The prognosis for patients with anaplastic glioma is heavily influenced by a number of molecular genetic factors. Patients with histologically defined anaplastic oligodendroglioma, in general, have a better prognosis. Other prognostic factors include age at diagnosis, mental status, and performance status (see Table 40.5). However, the prognosis of these patients is best defined by molecular factors, such as allelic loss of 1p and 19q and the presence of *IDH1* mutation (see later).

Anaplastic Oligodendroglioma

Anaplastic oligodendroglioma represents 3.5% of all malignant gliomas and 30% of oligodendroglial tumors. They occur predominantly in adults, with median age at diagnosis of 45 to 50 years, approximately 7 to 9 years older than grade II oligodendroglioma; this age difference reasonably corresponds to the average time of tumor "evolution" from grade II to grade III.

Molecular Genetics

Allelic loss of 1p and 19q is thought to be an early genetic alteration in the transformation and progression of oligodendrogliomas. Definitionally, 1p19q codeletion is a prerequisite to label a glial neoplasm and oligodendroglioma as per the current classification, and deletions in 1p and 19q have been associated with longer PFS, OS, and chemo- and radiosensitivity.[191-193]

Therefore, grade 3 (G3) glial neoplasms without this codeletion would be labeled G3 astrocytoma, or, as conventionally referred to, AA. Further, the presence or absence of an *IDH* mutation yields a further subclassification of AA into *IDH* mutated or wild type, with the former having significantly better survival probability and longevity.

The impact of 1p19q codeletion status on outcome has been confirmed in two phase III trials. RTOG 94-02 retrospectively assessed 1p and 19q status in 263 (71%) of 291 enrolled patients with anaplastic oligodendroglioma/oligoastrocytoma randomized to receive chemotherapy with PCV followed by RT or RT alone.[194] Combined loss of 1p and 19q was present in 44% of patients in the PCV plus RT arm and 52% in the RT-alone arm and was more frequent in anaplastic oligodendroglial tumors (76%) than in anaplastic oligoastrocytoma (24%). Combined loss of 1p and 19q resulted in a longer median survival time (14.7 vs 2.6 years [$P < .001$] in patients receiving PCV plus RT; 7.3 vs 2.7 years [$P < .001$] in patients treated with RT alone). In EORTC 26951, 368 patients with anaplastic oligodendroglioma/oligoastrocytoma were randomized to receive RT followed by PCV or RT alone.[195] The presence of 1p or 19q loss was found to be the most important predictor of outcome, with a median survival of 10.3 versus 1.9 years for tumors with or without combined allelic loss of 1p and 19q.

Other molecular factors with clinical implications, as indicated earlier, include somatic mutations in the *IDH1* gene and *MGMT* promoter methylation. *IDH1* mutations have been observed in 55% to 80% of grade II and III gliomas.[196] *IDH* mutations generate an oncometabolite that is believed to be contributory to malignant transformation for precursor cells to gliomas and, therefore, is an early event. Intriguingly, in spite of the fact that the mutation generates the causative oncometabolite, prospective trials of anaplastic gliomas have demonstrated *IDH1* mutations to be a strong positive prognostic factor. In EORTC 26951, *IDH1* mutations were observed in 46% of patients and demonstrated prognostic significance, independent of 1p/19q codeletion, in both arms of the trial for both PFS and OS.[197] In RTOG 9402, *IDH1* mutations were observed in 74% of patients, were associated with longer OS (9.4 vs 5.7 years), and identified patients without 1p19q codeletion who derived an OS benefit from the addition of PCV chemotherapy to RT (5.5 vs 3.3 years).[198] This suggests that both

subgroups, 1p19q codeleted (which almost always harbor *IDH* mutations), and the 1p19q noncodeleted (which now would not be labeled oligodendroglioma), but with *IDH* mutations, should be treated with combination chemoradiotherapy, and the third subset, 1p19q noncodeleted without *IDH* mutations, has the worst prognosis (similar to GBM, and many now qualify for a grade 4 label based on specific molecular alterations) and appears unlikely to derive benefit from the addition of chemotherapy. In both the EORTC and RTOG trials, the longest OS after PCV chemotherapy plus RT was observed in patients whose anaplastic oligodendroglial tumors contained both allelic loss of 1p and 19q and *IDH1* mutation (OS 12.8 years on EORTC trial, 14.7 years on RTOG 9402). *MGMT* promoter methylation has also demonstrated prognostic significance for anaplastic oligodendroglial tumors. However, unlike grade IV astrocytomas (GBM), in which *MGMT* promoter methylation predicts survival benefit from TMZ added to RT, *MGMT* promoter methylation has not shown similar predictive significance for outcome to PCV chemotherapy in anaplastic oligodendroglial tumors.[199] This is to be expected because *MGMT* methylation provides a mechanistic opportunity for TMZ to exert its specific cytotoxicity, and the PCV regimen does not contain TMZ or a drug that creates an identical cytotoxic DNA lesion. A German multicenter phase III trial of upfront RT versus upfront chemotherapy for newly diagnosed anaplastic gliomas observed *IDH1* mutations to be a stronger prognostic factor than either 1p19q codeletion or *MGMT* promoter hypermethylation.[200] The caveat of course is that both *MGMT* promoter hypermethylation and *IDH1* mutations are strongly correlated with 1p19q chromosomal loss.

Treatment

The current standard of care for patients with anaplastic oligodendrogliomas is maximal surgical resection followed by postoperative RT and chemotherapy. The RT target volume includes both the postoperative cavity and any residual enhancing disease, but also the FLAIR or T2 abnormality; unlike the situation with GBM, the postoperative FLAIR abnormality from anaplastic oligodendroglioma (and for that matter low-grade, grade 2 gliomas) most likely represents predominantly residual

tumor with minimal contribution from tumor-associated edema and, therefore, has to be included in the target volume. Indirect support for this comes from the small, but growing body of data regarding supraradical resection of lower grade gliomas, where complete resection of all MR abnormality is associated with longer survival.[201] Although the commonly used RT dose on prospective trials of anaplastic oligodendroglioma is 59.4 Gy, this never took into account molecular variability, and some have proposed that consideration could be made to lower the RT dose to 54 Gy for tumors with favorable prognostic features as outlined earlier, to minimize long-term toxicity (eg, 1p19q codeleted).

Anaplastic oligodendrogliomas are generally thought of as chemosensitive primarily based on high response rates to PCV in several studies. Two large randomized trials, described earlier, have investigated the use of sequential chemoradiotherapy compared to RT alone with chemotherapy reserved for salvage in patients with anaplastic oligodendroglioma and oligoastrocytoma.[194,195] With 11-year follow-up on RTOG 9402, the addition of PCV chemotherapy for four cycles prior to RT did not impact OS for the overall cohort, but did prolong OS for patients with allelic loss of both 1p and 19q from 7.7 to 14.7 years.[194] Among patients without combined allelic loss of 1p and 19q, the addition of PCV chemotherapy prior to RT prolonged survival for patients with *IDH1*-mutated tumors from 3.3 to 5.5 years.[198] With 11-year follow-up, the EORTC trial did observe an OS prolongation with the addition of PCV for six cycles after RT in the overall cohort from 2.6 to 3.5 years, with more benefit observed in tumors with combined allelic loss of 1p and 19q.[195] Therefore, currently, it would be prudent to conclude that in practice, both the 1p19q-codeleted and any *IDH*-mutated (with or without 1p19q codeletion) patients should receive chemoradiotherapy, but the role of combinatorial therapy for the 1p19q-noncodeleted and *IDH* wild-type tumors is questionable.

Because of the significant toxicity associated with PCV, many clinicians now use TMZ, which is much better tolerated. TMZ has produced high response rates in patients with anaplastic oligodendroglioma. Chinot et al[202] administered TMZ to 48 patients with anaplastic oligodendroglioma/oligoastrocytoma who had previously failed PCV chemotherapy. The ORR was 43.8% (complete response [CR] 16.7%, PR

27.1%). Vogelbaum et al[203] reported the results of RTOG 01-31, a phase II trial in which TMZ was given preradiotherapy to patients with newly diagnosed anaplastic oligodendroglioma/oligoastrocytoma. In the 27 patients available for review, the ORR was 33.3% (CR 3.7%, PR 29.6%). The 6-month progression rate was 10.3%. Toxicity was acceptable.

In addition, a recent international retrospective study of over 1,000 adults with anaplastic oligodendroglial tumors observed that combination chemotherapy and RT was associated with longer time to PFS and OS than either modality alone.[204] In cases without 1p19q codeletion, Lassman et al observed that combination chemotherapy and RT was associated with longer time to PFS and OS than either modality alone. In cases with 1p19q codeletion, combination chemotherapy and RT was associated with longer median time to progression compared to either modality alone, but this difference was not associated with a survival advantage. In addition, longer time to progression was observed with PCV, compared to TMZ, in codeleted cases. Therefore, although TMZ is widely used in lieu of PCV, the data supporting this practice are weak at best, and, based on Lassman's retrospective review, possibly deleterious. A North American Intergroup trial is currently enrolling patients in order to compare chemoradiotherapy with either TMZ or PCV for both grade 3 and grade 2 codeleted gliomas (CODEL).

Anaplastic Astrocytoma

Molecular Genetics

AAs are defined by the *IDH* mutation status. AA with *IDH* mutations carries the most favorable prognosis, whereas *IDH* wild-type AA carries the worst prognosis, comparable biologically to GBM.[205]

Treatment

For WHO grade 2 infiltrative gliomas, there is no established standard of care for initial therapy. For *IDH*-mutant diffuse gliomas, 1p/19q-codeleted oligodendrogliomas and, to a lesser degree, *IDH*-mutant astrocytomas, PCV neoadjuvant or adjuvant to definitive radiation or as monotherapy can be used initially or at recurrence.[195,200] *IDH* wild-type astrocytomas are more often treated with TMZ concurrent and adjuvant to radiation and/or as

monotherapy initially or at recurrence, with nitrosourea (BCNU or CCNU) monotherapy or PCV deferred to recurrence.[206] A double-blind, phase 3 trial recently showed increased PFS of vorasidenib (40 mg QD) compared to placebo for residual or recurrent grade 2 *IDH*-mutant glioma who had undergone no previous treatment other than surgery.[73] OS data are pending, and no comparison was made to alkylating chemotherapy and/or RT, yet the PFS was inferior to prior radiation or chemoradiation trial reports. The use of vorasidenib in these high-risk patients, as incomplete resection and/or measurable disease was required, in lieu of upfront chemoradiation remains controversial. Vorasidenib remains an alternative to observation for patients or providers preferring to defer chemotherapy and/or radiation as a salvage strategy.

For *IDH* wild-type diffuse astrocytomas, TMZ is established concurrent and adjuvant to radiation, initial monotherapy, and/or as salvage at recurrence, while nitrosourea (BCNU or CCNU) monotherapy is commonly deferred to recurrence. PCV is not commonly used due to the lack of efficacy in multiple trials.

The current standard of care for patients with AA is maximal surgical resection followed by postoperative RT and chemotherapy. The RT target volume and dose are similar to those for anaplastic oligodendroglioma.

TMZ has shown activity in patients with recurrent AA. In a phase II trial by Yung et al,[148] 162 patients with AA were treated with TMZ (150-200 $mg/m^2/d$ on days 1-5 every 28 days) at the first relapse. The 6-month PFS was 46%, and OS was 13.6 months. The ORR was 35% (CR 8%, PR 27%).

The effectiveness of TMZ was further tested in a phase III trial of non–1p19q-codeleted anaplastic glioma (ie, G3 AA) patients (the CATNON Intergroup trial). This trial randomized patients with newly diagnosed 1p/19q-noncodeleted anaplastic glioma to RT alone, RT with concurrent TMZ 75 mg/m^2 per day, RT followed by adjuvant TMZ of 150 to 200 mg/m^2 given on days 1 to 5 for twelve 4-week cycles, or RT concomitant with daily TMZ and followed by 12 cycles of adjuvant TMZ.[207] The second interim analysis declared futility of concurrent TMZ with no significant difference in mOS between concurrent TMZ (66.9 months, 95% CI: 45.7-82.3 months) and no concurrent TMZ (60.4 months, 95% CI: 45.7-71.5 months). Adjuvant TMZ improved OS (mOS 82.3 months, 95% CI: 67.2-116.6 months) compared with no adjuvant TMZ (mOS 46.9 months, 95%

CI: 37.9-56.9 months) with HR of death for adjuvant TMZ compared to no adjuvant TMZ of 0.64 (95% CI: 0.52-0.79, $P < .0001$).

RTOG 9813 was a phase III trial of RT plus TMZ versus RT plus nitrosourea.[205] This study closed early because of the inability to meet target accrual rate. However, with a median follow-up of 10.1 years, no difference in PFS or OS was observed. However, the RT plus nitrosourea arm experienced more grade 3 or higher toxicity (76% vs 48%) primarily because of myelosuppression, which led to discontinuation of therapy in 27.6% in the nitrosourea arm versus none in the TMZ arm. The trial demonstrated the prognostic benefit of the *IDH1* mutation in AA with *IDH1* mutation–positive patients having longer median survival time than *IDH1* wild-type patients (7.9 vs 2.8 years).

The NOA-04 trial compared radiation with two chemotherapy regimens for anaplastic gliomas, the majority of whom carried a diagnosis of AA.[200] In a 2:1:1 randomization, 318 patients were assigned to partial-brain irradiation alone versus PCV chemotherapy versus TMZ with time-to-treatment failure as the primary end point. Chemotherapy failures were salvaged with RT, and vice versa, and further, TMZ failures were salvaged with PCV and vice versa, almost ensuring that every patient received every therapy at some point. Time-to-treatment failure was similar between each of the arms, as was OS, imputing that the sequence of RT, TMZ, or PCV might not actually matter. This study also helped to establish *IDH1* mutation as an important prognostic factor for AA.

Evidence-Based Treatment Summary

1. Maximal resection is generally associated with more favorable outcomes and is recommended whenever feasible.
2. Molecular characterization of the tumor in terms of combined allelic loss of 1p and 19q and *IDH* mutational analysis carries important prognostic information and is necessary for accurate diagnosis; definitionally, anaplastic oligodendroglioma carries a codeletion of 1p19q.
3. Both AA and anaplastic oligodendroglioma can be either *IDH* wild type or carry a mutation, which imparts a prognostic advantage.

4. Postoperative RT has been shown to provide a survival advantage in several clinical trials, but these trials included patients with both WHO grade III and IV tumors; no trial for only grade III tumors, evaluating RT versus no RT, has been conducted. The RT dose is typically 59.4 to 60 Gy in 6 to 6.5 weeks. Some have proposed that tumors with prognostically favorable molecular features (1p19q codeletion and *IDH* mutation) could be treated to a slightly lower dose of 54 Gy in 6 weeks, given the potential for extended survival with the addition of chemotherapy and the desire to minimize long-term neurotoxicity.
5. In patients with anaplastic oligodendroglioma, the addition of PCV chemotherapy to RT prolongs OS, most notably in patients with combined allelic loss of 1p and 19q, but also in those with *IDH* mutation. Although TMZ is frequently used for these patients, there has been no direct comparison between PCV and TMZ, and limited evidence supports its use.
6. In patients with AA, the addition of adjuvant TMZ after RT provides a survival advantage, and *IDH* retains prognostic significance. The exact role of concurrent TMZ has not been fully defined. Based on the NOA-04 trial, if all three approaches, that is, radiation, TMZ, and PCV are to be used, sequencing may not matter.
7. The role of *IDH* inhibitors in the sequence of therapy remains to be established.

Low-Grade Glioma

LGGs are generally slower growing tumors that are divided into pilocytic and nonpilocytic subtypes. They account for 20% of gliomas and 10% of primary intracranial tumors in adults.

Pilocytic Astrocytoma

Pilocytic astrocytoma, also known as juvenile astrocytoma, corresponds to WHO grade 1. They are more common in children. On imaging, they are well-circumscribed enhancing lesions, often with a cystic component. Tandem duplication of chromosome 7q34 resulting in fusion of the *BRAF*

and *KIAA1549* genes is observed in 60% to 80% of sporadic pilocytic astrocytomas.[208]

Treatment

Pilocytic astrocytomas are more amenable to total resection than other LGGs. Fenestration of the cyst and resection of the mural nodule are usually curative. In tumors in which the wall of the cyst enhances, cystic degeneration is more likely, and resection of the entire cyst is necessary. Complete resection of pilocytic astrocytomas is associated with excellent survival, with the majority (>90%) of patients cured of the tumor; no adjuvant therapy is necessary. Incomplete resection is associated with long-term survival rates of 70% to 80% at 10 years.

The benefit of postoperative RT is unclear. The usual recommendation is for close follow-up following gross or subtotal resection and utilizing RT for tumors that have recurred more than once, or for those with considerable residual disease in a critical location, where even slight progression could result in significant morbidity. The North Central Cancer Treatment Group (NCCTG) 867251 enrolled 20 patients with supratentorial pilocytic astrocytoma on a prospective trial of RT after biopsy (3 patients) or observation after gross (11 patients) or subtotal (6 patients) resection.[209] With a 20-year follow-up, PFS was 95% and OS was 90%, with the cause of death in both patients who died being unrelated to tumor. If RT is indicated, the dose is typically 50 to 54 Gy (1.8-2 Gy fractions). However, there is evidence of improved PFS with RT, and immediate postoperative irradiation may be appropriate in some relatively uncommon cases, depending on the location of the tumor, the extent of residual disease, the feasibility of repeated surgical excision, and availability for follow-up.

The presence of the tandem duplication of chromosome 7q34 resulting in fusion of the *BRAF* and *KIAA1549* genes, observed in 60% to 80% of sporadic pilocytic astrocytomas, has prompted the use of BRAF inhibitors in some of these patients, especially at recurrence, and when other options have been exhausted. Occasional tumor responses have been reported.

For WHO grade 1 gliomas of all histologic and molecular subtypes, including the WHO grade 1 pediatric-like diffuse gliomas, circumscribed astrocytomas, and other glioneuronal tumors as per the 2021 classification,

systemic alkylating or other cytotoxic chemotherapy is reserved for recurrent tumors or malignant transformation. There is no accepted standard of care for salvage systemic chemotherapy, but multiple prospective clinical trials with over 2,000 pediatric patients with LGGs showed efficacy for vincristine and carboplatin, monotherapy with vinblastine, or a combination of thioguanine, procarbazine, CCNU, and vincristine. The typical 5-year PFS for sporadic pediatric LGG ranged from 35% to 45% despite the differing toxicity profiles of the regimens and was higher in patients with NF1-associated LGG (60%-70%). Subsequent progression was common across both sporadic and NF1-associated LGG.[72] Additional options include TMZ, nitrosourea, platinum, vincristine, and etoposide-containing regimens, namely based on approved treatment for infiltrative gliomas.[210] Future trials may help to better personalize therapies in patients with LGG.

Molecularly targeted options for LGGs are in rapid development. Combination dabrafenib and trametinib for *BRAF*V600E-mutated gliomas, such as pilocytic astrocytoma, ganglioglioma/gangliocytoma, or other glioneuronal histologies.[70] The 13 patients in the LGG cohort of the ROAR basket trial had a median follow-up of 32·2 months (interquartile range 25·1-47·8), with 9 patients (69%; 95% CI: 39-91) having an objective response, including 1 CR, 6 PRs, and 2 minor responses. Grade 3 or worse adverse events were reported in 31 (53%) patients, the most common being fatigue (5 [9%]), decreased neutrophil count (5 [9%]), headache (3 [5%]), and neutropenia (3 [5%]). MEK inhibitor monotherapy, such as trametinib and selumetinib, show promising efficacy in BRAF-rearranged (non-V600E mutant) LGGs of various histologies. BRAF inhibitors are contraindicated in BRAF- rearranged LGG due to paradoxical activation of MAPK signaling through increased RAF dimerization.[211] A Pediatric Brain Tumor Consortium phase 2 trial of selumetinib (RP2D of 25 mg/m^2/dose BID) was tolerable and beneficial in children with recurrent or progressive optic pathway and hypothalamic gliomas based on radiographic response and PFS (78% ± 8.5% at 2 years).[212] Visual outcomes also improved in most patients. Notably, visual acuity improved in 4 (21%) of 19 patients and was stable in 13 (68%) of 19 patients, while 5 (26%) of 19 patients had improved and 14 (74%) of 19 patients had stable visual fields. The most common toxicities were grade 1/2 creatine phosphokinase elevation, anemia, diarrhea, headache, nausea/emesis, fatigue, aspartate transaminase

and alanine transferase increase, hypoalbuminemia, and rash. The role of mTOR inhibitors and receptor kinase inhibitors, both as monotherapy and in combination, remains investigational. A Neurofibromatosis Clinical Trials Consortium phase 2 study of daily everolimus in 23 children with median age 9.4 (range: 3.2-21.6) years with recurrent/progressive NF1-associated LGG and prior treatment with carboplatin-containing chemotherapy demonstrated significant clinical benefit, 15 (68%) of 22 enrolled patients showed shrinkage (1 CR, 2 PR) or arrest of tumor growth (12 stable), of which 10 of 15 remained free of progression at a median follow-up of 33 months.[213] Treatment was well tolerated, and none discontinued due to toxicity. Bevacizumab, while approved for recurrent WHO grade 4 GBM, has little role and no clear proven benefit in LGG, but can be used for symptom management from radiation-induced necrosis or transformation to malignant grades. At the time of recurrence, treatment options are limited, with no accepted standard of care and reduced benefit for both *IDH*-mutant and wild-type tumors.[72]

Evidence-Based Treatment Summary

1. Maximal surgical resection, although not tested in a prospective trial, is associated with more favorable outcomes and is recommended whenever feasible. Molecular testing, especially for BRAF, should be conducted, if feasible.
2. Postoperative RT may be considered in patients with incompletely resected tumors, based on risk factors for progression and consequences of progression.
3. Chemotherapy does not have an established role in pilocytic astrocytoma in adults, but BRAF inhibitors are being used in situations where other options have been exhausted.

World Health Organization Grade 2 Gliomas

WHO grade 2 gliomas include those referred to as nonpilocytic or diffusely infiltrating LGGs. They may arise from an astrocytic or an oligodendrocytic lineage. Presentation usually occurs in the third or fourth decade of life, and only a small percentage of patients are younger than 19 or older than 65.

Approximately 80% of patients present with seizures.[214] CT typically demonstrates an ill-defined, diffuse, nonenhancing low-density region, often in the frontal or temporal lobes. Calcifications are commonly seen with oligodendrogliomas. MRI is more sensitive in detecting and defining these lesions, which are hypointense and nonenhancing on T1-weighted images and hyperintense on T2-weighted images. Because these tumors are highly infiltrative, tumor always extend beyond the abnormality observed on imaging. MRI analysis reveals an average growth rate of 5 mm/y.[215]

Histologically, there is increased cellularity compared to normal brain tissue with mild-to-moderate nuclear pleomorphism and no evidence of mitotic activity, vascular proliferative changes, or necrosis. Differentiation from reactive gliosis can be difficult.

Several clinical variables have been found to be of prognostic importance. Pignatti et al[216] performed the most comprehensive of these analyses and constructed a scoring system to identify patients at low and high risk. This study was based on data from two large European phase III trials for LGG designed to examine the dose and timing of postoperative RT, EORTC 22844, and EORTC 22845. Cox regression analysis was used to identify prognostic variables from 322 patients from EORTC 22844 and then validated on 288 patients from EORTC 22845. Multivariable analysis showed that age 40 or above, astrocytoma histology, maximum diameter 6 cm or greater, tumor crossing the midline, and the presence of neurologic deficits negatively impacted survival. A prognostic scoring system was derived: Patients with up to two of these factors were considered low risk (median survival 7.7 years) and patients with three or more as high risk (median survival 3.2 years). However, the data used to identify these prognostic factors predated modern clinical trials evaluating molecular genetics.

Molecular Diagnosis and Prognosis

The distinction between astrocytoma and oligodendroglioma rests on the detection of combined allelic loss of 1p and 19q, which is characteristic of oligodendroglioma, as well as additional genetic aberrations, such as ATRX, TP53, and TERT mutations. 1p19q codeletion is present only with an *IDH1* mutation and is the molecular signature with the most favorable

overall prognosis. The prior tumor subtype of mixed oligoastrocytoma is no longer considered a distinct entity, as the 1p19q-codeleted and *IDH*-mutant grade 2 oligodendroglioma and the *IDH*-mutant grade 2 astrocytoma are considered mutually exclusive subtypes. 1p19q-codeleted and *IDH*-mutant grade 2 oligodendroglioma, when associated with a TERT mutation, carries an mOS of 11 years, whereas *IDH*-mutant grade 2 astrocytoma associated with TP53 mutation and ATRX loss carries a median survival of only 6 to 8 years. LGGs identified as *IDH* wild type show clinical behavior similar to high-grade tumors with poor OS.[217]

In a review of 44 cases of low-grade oligodendrocytic tumors, Sasaki et al[218] considered half of the cases classic oligodendroglioma and the remainder nonclassical oligodendroglioma with more astrocytic features on histopathology. Deletion of 1p was detected in 86% and 27% of these groups, respectively. Response to chemotherapy was assessed at the time of recurrence in 13 patients. Of the 11 who responded to chemotherapy, 10 had a loss of 1p. Both of the nonresponders were found not to have a loss of 1p. A small prospective trial by Hoang-Xuan et al[219] found a similar trend. Loss of 1p with or without loss of 19q, which was detected in 12 of 26 patients with low-grade oligodendrocytic tumors treated with TMZ, was found to have a significant association with response to chemotherapy ($P < .004$).

IDH1 mutations may be predictive of a better prognosis in patients with LGGs, but this marker does not categorically appear to predict response to chemotherapy, with the caveat that the data testing this are dated and sparse.[220] In one prospective trial of RT with or without chemotherapy, the presence of *IDH1* mutation was associated with prolonged median survival from 5.1 years among patients without the mutation to 13.1 years among those with the mutation, when receiving the combined modalities.[221]

Unplanned molecular analyses of EORTC 22033-26033 demonstrated prognostic significance associated with molecular characterization.[222] Median PFS was 62 months for *IDH*-mutated/1p19q-codeleted tumors, 48 months for *IDH*-mutated/1p19q-noncodeleted tumors, and 20 months for *IDH* wild-type tumors. *MGMT* promoter was methylated in all patients with *IDH*-mutated/1p19-codeleted tumors, in 86% of *IDH*-mutated/1p19q-noncodeleted tumors, and 56% of *IDH* wild-type tumors.

Treatment

The clinical course for patients with diffusely infiltrative low-grade tumors is variable, with some patients having long survival even with treatment and others suffering from progressive deterioration despite treatment. In general, early intervention is indicated for almost all patients. Adequate tissue sampling is critical to ensure accurate diagnosis, and maximal surgical resection in this context may be advisable in appropriately selected patients. In younger patients (<40 years) who have undergone complete resection, observation with serial imaging is an option. In those who have undergone a subtotal resection or those with high-risk features, postoperative RT and chemotherapy are recommended, typically 50 to 54 Gy in 1.8 Gy fractions. The INDIGO trial testing an *IDH* inhibitor has introduced yet another possible therapeutic avenue.

Surgery

In practice, most patients undergo surgery at presentation in order to establish the diagnosis and to determine histology, grade, and molecular characteristics that affect treatment. However, even under the best circumstances, total resection with an adequate margin is rarely achieved because of the diffusely infiltrative nature of these tumors and the involvement of eloquent regions. Although controversial, most studies have found total or subtotal (>90%) resection to be associated with improved outcome.[223] Moreover, with the advent of modern MRI and intraoperative electrostimulation in the awake craniotomy setting to assist in identifying critical areas of the brain, resection may be achieved with less morbidity and mortality than in the past.[223,224] Proponents of aggressive resection are also supported by studies that suggest that radical surgery results in more accurate histopathologic diagnosis.[225] In RTOG 98-02, 5-year PFS in 111 good-risk patients, defined as patients younger than 40 years and gross total tumor resection, was 48%.[226] Review of postoperative MRI demonstrated crude recurrence rates of 26%, 68%, and 89% for less than 1, 1 to 2, and greater than 2 cm residual disease, respectively. More recently, some neurosurgeons have advocated for resection of more brain tissue than what appears to be involved on MRI for nonenhancing gliomas, to the extent that does not result in a loss of neurologic function,[227] in other words a

functionally guided resection rather than an anatomic resection. The excellent outcomes in these cases may be related to patient selection (eg, tumor location and tumor volume), and a systematic review did not support the routine use of this surgical approach.[228]

Radiotherapy

Three phase III trials provide the best evidence with respect to the indications for RT as well as the dose (Table 40.6).

TABLE 40.6 PHASE III TRIALS OF PATIENTS WITH LOW-GRADE GLIOMA TREATED WITH RADIOTHERAPY

Study	Treatment Arm	*N*	5-Year Survival (%)
EORTC 22845	Observation[a]	157	66
	54 Gy (30 fractions)	157	68
EORTC 22844	45 Gy (25 fractions)	171	58
	59.4 Gy (33 fractions)	172	59
NCCTG	50.4 (28 fractions)	101	72
RTOG 9802 (Age ≥40 or STR)	64.8 (36 fractions)	102	64
	54 Gy (30 fractions)	128	63
	54 Gy plus PCV	126	72

[a]Treatment with radiotherapy at progression.

Patients considered favorable by the scoring system introduced by Pignatti et al[216] are typically observed postoperatively and given RT at disease progression or recurrence. This practice is based on the results of a phase III trial by van den Bent et al in EORTC 22845.[229] In this multi-institutional trial, 314 patients with LGGs were randomized to receive postoperative RT to 54 Gy in fractions of 1.8 Gy (n = 157) or RT at progression (n = 157). A significant improvement in median PFS was found with early RT (5.3 vs 3.4 years, $P < .0001$), but there was no difference in median survival (7.4 vs 7.2 years, $P = .872$). It is of note that 65% of the patients in the delayed RT group received RT at progression. Malignant

transformation occurred in 65% to 72% of patients, with no difference between the two groups. Although seizure control was superior in the early RT group, adequate data on quality of life were not obtained. The authors concluded that although early RT may be appropriate in some situations, for example, patients with symptomatic lesions, withholding RT until tumor progression does not jeopardize survival.

For patients given RT postoperatively, the dose has been established by 2 phase III trials. In EORTC 22844, 379 patients were randomized to receive 45 Gy in 5 weeks or 59.4 Gy in 6.6 weeks postoperatively.[230] With a median follow-up of 74 months, OS (58% vs 59%) and PFS (47% vs 50%) were similar in both arms.

In a joint NCCTG, RTOG, and ECOG study, 203 patients were randomized to low-dose RT to 50.4 Gy in 28 fractions (n = 101) or high-dose RT to 64.8 Gy in 36 fractions.[231] There was no significant difference in PFS or OS. Survival at 2 and 5 years was 94% and 72%, respectively, with low-dose RT and 85% and 64% with high-dose RT. Grade 3 to 5 neurotoxicity occurred in 5% of patients in the high-dose cohort and 2.5% of patients in the low-dose cohort.

Consequently, low-dose RT, 50 to 54 Gy in 1.8 Gy fractions, is the standard of care for patients with LGGs. The target volume typically includes a margin of 1 to 2 cm beyond changes demonstrated on traditional MRI sequences. Using FLAIR images, which usually show abnormality beyond any enhancing or nonenhancing tumor, a smaller margin of 0.8 to 1 cm may be used.

However, this concept of dose will likely need to be revisited in light of the fact that it might be possible to decrease dose (to say 45 Gy) in the most favorable subset (1p19q codeleted, *IDH* mutated), but increase it (to say 59.4 Gy) in the most unfavorable subset (*IDH* wild type).

Chemotherapy/Chemoradiotherapy

There is no established standard of care for initial chemotherapy for WHO grade 2, *IDH*-mutant infiltrative gliomas. For *IDH*-mutant diffuse gliomas, 1p/19q-codeleted oligodendrogliomas and, to a lesser degree, *IDH*-mutant astrocytomas, PCV neoadjuvant or adjuvant to definitive radiation or as monotherapy can be used initially or at recurrence.[195,200] *IDH* wild-type

astrocytomas are more often treated with TMZ concurrent and adjuvant to radiation and/or as monotherapy initially or at recurrence, with nitrosourea (BCNU or CCNU) monotherapy or PCV deferred to recurrence.[206]

Multiagent chemotherapy, in particular PCV, appears promising with response rates ranging from 50 to 80% in recurrent and newly diagnosed tumors.[232,233] The publication of mature results from RTOG 9802 has significantly altered the standard of care, as the addition of PCV to RT provided a significant OS advantage.[221] In this phase III trial, 254 unfavorable patients (age ≥40 with subtotal resection or biopsy) were randomized to receive RT alone to 54 Gy in 30 fractions or RT followed by six cycles of standard-dose PCV. With a median follow-up of 11.9 years, mOS was extended from 7.8 years following RT alone to 13.3 years following RT plus chemotherapy, and 10-year OS was increased from 40% with RT alone to 60% following RT plus chemotherapy. The superiority of RT plus chemotherapy to RT alone was observed with all histologic subtypes, although the difference did not reach statistical significance among patients with astrocytoma. Patients with *IDH1*-mutated tumors had longer survival with the addition of chemotherapy to RT. The number of events in patients with *IDH1* wild-type tumors was too small to evaluate treatment effect in this subgroup. Acute grade 3 or 4 toxicity occurred in 67% of patients who received RT plus PCV as compared with 9% of patients who received RT alone.

TMZ has been shown to have activity in phase II trials in newly diagnosed and recurrent LGGs.[219,234-236] RTOG 0424[237] was a phase II study of patients diagnosed with LGG with three or more risk factors for recurrence as established by the aforementioned EORTC Cox regression analysis, reported by Pignatti and colleagues[216]: (1) age 40 years or above, (2) astrocytoma histology, (3) bihemispherical tumor, (4) preoperative tumor diameter 6 cm or larger, and (5) preoperative neurologic function status greater than 1. In this study, patients were treated with RT to 54 Gy in 30 fractions with concurrent and adjuvant TMZ for 12 cycles. With a median follow-up of 4.1 years, 3-year OS was 73%, which was significantly improved relative to the 54% rate derived from the prespecified historical control. Median survival time had not yet been reached. Three-year PFS was 59%. Grade 3 or higher toxicities were increased from 10% to 43% with the addition of TMZ.

Prior to the publication of the mature results of RTOG 9802, a number of efforts to exclude or delay RT in the management of LGG, based on the expectation of equivalent results from the use of TMZ, were undertaken.

EORTC 22033-26033 was a phase III intergroup trial that randomized 477 patients to either dose-dense TMZ (75 mg/m^2 QD for 21 days, repeated every 28 days—one cycle—for maximum of 12 cycles) or RT (50.4 Gy in 28 fractions) with LGG and at least one of the following high-risk features: (1) age 40 or above, (2) progressive disease, (3) tumor size greater than 5 cm, (4) tumor crossing midline, or (5) neurologic symptoms.[222] The primary end point was PFS, with the study powered to demonstrate a prolongation in PFS with the use of dose-dense TMZ as opposed to RT. The study observed no difference in PFS with median PFS of 46 months following RT and 39 months following TMZ. Unplanned analyses demonstrated improved PFS with RT relative to TMZ for *IDH*-mutated, 1p19q-noncodeleted tumors (55 vs 36 months). Other molecular subgroups did not show treatment-related differences, although patient numbers in this unplanned analysis were small. TMZ was associated with higher grade 3 to 4 hematologic toxicity (9% vs <1%) and more grade 3 to 4 infections (3% vs 1%). With a median follow-up of 3 years, no difference between health-related quality of life, assessed using the EORTC patient- reported questionnaires, and cognitive function, as assessed by the Mini-Mental Status Examination, was observed.[238] This trial, at least based on the results available to date, does not support the use of upfront TMZ and deferral of RT for WHO grade II gliomas. Similarly, a prospective single-institution trial of 120 patients with WHO grade II gliomas proactively treated with upfront TMZ, and deferral of RT demonstrated median survival of 9.7 years, considerably inferior to the 13.3 years noted on the chemoradiotherapy arm of RTOG 9802.[239] These data, therefore, should suffice to detract from the practice of RT deferral for these patients, outside the clinical trial context.[222,238]

IDH Inhibitors

The phase 3 INDIGO clinical trial of vorasidenib, an inhibitor of mutant *IDH1* and *IDH2*, demonstrated moderate efficacy in prolonging imaging-based PFS for patients with residual or recurrent grade 2 *IDH*-mutant

glioma who had undergone no previous treatment other than surgery. The median PFS was 27.7 months for patients treated with vorasidenib monotherapy compared to 11.1 months for observation alone. OS data are pending. No comparison was made to alkylating chemotherapy and/or RT, but the reported PFS is inferior to prior radiation or chemoradiation trials. Thus, the use of vorasidenib for high-risk patients, as incomplete resection and/or measurable disease was required, in lieu of upfront chemoradiation remains controversial, yet remains an alternative to observation for patients or providers preferring to defer chemotherapy and/or radiation as a salvage strategy. Until further evidence arises to modify evidence-based recommendations, current data still support the use of adjuvant chemoradiotherapy in high-risk WHO grade 2, *IDH*-mutant glioma.

Evidence-Based Treatment Summary

1. Maximal surgical resection is generally associated with more favorable outcomes and is recommended whenever feasible. Supramaximal resection may be of value for very selected cases.
2. Molecular analysis of resected tumors for 1p19q codeletion, *IDH1* mutation, and *MGMT* promoter methylation, as well as other genetic aberrations such as TP53, TERT, and ATRX, provides important prognostic information that complements known clinical risk factors and may aid in treatment decision-making; these should be obtained whenever feasible.
3. Postoperative RT has not been shown to provide a survival advantage in the only clinical trial testing this question, although PFS and seizure control were superior. The typical RT dose is 45 to 54 Gy; randomized trials do not show a survival advantage with higher doses, but dose tailoring based on molecular features has not been tested and could be considered in future trials. In fact, based on the longevity of patients with favorable features, other attempts to reduce RT-related toxicity should also be considered, and in that vein, NRG Oncology has recently completed accrual to a randomized trial testing protons versus photons for grade 2 gliomas.

4. In a practice-changing phase III trial, the addition of PCV chemotherapy to RT significantly lengthened OS in patients with subtotally resected tumors or whose age was 40 years or above. The addition of TMZ to RT has also improved survival in high-risk tumors relative to historical control data, but these data do not approach level 1. A randomized trial comparing TMZ RT to PCV with RT is underway, and enrollment has almost been completed.
5. The substitution of RT with dose-dense TMZ in high-risk tumors does not provide a PFS benefit, significantly augments hematologic toxicities, and does not impact long-term cognitive functioning or patient-reported quality of life. In *IDH*-mutated/1p19q-noncodeleted tumors, RT is associated with improved PFS relative to dose-dense TMZ. Retrospective comparison to a large multi- institutional experience raises concern about possible survival degradation when RT is deferred.
6. *IDH* inhibitors demonstrate activity as a single agent, delaying progression, compared to observation, but have not been tested against or with other therapeutic modalities such as chemoradiotherapy, and therefore, the precise role in practice remains undefined at present.

Gliomatosis Cerebri

Gliomatosis cerebri is a rare condition with diffuse involvement of multiple parts of the brain (greater than two lobes), frequent bilateral growth, and regular infratentorial extension. This entity has been removed from the 2016 revision of the WHO classification of CNS tumors but is instead considered a special pattern of spread of diffuse glioma subtypes, and therefore, obtaining tissue and performing molecular analysis are strongly recommended.[240] On MRI, there is typically diffuse increased signal on T2-weighted and FLAIR images and low or absent signal in the affected areas on T1-weighted images.

Treatment choices remain limited. Perkins et al[241] reviewed the treatment outcomes of 30 patients with gliomatosis cerebri treated with RT. Transient radiographic improvement or disease stabilization was achieved in 87% of patients with clinical improvement observed in 70%. Patients younger than

40 and those with nonglioblastoma histology had significantly improved OS.

In a French study, 63 patients with gliomatosis cerebri were treated initially with PCV or TMZ.[242] Objective responses were observed in 33% of patients and radiologic responses in 26%, with no significant difference between the two regimens. Median PFS and OS were 16 and 29 months, respectively. Regardless of regimen, patients with an oligodendroglial component had significantly better outcomes in terms of PFS and OS.

A recent German phase II trial treated 35 patients with gliomatosis cerebri with procarbazine and lomustine.[243] Median PFS was 14 months, and mOS was 30 months. Twelve patients received salvage RT at progression. *IDH1* mutation was a strong independent prognostic factor.

A retrospective review of 296 patients with gliomatosis cerebri from the literature (n = 206) and the Association des Neuro-Oncologues d'Expression Francaise (ANOCEF) network (n = 90) demonstrated median survival of 14.5 months.[244] Patients younger than 42, with better KPS, low-grade histology, or oligodendroglial subtype, had better outcomes. The impact of RT on survival remained unclear.

Evidence-Based Treatment Summary

1. Maximal surgical resection is not an achievable goal.
2. RT is considered the standard, but no trials have validated its role. Dose remains ill-defined.
3. The role of chemotherapy remains ill-defined.
4. In the absence of definitive data, our recommendation is, therefore, to treat based on histopathologic and molecular features; one such strategy includes the following:
    a. Nonglioblastoma, *IDH* mutated (grade 2 or 3): Treat all visible tumor to 45 Gy with concurrent and adjuvant TMZ.
    b. Nonglioblastoma, *IDH* wild type (grade 2 or 3): Evaluate for *MGMT* status; if methylated, treat all visible tumor to at least 45 Gy (and consider possible focal boosting to 54-59.4 Gy), with concurrent and adjuvant TMZ; if unmethylated, substitute PCV for TMZ.

c. GBM: If *MGMT* unmethylated, RT alone, and if methylated, TMZ alone; consider adding RT for methylated patients if performance status is high, or there is significant tumor response to TMZ.

Adult Brainstem Glioma

Brainstem gliomas account for 15% of all pediatric brain tumors but can occur in adults.[245] They can be divided into several distinct types. Diffuse midline glioma (DMG) is a narrowly defined but phenotypically and molecularly distinct tumor that is characterized by K27M mutations in the histone H3 gene *HeF3A*, or less commonly in the related *HIST1H3B* gene, occurring primarily in children (but sometimes in adults), with a diffuse growth pattern and midline location (eg, thalamus, brainstem, and spinal cord).[246,247] This entity was newly defined in the 2016 revision to the WHO classification system and includes tumors previously referred to as diffuse intrinsic pontine glioma (DIPG).[240] Although these tumors are associated with poor prognosis, their distinct molecular characteristic provides rationale for future targeted therapies.

DMGs can have diverse imaging appearances, ranging from expansile masses without enhancement or necrosis to peripherally enhancing masses with central necrosis but little surrounding T2/FLAIR abnormality.[248] In contrast, focal, dorsally exophytic, or cervicomedullary tumors can be low grade and have a much better prognosis, especially when found in the context of neurofibromatosis. In addition, enhancement, particularly in a focal lesion, may suggest a juvenile pilocytic astrocytoma rather than an HGG. Although rare, other aggressive tumors such as primitive neuroectodermal tumors and atypical teratoid-rhabdoid tumors can occur in the brainstem.[249,250] Nonneoplastic processes that may be confused with a primary brainstem tumor include neurofibromatosis, demyelinating diseases, arteriovenous malformations, abscess, and encephalitis.

Treatment

Corticosteroids may be necessary to manage neurologic symptoms until treatment is instituted. Patients with hydrocephalus may require placement of a ventriculoperitoneal shunt. The approach to treatment should be based on the type of brainstem glioma as determined by both the clinical

presentation and radiographic findings. Surgery is the treatment of choice for operable lesions (ie, accessible focal tumors, dorsally exophytic and cervicomedullary tumors). For low-grade tumors amenable to surgical resection, as in other LGGs, the role of postoperative RT is controversial, and many would advocate close observation. For unresectable low-grade tumors, RT should be delivered using volumes and doses as for LGGs in other locations.

Involved-field RT is the primary treatment for infiltrating pontine gliomas. The gross tumor volume (GTV) is usually best defined using T2-weighted or FLAIR MRI. A margin of 1 to 1.5 cm is added to create a CTV and further expanded by 0.3 to 0.5 cm to create a PTV. Margins may not need to be uniform in all directions, particularly where bone limits tumor extension. These lesions should be treated with doses on the order of 55.8 to 60 Gy using daily fractions of 1.8 to 2.0 Gy/d. Although RT provides short-term benefits, long-term results have remained dismal. There is no benefit from RT dose escalation. Chemotherapy has no established role. Chapters 90 provides more details as most data on intrinsic pontine gliomas come from pediatric trials.

Fewer data exist with respect to brainstem glioma in adults, but there is some evidence that these tumors may be less aggressive in adults, with OS ranging from 45% to 66% at 2 to 5 years, perhaps because of a greater frequency of more favorable tumor types.[251] Kesari et al[252] published a series of 101 adults with brainstem gliomas and observed 5- and 10-year OS rates of 58% and 41%, respectively. Of the 24 candidate factors, they observed prognostic significance associated with ethnicity, tumor location, age of diagnosis, and tumor grade. In the series from ANOCEF, 48 adult patients with brainstem gliomas were grouped on the basis of their clinical, radiologic, and histologic features.[253] Nearly half had nonenhancing diffusely infiltrative tumors and had symptoms that were present for more than 3 months. Eleven of these 22 patients underwent biopsy, and nine had low-grade histology. Nearly all underwent RT and had a median survival of 7.3 years. A second group of 15 patients who had presented with rapid progression of symptoms and had CE on MRI were described. Fourteen of these patients underwent biopsy and anaplasia was identified in all 14 specimens. Despite RT, the median survival in this group was 11.2 months, which approximates the survival in pediatric series.

Medical therapies for DIPG and H3 K27M DMGs remain limited. Radiation alone, at diagnosis or at recurrence, remains the only effective therapy with survival impact. More than 50% of patients with DIPG succumb within 12 months of diagnosis, and only 1 in 10 survive more than 2 years.[254,255] Enhancing response to standard-of-care RT and/or identifying monotherapies that increase patient survival remain elusive. The driver oncohistone H3 K27M remains untargetable,[247,256] yet exploiting the metabolic and immunologic programs promoted by recurring H3 K27 alterations in primitive oligodendrocyte precursor cells (the cell of origin of DMG) shows early promise.[257,258] Neuronal progenitor cells expressing the oncohistone showed carbohydrate metabolism, particularly glycolysis and tricarboxylic acid (TCA) cycle regulation, as a dominant feature underlying DMG tumor growth.[259] TCA cycle metabolites also dramatically regulate the epigenome, resulting in complex and heterogeneous somatic, epigenetic, and clonal landscapes of DMG.[260-262]

Therapies that address DMG metabolism may help reverse the currently unacceptable survival statistics for patients with DMG. ONC201 (dordaviprone), a first-in-class imipridone, selectively induces apoptosis in cancer cells by ClpP agonism and DRD2 antagonism.[263-265] ClpP normally degrades misfolded proteins in mitochondria, while ONC201 modifies ClpP conformation, promoting excess degradation of specific mitochondrial proteins important for cancer cell viability. DRD2 is a G protein coupled neuroreceptor regulating Ras signaling, while ONC201 antagonizes DRD2, thus inhibiting Ras signaling pathways. ONC201 inhibits TCA cycle and glycolysis, which are key drivers of proliferation in H3 K27M DMG.[266]

An integrated analysis of single-agent ONC201 (dordaviprone) was reported for 50 patients (4 pediatric, 46 adults) with recurrent H3 K27M-mutant DMG in four clinical trials or one expanded access protocol.[267] Eligible patients had measurable disease by RANO-HGG criteria assessed by dual-reader, blinded independent central review. Patients were eligible if performance score was 60 or more and started therapy for progression at 90 days or more from radiation. The ORR by RANO-HGG was 20.0% (95% CI: 10.0-33.7). The median time to response was 8.3 months (range, 1.9-15.9), while the median duration of response was 11.2 months (95% CI: 3.8 to not reached). Performance status improved in 6 (20.6%) of 34 (95% CI: 8.7%-37.9%) evaluable patients. Grade 3 treatment-related treatment-

emergent adverse events (TR-TEAEs) occurred in 20.0% of patients, mainly fatigue (*n* = 5; 10%). No grade 4 TR-TEAEs, deaths, or discontinuations occurred. ONC201 monotherapy was well tolerated and exhibited durable and clinically meaningful efficacy in recurrent H3 K27M-mutant DMG. ONC201 exhibits activity in H3 K27M-mutant gliomas, irrespective of CNS location.[268] A study evaluating the safety and PK of oral ONC201 administered twice weekly on consecutive days (D1D2) in pediatric patients with newly diagnosed DIPG and/or recurrent/refractory H3 K27M glioma was well tolerated without dose-limiting toxicities or grade 3 or higher treatment-related adverse events and associated with greater $AUC_{0\text{-}48}$ compared to once-weekly dosing.[269] The definitive randomized, placebo-controlled, phase 3 ACTION trial (NCT05580562) is assessing single dose weekly and 2-day consecutive weekly compared to placebo in the adjuvant setting, for pediatric and adult patients with non-DIPG, nonspinal, H3 K27M DMG who have not progressed immediately after standard radiation.[270]

A recent semi-systematic review published in December 2023 descriptively summarized 41 clinical trials for DIPG or K27-altered DMG.[271] The main therapeutic strategies under study included chemotherapy, vaccines, adoptive transfer therapy, small molecules, and focused ultrasound. Chemotherapy trials include a phase 2 trial of pomalidomide, next-generation immunomodulatory drug, that broadly affects various molecular and cellular elements within the tumor microenvironment, in turn affecting the concentration of various cytokines that support tumor cell growth.[272] Another phase 1 trial (NCT02992015) of gemcitabine focuses on assessing the intratumoral gemcitabine concentration after systemic treatment after a single IV administration prior to standard-of-care biopsy of radiographically diagnosed DIPG. Vaccine strategies in phase 1-2 trials include three H3 K27M-targeted peptide vaccines monotherapy (NCT04749641, NCT04808245) or in combination with nivolumab (NCT02960230), one PEP-CMV vaccine targeting the CMV (pp65) antigen (NCT05096481), and one rHSC-DIPGVax vaccine targeting neoantigens combined with checkpoint blockers balstilimab and zalifrelimab (NCT04943848). Adoptive transfer chimeric antigen receptor T-cell (CAR-T)-based phase 1 trials include (1) one trial using genetically

modified cells (KIND T cells) for HLA-A*0201–positive patients (NCT05478837), (2) two trials using CAR-T targeting GD2 (NCT05544526, NCT04196413), (3) one trial of B7-H3–specific CAR-T (NCT04185038), and (4) one trial of B7-H3, EGFR806, HER2, and IL-13-Zetakine (Quad) CAR-T (NCT05768880). Non–CAR-T–based adoptive transfer immunotherapy trials include the BRAVO (NCT03396575) and PEACH (NCT04837547) trials. Monoclonal antibody trials include pembrolizumab (anti–PD-1, NCT02359565) and APX005M (anti-CD40, NCT03389802) checkpoint inhibitor monotherapies. The phase 1 AloCELYVIR trial (NCT04758533) represents the only oncolytic virus strategy currently under study.

Aside from the ONC201-based trials now in phase 3 (ACTION, NCT05580562; BIOMEDE, NCT05476939), most small molecules are under study in phase 1-2 trials, including selinexor (selective inhibitor of nuclear export; NCT05099003), abemaciclib (CDK4/6 inhibitor; NCT02644460), ribociclib (CDK4/6 inhibitor) and everolimus (mTOR inhibitor; NCT05843253), vorinostat and temsirolimus (mTOR inhibitors) with or without RT (NCT02420613), CBL0137 (FACT sequestration; NCT04870944), fimepinostat (HDAC and PI3K inhibitor; NCT03893487), panobinostat (HDAC inhibitor; NCT02717455), marizomib (proteasome inhibitor) plus panobinostat (HDAC inhibitor; NCT04341311), OKN-007 (HIF1-α and VEGFR2 expression; NCT05518838), and indoximod (indoleamine 2,3-dioxygenase inhibitor; NCT04049669). Enhanced delivery techniques primarily utilize focused ultrasound for BBB disruption or for sonodynamic therapy (SDT). The phase 1-2 trials focusing on BBB disruption include the commercially available agents panobinostat (NCT04804709), doxorubicin (NCT05615623, NCT05630209), and etoposide (NCT05762419). The phase 1-2 trial of SDT using SONALA-001 (NCT05123534) utilizes noninvasive SDT through MR-guided focused ultrasound to activate protoporphyrin IX (PpIX), a metabolite of the administered IV prodrug ALA, intratumorally through the selective uptake of ALA by tumor cells relative to normal brain cells and local activation using MR-guided SDT. These varied trials highlight the expanding trials and novel medical strategies focused on enhancing the prognosis for DIPG and DMG, beyond the limited benefit radiation offers to date.

Evidence-Based Treatment Summary

1. Surgical resection is indicated for patients with favorable tumor types (based mostly on location) but is not an achievable goal in patients with intrinsic pontine gliomas; however, obtaining tissue is strongly recommended, and molecular testing should be considered.
2. The H3 K27M mutation defines a phenotypically and molecularly distinct tumor, called diffuse midline glioma (DMG), occurring in midline location and associated with an especially poor prognosis; however, this may be a targetable driver mutation. Gliomas with diffuse growth pattern and midline location should be tested for H3 K27M mutation.
3. For DMGs, RT is considered the standard. The addition of chemotherapy remains undefined.

Ependymoma

Ependymoma accounts for only 1.8% of all adult brain tumors.[273] Rosette formation is a hallmark of ependymoma on pathologic specimens. WHO grade I ependymomas include myxopapillary ependymoma, which typically occurs in the spine, and subependymoma.[240] In adults, the subependymomas, which are mostly intracranial, have favorable clinical outcomes. Ependymomas are otherwise divided between WHO grades II and III (anaplastic), with the latter showing increased mitotic activity, tumor necrosis, and microvascular proliferation, suggesting a diagnosis of anaplastic ependymoma. Unlike pediatric ependymomas, which largely arise intracranially, 75% of ependymomas in the adult population arise in the spinal canal. Spinal ependymomas typically present with sensory deficits. Ependymomas may expand locally, extend along ependymal spaces, and, occasionally, disseminate through the CSF. However, the predominant pattern of relapse is local, even when anaplasia is present.[274-279]

Posterior fossa and supratentorial ependymoma are biologically different tumors but are both treated with surgery and RT. In a recent international collaborative study,[280] nine molecular subgroups of ependymoma were identified, three in each anatomic compartment: spine (SP), posterior fossa (PF), and supratentorial (ST) region. In each compartment, one molecular

subgroup of WHO grade I subependymoma (ST-SE, PF-SE, and SP-SE) was observed, occurring in adults only. In the spine, the two other molecular subgroups matched the histopathologic diagnoses of myxopapillary ependymoma (SP-MPE) and WHO grades II and III ependymoma (SP-EPN). In the posterior fossa, the remaining two molecular subtypes were classified as PF-EPN-A and PF-EPN-B. PF-EPN-A occurs primarily in infants and young children (but is observed in 11% of adult patients), and because of its predominately lateral location, it can be difficult to completely resect and thus is associated with high relapse rates.[281] PF-EPN-B occurs primarily in older children and adults and is associated with a more favorable prognosis. More than 70% of supratentorial ependymomas are characterized by fusions between *C11ORF95* and *RELA* genes.[282] Termed ST-EPN-RELA tumors, these ependymomas can occur in both adults and children and are recognized as a distinct molecular entity by the 2016 revision of the WHO classification system. The remaining supratentorial tumors harbor fusions to the oncogene *YAP1* and have a highly favorable prognosis.

Treatment

Maximal surgical resection, including second surgery if necessary, is the initial treatment for ependymoma. Surgery alone may be sufficient in selected patients based on the results of a pediatric series described in Chapters 90. However, the standard of care for most adults is postoperative irradiation. There appears to be a radiation dose response with improved tumor control with doses greater than 50 Gy, and doses of 54 to 59.4 Gy are typically prescribed. Radiation dose for spinal ependymomas can be limited by spinal cord tolerance. At 1.8 to 2 Gy/fraction, the estimated risk of radiation myelopathy is less than 1% at 54 Gy and less than 10% at 61 Gy.[283]

Historically, for posterior fossa tumors, the entire posterior fossa has been irradiated. However, Paulino[284] has shown that the pattern of failure to be “local,” that is, within the tumor bed itself. In nine patients who received RT to the tumor bed plus a 2-cm margin, the two failures in this group were within the tumor bed (ie, there were no failures within the posterior fossa outside the tumor bed). For most patients, a more usual volume now

consists of the tumor bed and any residual disease (GTV) plus an anatomically defined margin of 1 to 1.5 cm to create a CTV. Larger margins may be required in areas of infiltration, and special attention must be paid to areas of spread along the cervical spine because 10% to 30% of the fourth ventricular tumors extend down through the foramen magnum to the upper cervical spine.[278,285] RT field size for spinal ependymomas commonly includes two cranial and two caudal vertebral bodies. Lumbosacral or sacral ependymomas should include coverage of nerve roots, with the caudal border extending to S4/S5 and lateral borders extending to the sacroiliac joints.

In the past, CSI was recommended for patients with high-grade and infratentorial tumors who were believed to be at an increased risk of CSF spread.[276] Modern series document that local recurrence is the primary pattern of failure and that the incidence of isolated spinal relapses is low even among the highest-risk patients, with the majority of spinal failures associated with local recurrences.[274,277] As a result, the current recommendation for patients with ependymomas is limited-field radiation if the spinal MRI scan and CSF cytology are negative. Patients with neuraxis spread (positive MRI or positive CSF cytology) should receive CSI (36 Gy) with boosts to the areas of gross disease and to the primary tumor to total doses of 50 to 59.4 Gy. One exception is spinal myxopapillary ependymomas (WHO grade I), where MR evidence of neuraxis spread can be treated with focal RT, rather than CSI.

Chemotherapy is not effective as primary treatment, thus usually reserved as salvage treatment for patients exhausting surgery and RT options. Randomized trials of chemotherapy in the pediatric population failed to show clinically useful benefit relative to RT,[286] although neoadjuvant chemotherapy in very young children (<3 years, and especially <1 year old) is used to spare or delay RT. In prospective clinical trials, postoperative chemotherapy using combinations of etoposide, vincristine, cyclophosphamide, platinum derivatives, and/or high-dose methotrexate showed a response rate of 40% to 50%.[287-289]

Phase II studies in children with relapsing ependymomas yielded low response rates with either standard- or high-dose chemotherapy (HDC).[290,291] Platinum-based regimens seem superior to nitrosourea-based regimens, in terms of higher response rates, though they failed to show a difference in

terms of PFS and OS.[292,293] Metronomic regimens may yield longer control, specifically oral etoposide or TMZ.[294,295] Targeted agents, such as bevacizumab (with irinotecan or lapatinib), erlotinib, or sunitinib, showed no significant efficacy in unselected populations.[294,296-298] In combination with TMZ, lapatinib showed responses were higher in patients with elevated ErbB2 messenger RNA expression in tumor tissue in a single-arm phase II study in patients with recurrent intracranial and spinal ependymomas.

Results of Treatment

In modern series that utilized mostly local fields for patients with nondisseminated disease, 5-year survival is on the order of 70%.[276,285,299-302]

Several authors have attempted to identify variables associated with improved outcome in adults. Ferrante et al[300] analyzed 20 patients with the fourth ventricle ependymomas. The 5-year survival rate in patients older than 16 years was 60%. The use of postoperative irradiation was associated with a markedly improved 5-year survival of 68% versus 18% without RT ($P = .011$).

Reni et al reported on a series of 70 adult intracranial ependymomas and observed 5-year OS and PFS rates of 67% and 43%, respectively. Older age and supratentorial location were poor prognostic factors, and the use of postoperative RT was associated with improved PFS and a trend toward improved OS.

Metellus et al evaluated 114 adult patients with intracranial ependymoma and observed incomplete resection and supratentorial location to be significant predictors of recurrence and poor survival. For incompletely resected tumors, postoperative RT improved both OS and PFS. In a study of spinal myxopapillary ependymomas from the Rare Cancer Network,[303] the use of postoperative RT was an independent predictor of PFS.

A retrospective study of 23 adult patients with supratentorial ependymomas treated at Columbia-Presbyterian Medical Center with a variety of RT field sizes and doses (including SRS) showed a 5-year survival rate of 100% for hemispheric tumors and 73% for the third ventricular tumors.[302] Of interest, six patients with low-grade tumors did not

receive postoperative irradiation. Five remained free of recurrence during a mean follow-up period of 69 months.

Five-year survival was 62% for a French series of 34 adult patients with ependymoma, 17 of whom had anaplastic histology.[304] Gross total resection was performed in 27 patients. Half of the 34 patients were irradiated; 13 of these received local fields to a mean dose of 56 Gy. Univariable analysis showed that anaplasia and location in the brain parenchyma predicted poor outcome.

Evidence-Based Treatment Summary

1. Maximal surgical resection should be performed when feasible.
2. Postoperative RT is considered the standard, but no prospective trials have validated its role. CSI is used only in patients with disseminated disease.
3. The role of chemotherapy remains to be defined.

Medulloblastoma

Medulloblastoma is a relatively rare tumor in adults with an incidence of 0.5 per 100,000.[273,305] The majority arise in the 20- to 40-year age group. Adult medulloblastomas are more frequently located laterally than those in childhood (50% vs 10%) and are more frequently desmoplastic.[306] In addition, the incidence of severe anaplasia is lower than in the pediatric population.[307] Medulloblastoma is a densely cellular tumor with small, darkly staining ovoid cells with hyperchromatic nuclei and frequent mitoses. Homer Wright rosettes (clustered cells surrounding a central eosinophilic core) are characteristic. CSF dissemination may manifest as positive cytology or macroscopic seeding of the subarachnoid space and is not uncommon. Systemic spread is seen in approximately 5% of patients, mostly in the bone and bone marrow. Shunt procedures have been suggested as a cause, although modern series dispute this.[308]

In children, adverse prognostic factors include male gender and age less than 3 years.[309] Patients with total or near-total resections fare better than those with subtotal resection or biopsy only, and residual tumor greater than 1.5 cm^2 on postoperative scans is an adverse prognostic factor. Patients with

CSF spread have a worse prognosis. Patients are classified as "average risk" if there is less than 1.5 cm^2 residual tumor and no dissemination; patients with greater than 1.5 cm^2 residual and/or dissemination are considered "high risk."

Molecular analyses have identified four distinct subgroups that have now been defined in the 2016 revision to the WHO classification system.[240,310] WNT tumors most frequently occur in late childhood and adolescence, are rarely metastatic, and have a favorable prognosis, regardless of metastatic status. Most WNT tumors display classic medulloblastoma histology and nuclear localization of CTNNB1 (β-catenin), as detected by immunohistochemical staining.[311] Ongoing research has focused on therapeutic de-escalation for this favorable subtype, although prognosis of WNT tumors is worse in adults, relative to pediatric patients.[312] SHH tumors account for most of the infant and adult medulloblastomas and are rare in children. SHH tumors are typically found within the cerebellar hemispheres and have an intermediate prognosis. All nodular desmoplastic medulloblastomas can be characterized as SHH subgroup.[313] Non-WNT and non-SHH tumors are classified as group 3 or 4. Although there can be considerable overlap between these groups, group 3 tumors have characteristically poor prognosis. Group 3 tumors affect mostly infants and children, are rare in adults, commonly present with metastases, and are characterized by MYC amplification. Group 4 tumors can affect patients of all ages.

Treatment

All patients with nondisseminated medulloblastoma should undergo complete resection if feasible. In cases where extension into the brainstem precludes complete resection without significant morbidity, there is no benefit to complete surgical resection as compared to near-total resection.[314]

In general, the treatment guidelines for pediatric medulloblastoma detailed in Chapters 90 should probably be followed. Postoperative RT should begin within 28 to 31 days following surgical resection whenever possible. RT is delivered to the entire craniospinal axis followed by a boost to the tumor bed for average-risk patients and to the posterior fossa and gross metastatic disease for high-risk patients. Although there may be less

concern over long-term toxicity of full-dose CSI in adults as compared with children, adults treated for medulloblastoma with a mean dose to the whole brain of 35 Gy have been shown to have long-term cognitive deficits.[315] It may be reasonable to extrapolate from the pediatric experience and to treat healthy young adults with average-risk disease with reduced-dose CSI (23.4 Gy) as long as appropriate multiagent chemotherapy is administered. For average-risk patients, boost to the tumor bed plus a 1.5-cm margin (as opposed to whole posterior fossa) to 54 Gy is associated with equivalent event-free survival outcomes, although a reduction in CSI to 18 Gy (as opposed to 23.4 Gy) leads to inferior event-free survival.[316] Full-dose CSI (36 Gy) should be delivered in the setting of high-risk disease. This is then followed by a boost to the posterior fossa. Intracranial and spinal metastases should be boosted as well to total doses on the order of 45 to 50 Gy for spinal metastases and 50 to 54 Gy for intracranial metastases. Treatment is usually delivered at 1.8 Gy/d.

The role of adjuvant chemotherapy with lomustine, vincristine, and cisplatin in children with medulloblastoma is well established but remains unclear in adults. A series of 32 adults with medulloblastoma from Germany has shown a nonsignificant trend to prolonged survival with adjuvant chemotherapy.[317] The NOA-07 prospective trial of chemoradiotherapy for adult medulloblastoma demonstrated favorable event-free survival rate of 67%.[318] The ability to complete at least four cycles of adjuvant chemotherapy was dependent on age, with leukopenia being the most common toxicity. The standard regimen of lomustine, vincristine, and cisplatin seems poorly tolerated in adults compared to children.[318,319] To improve tolerance in adults, vincristine dosing frequency is reduced to twice weekly, the maintenance phase limited to six cycles, and/or cisplatin substituted by carboplatin. Other regimens based on cisplatin or carboplatin plus etoposide are also used in adult patients.[320] There are no data supporting HDC/ASCT to further improve outcome in adults with medulloblastoma.

The use of proton therapy has been associated with a meaningful reduction in hematologic and GI toxicity and should be considered when feasible for adult medulloblastoma.[92]

Evidence-Based Treatment Summary

1. Molecular classification has identified four distinct subtypes: WNT, SHH, group 3, and group 4.
2. Maximal surgical resection should be performed, where feasible.
3. Standard treatment consists of postoperative RT to the craniospinal axis followed by a boost to the tumor bed for average-risk disease and to the posterior fossa and any intracranial/spinal metastases for high-risk disease.
4. The use of chemotherapy generally follows the pediatric indications and guidelines.

Primary Central Nervous System Lymphoma

PCNSL is a non-Hodgkin lymphoma that is restricted to the CNS (brain, spinal cord, meninges, and eye) and accounts for less than 3% of primary intracranial malignancies. It occurs in two distinct patient populations: immunocompromised (HIV, post-transplant, etc) and immunocompetent. Immunodeficiency is the only known risk factor. Immunocompetent patients present typically in the sixth and seventh decades of life, whereas immunosuppressed individuals more commonly present in the third and fourth decades of life.

The majority of PCNSLs are B-cell lymphomas of intermediate or high grade that are indistinguishable from high-grade non-Hodgkin lymphomas occurring elsewhere in the body. In immunocompetent patients, PCNSL typically presents with one or multifocal (in 30%) mass lesions primarily located in the frontal lobes, corpus callosum, and deep periventricular brain structures. Although the lesions appear focal, diffuse involvement of the parenchyma is invariably present. As a consequence of this deep localization, patients usually present with cognitive dysfunction or personality change. Other symptoms include headache or focal neurologic dysfunction, such as hemiparesis or hemisensory loss; seizures are rare. Symptoms often progress over weeks to months before a diagnosis is made.

On MRI, PCNSL is hypointense on T1 and hypointense to isointense on T2/FLAIR sequences with variable surrounding edema. There is usually homogeneous enhancement with IV contrast. Ring enhancement is

uncommon, except in immunocompromised patients. The appearance on T2 sequences and lack of central necrosis help differentiate PCNSL from glioma.

Even with the "classic" imaging appearance, histology is essential for diagnosis. If PCNSL is suspected, stereotactic biopsy is the best approach; extensive resection does not improve survival. Corticosteroids should be held at presentation unless absolutely necessary (eg, impending brain herniation) because their "lytic" effect on lymphoma may lead to a false-negative biopsy. Once a diagnosis of PCNSL is established, an extent of disease workup is required. At diagnosis of PCNSL, ocular disease is present in 20% (often misdiagnosed as idiopathic uveitis), and demonstrable leptomeningeal disease is present in 25% (usually asymptomatic until late). A complete staging workup consists of contrast-enhanced brain MR, lumbar puncture (for CSF cytology, flow cytometry, and Epstein-Barr virus PCR), slit-lamp ocular examination (to look for intraocular lymphoma), HIV serology, and contrast-enhanced spine MRI. Systemic staging (body CT, bone marrow biopsy) is rarely positive in patients with typical findings of CNS lymphoma but should be performed if systemic symptoms are present (weight loss, night sweats, and fever).

Age and performance status are the most important prognostic factors. An RPA analysis of 338 patients at Memorial Sloan-Kettering Cancer Center led to the identification of three RPA classes: class I (age <50) was associated with a median survival of 8.5 years; class II (age >50 years and KPS ≥70) 3.2 years; and, class III (age >50 and KPS < 70) 1.1 years.[321] The International Extranodal Lymphoma Study Group evaluated 378 patients and observed age less than 60, ECOG less than 1, elevated lactate dehydrogenase, high CSF protein, and deep regions of the brain as prognostic.[322]

Molecular analyses have identified activating mutations in MYD88 and CD79B in PCNSL, which are important in the Bruton tyrosine kinase (BTK) pathway.[323] BTK integrates B-cell antigen receptor (BCR) and Toll-like receptor (TLR) signaling. Diffuse large B-cell lymphomas (DLBCL), which include PCNSL, frequently harbor mutations in genes encoding members of the BTK pathway. These include the BCR-associated protein CD79B and myeloid differentiation primary response 88 (MYD88), a

cytosolic adapter protein that links IL-1 and TLRs with the nuclear factor κB.

Treatment

The role of surgery is limited to establishing the tissue diagnosis, typically by stereotactic biopsy. Extensive tumor resection offers questionable survival benefit based on a meta-analysis of the extent of surgery.[324] Because PCNSL often responds dramatically to corticosteroid therapy, corticosteroids should be avoided unless absolutely necessary until after tissue is obtained.

PCNSL is exquisitely sensitive to RT and chemotherapy. Although never studied in a prospective manner, WBRT is thought to be more effective than focal RT because of the extensive infiltration of lymphoma throughout the brain. The optimal dose is 45 to 50 Gy, and there is no benefit of adding a boost to the tumor site. With WBRT alone, the median survival is 12 to 18 months and the 5-year survival rate is only 4%.

The standard systemic lymphoma chemotherapy regimens are ineffective for PCNSL, as demonstrated in prospective clinical trials.[325-327] High-dose systemic methotrexate, administered at a high dose (1-8 g/m^2) and at a rapid rate of infusion to overcome the BBB, is the only agent that has demonstrated improved survival over WBRT alone. A randomized phase II study suggested that combination chemotherapy with methotrexate results in superior disease control and survival as compared to single-agent methotrexate.[328] High-dose methotrexate regimens produce adequate levels of drug in the CSF so that direct instillation of chemotherapy (eg, using an Ommaya reservoir) into the CSF is not necessary unless CSF cytology is positive.[329]

WBRT is typically used as postchemotherapy consolidation in patients younger than 60 years, as a salvage strategy for recurrence, or as upfront therapy alone for patients with poor performance status (KPS <40) or renal failure. Patients aged 60 years or above are at high risk of developing treatment-related neurotoxicity following treatment with methotrexate and WBRT; WBRT is often deferred in this subgroup, except for recurrence.

Neurotoxicity after PCNSL treatment is characterized by dementia, ataxia, and urinary incontinence, occurring at a mean of 7 months from

treatment. Both methotrexate and RT can cause this syndrome, and the combination is synergistic. The risk is greatest in patients aged 60 years or above at diagnosis and when methotrexate is administered concurrently or following RT. In one phase II trial, patients aged 60 years or above had a 100% incidence of neurotoxicity at 24 months, whereas those younger than 60 years had a 30% incidence at 96 months.[330]

The commonly used RT schedule for PCNSL in immunocompetent patients is 40 to 45 Gy to the whole brain. The posterior orbits should be included in the whole-brain fields. In patients with ocular involvement, the whole eye can be treated to 30 to 40 Gy, with shielding of the anterior chamber and lacrimal apparatus after this dose. However, most treating physicians reserve the use of ocular RT for failure of intravitreal methotrexate and rituximab. CSI has been advocated for patients with documented CSF involvement. However, intrathecal chemotherapy is preferred because it may be equally efficacious but less toxic with less impact on bone marrow reserve. RT dose reduction, especially in patients responding to chemotherapy, has been tested in a randomized trial and demonstrates a significantly positive impact on PFS, in that addition of low-dose WBRT to chemotherapy improved PFS.[331]

For immunosuppressed patients with PCNSL, modification of the irradiation dose and schedule may be necessary. Patients with poor prognostic features (low KPS, CD4 counts <200, advanced acquired immunodeficiency syndrome [AIDS]) may be treated with an abbreviated course of RT (eg, 36-40 Gy).

Results of Treatment

Unlike non-CNS lymphoma, there appears to be an RT dose response with a threshold between 30 and 50 Gy, with a median of 40 Gy. A study by Bessell et al[332] showed a higher relapse rate and reduced survival rate in patients who received 30.6 Gy WBRT as compared to 45 Gy in patients who had CR to chemotherapy. This was significant for patients younger than 60. However, radiation doses beyond 45 to 50 Gy are associated with a plateau in radiation response. The RTOG conducted a phase II study (RTOG 83-15) to evaluate WBRT as first-line treatment. Median survival was 12 months and recurrence in the brain occurred in 61% of patients,

with more relapses in the 60 Gy region, suggesting no clear dose response over 40 Gy.

The most widely used treatment regimen is based on a phase II study (RTOG 93-10) that treated 102 patients with newly diagnosed PCNSL with five cycles of high-dose methotrexate (2.5 g/m^2), vincristine, and procarbazine followed by 45 Gy WBRT and high-dose cytarabine (3.0 g/m^2) postradiotherapy.[333] Approximately halfway through the study, the dose of WBRT was decreased to 36 Gy delivered by hyperfractionation to those that achieved a CR after preradiotherapy chemotherapy. In all, 58% of patients achieved a CR, and 36% had a PR after preradiotherapy chemotherapy. Median PFS and OS was 24 and 37 months, respectively.

Long-term results with various combination chemotherapy regimens that include IV and intrathecal methotrexate, cranial RT, and IV cytarabine have been encouraging, especially in patients younger than 50 years (5-year survival rate of 60%). In older patients (>50 years), results are poor (5-year survival of rate of <10%) and toxicity is greater with dementia and ataxia in a substantial proportion of patients.[334]

Chemotherapy is also effective without RT or as a means of delaying RT, particularly in patients over age 60 years because of their substantial risk to develop treatment-related neurotoxicity.[335] CRs occur in more than 50% of patients. Single-agent methotrexate using a dose of 8 g/m^2 had a high response rate, but responses were relatively short in duration with a median PFS of approximately 1 year.[336]

Eliminating WBRT from treatment regimens results in higher recurrence incidence but does not translate into an OS detriment. The German PCNSL phase III trial randomized 524 patients to high-dose methotrexate-based chemotherapy with or without WBRT to 45 Gy in 1.5-Gy fractions.[337] The addition of upfront WBRT significantly prolonged PFS, especially among patients who did not achieve a CR following chemotherapy, but no significant OS benefit was noted. In patients with disease less sensitive or insensitive to high-dose methotrexate, WBRT seems more effective than high-dose Ara-C a salvage strategy. The addition of upfront WBRT led to greater impact in patient-reported cognitive functioning and global health status, as well as lower values on Mini-Mental Status Examination.[338]

Current work is focusing on methods to eliminate or reduce the risk of neurotoxicity without compromising long-term disease control. Shah et al[339]

reported a phase II study evaluating the effectiveness and toxicity of reduced-dose WBRT (23.4 Gy) in patients who achieved a CR following methotrexate-based chemotherapy. The estimated 2-year OS and PFS in these 19 patients was 89% and 79%, respectively. At a follow-up of 12 months, none of the patients treated with reduced-dose RT developed treatment-related dementia on neurocognitive studies. This approach was further evaluated in a multicenter phase II study of rituximab, methotrexate, procarbazine, and vincristine (R-MVP) followed by consolidative WBRT to 23.4 Gy in patients who achieve a postchemotherapy CR.[340] Consolidative cytarabine was given after RT. Among 52 patients enrolled, 60% achieved a CR after R-MVP, with a 2-year PFS of 77% and a 3-year OS of 87%. Cognitive assessments demonstrated improvement in executive function and verbal memory after R-MVP with stability of follow-up scores.

In RTOG 1114, 91 patients were randomized to receive R-MPV-A alone or combined with low-dose WBRT (23.4 Gy, 180cGy × 13). Methotrexate was dosed as 3.5 g/m^2 in 2-hour infusions. Radiographic CR rates improved from 76.3% for chemotherapy alone to 92.3% with WBRT consolidation. After a median follow-up of 4.6 years, median PFS was not reached (chemoradiation) versus 2.1 years (chemotherapy), HR = 0.47 (P = .007). The 2-year PFS was 78.7% versus 54%. The OS HR numerically favored chemoradiation but did not reach statistical significance (HR 0.71; P = .33). Comprehensive neuropsychological evaluation showed no differences in cognitive outcomes, with several tests intriguingly favoring chemoradiation, suggesting enhanced tumor control may aid in maintaining cognition.[331]

The use of HDC/ASCT in patients with newly diagnosed PCNSL is another strategy that has been explored as an alternative to WBRT. Available data are limited to a few small, nonrandomized phase 2 studies.[341] In a single-institution study, patients who developed a CR or PR to R-MVP proceed with HDC with thiotepa, cyclophosphamide, and busulfan, followed by ASCT.[342] In transplanted patients, 2-year PFS and OS were 81%. Two clinical trials (NCT00863460) randomized patients to consolidative WBRT versus HDC/ASCT to establish the most effective consolidation strategy.

The International Extranodal Lymphoma Study Group-32 trial was an international randomized phase 2 unblinded study randomizing to methotrexate, cytarabine, thiotepa, and rituximab (MATRix) compared to

other induction combinations. The study also secondarily randomized myeloablative chemotherapy followed by ASCT versus WBRT as consolidation after high-dose methotrexate-based chemoimmunotherapy for 227 patients with newly diagnosed PCNSL (NCT01011920).[343,344] HIV-negative patients (aged 18-70 years) with ECOG status of 0 to 3 received four courses of methotrexate 3.5 g/m^2 on day 1 plus cytarabine 2 g/m^2 BID on days 2 and 3 (group A); or the same combination plus two doses of rituximab 375 mg/m^2 on days −5 and 0 (group B); or the same methotrexate-cytarabine-rituximab combination plus thiotepa 30 mg/m^2 on day 4 (group C), all repeating treatment every 3 weeks. Of the 219 (97%) evaluable, patients treated with rituximab and thiotepa had a complete remission rate of 49% (95% CI: 38%-60%), compared with 23% (14%-31%) of those treated with methotrexate- cytarabine alone (HR 0.46, 95% CI: 0.28-0.74) and 30% (21%-42%) of those treated with methotrexate-cytarabine plus rituximab (0.61, 0.40-0.94). Grade 4 hematologic toxicity was more frequent in patients treated with methotrexate-cytarabine plus rituximab and thiotepa, but infective complications were similar. The most common grade 3-4 adverse events in each arm were neutropenia, thrombocytopenia, anemia, and febrile neutropenia or infections. In all, 13 (6%) patients died of toxicity. MATRix was deemed the most effective induction regimen for patients aged up to 70 years. Patients with responsive or stable disease after induction, with adequate autologous peripheral blood stem cell collection, and without persistent unresolved significant toxicities were further randomized between WBRT started within 4 weeks from the end of induction and carmustine-thiotepa conditioned ASCT (carmustine 400 mg/m^2 on day −6, and thiotepa 5 mg/kg every 12 h on days −5 and −4, followed by reinfusion of autologous peripheral blood stem cells). A permuted block randomized design was adopted for serial randomizations using a computer- generated randomization within each stratum. Of the 122 (54%) of 227 eligible patients, 118 (97%) of 122 were equally randomized to WBRT or ASCT (59 patients in each group). WBRT and ASCT were both effective, with no significant differences in 2-year PFS of 80% (95% CI: 70%-90%) and 69% (59%-79%), respectively (HR = 1.50, 95% CI: 0.83-2.71; P = .17). Grade 4 nonhematologic toxicity was uncommon, but more common with ASCT

than with WBRT. Two toxic deaths (infections) were recorded, both in patients who received ASCT.

Initial and long-term results of the Intergroup ANOCEF- GOELAMS randomized phase II PRECIS study similarly compared WBRT versus HDC (thiotepa-busulfan-cyclophosphamide) plus ASCT consolidation after high-dose methotrexate-based induction chemotherapy for 140 patients aged 60 years or below.[345,346] Both WBRT and ASCT met the predetermined threshold, PFS at 2 years were 63% (95% CI, 49%-81%) and 87% (95% CI, 77%-98%), respectively. Toxicity deaths were recorded in one and five patients after WBRT and ASCT, respectively. Cognitive impairment was observed after WBRT, whereas cognitive functions were preserved or improved after HDC/ASCT. The long-term data (median follow-up, 8 years) showed 8-year event-free survival from random assignment was 67% and 39% in the ASCT and WBRT arms, respectively (P = .03), with a significantly lower risk of relapse after ASCT (HR = 0.13; P < .001). Five and four patients died of ASCT- and WBRT- related toxicities, respectively. The 8-year OS was 69% and 65% in the ASCT and WBRT arms, respectively (not significant), but neurocognition (64% vs 13%, P < .001) was significantly deteriorated after WBRT compared with ASCT at the last follow-up. This study suggested 40 Gy WBRT is less preferable as first line due to increased neurotoxicity and suboptimal PFS, despite similar OS. In practice, the declining interest in WBRT by patients and providers, due to the risks on cognition, has led to increases in HDC/ASCT in select candidates, especially younger, healthier, and higher functioning patients.

Ibrutinib is a first-in-class, oral inhibitor of BTK. Ibrutinib induces death of DLBCL cells with deregulated BCR signaling and has shown promising activity in a variety of B-cell malignancies, with 70% to 90% response rates in patients with chronic lymphocytic leukemia, small lymphocytic lymphoma, mantle cell lymphoma, and Waldenström macroglobulinemia, but only about 25% response rates in relapsed/refractory DLBCL.[347] In a phase 1-2 study, ibrutinib was administered to 20 patients with relapsed or refractory PCNSL or secondary CNS involvement. Patients received ibrutinib at 560 or 840 mg QD in the dose escalation portion of the study and 840 mg QD in the expansion portion. Responses were observed in 15 (75%) of 20 patients; 10 of these had CR. For PCNSL, the response rate was 77%. Ibrutinib CSF concentrations 2 hours postdose were 0.77 ng/mL

(1.7 nM) and 1.95 ng/mL (4.4 nM) in the 560 and 840 mg groups, respectively, demonstrating a dose-dependent increase in CSF penetration, and levels sufficient to induce cell death in CNS lymphoma cells in culture. Upon mutational analysis, many tumors harbored mutations in the BTK pathway, but tumors without such mutations also responded. Ibrutinib, therefore, has substantial activity in patients with relapsed or refractory B-cell lymphoma of the CNS and is being further developed for front-line testing.[348]

Second-generation BTK inhibitors are in clinical testing for PCNSL.[349,350] A single-center retrospective analysis of 14 patients with CNS DLBCL treated with high-dose methotrexate, thiotepa, and second-generation BTK inhibitor orelabrutinib combined with or without rituximab concluded that this PCNSL treatment approach was efficacious and well tolerated. Median follow-up time was 12.8 months. For PCNSL, the CR and overall response rates were 55.6% and 88.9%, respectively. Grade 3 adverse events occurred in five patients (35.7%), were all hematologic, and did not lead to discontinuation of treatment.

In patients with immunosuppression and PCNSL, results are discouraging, although selected patients (non-HIV immunosuppression, favorable prognosis patients with AIDS) may have survival comparable with that of nonimmunosuppressed populations when treated in a standard manner.[351]

Evidence-Based Treatment Summary

1. Surgical resection is not necessary.
2. Avoiding or deferring WBRT results in inferior PFS but without significantly impacting OS. Lower dose WBRT added to aggressive chemotherapy improves radiographic CR rates and PFS. Neurocognitive dysfunction appears to be largely driven by disease recurrence.
3. High-dose systemic methotrexate is the only agent that has demonstrated improved survival over WBRT alone. High-dose methotrexate-based chemotherapy followed by WBRT is the standard treatment for patients younger than 60 years with a good performance status. Patients who achieve CR with high-dose methotrexate-based

chemotherapy should be treated with WBRT to a reduced dose of 23.4 Gy in 1.8-Gy fractions.

4. High-dose methotrexate-based chemotherapy alone with deferred RT may be preferred in older patients because of substantial risk of neurotoxicity associated with combined chemotherapy-RT regimens.
5. WBRT alone should be pursued for patients who are not candidates for chemotherapy.

Meningioma

Meningiomas account for approximately 30% of primary intracranial neoplasms and are the most common benign intracranial tumors in adults.[273] The peak age of incidence is in the sixth and seventh decades, although they may occur at any age. They are more common in women. Typical locations for meningiomas include the cerebral convexities, falx cerebri, tentorium cerebelli, cerebellopontine angle, and sphenoid ridge. Malignant varieties with invasive growth and aggressive behavior occasionally occur.

Grossly, meningiomas are well-circumscribed, firm, tan, or grayish lesions arising from the meninges. Hyperostosis of adjacent bone may be present. Microscopically benign meningiomas usually have a bland whorled appearance with little anaplasia or mitotic activity. Psammoma bodies may be present. Histologic variants (eg, fibrous, transitional, angiomatous) can be identified but are of little prognostic significance. Malignant varieties are identified on the basis of clinical behavior (rapid growth or recurrence, invasiveness) or pathologic features such as microscopic features of malignancy (cellular or nuclear anaplasia, mitotic figures) or specific histologic type (rhabdoid, papillary, anaplastic). The 2007 updated WHO grading criteria incorporate mitotic activity, nuclear-to-cytoplasmic ratio, spontaneous necrosis, brain invasion, and certain meningioma variants to assign grades I through III.[351] Benign meningiomas (~78%-80%) are classified as WHO grade I and associated with slower growth and lower risk of recurrence, atypical meningiomas (20%) WHO grade II with an increased likelihood of aggressive behavior, and anaplastic or malignant gliomas (3%-5%) WHO grade III and associated with high invasiveness and the worst prognosis. The 2016 update to the WHO classification system introduced brain invasion as a criterion that, similar to mitotic count of 4 or

more, can alone suffice for the diagnosis of an atypical WHO grade II meningioma.[240] The 2021 update to the WHO classification system most notably incorporated molecular information, adding *TERT* promotor (*pTERT*) mutation and homozygous deletion of *CDKN2A* and/or *CDKN2B* as grade III criteria, and removed papillary and rhabdoid meningiomas as grade III criteria that previously were present in the WHO 2016 system (Table 40.7).

TABLE 40.7 2021 WHO CLASSIFICATION OF MENINGIOMA[352]

Grade I (Benign)	Grade II (Required for Atypical)	Grade III (Required for Anaplastic/Malignant)
Does not fulfill criteria for grade II or III	Frequent mitoses (4-19 mitotic figures in 10 consecutive HPFs of each 0.16 mm^2, at least 2.5/mm^2) *or* Unequivocal brain invasion (not only perivascular spread or indentation of brain without pial breach) *or* Specific morphologic subtype: Chordoid meningioma, or Clear cell meningioma *or* Three or more of the following: Hypercellularity Small cells with high nuclear-cytoplasmic ratio Prominent nucleoli Sheeting architecture (uninterrupted patternless or sheet-like growth) Foci of spontaneous (noniatrogenic) necrosis	Excessive mitotic index (≥20 mitotic figures in 10 consecutive HPF of each 0.16 mm^2, at least 12.5/mm^2) *or* Frank anaplasia, meaning appearance resembling: Sarcoma Carcinoma, or Melanoma *or* *TERT* promotor (*pTERT*) mutation[a] *or* Homozygous deletion of *CDKN2A* and/or *CDKN2B*[a]

HPF, high-power field; WHO, World Health Organization.

[a]In the 2021 WHO classification, unlike the 2016 WHO classification, papillary and rhabdoid meningiomas have been removed from grade III criteria and can be any grade, and *pTERT* mutation or homozygous deletion of *CDKN2A* and/or *CDKN2B* are new, independent grade III criteria. WHO grades II and III criteria can apply to all meningioma subtypes. However, WHO grade II criteria are necessary for an atypical meningioma diagnosis, and WHO grade III criteria are necessary for an anaplastic (malignant) meningioma diagnosis.

Meningiomas are known to be induced by ionizing radiation, with an average interval to diagnosis of 19 to 35 years, depending on the dose of radiation. They may be multiple, particularly in patients with NF2 and in non-NF2 families with a hereditary predisposition to meningioma.

The most common cytogenetic alteration in meningiomas involves a deletion of chromosome 22. Molecular genetics findings indicate that approximately 50% of meningiomas have allelic losses that involve band q12 on chromosome 22. Allelic losses of chromosomal arms 6q, 9p, 10q, and 14q are seen in both atypical and anaplastic meningiomas. Genetic and cytogenetic alterations accumulate with progression from WHO grade I to WHO grade III lesions. Mutations in the *NF2* gene have been detected in 60% of sporadic meningiomas. The cumulative effect of NF2 mutations or copy number alterations affecting chromosome 22 is the loss of activity/function of a tumor suppressor protein, Merlin (Moesin-ezrin-radixin-like protein) encoded by the gene *NF2*. More recent genomic analysis of meningiomas reveals that in the 40+% of tumors without chromosome 22 loss or NF2 mutation, other somewhat uncommon, but potentially targetable mutations can be identified. In a whole-genome or whole-exome sequencing on 17 meningiomas and focused sequencing on an additional 48 tumors, most meningiomas were found to have "simple genomes," with fewer mutations, rearrangements, and copy number alterations than reported in other CNS tumors in adults. This study confirmed focal *NF2* inactivation in 43% of tumors and found alterations in epigenetic modifiers of NF2 in an additional 8% of tumors. A subset of meningiomas lacking *NF2* alterations harbored recurrent oncogenic mutations in *AKT1* and *SMO* with immunohistochemical evidence of activation of these pathways. These mutations are linked to the potential for identifying targeted therapeutics for some meningiomas.[353] A recent analysis of 274 high-grade meningiomas compared to 456 low-grade meningiomas concluded that high-grade meningiomas actually have a higher mutation burden, but no statistically significant mutated genes other than *NF2* could be identified.[354]

In an analysis of the histologically aggressive variant, rhabdoid meningiomas, designated in the WHO classification as high grade, sequencing of cancer-related genes in 27 meningiomas from 18 patients with rhabdoid features was performed, findings from which led to

specifically evaluating the breast cancer (BRCA)1-associated protein 1 (BAP1) expression by immunohistochemistry in 336 meningiomas. The tumor suppressor gene *BAP1*, a ubiquitin carboxy-terminal hydrolase, was found to be inactivated in a subset of high-grade rhabdoid meningiomas. Patients with BAP1-negative rhabdoid meningiomas had reduced time to recurrence compared with patients with BAP1-retained rhabdoid meningiomas, and a subset of patients with BAP1-deficient rhabdoid meningiomas harbored germline BAP1 mutations, indicating that rhabdoid meningiomas could be a harbinger of the BAP1 cancer predisposition syndrome.[355] These findings are beginning to provide clues toward the goal of identifying actionable mutations in meningioma.

The incidental finding of a meningioma on CT or MRI is not uncommon, particularly in the older patients. Many patients with meningioma are asymptomatic and may remain so for a long time.[356,357] Lesions in the cerebellopontine angle commonly present with symptoms of cranial neuropathy. Cerebral convexity meningioma may present with symptoms of headache or a seizure. Meningiomas of the sphenoid wing or optic nerve may be associated with visual loss. The differential diagnosis of meningioma in the base of the skull or spine includes bone metastasis or primary bone tumors (chondrosarcoma, chordoma, osteosarcoma). In the cerebellopontine angle, acoustic neuromas may resemble meningiomas on imaging.

The near ubiquitous expression of SSTRs on meningiomas has led to interest in developing PET imaging techniques targeting these receptors with somatostatin analogs conjugated to positron emitters, for example, ^{68}Ga-DOTATATE. In a recent RANO publication, ^{68}Ga-DOTATATE PET imaging was encouraged in patients with meningioma, with the expectation that it could impact multiple domains, including confirmation of diagnosis when in doubt, staging in the rare event of distant metastatic disease, support superior definition of targeting, either for resection or RT planning, and potentially for response assessment.[358]

Meningiomas typically grow slowly. In 47 asymptomatic patients with meningioma diagnosed incidentally by MRI, Nakamura et al[359] reported a mean annual growth measured using serial MRI of 14.6% and a mean tumor doubling time of 21.6 years. Higher annual growth rates were seen in young patients and lower annual growth rates in patients with calcification

and hypointense or isointense T2 signals on MRI. The location of the lesion, extent of surgical resection, and histopathologic features of the tumor (benign or malignant) are the most important determinants of prognosis.[360]

After surgery, the average time to recurrence is approximately 4 years. In a review of 38 patients who underwent subtotal resection, the mean diameter increase was 0.37 cm/y and mean tumor doubling time was 8 years.[361]

Treatment

Grade I Meningioma

Patients with asymptomatic lesions may be observed and followed with serial imaging. The treatment of choice for symptomatic or progressive benign meningiomas is complete surgical resection if it can be accomplished with acceptable morbidity. Resection of these typically vascular tumors may be facilitated by preoperative angiography with or without embolization. Even after complete resection, 7% to 12% of these tumors recur at 5 years and 20% to 25% recur at 10 years[362,363] so that follow-up with serial imaging is necessary.

Complete resection of skull-based, cerebellopontine angle, or cavernous sinus meningiomas may be difficult without significant morbidity. Subtotal resections are associated with higher relapse rates of 39% to 47% at 5 years and 60% to 61% at 10 years without adjuvant therapy.[362,363] For these patients, conservative subtotal resection followed by postoperative irradiation may give good local control with less morbidity than an aggressive base of skull resection. An alternative approach for patients who have undergone subtotal resection is follow-up with further surgery, if feasible, and RT delayed to time of recurrence.

In patients with subtotally excised unresectable or recurrent meningiomas, the typical RT dose is 50 to 54 Gy in 25 to 30 fractions over 5 to 6 weeks. The target volume for RT is defined by CT or MRI scan and modified according to the neurosurgeon's description of the location of residual tumor. SSTR-PET imaging with ligands such as ^{68}Ga-DOTATATE or ^{68}Ga-DOTANOC can be useful to identify tumor margins, particularly in the skull base where there are other anatomic structures that enhance with

MRI-based contrast agents, thereby creating uncertainty as to whether the signal seen on MRI is tumor versus a normally enhancing structure.[358] However, this approach has not yet been widely adopted into practice in the United States due to the limited insurance coverage for this type of imaging. The margin expansion for meningiomas is based on the knowledge of direction of spread, especially through neural foramina, bony invasion, dural tails, and so forth. The GTV is the enhancing abnormality on contrast-enhanced MRI. Margin expansions then incorporate setup errors and block margins; these can vary from 0.5 to 1 cm in total depending on the precision of the immobilization and delivery systems. Multiple fields with wedges or rotational fields and 3D conformal techniques are used for maximal sparing of normal brain tissue. IMRT or proton therapy may be helpful in avoiding adjacent surrounding structures.

Postoperative irradiation after less than complete resection improves local control, prolongs the interval to recurrence, and improves survival. In series by Condra et al,[362] subtotal resection with postoperative irradiation had a local control rate of 87% at 15 years compared to 76% following total excision and 30% after subtotal excision (P = .0001). In modern series using MRI and CT localization, 5-year local control is reported to be more than 90%.[364]

Radiosurgery as the sole modality or as postoperative adjuvant therapy may be of interest for selected patients, generally those with smaller tumors. In recent series, 5-year PFS rates are more than 80%.[365-369] In a recent single-institutional study, 85 patients eligible for a potential Simpson grade 1 or 2 resection were treated with SRS (usually because of preference). These patients received SRS either because of radiographic evidence of growth (72%) or due to postoperative recurrence (28%). With a mean follow-up of 69 months, the estimated 2-, 5-, and 10-year local control rates were 99%, 93%, and 93%, respectively, results that compare well with surgical series.[370]

Chemotherapy has not been useful in the treatment of benign meningiomas. Given the high estrogen and progesterone receptor expression on meningiomas, progesterone receptor antagonists have been tested but have not been found beneficial.

Grade II and III Meningiomas

For atypical or malignant meningiomas, the recurrence rate after surgery alone is high (41%-100% at 5 years), even after complete surgical resection,[371] and postoperative irradiation after maximal resection is recommended for all patients. The target volume is more generous than that used for benign meningiomas. The GTV and/or resection bed are typically expanded by 0.5 to 1.0 cm along the dural margin and into brain parenchyma in cases of brain invasion. The recommended dose is on the order of 54 to 59.4 Gy in 30 to 33 fractions for atypical meningioma and 59.4 Gy in 33 fractions for malignant meningioma, although some have reported improved local control with higher doses.[372]

RTOG 0539 enrolled 52 patients into an intermediate-risk cohort comprising WHO grade II tumors with gross total resection (70%) and recurrent WHO grade I tumors (30%) and treated with fractionated RT to 54 Gy.[372] The 3- and 5-year PFS were 92% and 84%, respectively, comparable to PFS estimates following observation of resected WHO grade I meningioma observed in the same trial. In a National Cancer Database analysis, the use of adjuvant RT for subtotally resected WHO grade II meningioma improved OS.[373] In the setting of gross totally resected WHO grade II meningioma, two randomized trials seek to address whether adjuvant RT prolongs PFS and OS.[374]

In a review of 38 patients with malignant meningiomas by Dziuk et al,[371] the use of postoperative RT resulted in superior local control. At 5 years, irradiation following initial resection improved 5-year disease-free survival from 15% to 80% (P = .002). PFS was 57% in patients treated with total resection and RT compared to 28% in patients treated with total resection alone.

Deng et al conducted a prospective phase 2 trial investigating bimodal RT using photons (50 Gy in 25 fractions) with carbon-ion boost involving 18 Gy (relative biologic effectiveness) in 6 fractions for 33 patients with WHO grade 2 meningiomas following subtotal resection. At 3 years, PFS, local PFS, and OS estimates were 80.3%, 86.7%, and 89.8%, respectively.[375]

Systemic therapy has no defined role. Combined chemotherapy with vincristine, adriamycin, and cyclophosphamide has shown some efficacy in

patients with malignant meningiomas.[376]

Unresectable or Recurrent Meningioma

In patients in whom aggressive surgery is not an option, RT may relieve symptoms and decrease the rate of tumor progression.

RT may be useful in the treatment of recurrent meningioma. In a review by Miralbell et al,[377] PFS at 8 years for patients treated with subtotal resection and RT at first recurrence was 78% compared to 11% in patients treated with resection alone ($P = .001$).

Various chemotherapy treatments that have been used in patients with recurrent meningiomas include combined doxorubicin and dacarbazine or ifosfamide and mesna.[378] Long-term, low-dose daily hydroxyurea may have some activity.[379]

Hormonal manipulation, including tamoxifen and the antiprogesterone drug RU486, showed some activity in a SWOG phase II evaluation of tamoxifen in unresectable or refractory meningiomas.[380] However, a subsequent SWOG phase III study of mifepristone for unresectable meningioma was negative.[381]

The EORTC recently reported results from a randomized open-label multicenter comparative phase II trial of trabectedin, which failed to demonstrate sufficient antitumor activity against recurrent grade II or III meningioma to justify further investigation in phase III or as adjuvant therapy for newly diagnosed disease after resection and RT.[382]

The Alliance for Clinical Trials in Oncology is currently conducting a trial of targeted agents selected by the presence of specific mutations in recurrent/progressive meningioma. In this three-arm phase II trial, patients with NF2 would be treated with vismodegib, those with SMO mutations with the focal adhesion kinase (FAK) inhibitor GSK2256098, and those with AKT mutations with a PI3 kinase pathway inhibitor.

Evidence-Based Treatment Summary

1. Small asymptomatic meningiomas in noncritical locations, especially in the older patients or in patients with other comorbidities, can be observed.

2. The goal of surgery is to completely resect the meningioma, with negative margins as patients with WHO grade I completely resected meningiomas have low rates of relapse and can be observed postoperatively.
3. For subtotally resected or unresectable progressive meningioma, RT is frequently used but has not been tested in a prospective clinical trial. Local control appears to be improved with postoperative RT. Both radiosurgery and RT have been used in this context, but have not been directly compared.
4. For grades II and III meningioma, postoperative RT is routinely recommended.
5. Primary RT or radiosurgery could be used for unresectable, progressive meningiomas.
6. Systemic therapy does not have a defined role in meningioma.

Craniopharyngioma

Craniopharyngiomas arise from epithelial remnants of the Rathke pouch and are typically found in the suprasellar region in children or adolescents. They account for less than 5% of all CNS neoplasms in adults. They are slowly growing tumors that often have solid and cystic components, the latter filled with lipoid, cholesterol-laden ("crankcase oil") fluid. Although appearing well encapsulated, craniopharyngiomas typically demonstrate invaginations into adjacent brain and may provoke a vigorous glial reaction.

The cystic nature of craniopharyngiomas is usually evident on CT and MRI and helps distinguish these tumors from other base of skull lesions and pituitary adenomas. The solid portion is often calcified and enhancing, whereas the cystic portion typically demonstrates a thin rim of enhancement. The finding of multiple cysts of varying intensity on T1- and T2-weighted MRI is characteristic of craniopharyngioma.

Intrasellar lesions may compress the pituitary gland and hypothalamus, producing hormonal abnormalities, especially antidiuretic and growth hormone deficits. Prechiasmal lesions may compress the optic pathway, leading to visual field cuts or decreased central visual acuity. Retrochiasmal lesions may grow into the third ventricle and cause hydrocephalus or

compress the optic tracts. Craniopharyngiomas can occasionally reach enormous size and produce neurologic impairment by direct impingement on brain parenchyma. Surgical decompression is the optimal treatment for rapid symptom relief. However, the location, proximity, and adhesiveness of the tumor to adjacent structures often preclude complete resection.

Treatment

A discussion of craniopharyngioma in the pediatric context is provided in Chapters 90. Management options include complete resection, subtotal resection alone, or subtotal resection or biopsy followed by postoperative RT.

Complete surgical resection, which is applicable only to a minority of patients, is associated with local control and long-term survival in 70% to 90% of patients.[383] However, aggressive resection may be associated with significant morbidity, with up to a 10% incidence of perioperative mortality and up to 30% severe morbidity, especially diabetes insipidus or other endocrine deficits, visual impairment, obesity, and memory impairment.

Partial resection or cyst aspiration and biopsy rapidly relieve local compressive symptoms and have less operative morbidity but are associated with eventual tumor progression in most cases. Long-term survival and local control are achieved only in approximately 30% of patients. In contrast to aggressive resections, subtotal resections carry a mortality of about 1%.

With a limited surgical procedure (partial resection or cyst aspiration plus biopsy) followed by RT, local control and survival rates are nearly equivalent to those achieved with complete resection, with survival rates of 89% and 77% at 5 and 10 years, respectively, as compared with 53% to 37% for patients who have had subtotal resection alone. Typically, doses of 50.4 to 54 Gy in 28 to 30 fractions (1.8 Gy) are delivered to the postoperative residual tumor and the borders of preoperative tumor extent with a 1- to 1.5-cm margin depending on the accuracy of the imaging used for planning and the reproducibility of the treatment setup. Reduction of margins to 0.5 cm can be considered when weekly MRI during treatment is used to monitor intratumoral cystic changes. In patients with compressive symptoms, surgical decompression before irradiation is essential because

the tumor typically responds slowly to RT, and radiation-induced edema may worsen compressive symptoms.

With these dose recommendations (ie, 1.8-Gy fractions to 50-54 Gy), the risk of visual impairment is very low (1% and 1.5%). In a retrospective analysis of patients treated with 51.3 to 70 Gy, a higher incidence of radiation-related complications was seen in those who received more than 60 Gy (with an actuarial incidence of optic neuropathy of 30% and brain necrosis of 12.5%), without any concomitant improvement in tumor control.[384]

RT may be given as salvage rather than immediately after subtotal resection. In a series of 76 patients treated at the University of Pennsylvania, long-term survival rates were equivalent.[385] In another series, RT given at recurrence yielded a 10-year PFS rate of more than 70%.[386] Recurrences occur from 3 to 192 months (median 12 months) after subtotal resection so that close surveillance is necessary during the first years following incomplete resection.

Other modalities used in the treatment of craniopharyngioma have included intralesional bleomycin and radioactive colloid instillations for cystic tumors. Radiosurgery may be useful in ablating small residual or recurrent tumors.[387] With radiosurgery, dose to the optic chiasm and nerves must be kept below 8 Gy, estimated to be radiobiologic tolerance for optic neuropathy with single-fraction radiosurgical doses. As a result, radiosurgery use should be restricted to tumors smaller than 3 cm in size and located greater than 3 to 5 mm from the optic apparatus.

Recent genotyping studies have demonstrated that the papillary variant of craniopharyngioma overwhelmingly expresses one or more BRAFV600 mutation(s). In a small, single-center study, 15 of 16 patients treated with the combination of vemurafenib and cobimetinib demonstrated a durable objective response, with median tumor volume recession exceeding 90%. This has led to a larger Alliance trial and the efficacy of this combinatorial regimen will likely impact future sequencing of various therapeutic modalities.[75]

Evidence-Based Treatment Summary

1. Surgical resection is recommended, when feasible.

2. The use of postoperative RT has not been tested in prospective trials but reduces the risk of recurrence and improves survival in incompletely resected tumors. Cyst decompression and biopsy followed by RT may be an acceptable treatment for patients for whom resection is not considered feasible.
3. Intracavitary bleomycin or radiocolloids may be useful in cystic tumors.
4. For papillary craniopharyngioma, dramatic durable responses are obtained with the combination of vemurafenib and cobimetinib, and this therapy is emerging as front line.

Vestibular Schwannoma and Neurofibroma

Neurilemomas, also known as schwannomas and neurinomas, arise from the Schwann cells of the myelin sheath of the peripheral nerves. When occurring close to the eighth cranial nerve, they are also called vestibular schwannomas or acoustic neuromas. These tumors account for approximately 6% of CNS neoplasms in adults. They may be sporadic or associated with NF2, with bilateral vestibular schwannomas being pathognomonic of this disease. Most sporadic vestibular schwannomas are unilateral and occur in the fourth and fifth decades of life. Those arising in patients with NF2 tend to occur in the second or third decade. These tumors grow slowly in a well-circumscribed, expansile manner, displacing adjacent nerves rather than invading them. Most arise from cranial nerve VIII in the medial internal auditory canal. Less commonly, they may arise from other cranial nerves, the trigeminal nerve being the most common alternate site.

Growth in the internal auditory canal gives rise to vestibular and hearing abnormalities in up to 95% of patients. A progressive unilateral sensorineural hearing loss is characteristic. Expansion into the cerebellopontine angle may lead to trigeminal symptoms, and a unilateral absent corneal reflex is an early sign of trigeminal involvement. Large tumors may impinge on the cerebellum and brainstem, leading to ataxia and long tract signs as well as involvement of cranial nerves IX, X, XI, and XII.

Pure tone and speech audiometry are the most useful screening tests. Selective loss of speech discrimination in excess of pure tone loss is particularly suggestive of vestibular schwannoma. Brainstem auditory evoked responses typically demonstrate a slowing of conduction, and

electronystagmography may detect a decrease in caloric response on the ipsilateral side. Thin-slice Gd-enhanced MRI through the cerebellopontine angle is the imaging modality of choice for suspected vestibular schwannoma. Thin-slice, contrast-enhanced, high-resolution CT scan is an acceptable alternative when MRI is not obtainable. An intensely enhancing lesion close to the internal auditory canal is highly suggestive of this diagnosis. Patients with suspected neurofibromatosis should have complete imaging of the craniospinal axis to document other neurilemomas, neurofibromas, and meningiomas that may be present.

Neurofibromas differ from neurilemomas in their cellular composition and growth pattern. Although neurofibromas also arise from peripheral nerves, they are most commonly multiple and associated with NF1. Neurofibromas expand rather than displace the nerve of origin. Histologically, neurofibromas are composed of a hypertrophied mass of fibroblasts and Schwann cells through which run normal neurons. Symptoms are caused primarily through compression of the involved or adjacent nerves.

Treatment

Treatment should offer a high chance of local control as well as preservation of cranial nerve function. Observation alone may be appropriate in patients willing to undergo regular clinical and imaging follow-up and may allow treatment to be deferred for some time. The mainstay of treatment has been microsurgical resection. Retrosigmoid (suboccipital) middle fossa and translabyrinthine approaches offer the possibility of hearing preservation but are associated with higher incidences of seventh nerve damage and postoperative complications. The translabyrinthine approach is associated with low operative morbidity and mortality but sacrifices hearing. At centers with expertise in microsurgical resection, total or near-total resection rates of 90% are routinely obtained with a surgical mortality rate of less than 2%. Anatomic preservation of the facial nerve may be achieved in 90% of patients and functional preservation in more than two-thirds. Preservation of useful hearing is reported in 30% to 50%. In patients in whom a near-total or total resection is achieved, the tumor recurrence rate is less than 10%. In patients in whom a subtotal

resection is achieved, tumor recurrence may occur in one-third to one-half. Adjuvant RT may reduce the rate of recurrence to that of complete resection.

In patients with a medical contraindication to surgery, treatment with external beam irradiation alone is an option. A dose of 50 to 55 Gy in 25 to 30 fractions over 5 to 6 weeks is recommended. Maire et al[388] evaluated 24 patients with stage III and IV cerebellopontine angle schwannomas treated with external irradiation. With a median follow-up of 60 months, there was an 88% tumor control rate with no injuries to the cranial nerve V or VIII.

Radiosurgery may be an alternative to microsurgical resection. The well-circumscribed nature of these tumors, coupled with their typical intense enhancement on MRI, facilitates their localization and treatment using stereotactic techniques. The PFS rate with radiosurgery is nearly 90% at 20 years. Radiosurgical treatment with higher doses yielded high rates of tumor growth arrest (>80%) and tumor shrinkage in up to two-thirds of patients, although facial or trigeminal neuropathy develops in nearly one-third of patients as long as 2 years after therapy. The volume of the lesion is a significant risk factor for complications involving cranial nerve V, VII, or VIII. Temporary enlargement may occur up to 2 years following radiosurgery.[389]

Noren[390] reviewed the results of 669 patients with vestibular schwannoma treated with Gamma Knife radiosurgery between 1969 and 1997. Long-term growth control was achieved in 95%. Facial weakness and/or numbness occurred in approximately one-third of patients during the 1970s but less than 2% in the 1990s. Hearing was preserved in 65% to 70% of patients, although tinnitus was rarely changed by treatment. With dose reduction to 12 to 13 Gy, high rates of tumor control and cranial nerve preservation may be achieved. Flickinger et al[391] reported the results of 313 patients treated with radiosurgery to a median dose of 13 Gy. The actuarial 6-year tumor control rate was 98.6%. The actuarial 6-year rates for the preservation of seventh nerve function, normal fifth nerve function, unchanged hearing level, and useful hearing were 100%, 95.6%, 70.3%, and 78.6%, respectively. Hayhurst et al[392] reported on their clinical series of 200 patients treated with radiosurgery to 12 Gy and observed 5 cm^3 to be the target volume threshold above which adverse treatment effects were more

likely. In addition, they observed a maximum dose threshold of 9 Gy to cranial nerve V as significantly associated with trigeminal neuropathy.

Radiosurgery provides similar local control with less morbidity than surgery for small (<3 cm) unilateral tumors. In a series from the University of Pittsburgh, radiosurgery was found to have improved preservation of facial function ($P < .05$) and hearing ($P < .03$) with decreased associated morbidity ($P < .01$) when compared to surgical resection.[393]

Fractionated RT has been shown to give local control rates of 91% to 97% with similar effects on cranial nerves V and VII.[394-397] However, in one series, fractionated resulted in 2.5-fold greater preservation of hearing compared to radiosurgery.[394] Multifraction SRS may be an option for tumors too large to receive radiosurgery.

Bevacizumab has been used in patients with progressive bilateral vestibular schwannomas associated with NF2, usually in the context of bilateral hearing loss, producing both tumor regression and restoration of hearing in some patients. This has led to this approach being actively investigated at present. Sporadic and NF2-related vestibular schwannomas express VEGF, and bevacizumab binds VEGF with high affinity. In the initial experience reported by Plotkin et al, 10 patients at with NF2 risk for complete hearing loss or brainstem compression were treated with bevacizumab on a compassionate care basis and demonstrated promising results with 6 of 10 patients experiencing 20% or more tumor volume reduction and 4 of 7 patients experiencing significantly improved hearing.[398]

Evidence-Based Treatment Summary

1. Small nonprogressive tumors can be observed.
2. Surgical resection is generally considered the standard of care for symptomatic lesions.
3. Radiosurgery produces outcomes equivalent to surgery, although these modalities have not been prospectively compared.
4. Fractionated RT is being increasingly employed, with institutional reports suggesting a lower incidence of cranial neuropathies than radiosurgery, but this has not been prospectively validated.

5. The role of bevacizumab in NF2-associated progressive bilateral vestibular schwannomas is being explored.

Hemangioblastoma and Hemangiopericytoma

Hemangioblastomas are benign vascular tumors that present during the third and fourth decades of life. They account for 1% to 2% of primary CNS tumors in adults. Most arise in the cerebellum, constituting the most common primary cerebellar tumors in adults. An association with von Hippel-Lindau disease is noted in 10% of patients. Histologically, the tumor consists of closely packed, thin-walled blood vessels in a stroma of large, oval foamy cells. The lesions are intensely enhancing on CT and MRI, and angiography confirms the vascular nature of the lesion. Imaging of the craniospinal axis often documents multiple lesions in patients with von Hippel-Lindau disease. Treatment is surgical, and complete resection is curative. Radiosurgery has also been shown to be useful in patients with unresectable disease but is associated with higher rates of recurrence.[399-401] In von Hippel-Lindau, treatment of symptomatic hemangioblastoma is warranted, but observation of asymptomatic tumors can be considered.[402]

Hemangiopericytoma is a sarcomatous lesion developing from smooth muscle in blood vessels usually along the base of the skull, although intraparenchymal lesions may be seen. In contrast to other primary CNS tumors, hemangiopericytomas commonly develop systemic metastases. There is a 90% 9-year actuarial risk for local failure following surgical resection only. Postoperative RT to total doses of 50 to 60 Gy reduces the risk of recurrence rate and improves OS. Tumor control is dose dependent, with doses greater than 50 Gy associated with superior outcomes. Radiographic response is slow. Radiosurgery has been used for recurrent hemangiopericytomas, with reported local control rates of approximately 80% following treatment.[403]

Evidence-Based Treatment Summary

1. Surgical resection is recommended, when feasible, for both of these diseases.

2. RT is generally reserved for subtotally resected progressive hemangioblastoma, but there are no prospective data.
3. Postoperative RT is recommended for subtotally resected hemangiopericytoma, but there are no prospective data.
4. RT or radiosurgery may be considered for unresectable tumors.

CHAPTER 41

Fractionated Radiation Therapy and Stereotactic Radiosurgery for Pituitary Adenomas

Chloe Dumot, Georgios Mantziaris, Salem M. Tos, and Jason P. Sheehan

ANATOMY

Gross Anatomy and Embryology

The pituitary gland is essential for sustaining life and controls multiple functions in systemic physiologic regulation. It averages an anteroposterior diameter of 8 mm and a transverse diameter of 12 mm. The average weight is approximately 0.5 g, but it almost doubles during pregnancy.[1] It is located within the sella turcica of the sphenoid bone, bounded anteriorly by the sphenoid sinus, laterally by the cavernous sinuses, and superiorly by a dural fold called the diaphragma sellae (Figure 41.1).[1] The superior aspect of the gland is related directly to the arachnoid and pia, and the subarachnoid space then extends below the diaphragma; the optic chiasm is located directly above the hypophysis.[1]

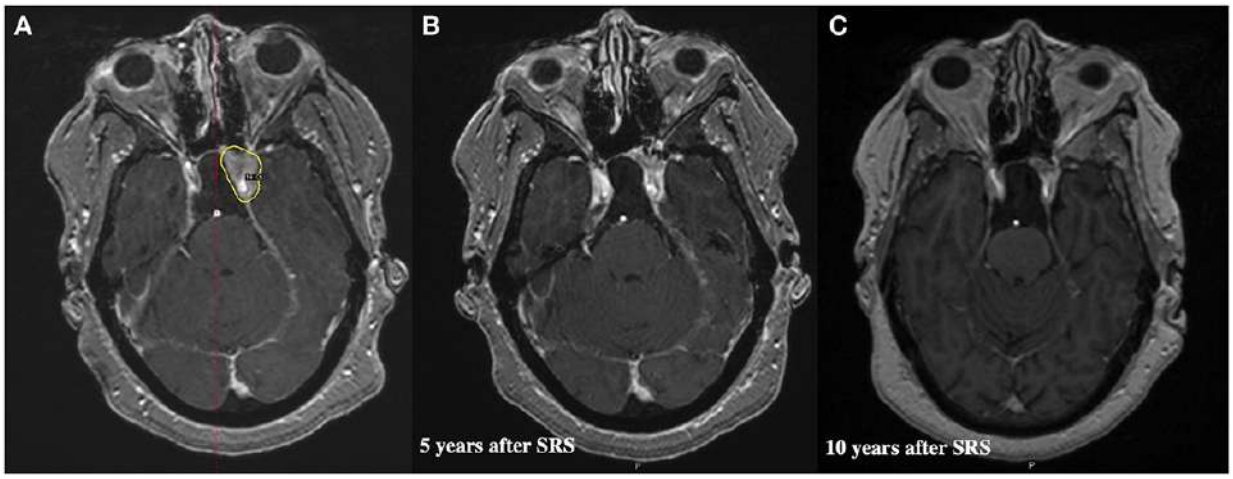

FIGURE 41.1 Illustrative case of a nonfunctioning pituitary neuroendocrine tumor. The tumor was invading the left cavernous sinus with sufficient distance from the optic nerve to allow stereotactic radiosurgery (SRS) in a single fraction. The tumor was treated with 16 Gy at an isodose line of 50% (A, yellow line). The tumor decreased after radiosurgery (B, at 5 years) with a long-term control (C, 10 years after SRS).

The pituitary is divided into two main parts based on embryologic origin: the adenohypophysis (anterior gland), deriving from the oral ectoderm of the Rathke pouch, and the neurohypophysis (posterior gland), deriving from the neural ectoderm.[1] The adenohypophysis encompasses the pars tuberalis, the pars intermedia, and the pars distalis; it constitutes the majority of the total volume of the pituitary gland. The pars tuberalis surrounds the infundibular stem that contains the unmyelinated axons from the hypothalamic nuclei. The pars intermedia forms the border between the pars distalis and the posterior gland; it is mostly nonfunctioning but also contains follicles that produce melanocyte-stimulating hormone (MSH) and endorphins. The pars distalis is the most distal part of the adenohypophysis and secretes the majority of hormones.[1]

Function and Blood Supply

The pituitary gland is connected to the tuber cinereum of the hypothalamus with the infundibulum through the diaphragma sellae. Hypothalamic nerve fibers in the median eminence secrete hypothalamic-releasing hormones into the capillary beds of the infundibulum, and these molecules are transported via the hypothalamohypophyseal portal vessels to the distal parts of the adenohypophysis, inciting the relevant effects. The neurohypophysis main hypothalamic nerve supply is fiber collectively known as the hypothalamohypophysial tract. Glial cells called pituicytes encircle the axons. This tract contains two main sets of fibers: the supraopticohypophysial tract and the tuberohypophysial tract.[1,2]

The pituitary gland is supplied through a number of hypophyseal arteries originating from the internal carotid arteries. The superior hypophyseal artery supplies the anterior lobe, the pituitary stalk, and the optic chiasm. It branches directly from the internal carotid artery or the posterior communicating artery.[1] The inferior hypophyseal artery, the meningohypophyseal trunk, which is a branch of the internal carotid artery, supplies the posterior lobe.[1] The intermediate lobe receives its blood supply from the anastomoses between the anterior and posterior lobe capillaries.[1] The pituitary gland drains into the cavernous sinus, releasing the produced hormones in the systemic circulation.[1] As such, the pituitary gland has a dual circulation; one is composed of arteries and veins, and the other is a portal venous system that links the hypothalamus and the anterior lobe.

The pars distalis area of the anterior pituitary gland produces the following hormones[1]:

- Adrenocorticotropic hormone (ACTH), MSH, and β-endorphin by basophilic-appearing corticotroph cells. The corticotropin-releasing hormone from the hypothalamus cleaves the proopiomelanocortin into ACTH, MSH, and β-endorphins. ACTH stimulates the release of cortisol from the adrenal cortex in conditions of stress.
- Thyroid-stimulating hormone (TSH) from the thyrotroph cells in response to thyrotropin-releasing hormone from the hypothalamus. TSH stimulates the release of T3 and T4 in the thyroid gland.
- Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from basophilic gonadotroph cells in response to the hypothalamic gonadotropin-releasing hormone. In males, LH acts on Leydig cells to stimulate the release of testosterone and FSH acts on Sertoli cells to secrete inhibin B for spermatogenesis. In females, LH initiates steroid production and causes ovulation, while FSH acts on granulosa cells to initiate estrogen production and stimulates follicular development.
- Growth hormone (GH) from acidophilic somatotroph cells in response to GH-releasing hormone. GH has anabolic properties and regulates cell division and protein synthesis.
- Prolactin (PRL) from acidophilic lactotroph cells, which is controlled by the dopamine system via an inhibitory mechanism. It primarily functions to stimulate mammary gland growth and milk production.

The neurohypophysis, despite its name, does not actually produce any hormones; instead, it should be considered a collection of axonal projections from the hypothalamus that store neurosecretions. The posterior gland hormones include[1]:

- Oxytocin that regulates milk ejection during lactation and uterine contraction
- Antidiuretic hormone that controls water content and prevents water depletion by increasing water reabsorption by the kidney tubules

PITUITARY DISORDERS

Pituitary disorders usually manifest by affecting hormone production, either through hypersecretion or through hypopituitarism. Most hypersecretion states are caused by functioning adenomas within the anterior lobe.[1] Functioning pituitary adenomas are usually composed of a single aberrant cell lineage that oversecretes a single hormone. The vast majority of pituitary adenomas are monoclonal in origin, suggesting a single somatic cell.[3] Hypersecretion of the anterior lobe pituitary adenomas results in gigantism, acromegaly, hyperprolactinemia, and Cushing disease.[3] Hypopituitarism may be caused by several destructive processes, such as ischemia (postpartum Sheehan syndrome), inflammatory diseases (granulomatous hypophysitis, lymphocytic hypophysitis, etc), iatrogenic injuries (resection, radiation), trauma, and nonfunctioning tumors

(nonfunctioning pituitary adenoma, and Rathke cleft cyst, craniopharyngioma, metastatic tumor).[1] Hyposecretion of the anterior hormones results in dwarfism, adrenal insufficiency, hypogonadism, and hypothyroidism. A posterior lobe deficiency can cause diabetes insipidus.

Besides endocrine abnormalities, pituitary diseases can cause symptoms through local mass effect on surrounding neurovascular structures. Neurologic signs include visual field defects due to optic chiasm compression, signs of increased intracranial pressure, double vision due to cranial nerve involvement, headache, and nausea.[4]

PITUITARY ADENOMAS

Pituitary tumors can be distinguished between those arising from the anterior lobe (adenohypophyseal) and those arising from the posterior lobe (neurohypophyseal) according to the new World Health Organization (WHO) classification.[5] Pituitary neuroendocrine tumors (PitNETs), usually named pituitary adenoma, are often classified as functioning and nonfunctioning based on pituitary hormone hypersecretion. The PitNETs are then subclassified based on the function of cell type and cell lineage and their related characteristics.[6] Due to their frequency including presence in 0.1% of the population and with an incidence of 3.9 and 7.4 per 100,000 per year, this chapter focuses on PitNETs.[7]

Histopathology and Grading

Approximately half of pituitary adenomas are macroadenomas (>10 mm), and two-thirds are functioning; the most common functioning adenomas are prolactinomas, followed by GH- and ACTH-secreting tumors.[3] Nonfunctioning pituitary adenomas constitute the second most common subtype after prolactinomas.[3] Up until the fourth edition of the 2017 WHO classification and adaptation of cell lineage as the main determining factor of pituitary adenoma classification, their histologic classification relied on pituitary hormone immunohistochemistry and cellular ultrastructural features.[3] Following the fifth edition of the WHO classification, immunohistochemistry (GH, PRL, TSH-β, ACTH, FSH-β, LH-β, and α-subunit of glycoproteins) is necessary for pathologic classification; transcription factors (PIT1, TPIT, and SF1) immunostaining are required when tumors cannot be classified by pituitary hormones alone or in the case of null cell adenomas.[3] The adoption of cell lineage classification is expected to result in a shift of reported PitNET histopathology groups; this is evident especially in the case of null cell tumors that currently represent only 1% to 2% compared to approximately 20% in prior PitNET registries.[3]

The overwhelming majority of PitNETs are benign, exhibiting a low recurrence rate following resection.[4] A few histologic subtypes, including sparsely granulated somatotroph, silent corticotroph, and Crooke cell PitNETs, are perceived as exhibiting a more aggressive clinical behavior; these so-called high-risk types tend to recur, be locally invasive, and be resistant to standard therapies.[8] Primary pituitary carcinomas are quite rare, and the clinical diagnosis requires the occurrence of craniospinal or systemic metastasis.[3]

Pituitary Neuroendocrine Tumors Clinical Presentation and Treatment

Prolactinomas are the most common PitNETs and range from small microadenomas to very large and invasive tumors associated with mass effect symptoms.[3,4] Serum PRL levels are usually correlated with tumor size. Patients presenting with amenorrhea, galactorrhea, loss of libido, and infertility should be evaluated with serum PRL.[4] Mild elevation does not always indicate a PRL-secreting PitNET; head trauma, use of drugs, renal failure, hypothyroidism, and a mass within the stalk disturbing the dopaminergic inhibition can result in a mild elevation of serum PRL.[4] Prolactinomas are usually well controlled with medical therapy, and resection is considered in the setting of refractory to medical management tumors.[9]

GH-secreting tumors are the second most common functional tumors. Children who develop these PitNETs prior to the epiphyses closing develop clinical gigantism, while older children and adults develop acromegaly. These clinical manifestations include enlarged hands and feet; increased bone density; enlarged thyroid, heart, liver, and adrenals; and broadening of the lower face with jaw protrusion.[4] Patients often have accompanying prolactinemia with gonadal dysfunction, hypertension, congestive heart failure, and an increased risk of gastrointestinal cancer.[4] Resection is the primary treatment of GH-secreting PitNETs in most patients, as it

produces immediate GH and insulin-like growth factor-1 (IGF-1) level normalization and provides pathologic characterization.[10] Medications for acromegaly (such as somatostatin receptor ligands, GH receptor antagonists, and dopamine agonists) can be effective and are often recommended for patients with persistent disease following resection; however, they require lifelong treatment, are not always fully effective, and are associated with significant side effects.[10]

ACTH-secreting PitNETs cause Cushing disease due to the chronic hypersecretion of cortisol from adrenal stimulation. Resection remains the first-line treatment of ACTH- secreting PitNETs, as it affords high rate of remission, allows for immediate control of hypercortisolemia and decompression of neural structures, and is associated with low complication rate in high-volume pituitary centers.[11]

Gonadotroph- and thyrotroph-secreting adenomas can occur, but these are much less frequent.[4] Most gonadotroph adenomas are LH- or FSH-producing tumors in middle-aged men and women with ambiguous clinical presentation, usually complaints of infertility and menstrual irregularities.[12] TSH-secreting PitNETs are rare, found in about 1% of patients, and are a rare source of hyperthyroidism.[13]

Radiotherapy (RT) and stereotactic radiosurgery (SRS) are typically used in the management of residual and recurrent PitNETs. Different techniques including SRS, conventional fractionated external beam RT, and proton beam therapy have been used to treat pituitary adenomas.[14]

IONIZING RADIATION TECHNIQUES

Conventional Fractionated External Beam Radiotherapy

Conventional RT uses doses of 1.8 to 2 Gy per fraction for treatment. This modality traditionally demonstrated a reasonable rate of tumor control and endocrine response but a moderate rate of short- to long-term complications.[15] Modern era RT using intensity-modulated RT, volumetric-modulated RT, and multiple beam arcs often allows for better preservation of surrounding organs.[16] The International Commission on Radiation Units and Measurements recommends that treating physicians delineate the volumes of treated targets and organs at risk (OARs).[17] Treatment plan volumes include the gross tumor volume (GTV), which is the visible demonstrable location and extent of the tumor; the clinical target volume (CTV), an expansion of the GTV to account for subclinical malignant disease; and the planning target volume (PTV), which is generated after applying a margin to the CTV to account for treatment uncertainties.[17]

Stereotactic Radiosurgery

SRS aims at delivering a high dose of radiation (overall and per fraction if hypofractionated), with appreciable conformality usually to a small target volume. Historically, SRS was performed using a single fraction, but due to evolution in the technology available, hypofractionated treatment (two to five fractions) using a mask-based approach is now available. Due to its cranial-specific design and its extensive use, Gamma-Knife radiosurgery (Elekta AB, Stockholm) is the most frequently used device in the published literature for SRS-related pituitary adenomas. Other technologies using a linear accelerator based (LINAC) (eg, CyberKnife, Novalis, and ViewRay) are also currently available.

A frame-based or frameless-based approach often with infrared tracking and cone beam computed tomography (CT) allows substantial precision in targeting the lesion and limits the risk of uncompensated movement associated with a mask-based procedure. Due to the high conformality of this technique, little to no margin dose is applied to the target, meaning that the GTV is usually equal to the PTV. SRS was developed, with one of its major goals being to reduce the dose to the surrounding tissue while achieving a high dose to the tumor. This translates to a lower risk of complication while achieving a faster endocrine remission and favorable tumor control rate.

Proton Beam and Other Particle Therapy

Due to their physical properties, proton beam therapy has the capability to improve the sparing of healthy tissue, which is of interest in a highly functional region such as the sellar region. The sharp dose fall-off of the Bragg peak effect needs to be considered when dose planning is performed. For now, due to the relatively limited availability of this technology, proton beam therapy is often reserved to treat larger tumor volume and

for pediatric patients with potentially greater risk for long-term adverse radiation sequelae.[18] Other options for particle- based therapy using linear energy transfer approaches such as with carbon ion therapy are showing promise for skull-based tumors.

Direct comparison of radiation treatment modalities is made difficult by the heterogeneity of published studies. The evaluation of brain and at-risk structure (eg, the normal pituitary gland, cranial nerves, vascular structures, hypothalamus, brainstem, and medial temporal lobes) sparing need longer term follow-up evaluation. The choice of RT modality included the proximity of the tumor to at-risk structure, particularly the optic nerve, the size of the tumor, and the patient characteristics (previous RT, age). The close proximity of the tumor to the optic nerve (often less than 3-5 mm) and a high volume (maximum diameter greater than 2.5-3 cm) could encourage the use of hypofractionation or standard fractionation schemes.

NONFUNCTIONING PITUITARY NEUROENDOCRINE TUMORS

Nonfunctioning PitNETs (NFPitNETs) present mainly with symptoms of mass effect, including optic nerve and cranial nerve compression and/or hormonal dysfunction. The first treatment is often maximal safe resection by a transsphenoidal resection. RT or SRS can then be utilized for residual or recurrent tumor. Alternatively, for patient unable or unwilling an open surgery, RT or SRS can sometimes be proposed as a primary treatment.[19,20]

Conventional RT was the first technique used to treat residual or recurrent lesion, with a local control of up to 90% at 10 years.[21] However, the risk of sequelae has led to a shift in practice toward more selective techniques, such as radiosurgery.[22]

Tumor Control

Tumor control is the primary goal of radiosurgery for NFPitNETs. Multiple studies using single-dose SRS revealed excellent tumor control after treatment, ranging from 93.3% to 100% and 76% to 92% at 5 and 10 years, respectively.[23-30] A recent meta-analysis provided an estimate of 94.0% (95% confidence interval [CI]: 93.0%-96.0%) of tumor control at 5 years and 83.0% (95% CI: 77.0%-88.0%) at 10 years using single-dose SRS[19] (Table 41.1; see Figure 41.1).

TABLE 41.1 MAJOR SERIES FOR NFPITNET TREATED WITH SRS IN A SINGLE FRACTION OR HYPOFRACTIONATED (TWO TO FIVE FRACTIONS)

Study	Technique	Year	*n*	Follow-Up Period (mo)	Median Prescription Dose (Gy)	Tumor Control	Hypopituitarism	New-Onset CN Deficits
Sheehan et al[25,a]	Single-dose GK	2013	512	36	16	98%, 95%, 91%, and 85% at 3, 5, 8, and 10 y, respectively	21%	6.6% from CN II, 2.7% from other CN

Series published after 2013 with 100 patients or more were included for single fraction.

Risk factors reported to be associated with post-SRS progression include cavernous sinus/parasellar invasion,[28,30] larger tumor volumes,[23-25,34] history of ³2 recurrences,[23] and tumor margin doses less than 12[28] or 13 Gy.[35] The recommended prescription doses for nonfunctioning pituitary adenoma single-session SRS range from 13 to 18 Gy and a typical dose is 16 Gy for single-dose radiosurgery.[36]

CN, cranial nerve; fx, fractions; GK, Gamma-Knife; N/A, not available; NF, nonfunctioning; NFPitNET, nonfunctioning pituitary neuroendocrine tumor; SRS, stereotactic radiosurgery.

[a]From a multicenter study.

[b]Linear accelerator series; others were Gamma-Knife.

Hypofractionated radiosurgery using two to five fractions is reported in fewer series with shorter follow-up. NFPitNETs and functioning tumors are frequently reported in the same series.[32,33,37-44] The same meta-analysis previously reported estimated the tumor control at 5 years at 97.0% (95% CI: 93.0%-98.0%).[19] The recommended prescription doses are 21, 20, and 25 Gy in three, four, and five fractions, respectively. Long-term analysis, larger series, and studies on dose selection are needed to evaluate the benefits and risks of a hypofractionated strategy (see Table 41.1). Hypofractionated SRS using a mask-based approach is often preferred for adenomas >3 cm in maximum diameter, for lesions less than 3 mm from the optic nerve and chiasm, and in those with contraindications to, or unwilling to undergo, frame-based SRS.

As an alternative to hypofractionated radiosurgery in three to five fractions, conventional RT with modern RT techniques can be an option for these patients (Table 41.2). Minniti et al[47] reported a series of 68 NFPitNETs of larger than 3 cm treated with RT in 45 Gy per 25 fractions in most of the cases and found a tumor control of 97% at 5 and 91% at 10 years. The rate of new hypopituitarism was 40% at 5 years, with 5.9% of patients developing transient cranial nerve deficits.

TABLE 41.2 MAJOR SERIES REPORTING EXTERNAL BEAM RADIOTHERAPY FOR NFPITNET

Study	Year	Technic	*n*	Follow-Up Period (mo)	Prescription Dose	Tumor Control	Hypopituitarism	New-Onset CN Deficits (%)
Kim et al[45]	2013	6 MV photon beams, 4 arcs in median	76 (54 NF)	81.6	50.4 Gy/28 fx	97.1% at 7 y	48%	0
Kopp et al[46]	2013	Five to six isocentric beam, 6 MV photons, and micro-multileaf collimator	37 (29 NF)	57	50.4 Gy/28 fx (except for eight 45-48 Gy)	91.9% at last f/u	N/A	5

Series published after 2010 with NFPitNET only and at least 30 patients treated with hypofractionated (3-5 fx) radiation.
CN, cranial nerve; fx, fraction; f/u, follow-up; N/A, not available; NF, nonfunctioning.

Wilson et al[39] compared 51 patients treated with SRS (median dose 14 Gy, single fraction), 67 treated with fractionated stereotactic RT (median dose 50 Gy in 28 fractions), and 53 with conventional RT (median dose 50.4 Gy in 28 fractions) performed from 1971 to 1991, for NFPitNETs. The 5-year probability of tumor control was 100% for SRS, 92.8% for fractionated stereotactic radiation, and 86.9% for conventional RT. Higher visual deficit was reported following conventional RT.

Most of the series with a modern conventional radiation technique included both functional and nonfunctional adenomas, which makes outcomes difficult to evaluate. The outcomes in terms of cognitive function or long-term evaluation compared to other strategies need further study. Ronson et al[49] reported a series of 47 patients treated with proton therapy for both FPitNET and NFPitNET (24 patients). At a median follow-up of 47 months, no tumor progression was reported. In all, 22.8% of patients with functioning tumors achieved endocrine remission. One patient developed temporal lobe necrosis, and 29.7% of the patients developed new hypopituitarism.

Timing of Radiation Therapy and Stereotactic Radiosurgery

The optimal timing of adjuvant RT and SRS after prior resection remains unclear. A recent matched cohort analysis comparing adjuvant SRS in the 6 months after resection to SRS at progression showed a similar tumor control, hypopituitarism, and visual deficit rate in both cases. The median time from resection to new pituitary deficiency was higher in the SRS at progression group.[50] Other studies demonstrated improved tumor control for patients treated during the 6 months after resection.[51,52]

Upfront Stereotactic Radiosurgery

A few studies evaluated the outcomes after upfront SRS before any surgical resection.[34,52,53] Lee et al[52] in a multicentric study reported the outcomes of 41 patients treated with SRS for NFPitNETs of a volume of 2.3 mL (range: 0.2-10.5). The probability of tumor control was 94% at 5 years and 85% at 10 years. In all, 24.4% of the patients had a new or worsened pituitary deficiency. One patient with tumor enlargement had a worsened visual field defect, and one patient had a new oculomotor nerve deficit. Kara et al[34] compared 216 patients treated with adjuvant SRS to 36 patients with primary treatment with no difference in tumor control and post-SRS pituitary deficiency.

Repeat Stereotactic Radiosurgery

Losa et al[26] described the profile of 39 patients with recurrent PitNETs after SRS for both functioning and nonfunctioning adenomas. In 56.4%, the tumor recurrence was considered out of the field of the previous treatment.

Reirradiation has been reported in a small series and can be associated with a mild to moderate rate of complications including temporal lobe necrosis and optic neuropathy in as much as 10% or more patients.[54,55] No precise guidelines on the feasibility of and preferred techniques to use for repeat radiation treatment are available. Prior dose to critical structures, timing of prior radiation, target delineation, and neurologic and endocrine function of the patient at that time should be carefully considered prior to reirradiation.

FUNCTIONING PITUITARY NEUROENDOCRINE TUMORS

FPitNETs are revealed by hypersecretory symptoms in most of the cases. Hypersecretion of ACTH, GH, and PRL are the most common functioning adenoma types. RT or SRS is recommended for failure to achieve endocrine remission after resection and/or medical management or for recurrence of hypersecretion. Pituitary adenoma control of an FPitNET is more often achieved than endocrine remission.[56]

Acromegaly

The differences in remission rates found in the literature could be at least partially explained by differences in estimating endocrine remission. Most of the studies did not use the Cortina acromegaly consensus criteria (random GH <1 ng/mL or nadir GH after an oral glucose tolerance test <0.4 ng/mL and normalization of age- and sex-adjusted IGF-1) to define endocrine remission.[57] In a similar way, comparing the various modalities of radiation delivery is difficult. Conventional RT was the first to demonstrate the efficiency in reducing GH and IGF-1 level.[58] Later, SRS was developed with the aim of reducing complications and is now frequently used to treat patients with persistent or recurrent acromegaly.

Knappe et al[59] described the outcomes of 233 patients treated with fractionated RT (stereotactic, conventional, or conformal) (follow-up: 13.0 ± 8.2 years) and 119 patients treated with single-dose SRS (follow-up: 8.9 ± 5.0). The 10-year remission probability was 48% for fractionated RT and 52% for SRS, with no statistical differences. The mean time to endocrine remission was faster after SRS (2.1 years) compared to fractionated (3 years) treatment. The rate of new pituitary deficiency was not different between groups.

Endocrine remission has been reported between 20.3% and 65% at 5 years after SRS.[60-64]

A multicenter study by Ding et al, published in 2019, reported the outcomes of single-dose SRS for 371 patients. The probability of maintained endocrine remission (defined as normalization of IGF-1 level based on age-matched cohort, off-lowering medication) was 43%, 59%, and 64% at 5, 10, and 15 years after SRS, respectively. The mean time from SRS to endocrine remission was 37.7 ± 32.5 months (Table 41.3).

TABLE 41.3 MAJOR RADIOSURGICAL SERIES FOR ACROMEGALY

Study	Year	*n*	Follow-Up Period (mo)	Definition of Endocrine Remission	Margin Dose (Gy)	Endocrine Remission	Delay From SRS to Endocrine Remission (mo)	Hypopituitarism (%)	New-Onset CN Deficits (%)

Study	Year	*n*	Follow-Up Period (mo)	Definition of Endocrine Remission	Margin Dose (Gy)	Endocrine Remission	Delay From SRS to Endocrine Remission (mo)	Hypopituitarism (%)	New-Onset CN Deficits (%)
				random GH level less than 1 ng/mL, or a nadir GH during glucose tolerance test <0.4 ng/mL					
Knappe et al[59]	2020	233 fractionated, 119 SRS	156 for fractionated, 107 for SRS	Normal or low IGF-1 without suppressive medication	N/A	48% for fractionated, 52% for SRS at 10 y	36 for fractionated, 25.2 for SRS	N/A	N/A

Studies with 100 patients or more and sufficient data were included.

CN, cranial nerve; fx, fractions; GH, growth hormone; HSRS, hypofractionated stereotactic radiosurgery; IGF-1, insulin-like growth factor-1, N/A, not available; SRS, stereotactic radiosurgery.

[a]Linear accelerator.

[b]From multicenter series.

[c]Patients treated with a rotational Gamma-Knife MASEP.

In a meta-analysis of 28 studies involving 1,335 patients, the crude endocrine remission rate was estimated at 44.0% (95% CI: 35.0%-53.0%). The mean margin dose was not associated with endocrine remission in this study.[56] Predictor factors of endocrine remission included temporary cessation of IGF-1–lowering medication,[62] a lower pretreatment IGF-1 index,[66,67] and a higher margin dose.[67] Improvements in radiation modalities and techniques to achieve a higher rate of endocrine remission are under investigation. For example, some studies showed that a higher biologic effective dose could be associated with a higher endocrine remission rate,[67] but this was not confirmed in other studies.[66,68] Compared to nonfunctioning pituitary adenomas, a higher dose to treat acromegaly and achieve endocrine remission is required, and prescription doses are usually between 20 and 25 Gy.

The effect of primary SRS in cases for which there is an operative contraindication or patient refusal of surgery is not fully defined. Only a small series have evaluated this outcome. Gupta et al[69] found 28% of endocrine remission at 5 years in a series of 25 patients. Two studies including a matched analysis showed no differences in endocrine remission rate compared to postresection SRS.[70,71]

Repeat SRS for persistent or recurrent acromegaly after failed SRS was evaluated in 21 patients. The crude endocrine remission rate was 42.9% at a median follow-up of 3.8 years. New cranial nerve deficit occurred in 19.0% of patients.[72]

Gonzales-Virla et al[73] reported a series of 94 patients treated with a LINAC in 20 to 25 fractions with a median dose of 52 Gy, with 61% achieving endocrine remission defined by IGF-1 level at 10 years. Abu Dabrh et al[74] performed a meta-analysis of patients with acromegaly treated with either SRS or conventional fractionated RT and showed no significant differences in the rate of remission rate and hypopituitarism between the two modalities.

The effect of proton therapy in acromegaly was reported in a series of 50 patients. The 5-year probability of endocrine remission was 67%. Endocrine remission occurred in a median of 32 months after the treatment.[75] Iwata et al[76] reported outcomes using three to five fractions CyberKnife radiosurgery in 52 patients and found 17.3% of the patients satisfied the Cortina consensus criteria, with a median follow-up of 60 months. Further studies are required to better define outcomes with the various techniques.

