping to illuminate relationships.[41,42] The scholarship of application takes knowledge and applies it in new and practical ways.[41,43] Finally, the scholarship of teaching refers to teaching practices approached with a scholarly lens. This expanded definition of scholarship allows for many activities in medical education to be viewed as grounds for scholarship outside research projects.

Scholarship is defined as a tangible product of knowledge or its presentation that is peer reviewed and disseminated publicly.[44] Hutchings and Shulman[45] defined the following three criteria as essential for scholarship:

1. The work must be made public.
2. The work must be available for peer review and critique according to accepted standards.
3. The work must be able to be reproduced and built on by other scholars.

Criteria for excellence in scholarship can be applied to educational scholarship and help to assess the quality of scholarship. Glassick[46] defined six criteria by which to assess scholarship: clear goals, adequate preparation, appropriate methods, significant results, effective presentation, and reflective critique.

Application of these criteria assists the radiation oncology educator to evaluate the potential to turn a medical education project into a work of scholarship. For example, a novel resident training curriculum implemented at a single institution and not disseminated in peer-reviewed literature does not qualify as scholarship based on the abovementioned definition. However, if the residency program director publishes learner assessment and program evaluation data in a peer-reviewed journal or disseminates the curriculum materials using *MedEdPORTAL*, an open-access journal of teaching and learning resources in the health professions published by the Association of American Medical Colleges, the implementation and evaluation of the curriculum qualify as scholarship.

The difference between scholarly teaching and the scholarship of teaching must also be defined. Fincher and Work[47] defined three levels of teaching (Figure 35.5). The first level is basic teaching. In radiation oncology, basic teaching examples include giving a lecture, facilitating a case conference, demonstrating proper history-taking or brachytherapy techniques to trainees, or educating patients regarding the radiation treatment process and potential toxicities. The second level is scholarly teaching. This implies that the instructor is using evidence-based practices when teaching trainees. Examples in radiation oncology could include using best practices when delivering a PowerPoint presentation,[48] providing patient educational materials at or below the sixth-grade reading level,[49] or

using the 1-minute preceptor model to teach a clinical pearl to a resident after an initial consultation.[50] The third level is scholarship of teaching, which includes developing and disseminating new knowledge through discovery, integration, or application.

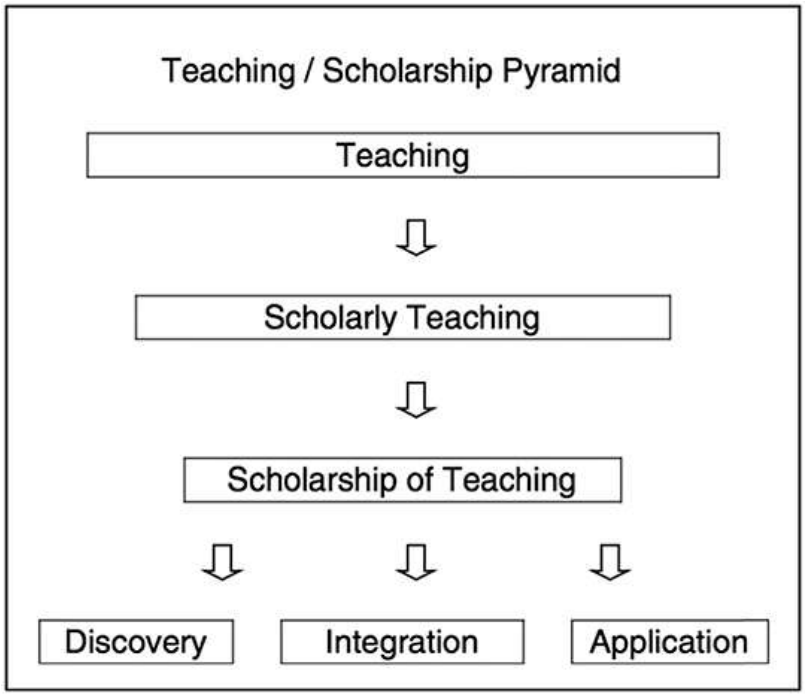

FIGURE 35.5 Fincher and Work's pyramid of teaching and scholarship. (From Fincher RM E, Work JA. Perspectives on the scholarship of teaching. *Med Educ.* 2006;40[4]:293-295. Copyright © 2006 Blackwell Publishing Ltd. Reprinted by permission of John Wiley & Sons, Inc.)

Drawing from Boyer,[41,46] discovery refers to obtaining new knowledge in a discipline. Scholarship examples in this context include the evaluation of new innovations or interventions. Examples in radiation oncology include demonstrating that students who participate in a radiation oncology clerkship with a didactic curriculum report increased confidence to function as a resident,[51] utilizing a novel internet-based contouring tool that can improve target delineation accuracy,[52] and demonstrating that inclusion of a radiation oncology lecture in the medical school curriculum is feasible and increases objective knowledge of the specialty.[53]

Scholarship of integration refers to making connections across scholarship and synthesizing data across studies.[46] Examples include a literature review of radiation oncology teaching in the undergraduate setting[54] or a Best Evidence in Medical Education systematic review on faculty development initiatives aimed to improve teaching effectiveness.[55]

The scholarship of application bridges theory with practice, often drawing together fields and disciplines.[41,56] In the context of radiation oncology, this could include assessing the value of simulation in brachytherapy training,[28,29] bringing simulation that is well utilized in other specialties to radiation oncology, and evaluating the impact on learner performance.

Without scholarship in radiation oncology education, educational programs will advance slowly. Individual training programs will be unaware of the best practices implemented at other training programs and may develop redundant educational material, which introduces inefficiency in a process that is already limited in resources. Just as clinical oncology and basic science research is disseminated as manuscripts in peer-reviewed journals, novel radiation oncology educational initiatives must be

rigorously developed and evaluated in preparation for dissemination to the international radiation oncology community.[40] However, because of limitations of journal publication alone in effecting change,[57] programs such as the Radiation Oncology Education Collaborative Study Group[58] have been established to improve dissemination and implementation of educational research and programs. These processes allow other institutions to adopt or adapt novel educational initiatives and subsequently build on them for further dissemination.

Qualitative Versus Quantitative Research

For health profession educators, scholarly research comes from both quantitative and qualitative sources, and many studies benefit from the use of both simultaneously.[59] Some studies refer to the term "mixed methods," which is a reference to the use of both quantitative and qualitative methods. While many radiation oncologists are familiar with quantitative research, they may be less aware of qualitative research methods. Qualitative methods are distinct from quantitative methods in their research paradigm, research design, method of data collection, types of data collected, and methods of data analysis.

With respect to research design, most quantitative research is hypothesis driven with the researcher developing research methods and collecting data to support or refute the hypothesis. In the case of qualitative methods, researchers start at the observational level and then move to explanation by building a theory. Several strategies for qualitative inquiry are commonly used, and a complete description is beyond the scope of this chapter. Some of the more commonly referenced terms in qualitative methods include ethnography, narrative inquiry, and grounded theory approach. Ethnographic research encompasses a variety of research techniques aimed at characterizing the authentic everyday experiences of subjects through observation and interviews.[60,61] An example of ethnographic research is a study utilizing detailed interviews with teaching faculty and observations of their teaching patterns on the ward to identify the characteristics of effective clinical teachers.[62] Narrative research is the study of participants through the analysis of documents, such as journals, letters, conversations, and transcripts of interviews.[61] Usually, the participant describes one or more pivotal life events, and the researcher interprets the construction of this narrative. Finally, *grounded theory* is a term used in qualitative methods to describe the process in which a "theory" is generated from data of the experiences of the participants.[61] Unlike quantitative research that starts with a theory, the grounded approach uses data to generate theory by looking for emerging themes through a process of constant comparative analysis.[60] Data are collected through interviews, document analysis, and focus groups. In a grounded theory approach, as data are collected, a theory is generated, then more data are collected, and the theory is revised as needed, continuing the process until it appears that the theory is relatively robust. An example of grounded theory methodology in radiation oncology is the use of focus groups and in-depth interviews to develop a four-step learning process for implementation of high-precision radiation technology[63]:

1. Anxiety as new skills are acquired
2. Learning to interpret new imaging and findings while continuing to experience uncertainty
3. Questioning assumptions and critical reflection resulting in new understanding
4. Constructing new knowledge through research, development, and dialogue

The processes and methods used in qualitative studies include distinguishable methods that help to build observations to support explanations.[64] Methods of data collection include focus groups, one-on-one interviews, surveys with open-ended questions, observations of behaviors, and document analysis (eg, themes in portfolios). Unlike quantitative data that are numeric, the data collected in a qualitative study are usually text or words. The analysis of qualitative data is an iterative process to conceptualize

and reduce data, analyze it to develop themes, elaborate on categories, and find relationships.[60] Common to qualitative methods, steps are taken to ensure reliability of the themes developed through stages of analysis. This may include having multiple raters of themes, peer review from others not involved in the study, checking the themes with study participants, and triangulation with established literature. Ultimately, the goal of qualitative research is to develop hypotheses, build theory through descriptions of observations, and describe and explain complex phenomena by analyzing data for themes and relationships. Table 35.1 summarizes key differences between quantitative and qualitative methods.

TABLE 35.1 SUMMARY OF DIFFERENCES BETWEEN QUALITATIVE AND QUANTITATIVE RESEARCH

	Quantitative Research	Qualitative Research
Research paradigm	• Deductive research • Collect data to test hypothesis	• Inductive research • Observations to explain and then develop theory
Research method examples	• Closed-ended surveys (ie, demographics of current radiation training programs) • Observations of time taken to complete a task (ie, contouring)	• Open-ended surveys (ie, resident descriptions of current challenges in training programs) • Observational study (ie, observations of differences of learner's contouring abilities at different stages of training) • Document analysis (ie, analysis of learner's portfolio reflections on dealing with patients with difficult cancer)
Data	• Numeric data	• Words as data

Qualitative research is important to medical education. There are certain educational research questions that are best approached using qualitative research methods,[65] such as:

- "How does charting influence the quality and quantity of communication between different health care professionals?
- How do health care professionals learn to teach on the job?
- What constitutes "professional competence," and how is that different from "professional identity"?
- What influences patients' adherence with their doctor's suggestions?"

Qualitative methods can be used specifically for radiation oncology scholarship in multiple settings (Table 35.2). For example, qualitative methods can be used to develop and evaluate a program to teach radiation oncology residents communication skills with older patients with cancer. One-on-one interviews, focus groups, and surveys with open-ended questions could be used to conduct a targeted needs assessment of learners (see "Curriculum Development") prior to developing a new educational program. The results would inform the development of the syllabus. Later, reflections on the new training program, collected through repeated one-on-one interviews, surveys, and analysis of reflective writing exercises, could be used to systematically evaluate the program once implemented. Years later, the clinical behaviors of oncologists in practice could be observed to reflect on the retention of skills in learners and the impact of the program on their communication skills. Utilizing both qualitative and quantitative methods for program development facilitates development and improvement of a training program in a scholarly manner.

TABLE 35.2 EXAMPLES OF USE OF QUALITATIVE METHODS IN RADIATION ONCOLOGY EDUCATION

Educational Issue	Qualitative Approach
Analyzing "memorable" in-training experiences of medical students on radiation oncology rotations[321]	Thematic analysis of written narratives to describe the training experiences of learners in a clinical education program
Needs assessment for development of a radiation oncology curriculum for medical students[189]	Analysis of written responses to open-ended surveys to analyze for gaps and strengths in current training Thematic analysis of one-on-one interviews with stakeholders
Establishing needs and priorities in a global radiation oncology training programs[322]	Facilitated group discussion with analysis of themes to develop consensus on possible goals and objectives for a training program
Evaluation of a contouring boot camp[21]	Thematic analysis of open-ended survey questions to provide evaluation data
Evaluation of a didactic curriculum for a radiation oncology medical student clerkship[198]	Thematic analysis of open-ended survey questions to provide evaluation data

Conceptual Frameworks

When approaching radiation oncology medical education endeavors through a scholarly lens, it is critical to define one or more conceptual frameworks used to guide the educational process. While medical education scholars often employ conceptual frameworks in curriculum development and program evaluation, it is helpful to be able to identify them. A systematic review found that a lack of a conceptual framework is one of the most common reasons education scholarship is rejected for publication.[66]

Conceptual frameworks are "ways of thinking about a problem or a study, or ways of representing how complex things work the way they do. Different frameworks will emphasize different variables and outcomes, and their interrelatedness."[67] Conceptual frameworks are not mutually exclusive, and there is the potential to apply multiple conceptual frameworks to a single curriculum development endeavor. For example, a radiation oncology educator developing a simulation-based education curriculum to train residents how to perform interstitial breast brachytherapy may use the six-step approach to curriculum development[68] to guide the overarching curriculum development process; the theory of deliberate practice from Ericsson.[69] when developing the specific educational method to develop adequate breast brachytherapy psychomotor skills; and Kirkpatrick's four-step framework[70] when developing a plan for program evaluation. Bordage defines 11 key points pertaining to conceptual frameworks (Table 35.3) that clarify the critical nature of conceptual frameworks to educational scholarship, both to guide curriculum development and to move the field of radiation oncology education forward in a logical and coherent manner.[67]

TABLE 35.3 KEY POINTS REGARDING CONCEPTUAL FRAMEWORKS

- Conceptual frameworks help understand (illuminate) problems.
- Different conceptual frameworks emphasize (magnify) different aspects of the problem or elements of the solutions.
- More than one conceptual framework may be relevant to a given situation.
- Any given conceptual framework, or combination of frameworks, can lead to a variety of alternative solutions.
- Conceptual frameworks can come from theories, models, or evidence-based best practices.
- Scholars need to apply the principles outlined in the conceptual framework(s) selected.
- Conceptual frameworks help identify important variables and their potential relationships; this also means that some variables are disregarded.
- Conceptual frameworks are dynamic entities and benefit from being challenged and altered as needed.
- Conceptual frameworks allow scholars to build upon one another's work and allow individuals to develop programs of research.
- Programmatic, conceptually based research helps accumulate deeper understanding over time and thus moves the field forward.

- Relevant conceptual frameworks can be found outside one's specialty or field.

From Bordage G. Conceptual frameworks to illuminate and magnify. *Med Educ*. 2009;43(4):312-319. Copyright © 2009 Blackwell Publishing Ltd. Reprinted by permission of John Wiley & Sons.

There are numerous conceptual frameworks in the medical education and general education literature that can be applied to radiation oncology educational scholarship. If an applicable conceptual framework is not available for a particular curriculum development program, existing conceptual frameworks can be modified and adapted to fit, or a new conceptual framework can be developed and reported in the peer-reviewed literature. To help guide the development of new literature in radiation oncology education, Table 35.4 provides examples of conceptual frameworks that may be applied when approaching common radiation oncology education issues. In summary, the radiation oncology educator should be able to identify the conceptual framework that applies to their educational intervention.

TABLE 35.4 EXAMPLES OF CONCEPTUAL FRAMEWORKS APPLICABLE TO DOMAINS OF RADIATION ONCOLOGY EDUCATION

Curriculum development
Six-step approach to curriculum development[68] 1. Problem identification 2. Needs assessment of the learners 3. Goals and objectives 4. Educational strategies 5. Implementation 6. Evaluation and feedback
Goals and objectives
Bloom's revised taxonomy of learning objectives[119,120] • Knowledge → Remember • Comprehension → Understand • Application → Apply • Analysis → Analyze • Synthesis → Evaluate • Evaluation → Create
Educational methods/learning theory
Miller's pyramid of clinical competence[126,127] • Knows • Knows how • Shows • Does Kolb's experiential model[30] • Concrete experience • Reflective observation • Analysis and integration • Application to new situations Ericsson's theory of deliberate (mixed) practice with feedback[69] • Motivate through improvement in real-life performance • Take into account the learner's preexisting knowledge (difficulty of the task tailored to the individual) • Allow repetition of the skills multiple times • Accompanied by feedback that is constructive and timely Merrill's first principles to facilitate learning[323]

Curriculum development

- Problem—Learners are engaged in solving real-world problems.
- Activation—Existing knowledge is activated as a foundation for new knowledge.
- Demonstration—New knowledge is demonstrated to the learner.
- Application—New knowledge is applied by the learner.
- Integration—New knowledge is integrated into the learner's world.

Skills acquisition/simulation-based education

Mastery learning[324]

- Baseline testing
- Clear objectives
- Engagement in educational activities
- Clear minimum passing standards
- Formative testing
- Advancement dependent on achievement
- Individualized time frame

Features of effective simulation education[325]

- Feedback to the learner
- Repetition
- Simulation integrated into the overall curriculum
- Learners practice with increasing difficulty and complexity
- Simulations adapted to multiple learning strategies
- Clinical variation built into the sessions
- Control of the environment
- Individualized learning options
- Defined outcomes, benchmarks
- Simulation closely represents practice

Kneebone's evaluation criteria for simulation programs[326]

- Allow for sustained, deliberate practice within a safe environment, ensuring that recently acquired skills are consolidated within a defined curriculum, which assures regular reinforcement.
- Provide access to expert tutors when appropriate, ensuring that such support fades when no longer needed.
- Map onto real-life clinical experience, ensuring that learning supports the experience gained within communities of actual practice.
- Provide a supportive, motivational, and learner-centered milieu, which is conducive to learning.

Assessment

NCME standards: Five sources of validity evidence[327,328]

- Content
- Response process
- Internal structure
- Relationship to other variables
- Consequences

Criteria for good assessment[329]

- Validity or coherence
- Reproducibility or consistency
- Equivalence
- Feasibility
- Educational effect
- Catalytic effect
- Acceptability

Evaluation

Kirkpatrick's four levels of program evaluation[70]

Curriculum development

- Reaction
- Learning
- Behavior
- Results

Grant's ACTION model for evaluating new technologies for learning[330]

- Access
- Cost
- Types of learning
- Integration
- Organization
- Novelty

Continuing medical education

Davis' characteristics of effective (best practice) CME programs[292]

- Needs assessment that can be either subjective (eg, questionnaires) or objective (eg, literature review)
- Focused initiative to meet the needs of the physician
- Interactive educational programs
- Multiple educational strategies
- Multiple sessions
- Time for feedback and practice
- Outcome evaluation

Harden's Crisis Criteria for effective CME[291]

- Convenience
- Relevance
- Individualization
- Self-assessment
- Independent learning
- Systematic

Interprofessional education

Ivey's categorization of interprofessional practices[331]

- Parallel practice
- Coordination
- Consultation
- Collaboration
- Multidisciplinary teams
- Interdisciplinary teams

Parsell and Bligh's elements of interprofessional education[332]

- Relationships
- Collaboration and teamwork
- Roles and responsibilities
- Benefits

MUSC spiral theory[333,334]

- Teamwork: prepare-think-practice
- Transforming ways of knowing: absolute-transitional-independent-contextual
- Ever-increasing acquisition, application, demonstration

Professionalism

Assessment of professionalism[335]

- Evaluations by faculty supervisors
- Nurses and patients
- Peer evaluation

Curriculum development
• Self-evaluation • Standardized patients • Longitudinal observations

CURRICULUM DEVELOPMENT

Using the background medical education theory and key principles to medical education scholarship, the radiation oncology educator can begin curriculum development. The objective of this section is to discuss the educational theory relevant to curriculum development, review curriculum development models, and then explore approaches to curriculum development with application to radiation oncology.

A curriculum can be defined as any planned educational experience.[68] In this context, radiation oncology curriculum examples include a 1-hour lecture on the history of radiation oncology for medical students, a residency training program's annual clinical rotation and didactic lecture schedule, a patient seminar on late effects of radiation oncology, or a national meeting for hands-on brachytherapy simulation and training. The common thread through all of these examples is that the educator has a goal for the curriculum—that is, some type of knowledge transfer.

Curriculum theory proposes three types of curricula in any educational setting (Table 35.5). The first type of curriculum is the "set" or explicit curriculum. The set curriculum is what the educator defines a priori as the instructional plan. A radiation oncology clerkship will have goals and objectives defined for participating medical students to orient them to the experience. The overarching goal of the clerkship is likely "to learn the fundamentals of clinical radiation oncology." A syllabus may be prepared, and the educational strategies employed are chosen to reach the explicit curricular goal.

TABLE 35.5 EDUCATIONAL THEORY'S THREE COEXISTING CURRICULUM TYPES

Type of Curriculum	Radiation Oncology Examples
Set, formal, or explicit curriculum	• Medical student clerkship lecture series • Residency lecture series and rotation schedule • Goals and objectives for society meeting educational session
Hidden or implicit curriculum	• Radiation oncology resident disparages a referring specialty in front of a medical student. • Radiation oncology attending models superb compassion when counseling a patient regarding terminal diagnosis. • Radiation oncology attending belittles a dosimetrist in front of a resident and medical student.
Null curriculum	• Medical school does not include any radiation oncology in their formal curriculum. • Residency program director decides to forgo a formal treatment planning rotation because of training time constraints. • Society does not include a session on palliative radiation because of space constraints at conference center.

The second curriculum in any educational setting is the "hidden" or implicit curriculum. The hidden curriculum is what the learner comes to "know" based on interactions that occur outside formal learning environments.[65] Examples in radiation oncology could include a medical student in a resident workroom overhearing a resident disparaging a referring service or a department choosing not to allocate resident education time to quality and safety or communication skills. The hidden curriculum is often referred to with a negative connotation, but there are positive effects of the hidden curriculum. For example, a resident may observe their attending physician during a particularly compassionate

patient encounter and take away a positive lesson on how to interact with a similar patient in future. Radiation oncology educators must consider their departmental and institutional hidden curriculum when developing a novel set of curriculum. Individual educators may be encouraged to view their behaviors as modeling and note the potential impacts on the hidden curriculum. Areas to consider relating to the hidden curriculum include policy development, evaluation, resource allocation, and institutional slang.[71] These four areas within a radiation oncology department can teach trainees both positive and negative lessons without the trainee ever being exposed to a formal learning environment.

The third type of curriculum is the "null" curriculum, which is defined as what is not taught.[72] The classic example in childhood education is removing art class from a grammar school curriculum, which results in a negative impact on the children by sending a message that art is not important and can, therefore, be neglected. Medical educators within radiation oncology are faced with limited time for education. Thus, during the curriculum planning process, radiation oncology educators must strive for a balance of including material that is important to their learners while not overburdening the learner or institutional resources. Topics that are important to functioning as a radiation oncologist but are often not taught formally during training because of resource constraints include (but are not limited to) treatment planning and plan evaluation, diagnostic radiology interpretation skills, effective communication, collaboration, leadership skills, and career development. The Accreditation Council for Graduate Medical Education (ACGME) permits residency programs to count resident attendance at multidisciplinary tumor boards as adequate training in medical oncology, radiology, and pathology in place of formal clinical rotations.[4] Because of training time constraints, this capitulation is necessary, but it may send a message to U.S. radiation oncology residents that knowledge pertaining to these specialties is less important. This may lead to the long-term detriment of patient care.[73] Radiation oncology itself suffers from the consequences of the null curriculum. Its status as a subspecialty means the formal medical school curriculum frequently does not include radiation oncology material, leading to reduced knowledge of the specialty.[74,75] In graduate medical education (GME), residency training programs outside radiation oncology frequently do not provide formal lectures or didactics pertaining to radiation oncology.[76,77] Radiation oncology educators must carefully consider the educational milieu of the institution and the department when deciding on which educational initiatives to pursue or cut.

Curriculum Development Models

Curriculum development should be a logical and rational process. Often in medical education, curriculum development is a haphazard ordeal or occurs in a reactive, rather than proactive, manner. Multiple curriculum development models have been proposed, such as empirical/analytical/systematic curriculum inquiry, deliberative curriculum inquiry, and reconceptualist curriculum inquiry.[78]

Systematic curriculum inquiry is perhaps the most commonly used medical education curriculum development model. It has been in the literature for more than 60 years, with multiple educators, medical and nonmedical, contributing to its current iteration.[68,79,80] Its six-step, systematic approach helps medical educators ensure critical components necessary for effective curriculum planning are not missed.[68] One criticism of the systematic approach is that it can be a top-down process, with curriculum deans, residency program directors, or clerkship directors dictating curriculum content and structure.

Deliberative curriculum inquiry focuses on the process of curriculum planning, implementation, and evaluation.[81] To be effective, deliberative curriculum inquiry requires a structure for "deliberation."[82] Curriculum stakeholders are given an opportunity to evaluate the curriculum goals and objectives, propose modification to educational methods, and suggest methods for assessment and evaluation. For example, a radiation oncology residency program choosing to employ deliberative curriculum inquiry would create an opportunity for stakeholders within the program (residency, chairperson, program

director, department faculty, institution, and patients) to provide feedback on the program. The ACGME now requires U.S. radiation oncology residency programs to have a program evaluation committee conduct an annual evaluation of the program.[5] Members of the program evaluation committee must include department faculty and residents. To improve the deliberative nature of this process, inclusion of other stakeholders can be considered (eg, patients, institution).

The final curriculum development model is reconceptualist curriculum inquiry.[83] This model of curriculum inquiry aims to explore how the curriculum relates to society. How does the curriculum interact with economic, cultural, and political institutions? An example of reconceptualist curriculum inquiry in radiation oncology is a program director's decision whether to include formal education (eg, a lecture) on health economics in a radiation oncology residency program. By choosing to educate the program's trainees about the economic implications of different radiation treatment modalities, the residency program can have a future societal impact on economic and political institutions.

The systematic, deliberative, and reconceptualist models of curriculum development are not mutually exclusive. Rather, these models can be used simultaneously to achieve the most effective radiation oncology curriculum possible that is properly structured, includes consideration of stakeholder viewpoints, and has potential for societal impact. Further discussion of curriculum development will focus on the systematic model,[68] but implications of the deliberative and reconceptualist models should be considered as well.

Systematic Curriculum Development

Systematic curriculum development for medical education is most clearly defined by the "six-step approach" suggested by Thomas et al[68] as follows: (1) problem identification and general needs assessment, (2) needs assessment of targeted learners, (3) goals and specific objectives, (4) educational strategies, (5) implementation, and (6) evaluation and feedback (Figure 35.6). Although these six steps are presented in a sequential order, in practice, they are often occurring simultaneously. Each step can have effects on or be affected by the other steps. The following discussion focuses on each of the six steps with relevant examples from radiation oncology cited where applicable.

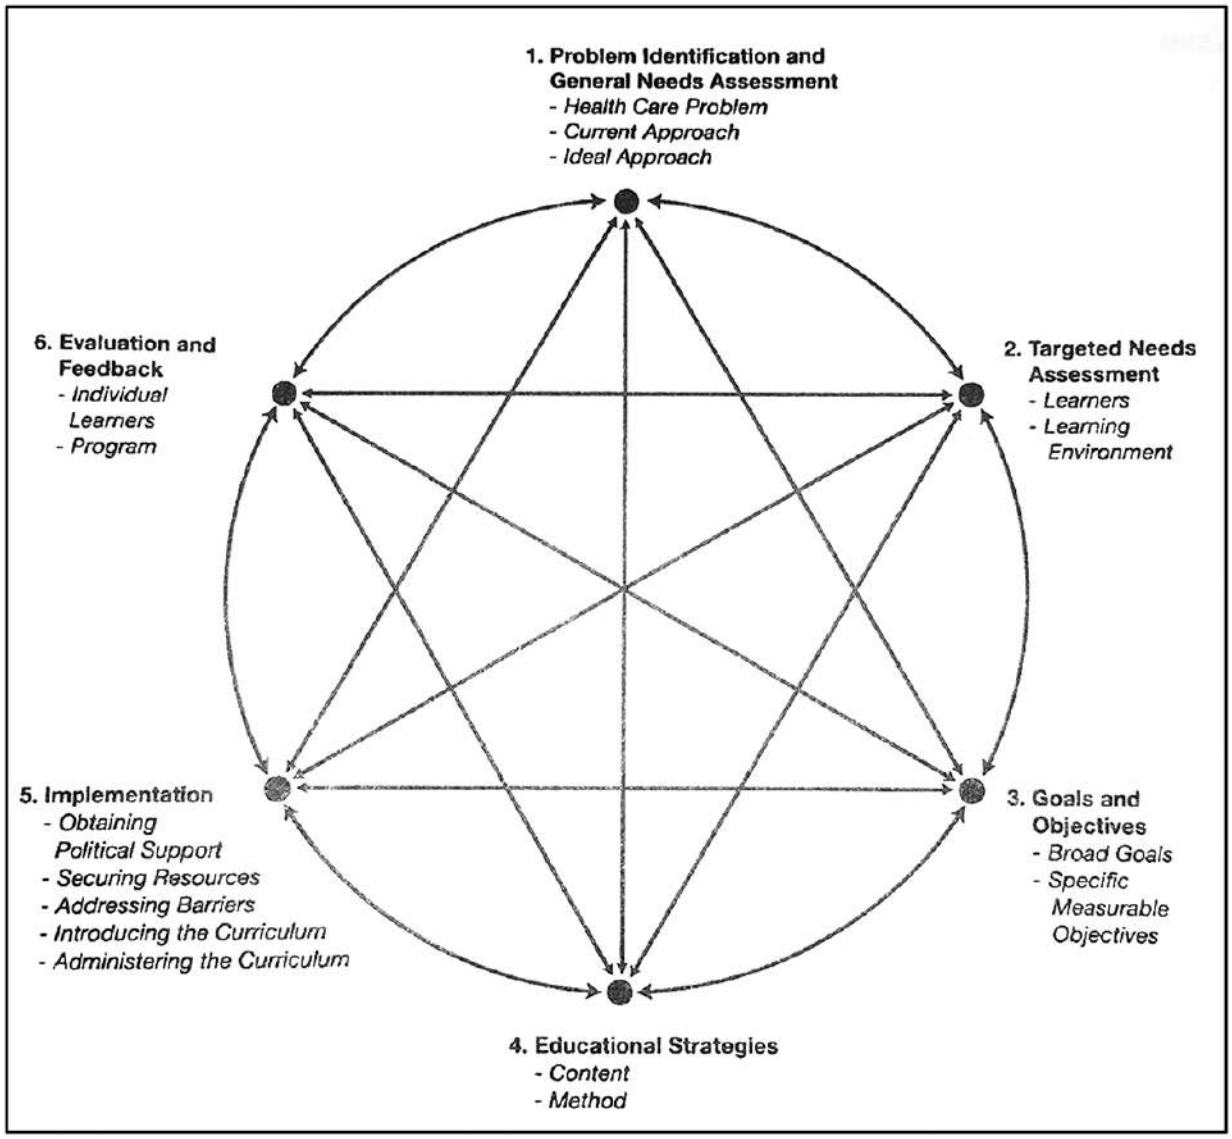

FIGURE 35.6 The six-step approach to systematic curriculum development. (From Thomas PA, Kern DE, Hughes MT, Chen BY, eds. *Curriculum Development for Medical Education: A Six-Step Approach*. 3rd ed. Johns Hopkins University Press; 2016:7, Figure 1. Copyright © 2016 Johns Hopkins University Press. Reprinted with permission of Johns Hopkins University Press.)

Problem Identification and General Needs Assessment

When beginning to develop an educational intervention, an initial problem identification and general needs assessment is done. With respect to radiation oncology, sample problems could include variability in the delineation of radiation target volumes between radiation oncologists[84-87] or lack of exposure to oncology training in medical school curriculum.[88] In either case, once the problem is identified, a general needs assessment is done. This includes determining the current approach to the problem and defining the ideal approach. Often, an educator may identify a problem in their local educational and clinical environment but on review of the literature discovers that another institution or organization is addressing the problem adequately. Rather than develop a new curriculum for the identified problem, the educator can adopt or adapt the existing curriculum to their local needs.

A systematic literature review is an excellent method to identify the current approach to a problem. A systematic literature review may not identify any published approach, in which case there is no curriculum precedent for the educator to follow. Conversely, the systematic review may identify other approaches to the identified problem and thereby provide the educator with a starting point for their curriculum development process. When conducting a medical education systematic review, it is necessary to review resources beyond the usual peer-reviewed literature databases (eg, *MedEdPORTAL*[89]) to ensure approaches to the identified problem are not previously published. Methodology for systematic reviews is defined in the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement[90] and the Institute of Medicine's *Finding What Works in Health Care: Standards for Systematic Reviews*[91] and is beyond the scope of this text. A systematic review of the medical education literature for curriculum development should follow the same rigorous approach used for a systematic review of clinical research.

Subsequent to identifying the current approach to the problem, the ideal approach should be defined. This is an opportunity to incorporate aspects of deliberative and reconceptualist curriculum inquiry. Stakeholders representing the targeted learners (eg, medical students or residents), patients, health care professionals, medical educators, and society can be included in this step of curriculum development to ensure all relevant parties agree with the proposed ideal approach. In the previous examples (ie, variability in contouring and lack of oncology undergraduate education), there would be different stakeholders. The contouring variability example could include residents, medical and physics faculty, and dosimetrists. For the undergraduate oncology education, stakeholders could include medical students, university faculty, teaching faculty, and accreditation bodies. Educators in radiation oncology must also consider accreditation bodies (eg, Liaison Committee on Medical Education, ACGME, Accreditation Council for Continuing Medical Education) and certifying organizations (eg, American Board of Radiology (ABR), the Royal College of Physicians and Surgeons of Canada (RCPSC), Canadian Medical Education Directions for Specialists (CanMEDS), the Royal Australian and New Zealand College of Radiologist, and the Royal College of Radiologists (RCR) in the United Kingdom) when considering the ideal approach to a problem. Training program requirements from these accrediting and certification bodies may direct the ideal approach to an educational problem. New information can be obtained from stakeholders through in-person interviews, focus groups, and questionnaires or surveys. Qualitative and quantitative methods can be used to collect data to define the problem and define goals for the ideal approach to achieve.

By obtaining input from all stakeholders, the educator minimizes the chance of overlooking a key component of the ideal approach to the problem and can begin to generate momentum with the stakeholders for eventual implementation of their new curriculum. The identified differences between the current and ideal approach to a specific health care problem should be the target of any subsequent curriculum development.

Finally, based on the problem identification and general needs assessment, the educator can decide the amount of time and effort to dedicate to curriculum development. If the potential for a positive impact on targeted learners, patients, and society is high, then more time and effort may be devoted to curriculum development. Conversely, if there is a low likelihood of significant impact on learners, patients, or society, less time and effort may be necessary to obtain an acceptable curriculum.

Problem identification and general needs assessments in the radiation oncology literature include surveys identifying a deficiency in medical student knowledge of radiation oncology,[74,75] an analysis of average volume of brachytherapy cases performed by resident volume,[92] studies showing failure of practicing physicians to implement best practices based on high-level evidence,[93,94] or evaluation of critical safety events.[95] These studies identify a problem and indicate a general need for curricular development to solve the problem. However, they do not provide detailed information regarding how best to design the curriculum to solve the problem.

Targeted Needs Assessment

Once the educational problem is identified and the differences between the current and ideal approach are realized, the educator should conduct a targeted needs assessment of the learning environment and learners. In radiation oncology, the targeted learner could be a medical student, resident, attending physician, patient, nurse, dosimetrist, or physicist. The learning environment may be a clerkship, residency program, society meeting, or any other myriad learning environments. The goal of this step in systematic curriculum development is to determine the specific needs of the radiation oncology educators, learners, and environment that differ from the ideal approach identified in the prior step. For example, the physics curriculum proposed by the American Society for Radiation Oncology (ASTRO) for radiation oncology residents[96] may not be feasible in a specific training program's learning environment. Alternatively, the literature reviewed in the general needs assessment may not be current, and educational methods will require updates and modification to be relevant to current learners. A radiation oncology residency program developed in 2002 in Singapore,[97] for instance, may not cover all aspects of radiation oncology training necessary in 2023. In addition, the program was designed to satisfy accreditation requirements of Royal Australian and New Zealand College of Radiologists and may need to be modified if implemented by a program in the United States or Canada because of different accreditation requirements set forth by the ACGME or RCPSC, respectively. However, the design and implementation of the Singapore residency program can provide a starting point for a new residency program followed by a targeted needs assessment within the new program's educational milieu.

Detailed information about the targeted learners and the targeted environment is necessary to develop an effective curriculum. Table 35.6 summarizes characteristics about the targeted learner and environment that are necessary to understand before proceeding further with curriculum development. If the targeted learner is a junior radiation oncology resident, understanding that they have limited or no prior education about contouring a prostate fossa will lead to a different curriculum design compared to that of an attending physician as the targeted learner in a refresher course. Similarly, the resources available within a targeted learning environment dictate how a curriculum is structured. A residency program with a proton center and busy pediatric service will design their resident rotation schedule differently than a training program that does not have a proton center and refers all pediatric cases to an out-of-area proton facility.

TABLE 35.6 CONTENT RELEVANT TO A TARGETED NEEDS ASSESSMENT

Content About Targeted Learners
Expectations regarding the scope of knowledge and skills needed
Previous training and experiences relevant to the curriculum
Already planned training and experiences relevant to the curriculum
Existing characteristics/proficiencies/practices
Cognitive: knowledge, problem-solving abilities
Affective: attitudes, values, beliefs, role expectations
Psychomotor: skills/capabilities (eg, history, physical examinations, procedures, counseling, current behaviors/performance/practices)
Perceived and measured deficiencies and learning needs
Attitudes and motivations of learners to improve performance
Preferences and experiences regarding different learning strategies
Synchronous (educator sets time, such as noon lecture)
Asynchronous (learner decides on learning time, such as with e-learning)
Duration (amount of time the learner think is needed to learn or that they can devote to learning)
Methods (eg, readings, lectures, online learning resources, large and small group discussions, problem-based learning, team-based learning, peer teaching, demonstrations, role-plays/simulations, supervised experience)
Content About Targeted Learning Environment
Related existing curricula

Needs of stakeholders other than the learners (course directors, clerkship directors, program directors, faculty, accrediting bodies, others)
Barriers, enablers, and reinforcing factors that affect learning by the targeted learners
Barriers (eg, time, unavailability, or competition for resources)
Enablers (eg, learning portfolios, electronic medical record reminders)
Reinforcing factors (eg, incentives such as grades, awards, recognition)
Resources (eg, patients and clinical experiences, faculty, role models and mentors, information resources, access to hardware and software technology, audiovisual equipment, simulation center)
Informal and collateral curriculum

From Thomas PA, Kern DE, Hughes MT, Chen BY, eds. *Curriculum Development for Medical Education: A Six-Step Approach*. 3rd ed. Johns Hopkins University Press; 2016:32, Table 3.1. Copyright © 2016 Johns Hopkins University Press. Reprinted with permission of Johns Hopkins University Press.

Given the critical nature of the targeted needs assessment to developing an effective curriculum, methods to obtain the necessary information must be carefully considered. Results of the National Resident Match Program,[98] Association of Residents in Radiation Oncology (ARRO) chief resident survey,[25] and the ASTRO workforce survey[99,100] can provide a starting point for curriculum development. These surveys can provide information on past experiences of targeted learners, work environment, and intrinsic and extrinsic motivation. In addition, these surveys frequently include information on the learning environment in residency programs for GME curriculum development or practice settings for CME curriculum development. An educator must consider how broadly they want their curriculum to be applicable. If the curriculum is developed specifically for a problem identified within their own institution, it may not be applicable to other institutions or educational programs. Thus, reviewing national survey data of training programs[25] and practice environments[100] will inform the radiation oncology educator how they can develop their curriculum in a manner such that it satisfies the needs at their local institution and will be beneficial to other educators in need of a similar curriculum. Table 35.7 summarizes methods commonly employed when conducting a needs assessment of targeted learners.

TABLE 35.7 METHODS FOR NEEDS ASSESSMENT OF TARGETED LEARNERS

Needs Assessment Method	Radiation Oncology Example
Informal discussion or interviews with individual learners, supervisors, or other stakeholders (in-person, over the phone, or by e-mail)	Development of an integrated interdisciplinary oncology elective[189]
Focus group discussions	Focus group discussions with oncologists on patient- and family-centered care[336]
Formal interviews	Interviews of radiation oncology professions regarding uptake of high-precision radiotherapy[63]
Formal questionnaires	Targeted needs assessment for radiation oncology medical student clerkship curriculum[51,106]
Direct observation of targeted learners	Mini-CEX[337]
Pretests of knowledge, attitudes, or skills	Pretest of prostate fossa contouring ability[2]
Audits of current performance	Analysis of brachytherapy procedure volume at U.S. residency programs[92]
Strategic planning sessions for the curriculum	Development of medical school oncology educational goals and objectives[190]

CEX, clinical evaluation exercise.

From Thomas PA, Kern DE, Hughes MT, Chen BY, eds. *Curriculum Development for Medical Education: A Six-Step Approach*. 3rd ed. Johns Hopkins University Press; 2016:37-38, Table 3.2. Copyright © 2016 Johns Hopkins University Press. Reprinted with permission of Johns Hopkins University Press.

Surveys represent the most common method for a radiation oncology targeted needs assessment published in the literature. Numerous resources are available to guide a radiation oncology educator designing a survey or questionnaire for a targeted needs assessment, including resources from the Association for Medical Education in Europe (AMEE)[101,102] and textbooks.[68,103,104] Surveys include interviews, focus groups, and questionnaires. Radiation oncology educators should decide which method best suits the needs of their curriculum development process. Advantages and disadvantages and basic techniques of each method are summarized elsewhere.[68] General considerations when designing a survey include paying careful attention to the goal of the survey (questions should have clear justification for inclusion) and avoiding subjective questions, sensitive questions, or lengthy surveys, as the response rate will decrease with increasing survey length or sensitivity of questions asked. The survey population should be informed of the purpose of the survey and whether responses are confidential. Surveys represent research; therefore, local Institutional Review Board (IRB) approval or exemption should be obtained prior to survey dissemination. A survey should be pilot tested to ensure clarity and understandability.[68] In addition, the pilot data should be analyzed to determine if the data collection format would allow the educator to obtain the desired needs assessment results.

Survey response rate is critical to obtaining representative data. Survey responses can suffer either when the targeted learner does not receive the survey (eg, requesting that a residency program coordinator forward survey invitations on to residents) or when the targeted learner elects not to complete the survey because of length, sensitivity of question topics, unclear questions, or other factors that inadvertently discourage responses. Methods by which to improve survey responses (unit response rate) and question responses (item response rate) are summarized elsewhere.[102]

Targeted needs assessments at the undergraduate medical education (UGME), GME, and CME levels are frequently reported in the literature, although many do not identify themselves as such. At the UGME level, targeted needs assessments provide perspective and guidance on radiation oncology education in the general medical school curriculum[74,105] and for radiation oncology clerkships.[51,106] At the GME level, examples of needs assessments include those investigating general residency experiences,[25,107] resident education in intensity-modulated radiation therapy (IMRT),[108] resident knowledge of caring for older patients with cancer,[109] palliative care training,[110,111] brachytherapy experience,[15,92,112] radiation physics education,[113,114] and radiobiology education.[115] Numerous other GME needs assessments for specific educational goals are reported in the literature. Finally, at the CME level, surveys of practicing physicians can inform educators regarding deficiencies in clinical knowledge that should be addressed. An example of a CME-targeted needs assessment is assessing expert consensus on prostate bed delineation for magnetic resonance imaging (MRI)-guided radiotherapy and determining that interobserver variability still exists despite international contouring guidelines and that strategies such as an education program or development of a contouring atlas may lead to diminished variability.[116] Although these studies provide some guidance, it is critical to incorporate alternative methods for the needs assessment, including focused interviews, discussion with multiple stakeholders, and evaluation of available resources.

Goals and Objectives

Once the radiation oncology educator has defined the health care problem, performed a general needs assessment, and conducted a targeted needs assessment, they can begin to formulate goals and objectives for the curriculum. Alternatively, the educator may begin the entire curriculum development process with a general goal or specific objective for their targeted learners. Goals and objectives are key to curriculum development because they help guide the choice of curricular content, educational strategies, learner assessment methods, and curriculum evaluation methods and communicate to others what the curriculum addresses and aims to achieve.[68] Curriculum goals are broad and general.

In contrast, curriculum objectives are Specific, Measurable, Attainable, and Relevant and have a Time frame.[117] Specific and measurable objectives help to refine the curriculum content and guide learner assessment and curriculum evaluation methods. Objectives should contain five basic elements: "(a) *Who* (b) *will do* (c) *how much (how well)* (d) *of what* (e) *by when*?"[118] By defining specific measurable objectives, the radiation oncology educator can determine the ideal educational, assessment, and evaluation methods that will demonstrate efficacy of the curriculum.

Learner objectives can be in one of three learning domains: cognitive, affective, or psychomotor. Within the three learning domains, cognitive refers to "knowledge," affective to "attitudinal," and psychomotor to "skill" or "behavioral" objectives.[68] Bloom's taxonomy for the cognitive domain defined six levels of the cognitive domain: knowledge, comprehension, application, analysis, synthesis, and evaluation (Figure 35.7A).[119] The cognitive domain taxonomy was subsequently modified to remembering, understanding, applying, analyzing, evaluating, and creating.[120] One of the modifications included changing the domains to verbs rather than nouns to emphasize the active nature of the learning process. The cognitive taxonomy was further refined to four levels: retrieval of knowledge, comprehension, analysis, and use of knowledge.[121] Taxonomies for the affective domain[122] (Figure 35.7B) and psychomotor domain[123-125] (Figure 35.7C) are also defined in the literature. Another conceptual framework used to define progressive levels of learning objectives is Miller's pyramid of clinical competence, which progresses through four phases: knows, knows how, shows, and does (Figure 35.8).[126,127]

When writing objectives, verbs that are open to fewer interpretations should be used. For example, "to list" or "to demonstrate" is better than "to know" or "be able to." Examples of action verbs that can be used to define objectives for the cognitive, affective, and psychomotor domains can be found in medical education texts.[128] The action verb used in the objective can guide what type of assessment method is used to determine if the learner meets the objective. The radiation oncology educator should

not overlook the critical nature of writing specific and measurable objectives. These represent the keystone of any curriculum. Unfocused, unattainable, or unclear objectives will lead to confusion regarding educational, assessment, and evaluation methods.

Learner objectives are generally written to the highest order expected of the learner. However, the radiation oncology educator needs to consider any enabling objectives at lower levels on the pyramid that provide a foundation for achieving the higher order target objective.[68] In addition to learner objectives, the curriculum designer may also define process objectives in relation to curriculum implementation. Table 35.8 provides examples of learner and related process objectives relevant to radiation oncology. Finally, outcome objectives can be specified that relate to patient or societal outcomes.[68] Demonstrating a positive effect of an educational curriculum on patient or societal health outcomes is the ultimate goal for any medical educator. However, measuring the direct effect of an educational intervention for medical trainees on outcome objectives can be challenging because of the numerous variables that determine health outcomes.

TABLE 35.8 SAMPLE LEARNER AND PROCESS OBJECTIVES FOR RADIATION ONCOLOGY EDUCATION

Domain	Level on Domain Taxonomy	Learner Objective	Process Objective
Cognitive	Remembering	The medical student will correctly identify three radiation emergencies at the end of the lecture.	80% of medical students will correctly identify three radiation emergencies at the end of the lecture.
	Applying	The resident will correctly compute the appropriate number of monitor units to treat an emergency spinal cord compression at the end of the workshop.	100% of residents will correctly compute the appropriate number of monitor units to treat an emergency spinal cord compression at the end of the workshop.
	Evaluating	The radiation oncologist will correctly revise incorrect head and neck target volumes at the end of the interactive contouring workshop.	80% of radiation oncologists will correctly revise incorrect head and neck target volumes at the end of the interactive contouring workshop.
Affective	Receiving	The medical student will acknowledge the importance of using nonmedical jargon with patients at the end of the clerkship.	100% of medical students will acknowledge the importance of using nonmedical jargon with patients at the end of the clerkship.
	Valuing	The resident will demonstrate a willingness to use nonmedical jargon during patient consultations at the end of their first year of clinical training.	100% of residents will demonstrate a willingness to use nonmedical jargon during patient consultations at the end of their first year of clinical training.
	Characterization	The radiation oncologist will modify their discussions with patients to minimize use of medical jargon after completing the communication workshop.	100% of radiation oncologists will modify their discussions with patients to minimize the use of medical jargon after completing the communication workshop.
Psychomotor	Perception	The medical student will correctly identify the bevel side of a brachytherapy needle after observing a permanent prostate implant.	100% of medical students will correctly identify the bevel side of a brachytherapy needle after observing a permanent prostate implant.
	Guided response	The resident will correctly reproduce the attending physician's needle placement technique after a lecture on technique and observing a complete permanent prostate implant.	80% of residents will correctly reproduce the attending physician's needle placement technique after a lecture on technique and observing a complete permanent prostate implant.
	Origination	The brachytherapy fellow will correctly and independently construct a new	100% of brachytherapy fellows will correctly and independently construct

HDR, high-dose rate.

Within the context of educational goals and objectives, competency-based education is gaining popularity. Competency- based education is defined as "an approach to preparing physicians for practice that is fundamentally oriented to graduate outcome abilities … It deemphasizes time-based training and promises greater accountability, flexibility, and learner-centeredness and focuses on the competencies required of learners driven by needs of the health care system."[129]

With respect to radiation oncology competency-based education, national accrediting bodies have developed structured guidelines to assist with defining goals and objectives for program graduates. In the United States, as a component of the Next Accreditation System,[130] the ACGME worked with a number of stakeholder groups, including the ABR, to develop the Radiation Oncology Milestones. The Milestones define competency levels for residents within the six competency domains of Patient Care, Medical Knowledge, Systems-Based Practice, Practice-Based Learning and Improvement, Professionalism, and Interpersonal and Communication Skills.[131] Competency objectives for levels of training are defined within the six domains. These narrative descriptions serve as targets for resident performance throughout their program. Level 1 is the knowledge or skill level expected of a novice or an incoming resident, level 4 is a graduation goal of a final-year resident, and level 5 represents an expert resident whose achievements in that category are above expectation. However, the levels are not meant to correspond with postgraduate year of education, and there is no predetermined timing for a resident to attain a particular level. Residents may also fluctuate throughout their years, such as regression due to overscoring previously, or a particularly difficult or discordant experience for the resident. Recent revisions to Milestones 2.0 also include revisions that preclude using Milestones as a sole assessment in critical situations, such as credentialing or readiness for graduation.[131] The ACGME currently mandates that a program's clinical competency committee assess residents using the Milestone framework semiannually.

Similarly, the RCPSC has developed the CanMEDS framework.[6,132] The CanMEDS competencies include medical expert, communicator, collaborator, leader, health advocate, scholar, and professional. The CanMEDS framework, a product of the Competence by Design (CBD) initiative,[133,134] has been integrated into the Royal College's accreditation standards, specialty training documents, final in-training valuations, exam blueprints, and Maintenance of Certification (MOC) Program. Similar to the ACGME Milestones, there are specific milestones for four levels of residency training, including transition to discipline, foundations of discipline, core of discipline, and transition to practice, as well as entrustable professional activities (EPAs).

Instruction/Educational Strategies

As discussed in the learning theory section, effective learning can be facilitated by addressing preconceptions, building expertise, and developing a metacognitive approach to learning.[135] Learners have prior experiences that shape their attitude and motivation toward learning new knowledge or a new skill. These experiences lead to preconceptions that may need to be addressed prior to engaging the learner. Building expertise requires repeatedly exposing learners to specific conceptual frameworks so they can develop fluency of retrieval known as "automatism."[68] As the learners gain experience, they improve their ability to utilize the specific knowledge or skill until they have achieved expertise. Metacognition refers to the learners' ability to recognize what they know or need to know in a specific

problem-solving situation. This concept is related to the learner's ability for self-reflection.[68] If a curriculum is able to lead learners to identify their preconceptions, build expertise, and improve their metacognition, the curriculum is successful in achieving transformative learning where the learner changes in a meaningful way. Learners may resist this type of change because it challenges their assumptions, beliefs, and values.[68]

Educational strategies for a radiation oncology educational curriculum should match the goals and specific measurable objectives defined previously. Educational strategies refer to both the content and methods by which the goals and objectives will be achieved.[68] A simple method by which to choose the content of a curriculum is to refer to the nouns in the specific measurable objectives. For example, if the objective is "the resident will demonstrate the ability to contour the prostate fossa by the end of the workshop," then the content of the curriculum will focus on the "prostate fossa." Although this seems obvious on the surface, a large curriculum such as that of a clerkship or residency program may have numerous subgoals and specific objectives. There is a risk of bias toward easily implementable and assessable content. If each specific objective is not considered when choosing content and educational strategies, the educator risks omitting content critical to one or more of the specific objectives. To prevent omission of content in a larger educational program with multiple goals and objectives, curriculum mapping can be pursued. A detailed discussion of curriculum mapping is beyond the scope of this text and can be found elsewhere.[68]

Educational methods to relay specific content must also be matched to the learning styles of individual learners. Multiple learning style theories exist in the literature.[136] An example of a learning style conceptual framework is Dunn and Dunn's visual, auditory, kinesthetic, and tactile categorization.[137] It is not usually feasible to create a specific curriculum for each individual learner's preferred learning style. In addition, most learners will learn from multiple different educational strategies. Thus, radiation oncology educators should include multiple educational methods that will allow learners with different learning styles to achieve the learning objective. For example, utilizing only slide-based didactic lectures to teach radiation oncology residents about radiation physics and radiation biology may hinder learners who prefer a problem-based format. When choosing educational methods available, resources must also be considered. The ideal approach identified after the problem identification and general needs assessment may not be feasible based on resources available (time, money, etc).

Commonly used educational methods in relation to radiation oncology include readings, lectures, online learning resources, small group discussion, problem-based learning, peer teaching, real-life supervised clinical experiences, role models, demonstration, simulation, and artificial models. There are other methods less commonly employed in radiation oncology because of restrictive resource requirements for development or implementation, limited numbers of faculty or learners, or lack of knowledge in the radiation oncology educator community of the educational method. These methods include large group discussion, team-based learning, reflection on experience, role-play, standardized patients, audio/video review of the learner, and behavioral/environmental interventions.[68]

Educational methods can be divided based on the domain objectives they aim to achieve. Cognitive objectives may be best achieved through readings, lectures, or discussion; affective objectives through standardized patients, reflection on experience, and role-play; and psychomotor objectives may be best achieved through real-life and supervised clinical experiences, simulation and artificial models, or demonstration with repetition and immediate feedback.

Radiation oncology educators face unique challenges when choosing appropriate educational methods. At the UGME and GME training levels, the number of learners is often small. Medical school clerkships may have one to three students rotating at any given time. Residency training programs also have limited numbers of trainees, often at different training levels. The limited number of trainees translates into limited resources (faculty time, money, space, clinical volume) that can be

dedicated to educational methods. Thus, radiation oncology educators must utilize educational methods that efficiently employ limited resources while achieving the goal and specific objectives of their curriculum.

To overcome the challenge of limited resources, individuals, collaborative groups, societies, and certifying organizations have developed curriculum proposals and specific educational methods to assist individual radiation oncology educators in achieving their local educational goals and objectives. Table 35.9 summarizes selected curricula and educational methods. In addition, educational methods utilized by other medical specialties to teach knowledge and skills that are not specific to radiation oncology (eg, breaking bad news, diagnostic radiology knowledge) should be adopted or adapted by radiation oncology educator so as not to reinvent the wheel.

Implementation

Once a curriculum is developed with content and educational methods are selected to accomplish the specified goals and objectives, implementation must occur. All too often, well-designed educational interventions are unsuccessful because of barriers encountered during the implementation phase. Consideration of barriers to successful implementation should start at the outset of the curriculum planning process. The general and targeted needs assessment phase of curriculum development is a useful opportunity to begin establishing rapport with stakeholders who will need to provide support for

successful implementation. For example, during the development of a new 1-month international clinical experience for radiation oncology residents, a program director must not only consider stakeholders (eg, the chairman, teaching faculty, GME office, and residents) for a needs assessment but also use the opportunity to develop relations that will be important for successful implementation. For example, if early in the development of the 1-month international clinical experience the residency program director fails to discuss the required funds with the chairman and/or international rotation requirements with the GME office, the resulting decrease in available residents for service coverage or the requirements for an international rotation with the GME office may present insurmountable barriers at the time of implementation. In addition, if the residents themselves were not made aware of the proposed experience prior to an attempt at implementation, they may choose not to participate, thus negating the effort put into the curriculum development.

Resources for successful implementation must be identified and obtained. These include personnel, time, facilities, and funding.[68] Successful implementation requires appropriate resources, and as Figure 35.6 demonstrates, barriers to implementation must be considered during the earlier phases of curriculum development. Table 35.10 provides a checklist that can be used early in the curriculum development process to streamline the implementation phase.

TABLE 35.10 CHECKLIST FOR IMPLEMENTATION

- **Identify resources**
  - Personnel: faculty, audiovisual, computing, information technology, secretarial and other support staff, patients
  - Time: curriculum director, faculty, support staff, learners
  - Facilities: space, clinical sites, clinical equipment, educational equipment, virtual space (servers, content management software)
  - Funding/costs: direct financial costs, hidden or opportunity costs, faculty compensation, costs of scholarship

Obtain support

- ***Internal***
  - From: those with administrative authority (dean's office, hospital administration, department chair, program director, division director, etc), faculty, learners, other stakeholders
  - For: curricular time, personnel, resources, political support
- ***External***
  - From: government, professional societies, philanthropic organizations or foundations, accreditation bodies, other entities (eg, managed care organizations), individual donors
  - For: funding, political support, external requirements, curricular or faculty development resources
- **Develop administrative mechanisms to support the curriculum**
  - Administrative structure: to delineate responsibilities and decision-making
  - Communication
    - Content: rationale; goals and objectives; information about the curriculum, learners, faculty, facilities and equipment, scheduling; changes in the curriculum; evaluation results; etc
    - Mechanisms: websites, social media, memos, meetings, syllabus materials, site visits, reports, etc
    - Operations: preparation and distribution of schedules and curricular materials; collection, collation, and distribution of evaluation data; curricular revisions and changes, etc
    - Scholarship: plans for presenting and publishing about curriculum; human subject protection considerations; IRB approval, if necessary
- **Anticipate and address barriers**
  - Financial and other resources
  - Competing demands
  - People: attitudes, job/role security, power and authority, etc
- **Pilot**
  - Phase-in
  - Full implementation

Plan for curriculum enhancement and maintenance

Any new or modified educational curriculum represents a change in the status quo, and therefore, radiation oncology educators must become familiar with methods to effect successful change. Kanter's six steps to leading positive change[138] (Table 35.11) and Kotter's eight steps to leading change[139] (Figure 35.9) are two examples of conceptual frameworks that can be employed to garner support from necessary stakeholders and successfully develop and implement a new curriculum or changes to an existing curriculum. One unifying theme in both conceptual frameworks is that to effect change, others must be involved in the process of change. Further discussion of leadership theory[140] and organizational culture[141] is beyond the scope of this text.

TABLE 35.11 KANTER'S SIX STEPS TO LEADING POSITIVE CHANGE

1. Show up

Evaluation and Feedback

Per the six-step framework,[68] evaluation and feedback is the final step in curriculum development. Evaluation takes place at both the learner and program levels. In education parlance, "assessment" refers to a test or survey to provide feedback to the learner, whereas "evaluation" refers to methods used to evaluate the educational program. These can include stakeholder surveys, review of aggregate assessment data to determine if the specific and measurable objectives were achieved, and so on. In this section, assessment of the individual learner is referred to as distinct from the evaluation of an educational program, although both are intimately linked.

Learner Assessment

Key to the delivery of any educational intervention is a clear plan for learner assessment. Assessment is defined as "any systematic method of obtaining information from tests and other sources, used to draw inferences about characteristics of people, objects of programs."[142] The purposes of learner assessment are multifold.[143] Many of the educational attributes or traits that educators assess are hypothetical concepts. Assessments allow educators to assign a measure or degree of quantification to such attributes. Assessments aim to document achievement of what was learned or taught, which is helpful to assess the competency of learners and generate learner feedback for areas of improvement. Assessments can also be useful to measure aptitude to gauge learner performance, assign grades or provide ranking, and predict future performances or suitability for certain educational programs (ie, MCAT for admission to medical school). Ultimately, in many settings, assessments are a requirement for accreditation and can inform decisions about the effectiveness of medical education programs and be integral to a programmatic evaluation (see later). To be meaningful, learner assessment must be clearly linked to objectives, define standards for performance, and include measurements that are reliable.

Assessments may be formative or summative. Formative assessments provide the learner with feedback with the intent to allow the learner to identify what they have learned and areas for improvement.[143,144] Formative assessments should occur at multiple defined points throughout a training program or course. In radiation oncology residency programs, formative assessments could include in-house written exams for physics or radiation biology, objective structured clinical examinations (OSCEs) to assess communication skills and end-of-life discussions administered midway through a clerkship rotation in medical school, or annual in-service training exams to assess clinical knowledge. Summative assessments are intended to provide an overall summary of a learner's achievement. They are generally done at the end of a defined curricular period. With respect to radiation oncology, this may include licensing exams at the end of residency, such as those administered by the ABR or RCPSC. Assessments can be "low stakes" and "high stakes." These are often linked, but not always, to formative and summative evaluations, respectively. The consequences of the exam define the stakes of the exam. High-stakes exams have "a serious impact on the examinee," whereas low-stakes exams have significantly lower potential for impact on the trainee.[144,145] Assessments can also be norm referenced (eg, percentile determines performance) or criterion referenced, which are interpreted in the context of specific objectives or learning standards (eg, "Pass/Fail" or "Meets Standard, Standard in Progress, Does not Meet Standard"). The annual in-service training exam is an example of a norm-referenced test, whereas competency-based assessment is usually a criterion-referenced test. Methods to set the pass threshold including the Angoff Method (used for the ABR-certifying exams) are discussed elsewhere.[144]

Assessment Methods

A wide range of assessment methods has been reported in the medical education literature.[68,145,146] Although not an exhaustive list, the following provides a sample of assessment methods. Downing and Yudkowsky[144] propose that there are four major types of assessment methods. Table 35.12 summarizes these methods with examples relevant to radiation oncology. The four groups include written tests, performance tests, clinical observations, and miscellaneous or other forms not classified. Written tests are among the most commonly used forms of assessment. Written tests may include open ended (a.k.a. constructed responses, short or long answer, essay) or closed ended (a.k.a. selected responses, matching, true or false, multiple choice). Closed-ended multiple-choice questions offer the advantage of being easy to administer and grade but may lack the ability to assess diagnostic reasoning. Well-constructed written tests may overcome this problem and allow for more detailed assessments of knowledge and reasoning.[145,147,148]

TABLE 35.12 COMMON ASSESSMENT METHODS AND RELEVANT RADIATION ONCOLOGY EXAMPLES

Assessment Method	Example	Radiation Oncology Example With Relevant Literature if Applicable
Written exam	Multiple-choice exam Essay exam Short-answer exam	• ACR Radiation Oncology In-Training (TXIT) Exam[217] • Pre- and post-test written exams after e-learning module[344] • American Board of Radiology Qualifying Exam • Royal College of Physicians and Surgeons of Canada Radiation Oncology Written Exam
Performance test	OSCE simulation	• Cancer Pain Management OSCE for Medical Students[345] • Standardized Patients to Assess Communication Skills in Radiation Oncology Residents[27] • Prostate or Gynecologic Brachytherapy Insertion Simulation on Phantom
Clinical observation	Structured clinical observation	• Mini-CEX • Direct Observation of Medical Student and Resident in Radiation Oncology Clinic rotations
Miscellaneous	Portfolio review Chart simulation	• Portfolio review to include clinical encounter notes, collection of clinical evaluations, sample of contouring tasks, quality improvement projects

ACR, American College of Radiology; OSCE, objective structured clinical examination.

Performance tests are those assessments that allow for direct observation of the learner. They allow the learner to demonstrate "what they can do."[144] The most common examples are the OSCEs or simulations. An OSCE consists of a series of stations with a distinct focus on a clinical task.[145] Many OSCEs use standardized patients trained to portray a patient and relevant medical scenario.[146] For the purposes of assessment at an OSCE station, an observer will assess the performance of the learner based on a checklist or global rating tool. Although this type of assessment can be constructed to be realistic and reliable, they can be expensive and highly dependent on checklist quality and observer consistency. The term *simulation* refers to a realistic representation of a real-world task.[144] High-fidelity simulations can be used to assess procedural skills or teamwork scenarios. They provide a relatively low-risk environment to assess high-risk and low-frequency scenarios.[149] While simulations can be realistic and provide reliable assessments, they can also be expensive and do not provide a "real-time/real-world" assessment.

Clinical observations are assessments made based on performance in the clinical setting.[144] The clinical performance evaluation or global assessment rating is one of the most common methods utilized during training. The ACGME toolbox distinguishes the global rating from other assessment methods in that "a rater judges the general categories of ability instead of specific skills or behavior and the ratings are completed retrospectively based on general impressions collected over a period of time derived from multiple sources or information."[150] These are easy to carry out for the rater and usually done in real time. There has been considerable literature, however, on the subjectivity of the raters and the variability in the assessments coupled with issues with rating tools.[151]

The final category of assessment includes tools not well positioned in any of the categories above. These include assessment tools such as portfolios, formal oral exams, and bedside oral exams. A portfolio is a purposeful sampling of work to support attestation of meeting a required level of training or competency. Portfolios are combined with self-reflection and allow the learner to demonstrate areas of strengths and potential areas for improvement.[145,152] Portfolios can include a broad sampling of a learner's experiences, including dictations, procedure logs, sample contouring logs, quality improvement projects, and even videos of procedural techniques or consults. Mentoring is integral to

the interpretation of the portfolio. Portfolios can provide a broad sampling to support assessment but can be labor intensive and dependent on faculty development.

The learner should also be positioned to perform accurate and frequent self-assessment. Self-assessment has been cited to yield both noncognitive benefits, such as improvements in morale, motivation, and communication skills, and cognitive benefits, including improvements in knowledge, performance, and self-analysis of performance.[153] Effective implementation of self-assessment would thus enhance professional learners not only to achieve necessary competencies but also to continue to grow and evolve their knowledge, skills, and behaviors as their professions grow and evolve.[6] Self-assessment has been integrated into the ACGME's recommendations for resident evaluation, as self-assessment using the Milestones "will enable residents/fellows to critically evaluate their abilities" and be compared to results from their attendings and supervisors for "more meaningful evaluation."[131]

Selection of Assessment Methods

Numerous resources provide guidance on the selection of specific assessment methods. From a conceptual perspective, the ACGME defined five characteristics integral to an assessment instrument or approach including that the approach should provide valid and reliable data, be feasible, apply to the assessment circumstances, and, finally, provide valuable information.[150] Van Der Vleuten and Schuwirth[154] developed a conceptual model that mirrors these criteria. Their model describes five criteria to help select an appropriate assessment tool. The criteria included are validity (if the assessment measures what it is intended to measure), reliability (does the tool reproducibly measure what it is intended to measure), educational impact (what are the effects of using the tool on learners and the educators), acceptability to learners and faculty, and costs. This model proposes that each of the criteria are weighted depending on the intended purpose of the assessment data and that all factors are multiplied together. For example, if the assessment would be for a certifying exam (eg, ABR-licensing exam), then more weight may be given to reliability and validity as opposed to an in-house physics exam intended to provide the learner with formative feedback where more weight may be given to costs and educational impact. This model is useful to conceptualize that each assessment method has inherent advantages and disadvantages and many factors should be both considered and relatively weighted in choosing a method appropriate to the educational context.

In the context of selecting an assessment method that measures what it is intended to, Miller's pyramid of clinical competence can help provide a framework.[126,144] As discussed previously, Miller's pyramid (see Figure 35.8) progresses through four levels of clinical competence: knows, knows how, shows, and does. It can be useful to map assessment methods to each of these levels. At the base level of "know," a learner may be asked to simply demonstrate factual knowledge of a concept. Here, assessment methods examine the ability of the learner to recite knowledge. Examples of assessment methods include traditional written tests, such as true or false. "Knows how" implies that the learner can use factual knowledge for the purposes of interpretation or application. This level may be assessed by more detailed written tests including short or long written answers or oral exams where the learner is required to illustrate not only their knowledge but also its application. The "shows" level implies an ability to demonstrate learned skills. Assessment methods include simulations or OSCEs. Finally, the "does" level moves the learner's performance into clinical practice. Assessments in this setting take place in the "real world" and include direct observations in a clinical setting and multisource feedback. Figure 35.10 depicts the selection of assessment methods in radiation oncology based on Miller's pyramid.

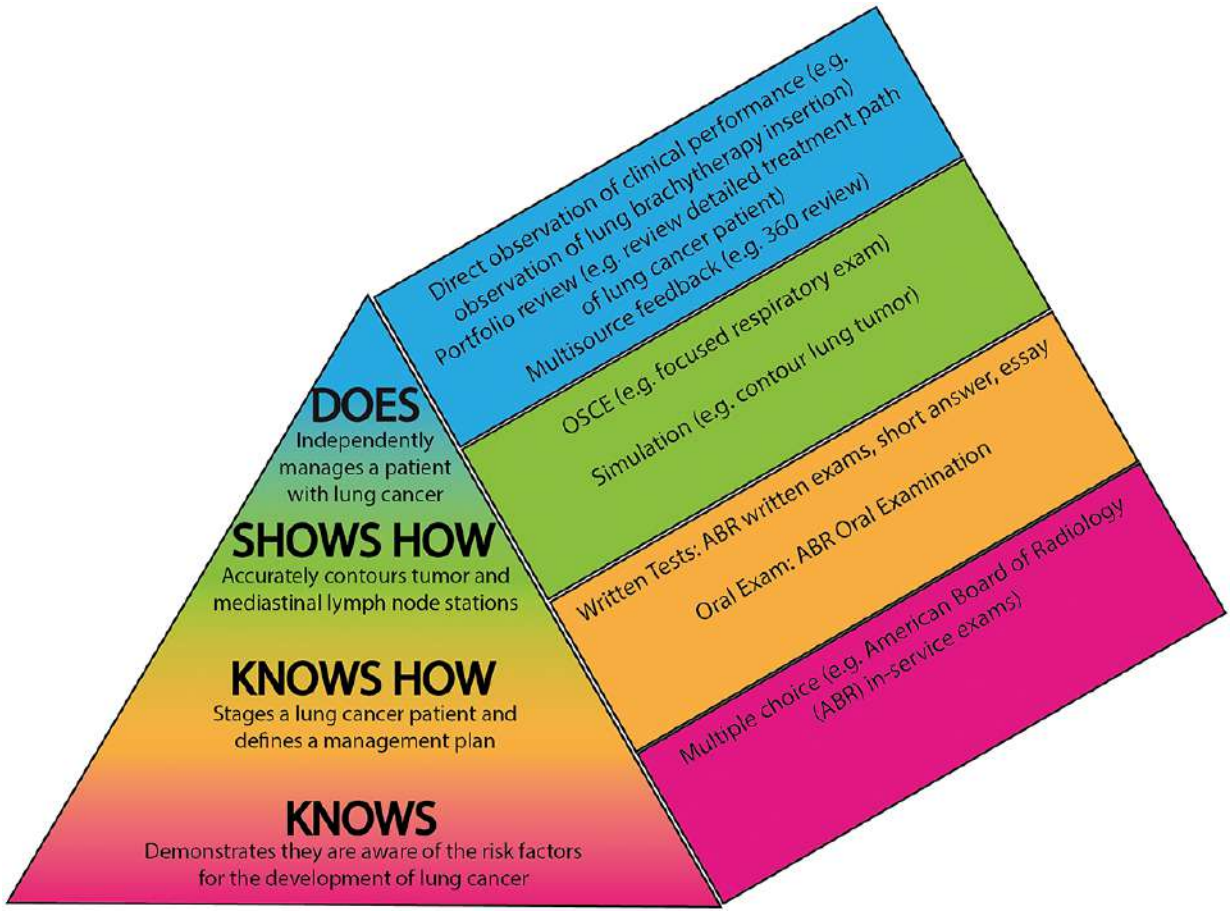

FIGURE 35.10 Miller's pyramid[116] applied to assessment methods in radiation oncology.