Cushing Disease

In a multicentric study including 278 patients with a mean follow-up of 5.6 years, the rate of endocrine remission was 64% at 10 years post-SRS. Of note, 18% of patients recurred after initial remission. The mean time from SRS to cortisol normalization was 14.5 months. New pituitary deficiency occurred in 25% of patients[77] (Table 41.4).

TABLE 41.4 MAJOR RADIOSURGICAL SERIES FOR CUSHING DISEASE

Study	Year	Radiation Modality	*n*	Follow-Up Period (mo)	Margin Dose (Gy)	Endocrine Remission (%)	Delay of Endocrine Remission (mo)	Hypopituitarism (%)	New-Onset CN Deficits (%)

Series with 30 cases were included.

CN, cranial nerve; FSRS, fractionated stereotactic radiosurgery; N/A, not available; SRS, stereotactic radiosurgery.

[a]Pediatric.

[b]From a multicentric series.

In a meta-analysis of 2021, Mathieu et al[56] reported outcomes from 13 studies including 416 patients. The estimated crude rate for endocrine remission and new hypopituitarism was 48.0% (95% CI: 35.0%-61.0%) and 21.0% (95% CI: 13.0%-31.0%), respectively. Mean margin dose was not associated with outcomes in this study. A margin dose between 20 and 25 Gy in one fraction is generally advised.

For patients with refractory Cushing disease, bilateral adrenalectomy can be proposed for prompt control of hypersecretion in selected cases. Nelson syndrome is a difficult-to-treat condition, characterized by hyperpigmentation, increased ACTH level, and expansion of pituitary adenoma. SRS and proton therapy can be the options to treat Nelson syndrome and allow for a high rate of tumor control and reduction in ACTH level.[75,84,85] A study, including a few number of patients due to the rarity of this condition, suggests that treating patients with SRS before bilateral adrenalectomy is associated with a decreased risk of Nelson syndrome occurrence.[86]

Fewer studies reported outcomes after proton therapy (either single dose or fractionated) for Cushing disease. In a series of 79 patients, the rate of endocrine remission was 67%, with a median time to remission of 32 months.[75] In the same way, the effect of fractionation and proton therapy on outcomes compared to single-session SRS needs further study.

Upfront SRS for Cushing disease was evaluated in 21 patients from a multicentric study. The endocrine remission rate at 5 years was 81%, with a median time of 12.7 months after treatment. The crude risk of hypopituitarism was 23.8%, and 4.7% presented with new cranial nerve deficits.[69]

Repeat SRS for recurrent Cushing disease was evaluated in 20 patients. The rate of durable endocrine remission was 47% at 5 years, with a median time from SRS to remission of 6 months. Ten percent of patients experienced new deficits (transient visual loss in one and permanent diplopia in one).[87]

Prolactinoma

Prolactinomas are more often managed with medical therapy and, in case of failure, by resection. SRS is usually reserved for those who failed the two previous strategies. As such, most of the published prolactinoma studies included a small number of patients who have failed multiple prior treatment approaches.[88-90] Patients with prolactinoma undergoing RT or SRS tend to be a heavily pretreated cohort with appreciable selection bias as compared to other pituitary adenoma cohorts.

A multicentric study evaluated outcomes in a series of 289 patients. The endocrine remission rates were 28%, 41%, and 54% at 3, 5, and 8 years after SRS, respectively. New hypopituitarism occurred in 25% of the patients and a new cranial nerve deficit in 3%, with a median follow-up of 60 months. Tumor progression occurred in 5% of the patients, with a median follow-up of 59 months.

A lower PRL level prior to SRS and an increasing margin dose are associated with better endocrine control.[91] Pan et al[92] in a series of 164 patients showed improved endocrine remission rate if the dose was more than 30 Gy. Typically, a dose between 18 and 25 Gy in a single fraction is delivered to the prolactinoma. Further studies on outcomes with different prescription doses are needed.

In a meta-analysis of 13 studies with 538 patients using Gamma-Knife, LINAC-based SRS, and rotating gamma unit (MASEP), the crude tumor control was 93.0% (95% CI: 90.0%-95.0%) and the endocrine remission was 28.0% (95% CI: 19.0%-39.0%).[56]

Wattson et al[75] reported nine patients treated with proton therapy for a refractory prolactinoma. The remission rate was 38% at 5 years, with an estimated median delay from SRS to remission of 60 months. Further studies on fractionation radiation and proton therapy for prolactinomas are required.

Whole-Sellar Treatment

When the adenoma target on MRI cannot be fully defined for FPitNETs, a whole-sellar treatment can be performed. Lee et al,[93] in a series of 64 patients with acromegaly (n = 22), Cushing (n = 20), and prolactinoma (n = 2), the probability of endocrine remission was 54%, 78%, and 87% at 2, 4, and 6 years post-SRS, respectively. New hypopituitarism was 43.5%, with a median endocrine follow-up of 41 months. Inevitable, such a whole-sellar approach will deliver more radiation to the normal pituitary gland and stalk. Durankus et al[94] in a series of nine patients with Cushing disease found similar results. The high rate of hypopituitarism found in these two studies was not confirmed in two comparative studies on Cushing disease and acromegaly.[95,96]

Temporary Cessation of Pituitary Adenoma Suppressive Medications

Some studies have shown evidence of cessation of pituitary adenoma suppressive medications at the time of SRS to be a predictor of endocrine remission.[62,79,97] This effect is not always reported[85,91,98] or maintained at long term.[99] Therefore, it is generally reasonable to stop such medications 4 to 12 weeks prior to SRS so as to improve the response of the adenoma to ionizing radiation. Discussion with the endocrinologist is recommended to ensure that the temporary cessation is prudent.[56]

TOXICITY

Hypopituitarism

The most common complication of radiation is the occurrence of new pituitary hormone deficiency. This rate of hypopituitarism after RT and SRS increases with time. A multicentric study including both NFPitNETs and

FPitNETs (1,023 patients with 410 NFPitNETs) found a probability of new hypopituitarism of 7.8%, 16.2%, 22.4%, 27.5%, and 31.3% at 1, 3, 5, 7, and 10 years, respectively. New diabetes insipidus was reported in 1.1% of patients in this study.[100] The thyroid axis followed by the corticotroph or gonadotroph hormones was the most frequently involved.[100]

The risk factors that increase the risk for hypopituitarism are male sex,[101] increasing age,[102] prior RT,[25] suprasellar extension,[103] small gland volume,[101] poor visualization of the pituitary gland,[104] high dose to the tumor margin,[25,101,103] lower isodose line,[100] higher dose to the pituitary stalk,[102] and a greater distance from the center of the target to the center of the pituitary gland (>4 mm).[105]

Graffeo et al[101] suggested that reducing the mean dose to the gland <11 Gy in one fraction may help decrease the occurrence of new pituitary deficiency. However, this should not compromised the coverage of the tumor.

Cranial Nerve Deficits

Cranial nerve deficit after SRS most frequently involved the optic nerve followed by other cranial nerve in proximity (eg, III, IV, V, and VI). Most of the studies reported in Tables 41.1 to 41.4 noted a cranial nerve palsy rate of approximately 1% to 5%. Some deficits occurred in the context of tumor progression,[30] and the rate without documented adenoma progression has been reported between 1.6% and 2.9%.[23,25]

Cranial nerve II is highly sensitive to ionizing radiation, whereas the dose tolerance to the cranial nerves in the cavernous sinus is usually higher.[106] For patients without prior RT, the maximum point dose to the optic apparatus to keep the risk of optic nerve neuropathy below 1% is approximately <10 Gy in a single dose, 20 Gy in three fractions, and 25 Gy in five fractions. The choice of RT technique should take these constraints into account to lower the risk of an optic nerve deficit.[107] Relevant to OAR constraints for pituitary RT/radiosurgery are available in Table 41.5.[108]

TABLE 41.5 ORGAN AT RISK RADIATION DOSE CONSTRAINTS

	Radiation Dose Constraints			
OAR	**Conventional Fractionation**	**Single-Fraction SRS**	**Three-Fraction SRS**	**Five-Fraction SRS**
Optic pathway	$D_{0.035\ cm^3} < 55$ Gy	$D_{0.035\ cm^3} < 10$ Gy (mandatory) $D_{0.035\ cm^3} < 8$ Gy (optimal)	$D_{0.035\ cm^3} < 20$ Gy (mandatory) $D_{0.035\ cm^3} < 15$ Gy (optimal) $V_{10.5\ Gy} < 0.5\ cm^3$	$D_{0.035\ cm^3} < 25$ Gy (mandatory) $D_{0.035\ cm^3} < 22.5$ Gy (optimal) $V_{12.5Gy} < 0.5\ cm^3$
	$D_{0.035\ cm^3} < 54$ Gy $D_{1\text{-}10\ cm^3} < 59$ Gy	$D_{0.035\ cm^3} < 15$ Gy (mandatory) $D_{0.035\ cm^3} < 10$ Gy (optimal)	$D_{0.035\ cm^3} < 23.1$ Gy (mandatory) $D_{0.035\ cm^3} < 18$ Gy (optimal)	$D_{0.035\ cm^3} < 1$ Gy (mandatory) $D_{0.035\ cm^3} < 23$ Gy (optimal)
Pituitary gland	$D_{0.035\ cm^3} < 50$ Gy	$D_{MEAN} < 9$ Gy

OAR, organ at risk; SRS, stereotactic radiosurgery.

Data from Bisello S, Cilla S, Benini A, et al. Dose-volume Constraints fOr oRganS At risk In Radiotherapy (CORSAIR): an "all-in-one" multicenter-multidisciplinary practical summary. *Curr Oncol*. 2022;29(10):7021-7050.

Long-Term Tumor Occurrence

The long-term risk of new tumor (benign and malignant) after conventional RT was estimated in a recent study of Hamblin et al[109] for patients treated for PitNET and craniopharyngioma. The probability of new tumor at 20 years was 4% (2.0%-6.0%) for the irradiated group, which was significantly higher than the 2.1% (1.1%-3.1%) probability in the control group.

In a SRS study involving a nonmalignant condition treated with SRS with 641 PitNETs, the risk of malignant transformation was estimated at 2.26 per 100,000 patient-years (95% CI:0.11-11.17) for radiosurgery-associated intracranial malignancy.[110]

Vascular Stenosis and Stroke After Prior Ionizing Radiation

Due to the frequency of cavernous sinus involvement, the treatment plan does not necessarily spare the internal carotid artery. Stenosis of the internal carotid artery after SRS has been reported, with an incidence of 0.70 per 1,000 patient-years (0.12-2.33) for FPitNET and NFPitNET.[111] Milanese et al[112] found one patient with a stroke due to carotid occlusion among 36 treated with conventional RT. The incidence of carotid stenosis and stroke was not reported for proton beam RT, so no comparison between modality can be performed.

Sims-Williams found no excess stroke compared to age- and sex-matched cohort for a series of patients with acromegaly treated with SRS, with a mean follow-up of 134 months.[113] Rim et al[15] in a small series using external beam RT reported a high rate of vascular complications (5%), suggesting that proton beam therapy can confer some sparing advantage for risk structures.

CONCLUSION

RT and SRS are important tools to manage patients with both NFPitNETs and FPitNETs. Long-term adenoma control is achieved in most patients with pituitary adenomas. A moderate rate of patients with functioning adenoma patients achieves endocrine remission. Hypopituitarism remains the most common complication following radiation to treat a pituitary adenoma; with timely diagnosis and hormonal replacement, this complication is a manageable one. Other complications such as cranial nerve dysfunction, cerebrovascular stenosis and stroke, and radiation-induced neoplasia are fortunately quite rare. The field is evolving with the aim of optimizing tumor control, endocrine remission, and minimizing side effects.

CHAPTER 42

Primary Base of Skull Tumors

Mark W. McDonald

ANATOMY

The skull base is a complex anatomic interface between the intracranial contents and the disparate extracranial compartments, including the paranasal sinuses, middle and inner ear, upper parapharyngeal space, and posterior neck and spine.[1] The skull base may be considered in three parts: anterior, central (or middle), and posterior (Figure 42.1). The petrous temporal bone is sometimes described as the posterolateral skull base and engages both the central and posterior skull base. Table 42.1 lists key skull base foramina or structures and their associated neurovascular structures, illustrated in Figure 42.2.

TABLE 42.1 KEY SKULL BASE FORAMINA/SPACES AND TRAVERSING NEUROVASCULAR STRUCTURES

Skull Base Location	Foramen or Space	Traversing Nerve/Neural Structure	Traversing Vessel
Anterior	Cribriform plate	Olfactory (CN I)	
	Optic canal	Optic (CN II)	Ophthalmic artery
Central	Superior orbital fissure	Ophthalmic (CN V1) Oculomotor (CN III) Trochlear (CN IV) Abducens (CN VI)	Superior ophthalmic vein
	Foramen rotundum	Maxillary (CN V2)	
	Foramen ovale	Mandibular (CN V3)	Accessory meningeal artery
	Foramen spinosum	Meningeal branch of mandibular nerve	Middle meningeal artery
	Vidian (pterygoid) canal	Vidian nerve	Vidian artery
	Meckel cave (aka trigeminal cave)	Trigeminal nerve ganglion (aka gasserian ganglion)	
	Dorello's canal	Abducens (CN VI) on way to cavernous sinus

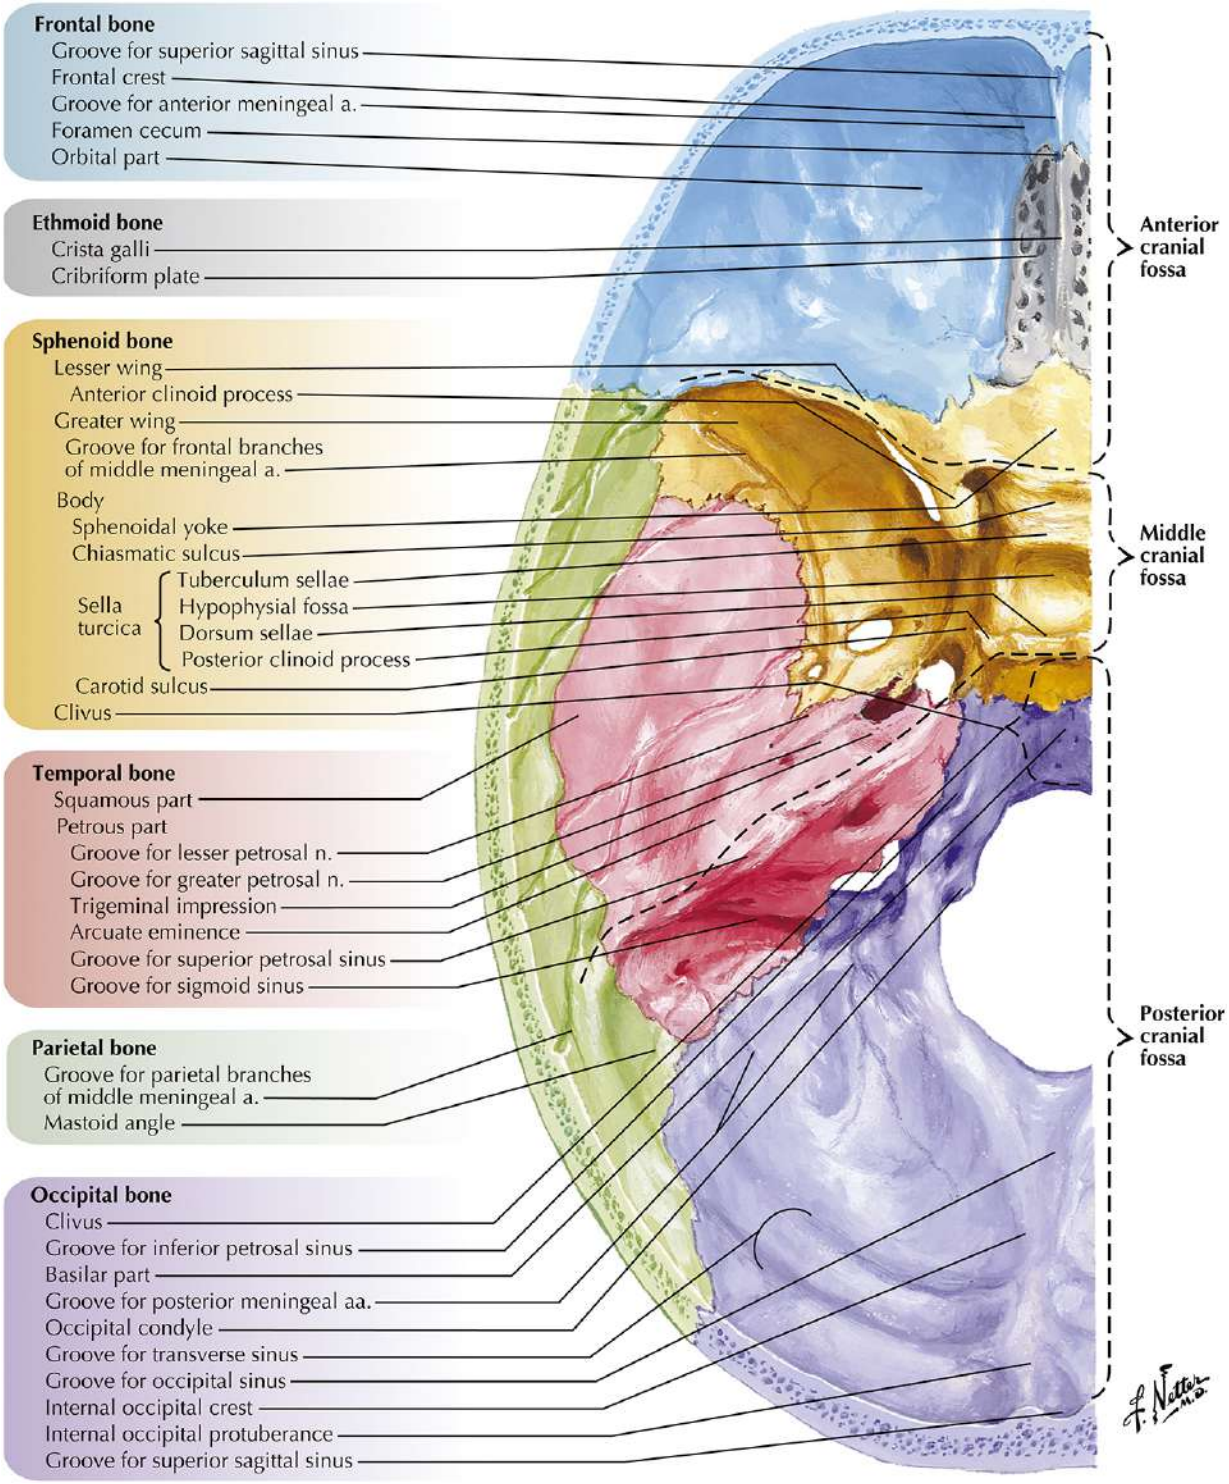

FIGURE 42.2 Skull base *foramina*. Foramina and canals of the cranial base: superior view. (Reprinted from *Netter FH. Netter Atlas of Human Anatomy: Classic Regional Approach*. 8th ed. Elsevier; 2023. Plate 34. Copyright © 2023 Elsevier. With permission.)

The anterior skull base interfaces with the orbit and sinonasal compartment. It is formed by the orbital plates of the frontal bone, the cribriform plate (cranial nerve [CN] I) and crista galli

of the ethmoid bone, and the planum sphenoidale and lesser wings of the sphenoid bone. The lesser wings of the sphenoid form the roof of the orbital apex and boundaries of the optic canals (CN II) and mark the division between the anterior and central skull base.

The middle or central skull base corresponds to the middle cranial fossa, pterygopalatine, and infratemporal fossae. Formed by the sphenoid and temporal bones, the central skull base contains the sella turcica (pituitary), clinoid processes, superior (sphenoid) portion of the clivus bone, and greater wings of the sphenoid. Paramedian to the central skull base are the cavernous sinuses containing CN III to CN VI and the cavernous portion of the internal carotid artery (ICA), and the temporal lobes of the brain. Foramen rotundum (V2), foramen ovale (V3), and foramen spinosum (meningeal branch of V3) traverse through the greater wings of the sphenoid. The petrous apex of the temporal bone forms the boundary between the central and posterior skull base, with the anterosuperior portion of the petrous apex forming the floor of the middle cranial fossa. At the superomedial aspect of the petrous apex is the petroclival junction, site of foramen lacerum, a predominantly fibrocartilaginous synchondrosis of the temporal bone with the occipital component of the clivus and the most common origin site for skull base chondrosarcoma.[2,3]

The posterior skull base is formed by the temporal, sphenoid, and occipital bones, with the posterosuperior portion of the petrous apex forming the anterior wall of the posterior cranial fossa. It contains the cerebellopontine angle, internal auditory meatus (CN VII, CN VIII), jugular foramen (CN IX, CN X, CN XI), hypoglossal canal (CN XII), and the foramen magnum (medulla, spinal component of CN XI, vertebral arteries, and anterior and posterior spinal arteries).

The clivus is formed from the sphenoid and occipital bones and bridges the central and posterior skull base. It may be conceptually divided into three levels (Figure 42.3). The superior (sphenoid) portion contains the dorsum sella and the posterior clinoids. At the caudal margin, the abducens nerve passes through Dorello's canal and marks the transition from the superior and middle clivus.[4]

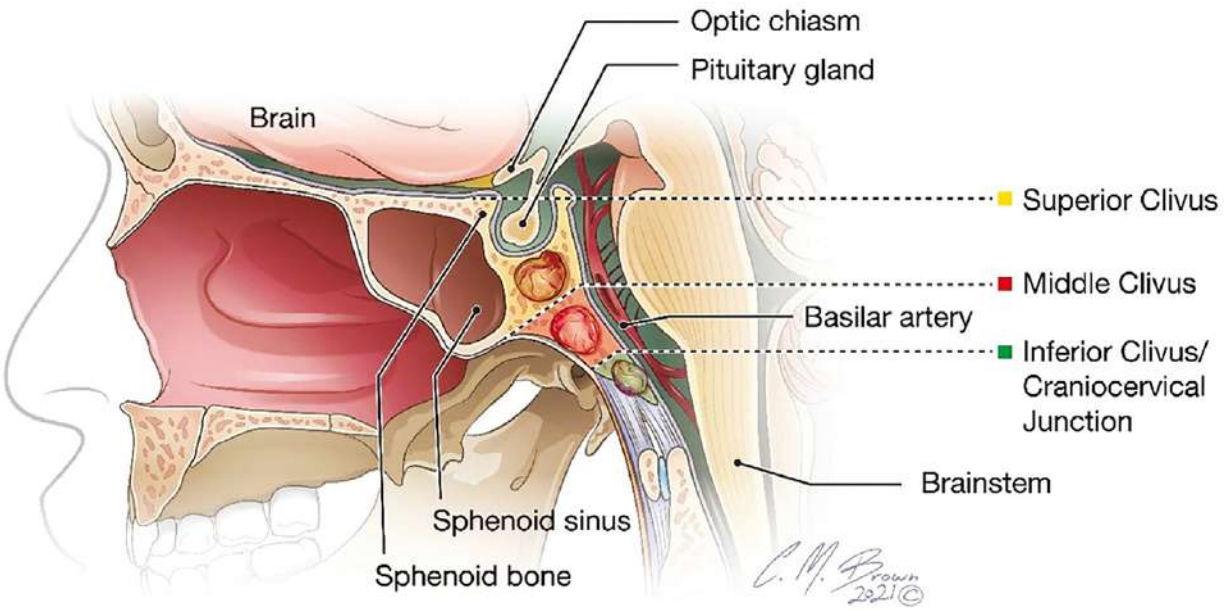

FIGURE 42.3 Illustration of the clivus. (Reprinted from Rao D, Stein R, Jenson M, Patel J, Fiester P. Imaging review of the endoscopic operative corridor for clivus lesions. *Curr Probl Diagn Radiol*. 2023;52[1]:66-76. Copyright © 2022 Elsevier. With permission.)

The middle (sphenoid) clivus extends from the sellar floor to the sphenoid body, with the lateral borders being the paraclival ICAs, foramen lacerum, and petroclival fissure. Middle clival lesions are most directly accessible and more likely to obtain a gross total resection via endonasal surgical approaches.[4]

The inferior (nasopharyngeal) clivus consists of the occipital portion of the clivus from the roof of the nasal choana to the foramen magnum. Lesions here are most difficult to access endonasally.

Paragangliomas arise along sympathetic or parasympathetic ganglia (Figure 42.4). In the past, paragangliomas have been called *chemodectomas* or *glomus tumors*, which are imprecise terms to be avoided.[5] Most head and neck paragangliomas are parasympathetic and arise, in order of frequency, at the carotid body, jugular, vagal, or tympanic sites.[6] Taken together, carotid body and jugular paragangliomas comprise about 80% of all head and neck paragangliomas.[7]

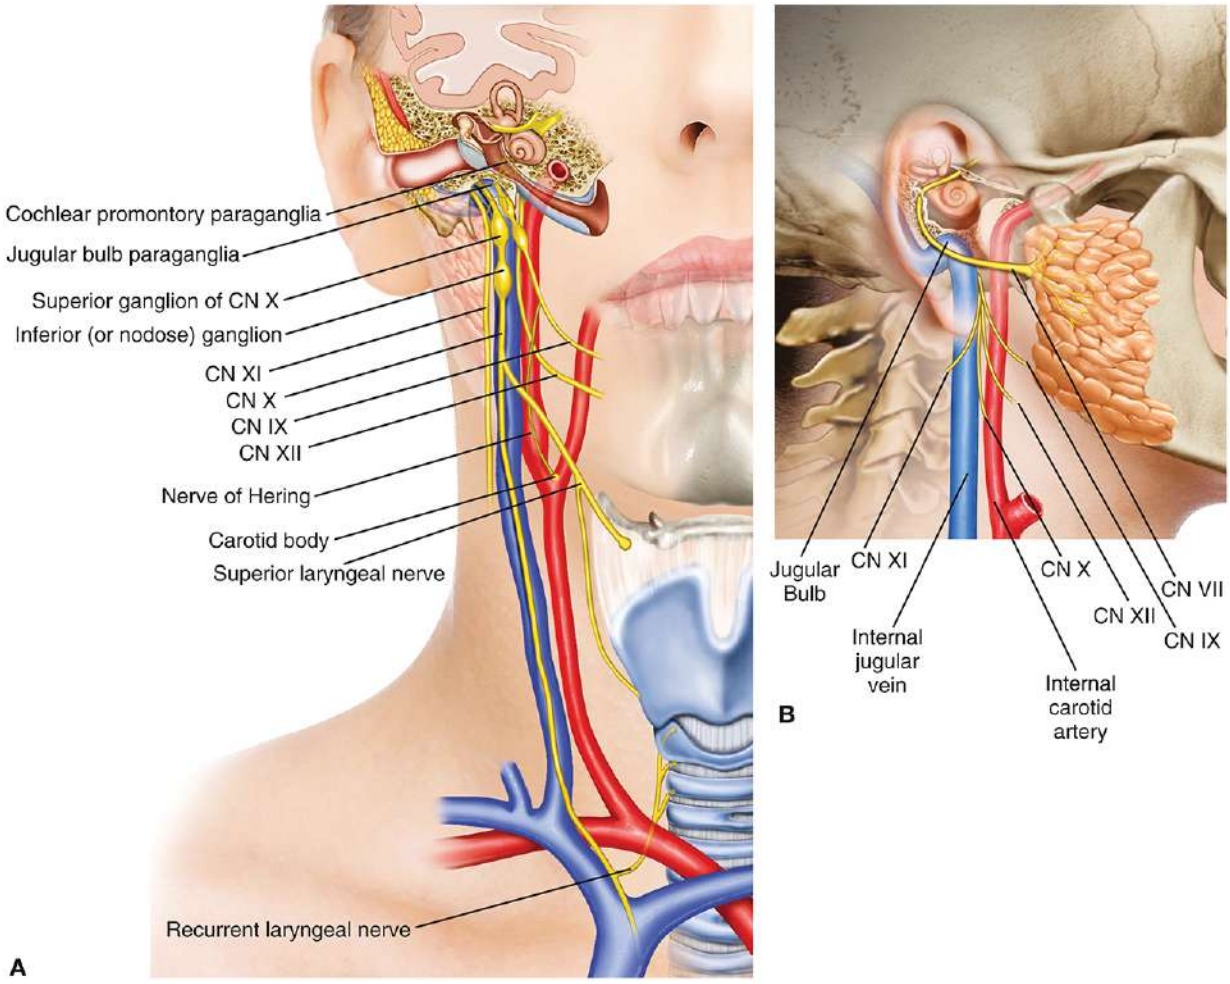

FIGURE 42.4 Anatomy relevant to head and neck paragangliomas. Anatomic site of origin of head and neck paragangliomas, in frontal (A) and lateral (B) views. CN, cranial nerve. (Reprinted from Verlicchi A, Nicolato A, Valvassori L, et al. Head and neck paragangliomas. In: Winn HR, ed. *Youmans and Winn Neurological Surgery*. 8th ed. Elsevier; 2023:1376, Figure 181.1. Copyright © 2023 Elsevier. With permission.)

Carotid body paragangliomas arise at the carotid bifurcation, at the plexus formed by the carotid sinus branch of the vagal nerve, and rami from the glossopharyngeal nerve and cervical sympathetic trunk.

Jugular paragangliomas arise at the superior ganglion of the vagal nerve at the jugular foramen. The jugular foramen is formed by the petrous portion of the temporal bone and the jugular process of the occipital bone, medial to the stylomastoid foramen, lateral to foramen magnum and the hypoglossal canal, and posterior to the carotid canal.

Vagal paragangliomas represent just 5% of head and neck paragangliomas and arise from the inferior ganglia of the vagal nerve (the ganglion nodosum), superior and medial to the carotid bifurcation and below the skull base.[5] Larger vagal tumors extending to the jugular foramen become indistinguishable from jugular paragangliomas with inferior extension.

Tympanic paraganglioma arises at the cochlear promontory, site of the tympanic plexus with the tympanic nerve (a branch of the glossopharyngeal nerve), and sympathetic branches from the internal carotid plexus. Jugulotympanic paragangliomas involve both sites or may be used as a catchall term for tumors of either location.

GENERAL PATHOLOGY

Many pathologies may involve the skull base. The anterior skull base is most commonly involved by direct extension of sinonasal malignancies or hematogenous metastases from other malignancies.[8,9] Sellar tumors including pituitary adenomas and craniopharyngiomas are discussed elsewhere. In the posterior skull base, the most prevalent pathologies include vestibular schwannomas and meningiomas, while perineural tumor spread may also be seen. Central skull base pathology can include perineural tumor spread from nasopharyngeal cancers, adenoid cystic carcinoma, and both cutaneous and mucosal squamous cell carcinomas.

Fibrous dysplasia is a mesenchymal disorder of bone that often involves the skull or facial bones. It may be an isolated finding or a part of McCune-Albright syndrome when accompanied by various endocrine abnormalities.[10] Most lesions are asymptomatic, incidentally detected, and managed with observation, while symptomatic patients may be treated with bisphosphonates.[11] While fibrous dysplasia can usually be diagnosed by computed tomography (CT), its appearance on magnetic resonance imaging (MRI) can mimic tumor with significant enhancement, and clinicians may be further mislead by avidity on positron emission tomography/CT (PET/CT).[12] The most common and easily recognized presentation of fibrous dysplasia is expanded bone with a ground-glass (pagetoid) appearance of both dense and radiolucent areas on CT.[2] Approximately a quarter of cases have a homogeneously dense (sclerotic) appearance on CT while a cystic (lytic) pattern is seen in a minority of presentations, with an expansile cystic lucency with a fluid or soft tissue appearing center surrounded by a dense bony shell.[13]

Skull base osteomyelitis, typically a bacterial or fungal infection from the sinonasal cavity or middle ear, can cause extensive bone and cartilaginous destruction, which may mimic an aggressive malignant process. Affected patients typically have an antecedent history of infection, surgery, or trauma, with patients who are diabetic and immunocompromised patients at greater risk.[14]

CHORDOMA

Pathology

Chordoma is a malignant mesenchymal tumor of bone. Chordomas are thought to arise from the remnant or ectopic notochord tissue,[15] and the diagnosis is confirmed by expression of brachyury, a notochord cell lineage transcription factor encoded by the *TBXT* gene.[16] Other common immunohistochemistry characteristics of chordoma include positive cytokeratin, epithelial membrane antigen (EMA), and S100 protein.[17] The histology of chordoma is notable for an abundant extracellular matrix with “physaliphorous” bubbly tumor cells, which may be found in solid masses or as cords and nests within a mucinous tumor matrix.[18] Mitotic figures are typically rare or absent.

The pathogenesis of chordoma has not been elucidated, but they may exist on a continuum of notochord remnant lesions. The notochord is a key structure in embryonic development as the precursor of the vertebrate nervous system.[19] While notochordal degeneration is typically complete by 10 weeks of gestation, persistent notochordal tissue may be found in the vertebral bodies of infants and children and rarely in middle-aged adults.[20]

Benign notochordal cell tumors (BNCTs), or *rests*, have previously been termed *ecchordosis physaliphora*, particularly when arising in the clivus. BNCTs appear to have a greater incidence than chordoma. In one study of 916 patients undergoing thin-slice CT and MRI for a variety of

indications, lesions with imaging characteristics consistent with BNCTs were incidentally detected in seven patients (crude incidence 0.76%).[21] While there are no agreed-upon features that distinguish radiographic BNCTs from chordoma, BNCTs are typically small (<2 cm) lesions without bony erosion, often arise on a filiform bony stalk or remain intraosseous, and are most often asymptomatic, although prepontine lesions may lead to compressive symptoms or a cerebrospinal fluid (CSF) leak.[21,22]

The difficulty in distinguishing between BNCTs and chordoma on both imaging and histologic examination suggests a link between them.[23-25] Proposed criteria for intervention of benign-appearing apparent notochordal lesions include symptomatic lesions, tumors >3 cm in size, atypical imaging characteristics (bony erosion, local invasion, or contrast enhancement), any appreciable growth on serial imaging, and patient preference.[24]

The subtypes of chordoma include conventional, chondroid, dedifferentiated, and poorly differentiated. In the National Cancer Database (NCDB) and Surveillance, Epidemiology, and End Results (SEER) data sets, the great majority of cases are conventional, with chondroid comprising 10% of cases, dedifferentiated ≤1%, and poorly differentiated not separately reported.[26]

Chondroid chordomas have a more hyaline-appearing matrix with cells that look similar to chondrocytes and may be confused with chondrosarcomas.[18] Chordomas are distinguished by positive brachyury staining and immunopositivity for cytokeratin and EMA, which are negative in chondrosarcoma.[27] The variant of chondroid chordoma does not appear to have any prognostic significance. In isolated series, the chondroid chordoma subtype has been variably reported to have a lower[28] or higher[29,30] likelihood of recurrence, while more studies[31-33] have found no difference. There was no statistically significant difference and not much numerical difference between survival outcomes for conventional and chondroid chordoma in NCDB and SEER data sets.[26]

Poorly differentiated chordomas, which occur more commonly in children, have a loss of *INI1* from isolated deletion of the *SMARCB1* gene and can be differentiated from other SMARCB1-deficient tumors such as atypical teratoid/rhabdoid tumor by brachyury expression and a distinct DNA methylation profile.[34,35] Dedifferentiated chordomas have a biphasic morphology with sarcomatous components. Both dedifferentiated and poorly differentiated chordomas have an aggressive clinical course and notably poor prognosis compared to conventional and chondroid chordoma.[36]

Epidemiology and Risk Factors

An analysis from the SEER database suggests that chordoma is the most common histology of malignant bone tumor arising in the head and neck in both adults and children.[37] The annual percentage change of age-adjusted incidence of malignant bone tumors of the head and neck between the years 2000 and 2019 was 1.52.

Chordomas arise at a median age of 58 with a male predominance (1.6:1) and are also more common in White patients.[26,38] There are no known exposures associated with an increased risk of developing chordoma.

Most chordomas are thought to represent sporadic malignant degeneration of notochord rests along the axial skeleton. The *TBXT* gene (previously known as the *T* gene), which is located on chromosome 6q27 and encodes brachyury, appears implicated in the pathogenesis of

chordoma.[39] The common *TBXT* gene rs2305089 variant is associated with a significant increased risk of sporadic chordoma in a White population,[40] but not in an Asian population.[41] A limited number of cases of familial chordoma have been reported, with a pedigree suggestive of an autosomal dominant inheritance with incomplete penetrance.[42] *TBXT* gene duplication is associated with susceptibility to familial chordoma[43] but rare or nonexistent in sporadic cases.[38,39] In young children, chordoma may occur within the setting of tuberous sclerosis.[44]

Retrospective evaluations have alternately associated female[45] and male sex[46] with a higher risk of disease progression and death. In multivariate analysis of NCDB and SEER data sets, there was no apparent difference in survival between men and women, nor by race.[26] Patients younger than 60 years had a decreased risk of mortality. Increasing tumor size, vascular encasement (ICA, basilar artery, or vertebral arteries), brainstem displacement, and prior site surgery or radiotherapy are correlated with lesser extent of resection, greater postoperative complications, higher tumor recurrence, and inferior survival.[47] In a multivariate analysis of 170 patients with skull base chordoma, avidly enhancing tumors with relatively less T2 hyperintensity were associated with a higher risk of progression (hazard ratio 1.88) than less enhancing more T2 hyperintense tumors.[29] A study of 174 patients with clival chordoma identified a radiomic score from preoperative multiparametric MRI features, which, together with gross total resection, was predictive of progression-free survival (PFS).[48]

Tumors with a Ki67 proliferation index ≥5% and homozygous 9p21 deletions appear to be associated with a more aggressive clinical course and shorter survival.[49,50] A larger study of 105 clival chordoma cases identified homozygous 9p21 deletions and 1p36 deletions as independent prognostic factors for PFS.[51]

Natural History

There are few data on the natural history of untreated chordoma. A series of 19 patients with skull base chordoma with serial imaging over a mean of 22 months prior to surgery was reported.[52] Compared to baseline MRI, the measured tumor volume increased by a mean of 8% per month for an absolute volume increase of 0.8 cm^3 per month (standard deviation ±0.7 cm^3). Their data showed that smaller tumors grew at a faster rate than larger tumors, consistent with a sigmoidal or Gompertzian model of growth in which the tumor growth fraction decreases exponentially as tumors enlarge.[53]

Skull base chordomas are primarily spread by direct tumor extension with local destruction. Tumors may extend superiorly to involve the sellar/suprasellar region displacing or encasing the pituitary or optic apparatus, laterally to involve the cavernous sinus or middle cranial fossa, posteriorly to involve the prepontine cistern with potential brainstem compression or, sometimes, invagination, and anteriorly into the sphenoid sinus or prevertebral soft tissues, the latter sometimes being substantially involved. Chordomas may have different degrees of dural involvement from dense adhesion to frank penetration, which is associated with a poorer prognosis.[54]

Local recurrence is the predominant pattern of failure for skull base chordomas. Maintenance of local tumor control is a prognostic factor for distant disease-free survival.[55] In the Paul Scherrer Institute (PSI; Villigen, Switzerland) experience, the 7-year distant metastasis-free survival was 92%, with all cases of distant disease seen in patients experiencing local failures.[56] Surgical seeding in the operative approach occurred in 12 (5.7%) of 210 patients in one series.[57]

Clinical Presentation

The most common presenting symptom in adults is a CN palsy.[58] CN VI (abducens) is most often affected with resultant diplopia. Most patients also note headaches, which may have been long-standing and progressive. CN V may be affected with tumor in the cavernous sinus, and lower CNs may be affected by disease involving the inferior clivus. Rhinorrhea from spontaneous CSF leak and compressive optic neuropathy are rare presentations.[59,60] Among children, ear pain, headaches, and diplopia are the most common presenting symptoms.[61] Clival chordomas are sometimes found incidentally on imaging obtained after trauma or for other reasons.

Diagnostic Workup

Initial evaluation should include both a skull base protocol MRI and CT. To screen for metastatic or multifocal chordoma, an MRI of the remainder of the spinal axis is recommended in guidelines[62] and a CT of the chest, abdomen, and pelvis is used for systemic staging. MRI of the spinal axis may also identify presumed benign notochord remnant tumors, which should be observed for growth. Chordoma has variable uptake on ^{18}F-fluorodeoxyglucose PET/CT, and its role in chordoma is poorly defined. In a series of 23 patients with chordoma (only one clival) undergoing PET/CT, the mean maximum standardized uptake value (SUVmax) was 5.8, and PET features did not correlate with MRI features.[63] The incidence of metastatic disease at presentation is low, but not well defined. A systematic review of published cases of metastatic chordoma identified the lungs and other spine bones as being the most common sites of distant metastases.[64] Cervical lymph node involvement may occasionally be seen and may be associated with cases with more significant prevertebral soft tissue involvement.

For many patients with skull base chordomas, the pathologic diagnosis (or at least confirmation of malignancy) is made intraoperatively during the definitive surgery. A biopsy is typically only considered when definitive surgery is not contemplated, or there is diagnostic uncertainty (eg, concern for clival metastasis, nasopharyngeal cancer, or other conditions for which radical surgery would rarely be indicated).

Imaging

Both CT and MRI are indicated in the evaluation of skull base pathology. CT is useful for evaluating cortical bone erosion and osseous changes, identifying tumoral calcifications, and for surgical planning. Permeative or erosive bone changes are suggestive of a more aggressive, rapidly proliferative process or infection, while bone expansion or remodeling with smooth cortical thinning is suggestive of a slow-growing process.[65] MRI provides optimal evaluation of soft tissue, perineural spread, dural, and marrow involvement. T1-weighted MRI sequences without gadolinium contrast and without fat saturation are recommended to identify tumor involvement in the marrow.[66] Dedicated skull base MRI protocols are required as routine MRI brain sequences can easily miss or mischaracterize skull base pathologies.[2] Recommended sequences include thin-slice T1 precontrast imaging *without* fat suppression, T2 sequences with fat suppression, and T1 postcontrast with fat suppression.[2]

On MRI, chordomas are typically intermediate or low signal on T1 sequences, with small foci of intrinsic T1 hyperintensity corresponding to intratumoral hemorrhage or mucous.[67] More than half of clival chordomas have no or mild contrast enhancement.[68] If enhancing, chordomas may

have heterogeneous contrast enhancement from minimal to moderate (Figure 42.5). Chordomas are typically T2 hyperintense. These characteristics are shared with skull base chondrosarcomas. A higher apparent diffusion coefficient value on MRI may help distinguish chondrosarcoma from chordoma,[69] and a multiparametric MRI radiomics analysis also showed good discrimination between the histologies.[70]

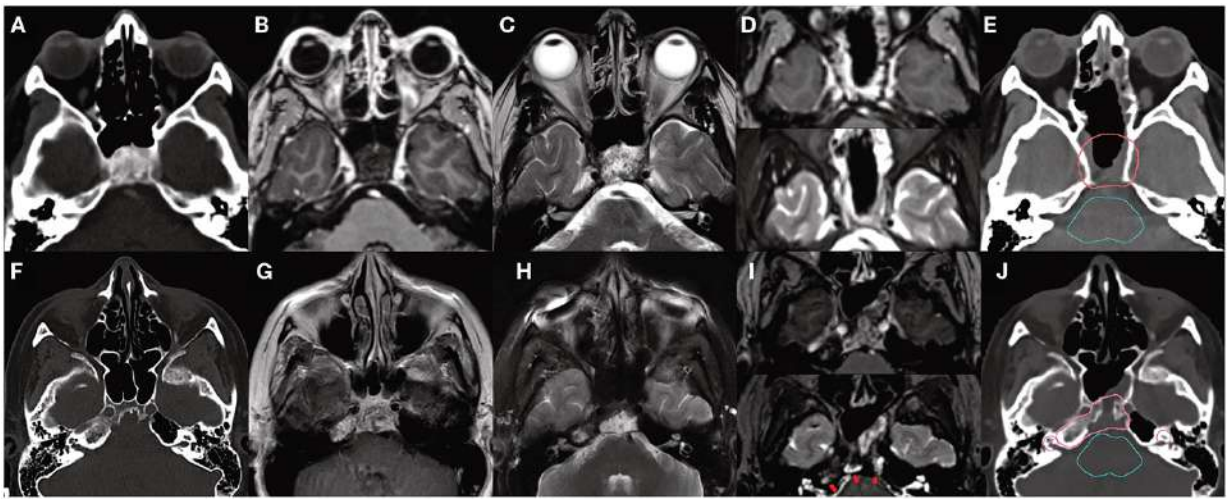

FIGURE 42.5 Variation in contrast enhancement patterns in clival chordomas. In first patient, an expansile ground-glass superior clival mass is on shown on computed tomography (CT) (A), with minimal T1 postcontrast enhancement (B), and T2 hyperintensity (C). Postoperative magnetic resonance imaging (MRI) (T1 postcontrast and T2; D) showed no residual tumor. E. Radiation treatment planning CT with the high-dose clinical target volume (74 Gy) in pink covering the primary tumor bed. In a different patient, a lytic expansile lesion involved the clivus and right petrous apex on CT (F) with heterogeneous T1 postcontrast enhancement (G) and T2 hyperintensity (H). Postoperative MRI (T1 postcontrast and T2; I) showed residual T2 hyperintense disease (red lines) in the right petrous apex and margins of the central clival resection. J. Radiation treatment planning CT with the high-dose clinical target volume (74 Gy) in pink covering the primary tumor bed and residual disease.

Staging

In the American Joint Committee on Cancer (AJCC) eighth edition staging system for primary tumors of bone of the skull and face, T1 tumors are those ≤8 cm in greatest dimension, which applies to nearly all skull base chordomas. The prognostic and therapeutic relevance of current AJCC staging is, therefore limited.

General Management

Patients with skull base chordomas should be evaluated by an experienced skull base surgical team for aggressive efforts at maximal surgical resection in an effort to achieve gross total resection. More than one surgery and more than one surgical approach may be required to achieve maximal tumor debulking. Postoperative radiotherapy is recommended for the majority of patients.

A suggested algorithm for management is presented in Figure 42.6.

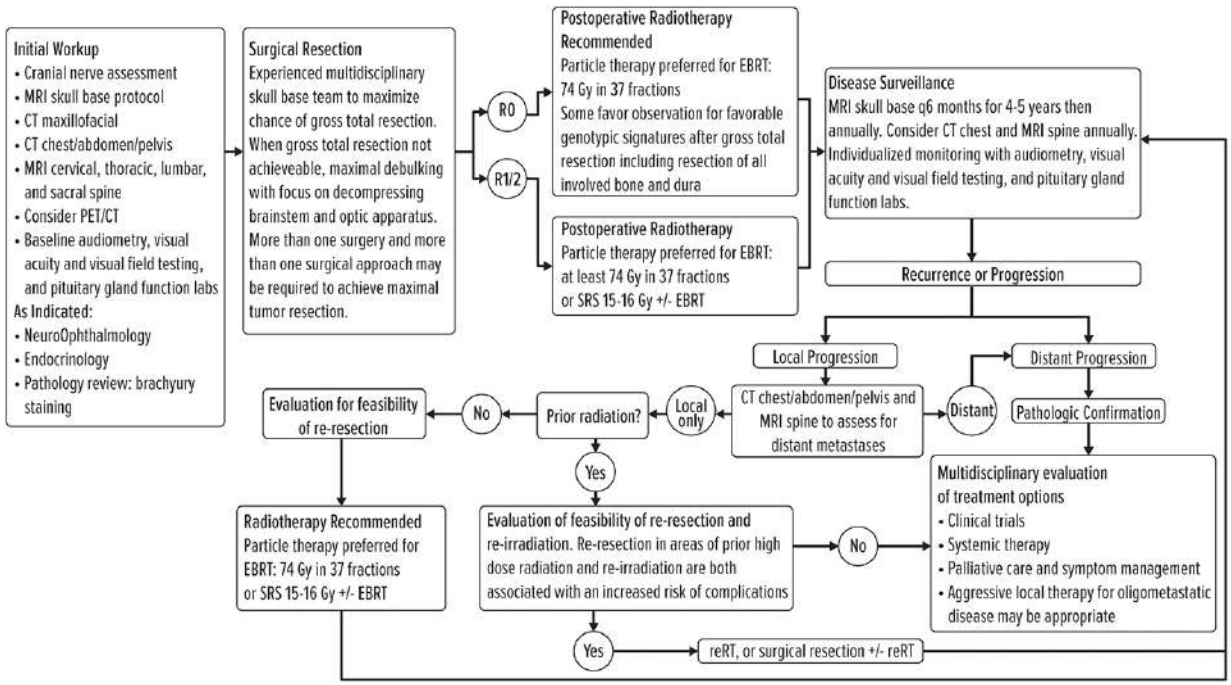

FIGURE 42.6 Suggested algorithm for skull base chordoma. CT, computed tomography; EBRT, external beam radiation therapy; MRI, magnetic resonance imaging; PET, positron emission tomography; q, every; RT, radiation therapy; SRS, stereotactic radiosurgery.

Surgery

An endoscopic transnasal transclival approach provides a direct corridor to the clivus without interposing major neurovascular structures and has become the mainstay for surgical resection of many clival lesions.[71] A variety of transcranial approaches may be selected or combined with an endoscopic approach based on the location of the tumor and experience of the surgeon.

The goal is maximal safe surgical resection. The chordoma tumor matrix is typically mucinous or gelatinous and more readily removed, while the outer layer is more fibrous and may be adherent to neurovascular structures.[72] Gross total resection is consistently associated with more favorable outcomes than a lesser extent of resection.[57,73,74] When a gross total resection is not achievable, maximal tumor debulking appears beneficial. A study of patients with skull base chordoma undergoing surgery and postoperative proton therapy found a residual tumor volume >20 cm^3 was associated with a higher risk of progression.[30] A larger chordoma tumor volume was associated with brainstem compression, which necessitates some compromise in target volume coverage by high-dose radiotherapy. A study of 195 patients with skull base chordoma identified a postoperative tumor volume >4.9 cm^3 was associated with a higher risk of progression.[75]

The extent of tumor resection achieved is greater and the complications fewer, with increasing operative volume and duration of skull base surgical experience and access to specialized tools and techniques.[76-78] Because skull base tumors are rare, surgical expertise is difficult to accrue and maintain outside high-volume centers with the associated interdisciplinary team and resources required for a successful skull base program.[79,80] Patients should be evaluated by an experienced skull base surgical team to explore all options to achieve maximal resection prior to radiotherapy, particularly for skull base chordoma.

Based on the long natural history of chordoma, some practices have favored observation following gross total resection, reserving radiotherapy for salvage therapy of recurrent disease. However, there are data to support adjuvant radiotherapy, regardless of the extent of resection, described below.

Principles of Radiation Therapy

In a series of 284 patients with skull base chordoma undergoing surgery, planned postoperative radiotherapy was associated with improved PFS and chordoma-specific survival compared to observation or when radiotherapy was delivered for recurrent disease.[81] The apparent benefit of postoperative radiotherapy was also seen in patients undergoing gross total resection of disease. In another series with multivariate analysis of 210 patients with skull base chordoma undergoing surgery, both non–gross total resection and omission of postoperative radiation therapy were associated with inferior PFS.[57] The best outcomes were observed in those undergoing both gross total resection and postoperative proton-based radiotherapy. Many studies have found salvage surgical interventions at the time of recurrence are less likely to achieve gross total resection and that radiotherapy is most effective in the setting of the least burden of residual disease, and so patients receiving salvage (rather than adjuvant) radiotherapy are more likely to have a larger volume of disease and unfavorable tumor geometry in relationship to critical organs at risk (OARs).

The team at the University of Pittsburgh have proposed a genotypic risk stratification to guide patient management based on the percentage of tumor cells with 1p36 and 9p21 chromosomal deletions on fluorescence in situ hybridization.[82] In their experience with 152 patients with clival chordomas, patients could be stratified into three risk groups. Group A patients (deletions of 1p36 <15% and 9p21 <4%) had the best prognosis with a 5-year PFS of ~85%. Group A tumors were more often asymptomatic smaller tumors in younger patients, with a less invasive phenotype more easily amenable to gross total resection. Group C (deletions of 1p36 >15% and 9p21 >25%) had the worst prognosis with a mean PFS of 16 months. Group B represented all other combinations and had a 5-year PFS of ~40%. All groups benefited from gross total resection compared to lesser surgeries. Following gross total resection, there was no apparent difference in PFS with the addition of postoperative radiation for group A or group B. Postoperative radiation was associated with improved PFS after subtotal resection in group B and for all patients in group C, regardless of the extent of resection. This management approach has not yet been externally validated, and as the authors note, less radical resections performed elsewhere that might still be considered gross total resection may not yield the same results.

Radiation Techniques

Treatment Modalities and Dose

A position paper sponsored by the Chordoma Foundation recommends postoperative particle therapy–based radiation for skull base chordoma after both gross total and subtotal resection.[62] A dose of at least 74 Gy (relative biologic effectiveness [RBE]) in 37 fractions was recommended, regardless of the extent of resection.

Outcomes with lower dose radiation are poor. Conventionally fractionated radiotherapy to 60 Gy after subtotal resection or biopsy yielded a 5-year PFS of 25% in a series of 18 patients.[83] An NCDB analysis in skull base chordoma found that among patients receiving radiation, doses

>60 Gy were associated with improved overall survival.[84] A separate NCDB analysis including chordoma of all sites found that proton beam therapy and doses >65 Gy were associated with improved overall survival.[85]

Kim and colleagues compiled skull base chordoma outcomes from a published series using photon, photon plus proton, proton, and carbon ion therapy to evaluate a dose-response relationship to local control.[86] Converting the varied fractionation schedules used in each study to an equivalent dose in 2 Gy fractions (EQD2) with an α/β of 3, their model estimates that a dose of 74 Gy (RBE) in 37 fractions would yield a 5-year local control rate of 82%, while a dose of 79 Gy (RBE) would be required to reach 90%.

Gamma Knife data also support a dose response, suggesting that a marginal dose of 15 or 16 Gy is desired. Koga and colleagues reported progression in all six patients with skull base chordoma treated with a median marginal dose of 12 Gy compared to no progression in four patients who received a marginal dose of at least 16 Gy.[87] Echoing the poor results of lower dose treatment, a separate series of 53 patients with skull base chordoma treated to a mean marginal dose of 13.5 Gy reported a 5-year PFS of 18%.[88] Multi-institutional data found improved local control following Gamma Knife with a marginal dose ≥15 Gy.[89]

The bulk of the clinical outcomes data for skull base chordomas are from patients managed with proton therapy, and the results appear superior to both stereotactic radiosurgery (SRS) and those managed with modern photon techniques even at higher doses.[57,90,91] A series of 57 patients with chordoma (n = 15 base of skull) treated with intensity-modulated radiation therapy (IMRT) to a median dose of 70 Gy in 35 fractions reported a 5-year local control of 47%.[92] A series of 24 patients with skull base chordoma treated with image-guided IMRT to a median dose of 76 Gy after biopsy (n = 1), subtotal (n = 15), or gross total (n = 8) resection reported a 5-year local control of 65%.[93] A series of 19 patients with clival chordoma treated with CyberKnife to a median dose of 37.5 Gy in 5 fractions reported a 5-year local control of 60%.[94] The North American Gamma Knife Consortium reported on 71 patients with skull base chordoma treated at six centers to a median marginal dose of 15 Gy.[89] The 5-year "treated tumor" control rate was 66% whereas the skull base tumor control rate was 58% due to recurrences outside the treated volume.

In contrast, the PSI experience using pencil beam scanning proton therapy in the treatment of 151 patients with skull base chordoma reported a 5-year local control of 81%.[95] At 7 years, the local control estimate was 71% and overall survival was 73%.[56] A systematic review of 16 studies including 752 patients treated with proton therapy for skull base chordoma to a mean dose of 74 Gy (RBE) reported a 5-year weighted average local control of 77% and overall survival of 80%.[96]

The team at Massachusetts General Hospital have also reported long-term follow-up on 204 children treated for clival chordoma over a 40-year period. The median age at treatment was 11 years. Patients were treated with surgery followed by a median dose of 76.7 Gy (RBE) with either protons alone or combined photon and proton treatment. The 20-year PFS and overall survival were both 64%.[61] Poorly differentiated chordomas were present in 9% and associated with worse outcomes.

Target Volume Definition

Detection of residual tumor on immediate and early postoperative imaging is challenging due to anticipated imaging changes from granulation tissue, blood, packing material, and fat grafting.[97]

By contouring the extent of the gross disease prior to surgical intervention on preoperative imaging, one can more readily recognize areas of concern for residual disease after surgery. Residual tumor is most often identified at the deep margin of the resection as well as posterior and lateral to critical structures, such as the ICA (eg, cavernous sinus). Tumor in the inferior clivus and occipital condyles is challenging to access for complete resection.[98,99] In addition, residual tumor may be identified in the prevertebral soft tissue or as residual involved bone (eg, posterior clinoids or occipital condyles). Diffusion-weighted imaging (DWI) appears to improve the detection of residual and recurrent disease with high signal on trace DWI sequences.[100] As always, consultation with the surgical team is essential to understand areas of greatest concern and to provide clinical context to observed radiographic findings after surgery.

There are limited available guidelines for contour delineation in skull base chordoma. Available recommendations from the European Society for Radiotherapy and Oncology Advisory Committee on Radiation Oncology Practice[101] and the Chordoma Foundation[62] are summarized in Table 42.2. Given the high risk for residual microscopic disease at the margins of the resection, patients treated with fractionated therapy typically receive high-dose radiotherapy to a large volume encompassing the preoperative tumor bed. Conversely, patients treated with SRS typically receive high-dose radiotherapy to a substantially smaller volume, typically the apparent residual tumor with a 1 to 2 mm planning target volume (PTV) expansion depending on the radiosurgery platform. Investigators from the Mayo Clinic evaluated the relationship of tumor recurrence to the prescription isodose line of treatment in eight patients with skull base chordoma who experienced a skull base recurrence after Gamma Knife.[102] Only two were in field, while 6/8 were either marginal (falling within the 20%-40% isodose line) or remote (outside the 20%-30% isodose line). These and other experiences[89] suggest that the larger volume treated with fractionated high-dose radiotherapy is associated with improved skull base tumor control. An example case is shown in Figure 42.7.

TABLE 42.2 SKULL BASE CONTOURING GUIDELINES

	ESTRO ACROP for Chordoma and Chondrosarcoma[101]	Chordoma Foundation Position Paper[62]
CTV1	Typically includes preoperative tumor volume with an anisotropic margin of 10-20 mm plus the residual tumor and surgical resection margins. Include posterior portion of residual sphenoid sinus for those who underwent transsphenoidal surgery	Encompass all volumes at risk for microscopic disease, including areas of preoperative tumor extension. Include prevertebral long muscles if they are infiltrated
CTV2	Residual tumor plus 5-10 mm expansion modified to natural barriers to tumor growth, plus the resection margins at higher risk of residual disease	Encompass any residual microscopic disease in the tumor bed after surgery, followed, in some cases, by a third volume (CTV3) to any sites of residual gross disease
Do not include	Previously compressed normal structures that have reexpanded after surgery, peritumoral edema, surgical tract	Inclusion of the entire surgical access path in CTV1 remains controversial. Inclusion of the retropharyngeal space in the target volume definition as a possible site of recurrence remains controversial

CTV, clinical target volume.

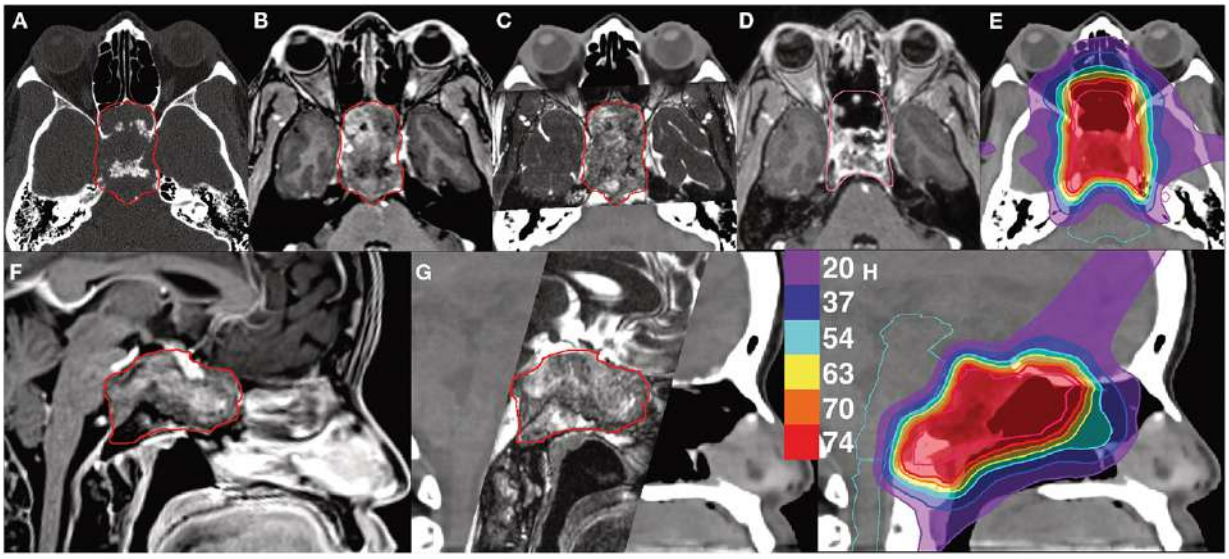

FIGURE 42.7 Example of chordoma of the skull base. This patient in their early 60s presented with headaches. A-C,F,G. Tumor volume is outlined in red on preoperative axial computed tomography (A) and axial and sagittal T1 postcontrast (B,D) and T2 (C,E) magnetic resonance imaging (MRI); a large clival tumor with prepontine, bilateral cavernous sinus, and sphenoid sinus extension, abutting the brainstem and optic chiasm. An endoscopic transnasal transclival resection was performed. DF. T1 postcontrast MRI at the time of radiation planning with a clival defect and enhancement related to right-sided nasal septal flap and abdominal fat graft. There was no apparent residual tumor. The high-dose clinical target volume to receive 74 Gy (relative biologic effectiveness) is shown in pink. GE,H. Proton radiation treatment plan.

Response Assessment and Surveillance

Following radiotherapy, the expected outcome is no growth of residual tumor or no recurrence of disease. During a course of fractioned radiotherapy, chordomas may experience a transient increase in tumor volume, presumably due to tumor necrosis and edema.[86] This is perhaps more relevant in patients with spine or sacral chordomas being treated with definitive radiotherapy and less frequently an issue for skull base chordomas. Sacral and spine chordomas treated nonoperatively often have some volumetric tumor response to the extraosseous soft tissue component of disease after high-dose radiotherapy.

There are few data to guide recommendations on surveillance imaging. The Chordoma Foundation position paper recommends an MRI every 6 months in the first 5 years and then annually through 15 years post-treatment with no specific recommendations for distant surveillance.[62] The group at MD Anderson Cancer Center reported on 91 patients with skull base chordoma in surveillance for a mean follow-up time of 79 months during which time 34 had experienced disease progression.[103] About half of recurrences occurred in the first 5 years and about one-third occurred more than 10 years after treatment, highlighting the importance of long-term follow-up. Pulmonary metastases and leptomeningeal spread were the two most common patterns of distant disease in their experience. Every instance of distant recurrence was preceded by an initial local recurrence. Based on their observed patterns of failure and timeline, they recommended both a CT of the chest/abdomen/pelvis and an MRI of the spine every 6 months in the first year and then annually to screen for distant disease. Compared to alternate published surveillance protocols, the authors noted their approach would reduce the time to diagnosis of recurrence (assuming patients lacked symptoms, which may have prompted earlier imaging).

Systemic Therapy

There are currently no systemic therapies approved for a chordoma indication. Chordomas often express a variety of potentially actionable targets, including c-KIT, epidermal growth factor receptor (EGFR), vascular endothelial growth factor, platelet-derived growth factor receptors, and HER2/neu. A genomic mapping of genetic dependencies in chordoma has been published, with preclinical data suggesting promising efficacy of small-molecule inhibitors of Src homology-2 domain-containing phosphatase 2 (SHP2).[104] Previous clinical results with targeted therapies have been modest. A phase II trial of imatinib in 56 patients with progressive locally advanced or metastatic chordoma reported a median time to progression of 9 months and a median overall survival of 35 months.[105] A phase II trial of sorafenib in 27 patients with progressive locally advanced or metastatic chordoma reported a 1-year PFS of 73% and overall survival of 86.5%.[106] Lapatinib was evaluated in a small phase II trial with only modest activity,[107] while case reports have reported the activity of other EGFR inhibitors.[108] A double-blind randomized trial in patients with locally advanced unresectable chordoma used radiotherapy with either a placebo or novel brachyury vaccine.[109] The trial closed early after treatment of 24 patients as there appeared to be no synergistic antitumor effects of the vaccine with radiotherapy. Nevertheless, the *TBXT* gene, which encodes brachyury, remains an attractive therapeutic target for chordoma, and other vaccine trials are underway. Immunotherapy has shown promise with some data to suggest that programmed death-ligand 1–negative chordoma may still benefit from immune checkpoint inhibitors.[110]

CHONDROSARCOMA

Pathology

Chondrosarcomas are mesenchymal tumors with cartilaginous differentiation. Skull base chondrosarcomas arise from the rests of chondrocytes within the synchondroses of the basilar skull bones.[111] The majority (80%-90%) of chondrosarcomas are "conventional," with a three-tier grading system based on degrees of atypia, cellularity, and mitotic activity.[112] Grade 1 chondrosarcomas are similar in appearance to normal cartilage or the appearance of benign enchondroma but with a permeative pattern of infiltration in which normal bone trabeculae are surrounded by neoplastic cartilage.[18] Skull base chondrosarcomas are most often conventional and grade 1 or 2.[16] More than 85% of skull base chondrosarcomas harbor *IDH1 or IDH2* mutations, most commonly $IDH1^{R132C}$.[113] The nonconventional chondrosarcoma histologies include mesenchymal, dedifferentiated, and clear cell. Mesenchymal chondrosarcoma is a rare small round blue cell histology,[114] which is more commonly seen in young adults and associated with a worse prognosis.[115] Dedifferentiated chondrosarcomas are very aggressive tumors with a poor prognosis.[116] Clear cell chondrosarcomas are low grade and occur primarily at an epiphyseal location in long bones.[117]

Epidemiology and Risk Factors

Chondrosarcomas are the second most common primary malignancies of bone after osteosarcoma,[118] but occurrence at the skull base is rare. Data on skull base chondrosarcoma from the NCDB suggest a median age of 51 years old with a near-equal prevalence by sex (55% male) and most cases (85%) occurring in non-Hispanic White patients.[119]

Extracranial chondrosarcoma has been reported as a rare secondary malignancy after radiation therapy for lung cancer, cervical cancer, Hodgkin lymphoma, and total body irradiation, among others,[120-123] and maxillary sinus chondrosarcomas have been reported after radiation for retinoblastoma.[124]

The majority of chondrosarcomas are thought to represent sporadic malignant degeneration of rests of chondrocytes along the spheno-petro-clival junction.[111] Ollier disease and Maffucci syndrome, caused by somatic mosaic mutations of *IDH1* and *IDH2*,[125] are both characterized by multiple enchondromas with an increased risk of developing chondrosarcoma[126] and low-grade gliomas.[127] About 1% of skull base chondrosarcomas arise in the setting of Ollier disease or Maffucci syndrome.[128]

Younger age is associated with a more favorable prognosis.[129-131] Conventional histology and grade 1 chondrosarcomas are associated with the best outcomes. Grade 1 and 2 chondrosarcomas appear to have nearly identical outcomes, while grade 3 histology was associated with a 33% recurrence rate, though not statistically significant, perhaps because of small numbers.[132] The extent of tumor resection for skull base chondrosarcomas appears less predictive of outcomes when adequate postoperative radiotherapy is given. The rate of tumor recurrence or progression is comparable after gross total resection and subtotal resection when patients receive postoperative radiotherapy.[132] For skull base chondrosarcomas, tumor within the cavernous sinus adherent to the ICA or CNs is the most common reason for a subtotal resection.[3]

Natural History

Many patients have a long antecedent history of slowly progressive symptoms before presentation, suggestive of a slow growth rate. Skull base chondrosarcomas spread by direct tumor extension with local destruction. There are very few data on the natural history of untreated skull base chondrosarcomas. A case report of a young patient with a radiographic diagnosis consistent with a chondrosarcoma observed with serial MRIs over 10 years noted varied growth rates, initially rather rapid followed by a prolonged period of stability without intervention.[133] Some have argued that we may be misinterpreting these sometimes prolonged periods of tumor stability as signs of efficacy of radiotherapy rather than simply the indolent course of the disease.[134]

Clinical Presentation

As with chordoma, patients with chondrosarcoma typically present with symptoms from tumor mass effect on adjacent neurovascular structures.[67] Diplopia and headaches are common presenting symptoms, with CN VI and CN V most commonly affected.[128] Hearing loss, dizziness, facial nerve dysfunction, trigeminal dysesthesias, and other cranial neuropathies may be seen depending on the extent of the disease. Fewer than 10% are asymptomatic and discovered incidentally.[128]

Diagnostic Workup

As with skull base chordomas, initial evaluation should include both a skull base protocol MRI and CT. Prior to establishing the histologic diagnosis, many patients will have undergone additional imaging workup to rule out a potential bone metastasis of unknown primary, but if

not already obtained, a CT of the chest may be obtained to evaluate for pulmonary metastatic disease and serve as a baseline. Metastatic disease is rarely identified at presentation of skull base chondrosarcoma— less than 2% in an NCDB analysis[135]—and subsequent development of extracranial metastases is very rare, observed in just 0.5% of patients in a systematic review.[128] This contrasts with extremity or extracranial chondrosarcomas, where 7% to 11% of patients may present with pulmonary metastatic disease.[136-138] In these patients with extracranial chondrosarcoma, factors associated with the development of pulmonary metastatic disease include dedifferentiated or high-grade histology, presence of lymph node metastases, large tumor size (>8.6 cm), and locally recurrent disease.[136] The incidence of osseous metastatic disease in extracranial conventional chondrosarcoma is very low (<1%), suggesting no role for routine skeletal imaging.[138]

As with skull base chordoma, the pathologic diagnosis is often made intraoperatively during the definitive surgery. A biopsy is typically only considered when definitive surgery is not contemplated, or there is diagnostic uncertainty (eg, concern for clival metastasis, nasopharyngeal cancer, or other conditions for which radical surgery would rarely be indicated).

Imaging

Chondrosarcomas share similar imaging characteristics to chordomas as previously outlined. Chondrosarcomas are more likely to be lateralized or paramedian in location.

Staging

As with chordomas, the AJCC staging is of limited prognostic or therapeutic value for skull base chondrosarcomas. Essentially, all will be ≤8 cm in greatest dimension and, therefore, T1.

General Management

Patients with skull base chondrosarcomas should be evaluated by an experienced skull base surgical team for maximal safe surgical resection while minimizing the risks of iatrogenic toxicity. Gross total resection is less common. When an R0 resection is not achievable, maximal tumor debulking should focus on decompressing the brainstem and optic apparatus to optimize the ability of radiation therapy to cover residual disease. More than one surgery and more than one surgical approach may be required to decompress critical OARs. Radiotherapy is a recommended adjuvant therapy for the majority of patients.

A suggested algorithm for management is presented in Figure 42.8.

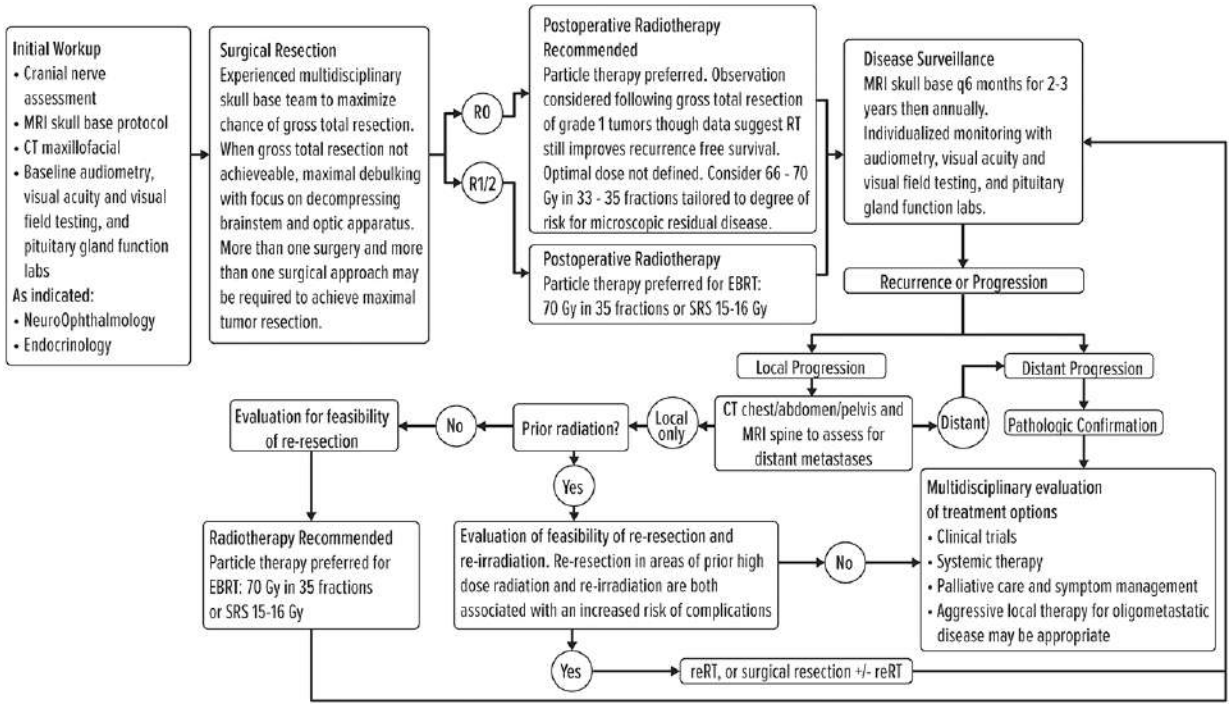

FIGURE 42.8 Suggested algorithm for chondrosarcoma of the skull base. CT, computed tomography; EBRT, external beam radiation therapy; MRI, magnetic resonance imaging; PET, positron emission tomography; q, every; RT, radiation therapy; SRS, stereotactic radiosurgery.

Surgery

As with chordomas, mucinous portions of chondrosarcoma tumors are more readily removed, while the outer layer may be adherent to neurovascular structures.[3] For mesenchymal and dedifferentiated chondrosarcomas, which are rare at the skull base, gross total resection is associated with improved PFS.[139] For conventional grade 1 to 2 chondrosarcomas adherent to critical neurovascular structures, leaving a moderate volume of residual disease to minimize risks has no apparent decrement in outcome when patients receive adequate postoperative radiotherapy. An NCDB analysis of patients with skull base chondrosarcoma undergoing combined surgery and radiation therapy found no difference in survival following subtotal versus complete surgical resection, although surgical cohorts fared better than radiotherapy alone.[135]

Data on 77 patients with skull base chondrosarcoma managed with subtotal resection and proton therapy at PSI found a tumor volume >25 cm^3 was associated with a higher risk of local recurrence.[131] The only local failures were in patients with tumors abutting or compressing the brainstem or optic apparatus. Optimizing the tumor geometry by decompressing the brainstem and optic apparatus is needed for the best outcomes in skull base chondrosarcoma and to mitigate radiation- induced toxicities to these critical structures.[128]

Based on the indolent growth rate of conventional chondrosarcomas, some have favored observation following gross total resection, reserving radiotherapy for salvage therapy of recurrent disease. However, there are data to support adjuvant radiotherapy, regardless of the extent of resection, described below.

Principles of Radiation Therapy

In a systematic review and meta-analysis including 560 patients with skull base chondrosarcoma, the best outcomes were observed in those treated with combined surgery and radiation therapy, with a 5-year freedom from recurrence/progression of 91%.[132] For those treated with surgery alone, the 5-year recurrence was 44%. Furthermore, even for the minority of patients undergoing gross total resection, postoperative radiation was associated with a statistically significant benefit in recurrence-free survival, suggesting a role for radiotherapy regardless of the extent of surgical resection. In an NCDB analysis of 718 patients with skull base chondrosarcoma, receipt of proton-based radiotherapy and a dose ≥60 Gy (RBE) was associated with improved overall survival compared to photon-based radiotherapy.[135]

Radiation Techniques

Treatment Modalities and Dose

An NCDB analysis that evaluated chondrosarcoma at all body sites evaluated the association of both radiation dose and technique with outcomes.[140] Patients treated with proton therapy had the highest 5-year survival, with both proton therapy and SRS associated with a statistically significant higher survival than IMRT. Those treated with >60 Gy had a statistically significant higher survival than those receiving 40 to 60 Gy, which, in turn, was associated with better survival than those receiving palliative (<40 Gy) radiation.

A multi-institutional analysis of 251 patients with skull base chondrosarcoma treated at PSI or the Centre de Protonthérapie in Orsay, France (CPO) to a median dose of 70 Gy (RBE) reported a 7-year failure-free survival of 93%.[141] In a separate report of the 77 patients treated at PSI with pencil beam scanning proton therapy for residual or progressive skull base chondrosarcomas, the crude rate of adverse radiation effects was 7.8% (three patients with hearing loss, two radiation necrosis, one optic neuropathy), with toxicity correlated with higher radiation dose.[131] The authors proposed a prospective trial to evaluate modest-dose de-escalation, reserving 70 Gy (RBE) for older patients with tumors abutting the brainstem or optic apparatus, using 64 Gy (RBE) in young (eg, ≤45 years) patients with small tumors not abutting OARs, and 68 Gy (RBE) for the remainder of patients.

The group at the Heidelberg Ion Beam Therapy Center reported on 101 patients with skull base chondrosarcoma treated with carbon ion therapy (n = 79) or proton therapy (n = 22).[142] Those treated with carbon ion therapy received a median dose of 60 Gy (RBE) in 20 fractions, while those treated with proton therapy received a median dose of 70 Gy (RBE) in 35 fractions. With a median follow-up time of 40 months, there was no statistically significant difference in the 5-year local control between carbon ion therapy (90.5%) and proton therapy (100%).

For SRS, there is also evidence for radiation dose response, suggesting a marginal dose of 15 to 16 Gy in a single fraction is optimal. In a multicenter series of 51 patients receiving Gamma Knife for residual or recurrence skull base chondrosarcoma (median tumor volume 8 cm^3), Kawashima and colleagues reported the best results in patients receiving ≥16 Gy with a 5- and 10-year local control of 83%.[143] Those receiving <15 Gy had a 5-year local control of about 50%. The North American Gamma Knife Consortium reported a multicenter study of 46 patients undergoing SRS for skull base chondrosarcoma who also had a median tumor volume of 8 cm^3.[144] The 22 patients with no prior history of radiation who received a marginal dose ≥15 Gy enjoyed 100% local control at 10 years compared to 47% with a marginal dose <15 Gy. The

rate of adverse radiation effects in those without prior radiotherapy was 7% (two instances of radiation necrosis, one cranial neuropathy).

Fewer data are available for IMRT in skull base chondrosarcoma. Sahgal and colleagues reported on 18 patients with skull base chondrosarcoma treated to a median dose of 70 Gy in 35 fractions with image-guided IMRT.[93] The 5-year local control rate was 88%.

Target Volume Definition

Available recommendations from the European Society for Radiotherapy and Oncology Advisory Committee on Radiation Oncology Practice[101] and the Chordoma Foundation[62] are summarized in Table 42.2. An example case is shown in Figure 42.9. There are few data on patterns of failure in skull base chondrosarcoma, which could inform an appropriate target volume. The high tumor control rates achieved with radiosurgery suggest that more limited margins are adequate for skull base chondrosarcoma. An analysis of patterns of failure from PSI included 5 patients with skull base chondrosarcoma and 30 patients with chordoma.[145] The majority of recurrences were localized to areas of compromised dose coverage to meet brainstem or optic chiasm constraints. The gross tumor volume (GTV) receiving <66 Gy (RBE) was associated with local failure on multivariate analysis. When the volume of GTV receiving <66 Gy was >3 cc, the 5-year local control was 86% versus 97% when <3 cc of GTV was underdosed.

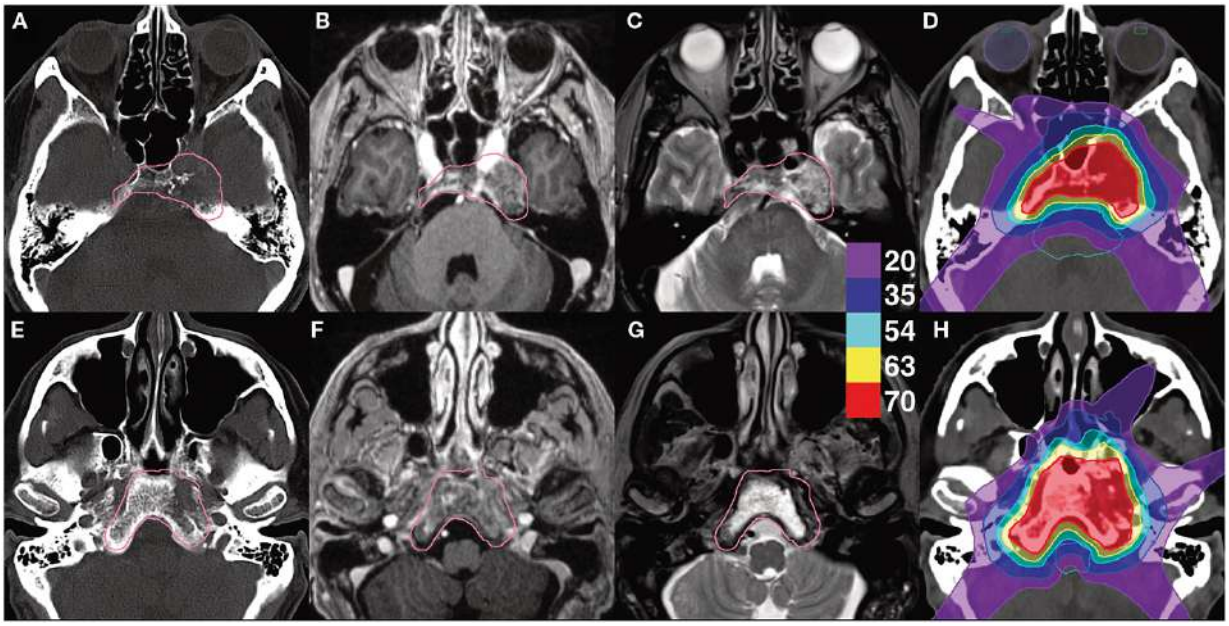

FIGURE 42.9 Examples of chondrosarcoma of the skull base. The high-dose clinical target volume in pink is overlaid on all images. This patient *in their* mid-70s presented with abrupt onset of vertiginous symptoms and initial computed tomography (A,B) and magnetic resonance imaging (MRI) showed an infiltrative clival mass eroding the left petroclival synchondrosis. A retromastoid suboccipital craniotomy was performed, which minimally decompressed the tumor. T1 postcontrast (C,D) and T2 (E,F) MRIs from the time of radiation planning with residual tumor extending to the left cavernous sinus. G,H. Proton radiation treatment plan to 70 Gy (relative biologic effectiveness) in 35 fractions. Follow-up imaging over the next 3 years showed interval decrease in contrast enhancement, especially of the extraosseous component of disease with no change in the tumor volume.

Response Assessment and Surveillance

Following radiotherapy, the expected outcome is no growth of residual tumor or no recurrence of disease. A systematic review included 247 patients with radiographic response assessment after radiotherapy, of whom 27% were noted to have reduced tumor volumes and 58% stable treated tumor.[128]

There are few data to guide recommendations on surveillance imaging. A skull base protocol MRI every 6 months in the first 2 to 3 years after treatment followed by annual imaging is one approach. Long-term follow-up is recommended, given the long natural history of this disease. Given the extremely low risk of developing distant disease, routine extracranial surveillance imaging does not appear indicated.

Systemic Therapy

Chemotherapy has poor activity and limited role in conventional chondrosarcoma, and trials of targeted agents have not yet been effective.[146] Mesenchymal chondrosarcoma may be managed like Ewing sarcoma with similar chemotherapy and multimodal therapy.[147] Dedifferentiated chondrosarcomas may be managed similarly to osteosarcoma.[146]

PARAGANGLIOMA

Pathology

Paragangliomas are malignant neuroendocrine tumors arising at sites of sympathetic or parasympathetic paraganglia. The histology of paragangliomas is notable for a so-called Zellballen growth pattern of polygonal or spindle cells arranged in nests surrounded by a fibrovascular stroma.[148] In the 2022 World Health Organization classification, all paragangliomas are considered malignant neoplasms with variable metastatic potential.[149] Paragangliomas have in the past been considered benign neoplasms, but there are no histologic differences or pathologic criteria to differentiate “malignant” from “benign” paragangliomas. Histologically, all paragangliomas may demonstrate cellular pleomorphism, mitotic figures, occasional necrosis, and local invasion of adjacent bone and soft tissue. All paragangliomas have metastatic potential so paragangliomas should be categorized as metastatic or nonmetastatic rather than using the term *benign* or *malignant*.[150] It is also challenging to differentiate potential sites of metastatic disease from synchronous or asynchronous multifocal paraganglioma. Because of the wide distribution of paraganglia in normal organs, paragangliomas arising in diverse organs including the liver and lungs may represent separate sites of disease rather than hematogenous metastases. In general, because lymph nodes and bone do not harbor paraganglia, involvement of these areas is clearly consistent with metastatic disease.[149]

Epidemiology and Risk Factors

The incidence of paraganglioma (inclusive of pheochromocytomas) is estimated between 4 and 8 per million per year.[151-153] The incidence appears to have increased over time as more incidental tumors are detected on imaging.[151,154] Only about 3% of extraadrenal paragangliomas arise in the head and neck.[155] The median age at presentation is around 50 years old, notably younger in those diagnosed with genetic causes and older in those with sporadic tumors.[154] Head

and neck paragangliomas are 2 to 3 times more common in women than in men.[155] It is unclear whether there is any variation in incidence by race or ethnicity.

Carotid body paragangliomas appear to be more common in patients in a chronic hypoxic state, for example, those living at extreme altitude, smoking, or with conditions like pulmonary fibrosis or emphysema.[156] In contrast to those arising at low altitude, paragangliomas in high-altitude populations appear to have a markedly stronger female predominance and lower rates of bilaterality or family history,[157] and the growth rate appears to be significantly faster.[158] Conversely, it has been posited that the more indolent natural history of paragangliomas in the Netherlands may be due in part to the country's low elevation, with many living near or below sea level.[159,160] Several of the genetic abnormalities associated with paraganglioma cause upregulation of the hypoxia- inducible factor signaling pathway despite normal blood oxygen levels, creating a pseudo-hypoxic state impacting cellular migration and proliferation, apoptosis, angiogenesis, and other processes implicated in tumorigenesis.[161,162]

Germline predisposing mutations are identified in about 40% of patients with paragangliomas, and somatic mutations are seen in about one-third of sporadic cases.[162] There are four autosomal dominant paraganglioma syndromes, PGL1 to PGL4, associated with mutations in the succinate dehydrogenase (*SDH*) complex. PGL1 syndrome involves *SDHD* mutations. It appears to be the most common mutation associated with head and neck paragangliomas[163] and has a favorable prognosis with a low risk of metastases (3%-5%) but a 60% rate of multifocal tumors and 50% to 60% risk of pheochromocytomas or thoracoabdominal paragangliomas.[6] PGL2 involves *SHDAF2* mutations and is notable for young age of onset, high frequency of multifocal disease, and very rare metastases.[164] PGL3 involves *SDHC* mutations and is also associated with multifocal disease and rare metastases.[162] PGL4 involves mutations of the *SDHB* gene. About 25% of patients with *SDHB* mutations have synchronous primaries at presentation, and a similar percentage have pheochromocytomas. The lifetime incidence of metastatic disease is as high as 40%.[165] *SDHB* mutations are associated with shorter survival in patients with metastatic disease.[166] *SDHB* mutations also have a higher incidence for developing other malignancies, including gastrointestinal stromal tumor, renal cell carcinomas, breast carcinomas, and papillary thyroid carcinomas.[162] Multiple endocrine neoplasia type 2, neurofibromatosis type 1, and von Hippel-Lindau diseases are associated with pheochromocytomas and less commonly with head and neck paragangliomas.[6,162]

A combined SEER and The Cancer Genome Atlas analysis of pheochromocytomas and paragangliomas identified younger age, female sex, aortic or carotid body tumors, and complete surgical resection as factors associated with a more favorable prognosis.[167]

Natural History

Head and neck paragangliomas are typically slow-growing tumors. In a series of 39 patients with head and neck paragangliomas, which were initially observed for a median of 2 years, 44% experienced tumor growth, with an estimated tumor doubling time of 5.7 years.[168] A larger series of 48 patients with head and neck paragangliomas under observation for an average of 4.2 years observed that 60% experienced a volume increase >20%, with a median growth rate of 1 mm per year and a median doubling time of 4.2 years.[169] A proportion of patients experience no measurable growth on serial imaging, at least initially. In one series of temporal bone paragangliomas with observation beyond 5 years, five of 11 had no demonstrable growth.[170] It is

important to note that patients under observation may develop new CN deficits without radiographic progression.[171] The growth rate of paragangliomas is also unpredictable. Some patients may experience a period of rapid tumor growth.[172]

Clinical Presentation

Carotid body paragangliomas generally present with a nontender and usually asymptomatic neck mass. On examination, a rubbery mass is palpable anterior to the sternocleidomastoid muscle. Though often a subtle finding, the tumor may be noted to be mobile in the horizontal plane but fixed in the vertical plane due to attachment to the carotid—the so-called Fontaine sign.[173] Large tumors may cause some degree of dysphagia or odynophagia from mass effect, as well as affect adjacent lower CNs with resultant dysphagia or hoarseness.

Vagal paragangliomas also typically present with a painless neck mass with associated hoarseness or dysphagia from lower CN involvement. Jugular paragangliomas commonly present with hoarseness or other lower CN palsies and may also cause pulsatile tinnitus or sudden hearing loss.

Tympanic paragangliomas often present with pulsatile tinnitus and unilateral hearing loss, initially conductive from mass obstruction or involvement of the tympanic membrane and later sensorineural or mixed hearing loss from involvement of the otic capsule, inferior cochlear vein, or direct involvement of CN VIII.[174] Otoscopy reveals a classic red or purple-red mass visible behind the tympanic membrane. More advanced disease may protrude as a friable mass in the external auditory canal. Patients may develop facial nerve weakness or palsy as the tumor erodes into the nearby facial nerve (fallopian) canal of the petrous temporal bone.

Patients with secretory paragangliomas may have hypertension, episodes of tachycardia, sweating, anxiety, diarrhea, orthostatic hypotension, or hyperglycemia.[150] Patients with secretory paraganglioma may be asymptomatic yet still at risk for cardiovascular toxicity from unrecognized and untreated catecholamine secretion. Secretory paragangliomas are associated with a high incidence of secondary diabetes mellitus ranging from mild insulin resistance to profound insulin deficiency.[175]

Diagnostic Workup

Paragangliomas are nearly always an initial radiographic diagnosis. Biopsy is not recommended due to the risk of life-threatening complications from percutaneous biopsy of these highly vascular tumors.[176] When a tumor is radiographically consistent with paraganglioma, pathologic confirmation is not required before radiotherapy.

Multiple clinical practice guidelines recommend that all patients with paragangliomas have plasma metanephrine levels measured at presentation.[150,177,178] It is often said that only about 5% of head and neck paragangliomas are metabolically active, but under-ascertainment is likely, given inconsistent awareness and screening practices. In a series of 182 patients with head and neck paraganglioma, 9% had hyperadrenergic clinical symptoms and/or laboratory normetanephrine values ≥2-fold normal reference values, and an additional 9% had less pronounced aberrations in plasma metanephrines without symptoms.[179] Elevated plasma metanephrines may also indicate the presence of a synchronous pheochromocytoma or thoracoabdominal paraganglioma.

Patients with secretory paragangliomas require medical management with α-blockers for 7 to 14 days before surgery to reduce the risk of intraoperative hemodynamic instability.[150] Following surgery on secretory tumors, annual metanephrine testing is recommended, which may help detect recurrence or metastasis, while those with nonsecreting tumors do not require continued biochemical surveillance unless they have a known genetic variant placing them at risk for future primary paragangliomas or if they were to develop signs or symptoms of secretory disease.[150] While most patients with secretory tumors are managed with surgery, if the patient is treated with radiotherapy, plasma metanephrines may be checked every 6 months to assess biochemical response to therapy and for the detection of tumor progression or potential metastasis. Patients with persistently elevated metanephrines require ongoing medical management to reduce the risk of cardiovascular toxicity from excess catecholamine secretion.

Contrast-enhanced MRI is used to image the primary site, while a high-resolution temporal bone or skull base CT is also necessary to evaluate the extent of tympanic and jugular paragangliomas. Either a whole-body MRI (skull base to kidneys) or DOTATATE PET/CT is recommended in all patients to screen for synchronous primaries or metastatic disease.[177] DOTATATE PET/CT has greater sensitivity than MRI or CT for the detection of multifocal or metastatic disease.[5] Genetic counseling should be offered to all patients, regardless of age at presentation or family history.[150,177,178]

Imaging

Paragangliomas are avidly enhancing on both CT and MRI due to their high vascularity. They are typically T1 isointense and T2 hyperintense. Internal flow voids are characteristic, sometimes described as a "salt and pepper" appearance. On both T1- and T2-weighted sequences, areas of high blood flow velocity result in multiple punctate or serpiginous areas of signal loss (the "pepper") amidst the background of contrast enhancement of the tumor (the "salt").[180] Areas of slow flow or subacute hemorrhage also yield hyperintense "salt" foci.[181] A salt and pepper appearance may not be seen in smaller tumors, especially those <1 cm in size.[182] Jugular paraganglioma typically features a moth-eaten appearance of the jugular foramen and mastoid bone on CT. CT is necessary to define the relationship of tympanic paragangliomas with osseous structures of the middle ear. Carotid body paragangliomas cause a splaying of the internal and external carotid artery, yielding a "Lyre sign" on conventional, CT, or MR angiography.[180]

Staging

The AJCC eighth edition staging for neuroendocrine tumors excludes head and neck paragangliomas.

For carotid body tumors, the Shamblin classification system (Figure 42.10) is based on the tumor relationship to the carotid arteries. As originally proposed, it is an intraoperative assessment, with group I being localized and more easily excised, group II adherent and partially surrounding carotid vessels, and group III intimately surrounding the carotid vessels.[183]

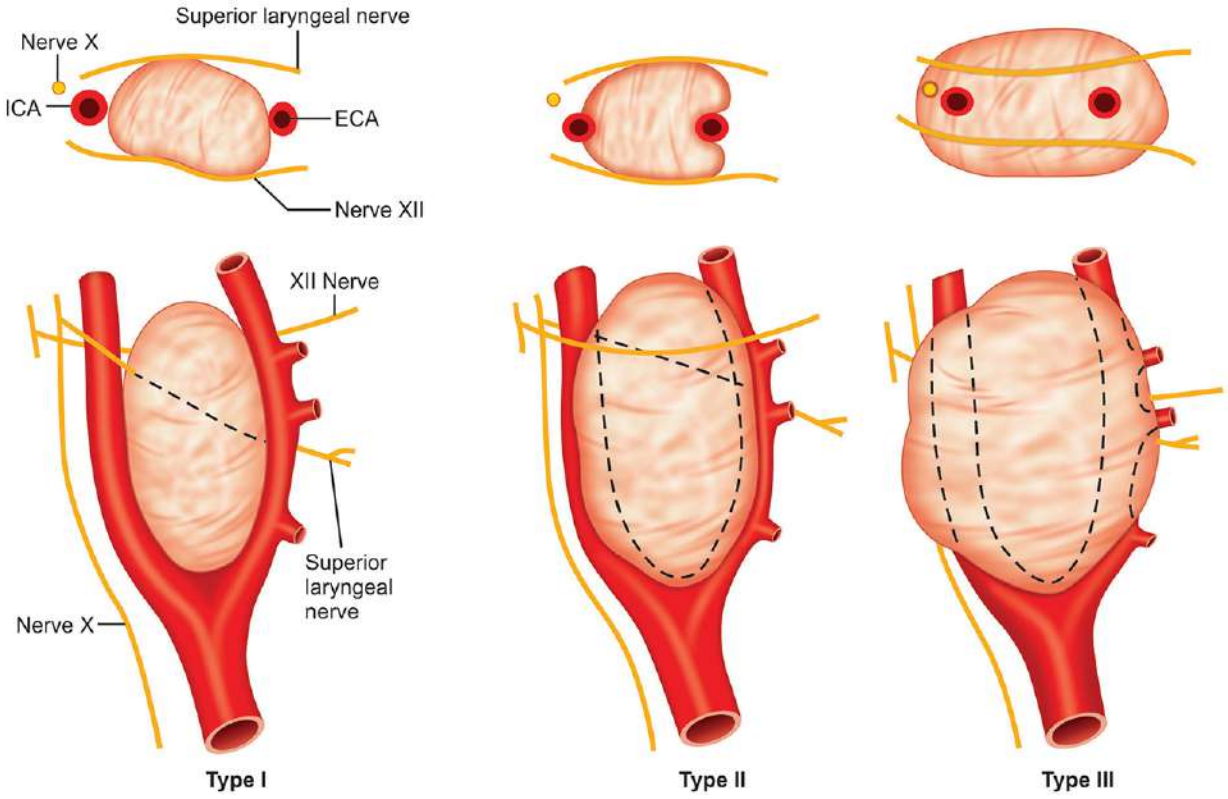

FIGURE 42.10 Illustration of the Shamblin classification of carotid body paragangliomas. ECA, external carotid artery; ICA, internal carotid artery. (Used with permission of Jaypee Brothers Medical Publishers from Myers EN. Management of tumors of the parapharyngeal space. In: De Souza C, ed. *Otorhinolaryngology: Head and Neck Surgery*. 2nd ed. Jaypee Brothers Medical Publishers; 2019:488; permission conveyed through Copyright Clearance Center.)

For tympanic and jugulotympanic paragangliomas, the Fisch and Mattox classification system (Table 42.3) describes the extent of the tumor.[184]

TABLE 42.3 FISCH AND MATTOX CLASSIFICATION SYSTEM FOR JUGULAR PARAGANGLIOMAS

Class	Extent
A	Tumors confined to the middle ear (tympanic paraganglioma)
B	Tumors limited to tympanomastoid area without bony destruction of the infralabyrinthine compartment of the temporal bone
C1	Tumors involving the jugular foramen and jugular bulb with limited involvement of the carotid canal
C2	Tumors involving the vertical portion of the carotid canal
C3	Tumors involving the horizontal portion of carotid canal
C4	Tumors involving foramen lacerum and cavernous sinus
De1/2	Intracranial extradural extension <2 cm or >2cm
Di1/2/3	Intracranial intradural extension <2 cm, 2-4 cm, or >4 cm

Note that D is not a separate class but a modifier of class C tumors. For example, a tumor may be described as C3Di2.

classification. *Audiol Neurootol*. 2012;17(4):243-255. Copyright © 2012 Karger Publishers, Basel, Switzerland.

General Management

Multidisciplinary patient care will consider the patient's age, comorbidities, and preferences and the size, extent, and growth rate of the tumor to develop a plan to control the tumor while minimizing the risks of iatrogenic toxicities (eg, CN dysfunction). For many patients, an initial "wait-and-scan" approach is favored. Typical indications for early intervention include small carotid body and tympanic paragangliomas amenable to surgery with minimal iatrogenic risk, patients with significant brainstem compression, conductive hearing loss, pulsatile tinnitus, facial nerve weakness, secretory tumors, evidence of metastatic disease, those with rapid growth, or patient choice.

A suggested algorithm for management is presented in Figure 42.11.

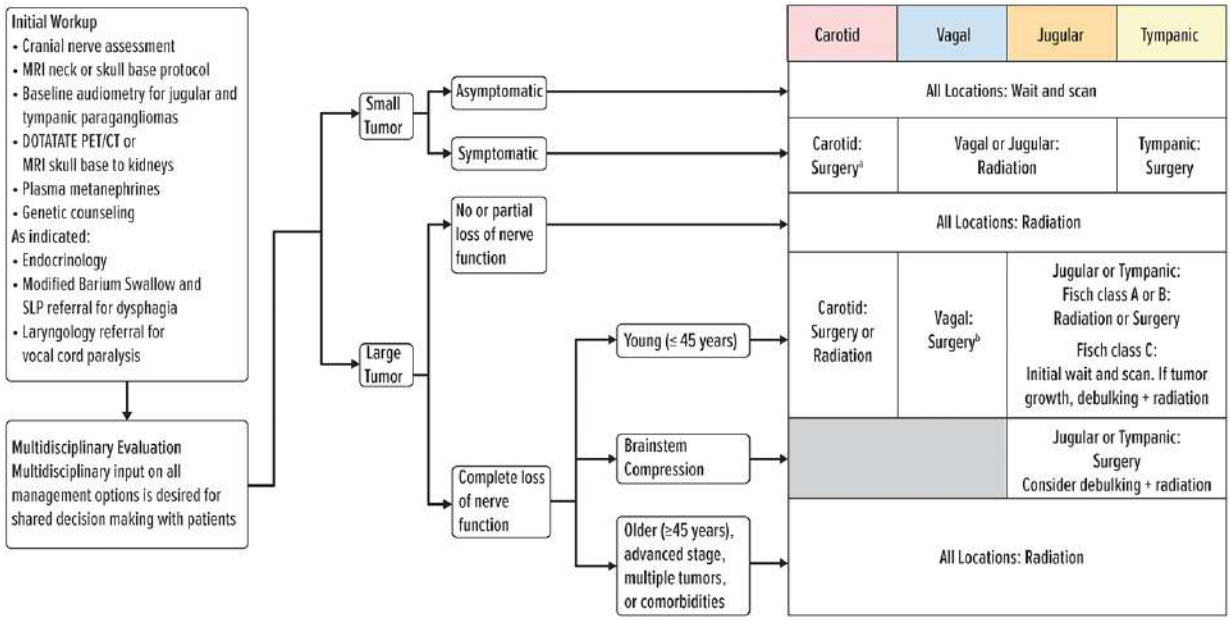

FIGURE 42.11 Suggested algorithm for *paragangliomas*. [a]For bilateral carotid body paragangliomas, consider surgery on one side and observation or radiotherapy for the contralateral side. [b]Caution that patients with deficits may retain residual tone and worsening of function may occur after surgical intervention; surgery for bilateral vagal paraganglioma is typically contraindicated. CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography. (Adapted from Verlicchi A, Nicolato A, Valvassori L, et al. Head and neck paragangliomas. Surgery

The role of surgery is significantly influenced by the age and comorbidities of the patient, location of the tumor, symptoms from secretory tumors or mass effect, existing CN deficits, and the risk of inducing new or worsening CN deficits. Improvements in surgical technique have significantly reduced the risk of perioperative stroke and mortality, but postoperative CN deficits remain common, developing in 40% or more.[185]

Shamblin group I carotid body paragangliomas and those <5 cm are typically amenable to resection with a modest risk of morbidity and high chance of tumor control.[155] Using cross-

sectional imaging, it can be difficult to distinguish between group I and II tumors, but group III may be recognized by the loss of a tumor to carotid adventitia interface, greater angle of contact with or encasement of the carotid vessels, and larger tumor maximal diameter.[186] Group II and III tumors and larger tumors (>3.2 cm) are associated with a higher risk of intraoperative and early postoperative neurovascular complications.[187] In a multivariate analysis of 184 patients undergoing surgery for 200 carotid body paragangliomas, tumors with a maximal diameter ≥5 cm and Shamblin group III were both associated with a higher risk of permanent CN dysfunction.[188] Patients with bilateral tumors may be considered for a staged surgical approach to avoid the risk of iatrogenic bilateral deficits. However, patients undergoing bilateral resection of carotid body paragangliomas are at increased risk of loss of carotid baroreceptor feedback with resultant hypertension and hemodynamic instability.[155] For that reason, some favor observation or radiation therapy to the contralateral tumor.

Surgical resection of vagal paragangliomas essentially always requires sacrifice of the vagal nerve,[155,189,190] with 60% reported to have an additional lower CN deficit after surgery.[191] Patients with bilateral vagal tumors or who may have a preexisting contralateral deficit of CN X or CN XII are typically not appropriate candidates for surgery as the development of bilateral deficits can lead to profound dysfunction requiring a tracheostomy and g-tube dependence.[190] Small asymptomatic tumors are typically observed, especially if bilateral. Growing or symptomatic tumors are typically irradiated.[192]

For jugulotympanic paragangliomas, the great majority of Fisch class A and B tympanic tumors are amenable to complete surgical resection while a subtotal resection is more likely in class C patients who may considered for planned conservative decompressive surgery with or without postoperative radiotherapy or primary radiotherapy.[193,194] A systematic review including 382 patients with jugulotympanic paragangliomas found class A and B tumors managed with surgery had a <1% risk of CN damage, which increased to 71% to 74% with class C tumors.[195]

In a meta-analysis, surgery for jugular foramen paragangliomas was associated with an approximately 60% rate of new lower CN deficits after a complete excision.[196] Gross total resection of tympanic and jugulotympanic paragangliomas is also associated with a high rate of hearing loss and facial nerve paresis or paralysis.[196] Proposed indications for surgery in these tumors include young age, secreting tumors, significant intracranial mass effect, tumor progression after radiotherapy, and cases with a perceived low risk of iatrogenic CN injury.[155]

While surgical intent is typically complete resection, in some instances, a subtotal resection may be warranted. For example, in a jugulotympanic tumor, resection of the tympanic portion can improve symptoms such as conductive hearing loss or pulsatile tinnitus, leaving the jugular fossa and/or intracranial extent of disease for observation or radiation therapy.[155] Preoperative embolization is commonly used before surgery of vagal and jugular paragangliomas.

When surgical intervention results in lower CN deficits, younger patients are more likely to be rehabilitated while older patients are more likely to experience chronic dysphagia.[171,197] In older patients, an argument is made for observation based on the idea that lower CN dysfunction from tumor is slowly progressive and often incomplete, allowing time for better physiologic adaptation.

Preexisting CN dysfunction does not obviate the functional risks of surgical intervention. Patients may retain (easily underappreciated) partial function or compensatory function, which, if lost, would meaningfully worsen their swallow and/or speech. Table 42.4 outlines common

nerve deficits and functional impairments from paraganglioma tumor involvement or surgical sequela.

TABLE 42.4 NEUROVASCULAR STRUCTURES AND IMPAIRMENTS THAT MAY RESULT FROM PROGRESSIVE TUMOR OR INTERVENTIONS IN HEAD AND NECK PARAGANGLIOMAS

Neurovascular Structure	Relevant Location	Component/Function	Functional Impairment	Intervention
Glossopharyngeal nerve (CN IX)	Jugular foramen and parapharyngeal space	Motor function to stylopharyngeus muscle	Palatal elevation	Swallow therapy
		Sensory function, afferent feedback from base of tongue and lateral pharyngeal wall	Dysphagia, loss of gag reflex	Swallow therapy, direct food to contralateral sensate pharynx
	Adjacent parasympathetic fibers depart CN IX at jugular foramen, pass through tympanic plexus to otic ganglion	Parasympathetic innervation of parotid gland	Temporary decrease in parotid salivary flow	Generally self-limited
Vagal nerve (CN X)	Superior vagal ganglion at jugular foramen or ganglion nodosum in carotid space	Sensory function from larynx and lateral pharyngeal wall	Aspiration, dysphagia	Swallow therapy
		Motor function of larynx	True vocal fold paralysis	Vocal fold injection/medialization
		Parasympathetic innervation of gastrointestinal viscera	Gastroesophageal dysmotility, gastroesophageal reflux, persistent nausea/vomiting	Motility/prokinetic agents, reflux medications
	Pharyngeal branch departs ganglion nodosum and passes between internal and external carotid, enters pharynx at upper border of middle constrictor	Motor function of palate	Unilateral palatal paralysis with velopharyngeal incompetence/nasal regurgitation	Swallow therapy; delayed surgery to create unilateral palatal adhesion to posterior pharyngeal wall
		Motor function of pharynx	Unilateral pharyngeal constrictor paralysis with aspiration	Swallow therapy, head positioning during swallow
Spinal accessory nerve (XI)	Exits jugular foramen, passes over internal jugular vein through sternocleidomastoid to trapezius	Motor function of sternocleidomastoid and trapezius muscles	Shoulder drop or weakness from loss of trapezius, can cause severe pain	Intraoperative grafting, physical therapy for shoulder strengthening
Hypoglossal nerve (XII)	Hypoglossal foramen, shares fibers with CN X at ganglion nodosum in carotid space, runs superficial to	Motor function of extrinsic and intrinsic muscles of tongue (excepting palatoglossus)	Dysphagia, food lodged on paralyzed side	Swallow therapy

Neurovascular Structure	Relevant Location	Component/Function	Functional Impairment	Intervention
	external carotid artery			
Cervical sympathetic chain	Superior cervical ganglion deep to internal carotid artery	Distribution to skin, pharyngeal plexus, ascending sympathetic plexus along internal carotid	Horner syndrome (ptosis, miosis, anhidrosis)	May have oculoplastic surgery for ptosis
		Sympathetic innervation of parotid gland	First bite syndrome—painful cramp or spasm in parotid area with the first bite of food	Avoid tart and bitter foods, may treat with carbamazepine
Carotid baroreceptors	Carotid body, carotid sinus to the glossopharyngeal nerve	Autonomic nervous system, cardiovascular equilibrium	Orthostatic hypotension, hypertension, paroxysmal tachycardia	Medical management; eg, clonidine, β -blockers

Principles of Radiation Therapy

Meta-analyses of treatment outcomes for jugular paragangliomas provide a compelling rationale for radiotherapy when local control measures are indicated (Table 42.5). In a 2011 study, compared to gross total resection, radiotherapy was associated with a higher rate of tumor control and a markedly lower rate of new lower CN deficits.[196] A larger study in 2023 found lower rates of toxicity with both modalities, but the toxicity profile still favored radiotherapy.[198] Suarez and colleagues performed a meta-analysis of a series including both jugular and vagal paragangliomas.[172] The mean rate of tumor control for jugular paragangliomas managed with radiotherapy was higher than in those managed with surgery (91.5% vs 78.2%, $P = .002$) with fewer major complications (11.4% vs 28.2%, $P = .003$). There was no difference in the mean rate of tumor control across series with fractionated therapy ($n = 461$, 89%) and SRS ($n = 254$, 94%, $P = .32$).

TABLE 42.5 POOLED ESTIMATES OF OUTCOMES FOR JUGULAR PARAGANGLIOMAS IN TWO META-ANALYSES

					New Cranial Nerve Deficits (%)				
Study	Treatment	# pts	Mean *f/u*	Tumor Control (%)	CN VII	CN IX	CN X	CN XI	CN XII
Ivan et al[196]	Gross total resection	351	88 mo	86	–	38	26	40	18
	SRS	339	71 mo	95	–	9.7	9.7	12	8.7
Campbell et al[198]	Surgery	2,215	–[a]	85	27	20	21	13	12
	SRS	1,283	–	93	4	1	3	<1	1

CN, cranial nerve; SRS, stereotactic radiosurgery.

[a]Follow-up duration inconsistently reported and, therefore, not reported or analyzed; however, authors considered >2 years to represent long-term follow-up.

Quality of life was measured in a small series of 42 head and neck paragangliomas in 30 patients: 14 treated with radiotherapy alone and 16 with surgery followed by radiotherapy.[199] Patients treated with definitive radiotherapy reported better overall quality of life, and those treated with combined modality therapy reported statistically significant worse symptoms of trismus and difficulty speaking. Volumetric analysis in 15 patients showed about 40% tumor regression at 2 and 3 years after radiotherapy. While stable disease is the definition of local control after radiotherapy, tumor response is underappreciated. Many authors who have performed volumetric analysis have observed tumor regression over time after radiotherapy, ranging from about 20% to 40% volume decrease.[200-203]

Tinnitus and conductive hearing loss are the symptoms most likely to improve with radiotherapy. Existing neurologic impairments from tumors are least likely to improve with radiotherapy.

Radiation Techniques

Treatment Modalities and Dose

Paragangliomas have typically been managed with a moderate dose of radiotherapy with excellent local control outcomes. For fractionated therapy, 45 Gy in 25 fractions provides excellent control with fewer risks of iatrogenic toxicities. For hypofractionated stereotactic radiotherapy, 25 Gy in 5 fractions or 21 Gy in 3 fractions is efficacious, and for SRS, a dose of 15 Gy appears optimal. The selection of radiation treatment modalities and fractionation is based on tumor size, proximity to critical normal structures, patient preference, and availability of advanced treatment modalities.

The University of Florida published long-term outcomes of conventionally fractionated radiotherapy in 176 head and neck paragangliomas in 149 patients, of whom 83% received 45 Gy in 25 fractions. The 15-year rate of local control was 95%, with no moderate or severe complications, no secondary malignancies, and no malignant transformations observed.[204] Princess Margaret Hospital published results using moderately hypofractionated radiation to 35 Gy in 15 fractions in 45 patients with jugulotympanic paragangliomas with ~93% tumor control at a median follow-up of 10 years.[205] A total of five studies and two abstracts have reported outcomes in 107 patients with head and neck paragangliomas treated with proton therapy with local control rates of 97 to 100%.[200,202,206-209] In a systematic review, there was some suggestion that tumor regression and symptom improvement may be greater with proton than photon radiotherapy.[210]

Hypofractionated stereotactic radiotherapy results were reported in a series of 34 jugulotympanic or carotid body paragangliomas treated to a median of 25 Gy in 5 fractions (prescribed at a mean isodose of 83%). At a median follow-up time of 66 months, 97% maintained local control.[211] A radiographic partial response was observed in 59% and 45% had symptom improvement, with a 7% rate of late toxicity—one grade 1 (asymptomatic) cerebellar radionecrosis and one facial nerve weakness.

A systematic review and meta-analysis of SRS in head and neck paragangliomas identified a median marginal dose of 15 Gy in 1 fraction was required to achieve a local control rate ≥90%.[212]

Metastatic sites of disease also respond to moderate-dose radiotherapy. In a retrospective review of 41 patients treated to 107 metastatic sites from paraganglioma or pheochromocytoma, when evaluating the biologic effective dose (BED) using an α/β ratio of 10, the 5-year local control was 91% for a BED ≥53 Gy_{10} versus 62% for a BED <53 Gy_{10} ($P = .001$).[213] Nearly all (94%) symptomatic patients experienced some symptom improvement.

Target Volume Definition

For paraganglioma, the GTV is typically well defined on contrast-enhanced CT and using a co-registered MRI where tumor is T2 hyperintense and avidly enhancing on T1 postcontrast imaging. The CT should be used to include adjacent areas of osseous erosion and bone involvement. For fractionated therapy, previous versions of the UK Royal College of Radiologists' clinical practice guidelines recommended a minimum expansion of 0.5 cm from the GTV to create a clinical target volume (CTV), plus additional expansion for setup uncertainties to create the PTV.[214] This is consistent with the total GTV to PTV expansion of 1 cm used in several series.[200,215,216] Current UK guidelines note that no margin from GTV to CTV is required but caution against margins that are too tight that could lead to marginal misses.[214] Some patients experience transient or variable tumoral swelling during a course of fractionated radiotherapy.[217] Given the moderate doses employed for paraganglioma in fractionated therapy, using this more generous margin to reduce the risk of a marginal miss is unlikely to be associated with a significant increase in morbidity. For SRS, the CTV is the same as GTV, and a 1- to 2-mm margin is applied to create the PTV depending on uncertainties inherent in the radiosurgery platform.

Systemic Therapy

A number of systemic therapies are available for patients with metastatic paraganglioma and/or pheochromocytoma. In a systematic review, cytotoxic chemotherapy with cyclophosphamide, vincristine, and dacarbazine achieved a partial response in 37% and a complete response in 4%.[218] Temozolomide and sunitinib are second-line therapies.[219] A similar rate of partial response in excess catecholamine secretion was also observed. A number of radiopharmaceuticals have been used, including ^{131}I-metaiodobenzylguanidine and peptide receptor radionuclide therapy with ^{177}Lu-DOTATATE.[220] Additional promising radiopharmaceuticals are under investigation.[221]

RADIATION DOSE CONSTRAINTS

The location of skull base targets in proximity to multiple critical normal structures makes radiotherapy planning a challenge. One must balance a desire to maximize target volume coverage, which appears critical to achieving tumor control, particularly for chordomas,[30,222,223] with the desire to maintain a reasonable level of iatrogenic risk. There is considerable variability in the reported literature on radiation dose constraints for challenging skull base tumors, but a common theme is that the radiation dose constraints are pushed higher than are commonly used in other scenarios. Using overly conservative dose constraints risks, compromising target volume coverage and disease control outcomes.

The European Particle Therapy Network (EPTN)[224] and the Chordoma Foundation position paper[62] have both outlined recommendations that are summarized in Table 42.6. The EPTN

constraints are based on calculating the BED to OARs using α/β ratios and converting to an EQD2. For example, a single-treatment plan that delivers a nominal dose of 63 Gy to the surface of the brainstem ($\alpha/\beta = 2$) over 37 fractions (~1.7 Gy per fraction) equates to an EQD2 of 58.32. When a sequential planning technique is used for the boost, the dose per fraction to OARs may vary between phases of the plan, requiring that the EQD2 be calculated separately in each plan and summed.

TABLE 42.6 DOSE CONSTRAINTS FOR SKULL BASE CHORDOMAS AND CHONDROSARCOMAS

	European Particle Therapy Network Consensus[224]			Chordoma Foundation Position Paper[62]	
Organ at Risk	α/β Ratio	Dose Constraint in EQD2	Toxicity End Point	Dose Constraint in Gy (RBE) for Standard Fractionation	Toxicity End Point
Cervical spinal cord	NR	NR	NR	$D_{surface}$ <67 D_{center} <55	Any clinical symptoms
Temporal lobe	NR	NR	NR	$D_{2\%}$ <71	Radiation necrosis visible on MRI
Brain	2	V_{60} ≤3 cc	Symptomatic brain necrosis		
Brainstem	2	$D_{surface\ 0.03cc}$ ≤60 $D_{interior\ 0.03cc}$ ≤54	Radiation necrosis	$D_{surface}$ <63 D_{center} <50	Any measurable toxicity
Chiasm and optic nerves (considered separately)	2	$D_{0.03cc}$ ≤55	Optic neuropathy	$D_{2\%}$ <60	Vision loss
Cochlea	3	D_{mean} ≤45	Hearing loss		
Cochlea	3	D_{mean} ≤32	Tinnitus		
Hippocampus	2	$D_{40\%}$ ≤7.3	Memory loss		
Lacrimal gland	3	D_{mean} ≤25	Keratoconjunctivitis		
Lens	1	$D_{0.03cc}$ ≤10	Cataract		
Pituitary	2	D_{mean} ≤45	Panhypopituitarism		
Pituitary	2	D_{mean} ≤20	Growth hormone deficiency		
Retina	3	$D_{0.03cc}$ ≤45	Vision loss		
Skin	2	$D_{0.03cc}$ ≤25	Permanent alopecia		

MRI, magnetic resonance imaging; NR, not reported; RBE, relative biologic effectiveness.

TOXICITIES OF RADIATION

Acute Toxicity

For these primary skull base malignancies, acute side effects of irradiation are typically modest.[225] Fatigue is common. Patients may experience odynophagia toward the end of

treatment depending on the inferior extent of the disease and target volumes, for example, when tumors involve the craniocervical junction and/or infiltrate the prevertebral muscles. Nausea may be seen when there is a meaningful dose to the area postrema or dorsal vagal complex of the brainstem. When disease extends laterally in the temporal bone, adjacent temporary epilation and alopecia may be seen.

If radiotherapy dose passes through the eyes, many patients will report blue flashing lights, which have previously been ascribed to direct retinal stimulation but appear to be production of Cherenkov light emission within the vitreous humor.[226]

Patients often have sinus congestion and nasal complaints after endoscopic sinus surgery, which may be exacerbated during radiotherapy. The flow of mucous within the paranasal sinuses complex depends on adequate mucous production and ciliary function, ostial patency, temperature, and humidity.[227] Endoscopic skull base surgery is associated with short-term sinonasal inflammation and impairment in sinonasal-related quality of life[228] and long-term smell impairment, increased incidence of posterior nasal discharge, and longer mucociliary clearance time.[229] High-dose radiation to paranasal sinus mucosa can lead to depletion of goblet cells and irreversible loss of cilia, which can result in nasal epithelial atrophy and chronic rhinosinusitis.[230]

Late Sequelae

If seen, most serious toxicities are late. In a systematic review including 818 irradiated patients with skull base chondrosarcomas, the most common late radiotherapy toxicities included hypopituitarism (15%), hearing loss (7%), radiation necrosis (4%), CN neuropathies (2%), and osteoradionecrosis (1%).[128] The profile is similar for chordomas. In a series of 112 patients treated with high-dose proton therapy, the most common late toxicities were hypopituitarism (17%), hearing loss (5%), symptomatic radiation necrosis (5%), and vision loss (<3%).[225] In a series of 204 pediatric patients with skull base chordoma irradiated with proton or mixed proton-photon therapy, the most common late toxicities were endocrine abnormalities and auditory toxicities including recurrent otitis and hearing loss.[61] Radiographic-only brainstem changes and temporal lobe changes were observed in 2% each.

Radiation Optic Neuropathy

Radiation-induced optic neuropathy (RION) is an irreversible vascular injury to the optic nerve or chiasm with subsequent demyelination. Patients typically develop abrupt and painless loss of vision, often with a long latency from radiation. In one study, the mean latency to RION was 31 months.[231] MRI at the time of onset typically shows discrete enhancement of the affected optic nerve, often with expansion and high T2 signal in the enhancing segment.[232] Pathology of optic nerves with RION shows ischemic demyelination, reactive astrocytosis, endothelial hyperplasia, obliterative endarteritis, and fibrinoid necrosis.[233]

A multi-institutional analysis from PSI and CPO evaluated the risk of RION in 289 patients irradiated for skull base chordoma or chondrosarcoma.[234] All patients had received a minimum dose of 45 Gy (RBE) to the optic apparatus and had a median follow-up time of 5.6 years. The median maximum dose to the optic apparatus was about 60 Gy (RBE), with a range of 45 to 76 Gy (RBE). Twelve patients developed any-grade RION for a crude incidence of 4.2%. No

radiation dose metrics were associated with the risk of RION, but advancing age and hypertension were associated with an increased risk on univariate analysis.

The University of Florida analyzed the risk of vision loss after high-dose radiotherapy for skull base chordoma or chondrosarcoma in a series of 148 patients.[235] All patients had received a minimum dose of 30 Gy (RBE) to the optic apparatus and had a median follow-up time of 4.1 years. The 5-year incidence of vision loss was 2%. There were no instances of vision loss observed when the maximum dose was <60 Gy (RBE) and a 3.6% crude incidence rate when the maximum dose was >60 Gy (RBE). The presence of multiple medical comorbidities was associated with the risk of vision loss on univariate analysis.

Radiation Necrosis

Given the high dose required for adequate disease control of skull base chordomas, and to a lesser extent chondrosarcoma, radiation-induced parenchymal brain imaging changes are seen relatively frequently during MRI surveillance. Parenchymal brain radiation necrosis can vary from minor imaging findings to devastating and life-threatening symptomatic necrosis.

The Quantitative Analysis of Normal Tissue Effects in the Clinic review suggests that partial brain irradiation to 72 Gy in standard fractionation is associated with a 5% risk of symptomatic radiation necrosis but provides no specific guidance on volume constraints.[236] One study found that the risk of radiation necrosis increased sharply when the absolute volume of temporal lobe receiving 60 Gy exceeded 5.5 cm^3 or the volume receiving 70 Gy exceeded 1.7 cm^3.[237] International guidelines for radiation planning in nasopharyngeal cancer suggest a planning goal that the temporal lobe dose to 0.03 cm^3 be restricted to ≤70 Gy with a maximum acceptable constraint of 72 Gy.[238] In radioresistant tumors such as chordomas that involve the cavernous sinus or otherwise abut parenchymal brain, these constraints cannot be met while adequately covering tumor.

Asymptomatic MRI changes can cause diagnostic confusion and concern for tumor recurrence, brain metastases, or glioma. Correlating the MRI findings with the prior radiation treatment plan can improve the assessment of probable radiation necrosis. MRI with perfusion or spectroscopy (depending on the size and location of the abnormality) can help distinguish radiation necrosis from tumor. Asymptomatic radiation edema or necrosis may be treated with pentoxifylline and vitamin E in an effort to improve or stabilize the process, hoping to avoid progression to symptomatic necrosis. The combination (typically pentoxifylline 400 mg with vitamin E 400 IU twice daily) is thought to improve oxygenation to tissues by reducing blood viscosity and increasing deformability of erythrocytes, to reduce cytokine-mediated inflammation, and to reduce oxidative damage by scavenging free radicals, among other effects.[239] The combination has shown some promise in the brain.[240] For patients with symptomatic radiation necrosis, dexamethasone provides short-term relief without addressing the underlying pathophysiology. Bevacizumab has been shown to improve symptoms and imaging findings in two small randomized controlled trials.[241,242] For those with contraindications to bevacizumab, hyperbaric oxygen can provide clinical and radiologic improvement or stability.[243]

Brainstem necrosis is of special concern. The University of Florida reported on the incidence of brainstem toxicity in 163 patients treated with high-dose radiotherapy for skull base tumors with a median follow-up time of 4 years.[244] All patients had received a minimum of 45 Gy (RBE) to the brainstem, with a median D0.03cc of 63.5 Gy (RBE) and median *D*max of 65.7 Gy

(RBE). The 5-year incidence of grade ≥2 brainstem toxicity was 1.3%. These and other experiences support the clinical safety of the higher dose constraints employed for skull base malignancies requiring high-dose radiotherapy.

Radiation Ototoxicity

Otologic complaints and complications are relatively common in skull base tumors from both tumor and treatment effect.[245] Hearing may be compromised by radiation-induced mucosal inflammation leading to mastoid effusion, radiation neuropathy of the vestibulocochlear nerve, or fibrosis, atrophy, or ossification of the inner ear. Patients may develop frequent inner ear infections, sensorineural and/or conductive hearing loss, otorrhea, otalgia, tinnitus, vertigo, or perforation of the tympanic membrane. A mean radiation dose >30 Gy dose to the mastoid air cells and posterior nasopharynx is associated with an increased risk of post-treatment mastoid air cell opacification.[246] Myringotomy can be performed to treat effusions and preserve hearing.[245]

Radiation-induced sensorineural hearing loss is associated with an increasing mean radiation dose to the cochlea.[247] Because no threshold dose has been established, the dose to the cochlea should be kept as low as possible. A ≥10 dB change in hearing on pure tone audiometry is considered clinically significant. A mean cochlear dose of 45 Gy is associated with about a 19-dB decrement in high-frequency hearing loss.[248] Unfortunately for tumors involving the petrous apex in close proximity to the cochlea, it is not always possible to spare both cochlea, and patients should be counseled on a significant risk of progressive hearing loss on the affected side after treatment.

CHAPTER 43

Spinal Canal Tumors

Nikhil Rammohan, Clifford G. Robinson, Jeff M. Michalski, and Jiayi Huang

Tumors of the spinal cord and cauda equina account for approximately 3% of primary central nervous system (CNS) tumors overall and 4% in children.[1] Spinal canal tumors are classified by the World Health Organization (WHO) according to histologic types. Clinically, they are also characterized by their location relative to the protective layers of the spinal cord as extradural, intradural–extramedullary, or intramedullary (Figure 43.1). Intramedullary lesions arise from the intrinsic substance of the spinal cord. Histologically, intramedullary spinal cord neoplasms include gliomas such as astrocytoma, ependymoma, and oligodendroglioma. Intradural-extramedullary tumors arise from the connective tissues, blood vessels, or coverings adjacent to the cord or cauda equina. Common histologies include nerve sheath tumor, meningioma, and ependymoma. Extradural tumors are most commonly metastatic, although primary tumors in this compartment may occur as well. Primary extradural tumors arising from the vertebral bodies may include benign tumors such as osteoid osteoma, osteoblastoma, and aneurysmal bone cysts, or malignant tumors such as plasmacytoma or myeloma, chordoma or chondrosarcoma, osteosarcoma, and Ewing sarcoma. Other primary extradural tumors arising outside the vertebral body include epidural hemangiomas, lipomas, extradural meningiomas, nerve sheath tumors, and lymphomas.

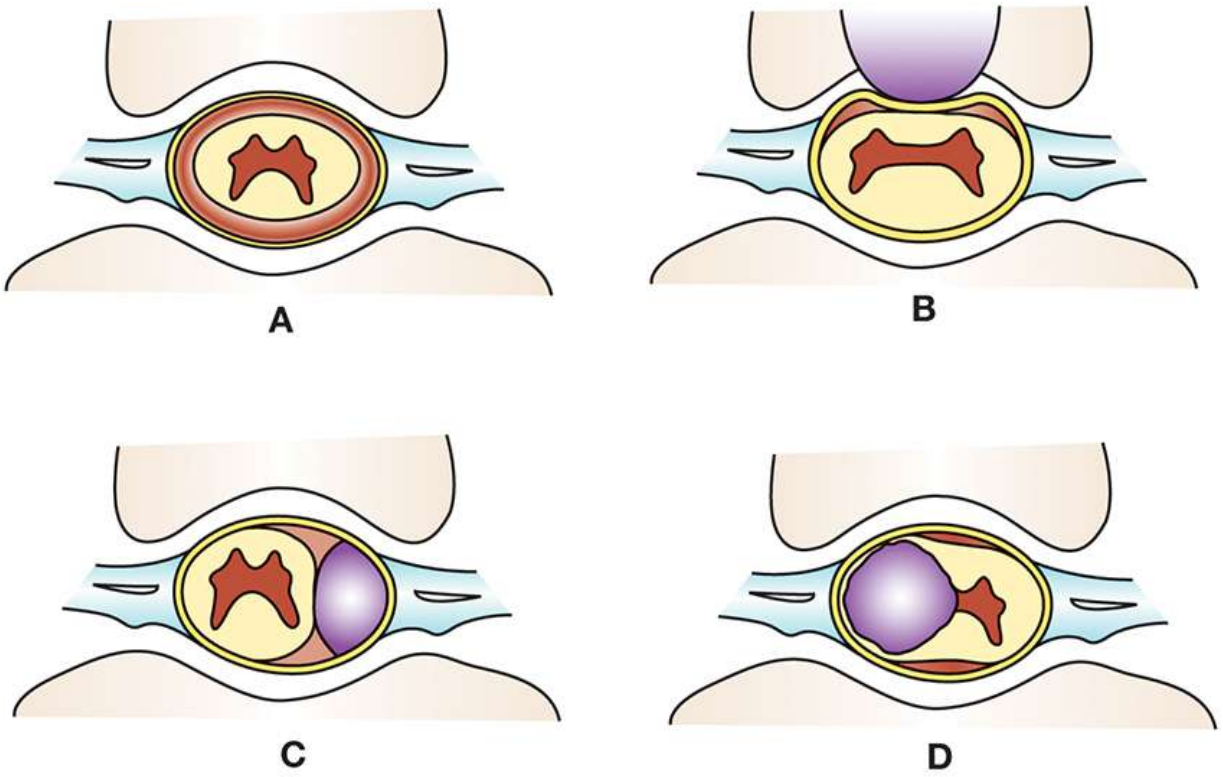

FIGURE 43.1 Neoplasms affecting the spinal cord. A. Normal transverse spine. The spinal cord is enveloped by the pia, arachnoid, and dura mater, which are housed in the spinal canal and surrounded by ligaments supporting the vertebral bony structures. The subarachnoid space contains cerebrospinal fluid (*brown*). B. Transverse spine with extradural mass. An extradural mass (eg, metastasis) from the vertebral body is compressing the dural sac and the spinal cord from the anterior direction. The subarachnoid space becomes obliterated at that level, causing a myelographic block. C. Transverse spine with an intradural-extramedullary mass. The mass, typically a meningioma or nerve sheath tumor, is compressing the spinal cord and roots in the dural sac, causing a myelographic block with a laterally displaced cord and, at times, producing a capping contour of contrast border. D. Transverse spine with intramedullary mass. An intramedullary mass (astrocytoma or ependymoma) is infiltrating and expanding the spinal cord within the dural sac, causing a myelographic block.

Radiation therapy is an important modality in the management of both primary and metastatic tumors involving the spinal canal. This chapter focuses primarily on the management of primary spinal cord tumors. Primary extradural tumors are usually managed in a manner similar to histopathologically identical tumors arising at other locations and are not discussed here in detail. The management of metastatic tumors involving the spinal canal is discussed in Chapters 102.

ANATOMY

Spinal Cord

The spinal cord is a slender cylinder composed of functional segments corresponding to 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. In contrast to the brain, the white matter of the spinal cord is located in the periphery and surrounds the central gray matter. The gray matter contains the cell bodies of sensory, motor, and autonomic neurons. On cross section, the gray matter is a butterfly-shaped region with anterior horns controlling motor function, lateral horns (in the thoracic and upper lumbar region) controlling autonomic functions, and posterior horns involved in sensation. The white matter contains the axonal elements of neurons that transmit impulses to and from the brain. As in the brain, the axons of the spinal cord white matter possess a myelin sheath formed by the cytoplasmic extension of glial cells. Schwann cells sheath the spinal nerves that enter and exit the spinal cord. The spinal cord is organized into somatotopically distinct regions (Figure 43.2). The lateral and anterior spinal cord white matter contains the nerve tracts that are involved with fine motor control and tone, including the corticospinal tracts. The spinocerebellar tracts transmit muscle stretch and tone sensation from the extremities to the cerebellum. The lateral spinal thalamic tract is located laterally near the spinal cord surface and carries ascending crossed pain fibers to the thalamus. The dorsal columns transmit fine touch and positional sensation from the extremities to the brain. Because of its serial organization, injury to the spinal cord results in characteristic neurologic findings that depend on the location of the insult.

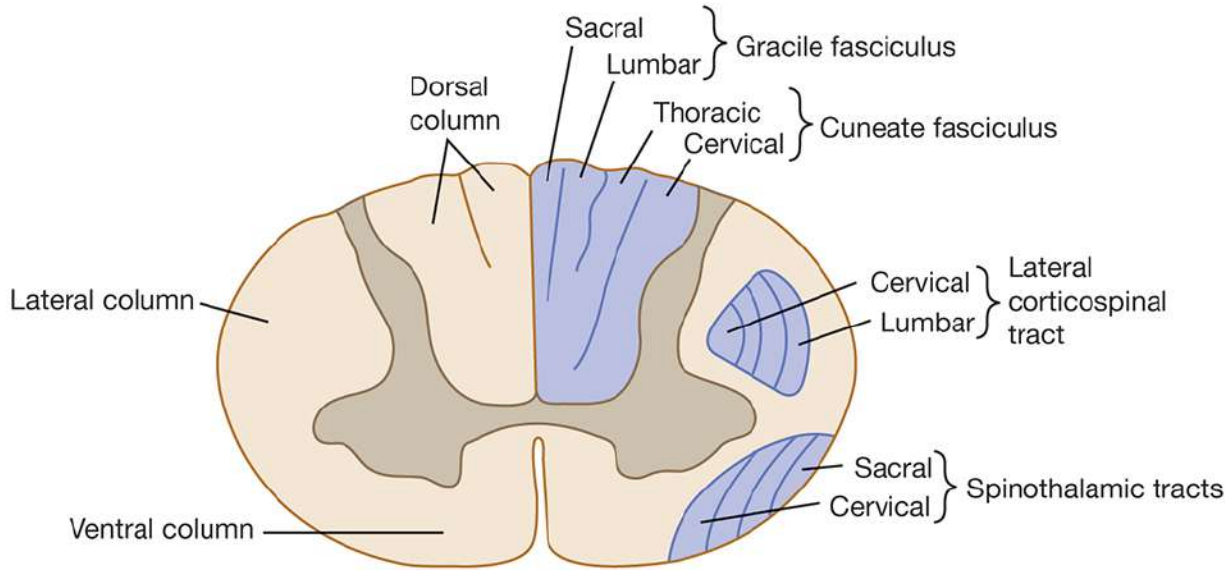

FIGURE 43.2 Somatotopic organization of the cervical spinal cord in transection. (Reprinted with permission from Waxman SG. *Clinical Neuroanatomy*. 30th ed. McGraw-Hill; 2024:54, Figure 5-15. Copyright © 2024 by McGraw-Hill LLC.)

The spinal cord is surrounded by the meninges, which are composed (from outer to inner) of the dura mater, arachnoid, and pia mater. The pia mater covers the spinal cord and its blood vessels. This layer condenses laterally into approximately 20 pair of dentate ligaments, which suspend the cord to the dura mater. The dura mater forms a dense, fibrous barrier between the bony spinal canal and the spinal cord. The dural sac ends inferiorly at S2-3, but the dura continues with the filum terminale down to the coccyx. The arachnoid mater resides between the dura mater and the pia mater. The arachnoid encloses the subarachnoid space filled with cerebrospinal fluid (CSF). The subarachnoid space follows the arachnoid down to the end of the dural sac.

The growth of the vertebral column during childhood takes place at a rate and extent greater than that of the spinal cord itself. By adulthood, the spinal cord is nearly 25 cm shorter than the vertebral column and ends near the level of the L1 vertebral body. Because of this differential growth, the exit level of each pair of spinal nerves in the spinal cord is usually higher than the corresponding vertebral body level. For example, in adults, the C8 nerve root leaves the cord at the C6 vertebral body, the T6 nerve at the T3 vertebral level, and the T12 nerve at the T9 vertebral level. All of the lumbar nerves exit the spinal cord from vertebral levels T10 through T12,

and all of the sacral nerves exit the spinal cord near the L1 vertebral level. The lower lumbar, sacral, and coccygeal nerves form the cauda equina, the collection of nerves that fills the thecal sac below L1. At its most caudal extent, the cord tapers to a thin segment, the conus medullaris. It is tethered to the coccyx by the filum terminale, a dense thread of pia mater.

Spinal Canal

The posterior body surfaces and neural arches of the vertebrae form the vertebral foramina, which in continuity form the spinal canal. Vertebral foramina are triangular in the lumbar and cervical regions, where the cord is mostly mobile, and round in the thoracic region. The spinal canal is lined with ligaments, including the posterior longitudinal ligament on its anterior wall, the flaval ligaments between adjacent arches, and the interspinous ligaments between the spinous processes. At each vertebral level, a spinous process protrudes from the posterior aspect of the neural arch, and transverse processes extend from the lateral edges of each arch. The laminae are those portions of the neural arch between the spinous and transverse processes, and the pedicles lie between the transverse processes and the body. At the intersection between the laminae and pedicles are superior and inferior paired articular facets. The superior articular facets are synovial joints that articulate with the inferior articular facets of the vertebra immediately above. The paired pedicles of each vertebra are notched at their superior and inferior edges such that the notches from two contiguous vertebra form an intervertebral foramen, through which the spinal nerve courses.

EPIDEMIOLOGY

Based on population data, 22% of primary spinal tumors are malignant and 78% nonmalignant (62% benign and 16% with borderline behavior).[2] The most common sites are the spinal cord (60%), followed by the spinal meninges (36%), and the cauda equina (4%). Incidence appears to increase with advancing age, peaking at the seventh decade of life. Age-adjusted incidence rates are 0.76 per 100,000 persons for nonmalignant tumors and 0.22 per 100,000 persons for malignant tumors. The frequency of nonmalignant cases is higher for females (60%), whereas malignant cases

are equally distributed by sex. Age-adjusted rates appear to be higher in Caucasian race and non-Hispanic ethnicity.[2] In adults, the most common histology types are meningioma (37.6%), nerve sheath tumor (23.1%), ependymoma (20.5%), and astrocytoma (4.2%). In children, the most common histology types are astrocytoma (31.4%), ependymoma (21.6%), oligodendroglioma (16.8%), nerve sheath tumor (13.3%), and meningioma (7.4%) (Table 43.1).[1]

TABLE 43.1 PRIMARY SPINAL CANAL TUMORS OF ADULTS AND CHILDREN: TYPES, LOCATIONS, AND FREQUENCIES

	Type	Location	Frequency (%)
Adults	Meningioma	Intradural-extramedullary	39.9
	Nerve sheath tumor	Intradural-extramedullary	30.5
	Ependymal tumors	Intramedullary or intradural-extramedullary	16.0
	Astrocytoma and other gliomas	Intramedullary	2.1
	Mesenchymal tumors	Intramedullary	3.8
	Others	—	7.6
Children	Astrocytoma and other gliomas	Intramedullary	28.1
	Ependymal tumors	Intramedullary or intradural-extramedullary	16.5
	Nerve sheath tumor	Intradural-extramedullary	17.6
	Meningioma	Intradural-extramedullary	4.6
	Mesenchymal tumors	Intramedullary	14.7
	Others	—	16.3

Based on Central Brain Tumor Registry of the United States (CBTRUS) statistical report from 2016 to 2020.

NATURAL HISTORY

Primary spinal tumors have the capacity to cause significant neurologic morbidity. Intramedullary tumors produce neurologic damage by local

invasion or cystic compression of the cord, whereas extramedullary lesions compress, stretch, or distort the cord or the spinal nerves. Primary spinal cord tumors may be focal or relatively localized in some patients but may involve nearly the entire length of the cord in others. Local tumor progression is the dominant form of treatment failure of spinal cord tumors, though leptomeningeal dissemination may occur rarely.[3,4] Spread to lymph nodes is not typically seen with spinal canal tumors. Extraneural spread is rare, occurring with an overall incidence of approximately 1%, though this risk appears to be higher than cerebral tumors.[5] The major causes of death in patients with spinal canal tumors are complications of paraplegia or quadriplegia, such as infection or respiratory compromise.

CLINICAL PRESENTATION

Pain is the most common presenting symptom, affecting approximately 72% of patients.[6] Often, the pain is localized to the region of involvement and may be present well before the patient manifests localizing neurologic signs. Radicular pain, a result of pressure on nerve roots, reflects the distribution of the involved root and indicates that conduction is intact. Numbness replacing pain is a more advanced sign that indicates compromise of spinal nerve or nerve tract conduction. Extramedullary tumors can cause distention of the dura with severe pain in the region of the tumor that is characteristically aggravated by recumbency because of venous congestion. Thus, pain is often worse at night. Movement or the Valsalva maneuver also may worsen pain.

Other symptoms of CNS involvement include weakness (55% of patients), sensory deficits (39%), and sphincter dysfunction (15%).[6] Low-grade tumors generally have a more prolonged duration of symptoms than high-grade tumors. Bladder and bowel dysfunction as presenting symptoms are relatively uncommon except for tumors that involve the conus medullaris and filum terminale.

Tumors involving the lumbosacral spine present with a cauda equina nerve root compression syndrome. Patients may have radicular pain in the anterior (L4), lateral (L5), or posterior (S1) thigh with corresponding paresthesias followed by muscle wasting of the glutei, hamstrings, or tibialis anterior muscles. Saddle anesthesia, absent ankle reflexes (S1), or

plantar (S2) responses may be present. Impotence and loss of anal or bulbar cavernous reflexes also may occur.

DIAGNOSTIC WORKUP

History and Physical Findings

Table 43.2 shows the diagnostic workup for primary tumors of the spinal cord. A meticulous and accurate patient history and physical examination are critical aspects of the initial assessment and can often localize suspected spinal tumors. The neurologic examination should concentrate on testing motor and sensory functions and reflexes. The differential diagnosis of a patient with a spinal cord tumor may include syringomyelia, multiple sclerosis, amyotrophic lateral sclerosis, diabetic neuropathy, viral myelitis, or paraneoplastic syndromes.

TABLE 43.2 DIAGNOSTIC WORKUP FOR PRIMARY SPINAL CORD TUMORS

General
History
Physical examination
Complete neurologic examination
Diagnostic Imaging Studies
Plain radiography
Magnetic resonance imaging (MRI) of the entire spine
MRI of the brain (consider for high-grade ependymomas or astrocytomas)
Myelography with computed tomography (if MRI is contraindicated)
Laboratory Studies
Cerebrospinal cytology (consider if clinical or radiologic suspicion of leptomeningeal disease)

A cutaneous sensory level may be definable, although the level of cord injury will be a few segments higher than the superior level of sensory loss because of pathway crossing characteristics. Loss of pain and heat and cold sensation below a specific dermatomal level indicates compromise of the spinothalamic pathway in the lateral columns. Impaired posture, gait, and coordination and loss of vibration sense indicate compromise of the posterior spinocerebellar pathways or the posterior columns.