Although a multitude of assessment methods exists, the role of the medical educator is to select methods that provide a broad sampling of performance and are reliable, reproducible, and free of bias. No single assessment can give a perfect measure of performance or knowledge, and the application of several methods will provide the most reliable data. Assessment should be mapped to the objectives and instructional methods within a curriculum map (see objectives section).[155,156] A purposeful discussion of assessment methods should happen at the time of curriculum development with the intent of clearly defining what needs to be measured, how this will be measured, who will measure (and how will their skills be developed to support this), and how will the data be used.[145,149] Table 35.13 summarizes some of the practical questions a radiation oncology educator could ask themselves when developing an assessment plan.

TABLE 35.13 PRACTICAL QUESTIONS TO ASK WHEN DEVELOPING AN ASSESSMENT FRAMEWORK

Question	Subset of Questions
What is the goal of assessment?	What is the intended purpose of the assessment data? Are the data meant to be formative or summative?
What are you trying to assess?	Where does the entity being assessed exist on the Miller's pyramid[116]? How best can the learner demonstrate what you are trying to measure (ie, written test or clinical observation)? How many measurements and methods would provide an adequate sampling of the entity to be measured?

Question	Subset of Questions
When will you assess?	How often should assessments take place? If the assessments are formative, what frequency is needed for the learner to improve their performance? Are assessments too frequent and thus not feasible or sustainable?
Who will conduct the assessments?	How will you ensure the assessments are similar and reproducible? Will you need faculty development? How many assessments do different observers need?
Who will manage the assessment data?	Where will the assessment data be kept? Who will collate, distribute, and review the assessment data? How will the security of the assessment data be maintained? How will feedback be given in a timely manner?

Competency and Assessment

As discussed previously in the Goals and Objectives section, medical training is shifting to competency-based frameworks.[129] Within radiation oncology GME, relevant frameworks include the RCPSC CanMEDS framework[6] and ACGME/ABR Radiation Oncology Milestone.[131] In Canada, the RCPSC developed specialty-specific competency frameworks for all specialties including radiation oncology through the CBD project.[133,157] Both the ACGME Milestone Project (Figure 35.11) and the Radiation Oncology Competence by Design define competencies related to the various roles (ie, Communicator, Collaborator, etc) and are specific to the level of training. By the end of a specific level of training, a learner is expected to demonstrate competency through the accomplishment of a number of training level–specific EPAs.[158] An EPA is a clinical task that is demonstrable and typically includes multiple milestones.

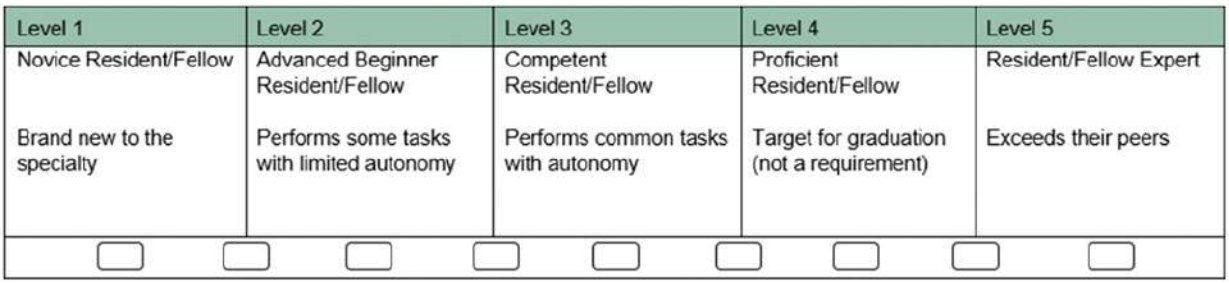

FIGURE 35.11 The Accreditation Council for Graduate Medical Education milestone levels of expectation. (From Edgar L, McLean S, Hogan SO, Hamstra S, Holmboe ES. *The Milestones Guidebook*. Accreditation Council for Graduate Medical Education; 2020. Reprinted with permission of Accreditation Council for Graduate Medical Education.)

Each of the competency-based frameworks in the United States (ACGME) and Canada (CanMEDS) has toolboxes that may help the educator select assessment methods by competency.[159,160] With the evolving competency-based curriculum, there will be changes to these toolboxes, but the foundations will likely remain similar. Although these toolboxes divide assessment methods by competency, it is well established that many of the competencies overlap and their assessment on an individual level is artificial at best. Competencies are not stable through training and develop with experience.[161] The most robust assessment of competencies will rely on features mentioned previously and will include broad, purposeful, and frequent sampling with reliable and reproducible methods. In the context of competency-based assessments, the assessment data can be used both "for learning" and allow self-reflection and to "assess learning" to ensure accountability to training programs and society.[162] Lastly, both the RCPSC and the ACGME mandate the involvement of a clinical competence committee to review competency assessments on a regular basis and help to provide feedback to the learner and the

program. With a shift to competency-based training and assessment, a considerable amount of faculty development will need to occur to ensure that the assessments are performed in a consistent and reliable manner and accomplish the intended outcomes.

Program Evaluation

Program evaluation is a key step in curriculum development. The purposes of evaluation are multifold. Program evaluation can be performed[163,164]:

- to determine the effectiveness of the curriculum for learners
- to document that curricular objectives have been met
- to enable faculty to make changes to improve the program
- to provide data to track program management, evaluate efficiency, and support accountability and dissemination

The following eight practical steps, adapted from the six-step curriculum approach,[68] Fitzpatrick,[165] and AMEE guides,[164,166] are proposed to guide program evaluation:

1. Identify users: As a first step, the stakeholders should be identified. Stakeholders refer to the likely users of the evaluation data. This will often include the learners, the faculty, the curriculum developers, the funders, the university, and the accreditation bodies when appropriate.
2. Determine the purpose of the evaluation: The purpose of the evaluation should be clearly defined. It is here that the approaches to evaluation and the dimensions should be reviewed as discussed earlier. Key questions to ask are as follows: What approach is this evaluation? Will this evaluation be summative or formative? How will the results of this evaluation impact the program, and how will the data specifically be used?
3. Identify resources and select an evaluation team: Resources will need to be allocated to conduct an evaluation. Such resources can include personnel, time, equipment (eg, computers, access to secure databases), and funding. Many medical schools and residency programs may have existing evaluation units, and it can be useful to identify this at the outset. With respect to choosing an evaluation team, it is useful to consider if an evaluation team is best composed of internal or external reviewers. In addition, depending on the approach to evaluation, it may be useful to include participants, faculty, learners, and health care consumers.
4. Determine the evaluation questions: The evaluation questions depend on the approach to the evaluation. With respect to an objective-oriented approach, evaluation should be linked to the process and outcome objectives of a curriculum (see section “Goals and Objectives”). As such, the evaluation will examine the *who will do how much of what* and *when*. It is best when writing program objectives that a lens is given to the evaluation questions to ensure they are in fact measurable and clear. If a participant-oriented approach is taken, evaluation questions could be directed to participants, and the questions asked are related to the perceived effectiveness of the program and the relative strengths and weaknesses.
5. Select an evaluation design: A variety of evaluation approaches can be taken. For the most part, these are dependent on the approach to evaluation and are well summarized elsewhere.[164] Some of the most common evaluation designs relate to an objective approach to document that learning objectives have been met. These can include a post-test design, a pre-/post-test design, or a controlled pre- and post-test design (ie, where an experimental group is exposed to a curricular intervention). As the degree of control increases, the complexity to administer also increases. There are well-known limitations to each design approach.[68]

6. Select a measurement method and relevant instruments to collect data: It is essential that the measurement method be aligned with the questions identified in the evaluation. Similar to the section on assessment, evaluation methods should be chosen to provide reliable and reproducible data that evaluate questions relevant to making appropriate judgments. In part, Kirkpatrick's hierarchy of evaluation[70] (Table 35.14) can help frame the possible methods one might use to evaluate a program examining learner outcomes. At the lowest level of the hierarchy, one could simply evaluate the participation and reaction of learners. One could use rating forms or conduct individual interviews to gain information on the satisfaction of learners (or stakeholders). To demonstrate that learning had taken place, one could examine the results of written or oral exams. With respect to documenting a change in behavior, this would likely be best done in the context of direct observation. Finally, improved patient care could be done through direct observation and performance audits. The most robust evaluation data would be both quantitative and qualitative.

TABLE 35.14 KIRKPATRICK'S HIERARCHY OF EVALUATION[64] IN RELATION TO RADIATION ONCOLOGY EDUCATION

Level 1: Reaction	Are participants satisfied with the educational experience? Example: Medical students rate a clerkship curriculum as useful.[88]
Level 2: Learning	Has learning taken place? Example: Medical students demonstrate improved knowledge on an objective assessment after a single lecture on radiation oncology.[178]
Level 3: Behavior	Is there a measurable change in professional behavior? Example: Learners demonstrate improved contouring accuracy after a teaching intervention.[52]
Level 4: Results	Is there an improvement in patient care? Example: Implementation of a contouring atlas to educate physicians on contour accuracy demonstrates improved tumor control probability and decreased normal tissue complication probability.[346]

7. Collect and analyze the data: The data must be both collected and analyzed. As part of curriculum design, it is essential to define the frequency with which evaluations will be done and how the data will be stored and analyzed. Data may require analysis with both descriptive statistics and qualitative analysis. When established standards are in existence, the data may be compared to these or the literature can be reviewed to relate the experience to other programs or institutions.
8. Dissemination and feedback: The last stage of program evaluation is the act of collating the results and dissemination. Evaluations should be timely and distributed to the relevant stakeholders. It is useful to review the purposes of the evaluation in order to assess who should receive the results and in what format.

Overall, program evaluation is a key component of curriculum development. Table 35.15 provides specific examples of radiation oncology program evaluation.

TABLE 35.15 EXAMPLES OF EDUCATIONAL EVALUATION STUDIES IN RADIATION ONCOLOGY

Study Summary	Evaluation Approaches	Evaluation Methods
Evaluation of a Radiation Safety Initiative for Nurses[347]	Objectives oriented	Pre- and poststudy written tests to assess for changes in knowledge and attitudinal objectives
Evaluation of Theoretical Radiation Oncology Training Programs[26]	Participant oriented	Written user satisfaction surveys
Evaluation of a Contouring Bootcamp[21]	Objectives oriented Participant oriented	Pre- and poststudy written tests Written learner satisfaction surveys

Study Summary	Evaluation Approaches	Evaluation Methods
Longitudinal Study to Assess Adherence to Clinical Pathways[348]	Objectives oriented	Pre- and poststudy written tests using Clinical Performance and Value Vignettes
10-y review of student accomplishments in rapid response radiotherapy program[349]	Objectives oriented/management oriented Participant oriented	Number of first authored papers produced by students in the program Written learner satisfaction surveys

Dissemination

To qualify as scholarship, any curriculum development project must be disseminated to the public.[45] Dissemination of a novel curriculum can help address a health care problem, stimulate change, provide feedback to curriculum developers, increase collaboration, prevent redundant work, and help curriculum developers achieve recognition and academic advancement.[68] Dissemination of a curriculum should be considered during all phases of curriculum development to develop a coherent strategy for dissemination, address ethical and legal issues related to protection of the participants and intellectual property, identify what curriculum material and data will be disseminated, identify the target audience, and identify venues for dissemination.[68] Innovations are more likely to be adopted if there is a perceived relative advantage over existing practice; compatibility with previous experience, beliefs, and values; simplicity of the innovation; trial ability allowing the innovation to be implemented in a stepwise manner; and observability.[167] Ethical and legal issues include consideration of whether local IRB exemption or approval is required prior to disseminating the curriculum. In the United States, many educational projects qualify as "exempt" from IRB review based on Health and Human Services Office for Human Research Protections guidelines for exemption.[168] Projects that are exempted include the following:

Category 1: Research conducted in established or commonly accepted educational settings, involving normal educational practices, such as research on regular and special education instructional strategies or research on the effectiveness of or the comparison among instructional techniques, curricula, or classroom management methods

Category 2: Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedures, or observation of public behavior, unless (1) information obtained is recorded in such a manner that human subjects can be identified, directly or through identifiers linked to the subjects, and (2) any disclosure of the human subjects' responses outside the research could reasonably place the subjects at risk of criminal or civil liability or be damaging to the subjects' financial standing, employability, or reputation

Radiation oncology educators are encouraged to speak with their institution's IRB representatives to obtain advice on whether IRB exemption or full review is required for an educational project. Professional ramifications for not obtaining proper IRB approval of a scholarship project can be significant.

Consideration of intellectual property issues is also important. Images, figures, and tables used in lectures may be subject to copyright protection. Publishers can be contacted for permissions, or more simply, when developing an educational product, care can be taken to avoid copyrighted materials. In addition, institutions may have copyright protections for patient images or photographs, and the curriculum developer is advised to discuss possible copyright issues with the appropriate institutional representative.

Multiple components of the curriculum development process can be disseminated, including a systematic review performed as a general needs assessment, a survey focus group done as the targeted needs assessment, the curriculum materials themselves including goals and objectives with educational methods (eg, lecture, workshop, small group), and then the assessment and evaluation data. Methods

for dissemination include presentations at national meetings, publication in peer-reviewed journals, and dissemination via the internet (eg, *MedEdPORTAL*[89]). A more detailed discussion of curriculum dissemination strategies is available elsewhere.[68]

CURRICULUM MAINTENANCE, RENEWAL, AND REFORM

Radiation oncology educational programs must adapt and evolve to accommodate changes in accrediting body requirements, learner preferences, turnover of faculty and staff, and changes in clinical practice. In addition, novel systemic therapies and radiation oncology techniques are continually being developed and implemented. As such, training programs must continually address these changes. A seminal paper by Abrahamson[169] describes nine "diseases" of the curriculum. Examples include "carcinoma of the curriculum" characterized by uncontrollable growth of one segment or component of the curriculum; "iatrogenic curriculitis" where the curriculum suffers from excessive tampering or meddling; "curriculum hypertrophy" with an increasingly crowded curriculum due to more and more content crammed into limited educational time; bad teaching leading to "idiopathic curriculitis"; and "curriculum ossification" where the curriculum is "cast in concrete" and is characterized by comments such as "What do you want to change anything for?" or "Well, we've always done it this way." These "diseases," although humorous on the surface, affect many radiation oncology educational programs, including medical school clerkships, residency training programs, educational sessions at society meetings, and CME programs. To prevent or treat Abrahamson diseases of the curriculum, radiation oncology educators should routinely reevaluate their curriculum for deficiencies and areas in need of improvement. A curriculum is never "done" and can be reevaluated utilizing the six-step model[68] or by applying Harden's 10 questions.[80] Without regular reevaluation, radiation oncology educators are at risk for curricular ossification or any of Abrahamson other diseases of the curriculum.

To achieve success when revising or reforming an existing curriculum, methods discussed previously for implementation strategies should be employed. In particular, utilizing a deliberative curriculum development model that includes as many stakeholders as possible will help garner political support for curriculum reform.[170]

CURRENT PRACTICES IN RADIATION ONCOLOGY TRAINING

Having a basic understanding of the principles of medical education can help facilitate the careful development, implementation, and evaluation of a new curriculum and educational scholarship. The following section focuses on the real-world application of medical education principles to UGME, GME, and CME in radiation oncology. This review focuses on the current educational landscape in each setting and identifies areas for potential future educational development and scholarship.

Undergraduate Medical Education in Radiation Oncology

Radiation oncology education as a specific discipline begins during the undergraduate phase of medical training. Students enter medical school with varied experiences and preconceptions about which specialty they plan to pursue. As a small specialty, radiation oncology may be relatively unknown to medical students relative to larger core clerkship specialties (internal medicine, pediatrics, surgery, obstetrics and gynecology, psychiatry, family medicine) or specialties that are commonly portrayed in popular culture (surgery, emergency medicine, etc.). Therefore, radiation oncology educators must work to ensure that the specialty is represented in their institution's core curriculum. In one U.S. needs assessment for radiation oncology education, only 30% of respondents reported receiving a lecture in their medical school on radiation oncology and 1% reported a mandatory radiation oncology educational experience.[51] A survey of students, primary care providers, and

radiation oncology attendings at seven U.S. medical schools demonstrated persistent misconceptions regarding radiation oncology.[105] For example, 23% of the fourth-year medical students and 19% of primary care providers responded that radiation oncologists "push a button to deliver RT every day," indicating a lack of knowledge regarding the daily clinical duties of a radiation oncologist. Similarly, in a survey at two U.S. medical schools, medical students reported increasing comfort regarding their knowledge of medical oncology, surgical oncology, and hospice/palliative care, but not of radiation oncology or survivorship care.[75] A survey of Canadian medical schools demonstrated similar deficiencies in radiation oncology education, with 17% of students reporting no radiation oncology training, a majority reporting no more than 2 hours of radiation oncology teaching, and 19% reporting they were deterred from considering radiation oncology as a career choice because of the lack of knowledge about the specialty.[171] Combined, these data indicate that medical students are not being adequately exposed to clinical aspects of radiation oncology during their core medical school curriculum and are uncomfortable with their radiation oncology knowledge. This deficiency may lead to potential negative consequences. First, students who may otherwise choose radiation oncology as their specialty are not being exposed early and in enough depth in medical school to consider pursuing the specialty. Second, for the majority of students who pursue specialties other than radiation oncology, lack of a basic understanding of the specialty may negatively impact future patient care, including recognizing the need for a radiation oncology consultation, toxicities commonly caused by radiation, or inaccurate counseling on the purpose of radiation within the broader scope of cancer care.

Radiation Oncology Education for All Medical Students

Multiple efforts to develop radiation oncology educational experiences for the general UGME curriculum are reported.[105,171-183] General exposure to radiation oncology can be achieved through development of a preclinical oncology interest group[184] or through tumor board shadowing experience.[183]

Hirsch et al[53,176,178] at Boston University developed a 1.5-hour didactic lecture on radiation oncology during the radiology clerkship. All students at their institution received the lecture. A pre- and postclerkship multiple-choice exam was administered to assess objective knowledge improvement. The average exam score increased, most significantly on the radiation oncology scores (56.5%-71.8% correct, $P < .001$), demonstrating that a single lecture can have a significant impact on knowledge of radiation oncology. The same group has developed the Oncology Education Initiative for preclinical students that includes a radiation oncologist-led oncology education block for the second-year medical students.[185] Students rate the oncology block favorably and specifically report that the oncology block "was effective in contributing to [their] overall medical education."

The group at Thomas Jefferson University has taken a different approach offering an optional 3-week radiation oncology elective during the third-year surgery clerkship.[180,186] Overall objective test scores improved after the rotation (64%-82%) and within the subdomains of clinical (63%-79%), biology (70%-77%), and physics (62%-88%) knowledge (all values $P < .001$).[186] On a follow-up survey, an average of 1.5 years after completion of the elective, improvements in knowledge persisted, with some decay seen for clinical and physics knowledge. Students felt that the elective helped them to understand when to consult a radiation oncologist, identify emergent situations where radiation is needed, and how to take care of patients with cancer, among other benefits.[180] The Department of Radiation Oncology at Thomas Jefferson University has also developed an annual 6-week summer externship during which the student works with the radiation oncology team to perform research and participates in educational activities that provide the student with breadth and depth within the field.[187,188] The program is made further accessible by providing a stipend for the summer program, allowing students who would otherwise need to find paid employment during the break an opportunity to enhance their education without financial burden. At the University of British Columbia, other

approaches have been used to increase medical student exposure to radiation oncology. During the third-year surgery clerkship rotation, only 10% to 15% of medical students partake in radiation oncology electives. As a result, upward of 85% to 90% of graduating medical students receive no clinical exposure to radiation oncology. A targeted needs assessment of learners identified that, relative to other areas of clinical training, medical students felt unprepared to take care of patients with cancer and that supplemental online resources were needed.[189] Based on the six-step method for curriculum development,[68] Ingledew and colleagues developed and implemented a series of online modules, supported by virtual patient vignettes and educational whiteboard videos to provide basic oncology instruction to medical students. User satisfaction surveys demonstrated that medical students completing the modules feel more prepared to deal with oncology in clinical scenarios.[189] The online modules are now being examined for impact on knowledge. The online materials are being utilized throughout Canada and in selected universities in the United States and elsewhere. New modules are being added to meet the objectives of the Canadian Oncology Education Goal and Objectives for medical students.[190]

The aforementioned programs represent methods by which a radiation oncology educator can include a radiation oncology educational experience in their school's core curriculum. Other institutions worldwide report strategies to include radiation oncology in the medical school curriculum.[179,181,191] Radiation oncology primers are available to supplement a course or lecture.[3] Oncology curricula for medical schools have also been proposed that include radiotherapy.[177,190] The primary challenge to implementing radiation oncology education within the core curriculum of a medical school is resource scarcity, in particular student time. Thus, it is critical that the radiation oncology educator utilize the methods discussed earlier to ensure successful implementation within a single institution.

The advent of the COVID-19 global pandemic also spurred the creation of various forms of collaborative, multi-institutional virtual radiation oncology curriculum. Radiation Oncology Virtual Education Rotation (ROVER)[192] was developed as a virtual platform to engage medical students in expert lectures presented as case-based teaching sessions with faculty from various institutions across the United States, facilitating interactive discussions of treatment options and latest research, as well as networking opportunities. Student pre- and postsession surveys demonstrated significant improvement in medical students' understanding of the role of radiation oncology in various disease sites after attending each session ($P < .0001$ for all 10 disease sites).[193] ROVER thus demonstrated its ability to virtually fulfill a need for national medical student education in radiation oncology.

Similarly, the Radiation Oncology Intensive Shadowing Experience (RISE) was created in response to the pandemic to expose medical students underrepresented in medicine (UIM) to the field. The 1-week virtual disease-specific curriculum was developed to incorporate four components: (1) foundational exposure to radiation oncology, (2) didactic teaching, (3) mentorship opportunities, and (4) a capstone experience. The program was initiated at two academic medical centers and created a unique virtual radiation oncology shadowing experience for UIM students to address a critical gap in exposure heightened by the pandemic, with the goal of improving diversity, equity, and inclusion (DEI) in the field.[194] Further details regarding DEI and its intersection with radiation oncology education are discussed later in this chapter.

Education for Students Pursuing a Career in Radiation Oncology

Medical students interested in pursuing a career in radiation oncology represent a different group of learners than the general medical student population. Prior to their first formal rotation in a radiation oncology department, the majority of U.S. medical students spend time in a radiation oncology department shadowing physicians (69%), work in a radiation oncology department conducting research (clinical, translational, or basic science) (60%), or had a lecture on radiation oncology during

the first or second year of medical school (30%). Only 26% report no prior radiation oncology clinical or research experience.[51] However, as mentioned prior, 23% of the fourth-year medical students who have not completed a rotation in radiation oncology still believe that radiation oncologists push a button every day to deliver radiation.[105] Thus, the radiation oncology clerkship is a critical educational experience for students considering radiation oncology as a specialty choice to ensure they understand what their clinical activities and professional responsibilities will entail once they complete residency training. In addition, the clerkship likely represents the student's first significant formal radiation oncology educational experience and is thus the beginning of their radiation oncology training.

The traditional radiation oncology clerkship in the United States and Canada employs the apprenticeship model. Students spend time working with attending and resident physicians in the clinic observing daily clinical activities, including consultations, simulations, treatment planning, contouring, plan review and approval, management of on-treatment patients, and follow-up visits to manage acute and late toxicities. Students report opportunities to participate in clinical care including performing an oncologic history and physical independently without resident or faculty supervision (90%), write or dictate a consult (73%), contour at a planning station for a clinical case (78%), participate in a brachytherapy case (60%), participate in a stereotactic radiosurgery case (57%), participate in a stereotactic body radiation therapy (SBRT) case (49%), and review port films (52%).[51] However, merely participating in these clinical experiences does not mean the medical student is learning the basic background knowledge associated with the experience. For example, participating in a plan review of a base of tongue squamous cell carcinoma being treated with IMRT does not mean the student learns the clinical, radiobiologic, and physics aspects of external beam radiation treatment. Students are encouraged to read primary and secondary literature outside of clinic, but as discussed previously, students will have different learning styles,[136] and thus educational strategies other than clinical observation and outside reading should be incorporated into the clerkship experience.

Students may attend resident-level didactics (clinical, physics, radiation biology) and shadow physicians at tumor boards, but the majority of clerkships did not include formal didactics at the medical student training level.[51,106] This apprenticeship model is not unique to radiation oncology and is frequently used in other subspecialty clerkships where there are limited students at any one time.

These clerkships are also sometimes referred to as "audition rotations", or now more widely known as visiting clerkships, where one of the student's goals for the period is to secure a competitive residency position. There are multiple critiques of the practice of audition rotations. First, visiting clerkships potentially waste valuable educational time during the final year of medical school when the student could be broadening their medical education before focusing on radiation oncology. Second, visiting clerkships outside of the geographic location where the medical student resides require the student to have sufficient funds to travel and pay for room and board during the elective rotation. Therefore, wealthier students may be more likely to take visiting clerkships at novel destinations. Because economic status correlates with race in the United States, selecting students for residency positions based on performance during a visiting audition rotation may discriminate against minority groups. Lastly, visiting clerkships may be difficult to arrange for students with significant home and family responsibilities, thus discriminating against married students or students with children. Residency training programs must be cognizant of the pitfalls of using audition rotations to select future residents and, rather, should holistically evaluate each applicant's medical school performance, letters of recommendation, and personal statement for potential fit with the training program.[195] In a national radiation oncology clerkship needs assessment in the United States, students reported giving a departmental talk on a topic of their choice at 87% of clerkship experiences, whereas 72% of clerkships had no medical student lectures, and 52% of clerkships had no formal lecture, case discussion, or hands-on didactic session at the medical student training level.[106] This disparity suggests

that clerkships may place an emphasis on the audition aspect of the experience rather than the educational experience.

The cessation of in-person "audition rotations" during the COVID-19 pandemic temporarily curbed some of their problematic attributes. Virtual clerkships were developed as part of ROVER, where the emphasis of the experiences was on medical student education and networking opportunities[193] as prospective residency applicants courted the various participating institutions, rather than "auditioning" or "performing." In addition, the ease of engaging with multiple programs virtually lessened the financial and time burden on the student, leading to more equitable opportunities across students of various socioeconomic status. However, with easing restrictions for in-person audition rotations 3 years postpandemic, many of the initial critiques listed above will slowly become relevant again.

Based on the aforementioned data demonstrating a lack of structured didactics for the medical student clerkship, the Radiation Oncology Education Collaborative Study Group (ROECSG) developed a structured, didactic curriculum for the radiation oncology medical student clerkship. Using the six-step model for curriculum development,[68] a series of targeted needs assessments were conducted to determine the target learners' (medical students) needs and preferred learning methods (Figure 35.12).[51,106] Based on these data, a structured, didactic curriculum was developed incorporating three lectures (Introduction to Radiation Oncology, Radiation Biology and Physics, and Simulations/Radiation Emergencies) and a hands-on treatment planning workshop.[196] The needs assessment demonstrated that students want the opportunity to give a lecture to the department (perhaps for the purposes of auditioning for residency) and to give formal case presentations. These activities were not removed from the clerkship but rather supplemented by the addition of the formalized lectures and a treatment planning workshop. The curriculum was piloted at two institutions in 2012[197] and subsequently expanded to 11 academic medical centers in 2013.[88,198] In all, 88 students completed the curriculum in 2013, and subjective evaluation of the curriculum was positive. All lectures and the treatment planning workshop were rated as "quite" to "extremely" useful. Students rated the curriculum as helping them to better understand radiation oncology as a specialty, increase their comfort with their specialty decision, and help the transition to radiation oncology residency.[88] The curriculum subsequently expanded to 22 academic medical centers, with 146 students completing it in 2017. Mean objective multiple-choice question test scores pre- and postcurriculum were 63% and 80%, respectively ($P < .01$). Postscores for students rotating de novo at ROECSG institutions ($n = 30$) were higher compared with prescores for students with 1 or more prior rotations at non-ROECSG institutions ($n = 55$) (77% vs 69%, $P = .01$).[199] This exploratory analysis showing students completing a clerkship at ROECSG institutions perform objectively better when compared with students who completed clerkships at non-ROECSG institutions supports a structured didactic curriculum as a standard component of a radiation oncology clerkship.

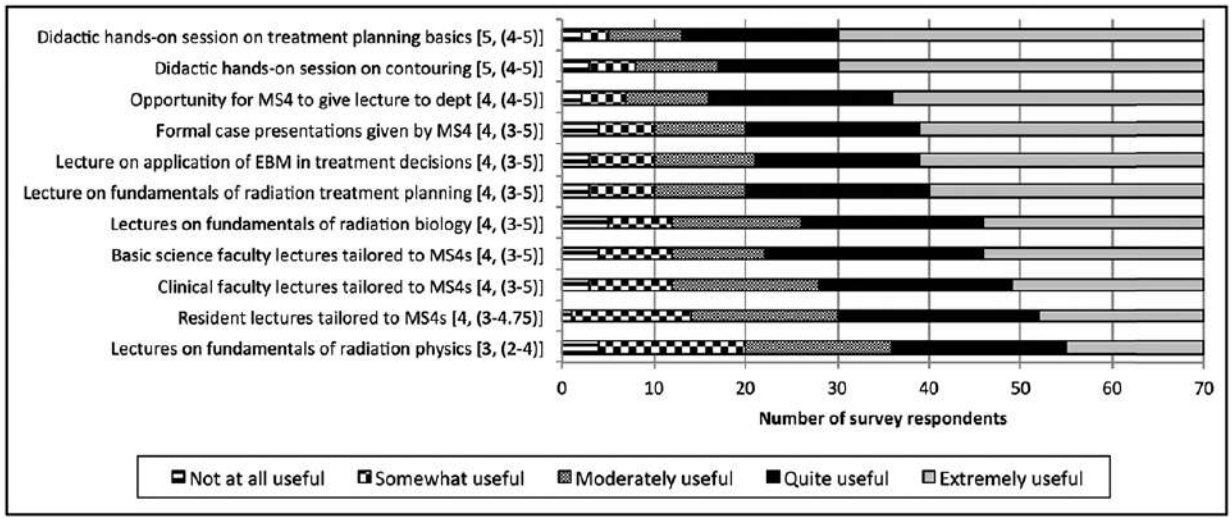

FIGURE 35.12 Survey respondent perspectives on the utility of specific curricular components of an ideal radiation oncology clerkship: median Likert scale (interquartile range). Based on the needs assessment indicating students desired hands-on training for contouring,[51] an additional module was developed that teaches fundamental concepts of atlas-based contouring of the prostate fossa.[200] Using a treatment planning station, students first contoured the prostate fossa on a standardized CT scan with no prior instruction. Utilizing Kolb's experiential learning model[30] (Figure 35.3), this represents the concrete experience. The student then receives a lecture on the CT anatomy of the prostate fossa and how to follow atlas-based instructions for contouring the target volume (reflective observation and abstract conceptualization). The student then repeats the contouring exercise using the atlas and their new knowledge from the lecture (active experimentation and concrete experience). Finally, the student turns on a "gold standard" contour as determined by experts in genitourinary radiation oncology (reflective observation). Students reported subjective improvements in comfort contouring a prostate fossa, ability to find references for contouring, knowledge of CT prostate/pelvis anatomy, and ability to use contouring software tools. In addition, objective analysis of contour accuracy when compared to the gold standard showed significant improvements after the educational intervention.[2]

Formal UGME curriculum development remains nascent in radiation oncology. Implementation of a formal didactic curriculum and hands-on planning and contouring workshops represent methods by which the UGME radiation oncology educator can ensure medical students are making the best career choice while enhancing the students' clinical knowledge to ease the transition to residency training.

Graduate Medical Education in Radiation Oncology

Clinical training in radiation oncology primarily occurs after graduation from medical school. Many countries including the United States,[5] Canada,[132] Australia, New Zealand,[19] and others[18,22-24] train radiation oncologists and medical oncologists as distinct medical specialties. Trainees in these countries complete medical school and a variable amount of non–radiation oncology clinical training followed by 3 to 4 years of full-time radiation oncology clinical training. A small minority of trainees in the United States complete postgraduate fellowships,[201] whereas in Canada, a majority of trainees pursue a postgraduate fellowship.[202] In the United States, these fellowships are not accredited by the ACGME. This discrepancy in fellowship training is likely due to a restricted job market in Canada and

associated difficulty securing employment after residency.[202] In contrast to the radiation oncology–specific training system, clinical oncology trainees in the United Kingdom[203] and other countries train as nonsurgical oncologists and learn to manage both systemic chemotherapy and radiation therapy.

Although certain disease sites, such as pediatric malignancies, and treatment techniques, such as interstitial brachytherapy, have relatively few numbers of cases and are not uniformly geographically distributed, trainees in the United States continue to be certified to treat all disease sites. This raises a dilemma of whether these trainees are adequately prepared to treat rare diseases or use specialized treatment modalities. While, in an ideal training environment, all trainees would see high volumes of rare cases or specialized procedures, analysis of radiation oncology training programs suggests that subspecialty certification in topics such as pediatric radiation oncology, brachytherapy, or particle ion therapy is unlikely in radiation oncology.[204] Despite efforts to find solutions such as modifying accreditation requirements or offering specialized fellowship training, implementing subspecialty training and certification in radiation oncology is currently not feasible. With pediatric radiation, for example, the unequal distribution of cases among residency programs remains a significant hurdle, and attempts to standardize training criteria face practical and regulatory obstacles. Various potential solutions have been proposed, including sending residents to centers with higher pediatric case volumes, restricting pediatric training to specific programs, or assigning specific centers for pediatric training. However, each solution comes with its own set of challenges, such as limited clinical exposure during rotations, scarcity of faculty resources, or resistance from regulatory bodies like the American Board of Medical Specialties. The process of obtaining subspecialty certification entails strict requirements, including the necessity for ACGME-accredited residency programs and a specified duration of training. Despite recognizing the value of subspecialty expertise, the current framework of radiation oncology training and certification is deemed inadequate for accommodating subspecialties such as pediatric radiation oncology in the immediate future. Thus, programs must continue to develop novel training methods including simulation-based education and case-based education to provide sufficient training for rare cases and techniques. U.S. residency program directors also address this problem by allowing residents to train at other centers that see higher volumes of rare cases or use specialized treatment procedures. For example, a residency program housed within a radiation oncology department that does not utilize proton therapy may send their senior residents to a proton center for 2 to 4 weeks of training. By ensuring trainees are competent in the clinical and technical fundamentals of radiation oncology as applied to any disease site or therapeutic technique, training programs will ensure that their graduates are competent to treat rare tumors (eg, pediatric malignancies) or use specialized techniques (eg, interstitial brachytherapy) when required.

CME may also play a pivotal role in the training of radiation oncologists specializing in rare cases. This is discussed in more detail further on in this chapter, in the section on CME.

Regardless of whether trainees focus solely on radiation oncology or learn radiation and medical oncology as in the UK system, during residency, trainees must become competent in all aspects of clinical radiation oncology, including obtaining a focused radiation oncology history and physical, making treatment decisions, simulation, contouring, treatment planning, plan review, and treatment and toxicity management. Residents must learn fundamental scientific knowledge of radiation biology and physics, research methods, and biostatistics. Residents in the United States are assessed semiannually by their department's clinical competency committee using the ACGME Radiation Oncology Milestones,[131] which, as described previously, are divided into the ACGME core competencies, including Patient Care, Medical Knowledge, Systems-Based Practice, Practice-Based Learning and Improvement, Professionalism, and Interpersonal and Communication Skills. In Canada, an almost analogous set of core competencies is represented by the CanMEDS framework and include medical expert, communicator, collaborator, scholar, leader, and health advocate.[6] Finally, residents must be responsible to themselves, their chosen profession, society, and the patient. Based on these

complementary learning goals, a conceptual framework of GME radiation oncology education is presented (Figure 35.13). Educational scholarship related to the clinical care path outlined in this conceptual framework is discussed henceforth.

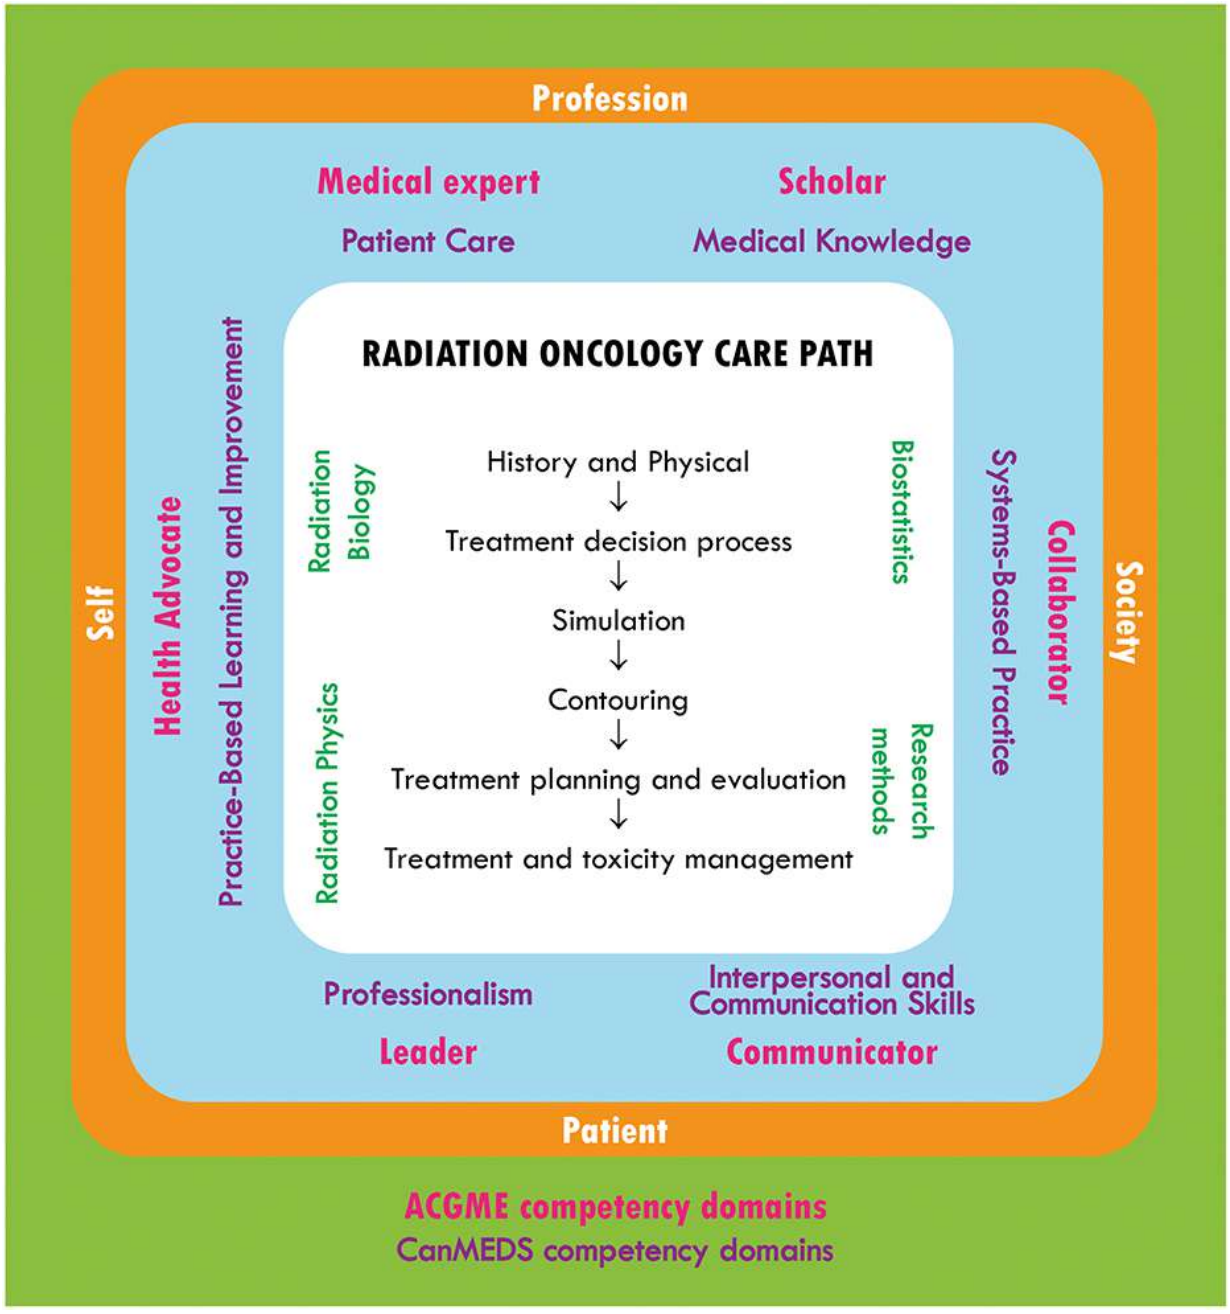

FIGURE 35.13 Conceptual framework for radiation oncology clinical education structured on learner obligations, Accreditation Council for Graduate Medical Education and Canadian Medical Education Directives for Specialists core competencies, fundamental knowledge of physics/radiation biology and research methodology knowledge, and the patient's clinical care path.

Outside accrediting bodies, working groups of stakeholders have also collaborated to develop nationally recognized radiation oncology curriculum. One such group is the ROECSG Core

Curriculum Project Leadership Committee. Competency-based training, as pioneered by CBD[157] as mentioned earlier, aims to direct medical education toward an outcome-based approach as opposed to a chronologic progression through postgraduate years. The cornerstone of competency-based education is the implementation of EPAs, which are "actionable units of work that are completed during clinical care and can be measured and observed" and ensure "meaningful assessment and individualization of education for residents toward ultimate mastery" when compared to more traditional forms of trainee assessment.[205] Given the lack of a current U.S.-specific radiation oncology curricular framework, the ROECSG Core Curriculum Project Leadership Committee recruited appropriate stakeholders in developing and defining content domains, time allocated to each, and radiation oncology EPAs. The resulting framework then underwent rigorous evaluation a Delphi process;[206] the details of the agreed-upon process are beyond the scope of this chapter and can be found in the publication.[205] The final ROECSG consensus curriculum content domains, applied science subdomains, and respective percentage of time allocated, can be found in Table 35.16.

TABLE 35.16 FINAL RADIATION ONCOLOGY EDUCATION COLLABORATIVE STUDY GROUP CONSENSUS CURRICULUM CONTENT DOMAINS, APPLIED SCIENCE SUBDOMAINS, AND PERCENT TIME ALLOCATED

Content Domain/Subdomain	Percentage Time Allocated[a]
Clinical oncology	63
Applied sciences (subdomains below)	16
Professionalism, leadership, and interpersonal communication skills	8
Quality and safety[b]	7
Bioethical and legal issues[b]	2
Diversity, equity, and inclusion[b]	2
Personal wellness	2
Applied Science Subdomains	
Radiotherapy Physics	40
Radiation and Cancer Biology	33
Clinical Research Methods and Biostatistics	27

[a]These content domains should also be integrated within other content domains. This represents additional dedicated curricular hours, independent of other content domains.

Of the 55 initial EPAs, 52 final EPAs met consensus for inclusion, with assigned CBD category; these are listed in Table 35.17. The 52 radiation oncology EPAs are comprehensive in their coverage of all U.S. clinical radiation oncology aspects at present and help to direct training programs on areas of trainee focus for future clinical practice. Trainees can self-assess their progress using an entrustability scale (Table 35.18), a scale that also provides educators and faculty a meaningful framework in which to provide feedback to trainees and to identify opportunities for growth.

TABLE 35.17 FINAL RADIATION ONCOLOGY EDUCATION COLLABORATIVE STUDY GROUP CONSENSUS CURRICULUM UNITED STATES EPAS AND ASSIGNED CBD PHASES

EPA No.	EPA	CBD Category
1	Triaging medically unstable patients	Transition to discipline
2	Establishing a professional relationship with patients, families, and caregivers from diverse backgrounds	Transition to discipline
3	Obtaining a disease site–focused patient history	Transition to discipline
4	Performing basic radiation oncology physical examination techniques (EPA 24)	Transition to discipline
5	Accurately, clearly, and concisely documenting radiation oncology clinical care (EPA 49)	Transition to discipline
6	Assessing patient capacity for medical decision-making	Transition to discipline
7*	Identifying and addressing knowledge deficits during routine patient care (EPA 52)	Transition to discipline
8[a]	Discussing and establishing patients' goals of care to ensure shared decision-making	Foundations of discipline
9	Counseling patients about lifestyle management to reduce long-term cancer risk and improve overall health	Foundations of discipline
10	Recommending and interpreting basic diagnostic studies (EPA 25)	Foundations of discipline
11	Providing evidence-based treatment recommendations for patients with simple radiation oncology clinical presentations (EPA 26)	Foundations of discipline
12	Educating patients, families, and caregivers about the radiation therapy experience and the radiobiologic rationale	Foundations of discipline
13	Presenting an oncologically focused clinical history	Foundations of discipline
14	Determining appropriate simulation techniques and ensuring appropriate execution of simulation for simple cases (EPA 31)	Foundations of discipline
15	Contouring simple target volumes and organs at risk using appropriate imaging modalities (EPA 32)	Foundations of discipline
16	Interpreting a radiation therapy treatment plan (EPA 42, EPA 50)	Foundations of discipline
17	Providing education, counseling, and management for patients regarding common acute and late treatment toxicities (EPA 39)	Foundations of discipline
18	Facilitating communication across professions within a radiation oncology department (EPA 48)	Foundations of discipline
19	Delivering oncologic care with cultural awareness and cultural humility (EPA 46)	Foundations of discipline
20	Delivering bad news and facilitating difficult conversations	Core of discipline
21	Managing appropriate disclosure and care for patients who have experienced a patient safety incident or severe adverse event	Core of discipline
22	Identifying and managing patients who require emergent radiation therapy	Core of discipline
23	Providing appropriate radiation therapy and palliative care for patients at the end of life	Core of discipline
24	Performing advanced radiation oncology examination techniques (EPA 4)	Core of discipline
25	Recommending and interpreting advanced diagnostic studies (EPA 10)	Core of discipline
26	Providing evidence-based treatment recommendations for patients with complex or atypical radiation oncology clinical presentations or complex medical issues (EPA 11)	Core of discipline

EPA No.	EPA	CBD Category
27	Assessing for the use of appropriate local and/or systemic management before, concurrent with, or adjuvant to radiation therapy	Core of discipline
28	Discussing outcomes of different cancers and treatment paradigms with patients, families, and caregivers	Core of discipline
29	Critically appraising evidence including study design, statistical methods, and generalizability as it applies to patient care	Core of discipline
30	Collaborating with other medical disciplines and other health professionals, synthesizing recommendations, and integrating these into the oncology care plan	Core of discipline
31	Determining appropriate simulation techniques and ensuring appropriate execution of simulation for complex or atypical cases (EPA 14)	Core of discipline
32	Contouring complex target volumes and organs at risk using appropriate imaging modalities (EPA 15)	Core of discipline
33	Prescribing target volume doses, selecting dose constraints for organs at risk, and calculating biologic dose conversions	Core of discipline
34	Participating in a radiation therapy quality and safety program (EPA 51)	Core of discipline
35	Reviewing pre-, intra-, and postfraction imaging and recommending appropriate patient shifts	Core of discipline
36	Determining appropriate clinical indications for and treating with unsealed sources	Core of discipline
37	Performing simple brachytherapy procedures	Core of discipline
38	Supervising stereotactic radiation therapy treatments	Core of discipline
39	Providing education, counseling, and management for patients regarding uncommon acute and late treatment toxicities (EPA 17)	Core of discipline
40	Formulating a plan, performing emergency monitor unit calculations, and supervising radiation therapy in an emergency clinical setup	Core of discipline
41	Formulating a long-term oncologic/survivorship care plan for patients	Core of discipline
42	Evaluating a radiation therapy treatment plan (EPA 16, EPA 50)	Core of discipline
46	Advocating for patients to receive appropriate oncologic care, taking into account health disparities and inequities (EPA 19)	Core of discipline
43[a]	Facilitating transfers of care through the health care system	Transition to practice
44	Advocating for appropriate use of radiation therapy as a treatment modality at multidisciplinary tumor board and educating other physicians and allied health professionals about the role of radiation therapy	Transition to practice
45	Performing complex brachytherapy procedures	Transition to practice
47	Identifying bias and harassment in the professional environment and using appropriate mitigation strategies	Transition to practice
48	Managing patient care across professions within a radiation oncology department (EPA 18)	Transition to practice
49	Appropriately documenting to convey management plan to patient and care team and to support billing charges (EPA 5)	Transition to practice
50	Providing feedback on a radiation therapy treatment plan to planning staff or peers (EPA 16, EPA 42)	Transition to practice
51[a]	Identifying and analyzing system-level safety, quality, or resource stewardship concerns in radiation therapy delivery (EPA 34)	Transition to practice
52[a]	Identifying continuing education needs in clinical practice and addressing them with a learning plan (EPA 7)	Transition to practice

EPAs in parentheses are related to the EPA.

This consensus reported the first curricular framework for U.S. clinical radiation oncology training programs and provided a comprehensive set of domains, with appropriate allocation of time, as well as specific EPAs to help guide trainee skill development. Further work is needed to explore its integration into structured radiation oncology residency curricula as well as its implications for assessing the relevance of domains for clinical certification, in addition to its utility as a self-assessment tool.

History and Physical Examination

Trainees entering radiation oncology GME should be competent in obtaining a focused history and physical examination. However, obtaining a history and physical specific for radiation oncology requires further development and refinement of skills developed during medical school and internship. A trainee must learn how to obtain information in the history of the patient that is relevant to radiation oncology, including the complete chronologic oncologic history, family cancer history, past radiation and systemic therapy, history of connective tissue disease or other contraindications for radiation, and other radiation oncology–specific history items. Trainees acquire this skill through clinical observation of attending physicians, feedback on the trainee's case presentations and clinical notes, and lectures on specific disease sites that include a review of relevant history information.

Physical examination is also a skill that is developed during the undergraduate medical training process. Similar to obtaining a history, obtaining a radiation oncology physical examination requires additional skill refinement. For example, trainees must learn to carefully examine the supraclavicular fossa in a patient with cervical cancer and periaortic lymphadenopathy on imaging, whereas patients with anal cancer must be assessed for inguinal lymphadenopathy, and patients with nasopharyngeal squamous cell carcinoma should have a thorough cranial nerve examination. Similar to the patient history, these skills are most commonly taught through faculty clinical observation and lecture format. Endoscopy performed in the clinic is also common; for example, fiberoptic nasolaryngoscopy is typically done on consultation and at follow-up visits for patients with head and neck cancer.[207] These skills can be taught in simulation and honed with practice under supervision during clinical visits.

To perform an appropriate physical examination, anatomic knowledge relevant to oncology is critical.[208] Time spent learning about anatomy is heavily frontloaded in the UGME curriculum with minimal time allotted during residency training, whereas the need for applied anatomy knowledge

increases drastically at the start of residency training (Figure 35.14). To address this need for applied anatomy knowledge, Duke University developed an oncoanatomy course for resident trainees that included a 1-hour didactic session, followed by a 1-hour session in the gross anatomy lab with cadaveric prosections. Implementation of this course demonstrated a significant improvement in objective anatomic knowledge, and residents rated the course as highly effective.[209]

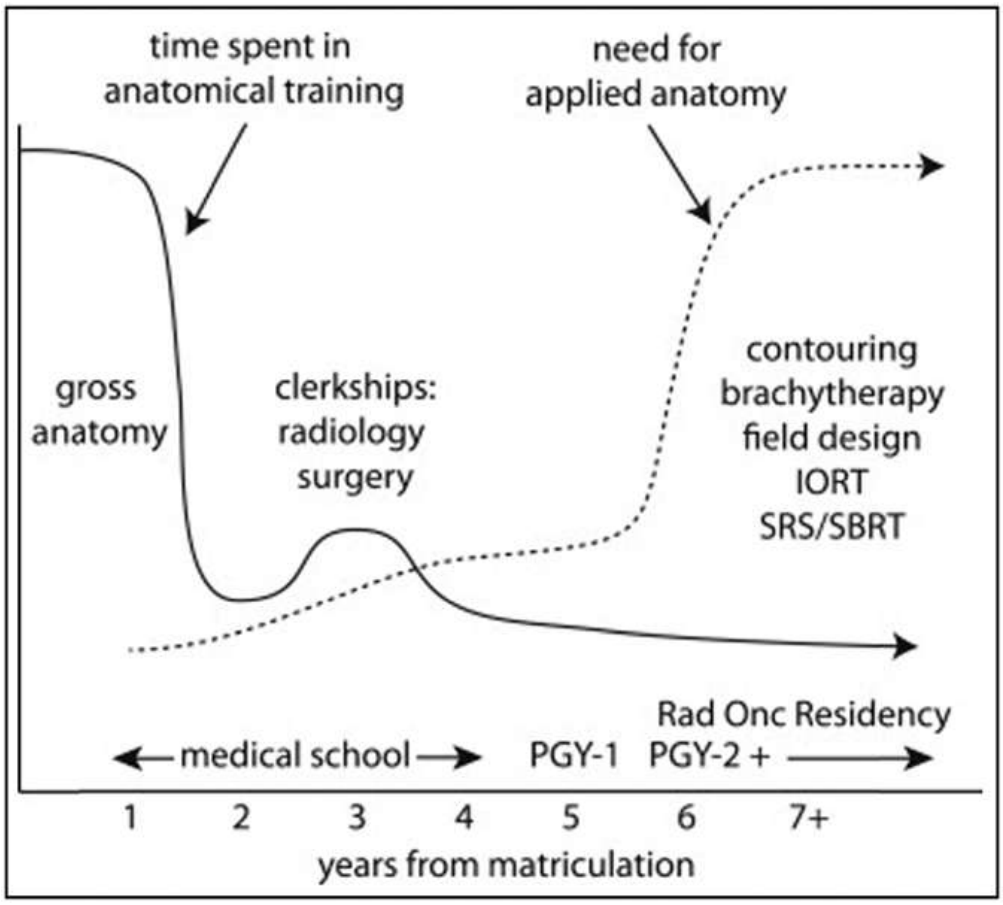

FIGURE 35.14 Schematic of time spent in anatomic instruction and the need to apply knowledge of anatomy for the radiation oncologist in training. There is a large temporal separation between instruction and application. IORT, intraoperative radiation therapy; PGY, postgraduate year; Rad Onc, radiation oncology; SBRT, stereotactic body radiation therapy; SRS, stereotactic radiosurgery. (Reprinted from Chino J, Doyle S, Marks LB. The anatomy of radiation oncology residency training. *Int J Radiat Oncol Biol Phys.* 2014;88[1]:3-4. Copyright © 2014 Elsevier. With permission.)

Communication skills are also necessary during the history and physical process. The University of Pennsylvania developed a novel OSCE with the goal of improving resident skills with regard to breaking bad news.[27] Residents were presented with two case scenarios and given the opportunity to work through the cases with standardized patients. Residents worked through an initial case and then underwent an evaluation by and feedback from the standardized patient, faculty, and residents themselves using the Kalamazoo Essential Elements Communication Checklist – Adapted.[210,211] The residents then completed a second case scenario. Although there was no difference demonstrated in resident performance between scenarios 1 and 2, barriers to developing strong interpersonal relationships were revealed, including perceived lack of empathy, absence of shared decision-making, and use of excessive medical jargon. Resident feedback included the suggestion to allow the resident to review the video recording of the encounter and then repeat the same encounter to try new

wording.[27] An OSCE encounter represents a novel method by which radiation oncology trainees can be taught methods to develop strong interpersonal relationships with their patients at the first clinical encounter.

Clinical Decision-Making

Once the trainee obtains a focused radiation oncology history and physical examination, they must make a treatment decision. Determining a treatment recommendation requires a strong fund of medical knowledge and clinical reasoning skills. Ensuring that graduating trainees obtain the requisite fund of medical knowledge required of a competent radiation oncologist is perhaps the most important role of a residency training program. Without knowledge of treatment guidelines and the primary literature supporting those recommendations, a radiation oncology trainee will have difficulty determining the optimal treatment approach for a specific clinical scenario.

Trainees most commonly learn medical knowledge through a variety of methods, including readings, lectures, online learning resources, peer teaching, and real-life supervised clinical experiences (personal observations of authors). Other teaching methods such as small group discussions and problem-based learning are less commonly employed and represent novel educational methods that may provide trainees with varying learning styles and additional opportunities to assimilate the material. Outside radiation oncology, there is a substantive body of literature on clinical decision-making,[212-215] with recommendations to clearly define critical thinking objectives in a course or curriculum.[216]

Trainee knowledge and clinical decision-making skills for radiation oncology are unique compared to internal medicine, surgery, or other core specialties. However, the same principles for teaching clinical decision-making in these specialties apply to radiation oncology. The most important clinical decision made by the radiation oncologist is whether a patient should receive radiation therapy. The radiation oncologist must evaluate clinical data to determine if radiation therapy is indicated and how best to integrate it with other forms of therapy. However, radiation oncologists also utilize clinical decision-making skills on a daily basis when determining the threshold to order a MRI of the brain in a patient with locally advanced node-positive breast cancer complaining of headaches midway through adjuvant breast radiation, whether a complaint of dysuria during prostate radiation should prompt a urinalysis or if a patient who completed radiation for lung cancer and is complaining of shortness of breath should be started on steroids for possible radiation pneumonitis. Clinical decision-making for radiation oncology trainees is assessed in the United States with formative methods via the American College of Radiology In-Service Exam.[217] Programs in Canada and the United States use internal assessment methods, including case-based skills assessment (colloquially known as “mock oral boards”), case presentations, and faculty feedback. Summative assessment in the United States is through the ABR board exams and through the RCPSC Radiation Oncology Certifying Exams. Studies evaluating methods to teach clinical decision-making specific to radiation oncology, however, are lacking.

Simulation

Subsequent to making a treatment recommendation, the vast majority of radiation oncology patients undergo a radiation therapy simulation scan (eg, CT simulation). Literature regarding formal resident education, specifically regarding the simulation process, is unavailable. Knowledge and skills pertaining to the simulation process are taught via lectures, clinical experience and observation, and informal peer teaching. At the UGME level, a formal lecture regarding the simulation process is included in a structured, didactic curriculum.[88] One study evaluated the efficacy of an educational program for residents on the use of intravenous (IV) contrast media as a component of CT simulation.[218] Resident knowledge regarding the use of IV contrast improved with the intervention,

although this effect was not sustained 1 year afterward. In addition, given the low incidence of IV contrast reactions, the study was unable to demonstrate a clinical effect of the educational intervention. Given the critical nature of the simulation process to the quality of effectiveness of radiation delivery, radiation oncology educators must consider how this is taught and assessed in their local training program.

Contouring

After a patient undergoes simulation, a trainee must be able to accurately and efficiently contour target volumes and adjacent critical structures. "Imaging literacy" for radiation oncologists likely requires collaboration from specialists outside radiation oncology alone.[219] An imaging literacy curriculum was developed using an international two-round Delphi process with four thematic groups of key competencies emerging: imaging fundamentals, clinical application, clinical management, and professional practice.[219] Perhaps the most pertinent competency to the specific technical skill of "contouring" is "delineate on any imaging modality the radiation therapy target and organs at risk in all cancer disease sites and identify targets in 2D, 3D, and 4D image guidance modalities."[219] Radiation oncology educators should review this proposed curriculum to determine where their local program may be deficient.

Multiple educational methods are reported to improve radiologic interpretation skills and contouring skills. Trainee daily clinical activities should include contouring to allow residents to gain a hands-on "concrete" experience per the Kolb experiential learning model.[26] If a program requires trainees to spend significant amounts of time seeing patients in clinic while attending physicians or dosimetrists complete contouring duties, the trainees may graduate deficient in this skill.

To address this curriculum gap, based on a pilot study at a single institution,[220] a two-and-a-half-day National Anatomy and Radiology Contouring Boot Camp was implemented in Canada with significant improvements in knowledge assessment scores and Dice similarity coefficients comparing contour accuracy.[21] In the United States, Memorial Sloan Kettering Cancer Center developed a contouring training module for head and neck cancer, demonstrating improvements in contouring accuracy, although there were still significant deviations in contours indicating a need for repeated exposure and possibly refinement of the curriculum.[221] This is similar to the prostate fossa contouring module developed for medical students.[2] Other contouring educational interventions are also published.[222-225]

Web-based educational methods are also under development. EduCase[226] (access with subscription at EduCase.com) was demonstrated to have a high usability as assessed by resident trainees for head and neck nodal station educational modules.[227] In a randomized study, the use of eContour[228] (access free with registration at eContour.org) compared with any other available contouring materials improved objective assessment of target delineation of the high-risk volume and contralateral parotid gland.[52] Of note, the high-risk volume showed consistently high variability in the Memorial Sloan Kettering study,[221] suggesting that the eContour educational format might further enhance the learning experience. Residents using eContour demonstrated greater knowledge of contour delineation and radiographic anatomy on an objective knowledge assessment, and the mean usability score was high.[52]

Treatment Planning and Treatment Plan Evaluation

Subsequent to accurately delineating contours, a radiation oncology trainee must become proficient in treatment planning and treatment plan evaluation. Working collaboratively with dosimetrists and physicists, the trainee must learn to create a treatment plan, and evaluate treatment plan quality, specifically, to determine when it is not meeting appropriate dosimetric constraints or adequately covering the target volume. Although the treatment plan will nearly always be created by the dosimetrist or physicist in clinical practice, an understanding of how the plan is created, along with the limitations and uncertainties involved, will be exceptionally valuable to the resident when they enter

clinical practice. In the United States, the current ACGME program requirements state that the educational program must include "regularly scheduled didactic sessions" with "instruction in medical physics that includes practical demonstrations of … the use of state-of-the-art treatment planning systems."[5] In the ACGME Radiation Oncology Milestones, each "patient care" milestone includes a competency stating that the resident "critically evaluates treatment plan options."[131] Similarly, the RCR in the United Kingdom calls for "comprehensive teaching of radiotherapy planning … including simulation, virtual simulation, three-dimensional conformal planning, image fusion and IMRT, Volumetric Modulated Arc Therapy (VMAT) and image-guided radiation therapy (IGRT),"[203] and similar content is found in the RCPSC Radiation Oncology Objectives of training documents.[132]

Currently, treatment planning and treatment plan evaluation concepts are taught in the course of regular clinical duties, didactic lectures,[96] and peer-to-peer teaching. The ASTRO physics curriculum developed by the ASTRO Physics Core Curriculum Subcommittee recommends 7 hours dedicated to photon beam characteristics and dosimetry, 2 hours dedicated to electron beam characteristics and dosimetry, 3 hours dedicated to IMRT, and 1 hour dedicated to prescribing, reporting, and evaluating radiation therapy treatment plans.[96] Training programs may include a treatment planning rotation for their residents, but given the competing demands for resident time, most programs do not offer a formal dosimetry rotation.[113] In the recent ARRO chief resident survey, only two-thirds of graduating residents reported receiving adequate experience in treatment planning.[25]

For plan evaluation, the employment of a simple acronym— CB-CHOP—provides a systematic, stepwise approach to analyzing multiple components of treatment plan quality.[229] CB-CHOP stands for *c*ontours, *b*eam arrangements/fields, *c*overage, *h*eterogeneity/*h*ot spots, *o*rgans at risk, and *p*rescription. Given the critical nature of radiation treatment plan evaluation for all modalities (three-dimensional conformal radiation, IMRT, SBRT, radiosurgery, etc), formal educational methods to teach treatment plan evaluation are also necessary. A series of self-directed modules teaching fundamentals of dosimetry and plan evaluation including anteroposterior/posteroanterior (AP/PA) spine, three-field breast, and intensity-modulated radiation was developed at the University of Chicago.[197] These modules provide an opportunity for "active experimentation" within Kolb's experiential learning model.[30] Completion of the modules by the resident physicians was associated with improved resident comfort with AP/PA treatment planning, three-field breast treatment planning, and IMRT planning. Resident understanding of dosimetry concepts including dose grid, beam energy selection, calculation point, iterations, segments, optimization, and ring structure was also significantly improved.[230] Additional structured educational methods to teach and assess competence with treatment planning and dosimetry are needed to ensure that trainees are graduating with the skills necessary to adequately evaluate and constructively critique treatment plans in independent practice. The ASTRO physics curriculum provides an outline for additional dosimetry module development.[96]

Treatment and Toxicity Management

Once a patient begins radiation treatment, the trainee must be proficient in evaluating portal images, volumetric image data and images from other modalities for image-guided radiation, adjusting treatment plans as needed, managing acute toxicity of treatment, and coordinating care with other specialties, including medical oncology and surgical specialties. Similar to other steps in the clinical care path, treatment and toxicity management is primarily taught through a combination of clinical experience, lectures, and reading. Investigations of novel educational methods to teach skills necessary for treatment and toxicity management are limited. A review of methods by which to assess residents' clinical skills proposes the use of OSCEs, standardized patients, and patient management problems in addition to the standard assessment methods of "ward" evaluation, multiple-choice question tests, and oral examinations.[231] An OSCE to teach residents communication skills was developed at the University of Pennsylvania.[27] Two cases representing treatment or toxicity management were

developed, including telling a patient 2 months out from radiation treatment that there is a tumor recurrence and telling the family of an 8-year-old patient that the proton machine is out of commission and the remainder of treatment will be IMRT. Residents received formative feedback from standardized patients and faculty observers. These educational strategies represent novel and effective methods by which to teach radiation oncology trainees about the management of patients receiving radiation and the management of acute and late toxicity, which is essential as toxicities from modern treatments become less common. Further development of teaching material for this component of the care path is needed.

Medical Physics

Medical physics is a key component of training in radiation oncology. The ACGME,[5] RCPSC,[132] and RCR[203] deem medical physics as a required training. According to a recent survey of residency program directors in the United States, 100% of residency programs provide a didactic course in radiation physics,[232] and more than 85% of U.S. residents report adequate formal courses in radiation biology and physics.[25] Didactic lectures represent one of many educational strategies to teach the concepts and knowledge required of a practicing radiation oncologist. Medical physics training for radiation oncology residents in the United States is heterogeneous, with a median of 42 lectures but a range from 10 to 90 per year and only approximately one-third of programs reporting physics rotations.[113] Additional educational strategies should be considered to allow optimal adult learning to occur. Providing an opportunity for hands-on experiences allows for learning in the context of Kolb's experiential learning cycle.[30] Didactic lectures alone cannot accomplish this.

The ASTRO Physics Core Curriculum Subcommittee developed a comprehensive recommended curriculum for medical physics education consisting of 56 hours of didactic sessions.[96] The curriculum also provides recommended references, a set of suggested practical clinical radiation oncology physics modules, and a set of suggested practical modules for radiation therapy treatment planning. The group recommends that training programs ensure residents complete the course at least twice during their training. A detailed physics curriculum for proton therapy is also proposed.[233]

A novel medical physics educational strategy is used at one training program in the United Kingdom where radiation oncology registrars (the equivalent of residents in the United States) spend 6 months completing a medical physics rotation.[234] These trainees continue to spend 1 day per week in clinic to maintain their clinical skills. The goal of the program is that by the end of the 6-month block, the trainee is competent in planning any case with the exception of total-body irradiation. This novel educational strategy utilizing a combination of continued clinical training and hands-on medical physics training could be adapted at other training programs. Importantly, the emphasis on advanced dosimetry over basic physical interactions has become more relevant to clinical practice in the setting of robust modern treatment planning systems.

In the advent of distance learning with the COVID-19 pandemic, trainees have also supplemented their didactic learning with asynchronous virtual tools. These tools, often in the form of free videos, were developed to meet the need for more homogeneous medical physics education across training programs. One such tool, High-Yield Physics (HiPhy),[235] was developed through a multidisciplinary, multi-institutional collaboration and comprises a set of high-yield physics concept videos. Its pilot series reached 154 eligible enrollees across the world. Participants reported improved understanding and confidence applying the knowledge acquired through the videos and improved comprehension of concepts with the use of graphic animation.[236] Similar endeavors include Eric Ford's interactive video series, produced with a textbook supplement "Primer on Radiation Oncology Physics,"[237] which seek to provide radiation oncology and medical physics trainees with a complete and effective introduction to radiation oncology physics. The rapid development of these free and accessible virtual resources

pave the way for incorporation of similar digital tools into the radiation oncology resident's toolbox; this is addressed later in this chapter.

Radiation Biology

Similar to radiation physics, radiation biology is a key component of training in radiation oncology, with the ACGME,[5] RCPSC,[132] and RCR[203] requiring a fundamental understanding of radiobiologic concepts. All U.S. radiation oncology training programs present formal radiation biology courses,[232] with residents reporting sufficient training in radiation biology.[25] A survey of U.S. and Canadian radiation biology educators indicates that many are not completely familiar with relevant radiation biology materials, some do not receive adequate departmental support, and more than 50% are not routinely provided with resident radiation biology performance on the in-training exam.[115] Many residents use the ASTRO radiation biology study guide as a learning resource.[238] In addition, the American College of Radiology in-training exam can be used as a teaching and assessment tool.[239] In recent years, incorporation of mechanisms of systemic therapies, some of which are delivered concurrent with radiation therapy, represents information that is more applicable to daily practice.

Scholarship

Scholarship is a core component of the trainee's educational experience. As noted by the ACGME, "medicine is an art and a science." To train residents to think critically, evaluate literature, incorporate new knowledge, and promote lifelong learning, the program and faculty must foster an environment in which trainees can acquire such skills through active participation in scholarly activities. Prior to completion of the program, residents must complete an investigative project under faculty member supervision. The projects can take a variety of forms, such as biologic laboratory investigation, clinical or translational research, medical physics research, or other research approved by the program director. Investigation into radiation oncology research productivity demonstrated that the amount of designated research time during residency training is the sole independent predictor of productivity as measured through publications.[240] Many U.S. residency programs now offer nonclinical time, which can be used for dedicated research, as part of the program timeline. The amount of nonclinical time varies, but the median nonclinical time across 82 U.S. radiation oncology programs is 10 months, with most programs ranging from 6 to 12 months.[241]

In addition, one unique training pathway available to U.S. radiation oncology residents through the ABR is the Holman Research Pathway (HRP),[242] designed for the trainee who has strong interest and commitment to basic science or clinical research and allows for simultaneous training in both clinical radiation oncology and vigorous research investigation. The goal of the HRP is to thus address the shortage of physician scientist investigators in the field. The trainees who leave this program still complete the 5 standard years of training but have housed within it 18 to 21 months of dedicated research time (21 months with 20% of this time devoted to clinical training; 18 months minimum is required to successfully complete the Pathway).[242] Evaluation of demographic characteristics and research productivity from 2010 to 2019 of HRP graduates has demonstrated its success in training a new cohort of physician investigators through first- or last-author publications, full-time clinical employment after completing residency, grant funding, and lab startup.[243]

Case Logs

One key component of tracking trainees' clinical development and the breadth of their exposure to various clinical case types is through the use of case logs. For example, the ACGME Case Log System is an online database that allows residents to document their clinical experiences while also allowing for the Review Committee for Radiation Oncology a uniform method for verifying clinical

experiences of residents in ACGME-accredited radiation oncology programs.[244] The Review Committee requires residents to log a minimum number of particular case types and procedures; these minimums are not the final target, and residents continue to log cases even after they are met. Meeting the procedural targets is also not the only means by which to evaluate resident competence; rather, they are taken into account with the summative evaluation of residents as detailed earlier.[244]

The minimum case requirements are constantly reevaluated by the ACGME, and new guidelines are published to reflect the changing landscape of disease incidence and use of novel treatment modalities. The most recent case minimums released on July 2023 are listed in Table 35.19. A separate set of case minimums apply for residents who pursue the HRP (Table 35.20).

TABLE 35.19 CASE MINIMUMS FOR NON-HOLMAN PATHWAY RESIDENTS (UPDATED JULY 2023)[5]

Procedural Category	Minimum Number Required	Number of Allowed Observed Cases	Additional Guidance Outlined in the Program Requirements
External beam radiation therapy	450 simulations	NA	No >350 performed in 1 y (detail program requirement).
Bone sarcoma/soft tissue sarcoma	5 simulations	2 simulations	
Breast: postmastectomy	11 simulations	3 simulations	
Central nervous system	19 simulations	5 simulations	
Head and neck subtotal (intact, postoperative, skin)	41 simulations	10 simulations	
Esophagus	5 simulations	2 simulations	
Anorectal (anus, rectum)	10 simulations	3 simulations	
Nonprostate genitourinary (bladder, testes, other)	3 simulations	2 simulations	
Gynecologic subtotal (cervix intact, cervix posthysterectomy, uterus, other)	10 simulations	3 simulations	
Lymphoma (Hodgkin lymphoma and non-Hodgkin lymphoma)	8 simulations	2 simulations	
Non–small cell lung cancer	16 simulations	4 simulations	
Brachytherapy interstitial	7 procedures	NA	
Brachytherapy intracavitary	15 procedures	NA	• 5 must be tandem-based insertions for at least 2 patients. • No >5 should be cylinder insertions.
Pediatric patients	12 patients	NA	Including at least 9 patients with solid tumors
Intracranial stereotactic radiosurgery (SRS-brain)	20 patients	NA	
Stereotactic body radiation therapy (SBRT)	20 patients	NA	To the liver, lung, spine, or other extracranial sites
Radioimmunotherapy, other targeted therapeutic radiopharmaceuticals, or unsealed sources	8 procedures	NA	
I-131	3 procedures	NA	Oral administration of I-131 with administered activity equal to or in excess of 1.22

Procedural Category	Minimum Number Required	Number of Allowed Observed Cases	Additional Guidance Outlined in the Program Requirements
			gigabecquerels (33 mCi)
Parenteral administration	5 cases	NA	Parenteral administration of any alpha emitter, beta emitter, mixed emission, or a photon-emitting radionuclide with a photon energy <150 keV, for which a written directive is required, and/or parenteral administration of any other radionuclide, for which a written directive is required

TABLE 35.20 CASE MINIMUMS FOR HOLMAN PATHWAY RESIDENTS (UPDATED JULY 2023)[5]

Procedural Category	Minimum Number Required	Number of Allowed Observed Cases	Additional Guidance Outlined in the Program Requirements

One point to consider is the significance behind the case logs in a resident's readiness for independent practice, especially in the context of programs that may have difficulty fulfilling the required minimums due to low case volume. As mentioned previously, there is ongoing debate regarding the need for subspecialization to ensure residents are able to practice in fields such as pediatric radiation, brachytherapy, or particle ion therapy.[204] For brachytherapy, there is a concerning decline in the number of interstitial cases performed by radiation oncology residents,[245] raising questions about training adequacy. Despite a requirement for minimum case numbers, residents often feel unprepared and advocate for more practical training. Brachytherapy fellowships offer additional training but face challenges, such as a lack of accreditation and program standardization. Workshops and simulation-based residency curricula aim to address training gaps, yet they too have limitations, including time constraints and variability in techniques across institutions.[246,247] Externships at high-volume brachytherapy centers present a promising alternative for senior residents seeking hands-on experience without prolonging their training. Such initiatives hold potential to enhance interest and competency in brachytherapy among residents, ultimately benefiting patient care.[248] In this way, case logs to document completion of hands-on cases performed during externships would allow residents to chronicle their training. However, this will ultimately place a large educational burden on high-volume centers; further efforts will be needed to ensure these designated centers are able to balance training of visiting residents with opportunities for their own native residents and to ensure the administrative aspect of coordinating experiences for a rapid throughput of visitors does not negatively impact the innate function of the program.

Virtual Education and Resources

Although digital resources had existed prior, the COVID-19 pandemic sparked the need for a paradigm shift in radiation oncology education and ushered in rapid integration of virtual education curriculum to support radiation oncologists in training, in addition to aspiring medical students as detailed earlier. Recent review of the landscape of digital resources in radiation oncology has demonstrated the multitude and variety of educational material available.[249] This detailed search, taking into account the credibility of these products, identified 47 free digital education resources, which included online radiation oncology tutorials, podcasts, videos, and slide sets (Table 35.21).

Adapted from Culbert MM, Brisson RJ, Oladeru OT. The landscape of digital resources in radiation oncology. *Tech Innov Patient Support Radiat Oncol*. 2022;24:19-24. With permission.

As demonstrated, the educators and creators of this content have delved into widely variable vehicles with which to convey information to their audiences. Live webinar sessions were one of the first collaborative efforts early in the pandemic, organized through Radiation Oncology Virtual Education Rotation (ROVER) 2.0, the subsequent iteration of ROVER 1.0. This was designed as a supplementary virtual education curriculum for radiation oncology residents worldwide.[250] The course was conducted through live virtual webinar sessions, structure as complex, ambiguous cases across multiple disease sites. Between October 2020 and June 2021, nine ROVER sessions were held, with 1,487 registered residents completing a presurvey, 786 attending the live case discussion, and 223 completing postsurveys. Those surveyed found learning accessibility to be "very easy" or "easy" (97.5%, n = 119), and a majority rated the ROVER 2.0 virtual sessions to be "valuable" or "very valuable" (99.2%, n = 121).[250] These results demonstrate the feasibility and value in virtual radiation oncology education as a supplement to core residency curricula.

Podcasts have also become a pervasive supplement to core education, with their utility as independent, asynchronous learning tools demonstrated by their popularity—more than 88% of polled U.S. medical residents, parsed by specialty, report listening to medically relevant podcasts.[251] Radiation oncology podcasts have risen in number (Table 35.21), as many pioneering creators stem from professional societies (American College of Radiation Oncology [ACRO],[252] ASTRO,[253] Radiation Research Society[254]) and medical journals (*Advances in Radiation Oncology*,[255] *Red Journal*,[256] *Practical Radiation Oncology*[257]). The scope of these podcasts, however, is broad, ranging from highlights of recent primary research results, to discussion of radiation oncology policy implementation, to advice for early career physicians and personal finance. Other podcasts are focused on medical physics specifically,[258,259] or radiology broadly.[260] Still others involve interviews of leading physicians, scientists, or other radiation oncology personnel, while many highlight recent news and current events within the field.[261] A survey of the range of available series illuminated the need for a podcast specifically targeting radiation oncology education, and thus At the Beam[262] was produced in July 2022, providing case-based workup and management pearls for a broad range of disease sites and pathologies, accompanied by high-yield notes. Of note, the unique perspective of At the Beam stems from its creators' roles as residents themselves; each episode's content is also carefully vetted by field experts. The podcast is open access, free, and catered toward radiation oncology trainees; subsequent analysis of the podcast's performance demonstrated accessibility and portability as its main benefits and found that high engagement for episodes up to 16.4 minutes supports existing data of declining attention spans after 15 to 20 minutes.[263] The podcast was also found to have a broad international reach, with audience members spanning across 53 different countries in 6 different continents. This radiation oncology education–focused podcast thus demonstrates the significance of such modern tools in wide and accessible dissemination of knowledge, and subsequent work will delve into their utility in knowledge retention and efficacy.

More traditional formats for digital education have continued to thrive. Slide decks with case-based learning have been a cornerstone of radiation oncology digital learning. ARROCase,[264] created by the ARRO, is a peer-reviewed, publically accessible educational database with slide decks containing case vignettes and contouring examples, spanning a wide variety of disease sites, for radiation oncology residents. Each case highlights key aspects of case presentation, workup, imaging and laboratory evaluation, treatment option and approaches, contouring guidelines, and follow-up. Similar work has been initiated by resident committee members of the ACRO. The ACRODecks[265] are introductory resources for radiation oncology residents to understand basic principles of oncologic malignancies and to introduce standard treatments to early residents.

Specific materials focusing on contouring, medical physics, and radiobiology have also been developed, as described previously. As vast as the current list of available digital and virtual resources stands, this repertoire of online education will only continue to grow. Further detailed, prospective

investigations into the efficacy, accessibility, sustainability, and durability of each resource will help to inform and guide the continued efforts of educators and content creators.

Continuing Medical Education in Radiation Oncology

For the practicing radiation oncologist, lifelong learning to ensure clinical knowledge and skills are up to date is critical. Perhaps even more so than other areas of medicine, radiation oncology is constantly evolving due to the development of new technologies and treatment techniques, and new treatment paradigms for cancer. The continued maintenance and acquisition of skills in radiation oncology is a complex process, and the implementation of new techniques and maintenance of competency can be challenging.[63] Evidence supporting the efficacy of CME for the maintenance of competency is mixed. Early studies suggested CME has a positive impact on physician performance and patient outcomes.[266] More recent studies failed to demonstrate a significant improvement in patient outcomes for physicians engaging in ongoing maintenance of competency activities.[267,268] A series of Cochrane literature reviews suggest that the impacts of CME may be linked with the type of CME activity, with isolated didactic lectures less effective as compared to interactive sessions, well-planned educational meetings, and quality improvement activities.[269-271] Within radiation oncology, the role for MOC programs administered by certification organizations remains controversial.[272] However, maintaining an up-to-date fund of clinical knowledge and ensuring clinical skills remain current are characteristics of any good physician. In addition, effective education of practicing physicians to drive a change in practice patterns to high-quality and high-value care is needed.[93,94] Thus, programs that educate practicing radiation oncologists are valuable, regardless of whether they are mandated by certifying organizations.

To encourage practicing radiation oncologists to engage in lifelong learning, certifying organizations such as the ABR and RCPSC have established MOC standards. In the United States, the ABR MOC process includes four parts: (1) Professionalism and Professional Standing; (2) Lifelong Learning and Self-Assessment; (3) Assessment of Knowledge, Judgment, and Skills; and (4) Improvement in Medical Practice.[273] Professionalism and Professional Standing requires a license to practice medicine in a jurisdiction in the United States, its territories, or Canada.[274] CME applies most directly to the Lifelong Learning and Self-Assessment and Assessment of Knowledge, Judgment, and Skills components of the ABR's MOC process. Lifelong Learning and Self-Assessment requirements include completing 75 American Medical Association (AMA) Category 1 CME credits every 3 years. Twenty-five of these credits must be SA-CME credits. The general CME credits can be obtained by attending local tumor boards, CME-accredited resident lectures, or any other AMA Category 1 accredited activity. The SA-CME credits can be completed at approved lectures or through journal CME offerings. A by-product of the SA-CME requirement is that residency training programs are now certifying resident didactics for SA-CME to encourage faculty to attend the resident lectures.[275] Assessment of Knowledge, Judgment and Skills requires passing the most recent Online Longitudinal Assessment (OLA) performance evaluation or having passed a Continuing Certification Exam in the previous 5 years. OLA became available to all radiation oncology diplomates in early 2020.[276] It consists of two question opportunities each week, available for 4 weeks to allow flexibility in completion. Once a question is opened, the diplomate is allowed a limited amount of time to answer the question, and they are provided immediate feedback on whether it was answered correctly, with a brief rationale and reference. A passing threshold for OLA is applied when the minimum number of questions, around 200, have been answered. Given only two questions are available a week, and only 52 questions are required a year, it can take a few years to reach the target.[277] Alternatively, the diplomate can opt to take the Continuing Certification Exam, which is a 200-question computer-based exam focusing on clinically relevant applications on all aspects of radiation oncology. However, the

exam is only needed in limited situations and only offered twice a year.[278] Finally, to satisfy the requirement for Improvement in Medical Practice,[279] a practice quality improvement project or other participatory quality improvement activity must be completed every 3 years.

CME requirements in the RCPSC construct are similar to the ABR lifelong learning and self-assessment. CME in Canada represents the culmination of the CBD competence continuum.[133] In contrast to the United States (until recently), in Canada, there is no recertification exam. The RCPSC MOC Program requires radiation oncologists to obtain at least 40 credits per year, at least 400 credits per cycle, with a minimum of 25 credits in each maintenance of competency program section per 5-year cycle. RCPSC maintenance of competency credits fall into one of three program sections: group learning, self-learning, and assessment.[280] More recently, the RCPSC has announced a new phase of high-quality simulation opportunities, and soon simulation education will be embedded into the Continuing Professional Development accreditation process for activities that will satisfy Section 1 and Section 3.[281] The MOC Program thus continues to grow and evolve in supporting the lifelong learning needs of radiation oncology practitioners.

CME activities cover a broad range of educational strategies, including didactic learning, interactive sessions, and practice audit and feedback. These activities often mirror those discussed previously for UGME and GME education. Some of the most commonly recognized CME activities include didactic learning activities at educational meetings (eg, ASTRO, European Society for Radiotherapy and Oncology [ESTRO], and Canadian Association of Radiation Oncology annual society meetings). A variety of interactive activities, including large contouring workshops,[282] provided through national societies, are also used in CME. Many national society meetings include seminars and workshops and allow for the discussion of or dissemination of new techniques. In Europe, the ESTRO School has developed the Fellowship in Anatomic Delineation and Contouring, which incorporates web-based contouring into their educational programs.[282] CME can also be delivered in a small group learning environment, such as weekly tumor boards, simulation-based education, or local grand rounds and lectures.[283,284] Despite the frequency with which such activities are offered, there is a relative paucity of scholarship. Very few publications have robust program evaluation from these CME activities, and the majority evaluate user satisfaction[284] as opposed to change in knowledge or behavior.

Although historically CME was designed to deliver educational content to individual physicians, a primary goal of CME is now systems based or quality improvement.[285] Quality improvement and "audit with feedback" CME programs are becoming more common.[270] Shakespeare et al[286] examined the effects of audit with feedback for practicing radiation oncologist's changes in behavior. Their audit included an assessment of patient charting and radiation plans. Radiation oncologists were provided individualized feedback. The audit with feedback resulted in improvements in some aspects of patient charting and documentation and radiation planning. These effects were retained through time and demonstrated that audit with feedback may be a useful CME exercise. As peer-review and quality assurance programs are developed at radiation oncology centers,[287,288] careful attention should be paid to not only improve consistency and quality in radiation plans[289] but also design programs that allow for continuous practice improvement. By educating individual physicians, CME can drive organizational change and overall improvements in health care delivery. In addition, when deficiencies are noted through the process of peer review, individual or group educational programs may be required, and review of medical education principles previously discussed may be helpful.

CME also plays a pivotal role in the training of radiation oncologists specializing in rare cases, such as pediatric radiation oncology, brachytherapy, and particle ion therapy, even in the absence of a formal fellowship program, as highlighted prior in the section on "Graduate Medical Education". A survey conducted at the 2019 Pediatric Radiation Oncology Society (PROS) Congress shed light on the educational preferences and practices of pediatric radiation oncologists worldwide.[290] The majority of respondents emphasized the importance of postresidency training programs, and while they

advocated for board certification in pediatric radiation oncology, more than 85% of practicing pediatric radiation oncologists did not complete a fellowship. Given these circumstances, pediatric radiation oncologists clearly rely heavily on various educational resources to enhance their knowledge and skills. A significant proportion of respondents reported acquiring knowledge through journals, books, live meetings, and tumor boards, underscoring the importance of continuous learning and collaboration within the professional community. The PROS, serving as a global platform for pediatric radiation oncologists, offers valuable CME opportunities through annual meetings, educational resources on its website, publications, and collaborative efforts aimed at improving pediatric radiation oncology practice worldwide. Despite the challenges and limitations outlined in the survey, the findings provide valuable insights that can inform the development of future educational initiatives and support the ongoing professional development of pediatric radiation oncologists, and similar such practitioners who specialize in rare cases.

In order to develop CME activities, similar to other areas of radiation oncology education, guiding principles and frameworks can help provide valuable perspective. CME activities include a broad range of educational interventions. These can include, among others, didactic programs (eg, lectures and journal clubs with question and answer session), interactive instruction (eg, interactive case discussion, group role-play), audit and feedback, and academic detailing (ie, individual education delivered by a trained professional to education on evidence-based techniques). Harden describes six criteria for effective CME: convenience, relevance, individualization, self-assessment, independent learning, and systematic.[291] The development of effective curriculum for CME programs can be based on the six-step model[68] and enhanced by Davis et al's[292] description of the seven characteristics of effective CME programs: needs assessment, focused initiative, interactive educational programs, multiple educational strategies, multiple sessions, time for feedback and practice, and outcome evaluation. The application of established frameworks to any CME activity or program should allow for robust development, implementation, and evaluation.

Although there is a significant body of literature examining the best practices in development, implementation, and outcomes of CME activities in a variety of other areas in medicine, radiation oncology remains ripe for educational scholarship. Work can be done to improve existing CME curricula and to develop novel CME educational strategies. Potential areas for scholarship include the application of established educational frameworks to CME development and evaluation outcomes linked to changes in knowledge, behavior, and clinical outcomes.

Areas for Further Scholarship in Radiation Oncology Education

Radiation oncology education at the UGME, GME, and CME levels continues to evolve. There remain a myriad of scholarship opportunities to rationally and methodically improve radiation oncology education. Examples include further developing and validating competency frameworks, such as the ACGME Milestones[131] and CanMEDS CBD.[6,160] Development of EPAs also represents an opportunity to move radiation oncology forward, as demonstrated through ROECSG Core Curriculum Project Leadership Committee's proposed curriculum content domains and EPAs.[205,293] Looking beyond the medical profession, there is ample opportunity to develop interprofessional educational activities at all training levels.[294,295]

Simulation-based medical education is being adopted into radiation oncology medical education.[296] There is ample evidence that increasing experience can improve outcomes for brachytherapy[297] and head and neck treatment, particularly in the IMRT era.[86] Reports of decreasing case volume for brachytherapy,[92] reports of limited pediatric cases,[204] and reports from graduating residents of inadequate training in intraoperative radiation, brachytherapy, and proton therapy[25] suggest that development of simulation-based education specific to radiation oncology may provide a solution to

the dilemma of how to safely train residents and assess competency for case scenarios or procedures that are less common or require high technical skill. Many educational reports within radiation oncology represent simulation-based medical education, although they are not identified as such. For example, there are multiple reports of contouring training on a standardized case.[2,52,221,222,227,282] This represents simulation-based education since the trainee is working in a simulated environment with no real-world consequences when making an error, though reports in radiation oncology less often self-identify as simulation-based medical education, with the few examples including brachytherapy training,[28] interprofessional team simulation,[298] and preparation for on-call emergencies.[299] Furthermore, incorporation of virtual and augmented reality in simulated-based education,[300] as well as integration and harnessing of artificial intelligence, are inevitable.[301] Continued work pushing the evolving frontier of clinical radiation oncology will assuredly involve leveraging these tools to enhance trainee education and knowledge.

Equity, Diversity, and Inclusion in Radiation Oncology Education

One area of growing attention but paramount importance is the promotion of equity, diversity, and inclusion (EDI) in health care, and it is critical to integrate these efforts into medical education. Diverse medical teams have been shown to improve patient-physician communication and trust, leading to more equitable patient care;[302,303] buttress innovation and research productivity;[304,305] and reducing physician burnout.[306] Representation impacts the clinical learning environment. In a cohort of 20,000 graduating medical students, White students attending racially diverse medical schools reported being better prepared to care for racial and ethnic minority patients compared to their counterparts at less diverse schools and had stronger attitudes about improving inadequate access to health care.[307] Health systems and medical schools across the United States are increasingly organizing department or institution-level EDI committees and leaders to evaluate their own commitment to equitable medical education, patient care, employment, promotion, and leadership and to develop strategies and initiatives to match the organization's unique needs. While a more detailed and nuanced discussion of EDI in radiation oncology extends beyond the scope of this chapter, highlighted here are ongoing initiatives to promote EDI in radiation oncology education, particularly in the recruitment of medical students into residency programs. Historically, groups underrepresented in the field of radiation oncology include African American, American Indian, Alaska Native, Hispanic American, Native Hawaiian, and Pacific Islander,[308] as well as sexual and gender minorities, such as those identifying as lesbian, gay, bisexual, transgender, queer, intersex, or other.

As discussed previously, the RISE exposes medical students UIM to the field.[194] The program, initiated at two academic medical centers, created a unique virtual radiation oncology shadowing experience for UIM students to address a critical gap in exposure heightened by the COVID-19 pandemic, with the goal of improving DEI in radiation oncology.[194] This 1-week intensive experience was limited to senior UIM medical students. Participants were very satisfied with patient interactions (71%), panel of minority residents/attendings (71%), morning didactics (86%), capstone presentation (86%), and assigned mentors (86%). All students agreed the course was helpful in decision-making regarding what specialty to pursue.[309] Virtual programs like RISE can provide a broad overview of radiation oncology training to a larger cohort of medical students. Conversely, in-person programs targeting a smaller number of participants can provide the depth needed for full immersion in the field's training. One example of this is the UCLA Department of Radiation Oncology's Medical Student Preceptorship Program, which commenced in 2020 with the intended goal of addressing persistent underrepresentation of racial and ethnic minorities in radiation oncology. The program, which supports the accepted students with a stipend, provides a mentored clinical and translational research experience, exposure to clinical radiation oncology practiced at a tertiary academic center,

and career development advice and guidance.[310] Participants in the program have reported firsthand experience as part of a multidisciplinary team, participating in evidence-based decisions in the clinic, and observing firsthand the various stages of workflow, including consultation, simulation, contouring, and review of treatment plans.[311] One such participant was motivated to apply to radiation oncology residency through this program.

Many institutions across the country also seek to offset the financial burden of "audition rotations" or visiting clerkships that may otherwise be inaccessible UCLA offers an Excellence in Medicine Visiting Student Scholarship[312] that provides a stipend to support travel and lodging expenses. Residency programs that offer such financial support for "audition rotations" can begin to offset some of the critiques of these clerkships as detailed earlier in this chapter.

Gender equity in radiation oncology also continues to lag behind other medical specialties.[313] This lack of diversity has been demonstrated at all levels of career, from medical school to department leadership,[314] and manifests as inequity in salary or industry payments,[315] underrepresentation in leadership,[316] and more time and effort invested into career activities by female physicians to accomplish the same levels of recognition as their male counterparts.[317] Many reviews have highlighted the multitude of barriers to gender equity, including unconscious bias, sexual harassment and discrimination, conflicting biologic and professional clocks, and lack of mentorship and/or sponsorship.[318] Crucially, the experiences and barriers facing nonbinary individuals are even further shrouded in the lack of routine or proper demographic documentation and exacerbated by pervasive misgendering in medicine.[319]

Efforts to address the barriers to gender equity have been proposed by Holliday and colleagues and reproduced in Table 35.22.[318] Widely incorporating these strategies into radiation oncology education can begin to shift practices toward diversity, parity, and the evolution of a radiation oncology workforce that more closely resembles the patient population it serves.

TABLE 35.22 EXAMPLES OF BARRIERS AND STRATEGIES TO ADDRESS GENDER EQUITY IN THE RADIATION ONCOLOGY PHYSICIAN WORKFORCE

Barrier	Strategy	Leadership Imperative
Bias	• Unconscious bias training • Blinded resume review • Standardized interviews, adjusting likeability scores	• Hiring and recruitment: • Increase representation of underrepresented groups on recruitment committees • Active recruitment of women and underrepresented minorities
Sexual harassment	• Proactive and enforced policies • Bystander training	• Transform culture: • Create culture that treats women with respect
Salary inequity	• Transparent salary scales • Standardized salary scales • Negotiation training	• Honest assessment of salary inequities at institution
Collisions between biologic and professional clocks	• Generous and transparent maternity leave policies • Support of lactation and integration of work and family responsibilities • On-site childcare options • More flexible tenure timelines • Meetings scheduled during workday to avoid conflict with family responsibilities	• Model practices of inclusion • Implement and support clear policies

Barrier	Strategy	Leadership Imperative
Mentorship	• Increase opportunities for networking and connecting residents and junior faculty with senior faculty	• Create and promote institutional and national career development programs
Exposure	• Debunk misconceptions (eg, lack of patient contact, radiation exposure) through early education of medical students • Include radiation oncology introductory teaching in preclinical curricula	• Connect faculty with medical school opportunities for education, such as guest lectures • Reward faculty for roles in medical school involvement and other diversity initiatives

CONCLUSION

Radiation oncology is a unique field within medicine. Although much of the essential cognitive, affective, and psychomotor knowledge acquired during medical school is useful to a radiation oncology trainee, the knowledge and skills required of a competent and compassionate radiation oncologist are unique and iterative. Curricula to teach this radiation oncology knowledge and skill set must be developed in a logical and rational manner to ensure desired goals and objectives of the learning process are achieved. Furthermore, curricula must be continually updated to meet changes in modern radiation oncology. Meanwhile, the approach to educational programs must reflect changes in information technology, with the potential to increase simulation-based training over traditional didactic lectures and for longitudinal assessments to replace exams performed once every decade. Dissemination of curricular innovations is essential to ensure the radiation oncology educational community is aware of the progress and can further build and improve radiation oncology education while ensuring the educator receives appropriate academic recognition. The radiation oncology profession must place value on medical education scholarship to encourage the advancement of the entire discipline.

Radiation oncology educators must critically evaluate the local, national, and international training milieu and consider disruptive innovation to ensure vigorous and active curriculum revision and renewal. Disruptive innovation is defined in the business sense as follows:

> "Dominant players in most markets focus on sustaining innovations …. That makes a market ripe for upstart companies seeking to introduce disruptive innovations … more convenient products or services."[320]

The concept of disruptive innovation can be applied to radiation oncology education. Current radiation oncology curricula across the globe evolved to satisfy the requirements set forth by accrediting bodies but are not necessarily the most effective and efficient methods for teaching a particular radiation oncology topic or concept. Educational innovations are demonstrated as effective through rigorous curriculum inquiry, learner assessment, and program evaluation and are disseminated have the potential to disrupt the status quo radiation oncology curriculum on a large scale with the ultimate goal of improving the quality of patient care.

CHAPTER 36

Ethics, Professional Values, and Legal Considerations in Radiation Oncology

Austin J. Sim and Brian D. Kavanagh

Although progress in medical science has improved the quality and duration of life for some patients with cancer and other serious illnesses, technical expertise alone does not fully account for the upsurge in the societal standing of medical doctors during the past 100 years.[1]

High regard for physicians is contingent on the trust that doctors act unselfishly in a patient's best interests, a role sometimes called moral fiduciary.[2] Essential to this role are medical knowledge and a firm grasp of ethics. Derived from the Greek *ήθοσ* (*ethos*), meaning *character*, ethics refers to the process of applying values and principles in professional interactions and particularly in medical decision-making on behalf of patients. Although not a routine requirement for admission, many medical schools encourage undergraduate applicants to take an introductory course in ethics, and the curriculum of most medical schools now includes coursework in ethics.

To foster an appreciation for the intellectual underpinnings of modern medical ethics, this chapter begins with an overview of scholarly approaches to ethics. Next is a discussion of selected proclamations and codes of ethics published by professional societies, federal commissions, and other authorities as guidelines for medical practice and research. Finally, common practical ethical issues in radiation oncology are addressed, including relevant medicolegal considerations.

CONCEPTUAL APPROACHES USED IN BIOMEDICAL ETHICS

The term *bioethics*, coined in the early 1970s, refers to the academic inquiry and public policy movement addressing the application of science and medicine from a humanistic perspective.[3] Medical ethics may be most

accurately viewed as a branch of bioethics, but the terms are commonly used interchangeably. Among the more influential theoretical approaches that are used in bioethics are *utilitarianism, deontology, casuistry, virtue theory, principlism, and feminism*.

Utilitarianism is based on the premise that, in any situation, the best course of action is the one that produces the maximum net positive value (or least negative value). Utilitarianism can be applied to an individual patient's case or to matters of health policy, in which decisions might be made to achieve the greatest overall benefit for the largest number of people.

Unlike utilitarianism, deontology is an ethical theory based on the morality of actions themselves rather than their net result. Deontology, sometimes called Kantianism in recognition of the influence of Immanuel Kant,[4] calls for consistent standards of behavior at all times, regardless of the consequences. One simple example of the difference between utilitarianism and deontology is the issue of educating patients about their diagnosis, especially if the prognosis is very poor. Whereas a deontologist would always feel obliged to tell the truth even at the risk of causing distress, a utilitarian considers whether telling a patient the complete truth about the disease does or does not really benefit the patient. In daily practice, finding the right balance between purely utilitarian and purely deontologic perspectives in a situation like this one requires consideration of case-specific factors. Respect for the patient's autonomy, for example, is one of the prima facie ethical principles discussed in the next section. Truth-telling is an integral component, and overriding this principle requires justification.

Casuistry is an approach to ethics that emphasizes inductive reasoning based on established precedents, and it is a common practice in both law and medicine. The proper course of action in any individual case is decided by recalling decisions made in prior similar cases. The major weakness of casuistry is the lack of a reference benchmark or settled opinion on novel technologies.

Virtue theory focuses on the character of moral agents, in this case, physicians and other health care providers, focusing less on actions or outcomes. As such, virtue theory captures the way in which correct moral actions occur. For example, it is not only important to tell patients the truth

about their diagnoses, but it is also critical to do so in a compassionate manner. In this case, the virtue is compassion. Accordingly, although virtue is a critical part of assessing moral action, virtues themselves have little guiding force.

Principlism is a system of applied ethics through which core principles ideally govern behavior in the absence of compelling reasons to override them. Principlism can be integrated with the other philosophical approaches already mentioned and serves as a unifying influence.

Feminism concentrates on the concerns of those who are vulnerable and marginalized, as well as categorized unjustly according to particular hierarchies. Frameworks such as structural violence aid in analyzing various practices and policies that perpetuate oppression and injustice. Narrative practice provides a voice to those who may be marginalized on the basis of sex, race, gender, age, disability, susceptibility or presence of stigmatized diseases, imprisonment, health status, and other social categorizations. As such, feminism does not focus solely on women's issues, but on those who are traditionally subject to discrimination.

ETHICAL PRINCIPLES IN BIOMEDICAL ETHICS

A prima facie obligation may be defined as one that is "binding unless overridden or outweighed by competing moral obligations."[4] Four prima facie principles of bioethics are highlighted here: *respect for autonomy, beneficence, nonmaleficence*, and *justice*.

Respect for a patient's autonomy is based on respect for the right to individual liberty. A patient's voluntary decision to seek medical care or comply with referral to a specialist is the starting point of most patient-physician relationships, and competent patients should remain free to forgo therapy or change physicians at any time. The responsibility to respect patients' autonomy is established not only in ethics but also in law. An example is the requirement to obtain a patient's informed consent for proposed medical therapy. In a landmark case involving postmastectomy chest wall radiation therapy, a patient who sustained soft tissue necrosis won a lawsuit against their radiation oncologist for negligence and for lack of proper disclosure regarding possible treatment-related toxicity. The Kansas Supreme Court ruled that doctors should explain "in language as

simple as necessary" the side effects associated with any recommended therapy.[5] Requirements and components for informed consent have since been codified in federal regulations (38 CFR §17.32).

The principle of *beneficence* is intertwined with that of *nonmaleficence*. Some authors have offered nuanced distinctions between the two principles,[4] but the key point is that physicians should act for the benefit of patients and should not harm their patients. Beneficence and nonmaleficence are typically concordant objectives, but sometimes, an intervention that is helpful also entails a high risk of adverse treatment-induced sequelae. For example, administering high-dose morphine to a patient severely dyspneic from an incurable lung malignancy can relieve symptoms but at the same time risks fatally suppressing respiratory drive. Here the quality of remaining life might be improved by a measure that also hastens death. Such an action can sometimes be justified by the principle of double effect, the earliest expression of which is generally attributed to St Thomas Aquinas.[6]

In recent years, a number of states in the United States have enacted the so-called Death with Dignity legislation that permits physicians to prescribe life-ending medications to certain patients with terminal illness when pain or other distress from the illness becomes intolerable to the patient. Generally, there is a stipulation that the patient must be able to self-administer the medication, and there is also a requirement that the patient is competent to make the decision to end their life. Individual hospitals and health systems retain local administrative authority regarding whether these statutes are implemented within the institution and, if so, what specific local regulatory requirements apply.

The principle of justice refers to fairness, typically the equitable distribution of health care resources. Justice-related questions often arise concerning matters of public policy. One specific example is the challenge of determining the means to allocate scarce organs for transplantation. A more global problem faced by all governments is the calculus of distributive justice, which implies that persons ought to be afforded medical care according to their medical needs and the ability of the system to provide.

FORMAL OATHS AND CODES OF ETHICS

There are many published declarations of medical ethics authored by physicians. Not surprisingly, the tone and language of each reflect the social mores and sometimes historical events of the era in which it was composed.

The Physician-Patient Relationship as a Fiduciary Relationship

The physician-patient relationship is a special class of relationship that fits into the broad category of fiduciary relationships, which come with specific ethical and legal obligations beyond those of a normal relationship. As noted in American Jurisprudence:

> *The relation of physician and patient has its foundation on the theory that the former is learned, skilled, and experienced in those subjects about which the latter ordinarily knows little or nothing, but which are of the most vital importance and interest to him, since upon them may depend the health, or even life, of himself or family; therefore the patient must necessarily place great reliance, faith, and confidence in the professional word, advice, and acts of the physician*.[7]

In contrast to the basic duty of care, fiduciaries are held to a much higher standard to act in the best interest of another.[8] Caselaw has clarified additional attributes of such relationships to include power over another (beneficiary), rendering of desirable services requiring special expertise, discretion on the part of the fiduciary to apply that expertise, and a beneficiary who is vulnerable and/or dependent on the fiduciary.[9] Although legal conceptions predate a formal ethical framework, others have developed these frameworks revolving around authority (as evidenced by expert knowledge and skill) and its use for the benefit of the patient, rather than self-interest.[10]

The Hippocratic Oath

> *I will prescribe regimen for the good of my patients according to my ability and my judgment and never do harm to anyone*

The *Corpus Hippocraticum* is a collection of medical treatises dating from around the 5th century BCE, believed to be the work of philosopher-physicians from the Greek island of Cos (Figure 36.1). Contained within the *Corpus* is the well-known oath of Hippocrates, an ancient physician's

pledge of professionalism. Curiously, the oath is inconsistent with some other sections of the *Corpus*, perhaps because it was added later. Comments about abortion and surgery, for example, are at variance with teachings elsewhere in the collected works.[11] Nevertheless, timeless themes are included, and the oath has survived in various modernized versions. The oath is often recited by medical students at the time of graduation—even if its contents are not always well remembered.[12,13]

FIGURE 36.1 Early 19th-century engraving depicting a likeness of Hippocrates, closely resembling images of ancient coins found on the island of Cos bearing his likeness. (Image courtesy of the U.S. National Library of Medicine.)

Percival's Medical Ethics

Hospital physicians and surgeons should minister to the sick, with due impressions of the importance of their office, reflecting that the ease, the health, and the lives of those committed to their charge depend on their skill, attention, and fidelity.

Thomas Percival (1740-1804) (Figure 36.2) published *Medical Ethics* at a time when there was considerable tension among clinicians in his community.[14] In the 1760s, Manchester, England, was a prosperous urban society that comfortably supported public health initiatives, including an infirmary serving as a charity hospital and teaching institution. But as the city grew and became crowded by the 1790s, tensions arose between rival groups in the medical community. Percival was prompted to draft a code of ethics after a contentious dispute about enlarging the infirmary's staff, a threat to the controlling physician faction.[15]

FIGURE 36.2 Thomas Percival (1740-1804). (From Brockbank EM. *Sketches of the Lives and Work of the Honorary Medical Staff of the Manchester Infirmary: From its Foundation in 1752 to 1830 When it Became the Royal Infirmary*. Manchester University Press; 1904.)

Ultimately, *Medical Ethics* provided a template for the codes of ethics adopted by the American Medical Association (AMA) and other societies in the 19th century. Early 20th-century pundits criticized Percival's work as merely a book of medical *etiquette* rather than medical *ethics*. However, revisionist historians have subsequently argued that although Percival focused on interprofessional relationships, he also taught that a physician's duty toward the patient outweighs obligations of civility toward other health care professionals. Furthermore, Percival advanced the enlightened view that indigent patients should receive the same quality of care as affluent patients.[16]

The American Medical Association Code of Ethics

The AMA first adopted a code of ethics at its inaugural meeting in 1847. The initial code was modeled on the work of Percival, but subsequent updates have reflected societal changes and technological progress. The 2016 update begins with an articulation of basic principles[17]:

I. *A physician shall be dedicated to providing competent medical care, with compassion and respect for human dignity and rights*.

II. *A physician shall uphold the standards of professionalism, be honest in all professional interactions, and strive to report physicians deficient in character or competence, or engaging in fraud or deception, to appropriate entities*.

III. *A physician shall respect the law and also recognize a responsibility to seek changes in those requirements, which are contrary to the best interests of the patient*.

IV. *A physician shall respect the rights of patients, colleagues, and other health professionals and shall safeguard patient confidences and privacy within the constraints of the law*.

V. *A physician shall continue to study, apply, and advance scientific knowledge; maintain a commitment to medical education; make*

relevant information available to patients, colleagues, and the public, obtain consultation; and use the talents of other health professionals when indicated.

VI. *A physician shall, in the provision of appropriate patient care, except in emergencies, be free to choose whom to serve, with whom to associate, and the environment in which to provide medical care*.

VII. *A physician shall recognize a responsibility to participate in activities contributing to the improvement of the community and the betterment of public health*.

VIII. *A physician shall, while caring for a patient, regard responsibility to the patient as paramount*.

IX. *A physician shall support access to medical care for all people*.

Among the numerous topics discussed in more detail in the 11 chapters of the code are conflicts of interest in patient care. The AMA code states that "under no circumstances may physicians place their own financial interests above the welfare of their patients. … Treatment or hospitalization that is willfully excessive or inadequate constitutes unethical practice."

The Nuremberg Code and the Declaration of Geneva

During World War II, odious crimes were committed by Nazi physicians who conducted horrific experiments on concentration camp prisoners who were coerced to submit. The Nuremberg Code was a formal response to these World War II–era human rights atrocities disguised as medical experiments.[18] Adopted by the ad hoc court that tried some of the Nazi doctors and medical administrators who conducted these experiments, the Nuremberg Code acknowledges that medical investigations are important and repudiates the defendants' assertions that they had followed contemporary standards of informed consent. For a medical experiment to be morally permissible under the Code, it must meet 10 criteria, paraphrased as follows:

- Voluntary consent of the human subject
- Necessity to yield results helpful to society
- Appropriate design based on knowledge of the disease under study

- Avoidance of unnecessary physical and mental suffering and injury
- Absence of reason to believe that death or disabling injury will occur
- Overall degree of risk in proportion to the nature of the problem to be solved
- Adequate precautions against the possibility of the subject's injury, disability, or death
- Qualified persons conducting the study
- Unrestricted freedom of the subject to end the experiment if they reach the physical or mental state where continuation of the experiment seems impossible
- Willingness of the investigator to discontinue the study at any time if there is reason to believe that continuing the experiment is likely to result in injury or death to the subject

In the aftermath of the war, the international medical community was especially sensitized to the need for universal adherence to high standards of ethical behavior. The Declaration of Geneva was adopted in 1948 by the World Medical Association and has been updated since then. The text includes the physician's vow to ignore "considerations of age, disease or disability, creed, ethnic origin, gender, nationality, political affiliation, race, sexual orientation, or social standing" in the treatment of a patient and to uphold "even under threat … the utmost respect for human life."

Case Study

Despite publicity about the Nuremberg Code and the Geneva Declaration, controversial large-scale, government-sponsored medical studies took place in the years following World War II. Experimentation on the effects of radiation exposure on humans was conducted in the United States during the Cold War, when fears of nuclear warfare prompted inquiry into the carcinogenic and other adverse health effects of environmental exposure to ionizing radiation. In response to public concern about thousands of federally funded studies conducted from the 1940s through 1970s without consent of the subjects, in 1994, President Bill Clinton established the Advisory Committee on Human Radiation Experiments (ACHRE). ACHRE was composed of ethicists, radiation oncologists, and others with relevant

expertise. It was charged with evaluating the experiments' ethical and scientific standards and recommending actions to ensure that any mistakes of the past would not be repeated. ACHRE reviewed all available documentation and also conducted an oral history project in which scientists described prevailing sentiments regarding human research ethics during the era of interest.

ACHRE found that government officials and investigators were in some cases culpable "for not having had policies and practices in place to protect the rights and interests of human subjects who … could not possibly derive direct medical benefit."[19] One example was the observational study of uranium mine workers exposed to radon levels known to be hazardous, without warning and without efforts to reduce the radon levels by ventilating the mines. As a result, lung cancer developed in hundreds of workers, and appropriate compensation was recommended for the individuals affected.

The Belmont Report

In 1972, Jean Heller[20] exposed the injustices of the U.S. Public Health Services (USPHS) Study of Untreated Syphilis in the Negro Male that was conducted in Tuskegee, Alabama. During a 40-year period beginning in the 1930s, 399 indigent African American sharecroppers with syphilis and 200 without syphilis were subjects in a natural history study of the disease. The men mistakenly believed that diagnostic blood tests and lumbar punctures composed treatment for their "bad blood"; when in reality, these were done solely to monitor the course of the infection. Moreover, years later when penicillin was discovered and found to be effective in the treatment of syphilis, it was withheld intentionally from the men. Subsequently, public awareness of the USPHS study likely contributed to enduring reluctance among some members of minoritized groups to participate in clinical trials,[21,22] and the political backlash provoked action by the federal government.

The 1974 National Research Act established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The commission met at the Belmont Conference Center in Maryland to develop ethical guidelines for the conduct of biomedical and

behavioral research. In 1979, the commission published *Ethical Principles and Guidelines for the Protection of Human Subjects of Research*, commonly known as the Belmont Report.[23]

In the Belmont Report, a clear distinction is made between medical research and clinical practice. The term *practice* describes interventions intended "to enhance the well-being of an individual patient … that have a reasonable expectation of success," whereas *research* is "designed to test an hypothesis, permit conclusions to be drawn, and … contribute to generalizable knowledge." Sometimes, a clinician uses good judgment and departs from standard methods for the benefit of an individual patient in special circumstances. However, if major innovations are proposed as a replacement for standard techniques, then a formal investigation should be conducted to assess safety and efficacy. The National Commission embraced a principlist perspective in drafting the report, emphasizing in particular respect for persons, beneficence, and justice. The Belmont Report's definition of respect for persons incorporates respect for autonomy and special concern for individuals with diminished capacity to exercise their autonomy. Involving prisoners in research activity is cited as an example. Although it is inappropriate to deny prisoners the possible benefit of experimental interventions, any direct or indirect pressure on prisoners to participate in clinical studies must be avoided. For instance, a promise of clemency in return for study enrollment is unacceptable. The report also addresses the nature of justice in medical research, emphasizing that the process of selecting subjects for a research study must be carefully examined. Investigators should minimize the chance that socioeconomically disadvantaged groups are represented disproportionately as a result of a vulnerability to manipulation in the health care environment.

The Common Rule

On the heels of the Belmont Report, modern regulations governing human subjects research in the United States were published in 1991 as The Federal Policy for the Protection of Human Subjects (the "Common Rule"). The Department of Health and Human Services regulations lie within 45 CFR part 46. Subpart A encompasses the Common Rule and is recapitulated by 20 federal agencies in their own regulations. Additional subparts

encompass special protections for specific vulnerable populations, including pregnant women, fetuses, neonates (B); prisoners (C); and children (D).[24]

National Electrical Manufacturers Association Code of Ethics

The makers of equipment and software used in the practice of radiation oncology are not required to demonstrate the clinical efficacy of a new device or software through the same sort of clinical testing that is required by the U.S. Food and Drug Administration (FDA) for approval of a new drug or implantable medical device. Rather, most treatment devices are approved after demonstration of safety and substantial equivalence to an approved device that is already commercially available. A company that wishes to sell a new device submits a premarket notification to the FDA at least 90 days before commercial distribution is to begin, in accordance with Section 510(k) of the FDA Modernization Act of 1997. Because devices may be introduced into the market without proof of superiority in any given clinical situation, manufacturers may promote their products to physicians by emphasizing intuitively attractive features that might or might not provide meaningful clinical advantage to patients.

On January 1, 2005, members of the National Electrical Manufacturers Association (NEMA) adopted a code of ethics regarding interactions between makers of medical imaging and treatment equipment and physicians (www.nema.org). Individual sections of the NEMA code address member-sponsored product training and education, support for third-party educational conferences, sales and promotional meetings, arrangements with consultants, gifts, provision of reimbursement and other economic information, charitable donations, and research grants. The guidelines are essentially consistent with the AMA policy on gifts and applicable federal regulations. NEMA members are allowed to support educational conferences and advertise their wares in these venues, and also they may provide educational support for individual customers in the safe use of their products. However, hospitality provided by NEMA members at conferences and meeting should be “modest in value and … subordinate in time and focus to the purpose of the meeting.” When it is necessary to demonstrate

nonportable equipment, members may pay for reasonable travel costs of attendees with a bona fide professional interest, but not for their guests.[25]

COMMON ETHICAL ISSUES IN RADIATION ONCOLOGY

> *Doctors wear a lot of hats these days; besides the usual physician role, we are expected to be a researcher, financial counselor, administrator, gatekeeper, patient advocate in the medicolegal system, ethicist, and Lord knows what else.*
>
> —*Thomas J. Smith*[26]

Financial Relationships With Hospitals and Referring Physicians

Reimbursement for radiation oncology services or other procedure-intensive subspecialties can be a major revenue source for hospitals. At the same time, subspecialists depend on other physicians to refer patients for evaluation and management. These situations can tempt hospital administrators to reward subspecialists for practicing in their facility and might tempt the subspecialists to induce referrals with financial incentives. In either case, a conflict of interests emerges: Treatment recommendations can be influenced not only appropriately by patient-centered beneficence but also inappropriately by the physician's interest in personal gain. In the United States, the Anti-Kickback Statute and the Stark Law make it illegal to engage in such unscrupulous medical business practices. These laws work in tandem with the False Claims Act to deter fraudulent claims to the government, including Medicare and other programs.

The Anti-Kickback Statute (42 USC §1320a-7b) includes both civil penalties and criminal prosecution for acts involving Medicare or state health care programs. Section (b) makes it a felony punishable by a fine up to $25,000 and up to 5 years in prison to solicit or receive "any remuneration (including any kickback, bribe, or rebate) directly or indirectly … in return for referring an individual to a person for … any item or service" reimbursed in whole or in part through Medicare or a state health care program. The Anti-Kickback Statute also bans other fraudulent transactions supported through the same funding sources. As violations come with criminal penalties, proof of improper intent is necessary prior to prosecution. Additional civil penalties include up to a $50,000 fine per

violation and 3 times the value of the kickback (treble damages), as well as *permanent exclusion* from Medicare and other programs; that is, the convicted individual would no longer be able to bill Medicare for any services and their services could no longer be billed by an employer or group practice. Lastly, a conviction also opens liability to the False Claims Act (*infra*).

Named for its leading congressional author, Rep. Pete Stark of California, the Stark Law (42 USC §1395nn; "Limitation on certain physician referrals") bans other misconduct involving Medicare and Medicaid patients. The Stark Law prohibits (1) a physician from referring a patient for a "designated health service" to a clinic or other facility with which the physician or an immediate family member of the physician has a financial relationship and (2) the designated health service from submitting claims for services resulting from prohibited referrals. Unlike the Anti-Kickback Statute, no proof of improper intent is required, and violations are regarded by actions alone under strict liability without any consideration of intent. A detailed discussion of the nuances of the Stark Law is out of scope, but any such conduct blanket illegal on its face unless it falls squarely within one of the dozens of explicit safe harbors (42 CFR §1001.952[a]-[u]). Radiation therapy is considered a designated health service, but it is clarified that a request by a radiation oncologist for radiation therapy is considered integral to the consultation request from the (non–radiation oncologist) referring physician and does not constitute a self-referral per se in most situations. Although sanctions for violations of the numerous Stark Law regulations are civil in nature (in contrast to the criminal penalties of the Anti-Kickback Statute), such violations can also be catastrophic. Each violation currently carries a fine of $15,000 to $100,000 in addition to 3 times the amount claimed (treble damages), as well as the potential from permanent exclusion from the Medicare program. The second piece prohibiting submission of claims stemming from prohibited referrals also opens violators to additional penalties through the False Claims Act (*infra*).

One such safe harbor concerns physician-owned hospitals, which grew in number until 2010, when the Affordable Care Act prohibited both the establishment of any new physician-owned hospitals and the expansion of preexisting ones in Section 6001 (42 USC §1395nn[i]). As an interesting counterpoint, the American Bar Association Model Rules of Professional

Conduct Rule 5.4 explicitly prohibits nonlawyer ownership of any firm or association.[27]

Under the False Claims Act (31 USC §3729), submitting fraudulent claims to the government for reimbursement of health care services is illegal without any consideration of intent. Any person who knowingly presents fraudulent claims to the U.S. government may be fined $5,000 to $10,000 per violation and may be liable for 3 times the amount of any damages (treble damages) sustained by the government. Upcoding (submitting a claim with a code of a higher value than services actually rendered) is a common example of fraudulent behavior under the False Claims Act. Each individual incidence of an upcode is considered an individual violation subject to its own fine and treble damages. Nearly all of these cases are settled, as a judgment for the actual total damages would be catastrophic for nearly all organizations.

Like the Anti-Kickback Statute and Stark Law, the False Claims Act violations may be pursued by the U.S. government. However, it also provides for a unique enforcement mechanism through a "qui tam" action wherein a private citizen functions as a whistleblower (relator) and brings a suit to the government, which can intervene and take the case (31 USC §3730[b]). If successful, the relator is entitled to between 15% and 25% of the recovered proceeds (31 USC §3730[d]), which can be in the hundreds of millions of dollars.[28]

Self-Referral for Radiation Oncology Services

In addition to being considered a designated health service per Stark Law language, radiation therapy is also considered in the category of in-office ancillary service exemptions for Medicare coverage. The implication is that radiation therapy is grouped with a number of less complex services such as simple blood tests or antibiotic injections that a physician might reasonably do in their office for the convenience of rendering a quick diagnosis or managing a simple medical problem on an outpatient basis. Because of this classification for radiation therapy, non–radiation oncologists may own linear accelerators and derive profit from the utilization of this technology on patients referred for treatment. One of the most contentious issues to emerge in recent years is the debate over the legitimacy and ethics of

business arrangements in which non–radiation oncologists own radiotherapy delivery technology and derive profit from self-referring patients for treatment.

In 2013, Jean Mitchell reported a study in *The New England Journal of Medicine* in which patterns of intensity-modulated radiation therapy (IMRT) utilization for prostate cancer were analyzed. Urologists were grouped according to whether they purchased radiotherapy equipment. For those who purchased equipment (the self-referring group), the use of IMRT in the periods before and during ownership was compared. To account for the changing baseline trends in prostate cancer management, the use of IMRT among patients seen by non–self-referring urologists who did not own radiotherapy equipment was also analyzed, and a "difference-in-differences" methodology was employed. It was observed that men treated by self-referring urologists, as compared with men treated by non–self-referring urologists, were significantly more likely to be treated with IMRT rather than less expensive options.[29] Other similarly constructed studies have yielded concordant results.[30,31]

Another concerning area lies in the rapid adoption and use of electronic surface brachytherapy by dermatology practices in the treatment of nonmelanomatous skin cancers. Despite a recommendation from the American Brachytherapy Society to not use this modality outside the auspices of a trial,[32] and a lack of evidence to make a recommendation to use at all from the American Academy of Dermatology,[33] routine clinical use of this modality continues, growing 20-fold over the course of 2 years from 2011 to 2013.[34] Even more concerning are the device manufacturers' billing recommendations to add codes for complex simulation, custom shielding, depth dose calculations, and special procedure for multiple radiation sources *for each fraction delivered*.[34]

Terry Wall[35] offers a perspective on both the legal and ethical aspects of this issue. He points out that advocacy efforts by the American Society for Radiation Oncology (ASTRO) to remove radiation therapy from the list of in-office ancillary service exemptions have been unsuccessful, and there is unlikely to be a legislative resolution. Dr Wall poses the question of whether an individual radiation oncologist who is the potential recipient of a self-referral is "eating fruit from a poisonous tree." He offers guidance for the individual practitioner to ensure that self-referral arrangements put the

patient's interest first, including a mandate to disclose the financial interests to the patient and inform patients of their alternative to receive care elsewhere.

Electronic Recordkeeping and Billing Practices

The principles of respect for autonomy and nonmaleficence oblige confidentiality in physician-patient communications. Publicizing private details of a patient's condition can create social and economic harms for the patient. With the advent of electronic medical records and internet communication, there is a greater need for vigilance in this respect.

The recent passage of the 21st Century Cures Act adds yet another wrinkle in communicating with patients. Among other provisions is one regarding information blocking in electronic medical records (42 USC §300jj-52). Under these provisions, all test results must be automatically released to patients through electronic portals immediately when available. While this serves the principle of respect for autonomy, premature release of results without review by the treating physician or context may at times violate the principle of nonmaleficence. Indeed, a single-institution study of over 5.5 million test results for 44,000 patients revealed a *doubling* in the proportion of test results reviewed by patients before the ordering clinician from 37% to 75% before and after the passage of the Cures Act.[36] Widespread release of pathology and imaging results in an oncology setting without any clinical context may generate unnecessary anxiety.[37]

In the United States, the Health Insurance Portability and Accountability Act of 1996 (HIPAA) empowers the Department of Health and Human Services to codify standards for storage and transmission of an individual patient's health information. Penalties for violations vary in proportion to their severity. In the worst case of wrongful disclosure of information with intent to sell it, a fine of up to $250,000 and a prison term of up to 10 years can be imposed. Of note, this statute does not come with a private cause of action, that is, a private citizen cannot directly sue the responsible party for a breach of information and only the government may bring such actions under HIPAA (see, eg, *Acara v Banks*).[38] However, a more recent case opens the door to an alternate theory of potential private damages under the

14th Amendment,[39] and additional state law claims may provide a private cause of action.[40]

Applications of New Technology

Innovative treatment delivery methods such as stereotactic body radiation therapy for oligometastatic/oligoprogressive disease, proton therapy, adaptive therapy, and other new treatment techniques/indications can be intuitively appealing but cannot be assumed to provide meaningful clinical benefit unless tested properly against existing standard treatment methods. A recent example underscoring this need is the lack of benefit of proton therapy over photon therapy for non–small cell lung cancer in the first randomized trial comparing these modalities.[41] Ideally, it is best that such innovations are tested in formal research protocols in which a clinical problem is identified and the new technology is proposed as a solution so that toxicity and efficacy can be monitored closely. A prospective clinical trial approved and monitored by an institutional review board affords the opportunity to advance knowledge in the field with ethical oversight.[42]

Clinical Trial Conduct

Instances of flagrantly improper clinical research taint the annals of medical history. The USPHS study of syphilis mentioned earlier and the human radiation experiments conducted during the Cold War without the consent of the participants are dark reminders of the need for ethical oversight of research.

Obtaining a participant's informed consent is of paramount importance in conducting most clinical research. Despite the recognized importance of informed consent, precisely how much information should be conveyed to a potential clinical trial participant is debatable. The Belmont Report offers this criterion: "The extent and nature of information should be such that persons, knowing that the procedure is neither necessary for their care nor perhaps fully understood, can decide whether they wish to participate" in the study. In certain situations, the nature of a study requires that there is incomplete disclosure of information to the participant to sustain the integrity of the study. The Belmont Report condones such research only when "(i) incomplete disclosure is truly necessary to accomplish the goals

of the research, (ii) there are no undisclosed risks to subjects that are more than minimal, and (iii) there is an adequate plan for debriefing subjects, when appropriate, and for dissemination of research results to them." The Federal Policy for the Protection of Human Subjects (45 CFR 46) reflects these arguments.

Advances in the biosciences, such as stem cell research, cloning, and manipulations of the human genome, have been associated with contentious public debate. The federal government and professional policies on such matters have sometimes been constructed as a compromise between scientific opportunity and political ideology.[43] Extra safeguards have been imposed in some settings; for example, the federal government requires an extra level of review for gene transfer experiments.[44]

Genetics

The management of some patients with cancer can involve assessment of genetic markers that might predict treatment response and reveal a predisposition to the development of certain cancers among the patient's family members. The National Society of Genetic Counselors has published a guideline concerning genetic cancer risk assessment, counseling, and testing.[45] It is recommended that the process of obtaining informed consent for genetic testing should include, among other considerations, an explanation to the patient of possible implications on the ability to obtain health or disability insurance in the future. In 2008, Congress passed the Genetic Information Nondiscrimination Act (GINA; 42 USC §2000ff), which prohibits discrimination on the basis of genetics and requesting genetic information (1) prior to the manifestation of a disease or disorder and (2) only for the purposes of health insurance and employment. Unfortunately, GINA does not provide any protection for other situations, including other types of insurance or lending. An erratic patchwork of various state laws attempts to fill gaps in various ways, but overall lacks cohesion.[46] Caselaw has also blurred the line of both when disease manifests and what is encompassed in "genetic information."[47] Lawmakers could not foresee the explosion of routine genomic sequencing in the clinical application of precision oncology and the legislative and regulatory

processes lag behind technological advances in this space, potentially leaving patients vulnerable.

Relationships With Industry Sponsors

Incentives from industry representatives to prescribe pharmaceuticals or purchase equipment threaten the fiduciary obligations physicians have to their patients. The AMA Code of Ethics states that physicians should decline cash gifts in any amount from any entity with a financial interest in the physicians' treatment recommendations.[17] The AMA code allows for accepting an in-kind gift that will directly benefit patients and is of minimal value and allows for support for educational programs with certain restrictions.

Advertising items such as patient education pamphlets and anatomic models bearing a sponsor's name are commonly found in radiation oncology clinics.[48] Physicians should be aware of any real or perceived influence on the patient- physician relationships resulting from their tacit compliance with such marketing activities.

Pharmaceutical companies may be prosecuted for kickback schemes or other illegal enticements to physicians, and the civil and criminal penalties paid by the corporations held responsible have ranged up to hundreds of millions of dollars.[49] Brennan et al[50] contend that voluntary self-regulation by physicians, industry, and government is an insufficient safeguard against the conflict of interests nurtured by close relationships between practicing doctors and sellers of pharmaceuticals and medical products. These authors argue that academic medical centers should set an example for the rest of the medical community by establishing policies that forbid gifts to physicians, funds for travel, unjustified consulting fees, participation in speakers' bureaus, and the practice of "ghostwriting" medical articles, among other things. Substantial attention has focused on implementing policies related to these issues.[51,52]

Prasad and Rajkumar[53] recommend a forward-looking strategy of transparency and full disclosure as a means of minimizing the impact of conflict of interest in academic publications and presentations. Their suggestions include excluding authors of reviews, editorials, and practice guidelines from having any financial interest that exceeds a reasonable

threshold[54]; stopping the practice of having professional medical writers funded by industry serve to prepare manuscripts; and open disclosure of the amount of support given to professional organizations by individual industry sponsors. The Physician Payments Sunshine Act was initially enacted as §6002 of the Affordable Care Act and expanded to include other health care providers, like advance practice providers by the SUPPORT ACT (42 USC §1320a-7h). This led to the creation of the Open Payments Program, which publishes all payment data annually in a publically searchable database to promote transparency and accountability.[55] Despite the tracking and disclosure of all these data, other studies continue to demonstrate the ability of these payments to influence physician prescribing practices,[56] even to the point of prescribing nonrecommended and low-value interventions in patients with cancer.[57]

CASE-SPECIFIC DILEMMAS: THE ROLE OF AN ETHICS CONSULTANT OR COMMITTEE

The radiation oncology–related ethical issues discussed thus far relate primarily to general practice and research guidelines. However, individual cases can also pose uncertainties regarding the proper choice of action for a specific patient.

Case Study

A 37-year-old woman undergoes modified radical mastectomy for a pathologic T3N2M0 breast cancer; postoperative chemotherapy and locoregional radiation therapy are recommended. The patient wishes to receive the therapy only if she can periodically interrupt it to alternate with what she calls a "natural herbal" therapy.

In this case, respect for a patient's autonomy conflicts with what is believed to be in the patient's best interests, but a physician cannot ethically abrogate the fiduciary responsibility to a patient simply for reasons of unfamiliarity with alternative medicine or prejudice against its worth.[58] Similar situations may arise when patients do not adhere to standard treatment recommendations because of a particular religious faith or cultural heritage. Although physicians must respect patients' choices, there is no strict obligation for a physician to accept a particular individual as a

patient if de novo, especially if there are foreseeable personal conflicts that might adversely affect the patient-physician relationship, unless the treatment is needed urgently and/or there are no other physicians with the same skills or knowledge to treat the patient. However, terminating an existing relationship requires adequate notice to the patient for the transfer of care and facilitation thereof.

Pediatric oncology also requires special considerations. Parents are the chief decision makers, but sometimes their wishes can seem discordant with the best interests of the child. In a different context, what should be done if the adult children of a patient with a heritable trait for malignancy inquire of the patient's diagnosis, but the patient has instructed the physician not to reveal any information to them? The obligation to patient-physician confidentiality conflicts with a potentially overriding obligation toward the family members who might benefit from guidance toward screening.

In cases such as these in which it is difficult to choose between two defensible courses of action, individuals and committees with experience in clinical medical ethics can provide the expertise needed to sort through the ethical, legal, and social issues involved.[59]

PALLIATIVE MEDICINE

Palliative medicine has become a well-established component of clinical practice, and numerous academic medical centers offer accredited fellowship programs in this field. Palliative medicine places emphasis on symptom management and the goals of care, not only at the end of life but also in the treatment of serious illnesses. An exclusively palliative approach is ethically justified when fully aggressive therapy might be intolerable or futile, but the use of early concurrent palliative care can also be beneficial for patients with metastatic cancer or cancer with high symptom burden who are still receiving aggressive anticancer therapy.

Case Study

A 92-year-old woman presented with stage IVA maxillary sinus cancer. She complained of sinus fullness and a painful 4-cm neck node. Radical radiation therapy to the primary and neck was recommended, and the patient underwent placement of a percutaneous gastric feeding tube and full

dental extraction. Midway through the course of treatment, the patient required a lengthy hospitalization for failure to thrive and severe mucositis.

In retrospect, a less aggressive course of radiation therapy intended to reduce the sinus and neck symptoms would have likely been a better choice for this patient, who was frail and unable to withstand intense treatment. Palliative medicine pays careful attention to a patient's individual needs, quality of life, and a discussion of goals of care. A recent randomized study demonstrated improved quality of life and overall survival when palliative care was given early alongside standard cancer treatment for metastatic lung cancer.[60] In many cases, aggressive symptom management and good communication among patient, family, and provider may result in better quality and, perhaps, quantity of life than would antineoplastic therapy that has little expectation of efficacy but significant risk of morbidity.[61]

ETHICS AND MEDICAL ERRORS

Soon after the discovery of x-rays by Wilhelm Röntgen more than 100 years ago, the first cases of malpractice involving the clinical use of radiation therapy were tried in the U.S. court system.[62] During the early 20th century, severe dermatitis was a frequent plaintiff's complaint—not surprising in view of the physical limitations of the low-energy machines available at the time.

In 1999, the Institute of Medicine published a report on medical errors, elevating the level of public awareness and stimulating inquiry into this topic.[63] One recent study has suggested that medical errors might be the third leading cause of death in the United States.[64]

Physicians are often reluctant to discuss errors. It has been suggested that doctors and patients "harbor deep within themselves the expectation that the physician will be perfect."[65] Other reasons for reticence include uncertainty about whether an event really is an error, concern for the patient's well-being, and fear of litigation.[66] To thread this needle and allow for sincere apologies and expressions of remorse that are not recorded as evidence of negligence, error, or malpractice, many states have enacted the so-called "apology laws," in which expressions of sympathy are inadmissible as evidence of liability in civil court.[67] As of 2021, 39 states, DC, and Guam have such provisions within their state laws.[68]

If a patient has an undesirable treatment outcome, careful review of the case can help distinguish error from untoward but unsurprising occurrence. For example, severe pneumonitis after breast radiation therapy is uncommon, but not necessarily proof of negligence. Concern that disclosing an error causes a patient undue anxiety is contradicted by studies revealing that patients prefer physicians to acknowledge errors[69] and that they might even sue for lack of apology.[70] In cases of alleged or suspected error leading to injury, the institutional risk management service should usually be contacted for advice. However, fear of litigation should be mitigated by the fact that a low overall percentage of patients who suffer negligent injuries actually file malpractice claims.[66] Indeed, Studdert et al[71] demonstrate just how imperfect a vehicle American tort law is to compensate for medical error. In their review of 1,452 closed claims, 3% had no injury and 37% did not involve errors. These with no errors accounted for 13% to 16% of the cost of the entire malpractice system. In contrast, 27% of claims involving injury due to actual error did not receive any compensation. Within radiation oncology, a study examining all cases between 1985 and 2015 found 32 results. The two most common causes of action were excessive radiation (34%) and failure to refer/order appropriate tests (28%). Thirty-four percent of cases resulted in a judgment for the plaintiff (mean amount $4.7 million) and 13% resulted in a settlement (mean amount $1.5 million).[72]

Nondisclosure of error can weaken the trust at the core of the patient-physician relationship. The argument for disclosure is especially strong when there is a specific preventive intervention that might lessen the severity of possible future injury. Nevertheless, the question still remains: Are physicians ethically obliged to disclose an error, even if there is no immediate harm to the patient?

Case Study

A patient with T3N1M0 squamous cell carcinoma of the left retromolar trigone received concurrent cisplatin plus IMRT to the gross disease, with elective coverage of adjacent nodal echelons. The intent was to give 54 Gy to adjacent uninvolved lymph nodes at a rate of 1.8 Gy/day and 66 Gy to the gross disease at a rate of 2.2 Gy/day using a simultaneous integrated

boost technique, with all treatment completed in 30 fractions. After the spinal cord was contoured as an organ at risk, the structure was inadvertently deleted on all planning computed tomography slices below the level of the gross disease. As a result, when the IMRT inverse planning software optimized the dose distribution according to the constraint of limiting the maximum dose to the spinal cord to 50 Gy, the entire cross section of a 6-cm length of cervical spinal cord received the full prescription dose. The error was not detected until 1 week after the patient completed treatment, during a routine quality assurance check.

In this example, no injury has yet occurred, but the patient is at increased risk for radiation myelitis. Although there is currently no available proven preventive measure, if the escalated risk of myelitis is unknown to the patient, they might later undergo misguided management by another physician if symptoms develop. For instance, if the patient develops arm and leg weakness, a magnetic resonance imaging scan showing nonspecific enhancement and edema in the cervical spinal cord might be interpreted as evidence of metastatic intramedullary or epidural tumor rather than radiation change. Unaware of the prior treatment error, the patient would be unable to inform the other physician involved about the high risk for radiation injury. As a result, the patient might be given only minimal supportive care on the assumption of incurable recurrent disease rather than appropriate efforts toward rehabilitation.