At the level of the lesion, flaccid weakness and loss of tendon reflexes may occur. Below the lesion, the same signs are noticed in acute stages, but spastic paralysis and hyperactive tendon reflexes plus an upward Babinski

toe sign ensue in subacute and chronic stages. These findings are consistent with lower and upper motor neuron involvement, respectively. The signs and symptoms of neurologic dysfunction may be asymmetric. In some cases, a classic Brown-Séquard syndrome may be present with ipsilateral loss of motor function and fine touch sensation and contralateral loss of pain and temperature sensation below the level of the lesion.

Autonomic reflexes (eg, sweating) are frequently increased below the level of the lesion and may encompass the whole body if the lesion is cervical. Sweating disappears at the level of the compressed cord. Disruption of urinary and bowel function usually occurs later than sensory and motor dysfunction. Early loss of bladder function, saddle anesthesia, and later pain characterize neoplasms of the conus medullaris and filum terminale.[7]

Radiographic Studies

Although plain films are not typically used as the principal imaging modality for the evaluation of suspected spinal canal tumors, abnormalities can be detected from increased intracanal pressure, including erosion of vertebral pedicles, enlargement of the anteroposterior diameter of the bony canal, or scalloping of the posterior wall of the vertebral bodies. Calcification may be seen in extramedullary tumors, especially meningiomas, and, less frequently, in nerve sheath tumors. Changes are more likely to be detected on plain radiographs in children than in adults, such as kyphoscoliosis or scalloping of the vertebral bodies.[8,9]

Myelography, once considered the standard examination in evaluation of the spinal cord and canal, is now used principally in patients who are unable to undergo magnetic resonance imaging (MRI) because of the presence of implanted ferromagnetic materials or for whom images at the level of concern are distorted by the presence of surgical hardware. In this situation, computed tomography (CT) scanning combined with myelography will give better spatial resolution. CT myelography may be particularly beneficial as part of radiotherapy treatment planning in the postoperative setting, where the spinal cord may be obscured by artifact on the MRI.[10]

Computed Tomography

CT is most helpful in evaluating the spine for extradural pathologic processes. Bone tumors or paraspinal soft tissue masses that secondarily involve the spinal cord (eg, dumbbell tumors) can be imaged with contrast-enhanced CT scans. Nerve sheath tumors can enlarge the intervertebral foramina or spinal canal and cause smooth erosion of bone. Meningiomas are occasionally calcified. Both of these neoplasms are partially outlined by CSF and produce extramedullary deformity by displacement of the spinal cord.[11]

Magnetic Resonance Imaging

MRI has replaced myelography and CT as the imaging study of choice in evaluation of tumors of the spinal canal. Sagittal and axial images give a three-dimensional (3D) appreciation of the patient's anatomy and help plan therapy. The various signal characteristics of the CSF—white and gray matter, bone and bone marrow, fat, and flowing blood—all facilitate the interpretation of the study. Some cystic tumors, vascular lesions, or lipomas can be diagnosed based on their characteristic signals on T1- and T2-weighted images without contrast injection. Intravenous gadolinium-containing contrast agent administration improves the sensitivity of MRI by enhancing the solid component of intramedullary tumors and differentiating them from surrounding edema or syrinx cavities (Figures 43.3 and 43.4). Unlike low-grade gliomas in the brain, nearly all spinal cord gliomas, regardless of grade, enhance with gadolinium contrast agents. Sagittal T1-weighted images usually localize intramedullary mass neoplasms along with adjacent cysts. Intradural-extramedullary lesions also show enhancement on T1-weighted images after administration of contrast. The use of contrast also increases the sensitivity of detecting leptomeningeal metastases.[12]

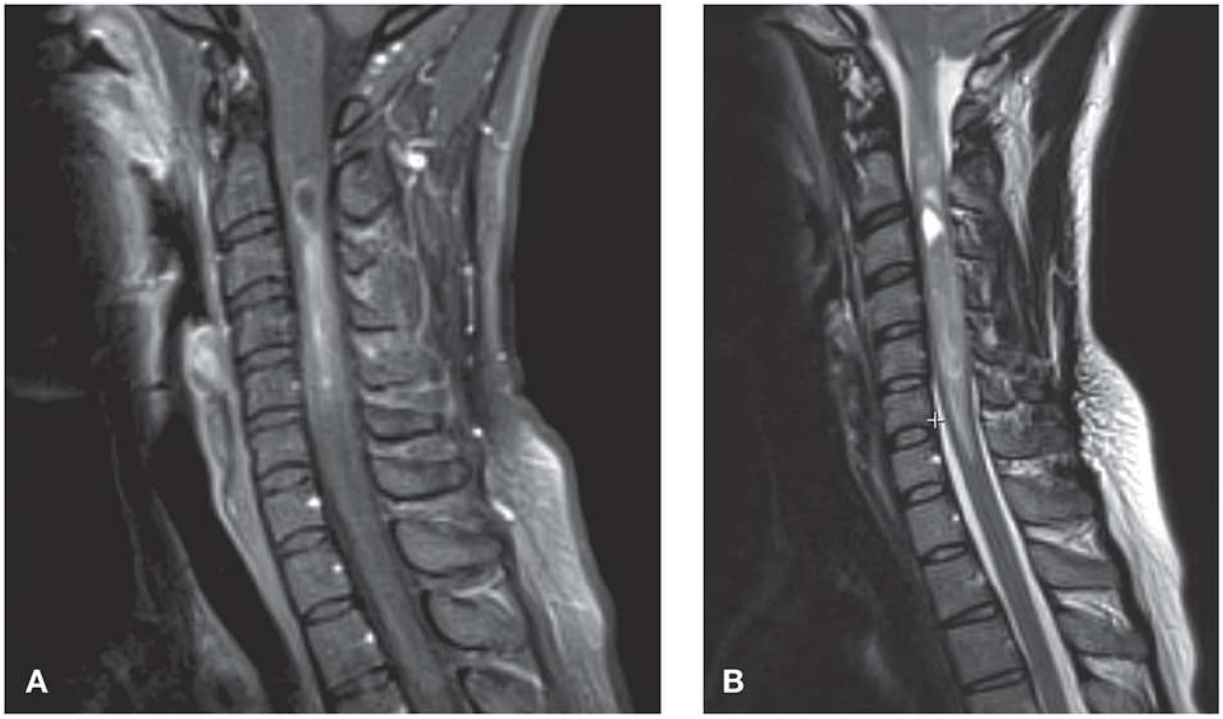

FIGURE 43.3 Sagittal magnetic resonance imaging scans of a 30-year-old woman with a low-grade astrocytoma involving the cervical spine. A. T1-weighted image demonstrates an intramedullary lesion that expands the cord from the level of the craniocervical junction to the level of C7. The enhancing component extends from mid C2 to C5, and there is an associated cystic component at the cranial aspect of the lesion. B. T2-weighted image demonstrates T2 hyperintensity within the lesion suggestive of edema and hypointensity suggestive of blood products.

FIGURE 43.4 Sagittal magnetic resonance imaging scans of a 12-year-old male with a myxopapillary ependymoma involving the lumbar spine. A. T1-weighed image demonstrates a homogeneously enhancing intradural-extramedullary mass at the level of L1. B. T2-weighted image demonstrates hyperintensity of the mass. (Courtesy of Aseem Sharma, MD, Mallinckrodt Institute of Radiology.)

MRI of the brain should be performed in patients with high-grade ependymomas or astrocytomas to exclude the possibility of neuraxis seeding or the presence of an intracranial primary tumor.

Cerebrospinal Fluid

A patient suspected of having a spinal canal neoplasm should not be subjected to a lumbar puncture before MRI. Symptoms may be exacerbated

after a spinal tap because of shifting of the spinal cord and incarceration before the tumor can be localized adequately. The CSF usually has increased protein levels and may exhibit xanthochromia, especially with extradural compression conditions, but lower values can be found in cases of intramedullary disease and with compression in the cervical region.[7] The incidence of leptomeningeal spread in patients with primary spinal cord glioma is low overall but is substantially more common with malignant tumors. Of note, two recently recognized entities have significantly higher risk of leptomeningeal dissemination: glioblastoma with primitive neuronal component and diffuse leptomeningeal glioneuronal tumors.[13,14] Cytologic examination of the CSF is not done routinely but may be considered in the presence of clinical or radiologic suspicion.

Tissue Diagnosis

Suspected primary tumors of the spinal cord and spinal canal should be pathologically confirmed whenever possible. Strong consideration should also be given to biopsy of any presumed metastatic tumors if they are the first site of disease recurrence after successful management of a previous malignant primary tumor. In rare circumstances in which emergency radiation therapy is indicated to relieve spinal cord compression in the absence of a confirmed cancer diagnosis, a patient should be made aware of the consequences of treatment in the absence of a definitive diagnosis, including the inability to tailor therapy based on histology and possible delay of appropriate treatment for nonmalignant etiologies.

PATHOLOGIC CLASSIFICATION

The current comprehensive classification system of spinal tumors was published by the WHO in 2007 and recently updated in 2021 to incorporate many molecular markers to establish histology types. The WHO classification groups CNS neoplasms by the tumor histology and provides a grading system to predict prognosis and guide therapy.[15,16] Tumor types include neuroepithelial (ie, astrocytoma, ependymoma, ganglioglioma), nerve sheath (ie, schwannoma, neurofibroma), meningioma, lymphoma, germ cell, and metastatic tumors. Clinically, spinal tumors are also

characterized by their location as extradural, intradural-extramedullary, or intramedullary.

Intramedullary Tumors

Intramedullary spinal tumors constitute approximately 20% to 30% of all primary spinal tumors, and approximately 80% are glial in origin, of which ependymoma is the most common histology (60%-70%) followed by astrocytoma (30%-40%).[17] Ependymomas are derived from glial cells similar to those lining the ventricular system and can be either intramedullary or intradural-extramedullary. The 2021 WHO classification defines ependymomas according to a combination of histopathologic and molecular features as well as anatomic sites, dividing them into molecular groups across the supratentorial, posterior fossa, and spinal compartments. Spinal ependymal tumors now include the following entities: spinal ependymoma (grade 2 or 3), MYCN-amplified spinal ependymoma (grade 2 or 3), myxopapillary ependymoma (grade 2), and subependymoma (grade 1).[18] For more information on spinal ependymoma in children, refer to Chapters 90.

In contrast to intracranial astrocytoma, most spinal cord astrocytomas are low grade (WHO grade 1 or 2), including 75% in adults and 85% to 90% in children.[6,19,20] Juvenile pilocytic astrocytomas (grade 1) in particular, as in other locations in the CNS, are not infiltrative in nature. Recognition of this feature, along with advances in surgical techniques and intraoperative monitoring, has led neurosurgeons to manage these tumors with more radical resections. However, diffuse astrocytomas (grades 2-3) or H3 K27-altered diffuse midline glioma (grade 4) is infiltrative, and complete resection carries a significant risk of neurologic disability. In these cases, a subtotal resection or biopsy may be the only safe surgical option.[21-23] A discriminating feature of intramedullary spinal cord tumors is the presence or absence of a syrinx. Syringes associated with spinal cord astrocytoma occur in 20% to 40% of patients. Syringes can span the entire length of the cord, although they tend to favor more rostrally located tumors, as well as favoring the more rostral portion of the tumor itself.[24] In certain instances, a syrinx may even extend into the medulla, producing an obstructive

hydrocephalus.[25] The syrinx itself can be responsible for significant neurologic deficit.

For more information on spinal astrocytomas in children, refer to Chapters 90. A variety of vascular neoplasms can arise from within the spinal cord, including arteriovenous malformations, hemangiomas, and hemangioblastomas. Approximately one-third of hemangioblastomas are associated with von Hippel-Lindau disease. These are benign neoplasms that are usually well circumscribed and amenable to surgery.[26] Unresectable or recurrent hemangioblastomas may be treated with stereotactic radiosurgery (SRS).[27]

Intradural-Extramedullary Tumors

Most intradural-extramedullary neoplasms are meningiomas, nerve sheath tumors, or extramedullary ependymomas such as myxopapillary ependymomas. They are usually amenable to complete surgical excision.

Meningiomas are usually benign, slow-growing, well-encapsulated neoplasms that are easily separated from the spinal cord; most can be completely excised, and they rarely recur. They may arise anywhere within the intradural space but are most commonly found in the cervicothoracic region and are uncommon in the lumbar region and rare in the sacrum. Spinal meningioma occurs more frequently in females. The peak incidence is between the sixth and eighth decades of life. The duration of symptoms before diagnosis is typically between 12 and 24 months, with longer duration as an independent predictor for a lack of improvement after surgery.[28]

Nerve sheath tumors arise from the Schwann cell, the cell responsible for insulating peripheral nerves and contributing to impulse conduction. Nerve sheath tumors have been called neurofibroma, schwannoma, neuroma, and neurilemmoma in the past. More recently, a distinction between neurofibroma and schwannoma has been made. Although both tumors arise from Schwann cells, certain gross, microscopic, and clinical features help distinguish the two. Growing evidence also suggests that they arise via distinct pathogenic mechanisms.[29,30] Neurofibromas typically encase involved nerve roots, whereas schwannomas commonly displace the nerve roots because of their asymmetric growth. The plexiform neurofibroma is

associated with type 1 neurofibromatosis, and the presence of multiple tumors helps establish the diagnosis of this genetic condition. In contrast, schwannoma is associated with type 2 neurofibromatosis. Patients with type 1 neurofibromatosis may be at risk for malignant tumor transformation following radiotherapy.[31,32] Nerve sheath tumors are usually solitary and may occur in any section of the spinal canal. They are evenly distributed in the cervical, thoracic, and lumbar regions; they are least common in the sacrum. They occur in men and women with equal frequency and are most commonly diagnosed in the fourth through sixth decades of life. Most of these tumors are completely intradural, although 10% to 15% may have an extradural component as well (the so-called dumbbell tumors). Most nerve sheath tumors are benign, well-encapsulated lesions that are amenable to total surgical excision. The rare malignant nerve sheath tumors have a natural history similar to soft tissue sarcomas, and they should be treated as such.[33,34]

Miscellaneous Neoplasms

Unusual intradural-extramedullary tumors include lipomas, dermoids, and epidermoid tumors. They are typically benign and amenable to complete resection. Even if incompletely excised, recurrences are usually slow.

Extradural Tumors

Most extradural tumors are metastatic, and the presentation and management of these is discussed in Chapters 102. A variety of primary bone and soft tissue tumors may arise from an extradural location and involve the spinal canal. Bone tumors include osteosarcoma, chordomas, chondrosarcoma, and Ewing sarcoma. Soft tissue tumors include soft tissue sarcomas, including malignant nerve sheath tumors, lymphomas, and neuroblastomas. These tumors and their management are discussed in Chapters 85 (lymphoma), 92 (neuroblastoma), 94 (soft tissue sarcoma), 95 (osteosarcoma/chordoma), and 96 (Ewing tumor).

PROGNOSTIC FACTORS

The major prognostic factors in patients with primary spinal canal tumors are tumor type and grade, tumor extent and location, patient age, and presenting neurologic function. Treatment-related factors that influence the outcome include tumor resectability and the use of radiation therapy for certain tumor types. Many of these factors are interdependent. For example, ependymomas occur most frequently in the distal spinal canal and are more often resectable than astrocytic tumors.

Milano et al analyzed 664 patients with spinal cord astrocytomas and 1,057 patients with spinal cord ependymomas using the Surveillance, Epidemiology, and End Results database. In this largest study to date on prognostic factors for long-term outcome, lower grade, younger age, and surgical resection were associated with significantly better overall survival and cause-specific survival for both astrocytomas and ependymomas. Radiotherapy was associated with worse cause-specific survival, but this is likely because of adverse selection bias. The 5-year overall survival of grades 1, 2, 3, and 4 astrocytomas was 82%, 70%, 28%, and 14%, and the 5-year cause-specific survival was 89%, 77%, 36%, and 20%, respectively. The 5-year overall survival of grades 1, 2, and 3 ependymomas was 92%, 97%, and 58% and the 5-year cause-specific survival was 100%, 98%, and 64%, respectively.[35] Weber et al analyzed the long-term outcomes of 183 patients with spinal myxopapillary ependymomas from a pooled database of the Rare Cancer Network and the MD Anderson Cancer Center and reported 10-year overall survival of 92% and 10-year progression-free survival of 61%. Tumor recurrence occurred in 32% of patients, and 85% of the recurrences were local. On multivariate analysis, older age (≥36), adjuvant radiation therapy, and gross total resection were associated with improved local control and progression-free survival.[36]

Several investigators have reported that patients with cervical spinal tumors have a worse survival and neurologic outcome than patients with more caudal tumors.[37-40] Guidetti et al stated that patients with cervical lesions had a higher surgical risk and complication rate, which made thorough resection of tumors in this location difficult and sometimes inadvisable.[40] In a series of 62 patients with exclusively intramedullary ependymomas, patients with high cervical presentations (above C5) accounted for four of six postoperative deaths because of apneic respiratory complications.[38] In the Mallinckrodt Institute of Radiology experience,

Garcia reported that the primary tumor location was the most important prognostic feature. It was suggested that a greater concentration of function per unit volume of the upper spinal cord compared with that of the cauda equina accounted for the worst neurologic outcome and survival in patients with rostral tumors.[39] In these studies, tumors affecting the cervical spinal cord were more likely to be astrocytomas, and tumors in the caudal spinal cord, filum terminale, or cauda equina were more likely to be ependymomas. The anatomic dependence of various tumor types may also contribute to the better prognosis seen in patients with tumors of the lower spinal canal.

Extensive involvement of the spinal cord with an ependymoma is associated with a worse outcome. Linstadt et al reported a 93% 10-year disease-specific survival rate with localized ependymoma compared with 50% for patients with diffuse tumors.[41] Extensive tumors have a 50% local failure rate after surgery and radiation therapy, compared with only 20% for limited disease (one to three vertebral body segments).[42] However, the extent of disease has not been a prognostic factor in other series.[43]

Neurologic function at diagnosis is an important clinical prognostic factor. In general, the fewer the symptoms and the better the neurologic function at presentation, the greater the likelihood the tumor will be controlled with fewer long-term adverse neurologic sequelae. Poor neurologic function in patients with spinal cord tumors is often attributable to the disease process and a prolonged delay in diagnosis rather than the effect of surgery or radiation therapy.[38,40,44]

GENERAL MANAGEMENT

Figure 43.5 is a treatment algorithm for intradural masses confirmed by MRI or CT.

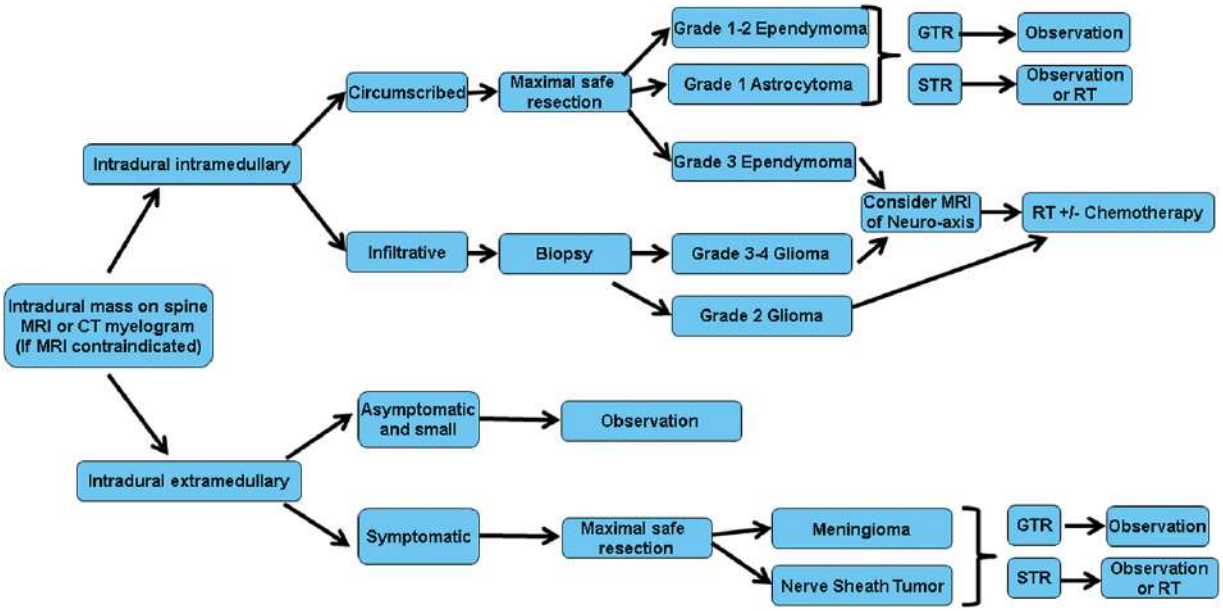

FIGURE 43.5 Intradural tumor treatment algorithm. CT, computed tomography; GTR, gross tumor resection; MRI, magnetic resonance imaging; RT, radiotherapy; STR, subtotal resection.

SURGICAL MANAGEMENT

Intramedullary Tumors

Intramedullary tumors, most of which are astrocytomas and ependymomas, present a surgical challenge. Complete surgical excision is the treatment of choice if it can be achieved without compromising neurologic function. Ependymomas are more frequently amenable to gross total excision than are astrocytomas.[21,40] Myxopapillary ependymomas most commonly involve the cauda equina and are less aggressive than other ependymomas, though they have been reported to seed the CSF.[45-49] Encapsulated myxopapillary tumors of the cauda equina are frequently amenable to complete en bloc excision, and the recurrence rate is very low. Unencapsulated or adherent tumors are often removed piecemeal and are associated with a high local recurrence rate after surgery alone, and adjuvant radiation therapy should be considered.[42,49-51]

Complete resection of intramedullary tumors with preservation of neurologic function was not possible until 1940, when Greenwood introduced the bipolar coagulation forceps. Since then, other technological advancements have emerged, including the dissecting microscope, intraoperative ultrasound, ultrasonic aspirator, contact laser scalpel, and

intraoperative neurophysiologic monitoring. These modern surgical techniques have increased the complete resectability of intramedullary tumors while minimizing neurologic injury.[52-55]

Intraoperative ultrasonography is used to localize the lesion, define its extent, and assess the progress of tumor resection.[56] The ultrasonic aspirator allows removal of tissue fragments from within 1 mm of the vibrating tip, permitting dissection immediately adjacent to vital neural tissue.[57] The contact laser scalpel only delivers thermal energy to tissue upon direct contact, and the laser beam resides entirely within a coated sapphire crystal probe tip. It provides precise dissection of tumor with little mechanical or thermal injury to normal spinal cord parenchyma.[58]

Intraoperative neurophysiologic monitoring is considered standard of care for resection of intramedullary tumors. It is dependent on two key components: somatosensory-evoked potentials (SEPs) and motor-evoked potentials (MEPs). SEPs are monitored continuously during the incision of the dorsal midline of the spinal cord to avoid injuring the dorsal column, as the cord anatomy is often distorted by the tumor. MEPs are monitored once the surgeon starts to dissect the tumor to avoid irreversible damage to the corticospinal tract. MEPs should be monitored using a combination of epidural electrodes (D waves) and signals from limb muscle. Typically, a decrement of 50% or more of D-wave amplitude is considered a major indication to stop surgery.[59] Sala et al reported that the use of intraoperative neurophysiologic monitoring during resection of intramedullary tumors significantly improved long-term ambulatory status as compared to historical controls.[60]

The risk of paralysis after surgery is <1% of patients with minimal or no preoperative neurologic deficits but may be much higher for those who present with more substantial deficits. Approximately one-third of patients will develop temporary motor deficits after surgery, and most will have at least some postoperative deterioration in neurologic status.[61,62] If complete excision of low-grade spinal cord tumors is achieved, the local recurrence rate is low and prognosis is excellent without additional adjuvant therapy. In patients who recur, tumor regrowth is often slow and second resection may be possible.[22,63-65]

Intradural-Extramedullary Tumors

The treatment of choice for most tumors in this location is maximal surgical excision with preservation of neurologic function. Most benign nerve sheath tumors can be completely resected with low risk of recurrence. In contrast, complete resection of malignant peripheral nerve sheath tumor is difficult, and local recurrence is high and typically occurs between 7 and 15 months after surgery. For spinal meningioma, local recurrence is low after Simpson grade I resection but can be as high as 30% after Simpson grade II resection with an average time of 12 years after surgery. Thus, Simpson grade I resection is preferred for spinal meningioma if attainable.[66-68]

CHEMOTHERAPY

The reported use of chemotherapy for primary spinal canal tumors is limited. Outside a clinical trial, chemotherapy is often reserved for patients with progression of disease following surgery and radiotherapy with no other treatment options. Combined with the low incidence of the disease, most studies are retrospective with very few patients, which limits any definitive conclusion regarding their efficacy. The use of chemotherapy for spinal canal tumors is often extrapolated based on the experience for intracranial tumors. However, such assumption requires further validation as the underlying oncogenesis and biologic pathways may be different between the two entities.[69]

Platinum and etoposide are generally considered the most active agents for ependymomas. In the setting of recurrent ependymoma, platinum-based chemotherapy has been shown to produce higher response rates than nitrosourea-based chemotherapy, but most patients in the studies had intracranial ependymomas.[70,71] In a prospective phase II study, 10 consecutive patients with recurrent cellular spinal cord ependymomas were treated with oral etoposide. Two patients had partial responses, and five patients had stable disease. The median overall survival was 17.5 months.[72]

Temozolomide is an attractive agent for primary spinal cord glioma, given its success in treating intracranial astrocytoma.[73] Kim et al reported their experience of treating two patients with primary spinal cord glioblastoma multiforme with concurrent radiotherapy and temozolomide followed by adjuvant temozolomide. The two patients survived 12 and 16

months, respectively, in contrast with a median survival time of 9 months in other reports.[74] Chamberlain reported a series of 22 patients with recurrent WHO grade II glioma treated with temozolomide. Overall, there were 18% partial response and 55% with stable disease. The median survival was 23 months, and progression-free survival at 2 years was 27%.[75]

For young children, especially those <3 years of age, there is an even greater interest in identifying effective and minimally toxic chemotherapy to delay or eliminate radiation therapy. There are two prospective cooperative group trials that have included children with primary spinal cord astrocytomas. In one clinical trial conducted by the French Society of Pediatric Oncology, eight children with unresectable or recurrent intramedullary low-grade gliomas were treated with a planned 16-month course of carboplatin, procarbazine, vincristine, cyclophosphamide, etoposide, and cisplatin. Seven of the patients had a clinical or radiographic response to the chemotherapy. Five of the patients remained progression free, with a follow-up ranging from 16 to 59 months.[76] In the Children's Cancer Group 945 trial, 13 children with high-grade astrocytic spinal cord neoplasms were assigned to receive two cycles of "8-drugs-in-1-day" chemotherapy before radiation therapy, then eight additional cycles thereafter. At 5 years, 46% of the children had no progression and 54% were alive. The authors argued that more intensive therapy was necessary.[77] Mora et al reported a small but thought-provoking study of three infants with spinal cord astrocytomas (WHO grade 2 or 3) treated with irinotecan and cisplatin. All three infants had subtotal resection and progressed on conventional carboplatin-based chemotherapy. After switching to irinotecan and cisplatin, all three patients had remarkable radiologic and clinical response. At the time of the last follow-up, they had remained in remission at 12, 20, and 48 months after diagnosis. The authors hypothesized that irinotecan and cisplatin may provide synergistic effect without overlapping toxicities.[78] A recent phase II Children's Oncology Group clinical trial (COG-ACNS0423) treated pediatric patients with high-grade glioma with adjuvant radiation and concurrent temozolomide followed by additional temozolomide and lomustine chemotherapy, which included 5% of spinal high-grade astrocytomas. The study demonstrated improved event-free survival and overall survival as compared to historical controls of similar regimen without lomustine.[79]

RADIATION THERAPY

There are currently no randomized controlled trials to guide the role of radiation therapy for primary spinal canal tumors. Clinical use of postoperative radiation therapy is generally guided by patterns of failure and the prevailing attitude of many radiation centers.[80] Patients with completely resected low-grade astrocytomas and ependymomas typically have an excellent prognosis, with local failure rates of <10% without additional therapy.[68,81-83] Most centers do not advocate routine use of adjuvant radiation therapy in this setting, but long-term follow-up is indicated as late failures can occur.

In contrast, adjuvant radiation therapy after incomplete resection or piecemeal excision of low-grade ependymomas and astrocytomas is supported by retrospective analyses. Guidetti et al first reported a beneficial outcome in patients receiving radiation therapy after an incomplete excision of an ependymoma.[40] Piecemeal removal of ependymoma in the region of the conus medullaris, cauda equina, and filum terminale (most commonly myxopapillary ependymoma) has high local failure rate ranging from 20% to 43%. Adjuvant radiation therapy in these patients after piecemeal excision produces a similar local recurrence rate equal to that of patients undergoing gross total resection.[42,49,51,84] The long-term outcome of 183 spinal myxopapillary ependymomas from Weber et al showed adjuvant radiation therapy improved 10-year progression-free survival from <40% to 70%. The authors advocated more liberal use of adjuvant radiation therapy for patients with myxopapillary ependymoma with subtotal resection, piecemeal resection, or questionable gross total resection.[36] In a multi-institutional series, adjuvant radiation therapy significantly improved progression-free survival in the 40 patients with low- and intermediate-grade astrocytomas.[21] After adjuvant radiotherapy, the cumulative incidence of local failure ranges from approximately 20% for low-grade ependymoma to 40% for low-grade astrocytoma.[80]

Nonetheless, there are clinical circumstances in which careful follow-up after incomplete resection is appropriate, with a second surgery or radiation therapy considered at the time of progression or recurrence. Radiation therapy of the spine in a child may produce a spinal deformity (ie, scoliosis or kyphosis) because of retardation of bone growth from damage to

epiphyseal plates of the vertebral bodies as well as soft tissue fibrosis and contracture.[85] Most spinal cord tumors in young children are either low-grade astrocytomas or well-differentiated ependymomas that have a very low growth rate. Delaying radiation therapy until recurrence or tumor progression may allow the child to grow at a normal rate for several years before receiving radiation therapy. Constantini et al reported a series of 164 patients younger than 21 years of age treated with radical surgery alone without adjuvant radiotherapy. Gross total resection or subtotal resection was achieved in 77% and 20% of patients, respectively. The 3-month neurologic function was 60% stable, 16% improved, and 24% deteriorated compared with preoperative function. The 5-year progression-free survival rate for low-grade and high-grade tumors was 78% and 30%, respectively.[86]

The prognosis of high-grade astrocytomas and ependymomas is dismal, and multimodality treatment is recommended, ideally on a clinical trial. Adjuvant radiation therapy is routinely recommended, regardless of the extent of resection. The role of concurrent and adjuvant chemotherapy for high-grade intramedullary astrocytoma remains inconclusive as discussed earlier. Despite aggressive treatments, few patients with high-grade astrocytomas survive beyond 2 years.[80,87] As with intracranial high-grade glioma, novel therapies beyond traditional radiotherapy and cytotoxic chemotherapy are desperately needed.

Relapse can occur years after treatment and is predominantly local. In a series of 37 spinal ependymomas treated with adjuvant radiotherapy, more than 50% of failures developed 5 years after diagnosis, and the extent of surgical resection correlated with time to progression.[88] These findings were confirmed in another series of patients with spinal myxopapillary ependymoma, where Chao et al reported a median time to recurrence of 7.7 years.[89]

The prognosis is excellent for most patients with intradural-extramedullary tumors, which rarely recur after total excision. However, subtotally resected meningiomas may recur late after surgery.[90] Some investigators have advocated postoperative radiation therapy using either conventional fractionated external-beam radiotherapy or SRS.[91,92] Data supporting the routine use of radiation therapy in the management of patients with nerve sheath tumors, vascular malformations, lipomas, hemangiomas, teratomas, and dermoids are limited.

Radiation Therapy Techniques

Target Volume

Historically, it had been recommended that superior and inferior field borders encompass two vertebral bodies above and below a tumor defined by myelography, with the width of the field approximated between the tips of the lateral processes of the vertebral bodies. With the advancement of CT simulation and MRI fusion, the gross tumor volume (GTV) can be more accurately defined and smaller margins may be used. For low-grade astrocytomas or ependymomas, a clinical target volume (CTV) margin of 0.5 to 1 cm is appropriate. The CTV should encompass the preoperative GTV plus any associated intratumoral cysts. It is not necessary to include an intramedullary syrinx that extends above or below the primary tumor unless there is radiographic or surgical evidence of tumor extension to these regions. Planning treatment volume (PTV) margins of 0.5 cm or less may be used to account for setup error, with smaller PTV margins necessitating adequate patient immobilization and optimal daily localization techniques (orthogonal kilovoltage imaging, cone-beam CT, etc).

High-grade astrocytomas and ependymomas can be more infiltrative, and a larger CTV margin of at least 1.5 cm craniocaudally should be used. Merchant et al described a diffuse failure pattern in children with high-grade gliomas shortly after completing radiation therapy, suggesting that the tumor was not adequately covered in the irradiated volume and the need for larger CTV margins of 1.5 cm.[93] The intervertebral foramina should be included within the CTV if tumor extension is suspected.

For myxopapillary ependymomas involving the conus, a 1.5-cm CTV margin cephalad and caudad to the GTV is used, but not beyond the thecal sac, which is typically at the level of S2-3. If the cauda equina is involved, the CTV should extend inferiorly to encompass the entire thecal sac, with the volume widened at the sacroiliac joints to ensure adequate coverage of the meningeal sleeves in the intervertebral foramina. Failure to adequately encompass the thecal sac has been associated with an increased rate of treatment failure.[84]

Craniospinal or spinal axis irradiation is usually not indicated in the treatment of most spinal cord tumors; local failure accounts for most tumor recurrences.[21,39,41,42,82] However, neuraxis dissemination may be seen in

patients with anaplastic ependymomas,[94] malignant astrocytomas,[95,96] and myxopapillary ependymomas.[46,47] Craniospinal irradiation may be considered if there is evidence of leptomeningeal dissemination.

Radiation Technique

The majority of primary tumors of the spinal canal are now treated with intensity-modulated radiation therapy (IMRT) methods, which reduce normal tissue dose and improve target dose conformality compared to conventional 3D-field arrangements. For younger patients, techniques utilizing proton beam radiation therapy are preferred to reduce dose to organs at risk even further and minimize secondary malignancy risk (Figure 43.6).[97]

FIGURE 43.6 Treatment planning for spinal cord tumors. This is a 67-year-old woman with a history of spinal ependymoma who underwent gross total resection and had subsequent disease progression treated with intensity-modulated proton therapy (IMPT), 54 GyE in 30

fractions to lower thoracic to upper sacral spine with protons. The clinical target volume is shown in green outline. A. Axial view showing the arrangement of the two posterior oblique proton beams. B. Sagittal view more clearly delineating the superoinferior extent of the target. Note the target conformality with IMPT and limited exit dose anteriorly into the bowel.

Radiation Dose

Low-grade astrocytomas and ependymomas should be irradiated to a total dose of 50.4 Gy, given in 1.8 Gy daily fractions. High-grade ependymomas or astrocytomas can be treated to a dose of 54 Gy with 1.8 Gy daily fractions.[80] Limited dose-response data exist for spinal cord tumors. In the Mallinckrodt series of 37 patients with primary spinal cord tumors, local control and survival were significantly better for those who received 40 Gy or higher.[39] Shaw et al reported that the local failure rate of ependymomas was 35% in patients receiving 50 Gy or less compared with only 20% in patients receiving more than 50 Gy.[42] However, doses beyond 50.4 Gy have not been shown to improve local control or survival.[41,96,98] In patients with evidence of CSF dissemination, craniospinal irradiation should be considered. Typical doses to the craniospinal axis range from 36 to 39.6 Gy, with a boost to sites of gross tumor to 50.4 to 54 Gy.

Stereotactic Radiosurgery

SRS provides the ability to deliver highly conformal, high-dose radiation in such a manner as to mitigate normal tissue injury while escalating dose to the target volume. Most spine SRS reports to date have focused on its use in the management of metastatic disease to the spine. In a recent review, Hsu et al found local control rates in excess of 80% in most series, with significant pain improvement in 43% to 97%.[99]

A few reports have also detailed spine SRS in the management of patients with intradural tumors. In the largest series reported to date, Gerszten et al treated 73 patients with benign intradural spinal tumors (meningioma, schwannoma, neurofibroma) using CyberKnife (Accuray Inc) spine SRS to doses ranging from 16 to 30 Gy in one to five fractions. At a median of 37 months follow-up, the local control rate was 98% and pain improved in 70% of meningiomas, 50% of schwannomas, and 0% of neurofibromas. Three patients developed radiotherapy-related spinal cord toxicity 5 to 13 months after treatment.[91] Overall radiographic response

rates for benign intradural tumors in the series reported to date range from 28% to 39%.[99]

Investigators from Stanford University have reported their experience treating spinal cord ependymomas and hemangioblastomas using spine SRS delivered with the CyberKnife system (Figure 43.7). In the earliest report, seven patients with 10 intramedullary spinal tumors (seven hemangioblastomas, three ependymomas) received spine SRS to a dose of 18 to 25 Gy in one to three fractions.[27] At a mean follow-up of 12 months, one ependymoma and two hemangioblastomas were smaller on follow-up imaging, with the remainder stable. No significant treatment-related complications were reported. In a follow-up study, Daly et al reported a 3-year actuarial control rate for 27 spinal hemangioblastomas treated with spine SRS to 18 to 25 Gy in two to three sessions. One patient developed a grade 2 foot drop 4 months after SRS, and two patients developed grade 1 sensory deficits.[100]

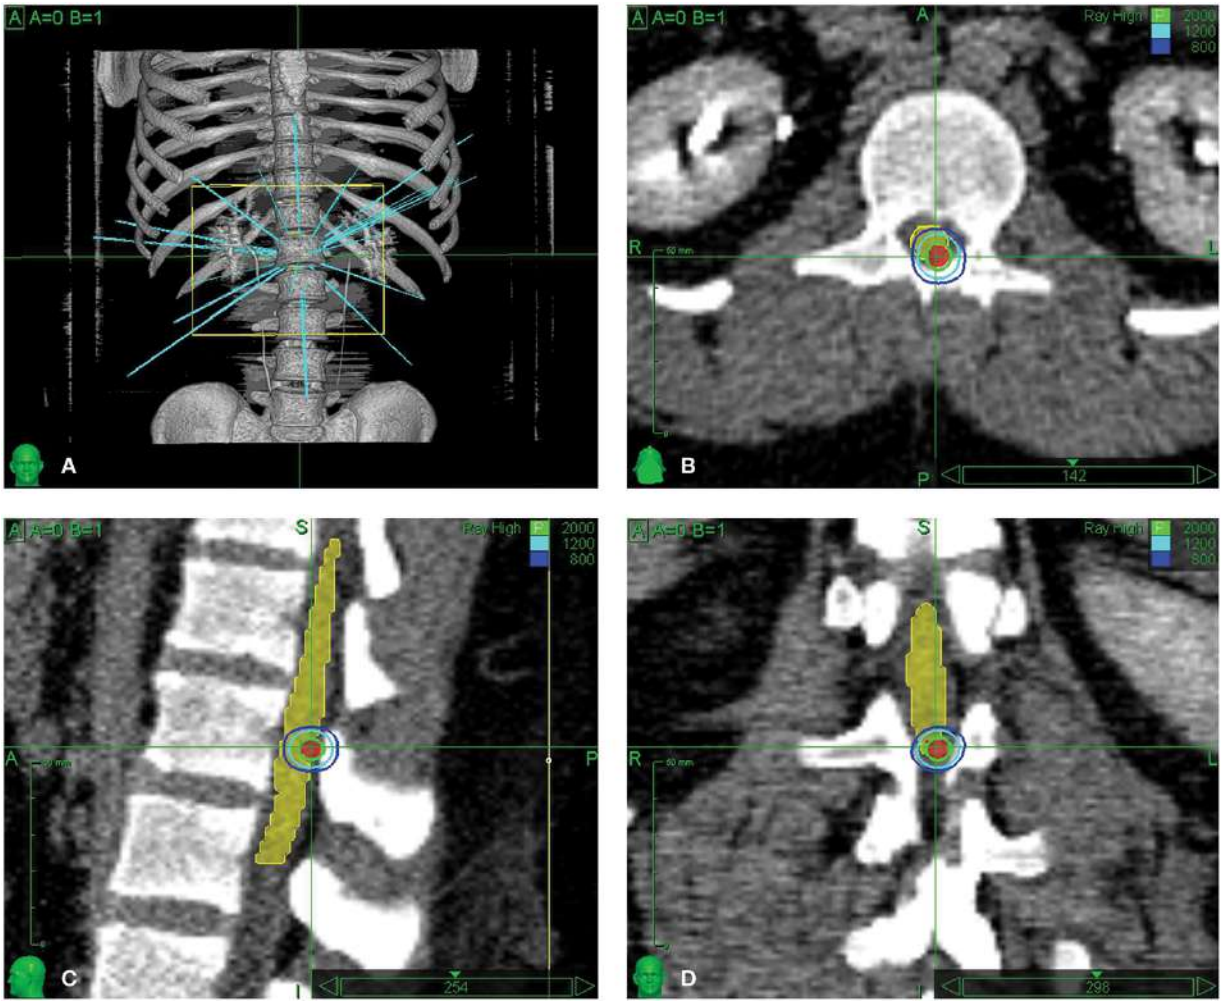

FIGURE 43.7 Stereotactic radiosurgery for an L1 hemangioblastoma. A single dose of 20 Gy was delivered with CyberKnife using 87 noncoplanar beams as shown in *blue*. As is typical of treatment delivery with this unit, the plan is nonisocentric. Gross tumor volume is shown in *solid red*, spinal cord in *solid yellow*. *Green line*, prescription dose of 20 Gy; *light blue line*, 12 Gy; *dark blue line*, 8 Gy. A. Early results of spine SRS for intradural-extramedullary or intramedullary lesions are promising, and with the rapidly increasing availability of extracranial radiosurgery devices, SRS for these patients will no doubt increase in utilization. However, with such few reports and limited follow-up to date, caution certainly seems warranted, given the potential for

late toxicity in these patients with high rates of long-term survival. Issues related to spinal cord tolerance after spine SRS are discussed below.

Proton Therapy

Proton therapy is a form of particle radiation that provides very conformal radiation therapy with a lower integral dose than other forms of photon radiation therapy.[101] Due to its unique physical property, it can spare low-dose exposure to the normal tissues distal to the proton beam, which theoretically should translate to reduction of late toxicities, such as secondary malignancy and cardiac disease, especially for young adults or pediatric patients.[102-104] Amsbaugh et al reported a prospective case series of seven pediatric patients with spinal ependymomas treated with proton therapy (ranging from 45 to 54 cobalt gray equivalents). They showed proton therapy was well tolerated and dramatically reduced dose to all normal tissues anterior to the vertebral bodies as compared to photon therapy. After relatively short median follow-up of 26 months, local control, event-free survival, and overall survival were all 100%, and there was no grade 3 toxicity.[105] However, due to the relative rarity of the primary spinal tumors and the required long-term follow-up for end points such as secondary malignancy and cardiac disease, sufficient clinical data to support or refute the benefit of proton therapy for spinal tumors will unlikely to emerge in the near future. Individualized decision based on tumor location, patient age, and access to proton therapy will be required to consider treatment for proton therapy.

Spinal Cord Tolerance

A reversible myelopathy can occur within 2 to 6 months after radiation therapy. L'Hermitte sign, characterized by shock-like sensations radiating to the hands and feet when the neck is flexed, is the classic finding. It is believed that this phenomenon is related to transient demyelination of the treated length of the spinal cord.[106,107] This syndrome usually lasts a few weeks, and no therapy is required. It is not associated with chronic progressive myelitis.

Chronic, progressive, or delayed myelopathy can occur months to years after radiation therapy. The latency period of chronic myelopathy has been

reported to be bimodal, with peaks of incidence occurring at 13 and 29 months. The early peak may correspond to white matter injury with subsequent demyelination, and the latter peak may correspond to microvascular injury. Permanent myelopathy is characterized by progressive motor weakness, paresthesias, and loss of pain or temperature sensation. Patients ultimately lose bowel and bladder control and experience complete sensory and motor function loss.[108] Diagnosis of radiation myelopathy requires that the dominant neurologic abnormality be localized to a segment irradiated and other causes have been ruled out. MRI may assist in the diagnosis, with cord edema frequently being present in the early delayed phase. Within 8 months of the onset of symptoms, the T1-weighted images may show low intensity in the region of spinal cord injury, whereas the T2 image shows high intensity. The lesion may enhance with contrast. Late changes in patients with permanent delayed myelopathy may include atrophy.[109] Even with modern imaging, it may be difficult to determine whether neurologic deficits after radiotherapy are related to tumor progression or treatment-induced myelopathy.

The occurrence of chronic progressive myelopathy depends on the total dose, fraction size, volume, and region irradiated. Historically, the spinal cord has been limited to maximum doses of 45 to 50 Gy with fractionation schedules of 1.8 to 2 Gy/day. These estimates came from an era of inexact dose estimation with a bias toward reporting injury in highly selected populations.[110,111] More recently, data have been published from institutions that have treated large groups of patients in a systematic and reliable manner. The Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) initiative comprehensively reviewed modern radiotherapy toxicity data and published guidelines on spinal cord tolerance.[112] For conventional external-beam radiation therapy at 1.8 to 2 Gy/day, a dose of 50, 60, and 69 Gy is associated with a 0.2%, 6%, and 50% rate of myelopathy, respectively. However, pediatric patients and patients receiving potentially neurotoxic chemotherapy may have decreased spinal cord tolerance, with reports of myelopathy at dose of 50 Gy or less.[113-115]

Dose-volume data for myelopathy after spine SRS are evolving. In a multi-institutional review of 1,075 patients treated with spine SRS principally for metastatic disease, the rate of spinal cord toxicity was 0.6%.[116] Data from the QUANTEC initiative indicate that the rate of

myelopathy will be <1%, with the maximum dose to the spinal cord limited to the equivalent of 13 Gy in a single fraction or 20 Gy in three fractions.[112] The most commonly employed dose constraint for single fraction SRS is to keep <10% of the spinal cord (defined as 3-6 mm above and below the target volume) to <10 Gy.[99] Intriguing data from investigators at Stanford University utilizing SRS for spinal hemangioblastoma suggest that spinal cord tolerance may be higher than predicted by conventional modeling.[100,117] Maximum cord dose delivered in two to three sessions in their series was an average of 22.7 Gy (range, 17.8-30.9 Gy) to small volumes, with only 1 of 24 treatments resulting in myelopathy. Such a phenomenon may at least in part be explained by preclinical experiments suggesting a dramatic length and partial volume effect to spinal cord tolerance after radiation. For example, in one animal study, the ED50 (dose at which 50% of animals developed limb paralysis) for single fraction full-thickness radiation to the spinal cord was 20.4 Gy for a 20-mm cord length, compared with 53.7 Gy for 4-mm and 87.8 Gy for 2-mm cord lengths.[118]

Both animal and human studies have demonstrated that irradiated spinal cord may recover at least partially over time. Animal experiments of reirradiation using Rhesus monkeys estimated cord recovery of 76%, 85%, and 100% at 1, 2, and 3 years, respectively.[119,120] In human studies, where reirradiation is at least 6 months after the initial radiation course, essentially no cases of myelopathy were observed when the cumulative 2-Gy equivalent doses are 60 Gy or less.[112,121]

CONCLUSION

Spinal canal tumors are relatively rare and consist of diverse histologic entities. Surgery remains the primary treatment modality, aided by gradual advances in neurosurgical techniques. Adjuvant IMRT is generally considered for incomplete resection, recurrent tumors, or high-grade tumors. New radiotherapy techniques such as proton beam therapy or SRS have shown promising potential to improve the therapeutic ratio. The role of chemotherapy is not clearly defined and is often extrapolated from intracranial counterparts. Continued long-term follow-up of clinical outcomes and innovation of novel approaches are essential for improving the management of spinal canal tumors.

PART C

Head and Neck

CHAPTER 44

Adult Tumors of the Eye and Orbit

Shervin Tabrizi and Helen A. Shih

Primary tumors of the eye and orbit are rare. The American Cancer Society estimates that in 2024, there were be 3,320 new cases with 560 deaths from primary eye cancers.[1] Male-to-female incidence is similar. In adults, uveal melanoma is the most common primary intraocular cancer, followed by lymphoma. Metastases, or secondary intraocular tumors, are more common than primary tumors and typically come from breast or lung cancers.[2] Numerous other tumors such as optic pathway glioma, conjunctival tumors, and eyelid carcinomas also occur in the orbit. Radiation therapy (RT) is effective in the treatment of many of these tumors, can be delivered externally or by brachytherapy depending on the clinical situation, and can be used exclusively or in combination with other treatments, such as surgery and chemotherapy. A variety of external-beam RT (EBRT) techniques, including photon techniques such as intensity-modulated radiation therapy (IMRT), stereotactic radiotherapy (SRT), and proton therapy, have key roles in the management of these tumors, given the anatomic proximity of critical structures in this location. This chapter outlines the most relevant benign and malignant conditions of the eye and orbit in adults, with an emphasis on radiotherapeutic management. Because cancers originating in the eye require significant radiation dose for their control, exposure of normal tissue is often inevitable, with possible late toxicities that warrant close monitoring, multidisciplinary care, and an ongoing need for interventions to mitigate these toxicities.[3]

ANATOMY

The eye is not an exact sphere but rather a fused two-piece unit. The smaller, more curved anterior unit is the cornea and is linked to the larger unit called the sclera. The transparent corneal segment is typically about 8 mm in radius. The sclera constitutes the remainder of the globe, with a radius of approximately 12 mm. The cornea and sclera are connected by the limbus. The area opposite the pupil, the fundus, shows the characteristic pale optic disc or papilla, where vessels enter and optic nerve fibers exit the eye. Dimensions of the globe differ among adults by only 1-2 mm. The vertical measure, generally less than the horizontal distance, is about 24 mm in adults. The eye is made up of three coats or tunics, enclosing three transparent structures (Figure 44.1). The outermost layer is composed of the cornea and sclera. The middle layer consists of the choroid, ciliary body, and iris, collectively known as the uvea. The innermost is the retina, which receives blood supply from the vessels of the choroid as well as the retinal vessels. The lens is suspended centrally to the ciliary body by the suspensory ligament, made up of fine transparent fibers.

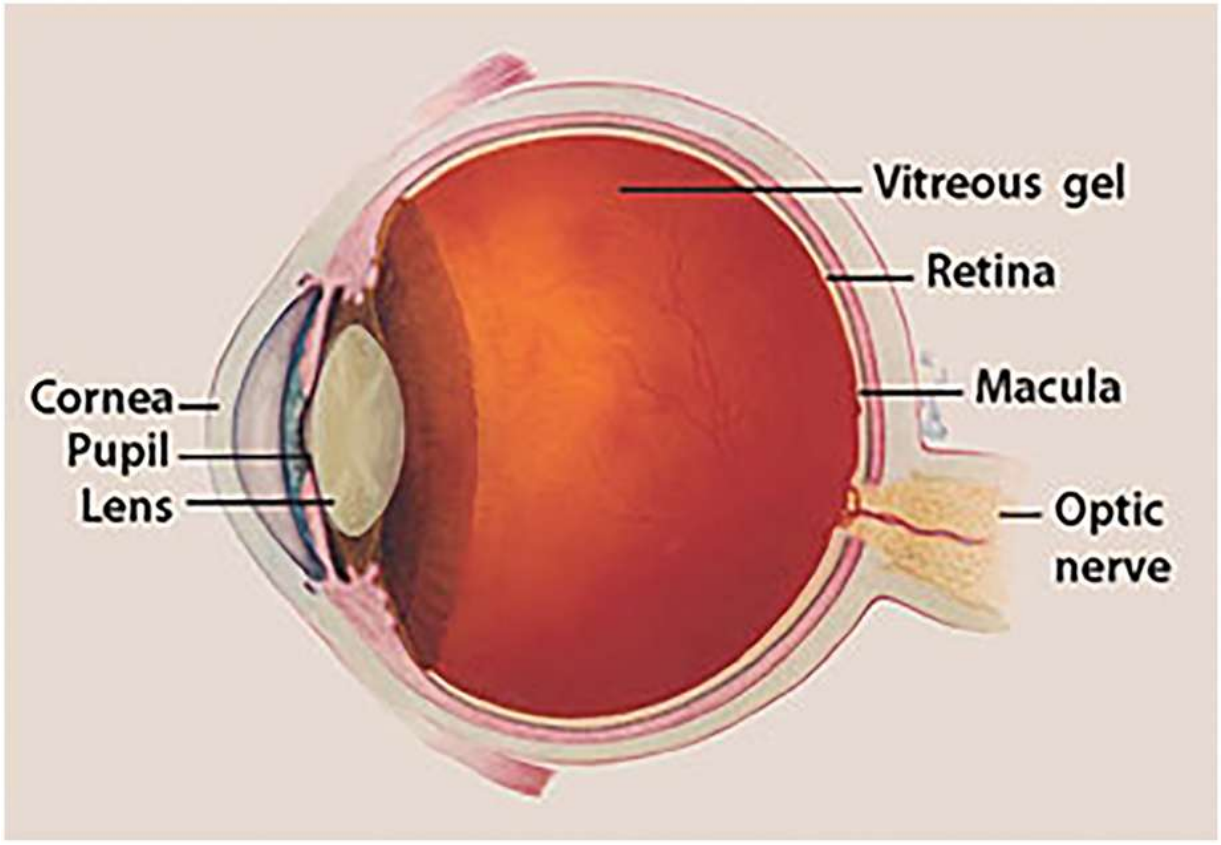

FIGURE 44.1 Normal eye anatomy. (Courtesy of National Eye Institute, National Institutes of Health (NEI/NIH).)

RADIATION TOLERANCE OF OCULAR STRUCTURES

Eyelid

Acute radiosensitivity of eyelid skin is comparable to the skin at other sites, and loss of eyelashes may occur at doses as low as 20 Gy using standard fractionation.[4] Late effects can include telangiectasia and atrophy. Xerophthalmia can result from doses as low as 24 to 26 Gy and may be the result of dysfunction of either the meibomian glands, lacrimal acinar cells, or both.[5] Significant xerophthalmia can cause corneal desiccation and pain. It is generally believed that smaller fraction sizes, longer treatment schedules, and smaller volumes will reduce late effects, but this must be weighed against the potential for ocular trauma if using shielding on a daily basis.[6] Optimum management of eyelid toxicity includes cleanliness, dressings for moist desquamation, healing time, and artificial tears to mitigate meibomian gland dysfunction.

Conjunctiva

Acute conjunctivitis is common with doses ≥30 Gy, and superimposed occasional bacterial or rarely viral infections may occur.[7] Conjunctivitis can be reduced by treating with an open eye with megavoltage equipment if the clinical situation permits. Treatment of acute conjunctivitis includes artificial tears to relieve symptoms and treatment of an underlying infection when indicated.

Lacrimal System

The lacrimal gland system includes the main lacrimal glands, accessory lacrimal glands, and the lacrimal duct system. Symptoms of dryness can occur if any of these structures receive radiation. The most concerning late effect is "dry eye syndrome," where patients can experience tearing, redness, discharge, foreign body sensation, blurred vision, and photophobia. Moderate-dose orbital RT (30-45 Gy) can cause dry eye syndrome 4 to 11 years after treatment, whereas higher doses (>57 Gy) can produce it in 9 to 10 months.[8] Lacrimal shielding should be used if it does not compromise tumor control. Similarly, if clinically feasible, shielding the accessory lacrimal glands may reduce toxicity if the main gland is irradiated. IMRT can help minimize risks of RT-induced xerophthalmia, and prophylactic nasolacrimal duct intubation with silicone tubing may be considered in high-risk patients.[9,10] Treatments available for RT-induced xerophthalmia include topical lubricants, moist chamber goggles, punctual occlusion with plugs, or tarsorrhaphy.

Cornea

Although RT can directly injure the cornea, most acute corneal toxicity results from loss of the tear film with secondary keratitis sicca. Punctate epithelial erosions are common after conventionally fractionated RT doses of 30 to 50 Gy.[11] They typically subside within several weeks but can persist for years. At higher doses, corneal edema (40-50 Gy) or perforation (60 Gy) may occur, causing pain, tearing, foreign body sensation, or reduced vision. Corneal toxicity can be reduced by using megavoltage equipment to reduce the surface dose or by using careful RT planning to minimize corneal

irradiation so long as tumor dose is not compromised. Commercially available eye shields may also be used, particularly for electron beam RT.[12] There are little published data on the management of corneal toxicity from RT. Close ophthalmologic follow-up is recommended, and topical treatment with steroids or antibiotics can be administered when indicated.

Iris

The iris is relatively radioresistant, and acute iritis is rare. Persistent iritis, with symptoms such as pain, red eye, and blurred vision, has been observed after hypofractionated RT doses of 30 to 40 Gy and after doses ≥70 Gy given with conventional fractionation.[13] A challenging late effect of the iris is neovascular glaucoma, where patients may present with ocular pain, headache, photophobia, decreased vision, and redness.[14] Risk factors include higher radiation dose, diabetes, vitreous hemorrhage, and retinal detachment. Whenever possible, techniques that spare the anterior chamber should be adopted. The primary treatments for iritis and neovascular glaucoma are topical steroids and cycloplegic drops, respectively. Laser panretinal photocoagulation or peripheral cryotherapy may prevent or delay the progression of glaucoma if performed early in the course of glaucoma development. However, in many cases, more aggressive intervention such as trabeculectomy may be required. Occasionally, progression to a blind, painful eye may necessitate enucleation. Intravitreal anti-vascular endothelial growth factor (anti-VEGF) therapy appears to be a promising option for the management of iris neovascularization associated with neovascular glaucoma.[15]

Lens

RT can lead to accelerated cataract formation, even at low dose, with the risk dependent on age at the time of treatment, total dose, and fractionation.[16,17] Hall estimated a 50% risk of cataract for 1-Gy exposure to the lens during childhood.[16] In adults, higher doses are associated with radiation-induced cataract: After 2.5 to 6.5 Gy, there is a 33% risk of progressive cataract with a latent period of 8 years, whereas after 6.51 to 11.5 Gy, there is a 66% risk with a latent period of 4 years.[17] Cataract risk can be reduced by using customized lens shields and lens-sparing

techniques or by using more fractionated RT schedules. IMRT may be used to reduce cataract risk by reducing overall lens dose. The corrective treatment for RT-induced cataract is surgery, which yields excellent results.

Retina

Radiation retinopathy is a late effect of RT that typically presents 6 months to 3 years after treatment, although cases have been reported as far as 15 years after therapy.[18] Patients may be asymptomatic or may complain of floaters or reduced visual acuity. Clinical signs include microaneurysms, telangiectasia, hard exudates, cotton-wool spots, and neovascularization. The threshold dose for retinal damage is 30 to 35 Gy. In a Cochrane database review of RT for macular degeneration, no retinopathy or optic nerve damage was reported in 1,154 patients treated with doses up to 24 Gy.[19] The risk of retinopathy increases dramatically when doses exceed 50 Gy using standard fractionation.[20] Incidence and severity also increase with coexistent diabetic retinopathy, hypertension, collagen vascular disease, simultaneous chemotherapy, and pregnancy.[21] The pathophysiology of radiation retinopathy is believed to involve radiation-induced loss of endothelial cells, leading to vascular closure, downstream ischemia, and vascular incompetence.[22] Several treatment options, including laser photocoagulation, intravitreal steroids, and anti-VEGF therapy, have been described, but currently, there is no standardized treatment approach for the management of radiation retinopathy. Local photocoagulation may delay progression of retinopathy and improve symptoms.[23-25] Intravitreal triamcinolone may reduce edema and improve vision in the short term, but with limited benefit to long-term vision outcomes.[26,27] Off-label intravitreal anti-VEGF therapy has been tested in several retrospective and prospective studies, which have confirmed tolerability and suggested benefits in reducing macular edema and potentially improving visual outcome. However, significant variability persists in reported outcomes of response to anti-VEGF therapy, and the optimal timing of initiation of therapy and dosing schedule remains a topic of ongoing investigation.[28-34]

Optic Nerve

Like the retina, the optic nerve manifests toxicity months or years after RT, with a peak incidence at 18 months.[35] Radiation-induced optic neuropathy (RION) has a variable presentation and is related to the nerve fibers most affected, usually causing visual field defects. In a review by investigators from the Mayo Clinic, the risk of RION was almost zero with conventionally fractionated doses ≤50 Gy and still rare with maximum dose <55 Gy. The risk of RION increases from 3% to 7% at 55 to 60 Gy and is substantial (>7%-20%) at doses >60 Gy.[36] Parsons and colleagues,[37] in a series of 131 patients (215 optic nerves) treated with RT for extracranial head and neck tumors, found no RION in nerves that received <59 Gy. Fraction size was of primary importance: In cases where >60 Gy was received, fraction size was more important than total dose in producing RION. The 15-year actuarial risk was 11% when the fraction size was <1.9 Gy compared with 47% when the fraction size was >1.9 Gy. A significant exception in the development of RION appears to exist for patients treated for pituitary tumors, where toxicity has been reported at doses as low as 46 Gy in 1.8-Gy fractions.[36] Similar relatively low risk of RION was seen with proton therapy in a retrospective series of 514 patients with cranial base chordomas or chondrosarcomas treated with mixed proton and photon therapy, with <1% rate of RION among 124 patients with optic nerves receiving <59 Gy (relative biological effectiveness [RBE]) versus 5.8% occurrence among 390 patients with optic nerves receiving ≥60 Gy (RBE).[38] Because there is no known effective therapy for RION, dose-sophisticated treatment planning should be implemented to minimize volume, total dose, and, especially, dose per fraction to the optic nerve.

MANAGEMENT OF BENIGN OCULAR DISEASES

Pterygium

Pterygium is a benign growth of fibrovascular tissue on the conjunctiva that can cause irritation, erythema of the cornea, and, in advanced cases, vision obstruction. The exact cause of pterygium is unknown, but it is associated with excessive exposure to wind, sunlight, or sand. It has also been postulated that ultraviolet light exposure may increase the risk of pterygium.[39] At present, no reliable medical treatment exists to reduce or even prevent pterygium progression. If symptoms are severe, the only

definitive treatment is surgical removal. Without adjuvant treatment, surgical resection alone carries recurrence rates of 20% to 80%.[39] Therefore, adjunctive measures are recommended, which can be broadly classified as medical methods, β-irradiation, and surgical methods. Intraoperative and postoperative mitomycin C are the most commonly used medical adjuncts, reducing recurrence rates to 3% to 37%.[40] However, topical chemotherapy is not commonly used out of concern for late complications, including scleral sclerosis, infectious scleritis, perforation, and endophthalmitis, all with consequences that can impair vision.[41] β-Irradiation has a historical role in the management of pterygium. In a prospective randomized study, 96 eyes with primary pterygium received β-irradiation with strontium-90 after resection or sham irradiation.[39] Local control was 93.2% for the irradiated group versus 33.3% for the sham radiation group. Like topical chemotherapy, however, β-irradiation has generally been abandoned due to the risk of sight-threatening complications, such as scleral necrosis, infectious scleritis, corneal perforation, and endophthalmitis.[42] Thus, this therapy is of historic interest. Surgical adjuvant therapy is the mainstay of management for primary and recurrent pterygium. Currently, conjunctival autografting is generally regarded as the procedure of choice because of its efficacy and long-term safety, with recurrence rates of 2% to 39% without the attendant sight-threatening complications of topical chemotherapy or β-irradiation.[43]

Choroidal Hemangiomas

Choroidal hemangiomas are benign vascular tumors of the choroid. Although probably congenital in all cases, they are frequently undetected until after the second decade of life and can have a wide range of clinical features and treatment options.[44] These tumors are characterized as either circumscribed or diffuse. Most circumscribed choroidal hemangiomas are noted first when they produce visual symptoms caused by accumulation of serous subretinal fluid, degenerative changes in the macula, or both. In contrast to circumscribed choroidal hemangiomas, the diffuse variety is larger and associated with Sturge-Weber syndrome, a neurologic disorder marked by a distinctive port-wine stain on the forehead, scalp, or around the eye. This stain is a birthmark caused by an overabundance of capillaries

near the surface of the skin. Blood vessels on the same side of the brain as the stain may also be affected. Diffuse tumors are usually diagnosed in young patients either because of the examination of the fundus prompted by a facial hemangioma (port-wine stain) or because of the visual impairment secondary to serous retinal detachment or hyperopic amblyopia (Figure 44.2). The clinical course of either form of choroidal hemangioma is highly variable, with visual impairment ranging from none to total blindness. Neither variety of choroidal hemangioma metastasizes or transforms to malignancy. Therefore, the primary indication for treatment is to prevent loss of visual acuity.

FIGURE 44.2 Diffuse choroidal hemangioma with exudative retinal detachment. (Reprinted from Kubicka-Trząska A, Kobylarz J, Romanowska-Dixon B. Ruthenium-106 plaque therapy for diffuse choroidal hemangioma in Sturge-Weber syndrome. *Case Rep Ophthalmol Med*. 2011;2011:785686. http://creativecommons.org/licenses/by/3.0/.)

Treatment options include laser photocoagulation, thermo therapy, photodynamic therapy, and RT. Photocoagulation is beneficial for circumscribed lesions, but diffuse lesions have a high recurrence rate and retinal damage is possible.[44] Low- to moderate-dose radiation using lens-sparing external-beam photon irradiation, episcleral plaque therapy, and proton beam therapy have all been used in the treatment of choroidal hemangioma.[45] Total doses of 18 to 30 Gy delivered in 10 to 18 fractions of external-beam photon RT can result in the partial flattening of the hemangioma, resorption of subretinal fluid, and reattachment of the retina within 6 to 12 months.[46] Heimann et al[46] reported no recurrence of subretinal fluid with a mean follow-up of 3.6 years. In another series with a follow-up of 66 months, Kivela et al[47] found that subretinal fluid had reaccumulated in only 1 of 12 patients treated, thus demonstrating response durability. In a series of 53 patients treated with IMRT to a mean dose of 21.6 Gy (range 21.6-42 Gy), Wang et al[48] reported resolution of subretinal fluid in all patients and resolution of exudative retinal detachment in 76.7% of patients. In very advanced cases with retinal detachment, a higher dose of 36 Gy in 1.8 Gy fractions appears to be efficacious, but larger series with longer follow-up are needed to reliably assess response durability and delayed side effects, including retinopathy and cataract formation.[46,47] Lens-sparing techniques, including three-dimensional conformal RT (3D-CRT) with computed tomography (CT) planning, should be considered to reduce the incidence of cataract formation.[49] Brachytherapy has also been used for choroidal hemangioma treatment, particularly for circumscribed lesions. This treatment usually achieves resolution of subretinal fluid and reattachment of the retina with preservation of pretreatment visual acuity.[50] Radiation dose varies with the isotope, but in a study using iodine-125 with target dose of 48 Gy to the apex of the lesion, tumor regression was noted in 8/8 cases treated.[50] Proton therapy can also be considered for choroidal hemangioma. On long-term follow-up in a series of 71 cases with circumscribed choroidal hemangioma treated with 20 Gy (RBE), retinal reattachment occurred in all cases, and a completely flat scar was obtained in 91.5%.[51] The main complications during the surveillance period were cataracts (28%) and radiation-induced maculopathy (8%). No cases of eyelid complications or neurovascular glaucoma were observed.

Capillary Hemangioma

Capillary hemangiomas are benign endothelial cell neoplasms that rarely occur on the eyelids or skin of the orbit. Retinal capillary hemangiomas may represent a component of the von Hippel-Lindau syndrome, and lesions of the face that occupy the distribution of the trigeminal nerve can be a component of Sturge-Weber syndrome. The natural history of these lesions is usually spontaneous regression over 3 to 4 years, making conservative management the treatment of choice.[52] Occasionally, however, lesions may be large enough to obstruct vision and amblyopia may occur. Treatment options then include corticosteroids, interferon α-2a, laser therapy, embolization, immunomodulators, surgery, and systemic propranolol.[53] Because of these many alternatives, RT in the management of capillary hemangiomas is primarily of historical interest, with original studies showing that doses in the 16 to 20 Gy range provide effective local control.[54]

Orbital Pseudotumor

Orbital pseudotumor is a rare inflammatory process that affects the soft tissue components of the orbit. Clinically, it presents in the fourth and fifth decades of life with signs and symptoms including proptosis, swelling, increased orbital pressure, and restricted ocular motion.[55] The diagnosis is based on history, imaging of the orbit, and pathologic examination of tissue in accessible lesions. Characteristic imaging features include extraocular muscle enlargement, optic nerve thickening, and inflammation of retrobulbar adipose tissue. Treatment options for orbital pseudotumor include corticosteroids, EBRT, immunotherapy, chemotherapy, and surgery. Corticosteroids are typically used as primary treatment.[56] RT is usually reserved for cases that are refractory to corticosteroid treatment. Matthiesen and colleagues[57] described 20 orbits treated with a median dose of 20 Gy and, at follow-up of 16.5 months, found improved symptoms and/or reduction of corticosteroid dose in 87.5%, with 56% able to discontinue steroid treatment completely. A systematic review of 19 studies with 241 patients reported significant heterogeneity in dose among studies, with a median total dose of 20 Gy (range 4-36 Gy), with response rates of 74% to 100%, and a median recurrence rate of 10%.[58] Based on these observations,

radiation appears to achieve durable control in orbital pseudotumor and is an effective strategy in patients who respond poorly to medical treatment.

Thyroid Eye Disease

Thyroid eye disease (TED), frequently termed *Graves ophthalmopathy*, is part of an autoimmune process that can affect the orbital and periorbital tissue, the thyroid gland, and, rarely, the pretibial skin or digits (thyroid acropathy).[59] Although the term *thyroid ophthalmopathy* is more general, the disease process is specifically an orbitopathy in which the orbital and periocular soft tissues are primarily affected with secondary effects on the eye. TED may compromise a patient's vision by causing diplopia, decreased ocular motion, exposure keratitis, or optic neuropathy. A variety of treatments exist, including thyroid hormone regulation, corticosteroids, EBRT, or surgical decompression.[60]

RT with moderate doses has historically been used in cases refractory to medical therapy, which are a minority of TED cases.[61] Abboud et al[62] reported symptom improvement in 87% of cases with doses of 20 Gy using standard fractionation. Numerous randomized controlled trials have tested orbital RT for TED, with heterogeneity among studies with respect to severity of TED on trial entry, radiation dose and fractionation, and inconsistent use of concurrent corticosteroids.[63-71] A further limitation of many of the randomized controlled trials is that they did not involve patients with sight-threatening ophthalmopathy and could not assess the role of radiation in this important subset.[72] Mourits et al[67] randomized 59 patients to either 20 Gy in 10 fractions to both orbits or sham RT and found improved globe motility and elevation, but no difference in change in lid fissure, soft tissue swelling, proptosis, or clinical activity score (a measure of disease activity and propensity to progress). The authors concluded that RT should be used only for motility impairment. Gorman et al[71] randomized 42 subjects to orbit RT to one orbit and sham RT to the other followed by the reverse therapy 6 months later. No clinically or statistically significant differences were observed at 6 months. At 12 months, muscle volume and proptosis were slightly improved in the orbit that was first irradiated. Prummel et al[70] conducted a trial where 88 patients with mild TED were randomly assigned to bilateral RT or sham RT. Radiation was effective in

improving motility and decreasing severe diplopia, but no differences in health-related quality of life were detected, although lack of complete quality of life data on 58% of subjects resulted in low power to detect a difference.

Retrospective studies suggest that RT may be effective for treating or preventing compressive optic neuropathy (CON). Shams and colleagues[73] compared 144 patients with TED who received steroids alone to 105 patients who received orbital RT and steroids. At an average follow-up of 3.2 years, the rate of CON was 17% in the steroid only group and 0% in the steroids and RT group. Gold and colleagues[74] reported on 104 patients with active TED and CON who received a steroid taper and RT and found that 94% did not require urgent decompression surgery. RT may also enable successful tapering or elimination of steroids in patients with TED.[75,76]

A 2022 report by the American Academy of Ophthalmology on the role of orbital radiation for TED concluded that despite a lack of definitive randomized data, the best available evidence currently suggests that orbital RT with or without steroids is effective in preventing CON, improving motility restriction, decreasing the clinical activity of TED, and potentially reducing steroid dose.[72] Orbital RT could therefore be considered for patients with TED, especially those with CON, those who are refractory to steroids, and those unable to reduce their steroid dose. Orbital RT is generally well tolerated, common side effects including dry eyes and cataracts.[76-79] Serious complications such as keratitis and retinopathy have been reported but are rare.[77,80] Radiation technique for TED usually involves treatment of both orbits with parallel-opposed lateral beams with low-energy (6-MV) photons, with 20 Gy in 10 fractions as a typical dose. A downward 5° tilt or use of half-beam block should be used to avoid direct irradiation of the contralateral lens.

Neovascular Age-Related Macular Degeneration

Neovascular age-related macular degeneration (nAMD) is a common condition affecting 8% of adults globally and is a leading cause of blindness.[81] The treatment for nAMD is long-term, repeated intravitreal injections of anti-VEGF therapy, but due to the costs and risks associated with long-term anti-VEGF therapy, there is interest in alternative treatments

to reduce the number of injections. RT has been tested as an approach to mitigate nAMD. The INTREPID study was a phase 2 double-masked, sham-controlled randomized trial of 230 patients treated with 16 Gy, 24 Gy, or sham SRT. SRT resulted in a 29% reduction in anti-VEGF therapy injections in the year following SRT.[82] The STAR trial was a large, multicenter follow-up trial that randomized 411 patients to 16-Gy SRT or sham SRT in a 2:1 ratio. On follow-up after 96 weeks, SRT was associated with a 22% reduction in the number of ranibizumab injections, reduction in macular central subfield thickness (due to less subretinal fluid), noninferior visual outcomes, and a higher rate of retinal microvascular abnormalities (35% vs 12%).[83] SRT could therefore be a viable option to reduce the need for anti-VEGF injections in nAMD.

Optic Nerve Sheath Meningioma

Optic nerve sheath meningiomas (ONSMs) are rare, usually benign, tumors that arise from the optic nerve sheath, represent 1% to 2% of all meningiomas, and are the second most common optic nerve tumor after optic nerve gliomas.[84] Patients typically present with slow and progressive vision loss.[85] Diagnosis can usually be made with contrast-enhanced magnetic resonance imaging, precluding the need for a surgical biopsy.[86] Without treatment, vision loss can progress in most patients, although close observation could be considered an initial strategy in asymptomatic patients.[85,86] RT is an effective treatment modality for preserving vision and preventing disease progression. In a series of 64 patients with ONSM managed with observation, surgery, RT alone, or combined surgery and RT, RT alone was associated with the best visual outcome and was the only group without a statistically significant decrease in vision over a mean follow-up of 150 months.[87] Surgery (with or without RT) was associated with a complication rate of >60% versus 33.3% with RT alone.[87] Conformal techniques for RT, such as IMRT or SRT, should be considered to minimize the risk of long-term toxicity in this patient population with an excellent prognosis. A dose of 50.4 to 54 Gy in conventional fractionation, below the tolerance of the optic nerve, is typically used.[88] Ratnayake et al[89] reported on long-term outcomes of 26 patients with ONSM treated with SRT to a median dose of 50.4 Gy in 28 fractions. At a median follow-up of 68

months, local control was 100% and visual acuity improved or remained stable in 77% of patients. Late toxicities included grade 1 dry eye in 12% of patients. One patient developed late grade 3 radiation retinopathy treated with an intravitreal VEGF inhibitor.[89] A systematic review and meta-analysis of 39 studies (736 eyes) evaluating the use of RT for ONSM found a local control rate of 97% with a mean follow-up at 46 months. IMRT, SRT, and proton therapy were associated with lower rates of complications compared to 3D-CRT.[88]

OCULAR AND ORBITAL MALIGNANT TUMORS

Ocular Metastases

Tumor metastases to the eye are more common than primary ocular tumors, with the uvea representing the most common site affected.[90] Shields and colleagues[2] described a comprehensive series of ocular metastases and found that within the uvea, 88% of metastases are to the choroid (Figure 44.3), followed by metastases to the iris (9%) and ciliary body (2%). This difference is hypothesized to reflect blood supply, which heavily favors the choroid as compared to the iris and ciliary body. The most common primary cancer sites for uveal metastasis in males were lung (40%), gastrointestinal (9%), and prostate (6%). The primary site was unknown at the time of presentation in 29% of males. In females, the most common sites were breast (68%) and lung (12%). Metastases can be either unilateral or bilateral. In a study of 264 patients with uveal metastases from breast cancer reported by Demirci and colleagues,[91] 62% of patients had unilateral metastasis at presentation. Patients with breast cancer metastatic to the uvea have survival rates of 65% at 1 year, 35% at 3 years, and 24% at 5 years.

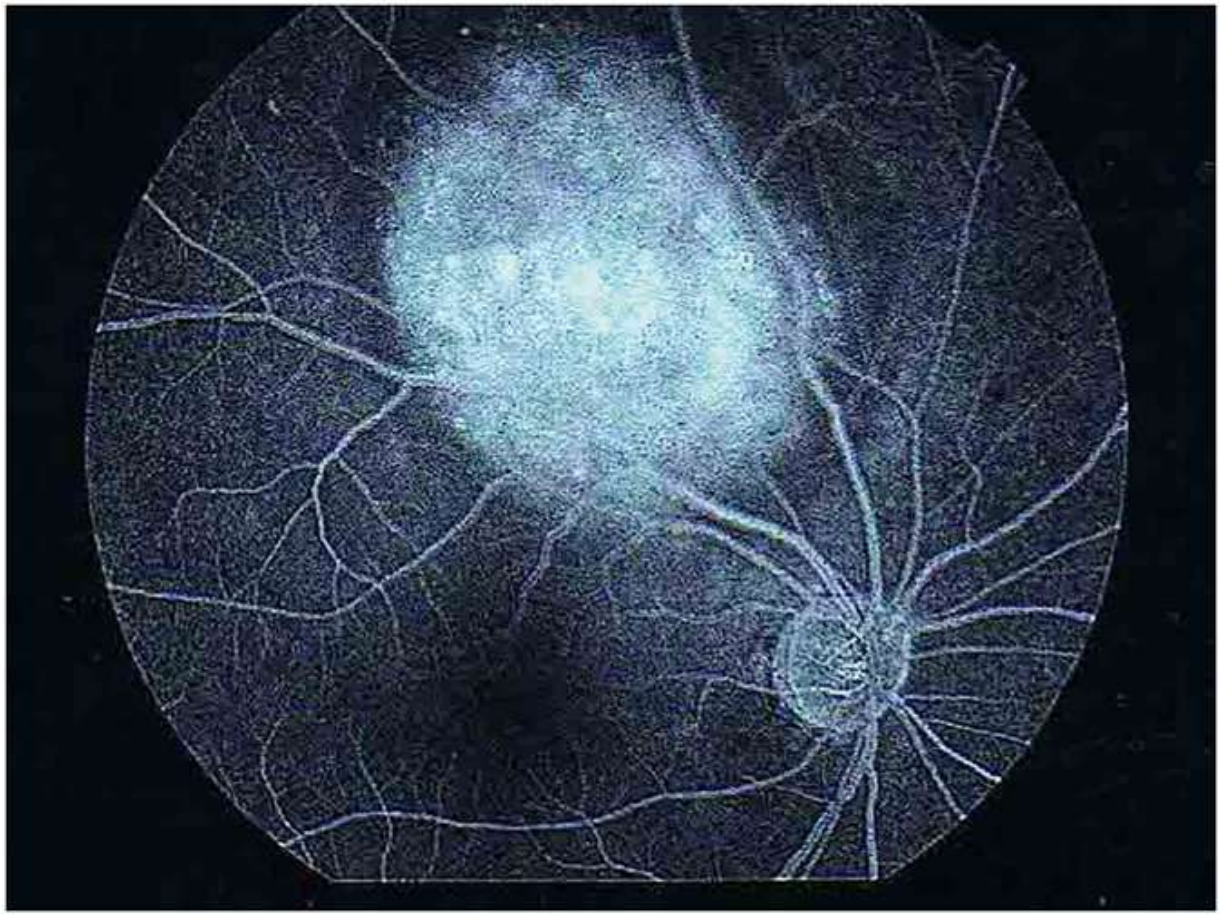

FIGURE 44.3 Fundus fluorescein angiography of choroidal metastasis from non–small cell lung cancer showing hyperfluorescence from the surface of the choroidal tumor in its late phase with the accumulation of subretinal fluid. (Reprinted from Singh A, Singh P, Sahni K, Shukla P, Shukla V, Pant NK. Non-small cell lung cancer presenting with choroidal metastasis as first sign and showing good response to chemotherapy alone: a case report. *J Med Case Rep*. 2010;4:185. http://creativecommons.org/licenses/by/2.0.)

Numerous treatment options exist for choroidal metastases, including systemic chemotherapy, hormonal therapy, EBRT, brachytherapy, and photodynamic therapy. Individualized treatment should be considered, taking into account disease extent and life expectancy, with the primary goal of maintaining visual acuity and quality of life. As systemic treatments for metastatic cancers improve, clinicians may be more frequently faced with the treatment of symptomatic choroidal metastases. For cases with multifocal or diffuse presentations, EBRT has been effective with doses in the range of 20 to 40 Gy. Rosset described 58 patients (88 eyes) treated with EBRT with a median dose of 35.5 Gy (range 20-53 Gy) in 10 to 30

fractions.[92] Various techniques were used, and lens sparing was achieved whenever possible. Visual acuity improved in 62% of patients, with significantly better results when doses >35.5 Gy were used. Complications included three cataracts, retinopathy in a single patient who underwent a biopsy, and one case of glaucoma from subretinal hemorrhage. In cases of unilateral disease undergoing bilateral radiation, the authors noted no cases of new contralateral lesions but did describe new contralateral lesions in three of 26 patients when unilateral technique was used. Although they recommended bilateral irradiation even for unilateral disease (Figure 44.4), unilateral treatment is favored with modern techniques that can easily avoid the contralateral side and make retreatment feasible if necessary. Kamran and colleagues[93] reported on a hypofractionated approach with proton beam irradiation in 77 patients (99 eyes) treated with a median dose of 20 Gy (RBE) in two fractions at Massachusetts General Hospital/Mass Eye and Ear. Tumor regression was observed in 100% of eyes, and local control was 94%. The rate of radiation vasculopathy, decreased visual acuity, or both was 46% at 6 months and 73% at 1 year. All six eyes with local recurrence were successfully retreated with the same regimen.

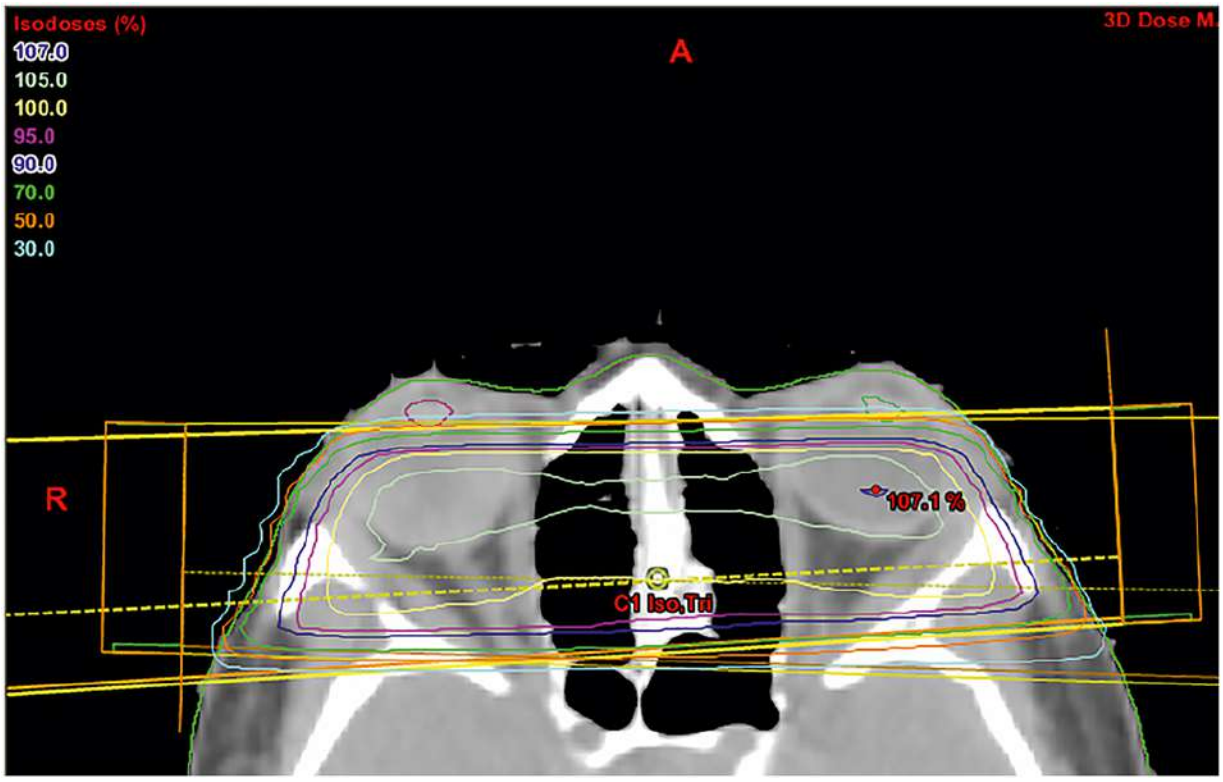

FIGURE 44.4 Bilateral radiation therapy for uveal metastases in a patient with widely metastatic lung cancer.

Plaque brachytherapy is usually reserved for solitary metastases. This modality offers precise, controlled radiation delivery to the eye over 3 to 4 days of treatment, an important consideration in uveal metastases because many patients have limited survival expectancy. Clinical factors to consider for plaque brachytherapy include the size and thickness of the lesion and the distance of the lesion from the optic nerve and fovea. Investigators from the Wills Eye Hospital studied 36 patients who received plaque brachytherapy as either primary or salvage treatment (after EBRT) for uveal metastases.[94] The mean duration of treatment was 86 hours, and mean doses to the apex and base of the tumor were 68.8 and 235.6 Gy, respectively. Tumor regression was documented in 94% of cases with a median follow-up of 11 months. Five of six cases where plaque brachytherapy was used after suboptimal response to EBRT were successfully salvaged. Complications from plaque brachytherapy are similar to those of EBRT, including dry eyes, radiation retinopathy, papillopathy, and cataracts. The investigators concluded that plaque brachytherapy is an effective, time-

efficient method for the treatment of selected solitary uveal metastases. Thus, both EBRT and plaque brachytherapy are effective therapies for uveal metastases, with the optimal treatment depending on the extent of intraocular disease, symptoms, and overall condition and prognosis of the patient. Close collaboration of ophthalmologists, radiation oncologists, and medical oncologists is imperative to tailor an appropriate treatment strategy for each patient.

Uveal Melanoma

Uveal melanomas represent <5% of all malignant melanomas, with an annual incidence of approximately five to six per million.[95-97] These tumors may arise from any of the three parts of the uvea and are sometimes referred to by their location, such as iris melanoma (Figure 44.5), ciliary body melanoma, or choroidal melanoma (Figure 44.6). True iris melanomas, originating from within the iris as opposed to originating elsewhere and invading the iris, are distinct in their etiology and prognosis, such that the other tumors are often referred to collectively as "posterior uveal melanomas." Incidence of uveal melanoma varies by race and ethnicity and is highest in the non-Hispanic White population.[98] Several epidemiologic and environmental risk factors have been associated with uveal melanoma, including fair skin, light eye color, increased tendency to sunburn, cumulative intense sun exposure, use of sunlamps, welding, and commercial cooking.[99-101] A study from the United Kingdom showed that 45% of patients were asymptomatic when their tumor was detected.[102] Advances in diagnostic techniques such as binocular indirect ophthalmoscopy, angiography, and B-scan ultrasonography have aided ocular oncologists in the evaluation and management of patients with uveal melanoma.[103]

Uveal melanomas are distinct from the more common cutaneous melanomas. Almost all uveal melanomas and most choroidal nevi have a mutation in a *GNA* family gene, such as *GNAQ* and *GNA11*.[104-106] Molecular characterization has led to the identification of subsets of uveal melanoma based on mutations, gene expression profiles (GEP), and other features. The Cancer Genome Atlas identified four subsets of uveal melanoma, characterized by distinct genetic and gene expression features and the presence or absence of inflammation.[107] Subsets A and B correspond to a favorable prognosis, GEP class 1, and gain of chromosome 6p, whereas subsets C and D correspond to a poor prognosis, GEP class 2, chromosome 3 monosomy, and chromosome 8q amplification (Table 44.1).[108,109] Commercially available tests can distinguish GEP class 1 versus class 2 tumors, and more recent versions further divide class 1 tumors into class 1A

and class 1B. The 5-year risk of metastasis is 2%, 21%, and 72% for GEP class 1A, class 1B, and class 2 tumors, respectively.[110-112] The 10-year risk of uveal melanoma metastasis was 25% in a series of 8,033 eyes, with significant variation based on tumor thickness (12% for 0-3.0 mm, 26% for 3.1-8.0 mm, 49% for >8.0 mm).[113] Risk of metastatic relapse appears to continue to rise with longer follow-up beyond 10 years.[114] Liver is the most common site of spread, and overall survival after the development of metastases is approximately 1 year.[115,116] Tebentafusp, a bispecific protein that binds the CD3 T-cell receptor and gp100 displayed on HLA-A*02:01, has demonstrated a survival benefit of 27% versus 18% at 3 years in patients with metastatic uveal melanoma who carry the HLA-A*02:01 allele.[117] But systemic therapy options are otherwise limited, and there is a need for more efficacious and widely applicable treatments.

TABLE 44.1 CHARACTERISTICS OF SUBSETS OF UVEAL MELANOMA

Subset	GEP Class	Chromosome 3	Chromosome 8q	Chromosome 6p	Metastatic Potential
A	Class 1	No change	No change	Partial or total gain	Low
B	Class 1	No change	Partial gain	Gain	Intermediate
C	Class 2	Monosomy	3 or more copies	No change	High
D	Class 2	Monosomy	3 or more copies	No change	High

Several local treatment options exist for uveal melanoma. Most patients are treated with the goal of eradication of disease and long-term survival. Local tumor recurrence is associated with increased mortality.[118] Factors predictive of local recurrence include epithelioid cell type, large tumor size, and posterior tumor extension.[119] When possible, curative treatment should be sought with the goals of preserving the eye and preserving as much vision as possible with acceptable cosmesis. In patients with known metastatic disease, the main objective is to preserve vision and remove any threat of the eye becoming painful within the patient's life expectancy.

Many factors influence treatment selection, including tumor characteristics (size, location, and extent), secondary effects (such as the risk of cataracts), concurrent ocular disease (such as diabetic retinopathy), the patient's general health and life expectancy, and the cost and duration of the treatment.[120] In cases where preserving the eye and maintaining some useful vision are feasible, organ preservation therapy should be considered. RT, delivered either externally or by brachytherapy, has been instrumental as an organ-preserving modality in the primary management of uveal melanoma.

Observation

Indeterminate pigmented choroidal nevi are typically observed without treatment until growth is documented. The probability of malignancy can be estimated according to tumor thickness, serous retinal detachment, orange pigment, and symptoms.[121] Patients and clinicians can then make a combined decision on when to commence therapy after discussion of risks and benefits. The annual risk of malignant transformation of choroidal nevi is reported at approximately 1 in 9,000.[122]

Enucleation

Enucleation was traditionally the standard of care for choroidal melanoma since the late 19th century, but its effectiveness in improving survival has never been clearly demonstrated.[123] A study from the Helsinki University Hospital looked at the long-term prognosis of patients treated by enucleation between 1962 and 1981 and found death was attributable to melanoma in 61% of cases.[114] They also reported that cause-specific mortality (CSM) increased with longer follow-up. The 5-, 15-, 25-, and 35-year CSM was 31%, 45%, 49%, and 52%, respectively, thus illustrating that a substantial number of patients die of metastatic disease more than 5 years after enucleation. The desire to improve survival and preserve vision stimulated the development of alternative, organ-preserving therapies for uveal melanoma. Still, enucleation is required in a subset of patients, typically because the tumor is too extensive at presentation. General guidelines for enucleation include large tumor size (tumor diameter >20 mm; thickness >12 mm); involvement of the optic nerve; invasion of more

than 30% of the iris, ciliary body, or angle; retinal perforation; or poor general health of the patient.[120]

Endoresection

Transretinal endoresection is controversial, mainly because of fears of seeding tumor cells, but has been advocated for juxtapapillary tumors up to 10 mm in diameter.[121] The operation involves vitrectomy, tumor removal with a vitrector either via a retinotomy or after lifting a retinal flap, fluid-air exchange to drain any subretinal fluid, endolaser photocoagulation to destroy any residual tumor in the sclera and to achieve retinopexy, air-silicone exchange, and, if possible, adjunctive brachytherapy.[124] Given the seemingly heightened risk of tumor seeding with endoresection, some investigators have recommended preoperative stereotactic radiation, but this practice is similarly controversial.[125] Endoresection carries an approximately 10% risk of local recurrence, which can arise from microscopic disease in the scleral bed or at the margins of resection.[124]

Transscleral Resection

Transscleral local resection (exoresection) has been promoted for tumors >6 mm thick in patients highly motivated to retain vision and in patients with severe exudative retinal detachment after RT.[120] The procedure carries substantial operative risk. Choroidectomy and cyclochoroidectomy, for example, require hypotensive anesthesia with systolic blood pressure lowered to approximately 40 mm Hg.[126] The operation involves the preparation of a lamellar scleral flap, ocular decompression by limited pars plana vitrectomy, resection of the tumor together with the deep scleral lamella, suturing of the scleral flap, intraocular injection of balanced salt solution, and adjunctive brachytherapy either at the end of the operation or several weeks later. This procedure has approximately 30% incidence of local relapse when performed exclusively, but this probability declines to approximately 10% when perioperative brachytherapy is delivered.[127]

Transpupillary Thermotherapy

Transpupillary thermotherapy (TTT) is a procedure in which 1-minute applications of 3-mm spots of low-energy diode laser are administered to

the tumor and the surrounding choroid.[128] The objective is not immediate thermoablation but rather heating the tumor by only a few degrees so that following treatment, tumor regression occurs slowly, often resulting in a white scar. A study of 391 patients treated with TTT reported a 5-year local recurrence rate of 29%, with higher recurrence rates for tumors with more high-risk features, suggesting that careful patient selection is critical for utilizing this technique.[129] TTT should be considered only for small and flat pigmented choroidal lesions with only a few risk factors. Some advocates of TTT recommend combined brachytherapy with TTT. Yarovoy and colleagues[130] reported improved tumor regression and recurrence-free survival with similar complication rates when TTT was used with brachytherapy compared with brachytherapy alone. By contrast, Marinkovic and colleagues[131] did not find better control rates with the combination of brachytherapy and TTT, but did find more rapid vision loss with combination therapy.

Plaque Brachytherapy

Plaque brachytherapy is a mainstay of treatment in many centers, with iodine-125 (I-125) and ruthenium-106 (Ru-106) being the most common isotopes, although palladium-103 (Pd-103) has also been used effectively.[132] I-125 emits γ rays, which have a range sufficient for tumors up to 8 to 10 mm thick, whereas Ru-106 delivers β particles that have a more limited range, which is suitable for tumors <5 mm thick. Historically, the general objective with all plaques was to deliver approximately 80 Gy to the tumor apex by fixing the plaque in the exact location of the tumor (Figures 44.7 and 44.8). However, some data suggest lower doses may be sufficient for tumor control with less toxicity. Perez and colleagues[133] examined 190 cases treated between 1988 and 2010 and analyzed outcome with respect to apical dose. Local control and overall survival did not differ according to dose quartile (<69, 69-81, 81-89, >89 Gy). However, visual acuity and radiation complications increased with increasing dose, and the authors concluded that doses as low as 69 Gy may be appropriate for uveal melanoma. Dedicated computer modeling has been developed for RT planning to create a 3D model of the eye and determine the appropriate treatment time and estimated dose to the optic nerve, macula, and lens.[134] Juxtapapillary tumors

approximating or overhanging the optic disc present a dosimetric challenge but may be treated with brachytherapy. Sagoo and associates[135] reported on 141 such patients treated with plaque brachytherapy. In 126 eyes, the plaque utilized a notched design, which created an elliptical dose distribution with a median dose of 85 Gy. Local control was 90%, and metastases developed in 13%. Visual acuity was generally poor, with 77% having a final acuity of 20/200 or worse. Given the alternative of enucleation, however, this technique represents a reasonable treatment choice.

The largest prospective experience of patients treated with plaque brachytherapy was conducted by the Collaborative Ocular Melanoma Study (COMS) group. From 1986 to 2003, COMS conducted two multicenter trials of brachytherapy with I-125 versus enucleation in selected patients with choroidal melanoma. Long-term results were subsequently published in COMS Report 28 in 2006, which evaluated 1,317 patients.[136] Eligible patients had unilateral choroidal melanoma with an apical height of 2.5 to 10 mm and a maximum basal tumor diameter (MBTD) of 16 mm. Patients whose tumors were contiguous with the optic disc were ineligible, as were

patients with metastases from melanoma or another malignancy. Patients were followed for 5 to 15 years. Within 12 years after enrollment, 471 (36%) of 1,317 patients died. Overall, CSM at 5 and 10 years for both treatment arms was 19% and 35%, respectively. Cumulative all-cause mortality was 43% in the I-125 arm and 41% in the enucleation arm, indicating that with long-term follow-up, there was no survival difference between plaque brachytherapy and enucleation. Age >60 years and MBTD >11 mm were the primary predictors of time to death. Local control was excellent in the COMS series, with only 12.5% of patients requiring salvage enucleation.[137]

Visual acuity after plaque brachytherapy depends on a number of factors. Shields et al[138] reported the outcome of 1,106 patients with baseline visual acuity of 20/100 or better who underwent brachytherapy for uveal melanoma and found that 34% of patients had poor visual acuity at 5 years and 68% at 10 years, defined as 20/200 to no light perception. Factors adversely affecting visual acuity were age >60 years, poor vision at baseline, tumor thickness >8 mm, proximity to the foveola of <5 mm, recurrent tumor, subretinal fluid, and history of diabetes or hypertension. The best results were obtained in eyes with small tumors outside a radius of 5 mm from the optic disc and foveola. The 2014 American Brachytherapy Society consensus guidelines on plaque brachytherapy for uveal melanoma determined that brachytherapy is appropriate for the majority of uveal melanomas.[139] Exceptions include tumors with >5 mm of extraocular extension, basal diameters that exceed the limits of brachytherapy applicators, patients with blind and painful eyes, and patients with no light perception.

Proton Beam Therapy

Proton beam therapy is often used to treat uveal melanoma and offers advantages for the treatment of tumors that extend close to or are contiguous with the optic disc, referred to as parapapillary and peripapillary tumors, respectively.[140] Because of the dosimetric properties of protons, which deliver a homogeneous dose to the tumor with a sharp field edge, a high tumor dose can be delivered with relative sparing of the optic nerve. In a dosimetric comparison of proton therapy versus I-125 plaque

brachytherapy, proton therapy provided better dose sparing of the fovea for most tumor locations and sizes, except for large, nasally located tumors, where brachytherapy enabled better sparing of the fovea.[141] The decision to use proton therapy over other forms of external-beam radiation often depends on the availability of treatment facilities. In a large survey of ocular proton therapy centers by The Particle Therapy Cooperative Oncology Group, the most common dose and fractionation used for proton therapy of uveal melanoma was 60 Gy (RBE) in four fractions over a week, utilized at seven of 10 surveyed centers.[142] Other dose and fractionation schemes were comparable in total dose and number of fractions and included 70 Gy (RBE) in five fractions, 58.4 Gy (RBE) in four fractions, and 56 Gy (RBE) in four fractions.

One of the largest experiences in proton beam therapy for uveal melanoma is from Massachusetts General Hospital/Mass Eye and Ear.[143] Treatment planning involves intraoperative examination by transillumination, and the edges of the tumor are delineated by four tantalum rings sutured to the sclera. For visible iridociliary tumors, surgery is not performed, and a light-field clinical setup is utilized. Radiation planning is done with the EyePlan treatment planning software and a geometric eye model to define the beam aperture and range modulation needed to adequately encompass the tumor with a 3-mm margin to allow for motion during treatment, setup error, and possible microscopic extension.[144] Patients receive a total dose of 70 Gy (RBE), delivered in 5 consecutive days.[143] For tumors ≤15 mm in largest diameter and ≤5 mm in thickness that are located within 1 disc diameter of the optic nerve or fovea, a reduced dose of 50 Gy (RBE) in five fractions is used with comparable rates of local control.[145] Long-term follow-up in a series of 573 patients with peripapillary and parapapillary uveal melanomas with a median surveillance of 96.3 months demonstrated low rates of local recurrence, with 5- and 10-year local recurrence of 3.3% and 6%, respectively.[140] Similarly, high rates of local control have been observed in a larger series from the same institution.[146] Enucleation rates were 13.3% and 17.1% at 5 and 10 years after treatment, respectively. Of 450 patients with baseline visual acuity of 20/200 or better, two-thirds had visual acuity <20/200 on long-term follow-up, although 56% could count fingers. The most common complications were radiation maculopathy and/or papillopathy. By 3 years, the cumulative

rate of both complications was 49%, and by 10 years increased to 61% for papillopathy and 68% for maculopathy. The visual outcome after proton therapy depends on the height of the tumor and its location relative to the fovea and optic nerve.[143] Anterior segment complications, such as rubeosis iridis and neovascular glaucoma, occur less frequently, with each occurring in approximately 15% of cases at 5 years after radiation.[147] These results indicate that although visual acuity is compromised with proton therapy, particularly in patients with juxtapapillary lesions, some preservation is possible and eye conservation is likely with low rates of local recurrence.

Stereotactic Radiotherapy

Stereotactic radiation can be delivered by linear accelerator (LINAC) or by specialized devices for focused radiation such as the Leksell gamma knife. Because gamma knife treatment is usually done in a single fraction, the term *radiosurgery* is applied, whereas for LINAC-based treatment, single-fraction or multifraction treatments are possible. Gamma knife radiosurgery (GKRS) for uveal melanoma was introduced in 1998 by investigators at the Indiana University School of Medicine.[148] Nineteen patients with uveal melanoma were treated to a dose of 40 Gy prescribed to the 50% isodose line. With a median follow-up of 40 months, 3- and 5-year overall survival rates were 86% and 55%, respectively. The 3- and 5-year tumor control rates were both 94%. Six (32%) of the 19 treated patients developed distant metastasis 31 to 75 months after GKRS. Out of the 19 patients treated, two had improved, four had stable, and 13 had worse vision in the treated eye. Similar results were reported in a larger series of 78 patients from investigators in Milan.[149] The dose was adjusted over the treatment period: seven patients received 50 Gy to the 50% isodose line (1994-1995), 21 patients received 40 Gy to the 50% isodose line (1995-1999), and 47 patients received 35 Gy to the 50% isodose line (2000-2006). Local tumor control was achieved in 91.0% of patients, and the eye retention rate was 89.7%. A significant relative reduction of visual acuity was observed during follow-up, most commonly because of exudative retinopathy (33.3%), neovascular glaucoma (18.7%), radiation retinopathy (13.5%), and vitreous hemorrhage (10.4%). In a retrospective comparison of 85 patients treated with GKRS (35 Gy to 50% isodose, 39 months average follow-up) versus

106 patients treated with proton therapy (58.4 Gy [RBE] in four fractions, 34 months average follow-up), local control rates were similar at 98% and 95% for GKRS and proton therapy, respectively.[150] GKRS was associated with more deterioration of vision (65% losing more than three lines of Snellen acuity compared to 45% with proton therapy), with 33% of GKRS and 54% of proton therapy patients retaining visual acuity of 6/60 or better.

In an effort to reduce the complications of single-fraction stereotactic radiosurgery, fractionated SRT has also been investigated. Muller and colleagues conducted a prospective study on 102 patients with uveal melanoma treated with fractionated SRT between 1999 and 2007.[151] Patients had uveal melanoma of the choroid or ciliary body with a tumor thickness <12 mm and diameter <16 mm with no metastases. The SRT technique, like GKRS, utilized a fixed immobilization system, and a dose of 50 Gy was delivered in five equal fractions on 5 consecutive days using 6-MV photons with stereotactic arcs. With a median follow-up of 32 months, local control was achieved in 96% of patients. Fifteen enucleations were performed 2 to 85 months after radiation, and best corrected visual acuity (defined as 20/x while using glasses if needed) decreased from a mean of 0.26 at diagnosis to 0.16 at 3 months after irradiation and declined to 0.03 at 4 years after therapy. Deterioration of visual acuity was in part related to complications. Grades 3 to 4 neurovascular glaucoma occurred in nine patients, eight of which required enucleation. In these nine patients, tumors were not anteriorly located, nor did they receive a high dose to the ciliary body, as one might expect, but were associated with grade 3 retinopathy. The authors hypothesized that the physical reaction of ischemic retinopathy might also affect vessels in the ciliary body. Thirteen (13%) patients developed grade 3 or 4 optic neuropathy, which was associated with posterior tumors and optic nerve dose, which was limited to 4 Gy/fraction. Grade 3 cataracts occurred in 10 (10%) patients and were managed by extraction and lens implantation. Cataract formation was dose related, with a median dose of 5 Gy/fraction to the lens causing cataract in 50% of cases. The authors concluded that although local control was excellent, the number of secondary enucleations was substantial, particularly from neovascular glaucoma.

Intraocular Lymphoma

Intraocular lymphomas consist of vitreoretinal lymphomas (VRLs) and choroidal lymphomas. Primary VRL is an uncommon clinical manifestation of non-Hodgkin lymphoma (NHL), which arises in the retina or the vitreous humor.[152] It usually develops in patients in the fifth and sixth decades of life as chronic, relapsing, and steroid-resistant uveitis and vitritis. Patients often complain of blurred vision, a painless loss of vision, and floaters. Primary VRL is generally considered a subtype of primary central nervous system lymphoma (PCNSL) based on frequent co-occurrence with PCNSL and similar clinical behavior. Primary VRL progresses to intracranial involvement in 60% to 85% of cases.[153] Historically, primary VRL has been difficult to diagnose, often taking several years from the onset of symptoms to establishing a diagnosis, which likely contributed to suboptimal outcomes in many cases.[154] Given the tumor's rarity, the optimal treatment of primary VRL is unclear. RT has been used with durable control after 35 to 45 Gy given exclusively to both eyes in the absence of central nervous system disease.[155] However, concerns of CNS relapse have led investigators to use chemotherapy as initial treatment and radiation as a consolidative therapy.[156,157] Methotrexate and cytosine arabinoside are most commonly used, given their ability to cross the blood-ocular barrier.

Primary choroidal lymphomas are usually low-grade B-cell lymphomas with similar features to other extranodal marginal-zone lymphomas.[158] EBRT can be used for primary choroidal lymphomas, with a typical dose of 30 Gy in conventional fractionation associated with high rates of local control and low risk of systemic spread.[159-161] Systemic therapy with rituximab can also be considered.[162] Intraocular lymphoma secondary to disseminated systemic disease also typically involves the choroid. The most common subtype for secondary choroidal lymphoma is diffuse large B-cell lymphoma.[158]

Orbital Tumors

Adult Optic Pathway Glioma

Optic pathway gliomas, with or without contiguous involvement of the hypothalamus, have an incidence of approximately 1 in 100,000, with 90% presenting in the first two decades of life.[163] Pediatric optic pathway gliomas are typically low-grade, benign entities that are sporadic or

associated with neurofibromatosis type 1 and can require long-term follow-up into adulthood.[164,165] By contrast, optic pathway gliomas that are diagnosed in adults are often higher grade (WHO grade III or grade IV) and have an aggressive disease course.[166] Adult malignant optic pathway glioma was first described by Hoyt et al[167] in 1973. Given the rarity of the disease, most published literature on this disease consists of case reports or small case series. Malignant optic pathway gliomas can mimic optic neuritis on initial presentation and typically present with rapidly progressive unilateral vision loss, which often spreads to bilateral blindness.[168,169] The treatment approach consists of RT and chemotherapy, similar to other high-grade gliomas. Outcomes remain poor, with overall survival of less than 1 year.[168]

Primary Orbital Lymphoma

Orbital NHLs account for only 0.01% of NHL and are typically B-cell lymphomas.[170] Depending on the stage and grade of disease, observation, first-line chemotherapy, and chemotherapy followed by RT are treatment options. RT is generally the treatment of choice for NHL localized to the orbit.[171] Local control rates of 90% to 100% can be achieved using doses of 30 to 36 Gy.[172] Historically, radiation was delivered with an anterior portal prescribed to the orbital apex or by wedged anterior and lateral fields. Late effects from these techniques include cataract formation, lens ulceration, glaucoma, and lacrimal impairment.[170] More recently, investigators have described the use of IMRT in orbital lymphoma to reduce dose to the contralateral orbit, lacrimal gland, and lens (Figure 44.9).[173]

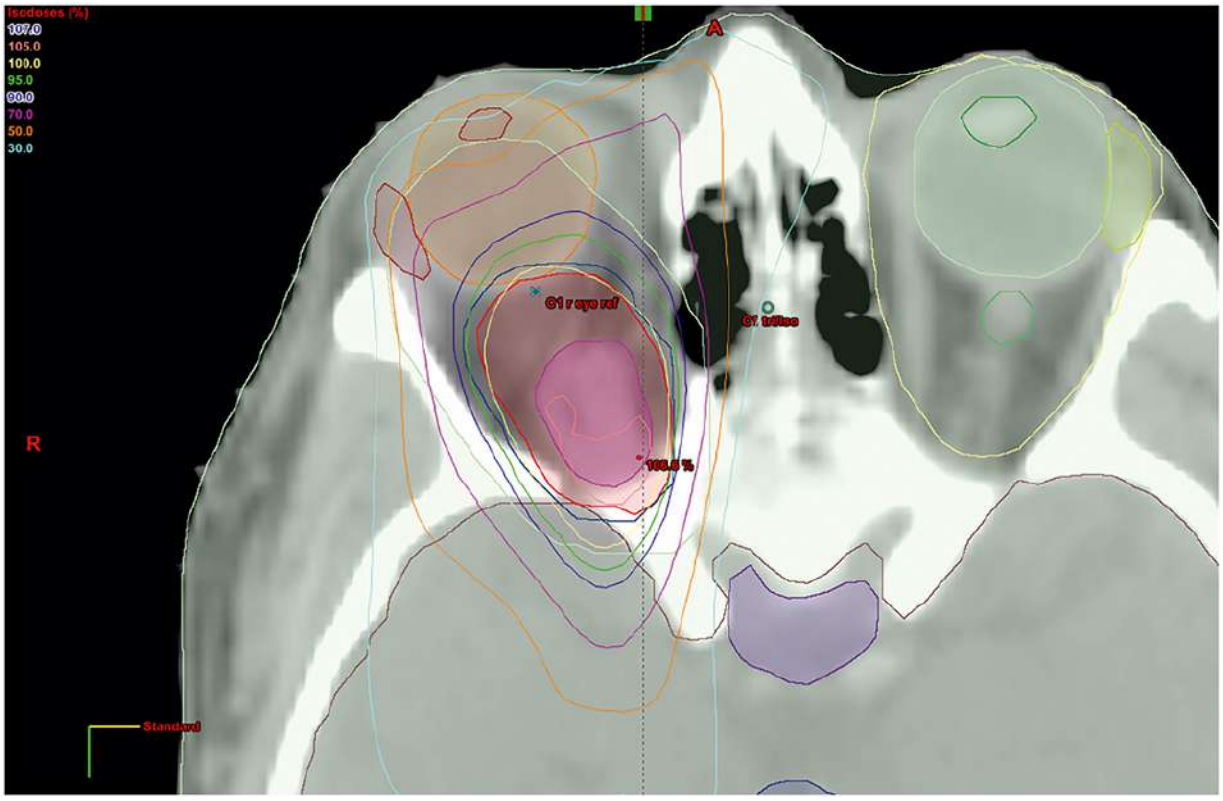

FIGURE 44.9 Primary orbital lymphoma treated with intensity-modulated radiation therapy illustrating sparing of lens, lacrimal gland, and contralateral orbit.

Conjunctival Tumors

Conjunctival tumors comprise a variety of conditions, from benign papilloma to malignant lesions such as squamous cell carcinoma (SCC). Radiotherapeutic management of these tumors is related to the histologic type. Mucosa-associated lymphoid tissue (MALT) lymphoma, for example, has been effectively managed with exclusive RT, with local control rates approaching 100%.[174] In a series of patients with MALT lymphoma of the ocular adnexa that included 37 patients with conjunctival disease, Hashimoto and colleagues[175] reported local control rates of 100% with a median dose of 30.6 Gy. Electron beam therapy was frequently used with eye lens shielding when possible, depending on the extent of disease (Figure 44.10). Treatment options for SCC include excision with or without adjuvant cryotherapy or topical chemotherapy, whereas advanced cases may require orbital exenteration.[176] RT has been used in the primary, adjuvant, and salvage settings with a variety of methods, including photon, proton, and electron beam therapy.[177,178] Most frequently, however, radiation is used

in patients with relapsed disease. The treatment volume typically includes gross tumor with margins of approximately 1 cm and doses of approximately 60 Gy, as in cases of SCC at other sites.[179]

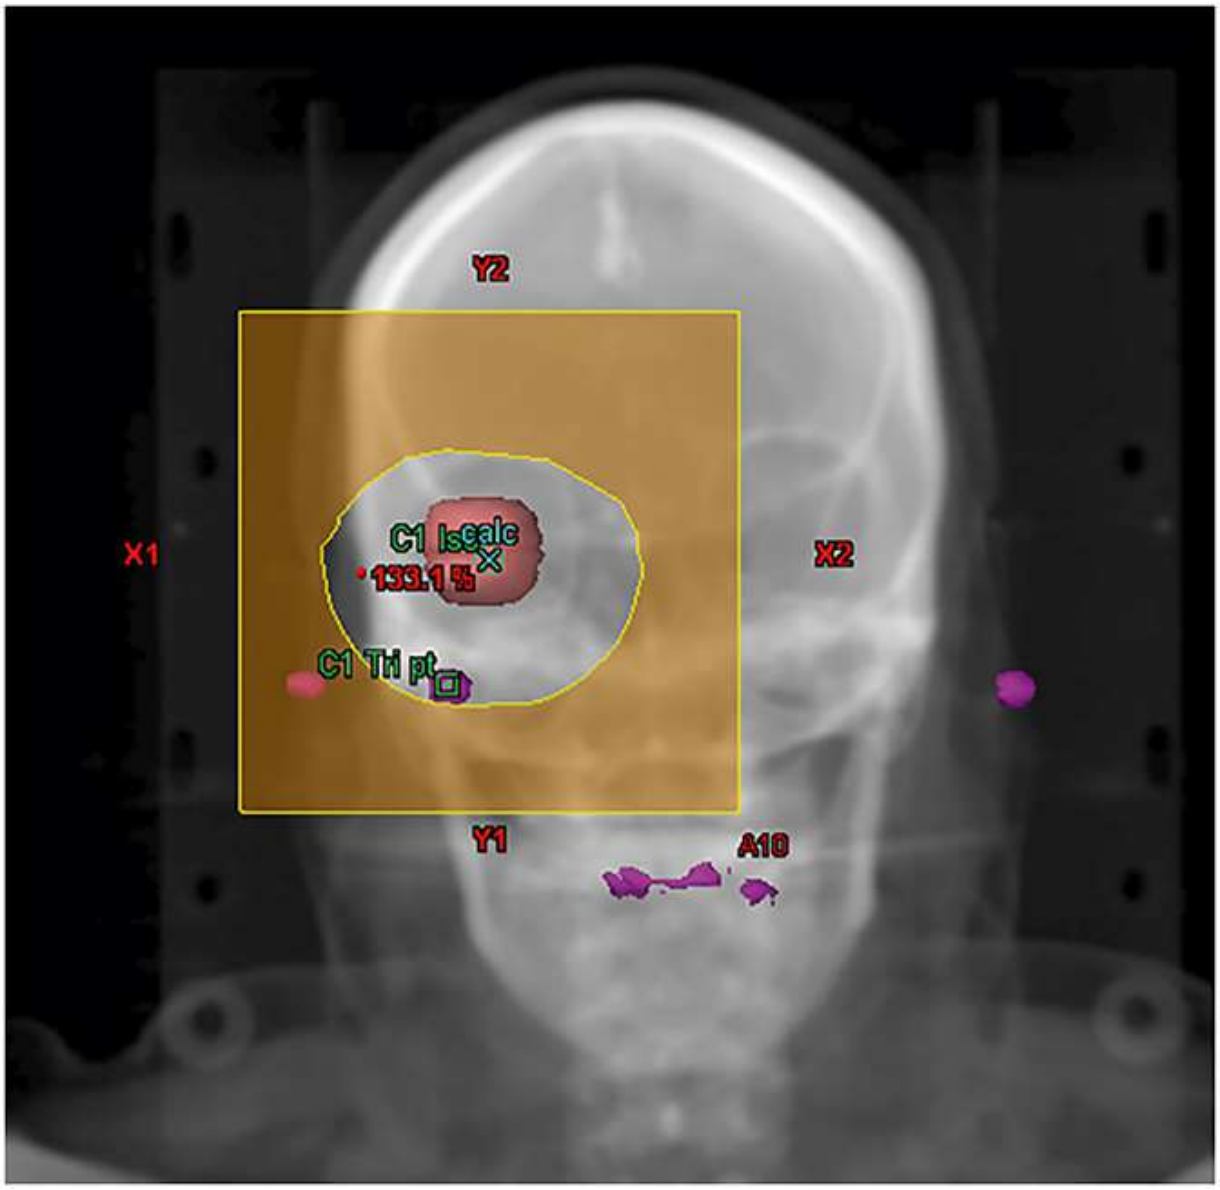

FIGURE 44.10 Electron beam therapy for mucosa-associated lymphoid tissue lymphoma of the conjunctiva. The patient received 30.6 Gy using 9-MeV electrons. Lens shielding was not used because of the extent of disease at presentation.

Sebaceous Carcinoma of the Eyelid

Sebaceous gland adenocarcinoma occurs in the periorbital area, usually in the eyelid.[180] It can exhibit aggressive local behavior and can metastasize to regional lymph nodes and distant organs. Older individuals tend to be affected, but it occurs with greater frequency and at an earlier age in patients with hereditary retinoblastoma treated with radiation.[181] The main systemic association is Muir-Torre syndrome, an autosomal dominant condition characterized by a greater frequency of sebaceous adenoma, sebaceous carcinoma, keratoacanthoma, and gastrointestinal malignancies.[182] The most common pattern of metastasis of eyelid sebaceous carcinoma is through the lymphatic channels to regional lymph nodes. Historically, regional node metastasis occurred in about 30% of cases, but metastases have become less frequent in recent years.[183] Tumors that originate in the upper eyelid tend to metastasize to preauricular and parotid nodes. Tumors of the lower eyelid region can metastasize to submandibular and cervical nodes. Until recently, orbital exenteration was believed to be the only reasonable option in the management of sebaceous carcinoma that involved most of the conjunctiva and invaded the orbit. However, local excision with adjuvant therapies, such as topical chemotherapy or cryotherapy, is becoming more common.[184,185] EBRT, with doses of approximately 60 Gy, is rarely used for primary treatment but should be considered for patients with adverse features such as regional lymph node involvement or recurrent disease.[186]

Periorbital Skin Cancers

Skin cancers of the eyelid and periorbital skin include most frequently basal cell carcinoma (BCC) and SCC, but also rare histologies such as Merkel cell carcinoma (MCC).[187] For small BCC and SCC, single modality treatment with surgery or RT results in good local control, but RT is frequently used due to cosmetic concerns. For more advanced tumors or more aggressive histologies, such as MCC, combined surgery and RT are typically recommended. Low-energy electron beam therapy or orthovoltage irradiation is useful in this setting and can be delivered with an eye shield. RT for skin tumors requires doses of 60 Gy or more for definitive treatment using standard fractionation, but altered fraction can be employed to shorten treatment duration and minimize ocular trauma of shield placement.

CHAPTER 45

Ear

Geoffrey Sedor, Luqman Dad, and Tony J. C. Wang

ANATOMY

The external, middle, and inner components of the ear develop from the three embryonic layers: ectoderm, mesoderm, and endoderm.

The external ear consists of the auricle or pinna, the external auditory meatus (canal), and the tympanic membrane (Figure 45.1). The auricle is composed of elastic cartilage covered with skin. The external auditory meatus connects the tympanic membrane to the exterior and is approximately 2.4-cm long. The outer third is cartilaginous, and the inner two-thirds is bony and slightly narrower. The external auditory canal (EAC) is anterior to the mastoid process and posterior to the parotid gland at the temporomandibular joint (TMJ). The inferior border of the canal lies near the jugular bulb and the facial nerve as it descends through the stylomastoid foramen. The skin lining the auditory canal is continuous with that of the auricle, and in the outer one-thirds of the canal, it contains hair follicles and sebaceous and ceruminous glands. The tympanic membrane, made of multiple layers of squamous epithelium, separates the auditory canal from the middle ear.

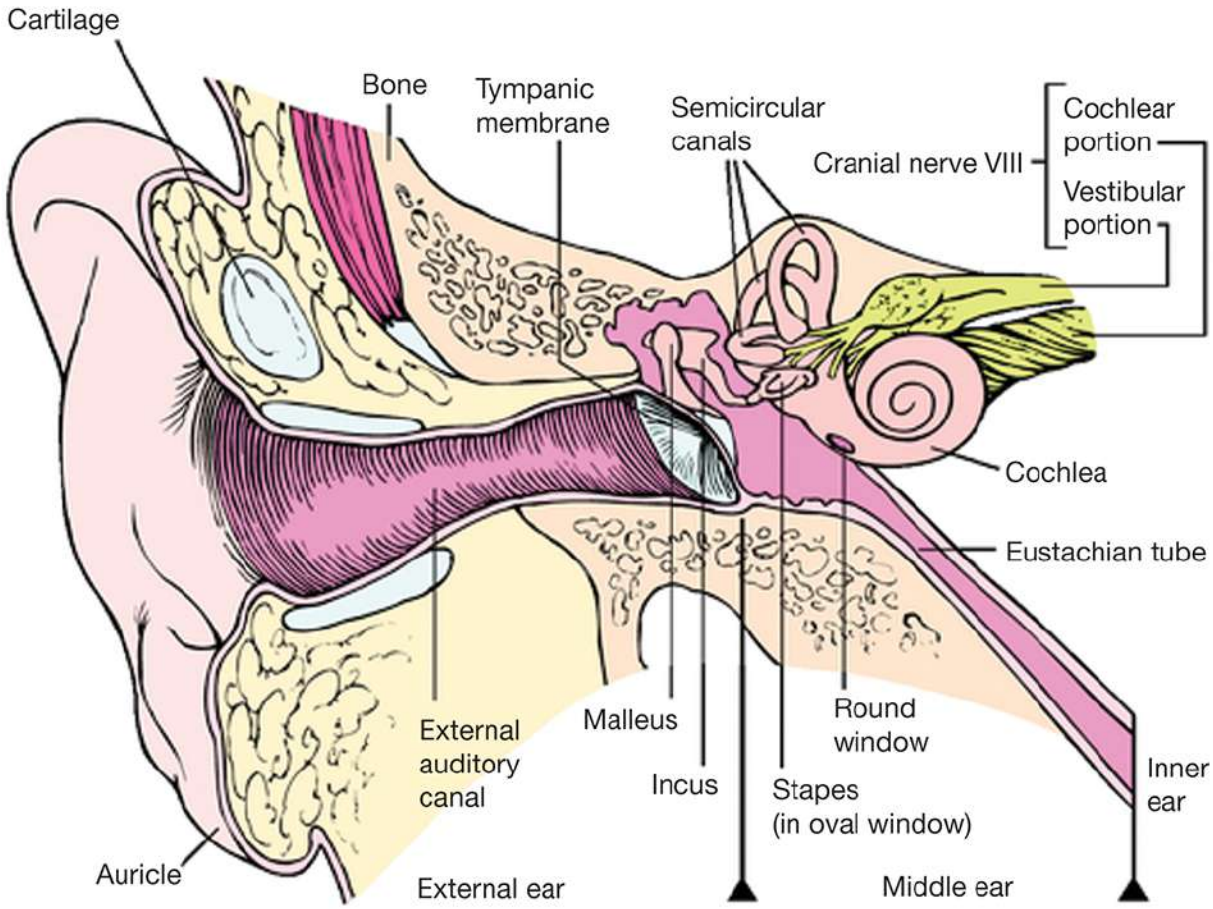

FIGURE 45.1 Ear anatomy.

The middle ear houses the auditory ossicles and the tympanic cavity and opens into the eustachian tube to communicate with the pharynx. The middle ear cavity is lined with a mucoperiosteal membrane, and the eustachian tube is lined with stratified columnar epithelium and has numerous mucous glands in two-thirds of the tube closer to the pharynx. The overall length of the eustachian tube is 3.5 cm.[1]

The inner or internal ear lies in the petrous portion of the temporal bone and consists of the bony labyrinth and the membranous labyrinth. The membranous labyrinth, which holds the organ of hearing, is housed within the bony labyrinth. The cochlea, which is responsible for hearing, and the vestibule, which is responsible for balance, are part of the inner ear.

Blood supply to the auricle and the EAC comes from branches of the posterior auricular artery and the superficial temporal artery, which arise from the external carotid artery. Blood is supplied to the middle ear region

by branches of ascending pharyngeal artery, the middle meningeal artery, and the artery of the pterygoid canal. The inner ear is supplied by the internal auditory artery, which is a branch of the basilar artery, and the anterior inferior cerebellar artery.

The nerves innervating the ear include cranial nerves V, VIII, IX, and X. The eighth cranial nerve or vestibulocochlear nerve is responsible for auditory and vestibular functions. It exits from the brainstem between the pons and the medulla and follows the internal acoustic meatus.

For the external ear, lymphatic vessels of the tragus and the anterior external portion of the auricle drain into the superficial parotid lymph nodes. The posterior and superior aspects of the auricle drain into the retroauricular lymph nodes, and the lobule drains into the superficial cervical group of lymph nodes. Lymphatics from the middle ear and the mastoid antrum pass into the parotid nodes and into the upper deep cervical lymph nodes. The lymphatics in the middle ear and eustachian tube are rather sparse, and the inner ear has no lymphatics.

EPIDEMIOLOGY

Malignant disease of the auricle is common (accounts for 6% of all skin cancers), but cancers of the middle ear and EAC are rare, with an incidence of approximately 1 per million people.[2-4] Tumors of the external ear are most often cutaneous malignancies and may be related to sun exposure.[5,6] Other predisposing factors described, although their significance is in question, are otorrhea, chronic eczema, chronic dermatologic conditions, and chronic ulcerations from trauma.[7]

Tumors of the external ear most commonly occur in patients 60 to 70 years of age; tumors of the middle ear and the mastoid are more common in patients 40 to 60 years of age.[8,9] More women than men have middle ear tumors, but more men have tumors of the external ear.[10,11]

CLINICAL PRESENTATION

External Ear

Basal cell carcinomas are more common than squamous cell carcinomas (SCCs) in the external ear, with a ratio of 1.3:1.[8] They present as small

ulcerations, mostly on the helix.[12,13] For SCCs, lymph node metastases occur in approximately 10% to 15%.[14] The common sites of lymph node metastases in order of frequency are the parotid gland, the upper deep cervical chain, and the postauricular nodes.[9,14] The rate of regional metastasis is higher in advanced disease and may involve the level 5 cervical lymph node group.[15]

External Auditory Canal

Most patients present with symptomatic lesions of the EAC. Pruritus and pain are common. Swelling behind the ear, decreased hearing, and facial paralysis are seen in advanced cases. Spread of the tumor into the lymphatic regions is more common than spread to other areas of the ear (~20%).[16,17] Tumors arising in the cartilaginous portion of the canal invade the cartilaginous walls and spread into the bony canal areas. However, those arising in the bony canal have a more effective barrier (preventing spread) and therefore progress predominantly along the main axis of the canal, eventually invading the middle ear or the cartilaginous part of the canal. The local spreading route is depicted in Figure 45.2. Distant metastases are rare.

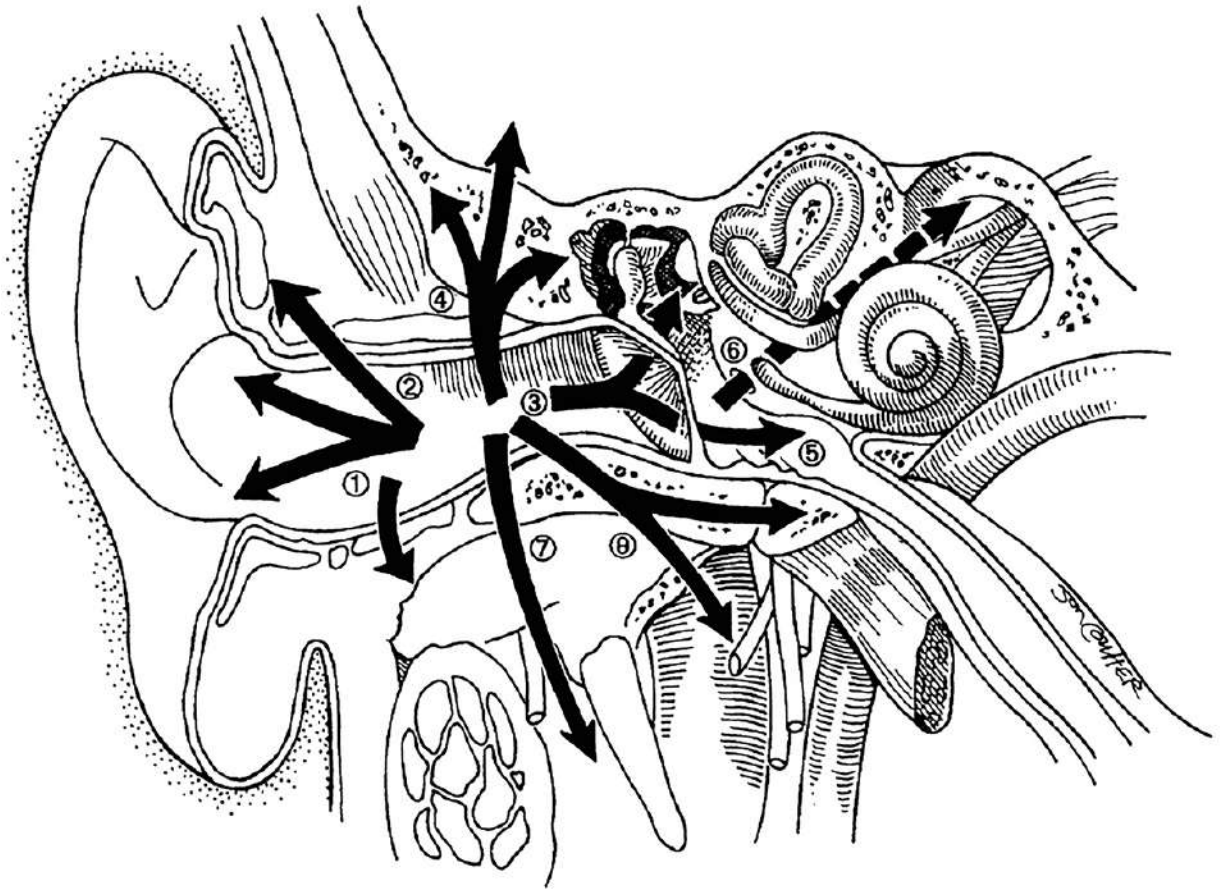

FIGURE 45.2 Coronal anatomy of pathways of spread of primary cancer of the EAC. Cancer can spread (1) anteriorly through the cartilaginous canal into the parotid gland, (2) through the concha into the postauricular sulcus, (3) through the tympanic membrane into the middle ear, (4) posteriorly into the mastoid, (5) into the anterior mesotympanum to the carotid artery and eustachian tube, (6) into the inner ear through the round window or otic capsule, (7) along the extratemporal facial nerve into the infratemporal fossa, and (8) inferomedially into the jugular fossa, carotid artery, and lower cranial nerves. DIAGNOSTIC WORKUP

Table 45.1 summarizes workup and diagnostic procedures. A history and physical examination, including otoscopy and a careful lymph node exam, should be performed. Neurologic exam findings of cranial nerve deficits may be an indication of advanced disease. A baseline audiology testing should be performed before any treatment.

TABLE 45.1 DIAGNOSTIC EVALUATION FOR CARCINOMA OF THE EAR

History
Physical examination
- Otoscopy
- Neurologic examination for cranial nerve function
- Careful assessment of regional lymph nodes

Laboratory tests
- Complete blood count
- Blood chemistry

Radiographic studies
- High-resolution computed tomography (standard)
- Magnetic resonance imaging (selected patients)
- Arteriography (optional)

Biopsy
- Other studies
- Audiology testing

Both multidetector computed tomography (CT) and magnetic resonance imaging (MRI) play an important role in visualizing tumors of the ear.[18] CT can show abnormal soft tissue, soft tissue enhancement, and distortion of the normal tissue planes. Most importantly, when evaluating EAC tumors, CT can provide an accurate prediction of bone erosion, such as wall of the EAC, middle ear, TMJ, carotid artery canal, and jugular fossa and thus can help to determine the extension and the operability of tumors (Figure 45.3).[19-21] Sometimes, MRI can differentiate the tumor from mastoiditis and cholesteatomas and provide excellent delineation of soft tissue tumor margins, muscle infiltration, intracranial extension, dural or cerebral involvement, and vessel encasement.[21,22] Except in selected cases, angiography and jugular venography have also been abandoned in favor of CT.

Diagnosis is always established by biopsy and occasionally by aspiration of the exudative material or by surgical exploration. A bone scan may be done to determine the changes in the temporal bone around the tumor, but it provides very nonspecific information and is not a recommended method of evaluation.

PATHOLOGIC CLASSIFICATION

Approximately 85% of the tumors involving the auditory canal, middle ear, and mastoid area are SCCs. Infrequently, basal cell carcinomas, adenocarcinomas, adenoid cystic carcinomas, and melanomas are seen.[23] Even rarer are sarcomas, specifically embryonic rhabdomyosarcomas. Ceruminous gland tumors and papillomas rarely arise in the auditory canal.[7,23,24] Carcinoid tumors of the middle ear are rare, and only 50 cases have been reported in the literature.[25,26] Endolymphatic sac tumors or aggressive papillary middle ear tumors are distinct from middle ear adenomas and act aggressively. They are characterized by slow growth but extensive local invasion and bone destruction.[27,28]

PROGNOSTIC FACTORS

Lesions of the external ear are usually more easily controlled than lesions of the middle ear or mastoid. External ear lesions are usually diagnosed earlier; they are mostly cutaneous, and adequate surgery or radiation therapy is usually effective.[3,9,29] Presence of large lesions involving the middle ear, especially those extending into the temporal bone or soft tissue, is a poor prognostic sign and makes treatment more difficult.[2,30,31] There does not appear to be a correlation between tumor differentiation, positive

margins, or perineural disease and survival, although they may serve as a predictor for local control in tumors involving the temporal bone.[30,32,33] Seventh cranial nerve palsy associated with middle ear tumors indicates poor survival as shown in pooled-data survival analysis and has been adopted into the staging system. Spread of tumors to the lymph nodes usually indicates a poor prognosis because this is often a late event in the natural history of the disease.[17,32,34] Nomogram for predicting overall survival and cause-specific survival in patients with middle ear cancer has been proposed using Surveillance, Epidemiology, and End Results database.[35]

STAGING

The eighth edition of the American Joint Committee on Cancer staging manual[36] includes the external ear in its staging system under *Cutaneous Squamous Cell Carcinoma and Other Cutaneous Carcinomas* (Table 45.2). A group from the University of Pittsburgh proposed a staging system for SCC of the EAC and temporal bone, which was updated in 2002.[17,37-39] The primary tumor stage is determined by the level of bony erosion, size, and involvement of the middle ear. Lymph node disease is considered an advanced stage with poor prognosis. This staging system has often been cited in the literature (Table 45.3).[2,17,34,38,40-46]

TABLE 45.2 THE AMERICAN JOINT COMMITTEE ON CANCER AND INTERNATIONAL UNION AGAINST CANCER STAGING SYSTEM FOR EAR CANCER

Stage	Staging Criteria
T Category	
Tx	Primary tumor cannot be assessed.
Tis	Carcinoma in situ
T1	Tumor ≤2 cm in greatest dimension
T2	Tumor >2 cm, but ≤4 cm in greatest dimension
T3	Tumor >4 cm in maximum dimension or minor bone erosion or perineural invasion or deep invasion[a]
T4a	Tumor with gross cortical bone/marrow invasion
T4b	Tumor with skull base invasion and/or skull base foramen involvement

Stage	Staging Criteria		
N Category			
Nx	Regional lymph nodes cannot be assessed.		
N0	No regional lymph node metastases		
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension and ENE(−)		
N2a	Metastasis in a single ipsilateral node >3 cm but not >6 cm in greatest dimension and ENE(−)		
N2b	Metastases in multiple ipsilateral nodes, none >6 cm in greatest dimension and ENE(−)		
N2c	Metastases in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension and ENE(−)		
N3a	Metastasis in a lymph node >6 cm in greatest dimension and ENE(−)		
N3b	Metastasis in any node(s) and ENE(+)		
M Category			
M0	No distant metastasis		
M1	Distant metastasis		
Stage Grouping

	T any	N any	M1

ENE, extracapsular nodal extension.

[a]Deep invasion is defined as invasion beyond the subcutaneous fat or larger than 6 mm (as measured from the granular layer of adjacent normal epidermis to the base of the tumor); perineural invasion for T3 classification is defined as tumor cells within the nerve sheath of a nerve lying deeper than the dermis or measuring 0.1 mm or larger in caliber, or presenting with clinical or radiographic involvement of named nerves without skull base invasion or transgression.

GENERAL MANAGEMENT

External Ear

Tumors of the external ear are most often treated with limited surgery or external radiation therapy. Treatment in the early stages with irradiation is usually in the form of megavoltage electron beam therapy or orthovoltage.[47,48] Most radiation techniques have been fairly successful in the treatment of lesions in this area, with local control rates of 80% to 97%.[3,49-51] Caccialanza et al[3] reported a 5-year cure rate of 78% with a mean follow-up of 2.4 years for 115 carcinomas of the pinna treated with definitive kilovoltage radiation to a total dose of 45 to 70 Gy, in 2.5- to 5-Gy fractions given 2 to 3 times per week. Surgery is beneficial if the lesion has invaded the cartilage of the ear or extends medially into the auditory

canal. If SCC of the external ear is treated with surgery alone, there is a recurrence rate of 14% to 19%.[9,52] Mohs surgery is another option, with reported local recurrence rates of 5% to 7%.[29,53] Advanced lesions involving a significant portion of the ear canal are managed with a combination of irradiation and surgery. Palmer and Snell[54] describe the use of radical soft tissue and subtotal temporal bone excision with deltopectoral flap coverage for extensive tumors of the auricular area.

Treatment of draining lymphatics is normally not required for early stages of external ear tumors.[13] Afzelius et al[12] indicate that lesions larger than 4 cm and those with cartilage invasion have an increased risk of nodal spread; they recommend prophylactic neck dissection.[55] Most investigators do not agree with this approach because the overall chance of lymph node involvement in tumors of the external ear is only 16%. Osborne et al[56] reported that parotidectomy may be unnecessary in the management of advanced auricular carcinoma without clinically positive parotid disease.

Interstitial irradiation using afterloading ^{192}Ir, particularly for tumors smaller than 4 cm, is also an effective method of treatment, affording excellent local control with good cosmesis[51] (Table 45.4).

TABLE 45.4 TREATMENT OF CARCINOMA OF THE EXTERNAL EAR

Result	Modality	
	Surgery	Irradiation
Cure at 3 y[57]	330/358 (92%)[a]	141/174 (81%)
Cure at 5 y[3]		(78%)
Local control at 2 y[29,50]	82/87 (94%)[b]	60/62 (97%)
Local control at 2 y[48]		(86%)[c]

[b]Treatment by Mohs micrographic surgery.

[c]Included advanced primary tumors.

External Ear Canal and Middle Ear

Radical surgery followed by postoperative radiation therapy is an acceptable method of treatment for more advanced lesions of the EAC and lesions in the middle ear and mastoid.[31,44,58] Pfreundner et al[31] recommended a postoperative radiotherapy dose of 54 to 60 Gy for patients with negative margins. Positive margins warrant higher doses of 66 Gy because of higher recurrence rates. Except for tumors detected early, neither modality alone is considered optimal; a combination of the two produces the best results.

Lesions of the outer part of the auditory canal require local excision with at least a 1-cm margin between the lesion and the tympanic membrane if there is no radiographic evidence of invasion of the mastoid. Surgery for tumors of the auditory canal is performed through a U-shaped incision with elevation of the flap from below. A split-thickness skin graft is usually required to cover the deficit along the auditory canal.

When the tumor involves the bony auditory canal and impinges on the tympanic membrane but does not involve the middle ear or the mastoid, a partial temporal bone resection may be necessary; in this procedure, the auditory canal, tympanic membrane, malleus, and incus are removed along with the TMJ, and the defect is grafted with a split-thickness skin graft. Postoperative radiation may be indicated, depending on margin status.

Middle Ear and Temporal Bone

In the management of temporal bone tumors originating from the middle ear and mastoid area, surgical options include subtotal temporal bone resection, total temporal resection, lateral temporal resection, or mastoidectomy. Complete resection with clear margins may be difficult to achieve, given that important structures reside around the temporal bone.[40,55,59-61] Postoperative radiation therapy is recommended and increases local tumor control.[31,40,62] In studies that suggest limited benefit of postoperative irradiation, the results may be related to the extent of the tumor.[63] Given that total and subtotal temporal bone resection can result in significant morbidity, some investigators favor limited surgery with postoperative or perioperative radiation, or even definitive radiotherapy in early or unresectable lesions.[62,64,65] Stereotactic ablative radiotherapy may represent a new treatment option for organ preservation. A study used 37.5

Gy/3 fractions or 40 Gy/5 fractions radiotherapy as a first-line treatment, resulting in 3-year overall survival rates: 69% for T1/2, 79% for T3 (95% CI, 47-93), and 0% for T4 disease with limited toxicities.[66] Murai et al reported their experience in treating unresectable locally advanced SCC of the EAC and middle ear with carbon ion therapy. The 3-year local control was 54%.[67] Chemotherapy has been used in tumors of the ear. The common regimen includes cisplatin, docetaxel, and mitomycin via intravenous or intra-arterial routes.[68,69] A meta-analysis suggested that preoperative chemoradiotherapy (CRT) followed by surgery may improve the survival of patients with SCC of EAC and that definitive CRT may be equivalent to surgical resection.[70] However, additional trials are necessary to determine efficacy because there was no controlled trial in this meta-analysis.

RADIATION THERAPY TECHNIQUES

Tumors involving the pinna can be treated with megavoltage electrons or with superficial or orthovoltage irradiation. The fields can be round or polygonal, drawn around the tumor to spare surrounding normal tissues. For small, superficial tumors, margins of 1 cm are adequate (Figure 45.4). However, more extensive lesions require larger fields, which may encompass the entire pinna or external canal and require 2- to 3-cm margins around the clinically apparent tumor.[71] Lesions involving the pinna must be treated with slow fractionation (1.8-2 Gy daily) to prevent cartilage necrosis. Doses of 66 Gy over a period of 6.5 weeks are required to achieve adequate tumor control.