Evans and Decker[73] have offered practical suggestions on how to address the issue of a medical error in radiation oncology once the event has been recognized. They advise disclosure for any errors that result in a perceptible clinical effect, change in diagnosis or treatment course, or a chance of future harm. Their two-phase response recommendation involves initial attention to the patient's immediate needs and an apology that avoids giving an impression of defensiveness. Later, after a more thorough analysis of the situation has been completed with the involvement of the hospital's risk management team, a carefully prepared discussion with the patient and other interested parties can occur.

Toward the goal of fostering a culture of safety across the field of radiation oncology and facilitating the identification of preventable systematic errors with different treatment delivery platforms, ASTRO and the American Association of Physicists in Medicine have created a national

Radiation Oncology Incident Learning System.[74] This program allows for anonymous, privacy-protected self-reporting of incidents and near misses. The information can be used locally to inform root cause analysis projects that identify ways of improving patient safety. Industrial engineering–based principles for minimizing errors in a busy radiation oncology clinic are now becoming widely implemented, and entire texts devoted to this topic are available.[75,76]

CONCLUSION

Society's view concerning medical ethics has shifted over time to adapt to the forces of advancing knowledge. Ethical guidelines have sometimes been constructed as formal documents or mandated as law, but no single system comprehensively predicts and resolves all situational dilemmas. The core principles of medical ethics remain essential foundations for the practice of medicine.

CHAPTER 37

Health Economics and Health Policy

P. Travis Courtney, Ann C. Raldow, Eric M. Chang, and Michael L. Steinberg

The 21st century has been marked by a continued increase in health expenditure in the United States, estimated at 16.7% of the country's gross domestic product (GDP) in 2019 and increased to 18.8% in 2020 during the COVID-19 pandemic followed by a decrease to 17.4% in 2021—the highest ranked in data collected from the Organization for Economic Co-operation and Development (OECD) member countries and nearly twice the OECD average[1] (Figure 37.1). Furthermore, national health spending is only expected to continue its rise in the coming years, with the Centers for Medicare & Medicaid Services (CMS) National Health Expenditures projecting health spending to grow 0.8% points faster than GDP per year over the 2022 to 2031 period, amounting to 19.6% share of GDP by 2031.[2] The cost of cancer care is escalating precipitously, estimated at $24.7 billion in 1987 (in 2007 U.S. dollars) versus $48.1 billion in the 2001 to 2005 period.[3] Although the double-digit growth rates in U.S. cancer expenditures observed prior to the Great Recession began to decline substantially in 2007, associated costs of cancer care are still projected to rise from $183 billion to $246 billion from 2015 to 2030 (in 2020 U.S. dollars), assuming constant incidence, survival, and cost.[4-6]

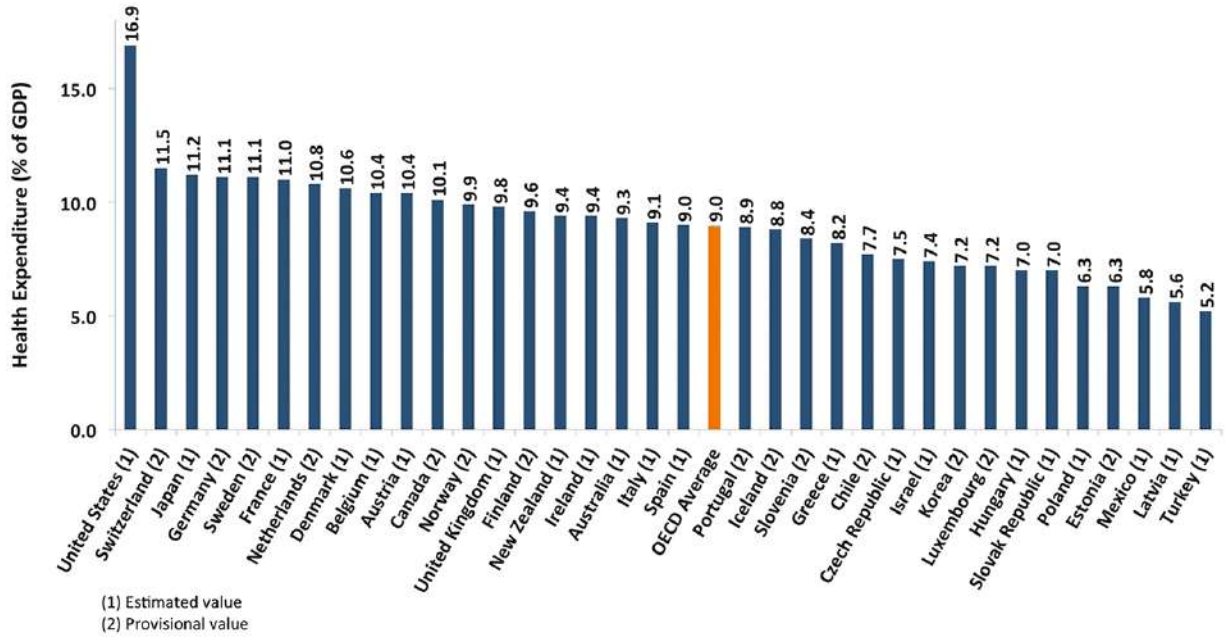

FIGURE 37.1 Health expenditure expressed as a percentage of gross domestic product (GDP) among the Organization for Economic Co-operation and Development (OECD) member countries. (OECD Health Statistics 2021.)

Many factors contribute to this rise in costs, including aging of the population, with anticipated increases in both the number and percentage of older patients and commensurate increases in new diagnoses, magnified by persistence of risk-increasing behaviors and earlier diagnoses via improved cancer screening.[7,8] These demographic factors warrant discussion regarding the allocation and prioritization of resources. Yet, the increasing cost to the individual patient merits further consideration as well. Driven partly by innovation—new advances in systemic therapies, radiotherapy (RT) techniques, surgical devices, and diagnostic tools—these investments pose a particular dilemma, as efforts to cut costs would potentially slow the development of lifesaving medications and technologies. However, in the setting of limited resources, these rising costs are not benign. In 2018, roughly 43% of expenditures in cancer care were publicly funded (33% by Medicare and 10% by Medicaid), and by 2030, more than 70% of cancer diagnoses will be made in persons eligible for Medicare.[7,9,10] Thus, from a societal perspective, we must consider whether our expenditure in cancer care is reasonable when balanced with other priorities in medical care and other areas. Furthermore, substantial out-of-pocket costs directly impact

patients' ability to access medical care and to afford other nonmedical life necessities, with having insurance often not enough to protect patients from the impact of the high costs of treatment.[11] Estimates by the Congressional Budget Office indicate that aging explains less than half of the estimated increase in spending for major health care programs as a share of GDP from 2016 to 2046, with most resulting from rising health care costs per person—indicating that these challenging questions and the need for the transformation of health care delivery will not go away.[12]

In this setting of mounting health care costs, interest in health policy and health economics has flourished in the past decades. Broadly, health policy as a discipline encompasses questions of access, cost, and quality of health care.[13] As a function of health policy, health economics addresses difficult questions regarding the appropriate and efficient allocation of resources in the health care setting as well as the behavior of stakeholders in the face of competing choices for financial resources. In his seminal article, "Uncertainty and the welfare economics of medical care," Kenneth Arrow, often credited with the birth of health care economics, distinguishes between health and other goods, noting that health care, in contrast with other goods and the free market ideal, is marked by uncertainty on behalf of the patient in evaluating the quality of care provided by their physician, leading to asymmetric information.[14] Physicians, serving as agents for their patients, are expected to act in their patients' best interests, though this system, based on trust, permits for misaligned incentives. Moreover, health care is awash in externalities or costs and benefits externally imposed by the purchaser on others not party to the transaction. Given these notable exceptions, it is imperative that health policy ensures symmetric access to quality health care. As defined by Steinberg, ideal health policy should ensure (1) that all patients get all necessary care, (2) that equivocal and nonindicated treatment be excluded, (3) that cost of care be socially responsible, (4) that variation in the quality of care be so small from a technical perspective that does not matter from which facility or provider a patient receives treatment, and (5) that when competition occurs, it should be over the quality of the art of care, such as how patient centered it is and how well staff and physicians communicate with patients.[13]

Radiation oncology, in particular, has been labeled as an outlier in its contribution to health care spending and as such has often been targeted in

policy discussions. Though Medicare's sustainable growth rate (SGR) formula for physician payment was permanently repealed in April 2015, radiation oncology was notable for exceeding its SGR target over the 2003 to 2009 period by nearly 300% expressed as a percentage of 2002 expenditure.[15,16] Between 2000 and 2009, the total Medicare expenditures for external beam RT increased from $256 million to $1.08 billion, mainly owing to reimbursement for intensity-modulated radiation therapy (IMRT).[17] In addition, the code for IMRT demonstrated the fourth highest percent increase of all Medicare codes between 2010 and 2011.[18] However, these disproportionate expenditures subsequently plateaued and even decreased in the following years.[19,20] It should also be noted that although approximately 30% to 50% of all patients diagnosed with cancer will receive some form of RT during their disease course,[21-23] radiation oncology represents only a small percentage of total Medicare spending. In 2017, radiation oncology accounted for just 1.4% of total charges allowed by Medicare, which was generally stable from 2002 (1.2%) and 2012 (1.6%).[19] For comparison, the percentage of Medicare spending on hematology/medical oncology increased from 5.6% to 6.5% in that same time period. A similar pattern was seen in Medicare payments for care at the end of life, in which the average payments per beneficiary between 2016 and 2019 for radiation oncology decreased by approximately 2%, whereas for medical oncology, average payments increased by more than 32%.[24] Furthermore, in 2020, CMS reported that the total spending for radiation oncology services was about $2 billion dollars less than Medicare Part B spending on just three drugs (Rituxan, Opdivo, and Keytruda) that were used in less than half of the number of beneficiaries.[25,26] Despite these trends, the specialty remains the subject of spending scrutiny and has experienced a decline in average Medicare reimbursements of more than 20% over the past decade.[27-29]

Although there are likely multiple underlying causes for the field's disparate, albeit stabilizing and perhaps overstated, contributions to health care spending, including the employment of advanced technologies and the complex teams required for their safe and effective use, they were at least in part secondary to our primarily resource-based payment system, in which hospitals and clinics are reimbursed for discrete elements of care.[30] In this system, there is incentive to maximize billable units, such as by using

advanced treatment modalities when not clinically indicated and by dividing dose over an increased number of fractions—all facilitated by the technological and complex nature of radiation oncology. This engenders further inefficiency as payers invest in the creation of guidelines to restrict payments and providers in turn require significant resources to guarantee appropriate billing. Although radiation oncology's role as a beneficiary of this system could be interpreted as cause for blame, it may also be seen as a charge for leadership by the field in health care reform discussions and in the development and use of modern methods for assessing quality of care and the comparative effectiveness of various treatment modalities.

RT plays a fundamental role in the curative and palliative treatment of cancer. Its continued value in cancer care will depend on the advancement of not only clinical evidence but also health services research. Toward this end, this chapter provides an overview of the value proposition in health care as it relates to radiation oncology, with a focus on modern methods for assessing comparative and cost-effectiveness, including decision analysis and cost-effectiveness analysis. These techniques provide an alternative method for approaching clinical questions not readily answered with standard data analyses and aim to maximize the value of each health care dollar spent. Thus, understanding their employ will be of importance in the establishment of the value of RT in health policy discussions moving forward.

VALUE IN RADIATION ONCOLOGY

Remarkable advances in RT have been made in the past decades, allowing for extraordinary precision in treatment delivery and the attainment of dose escalation paired with decreased morbidity to surrounding normal tissues. In particular, IMRT achieves highly conformal dose distributions using computer-based treatment planning and delivery. The advent of stereotactic body radiation therapy (SBRT) has further provided the ability to deliver large doses of radiation with extreme precision using complex methods of patient immobilization and tumor localization, at times supplanting or offering an alternative definitive treatment to surgery in multiple disease sites. An emerging technology, magnetic resonance imaging (MRI)-guided RT, allows for enhanced soft tissue resolution, beam-on gating, and real-

time online adaptive RT, further enabling the precise delivery of higher doses of radiation safely. Coupled with RT, concomitant advances in oncologic surgery, medical oncology, and diagnostic testing have ushered in an era of personalized medicine, with the promise of more effective, tailored therapy with reduced toxicity. However, historically in cancer care, as in most fields of medicine, doing more for patients has not always equated to improved outcomes. Rising health care spending has not necessarily met with a proportional improvement in outcomes, with the United States ranking 15th out of 42 OECD countries in mortality from cancer per 100,000 persons in 2018 to 2021, despite recent calls for an increased focus on "high-value care" by policy makers, providers, professional societies, payers, and patient groups in the context of health care reform.[31-33] The value proposition in health care is not merely an exercise in cost containment, but it also strives toward a delivery system that incentivizes high-quality, evidence-based, and cost-effective treatments.[34] In this section, we discuss the value proposition as it applies to the specialty of radiation oncology, describing current challenges and future directions in the advancement toward value-based care. Given the many stakeholders involved, it is important to note that the patient's voice is a highly valued component of value-based health care delivery. We, therefore, address these issues with a focus on the patient perspective of high-value care.

Defining Value

To discuss value and the metrics used to measure it, we must first establish a mutual understanding of what is meant by the term *value*.[34] Outside the world of health care, a "good value" can be described as a desirable product or service that can be purchased for a fair price.[35] Definitions of *value* from the Merriam-Webster dictionary center on the fair return in goods, services, or money for something exchanged, with clear parallels in the definition of value as it applies to medicine in terms of relative worth, cost, and quality of care.[36] These issues are reflected in the definitions of value as put forth by multiple governing bodies in health care from around the world, including the European Observatory on Health Systems and Policies, which describes value to include "patient preferences, quality, equity, efficiency,

and product acceptability among a wide range of stakeholders," and the United Kingdom's National Institute for Health and Clinical Excellence (NICE), which defines value as "based on scientific value judgments, including clinical evaluation and an economic evaluation, and social value judgments, including considerations of efficiency and effectiveness."[37,38]

The Value Equation

To unify the often-conflicting goals of the numerous stakeholders in health care delivery, Michael Porter and Elizabeth Olmsted Teisberg established a working definition of value in health care as health outcomes achieved per dollar spent (value = outcomes/cost).[39,40] Outcomes in this equation are specified to include both near-term and longer term health in order to cover the ultimate results of care and are noted to be condition specific and multitiered, with adequate measurement of risk factors and baseline condition to enable for risk adjustment. Costs are defined to include the total costs of the complete cycle of care as opposed to individual services; as Porter notes, narrowly targeted cost containment efforts may not maximize value for the patient, with at times the best approach to increasing value being spending more on some services to reduce the need for others.[40] As both outcomes and costs are dependent on results as opposed to inputs, the challenge in value-based care is to shift focus away from the volume of services as is typical in traditional fee-for-service systems. As described by Porter, "value should always be defined around the customer, and … the creation of value for patients should determine the rewards for all other actors in the system."[40] Recognizing the importance of the patient in the value proposition, Teckie and colleagues, in setting forth a framework for value in the field of radiation oncology, further expanded the numerator toward a more comprehensive definition of quality to include structure and process along with outcomes, in line with the classic Donabedian model[35,41] (Figure 37.2). The Donabedian model is a conceptual framework for evaluating the quality of medical care, in which assessments are drawn from three dimensions of care: structure, process, and outcomes. Structure encompasses the context in which care is delivered, including the physical facility, human resources, organizational characteristics, and, of particular importance in radiation oncology, the equipment and technology. Process

includes all acts of health care delivery, including interactions between the patient and physician and the technical delivery of care. In the Donabedian model, outcomes include not just objective measures, such as survival and functional status, but also subjective measures, such as quality of life and patient satisfaction. By this expanded framework (value = quality/cost), efforts to improve structure, process, and outcomes can all be seen as strides toward improving value.

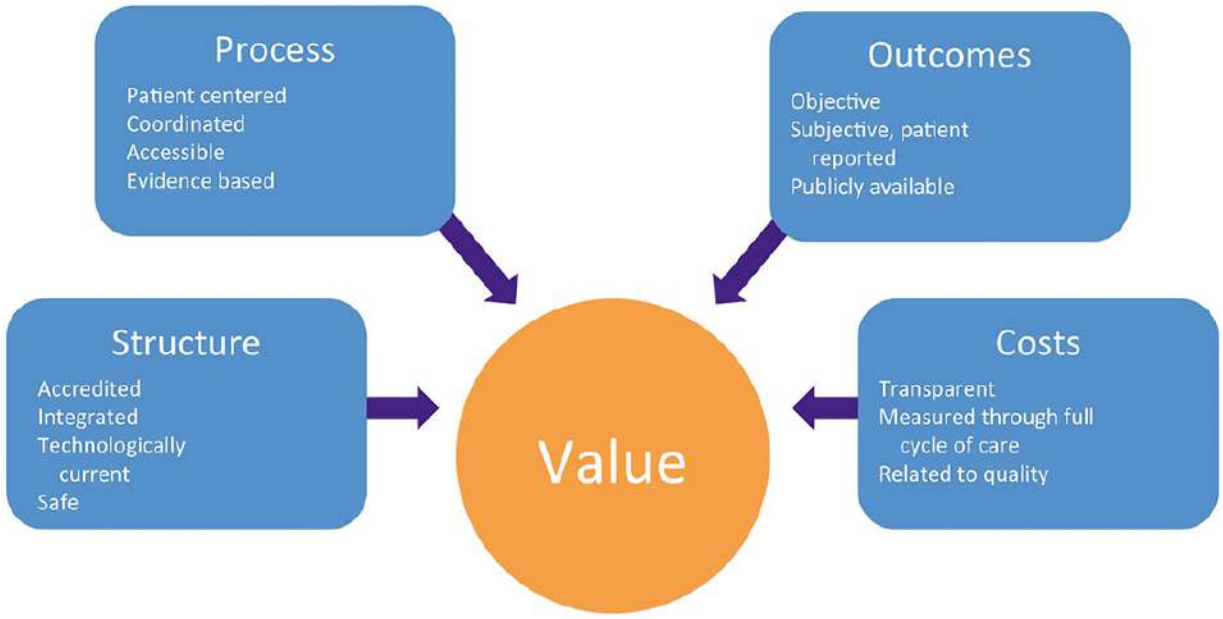

FIGURE 37.2 Components of value as defined by Teckie and colleagues, adapted from the Porter equation including elements from the Donabedian model. Structure

Donabedian defines structure as "concerned with such things as the adequacy of facilities and equipment; the qualifications of medical staff and their organization; the administrative structure and operations of programs and institutions providing care; fiscal organization and the like."[41] Radiation oncology, as a field, continues to become increasingly complex, with advances in treatment modalities involving multifaceted structural elements requiring multidisciplinary teams and state-of-the-art technology for adequate delivery. This complexity has allowed for wide variation in

structural practices. Although at times this variation is indicated based on an individual patient's needs, critics have noted that deviations may not be associated with increased quality of care, with an opportunity for enhancement of value via standardization.[8] In 2010, the American Society for Radiation Oncology (ASTRO) convened a total of 12 multidisciplinary societies to develop a guidance document describing the elements necessary for the safe delivery of RT. This document, entitled "Safety is No Accident," was published in 2012 and updated in 2019, and sets forth specific requirements for a radiation oncology facility in terms of structure, personnel, and technical process.[42] In 2014, in an effort to expand adoption of these principles and further unify variations in care delivery, ASTRO launched the Accreditation Program for Excellence (APEx), which provides impartial third-party review of practices' personnel, equipment, treatment planning, medical records, patient safety policies, and quality control/quality assessment activities against an established set of performance standards with focus on structure and process elements.[43] Radiation oncology practices (including freestanding single facilities, multisite organizations, and practices that are part of a hospital facility) that apply undergo a process of self-assessment and third-party review against a set of 16 established standards with accreditation granted for 3- or 4-year cycles. The Commission on Cancer and the National Accreditation Program for Breast Centers both accept APEx accreditation as fulfilling the RT component of their accreditation programs, and the U.S. Department of Veterans Affairs (VA) not only accepts APEx as an accrediting body for community-based facilities that treat veterans in the absence of a VA medical center but also awarded APEx a contract to accredit its 41 VA facilities providing radiation oncology services.[44,45] Since its inception, the number of participants has steadily grown. As of February 2025, 406 facilities have obtained APEx practice accreditation, and more are undergoing the painstaking application and accreditation process.[46] Accreditation ideally demonstrates achievement of a threshold level of quality and safety to referring physicians, peers, prospective patients, regulatory agencies, and payers. However, it remains to be seen whether these various stakeholders value accreditation or understand what the evaluation process involves. Moreover, without appropriate economic

incentives to pursue and maintain accreditation, it is unclear how many radiation oncology practices will ultimately elect to participate.

In addition, in 2014, ASTRO and the American Association of Physicists in Medicine (AAPM) launched the Radiation Oncology Incident Learning System (RO-ILS) to further promote safety and quality of care.[47] This system, in which more than 750 facilities in the United States currently participate, establishes a web-based national database of radiation oncology safety incidents. Participating facilities can share events in a secure, nonpunitive environment, which allows for tracking of incidents as well as shared learning for both individual facilities and the field as a whole. The RO-ILS program is free to join because it is supported financially by multiple organizations, including ASTRO, AAPM, the American Society of Radiologic Technologists, and the American Association of Medical Dosimetrists.

Radiation Oncology Equipment Approval

Radiation oncology equipment, such as a linear accelerator, is considered a medical device according to U.S. Food and Drug Administration (FDA) definitions,[48] and thus, its FDA approval process is considerably different than that of medications. The regulatory body overseeing this process is the Centers for Devices and Radiological Health (CDRH), which was established in 1982 under the FDA to ensure the safety and efficacy of medical devices.[49] Medical devices are divided into three classes: Class I devices are low risk, such as stethoscopes or bandages; class II devices are intermediate risk, such as computed tomography (CT) scanners or infusion pumps; and class III devices are high risk and important to supporting health and life, such as pacemakers or artificial heart valves.[50] The majority of radiation oncology equipment is considered class II devices.

The initial steps of obtaining CDRH approval to introduce a new medical device into the market typically include submission of a 510(k) application, which attests that the proposed device is as safe and effective, or "substantially equivalent," to a U.S. legally marketed predicate device.[51,52] A new medical device is considered "substantially equivalent" to the predicate device if the new device has the same intended use and technological characteristics as the predicate device, although a device with

different technological characteristics is considered substantially equivalent if it does not raise questions of safety and efficacy, and data submitted to the CDRH demonstrate that the new device is as safe and effective as the predicate device. As opposed to class III devices, class II devices do not require additional applications beyond the 510(k) to be introduced into the market, such as a Premarket Approval Application that often requires a premarket clinical trial of the proposed device under an Investigational Device Exemption. As such, using the 510k process, the vast majority of new radiation oncology technology does not require a clinical trial showing safety and efficacy prior to being FDA approved. This both reduces the time (510[k] approvals are determined by the CDRH within 90 days) and expenses required to bring new or updated radiation oncology equipment into the market, thereby encouraging continuous innovation and improvement of existing devices, although at times the "improvements" are only incremental.

Despite these potential benefits for the introduction of new medical devices, specifically in radiation oncology systems, concerns have been raised about this process.[53] The data used by the CDRH to evaluate a device's safety and efficacy are solely provided by the device manufacturer, who is understandably incentivized to obtain device approval. In addition, because of the FDA Modernization Act in 1997, the CDRH may outsource 510(k) reviews to third parties,[54] which often have insufficient expertise and/or time to conduct thorough reviews.[55] Furthermore, a 510(k) application is not required for modifications of an already approved device so long as it is not "significantly changed or modified in design, components, method of manufacture, or intended use,"[56] though this decision is also made by the manufacturer. Over time, sequential minor updates to a device can result in the newest version of the device being significantly different from the original predicate device, an effect known as "predicate creep."[57] Consequently, this introduces the possibility for device error and adverse safety events, especially in radiation oncology where new technology is exceedingly complex compared with former versions. As a result, the FDA announced three draft guidances in September 2023 related to the 510(k) process to improve its predictability, consistency, and transparency.[58] Ultimately for the medical device–approval process, a balance must be struck between a timely, relatively inexpensive process that

promotes innovation with thoroughness and appropriate regulatory oversight to ensure the safety and efficacy of the new devices being introduced to the market. Separately, as discussed later, FDA approval of radiation oncology equipment does not guarantee insurance coverage for the new process of care related to a new device, introducing yet another layer of complexity to regulatory processes surrounding radiation oncology device development.

Third-Party Payers

After a new medical device is granted FDA/CDRH approval, its manufacturers may apply for creation of a new Current Procedural Terminology (CPT) code for the service or procedure associated with the device so that it can be incorporated health care payment delivery system. The CPT coding system is managed by the American Medical Association (AMA),[59] and both CMS and commercial insurance companies use this system for the nomenclature used for reimbursement.[60] CPT codes are divided into three categories.[61] Category I CPT codes refer to services and procedures used in routine clinical care. There are several criteria that must be fulfilled for a device to be assigned a category I CPT code, including receipt of FDA approval, distinctness from existing CPT codes, widespread and clinically appropriate consistent use by many physicians across the United States, and demonstration of clinical efficacy in the literature.[62] After obtaining a category I CPT code, the procedure or service is then evaluated by the AMA/Specialty Society Relative Value Scale Update Committee, who determines its valuation in the CMS fee schedule based on the physician work and practice expenses associated with the procedure or service. Category II codes are supplemental codes used only for performance and quality measurement. Category III codes are temporary codes assigned to emerging technology that currently does not meet the criteria for a category I code. Although initially and primarily used for data collection purposes, category III codes may occasionally be used for the payment of the new procedure or service if local Medicare carriers see fit to assign a value and elect payment.

The determination of reimbursement for a new medical device and its associated service or procedure is, therefore, intimately tied to obtaining a

CPT code, and subsequent valuation by CMS is obtained through a complex policy process. Over the years, the level of evidence required for assignment of a category I CPT code has been raised, which has posed challenges for radiation oncology device manufacturers as it is often difficult to initially generate a substantial body of clinical data supporting a new technology because of the high upfront costs associated with radiation oncology technology development and the lack of vendor-based clinical trial infrastructure needed to run evidence producing trials. Even more complicating is that the evidence standards that must be met to obtain category I approval are open to interpretation by various parties in the approval process.[60] Given the challenges surrounding the process of incorporating new medical technology into the health care payment system, particularly in the context of ever-growing U.S. health care spending, health technology assessments (HTAs) have been proposed as a mechanism to improve this process. HTAs provide a framework to systematically and comprehensively assess a new device's impact on the health care system through a variety of data and stakeholder lenses to inform policymaking.[52,63] The data analyzed in an HTA include clinical efficacy and safety outcomes such as progression-free survival and toxicity as well as the cost-benefit and overall economic impact, or in the context of the current chapter, the value proposition, of a new device. It should be noted, however, that the criteria for obtaining a CPT code do not include cost or economic considerations, and this process is thus unable to fully engage the value equation described in earlier sections when evaluating new devices. More broadly, there is a dearth of single, national HTA bodies both in the United States and globally,[63,64] although organizations within the United States, such as the Institute for Clinical and Economic Review, were created to address these concerns and work with major public and private payers to inform coverage criteria.[65] Examples of nationalized HTA programs include the Institute for Quality and Efficiency in Health Care in Germany and the NICE in England and Wales.[66] Going forward, emphasis will continue to be placed on the implementation and uniformization of HTAs in order to address rising health care costs in the United States.

Integration of Care

In the traditional organizational structure of medical care, delivery of care is siloed according to separate medical specialties or departments. However, in the past decades, there has been a shift toward medical practices centered around the patients' perspective of their medical condition integrated across the continuum of care; additionally falling under the realm of structure, this strategy has received attention for promoting high-value care.[67] In the integrated practice unit model, clinical and nonclinical personnel deliver care according to evidence-based care pathways and treatment directives with responsibility for the full cycle of care, including inpatient, outpatient, rehabilitative care, and supporting services, such as nutrition and social work. Importantly, the team measures outcomes, costs, and processes for each patient with feedback mechanisms for refinement of care delivery, economic efficiency, and patient convenience, all relevant to the value proposition. This integration promotes value not only by limiting overuse of tests and procedures but also by increasing use of patient-centered shared decision-making. Specific to oncology, the multidisciplinary clinic model centers a team of multiple specialties, including medical oncologists, radiation oncologists, radiologists, surgical oncologists, and pharmacists, around a specific tumor site.[68] While requiring significant reorganization and reassessment of traditional interactions between subspecialists and ancillary staff, adaptation of these models has been successful at many high-volume centers, with suggestion of both improved outcomes and reduced costs compared to similar community groups.[69,70] For instance, comparison of a consecutive sample of 104 patients with melanoma with localized disease treated in the Michigan community with 104 blindly selected patients treated at the University of Michigan Multidisciplinary Melanoma Clinic during an identical time period matched for Breslow depth and melanoma body site indicated cost savings of $1,600 per patient for patients treated in the multidisciplinary clinic.[69] Via coordination between multiple specialties in complex decision-making, the multidisciplinary model may allow for higher attainment of benchmark measures for quality care in accordance with national practice guidelines. For example, a study of 609 patients with nonmetastatic breast cancer treated in the University of California, Los Angeles, multidisciplinary breast clinic indicated increased appropriate referral rates for genetic testing for family history–based (62% vs 92%) and overall (80% vs 96%) indications

after the inclusion of a genetic counselor in the multidisciplinary clinic.[71] Although limited primarily to observational studies because of difficulty in recruiting patients from practices in which the multidisciplinary model is not standard of care and confounded by parallel improvements in therapies, multiple studies have demonstrated potentially increased survival in patients treated in the multidisciplinary care setting.[72-74] Variations of care for complex patients and for those from underserved backgrounds or rural areas would ideally be minimized in the multidisciplinary setting,[75] and indeed, a study evaluating the impact of a pancreatic cancer multidisciplinary clinic found that disparities in treatment recommendations, surgical outcomes, and overall survival between low and high socioeconomic status patients were eliminated among patients managed within a multidisciplinary care clinic.[76] Cancer learning networks, such as the Canopy Cancer Collective for pancreatic cancer,[77] seek to further improve patient care integration by establishing a network of health care systems in which patient care can be more easily coordinated, while also allowing for the sharing of data and best practices among the involved organizations to improve patient experiences and outcomes.

Alternative Payment Models

Newer coverage models, under the umbrella of the Donabedian definition of structure, offer an opportunity to incentivize value by linking reimbursement to quality metrics as well as encouraging patients to select high-value centers or providers. Traditional fee-for-service reimbursement, in linking payment to the volume of services provided, has been criticized for incentivizing overutilization of care, often without proportionate benefit. The technological focus of radiation oncology, in particular, allows for a surplus of discrete billable units per treatment episode.[30] Pure prospective payment, proposed as an alternative to the traditional fee-for-service payment, reimburses providers a fixed amount independent of the volume of services provided, with the aim of promoting efficiency via incentivizing providers away from costly treatments.[78] However, by shifting the marginal cost of care—and associated financial risk—to providers, pure prospective payment may incentivize providers to select patients with lower risk of complications (“cherry picking”), to provide less care than would best treat

the patient ("stinting on care"), and to avoid treating patients whose optimal treatment involves costly interventions.[78] Thus, the ideal reimbursement system would fall in between these two extremes, with payment linked to value while still allowing for evenly distributed access to high-quality care.[79]

Unfortunately, even with an established definition of value, deriving applicable metrics for quantifying value in oncology remains elusive. Although there are widely accepted measurements of outcomes (eg, prostate-specific antigen progression-free survival in prostate cancer) and toxicities associated with treatment (eg, the Common Terminology Criteria for Adverse Events [CTCAE]), adequately assessing these metrics may require multiple years of follow-up, impractical for adaptation to a reasonable payment cycle. Likewise, it is often difficult to assess whether adverse effects are the result of surgery, chemotherapy, radiation, or something unrelated to treatment.[30] As noted before, linking payment to outcomes metrics without accurate risk adjustment algorithms could also discourage providers from treating sicker patients. Along with this, the rapidly and continually advancing nature of the field makes it challenging to maintain adequate yet up-to-date quality metrics.[80] In the field of medical oncology, the American Society of Clinical Oncology (ASCO), the European Society for Medical Oncology, and other national guidelines organizations have put forth frameworks for the evaluation of value, with notable overlap in their attempts to quantify the gradients of benefit associated with drug regimens, toxicity, and quality of life, though formal cost-effectiveness analyses are deemphasized.[81,82] Radiation oncology has been late in the development of its own value metrics, with many measures of quality advanced through more broadly focused organizations. In parallel with the efforts of the AMA Physicians Consortium for Performance Improvement and other similar organizations to develop, implement, and validate quality metrics, the National Quality Forum (NQF)[83] was funded by Congress with the aim of evaluating quality measures for transmission to the CMS for inclusion in eventual value-based penalties and bonuses. ASTRO endeavored to establish a series of best practice guidelines based on evidence and expert review in conjunction with the NQF, such as documentation of pain intensity and care plan and avoidance of overuse of bone scan for staging for low-risk prostate cancer.[84] However, in February

2023, CMS completed a competitive process to determine the entity responsible for the establishment and maintenance of quality measures and did not award the NQF this next phase of work. ASTRO has also worked with the Department of Veterans Affairs National Radiation Oncology Program to develop consensus quality measures in five cancer sites: lung, prostate, rectal, breast, and head and neck.[84,85] These guidelines include a variety of quality measures throughout the radiation oncology care process. For example, documentation of performance status and prior radiation status during the consultation and workup process; ensuring 14 days from simulation to treatment start and peer review of treatment plans during the simulation, planning, and treatment process; and completion of treatment summary during the follow-up process. In addition, in 2013, ASTRO determined a list of five interventions to only be used in specific situations because of proven lack of value as part of the American Board of Internal Medicine Foundation's *Choosing Wisely* initiative[86] (Figure 37.3), and proposed an additional five recommendations the following year.[87] Publication of these guidelines had a variable impact on the practice patterns they sought to address.[88-91] Although admirable steps toward the value proposition, early quality indicators have been criticized for representing little more than enforcers of current standard of care, with persistence of many low-bar measures such as documentation of stage of disease or presence of normal tissue dose constraints, which may or may not directly relate to the actual quality of care. These measures are further debilitated by minimal correlation with reimbursement, without tracking by payers or accrediting bodies, thus effectively having limited impact on patients or society with a call to focus metrics on true gaps in care.[92] Furthermore, care must be taken to ensure adherence to guidelines does not limit patients whose unique clinical situations call for individualized care, slow clinically meaningful advancement if innovation outpaces updates to guidelines, or inadvertently penalize hospitals caring for disadvantaged populations.[30,93]

1	Don't initiate whole-breast radiotherapy as a part of breast conservation therapy in women age ≥50 with early-stage invasive breast cancer without considering shorter treatment schedules.
2	Don't initiate management of low-risk prostate cancer without discussing active surveillance.
3	Don't routinely use extended fractionation schemes (>10 fractions) for palliation of bone metastases.
4	Don't routinely recommend proton beam therapy for prostate cancer outside of a prospective clinical trial or registry.
5	Don't routinely use intensity-modulated radiotherapy (IMRT) to deliver whole-breast radiotherapy as part of breast conservation therapy.

FIGURE 37.3 The American Society for Radiation Oncology's list of five radiation oncology–specific treatments that are commonly ordered but may not always be appropriate as part of the national American Board of Internal Medicine Foundation's *Choosing Wisely* campaign. (Reprinted from Hahn C, Kavanagh B, Bhatnagar A, et al. Choosing wisely: the American Society for Radiation Oncology's top 5 list. *Pract Radiat Oncol*. 2014;4[6]:349-355. With clear quality metrics still under development, payment reform thus far has mostly occurred in the form of narrow or tiered networks offered by health plans, often based on price or provider relationships with the larger market-dominant entity.[22] However, several alternative payment schemes, such as population-based shared savings arrangements, clinical pathways, and bundles of care and episodes of care payments, have been examined in oncology, accelerated by their inclusion in accountable care organizations (ACOs).[17] In population-based shared savings arrangements, providers are reimbursed via similar fee schedules though are rewarded when their fee-for-service payments are below a predefined target, often via the provider receiving a percentage of the savings. Despite the initial excitement surrounding implementation of these risk-sharing arrangements as elements of oncology-focused ACOs, the anticipated reductions in spending have not been realized.[94,95] It should also be noted that ACO implementation has primarily been within the field of medical oncology, and there is little data directly related to radiation oncology with regard to ACO incentivization. In the clinical pathway approach, best practices are established for each clinical scenario with providers rewarded for adherence with higher fee-for-service payments, bonuses, or other incentives. Providers are expected to adhere to pathways for 60% to 80% scenarios to allow for individualization

of care. This has demonstrated success in reducing treatment variation, drug trend, and hospitalizations in medical oncology; however, its application has been criticized as ill-suited to radiation oncology given the field's anatomic and technologic focus, which allows for potentially larger number of branch points in the decision-making process with a greater role for patient preference in the selection of treatment modality. Lastly, bundled or episodic payment has been described as a middle ground between fee-for-service and pure prospective payment, in which providers are reimbursed upfront based on the expected costs for a clinically defined episode of care, thereby incentivizing efficient use of resources. CMS has devoted significant focus to experiments in episodic payment systems, though with focus in oncology primarily on comprehensive bundles that include medical, surgical, and radiation services as well as the complications of care. Multiple companies have experimented with specialty-specific episodic bundles in radiation oncology with reported improvements in administrative efficiencies, though, in this model, attention to quality measurement will be necessary to ensure implementation actually yields higher value care without incentivizing providers away from high-risk populations. Likewise, to properly incentivize high-value care, bundled payment schemes will likely require context-specific models for different clinical scenarios as well as cost calculations based on updated RT codes that more accurately reflect the current clinical practice.[96]

In July 2015, Turning the Tide Against Cancer, an initiative convened by the American Association for Cancer Research, the Personalized Medicine Coalition, and Feinstein Kean Healthcare to identify policy solutions that will sustain medical innovation while addressing the issue of rising health care costs, held a roundtable consisting of a multidisciplinary group of stakeholders to review key considerations for oncology-focused alternative payment models.[97] Noting reliance on annually calculated spending benchmarks and only intermittently updated episode-of-care definitions, the panel highlighted the importance of having alternative payment models keep pace with emerging science via incentivizing adoption of innovative medicine and technologies that have the potential to improve patient outcomes and make health care more efficient. Toward this end, it stressed the avoidance of unintended barriers to patient access to novel therapies, particularly those that may be expensive in the short term but that may

result in savings in the long term. Given the trend toward more personalized medicine, the roundtable acknowledged that a critical step in this is the coverage of diagnostics that will enable identification of patients who respond best to targeted therapies and thus avoiding the cost of treating patients who will not benefit or will be harmed by adverse effects or delays in initiating more effective treatments. Likewise, the participants suggested that alternative payment models incentivize the physician's ability to appropriately tailor treatment to an individual patient's needs and preferences, furthermore noting that there is no one-size-fits-all model, with the impact of a payment system at times dependent on geographic region, practice characteristics, setting, and other factors. Finally, the panel indicated that alternative payment models should include mechanisms to encourage participation in clinical trials and ongoing postmarket clinical research. Given the potential for models to incentivize patients toward rigorous care protocols or clinical pathways, the panel indicated that care should be taken to make it financially feasible for practices to enroll patients and participate in clinical trials to support continued development of cancer treatment.

Radiation Oncology Alternative Payment Model. Given the concerns surrounding the fee-for-service model and prior history of rising radiation oncology expenditures without improvements in health care quality, Congress sought to create a radiation oncology alternative payment model (RO-APM) for Medicare payment for RT services in 2015.[98] The overall goal of the new model was to transition to a value-based payment system that emphasized high-quality care while also ensuring payment fairness and stability by changing from fee-for-service to prospective, episode-based (ie, bundled) payments based on the patient's cancer site. Payment was to be tied to quality through mechanisms including quality metric performance, clinical data reporting, and patient experience. Multiple stakeholders, including ASTRO, patient advocates, and other relevant interest groups, were going to work in conjunction with CMS to develop this new model; however, the proposed model was ultimately developed solely by CMS, and the associated groups were only able to make comments after the model was published. Moreover, there were several notable concerns with the model.[99] Although voluntary participation was initially proposed in 2017,

the final rule proposed mandatory participation of approximately 30% of all radiation oncologists in the country selected randomly by zip code, much to the dismay of ASTRO. Along with this, payment models were site of service neutral, and payment calculation methodology was flawed, complicated, and challenging for practices to implement. Notably, the implementation of these new burdensome administrative requirements was to take place during the COVID-19 pandemic. In addition, this new model created CMS spending savings through haphazard payment cuts and discount factors, estimated to be $250 million over 5 years, rather than prioritizing patient-centered, value-driven care that would reduce overutilization, among other benefits.

While one of the primary goals of the RO-APM model was to enhance quality of care by linking it to payment, the quality metrics included were limited with only four total: documenting a plan of care for pain, treatment summary communication, screening for depression and follow-up, and advance care planning. As acknowledged in a prior section, it has been difficult to develop quality indicators in radiation oncology, and as such, there exists a dearth of such metrics; however, it was felt that the quality metrics chosen for the RO-APM were not meaningful within radiation oncology and were possibly selected because they were easy to measure rather than reflective of actual quality of care. These metrics were primarily related to documentation, which is not necessarily indicative of higher quality of care, and in the case of depression screening, not generally a part of radiation oncology clinical care. On top of this, there were no relevant outcomes measures included. Other methods for incentivizing quality and value were not a part of this model that was supposedly designed to improve the existing insufficiencies in these areas. For example, missing were initiatives rewarding participation in standardized safety practices or programs, improving patient access and convenience by addressing disparities, or employing evidence-based hypofractionated treatment regimens.

Furthermore, the model did not account for the fact that radiation oncology is a highly technical and innovative field, which is continually evolving from a technologic standpoint. Although these advances are often associated with higher cost, they may also impart improved clinical outcomes. The RO-APM did not have a valid approach to incorporating

new technology into the payment schema. ASTRO, many other stakeholders, and politicians strongly opposed this model. Its implementation was indefinitely delayed by Congressional action in 2022.

In June 2023, ASTRO proposed the Radiation Oncology Case Rate (ROCR) program.[25,100] This model, similar to the CMS RO-APM, proposes a service site-neutral, cancer site-specific, episode- based payment model, with half of the payment being issued prospectively at the beginning of the radiation care process and the remaining half at the end of the treatment course or 90th day of the episode, whichever comes first. Payment is modality agnostic; however, proton therapy and brachytherapy are not included due to their lower utilization and unique cost structure, nor are newer technology and services, such as online adaptive RT. In addition, the ROCR APM seeks to address health care inequities and barriers to care by providing additional payments to facilities who incorporate a transportation screening question from the CMS Accountable Health Communities health-related social needs screening tool[101] into their clinical workflows. It also incentivizes quality through payments tied to accreditation by a credentialing body, such as APEx, and participation in patient safety practices, such as RO-ILS. This new model projects to save $212 million over 5 years. The ROCR model was introduced as bipartisan federal legislation in the U.S. Congress on May 15, 2024, and reintroduced on March 13, 2025 after the federal administration change.[102,103]

Process

Process includes all components of health care delivery, including both the technical processes in how health care is delivered and the interpersonal processes that describe the manner in which care is delivered, with a focus on patient-centered, accessible, and coordinated care.[41] As defined by Donabedian, process can be measured via review of medical records, interviews with patients and providers, and direct observation of health care visits with measurement intrinsically tied to metrics of quality. In a technologically focused specialty such as radiation oncology, the measurement of process goes beyond those components immediately noticeable by patients, such as the quality of the patient-physician interaction and the timeliness of care, to include less tangible components,

such as physician expertise and medical physics quality assurance oversight for treatment planning and delivery.[35] Thus, structural efforts to establish patient-centered and safety-focused process standards, such as the previously mentioned APEx accreditation program, are directly linked with process improvement. The Radiation Therapy Oncology Group (RTOG) cooperative group clinical trials, which specify treatment planning specifics such as contouring guidelines, dose constraints, and planning techniques as enforced by centralized review processes, are another example of process standardization, with evidence suggesting protocol deviations are associated with poorer outcomes.[35] In this light, ASTRO's previously mentioned best practice initiative, which establishes clinical practice guidelines based on the RAND/University of California, Los Angeles, appropriateness criteria, looks beyond defining guidelines to support the indication of radiation to include evidence-based and expert panel–devised assessment of the technical processes underlying the delivery of therapy.[104]

Physician Expertise

Regarding physician expertise, similar to surgical procedures, multiple studies have described the presence of a learning curve in the application of advanced radiation oncology techniques, including IMRT volume delineation, technical IMRT delivery, SBRT,[105] and brachytherapy procedures. For instance, in a single-institution study from the Department of Radiation Oncology at CancerCare Manitoba, the number of patients with prostate cancer treated with I-125 interstitial implant with D90 less than 140 Gy, a metric for the dosimetric quality of the brachytherapy implant, which correlates with decreased biochemical relapse-free survival, declined with increasing experience at the program, with brachytherapy team experience found to be a more important predictive factor of implant quality than size of the prostate.[106] Furthermore, with regard to IMRT, a population-based analysis by Boero and colleagues identified radiation providers from Medicare claims of 6,212 Medicare beneficiaries with head and neck cancer treated between 2000 and 2009 and found that among patients undergoing IMRT, those treated by higher volume providers had increased survival compared with those treated by lower volume providers. Specifically, for every five additional patients treated per provider per year,

the risk of all-cause mortality decreased by 21%.[107] Patients treated by higher volume physicians additionally had decreased head and neck cancer–specific mortality and decreased risk of aspiration pneumonia. Of note, no significant relationship between provider volume and patient survival or toxicity was observed among patients treated with conventional RT. Such results highlight the importance of improved training or novel educational resources for practicing physicians, with a focus on skills-based education, in the establishment of value in radiation oncology, particularly as technology continues to advance at a rapid rate. Other advancements, such as in semiautomated target delineation, knowledge-based planning, and telemedicine, may also assist toward this end without necessitating physician or patient travel.

Telemedicine

Although not a new concept, the implementation of telemedicine or telehealth, which the AMA refers to as "the exchange of medical information from one site to another through electronic communication,"[108] was significantly expedited within the field of radiation oncology, cancer care, and the medical system as a whole as a result of the COVID-19 pandemic. While this expansion was initially the result of infectious precautions and supported by temporary measures from CMS during the public health emergency, the use of telemedicine has persisted, prompting ASCO to endorse standards and practice recommendations for the use of telehealth in oncology.[109] Telemedicine, compared with traditional in-person medicine, offers multiple advantages with respect to the process of medical care and has been identified as a mechanism to increase patient-centered care,[110] even prior to the COVID-19 pandemic.[111] Telehealth increases patient access to and flexibility of care, particularly for vulnerable patients such as those with limited transportation ability or in rural settings,[110,112] which can translate into economic benefits for patients through less missed work and costs associated with in-person visits.[113,114] In addition, multidisciplinary oncology clinics have also incorporated telemedicine,[115,116] and telehealth has been proposed as a way to increase oncology clinical trial accessibility and equitability.[117] Emerging data of patient experiences with telehealth in radiation oncology have found high levels of patient

satisfaction, with significant proportions of patients reporting a preference for telemedicine over in-person visits.[118,119] Similarly, radiation oncologists have reported general satisfaction with and interest in continued use of telemedicine for a significant proportion of patients in their practice.[120-122] Beyond patients and providers, incorporation of telemedicine workflows and work-from-home capability may even confer cost savings to radiation oncology departments.[123]

However, there are some concerns with telemedicine, which must be addressed when considering its future role in health care services. The most obvious is the inability to perform a physical examination, as well as possible challenges establishing a personal connection via telecommunication.[121] This may be balanced by increased patient comfort from attending a health care visit in their own home or other familiar location along with more effective communication from patient friends or family members being able to join visits. Technical difficulties, from both technology and human sources, are also well-known problems, and increased and more widespread use of telecommunication systems for health care services may require additional staff and infrastructure for adequate support.[124,125] Furthermore, recent evaluations of telemedicine have found that it may paradoxically exacerbate health care disparities despite its proposed ability to increase overall access to care.[126-128]

With the end of the COVID-19 public health emergency on May 11, 2023, some of the temporary measures put in place by CMS to encourage widespread adoption of telemedicine may not be continued. These notably include policies related to reimbursement of telehealth services and geographic practice site restrictions.[125,129] There is concern that in the absence of regulatory support, particularly financial, the use of telemedicine will be stifled, and numerous national groups have advocated for its continued backing.[130,131] Given the proposed and already realized benefits of telemedicine, as well as its general acceptance by both patients and providers, support for and optimization of telemedicine should continue so that it remains an option for patients who wish to use it.

Fractionation

The impact of fractionation schedule on the process of RT is considerable. Recent technological advances have allowed for the implementation of hypo- and ultra-hypofractionated treatment courses. Clinical trials in multiple disease sites, such as prostate, breast, and rectum,[132-136] have demonstrated acceptable toxicity and efficacy profiles of these shorter regimens. Under the fee-for-service model, however, there is incentive toward longer fractionation schedules, despite the potential health care system- and patient-level benefits hypofractionated courses can offer. Several economic analyses have found shorter radiation treatment courses to be cost-effective or associated with lower overall costs.[137-141] It should also be considered that while on the per-patient level hypofractionated courses result in lower reimbursement compared with conventionally fractionated courses, total patient throughput can be increased with shorter courses, thus enhancing the value proposition of hypofractionation. Moreover, hypofractionated treatment courses improve patient logistics and financial toxicity, for example, through less missed work, fewer travel expenses, and reduced caregiver burden.[142-144] This may also help to mitigate health care–associated socioeconomic disparities, as increased utilization of hypofractionated RT can improve access to care, treatment compliance, and overall oncologic outcomes in low- and middle-income countries.[145-147] In addition, shorter treatment courses result in less patient travel, which may have a positive environmental impact.[148,149] The ability to hypo- and ultra-hypofractionate radiation treatment relies on continued advancement in treatment precision and accuracy, which improves the therapeutic ratio through tumor dose escalation with simultaneous reduction in dose to surrounding normal tissue. Through this mechanism, newer technologies, such as MRI-guided RT, may further promote the feasibility of shorter fractionation schedules.

Outcomes

Outcomes span all the effects of health care on patients or populations. These include objective outcomes providers and payers have traditionally assessed, such as survival, disease control, functional status, disease recurrence, and complications of treatment. Subjective outcomes, such as patient-reported outcomes, psychosocial ramifications of disease or

treatment, ability to maintain employment status, and patient's understanding of disease, although considered by some as more difficult to assess via traditional scientific methods, are also included and hold equal importance in the value discussion. Of the components in the value equation, the medical community is best at assessing objective outcomes, with wide support for furthering our understanding of the objective impact of particular interventions via high-level clinical research. However, given the expense of such research, there is a need for additional methods to assess objective outcomes at the population level in real-world settings, with multiple specialty-based and multidisciplinary real-time observation registries under development to meet this need.[150-152] The advancement of accurate methods for risk stratification is of particular importance if these outcomes are to be reported on an individual provider level to enhance patient selection of providers or if they are to be connected with reimbursement. This consideration is also relevant for comparisons between treatment modalities, with wider use of multiple research methods for comparative effectiveness in oncology; some of these methods are detailed in this chapter's section on research methods.

The Outcome Measures Hierarchy

As described by Porter, the outcomes for any medical condition can be arranged in a three-tier hierarchy[40] (Figure 37.4). Each tier includes two levels, each described by one or more distinct outcomes dimensions, with success for each dimension measured through specific metrics. In this hierarchy, tier 1 represents the health status achieved or retained, and it includes levels of survival and degree of health or recovery. Specific to cancer care, common metrics in tier 1 include 5-year overall survival and functional status. Tier 2 relates to the recovery process and includes levels of time required to achieve recovery and disutility of care. Common metrics specific to cancer care include time to remission and rates of adverse effects related to the treatment process. Lastly, tier 3 describes the sustainability of health and includes the levels of recurrence of the original disease and associated complications as well as new health issues caused by treatment. Common metrics in cancer include cancer recurrence and incidence of second primary cancers. In this hierarchy schema, tier 1 is generally

considered the most important, with lower tier outcomes dependent on success at higher tiers. However, trade-offs between tiers may exist—such as sacrificing survival benefit in favor of a less morbid treatment modality—and mapping these trade-offs is an important part in furthering innovation in care.

Patient-Reported Outcomes

The study of subjective outcomes, by comparison, is less mature in its development than traditional clinical research in radiation oncology. While initially falling under the purview of dedicated health services research, patient-reported outcomes are increasingly included in clinical research in oncology, in part spearheaded by the RTOG, which has developed a model for the inclusion of patient-reported outcomes as end points in clinical trials.[153] The FDA provides a broad definition of patient-reported outcomes as "any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else."[154] With respect to their inclusion in clinical trials, however, patient-reported outcomes typically include health-related quality of life (HRQoL) instruments, with hundreds of validated generic and disease-specific instruments available and radiation oncology–specific instruments currently in development.[155-157] For instance, the National Cancer Institute (NCI) developed a patient-reported outcome measurement system for use in cancer clinical trials, named the Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE). Designed to be used as a companion to the CTCAE, the PRO-CTCAE includes an item library of 124 and 130 items representing 78 and 62 symptomatic toxicities in adult and pediatric patients, respectively, drawn from the CTCAE and has been tested in a consortium of academic- and community-based cancer treatment sites in the NCI-sponsored clinical trial network.[158,159] Application of such HRQoL instruments through patient self-reporting via web-based platforms is a growing area of interest as well. Early prospective trials of these tools have demonstrated their ability to decrease health care usage and improve clinical outcomes, such as HRQoL and even survival.[160-162] Many challenges exist regarding the optimal application of such instruments, including refining the validation process, establishing the clinical meaningfulness of their results, ensuring inclusiveness and equitability,[163] and deciding how to handle missing data; further research to understand their utility in drawing conclusions in the trial setting, such as with regard to dose-limiting toxicity and overall/comparable tolerability, is necessary as well.[164] In the case of patient self-reporting, ensuring appropriate provider follow-up to reported symptoms and adequate patient response rate while minimizing survey fatigue may need to be improved upon.[165] Nevertheless, these tools offer an

opportunity to inform translational and comparative effectiveness research, health care technology assessment, and quality assurance, as well as to quantify value from the patient perspective. Another patient-reported outcome commonly measured is patient satisfaction, which refers to the patient's perception of the quality of care received.[166] Although limited by patients' relative inability to assess the technical quality of their care and inevitable dependence on patients' initial expectations, patient satisfaction remains an important part of the patient experience, and its inclusion in the value proposition reflects the greater shift in mindset in health care toward patient-centered care.

A Patient-Centered Approach to Value

Paralleling the rise of value-based care, patient-centered cancer care has received increasing focus in recent decades, as advocated by the Institute of Medicine (IOM), patient groups, and professional societies.[167] Patient-centered care, as defined by the Picker Institute, describes care that address multiple dimensions of patient care, including patient preference, emotional support, physical comfort, information and communication needs, continuity and transition, care coordination, involvement of family and friends, and access to care.[168] Patient-centered care, while inherently aligned with value-based care via a shared focus on high-quality care, has distinct attributes not typically included in discussions of value, such as patient experience and preference measures as well as conceptions of cost that are payer—as opposed to patient focused[33] (Figure 37.5). Patients themselves appear to intuit these contradictions: In a series of focus groups, interviews, and online surveys of health care consumers undertaken by the American Institutes for Research, respondents in general were unfamiliar with concepts related to evidence-based care, believing medical guidelines to reflect an "inflexible, bargain-basement approach" to treating unique individual patients.[169] Thus, for the transition to value-based care to be accepted and effective on a population level, patients—as recipients, co–decision makers, and co-financiers of this care—will need to be included in the discussion, with patient-centered outcomes, perspectives, and preferences explicitly incorporated into the definitions and metrics of quality and cost.

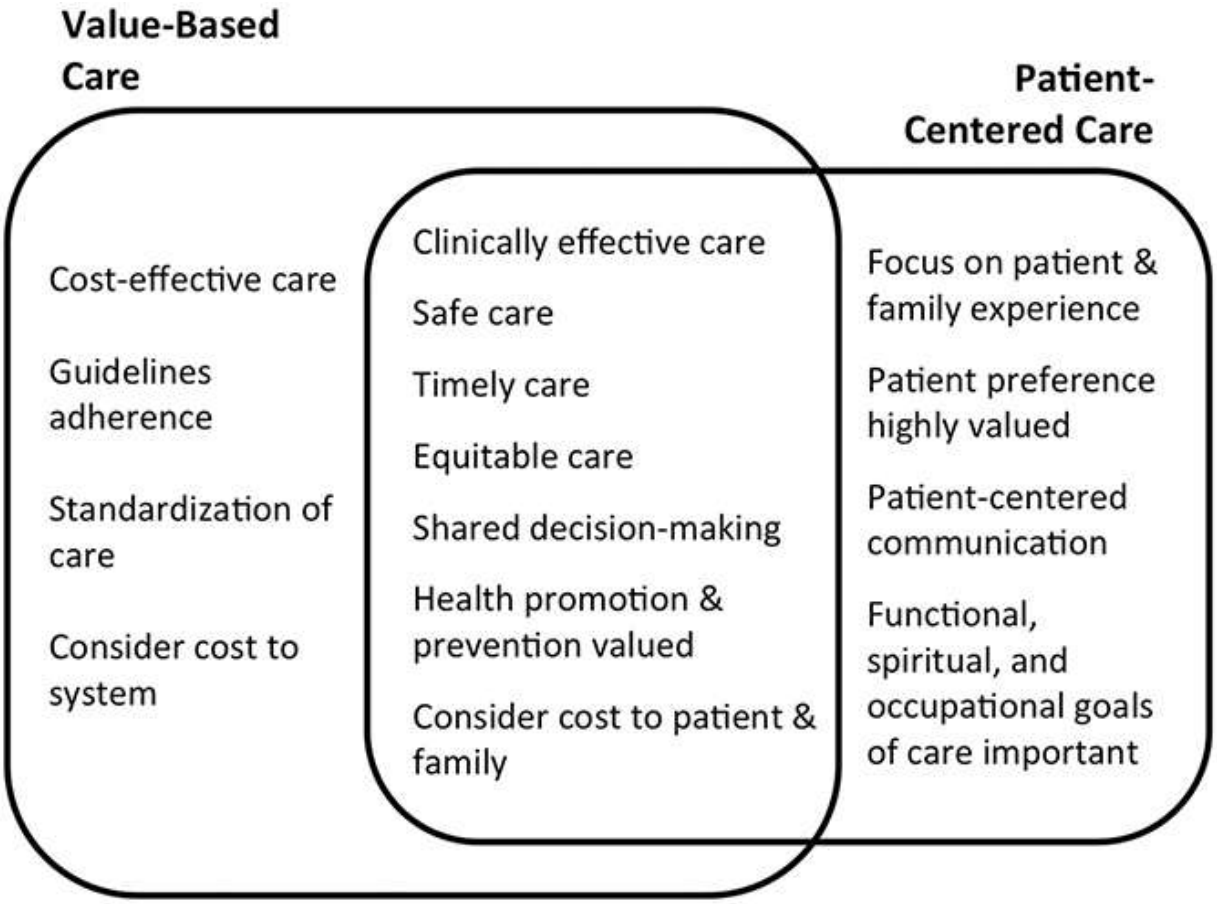

FIGURE 37.5 Attributes of value-based care and patient-centered care. (Adapted by permission from Springer: Tseng EK, Hicks LK. Value based care and patient-centered care: divergent or complementary? *Curr Hematol Malig Rep*. 2016;11[4]:303-310. Copyright © 2016 Springer Science+Business Media New York.)

Aligning Patient-Centered and Value-Based Care

Challenging the alignment of patient-centered and value-based care is the relative inability to assess cost in health care. Under the traditional fee-for-service–based system, although providers and administrators may have knowledge of individual billing charges and the direct costs of running a radiation oncology clinic, it is more difficult to calculate the total cost of care administered at a patient level. Furthermore, in our free market system, the charge for the same procedure can vary widely between providers, with no consistent correlation with the quality or outcome of care.[35] In comparison with how their purchasing decisions are made outside health care, patients are left to make important health care decisions with a relative deficiency of information, unable to assess the real costs or quality of care

offered by different providers; this is exacerbated in a system where the majority of patients are insured by a third party and bear only a small fraction of the total cost of care. Patients thus cannot function as "utility maximizers," choosing products that provide the highest utility for the lowest dollar. This discrepancy in effect removes the market pressure toward high-value care, in part contributing to increased cost, over- and underutilization, and decreased quality in health care. In effort to recreate this market pressure on patients, health plans have responded by increasing cost sharing via higher deductibles and copays. This practice, however, can counteract the achievement of value by preventing patients from pursuing necessary, high-cost sharing treatments, ultimately worsening patients' health and increasing the overall cost of care.

The Financial Burden of Cancer Care

Oncology care, in particular, has been presumed to be relatively shielded from the downward pressure of cost on demand, though evidence suggests that even patients with cancer consider treatment cost in their decision-making, suggesting that the cost of care should receive greater emphasis in assessments of value from a patient perspective.[170] Multiple studies have reinforced the detrimental effect that out-of-pocket costs have on patients' access to medical care as well as ability to pay for other nonmedical life necessities, with a report from the NCI indicating between 33% and 80% of patients with cancer using their savings to finance medical expenses.[35,171,172] In a population-based study from Western Washington State, a cancer diagnosis was associated with a 2.65-times greater likelihood of declaring personal bankruptcy. Upon further analysis, patients with cancer declaring personal bankruptcy additionally demonstrated a 79% greater mortality risk than those who did not.[173] This relationship between extreme financial distress and greater mortality risk is likely multifactorial, partly explained by overall poorer well-being, impaired HRQoL, or subpar quality of care.[174] Likely, further exacerbating the patient's sense of well-being, the burden of financial hardship for cancer care is not borne by the patient alone, with between 2% and 34% of patients borrowing money from friends or family to pay for care.[172] Unfortunately, as multiple forms of cancer are currently incurable with many patients eventually succumbing to disease, at least a

portion of these expenses are likely exhausted on futile care at the end of life. Although the administration of chemotherapy in patients in their last weeks of life has been well documented—indeed, chemotherapy administered the last 2 weeks of life was a previous quality indicator employed by the ASCO Quality Oncology Practice Initiative—evidence indicates that the field of radiation oncology is not immune to potential contributions to futile care, with a population-based study of Surveillance, Epidemiology, and End Results (SEER) Medicare and Texas Cancer Registry Medicare databases indicating an increase in use of advanced RT techniques in patients in the last 30 days of life from 2000 to 2009, with the proportion of patients treated with IMRT increasing from 0% to 6.2% and with stereotactic radiosurgery from 0% to 5.0%.[175-177] Although further research is necessary to determine whether these shifts in practice patterns improve palliative outcomes and to better identify patients who may benefit from advanced techniques in the palliative setting, such as SBRT for bone metastases[178-181] or locally advanced pancreas cancer,[182] consideration should be given toward the potential impact of the cost of these therapies on patients and their families.

Financial Toxicity

There now exists a wealth of evidence describing the deleterious effect of the cost of cancer care on patient well-being, which has led to a push for the inclusion of "financial toxicity," described as the harmful personal financial burden faced by patients receiving cancer treatment, in physicians' discussions with patients of the side effects associated with a particular treatment, with both the IOM and ASCO categorizing cost of care discussions as an essential component of high-quality care.[39,183-185] Additional strategies have been proposed to address financial toxicity, including implementation of screening for financial and health-related social needs (eg, housing and food insecurity, transportation, unemployment, and financial strains)[101]; providing financial literacy, navigation, and assistance to patients; incorporating cost information into treatment decision-making; and reducing low-value care.[186] The aforementioned ROCR APM includes an incentive for incorporating the transportation health-related social needs screening question into clinical

care. Clearly, however, numerous potential obstacles currently preclude effective cost of care discussions between patients and physicians, including uncertainty about the appropriateness of the topic and inability to accurately assess the cost of care.[72] Comprehensive intervention will likely require further research on the measurement of the material, psychological, and behavioral effects of financial toxicity and the identification of potential modifiable risk factors as well as further inclusion of these metrics at a policy level.[73] Composite scores using summary measures of multiple components of financial hardship, such as the Comprehensive Score for Financial Toxicity and Personal Financial Wellness Scale, have been employed in clinical studies as a patient-reported outcome, though results can be difficult to interpret with unclear application to the general population.[63]

Health Equity

Across all disciplines of medicine, inequity in health care results in significantly worse outcomes for socially disadvantaged groups, such as racial or ethnic minorities, people experiencing poverty, or those living in more geographically isolated areas. This is certainly true within the field of radiation oncology, where these disadvantaged populations are less likely to experience appropriate care across the entire cancer spectrum, from screening to treatment to outcomes, due to health care inequity.[187] As defined by the National Academies of Sciences, Engineering, and Medicine Committee on Community-Based Solutions to Promote Health Equity in the United States, health inequities are systematic differences in the opportunities groups have to achieve optimal health.[188] Systemic factors and structural inequities, such as racism and gender inequality, which can span from the individual to the system-wide level, impact social determinants of health, which, in turn, bring about health inequities.[189,190] On the other hand, health equity refers to the concept of all individuals being able to attain their highest level of health without being hindered as a result of their social circumstance. The ultimate outcome of health care inequity is health care disparities, which refers to differences in the receipt of health care and/or health outcomes among different populations.[191,192] Important to the understanding of health care disparities is that they are preventable through

the addressment of societal inequities, social determinants of health, and the subsequent health inequities.[193]

Although attention, albeit perhaps insufficient, had been previously directed toward health equity in radiation oncology, this focus was renewed during the COVID-19 pandemic when health care disparities in general were further amplified and spotlighted.[193] One of the overarching goals of *Healthy People 2030* is eliminating health disparities, achieving health equity, and attaining health literacy, and one of its five core objectives is focused on social determinants of health.[190] Within radiation oncology, the *Red Journal* recently published special issues devoted to Health Equity, Diversity, and Inclusion in which potential mechanisms to analyze and address health inequity in radiation oncology were highlighted, and a call for increased awareness, action, and accountability with regard to health equity was issued.[194,195] While there has been research identifying equal access health care systems as a potential mechanism for advancing health equity,[196,197] this and other broad solutions may currently be politically infeasible. In addition, as the field continues to develop and implement new and innovative treatments, care must be taken to not exacerbate health care inequity and subsequent disparities as the result of differential access to these treatments.[198-200] In addition to the obvious patient-centered benefits associated with improving health equity, strategies to eliminate inequities have also been shown to be cost-effective from a societal perspective.[201]

Value Proposition in Resource-Constrained Countries

Establishing access to RT services remains a challenge in lower income countries because of the resource intensive and expensive nature of RT.[202,203] While the fundamental principles of the value framework described earlier are relevant to all radiation oncology settings, their application can vary depending on the economic status and resource availability of the setting in question. In lower income, resource-constrained countries,[204] the relative weights of each input as well as the overall interpretation of the value proposition conceivably differs from that in higher income countries. In such settings, cost reasonably merits increased consideration as the costs required to establish and expand access to RT services in these countries are high. Yet despite these high upfront expenses, the overall net economic

impact associated with expanding global access to RT services is estimated to be positive, in addition to the positive health impact this would have.[201,205] As in higher income countries, health economic research and costing analyses can play a key role in evaluating the cost component of the value proposition for lower income countries,[206] and efforts to encourage such analyses should be undertaken.

Although providing access to care is an important goal for lower income countries, the quality of the care, the numerator of the value equation, is as equally if not more important in such countries.[207] Among the components that make up quality in the value framework (outcomes, structure, and process), ensuring that a proposed intervention, in this case, RT, can achieve successful outcomes is integral to determining its value in resource-constrained settings. As described earlier, Porter's Outcomes Measures Hierarchy can be used to prioritize multiple clinical outcomes, acknowledging that the outcome tiers may vary on the personal and/or cultural level. Taken together, additional emphasis can be placed on the cost and outcomes elements when assessing the value proposition in radiation oncology in resource-constrained, lower income countries.

Decisional Regret

As previously discussed, the effective measurement of more subjective outcomes in radiation oncology remains an area in need of further research, and their greater inclusion in assessments of value is a critical challenge in the alignment of value-based and patient-centered care.[33] Validated metrics of patient-reported outcomes, in which patients report directly on perceptions of their own health, have been developed and are now more broadly included in clinical trials, providing essential patient-centered data on the impact of interventions; likewise, development of validated instruments to assess patient-reported experience measures, or their perception of their experience with health care delivery, is ongoing. An intriguing example of a validated and well-studied patient-reported outcome with applications to radiation oncology is decisional regret, defined as the negative emotion experienced when we suspect that an alternative course of action would have resulted in a better outcome.[208] Cancer-related decision-making is complex, requiring an understanding of both the medical and

psychosocial impacts of treatment in the context of one's personal values and beliefs; given the complexity and multifactorial nature of these choices, decisional regret offers a broad measure of a patient's treatment experience and quality of life and has been shown to be a more sensitive outcome than patient satisfaction in certain settings. Decisional regret has been identified in multiple cancer sites where RT is commonly used, such as prostate,[209] lung,[210] and breast.[211] In prostate cancer, multiple factors have been associated with treatment regret, including poor HRQoL and global post-treatment quality of life. Interestingly, specific treatment modalities have also been associated with increased post-treatment regret. For example, at the University of California, Los Angeles, a survey of patients with localized prostate cancer treated with IMRT, SBRT, or high-dose rate (HDR) brachytherapy suggested that patients treated with SBRT experienced significantly less treatment regret compared with patients treated with IMRT or HDR.[212] Thus, when comparing modalities—particularly with equivalent long-term survival and comparable toxicity profiles—further understanding of the patient experience is informative in assessing the value of specific medical interventions.

Value in Radiation Oncology: Conclusions

Regardless of the volume of ongoing debate surrounding health care reform, in many ways, the transition to some form of value-based care is inevitable. Enacted in April 2015, the Medicare Access and CHIP Reauthorization Act repealed the SGR to establish the Quality Payment Program to encourage physician participation in APMs that utilize value-based payment; in response to unsustainable rising health care costs, multiple private payers have begun experimenting with APMs already.[30,213] This transition offers an opportunity to serve patients, providers, society, and shareholders alike through better alignment of incentives among stakeholders and reduced administrative costs. Although the recent attempt by CMS to create the RO-APM was unsuccessful, work is already underway to develop a new model, which, among other components, emphasizes value-based care. Whatever method of payment reform ultimately takes ahold will arise from iterative experimentation; radiation oncologists and the patients they treat will be best served by taking an

active role in this collaborative process, both via participation in health care advocacy and contribution to novel health services research.