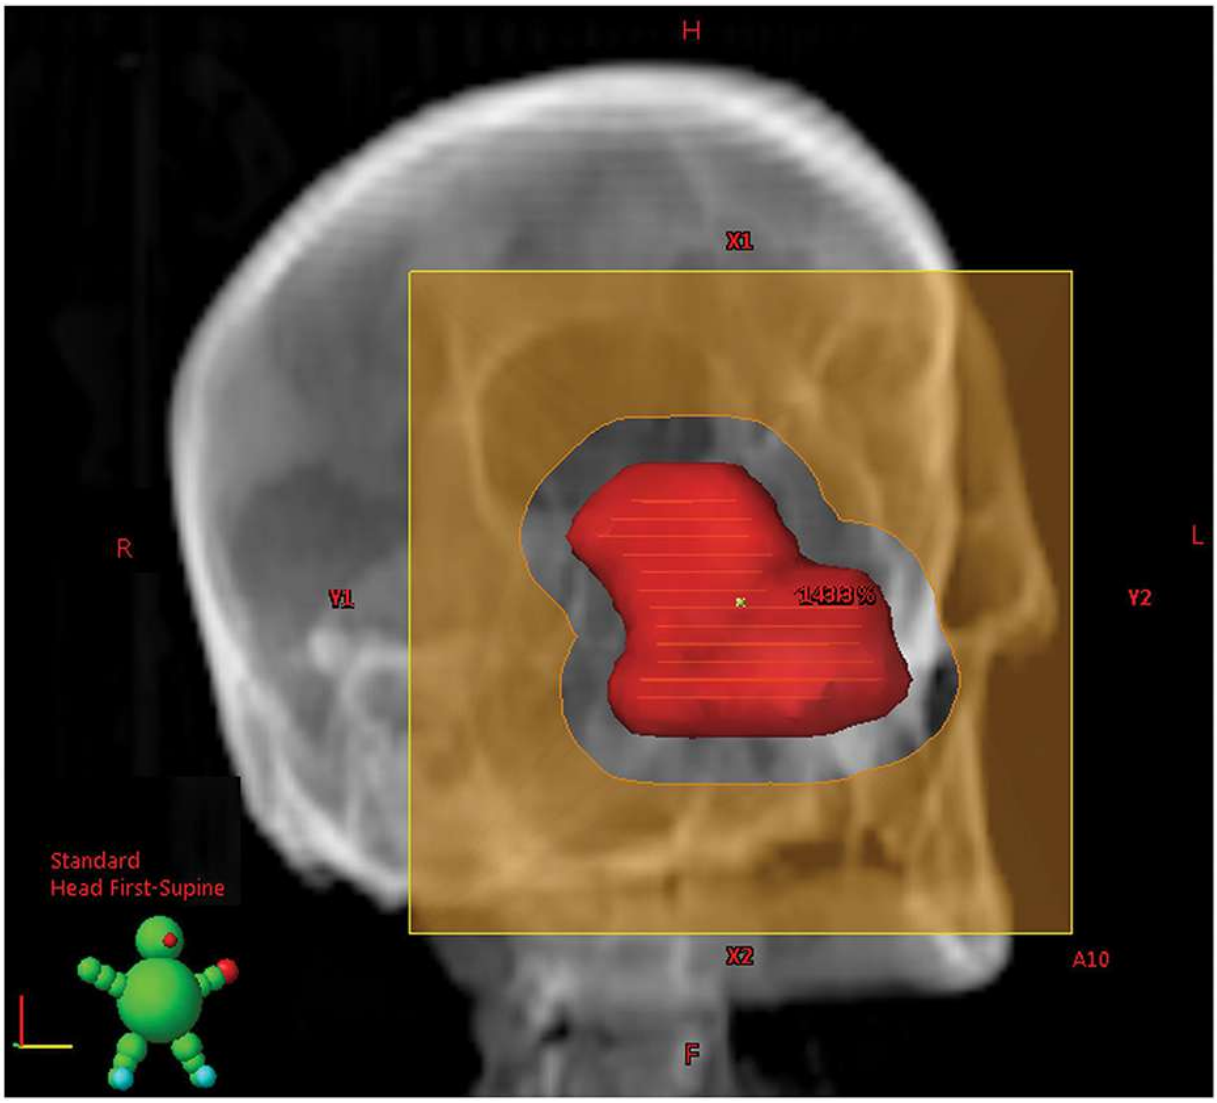

FIGURE 45.4 Example of beam's eye view of the target volume and electron aperture cutout. (Reprinted from Michiels S, Mangelschots B, Roover R, Devroye C, Depuydt T. Production of patient-specific electron beam aperture cut-outs using a low-cost, multi-purpose 3D printer. *J Appl Clin Med Phys*. 2018;19[5]:756-760. http://creativecommons.org/licenses/by/4.0/.)

Large lesions of the EAC are treated with radiation or in combination with surgery; the field should encompass the entire ear and temporal bone with an adequate margin (3 cm). The volume treated should include the ipsilateral preauricular, postauricular, and subdigastric lymph nodes. Treating lymphatics beyond the jugulodigastric area is usually not necessary.

The use of intensity-modulated radiotherapy (IMRT) can help improve target coverage and spare normal critical structures. Careful understanding of lymphatic drainage and tumor extension is crucial for target delineation and to avoid geographic misses. Pretreatment CT, MRI, or positron emission tomography-computed tomography scans should be reviewed along with any operative or pathology reports.

In the definitive treatment of advanced EAC or middle ear cancers, gross target volume (GTV) should include the clinical and radiographic gross disease (Figure 45.5). Clinical target volume 1 (CTV1) should encompass the GTV with a 0.3- to 0.5-cm margin to a dose of 66-70 Gy at 2 Gy per fraction. CTV2 should include CTV1 with a margin of 0.5 to 0.7 cm, as well as the preauricular nodes, postauricular nodes, ipsilateral upper cervical neck (level II), and parotid gland, receiving a dose of 63 Gy at 1.8 Gy per fraction. A CTV3 can be considered for some patients with more advanced and aggressive tumors for treatment of the ipsilateral middle and lower neck (levels III and IV) and contralateral upper neck (level II) to a dose of 56 Gy at 1.6 Gy per fraction. Planning target volumes are created with a margin of 3 to 5 mm around the CTVs.

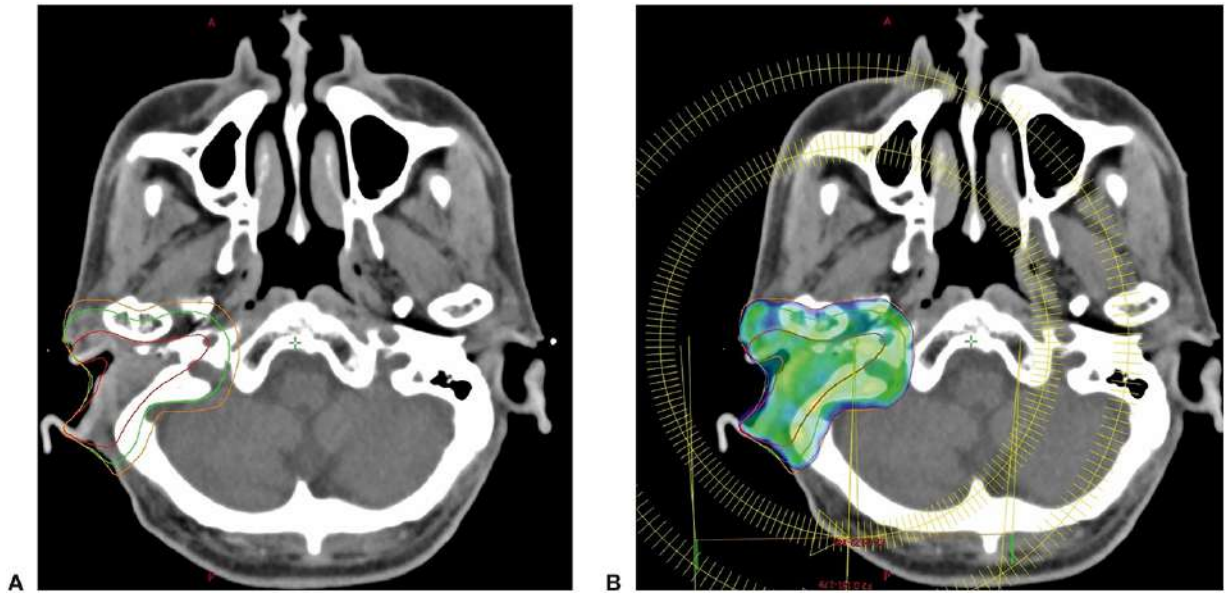

FIGURE 45.5 A. Treatment plan for external auditory canal squamous cell carcinoma: gross target volume is in red, high-risk clinical target volume (CTV1) is in green, and planning target volume is in orange. B. Dose color wash of two full-arc volumetric modulated arc therapy plans.

Chen et al[62] described the target volumes for postoperative IMRT of the EAC and middle ear. In the postoperative setting, CTV1 includes the original tumor region, surgical bed, soft tissue invasion, areas with positive residual disease, or positive margins to a dose of 60 to 66 Gy at 2 Gy per fraction. CTV2 includes CTV1 with a margin of 0.5 to 0.7 cm, depending on the anatomy, and the ipsilateral upper neck (level II), including the parotid region, to a dose of 54 to 60 Gy at 1.8 Gy per fraction. In some patients, CTV3 is included to cover the ipsilateral middle to low neck (levels III and IV) with or without the contralateral upper neck (level II) to a dose of 50 to 54 Gy at 1.6 Gy per fraction. Plans should be optimized to cover 95% of the planning target volume with 100% of the prescribed dose. In this case series, marginal failure occurred at the preauricular space and glenoid fossa of the TMJ. Caution should be taken to cover the area.

Extremely advanced tumors that are unresectable should be treated with high-energy ipsilateral electron beam therapy (16 to 20 MeV) alone or mixed with photons (4 to 6 MV), wedge pair (superior inferiorly angled beams) techniques using low-energy photons, or IMRT. IMRT is a reasonable option if nodal coverage is indicated. Doses of 60 to 70 Gy over 6 to 7 weeks are required. Doses higher than this may produce osteoradionecrosis of the temporal bone. If various types of radiation therapy beams are available, individualized treatment plans should be devised[72] (Figure 45.6). Most patients receiving radiation therapy to the middle ear and temporal bone regions benefit from immobilization devices such as the Aquaplast system. When electron beam radiation therapy is administered, using a water bolus in the EAC and concha may reduce the auricular complications.

FIGURE 45.6 Computerized isodose distribution for treatment of a middle ear tumor using a combination of photons and electrons. (From Foley H, Hopley S, Brown E, Bernard A, Foote M. Conformal orbit sparing radiation therapy: a treatment option for advanced skin cancer of the parotid and ear region. *J Med Radiat Sci*. 2016;63[3]:186-194. Reprinted by permission of John Wiley & Sons.)

Palliative Radiation Therapy

Radiation therapy offers significant palliation in recurrent or advanced disease. Pain relief is reported in 61% of patients with tumors of the auditory canal and middle ear.[73] Recurrences developing after previous irradiation may be retreated with low-dose radiation therapy and hope for control of tumor in approximately 20% of patients.[74] When a small-volume local recurrence occurs after previous radiation therapy, fractionated high-dose rate treatment may be considered.

RESULTS OF THERAPY

The series of patients reported from several institutions is small. Results of treatment with various modalities are shown in Table 45.5. In more extensive lesions, combinations of surgery and irradiation have yielded satisfactory results. Overall 5-year survival rates with combination therapy for tumors involving the middle ear and EAC range from 40% to 60%, whereas patients with early-stage tumors achieve a 70% 5-year survival rate with no evidence of disease.

[a]Meta-analysis, for published year.

Data from a multi-institutional series (Figure 45.7) indicate that there is a negative association between disease-free survival and the extent of disease using the University of Pittsburgh staging system.[44] These data also provide evidence of the success of combined surgery and postoperative irradiation for malignancies of the temporal bone.[75,76]

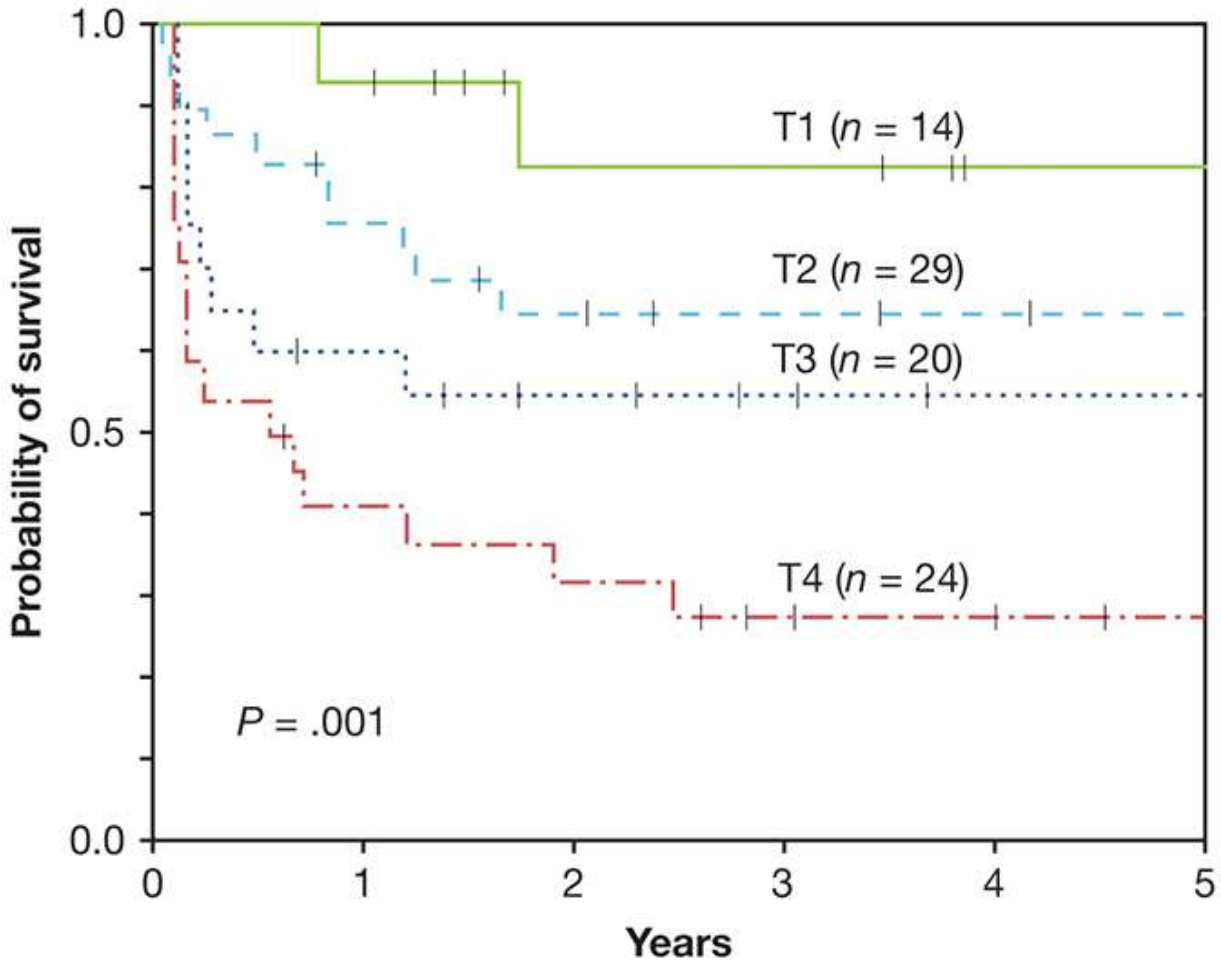

FIGURE 45.7 Data from patients with tumors of middle ear and EAC from a multi-institutional series demonstrate the association between disease-free survival and extent of disease using the University of Pittsburgh staging system. (Reprinted from Ogawa K, Nakamura K, Hatano K, et al. Treatment and prognosis of squamous cell carcinoma of the external auditory canal and middle ear: a multi-institutional retrospective review of 87 patients. *Int J Radiat Oncol Biol Phys*. 2007;68[5]:1326-1334. NORMAL TISSUE COMPLICATIONS

Organs at risk should include the brainstem, spinal cord, cochlea, eye, optic nerve, chiasm, lens, larynx, oral cavity, parotid glands, and temporal bone. Normal tissue constraints are given in Table 45.5.

For conventionally fractionated radiation therapy, the mean dose to the cochlea should be limited to less than or equal to 45 Gy, or more conservatively to 35 Gy, to reduce sensorineural hearing loss.[90] Modeling of some of the sensorineural hearing loss data from the Quantitative Analysis

of Normal Tissue Effects in the Clinic studies is presented in Figure 45.8. The phenomenologic binomial equation of Zaider and Amols was used.[91] Chen et al[92] noted that hearing loss at a given radiation dose increased as frequency of the sound increased. The data are reasonably represented by theoretical curves with a characteristic dose (parameter α_2) of about 10 Gy (Table 45.6).

TABLE 45.6 NORMAL TISSUE DOSE CONSTRAINTS

Structure	Constraints
Brainstem	Maximum <60 Gy
Spinal cord	Maximum <45 Gy
Cochlea	Mean dose <45 Gy
Optic nerve	Maximum <55 Gy
Optic chiasm	Maximum <55 Gy
Lens	Maximum <10 Gy
Larynx	Mean dose <44 Gy; maximum <66 Gy
Oral cavity	Mean dose <35 Gy
Parotid gland	Combined parotid glands mean dose <25 Gy or spare one parotid gland mean dose <20 Gy
Temporal bone	Limit to <70 Gy to reduce osteoradionecrosis chance

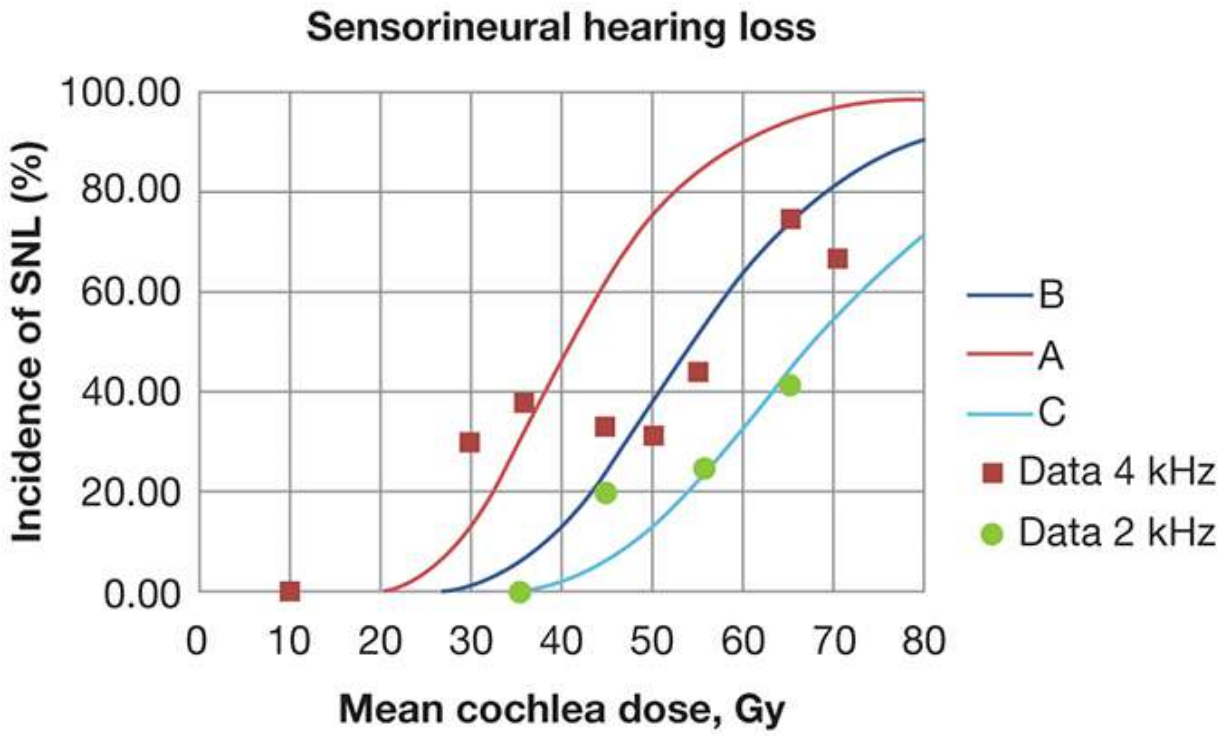

FIGURE 45.8 Modeling of the quantitative analysis of normal tissue effects in the clinic sensorineural hearing loss data using the phenomenologic binomial equation of Zaider and Amols.[91] Data for 2 kHz are shown as circles and those for 4 kHz as squares. All points are taken from Figure 1a, b of Bhandare et al.[90] Theoretical curves use a simple two-parameter variant of the nested exponential equation of Zaider and Amols[91]: $P(D) = 100 \exp[-\alpha_1 \exp(-\alpha_2 D)]$. The three curves are drawn with $\alpha_1 = 40$; the central curve has $1/\alpha_2 = 13.3$ Gy (B), and the outer curves are for $1/\alpha_2$ = (A), 10 Gy and (C), 16 Gy. SNL, sensorineural hearing loss.[94] (Reprinted with permission from Burri RJ. Ear. In: Chao KSC, Perez CA, Brady LW, eds. *Radiation Oncology: Management Decisions*. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2011:203-209.)

A relationship between mean dose to the cochlea and hearing loss was established by Schuette et al[93] in a retrospective cohort of patients with head and neck cancer treated with radiation therapy and/or cisplatin, finding an increase in pure tone average at 1, 2, and 4 kHz of 0.92 dB for every 10 Gy of mean dose to the cochlea.

SEQUELAE OF TREATMENT

Possible sequelae with surgery are hemorrhage, infection, loss of facial nerve function, and, rarely, carotid artery thrombosis. Occasionally, vertigo is reported after temporal bone resection. Vertigo may last for 2 weeks, and

a period of unsteadiness may last for a few months. Permanent deafness usually occurs on the operated side.

Radiation therapy sequelae include cartilage necrosis of the EAC and osteoradionecrosis of temporal bone.[13,95] Very rarely, secondary infections and meningitis are reported.[11] Due to the proximity of the brainstem and medulla oblongata, it is extremely difficult to deliver a high dose of irradiation to the temporal bone without a significant risk of injury to these structures. An overall 10% incidence of bone necrosis can be expected after administration of 60 to 65 Gy.

Reconstruction may be pursued after initial surgery, which may utilize autologous grafts or prosthetics. While radiation is known to cause fibrosis and bone demineralization, there has been no association found between adjuvant radiation therapy and osseointegrated implant complications.[96-98] Based on a large meta-analysis by Huang et al,[99] the dose delivered to the cochlea, radiotherapy technique (three- dimensional conformation), tumor type, concurrent chemotherapy, and the age of the radiotherapy population are all linked to radiation-induced ototoxicity.

After external ear lesions are treated with interstitial irradiation, there is a 4% incidence of late cutaneous and cartilage necrosis. Risk of necrosis increases for lesions larger than 4 cm.[51] Most patients can experience acute grade 2 and 3 skin toxicities with postoperative IMRT.[62] Following definitive or postoperative radiation, there is a 30% incidence of xerostomia.[58]

CHAPTER 46

Locally Advanced Squamous Carcinoma of the Head and Neck

Jessica W. Lee, Jessica L. Geiger, and David M. Brizel

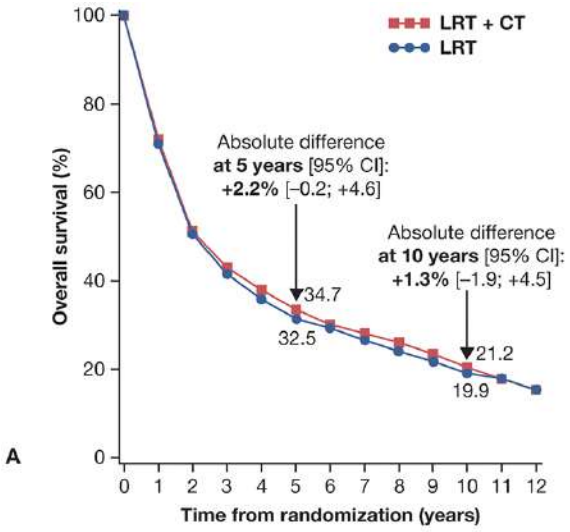
In the United States, an estimated 66,920 patients were diagnosed with head and neck cancer in 2023, with over 900,000 new diagnoses worldwide.[1,2] Locally advanced, nonmetastatic disease comprises about 60% of this population. Locoregional failure remains the predominant recurrence pattern, and most fatalities result from uncontrolled locoregional disease.

Historically, radiation therapy (RT) alone was the standard nonsurgical therapy for locally advanced disease, with dose fractionation evolving from daily treatment to hyperfractionation and accelerated fractionation regimens.[3-6] A meta-analysis of 11,423 patients on 33 trials from 1970 to 2010 (Meta-analysis of Radiotherapy in squamous cell Carcinomas of Head and neck) found that altered fractionation resulted in a 3.1% and 1.2% absolute improvement in overall survival (OS) at 5 and 10 years, respectively.[7,8] Nonetheless, even the most effective RT-alone regimens result in local control rates of 50% to 70% and disease-free survival (DFS) rates of 30% to 40%.

This circumstance stimulated the investigation of treatments combining chemotherapy and radiation (CRT). Landmark trials from the Veterans Affairs Laryngeal Cancer Study Group and the European Organization for the Research and Treatment of Cancer (EORTC) investigated larynx preservation with sequential chemotherapy and RT in locally advanced larynx and hypopharynx cancer, respectively. Both randomized patients to induction cisplatin (CDDP) and 5-fluorouracil (5-FU) followed by RT versus laryngectomy and postoperative RT and demonstrated that larynx preservation could be achieved without compromising OS.[9,10]

Subsequently, numerous randomized trials have demonstrated the superiority of CRT over RT alone in locally advanced, nonmetastatic head

and neck squamous cell carcinoma (HNSCC). A meta-analysis of 19,805 patients from 107 trials conducted from 1965 to 2016 (Meta-Analysis of Chemotherapy on Head and Neck Cancer [MACH-NC]) demonstrated that the addition of concurrent chemotherapy to RT resulted in a 6.5% and 3.6% absolute improvement in OS at 5 and 10 years, respectively[11,12] (Figure 46.1B). This benefit was greatest with the use of platinum-containing chemotherapy and predominantly attributable to improved locoregional control, with no significant difference seen in distant metastases and benefits decreasing with increasing patient age (Figure 46.2).



Number of deaths/person-years

	Years 0–2	Years 2–5	Years 5–10	Years 10+
LRT + CT	1657/4981	492/3573	150/1560	28/206

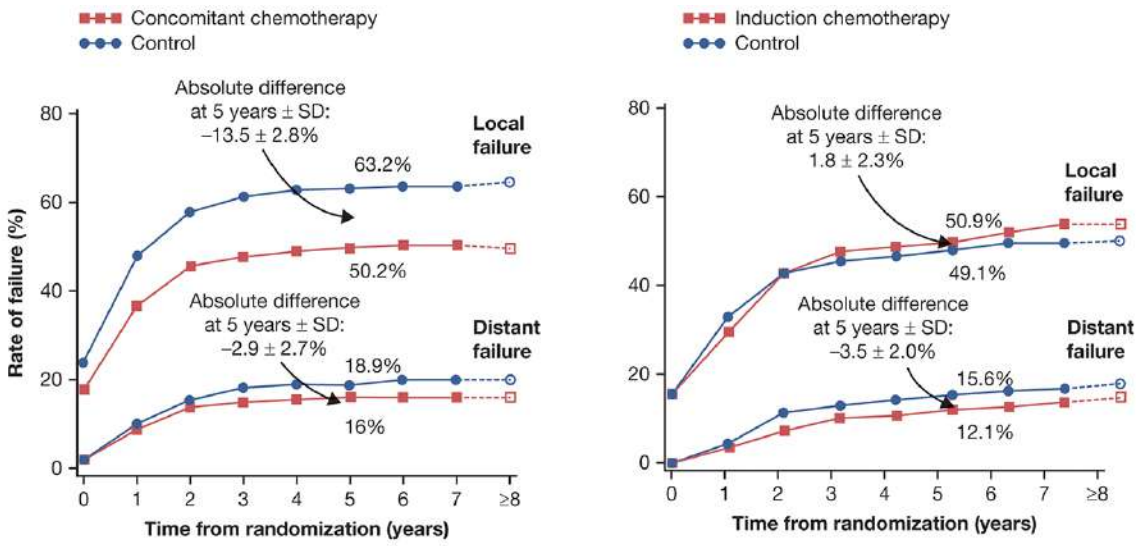
FIGURE 46.1 Data from the Meta-Analysis of Chemotherapy in Head and Neck Cancer trial demonstrating that adding concurrent chemotherapy to radiotherapy provides a significant improvement in survival while induction and adjuvant chemotherapy do not. A. Induction chemotherapy. B. Concurrent chemotherapy. C. Adjuvant chemotherapy. CT, chemotherapy; LRT, local radiotherapy.



Local failure and distant failure/person-years by period

	Years 0–2	Years 3–5	Years ≥6	Years 0–2	Years 3–5	Years ≥6
Local failure						
Control	493/1,648	22/406	2/165	497/2,627	38/1,073	10/684
Chemotherapy	373/1,837	20/603	1/240	519/2,749	58/1,142	22/751
Distant failure						
Control	82/1,756	8/416	1/166	90/2,788	18/1,116	8/711
Chemotherapy	83/1,915	6/616	0/241	62/2,929	23/1,204	9/773

FIGURE 46.2 Data from the Meta-Analysis of Chemotherapy in Head and Neck Cancer trial illustrating that the major therapeutic benefit of platinum-based chemotherapy results from an improvement in locoregional disease control when the drugs are given concurrently with radiotherapy. No significant improvement occurs with induction chemotherapy followed by radiotherapy.

The benefit of combined chemotherapy and RT is chiefly seen with concurrent delivery, which represents a biologically attractive approach as some chemotherapeutic agents may both radiosensitize cells and provide additive cytotoxicity. Direct comparisons of concurrent CRT versus induction chemotherapy with RT alone are few, but confirm that concurrent is superior.[13-15] Radiation Therapy Oncology Group (RTOG) 9111 was a three-arm trial of induction CDDP followed by RT alone versus concurrent CRT with CDDP versus RT alone in larynx cancer. Concurrent therapy constituted the most effective means of larynx preservation and provided the best disease control, albeit without a statistically significant survival benefit. The MACH-NC meta-analysis of this trial and others found that concurrent versus induction chemotherapy was associated with a 5-year absolute OS benefit of 6.2%, and generally, the addition of induction or

adjuvant chemotherapy to RT conferred no survival benefit[12] (see Figure 46.1).

Certain issues must be considered when evaluating randomized trials of CRT for advanced head and neck cancer. The first consideration relates to the effectiveness of the RT-alone control arm. Specifically, does it represent optimal single-modality treatment? If the CRT regimen is more effective than RT alone but the RT is suboptimal, then it is difficult to accurately gauge whether the combined modality regimen represents a true improvement in therapy. The second consideration concerns the toxicity of CRT itself. Typically, both acute and late toxicities from CRT are greater than from RT alone.[16-18]

Acute mucositis constitutes the most significant impediment to the timely delivery of concurrent CRT. Supportive care for mucositis and acute xerostomia, dysgeusia, and dermatitis includes oral rinses, saliva substitutes, topical moisturizers, and wound and pain management. Support for swallowing function from speech-language pathologists, as preventive therapy and after treatment, is a necessity. Still, up to about one-third of patients require enteral feeding tubes and hospitalization.[19-21] As prolongation of total treatment time adversely affects the success of RT, a major challenge has been developing regimens that integrate chemotherapy and RT but do not excessively increase total treatment time.[22-24] A thorough understanding of toxicity is mandatory, as avoidance of the functional morbidity associated with surgery in advanced head and neck cancer is one of the main reasons for using concurrent CRT in the first place.

Apart from supportive care, strategies for toxicity reduction include pharmacologic intervention with radioprotectors, reducing dose to normal tissues, and de-intensifying therapy by reducing target doses or volumes. Previously, a phase III trial published in 2000 demonstrated that administering the intravenous radioprotector amifostine prior to daily head and neck RT reduced acute and late xerostomia without compromising disease control or survival.[25] Subsequently, other randomized trials demonstrated that compared to older three-dimensional conformal RT (3D-CRT), intensity- modulated radiation therapy (IMRT) improved dosimetric sparing of parotid glands and reduced acute and late xerostomia, also without compromising clinical outcomes.[26] More recently, proton therapy has shown promising improvements in dosimetric normal tissue sparing and

toxicity in several retrospective studies in HNSCC.[27,28] Ongoing phase II trials are comparing protons to IMRT in unilateral neck RT (NCT02923570), oropharyngeal cancer (NCT01893307), and nasopharyngeal cancer (NPC) (NCT04528394), among others.

Late sequelae following RT include xerostomia, dysphagia, mandibular osteoradionecrosis, trismus, hearing loss, hypothyroidism, and accelerated carotid artery stenosis.[17,19,29] Prophylactic management with dental evaluation and thyroid labs following neck irradiation is standard of care, and the role of ultrasound screening for carotid artery stenosis has also been investigated.[30-32] Other therapeutic interventions include cholinergic agents to stimulate saliva flow, swallowing rehabilitation, and hyperbaric oxygen therapy for late tissue necrosis.[29] Aggressive lymphedema management by certified therapists is often required.[33] Patient-reported health-related quality of life (QoL) is also worse with concurrent chemotherapy but improved with IMRT compared to 3D-CRT. Health-related QoL often but not always recovers to baseline within 1 year, with certain symptoms such as xerostomia prone to persisting.[34] The severity and complexity of acute and late toxicities associated with head and neck CRT highlight the critical role of oncologists, nurses, dietitians, speech and physical therapists, social workers, and other multidisciplinary team members in optimizing patient care and QoL.

HISTORICAL DEVELOPMENT OF RADIATION AND CONCURRENT CHEMOTHERAPY

CRT may be administered in synchronous or alternating schemes. Synchronous administration results in the delivery of RT and chemotherapy on the same day. Typically, chemotherapy will be given for 1 day or more at the initiation of RT and then repeated in the same manner several weeks later. Alternating regimens usually sandwich RT and chemotherapy around one another. Radiation and drugs are, therefore, not necessarily, given on the same days. In such a scheme, chemotherapy would be given during the first week of treatment with RT following in subsequent week(s) before chemotherapy is given again.

Synchronous Radiation and Single-Agent Chemotherapy

Synchronous treatment is completed more quickly than alternating treatment. It is, therefore, preferable from a theoretical standpoint in terms of addressing the issue of accelerated repopulation, albeit at the expense of increased acute side effects. Early randomized trials used conventionally fractionated RT with single-agent chemotherapy. These studies are summarized in Table 46.1. The experimental arms of RTOG 9003,[3] EORTC 22791,[5] and DAHANCA 6-7[6] are included to provide a basis for comparison with optimal regimens of RT alone.

TABLE 46.1 RANDOMIZED TRIALS OF ONCE-DAILY IRRADIATION AND CONCURRENT CHEMOTHERAPY IN ADVANCED HEAD AND NECK CANCER

Institution	*N*	Radiotherapy	Chemotherapy	Outcome RT vs RT + CCT	Comments

5-FU, 5-fluorouracil; Bleo, bleomycin; CDDP, cisplatin; CI, continuous infusion; DFS, disease-free survival; EORTC, European Organization for the Research and Treatment of Cancer; LC, local control; MMC, mitomycin-C; MTX, methotrexate; NCI, National Cancer Institute; NCOG, Northern California Oncology Group; NICR, National Institute for Cancer Research.; NS, not significant; RT/CCT, radiotherapy and concurrent chemotherapy; RTOG, Radiation Therapy Oncology Group; S, survival.

Both the Northern California Oncology Group (NCOG) and the EORTC tested radiation and synchronous bleomycin against RT alone.[35,36] Acute toxicity was worse in the combined modality arm in both trials, but the outcomes were quite different with respect to efficacy. The EORTC trial showed no improvement in DFS or OS, while the RT/bleomycin combination in the NCOG program led to a statistically significant doubling of locoregional control and DFS, as well as a near-significant improvement in OS from 24% to 43%.

Differences in study design and execution may explain the discrepancy between outcomes in the EORTC and NCOG trials. Fractionation was similar in the two studies, but patients in the EORTC trial received 15 mg of bleomycin twice weekly during the first 5 weeks of RT for a total dose of 150 mg, whereas the NCOG patients received 5 mg twice weekly for a total dose of 70 mg. Acute mucosal and skin toxicity was worse in the RT/bleomycin arm in both trials. Toxicity significantly prolonged the RT delivery time in 30% of the combined modality patients in the EORTC trial, but not in any of the RT-alone patients. This prolongation of treatment time and associated tumor repopulation in such a large proportion of patients may have negated any benefit accrued from the use of concurrent therapy. There were no differences in overall treatment time between the two treatment arms in the NCOG trial. An important lesson from these two studies is that the dose administration schedules of concurrent chemotherapy must be carefully designed so that toxicity does not adversely affect overall treatment compliance.

The Christie Hospital in Great Britain evaluated RT and 100 mg/m^2 of single-agent methotrexate (MTX) given at the commencement of and after 2 weeks of a 3-week course of treatment.[37] Most of the 313 patients in this protocol received 50 to 55 Gy in 15 or 16 fractions. Mucositis was significantly greater in the patients receiving MTX, but there was no difference in long-term toxicity. The addition of MTX increased local control from 50% to 70% (P = .02) and OS from 37% to 47% (P = .07). The greatest benefit was seen in patients with oropharyngeal primary tumors who constituted one-third of the study population. Local control with RT/MTX was 78% versus 38% with RT alone (P = .002) in this patient subset. OS was 25% with RT alone and 50% with RT/MTX (P = .009). Unfortunately, the data from this trial are not generally applicable to current clinical practice because of the large radiation fraction sizes that were used.

5-FU has been used in conjunction with RT more frequently than any other chemotherapeutic agent. Lo et al[38] reported the first study to show a significant improvement in local control and OS with the addition of bolus 5-FU to RT in oral cavity SCC. Browman et al[39] compared RT and continuous infusion 5-FU against RT alone in a placebo-controlled randomized trial sponsored by the National Cancer Institute of Canada. All 175 patients received 66 Gy in 2-Gy fractions. 5-FU was given at 1,200

mg/m^2/d for the first 3 days of the first and third weeks of irradiation. Confluent mucositis was more frequent in the 5-FU arm than in the placebo arm (32% vs 11%; P = .001), as was weight loss >15% from pretreatment baseline (41% vs 11%; P < .0001). This increased acute toxicity did not prolong the delivery of RT in the RT/5-FU arm relative to the RT/placebo arm. Two-year DFS and OS were 30% and 50% for RT/placebo patients and 50% and 63% for RT/5-FU patients (P = .06 and .08), respectively.

The relative radioresistance of hypoxic cells in vitro is well understood.[40] Clinically, the existence of hypoxia in both head and neck primary tumors and metastatic lymph nodes has been described, and its adverse impact on the prognosis of patients treated with RT has been demonstrated.[41,42] Investigators from Yale University designed their treatment strategy around this principle. They treated 195 patients in two randomized trials with mitomycin-C (MMC). This agent is predominantly metabolized in and preferentially cytotoxic to hypoxic cells. The Yale treatment program consisted of 68 Gy ± MMC on days 1 and 43 of RT. Local control was improved with the addition of MMC from 54% to 76% (P = .003). OS improved from 42% to 48%, but this was not statistically significant. Most patients in these trials received adjuvant postoperative or preoperative irradiation, however. Only 74 (38%) received definitive, primary RT, and the benefit from the addition of MMC in this subset is unclear.[43]

Synchronous Radiation and Multiagent Chemotherapy

CDDP is a radiosensitizing chemotherapy frequently combined with radiation, too.[44] The combination of CDDP and 5-FU is also one of the most active cytotoxic drug combinations against HNSCC. Consequently, investigators have incorporated both into a variety of concurrent treatment strategies.

A prospective multicenter trial from the University of Munich randomized 298 patients with unresectable stages III to IV HNSCC to twice-daily (bid) RT with or without concurrent CDDP, 5-FU, and leucovorin.[45] RT was three cycles of 23.4 Gy at 1.8 Gy bid to 70.2 Gy total, and treatment breaks were scheduled on days 12 to 21 and 34 to 43. Chemotherapy was three cycles of CDDP 60 mg/m^2, bolus 5-FU 350 mg/m^2 then continuous infusion 350 mg/m^2/d × 4 days, and bolus leucovorin 50

mg/m^2 then continuous infusion 100 mg/m^2/d × 4 days on days 2, 22, and 44 with RT. CRT doubled both 3-year local control (36% vs 17%; $P < .004$) and OS (48% vs 24%; $P < .0003$). CRT also increased acute grade 3 to 4 mucositis (38% vs 16%; $P < .001$), though no difference in serious late toxicity was seen.

A phase III trial from the Cleveland Clinic randomized 100 patients with stages III to IV nonnasopharyngeal HNSCC to RT alone (66-72 Gy in 1.8-2 Gy/fraction) versus CRT with concurrent CDDP (20 mg/m^2/d × 4 days) and continuous infusion 5-FU (1,000 mg/m^2/d × 4 days) on weeks 1 and 4.[46] The main objective of this study was primary site organ preservation, with response assessment after ~55 Gy and surgical salvage pursued after 3 to 6 weeks recovery in patients with persistent or progressive disease. Five-year OS with primary site preservation was increased with CRT versus RT (42% vs 34%; $P = .004$), although there was no significant difference in OS. CRT versus RT was also associated with increased acute toxicity, particularly weight loss and feeding tube requirement (58% vs 32%; $P < .01$).

MMC and 5-FU were used in a trial from Princess Margaret Hospital of 209 patients with locally advanced larynx or hypopharynx SCC, which randomized patients to RT alone or split-course RT with concurrent chemotherapy.[47] RT alone was 2.5 Gy/d to 50 Gy in 28 days, and split-course RT included a planned 4-week break after 25 Gy, resulting in the same dose over a total time of 56 days. Two cycles of bolus MMC (10 mg/m^2) and continuous infusion 5-FU (1,000 mg/m^2/d × 4 days) were given on days 1 and 43. The intent of the treatment break was to maintain comparable levels of acute toxicity in the two treatment arms. Acute toxicity was, in fact, equivalent in the two groups. Unfortunately, however, there was no difference in 4-year local control (~40%) or OS (~40%).

The Princess Margaret trial raises an important question: Can one quantify the contribution provided by concurrent chemotherapy in terms of the delivery of an equivalent dose of irradiation? Approximately 0.6 Gy/d is necessary to compensate for the tumor repopulation that transpires with each day of prolongation of standard course RT.[23] Thus, the total dose in the Princess Margaret Hospital CRT arm would have needed 67 Gy [(2.5 Gy × 20) + (0.6 Gy/d × 28 days)] to be isoeffective with the 50 Gy continuous course RT-alone arm. The equivalent efficacy of the two treatments in this trial suggests that chemotherapy compensated for the tumor repopulation

that occurred during the treatment break. Thus, one could argue that the chemotherapy was equivalent to approximately 17 Gy of additional irradiation. There can be no doubt as to the inferiority of the split-course fractionation scheme in this trial had it been delivered without chemotherapy and compared directly to the continuous course RT regimen. Conversely, if CRT had been given with continuous course RT, it would quite probably have been more efficacious than the RT-alone regimen.

A Spanish three-arm randomized trial (N = 859) provides additional information that is pertinent to the estimation of the radiotherapeutic dose equivalent provided by the delivery of concurrent chemotherapy.[48] Patients were assigned to receive one of the following regimens:

(a) 2 Gy/d to 60 Gy/42 days,

(b) 1.1 Gy bid to 70.4 Gy/44 days, or

(c) 2 Gy/d to 60 Gy/42 days with concurrent bolus 5-FU 250 mg/m^2 given every other day.

Progression-free survival (PFS) and OS were significantly worse in arm A as compared with arms B and C, as one would expect. Arms B and C were equally efficacious. Not accounting for the different fractionation in arms B and C and the unconventional administration of chemotherapy, it is still clear that the addition of 5-FU was comparable to dose escalation of approximately 10 Gy. A modeling analysis of phase III trials comparing CRT with RT only suggests that concurrent chemotherapy provides the equivalent of a 10- to 12-Gy dose escalation.[49]

Neither the Princess Margaret nor the Spanish trial delivered maximally intensive RT in their respective control arms. The rationale for treatment intensification with the addition of concurrent chemotherapy as opposed to simple RT dose escalation is weak in such a context. The situation may be dramatically different, however, when the RT-alone arm is maximally intensive such as in RTOG 9003 or EORTC 22791. Dose escalations of 10 to 12 Gy are not possible with accelerated regimens that already deliver 72 Gy in 6 weeks or with hyperfractionated regimens delivering 79 Gy in 7 weeks (see section “Radiation Fractionation Scheme”). Concurrent chemotherapy, however, can be added to modified fractionation regimens ≥70 Gy.

Alternating Radiotherapy and Chemotherapy

Alternating therapy produces less acute mucosal toxicity than synchronous therapy but may prolong the overall treatment time by several weeks. Although longer treatment times adversely affect efficacy in programs of standard RT alone due to tumor repopulation, the significance of overall treatment time (for RT) in a continuous course of alternating RT and chemotherapy is controversial. Some investigators have suggested that the usual time-dose relationships do not apply.[50]

The National Institute for Cancer Research in Italy conducted a phase III trial comparing RT with alternating RT and chemotherapy in 157 patients with unresectable HNSCC.[51,52] The RT arm was designed to give 70 Gy/7 weeks via standard fractionation. The combined therapy arm scheduled chemotherapy on weeks 1, 4, 7, and 10 and radiation (60 Gy) on weeks 2 to 3, 5 to 6, and 8 to 9. Each 2-week cycle of radiation consisted of 20 Gy/10 fractions. Each cycle of chemotherapy included 5 days of bolus CDDP (20 mg/m^2/d) and bolus 5-FU (200 mg/m^2/day). The incidence of grades 3 to 4 mucositis (18%-19%) was the same in both treatment groups. However, RT treatment delays occurred more often in the RT-alone patients: 32% with a 1-week prolongation and 25% with a ≥2-week prolongation. The corresponding delays in the combined modality treatment group were 11% and 15%. The median dose of RT delivered in the combined modality treatment group matched the planned dose of 60 Gy, but it was only 62 Gy in the RT-alone group. Five-year actuarial survival was significantly better in the combined modality treatment patients (24% vs 10%; P = .01), as were DFS (21% vs 9%; P = .008) and local control (64% vs 32%; P = .04).

Given the similar levels of acute toxicity, it is unclear why treatment times were prolonged and total doses reduced so extensively in the RT-only patients. Better protocol compliance in the control arm might well have changed the outcome of this trial. There are no other randomized trials of RT and alternating chemotherapy. Further randomized trials of alternating therapy will be necessary to determine its true value because the deficiencies of the National Institute for Cancer Research study prevent definitive conclusions.

Despite its drawbacks, the Italian study, like the Princess Margaret Hospital trial, strongly reinforces the idea that in some settings,

chemotherapy counteracts tumor repopulation during treatment. The total RT treatment time was prolonged in the combined modality arms in both studies. The fundamental difference between these two trials is that patients received no treatment during the RT break in the Princess Margaret Hospital trial and the patients in the Italian trial received chemotherapy during each interruption of RT.

CONTEMPORARY RANDOMIZED TRIALS OF RADIOTHERAPY AND CONCURRENT CHEMOTHERAPY

Curative Intent Treatment

Based on promising phase I to II trials of concurrent CRT, the French cooperative group initiated GORTEC 94-01 to evaluate conventionally fractionated RT with or without concurrent chemotherapy. This phase III trial randomized 226 patients with stages III to IV oropharyngeal cancer to RT alone (70 Gy in 2 Gy/fraction) versus CRT with concurrent carboplatin (70 mg/m^2/d × 4 days) and continuous infusion 5-FU (600 mg/m^2/d × 4 days) on weeks 1, 4, and 7.[18,53] CRT versus RT was associated with improved 5-year locoregional control (48% vs 25%; P = .002), DFS (27% vs 15%; P = .01), and OS (22% vs 16%; P = .05). Improved efficacy with CRT was accompanied by a significant increase in acute grades 3 to 4 mucositis from 39% to 71% (P = .005) and hematologic toxicity, with one treatment-related death from febrile neutropenia and sepsis. Grades 3 to 4 late toxicity numerically higher with CRT versus RT, though not statistically significant (56% vs 30%; P = .12).

An Intergroup phase III trial also demonstrated the efficacy of conventionally fractionated RT with concurrent platinum chemotherapy, although this study closed early due to slow accrual, with 271 of 362 planned patients analyzable.[54] Patients with unresectable oral cavity, oropharynx, larynx, and hypopharynx primaries were randomized to three arms, all of which received a total of 70 Gy in 2 Gy/fraction daily: RT alone versus CRT with concurrent CDDP (100 mg/m^2 on days 1, 22, and 42) versus split-course CRT with a break after 30 Gy to allow for potential resection and three cycles of CDDP (75 mg/m^2) and continuous infusion 5-FU (1,000 mg/m^2/d × 4 days) every 4 weeks. Compared to RT alone, CRT with daily RT and CDDP had improved 3-year OS (37% vs 23%; P = .014),

while split-course CRT did not (27%). Grade 3 or higher toxicity was higher with daily CRT versus RT alone (89% vs 52%; $P < .0001$) and with split-course CRT versus RT alone (77% vs 52%; $P < .001$).

In locally advanced NPC, the Intergroup 0099 trial demonstrated a survival benefit with combined concurrent and adjuvant chemotherapy compared to RT alone.[55] One hundred and ninety-three patients were randomized to 70 Gy in 1.8 to 2 Gy/fraction daily RT alone versus the same RT with concurrent CDDP (100 mg/m^2 on days 1, 22, and 42) and three cycles of adjuvant CDDP (80 mg/m^2) and continuous infusion 5-FU (1,000 mg/m^2/d × 4 days) every 4 weeks. The trial was terminated early when an interim analysis demonstrated improved OS with the combined modality regimen. Concurrent and adjuvant CRT versus RT alone was associated with improved 3-year PFS (69% vs 24%; $P < .001$) and 3-year OS (78% vs 47%; $P = .005$). CRT was also associated with increased grades 3 to 4 leukopenia and vomiting ($P < .05$), and 73% of CRT patients completed treatment as planned, compared to 91% of the RT-alone patients. Table 46.1 summarizes the data from the trials of conventionally fractionated irradiation and concurrent chemotherapy.

One must not only ask whether CRT is more effective than conventionally fractionated RT but also whether it is superior to hyperfractionated or accelerated fractionation regimens, as these represent the most efficacious single-modality treatment strategies. A prospective randomized trial from Duke University was one of the first to provide insight into this issue.[56] Patients with locally advanced HNSCC were randomized to hyperfractionated irradiation alone versus split-course hyperfractionation with concurrent CDDP and 5-FU. Patients in the RT-alone arm received 1.25 Gy bid continuous course to 75 Gy in 6 weeks, whereas patients on the CRT arm received 1.25 Gy bid split course to 70 Gy in 7 weeks. Chemotherapy was given during weeks 1 and 6 of irradiation (CDDP 12 mg/m^2/d × 5 days and continuous infusion 5-FU 600 mg/m^2/d × 5 days).

The time-dose aspects of the RT in the combined modality arm are similar to those of the previously discussed trials. The time-dose characteristics of the RT in the control arm were similar to certain aspects of both the concurrent boost arm (decreased treatment time) and the hyperfractionation arm (increased total dose) of RTOG 9003. Most

importantly, these characteristics made the RT more intensive in the control arm than in the experimental CRT arm. This study design was intentional because the primary objective of the trial was to determine whether a lower dose of RT with concurrent chemotherapy would be superior to maximally intensive/effective RT alone. This trial enrolled 116 patients, with 54% presenting with unresectable disease and approximately 46% of primaries located in the oropharynx. Locoregional control was 70% versus 44% (P = .006), favoring the combined modality patients. An unpublished update of the 5-year survival revealed superiority in the combined modality patients (42% vs 27%; P = .04) (Figure 46.3). Grade 3 mucositis was seen in approximately 75% of the patients in both arms, the main difference being that the mean time to resolution of mucositis was 50% longer in the patients receiving radiation and concurrent chemotherapy (6 vs 4 weeks).

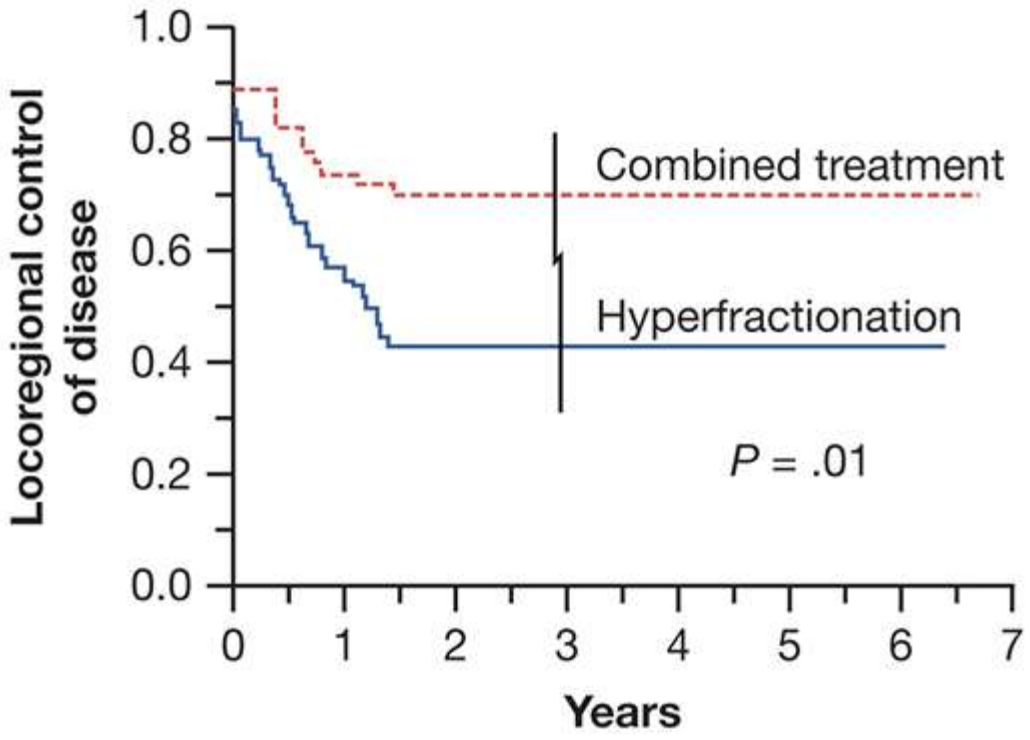

FIGURE 46.3 Five-year locoregional control in the Duke University randomized trial of continuous course accelerated hyperfractionation (44%) versus split-course accelerated hyperfractionation and concurrent cisplatin/5-fluorouracil (P = .01). Extended follow-up has demonstrated that the survival benefit of combined modality treatment is also statistically significant.

The German Cancer Society 95-06 trial also confirmed that CRT is superior to maximally intensive single-modality irradiation.[16] Three hundred and eighty-four patients, 93% of whom had either stage III or IV oropharyngeal or hypopharyngeal primaries, were enrolled. As in the Duke trial, the total dose of RT delivered in the CRT arm was lower than that in the RT control arm. RT patients received 77.6 Gy in 6 weeks (14 Gy at 2 Gy/fraction daily, then 63.6 Gy at 1.4 Gy bid), and CRT patients received 70.6 Gy in 6 weeks (30 Gy at 2 Gy/fraction daily, then 40.6 Gy at 1.4 Gy bid). Chemotherapy consisted of MXC (10 mg/m^2) on days 5 and 35 and 5-FU given as a single bolus of 350 mg/m^2 and a 5-day continuous infusion of 600 mg/m^2/d. Two-year survival was significantly better in the combined modality arm (54% vs 45%; P = .05), as was locoregional control (61% vs 45%; P = .001). Acute and chronic toxicity were equivalent in the two treatment populations.

Jeremic et al evaluated hyperfractionated irradiation (1.1 Gy bid to 77 Gy) with or without concurrent low-dose daily CDDP (6 mg/m^2) in stage III/IV patients.[57] This trial enrolled 130 patients, with approximately one-third of the primaries located in the oropharynx, 59% with T3-T4 primaries, and 80% with nodal involvement. Five-year locoregional control (50% vs 36%; P = .04), PFS (46% vs 25%; P = .007), and OS (46% vs 25%; P = .007) (Figure 46.4) were all significantly improved with the addition of concurrent chemotherapy. Of note, the distant metastasis-free survival was also improved in the concurrent therapy patients (86% vs 57%; P = .01).

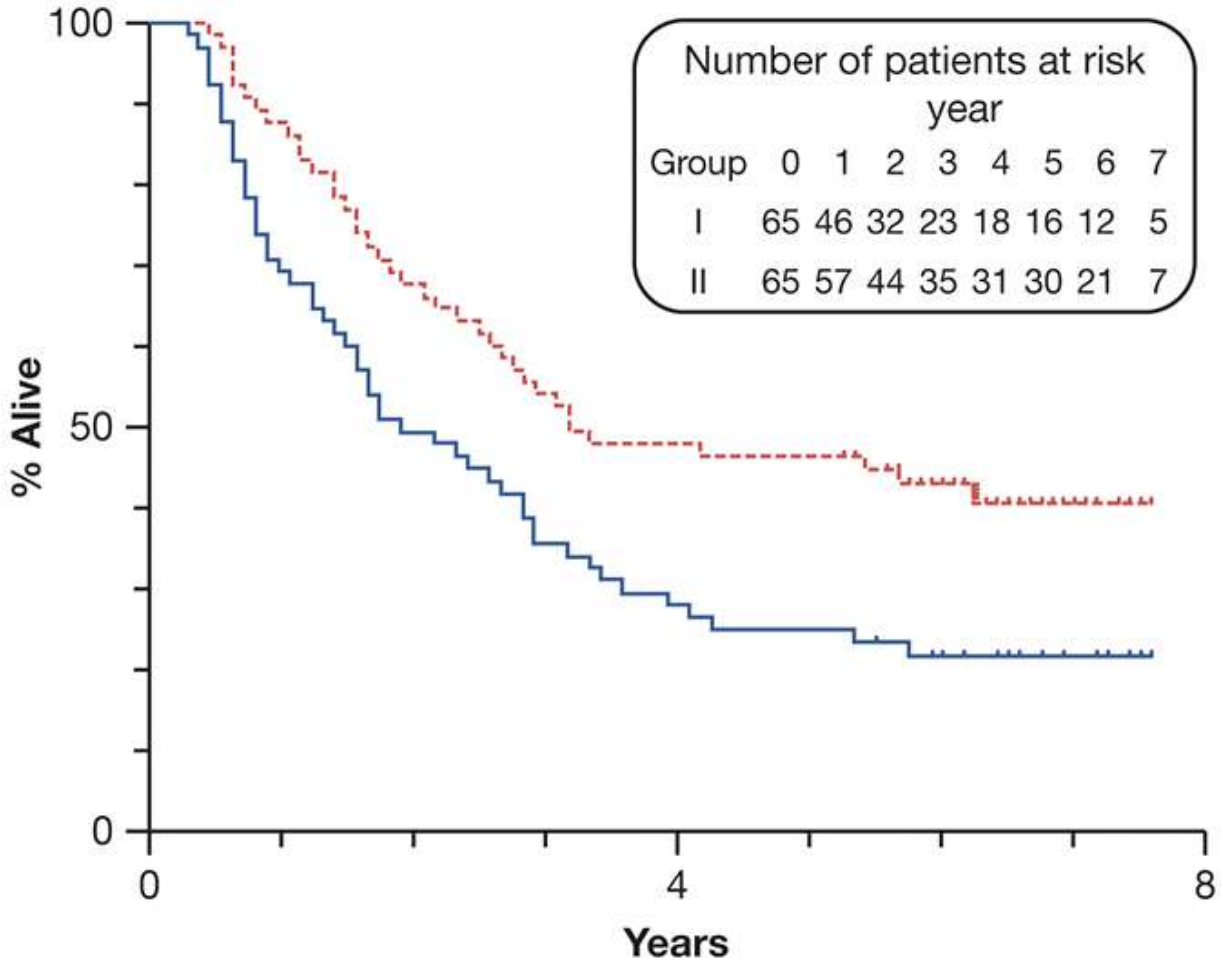

FIGURE 46.4 Five-year survival in the Yugoslavian trial of hyperfractionated irradiation alone (25%) or with daily low-dose concurrent cisplatin (46%) (P = .007).

A French cooperative group (FNLCC-GORTEC) tested a related concept in 163 patients with technically unresectable carcinomas of the oropharynx and hypopharynx.[58] RT was administered at 1.2 Gy bid to a total dose of 80.4 Gy/46 days to oropharyngeal primary tumors and 75.6 Gy/44 days to hypopharyngeal primary tumors. The experimental arm received the same RT and concurrent CDDP (100 mg/m^2) on days 1, 22, and 43 of RT. Three 5-day cycles of continuous infusion 5-FU were also administered. The first cycle was 750 mg/m^2/d and the second and third cycles were 430 mg/m^2/d. Three-year DFS favored the concurrent chemoradiation arm (48% vs 25%; P = .002), as did OS (38% vs 20%; P = .04). Post hoc subset analyses demonstrated that the larger (and statistically significant) benefit was confined to the patients with oropharyngeal carcinomas. However, the trial

was not designed to compare treatment efficacy in these two different primary sites of origin.

A three-arm randomized trial from the University of Vienna compared conventionally fractionated RT (70 Gy in 2 Gy/fraction daily) against continuous hyperfractionated accelerated RT with and without MXC (Vienna-Continuous Hyperfractionated Accelerated Radiation Therapy [V-CHART] + MMC and V-CHART, respectively).[59] RT was given as an initial 2.5-Gy fraction followed by 1.65 Gy bid to a total dose of 55.3 Gy in 17 days. MMC was given as a 20 mg/m^2 bolus on day 5 of RT. Of the 239 patients enrolled, 85% had T3/4 primary tumors, and 79% had nodal involvement.

Three-year actuarial locoregional control was 48% for V-CHART + MMC versus 32% for V-CHART and 31% for conventional fractionation (CF) (P = .05 and .03, respectively). Survival including death from all causes was also improved to 41% in the V-CHART + MMC arm as compared with 31% for V-CHART and 24% for CF (P = .03).

The incidence of confluent mucositis was 90% in both experimental arms as compared with 33% in the CF arm. The median time to complete resolution of mucositis was 6 to 7 weeks in all three arms. Grades 3 to 4 hematologic toxicity, primarily thrombocytopenia, developed in 20% of the V-CHART + MMC patients. Table 46.2 summarizes the data from the trials that used modified fractionation and concurrent chemotherapy and includes the RTOG 9003 and EORTC 22791 data as a point of reference for optimally delivered RT alone.

Adjuvant Postoperative Irradiation

The role of chemotherapy for patients receiving primary resection and postoperative irradiation has been studied less extensively than in the definitive irradiation setting. The National Cancer Institute Head and Neck Contracts Program[60] conducted a three-arm trial that evaluated the addition of one cycle of preoperative CDDP and bleomycin with or without six cycles of sequential CDDP (80 mg/m^2) maintenance chemotherapy after surgery and postoperative irradiation. The control arm consisted of surgery and postoperative irradiation alone. This trial enrolled 443 patients and demonstrated no benefit with respect to locoregional control or survival from the addition of chemotherapy. Nearly half of the patients who were randomized to receive maintenance chemotherapy never received it. Despite this flaw in study execution, the incidence of distant metastases as the site of first relapse was 9% in the patients assigned to maintenance chemotherapy as opposed to 19% in those who were not (P = .02).

Intergroup Study 0034 readdressed the issue of postoperative chemotherapy in a trial that randomized patients after surgery to three 21-day cycles of sequential CDDP (100 mg/m^2) and infusion 5-FU (1,000 mg/m^2/d × 5 days), followed by 50 to 60 Gy versus 50 to 60 Gy alone with no chemotherapy.[61] Again, there was no significant improvement in locoregional control or OS associated with the use of chemotherapy, but the incidence of distant metastases was reduced from 30% to 20% (P = .02).

In contrast to the use of sequential postoperative RT and chemotherapy, EORTC 22931 enrolled 334 patients with pT3-T4 disease (except pT3N0 larynx) with negative margins, pT1-T2 with pN2-N3 disease or risk factors

(extranodal spread, positive margins, perineural involvement, or vascular tumor embolism), or oral cavity or oropharyngeal tumors with level IV-V nodes. Patients were randomized to postoperative RT alone 66 Gy in 2 Gy/fraction daily versus the same RT with CDDP (100 mg/m^2 on days 1, 22, and 43).[62] Two-thirds of patients in the combined modality arm received all three cycles of chemotherapy. With a median follow-up of 5 years, chemotherapy significantly increased 5-year PFS from 36% to 47% (P = .04) and 5-year OS from 40% to 53% (P = .02). Acute grade 3 or high mucositis was significantly higher in the concurrent treatment arm (41% vs 21%; P = .001).

RTOG 9501 enrolled 459 patients with postoperative oral cavity, oropharynx, larynx, or hypopharynx SCC with ≥2 nodes involved, extracapsular extension (ECE), or positive margins.[63,64] Patients were randomized to postoperative RT alone 60 Gy in 2 Gy/fraction daily with or without a 6 Gy boost versus the same RT with the same CDDP used on EORTC 22931. Sixty-one percent of patients in the concurrent therapy arm received all three cycles of chemotherapy. With a median follow-up of 4 years, chemotherapy significant improved 2-year local-regional control from 72% to 82% (P = .01), with only eight local or regional recurrences occurring beyond the 2-year point. Initially, DFS also favored concurrent chemotherapy, although on long-term 10-year follow-up, RT versus CRT showed no significant difference in local-regional failure DFS (28.8% vs 22.3%; P = .1), DFS (19.1% vs 20.1%; P = .25), or OS (27.0% vs 29.1%; P = .31). Acute toxicity grade 3 or higher toxicity was increased with chemotherapy, with RT versus CRT (34% vs 77%; P < .001), but late toxicity was similar (17% vs 21%; P = .29).

A comparative analysis of the pooled data from these two studies ECE and/or microscopically involved surgical margins were the only risk factors for which the addition of chemotherapy to postoperative radiation was significant.[65] Patients with ≥2 nodes without ECE as their only risk factor did not benefit from the addition of chemotherapy. A trend in benefit to the addition of chemotherapy was seen in patients with stage III to IV diseases, perineural invasion (PNI), lymphovascular space invasion (LVI), and oral cavity or oropharyngeal tumors with level IV-V nodes. As such, concurrent chemoradiotherapy remains the standard of care for adjuvant therapy in patients with locally advanced HNSCC and the presence of ECE and/or

positive surgical margins. While long-term follow-up of RTOG 9501 found no significant outcome differences in analysis of all randomized patients, a subgroup analysis of patients with positive surgical margins and/or ECE demonstrated improved local-regional control and DFS with the addition of chemotherapy, further supporting these findings as poor risk factors in this disease.[64] Despite these recommendations, a retrospective analysis of the National Cancer Database identified a subset of patients with negative surgical margins and no ECE who still received adjuvant CRT.[66] Survival benefits of CRT versus RT alone increased in patients with multiple positive lymph nodes, despite the findings of the EORTC and RTOG studies, highlighting the need for ongoing evaluation into other poor risk factors for disease recurrence.

PRINCIPLES FOR THE CHOICE OF CONCURRENT TREATMENT REGIMENS

Three general statements can summarize the previously reviewed randomized trials:

1. RT with concurrent chemotherapy is more efficacious than conventionally fractionated RT alone in advanced head and neck cancer.
2. Concurrent therapy appears to be more effective than maximally intensive single-modality RT administered via a modified fractionation regimen.
3. Acute and late toxicity are increased with the use of concurrent chemotherapy.

No consensus exists, however, regarding either the optimal radiation dose fractionation scheme or the optimal scheduling of chemotherapy in these concurrent regimens. These controversies pose a decision-making dilemma to the physician when it is time to devise a treatment plan. Below, each component of concurrent treatment regimens is discussed to guide the selection process.

Radiation Fractionation Scheme

One rational approach to the choice of radiation dose fractionation within the context of concurrent chemotherapy would start with the selection of an optimal single-modality therapy and a definition of both its clinical efficacy and toxicity. Different dose fractionation schemes in concurrent treatment programs could then be normalized to one another using the biologically equivalent dose (BED) concept[67]: BED = $nd[1 + d/(\alpha/\beta)]$, where n = number of fractions delivered, d = dose per fraction, and α/β = 10 for tumors and acute responding normal tissues and 2 for late responding tissues. The intent of this normalization process is to allow a comparison of different treatment programs to identify those having a favorable profile in terms of maximizing the probability of tumor control while minimizing the risk of late toxicity. Kasibhatla et al evaluated prospective trials of CRT in order to estimate the radiotherapeutic dose equivalence of the concurrent chemotherapy.[49] They concluded that, with respect to the tumor, the administration of concurrent chemotherapy was equivalent to the delivery of an additional 10 to 12 Gy. Subsequently, Lee and Eisbruch estimated that concurrent chemotherapy was equivalent to the delivery of an additional 8 Gy when the development of acute mucositis was used as the end point.[68]

Whether modified fractionation irradiation and concurrent chemotherapy is superior to conventionally fractionated irradiation and concurrent chemotherapy was addressed in RTOG 0129.[69] Both RT and chemotherapy constituted experimental variables in this trial. This trial randomized 743 patients with stages III to IV oral cavity, oropharynx, hypopharynx, or larynx carcinoma to accelerated fractionation with concomitant boost (72 Gy in 42 fractions with 1.8 Gy/fraction daily and 1.5 Gy/ fraction boost as second treatment the last 12 days per RTOG 9003) and concurrent CDDP (100 mg/m^2 triweekly for two cycles) or conventionally fractionated RT (70 Gy in 2 Gy/fraction daily) and concurrent CDDP (100 mg/m^2 triweekly for two cycles for 3 cycles). No differences were observed in local-regional failure, PFS, distant metastases, or OS; 8-year OS was 48% in both arms. The findings show that one can compensate for the elimination of the third dose of CDDP by the more intensive radiation schedule. It should also be pointed out that on the conventionally fractionated arm, only 69% of patients could tolerate all three cycles of CDDP, a common occurrence with the use of high-dose CDDP. Outcome was also the same in the

conventionally fractionated arm patients who received two versus three cycles of CDDP.

Concurrent Chemotherapy Regimens

Concurrent CDDP with 100 mg/m^2 bolus dosing every 3 weeks on days 1, 22, and 43 of RT has historically been the standard based on multiple phase III randomized trials.[14,54,62,63,70] This schedule was originally developed in induction chemotherapy trials and later incorporated into concurrent chemotherapy regimens. However, smaller, more frequent chemotherapy doses may be preferable to bolus administration on two counts. Smaller individual doses may also reduce morbidity without compromising efficacy, which is especially critical as compliance is often limited with bolus administration. More frequent administration could provide radiosensitizing chemotherapy during a larger proportion of the RT course. Only around two-thirds of patients complete all three cycles.[62,63] RTOG 0129 and other studies have suggested that 200 mg/m^2 of CDDP concurrent with radiation is required to achieve maximal benefit when used concomitantly with radiation.[71]

Weekly CDDP regimens have been increasingly favored, in large part, because of their reduced toxicity and ease of administration. Recent prospective randomized trials have compared weekly versus triweekly regimens, mostly in the postoperative setting. In a phase III randomized trial from India, 300 patients with nonnasopharyngeal HNSCC received 60 to 70 Gy CRT with CDDP either every 3 weeks (100 mg/m^2 on days 1, 22, and 43) or weekly (30 mg/m^2).[72] 87.3% of enrolled patients had an oral cavity primary, with 93% receiving CRT in the adjuvant setting. In the triweekly arm, the median cumulative dose was 300 mg/m^2, although 56 of 150 patients received two instead of three cycles of CDDP. In the weekly arm, the median cumulative CDDP dose was 210 mg/m^2. Two-year locoregional control was higher with triweekly versus weekly CDDP (73.1% vs 58.5%; P = .014). There was also a trend toward improved survival with triweekly CDDP, and there was no difference in pattern of failure between the two arms. Acute severe toxicity was also higher with triweekly versus weekly CDDP (84.6% vs 71.6%; P = .006), although there was no difference in feeding tube placement or chronic toxicity. In updated

results presented at ASCO 2022, the triweekly versus weekly regimen remained more efficacious with 5-year locoregional control 55.2% versus 48.2%.[73]

In the phase II/III JCOG1008 trial, 261 postoperative patients with HNSCC receiving 66 Gy CRT were randomized to triweekly CDDP (100 mg/m^2 on days 1, 22, and 43) or weekly CDDP (40 mg/m^2).[74] The median cumulative dose of CDDP was 280 mg/m^2 in the triweekly arm and 239 mg/m^2 in the weekly arm. Survival was noninferior in the weekly arm; 2- and 3-year survival was 74.2% and 59.1% with triweekly CDDP and 77.7% and 71.6% with weekly CDDP, respectively. Grade 3 or higher neutropenia, infection, renal impairment, and hearing impairment were higher with triweekly CDDP. The discrepancy between this trial and the prior Indian trial may be due, in part, to the higher cumulative dose achieved in the weekly arm on this trial.

In the ConCERT trial, 278 patients with nonnasopharyngeal HNSCC receiving 70-Gy concurrent CRT in the definitive setting were randomized to triweekly CDDP (100 mg/m^2) versus weekly CDDP (40 mg/m^2). In all, 59.6% of patients had an oropharynx primary. In results presented at ASCO 2022, weekly CDDP was noninferior and associated with lower rates of acute grades 3 to 4 toxicity, including fewer hospitalizations and treatment breaks.[75] Two-year locoregional control was 57.69% versus 61.53% with triweekly versus weekly CDDP. An ongoing phase II/III trial, NRG HN009 (NCT05050162), is randomizing participants with oropharynx, larynx, hypopharynx, or human papillomavirus (HPV)-positive unknown primaries to triweekly CDDP (100 mg/m^2) versus weekly CDDP (40 mg/m^2), with an estimated enrollment of 464 participants.

In NPC, recent phase III trials of induction chemotherapy and sequential CRT have all used concurrent triweekly CDDP (80-100 mg/m^2 × 2-3 cycles).[76-79] Prior to these trials, one multicenter randomized phase II trial, KCSG-HN10-02, did compare concurrent triweekly CDDP (100 mg/m^2 on days 1, 22, and 43) versus weekly CDDP (40 mg/m^2) in 109 patients, with all patients receiving three cycles of adjuvant CDDP 80 mg/m^2 and 5-FU 1,000 mg/m^2/d every 3 weeks.[80] Three-year PFS was similar with triweekly versus weekly CDDP (63.8% vs 64.9%; P = .074), and grades 3 to 4 toxicity was also similar (39.3% vs 47.2%; P = .443).

ChiCTR-TRC-12001979 was the first phase III trial randomizing 510 patients with nonkeratinizing NPC to concurrent triweekly CDDP (100 mg/m^2 × 2 cycles) versus weekly CDDP (40 mg/m^2 × 6 weeks), with no induction or adjuvant chemotherapy given.[81] Three-year failure-free survival was similar with triweekly versus weekly regimens (85.4% vs 85.6%; $P > .99$), with acute grades 3 to 4 toxicity was lower with triweekly CDDP (55.8% vs 66.3%; $P = .015$). The median cumulative CDDP dose was also slightly lower in the triweekly vs weekly group (200 mg/m^2 vs 220 mg/m^2).

Phase III trials comparing of platinum-based and non– platinum-based concurrent treatment regimens are almost nonexistent, and the relative benefit of concurrent platinum versus fluorouracil or taxane therapy is unknown. Meta- analysis data have suggested that fluorouracil or CDDP regimens are more successful than carboplatin- or mitomycin-based treatments[82] and that concurrent platinum monotherapy is better than nonplatinum monotherapy.[11] In a single small phase III trial, a weekly paclitaxel concurrent regimen appeared equivalent to a weekly CDDP concurrent schedule.[83] Overall, however, the data must be considered limited and not definitive.

Most concurrent chemotherapy regimens use a single agent, an approach that, in general, suboptimally exploits the potential systemic benefits of this modality. In most other diseases, multiagent chemotherapy has been considered a better approach in controlling distant disease. In head and neck cancer, multiagent induction chemotherapy regimens have clearly demonstrated an impact on distant metastases, a benefit observed both from single trials and in a large meta-analysis.[11] This same meta-analysis demonstrated a significant but less pronounced impact on distant metastases from concurrent treatment schedules. However, no survival difference has been identified when comparing concurrent single-agent platinum regimens and concurrent multiagent schedules.

Radiation has also been administered in conjunction with concurrent high-dose intra-arterial CDDP. This approach has the hypothetical advantage of allowing selective delivery of chemotherapy to the tumor while sparing uninvolved organs and allowing for the administration of intravenous sodium thiosulfate, a systemic CDDP-neutralizing agent designed to protect the kidneys. Although the procedure proved technically

challenging, a phase II multi-institutional trial proved feasible.[84] However, a phase III trial comparing concurrent radiation and intra-arterial versus intravenous CDDP revealed no benefit,[85] and this mode of administration is not recommended.

The two most widely used CDDP administration schedules are 100 mg/m^2 every 3 weeks and 40 mg/m^2 once weekly. Equipoise exists regarding the relative efficacy of these different approaches. NRG-HN009 is an ongoing randomized phase III trial that is designed to answer this question (NCT05050162). Limited evidence suggests that CDDP may be more effective than carboplatin.[86] Taxanes are also active agents against HNSCC but have not been studied extensively as components of CRT regimens. The ongoing trial RTOG 1216 is a three-arm study comparing postoperative CRT with standard CDDP versus docetaxel-cetuximab versus CDDP-atezolizumab (NCT01810913).

Induction Chemotherapy and Sequential Chemoradiation

The use of induction chemotherapy for locoregionally advanced HNSCC is an attractive treatment option. The dramatic tumor shrinkage seen in previously untreated patients after CDDP-based chemotherapy regimens suggests that an improvement in locoregional control and even survival should also result. Multiple phase III clinical trials in nonnasopharyngeal HNSCC, however, have failed to demonstrate any reproducible impact from induction treatment schedules on overall outcome. The MACH-NC identified a marginal survival benefit with fluorouracil and platin induction chemotherapy with RT compared to RT alone, but this survival improvement was dwarfed by that obtained with the use of concurrent CRT regimens.[11,12]

Induction trials including the landmark Veterans Affairs (VA) larynx trial, however, have demonstrated a reduction in distant metastases compared to nonchemotherapy regimens.[9] The absence of impact on OS in this trial and others reflects the historically limited importance of distant metastases in the natural history of this disease. However, as locoregional control improved with concurrent CRT, distant metastases emerged as a more frequent cause of treatment failure, prompting renewed interest in induction chemotherapy.[87] Phase III randomized trials in locally advanced

nonnasopharyngeal HNSCC including TAX 323 and TAX 324 demonstrated the superiority of three-drug taxane, cisplatin, and fluorouracil (TPF) regimens when compared to cisplatin and fluorouracil (PF) alone[88-91] (Table 46.3). In these studies, successful induction was followed by definitive RT or CRT. TAX 323 randomized 358 patients with stages III to IV HNSCC to induction TPF versus PF followed by conventionally fractionated 66 to 70 Gy or accelerated/hyperfractionated 70 to 74 Gy RT alone, with 7% to 8% of patients discontinuing chemotherapy due to progression.89 TAX 324 randomized 501 patients with stages III to IV HNSCC to induction TPF versus PF followed by 70 to 74 Gy conventionally fractioned RT with concurrent weekly carboplatin area under the curve of 1.5, with 7% to 13% of patients discontinuing chemotherapy due to progression.[90] Long-term follow-up of both TAX 323 and TAX 324 confirmed significantly improved PFS and OS with TPF, with similar late toxicities.[92,93] A meta-analysis of these studies also found the taxane-containing induction regimens to be superior to platinum-fluorouracil alone.[94]

TABLE 46.3 TAXANE, CISPLATIN, AND FLUOROURACIL (TPF) VERSUS CISPLATIN AND FLUOROURACIL (PF) INDUCTION CHEMOTHERAPY: RANDOMIZED TRIALS

	Hitt et al[88]	Vermorken et al[89]	Posner et al[90]	Pointreau et al[91]

TPF	67%	37%	62%	60%
P value	.06	.02	.002	.57

The above studies established TPF as the preferred induction regimen but did not establish induction chemotherapy followed by concurrent CRT, also known as sequential chemoradiation, as the standard of care. The phase III trials PARADIGM and DeCIDE randomized stages III to IV nonnasopharyngeal HNSCC to induction TPF followed by concurrent CRT versus CRT alone.[95,96] PARADIGM compared three cycles of induction TPF followed by concurrent CRT with docetaxel or carboplatin versus CRT with two cycles of CDDP 100 mg/m^2; RT was accelerated with concomitant boost to 72 Gy in 6 weeks, except for patients with a favorable response to induction, who received conventionally fractionated 70 Gy with carboplatin. DeCIDE compared two cycles of induction TPF followed by concurrent CRT with 74 to 75 Gy RT bid and concurrent docetaxel, fluorouracil, and hydroxyurea versus the same CRT alone. Both PARADIGM and DeCIDE closed early after enrolling 145 and 285 patients, respectively, due to slow accrual. In PARADIGM, 56 of 69 who initiated induction completed CRT, while 66 of 72 who initiated CRT alone completed treatment. In DeCIDE, 122 of 136 who initiated induction completed CRT, while 130 of 133 in the CRT alone completed treatment. Neither trial observed a significant difference in the primary end point of OS or secondary end points of PFS (PARADIGM) or recurrence-free survival and distant failure-free survival (DeCIDE), though both were underpowered due to early termination. It is important to recognize that the treatment-related mortality rate was nearly 5% in both of these trials, which may have offset the effect of improved local-regional and distant control on OS. A meta-analysis of induction chemotherapy followed by concurrent CRT versus CRT alone revealed decreased distant metastasis rate with induction chemotherapy; however, there were no statistically significant differences in OS, PFS, overall response rate, or locoregional recurrence rate.[97]

Nonetheless, there are several situations where induction chemotherapy may have a role. In the organ preservation setting, induction chemotherapy has been investigated as a selection tool, with responders approached nonoperatively with RT, while nonresponders may be considered for surgery. This strategy is also grounded in part on historical studies demonstrating correlation between CDDP response and radiation response in untreated HNSCC.[98]

Using this paradigm, induction chemotherapy appears to be an acceptable strategy in the larynx preservation setting. The landmark RTOG 9111 trial in stages III to IV larynx SCC compared up to three cycles of induction PPF followed by RT alone in responders and surgery and postoperative RT in nonresponders versus concurrent CRT with single-agent triweekly CDDP versus RT alone. Five hundred and twenty patients were enrolled.[15] In the induction arm, around 85% of patients had a partial or complete response (CR) at the primary site after two cycles of induction PF, the same as the 85% seen in the VA larynx study. At 10 years, the primary end point of laryngectomy-free survival was similar between the induction chemotherapy and concurrent CRT arms (28.9% and 23.5%, respectively), but lower in the RT-alone arm (17.2%). Comparing the chemotherapy arms, although laryngeal preservation and locoregional control were superior in the concurrent CRT arm compared to the induction arm, distant metastatic control was equivalent. OS was not significantly different between the induction chemotherapy versus concurrent CRT versus RT-alone arms (38.8% vs 27.5% vs 31.5%).

Another trial from the University of Michigan (UMC 9520) used a single cycle of induction PF for subsequent treatment selection in stages III to IV larynx SCC. This phase II trial enrolled 97 patients.[99] In all, 75% of patients had a >50% response after a single cycle of induction chemotherapy and subsequently received concurrent CRT with triweekly CDDP (with two additional cycles of adjuvant chemotherapy), while most of the remaining patients underwent laryngectomy, with larynx preservation ultimately possible in 70% of the cohort. Importantly, there was no difference in OS in patients requiring laryngectomy due to failure to respond to induction chemotherapy versus those who did respond.

TPF is now the preferred induction regimen, though its increased side effects make compliance difficult with the full chemoradiation treatment package. On the phase II TREMPLIN trial, 153 patients with stages III to IV larynx/hypopharynx SCC received three cycles of induction TPF. In all, 85% had ≥50% response at the primary tumor. Responders received RT and were randomized to concurrent triweekly CDDP or cetuximab, while nonresponders underwent surgery. However, following induction therapy, just 43% and 71% of responders in the concurrent CDDP and cetuximab

arms, respectively, were able to complete the full protocol due to substantial acute toxicity.[100]

The evidence for induction chemotherapy as a predictive tool in oropharyngeal and oral cavity cancer is much more limited. The Southwest Oncology Group conducted a phase II trial in base of tongue or hypopharyngeal cancer, enrolling 59 participants who received two cycles of induction PF.[101] In all, 81% of the 37 base of tongue patients had a >50% response at the primary site and received concurrent CRT with triweekly CDDP. One of the four base of tongue nonresponders refused salvage surgery. Three-year PFS with organ preservation was 62% for the base of tongue. The University of Pennsylvania also conducted a phase II trial in resectable stages III to IV oropharyngeal cancer, enrolling 53 participants who received two cycles of induction carboplatin and paclitaxel.[102] In all, 89% of patients had a ≥50% response in the primary tumor and received concurrent CRT with weekly paclitaxel. Three of the six nonresponders refused surgery. The 3-year locoregional control was 82%, and the overall rate of organ preservation was 77%. Given the high rate of response to induction chemotherapy and the low compliance with salvage surgery, the use of induction chemotherapy for treatment selection is questionable, especially compared to upfront nonoperative or operative management.

The UMC conducted multiple single-arm phase II trials using induction chemotherapy for treatment selection in oropharynx cancer.[103] One of these was UMCC 9921, which enrolled 66 patients with stages III to IV oropharyngeal cancer who received one cycle of CDDP or carboplatin with fluorouracil.[104] In all, 81% had a >50% response in the primary tumor and received concurrent CRT with triweekly CDDP or carboplatin and adjuvant paclitaxel, with organ preservation achieved in 73% of patients. In this trial, high-risk HPV copy number was also positively associated with induction chemotherapy response and survival.

The relegation of induction chemotherapy to a purely predictive tool is disquieting to both medical and radiation oncologists. Induction adds significant cost and toxicity, especially when sequenced with concurrent chemoradiation. Compliance rates for an entire course of treatment with these regimens are only 65% to 70% in the most experienced hands.[88,105] It should provide an additional survival benefit or an improvement in distant

metastatic disease control. Other less toxic predictive "biomarkers" than responsiveness to induction chemotherapy might emerge in the future.

In NPC, nonoperative management is standard. Given challenges in tolerating adjuvant chemotherapy after concurrent CRT, several recent trials from China have examined induction chemotherapy instead, with several demonstrating a survival benefit.

A multi-institutional phase III trial randomized 241 patients with stages III to IVB NPC (except T3-T4N0) to induction docetaxel (60 mg/m^2), CDDP (60 mg/m^2), and continuous infusion 5-FU (600 mg/m^2/d × 5 days) every 3 weeks for three cycles, followed by concurrent CRT with three cycles of triweekly CDDP (100 mg/m^2) versus CRT alone.[76] Induction TPF versus CRT alone was associated with improved 3-year failure-free survival (80% vs 72%; P = .034). A second trial randomized 476 patients with stages III to IVB (except T3N0-1) NPC to induction CDDP (80 mg/m^2) and continuous infusion 5-FU (800 mg/m^2/d × 5 days) every 3 weeks for two cycles, followed by concurrent CRT with three cycles of triweekly CDDP (80 mg/m^2) versus CRT alone.[106] Induction PF versus CRT alone was associated with higher 5-year DFS (73.4% vs 63.1%; P = .007), 5-year distant metastasis-free survival rate (82.8% vs 73.1%; P = .014), and 5-year survival (80.8% vs 76.8%; P = .040).[77] In addition to induction TPF and PF, induction gemcitabine and CDDP have also demonstrated a survival benefit.[78] A third phase III trial randomized 480 patients with stages III to IVB NPC (except N0) to induction gemcitabine (1 g/m^2 on days 1 and 8) and CDDP (80 mg/m^2 on day 1) every 3 weeks for three cycles, followed by concurrent CRT with CDDP (100 mg/m^2 on days 1, 22, and 43) versus CRT alone. Compliance was excellent. In the induction arm, over 90% of patients received all induction chemotherapy and CRT with two to three cycles of concurrent CDDP, while in the CRT-alone arm, over 95% of patients received CRT with two to three cycles of concurrent CDDP. Induction gemcitabine and CDDP versus CRT alone significantly improved 3-year recurrence-free survival (85.3% vs 76.5%), 3-year distant recurrence-free survival (91.1% vs 84.4%), and 3-year survival (94.6% vs 90.3%). Both TPF and gemcitabine/CDDP are considered preferred regimens for induction chemotherapy treatment paradigms in locoregionally advanced NPC.[30]

These trials support a preferred strategy of induction chemotherapy and concurrent CRT for locally advanced nasopharyngeal cancer; CRT followed by adjuvant chemotherapy remains somewhat controversial. The ongoing phase II/III NRG-HN001 trial (NCT02135042) is investigating whether circulating Epstein-Barr virus (EBV) DNA may be used as a biomarker to identify patients who benefit from adjuvant chemotherapy. On this trial, patients with stages II to IVB nonmetastatic NPC with detectable pretreatment plasma EBV DNA will undergo conventionally fractioned RT with weekly CDDP (40 mg/m^2), with post-treatment EBV DNA assessed within 1 week after CRT. Patients with detectable post-treatment EBV DNA are randomized (phase II) to adjuvant gemcitabine and paclitaxel versus control CDDP and 5-FU, whereas patients with undetectable post-treatment EBV DNA are randomized (phase III) to observation versus control CDDP and 5-FU with a primary end point of PFS.

Radiotherapy and Molecularly Targeted Agents

Understanding the molecular basis of HNSCC has spurred interest in therapies targeting genetic mutations and aberrantly expressed proteins in HNSCC. Potential targets include epidermal growth factor receptor (EGFR), MET, and Notch transmembrane receptors and their downstream prosurvival PI3K, JAK/STAT, and Ras signaling pathways.[107] EGFR is upregulated in approximately 90% of patients with HNSCC and has been associated with a poor prognosis.[108-110] Cetuximab, a monoclonal antibody targeting EGFR, was the only Food and Drug Administration–approved targeted therapy available for HNSCC until the recent advent of immune checkpoint inhibitors, which are discussed separately. Of note, cetuximab is associated with rare hypersensitivity reactions that can result in anaphylaxis during initial infusion. Rates of grades 3 to 4 hypersensitivity reaction as high as 22% have been reported in North Carolina and Tennessee.[111] Hypersensitivity is likely mediated by immunoglobulin E antibodies directed against the oligosaccharide galactose-α-1,3-galactose, which is present on the cetuximab heavy chain; these pretreatment antibodies were found to be higher in patients from the southeastern United states.[112]

In 2006, Bonner and colleagues reported the results of IMCL-9815, a phase III randomized trial comparing RT alone or RT with weekly

cetuximab (400 mg/m^2 loading dose 1 week prior to RT followed by 250 mg/m^2 weekly during RT) in stages III to IV oropharynx, hypopharynx, and larynx SCC.[113] In all, 424 patients were enrolled. Cetuximab significantly increased OS when compared to RT alone, with a 2010 updated analysis reporting improved median OS from 29 to 49 months (P = .018) and improved 5-year OS from 36% to 46%.[114] Acute grade 3 or higher toxicity was generally similar between the two groups, including around 52% to 56% with mucositis. The two notable exceptions were higher rates of acneiform rash and infusion reactions with cetuximab. Around 17% of cetuximab-treated patients developed a grade 3 or higher acneiform rash. Grade 2 or higher acneiform rash was also associated with improved survival in cetuximab-treated patients, compared to grade 1 or no rash. An unplanned subgroup analysis found that cetuximab was more beneficial in patients with oropharynx cancers, smaller primary tumors, younger age, and higher performance status, initially suggestive of HPV association. However, a subsequent analysis found no interaction between cetuximab and HPV status.[115]

The control arm of the above trial was RT alone, which does not constitute optimal therapy for locally advanced disease. RTOG 0522 investigated whether cetuximab would be beneficial when added to chemoradiation. This phase III trial randomized 891 patients with stages III to IV oropharynx, hypopharynx, and larynx SCC to CRT without or with concurrent cetuximab. Accelerated RT (72 Gy in 42 fractions over 6 weeks or 70 Gy in 35 fractions over 6 weeks) and CDDP 100 mg/m^2 on days 1 and 22 were used in both arms. Addition of cetuximab increased treatment interruptions and mucositis and had no effect on 3-year PFS or OS or distant metastases. The absence of any benefit with cetuximab in RTOG 0522 contrasts with a phase III trial of untreated recurrent or metastatic HNSCC, where cetuximab significantly improved OS when added to CDDP or carboplatin and fluorouracil.[116]

Subsequently, multiple phase III trials have compared concurrent CDDP versus cetuximab with RT, largely in patients with HPV-associated oropharyngeal SCC (OPSCC), and found that cetuximab results in inferior OS compared to CDDP with no reduction in acute toxicities. RTOG 1016 randomized 987 patients with HPV-positive OPSCC to accelerated RT 70 Gy in 35 fractions over 6 weeks with concurrent CDDP 100 mg/m^2 on days

1 and 22 or concurrent cetuximab.[117] At 5 years, cetuximab versus CDDP was associated with inferior PFS (67.3% vs 78.5%, $P = .0002$), inferior OS (77.9% vs 84.6%, $P = .0163$), and higher locoregional failure (17.3% vs 9.9%, $P = .0005$). Rates of distant metastases and acute and late toxicity were similar between the two groups. The De-ESCALaTE HPV trial randomized 334 patients with HPV-positive low risk (smoking history 0-10 pack-years) OPSCC to conventionally fractionated RT 70 Gy with concurrent CDDP 100 mg/m^2 on days 1, 22, and 43 or concurrent cetuximab.[118] At 2 years, cetuximab versus CDDP was associated with higher recurrence (16.1% vs 6.0%, $P = .0007$) and inferior OS (89.4% vs 97.5%, $P = .001$). The ARTSCAN III trial randomized 291 patients with stages III to IV oropharynx, hypopharynx, or larynx SCC to daily fractionated RT with concurrent weekly CDDP 40 mg/m^2 or cetuximab. RT was conventionally fractionated to 68 Gy, with T3-T4 tumors undergoing a second randomization to 68 Gy versus 73.1 Gy. Eighty-five percent of patients had oropharynx primaries, and 89% of those oropharyngeal primaries were HPV positive. Unplanned interim analysis after 298 patients had been randomized demonstrated that cetuximab versus CDDP was associated with higher 3-year locoregional failure (23% vs 9%, $P = .0036$); 3-year OS was 78% versus 88% ($P = .086$), and distant metastases were similar. Dose escalation for T3-T4 tumors showed no benefit. Lastly, TROG 12.01 randomized 189 patients with stages III to IV HPV-positive OPSCC to conventionally fractionated RT with weekly CDDP 40 mg/m^2 or concurrent cetuximab, with no difference in the primary end point of symptom severity. Three-year failure-free survival was also inferior with cetuximab (80% vs 93%, $P = .015$). Together, these trials confirmed that concurrent CDDP remains the standard of care.

Another monoclonal anti-EGFR antibody, panitumumab, has also been investigated in HNSCC though has no role currently in therapy. In a phase III Canadian study, patients with locoregionally advanced SCC of the oral cavity, oropharynx, larynx, or hypopharynx were randomized to conventionally fractionated 70 Gy RT with CDDP 100 mg/m^2 on days 1, 22, and 43 versus accelerated RT 70 Gy in 35 fractions over 6 weeks with panitumumab 9 mg/kg every 3 weeks on days 7, 15, and 36 of RT.[119] No survival differences between the two groups were demonstrated. However, the study design was flawed, including no distinction of HPV-related

oropharynx tumors and low event rate. Furthermore, unlike cetuximab, panitumumab added to cytotoxic chemotherapy in the metastatic setting does not improve survival compared with chemotherapy alone.[120]

Apart from EGFR, molecularly targeted agents directed at tumor hypoxia have also been investigated in HNSCC. Hypoxia and dysregulated vasculature are common features of solid tumors. In HNSCC, overexpression of hypoxia-inducible factors is related to vascular endothelial growth factor (VEGF) expression, increased microvessel density, and reduced local control and OS after chemoradiation.[121] VEGF expression has also been associated with a 1.88-fold increased risk of death at 2 years in a meta-analysis of 1,002 patients with HNSCC.[122] Multiple studies assessing hypoxia by other means, including tumor oxygen tension or imaging with hypoxic radiotracers, have further cemented the correlation between hypoxia and reduced local control and survival following RT.[41,42,56,123]

Several therapeutic approaches directed at tumor hypoxia have been investigated in locally advanced HNSCC with limited success. Tirapazamine is a prodrug reduced to a cytotoxic free radical under hypoxic conditions and also sensitizes hypoxic cells to CDDP.[124] The randomized phase III TROG 02.02 (HeadSTART) trial of 861 patients with stages III to IV HNSCC found that adding tirapazamine to standard chemoradiation with CDDP had no effect on locoregional control, OS, or QoL.[125] However, a quarter of patients had noncompliant radiation plans, and a subset analysis of 693 patients who received at least 60 Gy to gross disease demonstrated a nonsignificant improvement in locoregional failure with tirapazamine.[126] Phase I/II trials have demonstrated that adding bevacizumab, a VEGF-A inhibitor, to CRT in HNSCC appears to be generally safe and feasible, although increased rates of hemorrhage and tissue necrosis have been reported, and one trial was terminated early due to reduced locoregional control with bevacizumab.[127-132] Several of these trials incorporated both bevacizumab and EGFR inhibitors such as erlotinib or cetuximab, as EGFR is one of many growth factors driving VEGF expression. In a phase III trial in recurrent or metastatic HNSCC, bevacizumab not only improved PFS when added to platinum-containing chemotherapy doublet but also increased treatment-related hemorrhage and deaths, with no improvement in OS.[133]

DEVELOPMENTAL ASPECTS OF COMBINED MODALITY THERAPY

De-escalation in Human Papillomavirus–Positive Disease

A landmark retrospective analysis of RTOG 0129 established HPV-positive oropharyngeal cancer as a distinct entity.[134] In a cohort of 323 patients, tumors positive for HPV DNA or p16 expression had significantly improved prognosis. At 3 years, HPV-positive versus HPV-negative OPSCC had PFS of 73.7% versus 43.4% ($P < .001$) and OS of 82.4% versus 57.1% ($P < .001$). Recursive partitioning analysis identified HPV status and smoking pack-years (≤10 vs >10) as the first and second major determinants, respectively, of OS and identified low-, intermediate-, and high-risk groups with 3-year OS of 93%, 70.8%, and 46.2%. Low risk was defined as HPV positive and ≤10 pack-years or HPV positive, >10 pack-years, and American Joint Committee on Cancer (AJCC) fifth edition stage N0-N2a disease. High risk was defined as HPV negative and >10 pack-years or HPV negative, ≤10 pack-years, and T4 disease; intermediate risk was in between. Subsequent analyses confirmed the prognostic and predictive importance of HPV status. HPV-positive versus HPV-negative disease demonstrated similar time to progression (~8 months) and patterns of failure, but significantly improved survival after first progression (2-year OS 54.6% vs 27.6%, $P < .001$).[135,136]

With the increased overall life expectancy and rising incidence of HPV-positive OPSCC, there has been significant interest in reducing treatment toxicities while maintaining excellent prognosis.[137] Approaches include using induction chemotherapy for risk stratification and de-escalating adjuvant or definitive chemoradiation.

ECOG-ACRIN E1308 investigated induction chemotherapy in 80 patients with HPV-positive AJCC seventh edition stages III to IV OPSCC. Patients received three cycles of CDDP, paclitaxel, and cetuximab followed by RT with concurrent cetuximab.[138] In all, 54 Gy in 27 fractions was given for a clinical CR at the primary site, while 69.3 Gy in 33 fractions was given for <CR. Fifty-one patients with a CR receiving 54 Gy with cetuximab had 2-year PFS and OS of 80% and 94%, respectively. One challenge to interpreting the data from this trial is that patients who had a CR at the primary site but <CR in the neck would have had the neck

boosted to 69.3 Gy, and the additional dose received by the primary site was not reported.

Another trial from University of California, Los Angeles enrolled 45 patients with HPV-positive stages III to IV OPSCC who received two cycles of induction carboplatin and paclitaxel followed by concurrent CRT with paclitaxel.[139] In this, 54 Gy in 27 fractions was given for a CR or partial response, while 60 Gy in 30 fractions was given for a less than partial response. Two-year PFS was 92%. While reduced dose RT was associated with reduced toxicity, it is unclear whether using induction chemotherapy for risk stratification represents true de-intensification. Recently, other means of risk stratification including serum and imaging biomarkers have been explored and are addressed below.

In the postoperative setting, ECOG-ACRIN E3311 enrolled 495 patients with HPV-positive AJCC seventh edition stages III to IVA OPSCC following transoral surgery and neck dissection.[140] Thirty-eight patients with low-risk disease (pT1-T2 N0-N1 and no risk factors) were observed, with a 2-year PFS of 96.9%. Two hundred and nine patients with intermediate-risk disease (close <3 mm margins, ≤1 mm ENE, 2-4 lymph nodes involved, PNI, or LVI) were randomized to reduced dose 50 Gy or standard dose 60 Gy, with similar 2-year PFS of 94.9% and 96.0%, respectively. One hundred and thirteen patients with high-risk disease (positive margins or >1 mm ENE or ≥5 lymph nodes involved) received 66 Gy with concurrent weekly CDDP 40 mg/m^2, with a 2-year PFS of 90.7%. Importantly, nearly one-third of patients received trimodality therapy on E3311, highlighting the need for careful patient selection.

A conceptually similar risk-stratified postoperative trial, PATHOS, is ongoing (NCT02215265). Another phase II trial from the Mayo Clinic, MC1273, enrolled patients with HPV-positive AJCC seventh edition stages III to IV OPSCC and ≤10 pack-year smoking history who underwent surgery with negative margins and at least one intermediate-risk factor (≥T3, ≥N2a, PNI, or LVI) or any ENE.[141] Thirty-six intermediate-risk patients received 30 Gy in 1.5 Gy fractions bid to the primary site and neck with concurrent docetaxel 15 mg/m^2 on days 1 and 8. Forty-three patients with any ENE received the same, with a simultaneous integrated boost to 36 Gy in 1.8 Gy fractions to lymph node levels with ENE. Two-year locoregional control was 96.2%, PFS was 91.1%, and OS was 98.7%.

Results from MC1675, a phase III trial randomizing patients 2:1 to the de-escalated paradigm above versus standard 60 Gy with or without weekly CDDP 40 mg/m^2, were presented at 2021 American Society for Radiation Oncology annual meeting.[142] De-escalated versus standard adjuvant therapy achieved similar 2-year locoregional control (95.5% vs 97.9%), PFS (86.5% vs 95.1%), and OS (96.1% vs 97.0%), with the notable exception of patients with pN2 disease and ENE, where 2-year PFS was lower with de-escalated versus standard therapy (42.9% vs 100%).

In the definitive RT setting, two different de-intensified regimens were assessed on NRG HN002, a phase II trial enrolling patients with HPV-positive OPSCC with AJCC seventh edition stage T1-T2 N1-N2b M0 or T3 N0-N2b M0 disease and ≤10 pack-year smoking history.[143] Three hundred and six patients were randomized to two parallel arms: concurrent CRT with 60 Gy in 6 weeks with weekly CDDP 40 mg/m^2 or accelerated RT alone with 60 Gy in 5 weeks. The primary end point was 2-year PFS superior to a historical control of 85%. The CRT arm achieved this standard (90.5%; P = .04), while the accelerated RT-alone arm did not (87.6%; P = .23). Thus, the concurrent 60-Gy CRT arm is one of three arms on HN005 (NCT03952585), an ongoing randomized phase II/III in patients with HPV-positive OPSCC with AJCC eighth edition stage T1-T2 N1 M0 or T3 N0-N1 M0 disease and ≤10 pack-year smoking history. The other two arms are accelerated RT 70 Gy in 6 weeks with concurrent CDDP (100 mg/m^2 on days 1 and 22) and accelerated RT 60 Gy in 5 weeks with concurrent nivolumab (starting 1 week prior to RT, 240 mg/m^2 every 2 weeks for six cycles). After phase II interim futility analysis, the 60-Gy CRT arm was closed as the prespecified noninferiority threshold was not reached.

Two multi-institutional phase II trials from the University of North Carolina and University of Florida have also investigated de-intensified definitive CRT, enrolling patients with AJCC seventh edition stage T0-T3 N0-N2c M0 HPV-positive OPSCC and either ≤10 pack-year smoking history or ≤30 pack-years and abstinent for 5 years. Patients received a de-intensified regimen of 60 Gy with weekly CDDP 30 mg/m^2. The first trial enrolled 44 patients, with patients assessed by primary site biopsy and dissection of initially involved nodes within 6 to 14 weeks post-treatment.[144,145] In all, 86% achieved a pathologic CR, and 3-year PFS and OS were 100%. The second trial enrolled 114 patients, and the patients

were assessed with standard post-treatment PET rather than surgery, with 2-year PFS and OS of 86% and 95%, respectively.[146] Thirty-four percent of patients required a temporary feeding tube, and no grade 3 or higher late toxicity was observed.

In the future, serum and imaging biomarkers may also be useful to select patients suitable for treatment de-escalation. Circulating tumor DNA (ctDNA) of high-risk HPV subtypes demonstrates high sensitivity and specificity for HPV-positive OPSCC at diagnosis and during post-treatment surveillance.[147] The relationship between ctDNA clearance kinetics during definitive radiation and clinical outcomes is an area of active investigation in HPV-positive OPSCC. For instance, one study from the UMC found that low pretreatment ctDNA with early increase at week 2 was associated with improved clinical outcomes, while studies from the University of North Carolina and Osaka University reported that ctDNA clearance at week 4 was associated with improved disease control.[148-150] Several ongoing phase II trials are using ctDNA clearance, largely at week 4, to select patients suitable for treatment de-escalation (eg, NCT04900623, NCT05268614, NCT03215719). Imaging biomarkers have also been investigated, including glucose metabolism parameters on ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) and hypoxia on ^{18}F-fluoromisonidazole (FMISO) PET.[151,152] Ongoing phase II trials are using metabolic response or absence of hypoxia on intratreatment FDG-PET or FMISO-PET, respectively, as biomarkers to identify patients suitable for de-escalated chemoradiation in HPV-positive OPSCC (eg, NCT04667585, NCT03323463).

Overall, several themes emerge from the de-escalation trials above. A sizeable fraction of patients in these trials received induction chemotherapy in addition to roughly 6 weeks of radiation, often with concurrent chemotherapy, or upfront surgery in addition to 6 weeks of chemoradiation. Arguably, neither of these represents meaningful treatment de-intensification. On the other hand, in the setting of definitive concurrent chemoradiation, caution is warranted as reducing, replacing, or omitting cytotoxic chemotherapy may result in inferior clinical outcomes, as evidenced by the results of RTOG 1016.[117] Improved upfront risk stratification of HPV-positive disease is needed, potentially with serum or imaging biomarkers, to better identify patients suitable for modest or

aggressive treatment de-intensification. Currently, in the absence of level I evidence for de-intensification, 70 Gy with concurrent CDDP remains the standard of care for nonoperative management of patients with HPV-positive and HPV-negative.[30]

Immunotherapy

Immune checkpoint inhibitors such as antibodies directed against programmed cell death 1 (PD-1) or programmed death ligand 1 (PD-L1) represent promising modalities of treatment since HNSCC is seen as an immunosuppressive disease. In recurrent or metastatic HNSCC, KEYNOTE-048 randomized 882 participants to first-line therapy with the PD-1 inhibitor pembrolizumab alone versus pembrolizumab with platinum and 5-FU versus cetuximab with platinum and fluorouracil.[153] Pembrolizumab with chemotherapy improved OS compared to cetuximab with chemotherapy across all arms, regardless of PD-L1 positivity. Pembrolizumab alone also improved OS over cetuximab with chemotherapy in patients with PD-L1 positivity (combined positive score [CPS] ≥1). In platinum-refractory recurrent or metastatic HNSCC, CheckMate 141 randomized 361 patients to the PD-1 inhibitor nivolumab versus standard single-agent systemic therapy and demonstrated an OS benefit with nivolumab.[154] Given this success, immunotherapy has also been assessed in locally advanced HNSCC in operative and nonoperative management.

In the preoperative setting, immunotherapy has demonstrated limited success in early-phase trials. CheckMate 358 was a multicohort phase I/II trial that included 52 patients with AJCC seventh edition stages III to IV resectable HNSCC. Neoadjuvant nivolumab 240 mg on days 1 and 15 was given prior to surgery on day 29, and while no pathologic CRs were observed, pathologic regression was seen in 23.5% of HPV-positive and 5.9% of HPV-negative tumors.[155] A phase II trial from the University of Cincinnati enrolled 92 patients with resectable locally advanced HNSCC and either cT3-T4 disease, ≥2 lymph nodes involved, and/or clinical ENE.[156] Patients received neoadjuvant and adjuvant pembrolizumab 200 mg for seven doses total. Compared to historical control, pembrolizumab improved DFS only in intermediate-risk patients without positive margins

and without ENE. In the postoperative setting, multiple ongoing phase III trials including IMvoke010 (NCT03452137), IMSTAR-HN (NCT03700905), NIVOPOSTOP (NCT03576417), RTOG 1216 (NCT01810913), and MK-3475-689 (NCT03765918) are investigating the addition of immune checkpoint inhibitors to standard adjuvant therapy.

In nonoperative management of locally advanced nonnasopharyngeal HNSCC, several phase III trials have failed to demonstrate any benefit for adding immunotherapy to standard CRT with 70 Gy and concurrent triweekly CDDP 100 mg/m^2. JAVELIN Head and Neck 100 randomized 697 patients receiving standard CRT with concurrent CDDP to either avelumab, a PD-L1 inhibitor, 10 mg/kg every 2 weeks for 12 months versus placebo.[157] The primary end point of median PFS was not reached in either arm but appeared to favor the placebo group. The similar GORTEC-REACH trial randomized 707 patients receiving standard CRT with concurrent CDDP or, if ineligible for CDDP, concurrent cetuximab to either avelumab 10 mg/kg every 2 weeks for 12 months or standard therapy alone.[158,159] Interim analysis presented at the 2021 European Society for Medical Oncology (ESMO) Congress showed that in patients receiving CDDP, the 1-year PFS rate was 64% with avelumab versus 73% with standard therapy, which crossed the futility boundary. In patients receiving cetuximab, avelumab did significantly reduce distant metastases (hazard ratio [HR] = 0.31, P = .007), but otherwise no significant improvement in PFS was seen. KEYNOTE-412 studied pembrolizumab, randomizing 804 patients receiving standard CRT to pembrolizumab 200 mg every 3 weeks for 17 doses versus placebo. In results presented at ESMO 2022, pembrolizumab was associated with a trend toward improved event-free survival (HR = 0.83, P = .0429), which did not meet the superiority threshold. Benefit was larger in patients with high PD-L1 expression (CPS >20) but remained nonsignificant. The final results of GORTEC-REACH and KEYNOTE-412 have not yet been published. In locally advanced nasopharyngeal SCC, several ongoing phase III trials are assessing the addition of immunotherapy to standard induction chemotherapy and concurrent CRT (eg, NCT04453826, NCT03700476, NCT04557020).

Disease and treatment-related factors may explain immunotherapy's absence of benefit in HNSCC chemoradiation trials such as JAVELIN and KEYNOTE. PD-L1 expression and tumor mutational burden (TMB) are

predictive biomarkers for immunotherapy response, and selection of patients with high mutation burden or PD-L1 expression may be necessary to realize a benefit with PD-1/PD-L1 inhibitors. However, in locally advanced non–small cell lung cancer (NSCLC), which has a similar rate of PD-L1 positivity and TMB to HNSCC, immunotherapy did improve survival when added to chemoradiation in unselected patients.[160,161] Patterns of failure may contribute to this discrepancy, as immune checkpoint inhibitors may have more of an impact on the distant metastases more common in NSCLC rather than the locoregional failures common in HNSCC.[162] Elective nodal irradiation, which is standard of care in HNSCC but not in NSCLC due to locoregional patterns of failure, may also hinder the process of T-cell priming by antigen-presenting cells, which occurs in lymph nodes. One analogous situation would be locally advanced cervical cancer, where elective nodal irradiation with CDDP-based chemoradiation is also standard, as in HNSCC. In the phase III CALLA trial, addition of immunotherapy to standard CRT in locally advanced cervical cancer did not show any significant improvement in PFS in results presented at the 2022 International Gynecologic Cancer Society meeting.[163] Overall, locally advanced HNSCC remains a challenging disease to eradicate, and thus far, immunotherapy has not demonstrated any benefit when added to standard CRT.

SUMMARY

Historic trials have demonstrated the superiority of altered fractionation as opposed to conventional once-daily fractionation in locally advanced head and neck cancer. Altered fractionation RT has, in turn, been superseded by conventionally fractionated RT with concurrent chemotherapy for locally advanced disease. Current standard of care remains RT with concurrent CDDP. In general, adding induction chemotherapy, adjuvant chemotherapy, targeted therapy, and, more recently, immunotherapy to the chemoradiation paradigm has shown limited success, although induction chemotherapy has demonstrated a survival benefit in locally advanced NPC.

The increased acute and late toxicity that results from combining these multiple modalities pose immediate challenges. These include the need for effective strategies in toxicity prophylaxis and management, as well as the

need to develop criteria for a priori selection of patients who may benefit from treatment de-escalation while not compromising disease control. Recent and ongoing studies de-intensifying chemoradiation in patients with HPV-positive oropharyngeal cancer have been promising. Incorporating serum and functional imaging biomarkers to disease site and stage-specific therapy is another area of active investigation. These efforts will allow for the optimal integration of RT, chemotherapy, biologically targeted therapy, and immunotherapy for those patients requiring combined modality therapy.

CHAPTER 47

Nasopharynx

Fan Yang, Benjamin H. Lok, Jonathan E. Leeman, and Nancy Y. Lee

ANATOMY

The nasopharynx is a cuboidal chamber, slightly broader in the transverse dimension than the anterior-posterior dimension (Figure 47.1). Anteriorly, it is continuous with the nasal cavity via the posterior choanae, whereas inferiorly, it communicates with the oropharynx. The roof of the nasopharynx is formed by the basilar portion of the sphenoid and occipital bones and the floor by the superior surface of the soft palate and nasopharyngeal isthmus. The lateral walls of the nasopharynx contain the pharyngotympanic tube (*eustachian tube*) openings, which are bounded by a prominence known as the *torus tubarius*. The *torus* is formed by the cartilage of the pharyngotympanic tube elevating the mucous membrane of the lateral nasopharynx. Posterior to the *torus* is the pharyngeal recess otherwise known as the *fossa of Rosenmüller*. The lateral walls, including the pharyngeal recess (fossa of Rosenmüller), are the most common origin of nasopharyngeal malignancies. The posterior wall of the nasopharynx contains the superior pharyngeal constrictor muscle, pharyngobasilar fascia, and buccopharyngeal fascia.

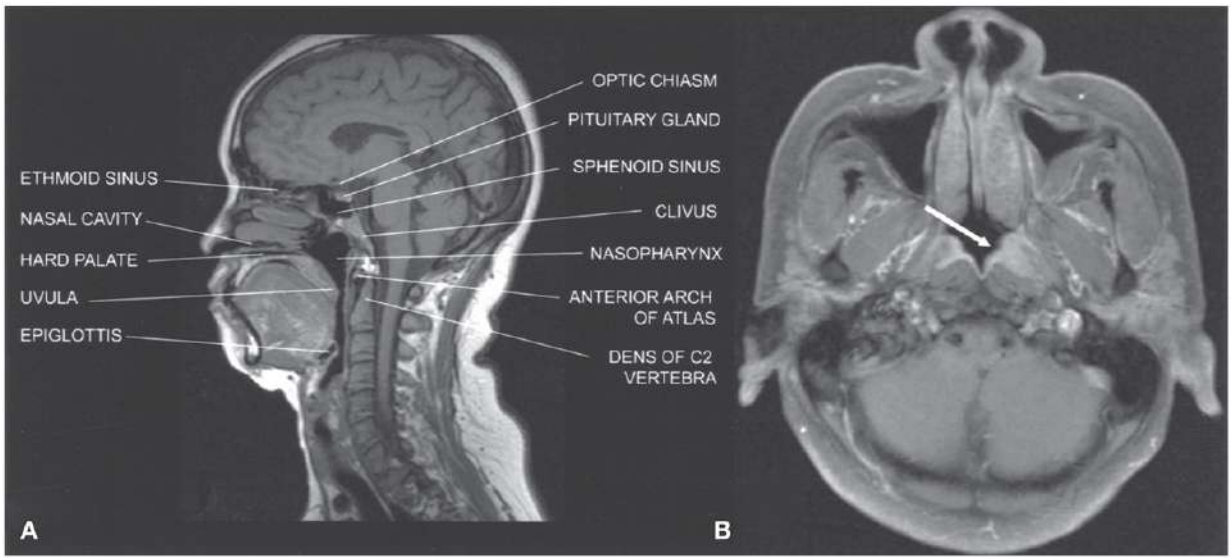

FIGURE 47.1 A. Midsagittal magnetic resonance image (MRI) of the head showing the nasopharynx and related structures. B. Axial contrast-enhanced MRI showing a small tumor in the left fossa of Rosenmüller (arrow) and normal structures in the rest of the nasopharynx.

The superior pharyngeal constrictor only extends superiorly to the skull base in the midline, and laterally, the pharyngobasilar fascia serves to attach the constrictor muscle to the base of the skull at the basiocciput and petrous portion of the temporal bone. This lateral area of muscular deficiency is otherwise known as the *sinus of Morgagni*, through which the pharyngotympanic tube and levator veli palatini pass. The pharyngobasilar fascia is continuous with the foramen lacerum and is in close proximity to the foramen ovale, foramen spinosum, jugular foramen, hypoglossal canal, and carotid space. The proximity of these foramina to the *sinus of Morgagni* assumes importance in the consideration of intracranial extension (Figure 47.2). A summary of the various foramina located in the base of skull is presented in Table 47.1.

TABLE 47.1 FORAMINA OF THE BASE OF THE SKULL AND ASSOCIATED ANATOMIC STRUCTURES

Foramen/Fissure	Cranial Nerve	Other Structures
Cribriform plate	Olfactory nerve (I)	Anterior ethmoidal nerve
Optic foramen	Optic nerve (II)	Ophthalmic artery
Superior orbital fissure	Oculomotor (III), trochlear (IV), ophthalmic division of trigeminal (V_1) nerve, abducens (VI) nerves	Ophthalmic vein, orbital branch of middle meningeal and recurrent branch of lacrimal arteries, sympathetic plexus, filaments from carotid plexus
Foramen rotundum	Maxillary division of trigeminal (V_2) nerve	
Foramen ovale	Mandibular division of trigeminal (V_3) nerve	Accessory meningeal artery, lesser superficial petrosal nerve
Foramen lacerum		Internal carotid, sympathetic carotid plexus, vidian nerve, meningeal branch of ascending pharyngeal artery, emissary vein
Foramen spinosum	Recurrent branch of V_3 nerve	Middle meningeal artery and vein
Stylomastoid foramen	Facial (VII) nerve	
Internal acoustic meatus	Auditory (VIII) nerve	Internal auditory artery
Jugular foramen	Glossopharyngeal (IX), vagus (X), spinal accessory (XI) nerves	Inferior petrosal sinus, transverse sinus, meningeal branches from occipital and ascending pharyngeal arteries
Hypoglossal canal	Hypoglossal (XII) nerve	Meningeal branch of ascending pharyngeal artery
Foramen magnum		Spinal cord, spinal accessory nerve, vertebral vessels, anterior and posterior spinal vessels

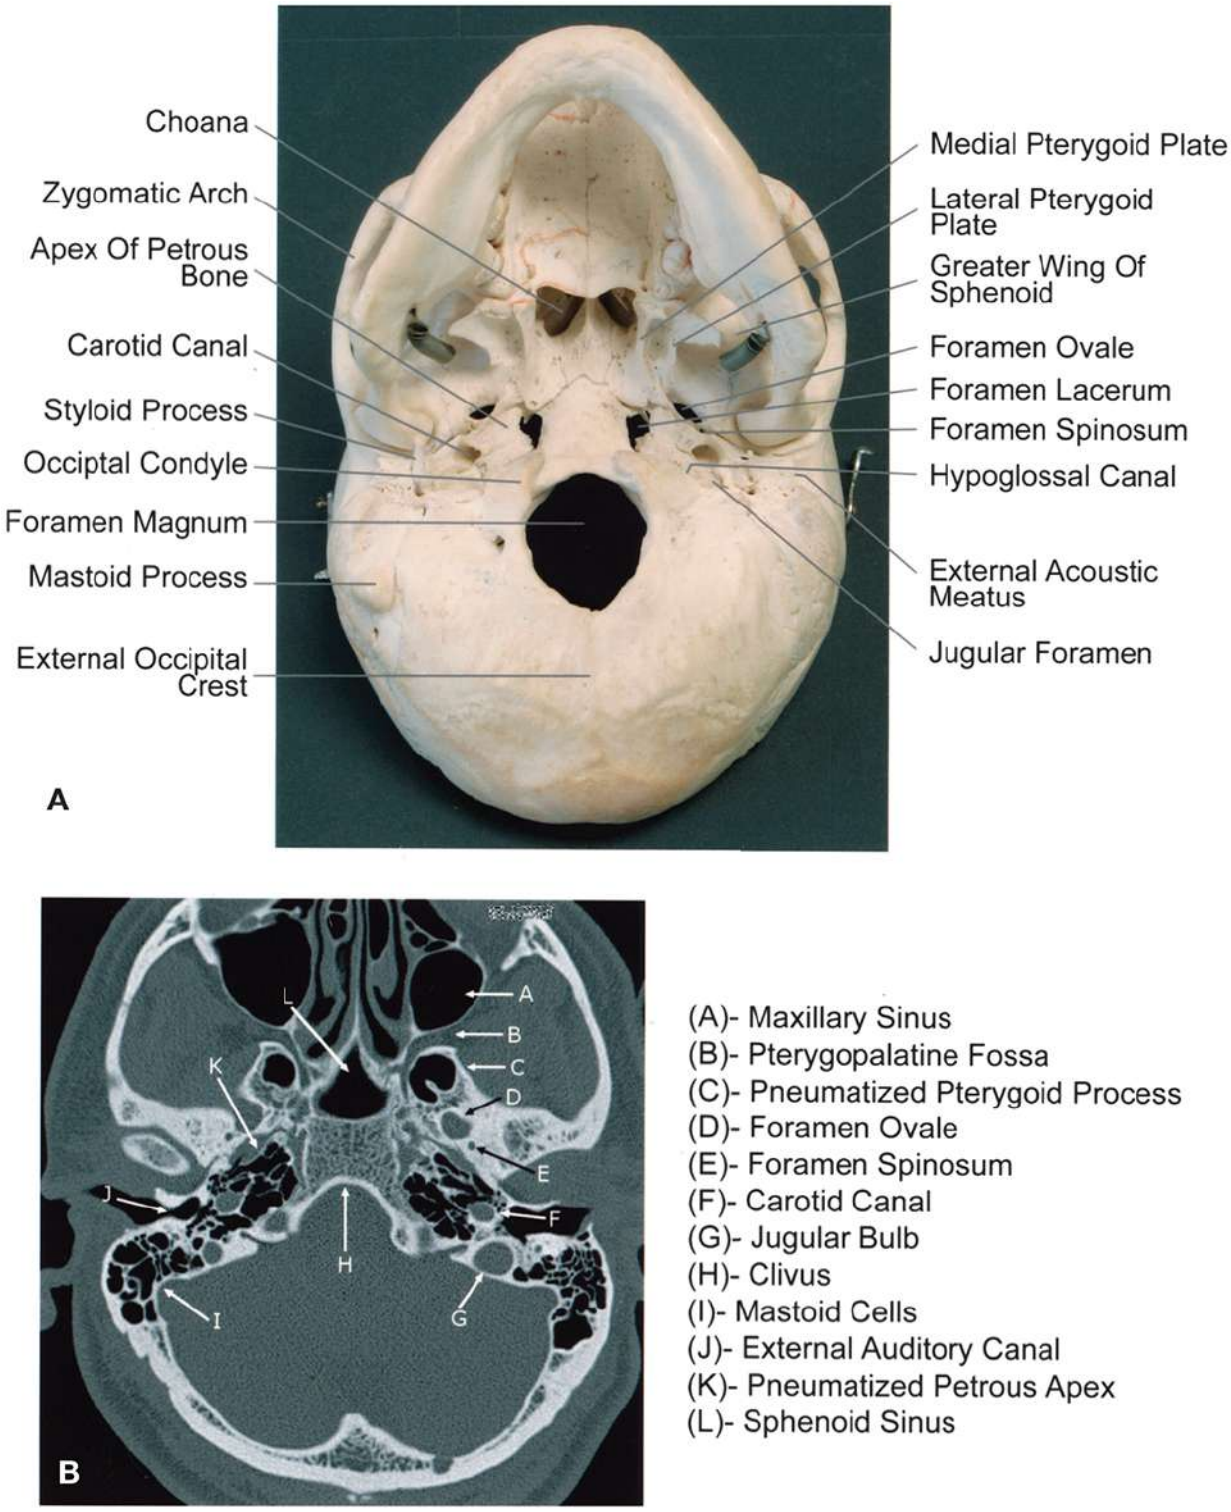

FIGURE 47.2 A. Basal view of skull illustrating the foramina of the base of the skull and the occupying structures. B. Axial computed tomography scan illustrating the bony anatomy.

The afferent innervation of the nasopharynx anterior to the pharyngotympanic tube orifice is provided by the maxillary division of the trigeminal nerve (V_2) and, posterior to the tubal orifice, the glossopharyngeal nerve. Motor supply is via the pharyngeal branches of the glossopharyngeal nerve, vagus nerve, and sympathetic fibers

from the superior cervical ganglion. The arterial supply of the nasopharynx is provided by the ascending pharyngeal artery, sphenopalatine artery, and the artery of the pterygoid canal. Venous drainage is provided by the pharyngeal plexus that drains into the internal jugular veins directly or via communication with the pterygoid plexus.

EPIDEMIOLOGY AND ETIOLOGY

Nasopharyngeal carcinoma (NPC) is an uncommon cancer in most parts of the world. The age-adjusted incidence rate (per 100,000 people per year) among men ranges from below 1 in the United States and Japan to 5.4 in Algeria; 5.8 in the Philippines; 11.0 in Singapore; 17.2 among Eskimos, Indians, and Aleuts in Alaska to 25 in Southern China.[1-4]

A bimodal age distribution is observed in low-risk populations. The first peak incidence arises between 15 and 25 years of age, with the second peak at 50 and 59 years of age.[5-7] In high-risk populations, the peak incidence occurs in the fourth and fifth decades of life.[5] Both genders have a similar age distribution; however, the male-to-female incidence ratio is 2:1 to 3:1.[8]

This distinct racial and geographical distribution of NPC suggests a multifactorial cause. Current epidemiologic and experimental data identify at least three important etiologic factors[1]: genetic,[2] environmental, and[3] viral.

The high incidence of NPC among Southern Chinese and populations of Southern Chinese descent suggests a component of genetic susceptibility. A genome-wide association study of NPC found three susceptibility loci[9] and confirmed a linkage study that found a gene closely linked to the human leukocyte antigen (HLA) locus conferred a greatly increased risk of this disease.[10] In addition, several HLA haplotypes, including A2, B46, and B17, are associated with an increased risk of developing NPC.[11,12]

The high consumption of salted fish in Southern China has been implicated as an important environmental factor.[13-16] Dimethylnitrosamine, a carcinogen found in salted fish, has been shown to induce carcinoma in the upper respiratory tract in rats.[14] Other potential environmental etiologic factors that have been associated with NPC include alcohol consumption and exposure to dust, fumes, formaldehyde, and cigarette smoke,[17,18] although definitive conclusion has been elusive. Descendants of Chinese who have migrated from endemic areas to Western countries show progressively lower risk, but their incidence remains higher than the indigenous populations.[19-21] Buell[19] observed that American-born second-generation Chinese had a lower risk than the Asian-born first generation, whereas Whites born in Southeast Asia had an increased risk compared to American-born Whites. Dickson and Flores[21] reported that the incidence rate in Chinese who were natively born in China was 20.5, compared with 1.3 for Chinese and 0.2 for Whites born in Canada. Taken together, environmental factors appear to play a role in the etiology of NPC.

Epstein-Barr virus (EBV) has been associated with NPC, especially the nonkeratinizing type, irrespective of ethnic or geographic origin.[22] Premalignant lesions of nasopharyngeal epithelium show increased levels of EBV, suggesting that EBV infection may influence the early stages of tumorigenesis in NPC.[23] Detection of a single form of EBV DNA in tumors suggests that clonal expansion from an initial EBV-infected and, ultimately, EBV-transformed cell is likely. EBV's tumorigenic potential is due to a set of latent genes, latent membrane proteins (LMP1, LMP2A, and LMP2B), and EBV-determined nuclear antigens (EBNA1 and EBNA2), which are the proteins predominantly expressed in NPC.[24] LMP1 is the principal oncogene with evidence that the C-terminal activating regions of the protein activate a variety of signaling pathways, including mitogen-activated protein kinases, phosphoinositol-3-kinase, nuclear factor κB, and epidermal growth factor receptor (EGFR).[25,26] LMP1 is also required for cell immortalization and is present in 80% to 90% of NPC tumors.[27] This mounting evidence highlights the likely etiologic role for EBV in NPC.

NATURAL HISTORY

Local Extension

A summary of structures locally infiltrated by NPC at diagnosis is provided in Table 47.2.

TABLE 47.2 STRUCTURES LOCALLY INFILTRATED BY NASOPHARYNGEAL CARCINOMA AT DIAGNOSIS

Structures Involved	Frequency (%)
Adjacent soft tissue	
Nasal cavity	87

Structures Involved	Frequency (%)
Parapharyngeal space, carotid space	68
Pterygoid muscle (medial, lateral)	48
Oropharyngeal wall, soft palate	21
Prevertebral muscle	19
Bony erosion/paranasal sinus	
Clivus	41
Sphenoid bone, foramina lacerum, ovale, rotundum	38
Pterygoid plate(s), pterygomaxillary fissure, pterygopalatine fossa	27
Petrous bone, petro-occipital fissure	19
Ethmoid sinus	6
Maxillary antrum	4
Jugular foramen, hypoglossal canal	4
Pituitary fossa/gland	3
Extensive/intracranial extension	
Cavernous sinus	16
Infratemporal fossa	9
Orbit, orbital fissure(s)	4
Cerebrum, meninges, cisterns	4
Hypopharynx	2

Based on magnetic resonance imaging of 308 patients from Pamela Youde Nethersole Eastern Hospital, Hong Kong.

Anterior

Anteriorly, it is common for the extension and infiltration of tumor into the nasal fossa. Invasion of the lateral wall of the nasal fossa can lead to involvement and destruction of the pterygoid plates. Beyond these structures, though less common, is invasion of the posterior ethmoid and maxillary sinuses. In advanced disease, infiltration of the orbital apex (typically through the inferior orbital fissure) can occur.

Superior and Posterior

Superiorly, tumors can directly invade the base of skull, the sphenoid sinus, and the clivus. The foramen lacerum, positioned directly above the pharyngeal recess (*Rosenmuller Fossa*), is a vulnerable spot through which the tumor may enter the cavernous sinus and the middle cranial fossa to invade cranial nerves II to VI (Figure 47.3). Figure 47.4 demonstrates involvement of the trigeminal cave (*Meckel cave*) and the maxillary branch of the trigeminal nerve (V_2). The foramen ovale also allows access for tumor to invade the middle cranial fossa, in addition to the petrous portion of the temporal bone, and the cavernous sinus. Posteriorly, invasion of the prevertebral (longus capitis) muscles is commonly seen.

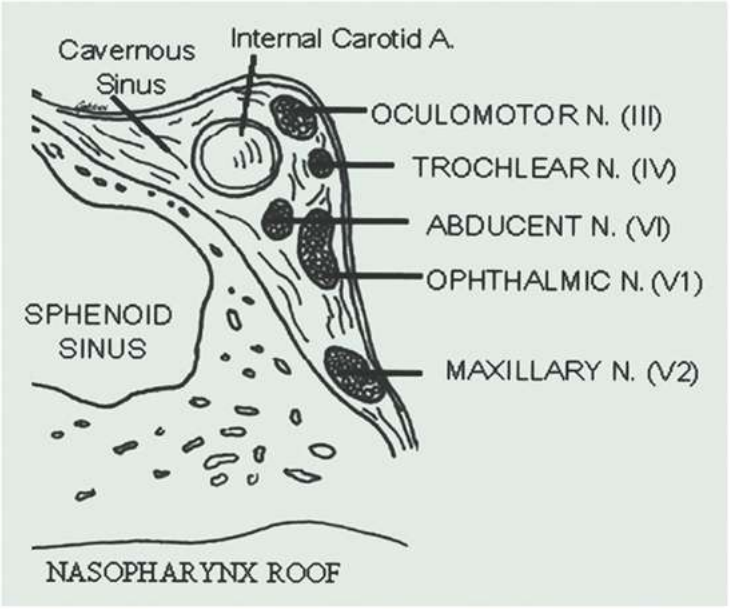

FIGURE 47.3 Coronal section through the sphenoid sinus and roof of the nasopharynx showing the relative positions of the cranial nerves III to VI. (Reprinted with permission from Chao KSC. *Practical Essentials of Intensity-Modulated Radiation Therapy*. Lippincott Williams & Wilkins; 2005:138.)

Coronal contrast-enhanced MRI showing involvement of the trigeminal cave (aka Meckel cave) by nasopharyngeal carcinoma (*arrow*). C. Coronal contrast-enhanced MRI showing involvement of the maxillary branch of the trigeminal nerve by nasopharyngeal carcinoma (V_2) (*arrow*).

Inferior

Extension inferiorly to the oropharynx is not unlikely, with potential involvement of the tonsillar pillars, the tonsillar fossa, and the lateral and posterior oropharyngeal walls. In advanced disease, invasion of the C1 vertebra posteriorly and inferiorly can occur. Direct invasion of the soft palate is uncommon.

Lateral

Lateral extension occurs early with involvement of the lateral parapharyngeal space along with invasion of the levator and tensor veli palatini muscles (Figure 47.5). In advanced disease, invasion of the pterygoid muscles can occur. Direct extension of the tumor or lateral retropharyngeal lymph node metastasis in the parapharyngeal space may lead to invasion or compression of cranial nerves IX to XI as they transpire the jugular foramen, cranial nerve

XII as it emerges from the hypoglossal canal, and the cervical sympathetic nerves. Direct invasion or compression of the internal carotid artery can occur in advanced disease (Figure 47.6). Tumor can directly invade the middle ear through the pharyngotympanic (eustachian tube).

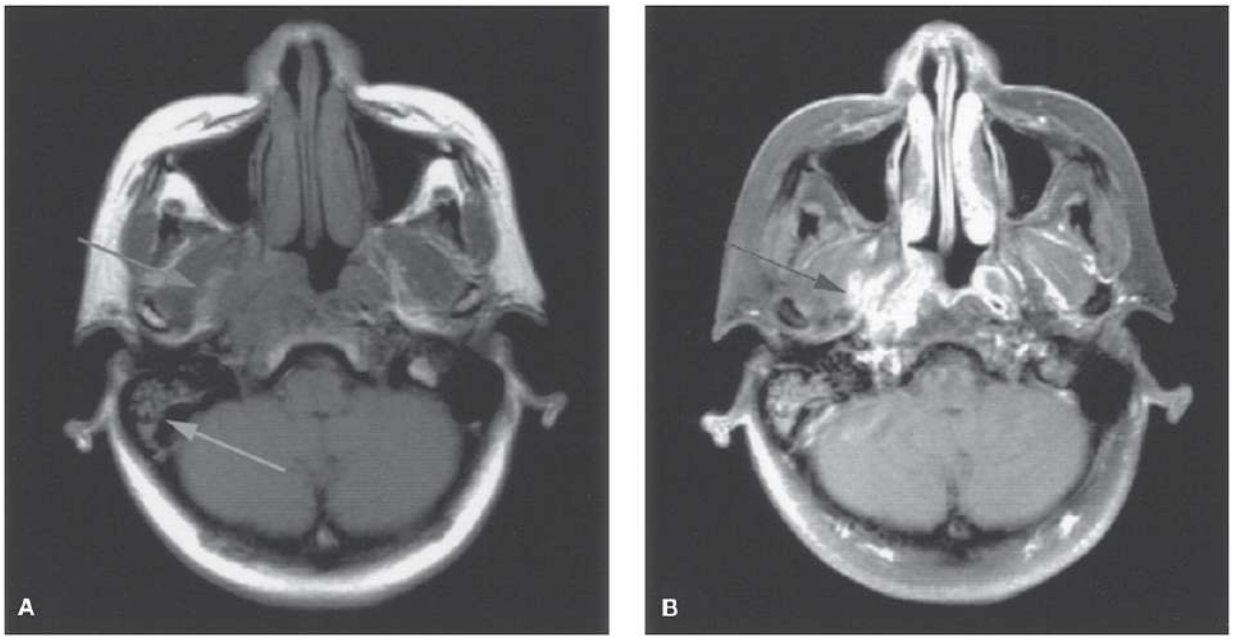

FIGURE 47.5 A. Axial T1-weighted magnetic resonance image (MRI) showing tumor infiltration of the right parapharyngeal space (*left arrow*). Note the resultant serous otitis media (*right arrow*). B. Axial contrast-enhanced MRI showing enhanced tumor involving the parapharyngeal space and medial pterygoid muscles (*arrow*).

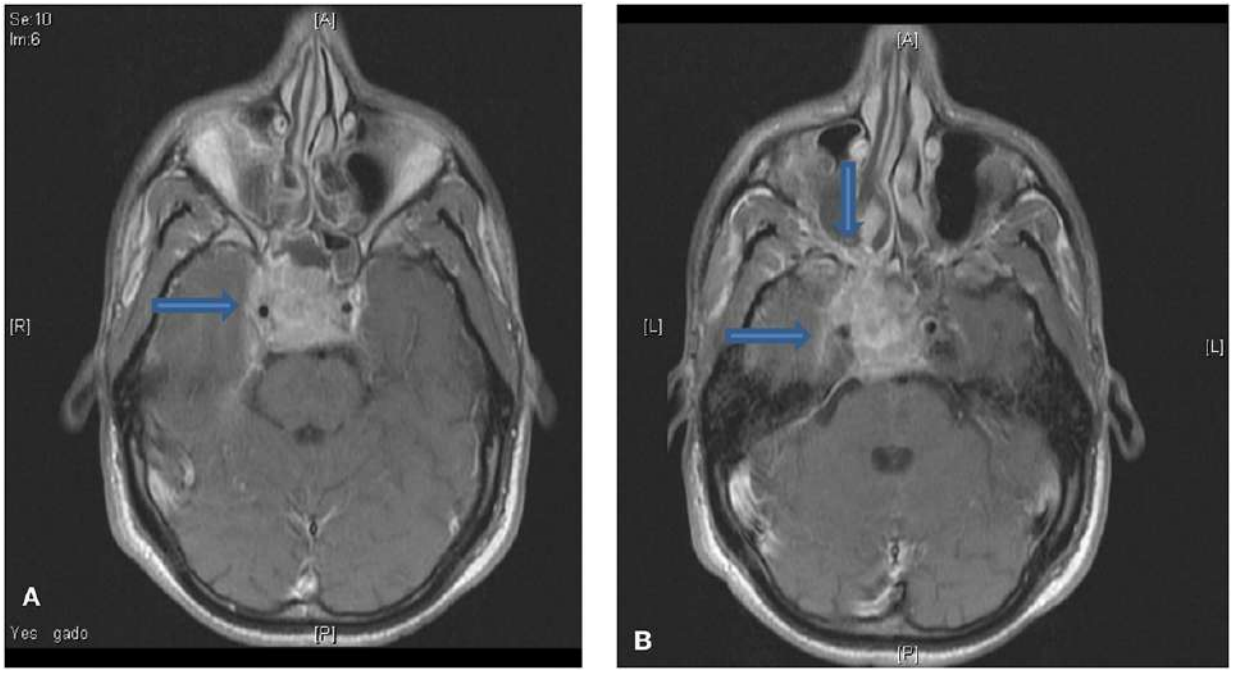

FIGURE 47.6 A. Axial contrast-enhanced magnetic resonance image (MRI) demonstrating involvement of the cavernous sinus by nasopharyngeal carcinoma. B. Axial contrast-enhanced MRI showing invasion of the pterygopalatine fossa (*vertical arrow*) with spread to cavernous sinus (*horizontal arrow*).

Lymphatic Spread

The nasopharynx is composed of a vast avalvular lymph capillary network that exists in the mucous membrane leading to frequent involvement of regional neck nodes (Figure 47.7). Up to 85% to 90% of cases present with lymphatic spread to the ipsilateral nodes.[28-30] Bilateral spread is present in approximately 50% of cases. The distribution of NPC-involved nodes at diagnosis is shown in Figure 47.8. An anatomic and radiographic study that directly examined lymphatic vasculature concluded that there are two major lymph collectors of the nasopharynx (Figure 47.7B).[31] One lymph collector runs along the lateral side of the pharyngeal wall, whereas the second runs more posteriorly. The lateral lymph collector empties into multiple first-tier nodes, which include the lateral pharyngeal node, the jugulodigastric/subdigastric node, and the third, fourth, and fifth nodes of the retropharyngeal group.[31] The posterior lymph collector empties into the first node (*node of Rouvière*) of the retropharyngeal group (Figure 47.9). This direct study is corroborated clinically by frequent observation of lateral and retropharyngeal lymph node involvement by magnetic resonance image (MRI) of computed tomography (CT) scans, even though they remain impalpable. Metastasis to the jugulodigastric and superior-posterior cervical nodes is also common. From these first-tier nodes, further metastatic spread to the midjugular, lower jugular, and posterior cervical and supraclavicular nodes can develop. Seldom, submental and occipital nodes can be involved secondary to lymphatic obstruction caused by widespread cervical lymphadenopathy. Mediastinal lymph nodes and, occasionally, axillary nodes may be involved with the presence of supraclavicular lymphadenopathy.

Axial T2-weighted magnetic resonance image showing involvement of bilateral retropharyngeal lymph nodes (*arrows*) by nasopharyngeal carcinoma.

Hematogenous Dissemination

Distant metastasis is present in 3% to 6% of the cases at presentation and may occur in 18% to 50% of cases during the disease course.[32-36] The rate of distant metastasis is highest in patients with advanced neck node metastasis,[28,37,38] especially with low-neck involvement.[39,40] The bone is the most common distant metastatic site followed by the lungs and liver,[41] with lung metastasis being associated with better prognosis than other sites. Brain and skin metastases rarely occur.[42,43]

CLINICAL PRESENTATION

NPC presents in patients with symptoms in one or more of the following three categories: (1) neck masses, usually appearing in the upper neck; (2) presence of tumor mass in the nasopharynx (epistaxis, nasal obstruction and discharge); or (3) skull base erosion and palsy of cranial nerves V and VI because of tumor extension superiorly (headache, diplopia, facial pain, and numbness).

The frequency of various presenting symptoms and signs is summarized in Table 47.3. A neck mass is the most common presenting symptom, followed by nasal and aural symptoms. The physical signs commonly present at diagnosis are enlarged neck node(s) and, less often, cranial nerve palsy. The cranial nerves V and VI are frequently involved, whereas cranial nerves I, VII, and VIII are rarely involved (Table 47.4).[30,44]

TABLE 47.3 SYMPTOMS AND PHYSICAL SIGNS OF NASOPHARYNGEAL CARCINOMA AT PRESENTATION

Symptom/Sign	Chao and Perez[45] (*n* = 164) (%)	Lee et al[30] (*n* = 4,768) (%)
Neck mass	66	76
Enlarged neck node(s)		75
Nasal (discharge, bleeding, obstruction)	>37	73
Aural (tinnitus, hearing impairment)	41	62
Headache	40	35
Cranial nerve palsy	23	20
Neurologic symptoms		
Ophthalmic (diplopia, squint)		11
Facial numbness		8
Slurring of speech		2

Symptom/Sign	Chao and Perez[45] (*n* = 164) (%)	Lee et al[30] (*n* = 4,768) (%)
Sore throat	16	
Weight loss		7
Trismus		3
Distant metastases		3
Dermatomyositis		1

TABLE 47.4 INCIDENCE OF CRANIAL NERVE INVOLVEMENT BY NASOPHARYNGEAL CARCINOMA AT DIAGNOSIS

Cranial Nerve	Chao and Perez[45] (*N* = 164) (%)	Chan et al[46] (*N* = 722) (%)
I	—	—
II	1.3	0.8
III	3.5	1.3
IV	2.4	0.6
V	7.8	V_1, 3.5; V_2, 5.8%; V_3, 3.9
VI	13.3	5.1
VII	3.6	0.1
VIII	4.8	—
IX-XII	IX, 2; X, 5.4; XI, 1.3; XII, 4.8	2.4

Cervical lymphadenopathy is present in up to 87% of patients.[47] Typically, a mass is observable in the upper posterior neck and palpable beneath the superior portion of the sternocleidomastoid muscle close to the mastoid process. This is caused by metastasis to the parapharyngeal nodes or superior-posterior cervical nodes of the spinal accessory chain.

DIAGNOSTIC AND STAGING WORKUP

Diagnosis of NPC is made by biopsy of the primary tumor. This can typically be performed with local anesthesia in an outpatient setting. Biopsy by direct visualization with general anesthesia may be necessary for diagnosis when the tumor is not visible or when the patient cannot cooperate. Not uncommonly, the tumor is submucosal and not visible. For suspicious cases of a nasopharyngeal primary tumor with lack of visible tumor, random biopsies of the most commonly involved sites are warranted: pharyngeal recess (*fossa of Rosenmüller*) on each of the lateral walls and superior-posterior wall of the nasopharynx. Fine-needle aspiration (FNA) of a suspicious neck mass may establish the presence of metastatic NPC in the regional lymphatics. This may be performed prior to the biopsy of the nasopharynx when the primary tumor is not clinically detectable.

Table 47.5 lists the pretreatment diagnostic evaluations and staging evaluations that are generally recommended for NPC.

TABLE 47.5 RECOMMENDED PRETREATMENT DIAGNOSTIC EVALUATIONS FOR NASOPHARYNGEAL CARCINOMA

General
Medical history
Physical examination
Palpation of neck node (record size, laterality, and lowest extent of enlarged nodes)
Testing of cranial nerve (including assessment of vision and hearing functions)
Exclusion of gross signs of distant metastases
Fiberoptic endoscopy examination
Nasopharyngoscopy and biopsies
± Panendoscopy
Otologic assessment
Inspection of tympanic membranes (as clinically indicated)

General
Baseline audiologic testing (preferable)
Laboratory studies
Complete blood count
Liver function tests
Urinalysis
EBV-specific serologic tests
Immunoglobulin A (IgA)
Antiviral capsule antigen (VCA) titers
Serum EBV DNA levels
Radiographic studies
Assessment of locoregional extent (imaging of the nasopharynx, paranasal sinuses, base of skull, nasal cavity, and neck)
Magnetic resonance imaging (study of choice)
Computed tomography (acceptable alternative)
Chest radiograph (posterior-anterior and lateral)
Additional metastatic workup if clinically indicated or N3 disease
Positron emission tomography (study of choice)
Computed tomography of the chest and abdomen
In patients with abnormal LFTs or clinical suspicion of lung or liver metastasis
Bone scan
In patients with advanced locoregional disease, symptoms suggestive of bone metastasis, or an elevated serum alkaline phosphatase

EBV, Epstein-Barr virus; LFT, liver function test.

Complete physical examination should include thorough palpation of the neck, cranial nerve examination, percussion and auscultation of the chest, palpation of the abdomen for possible liver involvement, and percussion of the spine and bones for possible bone metastasis. CT and MRI of the head and neck are useful in the evaluation of tumor erosion into the bony structures of the base of skull along with retropharyngeal and cervical lymphadenopathy. However, MRI is the preferred imaging technique in the staging evaluation of NPC.[48-50] The current American Joint Committee on Cancer (AJCC) T classification requires a search for tumor invasion into the soft tissue (eg, parapharyngeal space) and bony structures. MRI may be necessary for proper staging because CT has limitations in accurately defining tumor extension into these regions[51] and MRI was used[52] for the study that informed the updated 2017 AJCC system. MRI is superior to CT in delineating muscle and soft tissue involvement and examination of the skull base.[51,53,54] When utilizing MRI, thin slices (3 mm) should be used for accurate staging (Figure 47.10). Thicker slices (eg, ≥5 mm) risk misdiagnosis of what may be a higher T-stage disease.

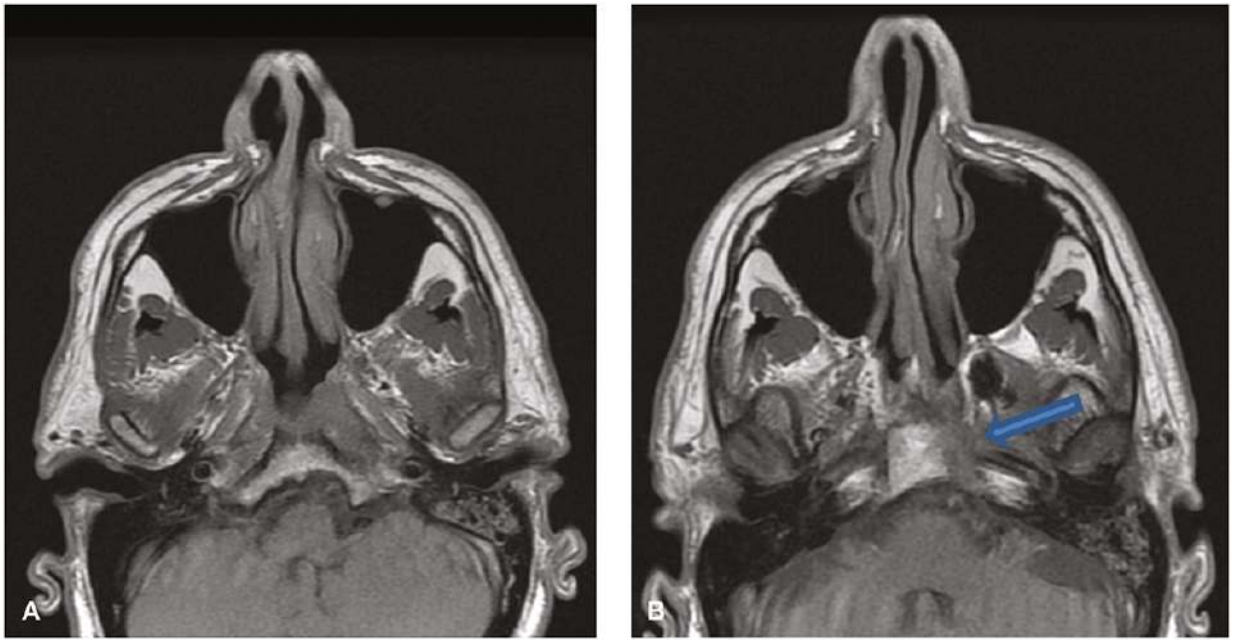

FIGURE 47.10 A. Axial T1-weighted magnetic resonance image (MRI) with 5-mm slices. B. Axial T1 MRI with 3-mm slices, skull base invasion (*arrow*) upstaged this tumor from T1 to T3.

Ng et al[55] compared MRI and CT in assessing the extent of disease. The study found a significantly higher sensitivity of MRI for skull base involvement (60% vs 40%), intracranial involvement (57% vs 36%), retropharyngeal node (58% vs 21%), and tumor infiltration of prevertebral muscles (ie, longus colli muscles) (51% vs 22%) compared to CT. By MRI, T staging was modified in 27% of patients, with 22% being upstaged and 4% being downstaged.

MRI and CT scans can detect lymph node metastasis that may not be clinically evident on physical examination.[56] According to a study by Van den Brekel et al,[57] lymph node metastasis is commonly recommended to be radiologically defined by the presence of central necrosis, extracapsular spread, shortest axial diameter ≥10 mm (11 mm for the jugulodigastric node and 5 mm for the retropharyngeal node), or a cluster of ≥3 lymph nodes that are borderline in size.

Detailed evaluation of nodal enlargement by palpation and imaging should consist of the size and location of the node, unilateral/bilateral involvement, and assessment of supraclavicular fossa involvement. Figure 47.8 defines the anatomic boundaries of the supraclavicular fossa, and Figure 47.11 demonstrates an example of bilateral cervical lymph node involvement seen by radiologic studies.

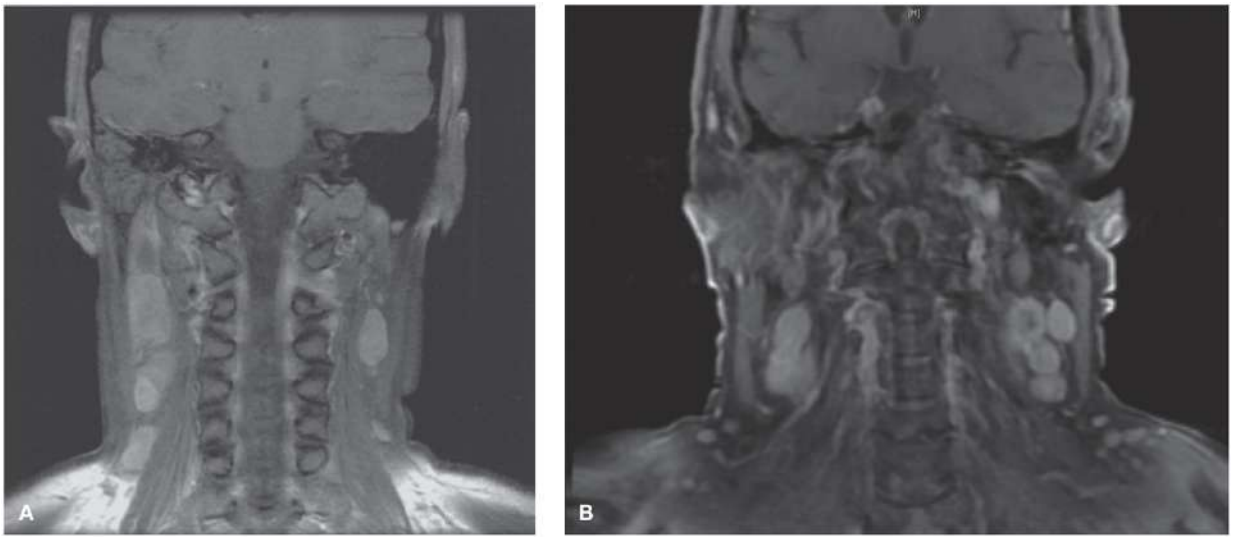

FIGURE 47.11 Two examples of coronal magnetic resonance images showing bilateral cervical lymphadenopathy. There is orderly downward lymphatic spread toward the supraclavicular fossa.

A complete search for distant metastasis is recommended for patients with advanced locoregional disease (eg, N3 disease) or patients with suspicious clinical or laboratory findings. Positron emission tomography (PET)/CT scanning (Figure 47.12) is now commonly utilized in place of conventional staging by CT, bone scans, and ultrasound and appears to be at least as sensitive. Chang et al[58] demonstrated that [^{18}F]fluorodeoxyglucose (FDG)-PET was superior to conventional workup (ie, chest x-ray, isotope bone scan, and abdominal ultrasound) in the detection of distant metastases, where 12% of patients were upstaged to stage IVC. PET, in the study, offered a sensitivity and specificity of 100% and 90.1%, respectively. However, large comparative studies of these various staging modalities have yet to be reported.[58-60]

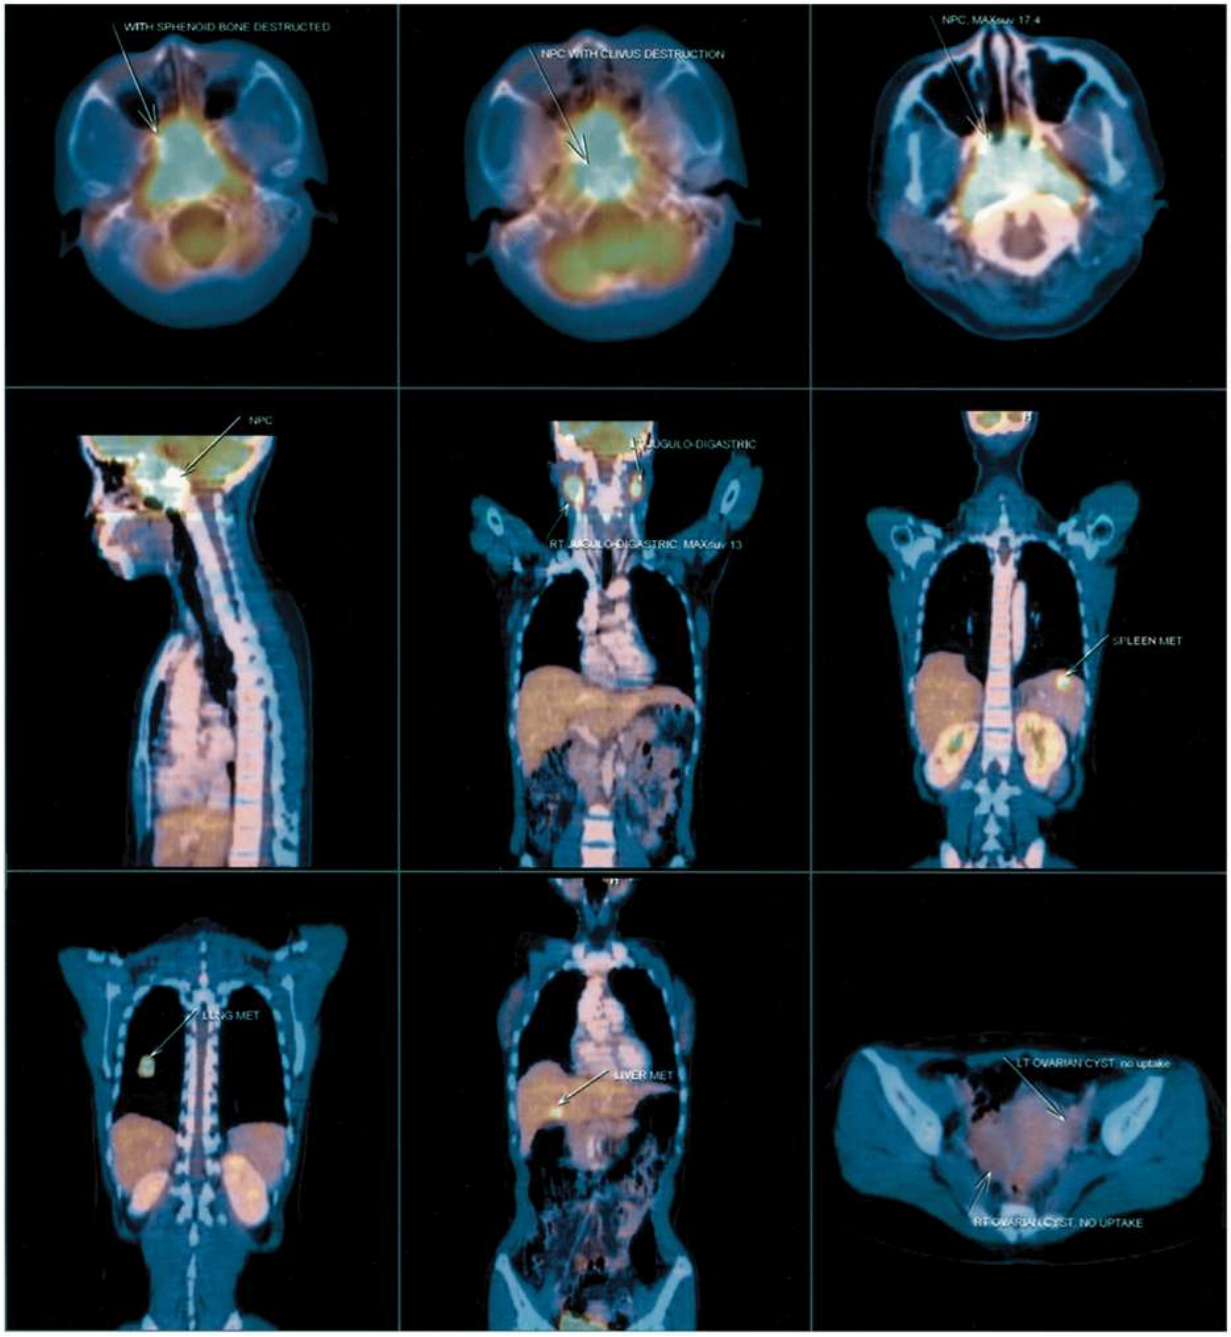

FIGURE 47.12 Positron emission tomography coupled with computed tomography (PET-CT) for a patient with nasopharyngeal carcinoma. Physical examination and biochemistry did not show any sign suggestive of distant metastases. X-ray of the chest was normal. PET-CT revealed multiple distant metastases in the lung, liver, and spleen, in addition to extensive local infiltration and bilateral cervical lymph nodes. World Health Organization Classification of Tumours*. Vol 9. 3rd ed. IARC Press; 2005. Copyright © Dr. A. W. M. Lee.)

The intimate association of EBV with NPC, independent of geographic and ethnic background, has provided clinicians with a tumor marker for disease diagnosis. Immunoglobulin A (IgA) antiviral capsid antigen (VCA) and IgG anti-early antigen (EA) antibodies are both sensitive for diagnosing NPC; however, IgA anti-VCA has better specificity.[61] More than 90% of untreated patients with NPC from California, East Africa, and Hong Kong have elevated IgA antibody titers.[62-64] Elevated IgA anti-VCA and IgG anti-EA antibody titers are typically associated with nonkeratinizing carcinoma (both the differentiated and undifferentiated histologic subtypes). Neel et al[65]

reported 82% and 86% of patients with nonkeratinizing carcinoma had elevated IgA anti-VCA and IgG anti-EA antibody titers, respectively, in contrast with only 16% and 35%, respectively, in patients with the keratinizing histologic type. IgA anti-VCA antibodies may serve as a screening test in high-risk patients as it can be found elevated in patients months before the onset of symptoms.[66,67] A baseline test of plasma EBV DNA may be useful for prognosis, and levels over time can be utilized as surveillance in a post-treatment setting.[68,69]

STAGING SYSTEM

Various staging systems have been devised to predict prognosis and guide treatment strategy for patients with NPC.[70-73] The AJCC, Union for International Cancer Control (UICC), and Ho staging systems are the most commonly used systems in the English literature. The AJCC and UICC systems are virtually identical in their 2002 version, and this continues in the 2010 and 2017 updates. Each system has particular limitations; however, they continually evolve and build upon each other's experience. Table 47.6 displays the 2017 AJCC staging system currently in use.[74]

TABLE 47.6 AJCC STAGING OF NASOPHARYNGEAL CANCER, 2017

Stage	Staging Criteria		
T category			
TX	Primary tumor cannot be assessed.		
T0	No evidence of primary tumor		
T1	Tumor confined to the nasopharynx or extension to oropharynx and/or nasal cavity without parapharyngeal involvement		
T2	Tumor with extension to parapharyngeal space and/or adjacent soft tissue involvement (medial pterygoid, lateral pterygoid, prevertebral muscles)		
T3	Tumor with infiltration of bony structures at skull base, cervical vertebra, pterygoid structures, and/or paranasal sinuses		
T4	Tumor with intracranial extension; involvement of cranial nerves, hypopharynx, orbit, and parotid gland; and/or extensive soft tissue infiltration beyond the lateral surface of the lateral pterygoid muscle		
N category			
NX	Regional lymph nodes cannot be assessed.		
N0	No regional lymph node metastasis		
N1	Unilateral metastasis in cervical lymph node(s) and/or unilateral or bilateral metastasis in retropharyngeal lymph node(s), 6 cm or smaller in greatest dimension, above the caudal border of cricoid cartilage		
N2	Bilateral metastasis in cervical lymph node(s), 6 cm or smaller in greatest dimension, above the caudal border of cricoid cartilage		
N3	Unilateral or bilateral metastasis in cervical lymph node(s), larger than 6 cm in greatest dimension, and/or extension below the caudal border of cricoid cartilage. Metastasis in lymph node(s) >6 cm		
M category			
M0	No distant metastasis		
M1	Distant metastasis

It is important to understand changes to the staging system over time for interpretation of older studies, which use prior classifications. The designation "T0" has been added for an EBV-positive unknown primary with cervical lymph node involvement. Tumors confined to the nasopharynx have similar outcomes to tumors that extend to the nasal cavity and oropharynx.[21,75] From the 2002 to 2010 system (Tables 47.7 and 47.8, respectively), T2a was, therefore, downstaged to T1, which is defined as tumor confined to the nasopharynx or tumor that extends to the nasal cavity and/or oropharynx. Tumors with parapharyngeal involvement were classified as T2 in the 2010 system and were no longer subdivided as T2b. Tumors with parapharyngeal space involvement are at higher risk for local and regional recurrence, as well as a high rate of distant metastasis.[76] Now, in the 2017 version, adjacent muscle involvement (including medial pterygoid, lateral pterygoid, and prevertebral muscle) is now designated as T2. Cranial nerve involvement has been shown to carry a worse prognosis than skull base involvement[28,39,77,78]; as such, T3 disease includes involvement of the bony structures of the skull base, whereas T4 includes involvement of the cranial nerves. The previous T4 criteria of extension to the "masticator space" or "infratemporal fossa" have been replaced in the 2017 by a specific description of soft tissue involvement "beyond the lateral surface of the lateral pterygoid muscle, parotid gland" to avoid ambiguity.

TABLE 47.7 AJCC STAGING OF NASOPHARYNGEAL CANCER, 2002

Stage	Staging Criteria
T category	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor confined to the nasopharynx
T2	Tumor extends to adjacent soft tissues: Nasal cavity,[a] oropharynx[b]
	T2a. Tumor without parapharyngeal extension[c]
	T2b. Tumor with parapharyngeal extension
T3	Tumor involves bony structures and/or paranasal sinuses.
T4	Tumor with intracranial extension, involvement of cranial nerves, hypopharynx, orbit, infratemporal fossa,[d] or masticator space[d]
N category	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Unilateral metastasis in lymph node(s), ≤6 cm in greatest dimension, above the supraclavicular fossa
N2	Bilateral metastasis in lymph node(s), ≤6 cm in greatest dimension, above the supraclavicular fossa
N3	Metastasis in lymph node(s)
	N3a. >6 cm in dimension
	N3b. Extension to the supraclavicular fossa[e]
M category	
MX	Distant metastasis cannot be assessed.
M0	No distant metastasis
M1	Distant metastasis

NPC has a unique pattern of nodal spread as compared to other sites in the head and neck region, which is reflected in the nodal staging classification. Retropharyngeal nodes are the first echelon of nodal metastases,[80] and retropharyngeal lymph node involvement independent of laterality and without cervical lymph node involvement was defined as N1 beginning in the 2010 system. Spread to the low-neck correlates strongly with the development of distant metastasis.[39,40] The previous N3b criterion of supraclavicular fossa extension was changed to lower neck involvement (as defined by nodal extension below the caudal border of the cricoid cartilage) in the 2017 update. In addition, N3a and N3b have been merged into a single N3 category. Lastly, the previous substages IVA (T4 N0-2 M0) and IVB (any T N3 M0) are now merged to form IVA, whereas the previous IVC (any T any N M1) is now staged as IVB.

These modifications to the staging classifications will require continued examination to determine if they improve prognostic accuracy.

PATHOLOGIC CLASSIFICATION

The vast majority of malignant nasopharyngeal tumors are carcinoma (80%-99%), with the remainder of these lesions (about 5%) being lymphomas.[81] Other rare malignant tumors of the nasopharynx include adenocarcinoma, plasmacytoma, melanoma, and sarcomas. Regarding NPC, the most current World Health Organization (WHO) pathologic classification, released in 2017,[82] includes three major types (Figure 47.13). Keratinizing squamous cell carcinoma is distinguished by the presence of keratin pearls or intracellular keratin. Nonkeratinizing carcinoma is characterized by the complete absence of keratin formation and is further subdivided into differentiated and undifferentiated subtypes. The third type is known as basaloid squamous cell carcinoma[83] and is composed of closely packed small tumor cells that form a lobular and, at times, palisading pattern along with focal squamous carcinoma elements. Basaloid squamous cell carcinoma is quite rare, with a frequency of less than 0.2%[46] (Figure 47.13). The nonkeratinizing type has a strong association with EBV positivity.[84] The keratinizing type may have a correlation with human papillomavirus (HPV); however, the small sample size of these studies requires continued investigation.[85]

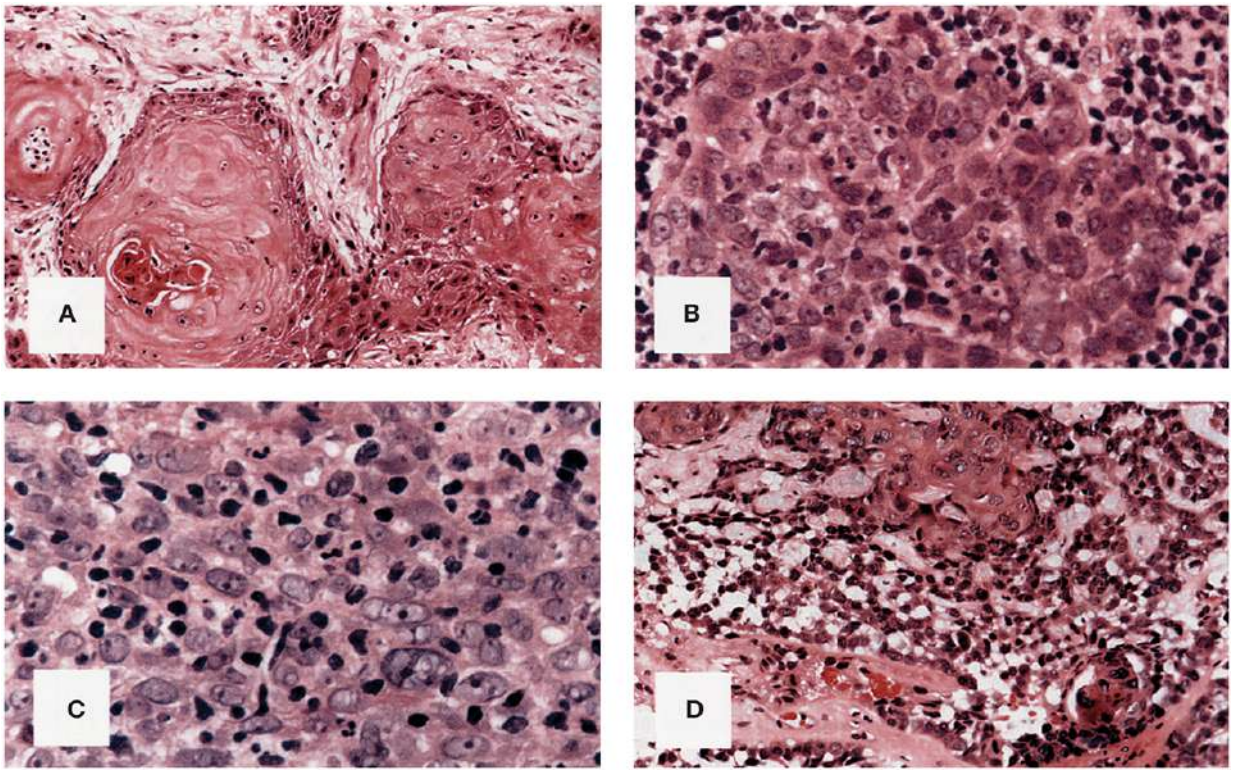

FIGURE 47.13 Photomicrographs of nasopharyngeal carcinoma. A. Keratinizing squamous cell carcinoma. B. Nonkeratinizing carcinoma, differentiated subtype. C. Nonkeratinizing carcinoma, undifferentiated subtype. D. Basaloid squamous cell carcinoma. (Reprinted with permission from Chan J, Bray F, McCarron P, et al. Nasopharyngeal carcinoma. In: Barnes L, Eveson JW, Reichart P, Sidransky D, eds. *Pathology and Genetics of Head and Neck Tumours. World Health Organization Classification of Tumours*. Vol 9. 3rd ed. IARC Press; 2005. Copyright © Dr. J. K. C. Chan.)

The histologic differences between these three types are by no means distinct. Lesions can share intermediate features, and some may be histologic hybrids. Lymphoepithelioma or lymphoepithelial carcinoma is considered a morphologic variant of undifferentiated carcinoma in which many lymphocytes are found among the tumor cells. Geography, race, and national origin affect the distribution of the WHO histologic types (Table 47.9). The frequency of nonkeratinizing carcinoma varies from 99% in Hong Kong to 75% in the United States.[46]

TABLE 47.9 FREQUENCY OF DIFFERENT HISTOLOGIC SUBTYPES OF NASOPHARYNGEAL CARCINOMA

	High Incidence Population (%): Hong Kong	Intermediate Population (%): Tunisia	Low Incidence Population (%): The United States
Keratinizing squamous cell carcinoma	1	8	25
Nonkeratinizing carcinoma	99	92	75
Undifferentiated	92	76	NA
Differentiated	7	16	NA
Basaloid squamous carcinoma	<0.2	NA	NA

Of note, the former WHO classification remains quite commonly used and classifies the three histologic types as (a) squamous cell carcinoma, (b) nonkeratinizing carcinoma, and (c) undifferentiated carcinoma.[70] This leads to unnecessary confusion with the new WHO classification as the former classification has been used in the majority of, albeit older, studies.

PROGNOSTIC FACTORS

The extent of local invasion, regional lymphatic spread, and distant metastasis, as reflected by the TNM staging, is the most important prognostic factor. In general, advanced T category is associated with worse local control and overall survival (OS); advanced N category predicts increased risk of distant metastasis and worse survival. The presence of distant metastasis (M1) upon presentation usually indicates poor prognosis, and treatment has conventionally been palliative in nature. A summary of the patterns of failure and survival rate for the different stages can be found in the "Results of Treatment" section.

The association of bone erosion, cranial nerve palsy, and lower nodal level with poorer survival is largely undisputed.[86-89] However, the prognostic significance of parapharyngeal extension has been a topic of controversy. In a study of 364 patients, Chua et al[90] showed that greater tumor extension as defined by extension to the prestyloid space or extension to the anterior part of the masticator space was associated with a worse local failure-free rate (L-FFR of 72% vs 86%) and lower distant failure-free rate (D-FFR of 68% vs 87%) compared to tumors with no extension or extension only to the retrostyloid space. Other investigators have reported similar significant findings.[76,88,91-93] Cheng et al[94] found parapharyngeal space extension to be the key factor in distant metastasis, even in N1 and N2 NPC.

However, Teo et al[87] did not find parapharyngeal space involvement to be an independent significant prognosticator in a study of 903 patients. Au et al,[95] using the AJCC/UICC definition of extension beyond the pharyngobasilar fascia in a study of 1,294 patients, also found that parapharyngeal extension was not a significant factor upon multivariate analysis.

These contradictory findings may be attributed to varying definitions of parapharyngeal space and incidence in the different series,[76,87,88,91] prompting some to advocate for consideration of the degree of parapharyngeal space extension in future staging systems.[93] In addition, suboptimal imaging by CT and conflation with retropharyngeal node enlargement likely contribute to the debate.[96,97]

Nevertheless, the 2010 AJCC staging system (Table 47.8) downgraded involvement of the oropharynx and/or nasal cavity without parapharyngeal extension from T2a to T1 while designating the presence of parapharyngeal extension to be the sole determinant of T2 classification. This was in light of recent multiple large retrospective studies that found no significant difference in disease failure hazard ratios (HRs) between former AJCC 2002 T2a and T1.[94,98-100]

In the current 2017 AJCC staging system,[74] further refinement to T2 stage has been defined. Soft tissue involvement of the medial and lateral pterygoid muscles was downstaged to T2 (from T4 in the 2010 AJCC system), based on a large analysis of 1,609 patients who all were staged by MRI and received intensity-modulated radiation therapy (IMRT).[52]

Another prognostic factor to consider is the gross volume of the primary tumor (GTV-P). Although it is highly correlated to T stage, considerable variability in tumor volume exists within the same T stage, and evidence

increasingly suggests that tumor volume as an independent significant factor can better predict prognosis than T category as specified by both AJCC/UICC and Ho staging systems[101-105] (Figure 47.14).

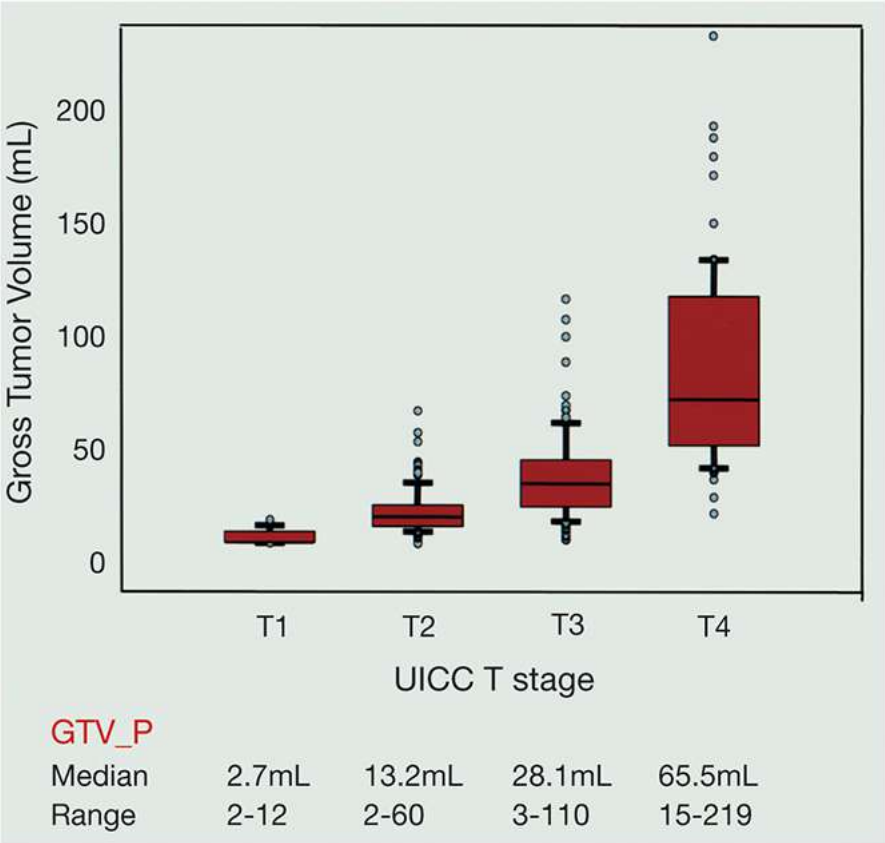

FIGURE 47.14 The correlation between T category and gross volume of primary tumor (GTV-P). UICC, International Union Against Cancer. (Modified from Sze WM, Lee AW, Yau TK, et al. Primary tumor volume of nasopharyngeal carcinoma: prognostic significance for local control. Int *J Radiat Oncol Biol Phys*. 2004;59[1]:21-27. Copyright © 2004 Elsevier. With permission.)

In a study of 308 patients staged with MRI, Sze et al[103] showed that those with GTV-P <15 cm^3 had significantly higher L-FFR than those with ≥15 cm^3 (97% vs 82% at 3 years; $P < .01$). Multivariate analysis confirmed GTV-P to be a strong significant factor independent of T category by 1997 AJCC/UICC fifth edition; the risk of local failure increased by 1% for every 1 cm^3 increase in volume. A similar observation between GTV and clinical outcomes has been observed in other head and neck tumors, including oropharyngeal cancers.[106] Further study is required to determine how tumor volume may be optimally incorporated into future staging systems.

Most series have found significantly better prognosis for females and younger patients.[86,95,107] In 759 patients, Sham and Choy[86] showed a higher 5-year survival rate in females compared with males (45% vs 28%) and in patients younger than 40 years of age versus those older than 40 (50% vs 40%, $P = .002$). However, they did not find age to significantly affect the 10-year survival rate. Multivariate analysis of 1,294 patients by Au et al[95] also showed worse cancer-specific death rates in males (HR = 1.28, $P = .02$) and patients older than 50 years (HR = 1.79, $P < .001$).

Although not all studies have found histology to be an independent prognostic factor,[28,108] many have found nonkeratinizing and undifferentiated carcinomas (formerly known as lymphoepitheliomas) to be more radiosensitive and offer better prognosis than keratinizing squamous cell carcinoma.[32,109,110] Of note, regarding ethnicity as a prognostic factor, a study by Corry et al[111] showed no prognostic difference between ethnic Asian and non-Asian patients with nonkeratinizing carcinoma.

Epstein-Barr Virus, Human Papillomavirus, and Other Biomarkers

Because of the association of EBV with NPC, various anti-EBV antibodies have long been studied for their potential as biomarkers. Although some studies have shown that elevated level of serum anti-EBV antibodies could indicate the presence[64,112,113] of disease, others have shown anti-EBV antibody titers to have little value for post-treatment surveillance.[65,114,115] The prognostic value of such titers prior to treatment has also been controversial. Although Xu et al[116] found that high EBV DNAase–specific neutralizing antibody at diagnosis predicted significantly worse event-free (EFS) and OS, others found that a number of antibodies (VCA-IgG, VCA-IgA, EA-IgG, EA-IgA, EBNA-IgG, EBNA-IgA) could not predict prognosis.[113,117,118]

Circulating cell-free DNA of EBV in the plasma of patients with NPC is a significant prognostic marker and has been found to be superior to serum anti-EBV antibodies.[118] Lo et al[119] showed that plasma EBV DNA had high sensitivity (96%) and specificity (93%) for detecting NPC, whereas Ma et al[120] showed that circulating EBV DNA levels correlated significantly with tumor burden. Studies by Lo et al[121] and Lin et al[68] found that high pretreatment levels were associated with advanced stages and poor prognosis. Meanwhile, Leung et al[69] showed that pretreatment plasma EBV DNA load was an independent prognostic factor for OS in 376 patients and could be used to segregate early-stage patients into poor- and high-risk subgroups. Thus, pretreatment EBV DNA assays have the potential to complement TNM staging in guiding treatment.

The ability of post-treatment EBV DNA to prognosticate outcomes has also been studied. Le et al[122] found no correlation between pretreatment EBV DNA levels and survival; they did find post-treatment levels to be a strong significant predictor of outcome; patients with no detectable EBV DNA had a 2-year OS rate of 94% versus 55% for patients with detectable post-treatment levels ($P < .002$).

Other studies have also consistently reported that patients with elevated post-treatment EBV DNA load have had higher risk of tumor recurrence.[68-125] Using multivariate analysis to compare various prognostic factors for NPC, Lin et al[126] found that the combined EBV DNA load (pretreatment and 1-week post-treatment) was the single most significant factor.

The ability of post-treatment EBV DNA to influence decisions regarding adjuvant therapy is currently being investigated in the NRG Oncology cooperative group HN001 trial (NCT02135042). This phase II randomized/phase III trial offers differing treatment regimens to patients with stages IIB to IVB NPC on the basis of post-chemoradiotherapy (CRT) EBV DNA levels. The hypothesis is that post-treatment EBV DNA can be used to risk-stratify patients following a course of definitive concurrent CRT. In this way, it could serve as a biomarker potentially identifying those at the highest risk for recurrence and most likely to benefit from adjuvant chemotherapy. Therefore, in the phase III cohort, patients with undetectable post-CRT EBV DNA will be randomized to observation alone versus standard adjuvant chemotherapy consisting of cisplatin and 5-fluorouracil (5-FU). The primary end point for this portion of the trial is OS with the hypothesis that observation will be noninferior to adjuvant chemotherapy. Patients with detectable post-CRT EBV DNA are randomized in the phase II portion of the trial to standard adjuvant chemotherapy or a non–cross-resistant, experimental doublet consisting of paclitaxel and gemcitabine with the hypothesis that experimental chemotherapy will be associated with superior progression-free survival (PFS). The outcomes of this trial may allow for the creation of individualized treatment recommendations using post-CRT EBV DNA as a guide.

Both Wang et al[127] and An et al[128] demonstrated that the clearance rate of plasma EBV DNA during the first month of salvage chemotherapy could predict tumor response and OS in patients with metastatic/recurrent NPC; undetectable levels after the first cycle indicated significant better survival. These data suggest that early evaluation of plasma EBV DNA can offer oncologists timely insight for potential alterations in the therapeutic regimen for patients with a slow clearance rate. In addition, Wang et al[129] prospectively monitored the plasma EBV DNA of 245 patients with NPC in clinical remission with assays every 3 to 6 months and found the plasma EBV DNA assay to have much greater sensitivity, specificity, and accuracy than FDG-PET in predicting relapse, suggesting its utility for post-treatment surveillance.

HPV-associated oropharyngeal carcinomas are now recognized as a separate subtype in the 2017 version of AJCC.[74,130] However, the implications of HPV to NPC with respect to etiology, prognosis, and treatment are unclear. Stenmark et al[131] reported on a 61-patient cohort from the Midwestern United States where 30% of patients were HPV positive/EBV negative. The patient outcomes in OS, PFS, and locoregional control (LRC) were worse in this HPV-positive/EBV-negative subgroup, when compared to EBV-positive tumors. Lin et al[132] evaluated NPC cases from southern China ($n = 86$) and Stanford, California, USA ($n = 108$), where no HPV-positive cases were detected in the Chinese cohort, whereas 5 of 11 EBV-negative cases in the Stanford cohort harbored HPV as confirmed by polymerase chain reaction. Of note, these 11 EBV-negative patients had a trend toward worse survival. Dogan et al[133] reported on a case series of 90 patients with NPC where six patients with confirmed

nasopharyngeal origin were HPV positive. These HPV-positive patients had a similar OS to EBV-positive NPC, whereas EBV/HPV-negative NPC had worse OS. Because of these conflicting studies and limited patient numbers, future work will be required to determine the prognostic significance of HPV positivity in NPC.

As with other head and neck squamous cell carcinomas, EGFR is commonly expressed in patients with NPC. Chua et al[134] found expression of EFGR in 89% of patients, in which overexpression was associated with significantly poorer disease-specific survival. Others have reported similar findings of prognostic significance.[25,135,136] Ma et al[135] performed multivariate analysis on several biomarkers in 78 patients, including microvessel density, Ki67 antigen, p53 oncoprotein, HER2, and EGFR, and found EGFR to be the only independent prognostic factor.

The study by Hui et al[137] showed that 58% of patients with NPC had expression of hypoxia-inducible factor 1-alpha (HIF-1α), 57% had carbonic anhydrase IX (CA IX), and 60% had vascular endothelial growth factor (VEGF). Those with positive hypoxic profile (high expression of HIF-1α and CA IX) had a worse PFS (P = .04); those with both positive hypoxic and angiogenic profile (high VEGF) were strongly associated with worse PFS (P = .0095). Multiple other studies have also shown that overexpression of these markers, particularly VEGF, is associated with poorer survival.[138-140]

Other biologic factors that might have prognostic significance include E-cadherin and β-catenin,[141] c-erbB2,[142] p53,[143] NM23-HI,[144,145] and interleukin-10.[146] Further validation of these potential biomarkers is needed.

TREATMENT STRATEGY

Because of the anatomic location, proximity to critical structures, surgical exposure, and tumor resection with sufficient margins have been very challenging.[147] Primary surgical intervention was rare after the 1950s for these reasons, with surgical interventions employed mainly for biopsy to gain histologic confirmation and salvage therapy for persistent or recurrent cancer. Primary treatment since has typically employed either radiation therapy (RT) alone and, more recently, in combination with chemotherapy.

Radiation Therapy

To achieve the best therapeutic ratio, every single step in the RT procedures (localization of gross tumor and target volumes, immobilization, optimization of dose fractionation, determination of treatment techniques, and precision in RT delivery) is important.

For planning, the patient should be set up in a supine position with head extended for adequate separation between the primary tumor/retropharyngeal nodes and the upper neck nodes. The tip of the uvula and the base of the occiput should be on a parallel plane to the beam axis. The patient is immobilized with a thermoplastic mask covering the head-to-shoulder region (Figure 47.15). For patients to be treated by conventional two-dimensional (2D) technique, a mouth bite is useful to minimize the dose to the oral cavity with enlarged neck nodes to be marked with wire before imaging.

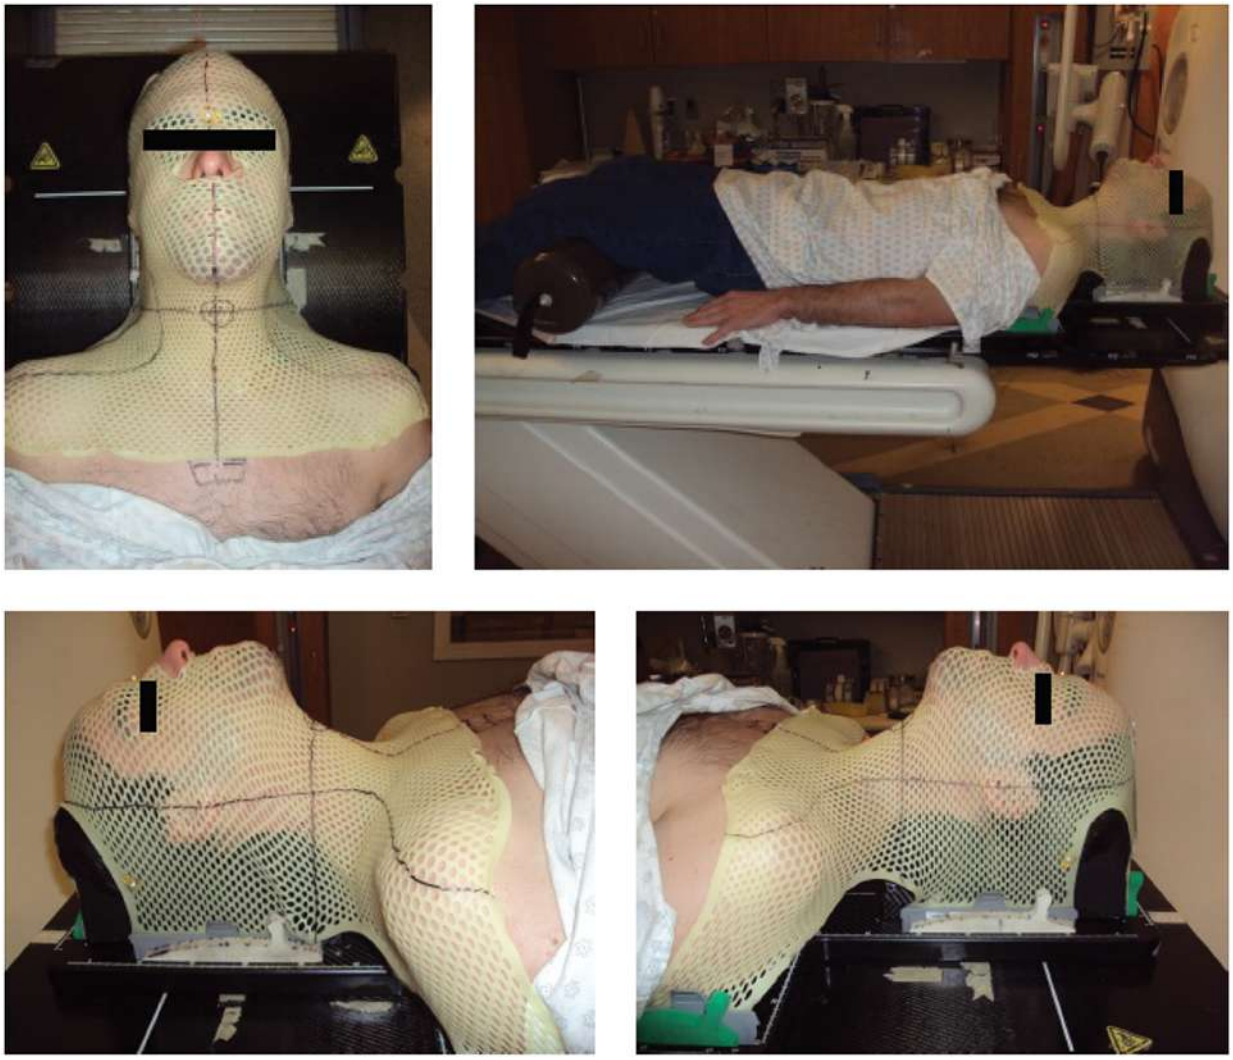

FIGURE 47.15 Immobilization of a patient in a customized thermoplastic mask covering the whole head-to-shoulder region.

Dose, Time, and Fractionation

A significant dose-response has been observed in the majority of retrospective studies, based on patients irradiated with 2D techniques. Marks et al[148] and Vikram et al[149] showed that local control was significantly improved in patients who received >67 Gy to the tumor target. Perez et al[28] observed that patients with T1-2 tumors had a local tumor control rate of 100% for those given >70 Gy, compared with 80% for those treated with 66 to 70 Gy. However, local control for patients with T3-4 tumors remained below 55%, even with a total dose >70 Gy. Similar findings were reported by Mesic et al,[150] where ≥70 Gy achieved better local control for T1-2 tumors compared with 60 Gy (94% vs 76%), but higher doses or larger fields did not significantly improve outcomes in T3-4 tumors. These observations suggest that, besides consideration of the prescribed dose, the problem of sufficient coverage has to be overcome for advanced tumors.

Lee et al[151] reported a study of 1,008 patients with T1 tumors irradiated by four different fractionation schedules and demonstrated that total dose was the most important radiation factor (P = .01). Dose fraction did not affect local control; however, it was a significant risk factor for temporal lobe necrosis (TLN).[152,153] Therefore, a fractional dose of >2 Gy should be avoided[154] (see section "Sequelae of Treatment").

The impact of the time factor is more contentious. A randomized study by Marcial et al,[155] where 62 patients were treated with split-course irradiation (30 Gy in 10 fractions over 2 weeks, then a 3-week rest period, and followed by an additional 30 Gy in 10 fractions) compared with 59 patients with 66 Gy in 33 fractions in 6.5 to 7

weeks, demonstrated no significant difference in 5-year local control (86% vs 80%), nodal control (86% vs 78%), or disease-free survival (40% vs 30%).

However, Vikram et al[149] observed that patients with interruption of RT for ≥21 days had significantly poorer local tumor control than patients without interruptions (34% vs 67%). Similar findings have been subsequently reported,[156,157] with the general consensus that prolongation is likely to be detrimental, even for nonkeratinizing NPC.

In general, the prescription recommended for NPC is to a total dose of about 70 Gy over 7 weeks to the gross tumor along with 50 to 60 Gy for elective treatment of potential risk sites.

Tumor Target Volumes

The GTV should encompass the primary nasopharyngeal tumor, gross retropharyngeal lymphadenopathy, and gross nodal disease as determined by clinical, endoscopic, and radiologic examinations. Lymph nodes ≥1 cm or with evidence of central necrosis are considered gross nodal disease. For patients given induction chemotherapy, it is recommended that the targets be determined by the prechemotherapy extent.

Prophylactic neck radiation is usually recommended in N0 patients because of the high incidence of occult neck node involvement. Lee et al[36] found patients with a clinically negative neck who underwent elective neck irradiation had a significantly lower nodal recurrence rate than those untreated (11% vs 40%). In addition, even with successful salvage by subsequent treatment, patients with nodal recurrence had a significantly greater incidence of distant metastases than those without recurrence (21% vs 6%).

The clinical target volume (CTV) includes the GTV, regions of microscopic disease, and potential infiltrative spread. Different centers may have different philosophies in defining the margins and dose level. For example, Table 47.10 shows the delineation criteria for the various CTVs currently employed at Memorial Sloan Kettering Cancer Center (MSKCC). A gross disease CTV (CTV_{70}) is defined as the GTV plus an additional margin of 5 mm to 1 cm surrounding all gross diseases. The margin may be decreased to as small as 1 mm in critical regions near the brainstem or spinal cord. The high-risk subclinical CTV ($CTV_{50\text{-}59.4}$) encompasses the GTV including all potential areas of microscopic spread of disease. This volume should include at a minimum the entire nasopharynx, retropharyngeal lymph nodal regions, clivus, skull base, pterygoid fossae, parapharyngeal space, sphenoid sinus, posterior fourth to third of the nasal cavity, and posterior fourth to third of the maxillary sinuses. This $CTV_{50\text{-}59.4}$ should also include lymph nodal groups that are at risk of potential microscopic disease spread: bilateral upper deep jugular (junctional, parapharyngeal), submandibular, subdigastric (jugulodigastric), midjugular, posterior cervical, and retropharyngeal lymph nodes. In patients with clinically N0 neck, it is not necessary to include level I nodal regions. It is reasonable to omit elective nodal irradiation for the uninvolved low neck (IV and Vb) based on prospective data from Tang et al.[158]

TABLE 47.10 EXAMPLE OF GUIDELINE ON ANATOMIC STRUCTURES/BOUNDARIES FOR DELINEATING CLINICAL TARGET VOLUMES (CTV) FOR INTENSITY-MODULATED RADIATION THERAPY

	Delineation of CTV	
CTV	**Structures**	**Anatomic Boundaries**
CTV_{70}	GTV + ≥5 mm margin (can be reduced to as low as 1 mm for tumors in close proximity to critical structures/neurologic structures)[a]	
$CTV_{50\text{-}59.4}$	CTV_{70} + ≥5 mm margin (as low as 1 mm when close to critical structures)[a]	
	Entire nasopharynx	5-10 mm from mucosal surface of nasopharynx
		Anterior: Junction with nasal choana
		Lateral: Medial border of parapharyngeal space
		Caudal: Caudal border of C1 vertebra
	Base of skull	Posterior: Anterior 1/2-2/3 of clivus (entire clivus, if involved)
		Lateral: Lateral border of foramen ovale
	Parapharyngeal spaces	Lateral: Lateral border of styloid processes
	Inferior sphenoid sinus	Cranial: Lower half of sphenoid sinus (in T3-T4 disease,

	Delineation of CTV	
CTV	**Structures**	**Anatomic Boundaries**
		include entire sphenoid sinus)
	Posterior nasal cavity	Anterior: Posterior fourth to third of nasal cavity
	Posterior maxillary sinuses	Anterior: Posterior fourth to third of maxillary sinuses (to ensure pterygopalatine fossae coverage)
	Cavernous sinus, include high-risk patients (T3, T4 bulky disease involving roof of nasopharynx)	
	High-risk nodal levels (include all bilaterally)	a. Upper deep jugular (junctional, parapharyngeal) b. Submandibular (level I)[b] c. Subdigastric (jugulodigastric) (level II) d. Midjugular (level III) e. Low jugular and supraclavicular (level IV)[c] f. Posterior cervical (level V)[c] g. Retropharyngeal

Based on guideline currently used at Memorial Sloan Kettering Cancer Center and detailed in RTOG 0615.

GTV, gross tumor volume (all gross primary tumor and involved lymph nodes); PTV, planning target volume (CTV + 3- to 5-mm margin).

Total dose prescription at:

PTV_{70}: 70 Gy in 35 fractions (2 Gy per fraction) or 70 Gy in 33 fractions (2.12 Gy per fraction).

$PTV_{50\text{-}59.4}$: 50 Gy in 25 fractions (2 Gy per fraction) or 59.4 Gy in 33 fractions (1.8 Gy per fraction).

[a]CTV margins may also be limited to exclude the bone *not* at risk for subclinical disease or air.

[b]Bilateral IB lymph nodes can be spared if patient is node negative. The treatment of level IB may result in the delivery of clinically significant radiation doses to normal structures, such as the floor of the mouth, mandible, and upper pharyngeal mucosa above the hyoid. At the discretion of the treating radiation oncologist, level IB may also be spared or limited to the anterior border of the submandibular gland in low-risk node-positive patients. Patients presenting with isolated retropharyngeal nodes or isolated level IV nodes are considered low risk for level IB involvement. Treatment of level IB should be considered in node-negative patients with extensive involvement of the hard palate, nasal cavity, or maxillary antrum.

[c]Uninvolved low neck (IV and Vb) can be spared at the discretion of the treating radiation oncologist.

The planning target volume (PTV) is defined as the CTV including a circumferential margin of typically 3 to 5 mm to all the CTVs to account for setup errors and potential patient motion. The PTV margin may be decreased to as small as 1 mm in regions near-critical normal structures, such as the brainstem or spinal cord.

Conventional Two-Dimensional Treatment Techniques

One of the most common RT approaches employed is composed of two phases.[159] Phase I consists of large lateral opposing faciocervical fields that encompass the primary tumor and the upper neck nodes in one volume, with a matching lower anterior cervical field for the lower cervical lymphatics. Phase II is used after 40 Gy to limit the dose to the spinal cord. This three-field technique includes lateral opposing facial fields coupled with anterior facial field for the primary tumor. Typical treatment fields and radiologic landmarks are shown in Figure 47.16. Shrinking treatment fields by cone down after 50 to 60 Gy should be done, when possible, to increase protection of critical structures.

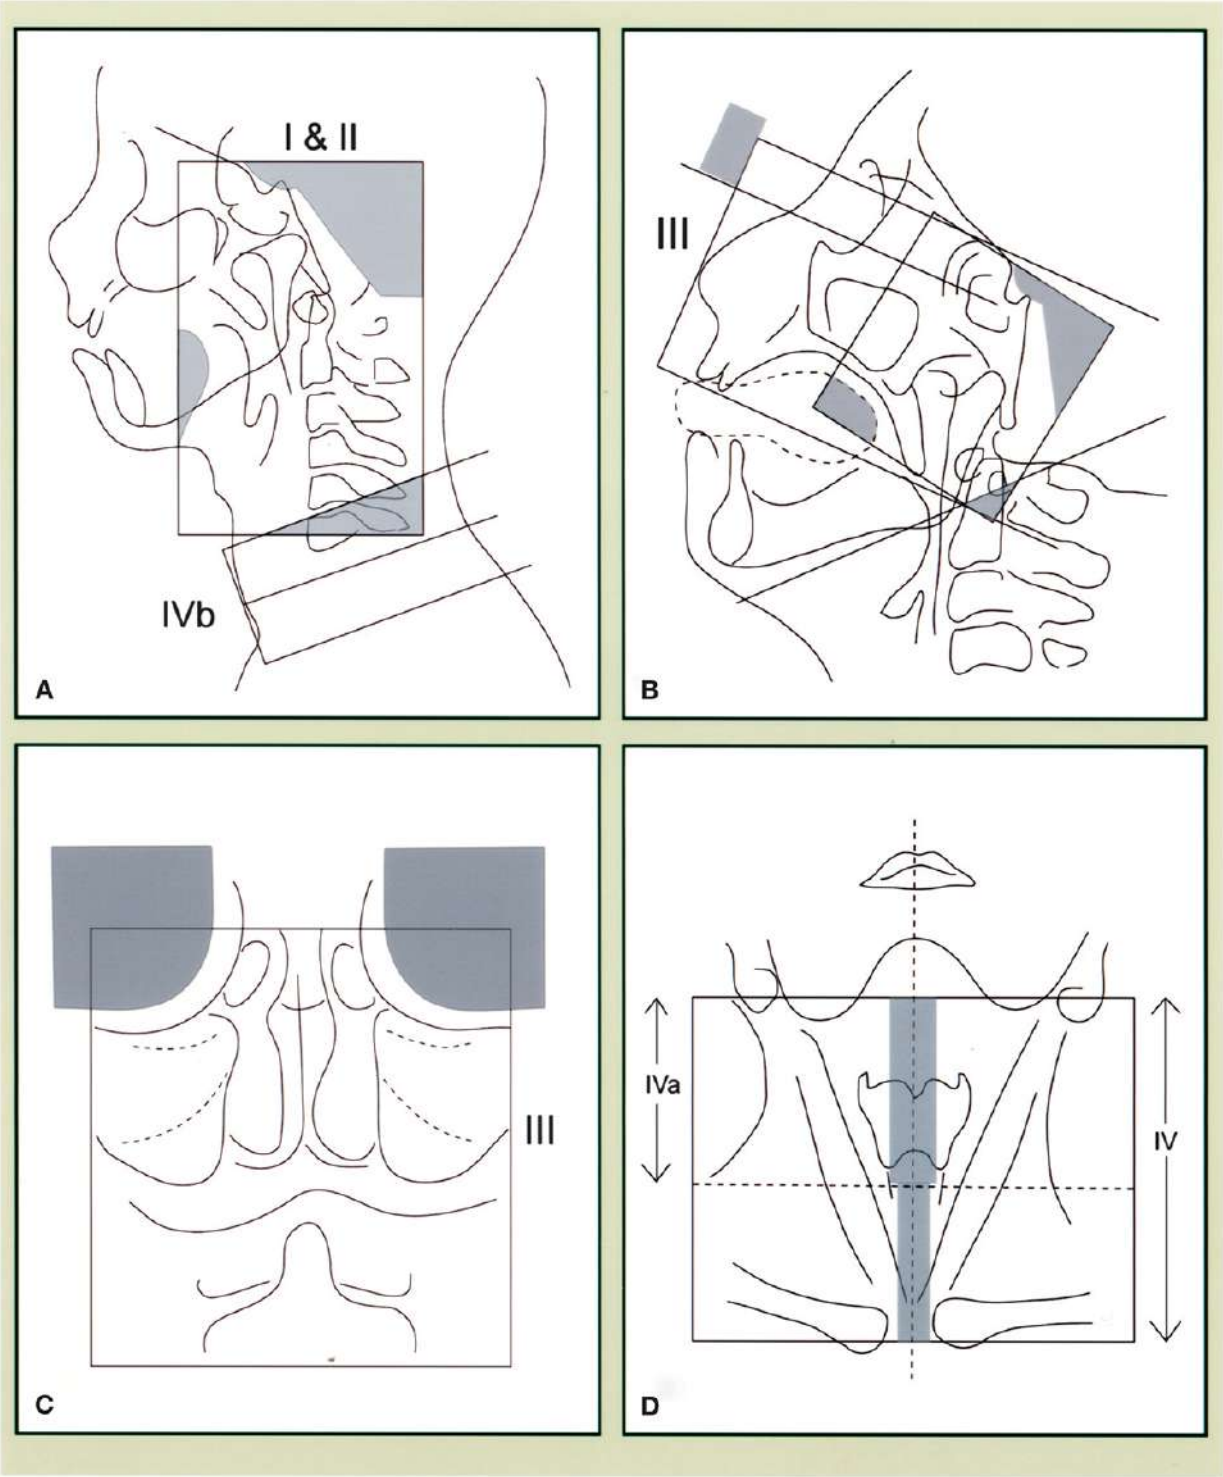

FIGURE 47.16 Conventional two-dimensional radiotherapy using Ho's technique. A. Phase I, lateral-opposed faciocervical fields (I-II) and lower anterior cervical field (IVb). B. Phase II, sagittal view showing lateral-opposed facial fields and noncoplanar anterior facial field (III). C. Coronal view of anterior facial field (III). D. Anterior cervical field for whole neck (IV).

The three-field technique in phase II allows the dose to be minimized to the temporomandibular joints and the bilateral temporal lobes. However, coverage may not be sufficient for tumors with extensive posterior-lateral

extension to the parapharyngeal spaces or caudal extension to the oropharynx. To remedy this deficit, an additional dose is delivered by a posterior-lateral field with avoidance of neurologic structures.[160]

Three-Dimensional Conformal Treatment Techniques

NPC presents most typically as a concave tumor allowing for computerized 3D treatment plans to be an important technical advance for improved radiation delivery. Several investigators have designed multifield conformal plans, including the seven-field technique used at MSKCC (The United States)[161] and the "boomerang" technique used at Peter MacCallum Cancer Center (Australia).[162] When compared to conventional 2D plans, 3D planning demonstrated better tumor dose coverage while decreasing normal tissue dose in several studies.[87,163,164]

Leibel et al[165] from MSKCC demonstrated that the target volume underdosed at the 95% isodose level was lowered with 3D plans when compared with 2D plans (7% vs 22%). On average, the mean tumor dose increased to 13%, leading to an estimation that tumor control would increase by 15%. However, a subsequent study in which 68 patients received this technique for a boost of 19.8 to 25.2 Gy following phase I conventional 2D treatment for 50.4 Gy to a total dose of 70.2 to 75.6 Gy did not show significant improvement; the 5-year L-FFR was 77%, and late toxicity grade ≥3 was 25%.[161]

More encouraging results were obtained by Jen et al,[166] who compared 72 patients treated with 3D conformal technique with 108 patients treated with 2D technique. A significant improvement in 3-year L-FFR for T4 (86% vs 47%), and EFS for both stage III (80% vs 56%) and stage IV (82% vs 33%), was observed. Furthermore, the incidence of xerostomia at 3 years was significantly less with 3D conformal treatment (69.2% vs 98.0%), although for most other late toxicities, little difference was seen.

Intensity-Modulated Radiation Therapy Techniques

IMRT has supplanted conventional RT in the treatment of NPC in an increasing number of institutions throughout the world. The intensity of the radiation beams can be modulated to deliver a high dose to the tumor with a superior target volume coverage while significantly limiting the dose to surrounding normal tissues.[167-172] Following the initial publication[173] and the subsequent update on IMRT for NPC from the University of California, San Francisco (UCSF),[171] several other institutions have utilized IMRT with similar excellent treatment outcomes.[174-180]

Another point of interest is the possibility of biologic enhancement by simultaneous modulated accelerated radiation therapy (SMART), also known as dose painting, as a new way of delivering an accelerated fractionation (AF) schedule, a concept that was first reported by Butler et al[181] for the treatment of other head and neck cancers with IMRT.

These differing methods and dose fractionation regimens for IMRT are being investigated by different groups. Table 47.11 summarizes the key features along with the reported results. The majority of the patients in these series received additional chemotherapy and/or enhanced RT with boosts or AF. All reported encouraging early results with local control in excess of 90% at 2 to 4 years.

3D, three-dimensional conformal boost; FFR, failure-free rate; GTV, gross tumor volume; ICB, intracavitary brachytherapy; MSKCC, Memorial Sloan Kettering Cancer Center (the United States); NR, not reported; PTV-G, planning target volume for gross tumor; PWH, Prince of Wales Hospital (Hong Kong); QMH, Queen Mary Hospital (Hong Kong); RT, radiation therapy; SYS, Sun Yat-sen Cancer Center (China); UCSF, University of California, San Francisco (the United States).

[a]Based on data reported by Lee N, Xia P, Quivey JM, et al. Intensity-modulated radiotherapy in the treatment of nasopharyngeal carcinoma: an update of the UCSF experience. *Int J Radiat Oncol Biol Phys*. 2002;53(1):12-22.

At the UCSF, patients were typically prescribed 70 Gy to the $PTV_{gross\ disease}$ and involved lymph nodes in 2.12 to 2.25 Gy fractions, whereas the $PTV_{high\text{-}risk\ subclinical}$ were prescribed 59.4 Gy in 1.8 fractions, and a clinical negative neck ($PTV_{low\text{-}risk\ subclinical}$) received 54 Gy at 1.64 Gy fractions all in conventional once-daily (QD) fractions.[171,182] Bucci et al[182] reported the updated results of 118 patients, which confirmed excellent LRC of 96%. Yet, distant failure remained high (28%) despite broad use of concurrent-adjuvant CRT. OS was 74% at 4 years.

At MSKCC, Wolden et al[174] reported their initial experience with 74 patients, where 59 were treated with AF using the concomitant boost method and 15 by the SMART method/dose painting. For the SMART cohort, a total dose of 70.2 Gy at 2.34 Gy/fraction was given to the gross disease, and the "microscopic" PTV received 54 Gy at 1.8 Gy/fraction. There was a trend, but no statistically significant improvement in 3-year L-FFR than for patients treated by 3D conformal boost (91% vs 79%, $P = .11$). Updated results by Setton et al[188] on 177 patients confirmed excellent rates of disease control (92% 3-year and 83% 5-year local control) and survival (87% 3-year and 75% 5-year OS) with this technique. Additional dose escalation by SMART boost in 50 patients with T3 and T4 tumors was reported by Kwong et al[184] from Queen Mary Hospital (Hong Kong). They sought to deliver a total dose of 76 Gy at 2.17 Gy/fraction to the gross tumor. The early result for LRC was excellent (96% at 2 years); however, serious late toxicities were observed, including 4% of patients having a life- threatening hemorrhage from carotid artery pseudoaneurysm and another 4% developing TLN with a median follow-up of 2.1 years.

Two different IMRT approaches are currently being utilized by different centers[1]: an extended whole-field (EWF) IMRT technique, in which the total target volume is encompassed in the IMRT plan, or[2] a split-field (SF) IMRT technique, in which the target volumes superior to the vocal cords are treated with an IMRT plan and the lower neck nodes are treated with a conventional low anterior neck field.[189-191] Discussions among practitioners on

which IMRT technique is best have been persistent. Concerns of potential failures at the SF matchline because of potential underdosing, or even complications resulting from overdosing, have caused many centers to implement EWF IMRT, even when no clinically involved neck nodes are evident in the matchline region. These concerns may be caused by the treatment delivery system that is used at centers where a perfect match between the IMRT fields and the low anterior neck field is not possible. However, with a EWF technique, an unnecessary dose of radiation is delivered to the normal glottic larynx.[192] Whereas with the SF IMRT technique, the dose to the vocal cords is minimal because of shielding by a midline Cerrobend block or the multileaf collimator (MLC). At the moment, no IMRT matchline failures or complications have been reported with the SF IMRT technique.[173]

Figures 47.17 and 47.18 show examples of MSKCC IMRT plans delivered with the dynamic MLC system using a sliding window technique to patients with early and advanced disease, respectively. A total dose of 70 Gy at 2.12 Gy/fraction to the $PTV_{gross\ disease}$ and 59.4 Gy to the $PTV_{high\text{-}risk\ subclinical}$ is given over 33 QD fractions (Table 47.10). For the low neck, if SF IMRT is used, a dose of 50.4 Gy at 1.8 Gy/fraction/day is generally prescribed. However, if the low neck is included in the IMRT fields and is considered at low risk for nodal involvement, the $PTV_{low\text{-}risk\ subclinical}$ typically receives 54 Gy at 1.64 Gy/fraction/d.

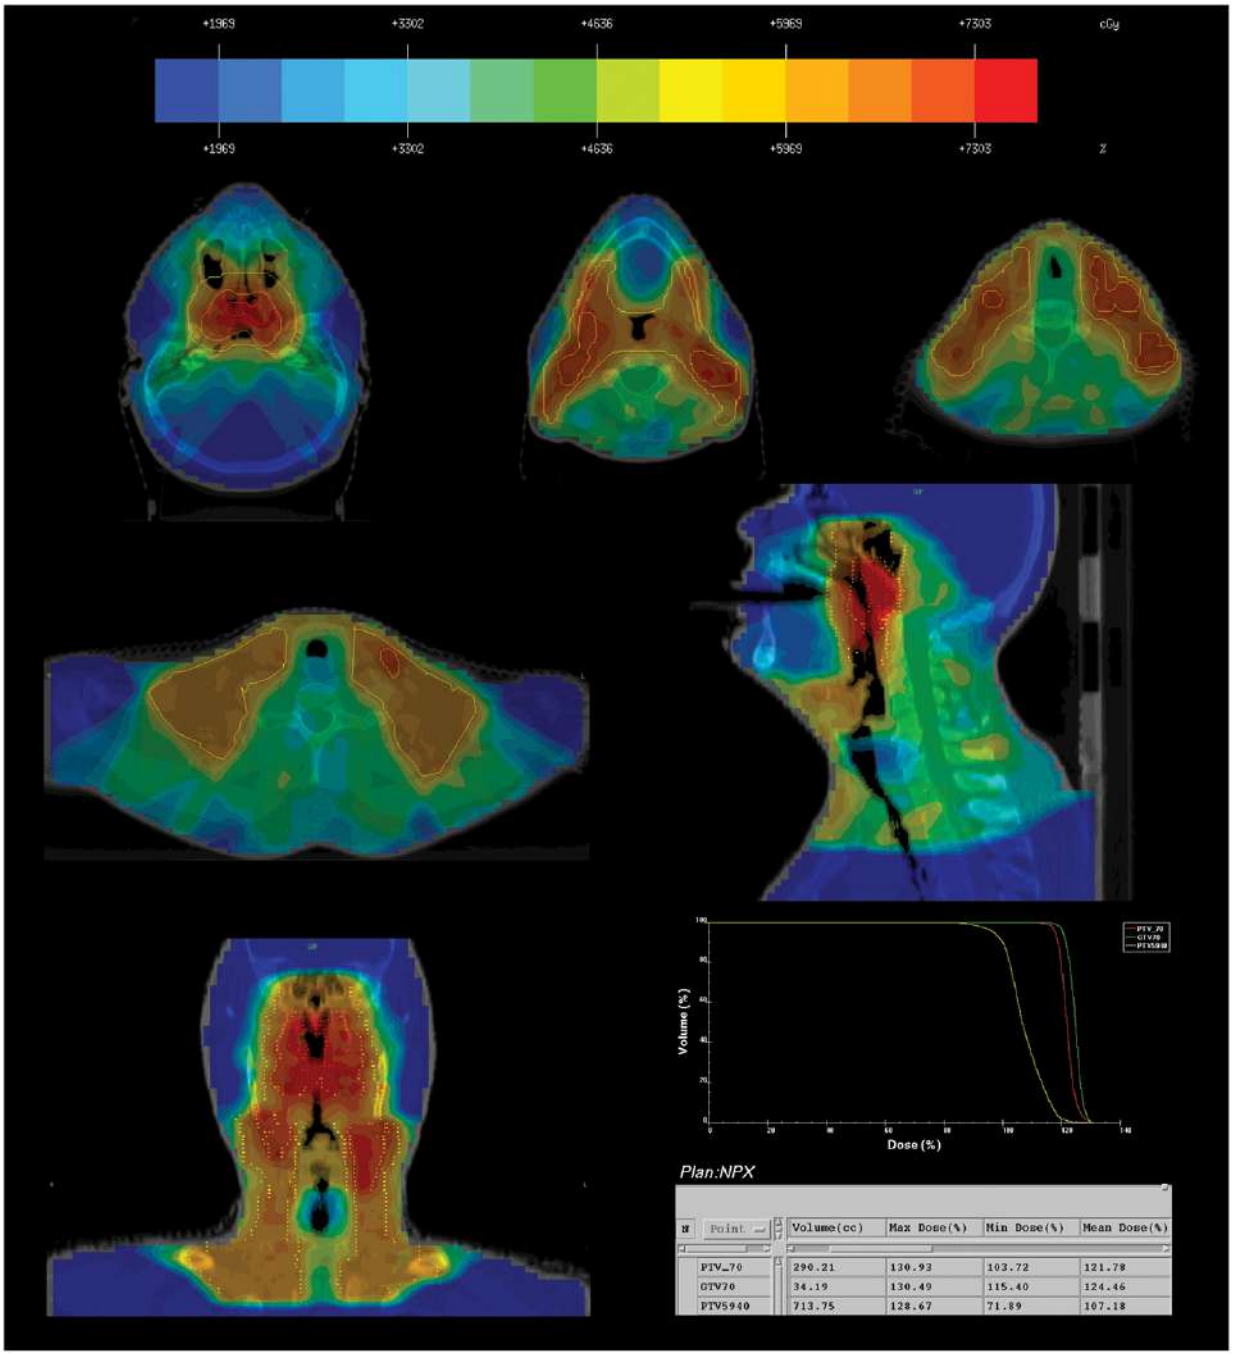

FIGURE 47.17 Intensity-modulated radiation therapy for a patient with T2N2M0 nasopharyngeal carcinoma treated at Memorial Sloan Kettering Cancer Center showing delineation of gross tumor targets (GTV) and planning target volumes (PTV) for 70 and 54 Gy, the dose distribution, and the dose-volume histogram (DVH) for GTV, PTV_{70}, and $PTV_{59.4}$.

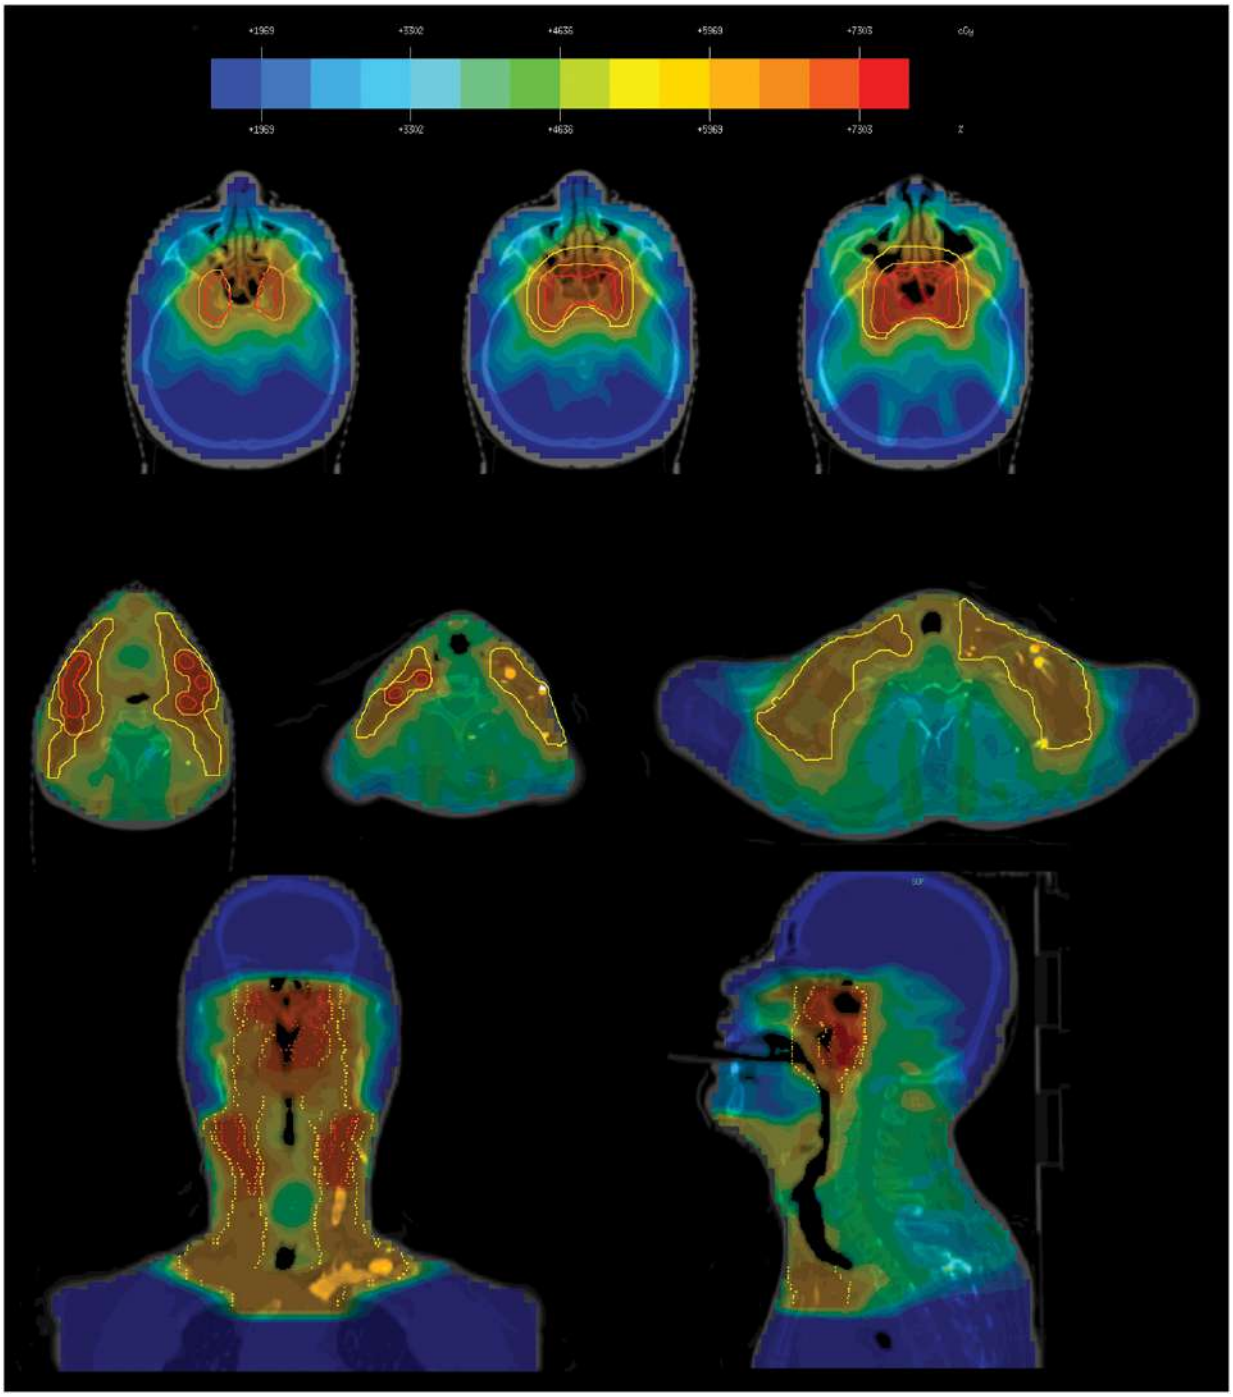

FIGURE 47.18 Intensity-modulated radiation therapy for a patient with T4N2M0 nasopharyngeal carcinoma treated at Memorial Sloan Kettering Cancer Center showing delineation of gross tumor (GTV) and planning target volumes (PTV) for 70 and 54 Gy, and the dose distribution.

Inverse planning involves the appropriate specification of normal tissue dose constraints. It is important to note that overstrigent use of normal tissue constraints might result in inadequate cover of tumor targets; therefore, optimal balance is essential. Different dose-constraint guidelines have been suggested.[193,194] An example of dose-constraint guidelines is provided in Table 47.12, which displays the guidelines presently used at MSKCC.

TABLE 47.12 INTENSITY-MODULATED RADIATION THERAPY FOR NASOPHARYNGEAL CARCINOMA: AN EXAMPLE OF NORMAL

TISSUE DOSE CONSTRAINTS	
Structures	**Constraints**
Critical Structures	
Brainstem	Max <5 Gy or 1% of PTV cannot exceed 60 Gy.
Optic nerves	Max <54 Gy or 1% of PTV cannot exceed 60 Gy.
Optic chiasm	Max <54 Gy or 1% of PTV cannot exceed 60 Gy.
Spinal cord	Max <45 Gy or 1 mL of the PTV cannot exceed 50 Gy.
Mandible and temporomandibular joint	Max <70 Gy or 1 mL of the PTV cannot exceed 75 Gy.
Brachial plexus	Max <66 Gy
Temporal lobes	Max <60 Gy or 1% of PTV cannot exceed 65 Gy.
Other Normal Structures	
Oral cavity	Mean <40 Gy
Parotid gland	Mean ≤26 Gy (should be achieved in at least one gland) or at least 20 mL of the combined volume of both parotid glands will receive <20 Gy or at least 50% of the gland will receive <30 Gy (should be achieved in at least one gland)
Cochlea	V55 <5%
Eyes	Mean <35 Gy, max <50 Gy
Lens	Max <25 Gy
Glottic larynx	Mean <45 Gy
Esophagus, postcricoid pharynx	Mean <45 Gy

Based on guidelines presently used at Memorial Sloan Kettering Cancer Center.

Dose Escalation

Excellent local tumor control has been reported by delivering an additional boost to patients with early disease treated by conventional 2D technique.

Brachytherapy

The most commonly used method is brachytherapy. Intracavitary insertions[195-203] or interstitial implants[204-207] have been used in T1 to T3 NPCs as a boost treatment following external beam radiation therapy (EBRT) or in the treatment of recurrent disease, either alone or in combination with EBRT. Brachytherapy is not suitable for the treatment of tumors with intracranial extension because of the rapid reduction of dose as distance from the radioactive source increases. Since the advent of IMRT as primary RT for NPC and with its demonstration of excellent local control, the use of brachytherapy as a boost treatment following definitive IMRT has dramatically declined. Multiple applicators and techniques have been developed for the delivery of intracavitary brachytherapy.[197-199,201,203-208] In the past, intracavitary brachytherapy was delivered using low-dose rate (LDR) techniques. However, currently, remote afterloading and fractionated high-dose rate (HDR) techniques are more commonly used (Figure 47.19).[208]

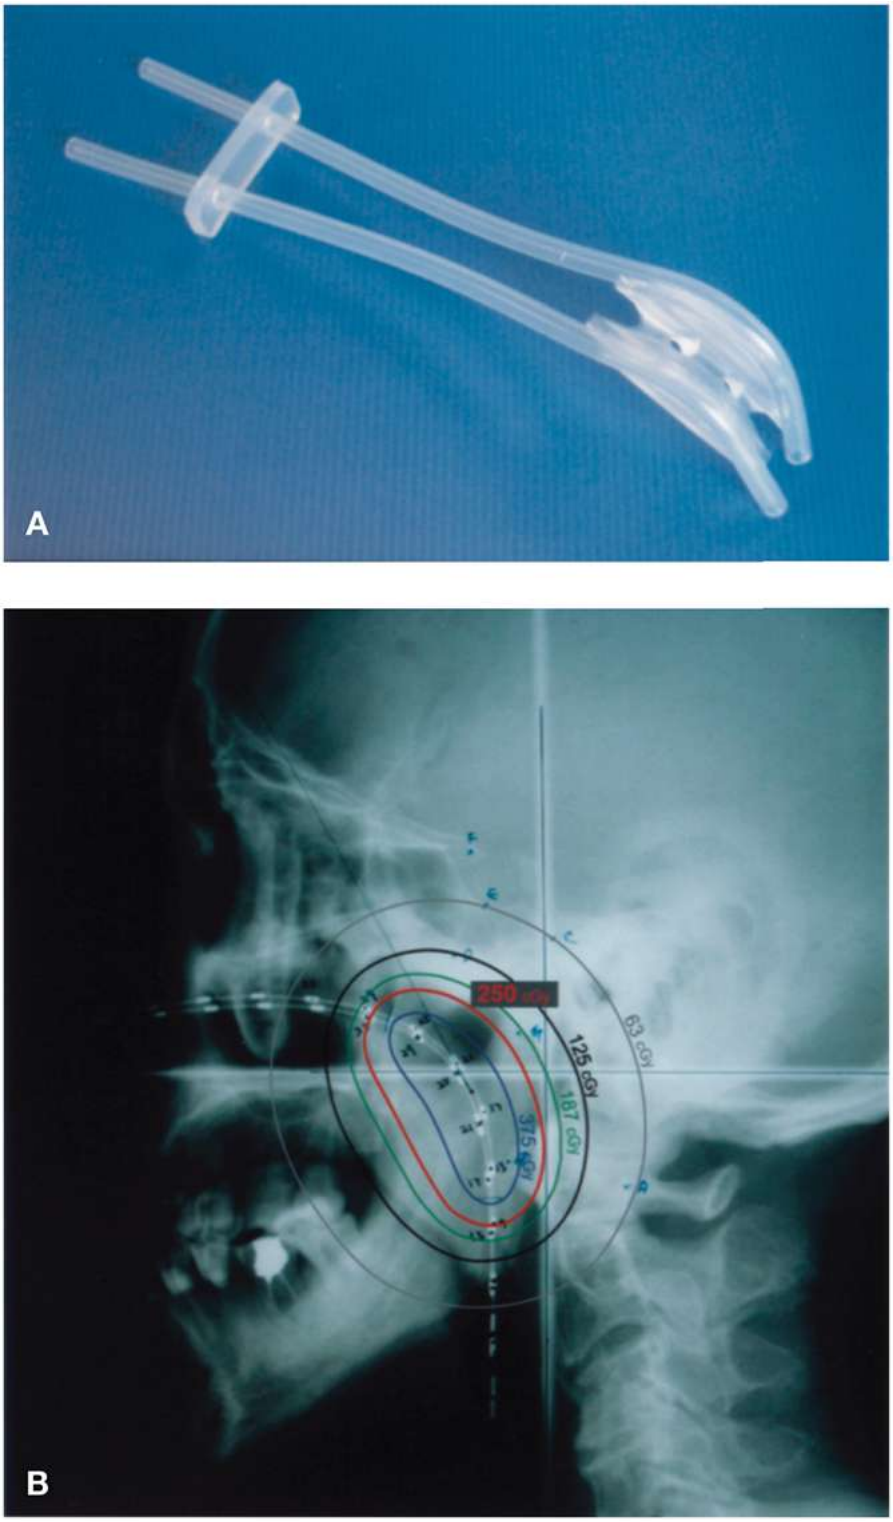

FIGURE 47.19 Endocavitary brachytherapy for nasopharyngeal carcinoma. A. The Rotterdam nasopharyngeal applicator. B. The simulator check film showing the position of the radioactive sources and the dose distribution.

Table 47.13 summarizes reports on the use of brachytherapy as a boost for dose escalation. Most studies demonstrated that local control up to 90% to 95% could be achieved for T1-2 tumors without excessive late damages. A retrospective comparison by Wang[198] from Massachusetts General Hospital (the United States)

reported that for T1 and T2 patients who received a 10- to 15 Gy, LDR brachytherapy boost after 60 to 64 Gy by EBRT had a 5-year L-FFR of 90% versus 54%, with $P = .001$ for patients receiving EBRT alone to 65 to 70 Gy. A similar study by Teo et al,[209] where delivery of 18 to 24 Gy in three fractions by HDR brachytherapy, showed a significant improvement of the 5-year L-FFR of 95% compared with a 90% 5-year L-FFR for EBRT-only patients ($P = .016$).

[a]By 2002 AJCC sixth edition or 1997 AJCC fifth edition.

However, a report by Ozyar et al[213] of patients with T1 to T4 tumors treated with HDR brachytherapy boost of 12 Gy in three fractions did not show improvement over EBRT alone (3-year L-FFR: 86% vs 94%; $P = .23$). More recently, a prospective trial by the International Atomic Energy Agency studied 275 patients with locoregionally advanced NPC disease (TNM stage III or M0 stage IV) who were all treated by induction chemotherapy followed by concurrent CRT to 70 Gy; then one randomized arm received a brachytherapy boost of 11 Gy LDR or three fractions of 3 Gy HDR. With a median follow-up of 29 months, the authors reported no additional benefit of brachytherapy boost compared with CRT alone toward 3-year OS (63.3% vs 62.9%, $P = .742$), locoregional-FFR (54.4% vs 60.5%, $P = .647$), or distant metastasis-free survival (52.6% vs 59.8%, $P = .496$).[216]

One major limitation of brachytherapy is that the dose delivered is adequate only for superficial nonbulky tumors. Furthermore, optimal positioning of the applicators depends on both the individual clinician's skill and the patient's anatomic features.

Stereotactic Radiosurgery

Stereotactic radiosurgery or fractionated RT allows for precise delivery of highly conformal RT with a rapid dose falloff and provides an alternative for dose escalation. Hara et al[217] reported a study of 82 patients with T1 to T4 tumors showing excellent 5-year L-FFR of 98% after receiving a median stereotactic RT (SRT) boost of 12 Gy (range, 7-15 Gy) following EBRT to 66 Gy. However, despite the addition of concurrent chemotherapy in 76% of the patients, the distant failure rate was 32% and OS was 69%. With a median follow-up of 40.7 months for living patients, 12.1% of patients developed radiographic TLN (only 2.4% were symptomatic with seizures) and 3.6% developed retinopathy. The risk was especially high in patients with T4 tumors.

Altered Fractionation

Over the past few decades, studies have been conducted to explore the role of altered fractionation regimens in head and neck cancers, along with NPCs. Hyperfractionation, AF, and a combination of which were explored in conjunction with concurrent chemotherapy.

Sanchiz et al[218] conducted a large randomized trial examining twice-daily (BID) versus QD irradiation for head and neck cancer including tumors of the nasopharynx. Eight hundred fifty-nine patients with advanced head and neck cancers (T3-T4, N0-3, M0 by UICC staging), which included 92 patients with NPC, were randomly assigned to QD irradiation (group A), BID irradiation (group B), or QD irradiation with concurrent 5-FU chemotherapy (group C). Groups B and C showed a significant improvement in median duration of response and OS when compared to group A. No significant differences were seen between groups B and C.

The first randomized trial on AF for NPC by Teo et al[219] used an uncommon schedule of 2.5 Gy/fraction QD for eight fractions before randomization to an experimental arm using 1.6 Gy BID for an additional 32 fractions versus a control arm treated with 2.5 Gy QD for another 16 fractions. The trial was terminated early because of excessive neurologic toxicities in the AF arm (49% vs 23%). For this series of 159 patients (62% with T1-2 tumors), the AF arm did not achieve a significant improvement in tumor control (5-year L-FFR, 89% vs 85%). Jen et al[220] reported on 222 patients where 76 patients received hyperfractionated RT at 1.2 Gy/fraction BID and 12 patients received accelerated-hyperfractionated RT at 1.6 Gy BID to a median dose of 80 Gy for these BID RT groups. The remaining 134 patients are treated by conventional QD fractionation to a median dose of 70 Gy. The patients treated by BID fractionation did not demonstrate a statistically significant difference in 5-year L-FFR when compared to QD fractionation (T1-3, 93% vs 86%; T4, 44% vs 37%). The 1.2 Gy/fraction regimen did not cause excessive toxicity; however, patients treated with 1.6 Gy/fraction had a 27% incidence of TLN.[221] See section "Sequelae of Treatment" for more details regarding the influence of dose fractionation on brain necrosis.

To minimize the risk of late damage, the more moderate AF schedule of the Danish Head and Neck Cancer Study Group 6 to 7 Trials using 2 Gy/fraction, six fractions per week[222] of 1,476 patients with head and neck cancer, of which 435 had pharyngeal tumors, including the nasopharynx, demonstrated AF resulted in significantly improved 5-year L-FFR (76% vs 64% for six and five fractions, $P = .0001$) and disease-specific survival (73% vs 66%, for six and five fractions, $P = .01$), but not for OS. This same fractionation schedule was tested retrospectively for NPC by Lee et al.[223] They reported for patients irradiated to a total dose of 66 Gy with 2D technique when on an AF schedule had significantly higher L-FFR than those treated with conventional five fractions per week. The benefit was significant particularly for T3-4 tumors (87% vs 62%; $P < .01$), and multivariate analyses confirmed that fractionation was an independent prognostic factor for overall progression (AF group, HR = 0.63, 95% confidence interval [CI], 0.41-0.98; $P = .04$). In addition, no significant increase in late toxicity was observed at 3 years (20% vs 15%).

This schedule was then used in the subsequent NPC-9902 trial initiated by the HKNPCSG,[224] which aimed to assess the therapeutic benefit of AF and/or concurrent-adjuvant CRT, that randomized 189 patients with locally advanced NPC (T3-T4, N0-1, M0) to four arms[1]: conventional fractionation (CF) alone,[2] AF (six fractions/week) alone,[3] CF with concurrent chemotherapy, and[5] AF with concurrent chemotherapy. Preliminary results with a median follow-up of 2.9 years showed that AF per se did not demonstrate a significant improvement in EFS when compared with CF (AF vs CF: HR 0.68, 95% CI 0.37-1.25, $P = .22$). However, AF combined with CRT (arm 4) achieved a strongly significant improvement when compared with CF alone (EFS: 94% vs 70%, $P = .008$) but without an improvement in OS. A significant increase in acute and late toxicity in the AF combined with CRT arm was also noted.

From these and other experiences with altered fractionation schedules in the treatment of NPC, in addition to other head and neck cancers, it has been concluded that both total dose and overall treatment time are important factors in determining outcomes.[225] With the increasing use of IMRT, dose escalation—to allow ample dose delivery to the gross and subclinical disease—has become achievable without associated changes in rates of toxicity, considerably improving the therapeutic ratio of concurrent chemoradiation and causing the above fractionation schemes to fall out of favor.

Chemotherapy

NPC is generally regarded to be a highly chemosensitive disease. Although RT alone is the standard treatment for stage I NPC, concurrent CRT with or without adjuvant chemotherapy is the current standard for locally advanced disease (stages III-VB) based on multiple randomized controlled trials and meta-analyses (Table 47.14). Although

there is less evidence for CRT in intermediate-stage (2010 AJCC stage II) disease, it is currently recommended that such patients be treated with CRT in light of pooled data from two phase III trials[226,227] and a more recent phase III trial from Chen et al.[228] In more detail, Chen and colleagues[228] demonstrated that Chinese stage II (equiv. to AJCC II-III; only 13% of the study patients were AJCC 2010 stage III) patients with NPC who received concurrent CRT had a superior 5-year OS compared to those treated with radiation alone (94.5% vs 85.8%, P = .007) with improved distant control (94.8% vs 83.9%, P = .007). Multivariate analyses found that the number of chemotherapy cycles was the only independent factor associated with improved OS, PFS, and distant control. With the addition of chemotherapy, an increase in acute side effects was observed, but no significant increase in late effects was reported.

[b]Stage II by Chinese 1992 staging system (equivalent to stages II and III by AJCC seventh edition), 13% of patients were AJCC stage III.

Concurrent Chemoradiotherapy

The landmark Intergroup 0099 trial was the first to document a significant survival benefit for CRT versus RT alone.[229] This trial randomized 147 patients with locally advanced NPC to either RT alone or CRT, at centers located in the United States. Chemotherapy consisted of concurrent cisplatin (CDDP; 100 mg/m^2 on days 1, 22, and 43), followed by three cycles of adjuvant CDDP (80 mg/m^2 on day 1) and 5-FU (1,000 mg/m^2/d on days 1-4) every 4 weeks. RT was delivered in 1.8 to 2 Gy fractions to a total dose of 70 Gy. The trial was closed early because of a significant OS benefit in favor of CRT (78% vs 47% at 3 years). A 5-year update confirmed PFS (58% vs 29%) and OS (67% vs 37%) in favor of CRT. Reactions to these findings were initially tempered by several limitations of the trial. Results achieved in the RT arm were much poorer than those generally obtained at centers treating endemic NPC. Outcomes in the CRT arm were in fact more consistent with outcomes obtained in endemic areas using RT alone. Another concern was that 24% of the enrolled patients had disease of keratinizing histology, and it was unknown whether the same benefit would be seen in endemic areas with predominantly undifferentiated disease.

Subsequent trials confirmed the benefit of concurrent CDDP-based chemotherapy in endemic populations. Wee et al[233] reported the results of 221 stage III to IVB patients from Singapore randomized to receive either RT alone or CRT. Chemotherapy consisted of a slightly modified version of the Intergroup regimen: CDDP (25 mg/m^2 on days 1-4) for three cycles every 3 weeks, followed by adjuvant CDDP (20 mg/m^2 on days 1-4) and 5-FU (1,000 mg/m^2/d on days 1-4) for three cycles. RT was delivered to a dose of 70 Gy in 2-Gy fractions. Three-year OS for the CRT and RT arms was 85% and 65%, respectively (P = .006). CRT reduced the incidence of distant metastasis by 17% at 2 years (P = .003).

Langendijk et al[240] performed a meta-analysis of 10 trials that randomized patients with NPC to conventional RT or CRT. The 10 studies included four neoadjuvant trials,[241-244] three concurrent (± adjuvant) trials,[229,230,245] two adjuvant trials,[246,247] and one neoadjuvant + adjuvant trial.[248] The authors found a pooled HR for death of 0.82, with an absolute survival benefit of 4% at 5 years. Subgroup analysis revealed that the OS benefit was only significant for those patients receiving concurrent chemotherapy, with an HR for death of 0.48 and absolute survival benefit of 20% at 5 years. Analysis of the neoadjuvant chemotherapy trials found a significant reduction in locoregional recurrence and distant metastasis, but no OS benefit.

These results, in combination with results from a second meta-analysis[249] and the Singapore trial, reported by Wee et al,[233] confirmed CRT as the standard approach in stages III, IVA, and IVB NPC. At many centers, the standard course of chemotherapy has been based on the U.S. Intergroup regimen, which consisted of concurrent high-dose CDDP (100 mg/m^2 × 3 cycles) and adjuvant CDDP/5-FU for three cycles. This regimen is associated with significant acute and late toxicities, and patient compliance is frequently difficult to achieve. In the Intergroup 0099 trial, for example, only 63% completed all three cycles of concurrent chemotherapy, and only 55% were able to receive all three courses of adjuvant therapy.[229] As a result, weekly CDDP has been adopted by many institutions, especially for patients with poor nutritional status.[250] In a phase III trial, comparing CRT versus RT alone in 350 patients with locally advanced disease, Chan et al[232] demonstrated good efficacy and tolerability for a regimen consisting of weekly CDDP (40 mg/m^2). Seventy-eight percent of patients in the CRT arm received at least four cycles of CDDP, and CRT was associated with a statistically significant survival benefit after adjusting for age and disease stage. A more recent randomized study by Chen et al[251] confirmed that OS and LRC of weekly CRT were superior to RT alone with weekly CDDP, though it did observe greater acute (63% vs 32%) and late (33% vs 26%) toxicity in the CRT arm. In addition, a retrospective comparative study by Jades et al[252] found similar clinical outcomes and toxicity profiles between concurrent weekly CDDP and the every 3 weeks schedule. Ultimately, whether weekly CDDP is equivalent to the every 3 weeks Intergroup regimen remains to be directly evaluated in a randomized manner.

Other Chemotherapy Agents

Weekly oxaliplatin (70 mg/m^2) has been demonstrated to have good tolerability and efficacy, albeit in the setting of a small phase III trial of 115 patients randomized to CRT or RT alone.[234] Carboplatin has also been employed as a substitute to high-dose CDDP, with comparable efficacy, in a noninferiority trial reported by Chitapanarux et al.[253] Two hundred and six patients were randomized to either concurrent high-dose CDDP and adjuvant CDDP/5-FU or concurrent weekly carboplatin and adjuvant carboplatin/5-FU. The trial had 80% power to detect an HR for death of 1.25 at 3 years. No significant difference in disease-free survival or OS was seen at a median follow-up of 26 months. Disease-free survival was 59.6% and 64.7% (P = .522) for the carboplatin and CDDP arms, respectively.

Cetuximab to target EGFR (EGFR overexpression is observed in >80% of patients with NPC) has been examined in a phase II trial with optimistic findings.[254] The 2-year rates of OS, locoregional PFS, distant metastasis-free survival, and PFS were 89.9%, 93.0%, 82.8%, and 86.5%, respectively. Bevacizumab, to exploit the angiogenesis pathway (VEGF is overexpressed in about two-thirds of NPC patients), has been studied in a phase II trial where the agent was added to the standard CRT schedule and demonstrated promising results.[255] Lee et al[255] reported, with a median follow-up of 2.5 years, a 2-year OS, locoregional PFS, distant metastasis-free survival, and PFS of 90.9%, 83.7%, 90.8%, and 74.7%, respectively.

Adjuvant Chemotherapy

Although good efficacy and tolerability have been shown for select alternative regimens, the greatest body of evidence for concurrent CRT has been with the CDDP-based U.S. Intergroup regimen of concurrent plus adjuvant chemotherapy. Nevertheless, it is unknown whether the adjuvant chemotherapy component of the U.S. Intergroup regimen contributed to its survival benefit. Randomized trials comparing RT alone to RT plus adjuvant

chemotherapy have all been negative to date.[247,248] Moreover, there are data to suggest a survival benefit for concurrent CRT without adjuvant chemotherapy.[230,232] Lastly, compliance with adjuvant chemotherapy can be especially difficult, as patients are recovering from the acute effects of CRT. In 2011, Chen et al[256] reported a randomized trial that compared concurrent CRT to concurrent CRT plus adjuvant chemotherapy (CDDP/5-FU) in 508 patients. With a median follow-up of 38 months, there were fewer failures at any site in the concurrent CRT plus adjuvant chemotherapy group versus the CRT group only (14% vs 16%); however, this difference was not statistically significant (P = .13). It is important to note that this trial was not designed as a noninferiority trial against the standard. In addition, compliance was an issue in this study, where about 18% of patients randomized to the adjuvant arm did not receive adjuvant chemotherapy.[256]

Two recently published studies from Sun Yat-sen University in China have found adjuvant capecitabine to be an efficacious and well-tolerated alternative to CDDP-based regimens.[257,258] The first study included 406 patients with stage III to IVA NPC and reported an improvement in the 3-year failure-free survival (FFS) (85.3% vs 75.7%, P = .0023) with the administration of 1 year of oral metronomic capecitabine following standard CRT. In this study, grade 3 or 4 adverse events were higher (17% vs 6%) in the adjuvant chemotherapy arm.[257] The second study included 180 patients with stage III to IVb NPC and reported that adjuvant capecitabine improved the 5-year FFS (78.5% vs 65.9%, P = .03) compared to CRT alone.[258] The adjuvant chemotherapy compliance rate was 79%.

In light of the above data, adjuvant chemotherapy, using either CDDP-based regimen or capecitabine, should be considered in patients with stage III to IV NPC who did not receive induction chemotherapy. Given concerns regarding the toxicities and tolerability of adjuvant systemic therapy, the final treatment decision should be individualized based on an analysis of the potential benefits versus risks. In this patient population, a biomarker such as post-treatment EBV DNA to help stratify patients for treatment with adjuvant chemotherapy versus observation would be extremely valuable. As discussed earlier, this is currently being investigated in the NRG Oncology HN001 trial, which randomizes patients with undetectable post-CRT EBV DNA to observation versus adjuvant chemotherapy consisting of cisplatin and 5-FU.

Neoadjuvant Chemotherapy

Several recent prospective phase III studies have demonstrated improved survival with neoadjuvant chemotherapy using a variety of systemic regimens.[259,260,261] In a phase III study of 480 patients with locoregionally advanced NPC, the regimen of three cycles of induction cisplatin and gemcitabine was shown to improve 3-year recurrence-free survival (85.3% vs 76.5%, HR 0.51; 95% CI 0.34-0.77) and 3-year OS (94.6% vs 90.3%, HR 0.43; 95% CI, 0.24-0.77) compared to CRT alone.[259] In another multicenter phase III study conducted by Sun Yat-sen University, 480 patients with stage III to IVB NPC were randomized to cisplatin chemoradiation with or without docetaxel, cisplatin, and fluorouracil induction therapy.[260] With a median follow-up of 45 months, patients treated with induction chemotherapy had significantly improved 3-year FFS (80% vs 72%, P = .034), OS (92% vs 86%, P = .029), and distant FFS (90% vs 83%, P = .031). Overall toxicity was higher in the induction arm, with 73% versus 54% of patients in the CRT alone arm experiencing a grade 3 or 4 adverse event (P < .0001). In a third multicenter trial reported by Cao et al,[261] 476 patients were randomized to cisplatin chemoradiation with or without cisplatin and fluorouracil induction therapy. Patients treated with induction chemotherapy had significantly higher 3-year disease-free survival (82.0% vs 74.1%, P = .028) with a strong trend for improved 3-year distant FFS (86.0% vs 82.0%, P = .056); however, there was no difference in OS, and toxicity was significantly increased during concurrent chemoradiation in patients who received induction. Figure 47.20 demonstrates the potential value of induction chemotherapy in tumor control.

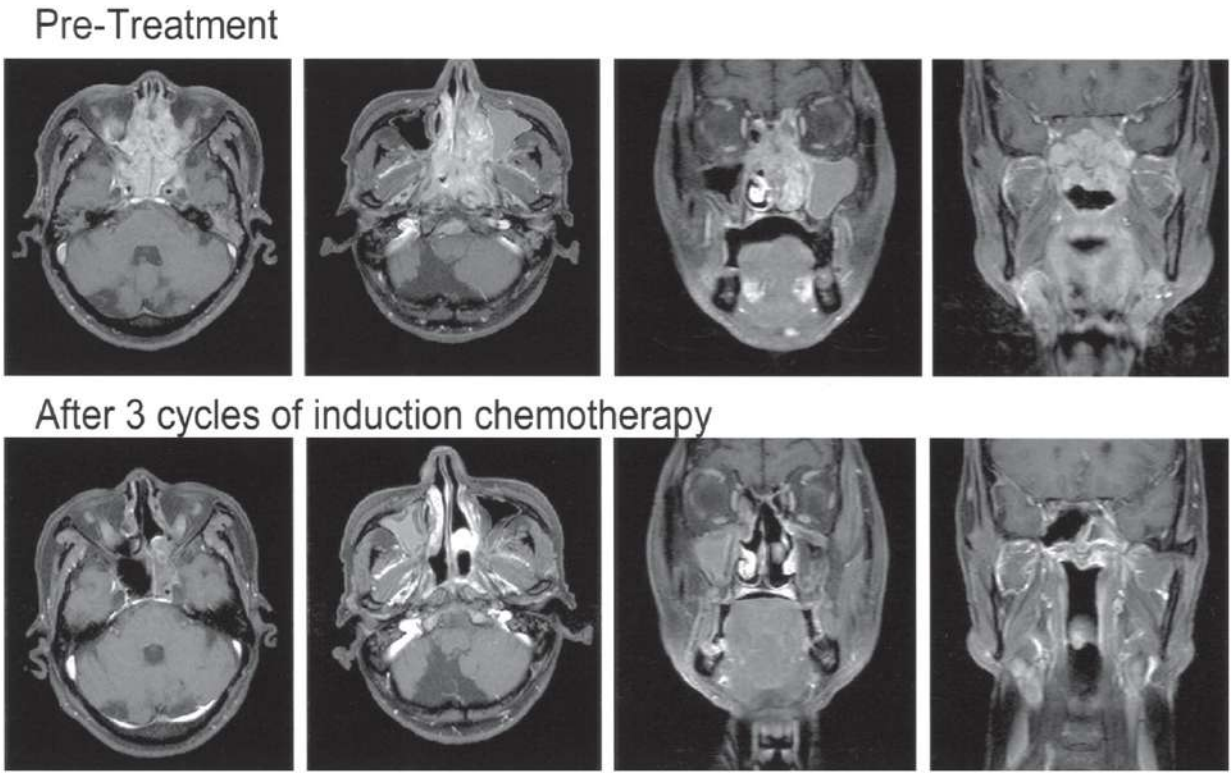

FIGURE 47.20 Magnetic resonance imaging showing shrinkage of primary tumor by induction chemotherapy using cisplatin and 5-fluorouracil before proceeding to concurrent cisplatin and radiotherapy. (Reprinted from Lee AW, Lau KY, Hung WM, et al. Potential improvement of tumor control probability by induction chemotherapy for advanced nasopharyngeal carcinoma. *Radiother Oncol*. 2008;87[2]:204-210. Copyright © 2008 Elsevier Ireland Ltd. With permission.)

The preliminary results of a phase III trial, organized by the Hong Kong Nasopharyngeal Cancer Study Group (NPC-0501), were reported. This study by Lee et al[262] randomized 706 patients to one of three arms: (1) CDDP/5-FU induction chemotherapy plus concurrent CDDP-RT, (2) concurrent CDDP-RT plus adjuvant CDDP/5-FU, or (3) CDDP/capecitabine induction chemotherapy plus concurrent CDDP-RT. In addition, patients in each of these three arms were randomized to either conventional or accelerated RT. Because of the multiarmed design, patient numbers were limited in each of the six arms. Overall, the benefit of induction chemotherapy with respect to OS remains uncertain; however, the capecitabine induction arm demonstrated an improved toxicity profile that may inform future studies.

RECURRENT/METASTATIC NASOPHARYNGEAL CARCINOMA

Because long-term survival can be achieved for a substantial proportion of patients with early locoregional recurrence, aggressive salvage treatment is usually advocated. Several approaches can be used successfully, including surgery, brachytherapy, and EBRT. In the reirradiation setting, a recently reported phase III randomized trial from Sun Yat-sen University reported that 65 Gy in 54 fractions, given BID, yielded better 3-year OS (74.6% vs 55.0%, $P = .014$) and led to lower rates of grade 3 or worse radiation-induced toxicity (34% vs 57%, $P = .023$) compared to standard fractionation (60 Gy in 27 daily fractions).[263]

In the recurrent metastatic setting, combination chemotherapy regimens such as cisplatin and gemcitabine have traditionally been used as first-line therapy. However, the recently published phase III JUPITER-02 trial demonstrated that the addition of toripalimab, a humanized immunoglobulin-G4K monoclonal antibody targeting programmed cell death protein 1, significantly improved median PFS (11.7 vs 8.0 months, $P = .0003$) compared to gemcitabine and cisplatin chemotherapy alone.[264]

For patients with symptomatic metastatic disease, palliation with RT is generally recommended. In addition, in the de novo metastatic setting, You et al[265] demonstrated a 2-year OS benefit (76.4% vs 54.5%, $P = .004$) with the addition of consolidative locoregional RT to patients who have at least a partial response to upfront chemotherapy.

Early Detection and Diagnosis

Although progress in surgical and reconstructive techniques and RT delivery methods has led to improvements in the control rate for primary treatment of NPC, local failure remains a problem for patients with advanced T category. Distinction should be made between persistent disease (tumors that do not completely regress following primary treatment) and recurrent disease (tumors that reemerge after initial complete regression) because the prognoses and therapeutic considerations are different, with better survival and control rates for persistent disease.[266]

As tumors regress at different rates following RT, one difficult decision is when to consider residual tumors as genuine persistence and proceed with salvage treatment. In one prospective study by Kwong et al,[267] serial biopsies of the nasopharynx were performed on 803 patients after RT treatment to observe the time course of histologic remission for NPC and determine its prognostic significance. The 5-year L-FFR was 82% for patients who achieved early histologic remission (<5 weeks) and 77% for those with delayed remission (5-<12 weeks), but only 40% for those with persistent disease at 12 weeks, despite subsequent salvage treatment.[267] Thus, although delayed histologic remission was not a poor prognostic factor, positive biopsies beyond 12 weeks did indicate poor prognosis. The optimal time for intervention remains uncertain, but because it is important to avoid both unnecessary overtreatment and excessive delay in treatment, the authors recommended an observation period of 10 weeks before additional treatment.[267]

Early detection of locoregional failure is crucial for a better chance of salvage, and regular follow-up after completion of primary treatment is recommended. Frequently used methods include manual palpation, rigid nasopharyngeal endoscopy and nasopharyngeal biopsies, imaging techniques (eg, CT and MRI), and serologic tests (eg, anti-EBV titers, plasma EBV DNA levels).

Nasopharyngoscopy is more sensitive than CT and MRI in detecting tumor persistence/recurrence and is the preferred method for initial screening.[268,269] If a patient presents with suspicious endoscopic findings or elevated anti-EBV titers, a nasopharyngeal biopsy is performed to confirm the diagnosis. CT or MRI is performed upon a confirmed diagnosis to delineate the tumor extent.[270] Although MRI has limitations in separating tumor recurrence from radiation fibrosis,[271] it is superior to CT in demonstrating the extent of soft tissue tumors, as well as identifying submucosal infiltration, marrow infiltration in the skull base, perineural invasion, and intracranial spread.[268,272,273]

Technetium-99m methoxyisobutylisonitrile single-photon emission computed tomography may be a useful tool for differentiating persistent or recurrent tumor from radiation fibrosis[274] and was shown by Kostakoglu et al[275] to be superior to MRI performed at 3 to 6 months post-RT in diagnosing complete response. The advent of FDG-PET is another valuable development. FDG-PET and MRI were compared in 67 patients with NPC 4 to 70 months after completion of RT and found FDG-PET superior to MRI in all aspects in the detection of local recurrence, with increased sensitivity (100% vs 62%) and specificity (93% vs 44%).[276] It may also contribute useful information to questionable findings on MRI.[277,278]

Paraneoplastic syndrome (PNS) can signal a silent neoplasm and may precede the clinical manifestation itself of persistent or recurrent NPC. PNS can follow the course of the tumor and can sometimes be used to diagnose recurrence and monitor its evolution, with the most common dermatologic manifestation being dermatomyositis and the syndrome of inappropriate antidiuretic hormone secretion being a common endocrinologic presentation.[279]

Circulating cell-free DNA of EBV may be another useful tool for early detection of treatment failure. A longitudinal study by Lo et al[121] showed that elevation of EBV DNA levels was noted in patients with relapse up to 6 months before detectable clinical disease. In addition, EBV DNA copy number has been shown to predict margin status postsalvage nasopharyngectomy. Wei et al[280] reported that in patients with early recurrent NPC with elevated EBV DNA copies, surgical resection reduced the copy number of EBV DNA postoperatively and that negative surgical margins are associated with zero EBV DNA copies postoperatively.

The incorporation of plasma EBV DNA measurements as screening prior to PET in detecting post-treatment failures of NPC has been investigated. In a prospective study by Wang et al,[129] 245 patients with NPC in remission were monitored prospectively via plasma EBV DNA assay every 3 to 6 months, where 36 patients with abnormal EBV DNA tests and 5 patients with clinical suggestion signs of recurrence, but undetectable EBV DNA levels, underwent FDG-PET scans. Elevated EBV DNA levels correctly predicted all 36 recurrences, whereas the 5 patients who presented with clinical signs suggestive of recurrent disease but with undetectable EBV DNA levels did not have recurrent disease. The authors concluded that plasma EBV DNA appears to be a useful biomarker for post-treatment surveillance in NPC.

Meanwhile, the clearance rate of plasma EBV DNA during the first month of chemotherapy has also been found to predict tumor response and patient survival in 30 patients with recurrent NPC and may have the potential as an early prognostic marker to help guide salvage treatment.[127]

Additional Radiation for Persistent Disease

Excellent results have been reported when using brachytherapy for locally persistent disease after a full course of EBRT (Table 47.15, part A), with 5-year L-FFR in the range of 87% to 95% for patients with initial T1 tumors (AJCC 2002 T1-2a).[209,266,281-283] Preliminary evidence suggests that patients with disease persisting from initial T2 tumors (AJCC 2002 T2b) could also be effectively treated by brachytherapy.[284]

TABLE 47.15 RESULTS OF LOCALLY PERSISTENT/RECURRENT NASOPHARYNGEAL CARCINOMA TREATED WITH BRACHYTHERAPY

[a]Median dose.

SRT is a valuable alternative for delivering additional EBRT. Yau et al[286] studied 755 patients with T1-4 tumors and found that 7% had positive biopsies 8 weeks after completion of primary RT. Twenty-one patients were treated with fractionated SRT to a median dose of 15 Gy and achieved a 3-year L-FFR of 82%, which was similar to the corresponding L-FFR of 86% in the complete responders and was significantly better than the corresponding L-FFR of 71% in 24 patients treated with HDR brachytherapy to a median dose of 20 Gy.

Reirradiation for Recurrent Disease

Various RT modalities are used to treat recurrent NPC, including intracavitary brachytherapy, external beam irradiation, interstitial implantation, particle beam RT, and stereotactic radiosurgery (Table 47.16).[197,202,203,205,206,287] IMRT has also been used with excellent preliminary results, with control rates of up to 100% for rT1-3.[288]

2D, conventional two-dimensional external radiotherapy and/or brachytherapy; 3D, three-dimensional conformal radiotherapy; IMRT, intensity-modulated radiation therapy; SBRT, stereotactic body radiation therapy.

[a]Patients with regional relapse included.

The most important prognostic factors are the TNM stage of the tumor at the time of recurrence and reirradiation dose. Thorough restaging, including metastatic workup, is necessary. A study of 891 patients with local recurrence from 1976 to 1985 by Lee et al[300] showed that only 32% of reirradiated patients achieved local salvage, with 54% developing regional and/or distant failure. Most series using conventional 2D technique showed that doses ≥60 Gy were associated with better outcome.[197,203,291,292] For IMRT, 60 to 70 Gy is recommended, taking into account factors such as previous radiation amount, overlap between previously treated area and target for reirradiation, interval between RT courses, tumor bulk, and whether concurrent chemotherapy will be given.[301]

Lee et al[302] retrospectively compared the symptomatic late toxicity rate in 487 patients with two courses of EBRT versus 3,635 patients with one course and found that the major determinant of late complications was the severity of damage during the initial course and that the sum of total biologic dose tolerated (BED-∑) was higher than expected with a single-course treatment (BED-1). This suggested partial recovery of normal tissue (especially in patients reirradiated after 2 years or more) and higher tolerance for reirradiation when primary treatment was

given with better sparing of normal tissues. Assuming an α/β ratio of 3 Gy, the BED-$\sum$ that incurred 20% toxicity at 5 years was 129% that of BED-1.

Brachytherapy has been widely used for the treatment of recurrent NPC (Table 47.15, part B) and can be used effectively on its own for early-stage recurrent NPC.[266,281] Using interstitial implants with radioactive gold grains, Kwong et al[266] reported a 5-year L-FFR of 63%; complications included headache (28%), palatal fistula (19%), and mucosal necrosis (16%). Law et al[281] achieved excellent local salvage up to 89% using iridium mold, but the complication rate was 53%.

The combination of brachytherapy and EBRT is useful, particularly when conventional 2D technique is used. Lee et al[291] showed that patients reirradiated by combined modalities had an improved 5-year L-FFR of 45% compared with 32% by EBRT alone and 29% by brachytherapy alone. The superiority of the combined method has been supported by other studies.[197,203,285,289] A study from MSKCC associated combined modality treatment (CMT), consisting of EBRT followed by brachytherapy, achieved similar L-FFR with previous historical series. CMT also demonstrated fewer late grade 3 or higher events compared with patients receiving EBRT alone (8% vs 73%).[297]

Stereotactic radiosurgery or fractionated SRT is another useful tool for retreatment of local recurrence, as it allows for rapid falloff of radiation dose outside tumor volume and near surrounding critical structures and can be used either alone for smaller lesions or in combination with EBRT for larger ones. Control rates ranging from 53% to 86% have been reported.[303-306] For advanced recurrence with extension beyond the nasopharynx, this method offers better dose coverage than brachytherapy. A higher salvage rate from adding stereotactic radiation as a boost after EBRT has been reported.[294,304,307] Although most series reported a low risk of complications, massive hemorrhage with potential fatal outcome has been described.[304] Radiosurgery should thus be avoided when there is direct tumor encasement of the carotid artery or when a high cumulative dose has already been delivered. Fractionated SRT has shown improved late toxicity profile compared to 3D conformal RT[298] and single-dose radiosurgery[308] and may also give better local control rates compared with single-fraction radiosurgery.[309]

Advances in imaging technology and RT techniques have made it possible to reduce target volume without jeopardizing local control, reducing complication rates. Table 47.17 summarizes the treatment outcome and severe late complications by external beam reirradiation. Past series using 2D technique achieved 5-year survival rates in the range of 16% to 63%, and the incidence of TLN ranged from 2% to 27%. The use of 3D conformal RT showed improving results. In one study by Chang et al,[294] none of the patients reirradiated by 3D technique developed TLN compared with 14% of those reirradiated by 2D technique. Zheng et al[295] reported a 5-year local salvage rate of 71% from 3D technique, but the actuarial rate of late toxicities (grade 4) was still as high as 49%.

The use of IMRT for reirradiation has shown very encouraging short-term results. Using IMRT to deliver 68 to 70 Gy, Lu et al[296] reported 100% salvage rate without any severe late complications in a series of 49 patients with a median follow-up of 9 months. Using IMRT to a median dose of 54 Gy in 31 patients (with or without induction chemotherapy and stereotactic boost), Chua et al[288] reported a 1-year control rate of 100% for rT1-T3 and 35% for rT4, with late complications (> grade 3) of 25% (at 1 year). Using a median dose of 70 Gy in 70 patients, Qiu et al[299] reported a locoregional salvage rate of 66% with a similar toxicity rate at 2 years. Although rT staging did not predict the control rate, original T classification remained a significant adverse prognostic factor and may serve as a strong marker for the underlying locally aggressive biology of the original disease. Longer follow-up is needed to better evaluate treatment results and sequelae resulting from IMRT.

As another alternative, proton beam therapy (PBT) allows for the delivery of RT dose distributions that are typically more conformal than can be achieved with IMRT. This is due to the physical properties of the proton beam that result in maximal dose delivery at a narrow specified depth in the tissue, a phenomenon known as the Bragg peak. Because of the increased precision, PBT is especially useful in the setting of reirradiation, where it is critically important to minimize overlap of radiation fields from multiple treatments, particularly for the dose to surrounding sensitive organs, such as the cranial nerves and brain. An analysis of DVHs from patients who underwent reirradiation with PBT for recurrent NPC found that patients with optimal dose coverage of target volumes experienced significantly improved outcomes (OS of 83% for optimal coverage, 17% for suboptimal coverage), highlighting the importance of high-quality RT for producing good outcomes in the recurrent setting.[312]

A multi-institutional study that included 92 patients who underwent reirradiation with PBT for multiple types of recurrent HNC found a favorable toxicity profile compared to historical controls of patients retreated with photon techniques.[313] This included a low risk of grade 3+ dermatitis (8.7%) and dysphagia (7.1%). Furthermore, locoregional failure was found to be only 25% at 1 year. However, two deaths occurred as a result of bleeding events, reflecting the increased risk of serious vascular toxicity with a second course of RT. In all cases, the risks of toxicities associated with retreatment must be weighed against the risk of uncontrolled tumor progression that is usually associated with significant morbidity and impairment in quality of life.

CRT may also improve treatment outcome for recurrent NPC in certain patients, and most recent salvage radiation series have included cisplatin-based chemotherapy for advanced-stage disease.[288,297,299,314] Using gemcitabine and cisplatin as induction chemotherapy followed by reirradiation with IMRT in 20 patients (95%

rT3-4), Chua et al[288] reported a 1-year local salvage rate of 75%. In a study of 35 patients (66% rT3-4), Poon et al[314] reported a 1-year EFS of 42% by CDDP followed by adjuvant chemotherapy with cisplatin and 5-FU. However, although concomitant chemoirradiation is increasingly used to treat primary NPC, it remains uncertain whether concomitant chemoirradiation is appropriate for retreatment of purely local recurrences (rT1-2), because of high rates of toxicity and potential complications.

Surgical Treatment

For patients with persistent nodal disease, radical neck dissection is the preferred treatment for persistent or recurrent lymph node involvement in the neck when there is no distant metastasis[315] and may achieve a 5-year nodal control rate of 66% and disease-free survival rate of 37%.[316] In cases with extension of disease beyond lymph nodes into nearby structures, additional afterloading brachytherapy to tumor bed may improve local control.[317]

Surgical management at the primary site is hampered by difficulties in obtaining adequate exposure and obtaining adequate surgical margins.[147,318-320] Various approaches have been employed, including an infratemporal approach from the lateral aspect[321]; transpalatal, transmaxillary, and transcervical approaches from the inferior aspect[320,322]; and an anterior-lateral approach.[323] More recently, minimally invasive techniques, such as a transnasal approach and an endoscopic approach, have also been employed successfully.[324] Although controversial, salvage surgery by nasopharyngectomy can be a viable option in certain patients in which the disease is localized in the nasopharynx, with acceptable results reported for rT1-3 tumors.[274] Wei et al[325] reported a 5-year control rate of 62% and 5-year disease-free survival rate of 49% in 60 patients who received curative resections. Typically, all patients with recurrence have undergone prior radical RT, thereby associated complications of trismus and palatal fistula being common; however, the mortalities associated with these surgical procedures are low.

Recurrent NPC is frequently located in the pharyngeal recess on the lateral wall. Access to this region is crucial for complete tumor extirpation. Wei and Sham[326] advocated the anterior-lateral approach or maxillary swing approach for localized recurrence in the nasopharynx. After facial incisions and the necessary osteotomies, the maxilla bone is swung laterally while remaining attached to the anterior cheek flap as one osteocutaneous entity (Figures 47.21 and 47.22). The nasopharynx with the tumor and its surrounding area including the paranasopharyngeal region are then widely exposed for resection. Upon completion of nasopharyngectomy, the maxilla is replaced and attached to the remainder of the facial skeleton with miniplates.

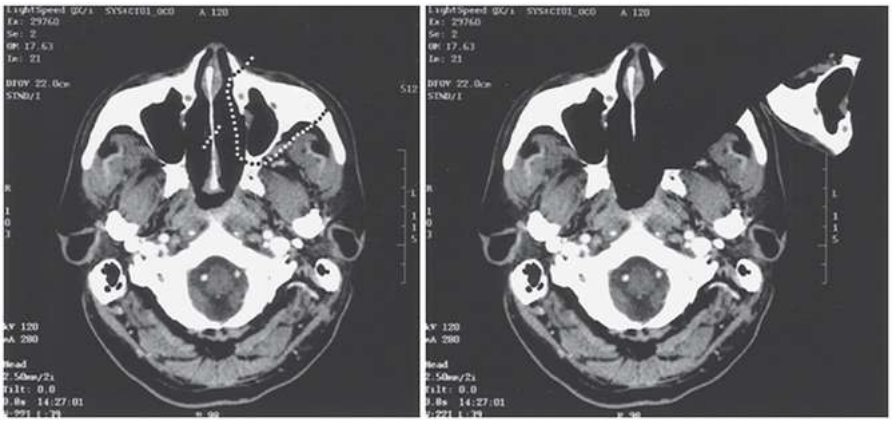

FIGURE 47.21 A. Computed tomography shows planned osteotomies of the maxilla and the posterior part of the nasal septum (broken line). B. The maxilla is swung laterally while still attached to the anterior cheek flap.

FIGURE 47.22 The left maxilla is swung laterally, exposing the nasopharynx (arrow).

Wei et al[323] reported 161 patients with salvage nasopharyngectomy employing this approach performed at Queen Mary Hospital (Hong Kong) for recurrent NPC following primary treatment by radical RT. Twelve patients had prior brachytherapy as a salvage procedure. All patients were recurrent stage T1, with 78% of these patients achieving negative tumor resection margins, confirmed by frozen section, with the remaining patients demonstrating microscopic tumor at the internal carotid artery or the skull base during surgery, making further complete resection unattainable. All patients recovered from this anterior-lateral approach and were discharged. Regarding treatment-associated morbidities, trismus of varying grades was present in 60% and palatal fistula in 25% of patients. Recent modification of the palatal incision has eliminated the problem of palatal fistula.[327]

Satisfactory long-term results can be achieved when persistent/recurrent tumor is completely resected. Several recent surgical series reported LRC and OS rates of 40% to 72% and 30% to 54%, respectively.[324,328-330] Postoperative reirradiation is recommended for patients with positive surgical margins and/or advanced disease[325,331,332] and may be beneficial even when surgical margins are negative.[274]

For recurrent tumors, margin status, adjuvant treatment type, and parapharyngeal space involvement were significant prognostic factors for local control, whereas dura or brain involvement, local recurrence, and adjuvant treatment type predicted survival.[324] Preoperative EBV DNA levels and PET-CT can assist in predicting the

outcome of salvage nasopharyngectomy, and PET-CT may predict the presence of extracapsular spread of metastatic lymph nodes.[333]

RESULTS OF TREATMENT

Specific results of various treatments are mentioned in the previous respective sections. This section focuses on summarizing these results.

The local and regional control rates in select conventional RT series are listed in Tables 47.18 and 47.19. Control of the primary lesion using conventional RT varied with the T classification (Table 47.18), ranging from 64% to 97% for T1 lesions, 54% to 94% for T2 lesions, 34% to 100% for T3 lesions, and 40% to 71% for T4 lesions.[28,32,33,149,150,334,335] Dose escalation with intracavitary brachytherapy if using non-IMRT treatment techniques[198] has been shown to improve local control. Stereotactic radiosurgery boost after EBRT (both conventional and IMRT) has also shown improved local control.[336,337] Nonkeratinizing squamous cell carcinoma (both differentiated and undifferentiated subtypes) had improved local control rates when compared to keratinizing squamous cell carcinoma in T2 to T3 lesions, but not in T1 or T4 lesions.[28,229,240]

OS, overall survival.

[a]Estimated from survival curve.

The 5-year survival rate with conventional non-IMRT radiotherapy correlated with the T stage, as well as with the N stage (Table 47.21), being 60% to 76% for T1, 48% to 68% for T2, 27% to 55% for T3, and 0% to 29% for T4 lesions[33,334] and 42% to 78% for N0, 27% to 70% for N1, and 32% to 52% for N2 to N3 disease. When nodes in the lower neck and/or the supraclavicular fossa are involved, prognosis is poor.

[b]Actuarial disease-free survival.

[c]Actuarial survival.

[d]Absolute survival.

Contemporary series with IMRT demonstrated excellent local and regional control was achieved in 97% and 98% of the patients treated at UCSF, respectively.[171] An update of the UCSF experience continued to show excellent local control of approximately 96%.[182] Subsequently, several other institutions also recently published their results, which further demonstrate excellent local control rates ranging from 82% to 100% and regional control rates ranging from 91% to 98% (Table 47.22).[154,174-176,184,186-188,254,255,339-347]

IMRT, intensity-modulated radiation therapy; M, distant metastasis stage; MSKCC, Memorial Sloan Kettering Cancer Center; N, regional lymph node stage; NA, not available; NPC, nasopharyngeal carcinoma; T, primary tumor stage; UCSF, University of California, San Francisco.

[a]By 1997 AJCC stage.

[b]By 2002 AJCC stage.

[c]By 2010 AJCC stage.

The RTOG conducted a phase II trial using IMRT+/− chemotherapy in the treatment of NPC where patients with ≥T2 (ie, ≥T2b by AJCC 2002) and/or node-positive disease also received concurrent CDDP followed by adjuvant CDDP and 5-FU chemotherapies. The results showed that a multi-institutional setting can reproduce the excellent results (local control rate of 92.3%) observed from single-institution studies.[339] This reproducibility of excellent LRC rates in a multi-institutional trial, along with several single-institution studies, with IMRT is encouraging; however, distant metastases remain a therapeutic challenge despite extensive use of chemotherapy. The distant recurrence rate ranges from 10% to 15% at 2 years[187,339] and 4-year rates are as high as 34% (Table 47.22).[171] Novel systemic therapies or regimens are needed for improved distant control and OS of this disease.

SEQUELAE OF TREATMENT

Overall Incidence and Types

Because of the anatomic proximity of the nasopharynx to critical structures, and the need for high radiation doses and adequate field coverage, the risks of radiation-induced toxicities are substantial. The overall complication rate from conventional treatment ranged from 31% to 66%, with severe sequelae including TLN, hearing loss, xerostomia, neck fibrosis, cranial nerve dysfunction, endocrine dysfunction, soft tissue necrosis, osteonecrosis, and

transverse radiation myelitis.[29,33,40] The diagnosis of irradiation injury can be difficult, as other possible causes (tumor recurrence in particular) must be excluded.

The toxicity results of five major series using conventional irradiation for NPC are summarized in Table 47.23.

TABLE 47.23 INCIDENCE OF LATE TOXICITY FOLLOWING RADIATION WITH CONVENTIONAL TECHNIQUE (WITHOUT CONCURRENT CHEMOTHERAPY) FOR NASOPHARYNGEAL CARCINOMA

Severe Late Complication	Sanguineti et al[29] (*N* = 378)	Chao and Perez[45] (*N* = 164)	Lee et al[40] (*N* = 4,527)	Yeh et al[310] (*N* = 849)	Leung et al[311] (*N* = 880)[a]

NR, not reported.

[a]Patients with one course of radiotherapy.

[b]Median dose equivalent to 2 Gy/fraction.

[c]Five-year actuarial rate.

[d]Bone necrosis, fracture, or osteomyelitis.

[e]Cataract, retinitis, corneal ulcer.

The series of 378 patients treated at MDACC during 1954 to 1992 showed an actuarial frequency rate in grade ≥4 toxicity of 16%, 19%, and 29% at 5, 10, and 20 years, respectively.[29] Despite the use of higher radiation doses, Sanguineti et al[29] showed a reduction in the 10-year actuarial rate of severe toxicity from 14% in 1954 to 1971 to 5% in 1983 to 1992. Other investigators have reported similar findings.

The decreased rates of complications over time were likely due to the use of newer oblique and opposed lateral field techniques instead of single central field, custom blocking, and image-guided (CT) treatment planning.[29]

Because of the extremely narrow therapeutic treatment margin of NPC, maximum conformity and precision in RT delivery are crucial for minimizing the risk of late damage. The emergence of IMRT is a major advance for improving physical dose distribution and has increased the potential for protecting normal tissues. Studies on patients treated with IMRT thus far have shown substantial sparing of salivary function,[171,175,176] whereas other benefits will require longer follow-up to confirm.

The improved conformity offered by IMRT has led to attempts at dose escalation in order to achieve better tumor coverage for patients with extensive locoregional infiltration. However, studies have shown that dose escalation together with concurrent chemotherapy may lead to severe toxicities.[184,349] Furthermore, extensive use of concurrent CRT independent from incorporation of dose escalation has been shown to significantly increase toxicities (grade ≥3) compared to RT alone.[224,229,233,235,236,350,351]

Temporal Lobe Necrosis

TLN is perhaps the most troublesome complication. Studies on patients with NPC treated with conventional 2D-RT found that TLN accounted for up to 65% of all irradiation-induced deaths; large fractions (>2 Gy) and overacceleration of treatment schedule greatly increased risk, with incidence as high as 33%.[40,152,153]

Diagnosis of TLN was often difficult and thus delayed. In Lee et al's examination of 102 patients with late TLN following conventional 2D-RT,[352] only 31% presented with classic symptoms of TLN (hallucinations, absence attacks, déjà vu), whereas 14% had headaches, confusion, convulsions, or hemiparesis. Thirty-nine percent had vague symptoms of dizziness, poor memory, or sudden changes in behavior, whereas 16% were asymptomatic.

TLN remains a serious concern in patients treated with IMRT, with incidence of 3% to 4% being reported for schedules of 70 Gy at 2.12 Gy/fraction,[182] 66 to 74 Gy at 2 Gy/fraction,[176] and 76 Gy at 2.17 Gy/fraction.[184] Series using larger fractions (70.2 at 2.34 Gy/fraction and 68 Gy at 2.27 Gy/fraction) had incidence rates as high as 12% to 14%.[154,343] According to Bakst et al,[154] a prospective trial of hypofractionated dose-painting IMRT using 2.34-Gy fractions to deliver a total dose of 70.2 Gy had favorable disease control and survival outcomes; however, 12% of treated patients developed TLN, with the conclusion that large fractional doses should be avoided to prevent infield brain radiation necrosis.

Cranial Neuropathy

Cranial nerves IX through XII, particularly XII, are the most frequently impaired by radiation.[40,311,353] This is related to marked radiation fibrosis, especially in patients who receive an additional boost dose to the parapharyngeal space. Common symptoms include slurring of speech, twitching of neck muscles, and/or dysphagia. In a study of 31 patients with NPC with post-RT dysphagia, Wu et al[354] found that 77% aspirated after the act of swallowing, raising concerns of fatal aspiration pneumonia.

Cranial nerve VI is also frequently affected, particularly in patients with TLN, whereas isolated palsy of branches of cranial nerve V is less common.[40] Optic neuropathy is rare with careful attention to the RT technique and should be considered when treating lesions with base of skull involvement.[355] The possibility of intracranial recurrence may confound the diagnosis of radiation injury, and exclusion of recurrence is necessary.

Oral Complications

Xerostomia is an almost universal complication from treatment with conventional RT and may lead to dental caries. Jen et al[356] showed that the salivary flow dropped by half with a dose of 7.2 Gy, reached the nadir after 36 Gy, and then further dropped after completion of RT without recovery during the following 2 years.

However, Lee at al[171] reported marked recovery of salivary function in patients treated with parotid-sparing IMRT (mean parotid dose, 34 Gy); the rate of grade 2 xerostomia decreased from 64% at 3 months to 2.4% at 2 years. Randomized trials comparing 2D-RT and IMRT in patients with T1-2 tumors have confirmed IMRT's advantage in this regard.[357,358] Nevertheless, it is important to rule out tumor invasion of the parotid gland prior to parotid-sparing IMRT, as recurrences have been reported. Cannon and Lee[359] concluded that PET alone may be insufficient for the detection of intraparotid lymph node involvement in patients with multilevel nodal disease, including disease in level II nodes. Even with negative PET findings, these patients may require additional evaluation of any benign-appearing parotid nodules before parotid-sparing IMRT by FNA or CT-guided biopsy.

Dental sequelae frequently accompany xerostomia. In a series of 1,758 patients, 2.7% developed osteoradionecrosis at the maxilla and 1.7% at the mandible. Tong et al[360] reported a 29% complication rate in patients who had post-RT extraction of posterior maxillary teeth, with 10.5% developing osteonecrosis. Prophylactic fluoride treatment should be employed to prevent dental decay, and decayed teeth should be extracted prior to RT to reduce this risk.[360,361]

Aural Toxicity

Hearing loss has always been a common radiation sequela, and the increasing use of cisplatin-based concurrent CRT has resulted in deafness rates as high as 42%.[362]

Sensorineural hearing loss (SNHL), particularly in the high-frequency range, was found in at least 30% of patients assessed with audiograms following RT, with higher rates in patients treated by concurrent CRT.[40,363-365] The primary determinant of high-frequency SNHL is mean cochlea dose, which should be kept below 48 Gy to minimize damage.[40,363-365] Because of the location of the primary tumor in the nasopharynx, pharyngotympanic tube (*eustachian tube*) damage resulting in otitis media is difficult to avoid. However, lowering the dose to the external auditory canal and mastoid air cells can reduce the incidence and severity of acute external otitis and chronic serous otitis media, respectively.

Carotid Artery Injury

Carotid stenosis is a potentially fatal complication reported in patients who undergo irradiation of the head and neck region. Interval from RT was a significant independent predictor for severe carotid stenosis. Some have advocated for routine duplex ultrasound screening for high-risk patients (older than 60 years, smoking, hypertension, hypercholesterolemia, cerebrovascular symptoms).[366,367] Severe cases may require carotid endarterectomy or endoplasty.

Massive bleeding from ruptured pseudoaneurysms at the petrous portion of the internal carotid has been reported following IMRT with dose escalation.[184,368] Urgent diagnosis and intervention with endovascular occlusion or stenting may be needed to prevent fatal consequences. Other concerns include severe telangiectasia and hypervascularization in the internal maxillary artery territory, for which emergency embolization may be considered.

Endocrine Dysfunction

The most common endocrine sequelae are amenorrhea and/or galactorrhea from hyperprolactinemia in female patients and followed by hypothyroidism and hypoadrenalism.

Lee et al[40] observed symptomatic hypothalamic-pituitary dysfunction in 5% of patients, with a median latency of 5 years, whereas a longitudinal study by Lam et al[369] with detailed endocrine assessment found a 5-year incidence of 62%, with dysfunction detected as early as 1 year following RT.[370] The deficiency of releasing of inhibitory factors indicated that the hypothalamus is the primary location of damage.[371,372] As many of these dysfunctions may be corrected pharmacologically, routine evaluation of hypothalamic, pituitary, and thyroid function should be considered in the follow-up examination of long-term survivors.

Shielding may help lessen endocrine dysfunction when using 2D technique.[373] The need for maximum conformity to protect normal tissues during RT is paramount.

Second Malignancies

Radiation-induced malignancy is rare, with an incidence of 0.04% and latency period >10 years. The most common histologic types are maxillary osteosarcoma[374] and soft tissue sarcoma.[80] Surgery presents the only chance of cure, but the prognosis is often poor. Although second primary head and neck cancer is relatively uncommon for patients with NPC, Teo et al[375] reported an excessive incidence rate of tongue cancer at 0.13% per patient-year. The possibility of radiation carcinogenesis cannot be excluded.

CHAPTER 48

Cancer of the Nasal Cavity and Paranasal Sinuses

Steven J. Frank, Anesa Ahamad, and Carlos A. Perez*

ANATOMY

Nasal Cavity

The nasal cavity extends from the hard palate inferiorly to the base of the skull superiorly. It is above and behind the vestibule and is defined anteriorly by the transition from the skin to mucous membrane and posteriorly by the choanae, which opens directly into the nasopharynx.[1] The nasal cavity consists of four subsites: the nasal vestibule, the lateral walls, the floor, and the septum.

The *nasal vestibule* is the triangular space located inside the aperture of the nostril as a slight dilation that extends as a small recess toward the apex of the nose. It is defined laterally by the alae; medially by the membranous septum, the distal end of the cartilaginous septum, and columella; and inferiorly by the adjacent floor of the nasal cavity. It is lined by the skin containing hairs and sebaceous glands; therefore, tumors at this location are often those that arise from the skin, usually squamous cell cancers,[2] but may occasionally be basal cell carcinoma,[3] sebaceous carcinoma,[4] melanoma,[5,6] or non-Hodgkin lymphoma.[7,8]

The *lateral walls* correspond with the medial walls of the maxillary sinuses and consist of thin bony structures that have three shell-shaped projections (superior, middle, and inferior conchae or turbinates) into the nasal cavity. The *floor* extends from the vestibule to the nasopharynx above the hard palate of the maxilla. The *septum* divides the nasal cavity into right and left halves.