HEALTH SERVICES RESEARCH

The field of health services research, often referred to as outcomes research, refers to the study of access to care, costs of care, and quality of care. Access to care concerns factors that expedite or hinder the use of medical services. Costs of care include payments by insurers and patients for medical services as well as the cost of lost productivity because of time away from work and decreased wages. As previously discussed, quality of medical care incorporates elements of structure, process, and outcomes. Although there are several methods of analysis relevant to health services research, decision analysis and cost-effectiveness analysis, in particular, are standard techniques used to evaluate and compare medical therapies. As the costs of oncologic care rise, it is vital to evaluate the cost-effectiveness of RT. Cost-effectiveness analyses assess the costs relative to health outcomes for a particular medical intervention. This section explains the theoretical aspects of decision and cost-effectiveness analyses.

Evidence for New Technologies

Prior to further description of decision and cost-effectiveness analyses, it is important to consider the role of health services research and other types of evidence in evaluating new technologies and treatments. The field of radiation oncology is constantly advancing and developing new treatments, though the process of incorporating emerging technology into the standard of care can be prolonged or challenged by the prerequisite of accumulating a sufficient body of supporting evidence. As such, it is imperative to examine the thresholds of evidence a new technology must satisfy so that it may be integrated into the standard of care, as this is intertwined with health care economics and policy. Moreover, emerging technology within radiation oncology often outpaces the evidence demonstrating its benefits to patients, providers, and the health care system, and the need for evidence must be balanced with the opportunity for these stakeholders to experience the advantages of cutting-edge treatments.

When considering the body of evidence needed to support or oppose a new treatment, emphasis is reasonably placed on level I evidence, namely, randomized controlled trials. There are, however, disadvantages with randomized controlled trials, such as feasibility (from resource, time, and ethical standpoints), statistical challenges, and generalizability. For instance, randomized trials often necessitate lengthy follow-up before showing differences between various treatments, and their results may not be available until the therapy itself is out of date. Randomized trials also report the best treatment for the "average person"; patient preferences are not considered. In addition, as described previously, patient-reported outcomes are an important aspect of determining high-value care, and there still exist some challenges with the inclusion and interpretability of these measures in randomized controlled trials. These concerns call into question their role as the predominant and often required source of data for implementing a new treatment.[214,215] While there are known, considerable limitations to observational research, such as selection bias, important conclusions can be drawn from these type of data, particularly in situations when conducting a randomized controlled trial is impractical. Furthermore, methods of research aside from comparative effectiveness, such as decision and cost-effectiveness analyses, might identify benefits or detriments aside from clinical outcomes, which influence a technology's fulfillment of high-value care. It should be noted as well that level I evidence is not required for the creation of a new CPT Category I code. As the field of radiation oncology and its treatments continue to progress, we must consider the quantity and quality of evidence required to implement innovative and potentially higher value technologies.

Decision Analysis

Decision analysis uses a set of mathematical tools designed to determine the most favorable outcome with regard to a particular endpoint, such as overall survival or time without recurrence, for individuals with a given starting situation under many different sets of circumstances, using existing data or assumptions regarding the effectiveness and toxicities of treatments. Decision models can help outline the trade-offs for different treatments in clinical situations when no good evidence is available.

To make a model, a decision tree is created to symbolize the results of clinical choices. The model requires making simplifying assumptions while still being sufficiently complex to correctly illustrate the important aspects of the decision. Figure 37.6 depicts a scenario in which a patient is faced with the treatment dilemma of whether to undergo RT for illness X.[216] Decision nodes are signified by squares in the decision tree, chance nodes by circles, and terminal nodes by triangles.

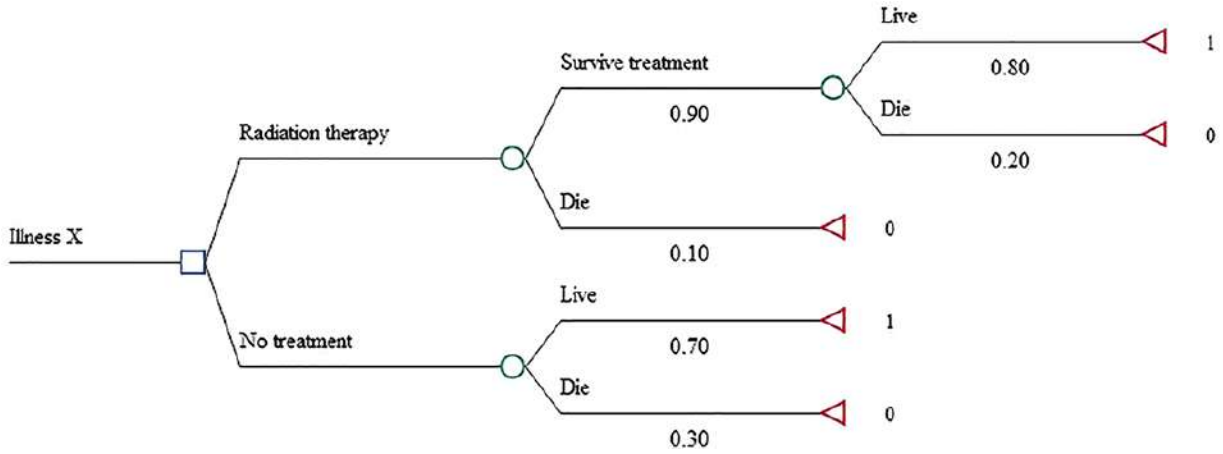

FIGURE 37.6 Decision tree of a patient with illness X. (Reprinted from Sher DJ, Punglia RS. Decision analysis and cost-effectiveness analysis for comparative effectiveness research—a primer. *Semin Radiat Oncol*. 2014;24[1]:14-24. Copyright © 2014 Elsevier. With permission.)

Subsequent to choosing a treatment, there is a chance node after which all potential events are shown as branches. The probability of a particular outcome following a chance node is determined from data from the literature or expert opinion. The probabilities of events at each chance node must add to 1. In Figure 37.6, if the patient with illness X chooses RT, they have a 90% chance of surviving the treatment and a 10% chance of dying from the treatment. If the patient survives the treatment, they then have an 80% chance of remaining alive and a 20% chance of dying. If the patient forgoes treatment, they have a 70% chance of living and a 30% chance of dying.

The terminal nodes depict the final outcomes states of each pathway. Next to each of the terminal nodes is a value associated with that state. In our example, the only two outcome states are living and dying. Being alive

and dead are associated with values of 1 and 0, respectively. When calculating the expected survival rate for RT, we see that if a patient survives treatment, they have an 80% chance of living (outcome of 1) and a 20% chance of dying (outcome of 0). The value at this chance node is calculated by multiplying the probability of the outcome with the associated value, resulting in a value of 0.80. We then substitute the value of 0.80 as the value associated with surviving treatment and multiply this value by its probability of 0.90. The resulting value (0.72) is then combined with that of dying from treatment (outcome of 0 with probability of 0.10), for an expected value of 0.72. The expected survival rate for no treatment is calculated by multiplying the likelihood of living (0.70) with its outcome of 1 and combining that to the product of the likelihood of dying (0.30) and its outcome of 0, to obtain a value of 0.70.

Outcome Values

In our simple example, the outcome value was the likelihood of survival with or without treatment for illness X. However, decision analyses can also model values associated with different health states. A utility is an econometric construct that describes how an individual values a given health state versus death (0) and perfect health (1).[217] The worse the health state, the lower the utility. For instance, experiencing a rectal toxicity may be associated with a utility of 0.7, and living with distant metastasis may be associated with a utility of 0.6. This ability to describe utilities for different outcomes states allows modelers to incorporate side effects of treatments into their model, an important consideration given that many cancer treatments affect a patient's quality of life. The benefit associated with various cancer treatments depends on the trade-offs between the fear and consequences of recurrence versus the inconvenience and potential toxicity of treatment.

Utilities are different from more familiar, descriptive quality-of-life measures as they reflect how a respondent values a state under conditions of *uncertainty*. Although there are several techniques for assessing utilities,[218] the most firmly grounded in expected utility theory is the standard gamble. The standard gamble assesses the utility for a health state by asking how high a risk of death a participant would accept to improve it (Figure 37.7).

The respondent is asked to choose between a certain life in an intermediate health state and a gamble between optimal health and immediate death. The probabilities in the gamble are varied systematically until the respondent feels that the two choices (life in an intermediate health state and the gamble) are equally desirable. At the "point of indifference," the respondent's utility for the health state is given by the probability of optimal health in the gamble. The utility of the health state is given by the probability of perfect health in the gamble such that the respondent is indifferent between the gamble and the certain intermediate outcome.

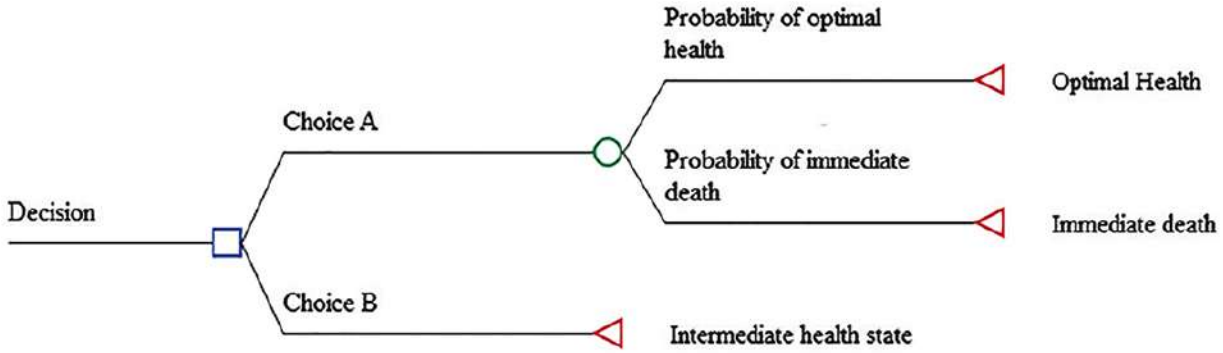

FIGURE 37.7 The standard gamble assesses the utility for a health state by asking how high a risk of death a participant would accept to improve it.

Utilities can also be used to calculate quality-adjusted life-years (QALYs), an index of survival that is adjusted to account for the patient's quality of life during a specific period. The QALY is the standard effectiveness measure.[219] A QALY is determined by multiplying the time spent in a certain health state with the utility associated with that state. For example, 2 years of time spent in a state whose utility is 0.5 would be the equivalent of 1 QALY.

Sensitivity Analysis

The published literature and expert opinion provide the basis for probabilities at the nodes of a decision tree. However, these estimates are often quite uncertain. Sensitivity analyses are, therefore, usually a critical part of decision models. Sensitivity analyses vary a certain parameter (eg, the probability of recurrence of cancer) over the entire plausible range of its

values and then study the effect of varying the parameter on the outcome. Sensitivity analyses provide a measure of the robustness of a conclusion in a similar way to confidence intervals and *P* values in biostatistics. They may also increase the level of confidence by confirming the lack of significant dependence of an outcome on a certain transition parameter. In addition, sensitivity analyses may also identify areas where further research may be valuable by revealing dependence of an outcome measure on the variable studied.[216] One-way sensitivity analyses provide threshold values, and one-way sensitivity analyses of multiple model inputs can be plotted in a Tornado diagram to depict which variables have the greatest impact on the model results.[220] Two- and three-way sensitivity analyses systematically vary two to three parameters simultaneously; the outcomes for each combination of variables can then be assessed.

In the example shown in Figure 37.6, we may not know the likelihood of treatment mortality for illness X. It may also vary by physician or with patient characteristics. In order to determine the optimal treatment strategy for a given treatment mortality, we can conduct a one-way sensitivity analysis. As shown in Figure 37.8, the expected value of RT decreases as the treatment mortality increases. The threshold mortality at which RT and no treatment yield equivalent expected outcomes is 0.125. Below this mortality threshold, RT is associated with the best expected value, but no treatment becomes the optimal strategy above this value.

Markov Models

Markov models are useful when time needs to be incorporated into a decision model. They allow the study of outcomes by describing events as discrete states. They are particularly helpful in modeling clinical situations where a patient is at risk for a given event over an extended period of time (eg, recurrence of cancer). Markov modeling works by making a number of assumptions. First, a patient is always in one of a finite number of discrete health states. Second, all events are represented as transitions from one state to another. Third, time is divided into equal increments referred to as Markov cycles, which may be days, months, or years depending on the

clinical situation. Fourth, transitions between health states occur only once per cycle. Finally, all patients in a given health state face the same transition probabilities, no matter when they entered that particular health state.[216] Patients start the model in a single health state. As the model cycles, the patients travel through time and may remain in their previous health state or transition to a different health state with a certain transition probability.

Figure 37.9 shows a simplified prostate cancer Markov model.[216] Patients who have completed initial therapy start in the "no-disease" health state. At each cycle, the patients may either remain in the "no-disease" health state, have a finite probability of having a recurrence and transition to the "recurrence" health state, or have a finite probability of dying of causes unrelated to their cancer and transition to the "death" health state. Once in the "recurrence" health state, patients may remain there or with a certain probability die from their recurrent disease and enter the "death" health state. Once the patients enter the "death" health state, they may not exit. (This is an example of an "absorbing" health state.) A type of a Markov model called an absorbing model runs until all patients are in the "death" health state and can be used to calculate residence times in transient states allowing for life expectancy and time spent without recurrence.

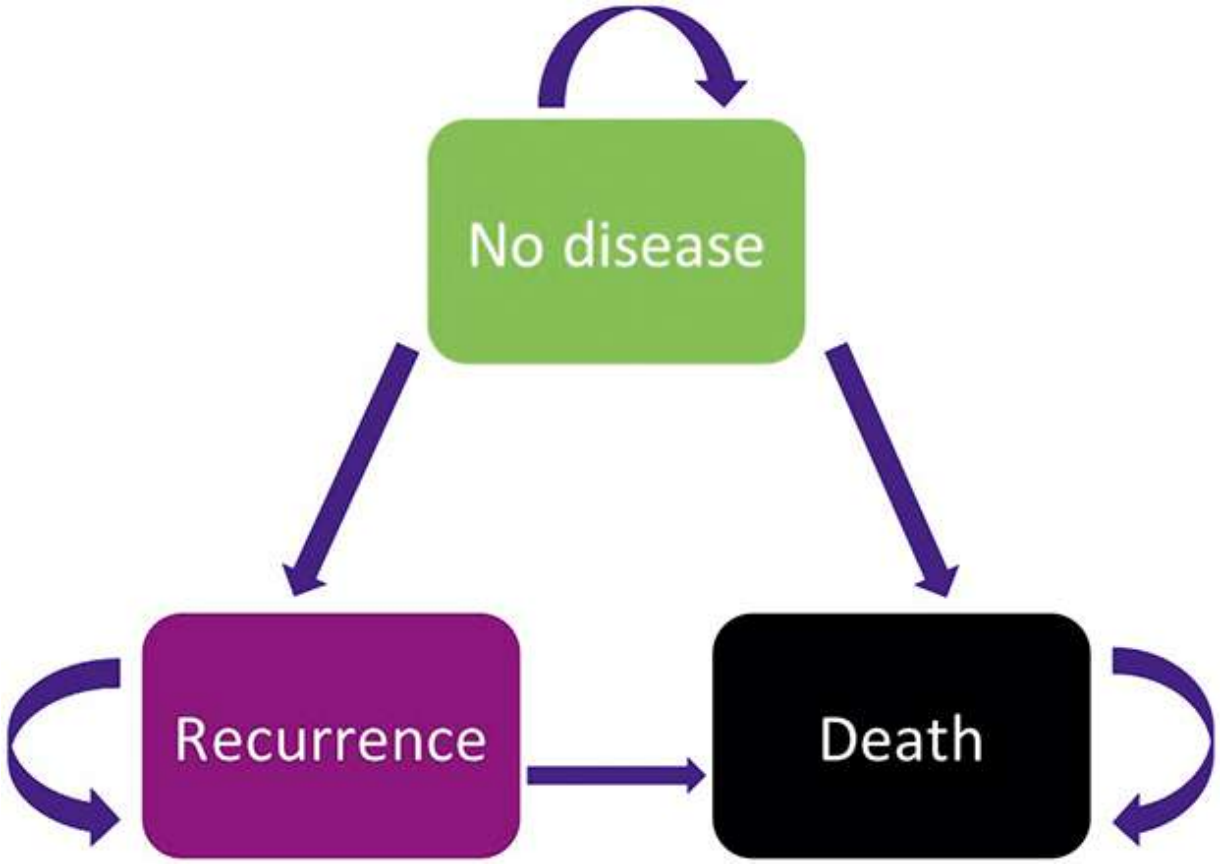

FIGURE 37.9 Markov model with three health states. (Adapted from Sher DJ, Punglia RS. Decision analysis and cost-effectiveness analysis for comparative effectiveness research—a primer. *Semin Radiat Oncol*. 2014;24[1]:14-24. Copyright © 2014 Elsevier. With permission.)

One common method to evaluate a Markov model is the Monte Carlo simulation, where simulated patients enter the model one by one. The computer program then randomly selects a value for a variable in the decision analysis using a probability distribution and tracks the outcome. The process is repeated thousands of times (simulating thousands of patients), and the mean and standard deviation for a result (eg, mean overall survival) are obtained.

Cost-Effectiveness Analysis

Cost-effectiveness analysis is a set of mathematical tools designed to compare the relative costs and benefits of treatment alternatives. The most common type of cost-effectiveness analysis uses a model-based study,

which is nearly identical to a classic decision analysis. A Markov model is created, and QALYs are accumulated over the time scope of the study. Costs are also accumulated during each stage, such that by the end of the analysis, there is a cost and QALY associated with each strategy. One then orders the strategies by effectiveness.

The end result of any cost-effectiveness analysis is reported as an incremental cost-effectiveness ratio (ICER), which is the ratio of the change in costs to incremental benefits of a therapeutic intervention or treatment.[221] The ICER is usually reported as a cost per QALY (eg, $55,000 per QALY). Treatments are considered "cost-effective" or not based on whether the ICER passes a particular threshold, the societal "willingness to pay" (WTP). The amounts $100,000 and $150,000 per QALY are commonly accepted values above which treatments are not considered cost-effective in the United States.[222] A new treatment is said to "dominate" the standard treatment if is more effective and less costly.[221] Model uncertainty and relationship with the WTP threshold can be further assessed through probabilistic sensitivity analysis.[223] In this type of analysis, probability distributions are created for each model variable and then used in a Monte Carlo simulation. Each simulation of the model will "randomly select" a value from each variable's probability distribution to generate thousands of unique ICERs. These data can be plotted on a cost-effectiveness acceptability curve, which graphically demonstrates the probability of an intervention being considered cost-effective at a certain WTP threshold.[224] In the example shown in Figure 37.10, a probabilistic sensitivity analysis was performed on a cost-effectiveness model evaluating the use of stereotactic ablative radiation therapy (SABR) in the treatment of oligometastatic cancer in comparison with the standard of care.[225] As the WTP threshold increases, the probability that SABR will be considered cost-effective (ie, the probability that the ICER will be less than the WTP threshold) increases. This cost-effectiveness analysis example is discussed further in a later section of this chapter.

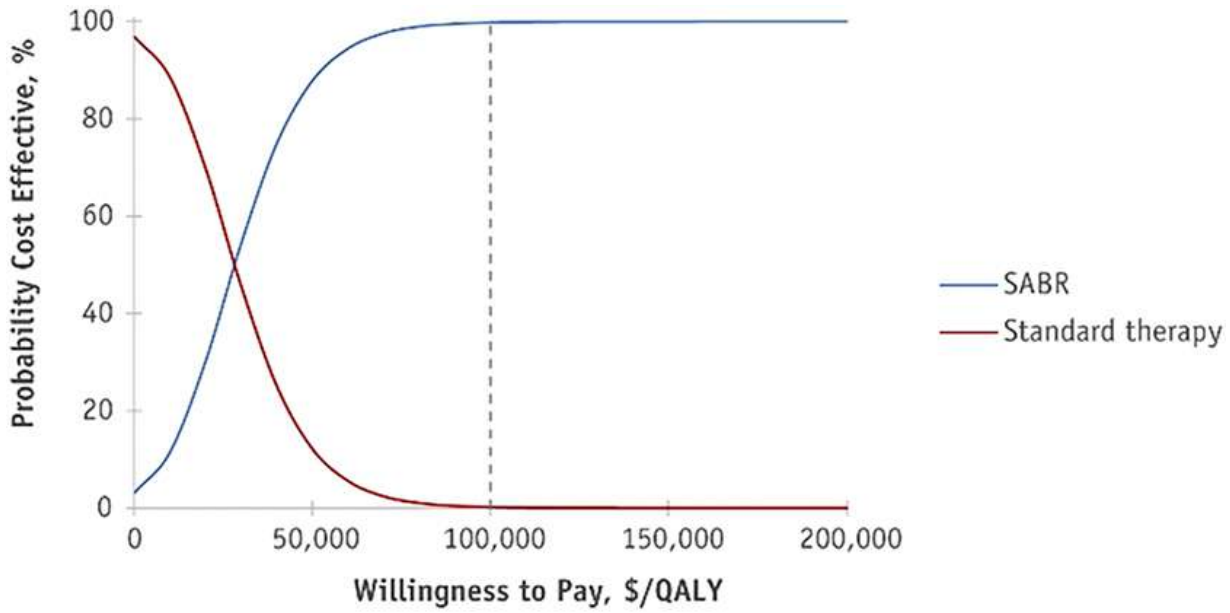

FIGURE 37.10 Probabilistic sensitivity analysis of stereotactic ablative radiation therapy (SABR) compared with standard therapy for oligometastatic cancer. Costs

Costs included in a cost-effectiveness analysis depend on the perspective of the analysis. In the societal perspective, every cost needs to be measured, including capital expenses and the lost economic productivity of both the patient and caregivers.[221] In the payer perspective, only costs paid by the payer are pertinent. Analyses from the payer perspective primarily take health care reimbursements into account. Costs associated with RT can be divided into fixed costs and variable costs. Fixed costs consist of costs of the facility, physics and engineering maintenance of the machine, and salaried labor.[226] The capital cost of purchasing a linear accelerator or building a proton therapy center makes up a substantial fraction of the fixed costs. The estimated cost of a CT-based linear accelerator is approximately $4 to $5 million, whereas the list price for MRI-based linear accelerators is approximately $8 to $9 million.[227,228] The market price of a proton center is estimated to be on the order of $25 to $200 million.[229-231]

The variable costs of RT vary substantially by radiation treatment modality. They can be broken down into three basic categories: treatment

simulation, treatment planning, and treatment delivery.[226] IMRT and three-dimensional conformal radiation therapy (3D-CRT) simulations involve a CT simulation, which necessitates more effort on the part of physicians, physicists, and therapists than a 2D simulation, which is done using a simple fluoroscopic simulator. Whereas the planning process for a 2D plan involves calculations that can be performed using a calculator, a 3D plan requires more work by the dosimetrist. An IMRT plan is even more complex and, for that reason, more costly. Moreover, quality assurance programs for IMRT plans often entail "dry runs" to guarantee that the planned dose approximates the delivered dose, adding to costs.[232] Because each Lucite compensator is custom-made for each proton patient, compensators used in proton beam therapy (PBT) are more expensive than the wedges used in conventional RT. By the same token, delivering a simple 2D plan is considerably less expensive than a 3D-CRT or IMRT treatment, and PBT is even more expensive (producing protons in a cyclotron is more resource intensive than producing photon from a linear accelerator). In addition, the daily image guidance associated with IMRT incurs additional costs. MRI-guided RT introduces unique costs into these three categories as well. MRI-guided RT employs MRI simulation, often in addition to CT simulation, and its treatment planning is more complex, given the newer technology and workflows. A key innovation of this modality is the improved feasibility and process for online adaptive RT, though this increases overall treatment time and required personnel.

Cost-Effectiveness Questions

Multiple types of questions can be answered within the field of radiation oncology with cost-effectiveness models.[216] For example, what is the cost-effectiveness of using RT, compared to other treatment options, such as surgery, systemic therapy, different RT techniques or regimens, or no treatment at all? In addition, in the setting of multimodal care involving RT, what is the cost-effectiveness of different combined modality regimens?

These questions, particularly regarding RT regimens, have inspired research within the field of prostate cancer, as the explosion of new and expensive technologies such as IMRT and SBRT calls for careful analyses of their cost-effectiveness. For example, Sher and colleagues developed a

Markov model comparing the cost-effectiveness of robotic (R-) and nonrobotic (NR-) SBRT to IMRT for a 65-year-old patient with low-risk prostate cancer from the payer perspective.[233] Their model included the six health states of alive with no evidence of disease, alive with asymptomatic local recurrence, alive with symptomatic local recurrence, alive with distant metastases, death from unrelated causes, and death from prostate cancer. Over time, the patient could also experience toxicity. Patients were allowed to have any combination of sexual, rectal, and urinary toxicities, with the assumption that the development of any toxicity was independent of the others. All toxicities from treatment were assumed to occur within 5 years of therapy; after 5 years, they assumed no new onset of toxicity. Given the lack of robust follow-up, it was assumed that the recurrence risk after SBRT was the same as the recurrence risk after IMRT (an assumption that later proved to be valid).[133,234,235] Each health state was associated with a cost and a utility derived from the published literature. Patients were followed until death. The baseline costs of each RT treatment were defined by the 2012 Medicare payment schedule for hospital-based practice. The total costs of IMRT, NR-SBRT, and R-SBRT were $27,564.21, $10,108.93, and $19,275.41, respectively. Costs after local or distant recurrence were taken from Bayoumi and colleagues, and costs for the management of proctopathy, bladder toxicity, and impotence were extracted from the Institute for Clinical and Economic Review. Quality-adjusted life expectancy after IMRT was slightly higher than after SBRT, because worse toxicity was assumed after SBRT. The ICERs for IMRT over R-SBRT and NR-SBRT were $285,000 and $591,100/QALY, respectively. On sensitivity analysis, SBRT was almost always the cost-effective therapy, in which the ICER for IMRT was generally over $100,000/QALY. Treatment efficacy, rectal toxicity, and impotence and the potential for unforeseen SBRT late effects were the most critical parameters in the model. When including these uncertain parameters in a probabilistic sensitivity analysis, SBRT was still most likely to be cost-effective at a WTP of $100,000/QALY. The authors concluded that SBRT clearly contained more value than IMRT for external beam treatment. One limitation of this study is that although outcomes are well established after IMRT, they are less mature after SBRT, with prospective trials reporting recurrence and toxicity data at relatively short follow-up.[133,234,235]

With the increased use of RT in oligometastatic disease, the cost-effectiveness of this strategy was evaluated by Kumar and colleagues.[225] In this study, the authors created a Markov model comparing SABR with standard-of-care therapy for a 66-year-old patient with oligometastatic cancer, defined as having five or fewer oligometastatic lesions. The model included three health states: alive with stable disease, alive with cancer progression, and death, and patients were followed until death. Patient outcome and toxicity probabilities were derived from the 2019 publication of the SABR-COMET trial.[236] In both alive states, patients could experience treatment-related toxicity within the first 2 years as this was the median follow-up time for the SABR-COMET trial at time of publication. For progression and survival beyond 5 years (the follow-up range the SABR-COMET trial), the probability of death for patients was assumed to follow survival estimates from the SEER database.[237] In addition, sensitivity of the model to this assumption was tested by generating scenarios in which patients were "cured" and their survival followed age-specific mortality rates from United States life tables as well as a scenario in which all patients died after the 5 years of reported trial follow-up. The cost of SABR was calculated from Medicare reimbursement rates for all components of the radiation oncology planning and treatment process for a five-fraction SBRT course. Costs and health utilities were derived from published literature. Given that multiple primary cancer types were included in the SABR-COMET trial, weighted averages based on the proportions of each cancer type in the trial were used for all model inputs when necessary. A WTP threshold of $100,000/QALY was chosen. In the base-case analysis, which was from the health care sector perspective, SABR increased the overall cost of treatment by $54,260, from $405,901 with standard therapy to $460,161 with SABR, as well as increased effectiveness by 1.88 QALYs, corresponding to an ICER of $28,906/QALY, which was considered cost-effective at the WTP threshold used in the study. Similarly, the ICER from the social perspective was also below the WTP threshold at $38,783/QALY. In one-way sensitivity analyses, the model was relatively insensitive to most variables, including the probability of progression and survival when ranged across the 95% confidence intervals for these outcomes reported by the trial. For example, the cost of SABR would have to increase more than 10-fold for this strategy to become cost-ineffective. Probabilistic sensitivity

analysis (Figure 37.10) showed that SABR would be the cost-effective treatment option, with 87.8% and 98.8% of the time at WTP thresholds of $50,000/QALY and $100,000/QALY, respectively. The authors concluded that SABR for oligometastatic cancer was a cost-effective treatment option. The authors acknowledged limitations of their model due to drawing a significant amount of model input data from a single, heterogeneous, phase II trial (SABR-COMET), which notably had updated but overall similar results published after publication of the cost-effectiveness article[238]; however, this is balanced by the fact that the model was relatively insensitive to the variables included.

In another cost-effectiveness study, Chin and colleagues developed a Markov model comparing short-course radiation therapy and total neoadjuvant therapy (SCRT-TNT), consisting of 25 Gy in five daily fractions via 3D or IMRT techniques followed by nine cycles of modified leucovorin calcium, fluorouracil, and oxaliplatin or six cycles of capecitabine and oxaliplatin, versus conventional long-course chemoradiotherapy (LCCRT), consisting of 50.4 Gy in 28 daily fractions with concurrent capecitabine with or without adjuvant chemotherapy for locally advanced rectal cancer.[141] In all cases, patients underwent total mesorectal excision (abdominoperineal resection or low anterior resection). Patients could transition between the five health states of no evidence of disease, resectable locoregional recurrence, unresectable locoregional recurrence, distant metastatic disease, and all-cause death. Patients who experienced resectable locoregional recurrence underwent reirradiation via a hyperfractionated technique of 39 Gy in 26 twice-daily fractions,[239] followed by salvage surgery in a proportion of patients, and patients with unresectable recurrence received palliative capecitabine for 1 year. Outcome and treatment-related toxicity probabilities were obtained from the RAPIDO trial,[134] though the probabilities of transitioning between states after the first cycle (ie, from any locoregional recurrence to metastases or death) were assumed to be the same in each treatment group. Similar to the other cost-effectiveness studies, costs and utilities were derived from the Medicare outpatient payment schedule and published literature. A WTP threshold of $50,000/QALY was chosen. Overall, SCRT-TNT incurred lower costs ($41,355) compared with LCCRT ($54,827) and a higher effectiveness (2.21 QALYs with SCRT vs 2.12 with LCCRT), resulting in a

negative ICER of –$141,256/QALY, indicating that SCRT-TNT "dominated" LCCRT and was overall cost-effective. Sensitivity analyses revealed the model was most sensitive to the probability of transitioning from the no evidence of disease health state to the distant metastasis health state, the probability of low anterior resection as initial treatment, the health utility of being in the no evidence of disease health state after low anterior resection, and the cost of LCCRT and adjuvant chemotherapy, though even if each variable was differed by 25% around the base-case values, SCRT-TNT remained cost-effective. This study, similar to the abovementioned study, was limited by the fact that it drew data primarily from a single phase 3 study (RAPIDO), and furthermore, quality of life and patient-reported outcomes data had not yet been reported for any prospective studies of SCRT-TNT for rectal cancer.

Health Services Research: Conclusions

Although randomized clinical trials are the gold standard for obtaining level I evidence, the dearth of long-term data directing therapeutic choices is one reason to perform decision analysis, which allows assumptions to be made and then varied over a wide range to determine their effects on results. The number of properly constructed cost-effectiveness analyses studying RT reported in the literature is growing; however, the pressing need for additional cost-effectiveness studies within the field of radiation oncology remains. As our treatments become more technical and expensive, it is our responsibility to prove that these treatments lead to benefits (either better survival or improved quality of life) that warrant the increased cost.

CHAPTER 38

Economic, Gender, and Racial Disparity in Radiation Oncology

Erica Fleming-Hall and Shearwood McClelland III

The field of radiation oncology (RO) has evolved rapidly since its inception, incorporating treatment modalities like hypofractionation and stereotactic radiotherapy (RT) aimed at reducing the number of fractions per treatment series. Technological advancements in this field have undoubtedly yielded numerous benefits, including decreased treatment volumes, shorter durations, improved treatment outcomes, and reduced toxicity. However, it is paramount to recognize that these advancements have not consistently resulted in fair and accessible outcomes for all patient populations.[1] Disparities persist within RO, stemming from factors such as race, gender, geographical location, and socioeconomic status (SES). These disparities have had a profound impact on both patients and health care practitioners, exerting far-reaching effects across the entire cancer care continuum.[2] They manifest throughout different stages, ranging from disease burden and associated risks to early detection, diagnosis, and treatment. They significantly affect critical outcomes, such as quality of life, mortality rates, and survival rates, often with social and economic conditions playing a substantial role in driving these disparities.[3] This chapter aims to explore economic, gender, and racial disparities within RO, advocating for health equity by encouraging the effectuation of the highest quality of health in this field for all individuals, particularly focusing on those at the greatest risk of less than optimal health outcomes due to social and economic factors. The reduction of health disparities serves as the metric to gauge advancement toward achieving this goal.[2]

SOCIOECONOMIC STATUS

Definition of Socioeconomic Status

Socioeconomic status (SES) refers to a conceptual framework that categorizes individuals and communities based on various indicators used for codifying a hierarchical structure for social stratification. These indicators often include measures, such as income, education, occupation, that can be reflective of social positioning and offer insights into access to essential material resources such as food, shelter, transportation, education, and health care services, such as RT.[4] Socioeconomic factors play a significant role in influencing cancer risk factors, including tobacco use, inadequate nutrition, physical inactivity, and obesity. In particular, income, education, and health insurance coverage have a direct impact on individuals' ability to access timely and appropriate early detection, treatment, and palliative care for cancer.[3] When understanding the risk, burden, and impact of socioeconomic factors on cancer across the socioeconomic strata, many studies have employed census tract data as a means to designate SES.

The Surveillance, Epidemiology, and End Results (SEER) Program of the U.S. National Cancer Institute (NCI), the preeminent repository on cancer incidence and survival in the United States uses four census tract-level attributes to quantify SES status: SES quintile, two rurality variables, and persistent poverty.[5] The SES quantile is based on the Yost state-based quintile, an index first introduced in 2001 in an effort to investigate SES in breast cancer (BC) incidence among different race and ethnic groups in California.[6] The SES quintile is constructed by first deriving composite SES scores from variables median household income, median house value, median rent, percent below 150% of the poverty line, education index, percent working class, and percent unemployed.[5] Education index, median income, median house value, and median rent correlate positively with high SES, contributing positively to the SES component, whereas the proportion below 150% of the poverty line, percentage of the working class, and percentage unemployed show an inverse relationship with SES, carrying negative loadings. A higher component score indicates a higher SES index.[6] The SES index census tracts are sorted into SES quintiles, ensuring equal populations in each quintile either within a specific state or across the entire United States. The lowest SES group, known as the first quintile, represents the 20th percentile or below, while the highest SES group, the fifth quintile, corresponds to the 80th percentile or above.[5]

The two rurality variables aid in the comparison of cancer incidence and survival disparities between urban and rural areas. The first variable, utilizing the U.S. Department of Agriculture's Rural Urban Commuting Area, classifies areas into two groups: those focused on commuting in urban regions and those not primarily centered on urban commuting. The second variable, the Urban Rural Indicator Code, relies on the Census Bureau's data, categorizing areas into four groups based on the percentage of population living in nonurban regions: all urban (100% urban), mostly urban (≥50% but <100% urban), mostly rural (>0% but <50% urban), and all rural (100% rural) census tracts.[5]

The persistent poverty variable is used to categorize census tracts as persistently poor if at least 20% of the population has lived below the poverty line for around three decades. This dichotomous poverty variable classifies census tracts as either persistently impoverished or nonpersistently impoverished.[5]

Cancer Disparities According to Socioeconomic Status

For all combined cancers for both men and women, the 5-year survival rate is more than 10 percentage points higher for persons who live in affluent census tracts than for persons who live in poorer census tracts.[3] Over the past three decades, there has been a widening of socioeconomic gaps in cancer mortality, particularly pronounced in largely preventable cancers.[7] For instance, women living in economically disadvantaged areas experience double the mortality rate from cervical cancer compared to those in more affluent regions, and men in these areas face mortality rates for lung and liver cancer that are more than 40% higher.[7] Moreover, a higher proportion of colorectal cancer cases diagnosed at an advanced stage are reported among individuals residing in poorer census tracts compared to those in more affluent areas.[3] The American Cancer Society released data on Cancer Statistics 2019; these data were used in Figure 38.1 to illustrate the differences in mortality rates according to SES from 2012 to 2016 according to cancer region. The released statistics show that, when compared to those from more affluent areas, individuals from poorer areas experience disparities in cancer incidence rates. These disparities are most pronounced for uterine cervix, with a relative risk (RR) of 2.00 (1.90-2.10),

liver with RR of 1.37 (1.35-1.40), colorectum with RR of 1.30 (1.28-1.32), lung with RR of 1.28 (1.27-1.29), and prostate with RR of 1.26 (1.23-1.28).[7]

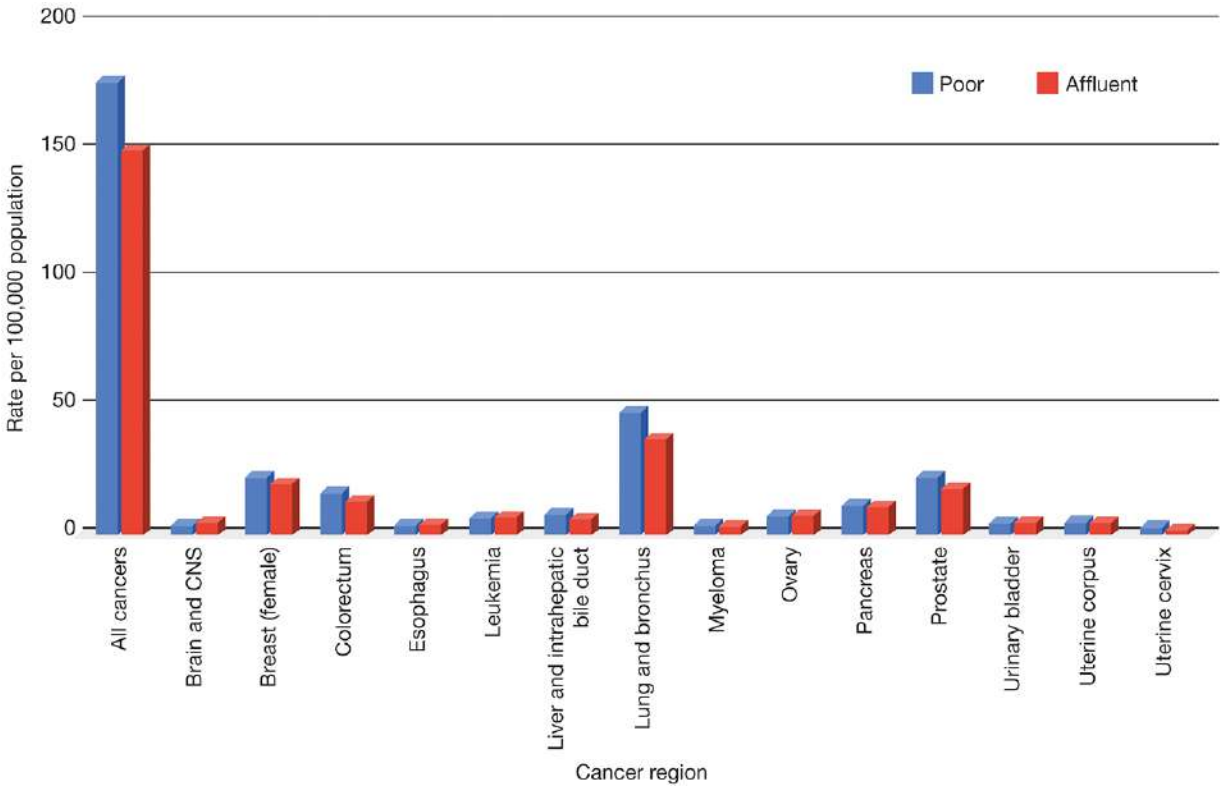

FIGURE 38.1 Cancer mortality rates according to socioeconomic status from 2012 to 2016. CNS, central nervous system. (Data from Siegel RL, Miller KD, Jemal A. Cancer statistics, 2019. *CA Cancer J Clin*. 2019;69[1]:7-34.)

These disparities for individuals of disadvantaged SES can potentially be explained by the notion that those of a disadvantaged SES face an elevated likelihood of encountering environmental or behavioral factors that raise their vulnerability to cancer development. They are more susceptible to encountering aggressive tumor characteristics, a greater incidence of coexisting medical conditions, and the presentation of advanced-stage diseases that pose challenges for curative treatments.[2] Moreover, individuals in less affluent census tracts are likely to experience social determinants that increase the risk of certain cancers. For example, poor and minority communities are selectively targeted by the marketing strategies of tobacco companies, may have limited access to fresh foods and healthy nutrition,

and are provided with fewer opportunities for safe recreational physical activity.[3]

These health disparities could potentially be further explained by biologic mechanisms, such as the phenomenon of telomere shortening. After controlling for individual characteristics, including SES at the individual level, research has shown that increasing levels of neighborhood socioeconomic deprivation are associated with shorter leukocyte telomere length (LTL) among a nationally representative sample of adults in the United States.[8,9] Comparing individuals residing in high deprivation neighborhoods to those in areas with lower neighborhood deprivation, it was found that the mean LTL of the former group was approximately 95 base pairs shorter. This reduction in telomere length is equivalent to around 7.5 years of accelerated cellular aging.[10]

Insurance Status Influencing Radiation Oncology Disparities

It is imperative to recognize the importance of health care access in shaping the overall health of a population, two essential aspects emerge as primary concerns: affordability and accessibility. Affordability is associated with health insurance, while accessibility pertains to geographic proximity to health care services.[10] Several studies have shown that compared to patients with cancer with non-Medicaid insurance, patients with Medicaid and no insurance have an elevated risk of death and tend to present with more advanced stages of cancer.[11,12]

A study to evaluate the relationship between insurance status and the use of brachytherapy using a logistic regression model on data collected from the public-use SEER database in patients with prostate cancer (PC), cervical cancer, BC, and endometrial cancer between January 1, 2007, and December 31, 2012, found that patients receiving RT were less likely to receive brachytherapy if they had Medicaid coverage (odds ratio [OR] 0.57, 95% confidence interval [CI] 0.53-0.61, $P < .001$) or lacked insurance coverage (OR 0.50, 95% CI 0.45-0.56, $P < .001$) compared to those with non-Medicaid insurance.[7]

In another study investigating the impact of insurance status on survival rates in patients with Hodgkin lymphoma found that patients with Medicaid or lacking insurance were less likely to receive timely RT and start

chemotherapy and that they were also less frequently treated at academic/research centers (all $P < .01$); even after controlling for other factors, an unfavorable insurance (Medicaid or uninsured) status was associated with a significantly decreased overall survival (hazard ratio [HR], 1.60; 95% CI, 1.34-1.91; $P < .01$).[13]

Yet again, in a study investigating the association of insurance status with detection of early-stage BC, it was determined that when compared with women without insurance or with Medicaid, insured women were slightly older at diagnosis (mean [standard deviation], 53.6 [6.8] vs 53.0 [6.8] years), less likely to receive a diagnosis of locally advanced stage III versus stages I or II BC (11% vs 20%) and more likely to receive a diagnosis of luminal A (HR-positive, ERBB2-negative) BC (69% vs 61%).[12]

While patients covered by Medicaid or lacking insurance face elevated mortality risks, often presenting with more advanced cancer stages and encountering treatment delays, the scenario changes concerning advanced RT, such as intensity-modulated radiation therapy (IMRT). The utilization of advanced RT techniques often requires prior authorization, potentially causing delays in starting treatment.[14] In a study examining the usage of IMRT in patients covered by private insurance versus those covered by Medicaid, significant shifts were observed. Specifically, the findings indicated an increase in the proportion of patients from non-Hispanic Black (NHB) backgrounds covered by Medicaid who received IMRT treatment (from 9.0% to 12.7%). Conversely, there was a decrease in the percentage of patients with private insurance undergoing IMRT treatment (from 37.6% to 32.5%).[15]

African American men face a more than 2-fold increased risk of dying from PC compared to non-Hispanic White men.[16,17] Interestingly, the racial disparity in overall cancer mortality in the United States diminishes after the age of 65, likely attributed to widespread Medicare coverage.[18] In a study evaluating PC-specific mortality in the equal-access Veterans Affairs (VA) health care system, it was found that African American men did not exhibit a higher likelihood of encountering delays in diagnosis or treatment. Second, there was not an increased tendency for African American men to present with more advanced-stage or aggressive forms of the disease. Lastly, African American men with PC did not face a higher mortality rate. In fact, there was a slight but statistically significant decrease in PC-related

mortality among African American men. These positive outcomes for African American men were observed, even though they resided in areas with lower SES.[19] This departure from national trends mirrors similar studies of equitable health systems that have shown no discernible differences in PC outcomes between non-Hispanic White and African American men covered by Medicaid.[20] These findings suggest that access to high-quality medical care plays a pivotal role in establishing racial equity among men diagnosed with PC.

The importance of health care access in shaping public health becomes evident through the critical elements of affordability and accessibility. Studies reveal disparities in cancer outcomes associated with insurance status, notably Medicaid, or with insurance, highlighting heightened risks of mortality, advanced cancer stages at diagnosis, and delays in treatment. However, a notable shift is observed in the context of advanced RT. Specifically, individuals covered by Medicaid displayed an increase in receiving IMRT, whereas those with private insurance demonstrated reduced utilization. In addition, investigations into PC outcomes among African American men exhibited a departure from national norms, indicating no differences in diagnosis delays, disease stages, or mortality rates, even in regions with lower SES within a health care system providing equal access.

Access to Care

Research has highlighted that reduced access to RT is linked to lower utilization of the treatment and poorer cancer-related outcomes.[10] Further, it has been shown that the proximity to the nearest RT facility had a negative association with breast-conserving surgery (BCS), with the OR decreasing by 3% for every 5-mile increase in distance.[21] It is widely accepted that the travel distance to access health care services can impact the type and timing of care received by patients. Patients generally prefer seeking care in close proximity to their homes. RT differs from other cancer treatment methods due to the need for daily visits for a period of up to 7 weeks.[10] This places a significant burden on patients, intensifying travel-related challenges and potentially worsening disparities caused by distance to health care facilities.

The availability of RT depends on the presence of radiation oncologists and linear accelerators, and this can be affected by geographic accessibility. Studies have revealed that radiation oncologists are unevenly distributed across the country, with a higher concentration in academic centers. This geographic maldistribution can create difficulties for patients, particularly when they are required to travel long distances to access cancer care. These travel barriers have been linked to reduced utilization of RT and could potentially result in poorer treatment outcomes for patients[22] (Figure 38.2). Studies have shown that residents of nonmetro (more rural), older, and less insured areas have disproportionately less access to RT and that increased traveling distance to treatment can delay treatment treat times and affect treatment decisions.[21] Further, it has been found that access to RT facility was lower with increasing rurality and worsening area deprivation index.[23]

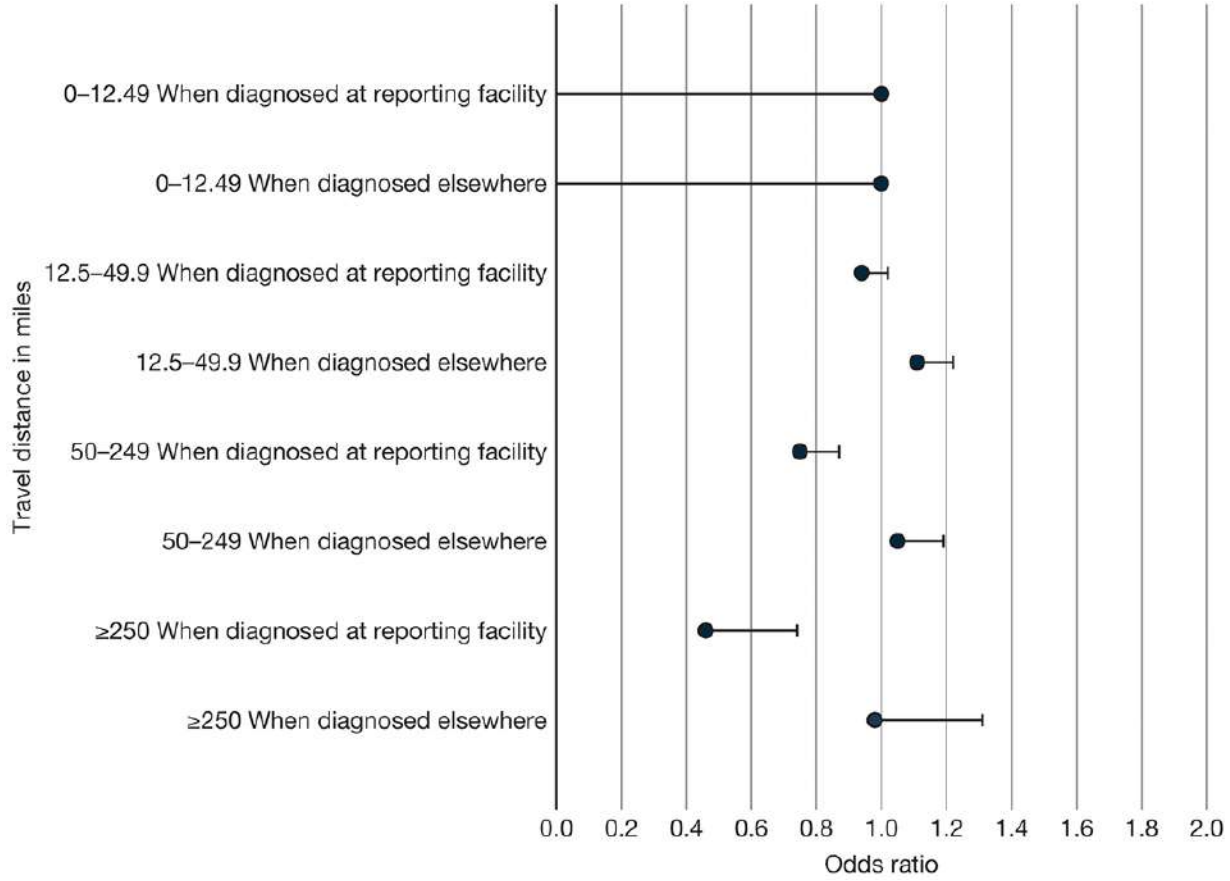

FIGURE 38.2 Likelihood of receipt of radiation therapy among patients with stages II to II rectal cancer based on distance to treatment facility. (Data from Lin CC, Bruinooge SS, Kirkwood MK, et al. Association between geographic access to cancer care and receipt of radiation therapy for rectal cancer. *Int J Radiat Oncol Biol Phys*. 2016;94[4]:719-728.)

Rural residents diagnosed with cancer often face later stage diagnoses and reduced access to treatment, influenced by individual- and community-level socioeconomic disadvantages. Rural residents are more likely to reside in areas that lack grocery stores and fresh produce, which offer limited access to employment opportunities providing health insurance, and lack public infrastructure, such as public transportation and broadband internet, thereby limiting travel options to care for those without vehicles and reducing access to telehealth. Many rural areas are classified as health professional shortage areas, and oncologists are underrepresented in rural areas, in part, due to increased hospital closure rates in rural areas, furthering the reduction in access to care.[24]

Advances in Radiation Oncology ran a four-part series focused on the vulnerable populations within the United States that are most likely to suffer disparities in RT access; this multipart series examined African American, Native American, Hispanic American, and Appalachian patients. The investigation into access to care disparities among African Americans revealed that African American women had lower rates of receiving chemotherapy and RT and experienced significantly higher mortality rates compared to Caucasian women, even after SES adjustments.[25] In addition, a study highlighted an inverse relationship between the distance to RT facilities and the utilization of BCS and RT, with African Americans being 42% less likely than Caucasians to receive BCS plus RT based on an analysis of the Florida Cancer Data System.[10] Furthermore, another study found that African Americans were more reliant on public transportation to reach RT facilities, which took 7 times longer than private vehicle transportation, creating a significant barrier to receiving optimal RT treatment.[26] Consequently, African American women with BC were less likely to undergo adjuvant RT due to increased distance from RT facilities and limited access to private vehicle transportation in comparison to Caucasian women.[27]

The first part of the series further concluded that the type of hospital where patients with BC receive treatment plays a significant role in causing delays in adjuvant RT or chemotherapy for women with stages I to III BC. Hospitals that have a higher probability of treatment delays tend to be smaller, have lower BC surgical volume, are located in rural areas, are not-for-profit, and are less likely to be approved cancer centers by the American

College of Surgeons and are more likely to treat African American women compared to Caucasian women.[27]

The investigation into access to care disparities among Native Americans revealed that American Indians and Alaska Natives are disproportionately diagnosed at more advanced stages of the disease. In recent years, cancer death rates among American Indians demonstrated a steady linear increase; conversely, the rates for Caucasians have seen to decrease linearly. Despite this, there is limited information available on RT access in American Indian and Alaska Native patients.[28]

The investigation into access to care disparities among Hispanic Americans revealed that, similar to African American RT access, Hispanic Americans have restricted access to RT compared to Caucasian patients. Interestingly, they are less likely to experience concurrent disparities in mortality when compared to other underrepresented minorities facing similar challenges.[29]

The last part of the series found that in comparison to the rest of the United States, Appalachians face unique challenges, such as lower education levels, higher poverty rates, and limited health care access. Consequently, the NCI has classified rural populations as special populations due to their elevated risk of cancer and other diseases.[30]

These disparities are also appreciated in the pediatric population. Pediatric patients encounter comparable discrepancies to their adult counterparts concerning access to RT. In a comprehensive study involving 12,000 pediatric patients, it was noted that individuals from neighborhoods characterized by lower median incomes and educational attainment, along with those lacking insurance or covered by Medicaid, face reduced likelihoods of receiving proton RT despite its increased usage in pediatric solid malignancies.[30]

GENDER

Definition

Sex and gender are distinct yet interconnected constructs that influence health and health research. Sex is a complex biologic concept, encompassing anatomy, physiology, genetics, and hormones. On the other hand, gender is a self-identified construct involving gender identity,

expression, and societal and cultural expectations related to specific sex traits. A person's gender identity, such as woman, man, trans man, gender diverse, or nonbinary, may undergo changes over their lifetime and may or may not conform with the cultural expectations of a society based on their biologic sex traits.[31]

Gender Disparities in Cancer Care

Despite advancements in addressing gender-based disparities in human studies, women continue to be underrepresented in cancer trials. For instance, among the 5,157 patients who participated in oncology trials leading to Food and Drug Administration approval of 17 new drugs in 2018, only 38% were women. The underrepresentation of women is evident in various clinical trials sponsored by the NCI, including those focusing on colorectal cancer, lung cancer, and surgical oncology. Even in cancers where females have a higher prevalence, such as lung cancer, melanoma, and pancreatic cancer, they were still underrepresented in therapeutic trials reported in ClinicalTrials.gov from 2003 to 2016, excluding PC and BC trials.[3]

Cancer Disparities in Sexual and Gender Minorities

Over 10.7 million adults in the United States identify as LGBTQ (lesbian, gay, bisexual, transgender, or queer), while at least 500,000 are adult cancer survivors.[32] Research has shown that there are associations between certain types of cancer and the risk of diagnosis or disease-specific mortality among LGBTQ patients.[33]

Sexual minority women experience disparities in cancer prevention, screening, prevalence, and mortality. For example, lesbian women are less likely to initiate human papillomavirus (HPV) vaccination for cervical cancer prevention compared to heterosexual women. In addition, cervical cancer screening rates may be lower in lesbian or bisexual women. Moreover, bisexual women and transgender individuals are less likely than heterosexual women to follow mammography guidelines for BC screening, despite facing a similar disease risk. Despite having similar rates of BC to that of the general population, sexual minority women may have higher BC mortality rates and an increased risk of oropharynx cancer compared to

heterosexual women. Similarly for men who have sex with men, regardless of their HIV status, anal cancer rates are higher than those in the overall U.S. male population.[34]

Approximately 1.3 million adults in the United States identify as transgender, this accounts for about 0.5% of the U.S. adult population.[35] Transgender individuals frequently face several unique challenges to accessing health care, and these challenges have far-reaching implications, affecting everything from cancer diagnosis to treatment, potentially leading to decreased survival rates. Some of these challenges are social in nature, as transgender individuals are nearly 3 times more likely to be unemployed, resulting in higher rates of being uninsured or underinsured. Other barriers experienced by transgender individual are rooted in the absence of appropriate transgender-specific screening guidelines. Despite the lower incidence of PC in transwomen compared to cisgender men, current screening guidelines recommend applying the same standards for PC screening in transwomen as in cisgender men.[32]

RACE AND ETHNICITY

Definitions

The concept of race is defined as a social construct primarily based on the expression of phenotypic genetic traits rather than being grounded in biology. It is widely recognized that there is greater genetic variation within racial groups than between them, leading to significant doubts about using race as a biologic construct to categorize distinct, genetically different population groups. The U.S. Bureau of the Census has underscored the importance of treating race as a social and political construct rather than a biologic one. In the realm of health-related research, the concept of race encompasses both personal identity and group identity aspects, in addition to the more conventional biologic indicators.[33]

The Office of Management and Budget (OMB) provides standards for categorizing race. According to these standards, “White” refers to individuals with origins in Europe, the Middle East, or North Africa. “Black or African American” encompasses individuals with origins in various Black racial groups in Africa. “American Indian or Alaska Native” refers to individuals with origins in the original peoples of North and South America,

including Central America, who maintain tribal affiliation or community attachment. “Asian” includes individuals with origins in the Far East, Southeast Asia, or the Indian subcontinent, such as Cambodia, China, India, Japan, Korea, Malaysia, Pakistan, the Philippine Islands, Thailand, and Vietnam. “Native Hawaiian or Other Pacific Islander” pertains to individuals with origins in the original peoples of Hawaii, Guam, Samoa, or other Pacific Islands. The OMB standards also allow for the reporting of more than one race.[33]

A closely related but distinct construct often intertwined with race is ethnicity. Ethnicity pertains to the sharing of a common culture, including common origins, shared psychological characteristics and attitudes, a common language, religion, and cultural traditions. Discussions on this topic have suggested that one’s race and/or ethnicity should be regarded as affiliations rather than genetic predispositions. Ethnicity can indirectly influence health outcomes by shaping health beliefs, the expression of symptoms, physical functioning, access to health care systems, and medical treatment processes.[33]

Racial Disparities in Radiation Oncology Treatment

In the United States, African Americans bear the highest burden of cancer incidence and mortality. Delays to initiation to treatment and underutilization of RT disproportionately affect race minority patients.[27] When compared to insured non-Hispanic White individuals, racial/ethnic minority group members and those without insurance are at a higher risk of encountering treatment delays and are less likely in some cancers to receive definitive treatment, such as radiation.[34]

A study using data from the National Cancer Database (NCDB) focused on the number of patients with cancer treated with definitive-intent IMRT of 10 primary disease sites (prostate, lung, head and neck, rectum, esophagus, anus, pancreas, stomach, cervix, and uterus) found that the percentage of non-Hispanic White patients facing delays in interval to initiation of treatment (IIT) ranged from 27.4% to 40.4%.[14] In contrast, this percentage varied from 38.4% to 58.9% for Hispanic patients, 38.1% to 57.9% for NHB patients, and 27.3% to 49.1% for Asian patients. Even after adjusting for clinical and sociodemographic factors, Hispanic patients were

notably more prone to experience delayed IIT in 9 out of 10 disease sites. Similarly, NHB patients faced significantly higher odds of experiencing delays in 7 out of 10 disease sites, while Asian patients were significantly more likely to encounter delayed IIT in 8 out of 10 disease sites compared to non-Hispanic White patients. Moreover, when considering primary insurance, non-Hispanic White, Hispanic, and Asian patients with private insurance encountered shorter IIT compared to their counterparts with Medicare. Furthermore, NHB patients with private insurance experienced longer IIT than NHB patients covered by Medicare.[14]

In a retrospective population-based study using the SEER database, researchers focused on 102,486 African American men and non-Hispanic White men diagnosed with localized high-risk PC between 2004 and 2010.[36] The study revealed significant disparities in receiving definitive therapy between African American and White men with high-risk PC. It was found that African American men were notably less likely than White men to receive definitive therapy (81.0% vs 87.4%, $P < .001$). The study further highlighted the disparity in definitive therapy based on race and regional income, showing that African American men in low-income regions were the least likely to receive definitive therapy (75.9%), whereas White men in high-income regions were the most likely (89.6%) (Figure 38.3). In addition, it was determined that African American men in high-income regions were significantly more likely to receive definitive therapy compared to those in low-income regions (87.5% vs 75.9%, $P < .001$). White men in high-income regions were more likely to receive curative therapy than their counterparts in low-income regions, as well as African American men in both high- and low-income regions (89.6% vs 83.6%, 87.5%, and 75.9%; $P < .001$, $P = .004$, and $P < .001$). The analysis, even after adjusting for various factors, including demographics, non–PC deaths within 5 years, and cancer-specific factors, indicated that African American men with high-risk PC were significantly less likely than White men to receive definitive therapy (adjusted OR [AOR] = 0.51; 95% CI: 0.49-0.54; $P < .001$). In addition, individuals from high-income regions had a significantly higher likelihood of receiving definitive therapy compared to those from low-income regions (AOR = 1.19; 95% CI: 1.08-1.32; $P = .001$).[37] When comparing treatment rates for PC in Black and White men, significant disparities can be appreciated as Black men were only half as

likely as White men to receive definitive therapy (surgery or radiation) for their PC. Moreover, Black men whose cancer had spread beyond the prostate were twice as likely as White men not to receive definitive treatment for their cancer (44% compared to 22%). It is important to highlight that when Black men receive the same treatment as White men for the same grade and stage of PC, their survival rates are equivalent.[36]

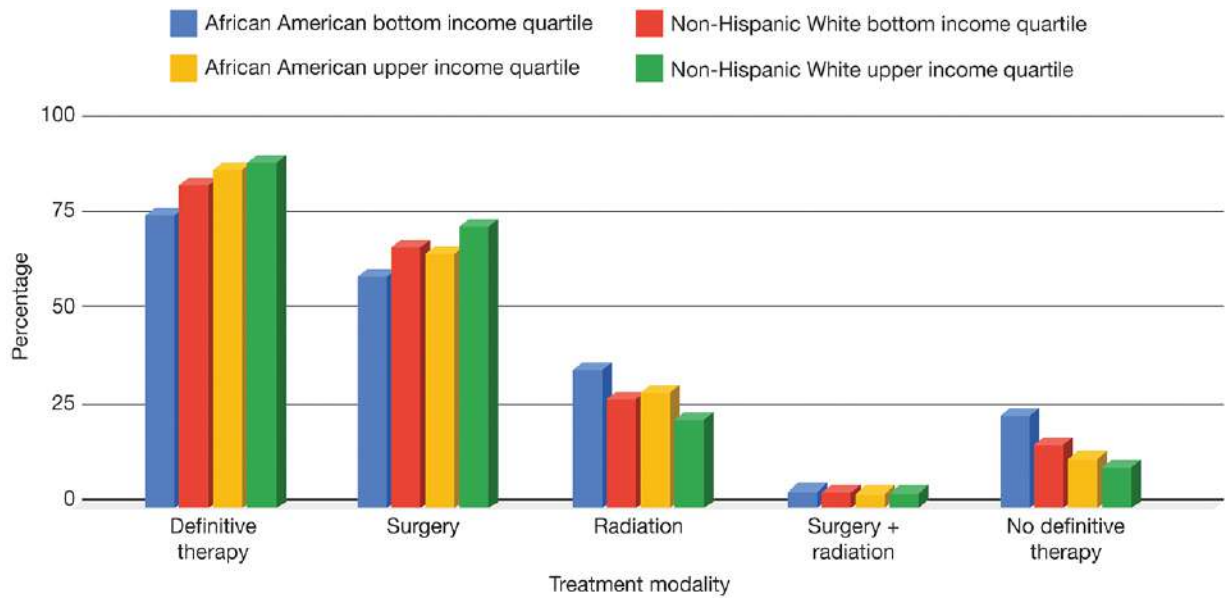

FIGURE 38.3 Receipt of definitive therapy stratified by race and regional income level among men with high-grade prostate cancer. (Data from Zeliadt SB, Potosky AL, Etzioni R, Ramsey SD, Penson DF. Racial disparity in primary and adjuvant treatment for nonmetastatic prostate cancer: SEER-Medicare trends 1991 to 1999. *Urology*. 2004;64[6]:1171-1176.)

Studies additionally have highlighted significant Black-White disparities in PC treatment that persist irrespective of patients' SES or other existing health conditions that might influence treatment decisions. Even after controlling for marital status, age at diagnosis, and geographical region, striking differences were still evident. White men diagnosed with highly aggressive PC were just as likely to receive definitive treatment as White men with moderately aggressive cancer. However, Black men with high-risk cancer were 50% less likely to receive definitive treatment compared to White men with moderately aggressive cancer. This is particularly striking because men diagnosed with poorly differentiated PC face a 2.5 times higher risk of PC-related mortality when lacking nondefinitive treatment.

Interestingly, no disparities between Black and White men were observed in receiving definitive treatment among those diagnosed with low-risk PC. However, among men diagnosed with moderately aggressive cancer, Black men were 36% less likely than their White counterparts to receive definitive treatment.[36,38-41]

Another aspect of the treatment disparities includes treatment completion rates. In a comprehensive national study involving patients who underwent radiation treatment for curable PC and BC, it was found that shorter treatment regimens were associated with decreased instances of treatment noncompletion. Notably, disparities were observed among Black men receiving conventional external-beam radiation therapy (cEBRT), demonstrating higher rates of treatment noncompletion compared to White men. However, this trend was not evident among Black men undergoing stereotactic body radiation therapy (SBRT) or moderately hypofractionated external-beam radiation therapy (mEBRT). Contrarily, no disparities were noted in treatment noncompletion among women with BC. Despite evidence suggesting the benefits of shorter radiation regimens, Black patients consistently received less hypofractionated radiation for PC and BC. A study, using data from the NCDB, showcased a rise in SBRT and mEBRT rates from 2004 to 2017. However, Black patients were less likely than White patients to receive these advanced radiation techniques. Moreover, the study highlighted a significant increase in hypofractionated external-beam radiation therapy (hEBRT) for BC over time, with a notable racial disparity as Black women were less likely to receive hEBRT compared to White women. Even in subgroup analyses, disparities persisted among Black women, both in node-negative and node-positive disease categories. The findings emphasized the lower adoption rates of hypofractionated radiation among Black patients compared to White patients over the study period.[36]

Racial Disparities in Cancer Pain Management

Cancer-related pain is a common challenge for patients undergoing therapy, yet many still do not receive adequate pain relief.[42] Studies have highlighted disparities in pain management, particularly with African American and Hispanic patients being less likely to receive sufficient treatment compared

to non-Hispanic White patients.[43] However, health care systems with equal access, such as the VA Healthcare System and among Black and White Medicare beneficiaries with stage IV BC, demonstrated no racial disparities in pain management. Achieving equity in cancer-related pain management will require maintaining and improving access to appropriate analgesic agents for all patients and addressing racial/ethnic disparities in pain assessment, opioid prescribing, and access to other pain management options.[44]

Racial Disparities in Cancer Survival

Racial disparities in cancer mortality persist, with the highest mortality rates observed among American Indian/Alaska Native populations followed closely by Black communities[45] (Figure 38.4). The death rates in both American Indian/Alaska Native and Black men are significantly higher compared to Asian American/Pacific Islander men and White men. While the Black-White disparity in overall cancer mortality has reduced from its peak in 1993, significant gaps persist. These disparities are rooted in historical wealth inequalities resulting from systemic racism, affecting risk factor exposure and access to equitable cancer prevention, early detection, and treatment across different socioeconomic strata. Even among individuals with higher incomes, Black individuals have lower cancer survival rates than their White counterparts.[36] For instance, within the demographic earning a median annual household income of $75,000 or greater, the 5-year relative cancer survival rate is higher for White individuals (72%) compared to Black individuals (67%).[45]

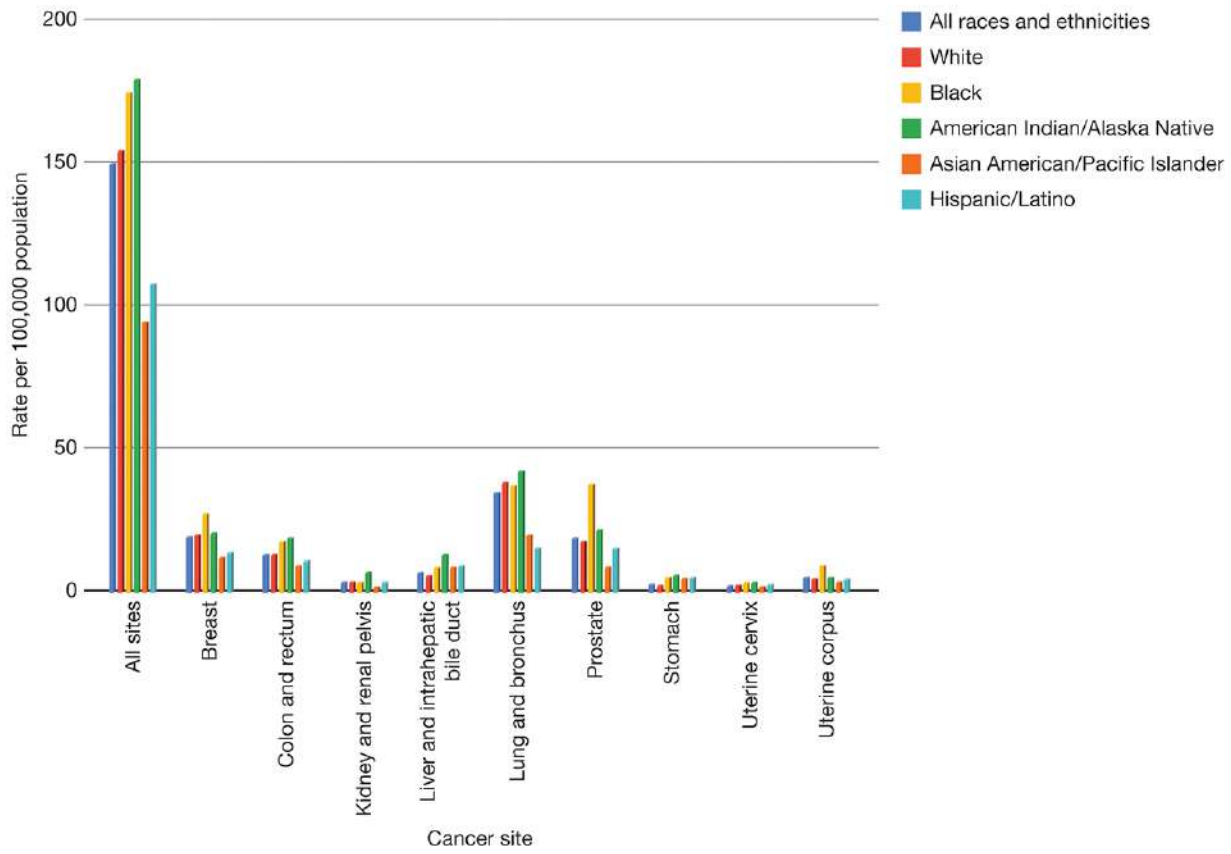

FIGURE 38.4 Mortality rates for select cancers by race and ethnicity, 2016 to 2020. (Data from Islami F, Guerra CE, Minihan A, et al. American Cancer Society's report on the status of cancer disparities in the United States, 2021. *CA Cancer J Clin*. 2022;72[2]:112-143.)

African Americans in the United States face considerable challenges in accessing effective cancer treatments, despite proven benefits demonstrated in randomized controlled trials. Across various cancer types, African Americans often experience higher death rates and shorter survival periods compared to other racial or ethnic groups. Specifically, African American men have an overall cancer death rate 24% higher, while African American women have a 14% higher rate than their Caucasian counterparts. Predominantly, PC (31%), lung (15%), and colorectal (9%) cancers are frequently diagnosed among African American men, while BC (32%), lung (11%), and colorectal (9%) cancers are more common among African American women.[27]

The current 5-year survival rates for BC stages show promising advancements, with rates nearly reaching 100% for stages 0 and I, 93% for stage II, and 72% for stage III. However, these improvements have not been

uniformly experienced across all patient groups. Racial and ethnic minorities, when compared to non-Hispanic White women, tend to receive diagnoses at later cancer stages. This disparity contributes to higher mortality rates, increased treatment-related complications, and reduced overall quality of life among minority populations. Consequently, these groups face a less favorable prognosis, undergo more aggressive treatments, and have a lower quality of life during their survivorship period.[12] In BC cases among African American women, a trend exists for diagnosis at a younger age, aggressive subtypes (such as triple-negative disease), and later stage diagnoses with metastases. These disparities contribute significantly to the overall higher death rates and reduced survival periods among African Americans compared to other racial or ethnic groups in the United States.[27]

In a study aimed to explore how rurality and race/ethnicity intersect in influencing BC outcomes, it was found that NHB and Hispanic women, irrespective of their rural or urban residence, exhibited increased odds of late-stage BC diagnosis, a higher likelihood of not receiving essential BC treatments (such as surgery, RT, and chemotherapy), and an elevated risk of BC-related death compared to Non-Hispanic White women in urban areas. On the other hand, rural and urban Asian and Pacific Islander women generally demonstrated better BC outcomes, experiencing a 10% to 20% reduced risk of BC-related mortality when compared to non-Hispanic White women in urban settings. The disparities observed were notably evident among NHB and Hispanic women, who were less likely to receive crucial treatments, consequently increasing their risks for later stage disease and mortality from BC. The study also noted that after accounting for potential influencing factors, the trends observed in late-stage disease, lack of chemotherapy, radiation, or surgical treatment remained consistent in fully adjusted models, emphasizing the persistent impact of race/ethnicity and treatment disparities on BC outcomes.[46]

INTERSECTIONALITY

Intersectionality acknowledges that individual identities intersect with systems of oppression such as sexism and racism. The overlap of various identities highlights unique experiences that cannot be fully understood by

focusing solely on one aspect of identity. This framework allows for exploration of differences within and among groups and underscores that privilege and oppression are context dependent, meaning an individual may experience privilege in one context while facing disadvantage in another. This nuanced understanding of identity and social systems challenges the simplistic categorization of individuals based on singular identities.[47]

Blacks tended to occupy a socially isolated class characterized by the lowest SES and poorer health outcomes. This underscores how racial disparities in health are closely linked to social forces that group individual characteristics, rather than being solely dictated by independent variations in those characteristics. A study comparing allostatic load among different socioeconomic groups found significant disparities in allostatic load among different socioeconomic groups, particularly emphasizing the contrast between privileged non-Black individuals displaying the lowest allostatic load and SES non-Black individuals exhibiting notably higher allostatic load.[48]

There is a significant interplay between race and regional income, highlighting pronounced treatment disparities among Black and White men based on income levels. Specifically, there are substantial treatment discrepancies between Black and White men in the lower income quintile compared to those in the higher income quintile. Regarding PC mortality, in the lower income quintile, a higher percentage of African American men died from PC compared to White men, while comparable rates were observed between African American and White men in the higher income quintile.[37] Females experience more significant constraints in social stratification compared to males. Being female increases the likelihood of belonging to lower socioeconomic classes.[48]

Moreover, Black individuals, particularly females, experience earlier and more pronounced physiological dysregulation compared to their White counterparts supporting the notion Black women face compounded negative impacts due to both gender and racial discrimination.[48]

Black women, while having lower incidence rates for BC and ovarian cancers compared to non-Hispanic White women, face higher death rates from these cancers and are less likely to participate in clinical trials.[49,50] Hispanic women face a higher risk of infection-related cancers such as cervical cancer, with significantly elevated incidence and death rates

compared to non-Hispanic White women. Limited access to screening and higher rates of HPV infections contribute to these disparities. While Hispanic women are underrepresented in BC, ovarian cancer, and uterine cancer trials, they are adequately represented in cervical cancer trials.[51]

American Indian/Alaska Native women experience cancer as the leading cause of death within their communities. Despite their diverse backgrounds and representation across various tribes and villages, clinical trials often lack representation from these groups. A vast majority of trials lack reporting of American Indian/Alaska Native participants, and the involvement of Native American women in cancer drug trials remains extremely low, reflecting a significant gap in research inclusivity and representation.[35]

SPECIAL CONSIDERATIONS FOR PEDIATRIC CANCERS

Children from racial and ethnic minority backgrounds or lower SES experience disparities in cancer care, resulting in higher relapse rates, lower survival rates, and poorer psychosocial outcomes compared to wealthier, non-Hispanic White counterparts.[52] These disparities extend to the accessibility and delivery of RT. For instance, Black pediatric patients are less likely to receive proton RT, despite being enrolled in national prospective trials with standardized treatment protocols.[53]

Health insurance serves as a critical marker for health care accessibility, playing a significant role in cancer outcomes. Disruptions in health insurance coverage in pediatric patients are linked to reduced access to care. Public or lack of insurance increases the risk of death, particularly with age, across most cancer types. Notably, adolescents/young adults enrolled in Medicaid at diagnosis, especially those previously uninsured, are significantly more likely to be diagnosed with later stage cancer compared to those with private insurance, emphasizing the importance of access to care in the context of health insurance.[52]

CALL FOR INCREASED DIVERSITY AND INCLUSION IN THE FIELD

Many communities, particularly minority groups, hold the hope that some of their own members will address their health care needs. Minority

physicians often feel a sense of responsibility to serve their community, potentially explaining why underrepresented health care professionals are more likely to work in underserved areas.[54] Studies indicate that racially discordant medical interactions tend to be less favorable and effective than those involving individuals of the same race. These cross-racial interactions are notably brief, less focused on the patient's needs, characterized by decreased positive engagement, and lack attempts at building strong rapport. Patients are less involved in decision-making, while physicians dominate the conversation more in such interactions.[55]

There is no observable shift toward increased diversity among female or underrepresented minority trainees over an 8-year span, indicating that the issue of underrepresentation is persisting. Across various levels in RO, females and traditionally underrepresented minority groups, such as Blacks, Hispanics, American Indians, Alaska Natives, Native Hawaiians, and Pacific Islanders, are notably underrepresented compared to their proportions in the wider U.S. population. The representation of females and underrepresented minorities remains lower among RO residents, faculty, and practicing physicians compared to their respective representations among medical school graduates and medical oncology fellows.[54]

Although there is an increase in female representation among RO residents compared to RO practicing physicians, Black, Hispanic, and female representation in RO residents is significantly lower compared to their proportions among medical school graduates (Figure 38.5). Underrepresented minorities collectively constitute 30% of the 2010 U.S. Census, but their representation as RO practicing physicians and faculty is notably lower. Specifically, Blacks, Hispanics, American Indians, Alaska Natives, Native Hawaiians, and Pacific Islanders are significantly underrepresented among RO practicing physicians and faculty compared to the overall U.S. population, indicating their underrepresented status in the field of RO.[54]

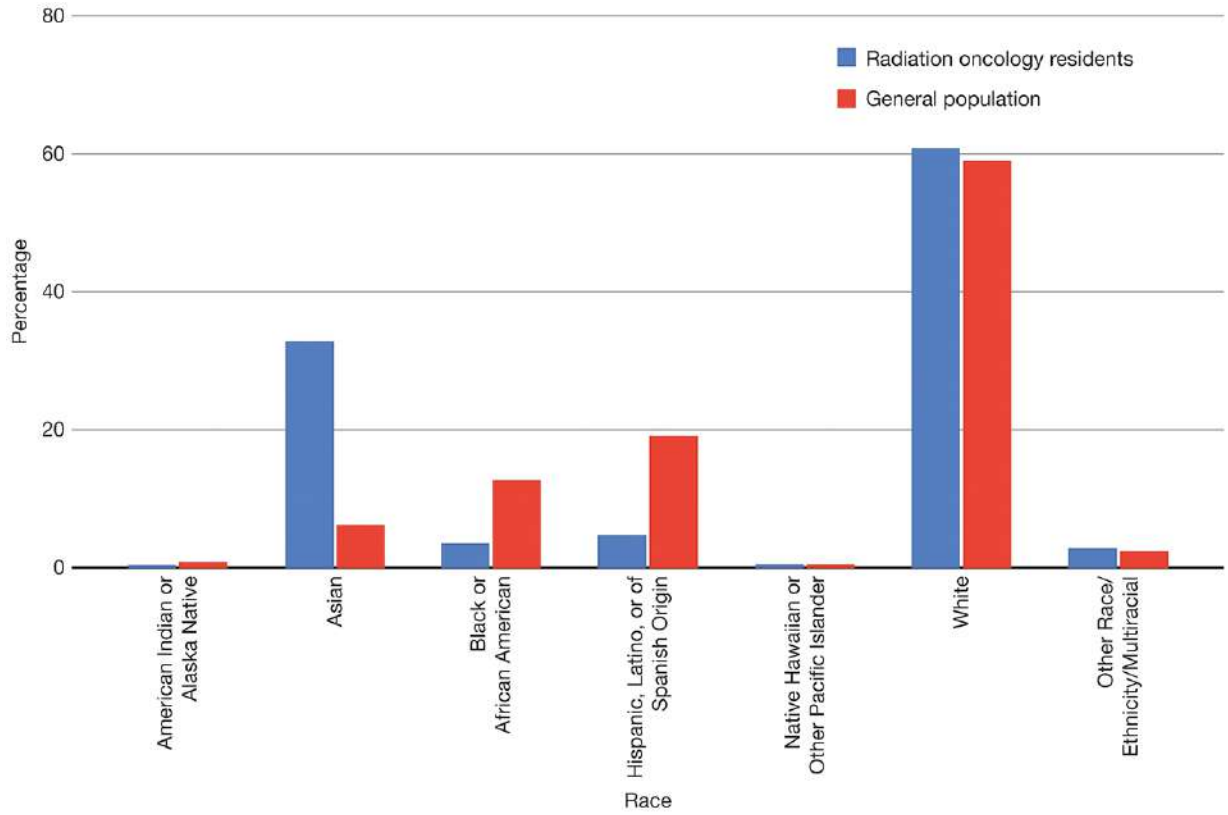

FIGURE 38.5 Active radiation oncology residents by race. (Data from Bitterman DS, Bona K, Laurie F, et al. Race disparities in proton radiotherapy use for cancer treatment in patients enrolled in Children's Oncology Group trials. *JAMA Oncol*. 2020;6[9]:1465-1468.)

CONCLUSION

To address persistent economic, gender, and racial disparities in RO, continuation of shaping effective policies and advocating for social policy changes is needed.[56] Literature suggests that reducing or eliminating disparities in treatable cancer outcomes is achievable when patients receiving definitive radiation have access to high-level and quality care that is comparable.[57] To attain equity in RO, it is essential to acknowledge and incorporate diversity within an inclusive framework. This objective is not solely a cultural aspiration but also brings tangible advantages to health outcomes. It entails ensuring fair treatment and providing equal opportunities for individuals, taking into account differences in gender, age, ethnicity, religion, sexual orientation, identity, socioeconomic background, and disability, particularly within the context of cancer care.[58]

Strategies for reducing cancer health disparities in RO involve interventions at both patient and facility levels. Patient-focused measures include securing financial support for modern radiation technology, building community partnerships, improving transportation options, and addressing financial toxicity. Facility-oriented actions encompass promoting diversity in cancer training, educating faculty and staff on diversity principles, overcoming barriers to clinical trial participation by minorities, and providing research funding to address disparities and enhance health equity.[56]

SECTION IV

Clinical Radiation Oncology

PART A

Skin

CHAPTER 39

Skin

William M. Mendenhall, Anthony A. Mancuso, Peter T. Dziegielewski, and Christiana Shaw

The purpose of this chapter is to discuss cutaneous carcinoma, including Merkel cell carcinoma (MCC) and melanoma. Uncommon cutaneous malignancies, such as angiosarcoma and dermatofibrosarcoma protuberans, are addressed elsewhere. Most skin cancers are managed surgically. Because of the functional and/or cosmetic deficits that may occur after surgery for skin cancers of the head and neck, the discussion occasionally focuses on lesions in this area.

Skin cancer is the most common of all malignancies. The American Cancer Society estimates that approximately two million basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs) are diagnosed annually in the United States, although the precise number is unknown because they are not reported.[1] The risk for carcinoma of the skin increases with sun exposure. A low incidence occurs in those with Fitzpatrick skin types V and VI; a corresponding increase occurs in those with Fitzpatrick skin types I and II. The mortality rate is about 1,800 per year, or 0.45%.

Several conditions are associated with carcinoma of the skin, including the following:

- Actinic exposure
- Ionizing radiation
- Scar (eg, burn scar)
- Chronic infection or draining of sinus or fistulous tract (eg, pilonidal sinus)
- Immune disorders
  - Chronic lymphocytic leukemia
  - Solid organ transplant patients
  - Discoid lupus erythematosus
- Chemicals
  - Arsenicals (herbicides, pesticides)
  - Psoralens and ultraviolet light treatment for psoriasis
  - Nitrates
  - Tars, oils, and paraffins
- Hereditary disorders
  - Xeroderma pigmentosum

- Basal cell nevus syndrome
- Albinism
- Congenital epidermolysis bullosa

Melanoma is less common than BCCs and SCCs. Siegel et al[2] estimated that approximately 76,380 melanomas will be diagnosed in the United States in 2016 and that about 10,130 deaths owing to the disease will occur. Dysplastic nevus may increase the risk of developing melanoma.[3]

ANATOMY

Epidermis

The epidermis is thinner in the face than in most portions of the body, measuring approximately 0.04 mm. No consistent change in the thickness of the epidermis occurs with increasing age, and no difference in skin thickness exists between men and women. The layers of the epidermis from superficial to deep are as follows:

- Stratum corneum
- Stratum lucidium
- Stratum granulosum
- Stratum spinosum
- Stratum basale

It is important to know these layers to understand the origin and behavior of a particular type of skin cancer.

Dermis

The dermis, which contains the blood and lymphatic vessels, adnexa, hair follicles, sweat glands, and sebaceous glands, is 1 to 2 mm thick; the dermis of the eyelid is thinner (≤0.6 mm). Beneath the dermis lies the subcutaneous tissue containing the fat and the superficial fascia. No distinct transition occurs from the dermis to the subcutaneous layer.

Lymphatics

No lymphatics exist in the epidermis. A superficial capillary lymphatic plexus lies in the dermis and is without valves.[4] The deep lymphatic trunks in the dermis and subcutaneous tissues have valves. The density of the capillary lymphatics has been noted to be about the same in all areas, except the sole of the foot and palm of the hand, where it is denser. Observation suggests that SCCs and melanomas occurring on the skin of the temple are particularly prone to develop lymphatic metastasis.[5] During the healing of wounds, such as incisions or burns, a regeneration of lymphatic capillaries across the scar occurs, similar to the regrowth of small blood vessels.[3]

The first-echelon lymph nodes for carcinomas of the face and scalp are the superficial network of lymph nodes that form a ring around the top of the neck: submental (level IA), submandibular (level IB), intraparotid or preauricular, postauricular (mastoid), and occipital lymph nodes as well as inconstant facial lymph nodes. The first echelon is highly associated with the exact location of the cancer on the face.

PATHOLOGY

The most common carcinomas of the skin are BCC (65%), SCC (30%), a variant of BCC or SCC, and the adnexal carcinomas. MCC is a rare neuroendocrine malignancy arising in the skin that was first described by Toker[6] in 1972. Verrucous carcinoma, a variant of SCC, occurs most often on the foot and is rare in the head and neck area. Carcinoma in situ (CIS) occurs frequently in the head and neck. Perineural invasion (PNI) is observed in 2% to 3% of patients with BCCs and SCCs.[7]

Noncutaneous carcinomas (eg, renal cell carcinoma) may metastasize to the skin and subcutaneous tissues.

Basal Cell Carcinoma

The common BCC, which arises from the basal layer of the epithelium, may have a variety of growth patterns merged into one another in the same tumor, and the different names applied to the gross and microscopic appearances have clinical implications. The morphea type (sclerosing BCC) shows little surface disease and a marked infiltrating pattern; it is an important subtype because of the higher risk for recurrence. Microcystic BCC is a histologic variant of BCC that exhibits the same natural history as the more common variety. Some lesions will have mixed BCC and SCC (basosquamous cell carcinoma or metatypical BCC). Melanin pigment may be seen on both gross and microscopic examinations of BCC.

Squamous Cell Carcinoma

SCC and its variants (ie, verrucous carcinoma, spindle cell SCC) are similar histologically to SCC occurring in other sites. Most are well differentiated. Evans and Smith[8] identified two categories of spindle cell tumors of skin: one was composed of SCC mixed with a spindle cell component; the other was predominantly spindle cells. The spindle cell component is similar in both groups; mitoses, giant cells, and epithelioid cells may be seen.

Keratoacanthoma

Keratoacanthoma is a benign tumor of the skin that grossly resembles a cystic BCC and microscopically resembles SCC or squamous papilloma. Part of the difficulty in histologic diagnosis is owing to an inadequate biopsy specimen. Ackerman[9] concluded that “the diagnosis of keratoacanthoma can only be made with absolute certainty by biologic behavior in the form of eventual involution.”

Adnexal Carcinoma

Carcinomas may arise from the epithelium of the sweat glands, sebaceous glands, or hair follicles and microscopically resemble the tissue of origin. Carcinoma of the sweat gland can arise from either the eccrine or apocrine glands; however, no reliable histologic criteria exist to differentiate the origin. It is difficult to distinguish between benign tumors and malignant carcinomas of the sweat gland in the absence of metastases. The differential diagnosis includes adenocarcinoma metastatic to skin and BCCs and SCCs with an adenoid cystic growth pattern. They are frequently misdiagnosed at the time of the first biopsy. Malignant trichilemmoma arising from hair follicles is extremely rare.

Microcystic adnexal carcinoma (sclerosing sweat duct carcinoma) is a rare variant of adnexal carcinoma first described in 1982. The lesion usually presents on the upper lip or skin of the periorbital area as an indurated plaque without direct invasion of the overlying epidermis. It often appears as a subcutaneous nodule. It tends to be slow growing and locally invasive.[10-12] Microcystic adnexal carcinoma exhibits a propensity for local recurrence after excision and is associated with PNI; lymph node metastases are rare. The role of radiation therapy (RT) in the treatment of this rare malignancy is undefined.

Merkel Cell Carcinoma

MCC is a small cell neuroendocrine carcinoma arising in the skin. It has been found to be associated with polyomavirus infection. As in neuroendocrine carcinomas arising in other primary sites, MCC produces a neuron-specific enolase and has been found to contain membrane-bound neurosecretory granules within the tumor cell. In the past, the correct diagnosis was often not obtained until an extensive recurrence was noted. MCC was often misdiagnosed as BCC, lymphoma, adnexal carcinoma, or carcinoma metastatic to the skin from another primary site (ie, small cell carcinoma of the lung or medullary carcinoma of the thyroid).[13]

Melanoma

Melanoma arises from melanocytes, which are present in the epidermis as well as in other parts of the body, including the eye and respiratory, gastrointestinal, and genitourinary tracts.

PATTERNS OF SPREAD

The patterns of spread for individual anatomic sites are outlined in section “Selection of Treatment Modality.” Some lesions remain confined to the epidermis (CIS) and may involve a large area of skin. Large in situ lesions occur more often on the trunk; however, small areas of CIS are common on the head and neck.

Basal Cell and Squamous Cell Carcinomas

Both BCC and SCC are usually well differentiated, and most have an indolent growth with distinct margins; a small proportion are poorly differentiated and grow rapidly. BCC occurs more frequently around the central portion of the face, whereas SCC occurs more often on the ears, preauricular and temporal area, scalp, and skin of the neck.

Most lesions remain superficial and invade the adjacent epidermis in a circumferential growth pattern. Invasion of the dermis is usually confined to the superficial (papillary) dermis. Eventually, penetration of the reticular dermis, subcutaneous tissues, and other underlying structures occurs. A few skin carcinomas tend to grow beneath the skin, and the surface lesion gives little indication of their extensive growth; this is more often seen in recurrent tumors. Most early BCCs and SCCs show an orderly invasion of the superficial dermis, which allows successful local therapy. Both BCCs and SCCs invade cartilage and bone, develop PNI, and eventually enter the lymphatics, although the latter is not common. BCC, in particular, has a low incidence of lymphatic involvement unless it is recurrent (0.05%), whereas the incidence of lymph node spread for SCC is estimated to be up to 10% to 20%. As the size and age of the lesion increase, the potential for lymphatic spread increases.

SCCs may develop distant metastases, whereas BCCs rarely produce metastases. BCC tends to be locally invasive and destructive. A variant of BCC known as basosquamous cell carcinoma or metatypical BCC acts more aggressively than BCC and has a propensity for lymphatic spread.

Metatypical BCC is intermediate between BCC and SCC as far as recurrence rates and the risk of metastases.[14]

Spindle cell tumors of the skin have a gross appearance and growth pattern similar to SCCs.

Carcinoma of the Sweat Gland

Carcinoma of the sweat gland occurs with equal frequency in males and females. It predominantly affects older people, although it may occur even in early adulthood. The lesion is generally a subcutaneous nodular mass, which may be solitary or multiple, and the larger lesions may be ulcerated. Carcinoma of the sweat gland most often occurs on the eyelid, face, and scalp. The growth rate varies from indolent to rapid. The tumor may be present for several years with little change and then suddenly begin to enlarge. PNI is frequent. Regional and distant metastases may develop. Scalp lesions are the ones most likely to develop metastases to regional lymph nodes.

Recurrence after excision is frequent, and multiple recurrences are often reported.[15,16] Little information exists on the response to RT.[16] In our limited experience, carcinoma of the sweat gland is sufficiently radioresponsive to justify RT, particularly in association with excision.

The mucin-producing sweat gland adenocarcinoma is a rare tumor. The eyelid is the primary site in about one-half of cases and the face and scalp in another one-fourth of cases. The tumor presents most often in middle-aged men. Wright and Font[17] reported 21 cases that originated on the eyelid. Eight (38%) patients developed one or more local recurrences, one patient died with extensive persistent disease in the face after a 15-year interval, and only one patient had metastasis to the submandibular lymph nodes successfully treated by radical neck dissection.[17] Regional or distant metastasis is a relatively infrequent event for lesions arising in the head and neck area.

Sebaceous Gland Carcinoma

Sebaceous gland carcinoma is rare. It occurs most often on the eyelids, predominantly on the upper lid in older women, although the lower lid and caruncle are also sites of origin; it may occur on other parts of the head and neck skin as well.[18] It is often indolent in its growth; however, it may be locally aggressive and develop regional and distant metastases. Local recurrence is common after excision because the lesions often have significant deep and lateral spread beyond the obvious lesion. Metastasis to regional lymph nodes is reported in about 20% of cases, and a small percentage of patients develop distant metastases.[19] Inadequate treatment often occurs because of incorrect histologic diagnosis.

Keratoacanthoma

Keratoacanthoma benign lesions start as a firm, round skin nodule and grow to 1 to 2 cm in a short time, usually a few weeks. As the lesion matures, the center becomes separate and can be removed, revealing a small crater. The lesion occurs most often in the exposed area of the head and neck. Keratoacanthoma is an unlikely diagnosis for a lesion of the lip vermillion. Typically,

keratoacanthoma is twice as common in men as in women. It occurs most often in patients older than 40 years of age, although it may be seen as early as the second decade of life.

Basal Cell Nevus Syndrome

The basal cell nevus syndrome (aka Gorlin syndrome) is an autosomal dominant disorder with a high level of penetrance but a variable clinical picture. The clinical syndrome may be composed of any or all of the following:

- Multiple BCCs (differing only in their tendency to develop at an early age and on unexposed skin areas)
- Jaw cysts (common)
- Palmar or plantar pits
- Skeletal abnormalities (short fingers, hypertelorism)
- Ectopic calcification
- Eye muscle palsies
- Hamartomas
- Epidermal cysts

The age at onset is frequently in the second or third decade of life, and a family history is often positive for the disorder.[20]

Merkel Cell Carcinoma

MCC occurs primarily in White men between 60 and 80 years of age.[21] The lesion often presents as a painless, raised skin nodule or mass that is red, pink, or blue and may have diffuse margins and is covered with an intact epidermis. Most lesions are 2 cm or smaller at diagnosis.[21] Human polyomavirus is thought to be etiologic in a significant proportion of patients; human polyomavirus DNA in the MCC cells may be associated with an improved prognosis.[21]

MCC displays an aggressive growth pattern. Mojica et al[22] reported on 1,665 patients from the National Cancer Institute's Surveillance Epidemiology and End Results database and observed the following extent of disease at diagnosis: localized, 55%; positive regional nodes, 31%; distant metastases, 6%; and no data, 8%.

Melanoma

Melanoma is more aggressive and prone to metastasize to regional lymph nodes and exhibit hematogenous dissemination compared with BCC and SCC. The likelihood of regional and/or distant metastases is related to the depth of invasion of the primary tumor. The incidence of positive sentinel lymph node biopsies (SLNBs) versus depth of penetration is depicted in Table 39.1.

TABLE 39.1 PRIMARY DEPTH OF INVASION VERSUS SENTINEL LYMPH NODE BIOPSY POSITIVITY

Series	Primary Site	Depth Invasion of (Number of Patients) ≤1 mm	1.01-2.00 mm	2.01-4.00 mm	>4.00 mm
Rousseau et al, 2003,[53] University of Texas MD Anderson Cancer Center	Various	4% (388)	12% (522)	28% (314)	44% (151)
Emery et al, 2007,[54] University of Oregon	Various	2% (41)	13% (85)	20% (35)	27% (11)

Lymphatic Metastasis

The overall risk of lymphatic metastases is estimated to be up to 10% to 20% for cutaneous SCC of the skin. The risk increases with the size of the lesion, depth of the penetration, histologic grade, and recurrence.

The risk of lymph node metastases from previously untreated BCCs is <1% and is not related to size, depth of penetration, or histologic subtype; the risk increases for recurrent BCCs, especially those with multiple recurrences over several years. Lymph node metastases, however, are seen on rare occasions without a history of recurrence, and an interval of several years may occur between the treatment of the primary lesion and the appearance of involvement in lymph nodes. When they do occur, lymph node metastases are often solitary.

CLINICAL PICTURE

Presenting Symptoms

The common history for BCC or SCC is a slowly enlarging growth on or just beneath the skin surface. Often, a history exists of a sore that will not completely heal. Other symptoms such as bleeding or pain are unusual until the lesion becomes large, and even then symptoms are relatively mild and infrequent. Patients with PNI may complain of paresthesia, especially the sensation of worms crawling under the skin (formication). PNI is usually observed with midface lesions and most often involves cranial nerves V2 and/or VII.[7] Advanced, neglected lesions with bone and cartilage destruction, orbit invasion, and regional metastases may be seen; these advanced lesions often produce few, if any, symptoms, and patients simply delay consulting a physician.

Melanomas usually present as a pigmented skin lesion associated with a change in color, shape, and/or size. Although most probably arise de novo, some may arise in a previously benign nevus. Occasionally, patients present with regional or distant metastases without an apparent primary tumor.

Physical Examination

The site, size, and mobility of the primary lesion are documented. Depending on location, evidence of PNI is assessed as well as any findings that might suggest involvement of underlying bone or cartilage. The regional lymph nodes must be carefully examined, even though they are not often involved. Because of the infrequent appearance of regional lymphatic metastases, and because cases of skin cancer are often not followed diligently, lymph node metastases are frequently missed. Although lymphatic metastases may appear within a few months of the management of the primary lesion, in some cases, many years intervene before the regional lymph nodes become apparent. It is not at all unusual for ≥5 years to intervene between the primary lesion and the appearance of metastases. Patients with chronic lymphocytic leukemia and concomitant skin cancer often have enlarged lymph nodes from both processes and may have elements of SCC and leukemia in the same lymph nodes.

METHODS OF DIAGNOSIS AND STAGING

Biopsy should be performed on the majority of lesions before deciding on treatment. We do not always insist on biopsy for older patients who have a typical skin carcinoma and are to be treated by RT.

Small lesions occurring on the free skin areas (ie, not involving the eyelid, ear, or periorbital areas) can usually undergo biopsy and be treated simultaneously with surgical excision. Larger lesions, or those involving areas where functional or cosmetic deficit might occur from excision, first undergo biopsy with a small incisional biopsy or with a skin punch. Shave biopsies are also often used, except in pigmented lesions where a melanoma is suspected. For the diagnosis and staging of a melanoma, a full-thickness skin biopsy (such as with a punch) is needed. Biopsy with a skin punch should include the subcutaneous fat; punch biopsy is contraindicated when differentiating between keratoacanthoma and SCC because of the small sample size.

The following is a partial list of conditions to be considered in the differential diagnosis of BCC and SCC:

- Senile keratosis
- Keratoacanthoma
- Nonpigmented nevi
- Melanoma
- Cutaneous horn
- Psoriasis
- Lymphoma (mycosis fungoides)
- Soft tissue sarcomas (dermatofibrosarcoma protuberans)
- Hemangiosarcoma
- Metastatic carcinoma
- Adnexal carcinoma of skin
- MCC

Staging

The 2017 American Joint Committee on Cancer (AJCC) systems for SCC of the head and neck and melanoma are depicted in Tables 39.2 and 39.3, respectively.[23] BCC and SCC outside the

head and neck were not included in the AJCC Staging Manual for 2017. Although there is an AJCC staging system for MCC, we prefer the Yiengpruksawan system for this rare entity because of its simplicity: stage I, localized (AJCC stages I and II); stage II, regional lymph node metastases (AJCC stage III); and stage III, distant metastases (AJCC stage IV).[24]

TABLE 39.2 2017 AJCC STAGING SYSTEM FOR SQUAMOUS CELL CARCINOMAS OF THE HEAD AND NECK

Primary Tumor (T)[a]	
TX	Primary tumor cannot be assessed
Tis	Carcinoma in situ
T1	Tumor smaller than 2 cm in greatest dimension
T2	Tumor 2 cm or larger, but smaller than 4 cm in greatest dimension
T3	Tumor 4 cm or larger in maximum dimension of minor bone erosion or perineural invasion or deep invasion[a]
T4	Tumor with gross cortical bone/marrow, skull base invasion, and/or skull base foramen invasion
T4a	Tumor with gross cortical bone/marrow invasion
T4b	Tumor with skull base invasion and/or skull base foramen involvement
Regional Nodes Lymph (N)	
NX	Regional lymph cannot nodes be assessed.
N0	No regional node lymph metastases
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and extranodal extension (ENE)(−)
N2	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−); or metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−); or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2a	Metastasis in a single ipsilateral lymph node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)
N2b	Metastasis in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2c	Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); or metastasis in any node(s) and clinically overt ENE (ENE[+])
N3a	Metastases in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b	Metastasis in any node(s) and ENE(+)
Distant Metastasis (M)	
M0	No distant metastases
M1	Distant metastases

Stage	***T***	***N***	***M***
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0

Stage III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage IV	T1	N2	M0
	T2	N2	M0
	T3	N2	M0
	Any T	N3	M0
	T4	Any N	M0
	Any T	Any N	M1

[a]Deep invasion is defined as invasion beyond the subcutaneous fat or >6 mm (as measured from the granular layer of adjacent normal epidermis to the base of the tumor); perineural invasion for T3 classification is defined as tumor cells within the nerve sheath of a nerve lying deeper than the dermis or measuring 0.1 mm or larger in caliber, or presenting with clinical or radiographic involvement of named nerves without skull base invasion or transgression.

TABLE 39.3 2017 AJCC STAGING SYSTEM FOR MELANOMA

Primary Tumor (T)

T Category	Thickness	Ulceration Status
TX	Primary tumor thickness cannot be assessed (eg, diagnosis by curettage).	
T0	No evidence of primary tumor (eg, unknown primary or completely regressed melanoma)	
Tis	Melanoma in situ	
T1	≤1.0 mm	Unknown or unspecified
T1a	<0.8 mm	Without ulceration
T1b	<0.8 mm 0.8-1.0 mm	With ulceration With or without ulceration
T2	>1.0-2.0 mm	Unknown or unspecified
T2a	>1.0-2.0 mm	Without ulceration1
T2b	>1.0-2.0 mm	With ulceration
T3	>2.0-4.0 mm	Unknown or unspecified
T3a	>2.0-4.0 mm	Without ulceration
T3b	>2.0-4.0 mm	With ulceration
T4	>4.0 mm	Unknown or unspecified
T4a	>4.0 mm	Without ulceration
T4b	>4.0 mm	With ulceration

Regional Lymph Node (N): Extent of regional lymph node and/or lymphatic metastasis

Primary Tumor (T)

T Category	Thickness	Ulceration Status
N Category	Number of tumor-involved regional lymph nodes	Presence of in-transit, satellite, and/or microsatellite metastases
NX	Regional nodes not assessed (eg, SLN biopsy not performed, regional nodes previously removed for another reason) **Exception:** pathological N category is not required for T1 melanomas, use cN.	No
N0	No regional metastases detected	No
N1	One tumor-involved node or in-transit, satellite, and/or microsatellite metastases with no tumor-involved nodes	
N1a	One clinically occult (ie, detected by SLN biopsy)	No
N1b	One clinically detected	No
N1c	No regional lymph node disease	Yes
N2	Two or three tumor-involved nodes or in-transit, satellite, and/or microsatellite metastases with one tumor-involved node	
N2a	Two or three clinically occult (ie, detected by SLN biopsy)	No
N2b	Two or three, at least one of which was clinically detected	No
N2c	One clinically occult or clinically detected	Yes
N3	Four or more tumor-involved nodes or in-transit, satellite, and/or microsatellite metastases with two or more tumor-involved nodes	
N3a	Four or more clinically occult (ie, detected by SLN biopsy)	No
N3b	Four or more, at least one of which was clinically detected, or presence of any number of matted nodes	No
N3c	Two or more clinically occult or clinically detected and/or presence of any number of matted nodes	Yes
Distant Metastasis (M)		
M Category	M Criteria	
	Anatomic Site	LDH Level
M0	No evidence of distant metastasis	Not applicable
M1	Evidence of distant metastasis	See below
M1a	Distant metastasis to skin, soft tissue including muscle, and/or nonregional lymph node	Not recorded or specified
M1a(0)		Not elevated
M1a(1)		Elevated

Diagnostic Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are only necessary in a carefully chosen group of patients being treated for skin cancer. CT is the primary modality for showing bone invasion and nodal metastases, although MRI is often useful in determining muscular or bony invasion in large or neglected lesions and is superior to CT for demonstrating PNI.[25] Positron emission tomography (PET) is useful to detect regional and distant metastases in patients with MCC and melanoma but should be restricted to patients who are found to be node positive.

SELECTION OF TREATMENT MODALITY

Basal Cell and Squamous Cell Carcinomas

The likelihood of cure is similar after surgery or RT for early-stage BCCs and SCCs.[26] Therefore, selection of one modality over another is based on other parameters such as function, cosmesis, age of the patient, convenience, cost, availability of appropriate RT equipment, and the wishes of the patient. Patients with advanced cancers are often best treated with surgery and adjuvant RT if the cancer is resectable and the functional and cosmetic outcomes are acceptable to the patient. It is important to recall that there are newer systemic options, such as immunotherapy, that may be indicated depending on the situation.

Radiotherapy Alone

Small skin cancers located on "free skin," such as the cheek or forehead, may be easily excised and reconstructed with a good cosmetic result and minimal inconvenience; therefore, surgery is usually the treatment of choice for such lesions. It is also desirable to avoid RT in young patients because the late effects of irradiation progress gradually with time and, with very long-term follow-up, may be associated with a suboptimal cosmetic result compared with resection and reconstruction. In contrast, resection of an early-stage skin cancer of the eyelid, external ear, or nose may result in a significant cosmetic deformity and necessitate complex reconstruction that compares unfavorably with RT. This is particularly relevant in the case of older patients who have a limited life expectancy and who are at higher risk for a perioperative complication if the lesion is large and general anesthesia is required. In contrast, small cancers suitable for Mohs excision with local anesthesia are well treated with this technique.

Patients with locally advanced skin cancers present a difficult problem because, although the likelihood of cure may be better with combined RT and surgery in some situations, the cosmetic result is sometimes unacceptable. Patients receive postoperative RT if surgery is indicated and feasible. If surgery is not feasible, the patient is managed with RT alone. Although it might seem that the risk of bone and/or cartilage necrosis would be high after RT for a skin cancer invading these structures, the observed risk of complications is relatively low.[27,28] Exceptions are advanced cancers of the scalp and those overlying the anterior aspect of the tibia where there is little tissue between the skin surface and the bone. Following definitive RT, bone exposure is likely and may progress to an osteoradionecrosis requiring surgical intervention.

Patients with SCC and BCC with incidental PNI have better outcomes after Mohs surgery and postoperative RT compared with RT following a non-Mohs resection.[29] Patients with lesions associated with clinical PNI with gross tumor extending to sites that render complete resection unlikely or unfeasible, such as the cavernous sinus, are treated with RT alone. Subtotal resection does not enhance the likelihood of cure and only increases the morbidity of treatment.

Adjuvant Radiotherapy

Postoperative RT is added after surgery if pathologic examination of the surgical specimen reveals findings indicative of a high risk for local recurrence, such as close or positive margins and/or invasion of nerve, cartilage, or bone. A significant proportion of patients with positive margins after resection of an early-stage skin cancer may never develop a local recurrence. Postoperative RT may be withheld if the lesion is a BCC, the primary site is located on the free skin, the patient is reliable and will return for close follow-up, and if salvage treatment would have a high likelihood of eradicating recurrent tumor with a good cosmetic result. BCCs of the nose, eyelid, or ear and lesions that would have immediate access to major nerve trunks are usually retreated immediately when resection margins are positive. The risk of recurrence is probably greater than for lesions of the free skin, and the consequences of recurrence may be significant. Observation is particularly attractive for the older patient in poor medical conditions who may not live to experience a local recurrence. Metatypical BCCs behave more aggressively than BCCs, and those with positive margins after surgery should be reexcised and/or treated with postoperative RT.

Patients with BCC or SCC and focal incidental PNI involving a small nerve trunk (<0.1 mm) and widely negative margins may be safely observed.[30,31] Otherwise, patients with incidental PNI should be considered for postoperative RT, particularly if the lesion is SCC.

The usual policy for patients with positive margins from SCC is immediate retreatment by either reexcision, RT, or both, depending on the situation. There is evidence that this approach leads to a reduced risk of metastasis and reduced likelihood of death from cancer.

Regional Lymph Node Metastases

Carcinoma of the skin metastatic to the parotid lymph nodes is managed as a high-grade parotid neoplasm, usually with superficial or total parotidectomy followed by postoperative RT.[26,32-34] If only one node is involved and there is no extracapsular extension, it may be safe to withhold RT. However, if the tumor recurs in the parotid area after parotidectomy, the likelihood of salvage is remote.[32] Therefore, it has been our practice to use combined treatment in all patients. If the parotid lymph node metastasis is fixed and thought to be incompletely resectable, the patient is treated with high-dose preoperative RT (6,000-7,000 cGy) followed by parotidectomy. RT alone is used only in patients who are inoperable because of tumor extent or poor medical condition. Patients who have positive parotid nodes and clinically negative cervical nodes may undergo a parotidectomy withholding the neck dissection, followed by postoperative RT to the parotid and the neck with a high likelihood of local-regional control.[35]

Cervical lymph node metastases are managed just as they would be for other carcinomas of the head and neck. Neck dissection alone is adequate treatment if only one node is involved and there is no extracapsular extension. If two or more nodes contain tumor or if extracapsular extension is noted, neck dissection is followed by postoperative RT.

Merkel Cell Carcinoma

The preferred treatment for MCC is resection of the primary tumor with wide surgical margins (2 cm) and sentinel node. Our bias is to treat both the primary site and regional lymphatics with postoperative RT. The dose-fractionation schedule is the same as that employed for SCC. The role of adjuvant chemotherapy is ill defined, but immunotherapy can be considered in all patients with regional disease. Patients who should be considered for adjuvant chemotherapy are those with

positive nodes and/or satellite lesions. Drugs employed are often those used for small cell carcinomas and include etoposide and cisplatin and PD inhibitors.

Melanoma

The preferred treatment for melanoma is resection of the primary lesion with or without sentinel node biopsy. Patients who have lesions with a depth of invasion exceeding 0.8 mm or ulceration and clinically negative nodes should be considered for SLNB. We also consider SLNB for lesions with depth of invasion ≤0.8 mm if there are high-risk features, including regression, invasion into Clark level IV or V, deep margin positive, or young age. Completion lymph node dissection for positive sentinel nodes is no longer considered standard of care as this has shifted to immunotherapy. Fine-needle aspiration should be performed on any grossly positive regional nodes, followed by immunotherapy. An adjunct for patients without gross residual positive nodes, but for high-risk features such as extranodal extension is postoperative RT. Patients with desmoplastic melanoma should be considered for postoperative RT. These patients are usually suitable for surgery alone unless there is extensive PNI associated with a lesion near a named nerve, in which case postoperative RT is considered. Postoperative RT can also be employed to treat the primary site when there are in-transit metastases and the margins are equivocal. Adjuvant postoperative RT is often employed for positive regional nodes. Patients who are at high risk for regional lymph node metastases and are unable to undergo SLNB and/or elective node dissection can be considered for elective nodal irradiation of the first-echelon lymphatics. The dose-fractionation schedule is usually the MD Anderson Cancer Center hypofractionation technique consisting of 3,000 cGy in five fractions over 2.5 weeks with a reduction off of the spinal cord and/or central nervous system (CNS) at 2,400 cGy.[36] Alternatively, conventional fractionation may be employed if late effects and suboptimal cosmesis are a concern.[37] These patients should also be strongly considered for immunotherapy.

Definitive RT using orthovoltage RT or electrons may be employed for older patients with lentigo maligna or lentigo malignant melanoma where excision is not feasible because of cosmesis function and/or medial comorbidities.[38-40] The dose-fractionation schedules are the same as those described for postoperative RT.

TREATMENT TECHNIQUES

Treatment techniques vary for primary lesions and for regional lymph node metastases.

Primary Lesion

RT of the primary lesion is usually accomplished using one of three basic external-beam techniques (orthovoltage RT, electron beam, and high-energy x-rays or photons) or with an interstitial implant either alone or in combination with external-beam techniques (addressed on the next page). Most early skin cancers are managed with orthovoltage RT with beam energies of 100 to 250 kVp. The advantages of this technique, compared with electron beam, are that the maximum dose is at the skin surface; bolus is not required; there is less beam constriction at both the surface and depth so that smaller fields can be used (Figure 39.1); shielding of the eye is easier and more effectively accomplished, particularly if electron energies ≥10 MeV are used (Table 39.4)[41]; it is less expensive; and the likelihood of tumor control may be higher, possibly as a result of increased radiobiologic effectiveness but more likely because of technical problems

that are difficult to overcome when using electrons alone. The disadvantages of orthovoltage x-rays, compared with electron beam, are that there is a higher dose to deeper tissues and to underlying bone and cartilage. The latter problem can be largely eliminated by using heavily filtered orthovoltage beams for tumors involving or overlying cartilage or bone. Another significant problem associated with orthovoltage RT is that most radiation oncology departments do not have an orthovoltage machine, and thus it is unavailable. Electron beam is usually used for lesions of the scalp to reduce the dose to the underlying brain; orthovoltage x-rays are used to treat most other skin cancers. Orthovoltage RT is particularly useful for lesions of the head and neck.

TABLE 39.4 OCULAR PROTECTION: DOSE BENEATH THE EYE SHIELD

		Electron-Beam Energy (MeV)						
Structure (Depth)	**250 kVp x-ray (HVL mm 1.4 Cu)**	**6**	**8**	**10**	**12**	**14**	**17**	**20**
Cornea (1 mm)	10%	18%	37%	64%	75%	93%	98%	102%
Lens (8 mm)	9%	9%	19%	36%	46%	61%	70%	87%
Retina (23 mm)	10%	19%	22%	22%	21%	23%	25%	29%

Dose is expressed as a percentage of the dose to D_{max} (depth of maximum dose deposition).

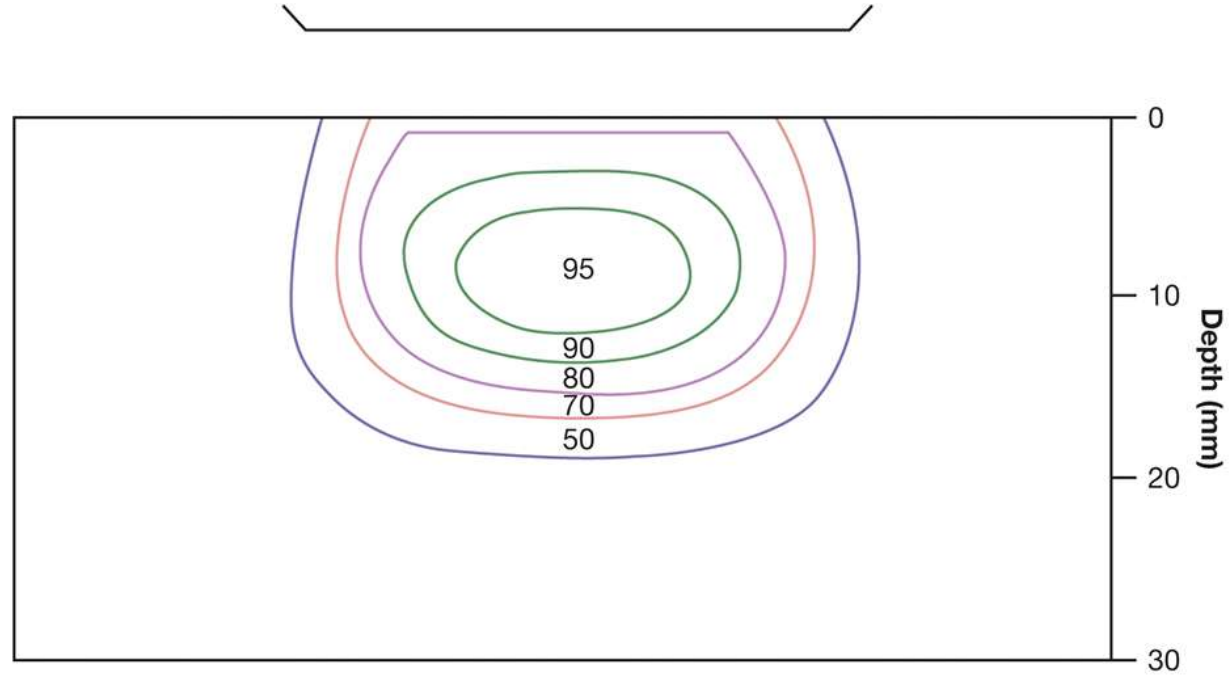
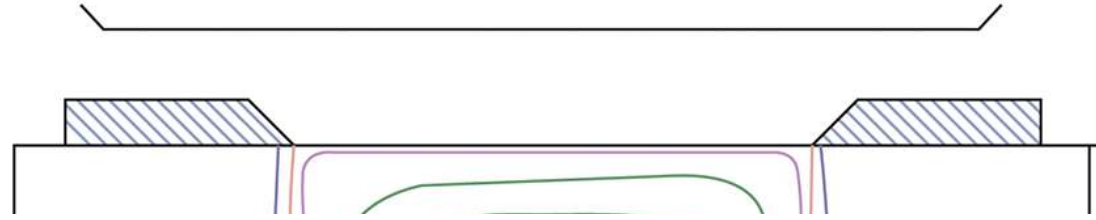
A



B



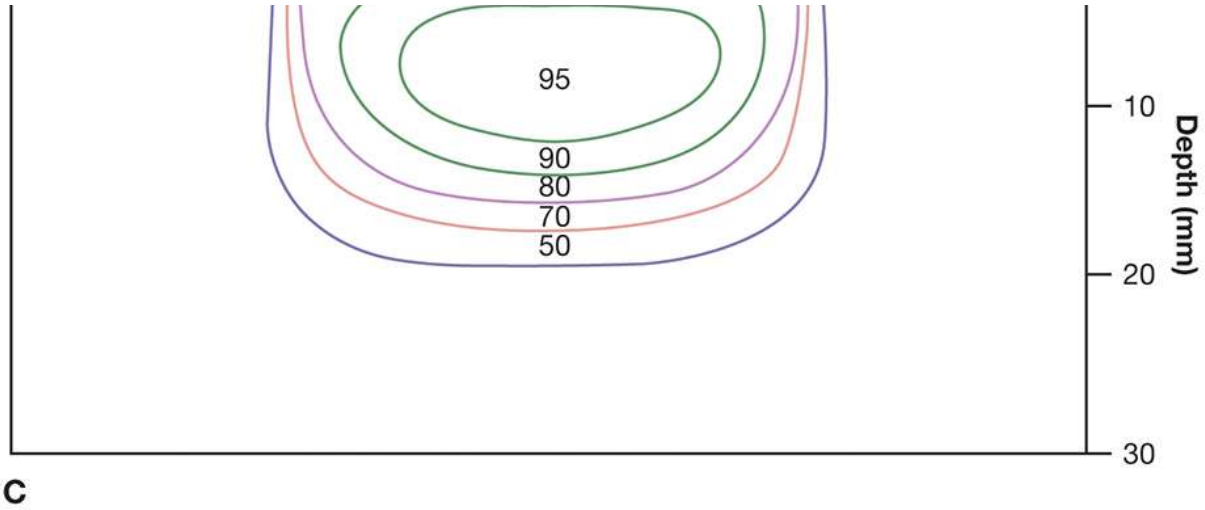


FIGURE 39.1 A. 250-kVp x-rays (half-value layer 1.4 mm Cu) with secondary collimation on the phantom surface. Source-to-surface distance (SSD) = 50 cm; isodose %: 95, 90, 80, 70. B. 6-MeV electron beam with secondary collimation 5 cm above the phantom surface (at the level of the electron cone). Source of collimator distance (SCD) = 95 cm; SSD = 100 cm; isodose %: 95, 90, 80, 70, 50. C. 6-MeV electron beam with tertiary collimation on the phantom surface. SSD = 100 cm; SCD = 100 cm; isodose %: 95, 90, 80, 70, 50.

Before treatment with either electron-beam or orthovoltage x-rays, a customized lead mask is constructed to collimate the beam directly on the skin surface. A 1.0- to 1.5-cm margin is adequate for a well-defined T1 lesion treated with orthovoltage RT. An additional 1 cm is added to the margin when the electron beam is used to account for beam constriction. For larger and/or ill-defined tumors, a 2-cm margin is usually necessary. If the tumor is located near the eye, a gold-plated lead eye shield is placed directly on the anesthetized cornea to minimize the irradiation dose to underlying structures (Figure 39.2). The dose beneath the eye shield is depicted for orthovoltage x-rays and electron beams of various energies in Table 39.4. Isodose distributions for the two techniques are shown in Figure 39.1; note that the dose distribution is better for orthovoltage RT than for electron beam, particularly if a lead mask is not used with the electron beam.

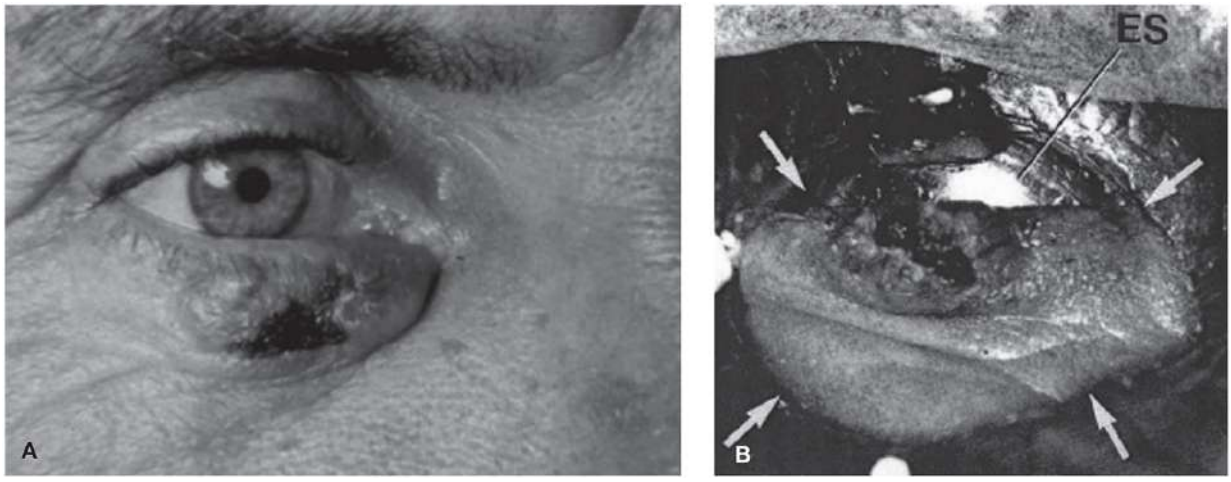

FIGURE 39.2 A. 1- × 1-cm^2 basal cell carcinoma of the midportion of the lower lid. B. Treatment setup that was used to irradiate the patient. Arrows indicate the field edge. ES, eye shield.

Advanced skin cancers that are deeply invasive are often treated with high-energy photons to adequately cover the deep extent of the tumor. Bolus is used to ensure an adequate surface dose. Field arrangement varies with primary site. For example, a wedge-pair technique may be used for lesions involving the external ear, whereas a three-field technique (similar to that used for paranasal sinus cancer) is frequently used for skin cancers with extension proximally along the second division of the fifth cranial nerve. The target volume includes the entire course of the involved nerve, which would include the Gasserian ganglion in this case, to the brainstem. Intensity-modulated radiotherapy (IMRT) may be used in some patients to produce a more conformal dose distribution to reduce the dose to surrounding normal structures. Proton-beam RT may also be used to produce a very conformal dose distribution with steep dose gradients to limit the dose to the visual apparatus and the CNS.[42,43]

The extent of RT fields for patients with PNI varies with the histology and extent of PNI. Patients with BCC or SCC and focal incidental PNI are treated with a wide local field. Those with extensive incidental PNI are treated with fields that include the at-risk nerves to the skull base, particularly if margins are positive or equivocal. The at-risk nerves receive 5,000 to 7,000 cGy depending on the extent of PNI and margin status. Patients with clinical PNI receive definitive RT to fields that include the primary site and involved nerves to the skull base.

The regional lymph nodes are electively irradiated if the suspected risk of subclinical disease exceeds 10% to 15%.[44,45] Patients with SCC and PNI should be considered for elective nodal RT, particularly if the lesion is located on the head or neck.

Dose-fractionation schedules used for irradiation of skin cancers are outlined in Table 39.5. We have recently used twice-daily RT with megavoltage photons or protons at 1.2 Gy per fraction to doses of 744 cGy in a continuous course with a minimum 6-hour interfraction interval for advanced lesions near radiosensitive structures. The suggested maximum doses for short-course orthovoltage RT are listed in Table 39.6.

TABLE 39.5 GUIDELINES FOR SELECTION OF EXTERNAL-BEAM DOSE

Orthovoltage Dose (cGy)[a]	Examples
6,500 over 7 wk	Large untreated lesion with bone/cartilage invasion or large recurrent tumor[b]
6,000 over 7 wk	Large untreated lesion with minimal or suspected bone/cartilage invasion[b]
5,500 over 6 wk	Moderate to large inner canthus, eyelid, nasal, or pinna lesions (20-30 cm^2 area)
5,000 over 4 wk	Small, thin lesion (<1.5 cm) around eye, nose, or ear (10 cm^2 area)
4,500 over 3 wk	Moderate-sized lesion on free[c] skin or postoperative treatment of moderate-sized cancer on free skin with positive margins
4,000 over 2 wk or 3,000 over 1 wk	Small lesions (1 cm) free on skin
The following schemes are used when the late cosmetic result is not important and travel for the patient is difficult:	
4,000 10 in fractions 3,000 or in fractions 5 or 2,000 in 1 fraction	Rapid fractionation produces schemes with a high cure rate for small lesions, although cosmetic may result be less than optimal after 5 y.

[a]Add 10% to dose for supervoltage therapy.

[b]All or a portion of the therapy is given with supervoltage photons and/or electrons.

[c]"Free" refers to not involving the ear, nose, eye, or eyelid.

Parotid Area Lymph Node Metastases

The parotid gland and upper neck are treated with an en face mixed beam of 6-MV x-rays and high-energy electrons (usually 20 MeV), weighted 1.0:0.67 in favor of the electron beam. The electron-beam field is 1 cm larger than the x-ray field to account for the beam constriction of the electrons, except where the field abuts the low-neck field (Figure 39.3). This field arrangement is treated to 4,600 cGy in 23 fractions, specified at a depth of 4 to 5 cm from the skin surface. An anterior field is matched to the lateral mixed-beam field to treat the ipsilateral low neck and is irradiated to 5,000 cGy in 25 fractions, specified at D_{max}.

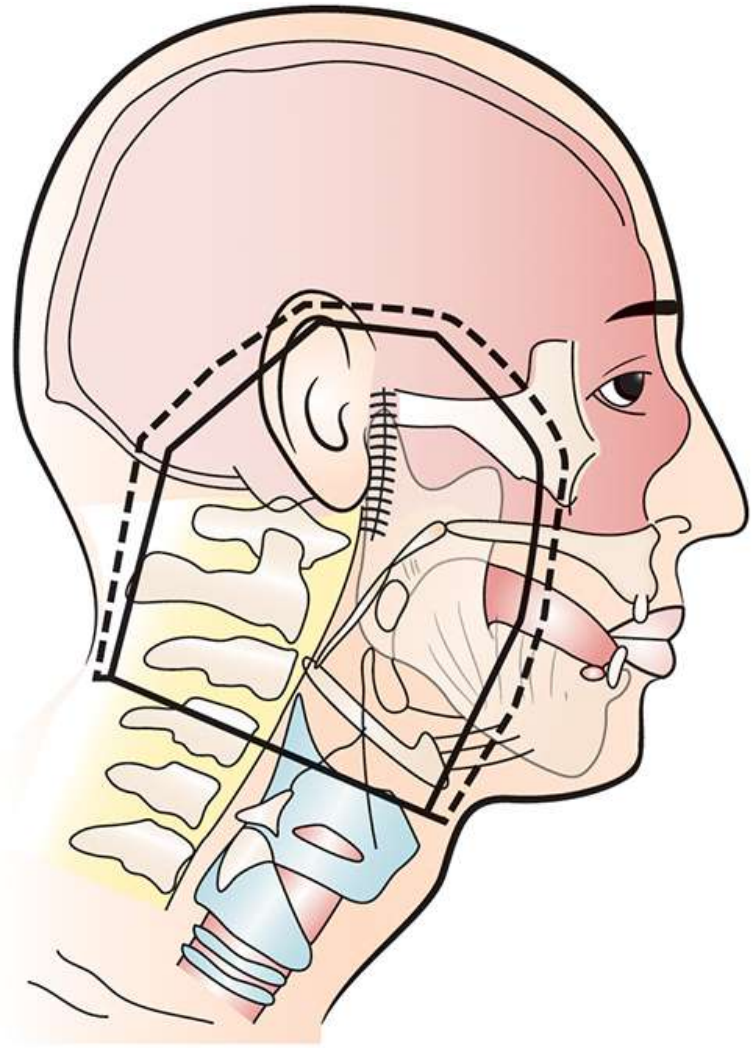

FIGURE 39.3 Typical en face mixed-beam field used in the treatment of parotid node metastases to encompass the entire parotid bed and surgical scar. Patients are treated supine with a face mask made of low-temperature thermal plastic (polycaprolactone) for immobilization and a lead lollipop to decrease the dose to the contralateral salivary gland. A bolus of petrolatum-coated gauze is applied to all scars.

At 4,600-cGy tumor dose, the primary field is reduced off of the spinal cord, and the dose to the tumor bed is boosted with an anteriorly angled 20-MeV electron-beam field or an appositional mixed-beam field with an abutting posterior electron strip. The final dose for patients treated at 200 cGy per fraction with negative margins is 6,000 cGy; with positive margins, 6,600 cGy; and with gross residual disease, 7,000 cGy. If the dose per fraction is reduced to 180 cGy, the total dose is increased by 500 cGy. An alternative to the mixed electron-photon beam is a wedge-pair technique using 4- to 6-MV photon beams. IMRT may also be considered to reduce the dose to the temporal lobe and cerebellum, particularly if the margins are positive and/or tumor involves the deep lobe of the parotid.

Axillary Metastases

Axillary lymph node metastases are irradiated with opposed anterior and posterior portals that include the supraclavicular fossa. The dose-fractionation schedule is 4,500 cGy in 25 fractions

with a reduction and boost depending on margin status.

Ilioinguinal Lymph Node Metastases

Ilioinguinal lymph nodes are usually irradiated with IMRT to reduce the volume of tissue irradiated, particularly small bowel. The femoral and external iliac vessels are contoured on the treatment planning CT, and a 1.5- to 2-cm margin is added to obtain the clinical target volume.

FOLLOW-UP AND MANAGEMENT OF RECURRENCE

After RT, patients are evaluated every 2 to 3 months for the first and second years, every 4 months for the third year, every 6 months for the fourth and fifth years, and annually thereafter. Chest roentgenograms are obtained annually, and follow-up CT, MRI, and/or PET-CT are obtained as needed for patients irradiated for advanced lesions.

Treatment of local-regional recurrences either after RT alone or combined with surgery is usually resection. If a local recurrence is amenable to en bloc surgical resection with frozen section control of the margins, this may be preferable for selected cases. Of note, the frozen section cannot be performed on melanoma due to the requirement for histopathologic staining. Local recurrences after RT may be significantly more extensive than is clinically apparent; thus, wide margins are preferred. Retreatment with RT is rarely indicated because of the high likelihood of complications. The most common scenario for recurrence in the neck nodes is failure in a solitary submandibular location; the success rate of salvage neck dissection is high in this circumstance.

RESULTS

Basal Cell and Squamous Cell Carcinomas

Most series reporting the results of treatment for skin cancer contain a preponderance of early lesions and do not employ a staging system, making it difficult to compare various series and the relative efficacy of different treatment modalities.

Primary Lesion

The likelihood of local control after irradiation for skin carcinomas of various sizes managed at the Mallinckrodt Institute of Radiology is outlined in Table 39.7.[46] The probability of local control is higher for smaller lesions, for BCC compared with SCC, and for previously untreated lesions compared with recurrent cancers. The results of RT using various beam energies are listed in Table 39.8; treatment with orthovoltage irradiation yields local control rates that are as good as, or better than, local control rates yielded by other treatment modalities.[46]

TABLE 39.7 LOCAL TUMOR CONTROL WITH RADIOTHERAPY ACCORDING TO SIZE, CELL TYPE, AND PRESENTATION (FROM MALLINCKRODT INSTITUTE OF RADIOLOGY—339 PATIENTS)

Al-Othman et al[48] reported on 85 patients with 88 clinical T4 SCCs (37), BCCs (41), and metatypical BCCs (10) treated with definitive RT at the University of Florida (Gainesville, FL) between 1964 and 1997. Forty-three lesions were previously untreated, and 45 cancers were recurrent after prior surgery. The 5-year outcomes were as follows: local control, 53%; ultimate local control, 90%; regional control, 93%; ultimate regional control, 100%; distant metastasis-free survival, 95%; cause-specific survival, 76%; and overall survival, 56%. Thirteen (15%) of 85 patients developed a severe treatment-related complication.

Balamucki et al[49] reported on 216 patients treated at the University of Florida for skin carcinomas with incidental (107 patients) or clinical (109 patients) PNI; median follow-up for living patients was 6 years (range, 0.6-2.3 years). One hundred eighty-five patients (86%) had SCCs, and the remainder had BCCs or metatypical BCCs. Patients with incidental PNI were treated with surgery and postoperative RT (99 patients), preoperative RT and surgery (four patients), and RT alone (four patients). Eight patients received adjuvant chemotherapy. Twenty-six (24%) of 107 patients presented with clinically positive nodes. The outcomes for patients treated with incidental PNI are depicted in Table 39.10. Seventeen (16%) of 107 patients developed treatment complications. Patients with clinical PNI were treated with surgery and postoperative RT (58 patients), preoperative RT and surgery (two patients), or RT alone (49 patients). Fifteen (14%) of 109 patients presented with clinically positive nodes. The outcomes for patients treated for clinical PNI are depicted in Table 39.11. Fourteen (23%) of 62 patients who had achieved continuous local control experienced symptomatic improvement in clinical

neuropathic symptoms after treatment. Thirty-nine (36%) of 109 patients developed treatment complications.

TABLE 39.10 OUTCOMES AFTER TREATMENT FOR SKIN CARCINOMA WITH INCIDENTAL PERINEURAL INVASION (107 PATIENTS)

Parameter	5-y Outcome (%)
Local control	80
Ultimate local control	82
Local-regional control	70
Ultimate local-regional control	74
Cause-specific survival	73
Overall survival	55

Balamucki et al[50] reported on a subset of these patients and compared their outcomes with radiographic extent of PNI and found that the extent of PNI was inversely related to the likelihood of local control and survival (Table 39.12).

TABLE 39.12 CLINICAL PERINEURAL INVASION: 5-YEAR OUTCOME VERSUS PRETREATMENT RADIOGRAPHIC FINDINGS (45 PATIENTS)

	Radiographic Findings			
5-y Outcome	Imaging Negative (*n* = 11)	Minimal or Moderate Peripheral PNI (*n* = 18)	Central and/or Macroscopic PNI (*n* = 36)	*P*
Local control (%)	81	60	47	.2321
Cause-specific survival (%)	100	58	65	.0815
Overall survival (%)	82	50	52	.2637

Regional Nodes

Veness et al[32] reported on 167 patients treated at Westmead Hospital (Sydney, Australia) between 1980 and 2000 for cutaneous SCCs metastatic to the parotid and/or cervical nodes. Twenty-one (13%) patients were treated with surgery alone, and the remainder received surgery and adjuvant RT. The median time to recurrence after treatment was 8 months. The 5-year local-regional recurrence and disease-free survival rates were as follows: surgery and RT, 20% and 73%, and surgery alone, 43% and 54%, respectively. Multivariate analysis revealed that multiple positive nodes and treatment with surgery alone were significantly associated with decreased survival.

Hinerman et al[33] reported on 117 patients with 121 clinically positive parotids treated at the University of Florida between 1969 and 2005. Patients were treated with preoperative RT and surgery (17 parotids), surgery and postoperative RT (87 parotids), and RT alone (17 parotids). The 5-year outcomes were as follows: local (parotid) control, 78%; local-regional control, 74%; distant metastasis-free survival, 92%; disease-free survival, 70%; and overall survival, 54%. The 5-year local-regional control rate was 83% after surgery and postoperative RT versus 47% after preoperative RT and surgery or RT alone. Three (3%) patients developed severe complications.

Merkel Cell Carcinoma

Mendenhall et al[51] reported on 59 patients treated with either RT alone (five patients) or combined with surgery (54 patients) at the University of Florida between 1984 and 2015. Fourteen patients received adjuvant chemotherapy. Twenty-five patients had AJCC stage I disease, seven patients had AJCC stage II MCC, and 27 patients had AJCC stage III disease. Median follow-up on survivors was 3.2 years (range, 0.3-20.9 years). Median follow-up for survivors was 6.7 years (range, 1.6-20.9 years). No patient was lost to follow-up. The 5-year outcomes are depicted in Table 39.13. No severe late complications were observed.

TABLE 39.13 MERKEL CELL CARCINOMA 5-YEAR OUTCOMES VERSUS STAGE

Outcomes	Stage 1 (*n* = 24)	Stage II (*n* = 16)	All Patients	*P*-value
Local control (%)	96	87	92	.3240
Regional control (%)	87	65	78	.1587
Local-regional control (%)	87	67	79	.1607
Distant metastasis-free survival (%)	71	37	57	.0073
Cause-specific survival (%)	58	27	45	.0090
Overall survival (%)	48	18	36	.0037

Melanoma

One of the largest experiences with adjuvant RT for melanoma has been reported by investigators from the MD Anderson Cancer Center (Houston, TX; Table 39.14). Although RT may be used to treat gross disease, this would only occur by default and in mostly palliative situations.