Paranasal Sinuses

The paranasal sinuses are named according to the bones in which they are located: the ethmoid, maxilla, sphenoid, and frontal.

Ethmoid Sinuses

The ethmoid sinuses are composed of several small cavities, the ethmoid air cells, within the ethmoid labyrinth located below the anterior cranial fossa and between the nasal cavity and the orbit. They are separated from the orbital cavity by a thin, porous bone, the *lamina papyracea*, and from the anterior cranial fossa by a portion of the frontal bone, the *fovea ethmoidalis*. They are in close proximity to the optic nerves laterally and the optic chiasm posteriorly. The ethmoid sinuses are divided into anterior, middle, and posterior groups of air cells. The middle ethmoid cells open directly into the middle meatus. The anterior cells may drain indirectly into the middle meatus via the infundibulum. The posterior cells open directly into the superior meatus.

Maxillary Sinuses

The maxillary sinuses, the largest of the paranasal sinuses, are pyramid-shaped cavities located in the maxillae. The lateral walls of the nasal cavity form the base and the roofs correspond to the orbital floors, which contain the infraorbital canals. The floors of the maxillary sinuses are composed of the alveolar processes. The apices extend toward and frequently into the zygomatic bones. Secretions drain by mucociliary action into the middle meatus via the hiatus semilunaris through an aperture near the roof of the maxillary sinus. Ohngren line is a theoretical plane dividing each maxillary sinus into the suprastructure and infrastructure; it is defined by connecting the medial canthus with the angle of the mandible.

Sphenoid Sinus and Frontal Sinuses

The sphenoid bone forms a midline inner cavity that communicates with the nasal cavity through an aperture in its anterior wall. It is directly apposed superiorly to the pituitary gland and optic chiasm, laterally to the cavernous sinuses, anteriorly to the ethmoid sinuses and nasal cavity, and inferiorly to the nasopharynx. The paired, typically asymmetric frontal sinuses are located between the inner and outer tables of the frontal bone. They are anterior to the anterior cranial fossa, superior to the sphenoid and ethmoid sinuses, and superomedial to the orbits. They usually communicate with the middle meatus of the nasal cavity.

EPIDEMIOLOGY

Cancers of the nasal cavity and paranasal sinuses are relatively uncommon. Fewer than 7,500 cases are diagnosed each year in the United States, with an incidence of 0.556 per 100,000.[9] Cancers of the maxillary sinus are twice as common as those of the nasal cavity; cancers of the ethmoid, frontal, and sphenoid sinuses are extremely rare. They generally develop after the age of 40 years, except for esthesioneuroblastoma (ENB), which has a unique bimodal age distribution[10] and occurs twice as often in men than in women.[11] These tumors are most common in Japan and South Africa.

The etiologic factors vary by tumor type and location. Adenocarcinomas of the nasal cavity and ethmoid sinus have been reported to occur more frequently in carpenters and sawmill workers who are exposed to wood dust.[12,13] Synthetic wood, binding agents, and glues may also be involved as cocarcinogens.[14] Squamous cell carcinomas (SCCs) of the nasal cavity have been seen more often in nickel workers.[15] Maxillary sinus carcinomas have been associated with radioactive thorium-containing contrast material (thorotrast) used for radiographic visualization of the maxillary sinuses in the past. Occupational exposure to the production of chromium, mustard gas, isopropyl alcohol, and radium also may increase the risk of sinonasal carcinomas.

Cigarette smoking is reported to increase the risk of nasal cancer, with a doubling of risk among those who smoked heavily or long term and a reduction in risk after long-term cessation. After adjustment for smoking, a significant dose-response relationship has also been noted between alcohol consumption and risk of nasal cancer.[16]

NATURAL HISTORY

Nasal Vestibule

Nasal vestibule carcinomas can spread by direct invasion of the upper lip, gingivolabial sulcus, premaxilla (early events), or nasal cavity (late events), as shown in Figure 48.1. Vertical invasion may result in septal (membranous or cartilaginous) perforation or alar cartilage destruction. Lymphatic spread from nasal vestibule carcinomas is usually to the ipsilateral facial (buccinator and mandibular) and submandibular nodes. Large lesions extending across the midline may spread to the contralateral

facial or submandibular nodes. The incidence of nodal metastasis at diagnosis is approximately 5%.[17,18] Without elective nodal treatment, approximately 15% of patients develop nodal relapse. Hematogenous metastases are rare.

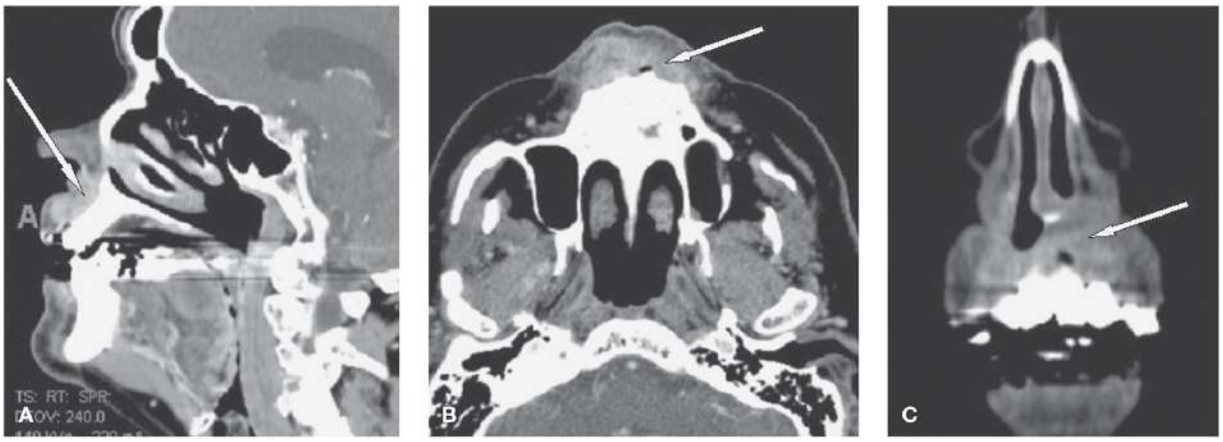

FIGURE 48.1 Computed tomography scans of a nasal vestibule squamous cell carcinoma that has spread by direct invasion of the upper lip (*arrow* in A) and gingivolabial sulcus and premaxilla (*arrow* in B and C).

Nasal Cavity and Ethmoid Sinuses

The pattern of contiguous spread of carcinomas varies with the location of the primary lesion. Tumors arising in the upper nasal cavity and ethmoid cells can extend to the orbit through the thin lamina papyracea and to the anterior cranial fossa via the cribriform plate, or they may grow through the nasal bone to the subcutaneous tissue and skin. Lateral wall primaries invade the maxillary antrum, ethmoid cells, orbit, pterygopalatine fossa, and nasopharynx. Primaries of the floor and lower septum may invade the palate and maxillary antrum. Perineural extension (typically involving branches of the trigeminal nerve) is seen most often with adenoid cystic carcinomas.

Lymphatic spread of nasal cavity primaries is uncommon, although spread to retropharyngeal and cervical lymph nodes is possible. In a series of 51 patients reported by the University of Texas MD Anderson Cancer Center, only one patient had palpable subdigastric nodes at diagnosis. Of the 36 patients who did not receive elective lymphatic irradiation, two (6%) experienced subdigastric nodal relapse.[19]

The risk of nodal involvement in patients with cancer of the nasal cavity and paranasal sinuses has not been well defined and may vary depending on the histologic subtype. Current decision-making on whether to cover specific nodal regions is based on interpretation of single-institution retrospective analyses.

Ahn[20] in a review of the Surveillance, Epidemiology, and End Results (SEER) database from 2004 to 2009 identified 1,811 patients who had local and nodal staging information, with paranasal sinus cancer as their first cancer diagnosis, defined histology (squamous, melanoma, adenocarcinoma, sinonasal undifferentiated, and ENB), and defined primary site. Of all the patients examined with information on local and nodal extent, 1,578 (87.1%) patients had no gross nodal involvement at presentation.

On presentation, level 1 was involved in 5.1%, level 2 in 6.7%, level 3 in 1.8%, level 4 in 1.2%, level 5 in 1.1%, retropharyngeal nodes in 0.7%, parotid nodes in 0.6%, and facial nodes in 0.2% of all patients. Isolated skip metastases to level 3 or 4 occurred in 0.7% of patients. On presentation, at least 2.5% presented with bilateral or contralateral disease. In patients with SCC of the nasal cavity, there was a clear gradation in nodal risk among patients with T1 versus T4 disease (4% vs 23%, $P < .001$); this was not evident in patients with melanoma of the nasal cavity, who had a 5% to 10% risk of nodal involvement regardless of local extension. Local extension of SCC of the maxillary sinus did not predict nodal involvement in a significant manner, although T1 tumors showed an 11% risk of nodal involvement compared to 21% to 24% for T2+ disease. SCC, small cell, and sinonasal undifferentiated (SNUC) carcinoma had higher rates of nodal dissemination at presentation (14.4%, 19.1%, and 25.3%, respectively), compared to adenocarcinoma, ENB, and melanoma (7.1%, 8.7%, 5.8%, respectively). Although confounded by stage and histology, maxillary sinus carries the highest risk (20.6%), followed by frontal/sphenoid (15.4%), ethmoid (11.9%), and nasal cavity (8.5%, $P < .001$).

The issue of appropriate radiation volumes in the treatment of these patients has not been entirely elucidated, although the data suggest that in some with potential higher nodal involvement, it is advisable to electively irradiate regions at risk. However, as noted by Ahn,[20] in the absence of gross

neck disease, the low neck and retropharyngeal nodes do not need to be treated.

Hematogenous dissemination is rare. In the MD Anderson Cancer Center series, for example, distant metastasis to the bone, brain, or liver occurred in only 4 of 51 patients.[21]

The olfactory region is the site of origin of ENB and, occasionally, adenocarcinomas. ENB constitutes approximately only 3% of all intranasal neoplasms. About 250 cases have been reported between 1924 and 1990.[21] The tumor is typically composed of round, oval, or fusiform cells containing neurofibrils with pseudorosette formation and diffusely increased microvascularity.[22]

ENB may be mistaken for any other "small round cell tumor," that is, a group of aggressive malignant tumors composed of small and monotonous undifferentiated cells that include Ewing sarcoma, peripheral primitive neuroectodermal tumor (also known as extraskeletal Ewing), rhabdomyosarcoma, lymphoma, small cell carcinoma (undifferentiated or neuroendocrine), and mesenchymal chondrosarcoma. The clinical presentations of these entities often overlap, but clinicopathologic features and immunohistochemical staining may help in distinguishing among them.

The route of contiguous spread of ENB is similar to that of ethmoid carcinomas. Lymph node involvement and distant metastasis are uncommon at diagnosis.[23,24]

Maxillary Sinuses

The pattern of spread of maxillary sinus cancers varies with the site of origin. Suprastructure tumors extend into the nasal cavity, ethmoid cells, orbit, pterygopalatine fossa, infratemporal fossa, and base of the skull (Figure 48.2A-C). Invasion of these structures gives lesions of the suprastructure a poorer prognosis. Their treatment is also associated with greater morbidity as a consequence of craniofacial resection or radiation of intracranial and ocular structures. Infrastructure tumors often infiltrate the palate, alveolar process, gingivobuccal sulcus, soft tissue of the cheek, nasal cavity, masseter muscle, pterygopalatine space, and pterygoid fossa (Figure 48.2D-J).

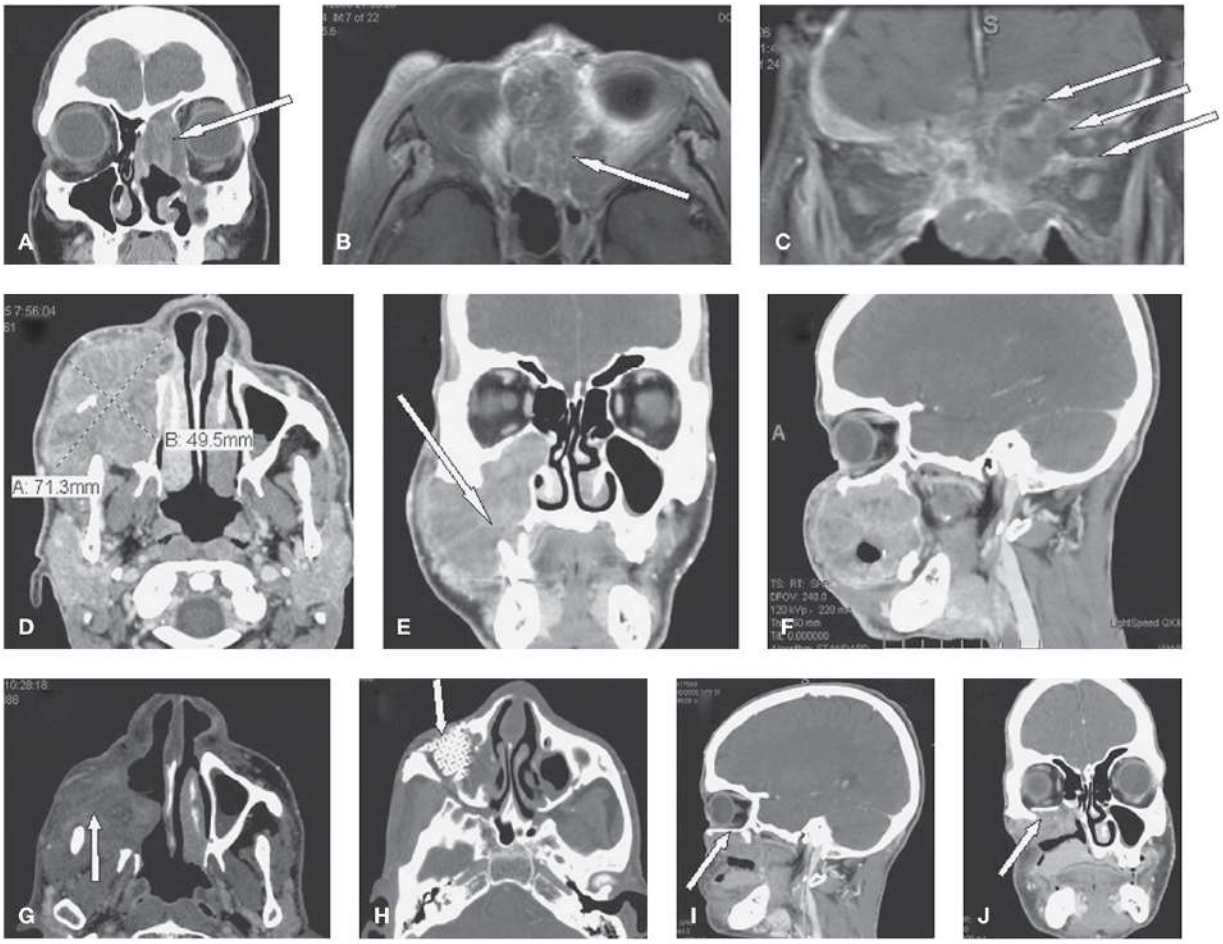

FIGURE 48.2 The pattern of spread of maxillary sinus cancers. A-C. Suprastructure tumors are shown, with *arrows* indicating the involvement of the nasal cavity and ethmoid cells (A), the orbit (B), and the base of the skull (C). D-J. Advanced tumor is shown, with *arrows* indicating alveolar process destruction with loosening of a tooth (E) and abutment of the orbital floor without frank intraorbital invasion (F). The patient had a maxillectomy and orbital floor resection with an anterior-lateral thigh flap (*arrow* in G), and titanium mesh reconstruction of the orbital floor (H-J).

The maxillary sinuses are believed to have a limited lymphatic supply[25] and a correspondingly low incidence of lymphadenopathy at diagnosis.[26,27] Only 6 (8%) of the 73 patients in the MD Anderson Cancer Center series had palpable lymphadenopathy at diagnosis. The incidence of nodal spread, however, varies with the histologic type (17%, or 5/29 patients with SCC or poorly differentiated carcinomas, vs 4%, or 1/27 for patients with adenocarcinoma, adenoid cystic carcinoma, or mucoepidermoid carcinoma). The incidence of subclinical disease, as reflected in the rate of nodal relapse in patients who did not receive elective neck treatment, also

varies with histologic type (38%, or 9/24 patients with SCC or poorly differentiated carcinomas, vs 8%, or 2/26 patients with adenocarcinoma, adenoid cystic carcinoma, or mucoepidermoid carcinoma). The cumulative incidence of nodal involvement (gross and microscopic) for patients with SCC and poorly differentiated carcinomas is about 30%. The risk of regional recurrence after treatment is 20% to 30% or higher, depending on the extent of disease and elective neck treatment.[28] Ipsilateral subdigastric and submandibular nodes are most often involved. Hematogenous spread is uncommon.

CLINICAL PRESENTATION

Nasal Vestibule

Carcinomas of the nasal vestibule usually present as asymptomatic plaques or nodules, often with crusting and scabbing. Advanced lesions may extend beyond the vestibule and may cause pain, bleeding, or ulceration. Large ulcerated lesions may become infected, leading to severe tenderness that requires anesthesia for complete clinical assessment.

Nasal Cavity

Nasal cavity tumors present with symptoms and signs of nasal polyps (eg, chronic unilateral discharge, ulcer, obstruction, anterior headache, and intermittent epistaxis), hence delaying the diagnosis. Additional symptoms and signs develop as the lesion enlarges: medial orbital mass, proptosis, expansion of the nasal bridge, diplopia resulting from invasion of the orbit, epiphora because of obstruction of the nasolacrimal duct, anomaly of smell or anosmia from involvement of the olfactory region, or frontal headache because of extension through the cribriform plate.

The common presenting symptoms of ENBs are nasal obstruction and epistaxis. Spaulding et al[29] found that anosmia could precede diagnosis by many years. Other symptoms are related to contiguous disease extension into the orbit (proptosis, visual field defects, orbital pain, epiphora), paranasal sinuses (medial canthus mass, facial swelling), or anterior cranial fossa (headache) or are due to inappropriate antidiuretic hormone secretion.[29]

Ethmoid Sinuses

The presenting symptoms and signs of ethmoid sinus tumors are central or facial headaches and referred pain to the nasal or retrobulbar region, a subcutaneous mass at the inner canthus, nasal obstruction and discharge, diplopia, and proptosis. In one study of 34 patients with ethmoid sinus cancers treated at MD Anderson Cancer Center between 1969 and 1993,[30] nasal cavity symptoms (nasal obstruction, epistaxis, discharge) were reported in 25 (74%) patients, orbital symptoms (diplopia, orbital pain, vision loss, proptosis, inner canthus mass, tearing) in 12 (35%), headache in 6 (18%), and hyposmia or anosmia in 5 (15%).

Maxillary Sinuses

Maxillary sinus cancers are usually diagnosed at advanced stages. Symptoms and signs are facial swelling, pain, or paresthesia of the cheek induced by disease extension to the premaxillary region, epistaxis, nasal discharge and obstruction related to tumor spread to the nasal cavity, ill-fitting dentures, alveolar or palatal mass, unhealed tooth socket after extraction from spread to the oral cavity, and proptosis, diplopia, impaired vision, or orbital pain because of orbital invasion.[31]

DIAGNOSTIC WORKUP

The recommended pretreatment physical, diagnostic, and staging evaluations are listed in Table 48.1.

TABLE 48.1 PRETREATMENT EVALUATION FOR TUMORS OF THE NASAL CAVITY AND PARANASAL SINUSES

General	Complete History and Physical Examination
	Fiberoptic endoscopic examination with biopsies
Radiographic	Computed tomography (CT)/positron emission tomography (PET)/magnetic resonance imaging (MRI) of the primary site and neck
Laboratory	Complete blood count
Others	Dental evaluation with extractions/restorations as needed
	Baseline ophthalmologic examination
	Baseline speech and swallowing assessment if surgery is planned

Physical Examination

Inspection and palpation of the orbits, nasal and oral cavities, and nasopharynx can provide preliminary determination of tumor extent. Bimanual palpation is important in assessing contiguous extension of nasal vestibule lesions and in identifying buccinator and submandibular nodal involvement. Careful examination of cranial nerves is required. Fiberoptic nasal endoscopy after mucosal decongestion and topical analgesia allows assessment of local extent and facilitates biopsy of tumor involving the nasal cavity or nasopharynx.

Radiographic Evaluation

Imaging has a crucial role in the staging of sinonasal tumors. Magnetic resonance imaging (MRI) and computed tomography (CT) scans are complementary.[32] MRI is superior at detecting direct intracranial or perineural or leptomeningeal spread.[33] T2-weighted MRI can be helpful in distinguishing tumor (low signal) from obstructed secretions (bright).[34] CT is superior for detecting early cortical bone erosion or extension through the cribriform plate or orbital walls.

MRI, especially T1 weighted with gadolinium contrast, may be used as a supplement or alternative to CT scanning. CT provides the best information about the tumor and its local invasion into surrounding bone structures. MRI allows an estimate of tumor spread into surrounding soft tissue areas, such as the anterior cranial fossa and the retromaxillary space. Bone scintigraphy scan is useful in detecting distant metastases.

The expansile tendency of olfactory neuroblastoma is characterized by bowing of the sinus walls. The destructive aspect is manifested as tumor replacing the turbinates, septum, and sinus walls with extension into contiguous areas. The density or signal and enhancement characteristics are nonspecific of olfactory neuroblastoma.

Certain features provide clues as to the nature of the tumors in this region. Slowly progressive lesions tend to deform instead of destroy bony structures. Intermediate-grade tumors can cause sclerosis of the adjacent bone. Lymphomas tend to permeate the bone without frank destruction, and carcinomas and sarcomas infiltrate and destroy adjacent bone.

Biopsy

Transnasal biopsy is preferred for tumors arising from or extending into the nasal cavity or nasopharynx. Some paranasal sinus tumors may be more easily sampled using transoral procedures or an open Caldwell-Luc approach.

Laboratory Studies

Complete blood counts and serum chemistries can be used to screen for the presence of distant metastases. Abnormalities of these tests can be further investigated as necessary.

STAGING

The eighth edition of the *American Joint Committee on Cancer's (AJCC) Cancer Staging Manual* tumor-node-metastasis (TNM) classification includes staging for cancers of the maxillary sinus, the ethmoid sinus, and the nasal cavity.[35] Significant updates from the sixth edition affect classifications of T4 lesions and hence stage IV disease. Specifically, T4 lesions are now considered either T4a (moderately advanced local disease) or T4b (very advanced local disease), which leads to stratification of stage IV disease as either IVA (moderately advanced local or regional disease), IVB (very advanced local or regional disease), or IVC (distant metastatic disease). Definitions of anatomic stage prognostic groupings and TNM classifications are given in Table 48.2.

TABLE 48.2 2017 AMERICAN JOINT COMMITTEE ON CANCER STAGING SYSTEM FOR CANCER OF THE NASAL CAVITY AND PARANASAL SINUSES

Definitions of TNM	
Primary Tumor (T)	
TX	Primary tumor cannot be assessed.
Tis	Carcinoma in situ
Maxillary Sinus	
T1	Tumor limited to maxillary sinus mucosa with no erosion or destruction of the bone
T2	Tumor causing bone erosion or destruction including extension into the hard palate and/or middle nasal meatus, except extension to posterior wall of

Definitions of TNM

	maxillary sinus and pterygoid plates
T3	Tumor invades any of the following: the bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of the orbit, pterygoid fossa, ethmoid sinuses.
T4a	Moderately advanced local disease
	Tumor invades anterior orbital contents, skin of the cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses.
T4b	Very advanced local disease
	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V2), nasopharynx, or clivus.

Nasal Cavity and Ethmoid Sinus

T1	Tumor restricted to any one subsite, with or without bony invasion
T2	Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
T3	Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate.
T4a	Moderately advanced local disease
	Tumor invades any of the following: anterior orbital contents, skin of the nose or cheeks, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses.
T4b	Very advanced local disease
	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than (V2), nasopharynx, or clivus.

Regional Lymph Nodes (N)

NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension, ENE neg
N2	Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension, or in multiple ipsilateral lymph nodes or contralateral lymph nodes, none >6 cm in greatest dimension and ENE neg
N2a	Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension and ENE neg

Definitions of TNM			
N2b	Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension and ENE neg		
N2c	Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension and ENE neg		
N3a	Metastasis in a lymph node >6 cm in greatest dimension and ENE neg		
N3b	Metastasis in any node(s) with clinically overt ENE (ENE positive)		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Anatomic Stage/Prognostic Groups			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0

PATHOLOGIC CLASSIFICATION

Most nasal vestibule cancers are SCCs; the remaining tumors are basal cell or adnexal carcinomas. Most cancers of the nasal cavity and paranasal sinuses are also SCCs, although minor salivary gland neoplasms (adenocarcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma) account for 10% to 15% of lesions in these locations.

Melanoma accounts for 5% to 10% of nasal cavity malignancies but is rare in the paranasal sinuses. Neuroendocrine carcinomas of the sinonasal region (including small cell carcinoma, ENB, and SNUCs), lymphomas, sarcomas, and plasmacytomas are even less common.

PROGNOSTIC FACTORS

Patient-specific factors (primarily prognostic for survival) include age and performance status. Disease-specific factors (primarily prognostic for locoregional control) include location, histology, locoregional extent (reflected in the TNM stage), and perineural invasion. Extensive local disease involving the nasopharynx, base of the skull, or cavernous sinuses markedly increases surgical morbidity as well as the risk of subtotal surgical excision. Tumor extension into the orbit may require enucleation, but minimal invasion of the floor or medial wall may be dealt with through resection and reconstruction, sparing the globe.

GENERAL MANAGEMENT

Nasal Vestibule Tumors

Nasal vestibule tumors can be treated definitively with surgery, primary radiation therapy (RT), or postoperative (adjuvant) RT when indicated because of tumor size or positive surgical findings. For small superficial tumors, standard treatment approaches are surgery or primary RT. Depending on the location and size of the primary tumor, radiation can be delivered as external beam RT, brachytherapy, or a combination of the two. Primary RT may be preferable for nasal vestibule carcinoma for better cosmetic outcome, although surgery can yield high control rates with excellent cosmetic results for selected small superficial tumors. Adjuvant radiation is indicated for cases involving positive surgical margins, positive lymph nodes, or perineural invasion. Cartilaginous invasion is not a contraindication for RT because fractionated treatment carries a low risk of necrosis.[36] For large invasive tumors with extensive tissue destruction and distortion, the combination of surgery and RT, with the radiation given either before or after surgery, is the mainstay of treatment. However, some clinicians favor primary radiation with salvage surgery for this situation.[37]

Cosmesis can be enhanced by having experienced prosthodontists design aesthetically satisfactory custom-made nasal prostheses after radical surgery. Patients who are older or who have poor performance status can be treated with RT alone. No role for systemic chemotherapy has been established for tumors of this type.

Nasal Fossa Tumors

Either surgery or primary RT can produce similarly high control rates for early-stage nasal fossa lesions. The choice of treatment modality is generally guided by the size and location of the tumor as well as the anticipated cosmetic outcome. Posterior nasal septum lesions or locally advanced lesions are generally treated surgically, but small anterior-inferior septal lesions (≤1.5 cm) can be treated effectively with interstitial brachytherapy (iridium-192 [^{192}Ir] implant). For lateral wall lesions extending to the nasal ala, primary external beam RT may produce the best cosmetic results.

Paranasal Sinus Tumors

Surgery can produce excellent control rates for T1 and T2 tumors and is generally the mainstay of treatment. The combination of surgery and postoperative RT is the treatment of choice for patients with more advanced but resectable SCC tumors who are medically fit to undergo surgery.[38] For SNUC tumors, response to induction chemotherapy (IC) guides chemoradiation strategies for complete (CR) or partial response (PR) and surgery followed by adjuvant therapy for nonresponders.[39] Maxillary sinus and ethmoid sinus tumors often present as locally advanced disease (large T3 or T4) and are commonly managed with surgery and postoperative RT. Ethmoid sinus carcinomas can be treated with radiation alone or with concurrent chemotherapy to avoid structural or functional deficits. Surgery generally involves medial maxillectomy and en bloc ethmoidectomy; a craniofacial approach is required if tumor extends superiorly to the ethmoid roof or olfactory region.[40,41] Primary RT, with or without concurrent chemotherapy, can be considered for patients who are not fit to undergo surgery owing to significant comorbid conditions or poor performance status or for patients who decline radical surgery.[42]

Early ENB lesions involving the ethmoids with little or no bony destruction or nerve invasion can be treated adequately by high-energy (photon, proton, or electron) RT with good cosmetic and functional results. Those with more extensive local disease benefit from surgery and adjuvant irradiation, although some have advocated against combined surgery and RT because of complications. Patients with locally advanced disease or high-grade tumors should receive aggressive treatment with combined modalities, such as surgery, RT, and chemotherapy. Elective nodal irradiation is not generally recommended for Kadish stages A and B because the incidence of nodal relapse is less than 15%. Distant metastasis is uncommon (10%) even among patients presenting with locally advanced disease.

CHEMOTHERAPY: NEOADJUVANT AND CONCOMITANT

Neoadjuvant chemotherapy (ie, chemotherapy given before surgery) can reduce tumor volumes, which may allow a less extensive surgical resection than would be possible otherwise.[39] Similarly, chemotherapy given before primary RT can also reduce tumor volumes and facilitate RT planning by increasing the distance between tumor borders and critical organ structures, such as the brain, chiasm, optic nerve, or spinal cord. Investigations are ongoing to determine whether the response (or lack of same) to neoadjuvant chemotherapy can help in the choice of definitive treatment. For example, if neoadjuvant chemotherapy produces a CR, then primary RT, with or without chemotherapy, can be considered; a less than CR would prompt surgical excision of the lesion followed by adjuvant RT.[43]

The optimal treatment strategy for patients with orbital encroachment of sinonasal cancer is controversial. Organ (orbital) preservation with neoadjuvant therapy may determine if patients require an orbital exenteration for locally advanced sinonasal cancer. Yusuf et al[44] reported on 20 patients determined by a multidisciplinary team to require an orbital exenteration as part of definitive treatment of their sinonasal cancer. Neoadjuvant treatment consisted of concurrent chemoradiation therapy (CRT) in all patients aside from two who refused chemotherapy and underwent RT alone. Six patients received primary surgery followed by adjuvant CRT. Five patients (36%) receiving neoadjuvant therapy had

complete disease response at the time of surgery. Fourteen patients underwent orbital preservation (OP). With a median time of follow-up of 18.8 months, actuarial exenteration-free survival was 62% at 2 years for patients undergoing OP. No patients receiving neoadjuvant therapy required an immediate post-treatment orbital exenteration; however, one patient required salvage orbital exenteration when they experienced local failure 35 months after treatment. At 2 years, there were no significant differences in locoregional control (75% vs 60%, $P = .997$), progression-free survival (40% vs 36%, $P = .493$), or overall survival (OS) (40% vs 58%, $P = .815$) between patients receiving OP or upfront surgery ($P = .815$). On multivariate analysis, tumor site predicted for locoregional control (maxillary, 86%; nasal cavity, 80%; ethmoid sinus, 40%; $P = .050$). Treatment was well tolerated in both groups. One patient treated with OP experienced grade 3 radiation-related toxicity, developing dysphagia, which improved with medical management. However, one patient developed renal failure following the first dose of cisplatin and subsequently died before completion of treatment.

Concurrent CRT can also be used for patients with medical conditions that preclude surgery if those patients have good performance status. Depending on the patient's performance status and renal function, single-agent cisplatin or carboplatin can be used concurrently with external beam radiation for locally advanced, unresectable SCC. Neoadjuvant chemotherapy or concurrent chemoradiation with etoposide and cisplatin or carboplatin can be used to treat SNUC, neuroendocrine carcinoma, or small cell carcinoma. Chemotherapy is not used routinely for ENB, and its role in the management of this disease is under investigation. Chemotherapy may have a role in the management of Kadish stage C disease, and although responses to chemotherapy have been reported, they are usually of limited duration.[45] Concurrent chemotherapy during radiation may be considered for inoperable cases.

PALLIATION

Symptoms of incurable sinonasal cancer are particularly distressing. Multidisciplinary input is required even for very advanced cases, as palliation may involve limited surgery, RT, chemotherapy, investigational

studies, or best supportive care. The morbidity of each modality must be balanced with the potential benefits in symptom control and improved quality of life. Particular attention is required to address the control of pain and discomfort as a first priority, and the impact of disfigurement and dysfunction, which is often present.

Chemotherapy can be given as single-agent therapy in investigational settings. If RT is given, large doses per fraction are usually given to reduce the duration of treatment. However, if concurrent chemotherapy is added, treatment with 2-Gy fractions should be considered to avoid severe acute effects. Radiation or chemotherapy is often effective in reducing tumor bulk and relieving symptoms associated with disfiguring masses, proptosis, discomfort or neuropathic pain, headache, epistaxis or other bleeding, nasal obstruction or discharge, and trismus.

RADIATION THERAPY TECHNIQUES

Tumors of the Nasal Cavity

Nasal Vestibule Tumors

Target Volumes

For small, well-differentiated lesions that are less than 1.5 cm in diameter, small fields with a 1- to 2-cm margin are appropriate. The initial target volume for all poorly differentiated tumors and well-differentiated primary tumors larger than 1.5 cm without palpable lymphadenopathy should include both nasal vestibules with at least 2- to 3-cm margins around the primary tumor (wider margins for infiltrative tumor) as well as bilateral facial, submandibular, and subdigastric nodes. When lymph node involvement is present at diagnosis, the lower neck is also irradiated. For larger nasal vestibule lesions, the lower half of the nose and the upper lip are treated as well as the regional lymphatics, including the facial lymphatics and upper neck nodes. For postoperative RT, the initial target volume includes the operative bed plus a 1- to 1.5-cm margin and the elective nodal regions.

Treatment Techniques

External Beam Radiation. Thin superficial nasal vestibule lesions can be treated with orthovoltage x-rays or electrons with skin bolus, whereas thicker lesions are generally treated with electrons, photons, or protons. In definitive therapy, the target volume is treated to a dose of 66 to 70 Gy, with a small reduction in the treatment fields after 50 Gy to boost the dose to the gross disease. For patients presenting with palpable neck adenopathy, the entire neck is treated with at least a subclinical dose of 50 Gy, and the gross disease plus a 1- to 2-cm margin is then treated with an additional 16 to 20 Gy. A technique for external beam irradiation using electrons is illustrated in Figure 48.3. The patient lies supine, immobilized with the neck slightly flexed by using a custom mask to align the anterior surface of the maxilla parallel with the top of the couch. For larger nasal vestibule lesions, the lower half of the nose and the upper lip are treated with an anterior appositional field using 20-MeV electrons and 6-MV photons weighted 4 to 1. Skin collimation is used to minimize scatter irradiation to the eye and reduce the penumbra of the beam and reduce the field size required. Custom beeswax bolus material is prepared to allow a relatively flat surface contour onto which the electron beam is incident, avoiding inhomogeneity because of oblique incidence and surface irregularity. A bolus is also used to fill the nares to avoid the dose perturbation from the air cavity with electron beams. In photon treatments, the bolus is removed to spare the skin unless the overlying skin is involved. An intraoral Cerrobend-containing stent is used to displace the tongue posteriorly and partially shield the upper alveolar ridge. In proton treatments, bolus material is not required and an aperture is used instead of skin collimation to minimize scatter irradiation to the eye and reduce penumbra of the beam.

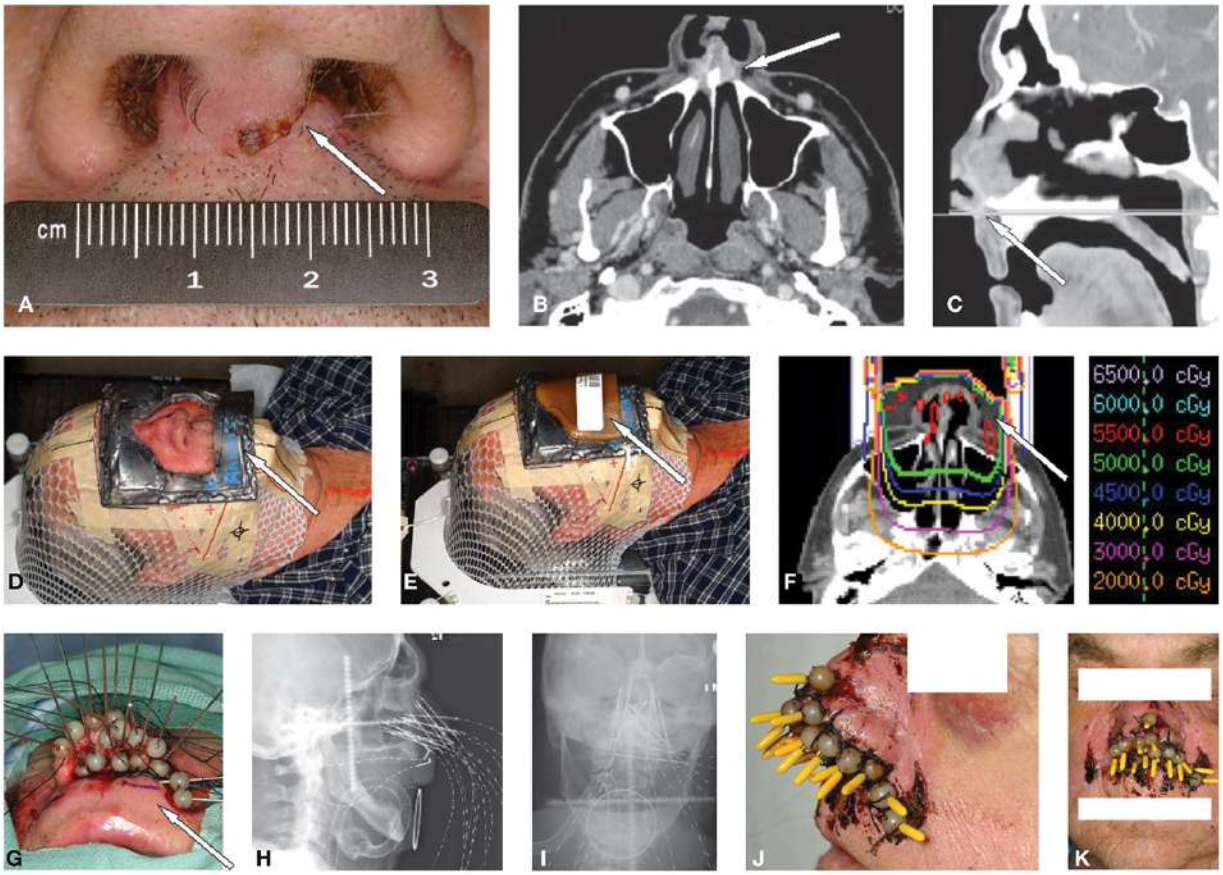

FIGURE 48.3 Nasal vestibule squamous cell carcinoma. A. *Arrows* indicate tumor expanding the columella. B and C. *Arrows* indicate invasion downward into the upper gingivobuccal sulcus on computed tomography (CT) imaging. D. *Arrow* shows setup for electron-beam phase of therapy with custom lead skin collimation in situ. E. *Arrow* shows the beeswax bolus in situ. F. Dosimetry to 50 Gy resulting from an appositional electron beam with beeswax bolus (*arrow*) to compensate for surface obliquity. The primary tumor, facial, and level II nodes were treated with 50 Gy. This was followed by 25 Gy administered by an interstitial low-dose rate iridium needle implant at 0.55 Gy/h. G. Dummy wires are inserted into each hollow tube. Each tube has a ball anchor at the distal end of the needles, which is pushed snugly against the skin and sutured to the skin. Note the placement of transverse "moustache" needles. H and I. Orthogonal x-ray (anterior-posterior, lateral) films taken to document the placement of the needles. CT-based planning was performed. J and K. Live sources in situ.

When indicated, the right and left facial lymphatics are irradiated with appositional fields; these require an approximately 15° gantry rotation to the respective side with 6-MeV electron fields, each abutting the appositional primary lesion portal and the upper neck fields. The medial border is matched to the lateral border of the anterior primary field. The anterior border extends down from the oral commissure to the middle of the

horizontal ramus of the mandible, whereas the posterior border extends from the upper edge of the anterior field to just above the angle of the mandible. The inferior border splits the horizontal ramus of the mandible and is matched to the upper neck field. The junctions are moved twice during the course of treatment to reduce dose heterogeneity. The submandibular and subdigastric nodes are treated with lateral parallel-opposed photon fields. For patients with involved nodes, these upper neck fields are matched inferiorly to an anterior portal treating the middle and lower neck nodes.

For definitive treatment, the external beam radiation schedule for lesions up to 1.5 cm in diameter for which a combination of electrons and photons is used is typically 50 Gy in 25 fractions followed by a boost of 10 to 16 Gy in 5 to 8 fractions (prescribed at the 90% isodose line). Larger lesions to be treated by external beam radiation alone receive 50 Gy in 25 fractions plus a boost of 16 to 20 Gy in 8 to 10 fractions. The schedule for elective nodal irradiation is 50 Gy in 25 fractions. Palpable nodes are given a boost to a total dose of 66 to 70 Gy in 33 to 35 fractions, depending on the size. For postoperative treatment, the volume is reduced off the undissected nodal regions after 50 Gy (25 fractions) to deliver an additional 6 Gy to the surgical bed. At 56 Gy, a final "cone down" is done to include a 4-Gy dose to the preoperative tumor bed, for a total dose of 60 Gy. If the excision was limited or positive margins are present, the final cone-down dose is 10 Gy for a total dose of 66 Gy.

Brachytherapy. Brachytherapy for small lesions is accomplished by using a ^{192}Ir wire implant or, in selected cases, by using an intracavitary ^{192}Ir mold. Hollow needles for afterloading are inserted under general anesthesia, which allows good exposure of the tumor and protects the airway in the event of bleeding from the vascular Kiesselbach plexus on the anterior nasal septum or from posterior hemorrhages originating from larger vessels near the sphenopalatine artery, behind the middle turbinate. Implantation of a T2 SCC of the columella is shown in Figure 48.3. The recommended doses for low-dose rate brachytherapy have evolved empirically and range from 60 to 65 Gy delivered during 5 to 7 days.

Brachytherapy can be used instead of an external beam boost for patients with T1 or T2 nasal vestibule tumors after initial larger field RT. After

delivery of 50 Gy, the patient is assessed, and if the tumor volume has been substantially reduced, a boost of 20 to 25 Gy may be administered in about 2 days by using low-dose rate brachytherapy.

High-dose rate brachytherapy has also been used to deliver the boost. A custom mold of the nasal vestibule is fabricated, and tumor is marked in the mold. Two to four plastic tubes are inserted into the mold alongside the tumor at 1-cm intervals. For tumors of the lateral part of the vestibule, two catheters are placed on the inner aspect of the nasal vestibule. For medially localized tumors, catheters are placed on both sides of the vestibule. After external beam radiation to 50 Gy in 5 weeks, high-dose rate brachytherapy is delivered in week 6. The dose is typically 3 Gy per fraction, given twice a day, to a total dose of 18 Gy specifically at the center of the tumor. With a median overall treatment time (external beam radiation plus brachytherapy) of 36 days, this technique has been reported to yield 2-year local control rates of 86% and ultimate locoregional control rates of 100%.[46]

Nasal Fossa Tumors

Target Volume

The technique for primary or postoperative external beam irradiation of nasal cavity tumors depends on the depth of the neoplasm. For tumors located less than 3.5 or 4.0 cm from the skin of the apex of the nose, electrons can be used, as 20-MeV electrons will provide coverage up to 5 cm in depth. A margin of at least 1 cm deep to the posterior edge must be included in the full-dose volume. The technique is as previously described for nasal vestibule carcinoma. CT-based treatment planning is necessary for accurate target localization and dose calculation.

Intensity-modulated radiation therapy (IMRT) with either photons or protons are recommended for tumors of the nasal cavity in which the target volume is more than 5 cm deep or for tumors of the ethmoid sinus[47] (Figure 48.4). This technique delivers the desired dose to the target volume while minimizing the dose to critical organs, such as the cornea, lens, lacrimal glands, retina, optic nerve, optic chiasm, brain, and brainstem. For postoperative RT, the primary clinical target volume (CTV) descriptions are given in Table 48.3. The CTV_1 consists of the primary tumor bed with a 1.0- to 1.5-cm margin. A boost subvolume consisting of high-risk regions

(sites of positive margins, gross macroscopic residual tumor) to be treated to higher doses may be outlined. The CTV_2 includes the entire operative bed. For ethmoid sinus tumors, this might include the frontal sinus, maxillary sinus, and sphenoid sinus. The bony orbit is part of the operative bed when orbital exenteration is performed because of tumor invasion. For lesions involving the ethmoid sinuses or olfactory region, the CTV should also include the cribriform plate. A third CTV may be delineated to encompass the tract of cranial nerve V2 to the foramen rotundum if perineural invasion is present. For primary RT given as IMRT, the CTV_1, consisting of the gross tumor volume plus a margin of 1 to 2 cm, receives the full dose of 66 to 70 Gy. For patients receiving neoadjuvant chemotherapy, target volume definition is based on the extent of disease before chemotherapy.

TABLE 48.3 TARGET VOLUMES FOR INTENSITY-MODULATED RADIATION THERAPY OF SINONASAL CANCERS

Target	Description	Dose (33-35 Fractions) (Gy)
Primary Radiation Therapy		
GTV	GTV (= prechemotherapy volume)	66-70
CTV_1 (primary CTV)	GTV + 1.0-1.5 cm	66-70
CTV_2 (intermediate-dose CTV)	Primary CTV + 1.0-1.5 cm	59-63
CTV_3 (elective CTV)	Nodal volumes, nerve tract, and base of skull margin	54-57
Postoperative Radiation Therapy		
CTV_{HR} (high-risk CTV)	Sites of suspected positive margins, gross macroscopic residual tumor, extracapsular nodal disease	66-70[a]
CTV_1 (primary CTV)	Primary tumor bed with 1.0-1.5-cm margin	60
CTV_2 (intermediate-dose CTV)	Surgical bed	57
CTV_3 (low-dose CTV)	Trigeminal nerve perineural invasion is present, additional skull base margin, elective nodal volume if indicated	54

CTV, clinical target volume; GTV, gross tumor volume.

[a]70 Gy may be given by adding a second boost plan or increasing the number of fractions to 35.

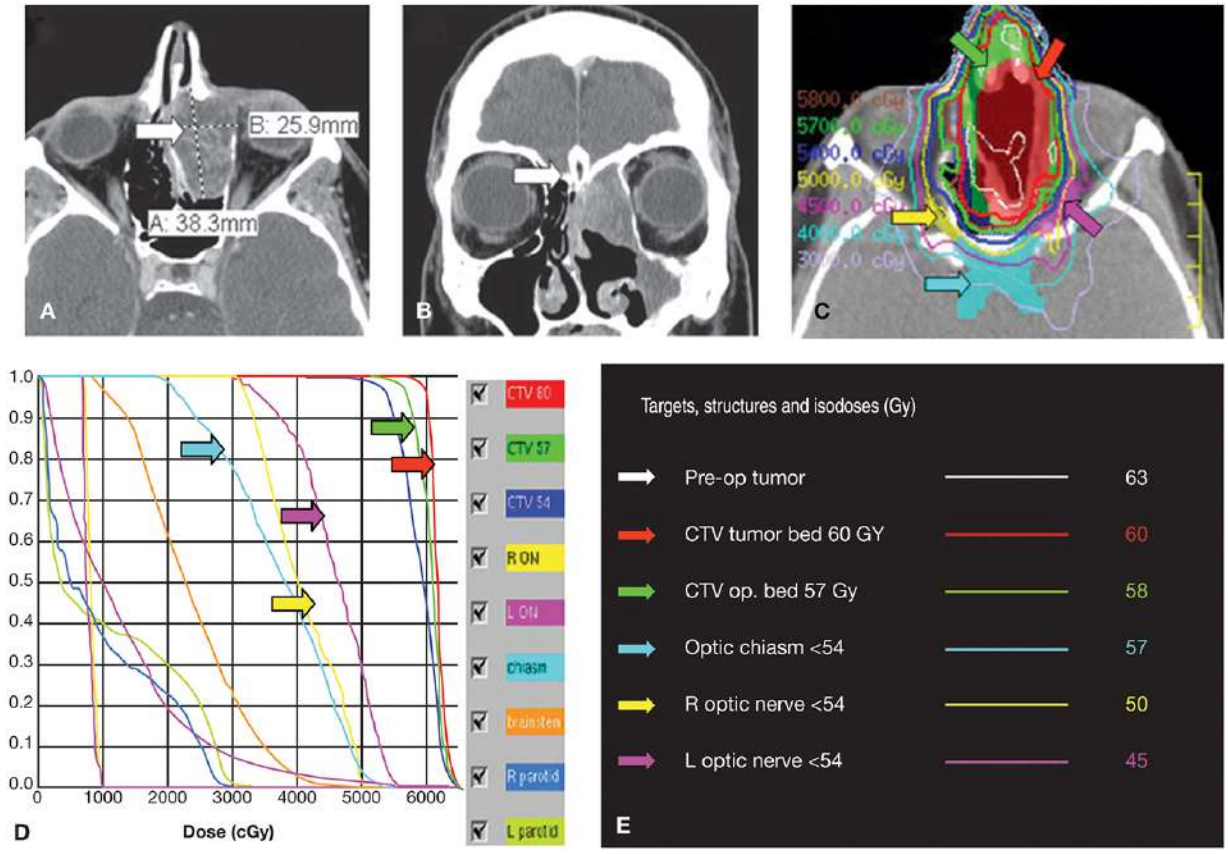

FIGURE 48.4 Intensity-modulated radiotherapy for adjuvant radiotherapy for an adenoid cystic carcinoma of the ethmoid sinus, anterior skull base, nasal cavity, and medial orbit following endoscopic anterior-posterior ethmoidectomy with resection of tumor, left maxillary antrostomy with disease removal, bilateral sphenoidotomy, and frontal sinusotomy with anterior approach to the anterior skull base including a left lateral rhinotomy and medial maxillectomy and extradural resection of anterior cranial base. A and B. Preoperative computed tomography scans with tumor indicated by *white arrow*. C. Transverse section at the level of the orbit that shows sharp dose gradient at the interface of the clinical target volume (CTV) and the optic nerves and chiasm. D and E. Cumulative dose-volume (*y*-axis) histogram.

For three-dimensional (3D) conformal RT, the initial target volume for postoperative radiation consists of the surgical bed with 1- or 2-cm margins, depending on the surgical pathology findings and the proximity of critical structures. The boost volume consists of areas at greatest risk of recurrence,

such as close or positive resection margins or regions of perineural invasion, with 1- to 2-cm margins.

For small anterior-inferior septal lesions, brachytherapy can be accomplished by using a single-plane implant of the lesion with 2 cm margins. Elective neck irradiation is not given routinely even for patients with large tumors or early-stage Kadish A or B ENB.

Setup and Field Arrangement

For target volumes less than 5 cm deep, an electron technique similar to that described for nasal vestibule carcinomas is used. Treatment devices include lead skin collimation to obtain a sharp penumbra as well as bolus material in the nasal cavity, in postoperative defects, and on skin scars. An intraoral stent is used to depress the tongue, provide a patent airway, and aid in immobilization. Tungsten internal eye shields may be used if the target volume approaches the orbits (see Figure 48.3).

For 3D conformal therapy or IMRT, the patient is immobilized in a supine position with the head positioned such that the hard palate is perpendicular to the treatment couch. Scars are marked with thin radio-opaque wires, bolus, and other devices are positioned, and transverse CT images are obtained from the vertex to the upper mediastinum. For IMRT, rigid immobilization is necessary, including the use of special head and shoulder thermoplastic masks that extend down to the upper thorax. The shoulders can be additionally depressed and fixed by using wrist straps tethered to a footboard. Target volumes are delineated as previously described.

For IMRT, multiple gantry angles are used based on beam optimization algorithms. An example of a 10-field noncoplanar arrangement with two vertex beams is shown in Figure 48.4. The beam angle selections are based on the same principles as for 3D conformal therapy:

1. Preference for the shortest path to the target
2. Avoidance of direct irradiation of the critical structures (eg, avoid beam entry through the contralateral eye after ipsilateral exenteration)
3. Use of as large a beam separation as possible

Inverse planning is usually done, and multiple iterations may be necessary to ensure that the following are accomplished:

1. Targets are covered.
2. Normal tissue constraints are respected.
3. Dose is relatively homogeneous.

Dose calculations should include heterogeneity corrections because of the significant amounts of air and bone in the sinuses. Radiation oncologists must work closely with physicists and dosimetrists. It is important to realize that the criteria for accepting or rejecting the plan may not be evident from the dose-volume histogram.

For 3D conformal RT, anterior oblique wedge-pair photon fields are appropriate for lesions located in the anterior lower half of the nasal cavity. Opposed-lateral fields can be used to treat tumors at the posterior part of the nasal fossa, provided the ethmoid cells are not involved. The optic pathway can be excluded from the radiation fields with this setup. For primaries of the upper nasal cavity and ethmoidal air cells, a three-field setup allows coverage of the ethmoid cells while sparing the optic apparatus. CT-based treatment planning is necessary to select beam and wedge angles (usually 45°-60°) and the relative loading of the fields, as well as to evaluate the dose to critical structures, such as the brain, brainstem, and optic structures.

Proton beam therapy techniques for treating nasal fossa tumors are rapidly evolving and include both passive scattering and discrete spot scanning beams. Theoretically, the advantage of proton therapy (PT) derives from the unique physical properties of protons that allow deposition of most of the particle's energy at the end of its range. Descriptions of the various techniques by which PT can be delivered are beyond the scope of this chapter. Nevertheless, with optimization of dosimetry, the conformality and heterogeneity within the target volumes provided by PT should be equivalent to what can be achieved with either electron or photon therapy, with the added advantage of minimizing the unnecessary dose or "dose bath" from IMRT to the surrounding normal tissue structures.

Greenwalt et al[48] reported on seven adult patients with primary mucosal nasal cavity,[4] ethmoid sinus, and maxillary antrum melanoma treated with external beam PT. Six patients underwent gross total resection before PT,

and one patient underwent a biopsy of unresectable disease from intracranial extension. In the postoperative setting, PT was initiated at a median of 53 days after surgery. The primary target volume was defined as the surgical bed plus a margin for microscopic disease and setup uncertainties. The median PT dose to the primary high-risk planning target volume was 74.4 Gy (relative biologic effectiveness [RBE]) (range, 69.6-74.4). Six patients were treated with elective nodal radiation to the neck to a median dose of 50 Gy (range, 48-50). None of the patients had neoadjuvant, concurrent, or adjuvant chemotherapy. Median follow-up was 1.4 years from the end of PT (range, 0.5-6.6 years). The cause-specific survival and OS rates were equivalent at 83% at 1 year and 67% at 1.5 years. Three patients died of metastatic disease, all died within 25 months of completing PT. One patient who was treated with 69.6 Gy (RBE) recurred locally at 2 months after completing PT and died of distant disease. The locoregional control rates at 1 and 1.5 years were both 86%, whereas the freedom from distant metastases rate was 71% at 1 and 1.5 years. One patient experienced grade 2 epiphora and grade 4 visual toxicity, leading to loss of useful vision in the treated eye. One patient with brain necrosis was found to have developed brain metastases requiring steroids following PT. Two patients reported grade 2 sinusitis, one patient had a grade 2 oral cavity fistula, and one patient reported grade 2 sensorineural hearing loss. No contralateral visual complications occurred.

Radiation Therapy Dose Fractionation Schedule

The dose schedule for low-dose rate brachytherapy is 60 to 65 Gy during 5 to 7 days. The external beam regimen for primary RT is 50 Gy in 25 fractions followed by a boost of 16 to 20 Gy in 8 to 10 fractions, depending on the size of the lesion. Postoperative RT consists of 50 Gy to elective tissue, 56 Gy to the operative bed, and 60 Gy to the tumor bed, with an optional boost to close or positive surgical margins, all given at 2 Gy per fraction. Dose regimens for intensity-modulated therapy, whether with photons or protons, are summarized in Table 48.3.

Tumors of the Paranasal Sinuses

Target Volume

Because maxillary cancers are usually diagnosed at a locally advanced stage and surgery is the primary therapy, most patients receive postoperative RT. Delineation of target volumes is based on physical examination, pretreatment imaging, intraoperative findings (tumor extension relative to critical structures such as orbital wall, cribriform plate, cranial nerve foramina, and ease of resection), and pathologic findings (such as positive margin or perineural invasion).

For photon-based treatment delivery, IMRT is the preferred treatment method as it generally yields better dose distribution in terms of both tumor coverage and sparing of normal tissues than can be achieved with 3D conformal RT.[47,49]

Jeong et al[50] compared in 10 patients volumetric modulated arc therapy (VMAT) and noncoplanar IMRT for nasal cavity and paranasal sinus cancer with regard to the coverage of planning target volume (PTV) and the sparing of organs at risk (OARs). Planning objectives were (a) to deliver 60 Gy in 30 fractions to 95% of PTV; (b) to ensure maximum dose (D_{max}) of optic nerves, optic chiasm, and brainstem to be less than 50 Gy, eyes to less than 40 Gy, and lenses to less than 10 Gy and the mean dose (D_{mean}) of parotid glands to less than 25 Gy; and (c) to reduce doses of OARs as much as possible without compromising coverage of PTV.

VMAT plan and each of noncoplanar IMRT (7-, 11-, and 15-beam) plans were evaluated by heterogeneity index (HI) and conformity index (CI) of the PTV, D_{max}, and D_{mean} of the OARs, treatment delivery time, and monitor units (MUs). The HI of PTV was defined as D5% to D95%/D_{mean}, where D5% and D95% are the minimum doses delivered 5% and 95% of the PTV, respectively. The CI of PTV was defined as VTV/VPTV, where VTV is the treatment volume enclosed by the prescribed 60-Gy isodose surface and VPTV is the volume of the PTV. The HI and CI of VMAT plan were better than each of 7-, 11-, 15-beam noncoplanar IMRT plans (mean HI, 0.07 vs 0.10 vs 0.09 and 0.10, $P = .004$, $P = .012$, and $P = .005$; mean CI, 1.05 vs 1.13 vs 1.10 and 1.10, $P = .002$, $P = .008$, and $P = .016$). In OAR-sparing effects, VMAT and each of noncoplanar IMRT (7-, 11-, and 15-beam) plans showed equivalent sparing effects for bilateral optic nerves, optic chiasm, brainstem, and bilateral parotid glands. For the eyes and lenses, VMAT achieved equivalent or better sparing effects when compared with each of

noncoplanar IMRT plans. For bilateral lacrimal glands, which did not apply constraint during planning, each of the noncoplanar IMRT plans showed better D_{max} and D_{mean} than VMAT. VMAT showed lower MUs and reduced treatment delivery time when compared with noncoplanar IMRT plans. The authors concluded that in the patients with nasal cavity or paranasal sinus cancer, VMAT provided better homogeneity and conformity for PTV than each of 7-, 11-, and 15-beam noncoplanar IMRT plans while achieving equal or better OAR-sparing effects and using fewer MUs and lower treatment delivery times.

PT and intensity-modulated proton therapy (IMPT)[51] may offer additional advantages over IMRT in terms of further reducing the dose to normal tissues while achieving equivalent doses to the target volume. The CTV_1 consists of the primary tumor bed with 1.0- to 1.5-cm margin of normal tissue. The CTV_2 encompasses the operative bed, including the bony orbit after orbital exenteration and the ethmoid, frontal, or sphenoid sinuses if explored during surgery. A third CTV may be delineated to encompass the tract of cranial nerve V2 to the foramen rotundum if perineural invasion is present. A CTV for high-risk areas (CTV_{HR}; see Table 48.3) may also be outlined to cover, for example, gross macroscopic residual tumor or positive margins to which a higher dose may be delivered.

Radiation Therapy Dose Prescriptions

For primary RT using IMRT, VMAT, or IMPT, the prescription doses are 66 to 70 Gy to the gross tumor volume (the prechemotherapy volume for those receiving systemic treatment), plus a 1- to 1.5-cm margin of normal-appearing tissue (CTV_1), 59 to 63 Gy to other secondary CTVs such as the rest of the involved sinus and wider region around the primary target, and 54 to 57 Gy to the tracts of nerves (if perineural invasion is present) and to elective nodal regions. An example of an IMRT plan for primary definitive RT of a T4N0 SCC is shown in Figure 48.5.

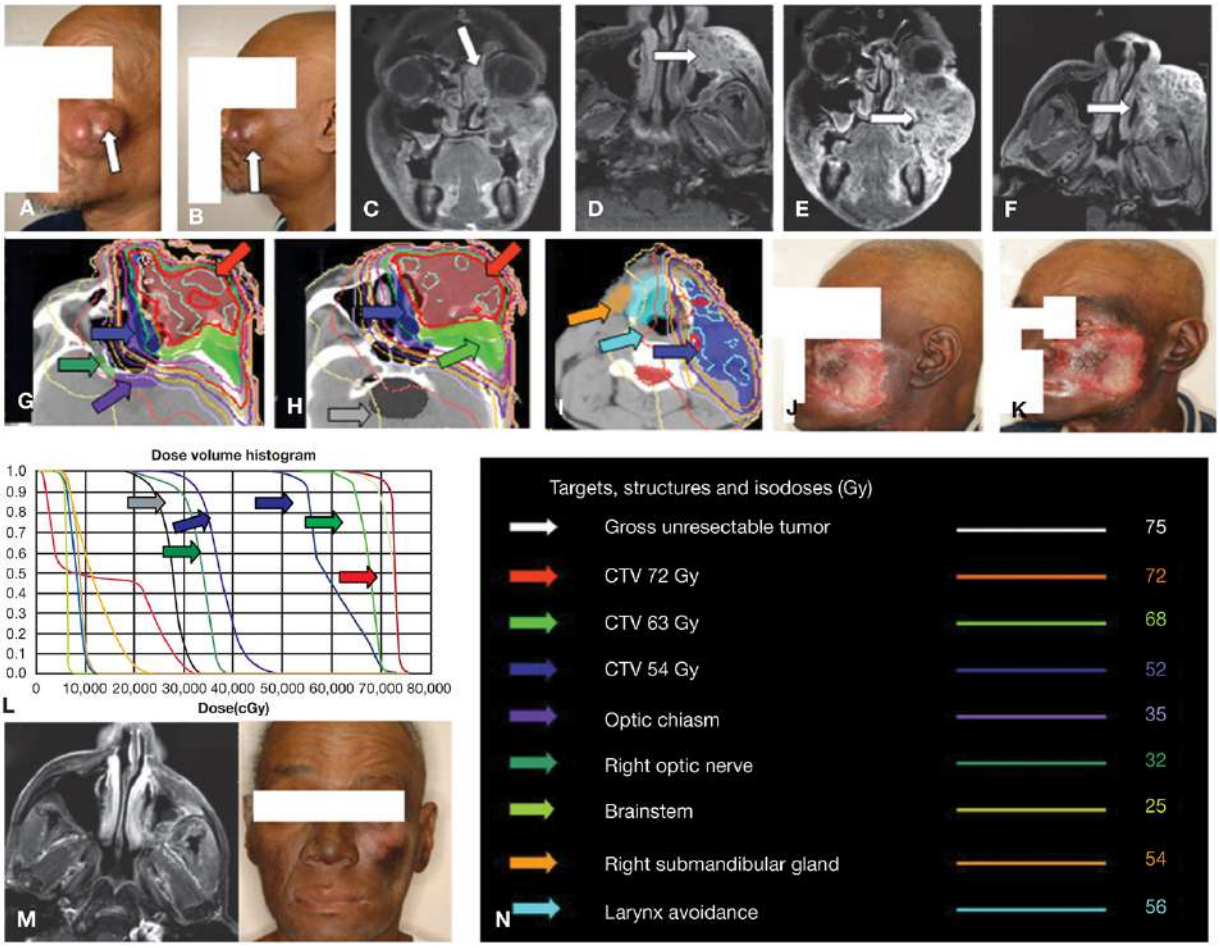

FIGURE 48.5 Intensity-modulated radiotherapy (IMRT) for definitive radiotherapy for T4N0 squamous cell carcinoma of the maxillary sinus. A and B. Pretreatment photographs showing the skin of cheek involvement. C and D. Magnetic resonance imaging (MRI) scans with tumor indicated by *white arrow*. E and F. MRIs following induction chemotherapy showed progressive disease involving the left maxilla, left nasoethmoid region, extending inferiorly into the premaxillary soft tissues. G-I. IMRT plan with sections showing coverage of the target volumes. The patient was treated using concomitant boost fractionation. The primary plan delivered 57 Gy and a concomitant boost plan administered an additional 15 Gy. G and H also show avoidance of the normal tissues, as listed in the key and illustrated further in the cumulative dose-volume histogram in (L). J and K. The skin reaction during the final week of radiotherapy. M and N. MRI and patient photo at follow-up, showing healed skin with hyperpigmentation. The tumor was in complete remission at the last visit 7 months after therapy. CTV, clinical target volume.

For postoperative RT using a 3D conformal technique, the initial target volume consists of the operative bed with 1- to 2-cm margins. The boost field consists of the primary tumor bed and areas at higher risk of recurrence, such as positive resection margins or perineural invasion.

Radiation is administered to the neck after node dissection if multiple nodes are involved or extracapsular extension is present. Elective radiation of ipsilateral submandibular and subdigastric nodes is given for patients with SCC or poorly differentiated carcinoma. An example of an intensity-modulated proton plan for postoperative RT is shown in Figure 48.6.

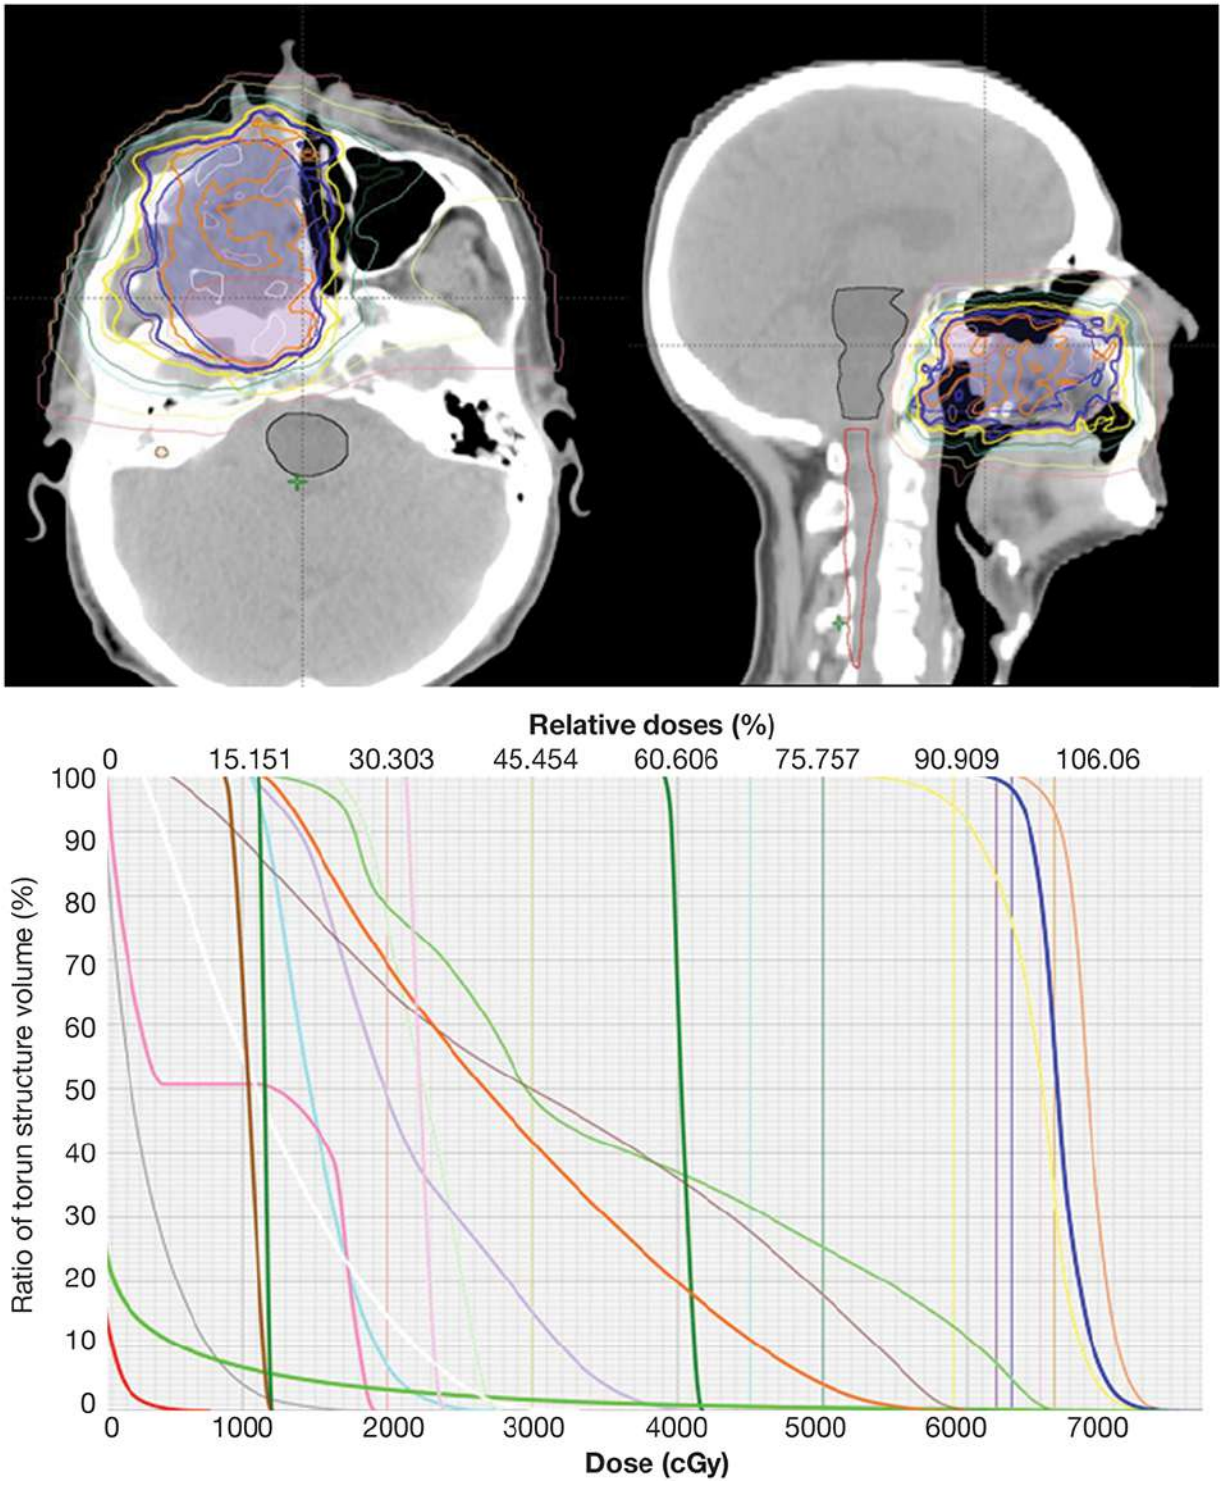

FIGURE 48.6 Proton therapy for recurrent adenoid cystic carcinoma (ACC) of the right hard palate. The patient had a palatectomy with radial forearm free flap reconstruction followed by postoperative external beam radiation therapy with intensity-modulated radiation therapy to 60 Gy in 30 fractions. One year later, the ACC recurred with enhancement in right V1 and V2, involvement of the right cavernous sinus, and an enhancing mass in the infratemporal fossa and pterygopalatine fossa. Salvage surgery involved a right total maxillectomy with

orbital preservation, pterygomaxillary space dissection and resection, and an extracranial dissection of Vidian nerve and cranial nerve 5, V2. With evidence of skull base and cavernous sinus involvement after surgery, he was treated with postoperative chemoradiation with intensity-modulated proton therapy (IMPT) and cisplatin to a dose of 66 Gy (RBE) in 33 fractions. No evidence of disease was present at 6 months after salvage therapy. The figure represents the axial, sagittal, and dose-volume histogram (DVH) of the IMPT plan. (DVH for the IMPT plan, from *left* to *right* on the graph: *red*, spinal cord; *green*, whole brain; *black*, brainstem; *pink*, left parotid; *white*, left eye; *brown*, right cochlea; *dark green*, left lens; *sky blue*, right parotid; *brown*, oral cavity; *violet*, optic chiasm; *red*, right eye; *green*, mandible; *light green*, left optic nerve; *soft pink*, right lens; *dark green*, right optic nerve; *yellow*, clinical target volume [CTV] or CTV_3; *blue*, CTV_2; *orange*, CTV_1.)

Setup and Field Arrangement

Patients undergoing treatment of paranasal tumors are immobilized in a supine position with the head slightly hyperextended to bring the floor of the orbit parallel to the axis of the anterior field. An intraoral stent is used to open the mouth and depress the tongue out of the radiation field. After palatectomy, the stent can be designed to hold a water-filled balloon to obliterate the large air cavity in the surgical defect to improve dose homogeneity. An orbital exenteration defect can also be filled directly with a water-filled balloon to decrease the dose delivered to the temporal lobe. Marking of the lateral canthi, oral commissures, external auditory canals, and external scars facilitates target volume delineation. The planning CT scan should include the entire head to allow the use of vertex beams. The principles of target delineation and plan evaluation for IMRT of maxillary sinus cancer are the same as those described for nasal cavity and ethmoid tumors.

For 3D conformal radiation, a three-field technique consisting of anterior and right and left lateral fields is used for tumors involving the suprastructure or extending to the roof of the nasal cavity and ethmoid cells. The lateral fields may have a 5° posterior tilt and 60° wedges. The relative loading varies from 1:0.15:0.15 to 1:0.07:0.07 depending on the tumor location and photon energy. For the initial target volume, the superior border of the anterior portal is above the crista galli to encompass the ethmoids and, in the absence of orbital invasion, at the lower edge of the cornea to cover the orbital floor. The inferior border is 1 cm below the floor of the sinus, and the medial border is 1 to 2 cm (or more if necessary) across the midline to cover contralateral ethmoidal extension. The lateral

border is 1 cm beyond the apex of the sinus or falling off the skin. The superior border of the lateral portals follows the floor of the anterior cranial fossa, the anterior border is behind the lateral bony canthus parallel to the slope of the face, the posterior border covers the pterygoid plates, and the inferior border corresponds to that of the anterior portal. The boost volume encompasses the tumor bed while sparing the optic pathway.

Anterior and ipsilateral wedge-pair (usually 45° wedges) photon fields are used for tumors of the infrastructure with no extension into the orbit or ethmoids. If necessary, the lateral portal can have a 5° inferior tilt to avoid beam divergence into the contralateral eye. Lateral-opposed photon fields are preferred for tumors of the infrastructure spreading across the midline through the hard palate. If necessary, the fields can be slightly angled (5° inferior tilt from the ipsilateral side and 5° superior tilt from the contralateral side) to avoid irradiating the contralateral eye. The use of a half beam with the isocenter placed at the level of the orbital floor and the upper half of the fields shielded further reduces exposure of the eyes by beam divergence.

The eyes and the optic pathway are of particular concern. With 3D conformal/IMRT/VMAT/IMPT techniques, the cornea can generally be shielded or a planned avoidance structure (to avoid keratitis) in patients with limited involvement of the medial or inferior orbital wall. If the tumor invades the orbital cavity without necessitating orbital exenteration, care should be taken to avoid irradiating the lacrimal gland to prevent xerophthalmia. It is important to keep the dose to the contralateral optic nerve as well as the optic chiasm below 54 Gy in 27 fractions to prevent bilateral blindness.

Treatment of the Neck

For squamous and undifferentiated carcinoma, elective neck irradiation is recommended. Ipsilateral upper neck treatment can be delivered using a lateral appositional electron field (usually 12 MeV). With conventional radiation techniques, careful matching is required to prevent hot or cold spots. The superior border of the field slopes up from the horizontal ramus of the mandible anteriorly to match the inferior border of the primary portal posteriorly, leaving a small triangle over the cheek untreated. The anterior

border is just behind the oral commissure, the posterior border is at the mastoid process, and the inferior border is at the thyroid notch (above the arytenoids). The nodal volume can also be covered by using IMRT with sparing of the parotid gland. Alternatively, the primary tumor bed and the upper neck can be treated with IMRT with the isocenter above the arytenoids and matched to a separate unmodulated lower neck field. This allows the laryngeal structures to be spared by using a larynx block.

If the maxillary sinus is being treated with conventional non-IMRT techniques, the central axes of the primary (sinus) fields and the opposed lateral upper neck fields all are placed in the plane of the inferior border of the maxillary fields (ie, usually 1 cm below the floor of the maxillary sinus). An independent collimator jaw is used to shield the caudal half of the maxillary fields and the cephalad half of the neck field. The junction between the primary and the neck fields can be moved during the course of treatment to reduce dose heterogeneity in this region. Portals are reduced after 42 Gy, and treatment to the posterior neck continues with abutting electron fields to the desired dose. The middle and lower neck are irradiated with an anterior appositional photon field matched to the inferior border of the opposed-lateral upper neck fields.

Dose Fractionation Schedule

Table 48.3 summarizes the dose regimens for IMRT/IMPT. With 3D conformal techniques, the dose for postoperative RT at 2 Gy per fraction is 50 Gy for elective nodal treatment, 56 Gy to the operative bed, 60 Gy to the tumor bed if resection margins are negative, and 66 Gy if margins are positive. For primary RT, the total dose to the primary tumor at 2 Gy per fraction is 66 to 70 Gy. The contralateral optic nerve and chiasm are excluded from the field after a dose of 50 to 54 Gy. When the tumor invades structures adjacent to the optic chiasm, a dose of up to 60 Gy to the chiasm may be acceptable because of the higher probability of control and the relatively low risk of visual impairment,[37] after clear discussion with the patient.

FOLLOW-UP AND RECURRENCES

Salvage is possible for some persistent or recurrent lesions. In particular, recurrent cancers of the nasal vestibule remain curable with salvage surgery after primary radiation or occasionally with salvage radiation after primary surgery. Regional recurrences can be treated successfully with neck dissection with or without postoperative radiation depending on the pathologic features. Treatment options are limited for tumors that recur after combined modality therapy, although a few highly selected patients may qualify for reirradiation with curative intent. Cumulative doses of radiation to neural tissues (spinal cord, brainstem, brain, optic structures) are the main limitation to reirradiation.

Most oncologists recommend a second baseline physical examination together with CT, MRI, or positron emission tomography with CT for patients with nasal cavity or paranasal sinus tumors at 3 months after treatment. Common practice is to repeat clinical examination and imaging when indicated every 4 months for the first 3 years after treatment, every 6 months for the fourth and fifth years after treatment, and annually thereafter. In addition to monitoring possible tumor recurrence, these follow-up visits are critical for identifying and managing side effects of treatment.

RESULTS OF TREATMENT

The results of treatment have improved from the 1960s through the 1990s, with OS rates increasing progressively from 33% ± 18% in the 1960s to 42% ± 15% in the 1970s, 54% ± 15% in the 1980s, and 56% ± 13% in the 1990s ($P < .001$).[52] In a systematic review of published series spanning 40 years, Dulguerov et al[53] demonstrated progressive improvements in outcome for all treatment modalities (surgery, surgery with radiation, and radiation). However, a more recent review of the experience at the University of California, San Francisco, showed no significant differences in 5-year OS rates or local control rates by a decade of treatment (1960s-2000s; OS, 46%-56%; local control 55%-62%) or by radiation technique (conventional, 3D conformal, or IMRT; OS 47%-57%; local control 59%-65%). However, the incidence of severe (grade 3 or 4) side effects declined significantly over time from 50% in the 1960s to 16% in the 2000s.[54]

For patients with SNUC, multimodality approach to treatment is necessary to achieve optimal disease-specific survival (DSS) and OS (Figure 48.7). IC response is used as a guide for treatment optimization at the UT MD Anderson Cancer Center. For patients with PR or CR to IC, 5-year DSS was 81% with chemoradiation therapy and 54% after surgery and postoperative radiation or chemoradiation. For patients not achieving a PR with IC, 5-year DSS was 39% in patients treated with surgery plus radiation or chemoradiation and 0% in patients treated with chemoradiation alone.[39]

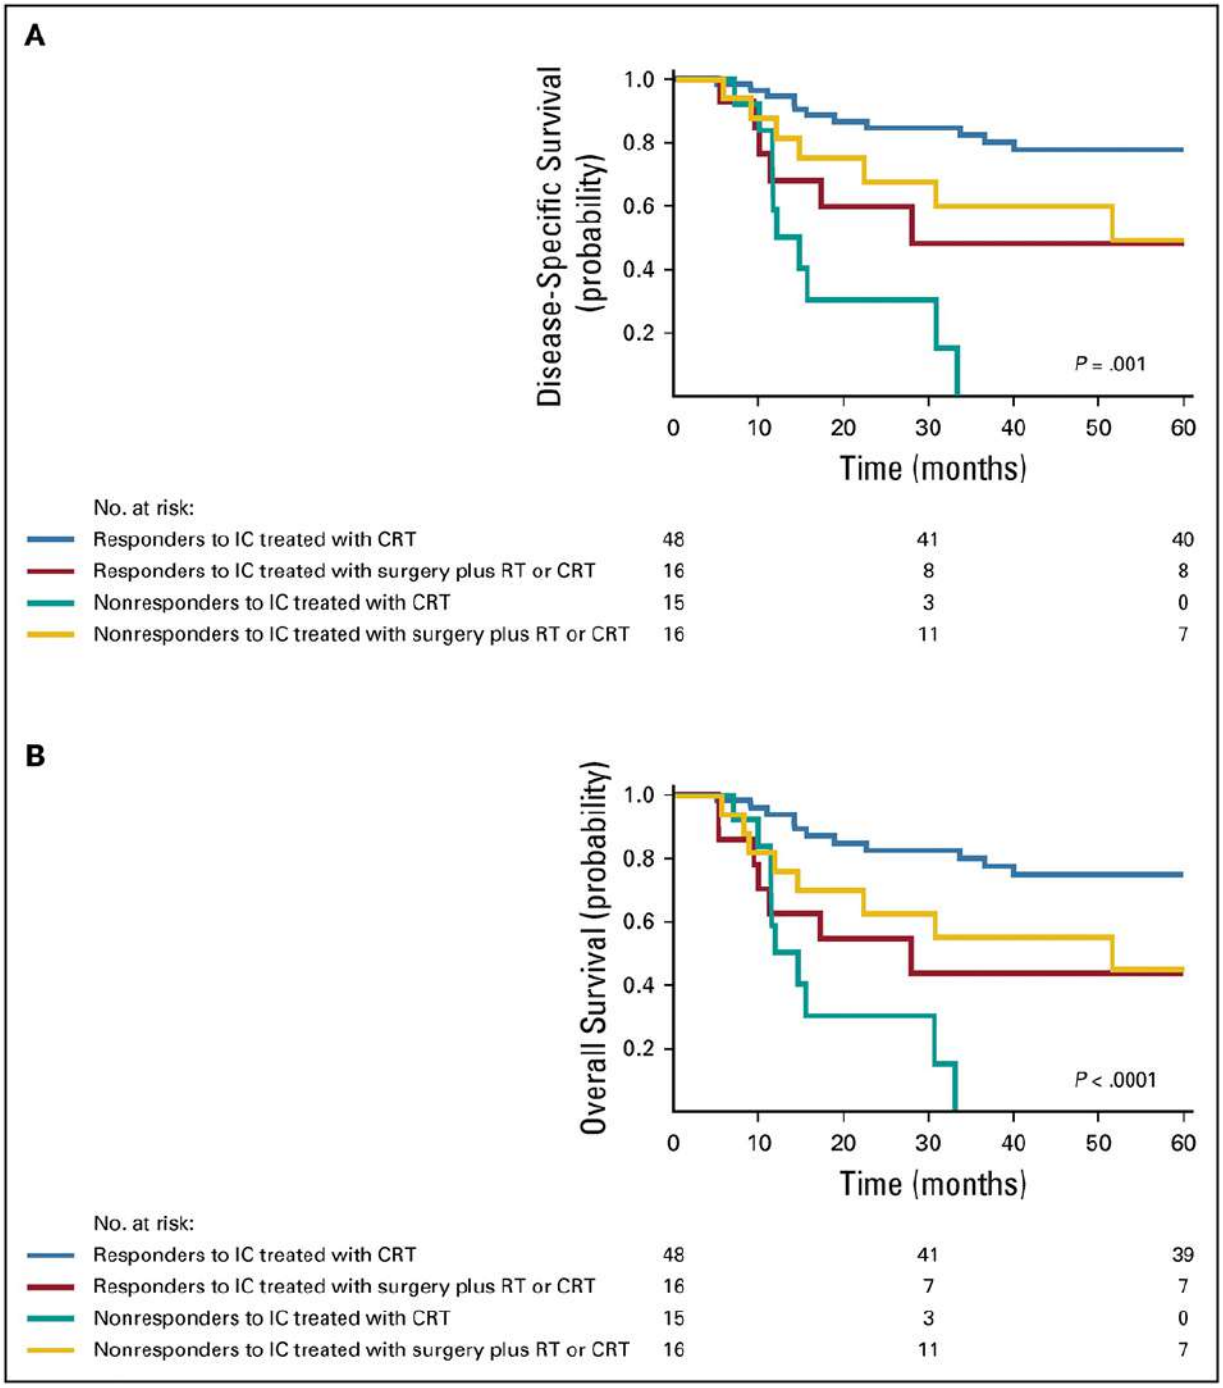

FIGURE 48.7 Survival outcomes according to definitive locoregional treatment by response to induction chemotherapy (IC). Disease-specific (A) and overall (B) survival in patients who responded to IC and were treated subsequently with concurrent chemoradiation therapy (CRT; blue) or surgery followed by radiotherapy (RT) or concurrent CRT (red), and in patients who did not respond to IC and were treated subsequently with concurrent CRT (green) and surgery followed by RT or concurrent CRT (orange). Tumors of the Nasal Cavity

Nasal Vestibule Tumors

Findings from several retrospective studies of RT for nasal vestibule tumors suggest that either brachytherapy or external beam RT can produce cure rates of up to 90% for small (<2 cm) lesions (Table 48.4).[2,3,17,18,55-64] For 2- to 4-cm lesions, external beam radiation can control 70% to 80% of tumors. Although nodal spread of disease is relatively rare for lesions smaller than 2 cm, up to 40% of patients with larger primary tumors have metastases to the cervical nodes at presentation. With the use of appropriate radiation techniques and fractionation schedules, severe and late complications after RT are uncommon (see Table 48.4).

TABLE 48.4 LOCAL AND REGIONAL CONTROL RATES OF NASAL VESTIBULE CARCINOMAS TREATED BY DEFINITIVE RADIOTHERAPY

Series	Patients	Local Control	Regional Control	Comments/Complications
MD Anderson 1967-1984[56]	32	BT: 11/11 controlled	Small lesions, no ENI: 11/11	Osteonecrosis, epistaxis: 1 patient each

Series	Patients	Local Control	Regional Control	Comments/Complications
French Groupe Europeen de Curietherapie[2]	1676	Skin of the nose and nasal vestibule carcinoma treated by BT or EB (ortho- or megavoltage) Overall LC = 93% (FU ≥2 y); <2 cm, 96%; 2-3.9 cm, 88%; ≥4 cm, 81% LC of nose skin: 94% LC of vestibule: 75% LC for previously untreated tumors: 95% vs 88% for recurrent tumors		
Daniel den Hoed Cancer Center, Rotterdam[59]	64	Local relapse-free survival: 92% at 5 y T1: 89% T2: 100%		Not reported

BT, brachytherapy; EB, external beam; ENI, elective nodal irradiation; FU, follow-up; IDR, intermediate-dose rate; LC, local control; RT, radiotherapy.

An analysis by the Groupe Europeen de Curietherapie of 1,676 carcinomas of the skin of the nose and nasal vestibule treated by brachytherapy or external beam irradiation revealed an overall local control rate of 93%.[3] Local control depended on tumor size (<2 cm, 96%; 2-3.9 cm, 88%; ≥4 cm, 81%), tumor site (external surface, 94%; vestibule, 75%), and status (new, 95%; recurrent, 88%). Local control was independent of histology for tumors <4 cm, but for those >4 cm, basal cell carcinomas

were more often controlled than were SCCs. Complications were rare (necrosis, 2%). The local control rate with surgery was approximately 90%.

Nasal Fossa Tumors

Documentation of treatment outcomes for nasal fossa tumors, like nasal vestibule tumors, comes mostly from retrospective studies.[19,65,66] Results are best for lesions confined to the nasal septum, which are generally small and well controlled with primary RT. Locoregional control rates range from 60% to 85%, and the rate of isolated regional recurrence for patients who did not receive elective nodal irradiation is approximately 5%. The most common complications after RT are soft tissue necrosis, visual impairment, and nasal stenosis, seen in 5% to 11% of patients (Table 48.5).[19,63-65] Ang et al[19] at MD Anderson Cancer Center reported better primary disease control and survival rates for patients with tumors located in the septum (86%) versus patients with tumors on the lateral wall or floor of the nasal fossa (68%). In that study, no patients with nasal septum carcinomas who underwent elective nodal irradiation had nodal relapses, whereas two of eight patients who did not undergo nodal irradiation experienced recurrence in the ipsilateral subdigastric nodes. Distant metastasis was more common among patients with lateral wall and floor disease, and ultimately, survival rates were best among patients with nasal septum tumors. However, other groups[65] found no differences in results for tumors at various sites within the nasal cavity. Results of the treatment for early-stage tumors are excellent after either RT or surgery.

TABLE 48.5 TREATMENT OUTCOMES FOR NASAL FOSSA TUMORS

Series	Patients	Treatments	Survival Rates at 5 Y	Late Complications
MD Anderson 1969-1985[19]	45	RT alone: 18 patients RT+ surgery: 2 patients Surgery + RT: 25 patients Median time to relapse: 9 mo	Overall: 75% Disease specific: 83%	Radiation-induced blindness: 2 patients Surgical blindness: 2 patients Maxilla necrosis: 3 patients Nasal stenosis: 2 patients

Series	Patients	Treatments	Survival Rates at 5 Y	Late Complications
				Septal perforation: 1 patient Severe dental decay: 1 patient
Roswell Memorial Park Institute 1942-1964[63]	57	RT alone: 30 patients Surgery alone: 13 patients Surgery + RT: 14 patients	Crude overall: 56% Disease free: 56%	Not reported
University of Puerto Rico 1976[64]	40	RT alone: 34 patients Surgery alone: 6 patients	Overall: 56%	Not reported
Mallinckrodt Institute of Radiology 1969-1984[65]	56	RT alone: 28 patients RT + surgery: 18 patients Surgery + RT: 10 patients	Overall: 52%	Soft tissue necrosis: 2 patients Cataract: 1 patient Nasal synechiae: 1 patient Severe otitis media: 2 patients Hemorrhage (fatal): 2 patients Optic neuropathy: 1 patient Brain necrosis: 1 patient

RT, radiation therapy.

An analysis of 783 patients with nasal cavity cancer included in the SEER database from 1988 through 1998[66] revealed SCC to be the most common tumor type (49.3%), followed by ENB (13.2%). More than half of the cases presented with a small primary tumor (T1), and only 5% had positive nodes at diagnosis. Overall mean survival time was 57 months, and the 5-year survival rate was 40.3%. On multivariate analysis, male sex, increasing age, T status, N status, and poorer tumor grade all adversely affected survival ($P < .05$). RT, given to 50.5% of patients, also independently predicted poorer survival ($P = .03$), probably because those patients had had poor prognostic features, such as perineural invasion,

positive margins, or poor performance status (medically unfit for surgery).[66] Five-year survival rates also correlated with the extent of tumor dedifferentiation, being 75.3%, 61.9%, 47.6%, and 36.8% for well-, moderately, poorly, and undifferentiated cancers, respectively.

Esthesioneuroblastoma

Either surgery or primary RT as single-modality therapy can produce locoregional control rates exceeding 90% for tumors that are confined to the nasal cavity (Kadish stage A).[9] Single-modality therapy has also been used for lesions involving the nasal cavity and one or more paranasal sinuses (stage B), as has surgery followed by adjuvant RT. However, the optimal therapy for stage B lesions is not clear because of the heterogeneity of these tumors. Disease that extends beyond the nasal cavity and paranasal sinuses (stage C) seems to be best treated with a combination of surgery and radiation, and the role of chemotherapy, if any, is being investigated. Elective nodal irradiation is not generally recommended because the incidence of nodal relapse is less than 15%. Distant metastasis is uncommon (10%) even among patients presenting with locally advanced disease. Among 783 nasal cavity cancers identified from the SEER database, 103 (13.2%) were ENBs; the median survival time for patients with these tumors was 88 months, and the overall 5-year survival rate was 63.6%.[66] Tables 48.6[67-72] and 48.7[10] summarize the results of treatment. The prognosis for patients with stage A disease is excellent. Overall, 30% of patients with stage B tumors died of the disease. About 60% of patients with stage C tumors died of the disease, primarily because of failure to control the primary tumor. As noted earlier, distant metastasis is uncommon (10%) even in locoregionally advanced disease.

RT, radiotherapy; S, surgery.
Data from Elkon D, Hightower SI, Lim ML, Cantrell RW, Constable WC. Esthesioneuroblastoma. *Cancer*. 1979;44(3):1087-1094.

Spaulding et al[29] reported results for 25 patients treated at the University of Virginia Medical Center from 1959 through 1986 who were followed for 2 years after therapy. Treatment approaches had gradually evolved during that period, with progressive introduction of craniofacial resections, complex field megavoltage radiation, and, for stage C disease, the addition of chemotherapy. Therefore, patients were assigned to two groups, based on treatment era, for comparative analysis. Although this series is relatively small, it revealed two interesting findings on this rare disease: First, that extensive craniofacial resection does not seem to confer a major advantage over wide local excision for patients with stage B lesions, and second, that the addition of chemotherapy to craniofacial resection and RT for patients with stage C tumors may yield higher DSS rates.

A larger series of 72 patients with sinonasal neuroendocrine tumors treated at MD Anderson Cancer Center between 1982 and 2002[67] included a spectrum of histologies: ENB (31 patients), SNUC (16 patients), neuroendocrine carcinoma (18 patients), and small cell carcinoma (7 patients). The OS rates at 5 years were 93.1% for patients with ENB, 62.5% for those with SNUC, 64.2% for neuroendocrine carcinoma, and 28.6% for small cell carcinoma (P = .0029; log-rank test). The local control rates at 5 years also were superior for patients with ENB (96.2%) compared with patients who had SNUC (78.6%), neuroendocrine carcinoma (72.6%), or small cell carcinoma (66.7%) (P = .04). The corresponding regional failure rates at 5 years were 8.7% for patients with ENB, 15.6% for SNUC, 12.9%

for neuroendocrine carcinoma, and 44.4% for small cell carcinoma, and distant metastasis rates were 0% for ENB, 25.4% for SNUC, 14.1% for neuroendocrine carcinoma, and 75.0% for small cell carcinoma. Moreover, local therapy alone produced excellent local and distant control rates for ENB. Among eight patients treated for ENB since 2000 with surgery and adjuvant IMRT to 60 Gy (one with stage B disease and seven with stage C [five of whom had intracranial extension]), there were no local recurrences, and one nodal recurrence was salvaged surgically. All eight patients were alive with no evidence of disease at the last follow-up. Institutional experience outcomes from several institutions are reported in Table 48.6.[67-72]

Ozsahin et al[24] described the results of treatment in 13 European and North American centers for 77 patients with olfactory neuroblastomas, 11 with Kadish stage A, 29 with stage B, and 37 with stage C; 56 patients had surgery, 44 with total tumor excision. All but 5 patients received RT (50% with 3D CRT) and 21 had chemotherapy. With a median follow-up of 72 months, locoregional tumor control was 62%, disease-free survival 57%, and OS 64%. Patients having total tumor resection or receiving greater than 54 Gy had better OS than those treated with lower doses. Six of the patients treated with RT (56-70 Gy) developed grade 3 or 4 late complications (five osteonecrosis and one retinopathy).

Madani et al[73] published a report on 84 patients (73 with primary and 11 with local recurrent sinonasal tumors), 9 of which were ENB, treated with IMRT (median dose of 70 Gy in 35 fractions). Mean D50 to the optic chiasm was 37.2 Gy, to ipsilateral optic nerve 49.4 Gy, to contralateral optic nerve 47.1 Gy, and to the retina 37.7 and 28.4 Gy.

Multimodality management has been correlated with improved outcomes.[74]

Modesto et al[75] described their experience in 43 patients with ENB, two groups, one of 26 and the other of 17 patients treated at separate institutions. Five patients had stage A at diagnosis (confined to the nasal cavity), 13 stage B (tumor extending into the paranasal sinuses), 16 stage C (beyond the paranasal sinuses), and 9 stage D (cervical lymph node involvement) according to the modified Kadish classification. Neoadjuvant platinum-based chemotherapy was administered to 24 patients, leading to a 70.8% response rate (6 CR and 11 PR). A total of 31 (72%) patients were treated by surgery; 39 (90.6%) underwent RT. Among them, 11 (28.2%)

patients were treated using IMRT. Median dose was 64 Gy (range 30-70 Gy). Twelve patients (28%) received bilateral cervical lymph node irradiation (LNI) (median dose 57 Gy, range 50-66 Gy). Twelve patients (21%) received platinum-based CRT. After a median follow-up of 77 months, the 5-year OS was 65% and the 5-year progression-free survival was 58%.Twelve patients (28%) developed locoregional relapse. The major prognostic factor was the modified Kadish stage with 3-year survival rates of 100% for Kadish A to B versus 48% for stage C and 22% for stage D. After adjustment for tumor stage, neither neoadjuvant chemotherapy nor LNI seemed predictive for locoregional tumor control or survival. Protons have been used sparingly in the treatment of some of these patients. Nakamura et al[76] reported on 42 patients with ENB treated with PT and 26% receiving chemotherapy. With a median follow-up time of 69 months, the 5-year OS and progression-free survival were 100% and 80% for Kadish A, 86% and 65% for Kadish B, and 76% and 39% for Kadish C, respectively. Dagan et al[77] reported on 84 adult patients without metastases receiving primary (13%) or adjuvant (87%) treatment with PT for sinonasal cancers, of which 23%[20] were olfactory neuroblastomas. Advanced stage (T3 in 25% and T4 in 69%) and high-grade histology (51%) were common. Surgical procedures included endoscopic resection alone (45%), endoscopic resection with craniotomy (12%), or open resection (30%). Gross residual disease was present in 26% of patients. Most patients received hyperfractionated PT (1.2-Gy RBE twice daily, 99%) and chemotherapy (75%). The median PT dose was 73.8 Gy (RBE), with 85% of patients receiving more than 70 Gy. The median follow-up was 2.4 years for all patients and 2.7 years for living patients. Local tumor control (LC), neck control, freedom from distant metastasis, disease- free survival, cause-specific survival, and OS rates were 83%, 94%, 73%, 63%, 70%, and 68%, respectively, at 3 years. The 3-year LC rate was 61% for primary RT and 59% for patients with gross disease. Late toxicity occurred in 24% of patients (with grade 3 or higher unilateral vision loss in 2%). Akimoto et al[78] reported on 339 patients with non–squamous cell cancer in the head and neck, of which 63 were olfactory neuroblastomas, treated with protons. The median follow-up was 64 months. OS, progression-free survival, and local control rate of all patients at 5 years were 61.2%, 36.8%, and 71.2%, respectively, and OS and local control rate were 86.2% and 79.0% in

olfactory neuroblastomas. Among all patients, 254 (75%) were not suited for photon RT because doses to OARs exceeded tolerance dose in the evaluation of dose-volume histogram. However, OS at 5 years of these patients was 65.5%. Regarding treatment morbidity, 34 (10%) patients developed grade 3 or 4 late toxicities, such as brain injuries and neuropathy. None experienced grade 5 toxicities.

Tumors of the Paranasal Sinuses

Five-year outcomes from studies reported since 1998 continue to illustrate that local control after treatment of paranasal sinus tumors remains problematic[79-86] (Table 48.8). For patients with carcinoma of the maxillary sinuses, the combination of surgery and radiation yields 5-year local control and survival rates ranging from 44% to 80%. These rates are better than those achieved with either surgery or RT alone. For RT alone, the 5-year local control rates range from 22% to 39%, and the 5-year OS rates from 22% to 40%. Findings from a large multicenter retrospective analysis of 418 patients with ethmoid sinus adenocarcinoma indicated that the size of the lesion (T4), the extent of nodal involvement (N+), and the presence of brain extension were the most significant prognostic factors for OS.[87] Although the authors concluded that surgery followed by postoperative RT remains the treatment of choice, they did note that 51% of the patients developed recurrences, 74% of which were local.

C. Side Effects of Combined Surgery and Radiation Therapy in Patients with Paranasal Sinus Cancer					
Vestibulocochlear			Vestibular dysfunction, persistent otitis, tinnitus, hearing impairment		
Ophthalmologic (lacrimal gland, eyes, lens, optic nerves, and chiasm)			Retinopathy, xerophthalmia, keratopathy, cataracts, visual impairment		
Neurologic (brain, brainstem, spinal cord, temporal lobe)			Neurocognitive impairment, cranial neuropathy, myelopathy, brain necrosis		
Endocrine (pituitary gland, hypothalamus, thyroid gland if neck is irradiated)			Multiple endocrine dysfunction: hyperprolactinemia, syndromes associated		

Study (Reference)	Year	Patients	5-Y Survival (%)	Local Recurrence (%)	Distant Metastasis (%)
			with decreased GH, FSH, LH, T4, TSH, ACTH, and their downstream hormones		
Oral (major salivary glands, oral mucosa, mandible, and temporomandibular joint)			Xerostomia, dental caries, dysgeusia, mandible exposure, necrosis, and trismus		
Connective tissue complications (oral cavity, soft palate musculature, pharynx, larynx, skin and subcutaneous tissues, skull bones)			Soft tissue necrosis, skin changes, persistent lymphedema, subcutaneous fibrosis, cartilage necrosis, nasal dryness, choanal stenosis, swallowing and voice dysfunction, bone necrosis		

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; OS, overall survival; TSH, thyroid-stimulating hormone.

[a]Patients with node-negative disease.

[b]Five-year relapse-free survival.

[c]Patients treated at MD Anderson Cancer Center with intensity-modulated radiation therapy.

A 1991 review of outcomes after treatment of 73 patients with maxillary sinus carcinomas at MD Anderson Cancer Center reported 5-year local and regional control rates according to pathologic T category as follows: for T1 and T2 tumors, 91% local and 71% regional control; for T3, 77% local and 80% regional; and for T4, 65% local and 93% regional.[31] Five-year regional control rates according to N category were 84% for N0 disease and 82% for N1 or N2 disease. The most common histologic subtypes were SCC (48%) and adenoid cystic carcinoma (27%); 5-year local and regional control rates were 62% (local) and 86% (regional) for squamous cell tumors and 82% (local) and 94% (regional) for adenoid tumors. Perineural invasion and nodal disease at presentation were poor prognostic factors. An update of this report published in 2007[79] showed that increasing the radiation portals to cover the skull base for patients with perineural invasion reduced the risk of local recurrence and that adding elective nodal irradiation for patients with squamous or undifferentiated tumors improved the rates of nodal control, distant metastasis, and recurrence-free survival.

The extent of neuroendocrine differentiation of sinonasal carcinomas also influences the patterns of failure. In one study, the 5-year actuarial rates of local, regional, and distant failure according to tumor histology were as

follows: ENB 4% local failure, 9% regional failure, and 0% distant failure; neuroendocrine carcinoma 27% local, 13% regional, and 12% distant; SNUC 21% local, 16% regional, and 25% distant; and small cell carcinoma 33% local failure, 44% regional failure, and 75% distant failure.[67]

IMRT has emerged as the standard of care for tumors of the paranasal sinuses with low toxicity and high local control rates.[47,73,88-91] Madani et al[73] reported the largest series to date, in which 105 patients (most of whom [56%] had ethmoid sinus tumors) were treated with IMRT. At a median follow-up time of 40 months, the 5-year actuarial local control and OS rates were 70.7% and 58.5%, respectively. In multivariate analysis, invasion of the cribriform plate was found to predict worse local control ($P < .001$) and lower OS ($P < .001$).

The role of PT using passive scattering and IMPT in the management of sinonasal malignancies is rapidly evolving and may be preferred to IMRT when dose-limiting structures may be compromised with definitive doses.[51] Resto et al[92] reported on 102 patients with various histologies receiving surgery and postoperative PT. With a median follow-up of 61 months, the 5-year local control and OS were 95% and 90% for complete resection, 82% and 53% for partial resection, and 87% and 49% for biopsy only, respectively. Toxicity was not reported. Russo et al[93] reported on 54 patients with SCC treated with PT of which 69% had surgery and 39% had chemotherapy. The 5-year local regional control rate and OS were 73% and 47%, respectively. Wound site complications (eg, fistulas) occurred most commonly with nine grade 3 and six grade 4 complications. Zenda et al[94] reported on 90 patients with various histologies of which 18% had surgery and 12% had chemotherapy. With a median follow-up of 57 months, the 5-year OS and progression- free survival rates were 64% and 44%, respectively. Linton et al[95] reported on 26 patients with adenoid cystic carcinoma of which 77% had surgery and 23% were treated with protons alone. The 2-year local control and OS were 95% and 93%, respectively. There were 17 (19%) late grade 3 and 6 (7%) late grade 4 toxicities including two patients with encephalomyelitis infection and four patients with an optic nerve disorder. Takagi et al[96] reported on 40 patients treated with definitive PT alone for adenoid cystic carcinoma tumors, and with a median follow-up of 38 months, the 5-year local control, progression-free survival, and OS were 76%, 30%, and 63%, respectively. There were 36

grade 3 or higher events in 21 (26%) patients. High-grade toxicities included osteoradionecrosis, vision loss, and nasopharyngeal ulcers, resulting in three grade 5 toxicities.

Dagan et al[97] described their experience in 84 patients treated with PT involving sinonasal sites: nasal/ethmoid (67), maxillary (15), and frontal or sphenoid (2). Histologies included SCC (22), adenoid cystic carcinoma (14), olfactory neuroblastoma (23), adenocarcinoma (8), SNUC (7), neuroendocrine carcinoma (4), mucoepidermoid carcinoma (3), and other histologies (3). Thirty-eight patients had intracranial tumors, and 31 had orbital invasion. Eleven patients were treated after biopsy alone, nine after subtotal resection, and two for recurrence after gross total resection. Twenty-two (26%) had gross tumor at the time of PT. Median PT dose was 73.8 CGE (range, 56.8-74.4 CGE) at 1.2 CGE/fraction twice daily with elective nodal therapy. Sixty-six (78%) of patients were treated to the neck electively. Sixty-three patients (75%) received chemotherapy (mostly concurrent low-dose weekly cisplatin). The median follow-up was 2.4 years (range, 0.4-6.7 years) for all patients and 2.7 years for living patients (range, 0.6-6.7 years). Three-year local control and nodal control rates were 83% and 94%, respectively. Freedom from distant mets was 73.2%, cause-specific survival was 70%, and OS was 68%. Grade 3 to 5 toxicities occurred in 24% of patients, with one fatal central nervous system necrosis.

Truong et al[98] described their experience with 20 patients with primary sphenoid malignancy who received proton beam to a median dose of 76 CGE with a median follow-up of 27 months. The 2-year local control, regional control, and freedom from distant metastasis rates were 86%, 86%, and 50%, respectively.

Patel et al[99] performed a meta-analysis summarizing the retrospective data of various histologies and performed comparative effective analysis between charged particle and photon therapy. The median follow-up time was approximately 40 months for both groups, and the pooled OS (relative risk 1.51, 95% confidence interval 1.14-1.99; P = .0003) and disease-free survival (1.93, 95% confidence interval 1.36-2.75, P = .0003) was higher at 5 years for charged particle than for photon therapy.

Future Directions in Radiation Therapy

IMRT has improved the cancer care in external beam RT for sinonasal malignancies.[47,80-83] Proton beam therapy confers further benefits for nasal and paranasal sinus tumors, and investigators at MD Anderson Cancer Center and others have demonstrated the clinical feasibility of IMPT for this purpose (Figure 48.6).[100] The additional advantages of this technique over photon-based IMRT are its ability to limit the low-dose radiation received by adjacent critical OAR structures and allow escalation of dose to the target volume. Well-designed clinical trials in cooperative group setting will be necessary to provide the evidence required for the widespread adoption of PT over IMRT for these rare malignancies. Finally, further improvements in the local control of sinonasal malignancies will require incorporating systemic agents as neoadjuvant or concurrent therapy. Again, the rarity of sinonasal cancer will most likely require international cooperative group trials to facilitate timely analyses of outcomes and design of future trials.

SEQUELAE OF TREATMENT

Soft Tissue and Bone

The formation of nasal cavity synechiae (fibrous mucosal bands causing airway stenosis) can be prevented by intermittent dilation of the nasal passages with a petroleum-coated cotton swab until mucositis has resolved. Dry mucous membranes can be managed symptomatically with saline nasal spray. Soft tissue or cartilage necrosis is uncommon after therapy, at an estimated incidence of 5% to 10%.[27,70]

Eyes and Optic Pathway

Chronic keratitis and iritis (dry eye syndrome) can develop after RT if tumor extension to the orbital cavity mandates irradiation of the lacrimal gland to doses of more than 30 to 40 Gy.[101,102] Without lacrimal irradiation, fewer than 20% of patients treated with up to 55 Gy to the cornea develop chronic corneal injury. The risk of cataract formation at 5 years is approximately 5% after doses of up to 10 Gy to the lenses using conventional fractionation; this risk increases to 50% at 5 years after 18 Gy.

Radiation retinopathy generally occurs within 18 months to 5 years after treatment.[103] It is rare after doses of less than 45 Gy, but the incidence increases to about 50% after doses of 45 to 55 Gy.[101,102] Optic neuropathy tends to develop between 2 and 4 years after RT, but it has been reported as late as 14 years after treatment. The reported incidence of optic neuropathy is less than 5% after 50 to 60 Gy but increases to around 30% for doses of 61 to 78 Gy. Factors that influence the risk of radiation-induced optic neuropathy were reported in 2006 for 273 patients treated between 1964 and 2000 in whom the radiation fields included the optic nerves or chiasm.[104] The likelihood of developing optic neuropathy was primarily influenced by the total dose, but fraction size was marginally significant. The 5-year rates of freedom from optic neuropathy were 95% for doses 63 Gy or fewer treated once daily, 98% for doses 63 Gy or fewer treated twice daily, 78% for doses greater than 63 Gy treated once daily, and 91% for doses greater than 63 Gy treated twice daily. On multivariate analysis, the risk of optic neuropathy was found to correlate with increasing total dose (P = .0047) and possibly with increasing patient age (P = .091), once-daily versus twice-daily fractionation (P = .068), and overall treatment time (P = .097). When the target volumes include the optic pathway, special attention must be paid to hot spots and dose per fraction to avoid optic neuropathies.

Optimizing the technique for paranasal sinus tumors is crucial so that the radiation dose to the optic apparatus is limited to the greatest extent possible to minimize the risk of complications. Investigators at the University of Florida, reviewing 464 patients treated from 1964 through 2001,[105] reported a 20% incidence of ipsilateral radiation retinopathy at 5 and 10 years after conventional or 3D RT. In that study, patients were deemed functionally blind when visual acuity dropped to 20/100 on the Snellen chart, and neovascularization (rubeosis iridis or neovascular glaucoma) was coincident with radiation retinopathy. The use of IMRT has been shown to limit the doses of the optic apparatus without compromising local control. Indeed, Chen et al[54] reported findings for 127 patients treated between 1960 and 2005 with a variety of RT techniques that had evolved over that period, namely, conventional, 3D conformal, and IMRT. They concluded that the incidence of severe (grade $\geq$ 3) complications depended on the radiation treatment technique used: 54% for conventional therapy, 22% for 3D conformal therapy, and 13% for IMRT. Specifically, the

incidence of grade 3 or 4 late ocular toxicity decreased from 20% with conventional techniques to 0% with IMRT, whereas grade 3 or 4 late auditory toxicity decreased from 15% with conventional to 4% with IMRT ($P < .001$).[54] Moreover, to date, no radiation-induced blindness has been reported among the collective experience, with 308 patients treated with IMRT as either definitive or postoperative therapy for nasal and paranasal malignancies.[47,54,65,73,88,90,91,106]

CHAPTER 49

Salivary Glands

Neil Panjwani, Pattana Wangaryattawanich, Brittany Barber, Lauren Shih, Christina P. Rodriguez, and Upendra Parvathaneni

The salivary glands consist of the three large, paired major glands—parotid, submandibular, and sublingual (Figure 49.1)—and many smaller, minor glands located throughout the upper aerodigestive tract. Salivary gland malignancies are rare and make up only approximately 0.4% of all cancers and account for less than 5% of the annual incidence of head and neck malignancies in the United States. The international variation in the incidence is between 0.4 and 2.6 in 100,000 per year, with a mean of approximately 1.2 in 100,000.[1] In the United States, the incidence of major salivary gland cancer increased from 1977 till 2009 from 1.0 to 1.6 in 100,000, mainly seen for the smaller tumors due to raised awareness and improved detection with modern imaging techniques.[2]

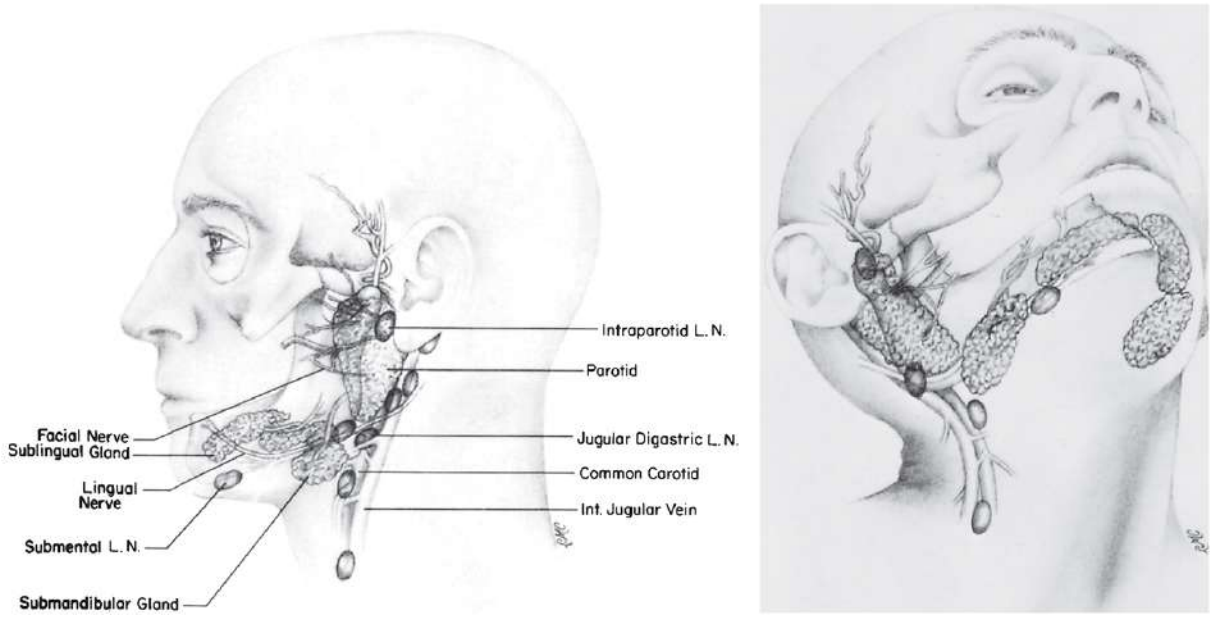

FIGURE 49.1 Anatomy of salivary glands.

ANATOMY

Major Salivary Glands

Parotid Gland

The parotid gland can be divided into two lobes—a superficial or lateral lobe and a deep lobe – by the plane of the facial nerve (VII) running through the gland. The main trunk of the VII exits the stylomastoid foramen, giving off branches to the posterior belly of the digastric muscle, then branches within the parenchyma of the gland. Typically, it divides into an upper temporofacial division and a lower cervicofacial division at the pes anserinus, located approximately 1 to 2 cm from the stylomastoid foramen. The upper division further branches into main temporal, zygomatic, and buccal branches, and the lower division divides into marginal mandibular and cervical branches. VII enters the deep surface of the gland as a single trunk, passing posterolateral to the styloid process in the retromandibular region and anastomoses with the auriculotemporal (ATN) branch of the trigeminal nerve's mandibular division (V3). It usually leaves the gland as five or more branches, emerging at the anterior, upper, and lower borders of the gland. VII runs superficial to the main blood vessels that traverse the gland but is interwoven within the glandular tissue and its ducts with the main lower trunk running between the superficial and deep lobe in the retromandibular location, an identifiable landmark on a contrast computed tomography (CT) scan. Thus, removal of all or part of the parotid gland demands meticulous dissection, if the nerve is to be spared. Notorious variation in branching patterns and cross-innervation exists within the gland, and as such, identification of the nerve during surgery is paramount to both minimizing morbidity and noting gross nerve invasion, which may alter the extent of resection thereafter.[3]

The parotid gland does not have a well-defined capsule, and its edges can be amorphous on imaging (especially CT scan), necessitating the use of established anatomic landmarks for radiotherapy (RT) planning. It is located superficial to and partly behind the ramus of the mandible, with the accessory glands covering the masseter muscle along the parotid duct and the lower zygomatic and upper buccal branches of VII. Superficially, it overlaps the posterior part of the muscle and largely fills the space between the ramus of the mandible and the anterior border of the

sternocleidomastoid muscle. One or more isthmi that wrap around the branches of VII connect the superficial and deep lobes of the gland.

The parotid gland contains an extensive lymphatic capillary plexus, many aggregates of lymphocytic cells, and numerous intraglandular lymph nodes in the superficial lobe (Figure 49.2). Lymphatics drain from more lateral areas on the face, and forehead, including parts of the eyelids, diagonally downward and posterior toward the parotid gland, as do the lymphatics from the anterior frontotemporal region of the scalp. Associated with the gland, both superficially and more deeply, are parotid lymph nodes. These drain downward along the retromandibular vein to empty in part into the superficial lymphatics and nodes along the lateral surface of the sternocleidomastoid muscle and in part into upper level 2 nodes of the deep cervical chain. Skin lesions of the face and scalp drain to the superficial parotid lymph nodes and are hence potentially amenable to treatment with electrons. Rarely, nasopharynx cancers that present with a heavy nodal burden have been known to involve the deep parotid nodes. Lymphatics from the anterior parietal region of the scalp drain partly to the superficial parotid nodes in front of the ear (preauricular nodes) and partly to the superficial nodes behind the ear (retroauricular nodes from the posterior scalp), which, in turn, drain into the upper deep cervical nodes.[4]

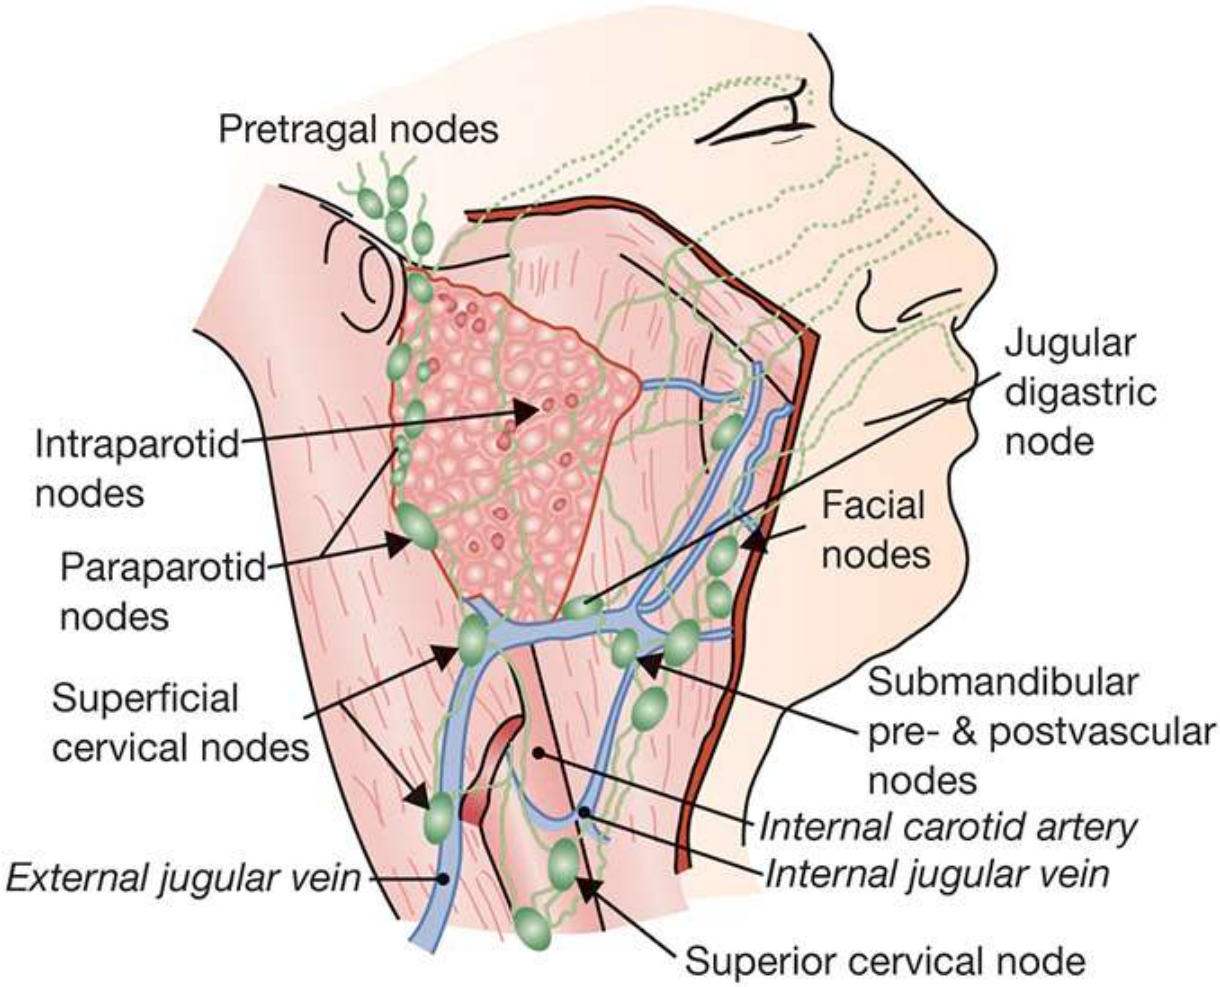

FIGURE 49.2 Lymph node distribution in and around the parotid gland.

Submandibular Gland

The submandibular gland (SMG) is well encapsulated and largely fills the triangle between the two bellies of the digastric and the lower border of the mandible and extends upward deep to the mandible. The SMG has a larger superficial part, or body, and a smaller deep process. The superficial component lies on the lower surface of the mylohyoid and deep process behind the muscle against the lateral surface of the extrinsic muscle of the tongue, the hyoglossus. The superficial part is adjacent and medial to the level 1B (submandibular) lymph nodes. The deep process of the SMG lies between the lingual nerve above and the hypoglossal nerve below.[5] Bimanual palpation with one finger in the floor of the mouth and one under

the edge of the mandible facilitates clinical detection of masses in this gland.

Unlike the parotid gland, there are no lymph nodes within the SMG itself. In other words, there will not be a cancer spread to the SMG from a draining primary site, for example, from the oral cavity or anterior nasal cavity, rather, nodal spread from primary sites is to the level 1B lymph nodes that lie adjacent to the SMG in close proximity. Hence, sparing of the SMG is possible, while treating 1B lymph nodes to elective doses (45-54 Gy) with highly conformal techniques such as proton therapy that has minimal exit dose beyond the Bragg peak. A cancer of the SMG has to originate from the gland itself, or be the result of direct infiltration (not via lymphatic spread) from an abutting structure, for example, the floor of the mouth or tongue. From the lateral and superior portions of the gland, lymph flows to the prevascular or preglandular submandibular lymph nodes. The posterior portion of the gland gives rise to one or two lymphatic trunks, which follow the facial artery and go directly to the anterior subdigastric nodes of the internal jugular chain.[6] The level 1B nodes overlying the SMG, followed by the subdigastric and high midjugular level 2 lymph nodes, are those involved in nodal metastases from a primary malignancy of the SMG. This gland is closely associated with the cranial nerve (CN) XII, marginal mandibular nerve branch of VII, and lingual nerve (V3). A dissection of this gland and level 1B lymph nodes usually leaves the patient with a (temporary) paresis of the marginal mandibular nerve with a lip droop and a functional consequence of dribbling while consuming liquids.

Sublingual Gland

This smallest of the three major salivary glands, along with many minor salivary glands, lies between the mucous membrane of the floor of the mouth above and the mylohyoid muscle below, the mandible laterally, and the genioglossus muscles of the tongue medially. This is a rare site for malignant neoplasms; they are difficult to distinguish from cancer of the floor of the mouth accounting for fewer than 2% of all reported cases of salivary gland tumors.[1,7] The sublingual gland drains either to the 1B lymph nodes or more posterior into the deep internal jugular chain level 2 nodes between the digastric and omohyoid muscles. Rarely, the lymphatics of the

sublingual gland drain into a submental (level 1A) node or supraomohyoid level 3 jugular node.

Minor Salivary Glands

Minor salivary glands are widely distributed in the upper aerodigestive tract, palate, buccal mucosa, base of tongue, pharynx, larynx, trachea, lip, gingiva, floor of mouth, paranasal sinuses, nasal cavity, and nasopharynx.

EPIDEMIOLOGY

Seventy percent of all salivary tumors arise in the parotid gland, 8% in the SMG, and 22% in the minor salivary glands.[7] The proportion of malignant tumors increases from parotid gland (25%) to SMG (43%) to minor salivary glands (65%).[7,8] There is a preponderance of benign tumors in women; malignant tumors exhibit an equal sex distribution.[1] Patients with benign tumors are younger (mean age, 46 years) compared with those with malignant tumors (mean age, 54 years), with a trend to an older age for SMG and minor salivary gland locations.[7] Two to three percent of salivary neoplasms occur in children, in whom half of the tumors are malignant.[9] Two-thirds of the cancers are located in the major salivary glands (parotid gland 53%, SMG 12%, sublingual 1.5%), and one-third in the minor salivary glands, predominantly in the oral cavity.[1] The tumors in children are mostly less advanced, and a 95% 5-year survival is reached.[9]

Etiologic factors are not clearly defined. Nutrition may be a factor because Eskimos in the Arctic, who have a low intake of vitamins A and C, have a high incidence. Cigarette smoking and alcohol consumption are in general not related to salivary gland cancers,[10] except Warthin tumors. In a study by de Ru et al,[11] patients with a Warthin tumor had a smoking history of 97%; their mean age at the time of operation was 11 years higher compared to the pleomorphic adenoma group. Irradiation can also be a cause, as evidenced by the increased incidence of survivors of the atomic bombs dropped on Hiroshima and Nagasaki.[12] Saku et al[12] studied salivary gland tumors in atomic bomb survivors of Hiroshima and Nagasaki. Two-thirds of all cases were parotid, and the remainder was equally distributed between SMG and minor salivary glands. Mucoepidermoid cancer (MEC) and Warthin tumor (benign) were particularly elevated compared with

nonexposed persons and disproportionately high at high radiation doses. The incidence of subsequent salivary gland cancer after radiation in childhood is increased compared to the general population.[13] There is a dose-response relationship with an excess relative risk of 0.27 to 0.36 per Gy.[14] The majority of these tumors are MECs[13]; however, less than 1% of salivary gland tumors may be caused by former irradiation.[15]

Workers in various occupations experience an increased risk of salivary gland cancer.[16] For women employed as hairdressers or working in beauty shops, a significantly elevated risk was observed in a study by Swanson and Burns.[17]

Women with salivary gland cancer may have a 2.5 elevated breast cancer risk.[18] After treatment for salivary gland cancer, an increased risk for subsequent cancer of the oral cavity (hazard ratio [HR] 3.5), thyroid (HR 2.7), lung and kidney cancer (HR 1.7), and second salivary gland cancer (HR 10), especially after acinic cell cancer (HR 31), is seen. For adenoid cystic cancer (ADCC), the risk of developing nasopharyngeal is increased with a factor of 17.[19]

NATURAL HISTORY

Local invasion is the initial route of the spread of malignant tumors of the salivary glands, depending on the location and histologic type. For parotid tumors, this may result in fixation to structures in around 20% of cases.[20] Skin invasion is more often seen in parotid tumors (8%-10%), compared with submandibular tumors (3%).[21,22]

Approximately 18% to 25% of patients with a malignant parotid salivary gland tumor present with facial palsy from nerve invasion, often misdiagnosed over the years as idiosyncratic Bell palsy.[7,20,22,23] Perineural tumor spread (PNTS) is well recognized with ADCC, salivary duct carcinoma (SDC), high-grade MEC, and squamous and undifferentiated cancers. Regional nodal spread and distant metastases are common among the higher grade malignancies.

A detailed study of the Dutch Head and Neck Oncology Group (NWHHT) concerning patients with a salivary gland malignancy found an overall incidence of clinically positive nodes of 14% and clinically occult, pathologically positive nodes in an additional 11% of patients.[21] This

percentage depends on the number of neck dissections performed, the tumor location, histology, and T-stage. The number of elective neck dissections performed varies between the tumor locations. Stennert et al[24] performed a neck dissection in all malignant *parotid* tumors and found 53% unilateral positive nodes and 0% contralateral nodes. In selected patients in other studies, the percentage of positive nodes varied between 20%[25] and 38%.[26] In the large National Cancer Database study of 22,653 parotid cases, positive nodes were found in 24% and occult nodes in 10%.[27] Three out of four involved lymph nodes in early parotid malignancies (21% occult nodes) were localized in the intraparotid nodes by Stenner et al.[28] Resection of *submandibular* tumors is combined with a (partial) neck dissection in most cases. Pathologic neck nodes may be seen in up to 42% of cases.[26] The risk of positive lymph nodes in *minor salivary gland* cancer depends on four prognostic factors: male gender, T3-T4, pharyngeal site, and histology (high-grade MEC and high-grade adenocarcinoma). Based on these factors, a scoring system from 0 to 4 was developed by Lloyd et al.[29] The risk of positive nodes in minor salivary gland cancer is less than 10% for scores 0 to 1, 17% for score 2, 41% for score 3, and 70% for score 4. Salivary gland tumors arising in the oral cavity produce an incidence of cervical node metastases of less than 10%.[8,26,30] In nasopharyngeal salivary gland tumors, a risk of around 20% has been shown.[31] In general, the risk of positive findings in the neck including *all salivary gland malignancies* may be based on a combination of T-stage, tumor localization, and histology. An example of a rating scale to estimate the risk of positive neck nodes, based on the tumor location, T-stage, and histologic type, is shown in Table 49.1. The highest risk is seen for squamous cell carcinoma, undifferentiated cancer, and SDC.[26,32] There is an intermediate risk for MEC and a low risk for acinic cell, ADCC, and carcinoma ex pleomorphic adenoma.[26] A 15% risk is found for T1 tumors, 26% for T2, and 33% for T3-T4.[26]

The overall distant metastases are encountered in 3% to 4% of patients at presentation and in 33% after 10 years.[21,23] They are fairly common with ADCC, SDC, high-grade MEC, and undifferentiated carcinomas; in the case of ADCC, they may occur quite late in the course of the disease, without recurrence of the primary tumor.[21,33,34] Distant metastases are primarily to the lung, bone, and, occasionally, the liver.[21] Reported incidence of distant metastases in patients with ADCC after 10 years of follow-up is around 40%.[21,34,35] Five years after the diagnosis of distant metastases of ADCC and acinic cell cancer, more than one-third of the patients are still alive; 10% are alive after 10 years. An update of the survival data of the NWHHT study after the diagnosis of distant metastases of salivary gland cancer is shown in Figure 49.3.

CLINICAL PRESENTATION

Clinical presentation of salivary gland malignancies can range dramatically from indolent asymptomatic masses present for several years or rapidly enlarging painful masses, with or without CN palsies, and/or neck lymph nodal masses. Three of four parotid masses are benign.[7] Patients most often have a painless, rapidly enlarging mass, often present for years before a sudden change in its indolent growth pattern prompts the patient to seek medical attention. Duration of clinical symptoms before diagnosis may last more than 10 years.[7,21] For malignant tumors, the median duration of

clinical symptoms generally is shorter (3-6 months)[21,38] compared to that of benign tumors, although, for some minor salivary gland tumors, median periods of 2 years have been reported.[30]

Pain and CN involvement is more frequently associated with malignant disease.[7] Although as many as one-third of parotid cancers may have involvement of VII, only 10% to 20% of patients complain of pain.[7,20,21] Often, these patients are managed unsuccessfully for a Bell palsy for a number of years before a scan is obtained that reveals a parotid malignancy. Pain and/or trismus may appear with the involvement of deeper structures and muscles of mastication (masseter, temporalis, and pterygoid muscles). Depending on the size and location, patients can present with salivary gland obstruction, pain, inflammation, and postprandial swelling, which can lead clinicians to a diagnosis of sialadenitis, rather than malignancy. Sialadenitis can be secondary to obstruction by salivary gland neoplasms, which can delay diagnosis if cross-sectional imaging is not arranged. Thus, clinicians must consider malignancy in any evaluation of salivary gland swelling with pain. A thorough examination of the parotid gland involves palpation of the gland over the face and neck, assessment of the overlying skin, bimanual palpation of the buccal space including Stensen duct, examination of the oropharynx and nasopharynx, and a thorough evaluation of facial nerve function and symmetry. The adjacent parapharyngeal space is divided into a prestyloid (anterolateral) and poststyloid (posteromedial) compartment by a fascial layer extending from the styloid process to the tensor veli palatini. Tumors of the parotid may involve the base of skull and cause intractable pain and paralysis of various CNs, especially VII (facial asymmetry) and ATN (paresthesia in the preauricular region). Deep lobe malignancies can be present as a submucosal mass bulging into the oropharynx, masquerading a tonsillar mass, or into the nasopharynx that obstructs the eustachian tube, causing otalgia and the sensation of a “blocked ear.” CN neuropathies may be present in deep lobe tumors that extend into the poststyloid compartment alongside CN IX, CN X, CN XI, and CN XII. Extension into the infratemporal fossa may cause trismus by invasion of the pterygoid muscles.

SMG and sublingual gland malignancies are present in close proximity to the lingual (V3) and hypoglossal (XII) nerves and thus, depending on the histology, may present with palsy of these nerves. Bimanual palpation of

the SMG should be performed to evaluate the extent of the tumor and invasion of adjacent structures, including the mandible, floor of mouth mucosa, skin, and mylohyoid. Asymptomatic swelling of the floor of the mouth is the primary presentation in sublingual salivary gland cancer, and SMG, with pain and ipsilateral tongue numbness (V3) or tongue asymmetry, deviation and fasciculations (XII), and weakness of the lower lip, suggests marginal mandibular nerve (VII) involvement as symptoms of advanced disease.[39]

The signs and symptoms associated with tumors of the minor salivary glands vary because of their diverse locations. The distribution of presenting sites and risk of malignancy for 380 cases of intraoral minor salivary gland tumors is shown in Table 49.2.[40] A painless lump is the most common presenting symptom. Almost all extraoral minor salivary gland tumors are malignant.[7] Extraoral minor salivary gland tumors are most frequently seen in the nasal cavity (52%), followed by the larynx (18%), the oropharynx (14%) mostly localized in the tongue base, nasopharynx (8%), and ethmoid (8%).[7] For tumors arising in the nasal cavity or sinuses, facial pain is the most common presenting symptom, followed by nasal obstruction. Laryngeal primary tumors most frequently cause hoarseness or voice change.

TABLE 49.2 DISTRIBUTION OF PRESENTING SITES OF INTRAORAL MINOR SALIVARY GLAND TUMORS

Site	Number of Patients (%)	Percentage Malignant
Palate	206 (54)	43
Upper lip	64 (17)	9
Buccal mucosa	54 (14)	37
Retromolar region	20 (5)	95
Lower lip	18 (5)	56
Floor of mouth	13 (3)	69
Tongue	5 (1)	60
Total	380	41

reports from other parts of the world. *J Oral Pathol Med*. 2007;36(4):207-214. Copyright © 2007 Blackwell Munksgaard. Reprinted by permission of John Wiley & Sons.

Clinical features suggesting a malignant salivary gland tumor are rapid growth rate, pain, PNTS with CN palsies, childhood occurrence, skin involvement, and cervical adenopathy.

DIAGNOSTIC WORKUP AND STAGING

Major Salivary Glands

The diagnostic workup of major salivary gland tumors includes a careful history and physical examination, with particular attention to signs of local fixation, regional adenopathy, and PNTS.

For superficial lesions of the parotid gland, the SMG, and sublingual gland and evaluation of the cervical lymph nodes, ultrasound (US) is the first diagnostic step, combined with fine-needle aspiration biopsy (FNAB), although one is justified to proceed directly to a resection if there are imaging features consistent with a malignant tumor. Radiologic examination plays a pivotal role in the comprehensive assessment of patients with salivary gland tumors. These imaging modalities provide crucial information regarding tumor localization, extent, number (single vs multiple), and potential regional or distant metastases, aiding in accurate diagnosis and treatment planning.[41] The available imaging techniques include US, CT, magnetic resonance imaging (MRI), and ^{18}F-fluorodeoxyglucose (FDG)-positron emission tomography/CT (PET/CT).[42-45] US is commonly employed as the initial imaging tool for evaluating superficial palpable lumps in the head and neck region, including the major salivary glands. Its wide availability, safety, and ease of use make it a preferred choice. In addition, it offers high-resolution imaging of accessible superficial lesions and can be effectively used for imaging-guided tissue biopsies, utilizing either FNAB or core-needle biopsy (Figure 49.4).[42] In US, signs of malignancy are ill-defined borders with heterogeneous architecture, internal necrosis, and cystic changes.[46] Benign salivary tumors are well defined and hypoechoic. However, the effectiveness of US is dependent on the operator, and it has limitations in assessing deeply located or bone-obscured lesions, such as deep parotid lesions or minor salivary

gland tumors. Furthermore, US is not optimal for assessing the full extent of tumors, including bone invasion, PNTS, and regional metastases. In such cases, CT and/or MRI are more appropriate for complete tumor staging.[42,43]

FIGURE 49.4 Mucoepidermoid carcinoma (MEC) of the right parotid. A 29-year-old woman presents with palpable lump over the right parotid area. Longitudinal (A) and transverse (B) ultrasound show a mixed iso- and hypoechoic mass with irregular margins centered in the superficial right parotid (arrows). C. Ultrasound with color flow demonstrates mild increased internal vascularity within the mass (arrow). D. Ultrasound-guided core-needle biopsy was subsequently performed, with the final pathology showing MEC.

CT and MRI are indispensable imaging modalities for evaluating salivary gland tumors, as they offer detailed cross-sectional images that provide valuable insights into the size, shape, and involvement of tumors with surrounding structures.[43] MRI is superior to CT, especially when malignancy is suspected, based on the excellent soft tissue contrast (Figure 49.5). When feasible, both CT and MRI should be performed with intravenous (IV) contrast to fully characterize tumors and thoroughly assess the extent of primary tumors and metastatic disease. The advantages of CT include its rapid acquisition time and wide availability in most health care

institutions, making it a practical choice for initial assessment. In addition, CT can provide valuable information about the integrity of bony structures, particularly the cortical bones (Figure 49.6). Detection of cortical erosion or destruction is possible with CT, aiding in the evaluation of tumor involvement with adjacent bone structures. On the other hand, MRI with contrast excels in offering exceptional soft tissue visualization and precise anatomical details, making it particularly valuable in identifying tumor boundaries. MRI is highly effective in assessing potential PNTS, a crucial factor in determining the extent of the disease and planning appropriate treatment strategies, especially for ADCC, SDC, squamous and undifferentiated carcinomas, and high-grade MEC (Figures 49.7 and 49.8).[47] The tumor extension along VII (stylomastoid foramen and temporal bone), the CNV3 (ATN and foramen ovale), or, less commonly, nerve V2 (foramen rotundum) as seen in tumors of the deep parotid lobe involving the pterygopalatine fossa may be visualized by T1-weighted images.[48] This is of special importance for the delineation of these nerves in case of postoperative radiotherapy (PORT) and definitive RT for extensive PNTS (Figure 49.9), involving V3 and VII. The imaging characteristics of salivary gland tumors can vary based on their histologic types and tumor grading.[49,50] However, there is a challenge in using imaging to reliably distinguish between benign and malignant salivary gland tumors. In many cases, low-grade malignancies exhibit well-defined margins that can resemble those of benign tumors (Figure 49.10). Conversely, high-grade malignancies frequently display infiltrative margins on imaging.[50] T1-weighted images are excellent for assessing the margins, extension into the deep tissues, and patterns of infiltration because the (fatty) background of the gland is hyperintensive. With T1-weighted gadolinium series, tumor infiltration and heterogeneous enhancement may be visualized, as seen in high-grade tumors.[46] With fat-suppressed T2-weighted images, the fluid content of a tumor is visualized. In general, benign tumors are hyperintensive, and malignant tumors show intermediate or low intensity at T2-weighted MRIs. Researchers have explored advanced imaging techniques, such as diffusion-weighted imaging and dynamic contrast-enhanced MR perfusion, to improve the differentiation between benign and malignant salivary gland tumors.[51-54] Despite these efforts, the precise role of these techniques in enhancing diagnostic accuracy still requires validation.

Axial T1 weighted (A) and T2 weighted with fat suppression (B) and axial (C) and coronal (D) contrast-enhanced T1 weighted with fat suppression demonstrate a small well-circumscribed enhancing mass in the left superficial parotid, mimicking benign salivary gland tumors such as pleomorphic adenoma. E. Corresponding parotid ultrasound with color-flow Doppler I age shows mild vascularity surrounding the lesion.

^{18}F-FDG PET/CT scans combine functional and anatomic information, offering valuable data on metabolic activity and assisting in the detection of distant metastases. It is of value for tumor staging and surveillance, especially in patients with advanced-stage or high-grade salivary gland malignancies (Figure 49.11).[44,45,55] The current American Society of Clinical Oncology guideline recommends obtaining PET/CT in patients with advanced-stage high-grade salivary gland malignancies.[41] However, when it comes to distinguishing between benign and malignant salivary gland tumors, PET/CT has limitations due to the overlapping metabolic activities of these tumors.[44] For instance, certain benign salivary gland tumors, notably Warthin tumor and pleomorphic adenoma, can exhibit

hypermetabolic activity with increased FDG uptake, resembling high-grade salivary gland malignancies (Figure 49.12). In contrast, some low-grade salivary gland malignancies such as acinic cell carcinoma and low-grade MEC tumor might not display elevated FDG uptake.[45] Therefore, the definitive diagnosis of salivary gland tumors still relies on histopathologic examination.