TABLE 39.14 OUTCOMES AFTER SURGERY AND POSTOPERATIVE RADIOTHERAPY AT THE UNIVERSITY OF TEXAS MD ANDERSON CANCER CENTER FOR LYMPH NODE–POSITIVE MELANOMA PATIENTS

Series	Number of Patients	Site	Follow-Up[a]	RC[b]	DMFS[b]	Survival[b]
Ballo et al, 2002[59]	89	Axilla	Median, mo 58 (range, 7-159 mo)	87% (5 y)	49% (5 y)	OS, 50% (5 y)
Ballo et al, 2003[60]	160	Cervical	Median, 78 mo (range, 6-224 mo)	94% (10 y)	43% (10 y)	CSS, 48% (10 y)
Ballo et al, 2004[61]	40	Ilioinguinal	Median, mo 23 (range, 4-107 mo)	74% (3 y)	35% (3 y)	OS, 38% (3 y)

CSS, cause-specific survival; DMFS, distant metastasis-free survival; OS, overall survival; RC, regional control.

[a]Follow-up for surviving patients.

[b]Outcome (interval).

From Mendenhall WM, Amdur RJ, Grobmyer SR, et al. Adjuvant radiotherapy for cutaneous melanoma. *Cancer*. 2008;112(6):1189-1196. Copyright © 2008 American Cancer Society. Reprinted by permission of John Wiley & Sons.

Drescher et al[52] recently reported on 131 patients treated with surgery and postoperative RT with either conventional fractionation (29 patients) or hypofractionation (102 patients); most of those treated with hypofractionated RT received the MD Anderson schedule of 30 Gy in five fractions over 2.5 weeks. The 10-year outcomes were as follows: in-field local control, 87%; local-regional control, 72%; distant metastasis-free survival, 48%; cause-specific survival, 44%; and overall survival, 31%. Six patients experienced late toxicity.

Tsang et al[38] reported on 36 patients treated between 1968 and 1988 with definitive RT for lentigo maligna at the Princess Margaret Hospital (Toronto, Canada) and followed for a median of 6 years. The 5-year local control rate was 86%. Farshad et al[40] reported on 150 patients treated at the University of Zurich with definitive RT for lentigo maligna (93 patients), lentigo maligna melanoma (54 patients), or both (three patients). One hundred one patients were followed for at least 2 years (mean, 8 years); the local control rate was 93%.

CONCLUSION

RT is an effective modality for the primary treatment of skin cancer as well as in the adjuvant setting. It is used to treat the primary skin lesion when resection would result in an unacceptable functional and/or cosmetic outcome as well as in the patient who is medically unsuitable for, or who declines, surgery. Adjuvant RT is usually indicated after surgery for close or positive margins, PNI, bone and/or cartilage involvement, metastatic parotid area lymph nodes, multiple lymph node metastases, and extracapsular extension.

PART B

Central Nervous System

CHAPTER 40

Primary Intracranial Neoplasms

Vinai Gondi, Qian S. Zhang, Michael A. Vogelbaum, Yazmin Odia, and Minesh P. Mehta

ANATOMY

The central nervous system (CNS) is enveloped by three meningeal layers: the *dura mater* (also known as the pachymeninges), the *arachnoid mater*, and the *pia mater*. The pia and arachnoid layers are also referred to as the leptomeninges and within them is the subarachnoid space, which is filled with cerebrospinal fluid (CSF). Dural folds separate the two hemispheres of the cerebrum (falx cerebri) and the cerebrum from the cerebellum and brainstem (tentorium or falx cerebelli). The frontal and parietal lobes are separated by a well-defined sulcus ("central sulcus"). The frontal and temporal lobes are separated by the Sylvian fissure, whereas the parietal and occipital lobes are separated by the calcarine sulcus (Figures 40.1-40.3).

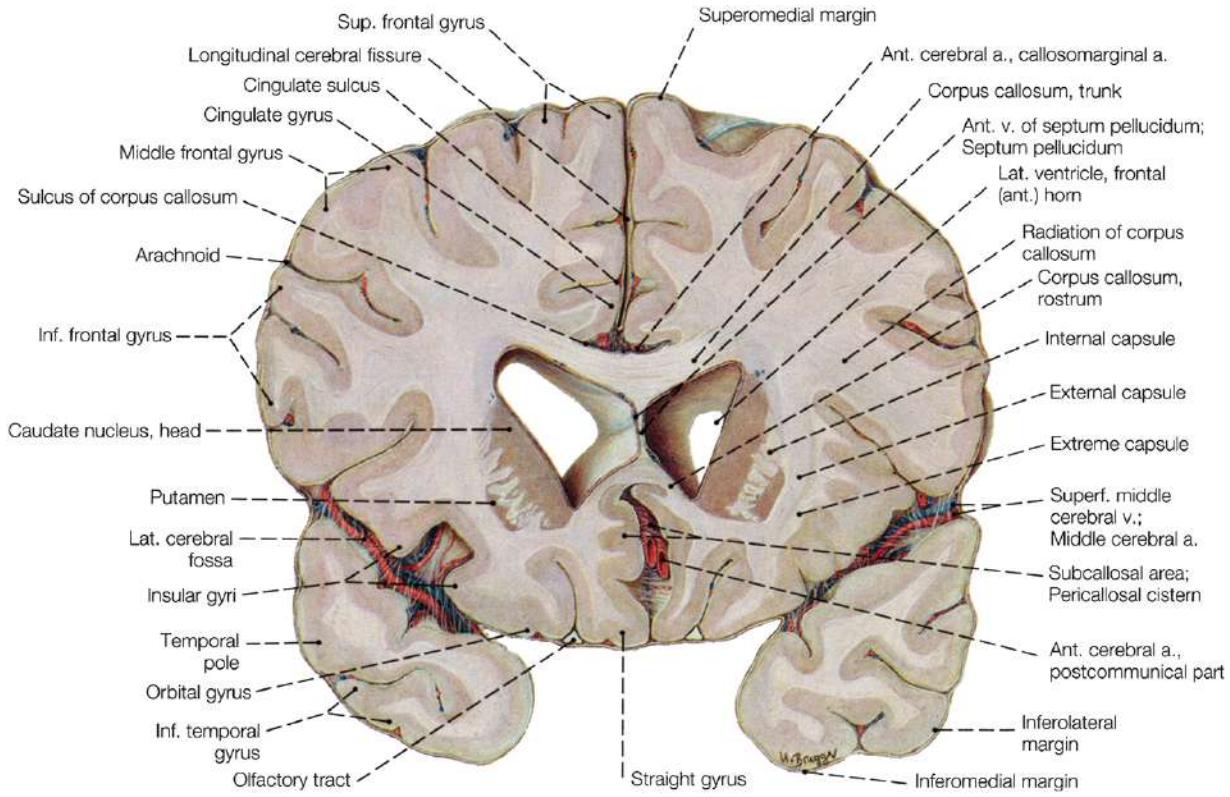

FIGURE 40.1 Coronal section through the telencephalon at the plane of the frontal horn of the lateral ventricle. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figure 12.218. Copyright © 2023 Elsevier GmbH Munich. With permission.)

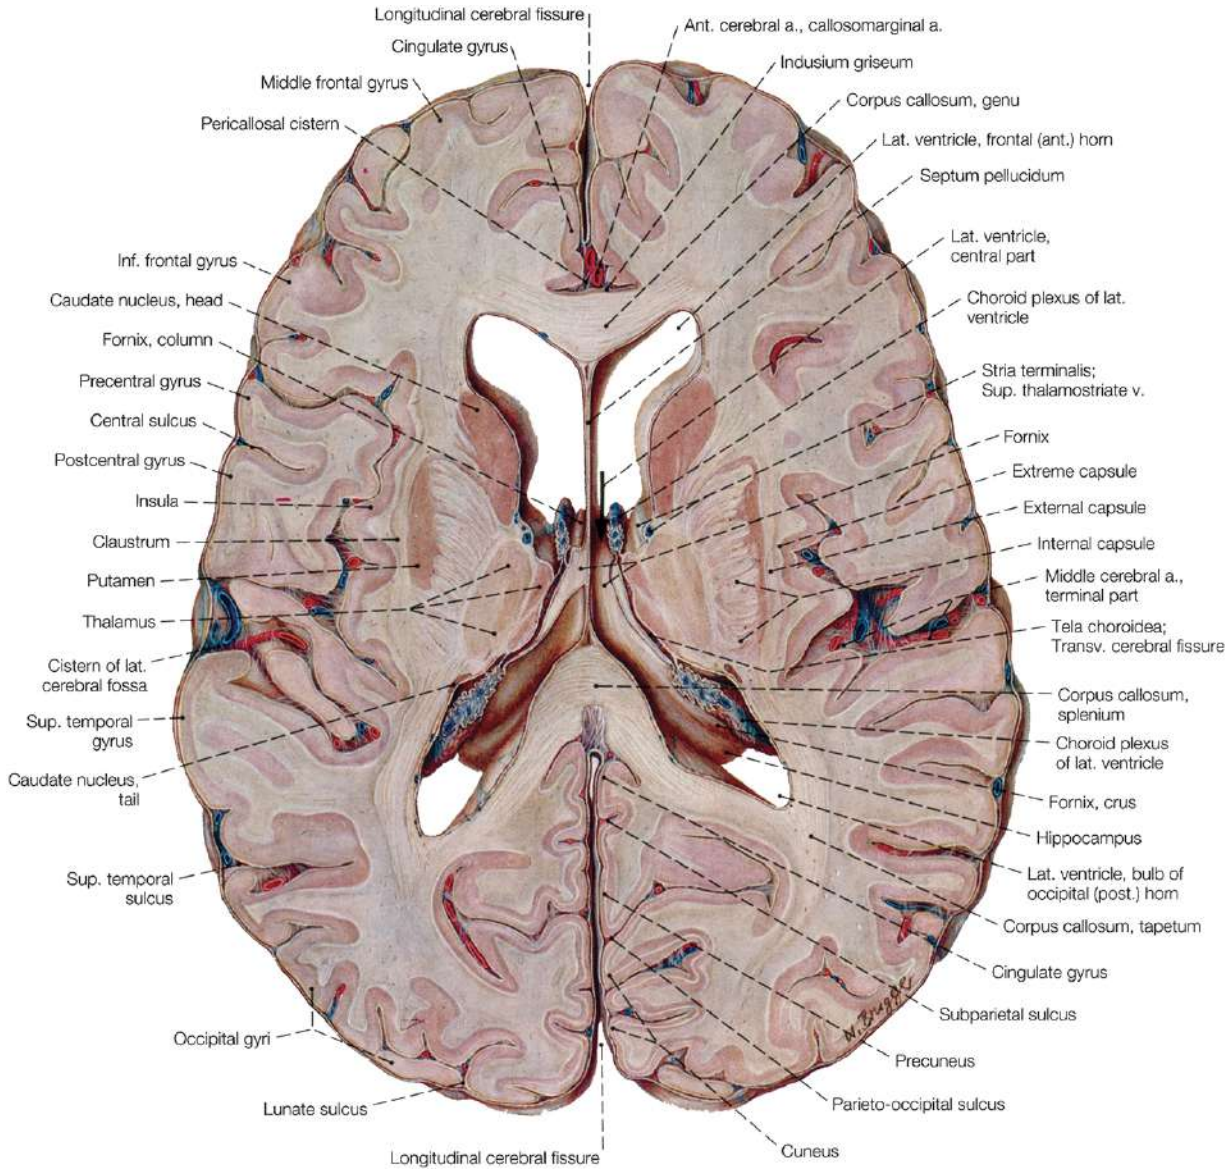

FIGURE 40.2 Transverse section at the level of the floor of the central part of the lateral ventricle. View of the superior surface of the plane of sectioning. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figure 12.228. Copyright © 2023 Elsevier GmbH Munich. With permission.)

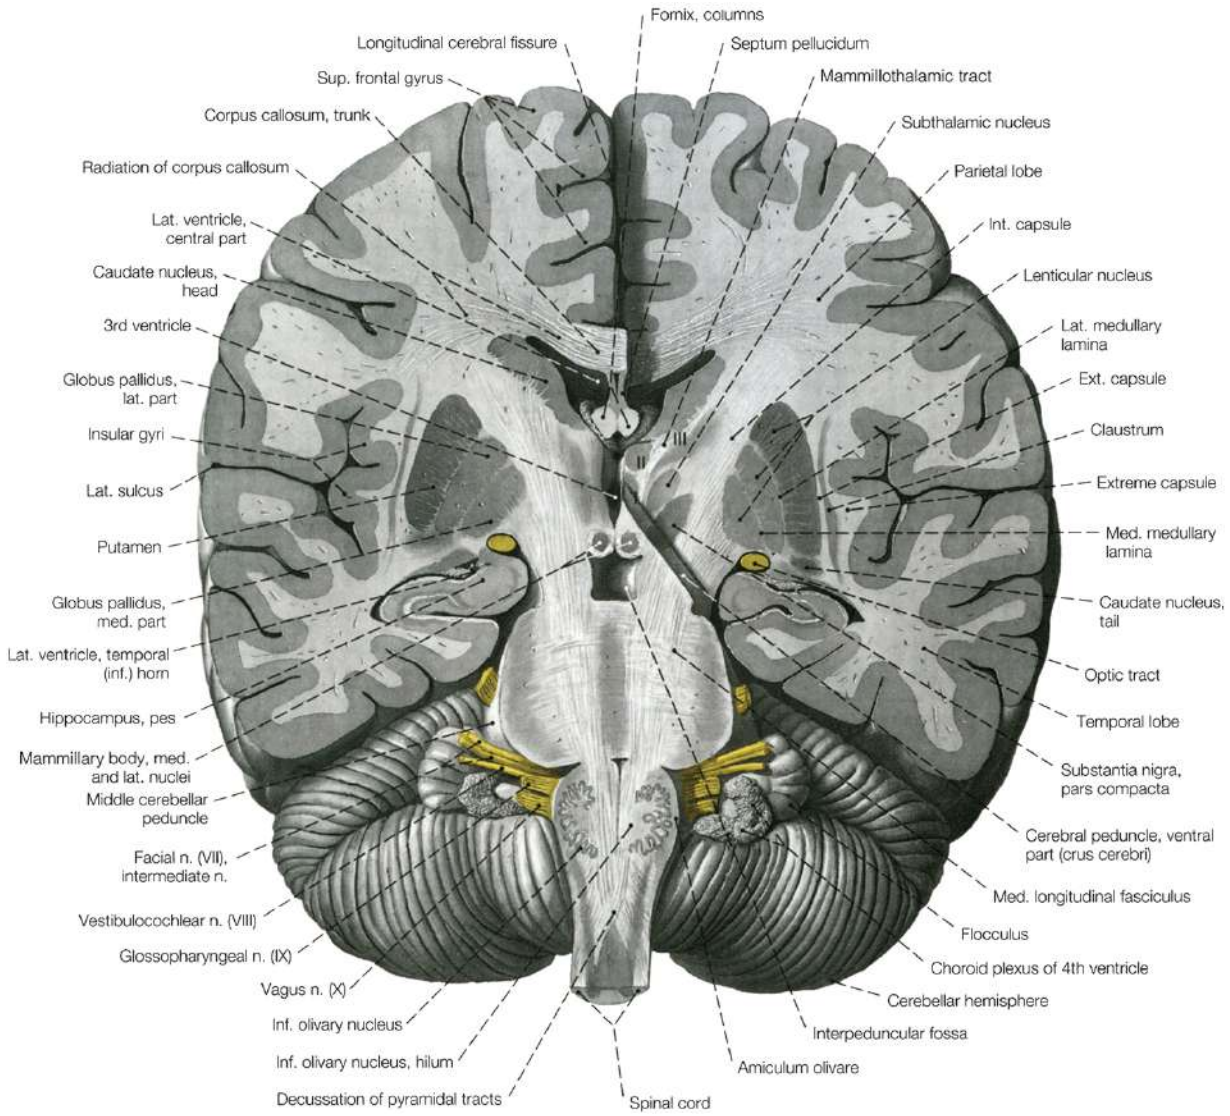

FIGURE 40.3 Section through the telencephalon and brainstem parallel with the cerebral peduncles. View of the posterior surface of the plane of sectioning. On the right side of the figure, the section reaches back to approximately the middle of the cerebral peduncle (oblique section). I to III indicate thalamic nuclei: I, medial nucleus; II, anterior nucleus; III, lateral nucleus. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figure 12.194. Copyright © 2023 Elsevier GmbH Munich. With permission.)

The diencephalon consists of the thalamus and the pineal region and is situated between the cerebrum and the mesencephalon, adjacent to the third ventricle. Lateral to the thalamus is the internal capsule, which carries the motor fibers (upper motor neurons) from the cortex en route to the brainstem and spinal cord.

At the tentorial notch, the mesencephalon rides on the upper part of the clivus. Its interior, the tectum, is partially occupied by cranial nerve nuclei (for the oculomotor, trochlear, and proprioceptive portions of the trigeminal nerves). The dorsal plate houses the superior and inferior colliculi, which regulate eye movements and hearing impulses, respectively. The trochlear nerve is the only cranial nerve that exits from this dorsal location.

The pons relays information between the two cerebellar hemispheres and, from the spinal cord to the cerebellum, carries the major ascending and descending pathways between the mesencephalon and the medulla oblongata, and contains the major motor and tactile sensory nuclei for the trigeminal nerve, which emerges from its lateral surface. The border between the pons and the medulla oblongata is noteworthy for the emergence of the abducens, facial, and vestibulocochlear (acoustic) cranial nerves.

The cerebellum develops laterally and posteriorly from the pons and differentiates into the median vermis and the bilateral hemispheres, which are flattened by the sloping tentorium on both sides. Anteriorly, the cerebellum faces the dorsal aspects of the pons and the medulla oblongata (the floor of the fourth ventricle).

The medulla oblongata forms the link between the pons, the spinal cord, and the cerebellum. It houses the majority of the cranial nerve nuclei (abducens, facial, vestibulocochlear, glossopharyngeal, vagal, accessory, and hypoglossal).

CSF is produced by the choroid plexus, which lies in the roofs of the fourth and third ventricles as well as in the medial walls of the central body and inferior horns of the lateral ventricles. The foramina of Monro transmit CSF between the third and lateral ventricles at the superolateral corners of the third ventricle. The aqueduct of Sylvius in the midbrain transmits CSF from the third to the fourth ventricles. It is the narrowest canal of the intracranial nervous system and is, therefore, the most common location of obstruction of flow by compression or tumor deposits, resulting in noncommunicating (obstructive) hydrocephalus. CSF in the fourth ventricle flows out of the ventricular system through the midline foramen of Magendie and the two lateral foramina of Luschka to the subarachnoid space.

CSF resorption back into the venous system occurs at arachnoid (or pacchionian) granulations, special outpouching structures from the arachnoid membrane that enhance fluid movement from the CSF space into the venous sinus system. Scarring from infection or inflammation or clogging of the arachnoid granulations causes increased pressure in the CSF space and communicating hydrocephalus. Recently, the concept of a lymphatic drainage system for the brain has been described (some would say "rediscovered") within the meninges, typically adjacent to dural sinuses.[1] This so-called glial-lymphatic (or "glymphatic") system is thought to provide a mechanism for immunologic cells and macromolecules to traffic between the CNS and the cervical lymph nodes.[2]

EPIDEMIOLOGY

From 2016 to 2020, there were an estimated 450,000 new cases of primary CNS tumors in the United States and 86,000 deaths, for an age-adjusted incidence of approximately 24.83 per 100,000 persons and an average mortality rate of 4.42 per 100,000 persons. The incidence of brain tumors increases with age.[3]

Occupational and environmental exposures have been associated with the development of CNS tumors. Farmers and petrochemical workers have been shown to have a higher incidence of primary brain tumors. A variety of chemical exposures have been linked, as reviewed by Ohgaki and Kleihues.[4] The use of cellular phones has been questioned as a contributing factor to the development of brain tumors. The World Health Organization (WHO) classified radiofrequency electromagnetic fields, such as those emitted by wireless phones, as "possibly carcinogenic to humans" (group 2B) based on limited clinical evidence.[4] Although prior cohort, case-control, and time trend analyses have shown no association between cell phone use and brain tumor risk,[5] subsequent case-control studies have suggested a potential increased risk of glioma, acoustic neuroma, and meningioma among individuals with higher cumulative lifetime cell phone use.[6-12] However, significant concerns with respect to recall and selection biases in most studies prevent a causal association from being concluded.

Prior exposure to ionizing radiation is a known risk factor for the development of primary CNS tumors, particularly meningiomas, but also

gliomas, sarcomas, and other tumor types.[10] There is a 2.3% incidence of primary brain tumors in children treated with prophylactic cranial irradiation for acute leukemia, a 22-fold increase over expected.[13-15]

The development of intracranial malignancy is also associated with several hereditary diseases such as neurofibromatosis types 1 (NF1) and 2 (NF2), von Hippel-Lindau disease, and tuberous sclerosis. Other hereditary associations are with retinoblastoma and Li-Fraumeni syndrome.

NATURAL HISTORY

The natural history of a primary brain neoplasm is determined by its histology, grade, and location. Most adult gliomas spread invasively without forming a natural capsule. They frequently cause edema in surrounding tissue. This edema is usually vasogenic but may be cytotoxic. It is seen best on T2-weighted magnetic resonance imaging (MRI) and is responsible for at least some of the clinical symptoms and signs. The edema is a consequence of altered blood-brain barrier (BBB) permeability. Different tumors cause varying amounts of edema (in descending order, metastases, astrocytomas, meningiomas, and oligodendrogliomas).

Some high-grade neoplasms metastasize by “seeding” the subarachnoid and ventricular spaces. Because of gravity or flow, these metastatic deposits are often present in the caudal portion of the spinal canal. Tumors that have a propensity for CSF spread include medulloblastomas, germ cell tumors, and CNS lymphoma. The exact frequency of CSF spread among other histologies (eg, germ cell tumors, ependymomas) is debated in the literature. Extracranial metastases from primary brain tumors are rare but can occur with medulloblastomas, germinomas, and high-grade astrocytomas.

CLINICAL PRESENTATION

The presenting symptoms of a primary brain tumor are classified as generalized or focal. Headache is more prevalent in patients with fast-growing, high-grade tumors. Seizures are a more common presenting feature in low-grade tumors. Focal neurologic deficits such as weakness, language dysfunction, or sensory loss are more frequent presentations of high-grade tumors. Acute events such as hemorrhage markedly alter the

tempo of symptom onset, regardless of tumor grade. Table 40.1 summarizes common clinical presentations of the more common CNS tumors.

TABLE 40.1 SYMPTOMS, SIGNS, AND DIAGNOSTIC CHARACTERISTICS OF VARIOUS INTRACRANIAL TUMORS

Tumor	Common Symptoms	Common Signs	Imaging Characteristics
Type			
Glioblastoma multiforme	Headache, seizure, unilateral weakness, mental changes	Focal presentation related to tumor location	Enhancing MRI or CT lesion, hypodense interior, often with associated edema
Meningioma	Localized headache	Focal presentation related to tumor location	Enhancing MRI or CT lesion associated with dura
Astrocytoma	Headache, seizure, unilateral weakness, mental changes	Focal presentation related to tumor location	May not enhance on CT or MRI, expansile mass-like T2/FLAIR signal abnormality
Medulloblastoma	Morning headaches, nausea, vomiting	Coordination, increased intracranial pressure (ie, papilledema), abducens and oculomotor nerve deficits	Heterogeneously enhancing on MRI or CT, diffusion restricting on MRI, typical more likely lateral location in adults relative to children
Ependymoma	Morning headaches, nausea, vomiting	Coordination, increased intracranial pressure (ie, papilledema), abducens and oculomotor nerve deficits	Heterogeneous enhancement on MRI or CT with or without calcification
Neurilemoma, schwannoma, neurinomas	Unilateral deafness, vertigo	Ipsilateral acoustic and facial or trigeminal nerve deficits	Homogeneous enhancing mass on MRI or CT, arising from cranial nerve

Tumor	Common Symptoms	Common Signs	Imaging Characteristics
Oligodendroglioma	Insidious headache, mental changes	Focal presentation related to tumor location	Expansile mass-like T2/FLAIR signal abnormality Heterogeneous lesion that may or may not enhance on MRI or CT, frequently with calcification, cystic regions, or hemorrhage
Lymphoma	Focal presentation related to tumor location	Focal presentation related to tumor location	Homogeneous, intense enhancement on MRI, may have a diffuse or “cotton-wool” appearance
Craniopharyngioma	Headache, mental changes, hemiplegia, seizure, vomiting, visual impairment	Cranial nerve deficits (II-VII), endocrine deficits)	Mixed cystic, calcified lesion on MRI and CT, arising from suprasellar region
Location			
Cerebral	Headache, seizure, unilateral weakness, mental changes	Focal presentation related to tumor location	
Cerebellar	Occipital headache	Increased intracranial pressure (ie, papilledema), abducens and oculomotor nerve deficits; coordination	
Brainstem or thalamus	Nausea, vomiting, ataxia	Increased intracranial pressure (ie, papilledema), abducens and	May be seen only on MRI

Tumor	Common Symptoms	Common Signs	Imaging Characteristics
		oculomotor nerve deficits; ataxia	
Optic nerve	Vision loss	Visual field deficit	Uniform enhancement on MRI or CT scan

CT, computed tomography; FLAIR, fluid-attenuated inversion recovery; MRI, magnetic resonance imaging.

Because brain parenchyma is anesthetic, headaches associated with brain tumors are due to increased intracranial pressure or to local pressure on sensitive intracranial structures (mainly dura and vessels). Headaches associated with increased intracranial pressure classically occur in the morning. Associated findings may include focal neurologic deficits, behavioral changes, and papilledema. Cushing triad is classically associated with increased intracranial pressure, but the full triad (hypertension, bradycardia, respiratory irregularity) is seen in only one-third of the cases of increased intracranial pressure. Long-standing increases in intracranial pressure may lead to optic atrophy and blindness because of transmission of the pressure to the optic nerves.

DIAGNOSTIC WORKUP

The initial workup of patients with brain tumors must include a complete history and physical examination. Information obtained from relatives and friends is helpful because many tumors cause changes in mentation not appreciated by the patient. In patients with symptoms, signs, or imaging suggestive of systemic dissemination, biopsy confirmation of the primary tumor or at least one of the extracranial metastatic sites is recommended. Solitary brain lesions in adult patients with certain types of known systemic cancer (eg, lung, breast, or colon cancers or melanoma) are far more likely to be a cerebral metastasis than a primary CNS tumor, although this is not always the case.

Imaging Studies

MRI with a gadolinium (Gd)-containing contrast agent is the imaging modality of choice for most CNS tumors. Computed tomography (CT) is generally reserved for those situations in which MRI is contraindicated, such as implanted pacemaker, metal fragment, or paramagnetic surgical clips, or where there is a need to image the extent of calcification or hemorrhage. Classically, the role of positron emission tomography (PET) imaging has been limited by the high baseline uptake of [^{18}F]fludeoxyglucose (^{18}F-FDG) by normal brain, but the advent of novel PET imaging agents is beginning to increase the utilization of this modality, especially ^{18}F-DOTATATE imaging for meningioma.

Magnetic Resonance Imaging

The most useful imaging studies are T1-weighted sagittal images, Gd-enhanced (usually obtained in high-resolution modes such as spoiled gradient recalled echo or Magnetization Prepared – RApid Gradient Echo) and nonenhanced T1 axial images, T2-weighted axial images, and FLAIR (fluid-attenuated inversion recovery) sequences.[16] As is the case with CT contrast agents, Gd-based contrast leaks into parenchyma in areas with BBB breakdown, and the paramagnetic properties of Gd generate hyperintense signal on T1 scans. T1 images are usually better at demonstrating anatomy and areas of contrast enhancement (CE). T2 and FLAIR images are more sensitive for detecting edema and infiltrative tumor. Tumor appearance on T1-weighted MRI is similar to that on CT, although tumor volumes are better delineated on MRI, particularly with low-grade neoplasms that do not demonstrate CE (Figure 40.4). Diffusion-weighted and functional MR also has utility in guiding resection. With the increasing incidence of post-treatment "pseudoprogression," additional specialized diffusion, perfusion, and spectroscopic sequences are being increasingly utilized to distinguish tumor from necrosis or pseudoprogression, and PET imaging may also have some role in this; in the United States, only FDG-PET is approved, but amino acid (FET), FLT, and F-DOPA PET imaging is being evaluated (Figure 40.5).[17] For meningiomas and other CNS tumors harboring somatostatin receptors (SSTRs), SSTR-PET imaging with ligands such as ^{68}Ga-DOTATATE or ^{68}Ga- DOTANOC can be useful to identify tumor margins, particularly in

the skull base where there are other anatomic structures that enhance with MRI-based contrast agents, thereby creating uncertainty as to whether the signal seen on MRI is tumor versus a normally enhancing structure.

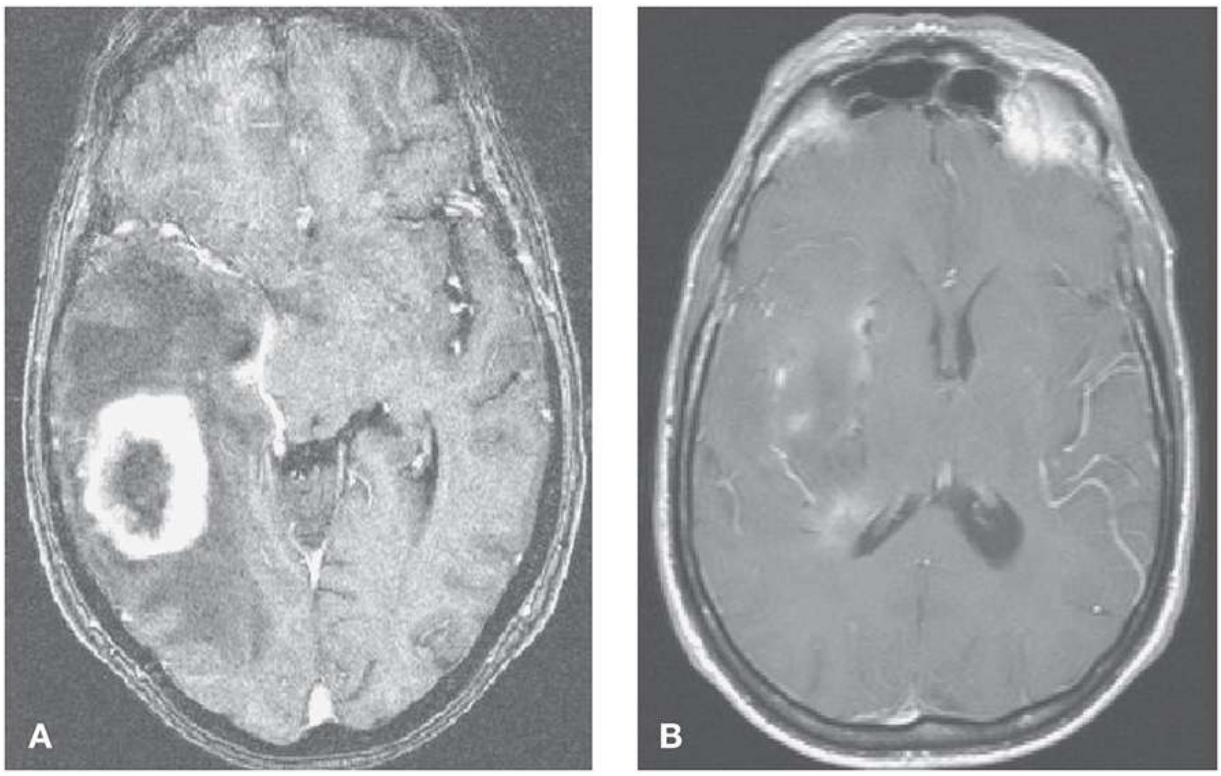

FIGURE 40.4 Magnetic resonance image of the brain showing glioblastoma (A), demonstrating a contrast- enhancing lesion with central necrosis and vasogenic edema, and low-grade glioma (B), illustrating a nonenhancing lesion difficult to delineate from normal parenchyma.

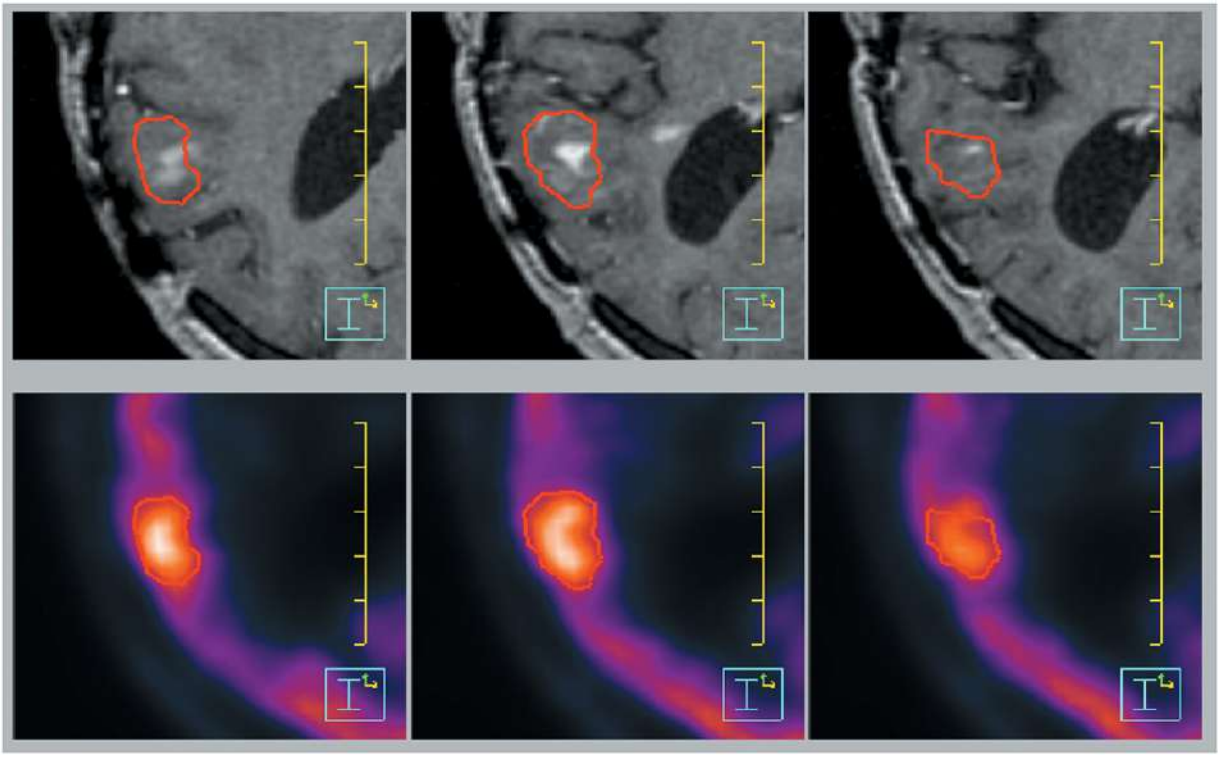

FIGURE 40.5 Oligodendroglioma images using an anatomic imaging technique, contrast-enhanced three-dimensional spoiled gradient recalled echo T1-weighted magnetic resonance image (top row), and a functional imaging technique, fludeoxyglucose positron emission tomography (bottom row). The red contour delineates the extent of increased metabolic activity seen using functional imaging. Looking at the top panel, one can appreciate the fact that if the anatomic image set alone would be used for target definition, it would yield a gross underestimation of the target volume as compared with the functional imaging technique.

Neuraxis Imaging

For neoplasms with a high risk of CSF spread, staging of the neuraxis is essential. Gd-enhanced MRI of the spine is the imaging modality of choice. Ideally, neuraxis imaging should be performed before surgery. In the immediate postoperative period, spinal MRI scans may be difficult to interpret because arachnoiditis and blood products in the CSF can mimic leptomeningeal metastasis. Delayed spinal MRI (>2 weeks after surgery), combined with an increased dose of intravenous (IV) Gd, is a sensitive imaging study to detect leptomeningeal disease.

Histologic Confirmation of Diagnosis

The morbidity of biopsy has decreased significantly with improvements in operative technique and anesthesia, as well as the availability of stereotactic biopsy techniques. Exception might be made in selected patients, such as those patients with known active systemic cancer and multiple lesions that are radiographically consistent with brain metastases, patients with typical clinical and MRI findings of a brainstem glioma or optic nerve meningioma, patients who are human immunodeficiency virus (HIV)-positive with CT or MRI findings consistent with primary CNS lymphoma (PCNSL) and positive Epstein-Barr virus polymerase chain reaction (PCR) in the CSF, or patients with secretory germ cell tumors.

Cerebrospinal Fluid Cytology

CSF cytology is essential for staging tumors with a propensity for CSF spread (eg, medulloblastoma, germ cell tumors, and CNS lymphoma). Sampling of the CSF in the immediate postoperative period may lead to false-positive results, however, and is best done before surgery or more than 2 weeks after surgery, as long as intracranial pressure is not elevated. CSF spread of tumor may be associated with several abnormal CSF findings. These include CSF pressure above 150 mm H_2O at the lumbar level in a laterally positioned patient, elevated protein level (>40 mg/dL in the lumbar cistern), a reduced glucose level (<50 mg/mL), and the finding of tumor cells by cytologic examination. Tumor markers in the CSF may help in making the diagnosis. Emerging assays are being developed and utilized to perform CSF-based cell-free DNA testing as a means of improving the sensitivity of CSF tumor evaluation, as well as providing the assessment of targetable mutations.

Differential Diagnosis

Most adults with new or persistent neurologic findings (focal deficit, increased intracranial pressure, seizures, altered mentation) are investigated using CT or MRI. There are many classical imaging features that help refine the differential diagnosis (Table 40.2).

TABLE 40.2 DIFFERENTIAL DIAGNOSIS OF SPACE-OCCUPYING LESIONS ON COMPUTED TOMOGRAPHY OR MAGNETIC RESONANCE IMAGING

Pathology	Features on CT or MRI
Neoplasm	
Primary	Solitary, no prior cancer, thick nodular CE
Metastatic	Multiple, prior cancer, ++edema, located at gray/white junction
Infectious	
Abscess	Fever, acutely ill, ±systemic infection, cyst cavity with smooth thin walls, CE, and restricted diffusion within cavity
Cerebritis	Fever, acutely ill, ±systemic infection, diffuse T2 change, no CE mass
Meningitis	Diffuse enhancement of meninges on T1-weighted imaging (may simulate leptomeningeal metastases)
Vascular	
Infarct	Gray and white matter involvement, wedge-like vascular distribution associated with restricted diffusion and low ADC signal
Bleeding	Homogeneous, clears quickly, residual hemosiderin ring
Treatment-related necrosis	Central hypodensity, ring CE, edema, >6 mo after radiation therapy or chemotherapy, metabolic scan shows low activity.

ADC, apparent diffusion coefficient; CE, contrast enhancement; CT, computed tomography; MRI, magnetic resonance imaging.

PATHOLOGY

Primary intracranial tumors are of ectodermal and mesodermal origin and arise from the brain, cranial nerves, meninges, pituitary, pineal, and vascular elements. In 2021, the WHO revised its classification system for pathologic subtypes of CNS tumors to combine histology with molecular parameters such as isocitrate dehydrogenase 1 (*IDH1*) mutation, 1p19q codeletion, and H3 K27M mutation for gliomas; RELA fusion for ependymoma; and WNT and sonic hedgehog (SHH) activation for medulloblastoma (Table 40.3).[18] DNA methylation provides a consistent biomarker and indicates the specific tumor cell type from which the tumor cell originates. Machine learning techniques employed to analyze DNA methylation have enabled classification of brain tumors that pose diagnostic challenges due to unusual histopathology or diverse molecular genetic profiles.[19] Guidelines for assigning the grade of malignancy are provided, where applicable.

TABLE 40.3 2021 WHO HISTOLOGIC CLASSIFICATION OF TUMORS OF THE CENTRAL NERVOUS SYSTEM

Gliomas, glioneuronal tumors, and neuronal tumors
Adult-type diffuse gliomas
Astrocytoma, IDH mutant
Oligodendroglioma, IDH mutant, and 1p/19q codeleted
Glioblastoma, IDH wild type
Pediatric-type diffuse low-grade gliomas
Diffuse astrocytoma, *MYB* or *MYBL1* altered
Angiocentric glioma
Polymorphous low-grade neuroepithelial tumor of the young
Diffuse low-grade glioma, MAPK pathway altered
Pediatric-type diffuse high-grade gliomas
Diffuse midline glioma, H3 K27 altered
Diffuse hemispheric glioma, H3 G34 mutant
Diffuse pediatric-type high-grade glioma, H3 wild type and IDH wild type
Infant-type hemispheric glioma
Circumscribed astrocytic gliomas
Pilocytic astrocytoma
High-grade astrocytoma with piloid features
Pleomorphic xanthoastrocytoma
Subependymal giant cell astrocytoma
Chordoid glioma
Astroblastoma, *MN1* altered
Glioneuronal and neuronal tumors
Ganglioglioma
Desmoplastic infantile ganglioglioma/desmoplastic infantile astrocytoma
Dysembryoplastic neuroepithelial tumor
Diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters[a]
Papillary glioneuronal tumor
Rosette-forming glioneuronal tumor
Myxoid glioneuronal tumor
Diffuse leptomeningeal glioneuronal tumor
Gangliocytoma
Multinodular and vacuolating neuronal tumor
Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease)
Central neurocytoma
Extraventricular neurocytoma
Cerebellar liponeurocytoma
Ependymal tumors
Supratentorial ependymoma
Supratentorial ependymoma, *ZFTA* fusion positive
Supratentorial ependymoma, *YAP1* fusion positive
Posterior fossa ependymoma
Posterior fossa ependymoma, group PFA
Posterior fossa ependymoma, group PFB
Spinal ependymoma

Spinal ependymoma, *MYCN* amplified
Myxopapillary ependymoma
Subependymoma
Choroid plexus tumors
Choroid plexus papilloma
Atypical choroid plexus papilloma
Choroid plexus carcinoma
Embryonal tumors
Medulloblastoma
Medulloblastomas, molecularly defined
Medulloblastoma, WNT activated
Medulloblastoma, SHH activated and *TP53* wild type
Medulloblastoma, SHH activated and *TP53* mutant
Medulloblastoma, non-WNT/non-SHH
Medulloblastomas, histologically defined
Other CNS embryonal tumors
Atypical teratoid/rhabdoid tumor
Cribriform neuroepithelial tumor[a]
Embryonal tumor with multilayered rosettes
CNS neuroblastoma, *FOXR2* activated
CNS tumor with *BCOR* internal tandem duplication
CNS embryonal tumor
Pineal tumors
Pineocytoma
Pineal parenchymal tumor of intermediate differentiation
Pineoblastoma
Papillary tumor of the pineal region
Desmoplastic myxoid tumor of the pineal region, *SMARCB1* mutant
Cranial and paraspinal nerve tumors
Schwannoma
Neurofibroma
Perineurioma
Hybrid nerve sheath tumor
Malignant melanotic nerve sheath tumor
Malignant peripheral nerve sheath tumor
Paraganglioma
Meningiomas
Meningioma
Mesenchymal, nonmeningothelial tumors
Soft tissue tumors
Fibroblastic and myofibroblastic tumors
Solitary fibrous tumor
Vascular tumors
Hemangiomas and vascular malformations
Hemangioblastoma
Skeletal muscle tumors
Rhabdomyosarcoma

Uncertain differentiation
Intracranial mesenchymal tumor, *FET-CREB* fusion positive[a]
CIC-rearranged sarcoma
Primary intracranial sarcoma, *DICER1* mutant
Ewing sarcoma
Chondro-osseous tumors
Chondrogenic tumors
Mesenchymal chondrosarcoma
Chondrosarcoma
Notochordal tumors
Chordoma (including poorly differentiated chordoma)
Melanocytic tumors
Diffuse meningeal melanocytic neoplasms
Meningeal melanocytosis and meningeal melanomatosis
Circumscribed meningeal melanocytic neoplasms
Meningeal melanocytoma and meningeal melanoma
Hematolymphoid tumors
Lymphomas
CNS lymphomas
Primary diffuse large B-cell lymphoma of the CNS
Immunodeficiency-associated CNS lymphoma
Lymphomatoid granulomatosis
Intravascular large B-cell lymphoma
Miscellaneous rare lymphomas in the CNS
MALT lymphoma of the dura
Other low-grade B-cell lymphomas of the CNS
Anaplastic large cell lymphoma (*ALK*+/*ALK*−)
T-cell and NK/T-cell lymphomas
Histiocytic tumors
Erdheim-Chester disease
Rosai-Dorfman disease
Juvenile xanthogranuloma
Langerhans cell histiocytosis
Histiocytic sarcoma
Germ cell tumors
Mature teratoma
Immature teratoma
Teratoma with somatic-type malignancy
Germinoma
Embryonal carcinoma
Yolk sac tumor
Choriocarcinoma
Mixed germ cell tumor
Tumors of the sellar region
Adamantinomatous craniopharyngioma
Papillary craniopharyngioma
Pituicytoma, granular cell tumor of the sellar region, and spindle cell oncocytoma

Pituitary adenoma/PitNET
Pituitary blastoma
Metastases to the CNS
Metastases to the brain and spinal cord parenchyma
Metastases to the meninges

CNS, central nervous system; IDH, isocitrate dehydrogenase; NK, natural killer; PitNET, pituitary neuroendocrine tumor; SHH, sonic hedgehog; WHO, World Health Organization.

[a]Provisional entries, that is, the WHO Working Group felt there was insufficient evidence to recognize these as distinct entities at this time.

From Louis DN, Perry A, Wesseling P, et al. The 2021 WHO classification of tumors of the central nervous system: a summary. *Neuro Oncol*. 2021;23(8):1231-1251. Reproduced by permission of Society for Neuro-Oncology.

GENERAL MANAGEMENT

The medical management of patients with brain tumors includes the management of increased intracranial pressure, seizures, and venous thromboembolic disease.

Cerebral Edema

Glucocorticoids are used to control neurologic signs and symptoms caused by cerebral edema. Lower doses of steroids (eg, 2-4 mg dexamethasone) twice daily (BID) have been shown to be as effective as higher doses, and in fact, based on pharmacokinetic (PK) properties, even once-daily (QD) dosing should be effective. Prolonged steroid use is associated with multiple medical problems; therefore, steroids should be discontinued or tapered to the lowest dose necessary, as soon as possible. Dexamethasone is the most common corticosteroid used for historical reasons and because of minimal mineral-corticoid effects. As with all corticosteroids, a taper is necessary to prevent a rebound in cerebral edema and also to allow the pituitary-adrenal axis to recover. As a means of avoiding or minimizing steroid usage, low-dose bevacizumab and *Boswellia* have also been utilized.[20,21]

Seizures

Patients with seizures require anticonvulsants. Because anticonvulsants such as carbamazepine, phenobarbital, and phenytoin induce hepatic

cytochrome P-450 isoenzymes, which increase the metabolism and clearance of several cancer chemotherapy agents such as paclitaxel and irinotecan,[22] non–enzyme-inducing anticonvulsants, such as levetiracetam, lacosamide, lamotrigine, and pregabalin, are preferred.

Prophylactic anticonvulsant use (in patients who have never experienced a seizure) remains controversial, although practice guidelines from the American Academy of Neurology recommend against their use because of the lack of data.[23]

SURGERY

Surgical procedures can be summarized as biopsy for diagnosis only, resection for cure, surgical debulking for the management of mass effect–related symptoms, CSF diversion procedures to relieve acute symptoms caused by increased intracranial pressure or hydrocephalus, and increasingly reresection to distinguish and manage the effects of progressive tumor from symptomatic necrosis or pseudoprogression. Other roles of surgery include the placement of chemotherapy wafers, brachytherapy devices, and catheters for interstitial drug delivery and for monitoring tumor drug concentrations and/or biologic effects and the procurement of tissue for further therapeutic selection. Complete resection of tumor is associated with a survival advantage for some tumor types.[24] However, for some radiosensitive and/or chemosensitive malignancies such as PCNSL, aggressive resection is unnecessary, and the surgeon's role is limited to providing diagnostic material.

Operative Technique

Ultrasound and CT- and MRI-guidance systems provide surgeons with intraoperative navigation based upon preoperative and/or intraoperative data. In general, these consist of a workstation into which the relevant imaging studies have been loaded, together with infrared or ultrasound detectors that recognize the three-dimensional (3D) orientation and position in space of various tools. Once the patient is registered, the tumor's margins are "visualized" below the scalp so that the surgeon can plan the smallest and safest approach. Resection may be assisted by the use of an intraoperative microscope and guided by the appearance and consistency of

tumor tissue compared with surrounding normal brain. Intraoperative CT, MRI, or ultrasonography can be used to evaluate the completeness of tumor resection. In the case of lesions that are in or near suspected functional cortex, cortical mapping under awake conditions can be performed to localize areas that are critical for motor or speech function. Preoperative functional imaging with functional MRI, diffusion-weighted MRI-based tractography, and/or navigated transcranial motor stimulation are sometimes used as well to localize functional cortex and white matter pathways. Endoscopy can be used to minimize access for resection of intraventricular lesions or pituitary tumors, as well as for reestablishing pathways of CSF flow, for example, in cases of tumors that have obstructed the cerebral aqueduct, thereby avoiding the need for a CSF shunt. In addition to intraoperative image guidance, the use of fluorescent tumor-localizing dyes such as 5-aminolevulinic acid (5-ALA) is approved in both the United States and Europe to enhance the completeness of resection.

Stereotactic biopsy is performed via either frameless or stereotactic frame–based approaches; a CT or MRI is performed, and the data are loaded into an image-guidance system. A target and entry points are selected, and the trajectory is visualized on a workstation. The entry point is located on the patient's scalp, and a small burr hole or twist drill hole is made. The biopsy needle is oriented using the image-guidance system and passed to the appropriate depth, and tissue samples are obtained. Multiple tissue samples may be obtained along the needle tract until the pathologist can provide an intraoperative diagnosis. The volume of tissue removed is insufficient to relieve mass effect, and patients who are symptomatic are better treated by open resection.

A more recently developed stereotactic technique for treating the mass component of brain tumors involves the use of laser interstitial thermal therapy (LITT). Briefly, this approach involves the temporary stereotactic implantation of a cooled laser probe, which can be activated and manipulated within the MRI environment. The laser is used to heat, but not coagulate, adjacent tissue, and it is progressively advanced through the target tissue as the treatment progresses. This approach takes advantage of a previously described relationship between temperature and time, which can be used to predict the likelihood of permanent injury even with relatively small (<10 °C) increases in local tissue temperature. A specialized MRI

technique, called MR thermometry, is used to monitor tissue temperature, and the combination of temperature data with duration of heating is used by the specialized LITT software to create a visual indication on each MRI slice of the probability of tissue death as a result of treatment. LITT for brain tumors was developed initially for the treatment of malignant tumors that would be difficult to access via conventional surgery, and its practice has expanded to include resectable and even benign pathologies. Although the LITT procedure has shown an encouraging safety profile, there have not been any randomized studies to date that have directly compared this approach to conventional surgical treatment.[25]

RADIOTHERAPY

Radiobiologic Considerations Underlying Tissue Injury

The process of radiation injury in the brain is highly complex and dependent on a variety of technical factors including dose, volume, fraction size, and the specific target cell population, as well as secondary mechanisms of expression of injury such as vascular leak causing edema, vascular endothelial loss resulting in hypoxic injury, reactive gliosis, and to date inadequately studied host factors. Some structures (eg, optic chiasm, hypothalamus, lacrimal gland, lenses) appear to be substantially more sensitive to radiation than others. Even focal lesions may result in widespread radiographic and/or functional perturbations. The time course for the manifestation of injury can be highly variable, and the clinical picture is easily confounded with tumor progression. The effect on endothelial cells often becomes manifest as an early T2 signal abnormality on MRI, possibly due to disruption of the BBB and edema formation. Metabolic perturbations observed with PET may reflect oligodendroglial demyelination. Further vascular perturbation and regeneration in response to injury results in an enhancing lesion on imaging. Delayed effects include white matter necrosis and vascular obliteration. The time course can be shortened from several months to a few weeks by increasing the volume of brain irradiated or by increasing the fraction size or total dose.

Historically, late injury from radiotherapy (RT) has been reported as the “tolerance” dose (TD) at either the 5% or 50% risk level at 5 years (TD 5/5 or TD 50/5, respectively). These values for whole-brain fractionated RT at 2

Gy/fraction are 60 and 70 Gy, respectively. With partial-brain irradiation, the corresponding values are 70 and 80 Gy. In the setting of partial-brain fractionated RT with a fraction size less than 2.5 Gy, quantitative analyses of normal tissues effect in the clinic (QUANTEC) have estimated 5% and 10% rates of symptomatic necrosis at 72 and 90 Gy maximum equivalent doses in 2-Gy fractions, respectively.[26]

Treatment Setup

The head should be positioned so that its major axes are parallel with and perpendicular to the central axis incident beam and the treatment table. It may be preferable to fully flex or extend the neck in some patients depending on tumor location and choice of beams, although the use of noncoplanar fields and intensity-modulated radiation therapy (IMRT) techniques makes this less necessary (Figure 40.6).

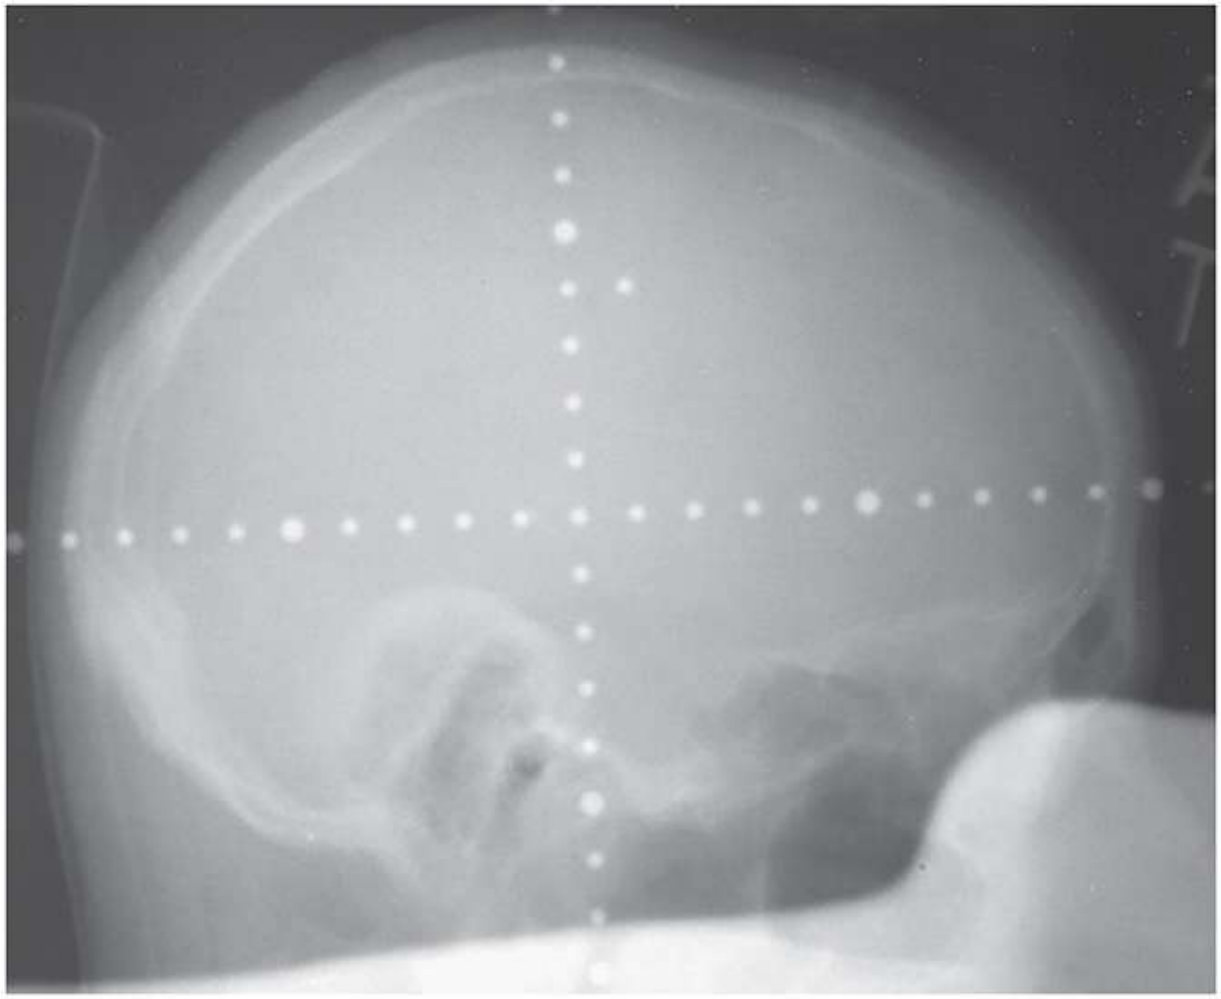

FIGURE 40.6 Lateral portal localization film of whole brain illustrating adequate inclusion of the cribriform plate and the anterior and middle cranial fossae.

Reproducibility of head positioning is achieved using a fixation/immobilization device. Many devices are available for this with reproducibility precision ranging from 1 to 5 mm. Image-guided RT can improve accuracy in delivering RT and reduce margins for setup variability.

Target Volume Definition

Two major factors drive margin selection: the inaccuracy of estimating the clinical target volume (CTV) and the specific dosimetric and setup variability components that are institution specific and determine the planning target volume (PTV).

Common sense and practice dictate that these CTV expansion margins should not traverse anatomically discontiguous structures or include areas unlikely to be infiltrated by tumor. Inclusion of the bony skull is unnecessary unless direct tumor extension is suspected. With some exceptions, "compartmental crossing" to the contralateral hemisphere or, for example, into the posterior fossa or the brainstem for a supratentorial cortical tumor is not necessary, but because many infiltrating gliomas "cross" through the anterior and/or posterior corpus callosal tracts, these should be adequately included in CTV margin selection.

Radiotherapy Techniques

The most commonly employed RT techniques in the management of CNS tumors are partial-brain irradiation, whole-brain radiotherapy (WBRT), craniospinal irradiation (CSI), stereotactic radiosurgery (SRS), fractionated SRS, brachytherapy, and proton therapy. The indications for each of these techniques are discussed under the sections on the individual tumor types. CSI is more frequently used in the management of pediatric CNS tumors and is discussed in detail in Chapters 90.

Whole-Brain Radiotherapy

WBRT is used most often for patients with brain metastases but also for patients with PCNSLs and as a component of CSI.

Conventional WBRT is administered through parallel- opposed lateral portals. The inferior field border should be inferior to the cribriform plate, the middle cranial fossa, and the foramen magnum, all of which should be distinguishable on simulation or portal localization radiographs. When in doubt about tumor coverage or lens sparing for tumors in a subfrontal or middle cranial fossa location, CT-based contouring and planning should be considered. CT-based planning is now the most common approach in the United States, and this allows individualization of beam/machine parameters to ensure adequate coverage.

Incorporation of hippocampal avoidance during WBRT (HA-WBRT) for brain metastases has demonstrated a significant reduction in cognitive toxicity.[27] HA-WBRT requires a thin-slice volumetric postcontrast MRI sequence fused to the treatment planning CT scan. The hippocampal dentate

gyrus should be contoured, and a 5-mm volumetric margin should be generated around the hippocampus to create the HA region.

Craniospinal Irradiation

Traditional CSI techniques utilize opposed lateral cranial fields and one or more posterior spinal fields depending on patient size. The junctioning of noncoplanar fields in the cervical region is potentially hazardous because of the risk of overlap resulting in radiation myelitis. Consequently, great attention needs to be paid to precise immobilization, and a variety of immobilization devices are available for this purpose. Image guidance during RT can help in ensuring day-to-day reproducibility. The prone position permits direct visualization of the light field from the linear accelerator on the patient, thereby allowing daily adjustments of the junctions. However, if anesthesia or sedation is required as may be the case with young children, a supine setup may be considered safer.[28] To avoid the risk of dose overlap, at least two techniques (with numerous variations) are commonly used, and several variations of these have also been reported. In the first, a gap is employed between abutting fields such that the beam edges intersect deep into the spinal cord. This gap could result in a cold spot in a small segment of the spinal cord. If the beam intersection point were raised dorsally, a hot spot would result.

The second technique attempts to avoid this problem using a half-beam technique in which the caudal edge of the brain is matched precisely with the cephalad edge of the abutting spine field without cold or hot spots. This requires collimator angulation and sometimes a couch rotation as well. For both techniques, the use of moving junctions (known as “feathering”) smoothens out any dose inhomogeneity.[29] Several studies have demonstrated that adequate coverage of the subfrontal region and posterior fossa and depth assessment of the cord require CT-based planning. Given the complexity of CSI, we recommend that it be delivered at centers with adequate staff, experience, and expertise.

With sophisticated techniques such as image-guided intensity-modulated helical tomotherapy, volumetric modulated radiotherapy, and intensity-modulated proton therapy (IMPT), it is possible to treat the entire neuraxis in a single setup.[30] Increasingly, proton therapy has been used for CSI with

placement of the finite distal range in the vertebral body, leading to negligent "exit" dose in visceral structures anterior to the spine and maximal sparing of vertebral body–based marrow (Figure 40.7). The recent publication of a randomized phase 2 trial demonstrating a survival advantage with IMPT CSI for leptomeningeal carcinomatosis has increased the utilization of this approach.[31]

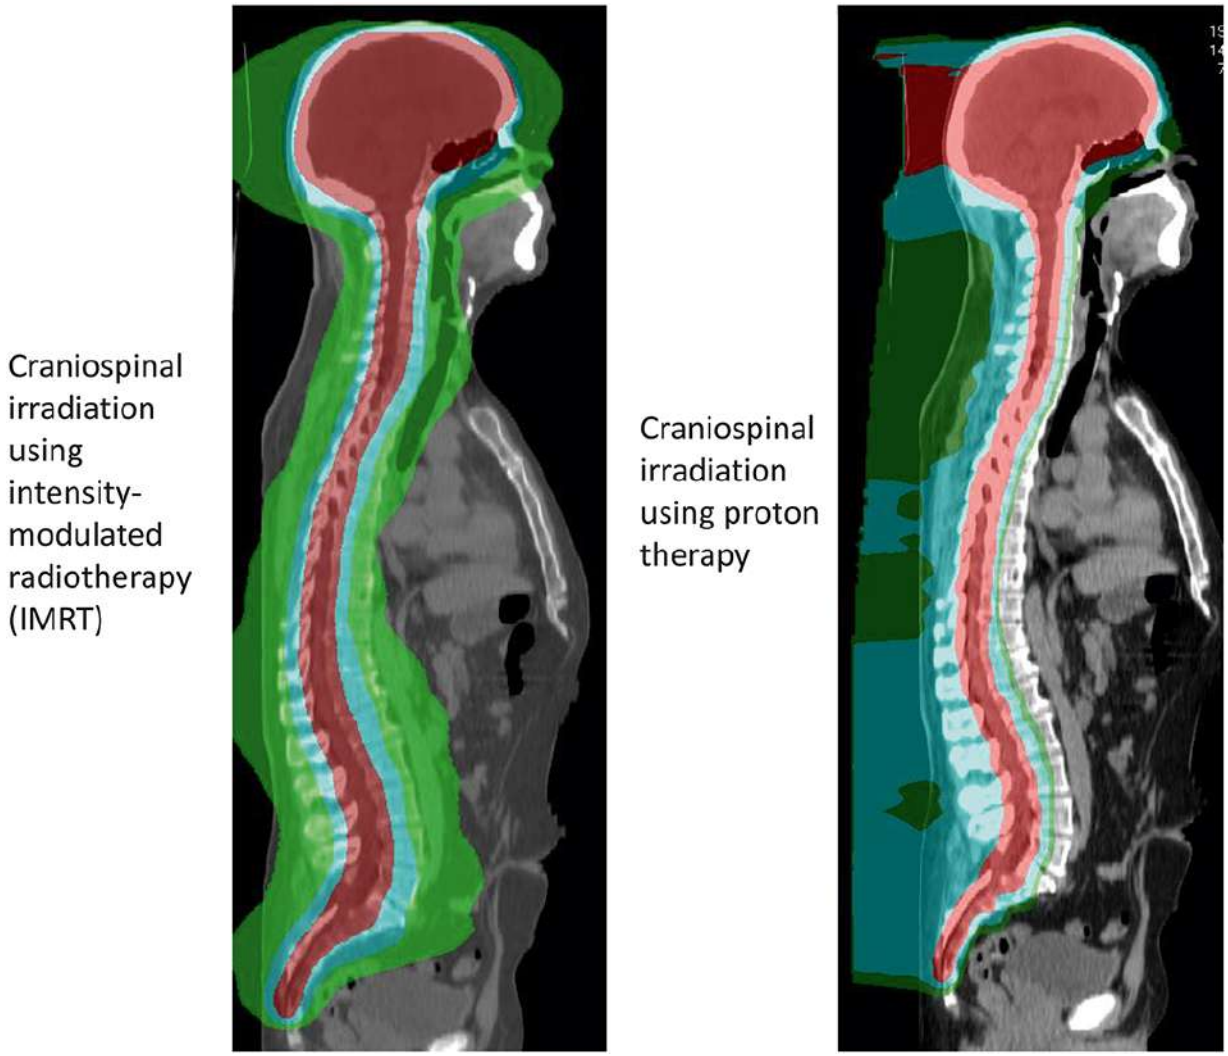

FIGURE 40.7 Comparison of proton therapy to intensity-modulated radiation therapy for craniospinal irradiation demonstrates negligent "exit" dose in visceral structures anterior to the spine and maximal sparing of vertebral body–based marrow achieved with proton therapy.

Stereotactic Radiosurgery

SRS requires a team composed of a radiation oncologist, neurosurgeon, and radiation oncology physicist, in addition to appropriate support staff. SRS can be delivered using a conventional or modified linear accelerator (LINAC) system, a Gamma Knife (Elekta Corp, Stockholm, Sweden), a robotically controlled miniaturized linear accelerator (CyberKnife), a dedicated gyroscopic self-shielded linear accelerator (Zap), or a modified proton system. In LINAC radiosurgery, circular or oval collimators (the so-called "cones") ranging from 4 to 40 mm have historically been used to collimate the treatment beam into a small circular beam, and treatment is delivered using multiple noncoplanar arcs that intersect at a single point to treat an approximately spherical target of less than 4 cm in diameter. Newer miniaturized multileaf collimators allow beam shaping without resorting to the use of externally mounted cones. Techniques incorporate multiple noncoplanar arcs with couch and jaw rotations, which permits a greater portion of the 3D space subtended over the skull to be utilized for beam entry. This approach, sometimes referred to as the "hyperarc technique," allows for better dose conformality and rapid treatment of multiple intracranial lesions, without the need for selecting individual isocenters for each lesion. The legacy Gamma Knife is a fixed beam multisource radiation unit containing 201 cobalt-60 (^{60}Co) sources that are collimated using a helmet with circular apertures ranging from 4 to 18 mm that is focused onto a single-target point. The newer Gamma Knife technology obviates the need for "helmet changes" and can effectively allow IMRT-like dose distributions to be created. For irregularly shaped lesions, treatments delivered using either noncoplanar arcs delivered through a single circular collimator or a single collimator helmet lead to the inclusion of a large amount of normal brain and yield inferior conformality. In these cases, it is advantageous to use multiple circular collimators or collimator helmets placed on different target points (and in the newer versions of the Gamma Knife [Perfexion, Icon, and Esprit], different segments can be treated with different collimator diameters, and differential weighting is also possible) or to consider the use of multileaf collimated beams. The "hyperarc technique" referred earlier also achieves improved dose conformality because of the combination of multiple noncoplanar arcs, the use of a sophisticated multileaf collimator, varying collimator rotations, and multiple couch angles. The newest versions of the Gamma Knife (Icon and Esprit)

incorporate an onboard kV imager capable of generating volumetric CT images that permit frameless and repetitive positioning for fractionated treatments.

The Radiation Therapy Oncology Group (RTOG) study 90-05 established the maximum tolerated dose of single faction SRS to be 24, 18, and 15 Gy for tumors 20 or higher, 21 to 30, and 31 to 40 mm in maximum diameter, respectively, and these and other parameters are frequently used to guide prescription doses.[32] In modern practice, because the number of intracranial lesions treated in one SRS session has increased significantly, there has been a tendency toward decreasing the SRS dose; for example, in a large Japanese study of multiple brain metastases, the SRS dose was decreased to 15 Gy.[33] Such across-the-board dose reductions in other studies have been shown to be associated with reduced local control, especially when WBRT is avoided.[34]

To limit the risk of radionecrosis, recent literature has identified the importance of limiting single-fraction SRS V_{12Gy} to normal brain and intracranial metastatic target volume to 10 mL or less; in situations where this metric cannot be achieved, multifraction SRS is recommended.[26,34,35]

Following surgical resection of brain metastases, postoperative SRS to the surgical cavity has become standard of care based on two prospective trials demonstrating improved surgical bed control with SRS as compared to observation[36] and less neurocognitive toxicity with SRS as compared to conventional WBRT.[37] Currently, as alternatives to postoperative single-fraction SRS, randomized trials are investigating preoperative SRS to reduce the risk of surgical perturbation failure and resultant nodular meningeal disease, and multifraction postoperative SRS to improve local control and reduce rates of radionecrosis. Current single-fraction SRS dosing guidance is from a randomized trial of single-fraction postoperative SRS versus WBRT (N107C/CEC.3) and is supported by existing literature (Table 40.4).[34,37]

TABLE 40.4 RECOMMENDED POSTOPERATIVE CAVITY SINGLE-FRACTION SRS DOSING GUIDANCE

Cavity Volume[a]	Single-Fraction SRS Dose (cGy)
<4.2 cm^3	2,000

Cavity Volume[a]	Single-Fraction SRS Dose (cGy)
≥4.2 to <8.0 cm^3	1,800
≥8.0 to <14.4 cm^3	1,700
≥14.4 to <20.0 cm^3	1,500
≥20.0 to <30.0 cm^3	1,400
≥30.0 to <5.0 cm max	1,200

SRS, stereotactic radiosurgery.