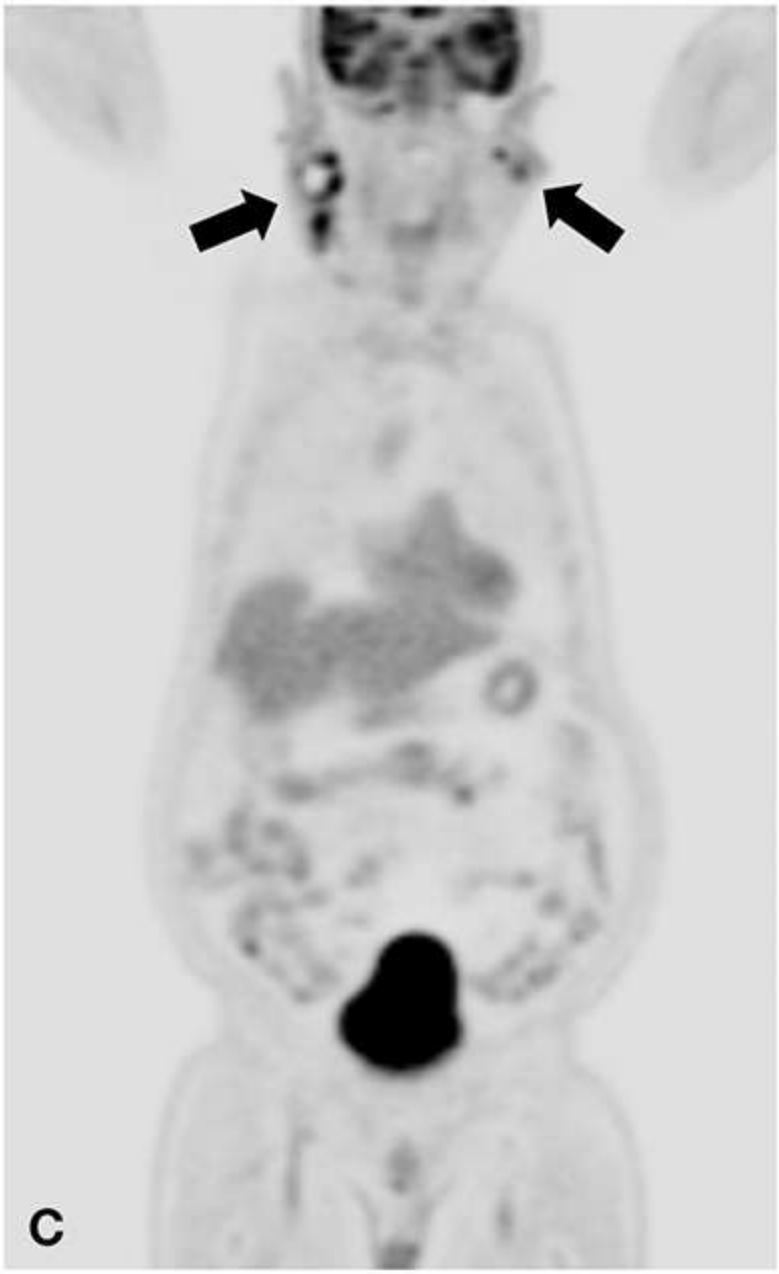

FIGURE 49.12 Warthin tumor (aka papillary cystadenoma lymphomatosum). A 75-year-old man with a history of smoking. Positron emission tomography/computed tomography (PET/CT) was performed for evaluation of progressively enlarging lung mass. Axial fused PET/CT (A) and coronal PET images with maximum intensity projection (B, C) demonstrate multiple fluorodeoxyglucose-avid masses in the bilateral parotid glands (arrows). Note cystic change with central photopenia within the dominant right parotid mass. Warthin tumor was histologically confirmed with tissue biopsy.

The eighth edition of the manual of the American Joint Committee on Cancer and the eighth edition of the classification system of the

International Union Against Cancer are identical for major salivary glands[56] (Table 49.3). They are based on size; tumor extension; nodal size, number, and location; and, a change from the seventh edition, extranodal extension. Relative survival rates for major salivary gland cancer according to stage are shown in Figure 49.13.

Minor Salivary Glands

Various radiographic studies may be used, including plain films, to ascertain bone erosion in advanced lesions, although CT is best to detect bone invasion and nodal involvement, and MRI for soft tissue infiltration and PNTS. CT and MRI scans may be used to evaluate depth, contiguous involvement, and the retropharyngeal nodes. US may be used to examine the neck nodes and is operator dependent. PET can be helpful for overall staging. The definitive diagnostic procedure is an excisional biopsy, particularly if malignancy is clinically suspected. Unplanned incisional biopsies should be avoided, and fine-needle biopsies are impractical because of the polymorphism of most malignant salivary gland tumors.

A formal staging system has not been developed for minor gland tumors. The same staging system of minor salivary glands for squamous cell carcinoma in sites other than the parotid gland or SMG may be used.[56]

PATHOLOGIC CLASSIFICATION

Salivary glands are composed of acinar-ductal units with acinar cells on the inside of the acinar units and ductal epithelial cells on the inside of the striated and excretory ducts. Myoepithelial cells are located in the outside of acini and intercalated and striated ducts. Basal (reserve) cells are found on the outside of the excretory ducts.[57] Carcinomas may arise from all these cell types, either separately or combined. The histologic classification of these salivary gland tumors is very demanding for the head and neck pathologist. In 1991, the World Health Organization (WHO) classification for salivary gland tumors of 1972 was expanded from 7 to 20 subtypes. Various types of carcinomas were distinguished based on precise histologic definitions, prognosis, and treatment, discussed more in detail by Seifert and Sobin.[58] In 2005, the WHO classification of malignant salivary gland tumors was extended. Again, 24 subtypes were specified[56] (Table 49.4). Classification may be difficult, as shown in a reevaluation of 101 intraoral salivary gland tumors by experienced pathologists; major disagreement was seen in 8, and there was minor disagreement in 33.[59]

TABLE 49.4 WHO CLASSIFICATION OF TUMORS OF SALIVARY GLANDS

Malignant tumors

Mucoepidermoid carcinoma

Adenoid cystic carcinoma

Acinic cell carcinoma

Polymorphous adenocarcinoma

Clear cell carcinoma

Basal cell carcinoma

Intraductal carcinoma

Adenocarcinoma, NOS

Salivary duct carcinoma

Myoepithelial carcinoma

Epithelial-myoepithelial carcinoma

Carcinoma ex pleomorphic adenoma

Secretory carcinoma

Sebaceous adenocarcinoma

Carcinosarcoma

Poorly differentiated carcinoma

- Undifferentiated carcinoma
- Large cell neuroendocrine carcinoma
- Small cell neuroendocrine carcinoma

Lymphoepithelial carcinoma

Squamous cell carcinoma

Oncocytic carcinoma

Uncertain malignant potential

- Sialoblastoma

Benign tumors

Pleomorphic adenoma

Myoepithelioma

Basal cell adenoma

Malignant tumors
Warthin tumor
Oncocytoma
Lymphadenoma
Cystadenoma
Sialadenoma
Ductal papillomas
Sebaceous adenoma
Canalicular adenoma and other ductal adenomas
Non-neoplastic epithelial lesions
Sclerosing polycystic adenosis
Nodular oncocytic hyperplasia
Lymphoepithelial sialadenitis
Intercalated duct hyperplasia
Benign soft tissue lesions
Hemangioma
Lipoma/sialolipoma
Nodular fasciitis
Hematolymphoid tumors
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

Most salivary gland subtypes are very rare. The percentage of the histologic subtypes varies from series to series and from the localization of the tumor (Figure 49.14). In 666 patients with a salivary gland carcinoma in a study performed in the Netherlands, for which the pathology was revised, ADCC was most frequently diagnosed (27%), followed by MEC (16%), acinic cell carcinoma (14%), carcinoma ex pleomorphic adenoma (8%), undifferentiated carcinoma (7%), SDC and adenocarcinoma not otherwise

specified (both 6%), polymorphic low-grade adenocarcinoma (PLGA) and squamous cell carcinoma (both 5%), and epithelial-myoepithelial carcinoma in 2%. In this large study, all other subtypes were rarely or not at all diagnosed.[21]

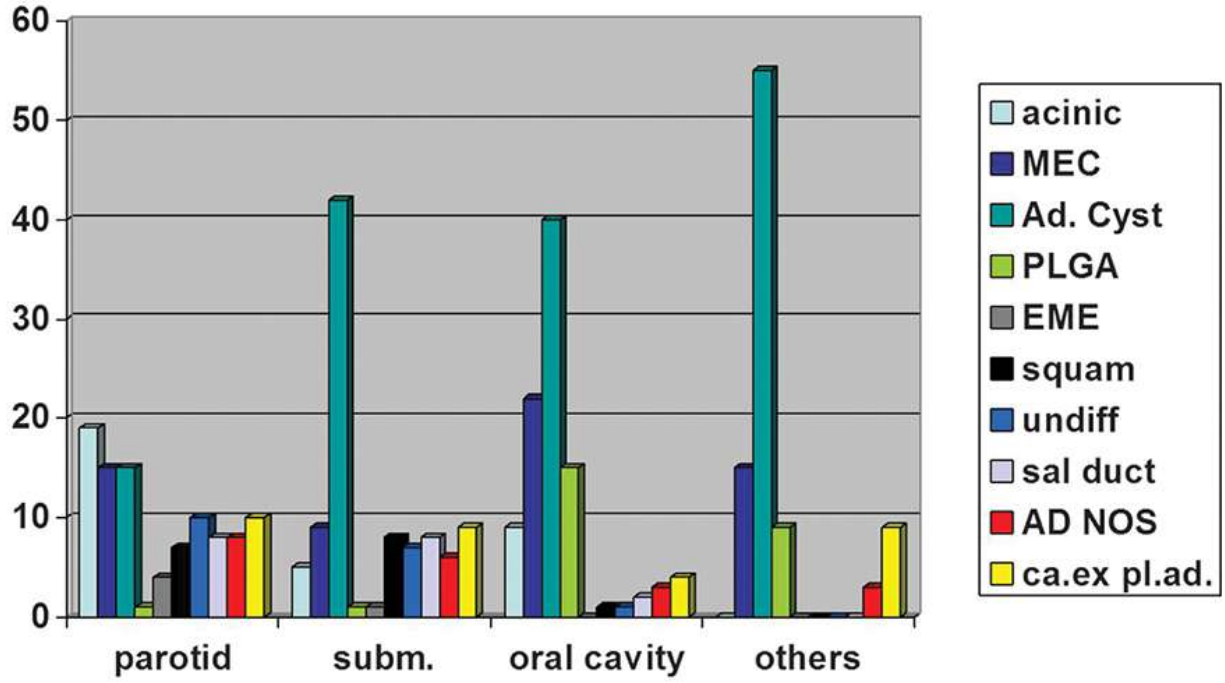

FIGURE 49.14 Distribution of various cell types (%) in series from the Dutch study, depending on site. Ad. Cyst, adenoid cystic; AD NOS, adenocarcinoma not otherwise specified; ca. ex pl. ad., carcinoma ex pleomorphic adenoma; EME, epithelial-myoepithelial carcinoma; MEC, mucoepidermoid cancer; PLGA, polymorph low-grade adenocarcinoma; sal duct, salivary duct carcinoma; squam, squamous cell carcinoma; subm, submandibular. undiff, undifferentiated.

Salivary gland carcinomas may be graded from low to high based on malignant potential, particularly for MEC. However, there is a disparity for grading, even among experienced pathologists.[60] Low- and intermediate-grade MEC, PLGA, epithelial-myoepithelial, cribriform and tubular ADCC, and acinic cell carcinomas comprise a group of low-to-moderate malignancy; high-grade MEC, malignant mixed, solid component and high-grade ADCC, undifferentiated carcinoma, and SDCs represent more high-grade primary malignancies.[60]

ADCC is the most common in minor salivary glands, followed by the SMG.[8,21,36,61,62] Perineural invasion and local and distant (usually lung)

recurrences are common in ADCC.[62-64] Indolent presentation and delayed recurrences are common and warrant a long-term follow-up program (>10 years). The ADCC variety has a tubular pattern that has been associated with the best prognosis, a cribriform pattern with an intermediate prognosis, and a solid pattern with the worst prognosis.[65]

In parotid tumors in children and adults, the most common malignant subtype is MEC.[9,66-68] MEC contains squamous cells, mucus-producing cells, and cells of intermediate type. Several grading criteria and cell cycle–based Ki 67 proliferation index of MEC have been published.[57] *Acinic cell* cancer derives from cells of the terminal ducts and intercalated ducts. An extensive update of the literature is published by Vander Poorten et al.[69] Most tumors (86%) are located in the parotid gland.[69] Like in MEC, Ki 67 proliferation index is a prognostic factor for disease-free survival.[57] *Carcinoma ex pleomorphic adenoma* may be localized in all salivary glands, although the majority is found in the parotid gland. In the development of carcinoma ex pleomorphic adenoma, a progressive loss of heterozygosity of chromosomes 8q, 12G, and 17P is seen.[70] The prognosis is poor with a high risk of distant metastases.[21] *Undifferentiated and squamous cell carcinoma* are mainly localized in the parotid gland. The prevalence of comorbidity for patients with squamous cell carcinoma of the salivary gland is comparable to other head and neck cancers, whereas the prevalence of comorbidity in all other malignant salivary gland cancer subtypes is significantly less.[71] Also, patients with squamous cell carcinoma of the salivary glands are mostly older.[1] So, squamous cell carcinomas of the salivary gland may be a different entity among salivary gland cancers and are most likely secondary, that is, regional nodal metastases to the intraparotid lymph nodes (especially superficial parotid) from a skin cancer of the face or scalp rather than a primary salivary gland malignancy. Similarly, melanomas and Merkel cell carcinomas of the parotid gland are very likely secondary from skin primary tumors. The PLGA, SDC, and epithelial-myoepithelial carcinoma are the most common new subtypes of the WHO 1991 classification. *PLGA* is a solid, ovoid, nonencapsulated mass with a highly variable growth pattern (Figure 49.15A). Most are located in the palate and are slowly growing tumors, and 80% are stage I/II. The prognosis is generally good, with a tendency to local and seldom regional recurrences or distant metastases.[72] SDC resembles ductal breast

cancer morphologically (Figure 49.15B). They derive from excretory duct cells. They are usually located in the parotid gland and are highly aggressive.[73,74] They are frequently positive for androgen receptors and positive for HER2/neu protein.[74] However, the gene amplification is seen in less than 50% of the cases.[57] There is also a low-grade subtype, resembling breast atypical ductal hyperplasia and low-grade ductal carcinoma in situ. The prognosis is excellent.[75] *Epithelial-myoepithelial carcinoma* is mainly localized in the parotid gland. The tumors are composed of myoepithelial cells, surrounded by epithelial-lined ducts, resembling intercalated ducts. It is a low-grade tumor, and all 14 patients of the Dutch study remained disease free. However, local recurrences may be encountered.[76] *Myoepithelial carcinomas* have exclusive myoepithelial differentiation. They are commonly seen in the parotid gland and the palate. Differentiation with other salivary gland cancers may be difficult. The prognosis is poor, with a 5-year disease-free survival of 40%.[77] *Basal cell adenocarcinoma* is a low-grade tumor, predominantly seen in the parotid gland, with a high risk on local recurrence but a low risk for regional recurrences or distant metastases.[78] *Malignant oncocytoma* is a high-grade malignant tumor, characterized by oncocytes, with necrosis, perineural spread, vascular invasion, and a high risk for cervical lymph nodes.[79] Most tumors are found in the parotid gland or SMG. Positive resection margins are a major source of poor overall survival.[79] *Salivary gland cystadenocarcinoma* is a low-grade tumor, predominantly localized in the parotid gland. It has an excellent prognosis.[80] *Mucinous adenocarcinoma* is a high-grade malignancy from the palate and floor of mouth, with a high risk for neck node and distant metastases.[81] Sebaceous carcinoma is mainly localized in the parotid gland and is a slow-growing, low-grade tumor.[82] In 2017, four new entities were described by Skálová et al.[83] *Mammary analog secretory carcinoma* (MASC), mostly a low-grade tumor, in the past was mainly classified as acinic cell carcinoma. They have specific chromosomal translocations and molecular and immunohistochemical findings.[84] Most cases are seen in the parotid gland and oral cavity. *Cribriform adenocarcinoma* mimics PLGA and is primarily seen in the tongue. It is a very rare tumor, with a high risk on positive cervical lymph nodes. *Sclerosing polycystic adenosis adenoma* involves the parotid gland and is, although benign, associated with a high risk of local recurrence after

surgery. Finally, a new myoepithelioma variant is the *mucinous (secretory) myoepithelioma*, with a benign to low-grade malignant behavior. It is a very rare subtype mainly seen in the minor salivary glands.

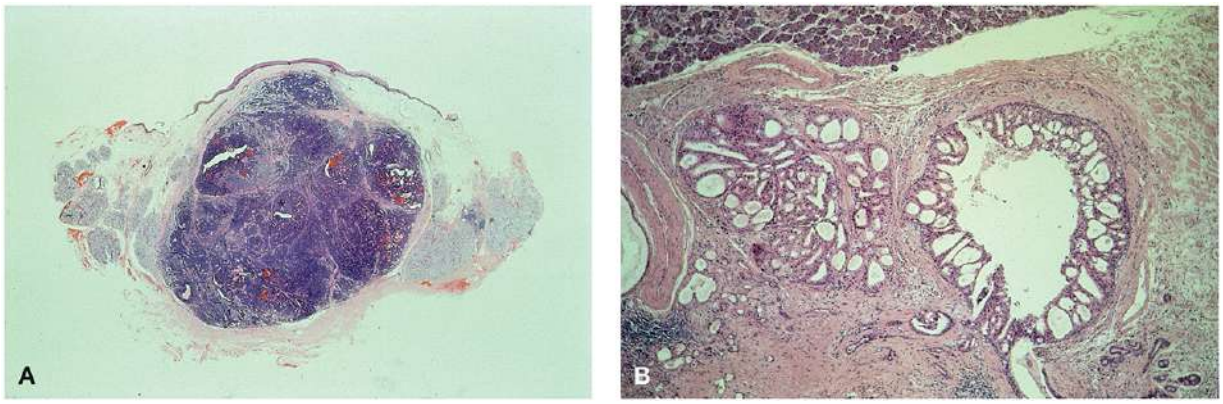

FIGURE 49.15 Examples of polymorphous low-grade adenocarcinoma (A) and salivary duct carcinoma (B). (Courtesy of Prof. Dr P. Slootweg, pathologist, Radboud University Medical Center, Nijmegen Netherlands.)

Based on the high morphologic diversity of salivary gland carcinomas, the differential diagnosis is a challenging task for the pathologist. Molecular testing may serve as a powerful diagnostic tool.[84]

PROGNOSTIC FACTORS

A number of prognostic variables have been studied in the management of salivary gland cancer. In these studies, multivariate analyses have been performed, considering locoregional control, distant metastases, and survival. Results of studies with sufficient number of patients and follow-up have been summarized in Table 49.5. Local control and overall survival are influenced by site, favoring tumors of the oral cavity.[21] T- and N-stages are independent variables for locoregional control, distant metastases, and survival, regardless of site.[8,21,23,34,66,67,85-91] As may be concluded from Table 49.5 in almost all studies, histologic subtype is not an independent prognostic factor for locoregional control but plays a role in risk on distant metastases and overall survival.[21] The added prognostic value of cytology and/or histologic subtype in salivary carcinoma is limited, largely because of the combined prognostic value of other prognostic factors, such as tumor size, N- and M-classification, and comorbidity.[92] Histologic subtypes may

be divided into low- and high-grade tumors, although a bit subjective. Grading is associated with the risk of recurrence and overall survival.[23,88] Comorbidity is associated with overall survival, but not with disease-free survival.[71]

Oncogene expression has been evaluated in the search for additional prognostic factors. In a review, Stenman et al discussed the diagnostics and therapeutic importance of new biologic markers for salivary gland cancer.[93] Overexpression of HER2/neu is related to aggressiveness, distant metastases, and poor survival in salivary gland cancer,[94] especially in SDC.[95] It also has been similarly associated with poor prognosis in carcinomas of the breast, ovary, and endometrium. High Ki 67 nuclear antigen and p53 tumor suppressor expression may be related to poor prognosis. In a study of Finland, comparing both markers, only Ki 67 expression was an independent prognostic factor for overall survival.[96]

Another molecular feature studied in relationship to prognosis was the DNA content in ADCCs. DNA aneuploidy is correlated with the solid type and poor prognosis.[65]

Major Salivary Glands

The survival of patients with submandibular cancers is inferior to that with parotid cancers according to a study by Spiro et al.[68] Extraglandular extension[66,67] and skin invasion[22,89,97] in parotid cancers result in decreased disease-free survival. More advanced age was found to be a negative prognostic factor for locoregional control in some studies[20,32,90] and for disease-free and overall survival in most studies.[22,66,68,89,91] Impairment of the function of the facial nerve is a known prognostic factor, influencing not only locoregional control[7,21,97] but also disease-free survival.[89,91,97,98] Pain at presentation may be associated with reduced disease-free survival.[89] Perineural invasion and pain are closely related; however, perineural growth, not pain, in some studies, is an independent prognostic factor for distant metastases[21] or disease-free survival.[67,86,99]

The importance of histologic subtype for major salivary gland cancer varies in published studies. In most studies, histologic types are subdivided into low and high grade. The main prognostic significance of grading relates to disease-free survival.[66,23] In the large Surveillance, Epidemiology, and End Results (SEER) database of major salivary gland carcinomas, higher grade was associated with higher stage and is an independent prognostic factor for overall survival in stages II to IV.[100] The best prognosis is seen for acinic cell and low-grade MEC[21,69] and the worst for undifferentiated[21,97] and squamous cell cancer.[21,68] At the Netherlands Cancer Institute, a prognostic score for patients with parotid carcinoma was developed and validated.[22,89] The preoperative prognostic score was based on a weighted combination of prognostic factors (age, pain, clinical T- and N-stages, skin invasion, and facial nerve dysfunction); histology and grading were not incorporated. Four subgroups were formed with markedly different prognoses. In the postoperative score, perineural invasion and positive surgical margins were also included. In ADCC, named major nerve involvement is a prognostic factor; however, this may not be true for microscopic invasion only.[101] Intraneural invasion is a more predominant

prognostic factor than perineural invasion.[102] Positive or close surgical margins result in an increase in local recurrence rate.[21,23,61,87,103] RT in addition to surgery improves locoregional control in patients with adverse prognostic factors.[20,26,86,88,97,104,105] Improvement of overall survival by PORT has been shown in data from the National Cancer Database[106] and even in early-stage ADCC.[107] In a matched-pair analysis of PORT, improved overall survival was found in stage III and IV major salivary glands.[108]

Minor Salivary Glands

Tumors located in the larynx or nasal cavity/paranasal sinus have significant lower cause-specific survival compared to location in the oral cavity.[109,110] The poorest prognosis is associated with ADCC.[30,37] Stage, base of skull involvement, and bone invasion are risk factors for locoregional recurrence and survival in minor salivary gland cancers.[8,30,37] Locoregional control may be improved by adding PORT.[37]

GENERAL MANAGEMENT

The general management of salivary gland malignancies in most patients includes surgical excision followed by PORT for unfavorable prognostic factors (Table 49.6). PORT to enhance local control is recommended for T3-T4 tumors, close or incomplete resection, bone involvement, perineural invasion, high-grade cancer, recurrent cancer, and neck node lymph metastases.[21,38,61,67,90,97,103] Elective neck RT prevents nodal relapses; however, it is in general not indicated for acinic cell and other low-grade carcinomas or ADCC.[111] According to Chen et al, study for carcinoma ex pleomorphic adenoma and ADCC, surgery and PORT are the standards.[86,105] Concurrent PORT plus platinum- and/or paclitaxel-based chemoradiotherapy for high-risk patients (nodal involvement, microscopic positive margins, T3-T4, perineural involvement) have been postulated to improve locoregional control rates. However, in the published data, the number of patients is small, the follow-up is short, the acute toxicity is more severe, and there is little proof that concurrent postoperative chemoradiotherapy is superior to PORT alone and is not indicated.[112,113] For advanced, inoperable, and recurrent salivary gland cancers, high linear energy transfer (LET) RT such as primary neutron therapy (NRT)[114] may

lead to superior local control rates, compared with primary photon therapy, without clear evidence of improved survival rates[115] Another treatment option in these cases is carbon ions, with the advantage of a higher relative biologic effectiveness (RBE) on tumor similar to NRT.[116] High local control rates may be achieved with primary treatment with carbon ions in ADCC.[117] In Table 49.6, indications for RT in salivary gland cancer are summarized.

TABLE 49.6 INDICATIONS FOR RADIOTHERAPY: SALIVARY GLAND CANCER

Local PORT	Regional PORT	Primary RT (≥70 Gy)	High LET RT Consider If Available
AJCC stage T3-T4	pN_+ (60 Gy)	Med. inoperable	R2 resection
High grade	ENE (66 Gy)	Funct. inoperable	Primary RT: T4
Perineural invasion	Elective (Table 49.1) 50 Gy	Irresectable	Reirradiation
Close res. (1-5 mm) (60 Gy)		Recurrent	
Incomplete res. (66 Gy)			

AJCC, American Joint Committee on Cancer; ENE, extranodal extension; Funct., functional; LES, low energy transfer; Med., medical; PORT, postoperative radiotherapy; Res., resection; RT, radiotherapy.

Major Salivary Glands

Surgical technique depends on the location and extent of primary disease and regional adenopathy.

Parotid Tumors

Superficial parotidectomy is generally sufficient for low-grade tumors with a well-defined capsule. Partial deep lobe dissection may be required for larger tumors extending between the upper and lower divisions of the facial nerve or deep to the mandible beneath the pes anserinus. A total parotidectomy involves removing the entire parotid gland both superficial and deep to the facial nerve and is typically indicated for high-grade tumors with extension to the deep lobe, those with suspected intraglandular lymphadenopathy, or tumors originating within the deep lobe.

Preoperatively, surgeons must be prepared to sacrifice the facial nerve and plan reconstruction accordingly when there is facial asymmetry in the presence of known malignancy or when there is obvious PNTS on preoperative imaging. If the preoperative examination and diagnostic evaluation reveal a fully intact VII, all attempts should be made to preserve it during surgery, except in the case of gross invasion encountered intraoperatively.[41]

Preservation of VII, at least partially, followed by PORT is the preferable treatment unless VII is already involved by tumor.[118] Aggressive surgery does not improve disease-free survival in the absence of nerve involvement. A decrease in extended surgery, resulting in a decrease in sacrifice of VII, has been shown in the course of years.[68] Cable facial nerve grafting with the greater auricular or sural nerve graft decreases the incidence of facial palsy postoperatively, especially if branches and not the main trunk are involved.[119] PORT has no negative effect on facial nerve function.[119] When there is nerve involvement, resection should proceed until proximal and distal facial nerve margins are negative, which may require mastoidectomy in order to transect the nerve proximal to invasion. Failure to do so is associated with an increased incidence of locoregional recurrence.[120]

Advanced tumors may invade into adjacent structures, including the overlying skin, muscle (masseter, sternocleidomastoid, pterygoid, or temporalis), bone (mandible, styloid, mastoid), and vasculature (external or internal carotid artery). Resectability should be determined by a careful review of the preoperative imaging and multidisciplinary tumor board review. In particular, careful consideration of potential encasement of the internal carotid artery should be reviewed in advanced malignancies. A multi-subspecialty approach (head and neck surgeon, reconstructive surgeon, radiation oncologist) may be necessary to optimize resection and reconstruction versus consideration of primary RT, especially with high LET particle beam RT (ie, NRT or carbon ion, if available) in all salivary gland origin malignancies. If a salvage surgical approach (in case of RT failure) and its morbidity are not going to be significantly different versus upfront surgery, an initial nonsurgical approach could be justified, with the caveat that postirradiation surgery could perhaps have greater perioperative complications. Multidisciplinary tumor board discussion between the

surgeon and radiation oncologist is essential and may also influence PORT fields.

It is well established that a clinically positive neck should be addressed with a neck dissection, followed by PORT.[26] The risk of occult nodal disease depends on T-stage and histologic type.[26,110] High-grade salivary histopathologies have a 49% risk of occult lymph nodal metastases compared to low- or intermediate-grade tumors.[121] High-risk histologies include high-grade MEC, adenocarcinoma NOS, carcinoma ex pleomorphic adenoma, SDC, squamous cell carcinoma, undifferentiated carcinoma, or any other tumor with high-grade transformation; have been shown to have a higher risk of occult metastases; and are typically treated with neck dissection at the time of resection of the primary.[32,121-126]

As shown in the scoring system in Table 49.1, the decision to treat the neck for parotid tumors will be indicated by a score of at least 4.[26] When local prognostic factors indicate PORT, no elective neck dissection has to be performed; the neck nodes could be electively irradiated without compromising regional control.[24,127] Parotid tumors with facial nerve involvement are associated with frequent occult neck nodes. Elective neck treatment is also indicated for all high-grade cancers. Elective neural treatment to the proximal origin of the involved nerve is indicated to all tumors with overt PNTS.[127] Specific levels of elective neck dissection or neck irradiation for occult metastases are dependent upon the site of disease. For parotid tumors, level IB-IV is generally recommended.[121] Involvement of level I for parotid tumors is an independent risk factor for disease-free survival.[128] For submandibular and sublingual malignancies, neck dissection of levels I to III is sufficient.[129]

The first echelon neck nodes in parotid salivary gland cancer are the intraparotideal,[28,130] followed by level IB-IV nodes.[111,130] Level IA and V nodes are only involved if other levels, especially level IB, are positive.[130] Contralateral neck nodes are generally not at risk. There is no indication for elective neck dissection or neck irradiation for T1 acinic and other low-grade tumors or ADCC (Table 49.1).[26,61,111]

Submandibular and Sublingual Gland Tumors

In most cases, elective neck dissection of levels I to III combined with a local resection is performed for submandibular tumors. SMG excision is generally uncomplicated due to the fascial capsule around the gland, which limits spread. Advanced tumors can, however, invade the adjacent mandible, lingual nerve (V3), XII, and marginal mandibular (VII) nerves. Similarly, sublingual gland malignancies necessitate a wide local excision of the floor of mouth mucosa and may require partial resection of the tongue musculature, mylohyoid, mandibular periosteum, and lingual nerve. Occasionally, a marginal or segmental mandibulectomy is necessary and requires osseocutaneous free flap reconstruction.

Minor Salivary Glands

Minor salivary gland malignancies may arise in a wide variety of locations, and site-specific surgery approaches are necessary. ADCC is the predominant histologic subtype in minor salivary gland cancer. Surgical resection is typically indicated for tumors arising in the palate, tongue, floor of mouth, oral cavity, or oropharynx, as surgical exposure is readily available and postoperative morbidity is acceptable. However, tumors arising in the nasopharynx, posterior nasal cavity, or sphenoid region may be less resectable.[131] Primary RT has been used in surgically inaccessible sites or combined with surgery because of locally aggressive tumor behavior and the occurrence of incomplete resection.[21,38,131]

The indication of elective neck treatment may depend on a prognostic index (scores 0-4) using four clinicopathologic factors associated with increased risk on positive nodes: male gender, stage T3/T4, pharyngeal location, and high grade.[29] For a score greater than 2, elective treatment of the neck nodes is indicated. The risk of occult neck disease is largest for oral cavity or oropharyngeal localizations. When PORT is indicated, it is advisable to treat the ipsilateral neck nodes as dictated by the location of the primary site and its draining lymph nodes.[132] Patients with ADCC can have a long natural history with late recurrences,[131] and consideration should be given to careful surgical reconstruction and rehabilitation because even patients who are not cured can live many years before dying of disease (Figure 49.3).[21] Occasionally, a patient may present after simple excision of a lesion, and the pathologic examination shows ADCC. If reexcision would

cause significant functional or cosmetic sequelae, RT alone may be used, and in terms of optimizing for the best probability of local control, particle beam RT such as NRT or carbon ions would be the treatment of choice, if available.[115] However, a planned simple excision is not recommended as the initial management of these tumors because of the potential for a significant volume of residual disease. Surgery alone may be used to treat early-stage hard palate lesions without evidence of positive margins, perineural spread, or bone invasion; simple excision must be avoided.[39]

RADIATION THERAPY TECHNIQUES

Pleomorphic Adenoma

The pleomorphic adenoma (benign mixed tumor) is histologically benign, occurs frequently in a relatively young population, and comprises 65% to 75% of all parotid epithelial tumors.[68] Standard therapy has been conservative (superficial) parotidectomy, with recurrence rates of about up to 6.5% after 2 years.[133-135] Simple excision results in a high recurrence rate of around 25% as focal capsular exposure occurs in virtually all cases.[136] Besides, local recurrence is more frequently encountered in younger patients and positive resection margins.[133,135] Indications for postoperative irradiation may include microscopically positive margins after surgical resection and large, deep-seated lesions that may not allow complete surgical excision with adequate margins or would require sacrificing the facial nerve and spillage during surgery. The risk of malignant transformation in a large Dutch study was only 0.15%; however, in recurrent cases, it is 3.2%.[135] The mean delay between surgery and the first recurrence was 7 years and only 2 years for the second recurrence. The risk of facial nerve paresis increases after repeated surgery.[136] Most recurrent pleomorphic adenomas are multinodular.[137] In a review of Witt et al, local control after surgery for recurrence was 63% after surgery alone and 91% after surgery with PORT.[137] RT may decrease the risk of a recurrence in case of multinodular recurrence only, not for uninodular disease.[138] The entire parotid area should be irradiated with a dose of 50 to 60 Gy in 5 to 6 weeks. In Figure 49.16, an example of a large, multicystic pleomorphic adenoma is shown, with a close safety margin and spillage during parotidectomy; PORT was indicated.

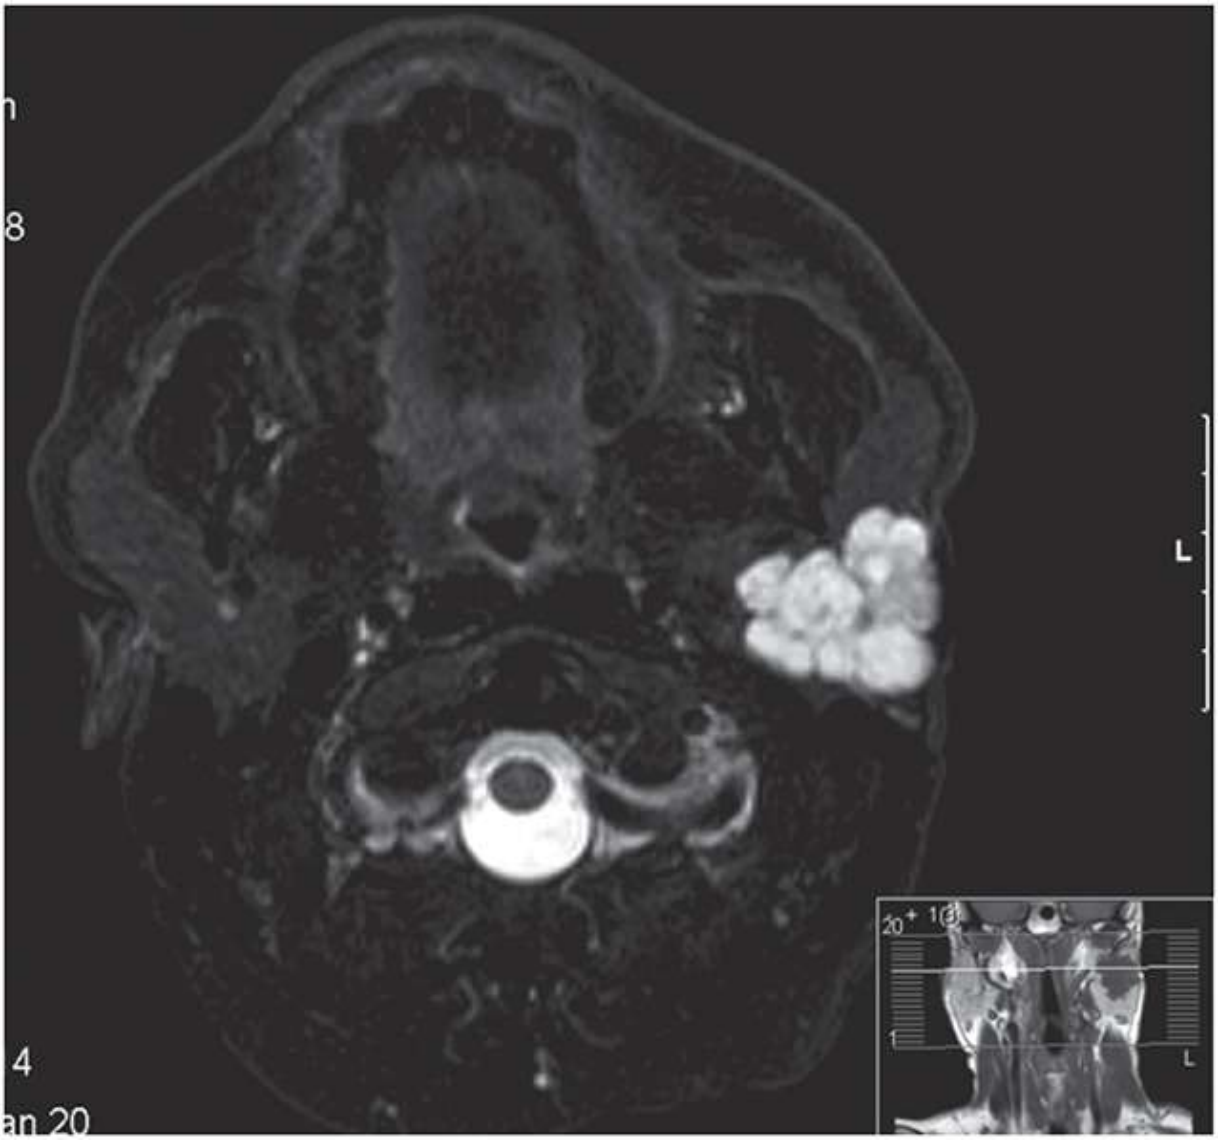

FIGURE 49.16 Multicystic pleomorphic adenoma, T2 STIR, transversal slice.

Parotid Gland

The volume of PORT is determined by pathologic findings, such as perineural invasion of a major nerve, lymph node involvement, and grade of the tumor. Typically, the entire ipsilateral preoperative parotid gland bed is delineated on the postoperative CT scan performed in a custom-made head and neck mold.[67,139] The delineation of the clinical target volumes will be individualized based on the extent and grade of the disease and surgery performed.[67] For example, in case of an aggressive tumor of the deep lobe, the parapharyngeal space and the infratemporal fossa have to be electively

covered. Although it is good practice to include the entire surgical bed, it is not necessary to treat the entire scar to full skin dose because only 1% of the patients have a scar failure.[89] For skin-invading tumors, a bolus over the scar is required. In tumors with named perineural invasion (eg, ADCC), especially in case of intraneural invasion,[101] the nerve provides a route to the base of skull. So, it is important to electively cover the entire CN pathways from the parotid up to the nerve origin at the base of the skull.[101] For perineural invasion, PORT with a dose of 50 Gy, including the base of skull, decreased the local recurrence rate from 15% with surgery alone to 5% with combined surgery and PORT in a study by Chen et al.[140] Focal microscopic perineural invasion only is not an indication for routine inclusion of the entire nerve pathway, although it would be prudent to cover the nerve foramina at the skull base, for example, the stylomastoid foramen and/or the mastoid segment of VII up to the distal genu, while sparing the cochlea, and the foramen ovale in case of ATN without including a large volume of the temporal lobe of brain. A clear relationship between dose and local control has only been found by Chen et al; a dose of 60 Gy or higher resulted in significantly higher local control rates for occult disease, and a dose of at least 60 Gy PORT is recommended[25,86,100,139] and at least 66 Gy (33 fractions) for high-risk patients with positive margins (<1 mm) and extensive PNTS.[67]

The ipsilateral neck is treated after a neck dissection has been performed for positive nodes; levels I to V should be included.[26] There is no indication for bilateral elective neck treatment.[24,28,111] The recommended PORT dose for positive nodes is at least 60 Gy (30 fractions) and 66 Gy for extranodal disease.[26] Elective irradiation of the neck should be considered for advanced T-stage, certain histologic subtypes (Table 49.1), facial nerve dysfunction at presentation, and recurrent disease. The intraparotid nodes should be included by treating the entire parotid bed in node-positive cancers.[28,129] In high-risk parotid cancer, level 1B-IV should be electively included.[26,28,127,141] A dose of around 46 to 50 Gy is recommended.[26,67]

Three basic conventional PORT approaches are widely used, depending on available equipment: three-dimensional conformal radiation therapy (3DCRT) planning procedure, electron/photon mixed technique, and intensity-modulated radiation therapy/volumetric modulated arc therapy (IMRT/VMAT) planning. The first involves unilateral anterior and posterior

oblique-wedged pair fields using 60Co or 4- to 6-MV photons (Figure 49.17A). Typical field boundaries to treat the parotid bed are the zygomatic arch superiorly, the anterior border of masseter muscle anteriorly to cover the parotid duct and accessory gland along the duct, just behind the mastoid process posteriorly, and the posterior belly of the digastric muscle near hyoid bone inferiorly.[105] These may have to be altered (enlarged) if elective treatment of lymph nodes or nerve pathways is indicated. A slight inferior angulation of the beams avoids an exit dose through the contralateral eye. A simpler technique uses homolateral fields with 12- to 16-MeV electrons in combination with photons.[77,142] Usually, 80% of the dose is delivered with electrons and 20% with 60Co or 4- to 6-MV photons to spare the opposite salivary gland, reduce mucositis, and decrease the skin reaction produced by electrons (Figure 49.17B). Yaparpalvi et al[142] compared nine conventional treatment techniques. Ipsilateral wedge pair technique with 6-MV photons, wedged anterior-posterior and posterior-anterior and supplemented by a lateral 6-MV beam, and mixed beam using 6-MV photons and 16-MeV electrons (1:4 weighted) were the most optimal, considering dose homogeneity within the target and dose to normal tissues. Electron beam (9-12 MeV) and tangential photon fields are effective conventional techniques for sparing the underlying spinal cord (< 45 Gy) and the contralateral parotid gland in elective neck RT. Conventional techniques do not allow for tissue heterogeneity (air cavity, dense bones, and tissues); underdose and overdose may be seen. However, this would not preclude efficacious PORT, where resources are scarce. Modern RT with conformal techniques like IMRT/VMAT should be the treatment of choice where available, due to superior dose homogeneity and target coverage while sparing organs at risk (OARs), especially the ipsilateral cochlea.

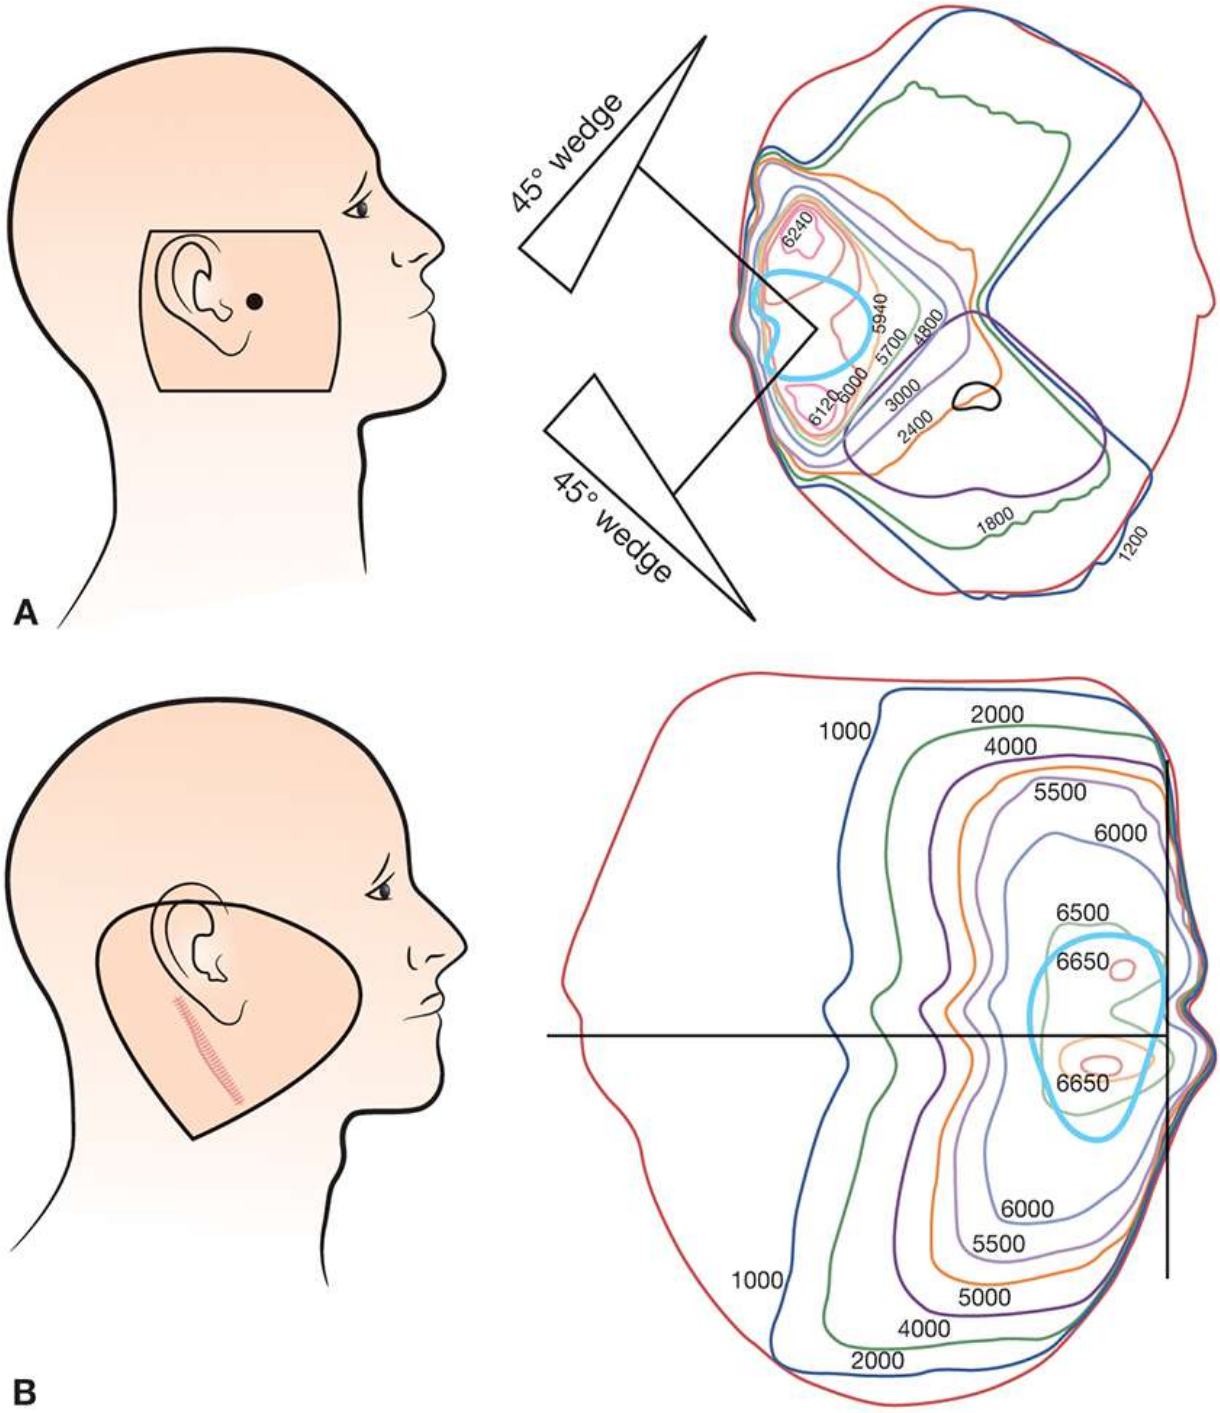

FIGURE 49.17 Conventional radiotherapy for parotid cancer. A. Unilateral wedge arrangement and isodose distribution using wedged pair. B. Ipsilateral 16-MeV electrons plus 60Co (4:1) electron beam field.

After outlining of the target volumes and critical normal tissues on the planning CT scan, a more conformal plan by the use of geometrically

shaped beams of uniform intensity may be reached.[139] More normal tissue may be spared with this technique.[139,143] In case of named perineural invasion, athin cut MRI, ideally in the treatment position, can be used to delineate the CNs be used to delineate the CNs (Figure 49.9). IMRT/VMAT can produce conformal dose distributions and steep dose gradients. Five- to seven-field inverse IMRT allows excellent coverage of the tumor with sparing of the mandible, cochlea, spinal cord, brain, temporal lobe, and oropharynx,[144] compared with 3DCRT. Especially the dose to the cochlea and eustachian tube should be limited to 45 to 50 Gy.[145,146] Compared to 3DCRT, IMRT may spare the inner ear better.[147] In the National Cancer Database, 5-year overall survival for major salivary gland treated postoperatively with IMRT or 3DCRT was, respectively, 84.7% and 80.7% (P = .06).[107] Figure 49.18 shows a comparison of 3DCRT and IMRT planning for a PORT plan for a parotid cancer, without named nerve involvement, treated with a dose of 66 Gy. The mean dose to the mastoid, meatus acusticus externus, and contralateral parotid gland was 53 and 43, 57 and 51, and 1 and 9 Gy, for 3DCRT and IMRT, respectively. The maximum dose to the cochlea was 39 and 32 Gy, respectively. In Figure 49.19, a patient with a recurrent adenocarcinoma of the parotid gland with named perineural involvement, for which a total parotidectomy was performed, is shown. The resection was incomplete. The involved facial nerve was delineated based on MRI (Figure 49.9B). A unilateral IMRT technique was used.

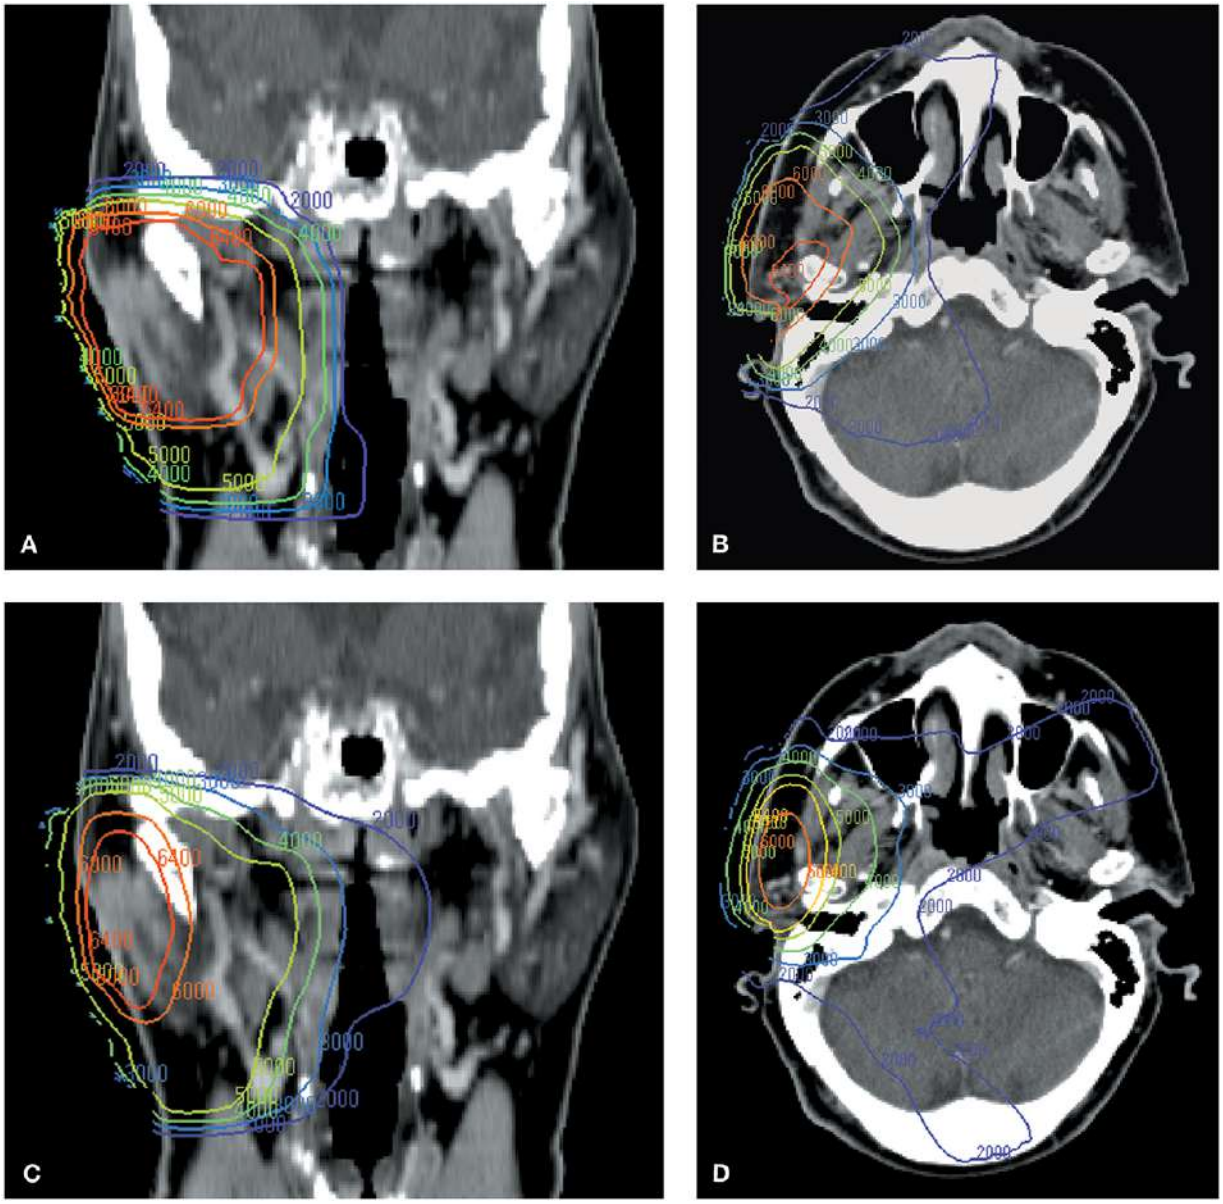

FIGURE 49.18 Postoperative radiation therapy of a parotid cancer, microscopically incomplete resected. Coronal (A and C) and transversal (B and D) dose distribution for three-dimensional conformal radiation therapy (25 × 2 Gy primary field, 8 × 2 Gy boost) (A and B) and intensity-modulated radiation therapy (inverse, 7 fields and 39 segments; simultaneously moderated accelerated radiotherapy [SMART]: 33 × 1.6 Gy primary field, 33 × 2 Gy boost) (C and D).

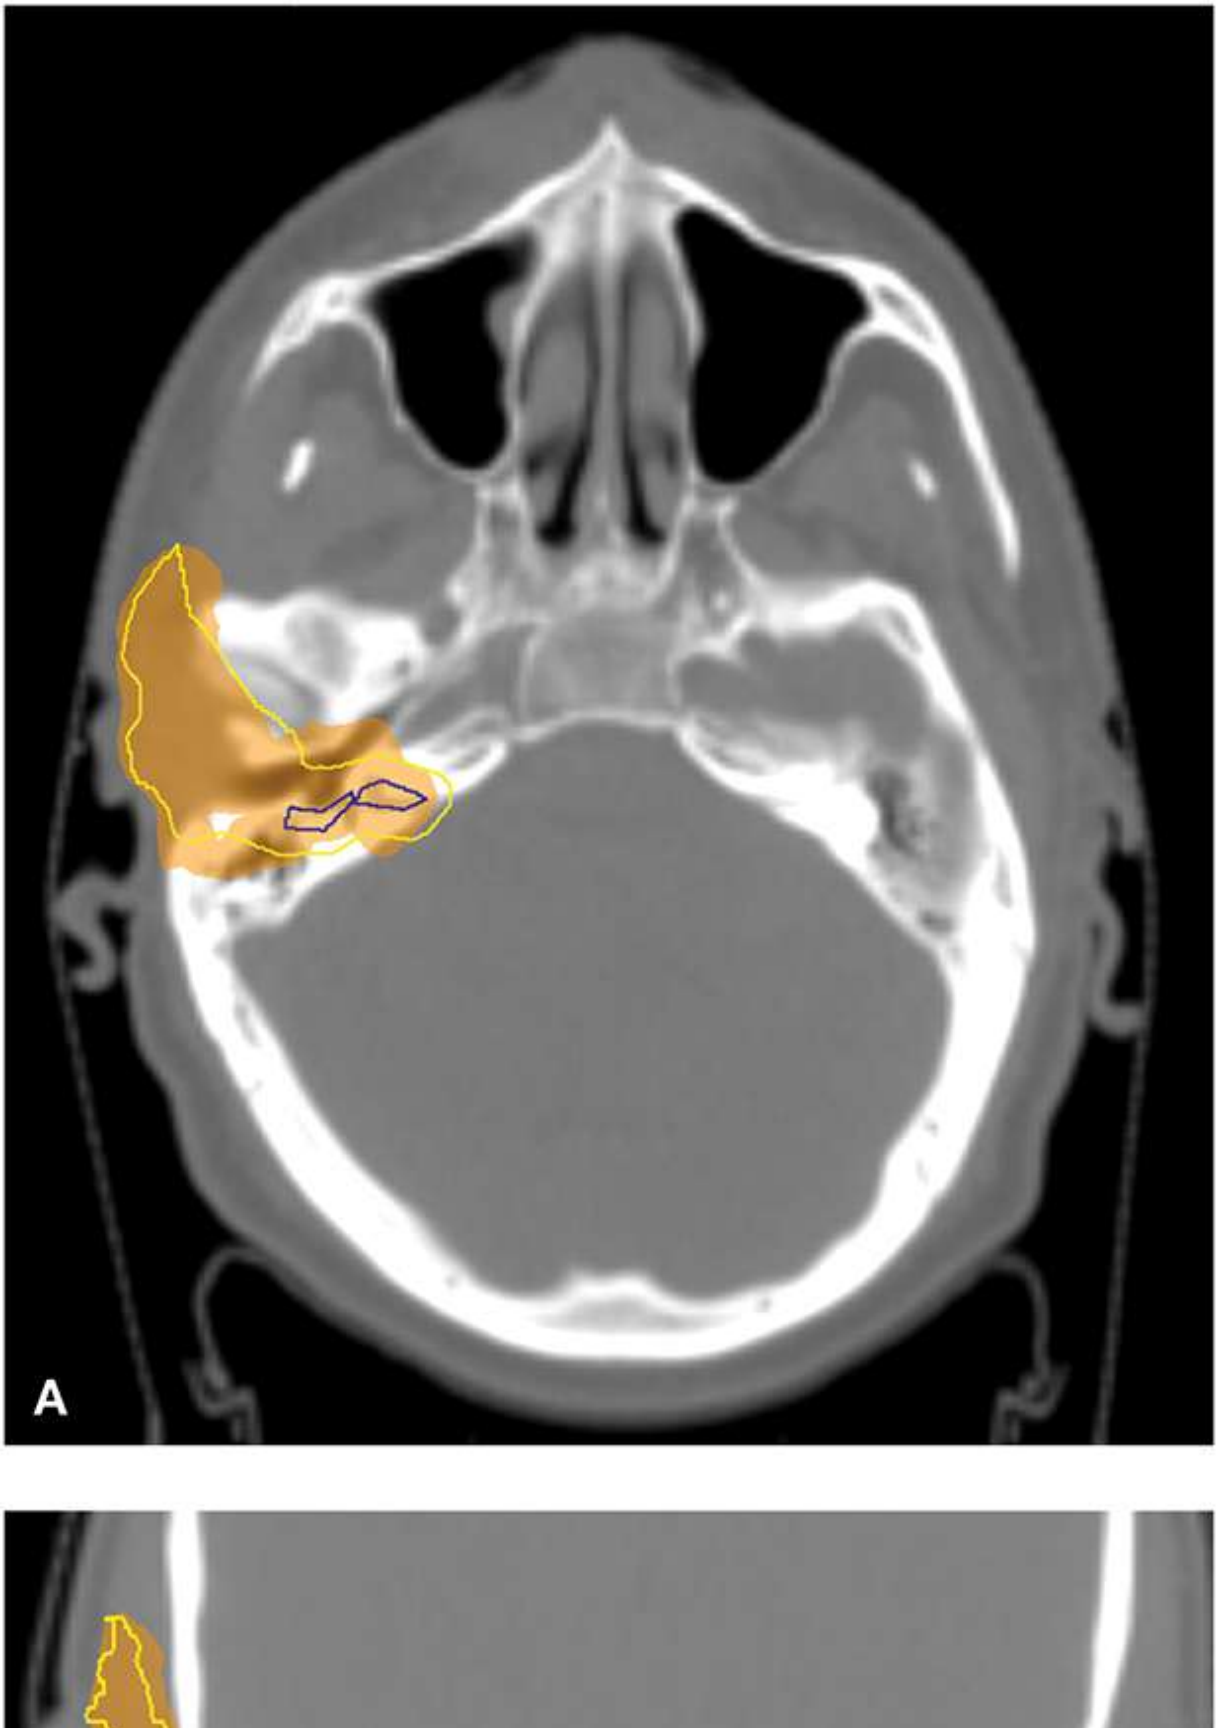
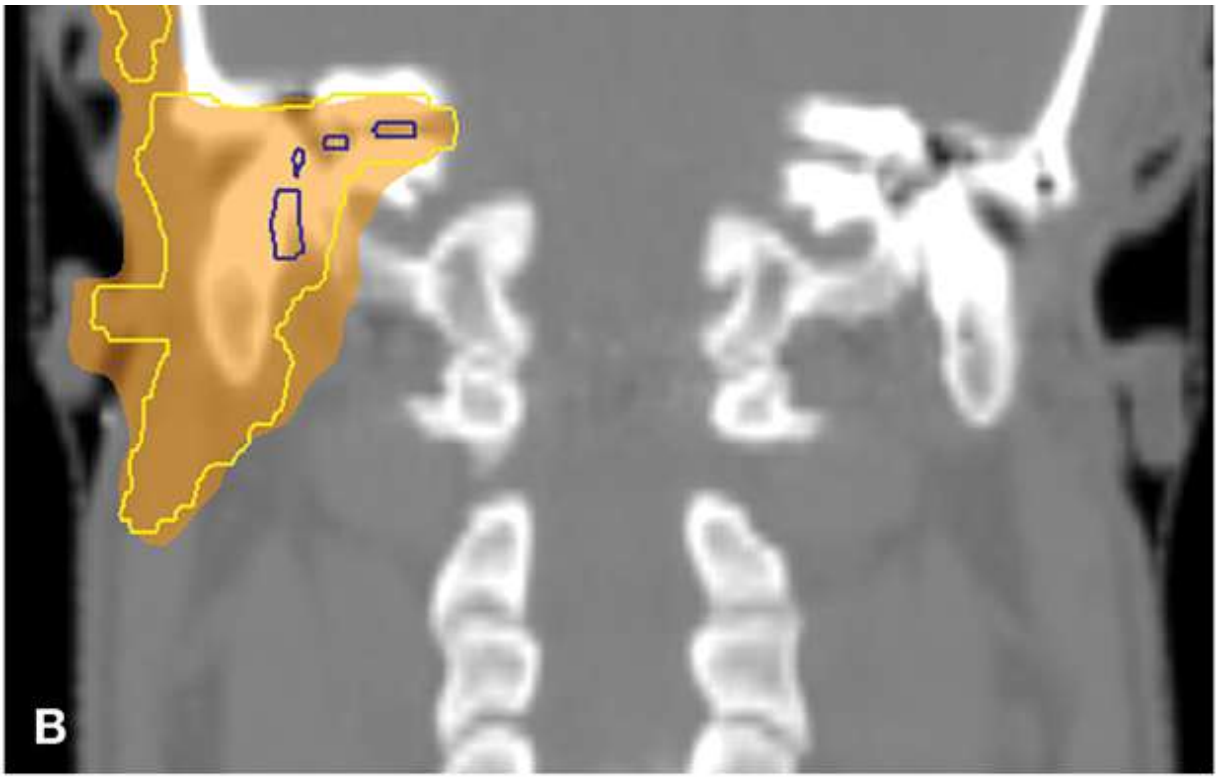


A



B

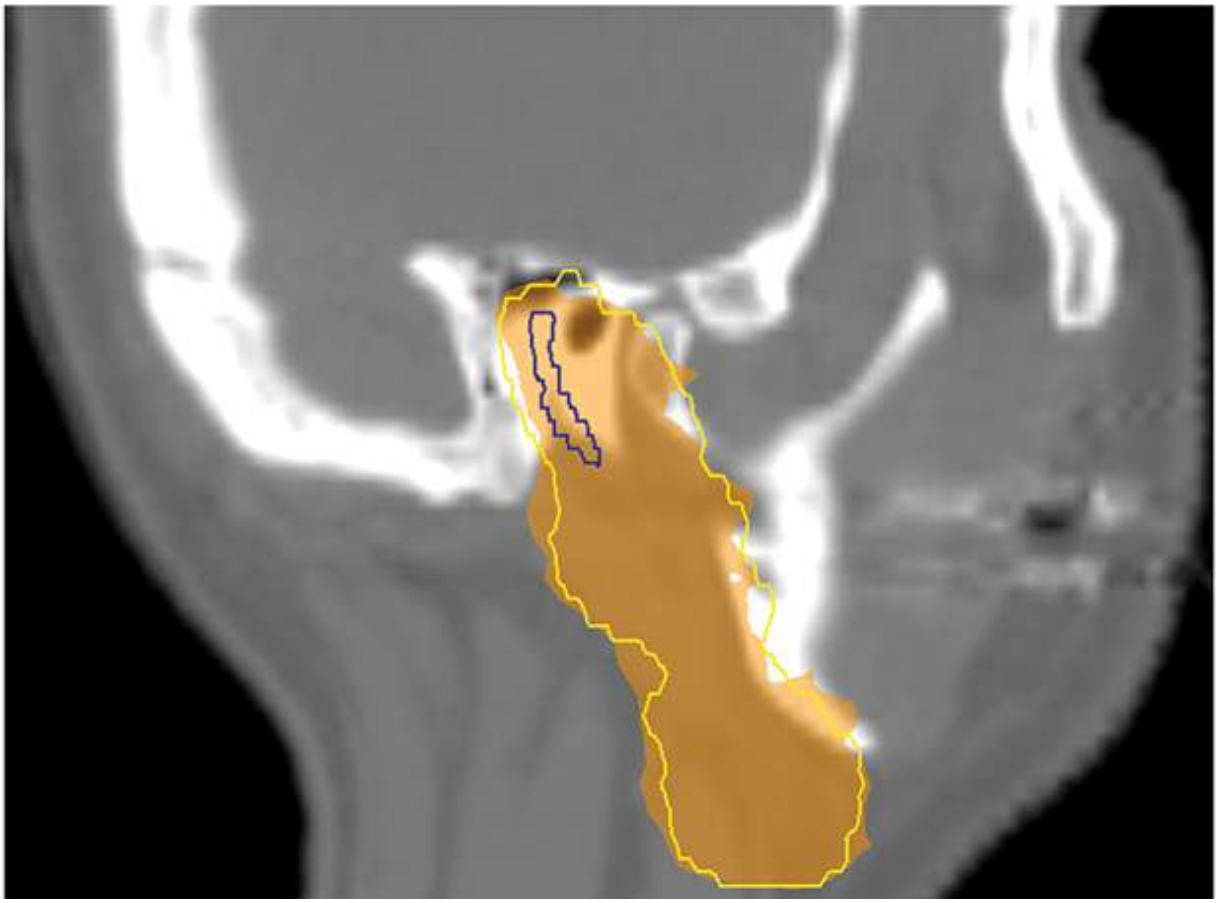


FIGURE 49.19 Recurrent adenocarcinoma of the parotid gland with named nerve involvement (nVII, in blue), delineated on the base of magnetic resonance imaging (Figure 49.9B). A unilateral intensity-modulated radiation therapy technique was used, in yellow 50-Gy isodose (boost not shown): transversal (A), coronal (B), and sagittal (C) planes.

Submandibular Gland

Except for small acinic cell, other low-grade tumors, and ADCC (see Table 49.1), the neck node level IB-IV[141] should be irradiated electively, following the indications outlined for parotid tumors; technical considerations are similar. Bilateral fields may be required for tumor extension toward the midline, although they should be set up to spare the contralateral salivary glands. Five-year locoregional control was significantly higher for a dose of more than 56 Gy in a study by Mallik et al.[148] If there is named perineural invasion of a major nerve, a tumor dose of 60 to 66 Gy in 6 to 6.5 weeks is recommended with the highest dose (66-72 Gy) to the grossly identifiable nerve involvement (per MRI), and electively the nerve path to the base of skull should be treated. For ADCC of the SMG with only focal microscopic perineural invasion, an attempt to encompass the base of the skull near the foramen ovale would require a significant change in the treatment volume and may not be warranted because of potential morbidity of including the entire ipsilateral parotid gland and the low rate of relapse at that site.[131] Sparing of the parotid while electively treating up to the inferior alveolar nerve foramen of the mandibular ramus is adequate. An example of 3DCRT for a T2 ADCC of the SMG is shown in Figure 49.20.

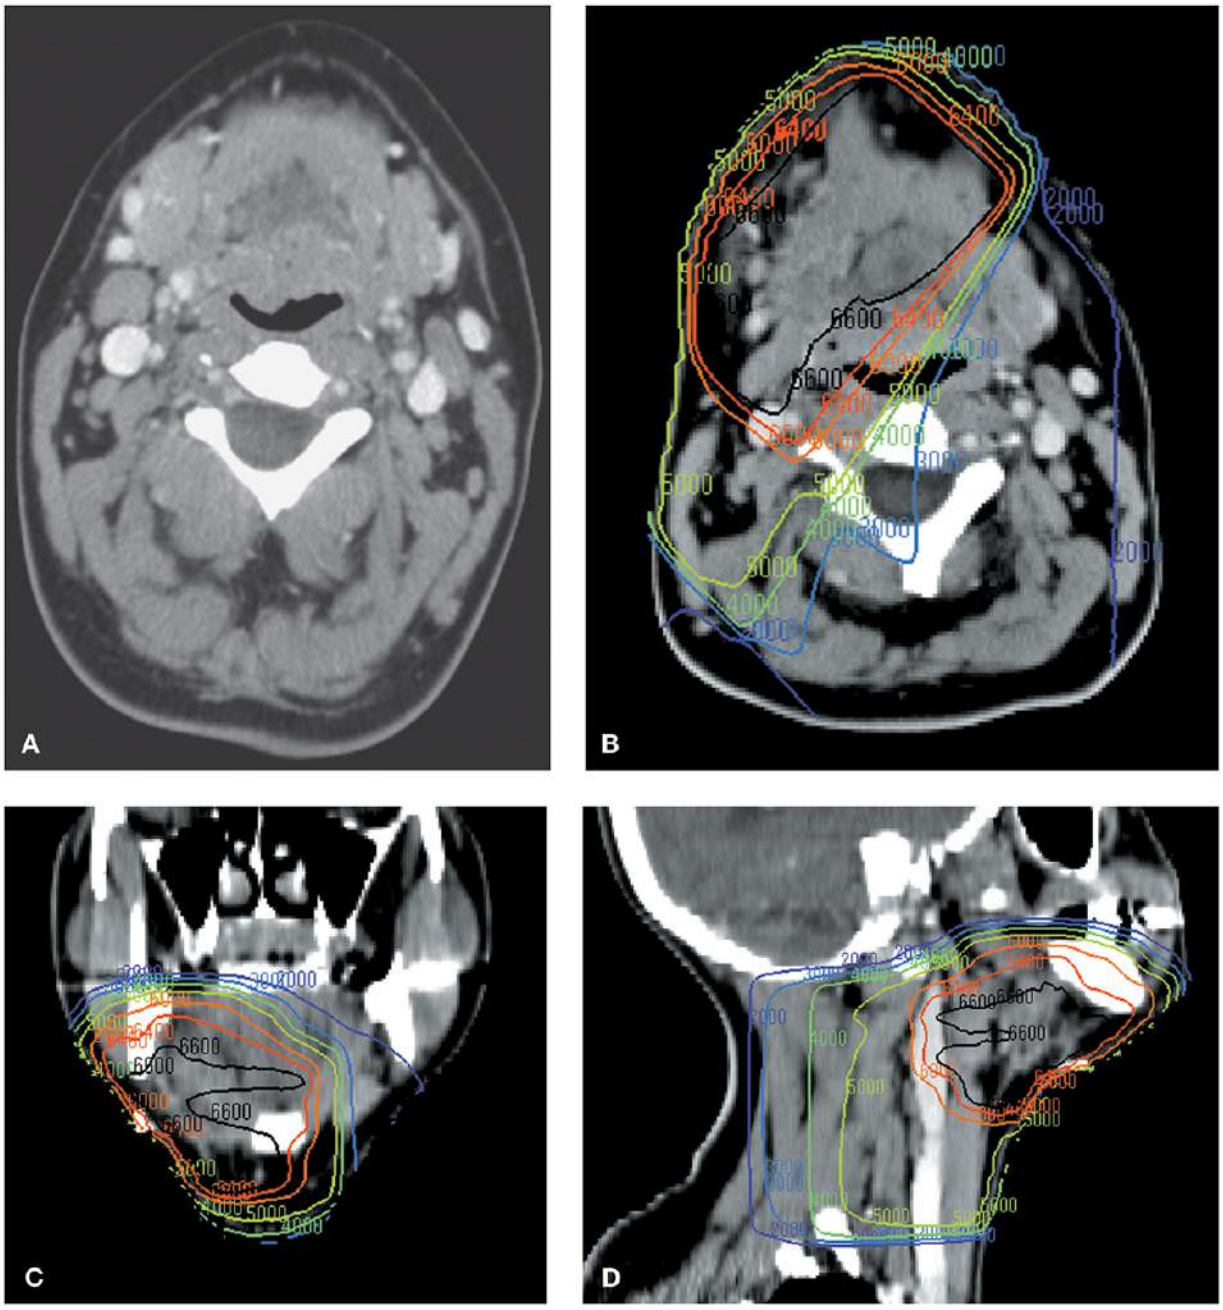

FIGURE 49.20 Dose distribution for a T2N0 adenoid cystic cancer of the right submandibular gland. Computed tomography performed before microscopically incomplete local excision (A). Three-dimensional conformal radiation therapy, three fields (one right and two left oblique): 25 × 2 Gy, 5 × weekly primary tumor and level I to III nodes, 8 × 2 Gy boost; transversal (B), coronal (C), and sagittal (D) planes. Mean dose to contralateral submandibular gland is 27 Gy.

Sublingual Gland

These tumors are mostly malignant and mostly ADCC, and most patients present with advanced disease and high grade but with a relatively lower risk of positive neck nodes. Aggressive surgery is required, with PORT in almost all cases,[39,149] with elective treatment of levels I to III.[140] In case of named nerve involvement, the lingual and/or XII nerve should be included in the RT portals.

Minor Salivary Glands

The RT technique for treating minor salivary gland tumors depends on the involved location and two additional considerations. First, when a named branch of a CN is involved by ADCC, the nerve pathways to the base of the skull should be electively treated. Second, for tumors of the paranasal sinuses, the base of the skull is electively included because of its proximity to the tumor bed. In case of ADCC with perineural invasion, IMRT may reduce the high-dose volume, compared to conventional bilateral opposed fields; Figure 49.21 shows an example for a patient with a minor salivary gland cancer of the palate. IMRT is a useful strategy for irradiating minor salivary gland sites such as the ethmoid sinuses while sparing the optic pathways.[150]

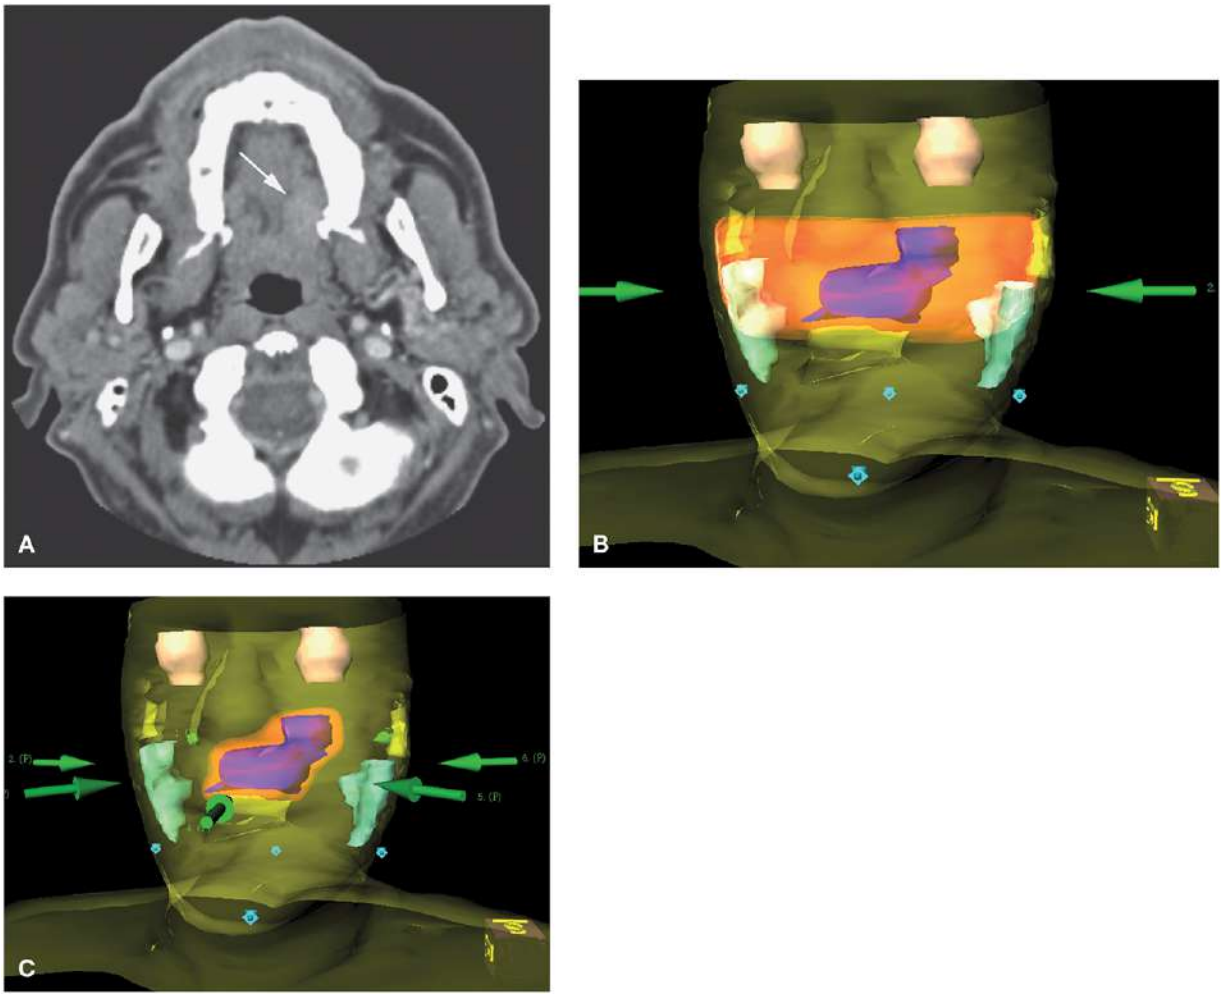

FIGURE 49.21 T2NO adenoid cystic cancer of the palate with major perineural invasion. Computed tomography performed before local excision (A, arrow: tumor); target includes right palatinus major nerve until base of skull. Dose distribution (25 × 2 Gy primary field) in transversal planes; conventional bilateral opposed fields (B); intensity-modulated radiation therapy (7 fields, 40 segments) (C); 95% isodose of 50 Gy in red.

Also, because the incidence of lymph node metastases is usually lower for ADCC than that for squamous cell carcinomas of similar size, the RT fields are rarely extended to cover nodal regions for N0 cancers. Indications for elective treatment of the neck nodes may depend on a scoring system.[26,29] Typically, for male patients with a T_3/T_4 N_0, pharyngeal site tumor neck nodes should be treated prophylactically.[131] In minor salivary gland cancers of the oral cavity, elective radiation of the neck nodes is indicated only for high-grade cancers. PORT is indicated after resection of metastatic neck lymphadenopathy.

For patients receiving PORT after surgical resection, a dose of 60 to 63 Gy is given for close margins and 66 Gy for microscopically positive margins. For gross residual disease after surgery or for lesions treated with RT alone, a total dose of 70 Gy is recommended at 2 Gy per fraction, although NRT or carbon ion should be used if available for optimal outcomes. Elective dose to the relevant nodal levels is in the range of 46 to 50 Gy.[26,131,151]

RESULTS OF THERAPY

Surgery Plus or Minus Postoperative Radiotherapy

Tables 49.7 to 49.9 list local control rates and 5- and 10-year survival rates for several series reporting the surgical, RT, and combination treatment of carcinomas of the major and minor salivary glands. Little adverse effect of delay between surgery and PORT may be predicted for what are, in general, slow-growing salivary gland cancers. In three studies, one concerning submandibular cancer,[61] one for minor salivary gland,[131] and another for ADCC,[86] impaired locoregional control rates were seen for a delay of more than 6 weeks, which was not confirmed in the Dutch study.[26] The prognosis for children with a malignant salivary gland cancer (mostly MEC of the parotid gland) is excellent, with a 5-year overall survival of more than 90%.[9] Most are treated with surgery alone because of the possible risk of radiation-induced malignancies.

Long-term follow-up is recommended because failures may appear after 5 years, especially for minor salivary gland tumors and ADCC.[8,21,23,86] Recurrent tumors in general are more difficult to control than are primary ones, so initially optimized locoregional control rates should be the goal. Because of high rates of local failure of approximately 40% for parotid gland, 60% for SMG, and 65% for minor salivary glands with surgery alone,[7] many institutions have advocated PORT especially to reduce the incidence of local failure. Local tumor control appears to be improved by the combination of surgery and PORT, although randomized controlled trials have not been performed. Evidence in favor of PORT is based on retrospective studies and matched-pair analyses. In the matched-pair study by Armstrong et al,[108] PORT significantly improved locoregional control (from 17% to 51% for stages III-IV), not for stages I and II major salivary gland cancer. Locoregional control for patients with positive nodes increased from 40% to 69%. In most studies, an imbalance in prognostic factors is seen comparing surgery alone with combined therapy, favorable surgery alone. Despite this imbalance, locoregional control with combined surgery and PORT is superior to surgery alone for patients with negative

prognostic factors, irrespective of site.[21,26,61,63,85,86,88,105,108,148] This was also shown for low-grade salivary gland cancer.[152] In the nationwide Dutch study, the relative risk for surgery alone, compared with combined treatment, was 9.7 for local recurrence and 2.3 for regional recurrence.[26] PORT is particularly effective if there are close (<5 mm) or microscopic positive resection margins, enhancing local control from around 50% to 80% to 95%.[26,86,87,118] Comparable results are noted for T3-T4 tumors and pathologically confirmed bone and perineural invasion.[26,63,85,148] For ADCC with perineural invasion, PORT increased 10-year local control rates from 30% to 80% in a study by Chen et al.[86] However, for a T1 or T2 low-grade tumor that was completely resected with no bone, lymph node, or perineural invasion, surgery alone will result in more than 90% 10-year local control rate and PORT is not indicated.[26]

Treatment results may also depend on histopathologic status. However, after review, histologic type may change, even among experienced pathologists. In general, the best prognosis is shown for *acinic cell* and low- to intermediate-grade MEC, with a 15% risk of distant metastases after 10 years and a 10-year locoregional control rate of around 85%. Ten-year overall survival is around 80% and 65%, respectively.[7,21,36,69] PORT is indicated for the high-grade group.[21,69] *Squamous cell* and *undifferentiated* tumors have been associated with a 10-year overall survival of 35% or less, caused by a high risk of distant metastases and locoregional recurrence of 35% and 50%, respectively.[7,21,87] PORT is indicated in all cases to improve locoregional control. The intermediate-risk group consists of *cancer ex pleomorphic adenoma and* ADCC. Distant failure after 10 years is around 35% after initial staging with CT scan.[21,34,105] Although the risk of nodal recurrence is low (5%-10%), local recurrence and neural pathway recurrence are diagnosed more often (20%-50%) in ADCC. PORT is indicated in almost all cases. In cancer ex pleomorphic adenoma, 5-year local control rates were 75% and 49% for yes or no PORT, respectively, in a study by Chen et al.[105] A precipitous decrease in relapse-free survival is noted among 5 (around 70%), 10 (around 50%), and 15 years (around 45%) for patients with ADCC, which are well known for late recurrences.[21,63,86] Significant improvement was reported in local control for ADCC with combined surgery and PORT in several studies,[64,86,103,104] regardless of site.

Local tumor control rates with combined modality therapy for these tumors approach 85% to 90% at 10 years.

In the WHO classification of 1991, among others, three new subtypes were described that are diagnosed relatively frequently. *PLGA* is situated predominantly in the palate. The vast majority is cured with a wide local excision, without a need for elective treatment of the neck. In the large SEER database, the 10-year disease-specific survival was more than 95%, and only 20% of the patients were treated with PORT.[72] SDC is a very aggressive disease, predominantly arising in the parotid gland. PORT is indicated in all cases. Most patients die of distant disease, despite often successful locoregional combined therapy. PORT improves locoregional control.[73,74] Because of a high percentage of distant metastases, 5-year survival is only around 30%.[73] The prognosis correlates with HER2/neu receptor status. HER2/neu overexpression correlates with decreased disease-specific survival.[74] *Epithelial-myoepithelial* cancers have a very favorable outcome, with the risk of distant metastases below 5% and a disease-free survival of more than 80% after 10 years. However, local recurrences may be seen in one out of three; PORT is indicated in case of incomplete margin, tumor necrosis, lymphatic invasion, and myoepithelial anaplasia.[76] In *basal cell adenocarcinoma*, PORT may increase overall survival for T3-T4 cases.[78]

Minor salivary gland tumors of the oral cavity have a more favorable prognosis than paranasal sinus tumors (maxillary and ethmoid sinus and nasal cavity), possibly due to dosimetric limitations of 3DCRT and initial extent of involvement at presentation.[131] Patients with hard palate lesions tend to be diagnosed when they have small asymptomatic disease, which is easily detected on physical examination. On the other hand, paranasal sinus tumors usually do not cause symptoms until they are locally advanced. The surgical approach for these tumors is more difficult, with a greater chance for leaving behind residual disease, leading to higher recurrence rates. A combined approach with surgery and PORT is recommended, with 10-year local control rates around 85% (see Table 49.9).[37,131,151]

Primary Radiotherapy

The poor results for salivary gland cancer with RT alone in several series have been attributed to the use of primary RT for patients with locally advanced lesions or distant metastases at presentation, who were essentially treated for palliation. In addition, margin-negative surgery as a sole modality is effective only in favorable low-grade histology with an operable presentation in a healthy patient. This imbalance effectively biases the outcomes in favor of surgery over primary RT. Locoregional control rates after conventional photon or electron therapy (low LET RT) are around 25%.[112,115] Ten-year locoregional control depended on T-stage in a series of the University of Florida, 72% and 20% for T1-T3 and T4, respectively.[85] For treatment with photons with curative intent, a clear dose-response relationship has been described.[26,153] A dose of at least 66 to 70 Gy should be adapted, resulting in a 5-year local control of 50% to 70%, although late recurrence was observed. The generally slow rate of regression of advanced salivary gland tumors and inadequate results with conventional RT have made them a logical target for alternative approaches, such as high LET particles (NRT and carbon ions), due to the superior RBE.

Particle Therapy

Patients with inoperable primary or recurrent major or minor salivary glands were included in the RTOG-MRC randomized phase III clinical trial.[115] Patients were randomized between 70 Gy for 7.5 weeks or 55 Gy for 4 weeks of photon therapy (x-ray radiation therapy [XRT] = low LET) and high LET fast NRT (16.5-22 nGy in 12 fractions over 4 weeks). The study had to be stopped because of ethical issues raised by a statistically significant difference (2- to 3-fold in favor of NRT) in 2-year locoregional control, after the inclusion of only 32 patients during a planned interim analysis. The review board prohibited further accrual of patients to the randomized study, given the magnitude of the efficacy in favor of NRT. The 10-year locoregional control was 17% after XRT and 56% after NRT.[115] However, there was no statistically significant improvement in survival (15% vs 25%), perhaps due to delayed onset of distant metastatic disease among survivors following the successful local treatment, as well as the small number of patients analyzed.[115] Late morbidity was somewhat higher for NRT, given the technical limitations of primitive NRT equipment

available at the majority of centers that participated in this study. For example, most lacked a multileaf collimated beam, couch rotation, and an isocentric gantry, which were available only at select centers. Primary NRT in salivary gland disease is reserved for macroscopically residual disease after surgery (R2) and unresectable tumors with local control rates far superior to conventional XRT. Stannard et al have published results of 335 patients treated with NRT.[114] The 5-year locoregional control was 80% after R2 resection, 55% for unresected cases, and 40% for irresectable cases. The risk of late grade 3 to 4 morbidity was 20%. Douglas et al performed a retrospective review of 279 patients treated at the University of Washington with fast NRT for salivary gland cancers, 263 of which had gross disease at the time of treatment. The 6-year cancer-specific survival and locoregional control were 67% and 59%, respectively, and grades 3 to 4 toxicity was 10%.[154] In small retrospective studies, modern XRT has been suggested to have similar efficacy as NRT but with less toxicity. Spratt et al performed a retrospective review of 27 patients with unresectable salivary cancer treated with XRT to a median dose of 70 Gy with IMRT or 3DCRT. Of these, 18 patients received chemotherapy. The 5-year locoregional control was 47%, which appears to compare favorably to the NRT arm of RTOG-MRC study.[115,155] However, interstudy comparisons are limited by the tumor stage heterogeneity and are fraught with selection bias, as well as other well-known inherent limitations of retrospective analyses.

Fundamentally, the x-ray beam and the neutron beam used in the RTOG-MRC study have not changed since their discovery. However, highly conformal techniques such as IMRT/VMAT have become the standard of care by conforming radiation around organs at risk to significantly reduce toxicity. The efficacy of XRT using modern techniques could only be possibly improved through superior targeting in situations that were previously limited by the historical XRT techniques, such as PNTS via CNs to the skull base and middle cranial fossa. Salivary gland cancers in general are well known to be relatively chemorefractory. Logically, combining XRT with an ineffective chemotherapy is not expected to improve the efficacy of XRT, and this was demonstrated in a large retrospective study of over 2,000 patients utilizing a national database.[112] The argument that modern XRT techniques such as IMRT/VMAT combined with chemotherapy could be as effective as NRT remains to be tested. Given the evidence from the RTOG-

MRC study, NRT (and other high LET modalities such as carbon ion) is the proven standard for superior local control in cases of unresectable salivary gland tumors.[115] Recent technical advances at the University of Washington have enabled the clinical implementation of intensity-modulated neutron therapy (IMNT) to leverage the therapeutic advantage of NRT while limiting dose and, therefore, toxicity to adjacent OARs as compared to historical 3D conformal NRT (Figure 49.22).[156]

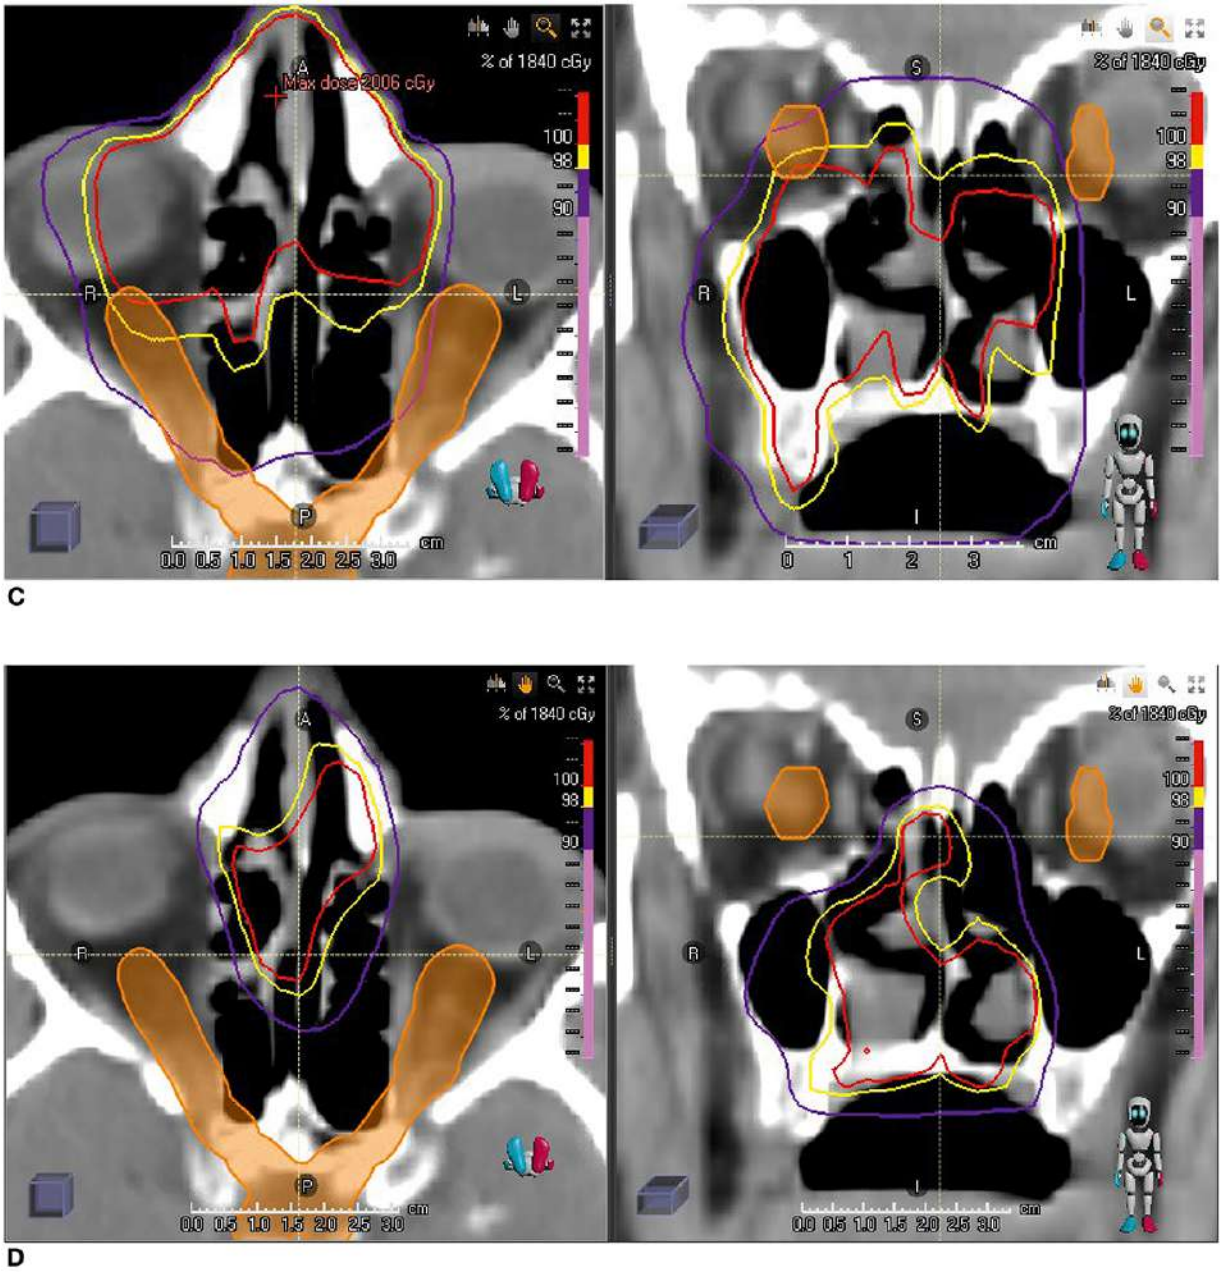

FIGURE 49.22 Three-dimensional (3D) fast neutron radiotherapy (NRT) plan (A) compared with intensity-modulated neutron radiotherapy (IMNT) plan (B) for a patient with advanced tongue base adenoid cystic carcinoma. Parotid gland (orange color wash) sparing is seen (green isodose line), while maintaining target cover (red isodose line). IMNT (C) versus 3D plan NRT (D) for postoperative sinonasal mucoepidermoid cancer. Optic nerves (orange color wash) being spared by IMNT (purple isodose line) while maintaining target cover (yellow isodose line). (Reproduced from Anderson AC, Stewart RD, Sponseller PD, et al. Intensity-modulated neutron therapy (IMNT) for head and neck cancer: early toxicity outcomes. *Int J Radiat Oncol Biol Phys*. 2023;117[2 suppl]:e561-e562.)

Treating disease involving the base of skull, such as cavernous sinus and Meckel's cave in the middle cranial fossa with historical 3DNRT was previously limited by dose to the adjacent temporal lobe of brain that is more sensitive to high LET therapy. Given this greater sensitivity of brain and neural structures to NRT, the dose to the targets adjacent to the brain (with cavernous sinus, Meckel cave, and/or middle cranial fossa involvement) was limited to two-thirds of the total prescribed dose, and as a result, excess skull base failures were noted. In an effort to improve results for tumors invading the base of skull, several new techniques were developed. A combination of NRT with a gamma knife stereotactic radiosurgical boost has been used for tumors invading the base of skull.[157] Compared to a historical control group, treated with NRT only, in 34 patients treated with combined NRT and gamma knife, the actuarial local control rate at 40 months was 82% versus 39% for the control group. Complication grades were equal.[157]

Alternatively, a proton beam (PBT) boost allows for a highly conformal and fractionated course that may be less damaging to the brain than a single high-dose gamma knife treatment and is superior for larger and irregular targets that are underdosed by NRT at the skull base.[158] However, with the recent availability of IMNT (since the fall of 2022), the vast majority of cases receive the entire prescribed dose with NRT and do not require a boost dose either through gamma knife or PBT.

Carbon ions have the theoretical advantage of higher biologic effectiveness similar to other high LET RT such as NRT, however, with a more precise targeting capability than historical 3D conformal NRT. In Heidelberg, 309 advanced ADCC, 60% T4, and 37% paranasal location were treated with a combination of photons (median 50 Gy) and carbon ions (median 24 GyE).[159,160] Five-year local control for R1 (29%), R2 resection (44%), and inoperable tumors (28%) were ±80%, 56%, and 51%, respectively. Toxicity was moderate. In a subset of R2 resection and inoperable cases (>90% T4, paranasal, parotid gland with base of skull invasion, nasopharynx), combined IMRT with carbon ion boost (n = 58) was compared with IMRT only (n = 37). Although not randomized, 5-year local control with carbon ion boost was significantly better (60% vs 40%).[160] In a series from Japan, primary carbon ion therapy (n = 40) was compared with primary PBT (n = 40) for advanced ADCC. Local control

after 5 years for T4 and inoperable cases was equal (68%) for both treatment options.[117] However, the incidence of late grade 3 or more late complications in their study was high (61% for protons and 39% for carbon ions) and dose dependent (>72 GyE).[117] Because of the favorable Bragg peak effect, PBT may be used to decrease toxicity, especially in the cases of completely resected tumors where PORT may be indicated. Given the lower dose to OARs, acute toxicity was lower in a retrospective study comparing protons with photons in pediatric salivary gland tumors.[161] However, in terms of efficacy, proton beam is also a low LET beam like XRT, although it has approximately 10% higher biologic effectiveness than XRT. The magnitude of biologic superiority (local control) of NRT is more than 3-fold compared to the XRT as per the RTOG-MRC study.[115] The main drawback with high LET RT consideration is the limited availability of these centers, with IMNT available at only one site in the world (University of Washington, Seattle) and a limited number of carbon ion facilities in Europe and Asia. Data concerning PBT for salivary gland cancer are scarce, and there is no comparative study versus NRT.

In conclusion, carbon ions or NRT should be taken into account, if available, for unresectable, residual, or recurrent salivary gland tumors.[115] Despite high locoregional control, historically, late toxicity was of concern with older NRT techniques that are no longer in operation. Despite the lack of published data, modern conformal high LET techniques such as IMNT are expected to maintain high local control while minimizing toxicity to adjacent OARs.

SYSTEMIC THERAPY

The rarity of salivary gland neoplasms and their localized nature provides limited opportunities for conducting randomized trials of systemic therapy. Most published studies are limited to small, single-arm trials and generally include different histologic subtypes; the heterogeneous natural history of disease within salivary neoplasms makes the determination of standard-of-care therapy challenging.

For *curative-intent* treatment of localized disease, patients are treated definitively with surgery and/or radiation, and the role of systemic chemotherapy is not established in this setting. While some small case

series and retrospective studies have suggested a benefit for postoperative concurrent chemoradiation, there is no consensus on its routine use outside a clinical trial at this time.[162,163] A retrospective study utilizing the National Cancer Database analyzing more than 2,000 patients who underwent resection of major salivary gland cancer with at least one high-risk feature (T3-T4 stage, N1-N3 stage, positive surgical margins) demonstrated that patients who received adjuvant chemoradiation had inferior overall survival compared to patients who underwent adjuvant radiation alone in a multivariate analysis.[112] The role of adjuvant chemoradiation is being investigated prospectively in the completed randomized phase II/III clinical trial, RTOG 1008 (NCT01220583), comparing radiation with chemoradiation using weekly cisplatin in high-risk patients following surgical resection.[164] In Europe, GORTEC 2016-02 (NCT02998385) is a similarly designed trial that includes both high-risk resected salivary gland and nasal minor salivary gland carcinomas and is expected to shed light on this unanswered clinical question.[165]

For patients with recurrent or metastatic salivary gland tumors, systemic therapy is given with *palliative intent*. Given the indolent nature of some salivary gland neoplasms, the decision to start systemic therapy should be individualized. In general, systemic therapy can be considered in patients with symptomatic disease not amenable to local therapy or with tumor growth that may compromise organ function. In select patients, such as those who are asymptomatic with low-volume indolent disease such as ADCC, observation may be appropriate. There is not currently a preferred treatment regimen or consensus standard-of-care first-line therapy that demonstrates significant survival advantage in this setting; there are no randomized data demonstrating the benefit of preventive treatment compared to best supportive care.

Some conventional chemotherapy agents have demonstrated activity in advanced salivary gland tumors, mainly in small phase II trials or case series, including cisplatin, paclitaxel, vinorelbine, epirubicin, mitoxantrone, and methotrexate.[166,167] A small phase II trial of 36 patients comparing vinorelbine and cisplatin with vinorelbine showed higher response rate (44% vs 20%) with combination therapy.[168] A phase II study of 32 patients were treated with gemcitabine and cisplatin (or carboplatin if prespecified contraindications to cisplatin were met) showed a response rate of 24%,

which fell below the prespecified trial criteria to be declared active.[169] In both trials, multiple tumor histology types were included. A phase II trial of single agent paclitaxel conducted by the Eastern Cooperative Oncology Group treated 45 patients, with 8 partial responses seen among patients with mucoepidermoid or adenocarcinoma histology for a response rate of 26%; however, no responses were seen for patients with ADCC.[170] The combination of carboplatin and paclitaxel was studied in 14 patients, with 2 (14%) patients demonstrating a partial response.[171] Overall, these prospective experiences are small and characterized by histologic heterogeneity and modest rates of objective responses. Although these studies often report high rates of disease stabilization, it can be difficult to discern whether this observation is attributable to drug activity or the inclusion of relatively indolent disease subsets.

More recently, molecularly targeted agents have been shown to be active in a select group of salivary gland cancers treated in the palliative setting. These approaches warrant additional and ongoing study in salivary neoplasms, especially given limited success with conventional chemotherapy. Lenvatinib, a multitargeted tyrosine kinase inhibitor, has been evaluated in two phase II trials for ADCC, demonstrating modest efficacy with partial responses seen in 11.5% and 15.6% of patients treated (three and five patients, respectively).[172,173] Toxicity necessitating dose reductions or treatment discontinuation was relatively common in both studies.

Next-generation sequencing and immunohistochemical biomarker testing can be considered to evaluate potential eligibility for other targeted therapies in advanced/metastatic salivary gland cancers. Many advanced salivary gland tumors are androgen receptor positive and may benefit from androgen deprivation therapy, such as leuprolide and bicalutamide, enzalutamide, and abiraterone.[174-176] In salivary gland neoplasms that overexpress HER2, small series or basket clinical trials have demonstrated activity with anti-HER2 agents including trastuzumab (either alone or in combination, such as trastuzumab and docetaxel), ado-trastuzumab emtansine, fam-trastuzumab deruxtecan, and combined pertuzumab and trastuzumab[177-181] The role of ado-trastuzumab emtansine is similarly being evaluated in patients previously treated with a prior HER2-targeted therapy.[182,183]

In the rare situation that salivary gland cancers harbor *NTRK* gene fusions (such as in MASC), *BRAF* V600E mutations, or *RET* gene fusions, oral tyrosine kinase inhibitors targeting these alterations can be considered. The Food and Drug Administration (FDA) has approved larotrectinib and entrectinib for the treatment of patients with *NTRK* gene fusion–positive tumors, with phase I/II studies of these agents showing high objective response rates in patients with *NTRK* gene fusion–positive cancers.[184-186] In addition, the FDA has approved the combination dabrafenib/trametinib for all advanced *BRAF* V600E–mutated tumors. Selpercatinib similarly has FDA approval in all advanced *RET* gene fusion–positive solid tumors, with ongoing evaluation in the LIBRETTO-001 trial (NCT03157128) for non–lung or thyroid solid tumors.[187]

Finally, based on the results of the KEYNOTE-158 trial, patients with either previously treated tumor mutational burden high (TMB-H) or microsatellite instability high (MSI-H)/deficient mismatch repair (dMMR) advanced salivary gland cancer are eligible to receive pembrolizumab. This trial included three patients with salivary gland cancer and TMB-H and two patients with MSI-H/dMMR.[188,189]

While the number of targeted agents is increasing rapidly, ongoing evaluation of these approaches warrants further study to evaluate the efficacy, risks, and benefits to inform appropriate patient selection and use.

SEQUELAE OF TREATMENT

The most notable complication of the treatment of parotid malignancies is facial nerve paralysis, which is often caused by the initial or repeated surgical procedure. However, various series have shown that sacrifice of VII is rarely necessary, unless the nerve is directly involved by tumor, particularly when PORT is given.[68,87] When sacrifice of VII is required, nerve grafting and PORT achieve comparable nerve function compared with unirradiated graft despite more negative prognostic factors.[118] Other postoperative sequelae, such as salivary fistulae, “first-bite” syndrome—where the patient experiences pain and/or jaw stiffness with only the first bite of their food—and neuromas of the greater auricular nerve, are sometimes seen. Frey syndrome (ie, gustatory sweating) may occur in a few patients after parotid surgery, but it is rarely bothersome.[90]

Partial xerostomia after irradiation of the parotid gland is frequently observed and may be permanent. Trismus may result from RT-induced fibrosis of the temporomandibular joint or the masseter and other muscles or mastication. It usually occurs when there is extensive tumor infiltration of the muscles of mastication and when high doses are given.

RT to the parotid gland may result in complications along the auditory system. Late toxicity, external canal stenosis, dryness, skin atrophy, and chronic otitis externa, resulting in conductive hearing loss, although rare, may be seen. Chronic otitis media has been documented in 35% to 40%, because of damage to the muscles of the eustachian tube. This may lead to conductive hearing loss, and repeated myringotomies may be indicated.[190,191] Radiation-induced hearing loss mostly is caused by progressive endothelial damage to the vascularization of the inner ear. This will cause sensorineural hearing loss, cognitive impairment, and, at the end, decrease quality of life. However, most hearing loss is seen above 4,000 Hz; for daily use, normal frequency ranges from 1,000 to 3,000 Hz. In a prospective study of patients treated for head and neck cancer, a 10 dB or greater hearing loss 2 years after RT was seen in 40% for 8,000 Hz and in 50% for 3,000 Hz.[146] A threshold of 45 Gy was seen at 2,000 Hz or greater, also depending on age and baseline hearing loss.[146] In published results, the mean threshold dose for the cochlea and eustachian tube for sensorineural hearing loss varies between 40 and 50 Gy.[145,146,191] The latency is around 1.5 to 2 years. After this time, hearing loss stabilizes. The risk of sensorineural hearing loss depends on the RT technique. From 2D conventional to 3DCRT, the mean dose to the cochlea may decrease from above 50 Gy to around 40 Gy,[139,144] and further improvement is noted with the use of IMRT.[139,147] No dose-response relationship has been published for vestibular damage.[191]

Garden et al[131] reported complications of RT in 51 of 160 patients receiving PORT with *2D* RT for minor salivary gland tumors. The most common complication was decreased hearing in 26 patients, 20 of whom had myringotomies or myringotomy tubes placed for serous otitis media. Bone necrosis or exposure was observed in several patients; however, this complication has been seen infrequently during the past decade with improved RT techniques and treatment of multiple, as opposed to single fields per day. Complications to the eyes or optic pathways were diagnosed

in patients with paranasal sinus primary tumors. At least six cases of contralateral optic atrophy occurred.[131] Other eye complications included dry eye syndrome, nasolacrimal duct obstruction, cataract, retinopathy, and perforated globe.[131] To reduce the incidence of bilateral blindness, the dose to the optic chiasm and contralateral optic nerve is limited to 54 Gy. In patients with extensive tumor involvement of the orbit, it may be preferable to remove the eye surgically rather than to subject the entire orbit to high doses. Radiation-induced injury to the visual pathway is dose dependent. None of the patients receiving a dose of less than 50 Gy develop optic neuropathy or chiasm injury, whereas the 10-year actuarial incidence of optic nerve chiasm injury is 5% and 30% for patients receiving 50 to 60 and 61 to 78 Gy, respectively.[192]

RT of tumors of the pharynx, and less frequently the oral cavity, may result in permanent complaints of xerostomia. In the largest published series, the mean dose to the parotid glands relative to a 50% risk of 1-year xerostomia was 39 Gy, and no threshold was seen.[193] A mean dose beneath 20 Gy is preferable to reach a low risk on xerostomia.[193] This serious late complication may be significantly reduced by the use of IMRT.[194] Data on quality of life are scarce. In a prospectively scored small series of 36 patients treated for parotid carcinoma with PORT, quality of life deteriorated during treatment and returned to almost baseline levels from 6 weeks to 1 year after RT.[195] In general, the risk of late toxicity is much lower using modern radiation techniques like IMRT and VMAT compared to 2D or 3D RT. Based on dose-response models for OARs, PBT may be preferred in some cases, depending on the estimated lower risk at late toxicity without compromising efficacy.[196]

TREATMENT OF RECURRENCE

Retreatment usually involves additional surgery, if feasible, and PORT in previously irradiated patients (Figure 49.23). In the retreatment of parotid neoplasms, preserving facial nerve function and obtaining local control are more difficult than for the initial tumor. Therapy consisting of surgery with PORT has demonstrated enhanced local control, and sacrifice of VII may be necessary less often if this combination is used. In certain histologic subtypes (eg, ADCC), retreatment of locally recurrent disease yields

prolonged survival. Aggressive local therapy for recurrent disease is indicated if the probability of long-term survival is high, as in the case of ADCC. Fractionated stereotactic reirradiation, with a dose of 5 times 6 Gy, resulted in a 50% locoregional control in a study by Karam et al.[197] Reirradiation is not advised within 1 year after the first course of RT and not for large tumor volumes.[197] PBT is a strong consideration in most cases of reirradiation, especially if "in-field" control could be achieved by prior XRT for a number of years and is now limited by the lack of the precision provided by the Bragg peak effect advantage inherent to PBT. For a central "in-field" failure, reirradiation with PBT would be necessary only in cases in which IMRT/VMAT plan could not spare critical structures located away from the target—in particular, tumors that are abutting OARs that are built in "series" and hence are "dose dependent" and "volume independent." Thus, optic nerves, optic chiasm, brainstem, and spinal cord will not meaningfully benefit from PBT. In this situation, a full dose to the target volume would also deliver the same dose to the abutting interface region of the OAR, regardless of the modality. And any underdosing to the target (to spare the OAR) would result in underdosing the target, regardless of the modality. It is in the "volume-sensitive" structures built in "parallel"—such as brain, cerebellum, oral mucosa, and salivary glands—that PBT could be superior to IMRT/VMAT in reducing mean dose (due to the reduced unnecessary irradiation beyond the Bragg peak) in the intermediate- (<50% of prescribed dose) to low-dose ranges. Multimodality treatment may be beneficial for recurrence disease of the minor salivary gland, if initial tumor classification is $T_{1\text{-}2.}$[198] For unresectable recurrences that have previously received low LET RT (x-rays, PBT), high LET RT such as NRT or carbon ions should be considered, if available.

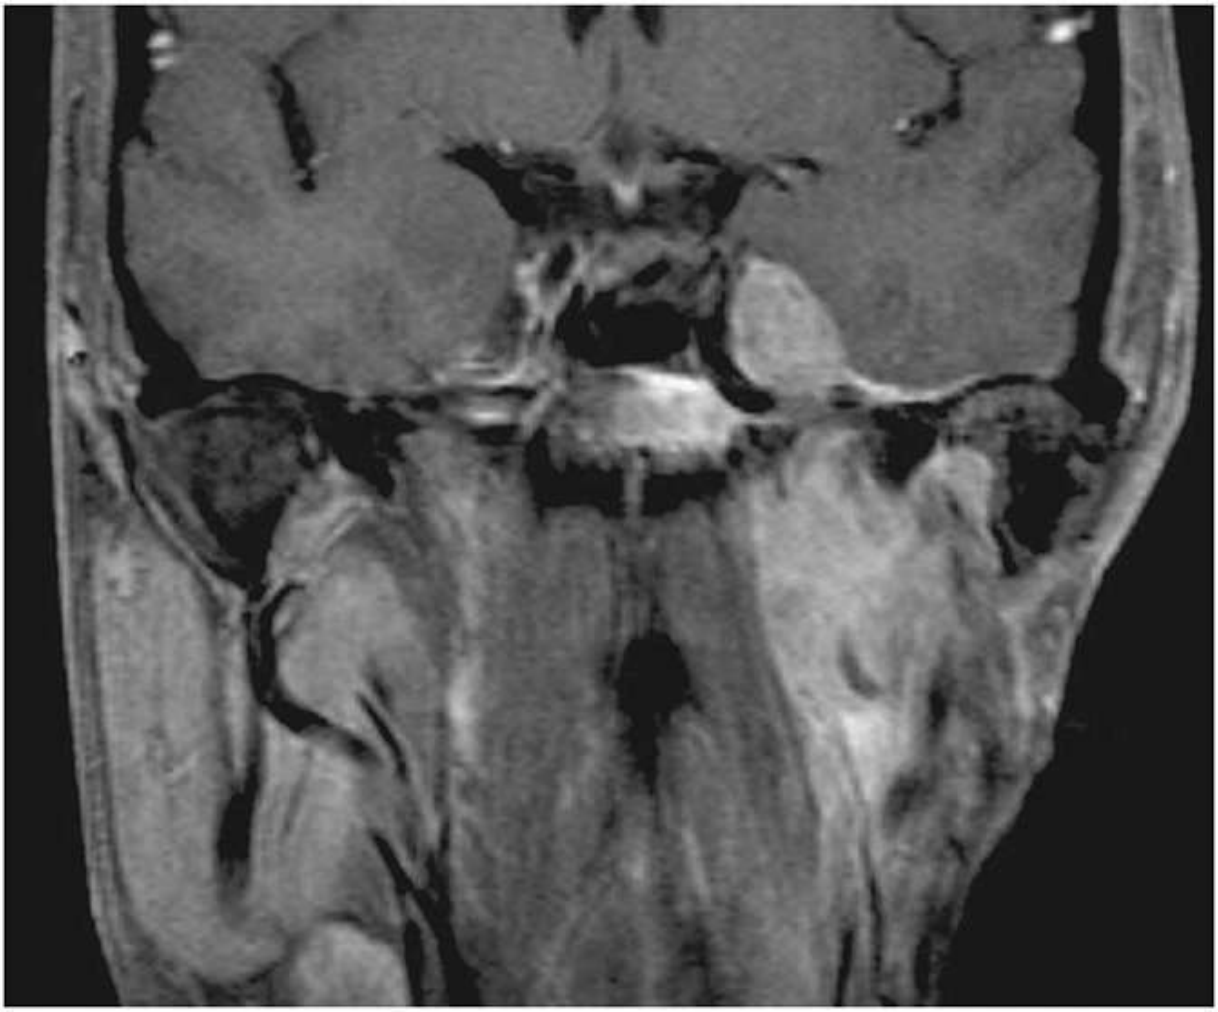

FIGURE 49.23 Coronal fat-suppressed contrast-enhanced magnetic resonance image shows a recurrence of squamous cell cancer of the parotid gland after total parotidectomy. The tumor is centered in the left masticator space with perineural spread along the nV3. Retrograde perineural spread of tumor through foramen ovale on the left side. (Courtesy of Dr F.A. Pameyer, Radiologist, University Medical Center Utrecht, Netherlands.)

Chemotherapy also has been used for recurrent disease.[167,168] However, in view of its significant toxicity and modest response rates in a population that may have recurrent yet indolent progressive disease, trials of aggressive cytotoxic therapy are recommended only on carefully drafted protocols. In the future, molecular target agents may be tested in selected recurrent salivary gland cancers.

CHAPTER 50

Oral Cavity

Irini Yacoub and Nancy Y. Lee

GENERAL PRINCIPLES

The management of squamous cell carcinoma (SCC) of the lip and oral cavity is primarily surgical, with adjuvant treatment based on stage and postoperative pathologic findings. Reconstructive microsurgery has acceptable functional outcomes,[1] as well as improved oncologic outcomes;[2] thus, organ-preserving approaches have largely grown out of favor in North America. Nevertheless, definitive radiotherapy may be a treatment option for patients who are not candidates for surgery because of medical reasons or who refuse surgery. A multidisciplinary approach is paramount in the evaluation and management of patients with oral cavity cancer. A team of health care providers including head and neck surgical oncology, radiation and medical oncology, plastic surgery, nursing, dentistry, dietary, speech pathology, and social work should evaluate the patient before treatment is delivered. Multidisciplinary evaluation prior to treatment disposition helps to ensure that broad consensus treatment recommendations are made and that interdisciplinary coordination of care is facilitated. Once treatment has been completed, the multidisciplinary team should provide follow-up to the patient to ensure early detection of recurrent disease and adequate management of treatment sequelae.

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Oral cancer is the 13th most common cancer worldwide[3] and 8th in the United States, with an estimated 54,540 adults (4% of all cancers) in the United States diagnosed in 2023.[4] The National Cancer Institute estimates of oral cavity and pharynx cancers contribute to 2% of all cancer deaths.[5] The estimated 5-year survival for all stages is 68.5%, whereas survival for cancer localized to the primary site is 86.6%.[5] According to the National

Cancer Institute, age-adjusted death rates have been rising on average 0.4% each year over 2011 to 2020.[5] Oral cavity cancer is more common in men than women, particularly among those with a history of alcohol or tobacco use.[5]

Approximately 747,316 newly documented instances of lip, oral cavity, and pharyngeal cancer were reported globally in 2020, an age-standardized rate (ASR) of 8.1 new cases per 100,000 individuals. Melanesia had the highest occurrence with an ASR of 19.8 per 100,000 individuals, followed by South-Central Asia (13.5), Central and Eastern Europe (10.3), Western Europe (10.0), and Australia and New Zealand (10.0). Countries with the lowest ASR included Central America (2.0), Western Africa (3.1), Western Asia (3.7), Northern Africa (3.9), and Eastern Africa (4.3). Males had a significantly higher incidence rate (12.2) compared to females (4.3), nearly triple the occurrence. The incidence of lip, oral cavity, and pharyngeal cancer increased with age, peaking among individuals aged 70 to 85 years and above (37.8). Lip and oral cavity malignancy had the highest incidence, followed by pharynx.[6] Finally, lip and oral cavity had the highest mortality, followed by pharyngeal and salivary gland.[6] The incidence of oral cavity cancer seems to be decreasing in many parts of the world, mirroring the overall decline in tobacco use since 1990.[7]

The epidemiology of oral cancer strongly reflects exposure to certain environmental agents, particularly tobacco and alcohol. Smoking is identified as an independent risk factor in 80% to 90% of patients who present with cancer of the oral cavity.[8,9] Tobacco users have a 5- to 25-fold higher risk of oral cavity and oropharyngeal cancer.[10] The combined use of alcohol and tobacco may have a synergistic effect on carcinogenesis.[10] International Head and Neck Epidemiology Consortium pooled analysis data demonstrate a greater than multiplicative joint effect between tobacco and alcohol on head and neck cancer risk, which is most pronounced in carcinoma of the pharynx and oral cavity.[11] Cessation of smoking and alcohol are associated with a decline in the risk of cancer of the oral cavity.[9,12] In India, Sri Lanka, and Taiwan, the habit of chewing betel nut leaves rolled with lime and tobacco (mixture known as “pan”), which results in prolonged carcinogen exposure to the oral mucosa, is thought to be the leading cause of oral cancer.[13,14]

Ultraviolet radiation has been associated with carcinoma of the lip.[15] Around 90% arise from the lower lip.[16] While the human papillomavirus (HPV) is a well-established risk factor for oropharyngeal malignancy,[17] its role in the incidence of oral cavity malignancy is less significant.[18] Certain syndromes such as xeroderma pigmentosum, Li-Fraumeni, ataxia telangiectasia, Bloom syndrome, and Fanconi anemia have been associated with a predisposition to oral cancer.[19,20]

Overall, there has been a declining trend in the overall incidence of oral cavity squamous cell carcinoma (OCSCC) over the past 30 years. However, Surveillance, Epidemiology, and End Results data suggest an increasing incidence of oral tongue carcinoma in young White individuals aged 18 to 44 years, which is most pronounced among young White women.[21-23] The increase in oral cavity malignancy among this group, despite decreasing tobacco and alcohol consumption worldwide,[24,25] suggests an unknown or yet identified risk factor in this specific population.

In patients with cancer of the oral cavity, the risk of developing a second primary cancer is well recognized and associated with worse prognosis and higher risk of treatment failure in patients with early-stage disease.[26,27] Schwartz et al demonstrated a 22% 5-year probability of a second head and neck cancer in 851 treated patients.[27] Modifiable risk factors, such as smoking cessation, may decrease the risk of oral cavity malignancy. Oral cancer risk decreases by about 35% in the first 4 years of cessation, with a reduction of about 80% by 20 years.[28] For those who quit smoking beyond 20 years, the risk parallels that of never-smokers; a similar effect is seen with stopping the use of alcohol.[29] Therefore, continued efforts toward tobacco and alcohol cessation are a central strategy in the management of patients with oral SCC.[29]

ANATOMY

The oral cavity is composed of the lips, oral tongue, floor of the mouth, retromolar trigone, alveolar ridge, buccal mucosa, and hard palate (Figures 50.1-50.3). The anterior boundary of the oral cavity is the skin-vermilion junction. The superior portion of the oral cavity extends posteriorly to the junction between the hard and soft palate, whereas the inferior portion

extends to the circumvallate papillae. The specific anatomic subsites of this region are noted below.

Lip

The lips begin at the junction of the vermilion border with the skin and form the anterior aspect of the oral vestibule. The lips are composed of the vermilion surface, which is the portion of the lip that comes in contact with the opposing lip. The lips are well defined into an upper and lower. The primary motor control of the lips is provided by the buccal and mandibular branches of the facial nerve. Most tumors of the lip arise at the vermillion border and can invade adjacent skin, whereas lesions near the gingivobuccal sulcus may invade the alveolar ridges.[30] Lymphatic drainage of the upper

and lower lip is primarily to the submental and submandibular group, with some to the preauricular nodes.[31,32]

Oral Tongue

The anterior two-thirds of the tongue is mobile and considered part of the oral cavity. The oral tongue extends anteriorly from the circumvallate papillae to the undersurface of the tongue at the junction of the floor of the mouth. The fibrous septum divides the tongue into right and left halves. The oral tongue can be demarcated into four anatomic areas: the tip, lateral borders, dorsal surface, and undersurface (ventral surface). There are six pairs of muscles that form the oral tongue. Three of these muscles are extrinsic, whereas the other three are intrinsic. The extrinsic muscles include the genioglossus, hyoglossus, and styloglossus. The intrinsic muscles include the lingual, vertical, and transverse muscles. The former primarily move the body of the tongue, whereas the latter alter the shape and conformation of the tongue during speech and swallowing. The blood supply to the tongue is primarily via the lingual artery, tonsillar branch of the facial artery, and the ascending pharyngeal artery with primary drainage by the internal jugular vein. General sensation of the anterior two-thirds of the tongue is supplied by the lingual nerve. Excluding the circumvallate papillae, taste fibers from the anterior two-thirds of the tongue run in the chorda tympani branch of the facial nerve; the glossopharyngeal nerve provides sensation and taste to the posterior third of the tongue and circumvallate papillae. The oral tongue is the most commonly involved in oral cavity sites. These tumors may spread to involve the muscles of the tongue, floor of the mouth, or mandible.[30] Primary sentinel lymph nodes for the anterior tongue are submental lymph nodes, submandibular lymph nodes, and jugulo-omohyoid lymph nodes. The lateral and middle tongue drain into submandibular, jugulodigastric, and thyroid lymph nodes. The root of the tongue drains into the jugulodigastric lymph nodes. The tongue drains into the bilateral neck. The lateral tongue has pathways that can skip directly to level IV.[32-34]

Floor of the Mouth

The floor of the mouth is a semilunar space extending from the lower alveolar ridge to the undersurface of the tongue. The floor of the mouth overlies the mylohyoid and hyoglossus muscles. The posterior boundary of the floor of the mouth is the base of the anterior tonsillar pillar. This region is divided into right and left by the frenulum of the tongue and contains the ostia of the submandibular and sublingual salivary glands. A sling formed by the mylohyoid muscles medially supports the anterior floor of the mouth, and the hyoglossus supports the posterior floor of the mouth. The lingual and hypoglossal nerves are lateral to the hyoglossus, whereas the lingual artery is medial to the hyoglossus. Innervation of the floor of the mouth is provided by the lingual nerve. Tumors of the floor of the mouth may spread laterally into the mandible, superiorly into the tongue, or posteriorly into the base of tongue.[30] The floor of the mouth drains into bilateral levels I to III.[32]

Hard Palate

The hard palate extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone. This is a semilunar area between the superior alveolar ridge and the mucous membrane covering the palatine process of the maxillary palatine bones. Tumors of the hard palate may invade the greater palatine nerves, along cranial nerve V2, and into the base of skull through the foramen rotundum.[30] The hard palate drains into the submandibular nodes and levels I to III.[35]

Alveolar Ridge

The alveolar ridges include the alveolar processes of the maxilla and mandible and the overlying mucosa. The mucosal covering of the lower alveolar ridge extends from the line of attachment of mucosa in the buccal gutter to the line of free mucosa of the floor of the mouth. The lower alveolar ridge extends to the ascending ramus of the mandible posteriorly. The superior alveolar ridge mucosa extends from the line of attachment of mucosa in the upper gingival buccal gutter to the junction of the hard palate. The posterior margin is the upper end of the pterygopalatine arch. Carcinomas of the alveolar ridge invade bone early. Lower ridge malignancies may invade the mandibular canal and inferior alveolar nerve.[30]

Retromolar Trigone

The retromolar trigone is the triangular area overlying the ascending ramus of the mandible. The base of the triangle is formed by the posterior most molar, and the apex lies at the maxillary tuberosity. Tumors of the retromolar trigone tend to invade bone early.[30] The retromolar trigone drains into levels I to III.[32]

Buccal Mucosa

The buccal mucosa includes the mucosal surfaces of the cheek and lips from the line of contact of the opposing lips to the pterygomandibular raphe posteriorly. This extends to the line of attachment of the mucosa of the upper and lower alveolar ridge superiorly and inferiorly. Innervation is supplied by the buccal nerve, a branch of the mandibular nerve. Buccal mucosa tumors may invade the buccinator muscle, fat, or subcutaneous tissue.[30] The buccal mucosa most commonly metastasizes to level I nodes.[32]

Nodal Levels

The neck is traditionally divided into five primary nodal levels (ie, levels I-V) plus the retropharyngeal nodes that are relevant to the staging and management of oral cavity carcinoma. The level VI nodal station is not discussed in this section because it is rarely pertinent for oral cavity cancer. The classification of neck nodal regions, initially popularized by Robbins et al,[36] has served as a surgical reference system based on visible landmarks. Over the years, there have been several revisions regarding the proposed boundaries of nodal stations in the neck, with refinements to include radiologic landmarks.[37,38] Gregoire et al[39,40] published consensus guidelines for the computed tomography (CT)-based delineation of nodal levels in the node-negative neck that were revised in 2014 to serve as a guide in the practice of radiation oncology. In the following discussion, we incorporate radiographic landmarks and anatomic considerations from these guidelines (where relevant) alongside traditional surgical anatomic landmarks.

Level I

Level I includes the submental (Ia) and submandibular (Ib) triangles. Level Ia is limited anteriorly by the mandibular symphysis, posteriorly by the

body of the hyoid bone, and cranially by the geniohyoid muscle. The medial border is virtual because this region continues to the contralateral Ia station. Level Ib is located within the space bounded by the inner table of the mandible laterally, the digastric muscle medially, the mandibular symphysis anteriorly, and the submandibular gland posteriorly.

Level II

Level II includes the upper jugular chain lymph nodes from the base of the skull to the carotid bifurcation (surgical landmark) or the caudal body of the hyoid bone (clinical landmark); this nodal station extends from the posterior edge of the submandibular gland anteriorly to the posterior border of the sternocleidomastoid posteriorly. The level II nodal region is further subdivided into IIa and IIb. The vertical plane defined by the spinal accessory nerve (surgical landmark) or the posterior edge of the internal jugular vein (radiographic landmark) defines each subdivision within this level; level IIa lies anterior whereas IIb lies posterior to this plane.

Robbins et al[36] initially defined the cranial limit of level II as the base of the skull. However, from a practical standpoint, during surgical management of the neck, the cranial border of level II is taken as the insertion of the posterior belly of the digastric into the mastoid.[40] It was later proposed that the bottom edge of C1 serve as the radiographic landmark for defining the cranial border of level II in the node-negative neck.[40] Consequently, the retrostyloid space is considered the cranial continuation of level II from C1 to the skull base.[39,40]

Level III

Level III is the caudal extension of level II. It includes the midjugular nodes, of which the surgical landmarks extend from the carotid bifurcation to the omohyoid muscle inferiorly, the sternohyoid medially, and the posterior aspect of the sternocleidomastoid posteriorly. The corresponding radiographic landmarks are the caudal edge of the hyoid bone superiorly and the caudal edge of the cricoid cartilage inferiorly.

Level IV

Level IV includes the inferior jugular nodes located around the inferior third of the internal jugular vein. Level IV is bounded by the omohyoid muscle superiorly, the clavicle inferiorly, and the posterior aspect of the sternocleidomastoid posteriorly.

Level V

Level V includes nodes in the posterior triangle, which are located posterior to the sternocleidomastoid muscle. This space is bordered by the base of the skull superiorly, clavicle inferiorly, and posterior aspect of the sternocleidomastoid anteriorly. The uppermost part of level V is generally thought to belong to the occipital nodal region.[39] Therefore, from a practical standpoint, the radiographic cranial border of level V has been accepted as a horizontal plane crossing the cranial edge of the hyoid bone.[40] From a surgical perspective, level V is further subdivided into Va and Vb, and the caudal edge of the cricoid arch is the anatomic landmark denoting this subdivision (Vb lies below this boundary).

Retropharyngeal Nodes

The retropharyngeal space, which contains the retropharyngeal nodes, extends from the skull base (cranially) to the hyoid bone (caudally). The anterior boundary of the retropharyngeal space is the pharyngeal constrictor muscles, and the posterior boundary is the prevertebral fascia. The retropharyngeal nodes are further divided into medial and lateral groups. The lateral retropharyngeal nodes lie medial to the carotid artery and lateral to the longus capitis and longus colli muscles, whereas the medial group consists of one or two nodes intercalated along the midline lymphatics.

MOLECULAR BIOLOGY

In parallel to the Fearon and Vogelstein model describing the genetic basis of colon cancer,[41] there are a series of specific genetic events that precede the development of oral SCC.[42] Cancer progression models describe several steps that occur during tumor development: Oncogenes become activated and tumor suppressor genes become deactivated, and a series of these alterations are required for carcinogenesis. In the oral mucosa, this genetic progression is reflected histologically by the transformation from normal

mucosa to dysplastic epithelium and ultimately to frankly invasive SCC. Data to support this model come from studies that reveal genetic alterations in histologically normal tissues and in premalignant lesions, including loss of heterozygosity at chromosomes 3p14 and 9p21. Furthermore, mutations in the region of chromosome 17p13, which encompasses the tumor suppressor gene *TP53*, are among the early events that contribute to malignant transformation. Indeed, biopsies of normal mucosa from patients with upper aerodigestive tract carcinomas frequently harbor *TP53* mutations.

Comprehensive studies of whole-genome sequencing, gene copy number analysis, and messenger RNA and protein expression of head and neck SCC have been performed and have helped to provide an unbiased characterization of the genomic alterations seen in this disease.[43-46] Known tumor suppressor genes and oncogenes were found to be mutated, including *TP53, PIK3CA, PTEN, HRAS*, and *CDKN2A*. It was observed that HPV-positive tumors had a reduction in mutation rate of at least 50% relative to smoking-associated tumors. Moreover, they were inversely correlated with *TP53* mutations, suggesting that HPV-positive tumors are genomically distinct. However, very few oral cavity tumors (~4%) appear to be driven by high-risk HPV.[47]

The first genomic analyses have identified loss-of-function mutations in *NOTCH1* that suggest that *NOTCH* may act as a tumor suppressor gene in head and neck cancers rather than as an oncogene, as it had been identified in other malignancies.[48] The Cancer Genome Atlas published results validating the initially identified genomic findings in head and neck cancers.[43] Subset analysis of patients with oral cancer has found that reduced copy number alterations and activating mutations in *HRAS* or *PIK3CA* are associated with improved clinical outcomes.

The use of whole-exome sequencing has also been applied to evaluate genomic alterations in younger, nonsmoking patients, and this analysis surprisingly found no significant difference in mutation frequencies, types of mutations, or copy number between younger and older patients with oral tongue cancers.[45] Smoking was seen to have a minimal effect on genomic changes. *FAT1* and *TP53* mutations were not significantly increased in the younger cohort and may represent a novel area of study. Although the genomic characterization has allowed clinicians to better understand the

molecular alterations underlying the development of oral cancers, the majority of known mutations represent nontargetable tumor suppressor genes. Therefore, further studies of these alterations as potential prognostic and predictive biomarkers and synthetic lethality approaches are needed to fully realize the immense potential of assessment of the genomic alterations in the tumor of an individual patient with oral cancer.

More recent analyses have focused on recurrent and metastatic head and neck cancers that suggest the potential for precision approaches to treating these advanced tumors with more than 20% showing "actionable" mutations.[49] Liquid biopsy approaches analyzing tissue fluids including saliva and blood also hold tremendous promise in the early detection of recurrence of oral cancers.[50] Furthermore, immunoprofiling of squamous cancers of the head and neck inclusive of oral cavity tumors indicates that immune-oncologic approaches to treating these tumors should be considered in future clinical investigations.[51]

NATURAL HISTORY AND PATTERNS OF SPREAD

Premalignant Lesions

Leukoplakia

Leukoplakia and erythroplakia are gross clinical descriptors that do not always correspond directly to specific pathologic entities.[19,52] The World Health Organization defines leukoplakia as a white patch or plaque that cannot be rubbed off or characterized clinically or pathologically as any other disease[52] (Figure 50.4). Leukoplakia is not related to the presence or absence of dysplasia; however, it is the most common precursor of cancer of the oral cavity. Leukoplakia is primarily a clinical entity, with certain key pathologic features. These features include hyperkeratosis and acanthosis. Leukoplakia may begin as a thin gray or gray/white plaque that may appear translucent, is sometimes fissured or wrinkled, and typically soft and flat. They frequently have sharply demarcated borders but occasionally blend gradually into normal surrounding mucosa.

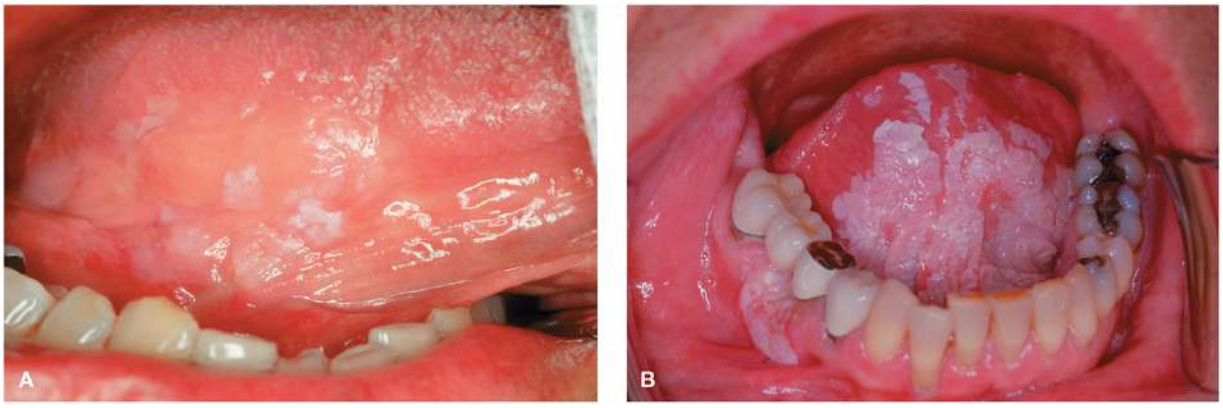

FIGURE 50.4 A. Superficial patches of leukoplakia involving the lateral and ventral surface of the oral tongue. B. Extensive leukoplakia involving the ventral oral tongue, floor of the mouth, and mandibular alveolus.

Homogeneous leukoplakia is a uniform white lesion that is prevalent in the buccal mucosa; it is the most common variety of leukoplakia and has a low malignant potential. Conversely, high-risk oral leukoplakia demonstrates abnormal orientation of cells, nuclear hyperchromatism, increased mitosis, and nuclear cytoplasmic ratio.[19] Clinically, these lesions are nonhomogeneous, nodular, speckled, or verrucous, with central ulceration or erosion.[52] Follow-up studies demonstrate that between <1% and 18% of oral leukoplakias develop into oral cancer, with the latter clinical subtype conferring a higher risk of malignant transformation.[53,54]

Leukoplakia may regress spontaneously without therapy. A baseline biopsy may be performed to establish diagnosis and rule out malignant transformation. Leukoplakia with clinically or histologically aggressive features, demonstrating dysplasia, should be excised. Reported recurrence rates after surgical resection ranges from 0% to 35%.[55] However, there is no good evidence that treatment of oral leukoplakia may prevent the development of oral cancer.[56]

Erythroplakia

Erythroplakia describes a chronic, red, generally asymptomatic lesion or patch on the mucosal surface that cannot be attributed to a traumatic, vascular, or inflammatory cause. Erythroplakia, like leukoplakia, is a clinical diagnosis of exclusion that requires the clinician to rule out all other erythematous oral lesions.[57] However, erythroplakia is associated with a

higher risk of malignant transformation than leukoplakia. Transformation rates are considered to be the highest among all precancerous oral lesions and conditions.[58] Histopathologically, it has been documented that in homogeneous oral erythroplakia, 51% showed invasive carcinoma, 40% carcinoma in situ, and 9% mild or moderate dysplasia.[58] The treatment of choice for erythroplakia is surgical excision.

Oral Submucous Fibrosis

The term describes a generalized fibrosis of the oral cavity tissues resulting in marked rigidity and trismus. At early stages, these premalignant lesions are characterized by blanching of the mucosa with a marble-like appearance. At more advanced stages, palpable fibrous bands become evident around the buccal mucosa and the mouth opening. Once oral submucous fibrosis reaches advanced stages, approximately 25% of cases biopsied demonstrate epithelial dysplasia in addition to subepithelial alterations.[10] Oral submucous fibrosis is associated with the use of betel quid (with or without tobacco) or pan masala.[10] In India, it is estimated that as many as 5 million individuals are afflicted with oral submucous fibrosis.[10]

Oral Cavity Cancer

Relative Distribution

The most common subsite for OCSCC (excluding the lip) is the oral tongue.[59] In a review of 3,308 cases of oral cavity cancer treated at the University of Texas MD Anderson Cancer Center between 1970 and 1999, 32% involved the oral tongue.[19] The floor of the mouth is the second most common subsite where oral cavity carcinomas may arise. Carcinoma of the alveolar ridge accounts for approximately 10% of oral cavity carcinomas. SCC of the retromolar trigone and hard palate is rare. Similarly, carcinoma of the buccal mucosa is rare in the United States but is the most common carcinoma of the oral cavity in Southeast Asia because of the widespread use of betel nut.[19]

Patterns of Spread

Local Spread

Carcinoma from distinct anatomic subsites may exhibit different tendencies for spread based on natural anatomic barriers and location. For instance, the majority of lip cancers are local growths that do not invade deeply into the tissues of the oral cavity or mandible.[60] However, a select few lip carcinomas may be deeply invasive with perineural involvement, posterior spread to involve cortical bone, extension to the inferior alveolar nerve, or spread to the skin of the face.[59] SCC of the floor of the mouth can secondarily involve the ventral tongue, extend along the lingual nerve and submandibular duct, or invade the cortex of the mandible. Tumors in this location can invade deeply, involving the muscles of the floor of the mouth. There is an anatomic gap between the mylohyoid and hyoglossus muscles through which a carcinoma can gain access to submandibular and sublingual areas. Carcinomas of the alveolar ridge and retromolar trigone tend to invade bone early. Tumors of the inferior alveolar ridge may access the mandibular canal and the inferior alveolar nerve, whereas tumors of the superior alveolar ridge may pass into the maxillary antrum or floor of the nose. Infiltrating lesions of the buccal mucosa can invade the buccinator muscle, extend to the buccal fat pad, and invade the subcutaneous tissue. The hard palate has a relatively dense mucoperiosteum that is relatively resistant to tumor invasion. However, the primary and secondary palates are fused at the incisive fossa, where tumors can gain access into the nasal cavity. The greater palatine foramina can allow tumors to spread posteriorly and enter the pterygopalatine fossa and skull base.

Lymphatic Metastases

The oral cavity has an extensive group of lymphatics that manifest a fairly predictable lymph node drainage pattern based on location (subsite) within the oral cavity[59] (Table 50.1).

TABLE 50.1 RELATIVE INVOLVEMENT OF LYMPH NODE REGIONS BY ORAL CAVITY SUBSITE

	Percentage Involved			
	Submaxillary	**Submental**	**Upper Jugular**	**Midjugular**
Oral tongue	18	9	73	18

	Percentage Involved

The lymphatic nodal stations most commonly involved include levels I to IV.[61,62] Site-specific metastases have been previously mentioned above, for each subsite. The retrostyloid space is potentially at risk for involvement by metastatic disease when upper level II nodes are grossly positive.[39] The medial retropharyngeal nodes are rarely a site of metastases in head and neck SCC.[63] The lateral retropharyngeal nodes generally at risk in primary carcinoma of the nasopharynx and oropharynx are rarely involved in oral cavity cancer unless there is oropharyngeal involvement or a significant nodal burden.[64-66] The lymphatic drainage pattern to the upper and lower lip is distinct. The principal lymphatic drainage of the upper lip is to preauricular, periparotid, submental, and submandibular lymph nodes, which secondarily drain into deep jugular lymph nodes. The medial portion of the lower lip drains primarily to the submental lymph nodes, whereas the lateral portion drains into the submandibular triangle.[67]

A classic study by Lindberg[68] demonstrated that the superior deep jugular nodes are most frequently involved by cancers of the oral cavity. The anterior portion of the tongue drains into the submental nodes (level Ia), and the lateral portion drains into the submandibular (level Ib) and deep jugular nodes (level II). The posterior oral tongue drains into the upper jugulodigastric group of lymph nodes (level II). The lymphatics of the oral tongue also have extensive communication across the midline; thus, carcinomas of the oral tongue can metastasize bilaterally. Studies suggest that some carcinomas of the lateral oral tongue may metastasize to level IV lymph nodes without involving level I, II, or III.[69] This implies that there may be separate lymphatic channels draining from the oral tongue directly to level IV nodes, allowing for apparent “skip metastases.”

Dye injection studies have shown that the floor of the mouth has superficial and deep lymphatic drainage systems.[69] The superficial system crosses randomly in the midline and drains into both the ipsilateral and contralateral submandibular lymph nodes. The deep lymphatic system is thought to penetrate the periosteum and drains into the submandibular and upper jugular lymph nodes. Lymphatics from the buccal mucosa drain into the periparotid, submental, and submandibular nodes. Tumors of the alveolar ridge may drain into the submental and submandibular triangles, upper deep jugular, and retropharyngeal lymph nodes. Tumors of the inferior alveolus are more likely to metastasize to the neck than tumors of the superior alveolus. The main lymphatic drainage from the retromolar trigone is into the superior deep jugular lymph nodes; however, there may be some drainage into periparotid and retropharyngeal lymph nodes. Lymphatics in the hard palate are few, but drainage is into submandibular, superior deep jugular, and retropharyngeal nodes.