[a]Given the irregular shape of surgical cavities, the total prescribed dose should be based on the surgical cavity volume with a maximum cross-sectional diameter of <5.0 cm.

Fractionated Stereotactic Radiosurgery

For lesions larger than 4 cm and/or located in critical regions and/or for situations where single-fraction SRS V_{12Gy} to normal brain and intracranial metastatic target volume exceeds 10 mL,[26,35] the delivery of single-fraction SRS is not desirable because of a high risk of CNS toxicity. Multifraction SRS is a hybrid between conventionally fractionated RT and SRS that combines fractionation with stereotactic localization and targeting techniques. Various systems for multifraction SRS have been developed, with a reported accuracy of 1 to 3 mm. As for SRS, the use of multiple arcs and circular collimators for irregularly shaped lesions leads to the inclusion of a large amount of normal tissue. The use of multiple noncoplanar fixed fields each having a unique entrance and exit pathway will be preferable because of better conformality, as multileaf collimators are almost always used.[38-40] With the Perfexion device, the use of the "Extend" frame permits multifraction SRS as well as targeting of lower cranial lesions. With the incorporation of onboard volumetric imaging, modern LINACS and the most recent version of the Gamma Knife (Icon and Esprit) also permit fractionation, using noninvasive mask fixation systems. The CyberKnife also permits this option using repetitive 2D radiographic imaging incorporated into a sophisticated skull anatomy–based visualization software. There is increasing use of 9 Gy × 3 fractions or 6 Gy × 5 fractions

schedules of multifraction SRS for larger (>3 cm) brain metastases,[34] both to improve the rate and durability of local control and to decrease side effects; an ongoing NRG Oncology randomized trial is prospectively evaluating this approach.

Heavy Charged Particles

Heavy charged particle beams deposit their dose at a depth that depends on their energy over a distance of a few millimeters when the heavy charged particles come to rest, the so-called Bragg peak. To cover a larger volume, the particle beam can be modulated, in effect adding up multiple Bragg peaks. The very sharp dose gradient at the distal edge permits the use of high-dose RT for tumors in critical locations, such as at the clivus and base of the skull, and provides better normal tissue sparing in other situations, especially, for example, in CSI (Figure 40.8).[41,42] Currently, a small number of European and Japanese centers are treating CNS tumors with carbon ions, which putatively have higher linear energy of transfer and presumed superior biologic effect, but mature clinical data are not yet available. There are currently no U.S. centers utilizing these technologies. Neutron-beam irradiation continues to be used in some U.S. centers, but the targeted approach of boron neutron capture therapy, which is rapidly expanding in Asia and Europe, has no U.S. footprint at this time.

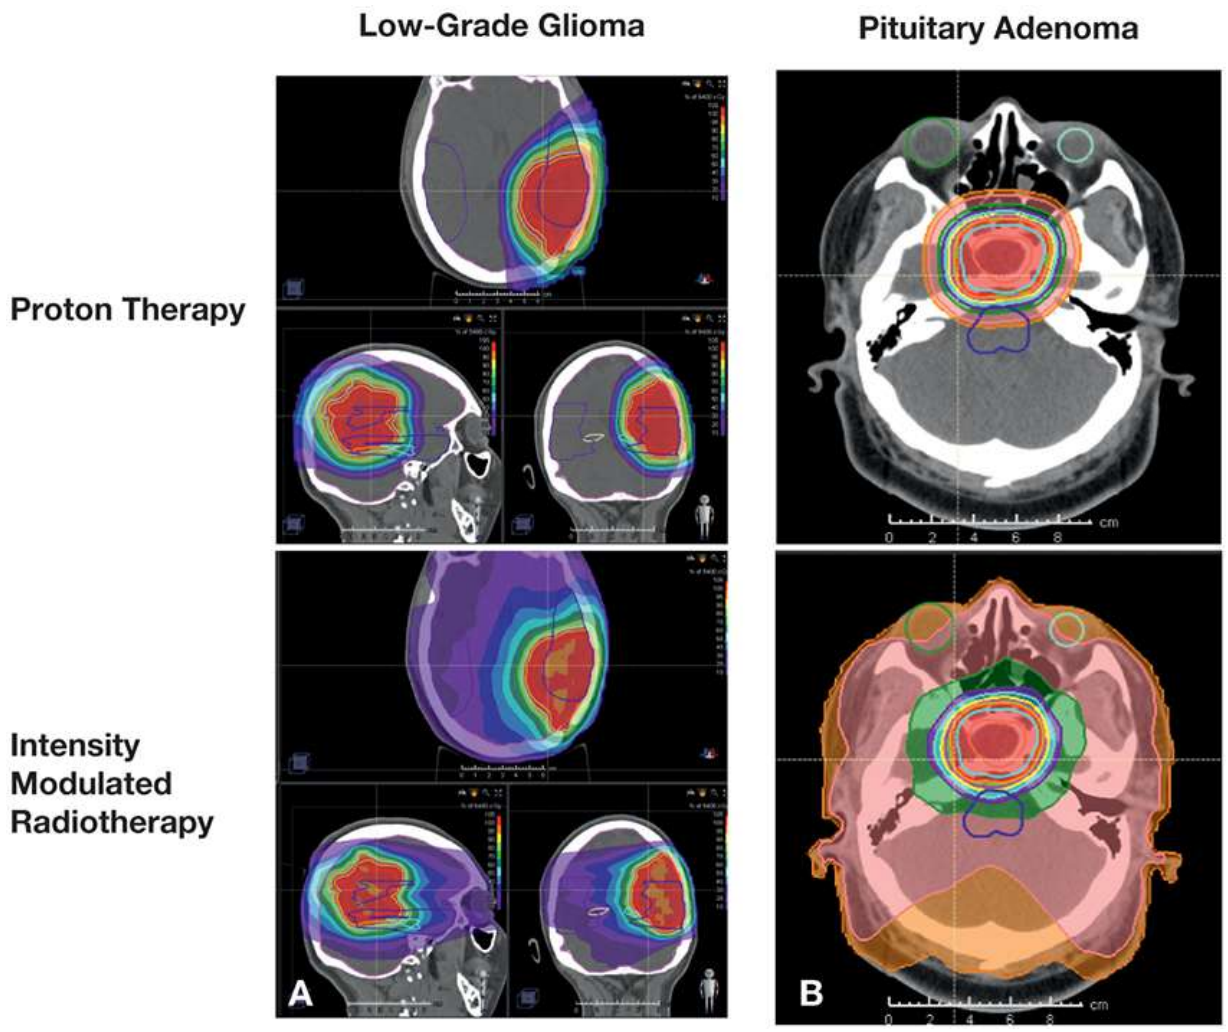

FIGURE 40.8 Comparison of proton therapy to intensity-modulated radiotherapy treatment plans for left temporal oligodendroglioma (A) and nonfunctional pituitary adenoma (B), demonstrating tight target coverage and significant sparing of low-dose radiation exposure to normal tissues throughout the brain in tumor types with favorable prognosis.

Brachytherapy and Radiocolloid Solutions

Selection criteria for brachytherapy include tumor confined to one hemisphere, no transcallosal or subependymal spread, small size (<5-6 cm), well circumscribed on CT or MRI, and accessible location for the implant and often all of the abovementioned combined in the context of a previously irradiated tumor, now locally recurrent, and requiring resection. A balloon-based system, GliaSite, placed into the cavity at the time of surgery has been employed in the treatment of recurrent malignant gliomas whose largest spatial dimension is less than 4 cm and is roughly spherical.[43]

After treatment planning, the balloon is filled with a liquid that contains organically bound iodine-125 (^{125}I) and treatment is completed within 3 to 7 days. Direct infusion of radioimmunoglobulins has been used in primary and recurrent brain gliomas.[44] GammaTile, a newer form of brachytherapy that uses cesium-131 (^{131}Cs) seeds embedded with an absorbable collagen matrix, has been evaluated for its use in selective reirradiation of recurrent brain metastases,[45] meningioma,[46] and glioblastoma (GBM)[47] and is being investigated for upfront surgical cavity irradiation of resected brain metastases in a prospective randomized trial.

CHEMOTHERAPY AND TARGETED AGENTS

Conventional Chemotherapy

Many conventional chemotherapy agents do not adequately penetrate normal or nonenhancing tumor-infiltrated brain, while some drugs, despite having a molecular weight and chemical structure that make them appear capable of crossing the BBB, are actively effluxed out of the brain parenchyma by p-glycoprotein and other active transporter substrates. Even when drug delivery is adequate, most CNS tumors are resistant to most conventional chemotherapeutic agents. Alkylating agents such as BCNU (carmustine) and CCNU (lomustine) have been the most widely studied drugs in CNS tumors. These agents cross the BBB, but prolonged use is difficult because of cumulative myelotoxicity and the dose-related risk of pulmonary fibrosis. Despite radiographic responses in 15% to 40% of patients, the impact on survival is modest at best.

Alkylating chemotherapies, being the only systemic therapy with survival benefit, remain the standard-of-care systemic upfront and salvage therapies for GBM. Temozolomide (TMZ) therapy extended median survival from 12.1 to 14.6 months for newly diagnosed GBM as demonstrated in a randomized, unblinded phase III National Cancer Institute of Canada/European Organisation for Research and Treatment of Cancer (NCIC/EORTC) trial.[48] Most of the survival benefit of TMZ therapy are derived from patients with GBM with O6-methylguanine-DNA methyltransferase (*MGMT)* promoter methylation.[49] Nitrosoureas, in the form of oral (lomustine) or infusion (carmustine), were first approved in 1970 for newly diagnosed gliomas. Carmustine administered via a

surgically implanted, biodegradable polymer (wafer) was also approved for newly diagnosed and recurrent high-grade gliomas (HGGs) because of improved survival (overall survival [OS] 31 vs 23 weeks; hazard ratio [HR] 0.67; *P=0.006*) compared with surgery alone.[50,51] Oral or IV nitrosoureas now largely serve as first-line salvage options for recurrent GBM as endorsed by worldwide guidelines.[52,53] The randomized German CeTeG/NOA-09 trial suggested benefit in combining TMZ with nitrosoureas compared to TMZ alone (median OS [mOS] 48.1 vs 31.4, *P* = .0492; HR = 0.60), specifically for patients with *MGMT* promoter–methylated GBM.[54] Similar benefit was reported in terms of response rates (objective response rate [ORR] 46%) for neoadjuvant carmustine and TMZ in a French trial,[55] and in the ACNS0423 pediatric, single-arm trial of adjuvant TMZ and lomustine for malignant astrocytomas.[56]

Other CNS tumors in which combination regimens are standard of care include PCNSL (high-dose methotrexate with procarbazine/vincristine, or high-dose cytarabine, or TMZ) and medulloblastoma (CCNU, cisplatin, and vincristine or cisplatin and cyclophosphamide and vincristine).

For diffuse low-grade gliomas (LGGs), both TMZ and PCV (procarbazine, CCNU, and vincristine) are effective in newly diagnosed and recurrent diseases. IDH-mutant, 1p/19q- codeleted oligodendrogliomas, and IDH-mutant, noncodeleted astrocytomas are more commonly treated with PCV initially or at recurrence, respectively, whereas IDH wild-type astrocytomas are often treated with TMZ due to the lack of evidence supporting the use of PCV.

There is an urgent unmet need for innovative treatment strategies for infiltrative gliomas. A recent randomized clinical trial of a personalized medicine assay (ChemoID™) guided treatment paradigm compared to physician's choice therapy showed improved survival (mOS 12.5 vs 9 months, *P* = .010; HR: 0.44, *P* = .008).[57] The ChemoID assay tests both the bulk of tumor and the therapy-resistant cancer stem cells (CSCs) from an individual glioma sample for sensitivity to chemotherapy monotherapies or combination regimens listed in the NCCN guidelines. An assay based on assessing the bulk of tumor only (3D Predict) also accurately and prospectively predicted patient-specific responsiveness to TMZ in 17 (85%) of 20 (*P* = .007) patients with newly diagnosed gliomas.[58] OS was significantly longer for "responders" compared to "nonresponders" (mOS

11.6 vs 5.9 months; HR 0.93, $P = .0376$). These chemotherapy sensitivity assays have the potential of enhancing the survival benefit of cytotoxic therapies with minimal, if any, survival benefit in the general GBM population when administered without selectivity.

Direct Delivery of Therapeutic Agents

Methods for circumventing the BBB include implantation of slow-release chemotherapy wafers into a tumor resection cavity;[50,59] pharmacologic, osmotic, or ultrasonic BBB disruption;[60,61] and convection-enhanced drug delivery (CED). CED involves the use of intracerebrally implanted catheters to deliver a drug into the brain parenchyma or tumor, at a slow but continuous rate of flow. Unlike diffusion, in which a drug distributes along an exponentially decaying concentration gradient depending on the size of the molecule, drug distribution by CED is less size dependent, occurs over a larger volume of brain tissue, and results in a more uniform drug concentration within the volume of distribution.[62,63] Large and/or hydrophilic agents that do not cross the BBB are ideal candidates for delivery via CED. Examples of agents used in CED studies include viruses,[64] paclitaxel,[63] topotecan,[65] and a variety of engineered, targeted protein toxins. These toxins are engineered to include a targeting ligand (eg, interleukin-4 [IL-4], IL-13, tumor growth factor-α, transferrin) and a genetically altered bacterial toxin that is effective only when internalized by a cell that expresses the target of the ligand.[66] Two phase III clinical trials have evaluated the use of CED. The PRECISE trial studied CED of IL-13 linked to *Pseudomonas* exotoxin (cintredekin besudotox), as compared to Gliadel wafers in patients with GBM at first recurrence. No difference in OS was observed, but cintredekin besudotox was associated with a higher rate of complications. The TransMID trial evaluated the efficacy of transferrin CRM107 delivered by CED to patients with inoperable recurrent or progressive GBM. The trial was terminated early in 2007 because it was deemed unlikely to meet the prespecified criteria for efficacy. Post hoc analysis of the PRECISE trial indicated that the nonspecialized delivery technology that was used in all of the prior CED studies ("off-the-shelf" single-lumen catheters) could not be placed sufficiently close to target tissue because of concerns about backflow of infusate, or leakage into CSF

spaces that would prevent effective intraparenchymal delivery. These concerns were magnified by the lack of imaging data to verify the extent of delivery in real time. Recently, several specialized, backflow-resistant delivery devices have been introduced into clinical trial, and coinfusion of Gd conjugates, which are visible on MRI, has verified the ability of these devices to produce clinically relevant volumes of distribution. These devices are currently incorporated into new, early-stage therapeutic trials involving CED, and more trials are expected to open over the next few years.

BCNU impregnated in a polymer and made into a wafer has been used for local delivery and placed on the walls of the resection cavity at the time of surgery. The wafer slowly undergoes biodegradation, releasing the active drug. This local delivery system has the advantages of minimal systemic toxicity, no limitation posed by the BBB, and delivery of very high local concentrations of chemotherapy. Studies in GBM have shown the benefit of biodegradable polymers impregnated with carmustine compared to placebo,[67] but not compared to CED.[68]

Recent efforts have sought to use low-intensity pulsed ultrasound with concomitant administration of IV microtubules to open the BBB to enhance the delivery of albumin-bound paclitaxel to the peritumoral brain of patients with recurrent GBM.[69]

Targeted Agents

Molecularly targeted options are expanding rapidly for WHO grade 2 diffuse and WHO grade 1 gliomas, including MEK inhibitor monotherapy or in combination with BRAF inhibitors for BRAF-rearranged and V600E-mutant LGG, respectively.[70-72] mTOR inhibitors also show early efficacy signal for NF1- associated LGG. A double-blind, phase 3 trial recently showed an increased progression-free survival (PFS) of vorasidenib compared to placebo for residual or recurrent grade 2 IDH-mutant glioma with no prior treatment, except surgery.[73] This may be a reasonable alternative to observation in selected patients who wish to defer chemotherapy and/or radiation.

Another targeted strategy successful in gliomas is the use of inhibitors of mTOR for the treatment of subependymal giant cell astrocytomas (SEGAs),

seen in association with tuberous sclerosis. Franz et al prospectively treated 23 patients with a definite diagnosis of tuberous sclerosis and increasing SEGA lesion size with daily everolimus. Twelve (52.2%) patients experienced SEGA volume reductions of 50% or more relative to baseline after 60 months of treatment. The proportion of patients experiencing daily seizures was reduced from 26.9% to 11.1% at 60 months.[74]

Given the high frequency (90%) of BRAF v600E mutations in papillary-subtype craniopharyngiomas, combined inhibition of BRAF (vemurafenib) and MEK (cobimetinib) led to the partial response (PR) in 15 of 16 patients with PFS of 87% at 12 months and 58% at 24 months.[75] The sole patient who did not show response discontinued medical therapy after 8 days due to intolerable toxicity. Case reports have also demonstrated radiographic response to dabrafenib and trametinib.[76-78]

Beyond alkylating chemotherapies, progress in GBM has been elusive. Although no single defining genetic mutation has been identified for gliomas, several key proliferation and survival signaling pathways appear to be important in GBM. The vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), and insulin-like growth factor (IGF) pathways are thought to be particularly relevant in the growth and proliferation of GBM. These pathways are characterized by receptors associated with tyrosine kinase activities and share common mechanisms of pathway activation and intracellular signaling. Overexpression or mutations of receptors and intracellular downstream effectors have been identified in GBM, leading to constitutive activation of signaling pathways, resulting in uncontrolled cellular proliferation, survival, and invasion. The Cancer Genome Atlas Research Network demonstrated that 88% of primary GBMs have deregulation in the receptor tyrosine kinases and downstream RAS or PI3K pathways. Laboratory and clinical trials have focused on targeting these pathways with a variety of agents, including monoclonal antibodies, low-molecular-weight tyrosine kinase inhibitors, and ligand-toxin conjugates.

Bevacizumab, a VEGF-targeted antiangiogenic therapy, failed to yield survival benefit in concurrent U.S. and European phase III randomized, placebo-controlled trials, despite promise in early-phase trials.[79-82] Bevacizumab remains approved in the United States, largely as a steroid-

sparing palliative therapy. Regorafenib, another antiangiogenic agent with dual VEGFR2-TIE2 tyrosine kinase inhibition, is now endorsed by national guidelines based on a randomized phase 2 trial comparing salvage regorafenib with lomustine (mOS 7.4 vs 5.6 months; HR: 0.50; $P = .001$).[83] The most promising molecularly targeted therapy serves less than 5% of patients with GBM with oncogenic mutations, such as BRAF-V600E or NTRK fusions.[70,84]

One-third of GBMs express an aberrant EGF receptor (EGFR) surface receptor, targeted by various small molecule inhibitors, antibodies, and vaccine-mediated approaches. A phase III study of rindopepimut, an EGF receptor variant III (EGFRvIII) peptide conjugated to keyhole limpet hemocyanin failed to improve survival in newly diagnosed GBM in a prospective, randomized, phase III study.[85] Depatuxizumab mafodotin (depatux-m) is an antibody-drug conjugate that preferentially binds cells with EGFR amplification. It is internalized by targeted cells and releases a potent antimicrotubule agent, monomethyl auristatin F. A phase III, prospective, randomized, placebo-controlled trial of depatux-m in newly diagnosed GBM with EGFR amplification demonstrated no OS benefit of depatux-m over placebo but did find statistically significantly longer PFS benefit with depatux-m compared to placebo, a benefit that was greater among the patients with EGFRvIII-mutant or *MGMT*-unmethylated tumors.[86] There was grade 3 to 4 corneal epitheliopathy occurring in 61% of patients treated with depatux-m.[86]

Investigators have studied various adoptive and active immunotherapies in the treatment of GBM. Despite limited success, there has been renewed interest recently with the development of tumor-specific vaccines and the approval of new agents for other solid tumors. The use of an active, tumor-specific immunotherapy is appealing as it could potentially maintain long-term antitumor response while limiting toxicity. In addition to Rindopepimut (EGFRvIII-targeted peptide vaccine), other vaccine strategies in clinical trials include DC Vax (autologous tumor lysate–pulsed dendritic cell vaccine), ICT-107 (dendritic cells prepared from autologous mononuclear cells that are pulsed with six synthetic peptides), and HSPPC-96 (autologous tumor-derived heat shock protein [glycoprotein 96]), and unfortunately, these too, have largely failed. A recent prospective randomized trial replacing TMZ with ipilimumab (anti-cytotoxic T-

lymphocyte antigen 4 [CTLA4]) and nivolumab (anti-programmed death ligand 1 [PD-L1]) for *MGMT* promoter–unmethylated GBM demonstrated no survival benefit.[87] A prospective externally controlled nonrandomized trial adding DC Vax to the standard of care demonstrated favorable OS outcomes in both newly diagnosed and recurrent GBM compared to contemporary, matched external controls who received standard of care alone.[88] Validation of these results in a prospective randomized trial has not been conducted, and DC Vax remains an investigational therapeutic.

Tumor-Treating Fields Therapy

Tumor-treating fields (TTFields) are a novel treatment modality approved for the treatment of either newly diagnosed or recurrent GBM. TTF therapy involves a medical device and transducer arrays to provide targeted delivery of low-intensity, intermediate-frequency, alternating electric fields to produce antimitotic effects selective for rapidly dividing tumor cells with limited toxicity. In the phase 3 EF-14 trial, TTFields plus TMZ provided significantly longer PFS and OS compared with TMZ alone in patients with newly diagnosed GBM after initial chemoradiotherapy. In the phase 3 EF-11 trial, for recurrent GBM, TTFields provided comparable efficacy as investigator's choice systemic therapy, with improved patient-reported quality of life and a lower incidence of serious adverse events.[89] Primary toxicity associated with TTFields is skin irritation generally managed with array relocation and topical treatments, including antibiotics and steroids.

FOLLOW-UP

The follow-up schedule for a patient with brain tumor must be frequent enough to check on side effects and to taper steroids shortly after completion of RT. Periodic MRIs are used to detect tumor recurrence at a stage when further therapy may be contemplated. Assessment of cognitive functioning and quality of life is important, and patients must be monitored for neuroendocrine and ophthalmologic side effects.

SEQUELAE OF TREATMENT

Surgery

With appropriate patient selection, diligent surgical technique, and the use of surgical adjuncts such as speech and/or motor mapping, the rate of complications can be minimized. Even in the best of hands, new temporary neurologic deficits can be seen in 15% or more of patients, although the rate of permanent new deficits is typically now less than 5%.[90] The incidence and types of deficits seen following surgery depend upon the location of the tumor and the deficits present preoperatively. The most common complications associated with surgery are bleeding and infection, particularly in the case of reoperation in a patient who has received prior RT and/or chemotherapy or when chemotherapy wafers are placed into a resection cavity.[91] It has been suggested that the use of linear incisions (as opposed to U-shaped flaps) can help reduce the incidence of incision-related complications, such as infection.[91] Posterior fossa resections, particularly in children with medulloblastoma, may be associated with posterior fossa syndrome (mutism plus bulbar symptoms). Transient perioperative edema, within about 48 hours of surgery, may be responsible for early postoperative neurologic worsening and can often be mitigated with the use of a short course of high-dose steroid therapy.

Patients with postoperative neurologic deterioration require careful clinical assessment, and in most cases, a CT or MRI is required to determine the cause of the deterioration. MRI diffusion-weighted sequences can be used to detect the presence of a new infarct. A high index of suspicion should be maintained for postoperative infection because symptoms may be masked by perioperative steroid use, and the headache and fever associated with craniotomy may obscure the classic signs of meningitis.

Radiotherapy

The response of intracranial tissues to radiation has been classically divided into three phases based on the timing of onset of symptoms: acute, subacute, and late.

Acute Toxicity

Transient worsening of pretreatment deficits may develop during the course of treatment, and further acute toxicities may manifest up to 6 weeks

following completion of irradiation. These symptoms are believed to be the consequence of a transient peritumoral edema and usually respond to a short-term increase or the institution of corticosteroids. Persistent or refractory symptoms may be caused by tumor progression, and repeat imaging while under treatment may be indicated if the clinical condition worsens despite steroids.

General symptoms such as fatigue, headache, and drowsiness may be seen, especially in individuals treated with large brain fields or with CSI. A mild dermatitis that develops in irradiated areas may be treated with topical agents if necessary. Alopecia within the irradiated areas is common and may be permanent with higher total doses. Nausea and vomiting, independent of changes in intracranial pressure, may occur, particularly with posterior fossa or brainstem irradiation. Otitis externa can be seen if the ear is included in the irradiation fields, and serous otitis media also may occur. Patients treated with CSI with photons are at risk for mucositis and esophagitis because of the exit dose from the spinal fields through the oropharynx and mediastinum. Hematologic toxicity may also be seen in these patients because of irradiation of the vertebral bodies, a major depot of bone marrow in adults. These gastrointestinal (GI) and hematologic effects are less severe and less frequent with the use of proton therapy for CSI.[92]

Subacute Toxicity

Subacute or "early-delayed" toxicity that develops during the 6-week to 6-month period following irradiation is attributed to changes in capillary permeability as well as transient demyelination due to damage to oligodendroglial cells. Symptoms, which include headache, somnolence, fatigability, and deterioration of preexisting deficits, usually respond to steroids. The main challenge is to distinguish the clinical and imaging findings from tumor recurrence. The phenomenon of "pseudoprogression" temporally fits within the subacute toxicity time frame.

Late Sequelae

Late sequelae of RT appear from 6 months to many years following treatment and are usually irreversible and progressive. They are thought to

be due to white matter damage from vascular injury, demyelination, and necrosis. The pathophysiology of radiation-induced neurocognitive damage is complex and involves intercellular and intracellular interactions between vasculature and parenchymal cells, particularly oligodendrocytes, which are important for myelination. Oligodendrocyte death occurs either because of direct p53-dependent radiation apoptosis or because of exposure to radiation-induced tumor necrosis factor-α.[93] Postradiation injury to the vasculature involves damage to the endothelium leading to platelet aggregation and thrombus formation, followed by abnormal endothelial proliferation and intraluminal collagen deposition.[93]

The most serious late reaction to RT is radiation necrosis, the incidence and onset of which is radiation dose dependent. Radiation necrosis can mimic recurrent tumor clinically by the reappearance and worsening of initial symptoms and neurologic deficits and radiographically with the development of a progressive, irreversible, enhancing mass with associated edema on imaging. PET, MR spectroscopy, and nuclear and dynamic CT scanning procedures may aid in the differentiation of radiation necrosis from recurrent tumor. The best treatment for symptomatic necrosis is control of symptoms with steroids followed by surgical debulking, although, even after resection, necrosis may progress. Given the central role of capillary leakage to radiation necrosis, bevacizumab, an antibody against VEGF, has been tested clinically as the treatment for radiation necrosis and has shown encouraging results.[94] Other measures include the use of corticosteroids with anticoagulation or hyperbaric oxygen, although randomized trials have not shown these to be useful. In clinical series, LITT has shown utility in treating focal radiation necrosis.[95] Although focal necrosis is usually due to RT alone, diffuse leukoencephalopathy is more commonly associated with the combination of RT and chemotherapy, particularly methotrexate.

Inclusion of the middle ear may result in high-tone hearing loss and vestibular damage, especially in patients who receive cisplatin. Retinopathy or cataract formation may be seen if the eye is in the radiation field. Optic chiasm and nerve injury may manifest as a decrease in visual acuity, visual field changes, or blindness at doses greater than 54 to 60 Gy. Onset of hormone insufficiency from irradiation of the hypothalamic-pituitary axis is variable but may be seen with doses as low as 20 Gy.

Cranial irradiation can produce neuropsychological changes and neurocognitive impairment; other factors such as tumor-related morbidity, as well as the effects of surgery and chemotherapy, may also contribute. Decline in list-learning recall has been observed in prospective clinical trials of therapeutic and prophylactic cranial irradiation.[96,97] These changes are thought to be due in part to interactions between the vasculature and parenchymal cells. Hippocampal-dependent functions of new learning, memory, and spatial information processing appear to be most affected.[98-100] Doses as low as 2 Gy can induce apoptosis in the proliferating cells in the hippocampus.[101] Neuroprotective strategies, including technical approaches of HA using IMRT and pharmacologic approaches using memantine, prevent this neurocognitive toxicity.[101-104]

MANAGEMENT OF INDIVIDUAL TUMORS

Malignant Glioma

Malignant gliomas or HGGs account for approximately half of all primary brain tumors in adults. They are rapidly growing tumors that directly invade the brain parenchyma but almost never metastasize outside the CNS. They present in any age group, although most occur in late adulthood. Prior to the most recent WHO classification, the management of malignant gliomas was approached based on histologically assigned grade, that is, anaplastic gliomas (WHO grade III) and GBM (WHO grade IV). In fact, historical trials included grade III and IV gliomas together, and these are, therefore, described in the section on GBM, as patients with GBM constituted the majority of subjects, whereas anaplastic gliomas are discussed in further detail in the following section. In the new WHO classification, all GBMs by default are wild type for the *IDH* gene, although there are no large clinical trials reported so far that have used this definitional approach. The *IDH*-mutant gliomas are more favorable in terms of prognosis and include the most favorable, that is, those with 1p19q codeletions (oligodendroglioma, either grade 2 or 3 [anaplastic]) or those without (astrocytoma, either grade 2 or 3 [anaplastic]), and yet, there are also *IDH* wild-type astrocytomas that are not definitionally GBM. Given that these are newer categories and no major trials (except for the INDIGO trial) have reported on outcomes using

these definitions, we have provided management strategies using legacy definitions and incorporating IDH status as appropriate.

Glioblastoma

GBM accounts for approximately 75% of all HGGs. The histopathologic features of GBM include nuclear atypia, mitotic activity, vascular proliferation, and necrosis; any three of these suffice to make the diagnosis. GBM is diffusely infiltrative, involving large portions of the brain. MRI characteristically shows vasogenic edema and ring enhancement around central necrotic regions. The current WHO classification requires wild-type IDH for a diagnosis of GBM. In addition, the current classification also includes previous grade 2 and grade 3 astrocytomas with specific molecular characteristics, which would result in these tumors being reclassified as "molecular" GBM; these patients were historically excluded from the majority of trials discussed earlier; as such, a category did not exist when the trials were conducted.

The prognosis for patients with GBM is poor, with a median survival time of approximately at least 18 months in highly selected patients receiving contemporary treatment. Pretreatment patient and tumor characteristics such as age at diagnosis, tumor histology, and Karnofsky performance status (KPS) are the best predictors of outcome. The extent of resection, duration of neurologic symptoms, and radiographic response to treatment have also been suggested as predictors of survival.

Curran et al[105] used nonparametric recursive partitioning analysis (RPA) (a statistical tool that allows for the identifi cation of significant prognostic factors and subsequent classification of patients into groups with similar outcomes) to analyze data from three RTOG trials that included 1,578 patients with malignant gliomas. Age was the most important predictor of survival, with patients younger than 50 faring best; KPS 70 or higher was the next most significant prognostic factor. Taking into account these and other variables, patients could be divided into groups with similar outcomes, with 2-year OS ranging from 4% to 76% and median survival ranging from 2.7 to 58.6 months (Table 40.5). Though developed in patients receiving RT alone, the RPA classification retains prognostic significance in patients treated with RT plus TMZ.[106] More recent studies have integrated

molecular data from *MGMT* promoter methylation status and other novel biomarkers to develop novel risk stratification models.[107]

TABLE 40.5 RADIATION THERAPY ONCOLOGY GROUP RECURSIVE PARTITIONING ANALYSIS OF MALIGNANT GLIOMA

Class	Patient Characteristics	Median Survival (mo)
I, II	Anaplastic astrocytoma	40-60
	Age ≤50 y, normal mental status or age >50 y, KPS >70, symptoms >3 mo	
III, IV	Anaplastic astrocytoma	11-18
	Age ≤50 y, abnormal mental status	
	Age >50 y, symptoms <3 mo	
	Glioblastoma	
	Age <50	
	Age >50 y, KPS ≥70	
V, VI	Glioblastoma	5-9
	Age >50 y, KPS <70 or abnormal mental status	

KPS, Karnofsky performance status.

Molecular Genetics

GBM may arise de novo (primary) or from an LGG that has transformed into a higher grade tumor (secondary). Secondary GBM arises in younger patients and are associated with a more favorable prognosis than those with primary GBM. The more favorable prognosis may be related to the impact of younger age and better performance status of this group. Emerging data suggest that promoter methylation of the *PTEN* gene in LGGs may be causally linked to secondary malignant transformation to GBM. Secondary GBM usually has a mutation in the *IDH1* gene and often have p53 mutations and are no longer classified as GBM.

Treatment

Standard treatment consists of maximal safe surgical resection followed by RT with concurrent TMZ chemotherapy and subsequent adjuvant TMZ

chemotherapy and consideration for application of TTFields. The benefit of surgical resection on survival has been a subject of debate, but over time, a growing body of evidence has supported the concept that survival from GBM relates to the residual disease burden after surgery. Most recently, a Response Assessment in Neuro-Oncology (RANO) group (RANO-resect) performed a volumetric analysis of the impact of extent of resection (and residual disease burden) on survival in over 1000 patients from centers in the United States and Europe. After taking into account demographic and molecular genetic variables known to impact on outcome, the investigators validated the prognostic value of a previously published categorization of extent of resection and showed a substantial difference in survival of patients who could undergo a supramaximal resection versus complete resection, partial resection or biopsy only (mOS 29 vs 19 vs 16 vs 10 months).[24,108] Other approaches including alterations in the delivery of RT, newer chemotherapeutic agents, immunotherapy, and other agents are the subject of ongoing research.

Radiotherapy Target Volume

Randomized trials have demonstrated a clear survival benefit to the use of RT after surgery.[109] Localized irradiation volumes are recommended despite the fact that GBM is usually more widely disseminated. Dandy,[110] for example, identified recurrences in the contralateral hemisphere even after hemispherectomy, showing the phenomenal capability of malignant gliomas to spread along white matter tracts. Such findings as well as autopsy studies[111-113] led to recommendations that the entire intracranial contents should be irradiated. However, Hochberg and Pruitt[114] reported that in 35 patients who had a CT scan within 2 months prior to autopsy, 78% of recurrences of GBM were within 2 cm of the margin of the initial tumor bed and 56% were within 1 cm or less of the volume outlined by the CT scan. These findings were confirmed by Wallner et al[115] who showed that 78% of unifocal tumors (25/32) recurred within 2 cm of the initial tumor volume, defined as the enhancing edge of the tumor on CT scan, and 56% of tumors (18/32) recurred within 1 cm of the initial tumor margin. No unifocal tumor recurred as a multifocal lesion, and large tumors were not more likely to recur farther from the initial tumor margin than smaller tumors.

In a correlative study, Halperin et al[116] reviewed CT scans and pathologic sections of 15 brains of patients with GBM who received minimal or no RT. If radiation treatment portals had been designed to cover the contrast-enhancing volume and peritumoral edema with a 1-cm margin, the portals would have covered histologically identified tumor in only 6 of 11 cases. However, treatment of the contrast-enhancing area and all surrounding edema with a 3-cm margin around the edema would have covered histologically identified tumor in all cases.

Kelly et al[117] reported on 40 patients with intracranial glial neoplasms who underwent CT- and MRI-guided stereotactic serial biopsies. Histologic analysis of 195 biopsy specimens showed that CE most often corresponded to tumor tissue without intervening parenchyma and hypodensity most often corresponded to parenchyma infiltrated by isolated tumor cells, tumor in LGGs, or edema. Isolated tumor cell infiltration extended at least as far as T2 changes on MRI. T2-weighted MRI revealed much larger volumes of infiltrated parenchyma than shown by low attenuation on CT scans.

Therefore, inclusion of all radiographic evidence of tumor and associated edema with generous margins is common practice in the design of treatment portals. The extent of margin expansion remains a relatively poorly studied and controversial area, with considerable variance.[118] With advances in MRI technology, the definition of tumor margins continues to change. For example, Pirzkall et al[119] showed metabolically active tumor extending outside the region defined on T2-weighted MRI in 88% of patients. PET imaging with methionine and/or thymidine may also prove useful.

For some time now, various single-institution reports suggest using smaller and smaller margins, and the rationale is “no reduction in survival observed compared to historic controls.” These reports, being retrospective, of course carry inherent biases. Intriguingly, recent surgical approaches have started moving in a direction opposite to the RT paradigm of margin reduction. Well-conducted analysis reveals that when the surgical resection is extended to remove not only the contrast-enhancing component but also the nonenhancing compartment, survival improves.[120] Such observations should inform radiotherapeutic margin planning.

Radiotherapy Dose

The current "standard approach" delivers a total dose of 59.4 to 60 Gy in 30 to 33 fractions of 1.8 to 2 Gy/fraction, using a "shrinking field" technique. Walker et al[121] performed a dose-response analysis using data from 420 patients treated on Brain Tumor Cooperative Group protocols. Doses ranged from less than 45 to 60 Gy using daily fractions of 1.7 to 2 Gy; only one-third of the patients received less than 60 Gy. A significant improvement in median survival from 28 to 42 weeks in the groups treated with doses of 50 to 60 Gy was found. A Medical Research Council study of 443 patients also showed a significant survival advantage in patients who received 60 Gy compared to those who received 45 Gy (12 vs 9 months; $P = .007$).[122]

For patients with poor pretreatment prognostic factors and a limited expected survival who are not able to tolerate conventional treatment, a shorter course of treatment may provide good palliation. Older patients (>65 years), especially those with poor performance status, have been shown to experience limited post-treatment improvement or rapid neurologic deterioration following conventional RT. Short-course RT, utilizing hypofractionated techniques, some as short as only 1 week, has been tested in older patients, and the results are described later. In Europe and Canada, such hypofractionated schedules are considered "standard" for "older patients" or "poor performance" status patients, and such techniques are also being increasingly utilized in the United States. In one small study, an ultrahypofractionated 5-day regimen was utilized and could possibly be considered for select patients.[123]

Dose Escalation and Altered Fractionation

With the vast majority of tumor recurrences occurring within the previous irradiation field and the poor outcomes associated with standard therapy, regimens designed to deliver a larger dose have been attempted to improve local control and enhance survival.

A benefit for doses greater than 60 Gy either without chemotherapy or with nitrosourea-based chemotherapy has not been demonstrated. The RTOG and Eastern Cooperative Oncology Group (ECOG) randomized 253 patients to either whole-brain irradiation to 60 Gy given in 6 to 7 weeks or

60 Gy plus a 10-Gy boost to a limited volume given in 7 to 8 weeks.[124] There was no benefit for the higher irradiation dose.

Several groups have used hyperfractionated or accelerated regimens as a means to escalate dose, using BID, 3 times daily, and even 4 times daily fractionation.[125,126] Only the study of Shin et al[126-128] showed an improvement in survival using multiple fractions per day compared to one fraction per day. In this study, 81 patients were randomized to 61.4 Gy in 69 fractions of 0.89 Gy given 3 times daily over 4.5 weeks or conventional fractionation to 58 Gy in 30 fractions given QD over 6 weeks. Median survival in the two groups was 39 and 27 weeks, respectively, and the 1-year survival rates were 41% and 20%, respectively ($P < .001$). Others have failed to confirm these results. In a prospective, randomized phase I/II trial, RTOG 83-02 examined dose escalation using BID fractionation in patients with malignant gliomas. Hyperfractionated regimens studied were 64.8, 72.0, 76.8, and 81.6 Gy given in 1.2 Gy fractions BID, and accelerated hyperfractionated regimens were 48 and 54.4 Gy given in 1.6 Gy BID fractions. Patients also received chemotherapy with BCNU. In the final report on all 747 patients, there were no significant differences between the treatment arms with regard to median survival time.[128] A phase III trial compared conventional RT to 60 Gy in 30 daily fractions to hyperfractionated RT to 72 Gy in 60 fractions of 1.2 Gy given BID.[129] No difference in survival was found.

In the contemporary era of concurrent and adjuvant TMZ, escalation of both dose and dose per fraction using IMRT was tested in a prospective phase I/II study. The maximum tolerated dose with TMZ was 75 Gy in 30 fractions (2.5 Gy/fraction). Median survival was 20.1 months, suggesting improved efficacy compared to other contemporary studies. The probability of in-field failure decreased with increasing dose escalation. A prospective randomized trial of this dose fractionation regimen using IMRT demonstrated no OS benefit.[130] The results of this dose fractionation on the same trial using proton therapy are pending.

Dose Escalation Using Radiosurgery

A radiosurgical boost was reported as effective in patients with newly diagnosed malignant glioma in a retrospective analysis of 115 patients

treated at three institutions with a combination of surgery, external beam RT, and LINAC-based radiosurgery on similar institutional protocols.[131] In a prospective randomized trial, Souhami et al[132] compared conventional RT (60 Gy) plus adjuvant BCNU with and without radiosurgery in 203 patients with GBM. At a median follow-up of 61 months, no significant improvement in median survival was observed (13.5 vs 13.6 months). Other trials have explored alternative schedules, without evidence for benefit.

Dose Escalation Using Brachytherapy

Laperriere et al[133] used brachytherapy as a boost to conventional RT in patients with malignant gliomas. Patients were randomized to either external beam RT (50 Gy in 25 fractions) alone (n = 69) or external beam RT plus a temporary stereotactic ^{125}I implant delivering a minimum peripheral tumor dose of 60 Gy (n = 71). Median survival was not significantly different between the two arms (13.8 vs 13.2 months; P = .49).

The results of the Brain Tumor Cooperative Group National Institutes of Health Trial 8701 reported by Selker et al[134] support these findings. In this randomized, prospective trial, 299 patients with newly diagnosed malignant glioma received surgery, external beam RT, and BCNU with or without an interstitial RT boost with ^{125}I. Treatment with an interstitial boost did not prolong survival as compared to conventional treatment.

Dose Escalation Using Proton Therapy

Dose escalation up to 90 cobalt gray equivalent (CGE) with mixed photon and proton-beam irradiation has been tested in two prospective trials.

Fitzek et al[135] reported on a phase II study of 23 patients with newly diagnosed GBM. The 2-year OS was 34% and mOS was 20 months, which compared favorably to historical data. Recurrence was observed in regions treated to 60 to 70 CGE, but only one recurrence was observed in regions treated to 90 CGE. More recently, Mizumoto et al[136] reported on a phase I/II study of 20 patients with supratentorial GBM treated with mixed photon and proton-beam irradiation to 96.6 Gy in 56 BID fractions with concomitant nimustine chemotherapy. MRI-defined T2-enhancing region was treated to 50.4 CGE in 28 daily morning fractions. In daily evening fractions, patients were treated to 23.1 CGE for the first 14 fractions to the

T1-enhancing region plus 1 cm and then 23.1 CGE for the subsequent 14 fractions to the T1-enhancing region only. Median survival was 22 months, and 2-year OS was 45%. Late radiation necrosis was noted in one patient, and late leukoencephalopathy was observed in a second patient. A phase 2 randomized trial comparing photon versus proton RT did not demonstrate improvement in neurocognitive function, a finding not surprising in GBM, but did demonstrate less patient-reported fatigue, a reduction in toxicity and a marked reduction in RT-associated lymphopenia in favor of proton therapy.[137,138] As part of a prospective randomized trial, dose escalation to 75 Gy in 30 fractions using proton therapy is currently under investigation; the trial has completed accrual, but the results are pending.

Radiosensitizers

Studies using radiation modifiers in conjunction with RT to overcome the hypoxia present in malignant gliomas have shown disappointing results. Chang[139] reported on 38 patients treated with hyperbaric oxygen and irradiation using fractionation schedules ranging from 36 Gy given in 3 weeks to 60 Gy given in 6 to 7 weeks and compared them with 42 patients treated with RT alone. An improvement in 18-month survival rate from 10% to 28% and an increase in median survival from 31 to 38 weeks were noted. Perfluorocarbon emulsions, such as Fluosol, which have enormous oxygen-carrying capacity, have been tested as hypoxic sensitizers without significant benefit.[140] Randomized studies failed to show significant improvement with the addition of the hypoxic cell sensitizer misonidazole.[141] Miralbell et al[142] reported the results of EORTC trial examining the addition of carbogen and nicotinamide to overcome the effects of proliferation and hypoxia presumed responsible for radioresistance in GBM. OS was similar in all arms and did not differ from the results of a series using RT alone.

S-phase sensitizer trials using halogenated pyrimidines also failed to improve survival, but contemporary oral prodrug versions are reviving interest in this line of clinical research. The redox-modulating radiosensitizer motexafin gadolinium (MGd) showed encouraging results in a phase I clinical trial[143]; however, the results from a single-arm phase II

trial, RTOG 0513, of MGd and conventional therapy in newly diagnosed GBM showed no survival improvement.[144]

Chemotherapy

The use of cytotoxic chemotherapy for GBM dates back to the 1960s with a controlled study using carmustine.[145] Postsurgical patients were assigned to no further therapy, carmustine alone, radiation alone, and radiation followed by carmustine. At 18 months, 23% of those treated with radiation plus carmustine were still alive as compared to 5% with carmustine or RT alone. The Food and Drug Administration (FDA) approved carmustine and lomustine for the treatment of brain tumors (including GBM) in the 1970s. Subsequent prospective studies failed to demonstrate a survival advantage to carmustine or other cytotoxic chemotherapy for GBM, although two meta-analyses demonstrated a small survival benefit.[146,147]

TMZ is the only chemotherapeutic agent with OS benefit for patients with GBM and anaplastic astrocytoma (AA). TMZ, an oral imidazotetrazine derivative of dacarbazine, is metabolized in vivo to an active agent. Like the nitrosoureas, it alkylates the O^6 position on guanine, producing single-strand DNA breaks. Fatigue, constipation, and nausea are the most common toxicities. While overall well tolerated, TMZ is myelosuppressive in a minority of patients. The FDA approved TMZ for recurrent AA in 1999.[147,148] Approval as adjuvant therapy for GBM was based on a large phase III clinical trial conducted by the EORTC and NCIC[48] that randomized 573 adult patients (ages of 18 to about 70, KPS >70) with newly diagnosed GBM to either radiation alone (total 60 Gy in 30 fractions) or in combination with TMZ. Patients on the experimental arm received TMZ daily at a dose of 75 mg/m^2 during RT due to the expected radiosensitization effect based on preclinical studies, followed by monthly TMZ at a dose of 150 to 200 mg/m^2 for 5 consecutive days in 28-day cycles for six cycles. Survival was improved for those treated with chemoradiation compared to RT alone, specifically mOS was 14.6 months compared to 12.1 months,[48] 2-year survival was 27.2% compared to 10.9%, and 5-year survival was 9.8% compared to 1.9%.[149] Toxicity was acceptable for those treated with TMZ concurrent with RT, including 7% grade 3 or 4 hematologic toxicities.[48]

The benefit of TMZ has also been demonstrated for older patients (age ≥65) with GBM. A randomized phase III trial adding TMZ to hypofractionated RT, followed by monthly adjuvant TMZ improved survival from 7.6 to 9.3 months with combination therapy.[150] PFS was 5.3 versus 3.9 months, 1-year survival rate was 37.8% versus 22.2%, and 2-year survival rate was 10.4% versus 2.8% with radiation plus TMZ versus radiation alone.

Identifying potential predictive laboratory markers aids in selecting candidates for chemotherapy, thus limiting toxicity for patients unlikely to respond to TMZ. Epigenetic silencing of the *MGMT* DNA repair gene by promoter methylation predicts longer survival for patients with malignant glioma treated with alkylating agents.[151] A retrospective analysis of the EORTC/NCIC TMZ study demonstrated a survival benefit for patients treated with TMZ and RT if their tumor contained a methylated *MGMT* promoter (median 21.7 months) as compared to tumors with unmethylated *MGMT* promoters (median 12.7 months).[49] In the NCIC (also known as CCTG)-EORTC trial of older patients with GBM,[150] the *MGMT*-unmethylated group did not achieve a statistically significant benefit in survival from combination RT plus TMZ compared to RT alone, and consequently, modern clinical trials often omit TMZ in the experiment and, occasionally, in the control arm of trials enrolling patients with *MGMT*-unmethylated GBM.

Although the standard adjuvant TMZ dosing is 150 to 200 mg/m^2 for 5 days per 28-day cycle for six cycles, variations in practice include dose intensification and continuing TMZ beyond six cycles despite the lack of OS benefit in randomized trials. An RTOG randomized, phase III trial compared standard adjuvant TMZ with a dose-dense schedule in newly diagnosed GBM (N = 1,173),[152] and 833 patients were randomized to standard RT plus concurrent and standard adjuvant TMZ (150-200 mg/m^2 for 5 days per 28-day cycle) or adjuvant dose-intense TMZ (75-150 mg/m^2 on a 21/28 day schedule). There was no significant difference in mOS (16.6 vs 14.9 months, P = .63) or median PFS (5.5 vs 6.7 months, P = .06). The trial prospectively stratified for *MGMT* methylation status, and no survival benefit with dose-intense therapy was identified in any subgroup. *MGMT* methylation was associated with improved mOS (21.2 vs 14 months, P < .0001), median PFS (8.7 vs 5.7 months, P < .0001), and response (P =

.012). As expected, the dose-intense arm resulted in increased toxicity. Thus, dose intensification of TMZ is not advised for patients with newly diagnosed GBM. A pooled analysis of patient-level data from four randomized trials of newly diagnosed GBM also assessed the benefit of prolonging TMZ beyond six adjuvant cycles, but only demonstrated a slight improvement in PFS (HR 0.80, $P = .03$), particularly in *MGMT*-methylated patients (HR 0.65, $P < .01$).[153] Continuing TMZ beyond six cycles demonstrated no difference in OS in the overall population or in the *MGMT*-methylated subgroup. Thus, neither dose intensification nor prolonged standard adjuvant TMZ is considered standard of care, given the potential for increased toxicity.

A comprehensive review of clinical trials involving RT in combination with radiosensitizing agents on patients diagnosed with GBM analyzed 63 relevant trials published between 1976 and 2021.[154] Despite several approaches of optimizing radiation effectiveness using radiosensitizers, there is no clear evidence of improved patient outcome with putative sensitizers. Tissue selectiveness and penetration of the BBB appear the greatest limitations, shifting the current focus to novel sensitizers and/or alternative delivery methods. Poly(ADP-ribose) polymerase inhibitors, for example, have been explored as putative radiosensitizers and chemosensitizers for their effects on DNA repair mechanisms evidenced in human GBM.[155] All studies have failed to show improved efficacy, including combining veliparib with TMZ and most with RT in children with recurrent CNS tumors,[156] or in children with diffuse intrinsic pontine glioma (DIPG).[157]

In adult patients with recurrent GBM, veliparib added to TMZ showed no improved survival, but worsened myelosuppression was noted,[158] similarly reported in the OPARATIC trial of olaparib combined with TMZ.[159] Even when veliparib was combined with standard 60 Gy irradiation with concurrent and adjuvant TMZ, there was no survival benefit for patients with newly diagnosed GBM.[160] The OLA-TMZ-RTE-01 trial of olaparib with standard chemoradiation for newly diagnosed GBM was deemed tolerable, grade 3 to 4 thrombocytopenia ($n = 4$, 13%) and grade 4 neutropenia ($n = 2$, 7%) as the reported DLTs.[161] The phase II portion is still recruiting with the recommended phase 2 dose of olaparib 100 mg BID on days 1 to 3 every 28 days concurrent with the six adjuvant cycles of TMZ.

The randomized German CeTeG/NOA-09 trial suggested benefit in combining TMZ with nitrosoureas compared to TMZ alone (mOS 48.1 vs 31.4 months, $P = .0492$; HR = 0.60), specifically for patients with *MGMT* promoter–methylated GBM.[54] Similar benefit was reported in terms of response rates (odds ratio 46%) for neoadjuvant carmustine and TMZ in a French trial,[55] and in the ACNS0423 pediatric, single-arm trial of adjuvant TMZ and lomustine for malignant astrocytomas.[56] Alkylating chemotherapies, as the only systemic therapy with survival benefit for GBM, thus remain the standard-of-care systemic upfront and salvage therapies for GBM.

Tumor-Treating Fields

TTFields involve the placement of noninvasive transducer arrays on the scalp and the delivery of low-intensity (1-3 V/cm), intermediate-frequency (100-300 kHz), alternating electric fields to the tumor. TTFields lead to tumor cell kill through their action during two phases of mitosis: (1) during metaphase, by disrupting the formation of the mitotic spindle, and (2) during cytokinesis, by dielectrophoretic dislocation of intracellular constituents resulting in apoptosis.[162] TTFields are most effective when applied in the direction of the division axis of the dividing cell, and therefore, two sequential field directions are applied to tumors using two perpendicular pairs of transducer arrays in order to increase the efficacy of TTFields.[163] Following preclinical studies demonstrating in vitro and in vivo activity in glioma,[164] a prospective randomized trial of TTFields and TMZ versus TMZ alone for newly diagnosed GBM after completion of radiochemotherapy demonstrated no significant difference in patient-reported quality of life with TTFields, except for itchy skin, which was to be expected from transducer arrays.[165]

Long-term results of a prospective randomized trial demonstrated improvement in OS and PFS with the addition of TTFields to conventional treatment involving maximally safe resection and adjuvant chemoradiotherapy for newly diagnosed GBM; mOS improved from 16.0 to 20.9 months.[166] Based on these results, TTFields have been approved for the treatment of recurrent and newly diagnosed GBM by the FDA in the

United States and have obtained a CE mark in Europe for the same indications.

Investigational Approaches

Immunotherapy

Modulation of the immune system is being explored in the setting of GBM through such therapeutic interventions as blocking naturally occurring inhibitory immune checkpoint molecules, adoptive T-cell therapeutics, or vaccine therapy against tumor-specific antigens. Nivolumab, a human immunoglobulin G4 monoclonal antibody targeting programmed cell death protein 1 (PD-1), demonstrated no improvement in OS relative to bevacizumab for recurrent GBM in preliminary results from a phase III trial.[167] Rindopepimut, a peptide vaccine targeting EGFRvIII, has been tested in multicenter trials of newly diagnosed EGFvIII-expressing GBM following gross total resection and conventional RT with concurrent TMZ. Although phase II results demonstrated promising outcomes,[168] a double-blind, randomized phase III trial failed to demonstrate an improvement in OS with the use of rindopepimut.[169] Heat shock protein-peptide complex-96 (HSPPC-96) vaccine is an autologous treatment derived from dendritic cells extracted from the patient's tumor to induce antitumor antibodies, demonstrating no survival benefit when added to bevacizumab for recurrent GBM in preliminary results from a randomized trial. Replacement of TMZ with ipilimumab (anti-CTLA4) and nivolumab (anti–PD-L1) for *MGMT* promoter–unmethylated GBM demonstrated no survival benefit.[87]

Radioimmunotherapy

Radioimmunotherapy using monoclonal antibodies against EGFR tagged with ^{125}I has been evaluated in the treatment of HGGs. In an updated report of one study that included a total of 180 patients with a minimum follow-up of 5 years, median survival was 13.4 months for those with GBM.[170]

Another potential target is tenascin, an extracellular protein overexpressed in malignant gliomas but not found in normal tissue. Radiolabeled monoclonal antibodies to tenascin have been evaluated in phase I or II trials showing activity against newly diagnosed and recurrent malignant gliomas. In a phase II trial by Reardon et al,[171,172] ^{131}I-labeled

murine antitenascin monoclonal antibody was injected directly into the surgical resection cavity in 33 patients with untreated malignant glioma. The patients were subsequently treated with external beam RT and 1 year of alkylator-based chemotherapy. Even after accounting for prognostic factors, median survival (86.7 weeks) was longer than that of historical controls. Treatment-related toxicities were mild; only one patient required reoperation for radionecrosis.

Targeted Therapies

Beyond alkylating chemotherapies, the development of targeted therapies for GBM has been elusive. Bevacizumab, the first antiangiogenic therapy approved for GBM, failed to yield survival benefit in concurrent U.S. and European phase III randomized, placebo-controlled trials, despite promise in early-phase trials.[79-82] Bevacizumab, while still approved in the United States, is largely utilized as a steroid-sparing palliative therapy. Regorafenib is an oral multikinase inhibitor with effects against tumor angiogenesis (VEGFR1-3, TIE2), oncogenesis (*KIT, RET, RAF1, BRAF* genes), tumor microenvironment (PDGFR, FGFR), and tumor immunity (CSF1). Regorafenib is now endorsed by national guidelines at recurrence based on the randomized phase 2 REGOMA trial of salvage regorafenib versus lomustine that showed a mOS of 7.4 versus 5.6 months (HR: 0.50; P = .001).[83]

EGFR gene amplification is seen in approximately 40% to 50% of patients with GBM. EGFR is associated with control of cell growth through autocrine and peregrine effects of growth factors. Inhibitors of EGFR tyrosine kinase, such as gefitinib and erlotinib, and and EGFR antibodies have not been successful to date likely because of mutational resistance mechanisms, limited brain penetration of tyrosine kinase inhibitors, and the presence of multiple signaling bypass opportunities. Clinical trials of vaccine therapy directed against EGFRvIII are discussed earlier. A randomized trial of ABT-414, an antibody-drug conjugate targeting EGFR, added to conventional RT and TMZ for newly diagnosed GBM with EGFR amplification did not demonstrate a survival benefit.

Mutations and loss of the *PTEN* gene are encountered in approximately 70% of patients with GBM. PTEN inhibits signaling through the PI3 kinase

and AKT signaling pathway. Loss of PTEN results in loss of effectiveness of EGFR inhibitors, probably because of constitutive signaling through PI3 kinase, which bypasses any upstream EGFR inhibitor effect. Specific inhibitors, such as CCI-779 and everolimus, are ineffective as single agents. Although preclinical experiments suggest that these agents are potential radiosensitizers,[173-175] a prospective trial of everolimus added to conventional RT and TMZ demonstrated no survival improvement compared to historical controls in newly diagnosed GBM.[176]

Cilengitide, a selective integrin inhibitor that acts on tumor cell motility and impacts tumor interaction with brain microenvironment, demonstrated no improvement in OS when added to conventional RT and TMZ for newly diagnosed *MGMT* promoter–methylated GBM in a large phase III trial.[177]

Neovascularization is a major feature of GBM, and many studies demonstrate that GBM secrete VEGF in abundance. The supporting endothelium strongly expresses receptors for VEGF. Bevacizumab, anti-VEGF antibody, has demonstrated impressive radiographic response rate and reduction in peritumoral edema in multiple phase II trials and is FDA approved for the treatment of recurrent GBM (see later). However, two large phase III randomized clinical trials investigating the addition of bevacizumab to the EORTC/NCIC regimen demonstrated no improvement in OS.[79,80]

The most promising molecularly targeted therapy serves less than 5% of patients with GBM with oncogenic mutations, such as BRAF-V600E or NTRK fusions.[70,84] Combination dabrafenib (150 mg BID) and trametinib (2 mg QD) for adults with *BRAF*V600E mutated was primarily assessed based on ORR by RANO criteria.[70] Best ORR was 26% (95% confidence interval [CI]: 12%-45%) in the intention-to-treat glioma population, 29% (95% CI: 11%-52%) for the GBM subset. Durable responses were noted with five of eight (62.5%) responses ongoing for more than 12 months. Median PFS was 1.9 months (95% CI: 1.7-18.5), while the PFS6 rate was 43% (95% CI: 25%-60%). mOS was 11.7 months (95% CI: 6.4 to not reached), while the OS12 rate was 71% (95% CI: 50%-84%). Toxicities of any grade were observed in 92% of patients with HGGs. Grade 3 or worse adverse events were reported in 31 (53%) patients, mainly fatigue (5 [9%]), decreased neutrophil count (5 [9%]), headache (5 [5%]), and neutropenia (3 [5%]). Larotrectinib is a first-in-class, highly selective tropomyosin receptor kinase

(TRK) inhibitor approved to treat TRK fusion–positive cancer, agnostic to histology. The efficacy and safety of larotrectinib in 33 patients (median age: 8.9 years; range: 1.3-79.0) with TRK fusion–positive primary CNS tumors were evaluated using investigator-assessed ORR.[84] The most common histologies were HGG (*n* = 19) and LGG (*n* = 8). ORR was 30% (95% CI: 16-49) overall. The 12-month rates for duration of response, PFS, and OS were 75% (95% CI: 45-100), 56% (95% CI: 38-74), and 85% (95% CI: 71-99), respectively. Median time to response was 1.9 months (range 1.0-3.8 months). Duration of treatment ranged from 1.2 to 31 or more months. Treatment-related adverse events were reported for 20 patients, with grade 3 to 4 in three patients. No new safety signals were identified. Successful treatment of these driver mutations showcases the promise of molecularly targeted therapies for gliomas.

Treatment of Older Patients

Approximately one-third of patients with GBM are 65 years or above. Older age has been demonstrated to be an important adverse prognostic factor in GBM. In a population-based survey of 3,298 patients with GBM in Ontario,[178] each decade increase in age has been associated with a reduction in OS, with patients older than 70 years having a median survival of 4 to 5 months. In the updated results from the EORTC/NCIC trial, Stupp et al[149] observed a survival advantage to RT with concomitant and adjuvant TMZ compared to RT alone in all age subgroups, including patients older than 60 years.

However, because of concerns over the tolerance of conventional chemoradiotherapy for older patients, particularly those with poor performance status, nonconventional approaches to adjuvant therapy have been tested. A phase III Association of French-Speaking Neuro-Oncologists group trial observed improved median survival (29.1 vs 16.9 weeks) and PFS, but equivalent toxicity, with adjuvant RT to 50 Gy plus supportive care compared to supportive care in patients aged 70 years and above with KPS 70 or higher.[179]

Short-course RT and single-agent TMZ have also been investigated. As described previously, Roa et al observed no difference between standard RT of 60 Gy in 30 fractions or a shorter course of 40 Gy in 15 fractions in

patients with GBM older than 60 years.[180] A more recent European trial compared OS between standard RT (60 Gy in 30 fractions), short-course RT (34 Gy in 10 fractions), and single-agent TMZ in patients older than 60 years.[181] This trial demonstrated inferior median survival with 60 Gy RT versus TMZ in the overall population and inferior median survival with 60 Gy RT versus short-course RT in patients older than 70 years. TMZ was associated with more grade 3 to 4 toxicity. The NOA-08 phase III trial demonstrated noninferior survival but higher grade 3 to 4 toxicity with 1-week-on/1-week-off TMZ compared to RT to 54 to 60 Gy in patients older than 65 years with AA or GBM.[182] These trials also demonstrated that when single-modality therapy is being considered because of poor performance status, tolerability concerns, and so on. TMZ alone is superior to RT for the *MGMT*-methylated patients, but the converse is true for the unmethylated patients.

A Canadian-led phase III trial demonstrated improvement in PFS and OS with the addition of TMZ during and as monthly maintenance doses following short-course RT (40 Gy in 15 fractions) in older (65 years or above) patients with newly diagnosed GBM.[150] Median age of patients was 73 years, and two-thirds were older than 70 years. TMZ prolonged mOS from 7.6 to 9.3 months and increased 1-year survival rate from 22.2% to 37.8%. This survival benefit was most marked in patients with *MGMT* promoter methylation where median survival was extended from 7.7 to 13.5 months, and for the *MGMT*-unmethylated patients, the survival difference did not reach statistical significance. Quality-of-life analyses demonstrated no difference in functional domains but noted more nausea, vomiting, and constipation in patients receiving TMZ. Therefore, in older patients, and poor performance status, in the absence of statistically significant survival improvement, and the increase in toxicity, the use of TMZ for the unmethylated patient needs to be questioned.

Treatment at Recurrence

Although several therapeutic options have been considered for patients with recurrent GBM, none are curative, and therefore, the management goals should be palliative. Hospice referral for palliative care is reasonable for many patients, particularly if they have poor performance status. However,

most patients go on to additional therapy, which may include surgery, reirradiation, additional chemotherapy, and/or a clinical trial. The value of palliative debulking has recently been reexamined by the RANO-resect group. They showed that patients who underwent reresection had a median survival of 11 versus 7 months from time of recurrence and that the benefit was largely restricted to patients who could undergo a resection that left residual enhancing disease of 1 mL or less.[183] Based on an impressive radiographic response rate in two nonrandomized, phase II clinical trials,[48,149] single-agent bevacizumab was approved by the FDA in 2009 for the treatment of recurrent GBM. In a study of 49 patients with GBM, Stupp et al[149] reported ORR of 35%, 6-month PFS of 29%, 3.7-month median PFS, and 7.2-month mOS. Similarly, Stupp et al[48] reported an ORR of 28%, 6-month PFS of 43%, median PFS of 4.2 months, and mOS of 9.2 months in a total of 85 patients. Subsequent randomized trials have shown, however, that bevacizumab does not provide a survival benefit in patients with GBM and that the radiographic "responses" were likely related to the impact that bevacizumab has on microvessel stabilization (thereby reducing enhancement) and reduction of tumor-associated edema.[79,184]

Polymer-based local chemotherapy (carmustine wafers) has been tested in a randomized trial that included 222 patients with recurrent glioma (mostly GBM); survival increased from 44% to 64% at 6 months ($P = .02$) for patients with GBM, and median survival from 23 to 31 weeks.[67] Systemic chemotherapeutic agents have been tested mostly in the context of clinical trials and have been uniformly disappointing, as have targeted agents with the notable exception of EGFR tyrosine kinase inhibitors in patients with recurrent GBM expressing wild-type PTEN and mutant EGFR. Of 26 patients with recurrent GBM treated with EGFR tyrosine kinase inhibitors at the University of California, Los Angeles and who had pretreatment tissue, there were seven responders, while 19 had early progression.[185] Coexpression of mutant EGFR and wild-type PTEN had 86% sensitivity, 89% specificity, and a positive predictive value of 75% for response. The BELOB trial was an open-label phase II trial that randomized patients to single-agent bevacizumab or lomustine versus combination of bevacizumab plus lomustine in recurrent bevacizumab-naïve GBM.[186] This trial demonstrated promising 9-month OS of 59% with combination bevacizumab plus lomustine 90 mg/m^2 relative to single-agent bevacizumab

(38%) or lomustine (43%). During this trial, lomustine administered in combination with bevacizumab required dose reduction from 110 to 90 mg/m^2 because of severe thrombocytopenia. However, subsequent phase III trial of single-agent lomustine 110 mg/m^2 versus combination bevacizumab and lomustine 90 mg/m^2 for recurrent GBM at the time of first progression prolonged PFS but did not confer a survival advantage.[187]

In the treatment of recurrent GBM, a randomized clinical trial found a statistically significant survival benefit with FDA-approved chemotherapy selected using chemosensitivity tumor testing on CSCs (ChemoID) compared to physician-chosen chemotherapy.[57] The survival benefit seen in this trial for recurrent GBM suggests guiding chemotherapy selection using chemosensitivity tumor testing as a strategy for future testing in newly diagnosed GBM.

Repeat RT using one of several different methods (including radiosurgery, brachytherapy, GliaSite balloon brachytherapy, and even repeat external beam photon or proton RT) may be considered for carefully selected patients. Hypofractionated reirradiation with bevacizumab has shown promising results in small single-institutional reports, with surprisingly limited toxicity, attributed to "vascular stabilization and protection" resulting from bevacizumab, and more investigations of this approach are being considered.[188] A prospective randomized trial of hypofractionated reirradiation with bevacizumab compared to bevacizumab alone demonstrated increased 6-month PFS by 25% with relative safety but no effect on OS.[189]

Evidence-Based Treatment Summary

1. Maximal surgical resection is generally recommended to establish pathologic diagnosis, provide tissue for molecular studies, and achieve cytoreduction that may improve neurologic deficits. Increasingly, in the surgical literature, data suggest that a resection should also include the nonenhancing component if feasible and safe.
2. Postoperative RT has been shown to provide a survival advantage in several clinical trials. The typical RT dose is 60 Gy in 6 weeks for younger and prognostically favorable patients. Dose escalation beyond

60 Gy has not proven to be effective; radiation sensitizers have not provided a survival benefit.

3. TMZ, given during and after RT for six cycles, provides a significant survival advantage that is greatest in patients with methylation of the promoter region of the *MGMT* gene. The benefit in the unmethylated population is questionable. Even older patients benefit from this approach. Prolongation beyond 6 months does not enhance survival; neither does dose intensification or chemosensitization strategies.
4. TTFields administered after RT and concomitant with high-dose TMZ also prolong survival.
5. Bevacizumab confers no survival benefit for newly diagnosed GBM but can be an effective salvage therapy at the time of progression, although there are no categorical data demonstrating that it prolongs survival in patients with recurrent GBM. It can also be useful in large tumors with significant cerebral edema by improving neurologic disability and sparing prolonged steroids. The addition of reirradiation improves PFS compared to bevacizumab alone for recurrent GBM.
6. Short-course RT is a reasonable option for older patients or those with poor performance status or transportation limitations.
7. If unimodality therapy is being contemplated (especially in sicker patients, less likely to tolerate combination therapy), TMZ alone for the *MGMT* methylated and RT alone for the *MGMT* unmethylated are reasonable considerations.

World Health Organization Grade 3 Gliomas

Conventional approaches at discussing management utilized grade as a division point to identify different entities. The recent utilization of *IDH* mutation status, and especially the availability of *IDH*-targeted therapeutics, is leading to classification dichotomization, based on the presence or absence of this mutation. Because the majority of the legacy data, with exception of the recently published INDIGO trial, have not used such dichotomization, we continue to present therapeutic strategies as historically developed and driven by grade and separately address the use of *IDH* inhibitors in a latter section.

WHO grade 3 gliomas (see Table 40.3) constitute approximately 25% of HGGs in adults, generally occurring during young to middle adulthood. Histologically, these tumors have increased cellularity, nuclear atypia, and marked mitotic activity, without necrosis or neovascularization. On imaging, anaplastic gliomas may show enhancement and necrosis similar to GBM, although up to one-third of tumors may not enhance.[190] The classification for these gliomas has changed dramatically over the past decade, and some of the older terminology (eg, oligoastrocytoma, "anaplastic") has been dropped in favor of more descriptive terminology that is based upon the molecular genetic makeup of each tumor. Due to the extent of the older terminology in the literature, particularly with respect to clinical trials, we have maintained the use of this language for discussing the historical approaches to the treatment of these tumors.