The risk of neck metastases depends on several factors, including the site and size of the primary tumor. Overall, for patients with OCSCC, cervical metastases occur in approximately 30% of cases.[70] The rate of neck metastases for carcinoma of the lip is approximately 10%.[71] SCC of the oral tongue carries a higher risk of nodal metastases, the frequency ranging from 15% to 75%, depending on the size and depth of the primary lesion.[68,72] Approximately 25% of patients with carcinoma of the oral cavity will have occult nodal metastases, and 3% of patients will have contralateral metastases.[68,72] Contralateral metastases are more common in tumors that approach or cross the midline. Early tumors of the floor of the mouth have approximately a 12% to 30% incidence of occult nodal metastases depending on the thickness of the lesion, whereas larger lesions can have an incidence of nearly 50%.[73] Approximately 15% to 20% of upper alveolar ridge tumors will involve the neck at presentation; the risk of occult metastases in a clinically negative neck is approximately 15% to 20%.[68] The incidence of neck metastases in lower alveolar ridge tumors is higher than for tumors of the upper alveolar ridge.[68] For cancers of the buccal mucosa, the incidence of positive cervical lymph nodes at diagnosis is 10% to 30%; the incidence of pathologically positive nodes in a clinically negative neck is about 15%. Similar rates of occult metastases occur for SCC of the retromolar trigone; however, patients tend to present with more advanced

disease, resulting in a somewhat higher rate of regional metastases.[74] The incidence of lymph node involvement from carcinoma of the hard palate is low, approximately 15%.[60,75]

Distant Metastases

Distant metastasis occurs in approximately 15% to 20% of patients who eventually die of their disease.[76] The risk of distant metastases increases with the degree of lymph node involvement. Patients with recurrent disease are also at higher risk for distant metastases.[77] Patients without clinically appreciable neck disease rarely fail distantly after treatment. In general terms, with respect to head and neck cancer, 66% of distant metastases are to the lungs, 22% to the bones, and 9.5% to the liver.[78] On rare occasions, the oral cavity will serve as a site for distant metastasis from another anatomic primary tumor site.[59]

PATHOLOGIC CLASSIFICATION

The predominant histopathologic type of cancer in the oral cavity is SCC. There are several variants of SCC, including basaloid and verrucous carcinoma. Basaloid SCC is believed to have a worse prognosis than traditional SCC. In a retrospective comparison between basaloid SCC and traditional poorly differentiated SCC, the former had a higher incidence of advanced disease at presentation, distant metastases, and poorer overall survival (OS) rate.[79] Verrucous carcinoma is a less common variant of SCC. It is generally considered a low-grade malignancy with low metastatic potential and good overall prognosis, although often with challenges for local control in elderly patients.[19] For most cases, adjuvant radiation and elective neck dissection (END) are not indicated. Sarcomatoid carcinomas can be found in the oral cavity and larynx. This variant of SCC carries a poor prognosis with a mean survival of approximately 2 years.[80]

Less than 10% of neoplasms of the oral cavity have nonsquamous histology. Most of these are minor salivary gland tumors, which tend to arise in the hard palate. Adenoid cystic carcinoma accounts for approximately 30% to 40% of minor salivary gland cancers of the oral cavity.[81] Other histologies that can occur in the oral cavity include adenocarcinomas, melanoma, ameloblastoma, lymphoma, and Kaposi

sarcoma.[59] Approximately 50% of acquired immunodeficiency syndrome–related cases of Kaposi sarcoma have oral cavity involvement.[82] Most lymphomas in the head and neck arise in Waldeyer ring (tonsil, base of the tongue, and nasopharynx). Only 2% of all lymphomas are found in the oral cavity.[83] Fortunately, melanoma of the oral cavity is very rare and represents only 0.2% to 8% of all melanomas.[84] Mucosal melanomas generally have a worse prognosis than cutaneous melanomas.[85]

CLINICAL PRESENTATION

The oral cavity is an anatomic region that is readily accessible to visual inspection and palpation. Despite this fact, many patients with oral cavity tumors present with advanced-stage disease as initial symptoms may be vague and painless. Tumors of the oral tongue often present as small ulcers and gradually invade the musculature of the tongue. Advanced lesions may be either ulcerative or exophytic and are usually quite evident. Some cancers of the oral tongue are painful even in their early stages. Cervical metastases occur early in the natural history of the disease, with 30% to 40% of patients harboring cervical lymph node metastases at diagnosis. SCCs of the oral tongue most often arise along the lateral borders of the tongue[19] (Figure 50.5).

FIGURE 50.5 T2N0M0 squamous cell carcinoma involving the right lateral oral tongue.

Lesions of the floor of the mouth are often infiltrative and may invade bone, the muscles of the floor of the mouth, and the tongue. The frenulum is frequently a site of involvement. Clinical fixation of the tumor to the mandible suggests periosteal involvement, which may occur early.

Tumors of the alveolar ridge may present with pain while chewing, loose teeth, or ill-fitting dentures in edentulous patients. These cancers often arise in edentulous areas or along the free margin of the mandibular alveolus[86] (Figures 50.6 and 50.7). Anesthesia of the lower lip and teeth may indicate involvement of the mandibular canal and inferior alveolar nerve.[87] Tumors of the lip may abut the mandible and require imaging to evaluate the integrity of the mandible.[88]

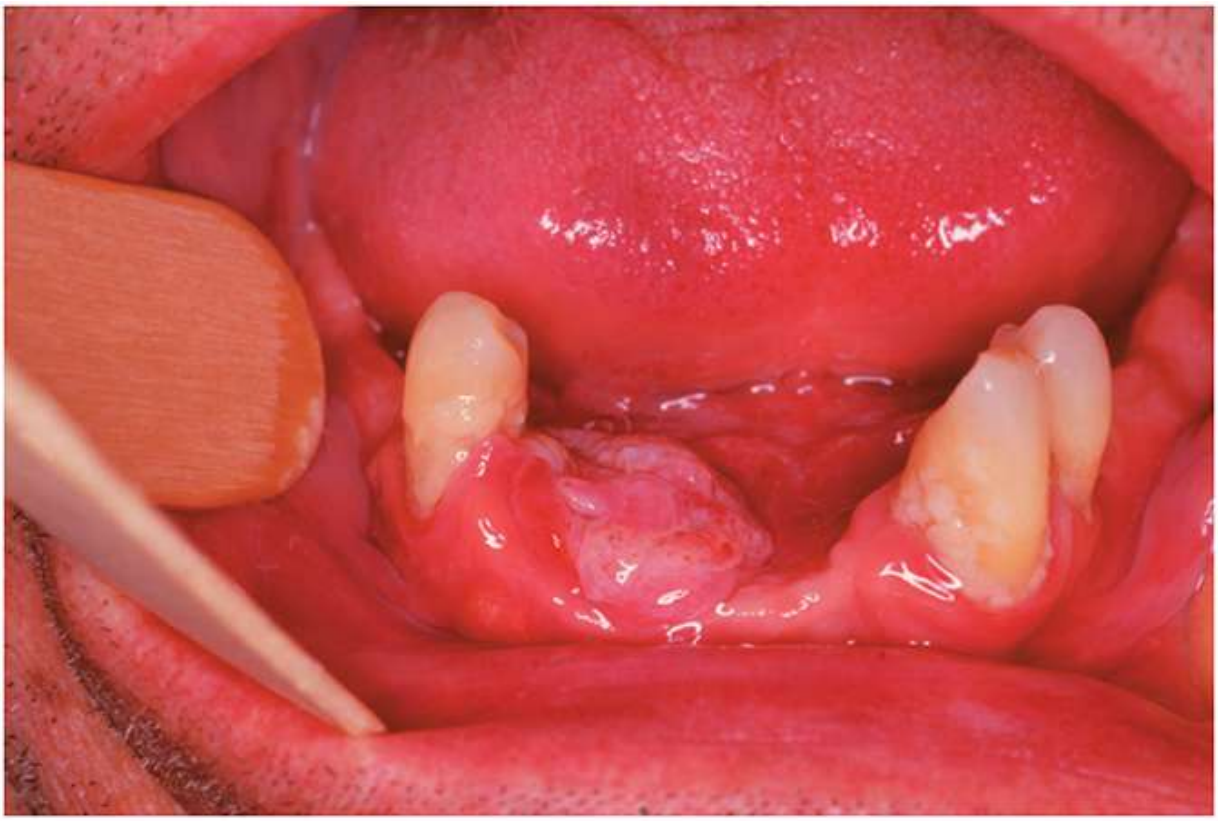

FIGURE 50.6 T1N0M0 squamous cell carcinoma of the mandibular alveolus. No evidence of bone invasion identified on panorex or computed tomography imaging.

FIGURE 50.7 Squamous cell carcinoma involving the mandibular alveolus and buccogingival space.

Tumors involving the retromolar trigone region may present with an exophytic growth pattern and limited involvement of underlying bone (Figure 50.8), or they may infiltrate cortical bone and spread along regional tissue planes to involve the pterygoid complex and parapharyngeal space. These latter lesions often induce trismus early in the clinical course.

FIGURE 50.8 Exophytic T3 carcinoma involving the right retromolar trigone, anterior tonsillar pillar, and proximal soft palate with minimal infiltration into the right base of the tongue.

Carcinoma of the buccal mucosa is rarely symptomatic early in its course. Lesions may be papillary or erosive and located near the dental occlusal line. These tumors are often relatively asymptotic and, therefore, seldom come to medical attention as T1 lesions. Often, these tumors manifest associated leukoplakia.[89] Multiple primary sites and local recurrence are also common. These tumors most frequently arise adjacent to the lower molars along the occlusal line of the teeth.

Carcinoma of the hard palate is often painless, and the sole presenting symptom may be an irregularity in the mucosa or ill-fitting dentures. Other presenting symptoms include nonhealing ulcers of the hard palate, intermittent bleeding, and pain.[90]

DIAGNOSTIC EVALUATION

Patients with oral cavity cancer should undergo a comprehensive history and physical examination. Detailed visual and digital examinations are particularly important for oral cavity tumors. A biopsy of lesions in question should be obtained as well as a thorough dental assessment. CT scans, panoramic radiographs, magnetic resonance imaging (MRI), and other imaging studies may also be important for accurate staging of the tumor and in treatment planning.

The history of present illness should address the following issues: tobacco and alcohol use; dysphagia; odynophagia; pain; trismus; difficulties with speech; hoarseness; loose teeth; ill-fitting dentures; hypoesthesia of the face, lips, or mandible; weight loss; and malnutrition. Otalgia suggests involvement of the ninth or tenth cranial nerve; facial numbness may suggest involvement of the fifth cranial nerve. Hypoesthesia usually results from perineural invasion (PNI), often from penetration of the mandible and perineural spread along the inferior alveolar nerve. The presence of trismus may indicate extension into the pterygoid musculature, signifying locally advanced disease. Other symptoms include a persistent ulcer, bleeding, drooling, or respiratory distress. A patient's comorbid illnesses must also be considered in designing the overall treatment strategy.

A detailed examination of the head and neck should be performed, with particular focus on the oral cavity and oropharynx. This usually begins with a full inspection of the oral cavity, including thorough inspection of the teeth. Palpation of the oral cavity can help assess bony involvement, tongue fixation, and depth of involvement. Deviation or fixation of the tongue suggests involvement of extrinsic muscles of the tongue. Bimanual palpation can help assess the depth of tumor invasion into musculature of the tongue and floor of the mouth. A thorough palpation of the neck is important to assess regional nodal disease.

Imaging can complement the physical examination in determining the extent of disease. A chest x-ray should be performed to exclude lung metastases or a second primary cancer. CT is the modality most commonly used to determine the extent of soft tissue and bony involvement and occult disease in the neck (Figure 50.9). CT may be used to determine the extent of invasion into the deep musculature of the tongue and adjacent structures. Moreover, CT is a valuable modality for visualizing invasion of the mandible, palate, and pterygopalatine fossa. If CT scanning is not available,

then panoramic radiographs can be used to demonstrate mandibular invasion. MRI may be used in case of contrast allergy or a lesion that is not well visualized on CT. For instance, MRI may be used if a patient has significant dental artifact that obscures visualization of the primary tumor on CT. MRI provides excellent definition of tumor involving the tongue and is a good modality for evaluating the possibility of perineural spread. Ultrasound may be used to screen for enlarged lymph nodes that are not clinically detectable. In experienced hands, the accuracy of ultrasound when combined with fine-needle aspiration may be superior to CT or MRI for staging the neck.[91]

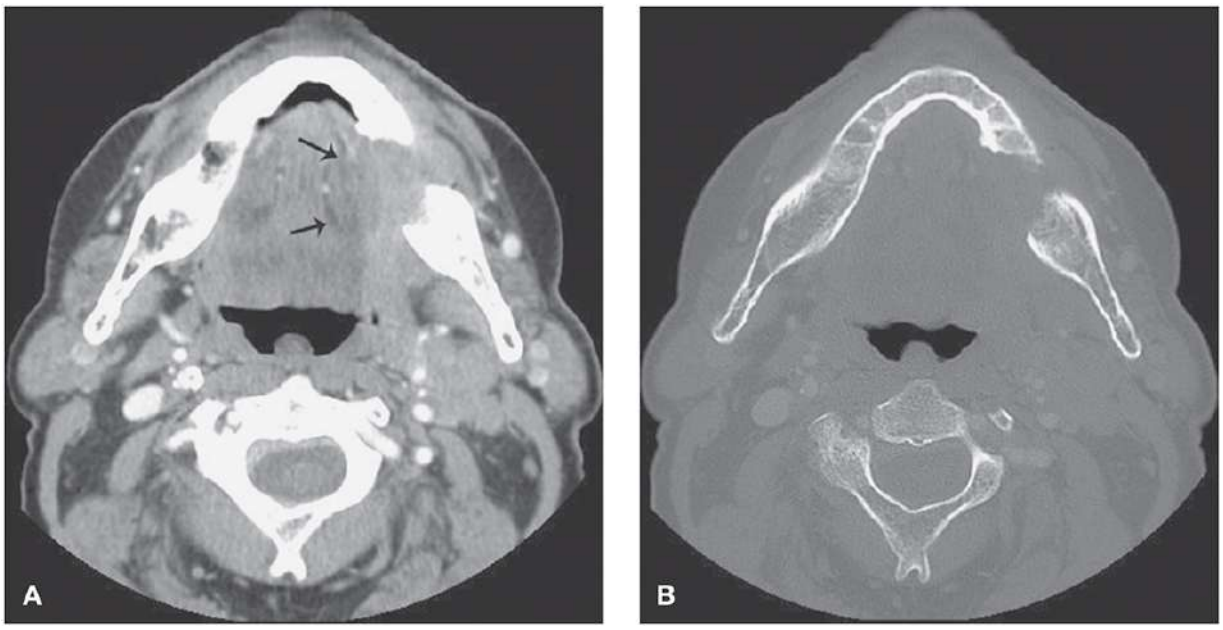

FIGURE 50.9 A. Transverse computed tomography (CT) image with contrast depicting infiltrative squamous cell carcinoma of the left lateral oral tongue and floor of the mouth with associated bone destruction (arrows). There is posterior tumor extension to involve the retromolar trigone and tonsillar complex. B. Corresponding CT bone window views demonstrating destruction of the mandibular body.

Positron emission tomography (PET) and PET/CT have been used increasingly in head and neck cancer evaluation for staging disease in the neck, evaluation of perineural and skull base involvement, identification of distant metastases, and detection of recurrence. In the initial staging, the use of PET/CT may assist with the determination of the depth of invasion, which is routinely determined pathologically.[92] In addition, several studies

suggest that PET is more sensitive and specific in evaluating lymphatic metastases compared to CT and MRI.[93,94] PET/CT may improve the anatomic localization of abnormalities identified on PET and decrease the number of equivocal PET findings.[95] Liao et al[96] prospectively evaluated 473 patients with OCSCC and reported a sensitivity of 77.7% and a specificity of 58% for PET/CT after histopathologic correlation of nodal metastases to the neck. Linz et al, demonstrated a negative predictive value (NPV) for PET/CT of 93% in a prospective study evaluating 150 patients with OCSCC.[97] Pentenero et al[98] report an accuracy of 66.7%, a specificity of 76.9%, and an NPV of 83.3% for staging of the neck with PET/CT. Despite the improved overall accuracy, clinical application of PET/CT is limited by the suboptimal detection of small metastases. Therefore, the decision to pursue a neck dissection should not be based solely on PET/CT findings.

Reports have indicated that the overall sensitivity and specificity of PET may be superior to CT and MRI for evaluating persistent or recurrent disease, particularly in patients who have received previous radiotherapy.[99,100] The accuracy of PET in detecting disease recurrence or persistence may be influenced by the time post-treatment when images are acquired. It is recommended that a PET scan not be performed until 8 to 12 weeks post-treatment to minimize the risk of both false-negative and false-positive interpretations.[101-104] Postoperative PET/CT may also improve the detection of early recurrent disease. A disease by Yu et al analyzed the charts of 391 patients treated for oral malignancy, of which 237 underwent PET/CT planning and 154 were planned with CT only. Patients screened with postoperative PET/CT were more likely to be diagnosed with early recurrence compared to those who received CT only and were more likely to undergo treatment intensification. The authors also showed postoperative PET/CT was associated with improved disease-free survival (DFS) and OS for patients with intermediate-risk features (T3-4, node positivity, lymphovascular invasion, PNI, tumor thickness >5 mm, and close surgical margins).[105]

STAGING

The American Joint Committee on Cancer (AJCC) has established a staging system for cancer of the oral cavity. The staging guidelines apply to all forms of carcinoma and are based on the eighth edition of the AJCC Staging Manual (Table 50.2).[106] Nonepithelial malignancies and melanoma of the lip and oral cavity are not included in the staging system. There are several pertinent changes from prior editions of the AJCC Staging Manual: (a) clinical and pathologic depth of invasion are now used in indicating the T category, (b) extrinsic tongue muscle involvement is no longer denoted as T4, (c) separate N staging categories are now present for patients treated with and without neck dissection, and (d) the presence of extranodal extension (ENE) is introduced as a descriptor of HPV-negative SCC.[106]

TABLE 50.2 STAGING OF ORAL CAVITY CARCINOMA (INCLUDING MUCOSA OF THE LIP)

Definition of Primary Tumor

T Category	**T Criteria**
TX	Primary tumor cannot be assessed.
Tis	Carcinoma in situ
T1	Tumor ≤2 cm in greatest dimension, ≤5 mm depth of invasion (DOI)
T2	Tumor ≤2 cm in greatest dimension, DOI >5 mm, *or* tumor >2 cm, and ≤4 cm, with ≤10 mm of DOI
T3	Tumor >2 cm and ≤4 cm, with DOI >10 mm or tumor >4 cm, with DOI ≤10 mm
T4	Moderately advanced or very advanced local disease
T4a	Tumor >4 cm with DOI >10 mm or tumor invades adjacent structures only (eg, through cortical bone of the mandible or maxilla, or involves the maxillary sinus or skin of the face)
T4b	Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery.
Definition of Regional Lymph Node (N)	
Clinical N (cN)	
N Category	**N Criteria**
Nx	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastases

Definition of Primary Tumor

N1	Metastases in a single ipsilateral lymph node, ≤3 cm in greatest dimension, ENE (−)
N2	Metastases in a single ipsilateral lymph node >3 cm, but ≤6 cm in greatest dimension and ENE (−); in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension and ENE (−); *or* in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension and ENE (−)
N2a	Metastases in a single ipsilateral lymph node >3 cm, but ≤6 cm in greatest dimension and ENE (−)
N2b	Metastases in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension, and ENE (−)
N2c	Metastases in bilateral or contralateral lymph nodes ≤6 cm in greatest dimension and ENE (−)
N3	Metastases in a lymph node >6 cm in greatest dimension and ENE (−) *or* in any node with clinically overt ENE (+)
N3a	Metastases in a lymph node >6 cm in greatest dimension and ENE (−)
N3b	Metastases in any lymph node(s) and clinically over ECE (+)

Definition of Regional Lymph Node (N)

Pathologic N (pN)

N Category	**N Criteria**
Nx	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastases
N1	Metastases in a single ipsilateral lymph node ≤3 cm in greatest dimension and ENE (−)
N2	Metastases in a single ipsilateral lymph node ≤3 cm in greatest dimension and ENE (+); >3 but ≤6 cm in greatest dimension and ENE (−); in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension and ENE (−); *or* in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension and ENE (−)
N2a	Metastases in a single ipsilateral or contralateral lymph node ≤3 cm in greatest dimension and ENE (+), *or* in a single ipsilateral lymph node, >3 but ≤6 cm in greatest dimension and ENE (−)
N2b	Metastases in multiple ipsilateral lymph nodes ≤6 cm in greatest dimension and ENE (−)
N2c	Metastases in bilateral or contralateral lymph nodes ≤6 cm in greatest dimension and ENE (−)

Definition of Primary Tumor

N3	Metastases in a lymph node >6 cm in greatest dimension and ENE (−); in a single ipsilateral lymph node, >3 cm in greatest dimension and ECE (+); *or* multiple ipsilateral, contralateral, or bilateral lymph nodes, any with ENE (+)
N3a	Metastases in a lymph node >6 cm in greatest dimension and ENE (−)
N3b	Metastases in a single ipsilateral lymph node >3 cm in greatest dimension and ECE (+), *or* in multiple ipsilateral, contralateral, bilateral lymph nodes, any with ENE (+)

Note. A designation of "U" or "L" may be used for any N category to indicate metastases above or below the lower border of the cricoid, respectively. Similarly, clinical or pathologic extranodal extension (ENE) should be recorded as ENE (−) or ENE (+).

AJCC Eighth Edition Prognostic Stage Groups

Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1, T2	N1	M0
	T3	N0, N1	M0
Stage IVA	T1, T2, T3	N2	M0
	T4a	N0, N1, N2	M0
Stage IVB	Any T	N3	M0
	T4b	Any N	M0
Stage IVC	Any T	Any N	M1

GENERAL MANAGEMENT

Surgical resection, radiation, chemotherapy, or combined modality approaches are classic treatment options that have been employed for patients with cancer of the oral cavity. The choice of treatment modality, either singly or in combination, depends on the stage and size of the tumor and relevant patient factors, such as toxicity, performance status, comorbid disease, and convenience. The overall health and functional status of the patient are important determinants in choosing between surgical and nonsurgical approaches.

Surgery is the mainstay of treatment for lesions of the oral cavity.[107] Surgical resection is expeditious, effective, and often associated with modest morbidity and good functional outcome, particularly for patients with small- to moderate-sized lesions. Definitive radiation therapy can be considered for patients with early-stage disease who either are not surgical candidates or refuse surgical management. For patients with advanced lesions of the oral cavity, a combined modality approach is generally recommended. In patients with high-risk pathologic features including nodal extracapsular extension and positive resection margins, the addition of concurrent chemotherapy during the postoperative radiation treatment course may further augment tumor control rates, provided the chemotherapy can be tolerated.[108-111]

PRINCIPLES OF SURGERY

All patients with oral cavity carcinoma should be evaluated by a head and neck surgical oncologist. In patients who are not surgical candidates, definitive high-dose radiation has been associated with higher rates of osteoradionecrosis (ORN) and inferior control rates, particularly in the setting of more advanced disease, highlighting the role of surgery as optimal management.[112-115] The primary objectives of surgery are complete resection of the primary tumor with negative margins and staging and treatment of the regional lymphatics. Margin status is one of the most important variables associated with survival, as locoregional control is significantly improved with margins of 0.5 cm or greater, relative to margins of <0.5 cm (36% vs 18%).[108,109,116]

Surgical Management of the Primary Tumor

In treating cancer of the oral tongue, it is best to obtain adequate margins during initial resection. Data from the National Cancer Database (NCDB) have demonstrated worse OS, by a reduction of survival of 13%, compared to negative margins.[117] The outcome of intraoperative positive margins followed by immediate repeat resection revised to negative margins is associated with worse survival compared to negative margins achieved with initial resection (31% vs 49%).[118] Several strategies are being developed to enhance the ability of surgeons to detect margins intraoperatively. However,

these remain largely experimental and are yet not being used in routine clinical practice.[119-121] Although surgeons and pathologists agree on the quantified distances for free margins, pathologic findings of margin status can be misclassified because of tissue shrinkage, inaccurate sampling, and improper orientation.[122] Although shrinkage is unavoidable, accurate assessment of all margins can be performed from the main specimen, as opposed to sampling from the tumor bed. How the surgeon takes the margins is also extremely important, and it is recommended that the margins be taken from the tumor specimen rather from the tumor bed, as the latter is associated with higher risks of local recurrence.[123] Furthermore, proper orientation of the specimen and communication with the pathologist are vital to assessing accurate margin status.

The ability to obtain clear, three-dimensional margins is the most important factor in selecting the surgical approach, and this is typically guided by the size and location of the tumor as well as factors related to the patient's dentition as well as the presence or absence of trismus. Most often, lesions of the anterior or lateral oral tongue and floor of the mouth can be resected transorally; however, in cases with significant posterior extent and/or in patients with trismus and/or obstructive dentition, a visor flap with lingual release—sometimes referred to as a pull-through or lip-splitting incision with mandibulotomy—may be required for optimal resection. The visor flap is an approach that avoids a facial incision and is associated with lower rates of oral incompetence and fistula.[124] Buccal resections can often be performed with a transoral approach or with a lip-split incision to allow adequate exposure for mandibular or maxillary resection. Retromolar trigone resections often require mandibulectomy because of the posterior extent and increased rate of bone invasion. The introduction of transoral robotic surgery offers a novel approach for resecting more posterior tumors without mandibulotomy.

Transoral resection is often used for excision of floor of the mouth tumors, and these excisions often involve marginal or segmental mandibulectomy because the presence of mandibular invasion is associated with worsened local control. The decision on whether to perform a marginal versus a segmental resection is based on the preoperative assessment of invasion of the periosteum and cortex.[125] However, this type of assessment remains a challenge because results of preoperative physical examination

are predictive of bone invasion only two-thirds of the time. This can be enhanced using imaging that has excellent specificity despite limitations in assessment of microscopic invasion.[126] For the management of small tumors with periosteal involvement, marginal mandibulectomy is associated with outcomes equivalent to those of segmental mandibulectomy. The major indications for segmental mandibulectomy include preoperative or intraoperative findings of bone invasion, tooth loss with low mandibular bone height, and bone that has previously been irradiated. In cases in which both a mandibulotomy and marginal mandibulectomy are contemplated, the risk of postradiation ORN is high and should be considered with caution.[127] Transoral resection can often be employed to resect lesions of the hard palate and maxillary alveolar ridge, though larger tumors that extend into the paranasal sinuses, masticator space, or infratemporal fossa and may require a facial incision to improve access.

Surgical Management of the Neck

The relatively high rate of cervical nodal metastasis associated with oral cavity cancers warrants management of the neck in the vast majority of patients with oral tongue, floor of the mouth, buccal, and retromolar trigone tumors. The selection of type and extent of neck dissection is dependent on whether the patient is clinically node negative based on physical examination and imaging; in clinically node-negative patients, a neck dissection is considered elective. In contrast, patients with nodes that are palpable or detected on imaging require a therapeutic neck dissection. Although neck dissection is a safe procedure, it is not without morbidity; shoulder dysfunction, iatrogenic cranial nerve injuries, and vascular insult remain significant complications of neck dissection.

Therapeutic neck dissection in clinically positive disease is a well-established treatment strategy, and the extent of dissection recommended in this setting has decreased considerably over the past several decades. In the early 1900s, radical en bloc resections according to the surgical oncologic principles advanced by Dr William Halsted were recommended. Over the intervening years, these relatively morbid operations have largely been replaced by more selective approaches to involve only the nodal basins with expected metastasis with preservation of uninvolved nonlymphatic

structures, including the internal jugular vein, sternocleidomastoid muscle, and spinal accessory nerve. The contemporary practice of these more limited procedures has been supported, with data demonstrating that regional control and survival rates do not decrease with more selective approaches, particularly when adjuvant therapies are used to manage microscopic residual disease in high-risk patients.[100]

Koyfman et al recently published guidelines on the management of the neck in oral cavity malignancies. For patients with cT2 to cT4 disease with a clinically negative neck, who are treated with curative intent, an ipsilateral neck dissection should be performed.[128] For patients with a clinically negative neck, the dissection should include levels Ia, Ib, II, and III, and at least 18 nodes should be removed.[128] For patients whose preoperative examination reveals a cN-positive neck, a selective neck dissection at levels I to IV or I to V is recommended. In these cases, positive pathologic nodes are found in more than 75%, with 15.8% having skip metastasis to level III or IV, without involvement of level I or II.[33,59,69,129] The use of radical and modified neck dissections is typically reserved for patients with advanced nodal disease (N3), disease extending into level V, or invading critical structures in the neck. In addition, contralateral neck dissection should be performed in patients with a clinically node-positive neck.[128] In patients with advanced disease of the oral tongue, lip, or mandible, tumor crossing midline, and floor of the mouth involvement, bilateral neck dissection may be required.[130,131]

For patients with cT1 disease and cN0 neck, an ipsilateral neck dissection should be performed.[128] The decision to proceed to END is based on a >20% probability of occult nodal disease being present for patients with early-stage tumors that are clinically node negative (cN0).[132] END can be therapeutic if no positive nodes are found at pathologic review, and it can provide important staging information to guide decision about the need for adjuvant therapy in patients found to have pN-positive disease with or without ENE. The depth of tumor invasion has been reported to be the best predictor for regional metastasis in the cN0 neck. Nevertheless, cutoffs for the extent of depth of invasion for which neck dissection is recommended remain ill-defined. A meta-analysis identified a depth of 4 mm from the mucosal surface in oral tongue cancers as the cutoff most frequently cited as an indication for END, based on an NPV of 95.5%.[133] Other analyses have

shown that the depth of invasion >4 mm is associated with an increased risk of occult metastasis and late cervical recurrences.[134-136] In floor of the mouth tumors, a depth of invasion >1.5 mm is associated with 33% occult regional metastasis, whereas in buccal carcinomas, tumors of the maxillary alveolar ridge, and tumors of the hard palate, depth has not been extensively studied, and occult metastases are rare, occurring in 9% of patients and most often associated with T4 tumors.[137,138] Therefore, END is not indicated for early-stage buccal, maxillary alveolar ridge, or hard palate cancers in cN0 cases. In addition to the depth of invasion, growth type, number of mitoses, PNI, lymphovascular invasion, and poorly differentiated and infiltrative growth patterns are associated with metastasis.[136,138] There is no clear consensus regarding which of these risk factors necessitate END. Once the decision to proceed with END is made, the literature supports dissection of at least the supraomohyoid neck, including levels I to III. The notable exception is cancer of the oral tongue, for which extension to remove level IV can be considered because of the occasional identification of skip metastases, which are difficult to salvage.[69] The need to extend a neck dissection to include level IIB has been questioned because dissection of this nodal level requires dissection of spinal accessory nerve, which, in turn, is associated with greater morbidity. The results of several prospective studies support the exclusion of level IIB in ENDs for patients with oral cavity cancer as the incidence of nodes with occult regional disease is 11.1% in cN0 patients.[139] If dissection is not feasible, elective radiation to a dose of 50 to 56 Gy may be efficacious.[128]

Given that as many as 70% of END are found to have no pathologic lymph nodes at pathologic review and neck dissection can be both morbid and costly, alternatives to END have been explored, and these include observation, elective radiation, or sentinel lymph node biopsy (SLNB). There have been several prospective studies performed to evaluate observation versus END, with one study demonstrating a survival benefit with END.[140] The rate of nodal recurrence in the observation arms in that study performed in Brazil was 41.7% compared with 15% in the END arm. Although successful salvage was higher with observation than with END (57% vs 16%), 66% fewer salvage attempts occurred in the END groups. Because the node-related mortality is higher with observation than with

END (22% vs 10%), END has been the standard of care for most patients with oral cavity cancers.[141]

In a recent landmark study, D'Cruz and colleagues at Tata Memorial Hospital in Mumbai evaluated 500 patients with early-stage OCSCC who were randomly assigned to undergo END versus observation with therapeutic neck dissection to evaluate survival differences between treatment options.[142] The unadjusted improvement in OS for END was 12.5% (END vs observation with TND, 80% vs 67.5%), and this result was confirmed after the investigators adjusted for other covariates (hazard ratio [HR], 0.63; $P < .001$). Although no difference was observed in the cohorts when patients had pN0 disease (HR, 1.2; $P = .54$), among pN-positive cases, significant improvement in survival was noted in the END cohort (HR, 0.52; $P = .008$). In addition, data from this study confirmed that depth >3 mm was a significant independent predictor of regional metastasis (HR, 2.17; $P < .001$). There was no difference observed for OS when patients with tumor depth <3 mm were compared across the two cohorts ($P = .12$); however, the study was not powered to definitively address this issue.[142] Overall, this study's results support the practice of END for early-stage N0 OCSCC and confirm that depth is an important variable in the decision between END or observation and therapeutic neck dissection.

Another option for managing the clinically node-negative neck is SLNB, which is a less invasive approach used to accurately identify occult metastasis in early-stage oral cancer. SLNB is based on the principle that cancer spreads first to a primary echelon lymph node known as the "sentinel node" that can be readily identified and meticulously evaluated for microscopic disease. This minimally invasive technique to stage regional lymph nodes is well established in melanoma and breast cancer and allows for a more systematic and accurate pathologic assessment of regional lymph nodes for metastasis without the morbidity of END. There have been several multi-institutional prospective studies that have been performed to assess the efficacy of SLNB in oral SCC. In a trial completed in Europe, sentinel lymph nodes were identified in 93% of patients with a low false-negative rate.[143] In a study performed in North America (ClinicalTrials.gov identifier: NCT00042926), SLNB was found to have a 96% NPV overall in cancers of the oral tongue.[144] Hasegawa et al conducted a multi-institutional study of patients with T1-2 node–negative disease with ≥4 mm depth of

invasion randomized to sentinel node versus neck dissection. Metastases-positive nodes were observed in 24.8% and 33.6% of patents in the dissection and sentinel biopsy group, respectively (P = .19), without a survival disadvantage, but with improved neck functionality in patients in the sentinel node group.[145] Similar results were shown by Garrel and colleagues who reported a neck node recurrence-free survival of 89.6% versus 90.7% in the neck dissection and sentinel node arm.[146]

A meta-analysis showed a pooled NPV of 96% in early-stage oral cavity tumors, with no difference in regional recurrence between SLNB and END (6.7% and 6%, respectively). The accuracy and consistent NPV found in most studies indicate that SLNB offers an excellent alternative to END in cN0 patients with early oral squamous cancers. Although this approach has become a standard of care for the management of the cN0 neck in patient with oral cavity cancer in Europe, its use in the United States has been much more limited. Factors that might explain the slow adaptation of SLNB in this country include the steep learning curve, the additional preoperative workup required, and the need for an experienced multidisciplinary team. There is no level I evidence yet available regarding survival equivalency with END.

Reconstruction

The oral cavity is a complex site made up of several structures critical for speech, swallowing, and appearance, and successful rehabilitation of these functions in patients who have undergone oral cancer extirpative surgery involves meticulous anatomic restoration post-resection. A successful, reconstruction should attempt to address all three of these functions, and it must be tailored to the site of the defect. Patients with advanced-stage disease are often best reconstructed with microvascular free tissue transfer, which has become standard in head and neck reconstruction and has improved both oncologic and functional outcomes.[1] In the case of oral tongue reconstruction, which is critical to restoring function, the major goals of reconstruction are to allow obliteration of the oral cavity to minimize dead space, to maintain premaxillary contact for articulation and the oral phase of swallowing, and to optimize the mobility of the tip of the tongue to maximize tongue sweep. Postoperative measures of tongue

protrusion and elevation have helped to identify objective targets for favorable speech and swallowing outcomes.[147] Also, for total glossectomy, the volume and convexity of the flap are critical to the achievement of optimal functional outcomes.[148]

For patients with oral cancers requiring mandibulectomy, mandibular reconstruction with bone ensures the best outcomes for speech, swallowing, and cosmesis and also helps to maintain symmetric temporomandibular joint articulation, enabling mouth opening and maintenance of an occlusal plane for chewing. The major cosmetic goals of mandibular reconstruction include providing facial height and projection to prevent the "Andy Gump" deformity.[149] Reconstruction of maxillary and hard palate reconstruction can provide oronasal separation as well as a surface necessary for premaxillary contact and obliteration during the oral phase of swallowing. Although prosthetic palatal obturation can also help achieve these objections, the choice between prosthetic obturation and free tissue is based on the size of the defect, the location, and the number of remaining teeth.[150] The major goals for reconstruction of the floor of the mouth include separation of the oral cavity from the neck and provision of soft tissue bulk between the ventral tongue and the mandible that prevents tethering of the tongue as well as provision of a platform for tongue elevation and protrusion. Major objectives of buccal reconstruction include resurfacing the cheek with prevention of cicatricial scarring and trismus. As swallowing function is well established as one of the most important factors associated with improved quality of life, oral cavity reconstruction and swallowing therapy under the guidance of an experienced speech pathologist are the critical elements in the successful functional rehabilitation after oral cavity cancer resection.

PRINCIPLES OF RADIATION THERAPY

Primary Radiation Therapy

Surgery is the primary treatment modality for oral cavity malignancy. When using radiation alone as the primary management, it is important to consider that the bony structures of the mandible and maxilla may impact the transmission of ionizing radiation. For early-stage disease, a combined approach including both external beam radiation and interstitial

brachytherapy is often recommended for optimal outcome. Thus, a course of radiation can require several weeks of daily therapy followed by an interstitial implant. The normal tissue toxicity risks of xerostomia, dental and gum injury, and occasional ORN may render radiation therapy a less attractive option for single modality treatment of patients who are candidates for surgery. For locally advanced disease, definitive radiation or chemoradiation is not advised in patients who are candidates for surgery.

Historically, sites commonly treated with single modality radiation include the lip, floor of the mouth, and oral tongue.[151,152] Early work indicates that the success rate of radiotherapy is higher if some or all of the treatment is administered with brachytherapy.[153,154] Decroix and Ghossein[155] reported outcomes in 602 patients with cancer of the oral tongue treated with radium implantation or implantation plus external beam radiation. In this series, recurrence at the primary site or at the primary site and neck was 14% and 22% for T1 and T2 lesions, respectively. The Royal Marsden Hospital reported local control rates of 90% at 5 years for T1 and T2 tumors treated with interstitial radiation with or without external beam radiation.[156] Pernot et al[157] reported local control rates of 96% for T1, 85% for T2, and 64% for T3 lesions of the oral cavity treated with brachytherapy and neck dissection. In this series, locoregional control rates were 83%, 70%, and 44%, respectively. Retrospective studies suggest that control rates at the primary site of early oral cavity lesions treated with either brachytherapy alone or a combination of brachytherapy plus external beam radiation range from approximately 70% to >95%.[155-158] For tumors that either involve the mandible or are immediately adjacent to it, definitive radiotherapy is contraindicated because it compromises control and increases the risk of ORN.

Intraoral cone, like interstitial brachytherapy, is a localized radiation therapy technique that has been used to boost the dose to the primary tumor in the oral cavity. Institutions with significant experience with this technique have reported results that rival those obtained by interstitial brachytherapy.[159,160] Either technique for boosting the primary tumor has resulted in improved outcomes compared to high-dose radiation therapy alone.[160,161] In general, external beam radiation therapy followed by either technique is preferable to radiation therapy alone. As with all specialized procedures, the skill and experience of the radiation oncologist are of

critical importance to the successful delivery and outcome of interstitial radiation or intraoral cone therapy.

It is difficult to compare radiation alone to surgery using retrospective analyses as patients who receive radiation alone are at baseline poor surgical candidates and/or with very invasive unresectable or morbid disease. The outcomes for advanced lesions of the oral cavity (T3 and T4) are less than satisfactory with either surgery or radiation alone. Membreno et al conducted a systematic review evaluating the outcomes of primary radiation with or without chemotherapy. Radiotherapy showed less favorable outcomes compared to surgery including lower OS and progression-free survival, with higher feeding tube dependency in the radiotherapy alone group.[162] In most advanced-stage cancers, single modality therapy is inferior to combined modality therapy.[154,163,164] Adjuvant radiation therapy can be delivered preoperatively or postoperatively.[159,163] Although each strategy has potential advantages and disadvantages, postoperative radiation therapy is generally preferred. Postoperative radiation treatment carries the advantage of no delay in the implementation of surgical resection and complete pathologic staging of the tumor. However, it must be borne in mind that postoperative wound complications may delay the implementation of radiation therapy.

Adjuvant Radiation

Although surgery has emerged as the preferred initial treatment approach for the majority of patients with tumors of the oral cavity, adjuvant radiation is commonly recommended to enhance the likelihood of locoregional tumor control. Robertson et al[165] conducted a phase III study in the United Kingdom of 350 patients with T2-T4/N0-N2 oral cavity or oropharyngeal cancers comparing surgery and postoperative radiation versus radiation alone. Because a difference in survival was identified, the study was closed early. The authors found that after 23 months, OS, cause-specific survival, and local control were all improved in the surgery plus radiation arm. Traditionally, indications for postoperative radiation therapy include multiple cervical metastases, positive or close margins, extracapsular extension, PNI, advanced T stage, and mandibular bone involvement. A phase III study conducted at the University of Texas MD Anderson Cancer

Center established the relative prognostic significance of clusters of two or more clinicopathologic features.[166] The adverse clinicopathologic features in this study included (a) close or positive margins, (b) nerve involvement, (c) ≥2 positive lymph nodes, (d) largest node >3 cm, (e) treatment delay >6 weeks, and (f) Zubrod performance status ≥2. This landmark trial demonstrated several now well-established management recommendations: Dose of ≤54 Gy postoperatively was associated with higher primary failure rates compared to ≥57.6 Gy, ≥63 Gy is necessary for ENE, and the presence of ENE as the only factor independently predictive of locoregional recurrence. Moreover, the authors concluded that escalation of dose beyond 63 Gy (in 1.8 Gy per fraction) to sites of increased risk did not yield improved locoregional control. Koyfman et al recently published American Society of Clinical Oncology (ASCO) guidelines on the adjuvant management of patients with oral cavity malignancy. For patients with pathologically negative neck, or a single node that does not have ENE, adjuvant neck radiation is not typically recommended unless there are indications to radiate from the primary characteristics, including PNI, lymphovascular space invasion, or a T3/T4 tumor.[128] For patients with pN1 disease who did not undergo a high-quality neck dissection, adjuvant neck radiation is also recommended.[128]

It is well established that head and neck tumors are rapidly proliferating. Several retrospective series have demonstrated an association between diminished outcomes and a delay beyond 6 weeks in initiating postoperative radiation.[167-169] A multi-institutional prospective study by Ang et al demonstrated that the total treatment time from the completion of surgery to the completion of radiation may affect the likelihood of ultimate disease control.[170] This study illustrated the impact of overall treatment time on 5-year locoregional control: Patients with overall times <11 weeks demonstrated a locoregional control rate of 76%, compared to 62% for 11 to 13 weeks, and 38% for times beyond 13 weeks. An observation study of 25,216 patients from the NCDB demonstrated a time from surgery to radiation of 42 days or less was associated with improved survival compared with 50 days or longer.[171] Hence, it is recommended that adjuvant radiation proceed as soon as surgical wounds are well healed, optimally 4 to 6 weeks after completion of surgery.

There has been significant interest in the use of intensified radiation fractionation schedules to counter rapid tumor cell repopulation as a means of improving outcomes in patients with head and neck cancer treated with radiation. Altered fractionation regimens such as hyperfractionation or accelerated fractionation have been considered for patients being treated with radiation alone, as this approach has been demonstrated to improve the likelihood of locoregional tumor control in the definitive setting.[172] Overgaard demonstrated an accelerated schedule of 6 days per week was associated with significantly higher OS compared to 5 days a week.[173] However, the use of altered fractionation in the postoperative setting has not been resolved. Ang et al reported a trend toward higher locoregional control and survival with a concomitant boost schedule compared to a standard fractionation schedule.[170] However, in a subsequent study, Sanguineti et al[174] demonstrated no benefit for accelerated fractionation, except in patients for whom postoperative radiation was delayed.

There has been recent interest in postoperative chemoradiation for patients with high-risk pathologic features. The results of two randomized trials suggest that postoperative chemoradiation may be beneficial for improving locoregional control and DFS among selected patients with specific high-risk features.[108,109] The impact of chemoradiotherapy appears to be most pronounced in patients with ENE and/or microscopically involved surgical margins.[109,110]

Radiation Techniques

General Considerations

Historically, carcinoma of the oral cavity has been treated with opposed lateral fields, using either two-dimensional or three-dimensional (CT-based) techniques. However, since the emergence of intensity-modulated radiation therapy (IMRT) at the turn of the millennium, there has been a dramatic shift in the radiotherapeutic management of head and neck cancer. Since that time, IMRT has gained widespread adoption and has become the de facto standard in the management of carcinoma of the head and neck.[114,175] The major driver for this dramatic shift away from conventional techniques has been the potential for normal tissue sparing and consequent

improvement in functional outcomes, particularly in the realms of salivary function and dysphagia.

With respect to oral cavity cancer, the improvements in conformality afforded by IMRT have opened the opportunity to mitigate damage to major salivary glands (xerostomia), the mandible (ORN), and the pharyngeal structures (dysphagia).[63,176-180] However, it is important to bear in mind that there are instances in which IMRT may not provide significant additional benefit in the treatment of oral cavity cancer and conventional techniques may be fully adequate. It is also valuable to consider that practitioner and treating center experience may be important indicators of potential outcomes when IMRT is utilized in the treatment of patients with head and neck cancer.[181,182]

Each institution should select appropriate oral cavity cases for treatment with IMRT. For instance, patients with T1/T2N0 carcinoma of the floor of the mouth or alveolar ridge who have undergone surgical staging of the neck may not benefit from IMRT because the bulk of both parotid glands can be excluded from opposed lateral portals (Figure 50.10). Ideal candidates for IMRT include patients with T1/T4 primary lesions with ipsilateral neck disease. In patients who have ipsilateral positive neck nodes, IMRT may allow dose limitation to the contralateral parotid gland without compromising treatment results.[183] In patients with bilateral neck disease, it may be difficult to effectively spare the parotid glands, particularly when superior level II cervical lymph nodes are involved, because of the coverage of the retrostyloid space in this setting.[184]

Treatment of the neck was omitted in lieu of a negative neck dissection. A and B. Relevant isodose lines. C. Right lateral digitally reconstructed radiograph of the field. The parotid tissue is nearly completely spared by this field arrangement.

Intensity-Modulated Radiation Therapy

The use of more conformal techniques may be associated with a unique set of potential pitfalls. Whereas treatment planning with two-dimensional or three-dimensional techniques does not universally mandate careful interpretation of cross-sectional imaging and attention to anatomic detail, IMRT requires precise target volume delineation. If a target volume is not included within the clinical target volume (CTV), it may receive a subtherapeutic dose of radiation and thus portend marginal recurrence. The quality of conformal radiation therapy is significantly associated with outcomes in the treatment of head and neck cancer.[181,182,185]

Most cases of oral cavity cancer will be treated postoperatively. It is important to consider that neck dissection tends to disrupt the anatomic landmarks defining borders between nodal levels. The task of distinguishing the primary tumor resection bed and adjacent neck dissection poses a significant challenge in target volume design. Gregoire et al[39,184] proposed guidelines for target volume delineation in the postoperative patient that are available as a reference. The authors encourage the reader to review these guidelines as they consider more selective coverage of nodal regions during target volume delineation. These guidelines serve in part as the basis for the recommendations presented in this section. Treatment considerations for each oral cavity subsite are presented in the section "Subsite-Specific Treatment and Results."

The discussion to follow is relevant to target volume design in the postoperative setting. Figure 50.11 illustrates relevant target volumes for a typical postoperative oral cavity case. Figures 50.12 and 50.13 provide examples of special considerations for patients with positive margins/ENE and ipsilateral treatment, respectively. There are three classes of CTVs that can be defined based on the practice of a range of North American institutions and cooperative group guidelines.[39,40,64,184,186,187]

FIGURE 50.11 T3N1M0 squamous cell carcinoma of the right oral tongue. The patient underwent right hemiglossectomy, including resection of the floor of the mouth, and right selective neck dissection. The tumor was 3 cm in size, with a depth of invasion of 1.3 cm, and 1/46 lymph nodes with evidence of carcinoma (no evidence of elective neck dissection). Adjuvant treatment was delivered with radiation therapy alone using intensity-modulated radiation therapy with the intent of maximizing coverage to regions at risk while sparing salivary glands and pharyngeal tissues. Note that the ipsilateral retrostyloid space and entire tongue, intraoral free flap, and dissected neck are included in CTV_{60}. The cranial extent of CTV_{54} in the contralateral neck is the bottom edge of the body of C1. The retropharyngeal nodes are not covered in this setting to allow sparing of the pharyngeal structures.

The patient underwent left mandibulectomy, composite resection of the floor of the mouth, left hemiglossectomy, and neck dissection. The final pathology demonstrated 3 cm primary lesion, with 6/55 lymph nodes positive for carcinoma, and ENE in a lymph node at left level II. The treatment was delivered with intensity-modulated radiation therapy using a simultaneous integrated boost concurrently with chemotherapy. The neck region with evidence of ENE received 66 Gy in 2.2 Gy per fraction, whereas the primary site, free flap, and ipsilateral neck received 60 Gy in 2.0 Gy per fraction. The contralateral neck received 56 Gy in 1.87 Gy per fraction. A and B. Preoperative positron emission tomography showing primary and nodal disease. C-F. Postoperative target volume delineation.

- The GTV_{70} is defined as all areas of gross disease as can be seen on CT, MRI, PET, and physical examination, including all nodes measuring >1 cm, containing a necrotic center, or fluorodeoxyglucose avid on PET imaging. An expansion on this volume will yield the CTV_{70}.[30]
- The high-risk CTV (CTV_{66}) is defined as the volume harboring ENE or a positive margin. The CTV_{66} 66 Gy can be delivered as either a simultaneous integrated boost (SIB) (2.2 Gy per fraction over 30 fractions) or a sequential boost.
- The intermediate-risk CTV (CTV_{60}) is defined as the volume that includes the primary tumor bed (based on preoperative imaging, physical examination, and operative findings) plus regions of grossly involved adenopathy. The target volume should include the entire primary surgical bed and the pathologically positive hemineck; this frequently requires coverage of nodal levels I, IIa-b, III, and IV for most cases. It is recommended that CTV_{60} receives 60 Gy in 2.0 Gy per fraction.
- The low-risk CTV ($CTV_{54\text{-}56}$) usually includes the prophylactically treated neck felt to have a low risk of harboring microscopic disease (eg, the uninvolved low or contralateral neck) and should receive 54 to 56 Gy as a SIB in 1.8 to 1.87 Gy per fraction.
- For patients with oral tongue or floor of mouth tumors approaching midline, who received ipsilateral neck dissection and are at high risk of contralateral nodal involvement, bilateral neck radiation should be administered.[128]

It is common practice for the radiation oncologist to consider selective coverage of the neck and retropharyngeal nodes in order to limit dose to critical organs at risk. This generally involves limiting cranial coverage of

the level II neck to the level of C1 in the N0 neck to spare the parotid gland and the upper pharyngeal structures.[64,177,178,184,188] This is an accepted standard in the N0 neck, which may potentially be extended to patients with small N1 disease.[64,184,189] Marginal recurrences near the base of the skull, above this cranial border of level II, have been reported in the node-positive neck.[183] The retrostyloid space represents the cranial extension of level II to the skull base. In cases where involvement of upper level II with one or more lymph nodes is evident, it is suggested that the retrostyloid space be included in the intermediate-risk target volume (ie, CTV_{60}) (see Figure 50.11).[184] In addition to this principle, there are several target volume design details specific to the postsurgical patient with head and neck cancer that should be considered.

- When a metastatic lymph node abuts or infiltrates muscle (most commonly the sternocleidomastoid or paraspinal musculature), it is recommended that the muscle be included in CTV_{60}, at least for the invaded nodal station (Figure 50.12).[184]
- When a metastatic node lies at the boundary with a nodal level that was not intended to be part of the intermediate-risk CTV, it is recommended that CTV_{60} be extended to encompass this adjacent level.[184]
- If level IV or Vb is involved, it is suggested that CTV_{60} be extended to include the supraclavicular fossa.[184]
- In the event of flap reconstruction of the oral cavity or neck, it is recommended that the entire flap be considered for inclusion in the IMRT field (either CTV_{60} or $CTV_{54–56}$ based on physician discretion), particularly if there is evidence of ENE.[190]
- In the case of extensive perineural spread, it is recommended that the proximal course of the involved nerves be included in the treatment field to the level of the infratemporal fossa or skull base.[191]

Conventional Radiotherapy

For the treatment of oral cavity cancer with either two- dimensional or three-dimensional techniques, the oral cavity tumor bed and upper echelon lymph nodes are included within the initial lateral fields (Figure 50.14). The

upper border of the field is positioned to provide a 1.5- to 2.0-cm border on the tumor bed in an attempt to partially spare parotid glands and hard palate without compromising coverage of the tumor bed and regional lymphatics. The inferior border of the field resides at approximately the thyroid notch, just above the true vocal cords. The posterior border is set at the midvertebral body level if level V nodal coverage is not required. The nodal volume should include levels Ia to Ib, II, and III. For patients with more advanced neck disease or positive level V lymph nodes, where the posterior chain requires radiation, the initial fields should be set behind the C1 vertebral body spinous process. The portals are then reduced at approximately 45 Gy to spare high dose to the spinal cord. If patients harbor cervical lymph node metastases, or high-risk disease, then the lower neck will also be treated. In this case, half-beam–blocked anteroposterior (AP) or opposed AP/posteroanterior (PA) fields can be matched to the inferior border of the opposed lateral fields at the level of the thyroid notch. An anterior larynx block is used, which protects not only the central larynx from unnecessary radiation dose but also against spinal cord overdose because of a three-field overlap.

Dose and Fractionation

When postoperative radiation is used for oral cavity cancer, the most common dose fractionation in the United States is 1.8 to 2.0 Gy/day. The authors generally recommend 2.0 Gy daily fractions. Dissected tissues that harbored the original tumor should generally receive dose on the order of 60 Gy. However, for close or positive microscopic margins or ENE, either an SIB to 66 Gy (eg, 2.2 Gy per fraction over 30 fractions) or a sequential 6.0 Gy localized boost should be considered. In the former scenario, the SIB volume should be kept small to minimize normal tissue complications (see Figure 50.12). If there is gross residual disease, either further surgical resection or focal boosting up to 70 Gy may be necessary. Regions of somewhat lesser risk (ie, clinically or pathologically uninvolved necks) should receive dose on the order of 54 to 56 Gy if treatment is delivered with an SIB.

When definitive radiation is used for oral cavity cancer, boosting the primary tumor with either interstitial implantation, submental, or intraoral cone therapy can result in increased tumor control and decreased complications, particularly ORN.[130] When external beam radiation therapy is used as the sole treatment modality, even small lesions that cannot be excised or treated with brachytherapy require doses in the range of 66 Gy in 2.0 Gy fractions for reliable control. For larger tumors, local control rates are generally unacceptable, even with the utilization of IMRT.[114,115] In patients who are unable to receive necessary chemotherapy, a hyperfractionated regimen or an extra fraction a week should be considered.[172,173] This has been demonstrated in the Meta-Analysis of Radiotherapy in squamous cell carcinomas of Head and Neck, which showed hyperfractionated regimens, along with concomitant chemoradiation, are associated with improved outcomes.[192]

Lower doses to the elective neck may be acceptable in patients treated with definitive radiation. Nevens et al[193] demonstrated an equivalent rate of local failure (14.1% vs 14.4%) in the 40 Gy compared to 50 Gy arm, with a trend toward less dysphagia at 6 and 24 months, and reduced salivary gland toxicity, although oral cavity cancers represented only 9% to 11% of patients in each arm in this study.

Simulation and Treatment Considerations

The patient should undergo simulation in the supine position with the neck extended. A thermoplastic mask is generally used to immobilize patients during simulation and treatment. Shoulder immobilization is important during this process, which is accomplished by using either a three-/four-point Aquaplast mask along with a shoulder immobilization device or a five-point mask that also encompasses the shoulders. For most oral cavity simulations, a bite block should be used to depress the tongue away from the hard palate; some institutions use a cork and tongue blade or a custom intraoral stent[194] for this purpose (Figure 50.15).

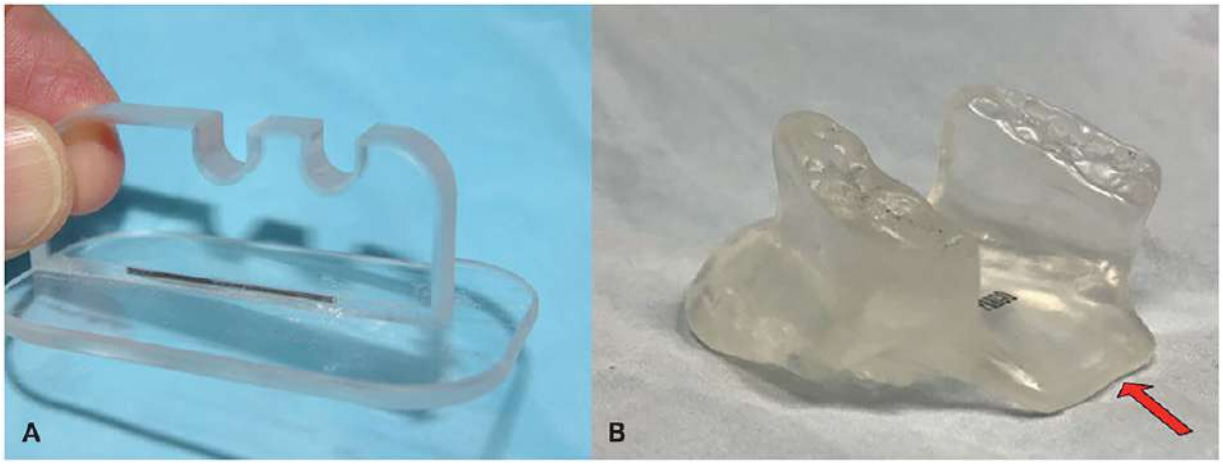

FIGURE 50.15 A. Lucite oral cavity mouthpiece fabricated at the University of Wisconsin for patients with oral cavity carcinomas. Upper dentition or maxillary alveolus links to U-shaped notch, and tongue rests beneath smooth undersurface of mouthpiece. Note embedded solder wire in mouthpiece floor to facilitate visualization of tongue positioning at the time of simulation and beam design. B. Custom acrylic mouth-opening and tongue-depressing stent utilized at several centers for the treatment of oral cavity carcinoma. The posterior edge (red arrow) helps to immobilize the tongue, whereas the superior ridges allow the maxillary teeth to rest and secure the stent in place.

CT simulation should be performed using a slice thickness of ≤3 mm, and intravenous contrast should be utilized in patients who have adequate renal function. The addition of contrast dye during simulation facilitates target volume delineation. The CT acquired during simulation should extend from the top of the head to the carina. During the treatment planning process, the planning treatment volume (PTV) for each region at risk should receive 95% of the prescription dose, and efforts should be made to spare

critical structures at risk. Table 50.3 lists normal tissue dose constraints for IMRT treatment planning.

TABLE 50.3 NORMAL TISSUE DOSE-VOLUME CONSTRAINTS[A]

Organ at Risk (OAR)	Dose-Volume Constraint
Spinal cord (+*5 mm*)	Dose to 0.03 mL ≤ 48 Gy
Brain stem (+*3 mm*)	Dose to 0.03 mL ≤ 52 Gy
Parotid glands	(a) Mean dose to single gland ≤ 26 Gy
	(b) *20 mL* of combined volume of both parotids <20 Gy
	(c) *50% single gland <30 Gy*
OAR pharynx	(a) *Dose to 33%* ≤ 50 Gy
	(b) *Mean dose ≤ 45 Gy*
	(c) Dose to 15% ≤ *60 Gy*
Glottic/supraglottic larynx	Mean dose ≤ 44 Gy
Cochlea	Max dose <35 Gy
Optic apparatus	Max dose <54 Gy
Brachial plexus	Max dose <66 Gy

IMRT, intensity-modulated radiation therapy.

[a]Dose-volume constraints for IMRT planning adapted based on Qualitative Analysis of Normal Tissue Effects in the Clinic recommendations,[195-198] practice standards, and Radiation Therapy Oncology Group protocol guidelines (RTOG 0920, ClinicalTrials.gov identifier, NCT00956007; and RTOG 1216, ClinicalTrials.gov identifier, NCT01810913).

IMRT may be more sensitive to intertreatment setup variations than conventional radiation therapy.[199] Daily imaging and strict immobilization protocols may decrease setup error and improve the fidelity of treatment delivery.[199-201] It is recommended that institutions use daily image-guided radiation therapy (IGRT) to enhance the setup reproducibility of IMRT treatment delivery. This may be accomplished with several IGRT techniques, including orthogonal kilovoltage films, kilovoltage cone beam CT, or megavoltage CT imaging. With the use of IGRT techniques, PTV expansions on the CTV may be limited to 2 to 5 mm. However, larger margins may be necessary for target volumes subject to significant interfraction variability; examples include the tongue in the absence of an

intraoral stent, a large flap in the oral cavity or neck, and some cases where there is significant shoulder motion and the low neck must be included in an extended IMRT field.[202] For these circumstances, a CTV-PTV expansion margin of 10 mm or greater may be necessary.

The delivery of a single IMRT plan throughout the course of treatment provides better dose conformality compared to the delivery of several consecutive (sequential) plans.[203] In the absence of low-lying cervical adenopathy, the low anterior neck can be treated with a single AP field or AP/PA fields matched to an upper IMRT field. The advantage of this split-field technique, compared to treating the low neck with an extended IMRT field, lies in the ability to decrease the mean dose to the larynx and inferior pharyngeal constrictors.[204]

Prior to the initiation of head and neck radiation, a careful oral and dental evaluation, including a panoramic radiograph, should be performed. Dentition in poor condition should be identified and considered for extraction to minimize the subsequent risk of ORN. Specifically, those teeth that will reside within the high-dose radiation volume that demonstrate significant periodontal disease, advanced caries, or abscess formation or are otherwise in a state of disrepair should be extracted. In addition, impacted teeth, unopposed teeth, and teeth that could potentially oppose a segment of a resected jawbone should be considered for extraction if they are anticipated to reside within the high-dose radiation treatment volume. Extraction of marginal teeth should also be considered in patients who are deemed unable to maintain adequate oral hygiene.

Radiation can induce several chronic effects in the oral cavity that warrant routine surveillance. Radiation can impair bone healing and diminish the capacity for successful recovery following trauma or oral surgery. For this reason, elective oral surgical procedures including extractions must be very carefully considered after radiation. Escalation of dental caries deriving from xerostomia following radiation is well recognized (Figure 50.16). Radiation of the major salivary glands changes the nature of salivary secretions,[60] which can increase the accumulation of plaque and debris and reduce salivary pH and the buffering ability of saliva.[205] This creates an environment in the oral cavity, which predisposes patients to caries. During a course of radiation to the oral cavity, simple techniques such as the use of custom molds or wax to absorb electron

backscatter can diminish hot spot mucositis from dental fillings and improve treatment tolerance.[59] Attention to oral hygiene with frequent dental follow-up examinations and cleanings, daily fluoride therapy (Figure 50.17), flossing, and brushing should be an integral component of the education and postradiation care of patients who undergo radiation to the oral cavity.

FIGURE 50.16 Advanced dental caries in a patient with profound radiation xerostomia and lack of attention to dental hygiene over many years following treatment.

FIGURE 50.17 Custom-designed fluoride carrier trays to facilitate daily fluoride application to existing dentition.

Proton Radiation

Proton beam therapy is increasingly used in the management of head and neck malignancy due to its ability to spare nearby critical organs. Although there are yet no randomized data comparing photons to protons in the management of oral malignancies, several retrospective analyses have reported favorable dosimetric profiles using intensity-modulated proton therapy.[206,207] Particularly in the recurrent setting, the use of proton radiation has demonstrated impressive local control rates as high as 77% at 1 year.[208] A systematic review on the use of proton radiation for oral and oropharyngeal carcinoma demonstrated improved acute toxicity profiles compared to photon therapy.[209]

Brachytherapy

Historically, brachytherapy has played an important role in the treatment of oral cavity carcinoma. Brachytherapy has been used to boost the primary

site in the oral cavity before or following external beam radiation (Figure 50.18). This technique has also been used as a sole modality in the treatment of selected (early-stage) tumors of the oral cavity with good results.[157,158,210] When brachytherapy is used as a sole treatment modality, doses of 65 to 75 Gy are commonly prescribed over 6 to 7 days. Traditionally, radiation has been delivered using low-dose rates of 0.4 to 0.6 Gy/hour to the target volume.[211,212] However, there has been recent interest in high-dose rate (HDR) (Figure 50.19) and pulsed dose rate techniques,[213,214] although there is no compelling evidence that these techniques are superior to traditional low-dose rate radiation in the treatment of head and neck cancer. There have been several dose and fractionation schedules published for HDR brachytherapy in the treatment of oral cavity cancer.[215-218] Although the American Brachytherapy Society has not provided a consensus as to optimal dose and fractionation,[219] there is concern regarding the potential morbidity with fraction sizes ≥6.0 Gy in this setting.[219,220]

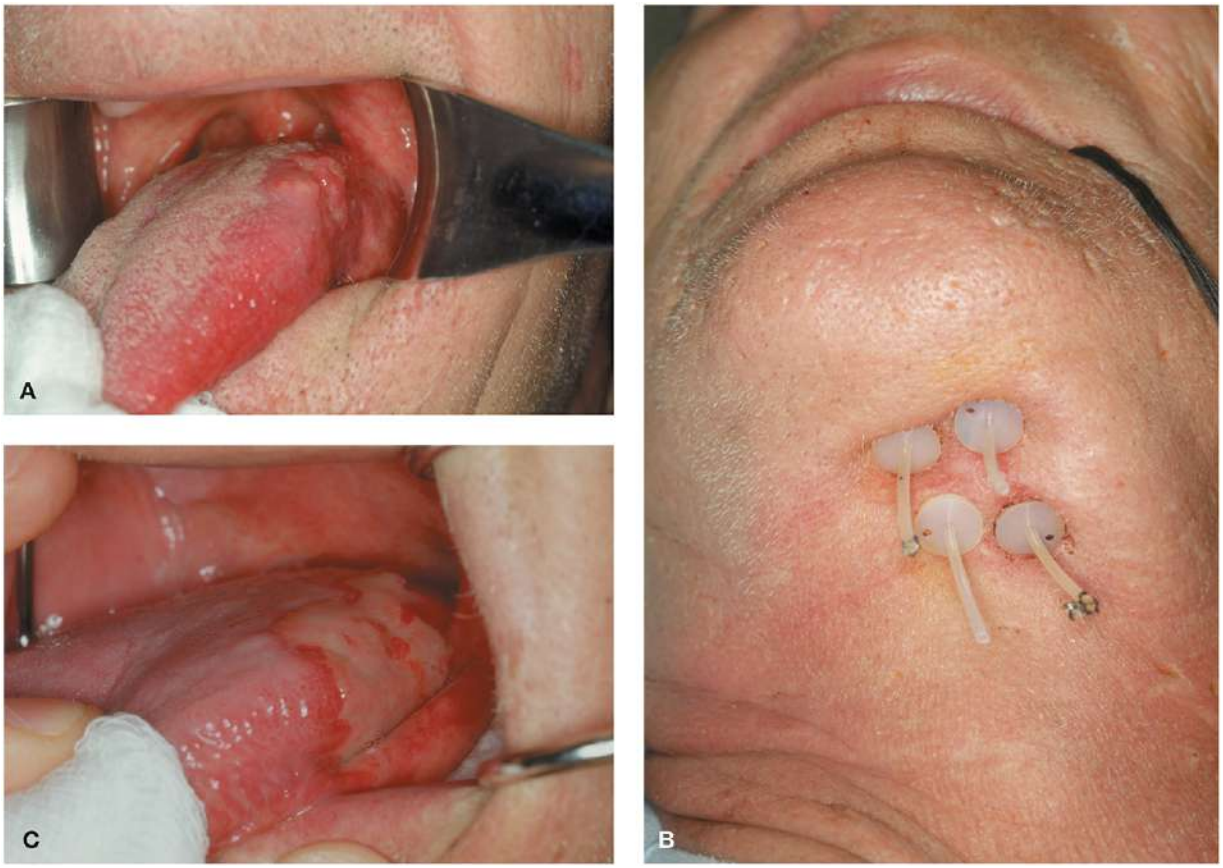

FIGURE 50.18 A. T2N0M0 squamous cell carcinoma involving the left lateral oral tongue. B. Submental view of interstitial implantation catheters housing ^{192}Ir seeds for delivery of 25-Gy tumor boost following external beam radiation of 50 Gy. C. Implantation bed mucositis conforming to the tumor distribution 7 days following 25-Gy implant boost.

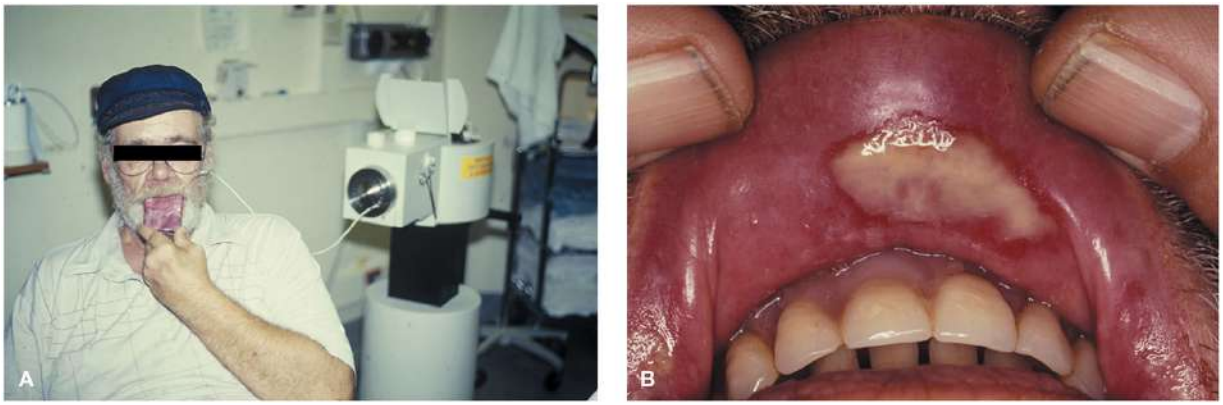

FIGURE 50.19 A. Patient undergoing high-dose rate (HDR) brachytherapy for superficial T1 upper lip squamous cell carcinoma (buccal surface) using a single interstitial catheter for source delivery. B. Focal mucositis 1 week following completion of HDR brachytherapy treatment course.

Many techniques for brachytherapy in the oral cavity have been described.[221] Brachytherapy can be accomplished with either rigid cesium needles or iridium-192 (^{192}Ir) sources afterloaded into angiocaths. The most common technique is afterloading with ^{192}Ir.[179] Guide needles can be inserted either freehand or with the aid of a custom template to help maintain optimal source spacing.

Depending on the size of the lesion, a single plane, double plane, or volume implant can be used to cover the tumor with a 1-cm margin. For tumors <1 cm in thickness, single-plane implants are adequate. Surface mold radiation can also be considered for small tumors <1 cm depth or superficial lesions of the lip, hard palate, lower gingiva, and floor of the mouth. However, when lesions exceed 2.5 cm, it is difficult to avoid significant cold spots in the implant volume. For this reason, it is recommended that for lesions larger than 2.5 cm, part of the treatment is given with external beam radiation to supplement the dose to the cold spots. In this setting, a combined treatment plan typically gives 50 Gy over 5 weeks with external beam radiation followed by 30 Gy with a brachytherapy implant. What must be borne in mind is that as tumors get too close to the mandible or are large in volume, the risk of ORN increases.[222]

Over the past decade or more, stepwise improvements in reconstructive surgery techniques have diminished the practice frequency of brachytherapy in the treatment of oral cavity carcinoma. In addition, a diminishing percentage of radiation oncologists remain highly skilled and experienced with the requisite implant techniques. Nevertheless, in experienced hands, the expert use of brachytherapy can provide excellent tumor control and high-quality cosmetic and functional results. An example of the use of HDR interstitial brachytherapy for a patient with advanced T2N0 lower lip cancer is illustrated in Figure 50.20. Similar comments parallel the use of intraoral cone radiation treatment described further in the section below.

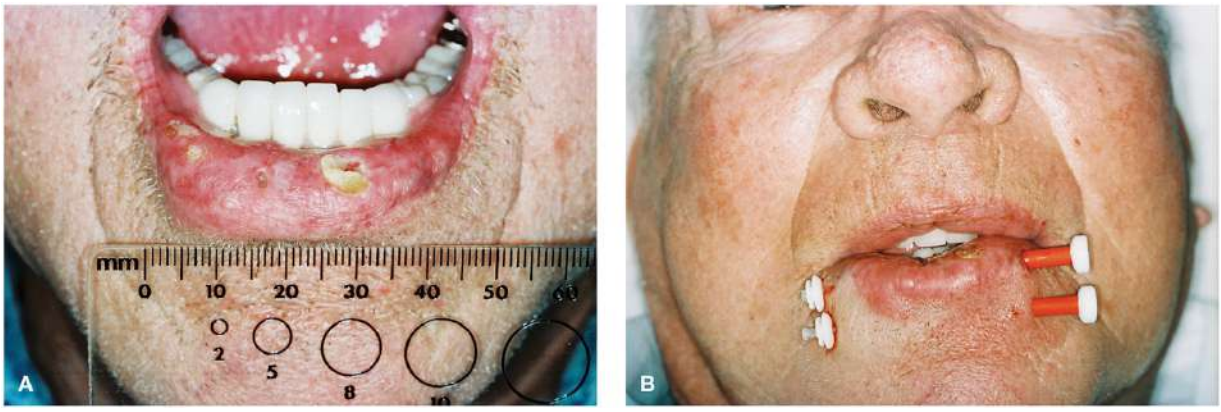

FIGURE 50.20 A. Infiltrative T2N0 squamous cell carcinoma of the lower lip measuring 3.5 cm × 1.2 cm × 1.2 cm. B. Interstitial iridium-192 implant performed (two catheters) for high-dose rate brachytherapy delivery over 11 elapsed days as sole treatment. The patient remains with no evidence of disease at 6 years with excellent cosmetic and functional status.

Intraoral Cone

The intraoral cone is another delivery tool to enable boosting of radiation dose to sites within the oral cavity while avoiding direct dose to the mandible (Figure 50.21). This technique is generally best suited for anterior oral cavity lesions in edentulous patients. However, palatal arch sites can be targeted with the intraoral cone as well. Treatment with intraoral cone involves either 100 to 250 kilovolt (peak) (kvp) x-rays or electron beams in the 6 to 12 MeV range.[159,160] Lesions up to 3 cm are amenable to treatment with intraoral cone as long as they are accessible. Intraoral cone therapy requires careful daily positioning and verification by the physician. For this purpose, the device is equipped with a periscope to visualize the lesion. The cone abuts the mucosa and is centered directly over the lesion. Intraoral cone treatment should take place prior to external beam radiation so that the lesion can be adequately visualized. A major advantage of cone therapy is that it is highly focal to the tumor bed but noninvasive. Hence, when available, for suitable lesions, it may be preferred to brachytherapy. However, as noted for brachytherapy delivery, operator experience and dedication are essential to optimize outcome.

FIGURE 50.21 A. Intraoral cone boost technique at the University of Wisconsin for focal delivery of electron beam radiation. The electron cone is mounted directly to the accelerator gantry with a sideview periscope enabling direct vision and positioning for daily treatment. B. Focal mucositis involving the distal oral tongue following treatment of a 1-cm tumor in this location with intraoral cone technique.

PRINCIPLES OF SYSTEMIC THERAPY

Over the decades, the role of chemotherapy has advanced from use only in the recurrent or metastatic setting to use in the definitive treatment setting. The advantage of systemic therapy was explored by the meta-analysis of chemotherapy in head and neck cancer (MACH-NC).[223,224] The study included pooled data from randomized trials of patients with a diagnosis of oral cavity, oropharynx, hypopharynx, and larynx cancer who received chemotherapy in the induction, concurrent, or adjuvant setting.[223] Although the trials included in this analysis vary with respect to radiation dose, fractionation schedule, and chemotherapy regimen, they have in common a randomized comparison between radiotherapy and radiotherapy plus chemotherapy. The updated MACH-NC report of 93 randomized trials identifies an absolute survival benefit of 4.5% at 5 years with the addition of chemotherapy, which is mainly driven by the effect of concurrent chemoradiation (6.5% at 5 years).[223] However, patients with oral cavity comprised only 21% of the patient population in the pooled analysis.[112] The ASCO guidelines on the management of the neck in oral cavity malignancy recommend the use of chemotherapy with radiation in patients with ENE.[128] The currently accepted chemotherapy regimen is cisplatin 100 mg/m^2 delivered every 3 weeks. The use of lower dose cisplatin (30-40 mg/m^2) has been studied, but not in the adjuvant setting.[225] Due to a lack of phase III

data in the adjuvant setting, high-dose cisplatin should be used unless there is a medical contraindication.

Several studies have focused on the use of chemoradiation in patients with high-risk pathologic features following initial surgery. Cooper et al[108] reported the results of RTOG 9501 comparing radiation alone (60-66 Gy) to chemoradiation (same radiation dose plus three cycles of 100 mg/m^2 cisplatin) in patients with head and neck carcinoma demonstrating high-risk features after gross total resection. High-risk disease was defined as any or all of the following: two or more involved lymph nodes, extracapsular extension of nodal disease (ENE), and microscopically involved resection margins. This study demonstrated a benefit in locoregional control and DFS for the chemoradiation arm, but no OS benefit was appreciated. A parallel study, EORTC 2931, reported by Bernier et al[109] randomized patients to essentially equivalent treatment arms following head and neck cancer surgery. Eligibility criteria included patients with pathologic T3 or T4 disease (except T3/N0), patients with any T-stage disease with two or more involved lymph nodes, or patients with T1/T2 and N0/N1 disease with unfavorable pathologic findings (ENE, positive margins, perineural involvement, or vascular embolism). Local control, progression-free survival, and OS were superior for patients in the chemoradiation arm. In a subsequent comparative analysis using pooled data from these two studies, ENE and/or microscopically involved surgical margins were the risk factors for which the impact concurrent chemoradiation was significant.[110] There was a trend favoring concurrent chemoradiation in the subset of patients with stage III to IV diseases, vascular embolism, perineural infiltration, and/or positive lymph nodes at levels IV and V with oral cavity or oropharyngeal primaries.[110] The subset of patients with two or more involved lymph nodes, without evidence of ENE, did not appear to benefit from chemotherapy in this analysis.

Laskar and colleagues also evaluated the role of adjuvant therapy in patients with adverse prognostic features including ECE, ≥2 nodes, involved margins, extensive soft tissue infiltration and/or skin infiltration requiring major reconstruction, PNI, or lymphovascular embolization. Patients were randomized to standard 60 Gy given 5 days a week, or concurrent chemoradiation with weekly cisplatin, or a third arm with radiation delivered six fractions per week. The authors did not find a

difference between the three arms in terms of locoregional control or DFS. There was no benefit to intensification with either modality in patients with a single adverse factor, although a benefit was seen in patients with a combination of high-risk features for example, T3 to T4 primary with N2 to N3 nodes along with ECE.[226] These studies suggest that the addition of chemoradiation following surgery should be considered in patients with high-risk head and neck cancer features who are able to tolerate treatment.

Neoadjuvant systemic therapy is generally not recommended in the standard management of resectable OCSCC. In the case of technically unresectable OCSCC, the concept of neoadjuvant chemotherapy as a means of downstaging disease in order to enable surgical resection has been explored.[227] In a study by Chaukar et al, the authors randomized 68 patients with stage T2 to T4 oral cavity cancer necessitating resection of the mandible for paramandibular disease in the absence of radiologic or clinical evidence of bone erosion to either upfront surgery or two cycles of docetaxel, cisplatin, and fluorouracil every 3 weeks. The authors did not demonstrate any compromise in outcomes, with 47% of patients achieving mandibular preservation.[228] The engagement of an experienced head and neck surgical oncologist to explore the technical feasibility of resection is paramount due to the potential of disease progression and the consequent risk of compromising the potential for resection in borderline patients. Generally, in this context, a combination of docetaxel, cisplatin, and 5-fluorouracil (5-FU) is the preferred induction regimen for clinically fit patients[184] with reported response rates of 17% to 50%.[227] However, it is important to consider that the inherent toxicity of these regimens may compromise the ability to deliver local therapy.[229-231]

The use of molecular targeted therapies has steadily advanced in the field of head and neck oncology. Cetuximab is a monoclonal antibody against the epidermal growth factor receptor that has been approved for the management of locally advanced, recurrent, or metastatic head and neck SCC.[229,232] In the context of locally advanced head and neck SCC, Bonner et al reported the results of a multinational study demonstrating the superiority of cetuximab plus radiation to radiation alone.[233] However, this study did not include patients with OCSCC. The RTOG launched a study (RTOG 0920) to evaluate the impact of cetuximab in the postoperative treatment for intermediate-risk disease. The study defines intermediate-risk disease as

PNI, lymphovascular space invasion, close margins, T3/T4a disease, T2 disease with >5 mm thickness, and single lymph node >3 cm or ≥2 or lymph nodes <6 cm without ENE. After an R0 resection, patients are randomized to either radiation or cetuximab plus radiation. A parallel study (RTOG 1216, ClinicalTrials.gov identifier: NCT01810913) was launched to explore the benefit of cetuximab and docetaxel compared to standard platinum-based chemotherapy in the setting of patients with high-risk disease (ENE or positive margins). Over two-thirds of patients in RTOG 0920 had oral cavity cancer. At a median follow-up of 7.2 years, OS was not improved with cetuximab, although DFS was improved.[234] The results of RTOG 1216 are awaiting publication.

Neoadjuvant Immunotherapy

Novel approaches are needed to improve outcomes in patients with oral cavity malignancy who continue to have moderate outcomes. In recent years, the use of immunotherapy for head and neck SCC has increased substantially. There are numerous trials evaluating immunotherapy in the neoadjuvant, definitive, and salvage setting. In a randomized phase 2 trial of neoadjuvant nivolumab and nivolumab plus ipilimumab in untreated oral cavity cancer, 53% and 69% had pathologic downstaging, respectively.[235]

Uppaluri et al published in their phase III trial of neoadjuvant and adjuvant pembrolizumab in resectable, locally advanced, non–HPV-related head and neck cancer.[236] Thirty-six patients were enrolled. One-year relapse rate was 17% in patients with high-risk pathology (lower than the historical rate of 35%), including ENE and/or positive margins. In addition, eight (22%) patients experienced pathologic tumor response ≥50% with necrosis, debris, and giant cell/histiocytes. However, no patients experienced a pathologic complete response.[236] This trial provides the rationale for trial KN689, an ongoing phase 3 trial of perioperative pembrolizumab (NCT03765918).

PROGNOSTIC AND PREDICTIVE FACTORS

The most significant prognostic factor for outcome in oral cavity carcinoma is the presence of cervical metastases.[237] In patients with positive cervical metastases, the 5-year survival is reduced by approximately 50% compared

to those without cervical metastases.[238] The prognosis diminishes further when patients harbor multiple levels of nodal involvement or ENE. In a retrospective review, Myers et al[237] found that 5-year disease-specific and OS rates for pathologically N0 patients were 88% and 75%, respectively; these decreased to 65% and 50%, respectively, if patients were node positive but without evidence of ENE. Patients who were node positive with evidence of ENE had 5-year disease-specific and OS rates of 48% and 30%, respectively.

Several histopathologic factors in the primary lesion are associated with adverse prognosis. Tumor thickness and depth of invasion have been shown to confer a higher risk of regional metastases.[19] PNI has been correlated with cervical lymph node metastases, extracapsular extension, and diminished survival.[239-241] Microvascular invasion has also been correlated significantly with cervical lymph node metastases.[241,242] However, lymphatic invasion has not been correlated significantly with cervical lymph node invasion.[19] The prognostic significance of grade has also been evaluated.[203] Because of the wide variation in pathologic interpretation, it is difficult to discern the independent value of histologic grading as a prognostic or predictive value.[19]

SURVEILLANCE

The major goals of surveillance include early diagnosis of recurrence and second primary tumors and management of the ongoing sequelae of head and neck cancer treatment. It is advisable that follow-up be conducted by the multidisciplinary team that provided oncologic management to the patient.[243,244] National guidelines recommend a history and physical examination, including a complete head and neck examination with fiberoptic examination, about every 3 months for the first year following treatment. Follow-up may be spaced out to every 6 months after the first year if there is low suspicion for disease recurrence.[245] All patients who have completed radiation treatment for oral cavity cancer should undergo routine head and neck examination, imaging, and dental evaluation. Dreizen et al also showed that caries development may be prevented by daily use of a gel containing 1% sodium fluoride.[246] In addition, it is recommended that the follow-up protocol include an assessment of thyroid function (thyroid-

stimulating hormone level) every 6 to 12 months. Radiation-induced hypothyroidism is detected over the subsequent years in 20% to 25% of patients who undergo neck irradiation.[247,248] Smoking and alcohol cessation, as well as screening for lung cancer in clinically indicated patients, are also important components of an ongoing follow-up program for all patients with head and neck cancer.[249]

SUBSITE-SPECIFIC TREATMENT AND RESULTS

Lip

The treatment approach for lip cancer is driven by the stage of disease and the expected functional outcome. Surgery is generally the preferred treatment modality for early-stage carcinoma of the lip, although radiation therapy is an option for local tumor control. Although the local control of T1 and T2 squamous cancers of the lip is excellent with surgical resection, disruption of the oral sphincter provided by the orbicularis muscle can lead to oral incompetence if not properly reconstructed. Therefore, several reconstructive methods have been developed to help preserve oral sphincteric function, even following large excisions for T3 and T4 lesions. For these larger lesions, surgery followed by radiotherapy remains a standard therapy (Figure 53.2). One possible exception is a superficial cancer that occupies most of the lip, which is best managed with primary radiation therapy because of the potential functional and cosmetic implications of primary surgery.

The successful surgical management of lip cancers includes the eradication of the primary tumor with free margins with preservation of the oral sphincteric function of the lip. For small lesions, excision with primary closure can be highly effective in achieving both of these objectives, whereas resection of larger legions can often require complex local flap repairs to attain satisfactory oncologic, cosmetic, and functional outcomes. SLNB can also prove to be useful in the management of patients with node-negative lip cancers, but further clinical investigation in this area is needed.

When primary radiotherapy is used to treat lip cancer, the target volume should include the primary tumor plus a 1.5- to 2.0-cm margin. For early-stage lesions, photons in the orthovoltage range (100-200 keV) or electrons may be used. The electron energy should be chosen based on the thickness

of the lesion (commonly 6-9 MeV). Efforts should be made to shield the underlying gum, dentition, and mandible as appropriate. This can be accomplished with the use of oral shields or Cerrobend stents. The recommended dose is 50 Gy in 4.5 to 5 weeks for smaller lesions and 60 Gy in 5 to 6 weeks for larger lesions. Some institutions have used an approach where external beam radiation is given to approximately 40 to 50 Gy followed by a brachytherapy boost; however, small- to intermediate-stage lesions can be treated by primary brachytherapy alone (Figure 50.18).

An important consideration in managing lip cancer is the risk of regional metastatic disease. Generally, the risk of regional lymph node metastatic disease for T1 and T2 cancers of the lip is lower than for stage-matched tumors of other oral cavity sites. Thus, END is recommended for patients with T3 and T4 carcinomas of the lip; however, it may not be warranted for all T1 and T2 lesions. Some institutions have used a "moustache field" for elective irradiation of the perifacial lymphatics (~50 Gy) for more advanced upper lip lesions.[250]

Oral Tongue

Although primary radiation therapy and surgery are potential treatment options for early-stage carcinoma of the oral tongue, the preferred treatment for most oral tongue cancers in the United States is primary surgery.[19] Surgical resection and reconstruction as appropriate is generally preferred for medically operable patients. Postoperative radiation therapy is recommended for patients with large primary tumors (T3, T4), close or positive surgical margins, evidence of perineural spread, multiple positive nodes, or ENE.[250] Postoperative chemoradiation should be considered for patients with adverse risk factors who are able to tolerate combined modality treatment.[108-111] Primary radiotherapy techniques can be used for patients who refuse or are unable to tolerate surgery.

Surgical approaches to oral tongue cancers can be either transoral, transcervical, or via mandibulectomy to obtain the exposure necessary to achieve adequate margins. Partial glossectomy is the most common procedure performed for oral tongue cancers, and the extent of resection depends on the size and growth pattern of the tumor, as some lesions are relatively infiltrative, while others may be more exophytic. Because the

tongue is essentially composed of skeletal muscle covered by mucosa, the tissue is extremely elastic, and wide margins are encouraged at the onset of resection to avoid retraction of muscle fibers with microscopic tumor cells that could serve as a source of local recurrence.

Total glossectomy may be indicated for extensive tumors or those that involve the intrinsic tongue musculature. Total glossectomy, even with reconstruction, can result in difficulty with deglutition and maintenance of an adequate airway. Aspiration may be a chronic problem; thus, laryngectomy may be necessary in some cases. However, properly selected patients with adequate postoperative rehabilitation can be treated with total glossectomy without laryngectomy. If the larynx is preserved, laryngeal suspension and palatal augmentation may help with the rehabilitative efforts.

Tumor size and depth of invasion are currently the most reliable indicators for predicting cervical metastases in patients with oral tongue SCC. Because of the high risk of nodal metastases, the neck should be addressed with either surgery or radiation in all but the earliest tumors of the oral tongue. Patients with small oral tongue cancers should be considered for neck therapy, particularly if the primary tumor exhibits extension onto the floor of the mouth or if there is increased tumor thickness. Treatment of the clinically negative neck is most often accomplished by supraomohyoid neck dissection. END appears to result in better overall cancer outcome than observation. Potential pitfalls of observation include a salvage rate of only one-third for patients who do not undergo END along with resection of the oral cavity primary.

Superficial T1 lesions can be treated with brachytherapy alone. Commonly, ^{192}Ir temporary implants are used to deliver 50 to 60 Gy with dose rates of 40 to 60 cGy/hour. However, HDR techniques can also be considered. For infiltrating T1 or T2 lesions, a combined approach using external beam and a brachytherapy or intraoral cone boost should be considered. More advanced lesions should be treated with an approach combining surgery and radiation therapy. In patients treated with IMRT, the intermediate-risk CTV (see “Intensity-Modulated Radiation Therapy” section) should include the intrinsic and extrinsic muscles of the tongue, the floor of the mouth, base of the tongue, glossotonsillar sulcus, and the anterior tonsillar pillar (Figure 50.11). The adjacent dissected neck should

also be included in this volume. Patients with advanced lesions and high-risk disease (particularly with multiple positive nodes) should receive radiation treatment to the bilateral necks. In patients with early-stage disease close to midline or patients with well-lateralized disease that is deeply invasive (>4 mm), both sides of the neck should be considered for treatment. For patients with a clinically and radiographically N0 neck, with well-lateralized and superficial disease (<4 mm invasion), 50 to 54 Gy should be considered for the ipsilateral neck as elective nodal irradiation. The appropriate draining lymphatics (usually levels I-IV unilaterally or bilaterally) should be included in the low- to intermediate-risk CTV (Figure 50.11 and Table 50.1). Ipsilateral versus bilateral neck treatment has also been evaluated. A study of a collaborative database of 176 patients with pathologic stage T1-T2N0-N2b SCC of the oral tongue and floor of mouth treated with surgery and unilateral neck dissection demonstrated an ipsilateral and bilateral/contralateral failure rate of 11.9% and 3.6%, respectively. The authors concluded in well-lateralized pathologic T-stage with contralateral node-negative neck, unilateral treatment is associated with low contralateral neck failures.[251]

Floor of the Mouth

Surgery is usually preferred in patients who are medically operable because proximity of the tumor to the mandible confers a significant risk of radiation-induced ulceration and ORN. Small lesions of the floor of the mouth are most commonly resected transorally. The surgical defect can be left to heal by granulation or reconstructed with a split-thickness skin graft or local flap. Advanced stage of floor of the mouth cancers is usually managed by a combination of surgery and radiation or chemoradiation.

In the surgical management of floor of the mouth cancer, special attention should be paid to mandibular invasion. A cancer that appears to involve only the periosteum or that only superficially invades the mandible can be removed via a transoral or transcervical approach in which a marginal mandibulectomy is performed. However, segmental mandibulectomy may be necessary for patients with a limited mandibular height when there is no direct bone invasion, because marginal mandibulectomy may leave these patients with insufficient bone, placing

them at high risk for radionecrosis or pathologic fracture. A full-thickness segmental resection may be necessary if there is frank bone invasion. For advanced cancers, resection of the anterior arch of the mandible may be necessary. Defects of the anterior segment of the mandible require reconstruction with bone, usually with a free fibular or iliac crest graft.

Management of the neck is similar to that for other tumors of the oral cavity. Patients with lesions <2 mm thick with no adverse pathologic factors and a clinically and radiographically negative neck may be observed after primary resection and observation. Otherwise, most N0 patients should receive either selective neck dissection or radiation therapy. Patients with advanced lesions and high-risk disease (particularly with multiple positive nodes) should receive radiation treatment to bilateral necks.

Small (T1 and T2) lesions may be treated with a combination of external beam radiation and boost with interstitial implant or intraoral cone. For lesions that are very close to the mandible, brachytherapy is contraindicated because of the risk of ORN. Infiltrative lesions that are tethered to the mandible and advanced lesions following surgical resection should receive postoperative radiation. Target volume design considerations for postoperative treatment are similar to that for oral tongue carcinoma. In cases where IMRT is used, the intermediate-risk CTV (see "Intensity-Modulated Radiation Therapy" section) should include genioglossus and geniohyoid muscles bilaterally, the sublingual and submandibular glands ipsilaterally (bilaterally if the tumor is midline), adjoining alveolar ridge and mandible, the muscles at the root of tongue, and the dissected necks.[189] Because of the close proximity of floor of the mouth lesions to the midline, treatment of both sides of the neck should be considered. The low- to intermediate- risk CTV (see "Intensity-Modulated Radiation Therapy" section) should include the appropriate electively treated necks (Figure 50.12 and Table 50.1). Another important consideration is the presence of gross PNI of the branches of the inferior alveolar nerve. In the event of extensive perineural involvement, coverage of the mandibular canal to the infratemporal fossa should be considered.[191]

Cases of floor of the mouth carcinoma in which there is no indication for neck irradiation (eg, a T4N0M0 primary with early mandibular involvement and a negative bilateral neck dissection) may be good candidates for treatment with conventional techniques. In this setting, opposing lateral

fields may be used to encompass the oral cavity tumor bed (including the mandible, floor of the mouth, and oral tongue); this volume is commonly treated to 50 to 54 Gy. High-risk areas (primary surgical bed, close margins, perineural spread) may receive additional boost treatment up to 60 to 66 Gy.

Hard Palate and Upper Alveolar Ridge

Tumors of the hard palate are quite rare, accounting for only 0.5% of all oral cancers in the United States. Most carcinomas manifest as a granular superficial ulceration of the hard palate. Initial growth tends to be superficial, although these tumors can extend through the periosteum of bone into regions adjacent to the oral cavity, such as the paranasal sinuses and floor of the nose. Surgery is the preferred modality for the treatment of this subsite.

Wide local excision may be adequate to obtain surgical margins. However, infrastructure maxillectomy may in some cases be necessary. For tumors that extensively involve the adjacent bony and soft tissue structures, a total maxillectomy, with or without orbital exenteration, may be required. A defect in the maxilla results in the lack of oral/nasal separation that can impair the ability to speak and swallow effectively. An obturator with or without a skin graft is the most common method used to restore oral/nasal separation. The obturator is commonly fabricated from a synthetic polymer and provides oronasal separation that can yield improved speech and swallowing function. Regional pedicled flaps and free tissue transfers may provide alternatives to obturation. One consideration in the reconstruction of palatal defects with nonremovable flaps is that they can mask local recurrences that can be more readily identified in patients whose defects are obturated.

Postoperative radiation therapy should be delivered when there are adverse features, that is, close/positive margins, perineural extension, vascular invasion, high-grade histology, multiple positive nodes, or ENE. The radiation field should encompass the entire surgical bed. In many cases, it may be feasible to treat with opposed lateral fields to cover the volume at risk (Figure 50.10). However, for well-lateralized lesions of the upper alveolar ridge, ipsilateral radiation with a wedge pair may be adequate. Conformal treatment techniques, including IMRT, can also be used to tailor

the radiation coverage to the high-risk tissue bed, draining lymphatics, surgical flap, and routes of perineural spread along V2 as deemed appropriate.

Elective treatment of the neck is controversial for hard palate region tumors. Although some series have shown lower rates of occult metastases for palatal tumors when compared to other oral cavity sites, preoperative imaging should be performed to evaluate for the presence of metastases to the retropharyngeal nodes because these are difficult to evaluate on clinical examination and are at some risk for spread from primary palatal tumors. Elective treatment of the clinically negative neck should be considered in high-grade tumors or lesions that present with advanced T stage.

Retromolar Trigone

SCC of the retromolar trigone is uncommon, and the true incidence is difficult to determine because these cancers often involve both the retromolar trigone and adjacent sites, thereby making it difficult in some cases to identify the original tumor epicenter. Cancers of the retromolar trigone may be advanced at presentation because only a thin layer of soft tissue overlies the bone in this region and invasion of the underlying bone may occur early. In addition, there are multiple pathways for spread from this site, including the buccal mucosa, tonsillar fossa, glossopharyngeal sulcus, floor of the mouth, base of the tongue, hard and soft palate, masticator space, and maxillary tuberosity. As patients tend to present with advanced disease of the retromolar trigone, many have regional metastases at the time of presentation.

The treatment of carcinoma of the retromolar trigone has been controversial.[252] Traditionally, surgery and radiation have been felt to be comparable modalities of treatment. However, recent reports suggest that surgery with adjuvant or neoadjuvant radiotherapy may be associated with better outcomes compared to radiation alone.[253,254] Although early-stage T1 and T2 cancers may be treated equally effectively with surgery or radiation, the probability of ORN is likely higher with definitive radiation.[252] Stage III and IV lesions commonly require combined surgery and radiation. The resection of advanced cancer of the retromolar trigone usually requires a composite resection of soft tissue and bone. Transoral robotic surgery can

be helpful in the management of smaller tumors in the retromolar trigone.[255] A limiting factor for the achievement of adequate surgical resection margins for tumors in this area includes extension of tumor posterosuperiorly into the pterygopalatine fossa and/or the base of the skull.

Well-lateralized lesions of the retromolar trigone can be treated by ipsilateral treatment using mixed beam techniques or angled wedge techniques. In the case of more extensive lesions that require free flap reconstruction, IMRT may be beneficial to aid in covering the postoperative tumor bed and neck (Figure 53.15). For extensive tumors of the retromolar trigone (or those with evidence of perineural spread), the infratemporal fossa should be included in the CTV. Treatment of the contralateral neck is at the discretion of the treating physician. In considering treatment options for carcinoma of the retromolar trigone, it is important to consider that some HPV+ tonsil tumors can largely involve the retromolar trigone and are ideally managed with nonsurgical treatment, highlighting the importance of testing tumors in this area for the presence of high-risk HPV subtypes.

Buccal Mucosa

Verrucous carcinoma accounts for <5% of all oral cavity carcinomas, occurs most often in the buccal mucosa, has a more favorable prognosis, and is considered a low-grade malignancy. Surgical resection remains the preferred mode of treatment for primary lesions of the buccal mucosa. Adjuvant radiation treatment is usually not indicated in the setting of completely excised verrucous carcinoma of the buccal mucosa. Because verrucous carcinomas rarely metastasize, END is often not indicated for patients with this disease. Careful pathology review with clinical correlation is important in the categorization of verrucous carcinomas, as this diagnosis can influence subsequent treatment recommendations.

SCC of the buccal mucosa can be an especially aggressive cancer of the oral cavity, as buccal cancers have multiple potential routes of spread to adjacent areas in the head and neck. Posteriorly, they can extend to involve the pterygoid muscles, and superiorly, they can grow to involve the alveolar ridge, palate, or maxillary sinus. The majority of patients have cancer that extends beyond the buccal mucosa. Metastasis to the cervical lymph nodes most commonly affects the submandibular nodes.

Transoral resection is preferred and is most convenient for small lesions of the buccal mucosa. Tumors approximating the gingiva should be resected with the gingiva and periosteum as an additional deep margin, whereas those that involve the periosteum should be resected with an additional deep margin of bone provided by a marginal mandibulectomy. Cancers that directly invade bone should be resected with a segment of bone. Larger tumors (T3 or T4) may require surgery combined with radiation therapy or chemoradiotherapy.

When considering target volume delineation for carcinoma of the buccal mucosa, it is important to be comprehensive in covering the inner cheek and entire buccal mucosa. The CTV should extend from the orbital rim (superiorly) to the retromolar trigone (posteriorly). Moreover, in the event of extensive disease (ie, T3/T4 or N2/N3) that is treated postoperatively, the masticator space and infratemporal fossa should be covered within the CTV. As is the case with retromolar trigone carcinoma, treatment of the contralateral neck is at the discretion of the treating physician.

MANAGEMENT OF RECURRENT DISEASE

The recurrence rates after treatment of cancer of the oral cavity are approximately 30%, with local recurrence being the most common.[256] Unfortunately, the survival after salvage treatment remains quite poor at 20% to 30%.[217] The appropriate management of recurrent oral cavity cancer depends largely on the extent of disease, the prior therapy administered, and whether the recurrences are local, regional, or both. The disease-free interval between initial treatment and recurrence is among the most important factors associated with survival after salvage surgery, and a disease-free interval of more than 10 months is significantly associated with improved survival.[256] Although surgery and chemoradiotherapy have similar outcomes in the case of early recurrences, surgical salvage has been found to be superior to chemoradiotherapy for late recurrence (84.4% vs 52% 5-year disease-specific survival).[256] In the case of small recurrences at the primary site in patients whose index therapy was surgical excision only, further excision with postoperative radiotherapy is often recommended. For larger recurrences in patients who received radiation as part of their initial management, the rate of surgical salvage is quite low. In some cases, further

resection may be considered for palliation or curative treatment attempt, particularly in the setting of a clinical trial. Systemic therapy, reirradiation, and palliative care are other options for this group of patients, and the risks and benefits of each should be discussed with the individual patient.

If there is distant disease recurrence, systemic therapy approaches will likely assume primary importance. A combination of docetaxel, cisplatin, and 5-FU or a platinum doublet (plus a taxane or 5-FU) combined with cetuximab are commonly used regimens for first-line treatment.[229,257] Immunomodulating agents targeting the programmed death -1 receptor and its ligand represent novel and promising strategies in the treatment of metastatic and recurrent SCC of the head and neck.[258,259] In a phase III trial enrolling patients with platinum-refractory disease, about 50% of whom had oral cavity cancer, nivolumab improved OS from 5.1 to 7.5 months.[258] These agents have demonstrated a survival advantage compared to standard single-agent chemotherapy in the setting of platinum-refractory head and neck SCC.[258] The use of cetuximab may also play an important role in the recurrent or metastatic setting. In the phase III trial evaluating cetuximab plus platinum-based chemotherapy in patients with recurrent or metastatic SCC of the head and neck (where 20% of patients had oral cavity malignancy), the addition of cetuximab resulted in an OS improvement of 10.1 months compared to chemotherapy alone.[260] Ongoing concepts being investigated include combining these agents with standard cetuximab-containing regimens.[261]

CHAPTER 51

Oropharynx

Pooja Karukonda, Joseph K. Salama, and Yvonne Marie Mowery

The incidence of oropharyngeal cancer (OPC) is rising, a phenomenon largely attributable to human papillomavirus (HPV). HPV-associated OPC carries a significantly more favorable prognosis than HPV-negative disease, regardless of the chosen treatment modality. The recognition that HPV-associated OPC is a distinct pathologic and clinical entity has led to significant multidisciplinary interest in redefining and tailoring treatment paradigms for OPC based on HPV status.

In general, appropriate treatment strategies should focus on maintaining high cure rates while minimizing long-term, treatment-induced functional morbidity. Early-stage OPC is best managed with single-modality therapy, namely, radiation therapy (RT) or surgery, with the choice based upon anticipated post-therapy morbidity. Treatment of locoregionally advanced OPC typically involves multiple treatment modalities. The most common definitive strategies are either concurrent chemoradiation (CRT) or surgery followed by adjuvant RT with or without chemotherapy, based on pathologic risk factors.

Innovative approaches to surgery and RT, as well as the incorporation of novel systemic therapies, are currently under investigation with the intent to maximize the therapeutic index for both HPV-associated and non–HPV-associated OPCs. Transoral surgical techniques including laser and robotic resection have the potential to reduce morbidity. Advances in RT allow for optimized dose delivery to the primary tumor and involved nodes while sparing normal tissues, particularly the major salivary glands and pharyngeal constrictor muscles. The use of immune-modulating agents has improved outcomes in patients with metastatic and recurrent OPC, establishing these agents as an integral component of OPC therapy. Incorporation of immunotherapy into definitive treatment is an area of active investigation.

EPIDEMIOLOGY

Despite the variable incidence of OPC worldwide due to differences in behavioral and environmental risk factors, the international burden of OPC is projected to increase by 2030. Most OPC diagnoses around the world, particularly in developing nations, are associated with major risk factors of tobacco consumption and/or excessive ingestion of alcohol.[1] In the United States, there are about 55,000 newly diagnosed cases of OPC annually.[2,3] The annual percentage change of OPC incidence rates in the United States is generally higher for men than for women (5.4:1), and particularly high for non-Hispanic White men in the sixth decade of life.[3] These incidence rates have steadily increased since the 1980s; however, in contrast to much of the world, this is due to a 225% increase in

HPV-associated OPC. In fact, approximately 70% of newly diagnosed OPCs in the United States are HPV associated, while non–HPV-associated OPC has declined by at least 50% over the same time period, correlating with an overall decrease in tobacco consumption among the U.S. population.[4]

HUMAN PAPILLOMAVIRUS–ASSOCIATED OROPHARYNGEAL CANCER

Human Papillomavirus

HPV is a circular, double-stranded DNA virus that infects epithelial tissues. It was found to be associated with cervical cancer in 1983[5] and was subsequently established as a significant human carcinogen in 1995.[6] Over 200 HPV subtypes have been identified to date, and they are classified as high risk or low risk based upon epidemiologic associations with cervical cancer in case-control studies.[7] HPV16 is identified in >90% of all HPV-associated OPCs, while HPV18, HPV33, and HPV35 are associated with the majority of the remainder.[8] Infection with HPV16 confers an approximate 14-fold increase in the risk of developing OPC.[9]

See Chapters 2 for details on HPV-associated tumorigenesis. In brief, the HPV genome notably encodes two oncoproteins, E6 and E7, which inhibit the tumor suppressors p53 and Rb, resulting in dysregulation of the G1/S and G2/M checkpoints.[10] Although E6 and E7 oncoprotein function is necessary for the development of an HPV-associated malignancy, it is not sufficient, highlighting that yet undefined genetic events are required for malignant transformation.[11]

A number of different techniques are used to detect HPV in OPC biopsy specimens. The ability to reliably detect HPV E6/E7 messenger RNA in clinical specimens would be ideal. However, this approach is clinically impractical because it is very difficult to detect viral RNA in cytologic fluid and paraffin-embedded tissues. The gold standard is thus the detection of HPV DNA via polymerase chain reaction (PCR) or in situ hybridization (ISH). PCR is a technique with high sensitivity but low specificity, as cross-contamination or transcriptionally inactive DNA can confound results. ISH involves the use of oligonucleotide probes designed to anneal to complementary strands of HPV DNA within the tumor specimen. Advantages of ISH include localization of DNA within the tumor specimen and identification of even a sole viral copy.[12] A consequence of HPV E7-mediated Rb inhibition is induction of demethylases, resulting in overexpression of $p16^{INK4A}$ (p16), an upstream tumor suppressor that functions as a cyclin-dependent kinase inhibitor.[13] Immunohistochemistry (IHC) staining for p16 is regarded as a highly sensitive surrogate for HPV status and is frequently utilized in clinical practice without the need for confirmatory studies. Indeed, p16 IHC is the preferred assay to guide American Joint Committee on Cancer/Union for International Cancer Control (AJCC/UICC) eighth edition staging, and tumor p16 status alone is often sufficient to define patient eligibility for inclusion in clinical trials. However, there is up to a 20% discordance rate between HPV ISH and p16 IHC results, which is likely attributable to a number of factors, including infection with non-HPV16 subtypes (which some assays do not cover),

undetectably low viral copy numbers, and/or true biologic discordance.[14] Patients with discordant p16 and HPV testing have been shown to have a significantly worse prognosis than patients with concordant (p16-positive/HPV-positive) OPC, albeit still better prognosis than p16-negative/HPV-negative OPC. There is ongoing discussion regarding whether additional biomarker confirmation beyond p16 IHC should be mandatory for patients enrolling in clinical trials in which therapeutic de-escalation is contingent on HPV status.[15]

Clinical Characteristics of Human Papillomavirus–Associated Oropharyngeal Cancer

HPV-associated OPC is more likely to occur in males than in females (3:1), particularly non-Hispanic White males.[3] The latency period between exposure to HPV and diagnosis of HPV-associated OPC is typically greater than 10 years[16]; however, patients with HPV-associated OPC are still on average 5 to 10 years younger than patients with non–HPV-associated OPC. Patients with HPV-associated OPC are also more likely to be married, college educated, and have a median income >$55,000. The use of marijuana additionally elevates the odds of developing HPV-associated OPC.[17] Analogous to cervical cancers, certain sexual behaviors have been associated with an increased risk of developing HPV-associated OPC. These include a higher number of vaginal or oral sex partners, infrequent condom use, and early age of first intercourse.[18] While the majority of patients with HPV-associated OPC are nonsmokers, tobacco use is an independent prognostic factor, with studies demonstrating a positive correlation between disease progression, death, and smoking history.[19,20] Whether there is a synergism between exposure to HPV, tobacco, and/or alcohol in terms of increased risk of developing HPV-associated OPC is a matter of ongoing controversy.

HPV-associated OPCs are characterized frequently as poorly differentiated, nonkeratinizing, or basaloid upon histopathologic examination.[21] HPV-associated and non–HPV-associated OPCs also differ in regard to molecular alterations. HPV-associated OPCs are associated with wild-type p53, upregulation of p16, and infrequent amplification of cyclin D, whereas the converse is true for non–HPV-associated OPCs. A subset of patients with HPV-associated OPC with more extensive smoking histories have tumors more likely to exhibit *TP53* mutations, higher epidermal growth factor receptor (EGFR) and Bcl-xL expression, and tend to have oncologic outcomes similar to those of patients with non–HPV-associated OPC.[10]

Response of Human Papillomavirus–Associated Oropharyngeal Cancer to Standard Therapy

In general, patients with HPV-associated OPC have significantly better treatment response and survival outcomes than patients with non–HPV-associated OPC.[22,23] A reanalysis of RTOG 0129, a randomized study comparing cisplatin administered with either accelerated concomitant boost RT or conventionally fractionated RT, revealed that HPV status was

independently associated with improved outcomes. Three-year overall survival (OS) was 82% in patients with HPV-associated OPC compared to 54% in patients with non–HPV-associated OPC. Even after adjustment for age, tumor and nodal stage, treatment assignment, and tobacco use, HPV status independently predicted for improved survival (hazard ratio [HR] = 0.42, 95% confidence interval [CI] = 0.27-0.66). In addition, locoregional progression (13.6% vs 24.8%) and progression-free survival (PFS) (71.8% vs 50.4%) were significantly improved in patients with HPV-positive disease. Other large cooperative group studies have demonstrated similar findings.[23,24] It is important to realize that the prognostic significance of HPV is independent of the utilized CRT platform and additionally applies to treatment with RT alone[25] or surgery.[26]

ANATOMY

The oropharynx is contiguous with the oral cavity anteriorly, the larynx and hypopharynx posterior/inferiorly, and the nasopharynx superiorly. Four main subregions compose the oropharynx: the tonsil, base of tongue, pharyngeal wall, and soft palate. The tonsillar region contains the anterior and posterior tonsillar pillars and the palatine tonsil. The base of tongue comprises the posterior third of the tongue. The main sensory innervation of the base of tongue is via the glossopharyngeal nerve (cranial nerve [CN] IX), with a small portion supplied by the internal laryngeal nerve (CN X). The soft palate is a fibromuscular structure, the muscles of which are innervated by branches of CN V2, CN IX, CN X, as well as sympathetic branches of the superior cervical ganglion. Sensory innervation of the soft palate is via CN IX. See Chapters 30 for further detail.

The oropharynx contributes to many key functions, including degustation, respiration, and speech. Advanced tumors arising in the oropharynx can infiltrate muscles and nerves, significantly impeding these functions. A major goal of successful therapy is to limit long-term functional morbidity.

ROUTES OF SPREAD

The primary routes of dissemination of OPC include direct extension and lymphatic drainage, with hematogenous spread being less common. OPCs have a predilection for submucosal extension, often visualized as raised erythematous regions without distinct borders or ulceration. This can best be appreciated by direct visualization rather than on radiographic imaging.

Lymphatic Spread of Oropharyngeal Cancer

The lymphatic drainage of the oropharynx and the neck was first described by Rouvière in 1938[27] and has since been elucidated by others.[28] Nodal groups are classified by the level system[29] and defined by surgical, anatomic, and radiologic landmarks. Recently, this system (levels I-VI) was refined with the addition of sublevels (Ia/Ib, IIa/IIb, and Va/Vb), also incorporating radiologically defined landmarks (as shown in Table 51.1).[30] The most common location for regional lymph node (LN) metastasis from OPC is ipsilaterally in

level II. The probability of regional metastasis is related to the size and location of the primary tumor within the oropharynx. Subsequent lymphatic spread typically proceeds in a systematic manner through the draining LN stations with only rare isolated skip metastases (0.3%).[31] Tumors encroaching midline or involving the posterior pharyngeal wall notably exhibit a higher propensity for bilateral lymphadenopathy.[32]

TABLE 51.1 RADIOGRAPHIC BOUNDARIES OF NECK NODE LEVELS

Level	Cranial	Caudal	Anterior	Posterior	Lateral	Medial
Ia	Geniohyoid m, plane tangent to basilar edge of mandible	Plane tangent to body of hyoid bone	Symphysis menti, platysma m	Body of hyoid bone	Medial edge of anterior belly of digastric m	NA
Ib	Mylohyoid m, cranial edge of submandibular gland	Plane through central part of hyoid bone	Symphysis menti, platysma m	Posterior edge of submandibular gland	Inner side of mandible, platysma m, skin	Lateral edge of ant. belly of digastric m
II	Caudal edge of lateral process of C1	Caudal edge of body of hyoid bone	Posterior edge of submandibular gland; ICA; posterior edge of posterior belly of digastric m	Posterior edge of SCM	Medial edge of SCM m	Medial edge of ICA, paraspinal m
III	Caudal edge of body of hyoid bone	Caudal edge of cricoid cartilage	Posterolateral edge of sternohyoid m; anterior edge of SCM m	Posterior edge of SCM m	Medial edge of SCM m	Int. edge of ICA, paraspinal m
IV	Caudal edge of cricoid cartilage	2 cm cranial to sternoclavicular joint	Anteromedial edge of SCM m	Posterior edge of SCM m	Medial edge of SCM m	Medial edge of ICA, paraspinal m
V	Cranial edge of body of hyoid bone	CT slice including transverse cervical vessels	Posterior edge of SCM m	Anterior border of trapezius m	Platysma m, skin	Paraspinal m
VI	Caudal edge of body of thyroid cartilage	Sternal manubrium	Skin, platysma m	Separation between trachea and esophagus	Medial edge of SCM, thyroid gland, skin	NA
RP	Base of skull	Cranial edge of body of hyoid bone	Fascia under pharyngeal mucosa	Prevertebral m	Medial edge of ICA	Midline

CT, computed tomography; ICA, internal carotid artery; m, muscle; NA, not applicable; RP, retropharyngeal; SCM, sternocleidomastoid muscle.

The extent of occult pathologic LN involvement in patients undergoing elective neck dissection[33] has helped to guide not only the scope of selective neck dissection but also standardized contouring atlases, which aid in delineating appropriate elective RT volumes.[34-35]

Distant Metastatic Spread of Oropharyngeal Cancer

Distant metastatic spread of OPC is relatively uncommon, affecting approximately 15% of patients during the course of their disease.[36] The most common locations for distant metastatic spread are the lung parenchyma,[36] followed by bone and liver. Distant metastases are more common in patients presenting with locoregionally advanced or recurrent tumors, with the risk increasing with the primary tumor stage and the extent of cervical lymphadenopathy.[37] Extranodal extension (ENE), lower cervical lymphadenopathy (level IV), and lymphovascular invasion (LVI) have also been associated with increased rates of distant metastasis.[38]

CLINICAL PRESENTATION

OPCs present with a constellation of symptoms, dependent upon the location of the primary tumor, invasion of nearby organs, and extent of nodal disease. Often, patients present with an asymptomatic neck mass, which is usually mobile, firm, and nontender. A fixed mass can be indicative of ENE and invasion into surrounding structures. Some patients complain of deep-seated otalgia within the auditory canal. This is mediated via irritation of branches of CN IX with referral via the petrosal ganglion to the tympanic nerve of Jacobson. Regurgitation of foods can occur with tumor invasion of the soft palate and resultant inhibition of its ability to elevate during swallowing. Trismus is seen with more advanced tumors and reflects tumor invasion of the pterygoid fossa and/or musculature. Odynophagia and dysphagia are other common presenting symptoms that occur with tumor invasion of the pharyngeal musculature or obstruction by pathologic lymphadenopathy and can result in aspiration, decreased oral intake, and weight loss. Based on initial presenting symptoms and clinical status, baseline evaluation by a multidisciplinary supportive care team inclusive of a swallowing specialist, dietician, and dentist/oral surgeon prior to initiation of treatment may be advised.

DIAGNOSTIC EVALUATION

Physical Examination

A complete examination of all accessible mucosal surfaces within the head and neck should be performed in any patient with a known or suspected diagnosis of OPC. This process serves not only to characterize the extent of the primary tumor and optimal biopsy sites but also to evaluate for synchronous malignancies in the upper aerodigestive tract,

given the relatively high incidence of such, particularly in patients with a significant smoking history. Physical examination should be systematic and reproducible. Following examination of the oral cavity, where particular attention should be directed to dental health (if RT is indicated, necessary extractions should ideally be completed at least 2 weeks prior to the start of treatment), one should closely examine the anterior tonsillar pillars, tonsillar fossae, posterior tonsillar pillars, and soft palate. Proper exposure can be achieved with either gloved index fingers or simultaneous use of two disposable tongue depressors. Palpation of the tonsillar fossa and the base of tongue should be performed since these locations can harbor occult primary tumors. Palpation of the base of tongue should be at the end of the examination due to its propensity to trigger the gag reflex. Direct visualization should be followed by fiberoptic examination for optimal inspection of the base of tongue, posterior-inferior tonsils, and vallecula, as well as evaluation for disease extension to laryngeal and hypopharyngeal sites. Fiberoptic examinations should be recorded and compared to assess response during the course of therapy.

OPCs often appear as ulcerated masses with associated erythema, neovascularization, and mucositis. Tenderness, evidence of recent bleeding, obstruction of the airway, skin invasion, alteration of gag reflex, and extent of trismus (measured from upper to lower incisors) should be documented. Bulging of the parapharyngeal space should also be noted, as this could represent retropharyngeal lymphadenopathy.

Careful examination of the neck is also important for staging and management. The neck should gently be turned to the side being examined in order to relax the sternocleidomastoid muscle, which, in turn, facilitates the detection of smaller LNs. Lymphadenopathy should be documented in terms of neck level, size, firmness, degree of fixation, and whether there is skin involvement/ulceration.

Biopsy of the primary site should be performed. Adequate exposure for in-office biopsies of the proximal oropharynx is usually achievable. Posterior oropharyngeal tumors are often biopsied under general anesthesia in the operating room, typically as part of a comprehensive examination and endoscopic evaluation (laryngoscopy, bronchoscopy, and esophagoscopy). Tumor HPV status should be assessed, typically via p16 IHC, as discussed previously. Fine-needle aspiration (FNA) specimens obtained from cervical lymphadenopathy may not be sufficient for HPV testing. If FNA specimens are nondiagnostic, oftentimes in the setting of cystic or necrotic tissue, then core needle biopsy can be performed.

Computed Tomography

Computed tomography (CT) imaging of the head and neck with intravenous contrast should be performed for all patients with newly diagnosed OPC in order to assess the extent of the primary tumor and to determine the presence of cervical LN metastases. Scan slice thickness <5 mm is necessary to optimize the detection of smaller pathologically involved LNs and to provide the best anatomic delineation of both primary and nodal diseases. Radiographically concerning LNs are enlarged (>1 cm in any axis) with no apparent fatty hilum, contrast enhancing, and/or partially necrotic. Primary tumors

appear as contrast-enhancing masses, often distorting normal anatomic relationships. LN and primary tumor size should be measured in cephalad-caudad as well as axial dimensions in order to accurately stage patients. Dental artifact may obscure visualization, requiring further scanning with an adjusted head position or the use of metal artifact–reducing reconstruction algorithms. Thoracic CT should be performed routinely (either alone or in combination with a positron emission tomography [PET] scan) to assess for pulmonary metastases in patients with N2 or greater nodal disease, lower neck nodal involvement, and/or advanced primary tumors.

Positron Emission Tomography

^{18}F-fluorodeoxyglucose (^{18}F-FDG) PET/CT imaging incorporating tumor physiology in conjunction with anatomic information is routinely recommended for the initial staging of patients with OPC. From a practical standpoint, PET-based imaging can sensitively assess not only the locoregional burden of disease but also the presence of distant metastases. See Chapters 30 for further detail. Clinical status and knowledge of prior procedures are critical to PET interpretation, as recent biopsies and infections can lead to nononcologic hypermetabolic activity.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can be a useful imaging tool for oropharyngeal squamous cell carcinoma (OPSCC), particularly when there is concern for CN involvement and/or tumor impingement on the skull base. Squamous cell carcinoma appears hypointense in T1-weighted images and hyperintense in T2-weighted images. The ability of MRI to differentiate tumor from soft tissue is particularly useful when determination of the extent of base of tongue or oral tongue invasion is necessary. In addition, MRI is useful in patients with compromised renal function who are unable to receive iodinated contrast agents. See Chapters 30 for further detail.

PATHOLOGIC CLASSIFICATION

Squamous cell carcinomas are the most common histologic subtype, comprising >95% of all OPCs. Uncommonly, minor salivary gland tumors and mesenchymal tumors can affect this region. Given the proportionally high content of lymphoid tissue in the region within Waldeyer ring, malignant Hodgkin and non-Hodgkin lymphomas can also arise in this region. This chapter discusses only squamous cell and related (poorly differentiated and lymphoepithelioma) histologic subtypes.

STAGING

OPC staging was revised in the AJCC/UICC eighth edition to reflect the significant differences in prognosis between HPV-associated and non–HPV-associated disease.[39] Clinical staging is based on all available history, physical examination, endoscopic, and

radiographic data. For both HPV-associated and non–HPV-associated OPSCCs, the size and extent of the primary tumor define the T stage, with T1 being <2 cm, T2 >2 cm but ≤4 cm, and T3 >4 cm. For non–HPV-associated primaries, T4a describes tumors invading the larynx, extrinsic muscles of the tongue, medial pterygoid, hard palate, or mandible. T4b describes tumors encasing the carotid artery or invading the lateral pterygoid, pterygoid plates, lateral nasopharynx, or skull base. For HPV-associated (p16-positive) primaries, T4 disease is more simply classified as tumor invasion of the larynx, extrinsic muscles of the tongue, medial pterygoid, hard palate, mandible, or beyond. Clinical nodal staging for HPV-associated disease is also simplified. N0 signifies the absence of lymphadenopathy; N1 is one or more ipsilateral LNs <6 cm, N2 is contralateral or bilateral LNs <6 cm, and N3 is defined as LN(s) >6 cm. The resultant clinical stage grouping of HPV-associated OPSCC is as follows: Clinical stage I now comprises T0-2N0-1; stage II is now T0-2N2 or T3N0-2; and stage III is composed of T0-4N3 or T4N0-2. Pathologic LN staging is also simplified to equate pN1 with ≤4 LNs and pN2 with >4 involved nodes. The resultant pathologic stage grouping of HPV-associated OPSCC is as follows: Stage I includes T0-2N0-1; stage II is T0-2N2 or T3-4N0-1; and stage III is composed of T3-4N2. Both clinical and pathologic stage IV are limited to patients with distant metastatic disease (M1) (Tables 51.2-51.4).

TABLE 51.2 AJCC/UICC EIGHTH EDITION TNM STAGING SYSTEM FOR HPV-MEDIATED (P16-POSITIVE) OROPHARYNGEAL CANCER

Primary Tumor (T)	
T0	No primary identified
T1	Tumor 2 cm or smaller in greatest dimension
T2	Tumor larger than 2 cm but not larger than 4 cm in greatest dimension
T3	Tumor larger than 4 cm in greatest dimension or extension to lingual surface of epiglottis
T4	Moderately advanced local disease; tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible or beyond
Clinical Regional Lymph Nodes (cN)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	One or more ipsilateral lymph nodes, none larger than 6 cm
N2	Contralateral or bilateral lymph nodes, none larger than 6 cm
N3	Lymph node(s) larger than 6 cm
Pathologic Regional Lymph Nodes (pN)	
NX	Regional lymph nodes cannot be assessed.
pN0	No regional lymph node metastasis
pN1	Metastasis in four or fewer lymph nodes
pN2	Metastasis in more than four lymph nodes
Distant Metastasis (M)	

M0	No distant metastasis present
M1	Distant metastasis present

For non–HPV-associated (p16-negative) tumors, the staging is similar to the prior AJCC/UICC seventh edition aside from factoring in ENE. Primary tumor staging is as above. For clinically staged OPSCCs without ENE, N0 indicates no clinical or radiographic evidence of pathologic lymphadenopathy; N1 indicates a single LN <3 cm in the ipsilateral neck; N2a indicates a single LN >3 cm and <6 cm in the ipsilateral neck; N2b indicates multiple ipsilateral cervical LNs, all <6 cm in size; and N2c indicates bilateral cervical LNs, all <6 cm. N3 is now divided into two subcategories: N3a indicates

the presence of at least one LN >6 cm, while N3b indicates overt clinical evidence of ENE, irrespective of LN number, size, or laterality (Tables 51.5 and 51.6).

TABLE 51.5 AJCC/UICC EIGHTH EDITION TNM STAGING SYSTEM FOR P16-NEGATIVE OROPHARYNGEAL CANCER

Primary Tumor (T)

TX	Primary tumor cannot be assessed.
Tis	Carcinoma in situ
T1	Tumor ≤2 cm in greatest dimension
T2	Tumor >2 cm but not >4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension or extension to lingual surface of epiglottis
T4	Moderately advanced or very advanced local disease
T4a	Moderately advanced local disease Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible.[a]
T4b	Very advanced local disease Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery.

Clinical Regional Lymph Nodes (cN)

NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension and ENE negative
N2	Metastasis in a single ipsilateral node >3 cm but not >6 cm in greatest dimension and ENE negative; *or* metastases in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension and ENE negative; *or* in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension and ENE negative
N2a	Metastasis in a single ipsilateral node >3 cm but not >6 cm in greatest dimension and ENE negative
N2b	Metastasis in multiple ipsilateral nodes, none >6 cm in greatest dimension and ENE negative
N2c	Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension and ENE negative
N3	Metastasis in a lymph node >6 cm in greatest dimension and ENE negative; *or* metastasis in any node(s) and clinically overt ENE positive
N3a	Metastasis in a lymph node >6 cm in greatest dimension and ENE negative
N3b	Metastasis in any node(s) and clinically overt ENE positive

Pathologic Regional Lymph Nodes (pN)

NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension and ENE negative
N2	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension and ENE positive; *or* >3 cm but not >6 cm in greatest dimension and ENE negative; *or* metastases in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension and ENE negative; or in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension and ENE

	negative
N2a	Metastasis in single ipsilateral or contralateral node ≤3 cm in greatest dimension and ENE positive; *or* a single ipsilateral node >3 cm but not >6 cm in greatest dimension and ENE negative
N2b	Metastasis in multiple ipsilateral nodes, none >6 cm in greatest dimension and ENE negative
N2c	Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension and ENE negative
N3	Metastasis in a lymph node >6 cm in greatest dimension and ENE negative; *or* in a single ipsilateral node >3 cm in greatest dimension and ENE positive; *or* multiple ipsilateral, contralateral or bilateral nodes, any with ENE positive
N3a	Metastasis in a lymph node >6 cm in greatest dimension and ENE negative
N3b	Metastasis in a single ipsilateral node >3 cm in greatest dimension and ENE positive *or* multiple ipsilateral, contralateral, or bilateral nodes, any with ENE positive
Distant Metastasis (M)	
M0	No distant metastasis present
M1	Distant metastasis present

For p16-negative pathologically staged nodal disease, the eighth edition now classifies a single LN (ipsilateral or contralateral) <3 cm with ENE as N2a, while either a single pathologic LN >3 cm with ENE or multiple LNs with ENE is N3b. The presence of distant metastatic disease is classified as M1. The stage grouping for p16-negative OPSCC is unchanged from prior editions. Stage I comprises T1N0 disease, and stage II comprises T2N0 disease. Stage III includes patients with T3N0-1 or T1-T2N1. Stage IV is divided into three subgroups. Stage IVa includes patients with T4aN0-2a-c and T1-3N2a-c disease.

Stage IVb defines patients with technically unresectable disease, including patients with an extensive primary tumor (T4b, any N) or extensive lymphadenopathy (any T, N3). Stage IVc includes patients with distant metastases (M1).

MANAGEMENT STRATEGIES

Functional organ preservation with minimal toxicity is the management goal for all patients with OPC. Based on AJCC stage, patients are usually divided into two different treatment groups to help guide therapy decisions: early stage and locoregionally advanced. Those with stage I and II diseases are typically considered early stage, while others are considered to have locoregionally advanced disease. For all subsites, early-stage tumors are usually well controlled with a single local treatment modality, namely, RT or surgery. This paradigm is in flux for HPV-associated disease as some presentations that would have been considered locoregionally advanced based on AJCC seventh edition, for example, T1N1 or T2N1, are classified as early stage in AJCC eighth edition staging. Ultimately, treatment modality selection should be based on the primary tumor size, extent of local spread, and involved subsites. Small tumors of the tonsil and small exophytic tumors of the base of tongue can typically be managed surgically with a favorable toxicity profile, whereas the morbidity of surgery for tumors involving the soft palate is less favorable, resulting in a preference for primary RT for these tumors. For locoregionally advanced disease, two appropriate treatment strategies are used: either surgery followed by RT with or without chemotherapy based on pathologic risk factors or RT, usually with concurrent chemotherapy.

SURGICAL TECHNIQUES, APPROACHES, AND RESULTS

Neck Dissection

Cervical LN dissections, otherwise known as neck dissections, can be both diagnostic and therapeutic for pathologic lymphadenopathy. Modern nomenclature classifies neck dissections as either comprehensive, with removal of all nodal groups (I-V), or selective, with removal of only the nodal groups felt to be at high risk of pathologic involvement based on patterns of spread. Comprehensive dissections are typically recommended for patients with evidence of advanced nodal disease, whereas selective dissections are usually recommended for patients who are clinically node negative or have minimal nodal disease.[40,41] For patients with OPSCC, selective neck dissections typically target the nodes in levels II and IV, and sometimes V; this practice results in removal/identification of all pathologic lymphadenopathy in >90% of clinically node-negative patients.[31,42] The extent of the tumor and lymphatic drainage patterns of the anatomic subsite determine whether ipsilateral or bilateral neck selective dissection is indicated.

Base of Tongue

Surgery plays a limited role in the management of large and/or midline base of tongue tumors, given the inherent morbidity of a near-total or total glossectomy.[43] For select,

well-lateralized or polypoid base of tongue tumors with minimal associated cervical lymphadenopathy, a partial glossectomy can be performed. Given the high propensity for occult microscopic nodal involvement, bilateral cervical LN dissection is recommended. Base of tongue tumors in close proximity to the laryngeal apparatus, such as those arising in the vallecula, often require a supraglottic or total laryngectomy to achieve adequate margins of resection. Traditional surgical approaches for base of tongue tumors include the midline mandibulotomy (splitting the lip, mandible, and oral tongue midline), the lateral mandibulotomy (dividing the mandible near the angle and approaching the base of tongue from the side), and the floor drop procedure (elevating the inner periosteum from the mandible from angle to angle which releases the entire floor of mouth and oral tongue into the neck exposing the base of tongue). These approaches have largely been replaced by transoral robotic surgery (TORS), as discussed below.

Tonsil Cancers

For small (<1 cm) early-stage tonsil cancers confined to the anterior pillar, a wide local excision can achieve adequate tumor-free margins, whereas tumors involving the palatine tonsil often require a radical tonsillectomy. For both of these situations, the tonsil is approached transorally with primary closure. Larger tumors with extension onto the tongue, mandible, or into surrounding tissue often require a composite resection, usually including resection of the tonsil, tonsillar fossa, pillars, a portion of the soft palate, tongue, and mandible. For tumors not adjacent or adherent to the mandible, a midline mandibulotomy approach is used. For tumors adherent to the mandible, a partial mandibulectomy is used. Defects are often closed with a myocutaneous flap. Complications from surgery depend on the extent of resection, with impairment in swallowing possible with removal of part of the tongue or soft palate. Certain patients with well-lateralized, small tonsil primaries can be managed with ipsilateral neck dissection.

Soft Palate Cancers

Surgical resection is rarely recommended as initial therapy for soft palate tumors. Resection of the soft palate is often associated with significant reflux into the nasopharynx during swallowing, even with the use of custom prostheses. In addition, due to the midline location, primary disease can spread to the bilateral cervical and retropharyngeal LNs, with frequency high enough to require elective treatment. When surgery is performed, the tumors are approached transorally, and a full-thickness wide local resection is performed when tumors are limited to the soft palate. A more extensive composite resection is required if disease extends to surrounding structures. Flaps or prostheses are used to preserve velopharyngeal competence. Nasal speech is also often a consequence.

Minimally Invasive Transoral Surgical Approaches

Minimally invasive transoral surgical approaches, such as transoral laser microsurgery (TLM) and TORS, which were previously only routinely used as an alternative to open surgical procedures in the setting of limited tonsillar resections, are now increasingly being utilized in the United States for a diverse array of patients with OPC.[44] Indeed, a systematic review and meta-analysis, inclusive of a randomized controlled trial, has demonstrated that TORS results in improved peri- and postoperative outcomes as well as decreased local recurrences, when compared to open operations for patients with head and neck squamous cell carcinoma (HNSCC).[45] Importantly, candidates for minimally invasive surgical procedures should be carefully selected to minimize the necessity of multimodal treatment (ie, adjuvant RT/CRT), which is associated with increased late toxicity.

Transoral Laser Microsurgery

TLM makes use of a laser to excise tumor. Small series report favorable outcomes for select patients with stage I to IV OPSCC treated with TLM with or without neck dissection, followed by adjuvant RT or CRT.[46-49] Positive margin rates are variable (3%-24%) and differ based on the primary site (eg, more common when operating on base of tongue tumors). Notable complications include postoperative hemorrhage (5%-10%) and temporary tracheostomy placement (17%-30%). The latter is often needed for exposure, airway control, and/or aspiration management following extensive resection. High rates of locoregional control (LRC) following this procedure have been reported, primarily for stage I and II patients (87%-100%); for stage III and IV patients, local recurrence is more common (20%-30%). Swallowing outcomes are favorable, with series reporting most patients tolerating a normal diet postoperatively.[46,49]

Transoral Robotic Surgery

The use of a computer-aided interaction between the surgeon and the patient is commonly referred to as “robotic” surgery. The most common robotic surgical system, the da Vinci Surgical system, is composed of three surgical instruments and a binocular endoscope controlled by robotic arms and inserted under direct or endoscopic guidance by the surgeon from a patient-side apparatus. The surgeon controls the instruments from a console separated from the patient. The operative environment is visualized virtually, in a 3D environment created via a computer, which links the environment provided by the binocular endoscope to the position of the instruments. The surgeon’s movements are translated into micromovements of the instruments. The advantages of this system include motion scaling, which can increase precision, as well as reduce hand tremor and fatigue. When the system is used for transoral surgeries, an assistant is often positioned by the patient’s head.

There have only been two prospective randomized trials comparing RT to TORS in the treatment of patients with OPC that have published results to date. ORATOR was a phase II randomized trial that enrolled 68 patients with T1-2N0-2 OPC from multiple hospitals in Canada and Australia and randomized them to primary RT/CRT versus TORS and neck

dissection with or without adjuvant RT/CRT based on pathologic risk factors. The primary outcome was swallowing-related quality of life (QoL). Notably, 88% of patients had p16-positive disease. The investigators found that swallowing-related QoL outcomes were significantly improved in the primary RT cohort at 1 year post-treatment. However, the difference did not appear to be clinically meaningful, and the differences between the two arms became less pronounced with longer follow-up. The risk of postoperative hemorrhage in the TORS arm was higher than expected, with four grade 2 or higher events, including one grade 4 and one grade 5 event. In light of this, the trial was modified to mandate elective temporary tracheostomy for patients undergoing TORS. PFS and OS were similar between the two arms.[50,51] ORATOR2 was an international phase II study randomizing patients with T1-2N0-2 HPV-related OPC to primary RT/CRT (de-escalated dose of 60 Gy) versus transoral surgery (TLM or TORS) plus neck dissection with or without adjuvant RT/CRT based on pathologic risk factors. The trial was terminated early after accrual of 61 patients due to an unacceptable number of grade 5 toxicities in the transoral surgery arm, most notably two treatment-related deaths (attributed to postoperative hemorrhage and spondylodiscitis).[52] Thus, while the current data show that RT and transoral surgical approaches may result in comparable oncologic and QoL outcomes for patients with early stage, primarily p16-positive OPC, the spectra of toxicities differ and there appears to be a significant risk of upfront treatment-related mortality with transoral surgery, which should warrant caution particularly at institutions without significant experience with this technique. There are other ongoing randomized phase II/III trials comparing primary RT to transoral surgery approaches (SCOPE, BEST OF) that will provide further data to guide management of these patients. In the meantime, careful multidisciplinary evaluation factoring in institutional experience is essential to determine the appropriate treatment modality.

ADJUVANT THERAPY FOLLOWING DEFINITIVE SURGICAL RESECTION

Following surgical resection of OPC, pathologic features including advanced primary T stage (T3 or T4), LVI, perineural invasion (PNI), positive margin, multiple pathologically involved cervical LNs, and ENE place patients at increased risk for locoregional recurrence.[53] In these cases, postoperative radiotherapy (PORT) has been shown to reduce the risk of locoregional relapse and is thus typically recommended.[54,55] The time interval between surgical resection and initiation of PORT has been shown to significantly impact patient outcomes and should ideally be ≤6 weeks.[56]

Adjuvant Chemoradiotherapy for Oropharyngeal Cancer

The addition of cisplatin-based chemotherapy to PORT has been compared to PORT alone for medically fit patients with HNSCC with high-risk pathologic features in a number of randomized studies,[57-61] the majority of which have demonstrated statistically significant[57-59] improvements in LRC and disease-free survival (DFS) with the addition of chemotherapy to PORT. Two of these studies also demonstrated statistically significant

improvements in OS with chemotherapy plus PORT versus PORT alone.[57,58] Two seminal randomized phase III trials are described here. RTOG 9501 randomized patients with pathologic features of two or more involved nodes, ENE, and/or positive margins to PORT versus PORT plus bolus cisplatin 100 mg/m^2 every 3 weeks, and EORTC 22931 randomized to similar arms, but also included patients with other high-risk features such as PNI, vascular tumor embolism, and/or nodal involvement in levels IV to V from an oral cavity or oropharyngeal primary. Notably, a significant portion of patients in these studies had OPC (EORTC 30%, RTOG 43%).[57,60,61] A pooled comparative analysis of patients in these two trials revealed that the presence of ENE and/or positive surgical margins were the only risk factors for which the addition of bolus cisplatin to PORT significantly improved oncologic outcomes.[62] An unplanned subset analysis from the reported long-term follow-up outcomes of RTOG 9501 supported this conclusion, with improved LRC, DFS, and cause-specific survival noted only in the subset of patients with ENE and/or positive margins.[61] Adjuvant PORT plus chemotherapy is thus currently recommended primarily for patients with OPC with ENE and/or positive surgical margins. Given the increased toxicity associated with the addition of chemotherapy, patient performance status should always be factored into decision-making.

Concurrent Chemotherapy Regimens for Adjuvant Chemoradiotherapy

The optimal chemotherapy regimen to be delivered concurrently with PORT is unknown. Regimens of 100 mg/m^2 bolus cisplatin every 3 weeks,[57,60,61] 50 mg/m^2 cisplatin weekly,[58] and 20 mg/m^2 cisplatin/600 mg/m^2 5-fluorouracil (5-FU) on d1-5 and d29-33[59] have all been utilized in randomized studies investigating PORT alone versus chemotherapy plus PORT. A randomized comparison of weekly cisplatin (40 mg/m^2) versus bolus cisplatin (100 mg/m^2 every 3 weeks) in patients receiving postoperative CRT for high-risk locally advanced HNSCC (14% OPC) was recently conducted, with results demonstrating noninferiority of the weekly cisplatin regimen in terms of OS. Patients in the weekly cisplatin arm also demonstrated significantly decreased frequency of grade 3+ neutropenia, infection, renal toxicity, and ototoxicity.[63] Weekly cisplatin at a dose of 40 mg/m^2 is thus a reasonable alternative regimen to bolus cisplatin for patients who require adjuvant CRT.

RTOG 0234 was a phase II trial that randomized patients with stage III and IV HNSCC (39% OPC) with high-risk postoperative features (positive margin, ENE, and/or at least two pathologically involved cervical nodes) to PORT (60 Gy) with cetuximab (400 mg/m^2 loading dose, followed by 250 mg/m^2 weekly) and weekly docetaxel (15 mg/m^2) versus PORT with cetuximab and weekly cisplatin (30 mg/m^2). Patients who received the docetaxel regimen had higher 2-year OS (79% vs 69%) and 2-year DFS (66% vs 57%).[64] RTOG 1216 is an ongoing randomized phase II/III trial designed to determine if there is an OS benefit for patients with high-risk non–HPV-associated HNSCC treated with the combination of cetuximab and docetaxel versus cisplatin alone (40 mg/m^2 weekly) or the combination of programmed death-ligand 1 (PD-L1) inhibitor atezolizumab and cisplatin versus cisplatin alone, all in the setting of adjuvant PORT. In summary, based on the

available data, many consider bolus cisplatin 100 mg/m^2 every 3 weeks to be the standard chemotherapy regimen to be used concurrently with PORT in patients with high-risk OPC (ENE and/or positive margins), based primarily on RTOG 9501 and EORTC 22931. However, weekly cisplatin can be considered based on randomized noninferiority data and is being increasingly used in the standard arm in clinical trials. For cisplatin-ineligible patients, the combination of docetaxel and cetuximab can be considered, though further confirmatory data are pending.

Adjuvant Radiation Therapy Dose

The optimal dose for PORT is also not well studied. An early dose-finding randomized trial established the efficacy of 57.6 Gy in 1.8 Gy daily fractions to the tumor bed, with a boost to 63 Gy to areas at high risk (ie, nodal regions with ENE), without clear benefit to further dose escalation.[65,66] Most randomized studies demonstrating the benefit of concurrent chemotherapy with PORT used conventionally fractionated RT, namely, 60 to 66 Gy in 2 Gy daily fractions, to high-risk areas (primary tumor bed with positive margin, or nodal regions with ENE). In three of the four studies, doses >65 Gy were delivered to high-risk areas.[57-59] The fourth study, RTOG 9501, allowed a dose of 60 Gy with an optional 6 Gy boost; however, only 13% of patients received this optional boost.[60,61] Accelerated PORT has been studied in randomized trials, which consistently showed no OS benefit as well as significantly increased toxicity with acceleration; thus, this approach is not recommended.[67,68] Based on the available data, doses between 60 to 66 Gy in 2 Gy daily fractions to high-risk areas and 50 to 54 Gy in 1.8 to 2 Gy daily fractions to low-risk areas are considered most appropriate. For patients with HPV-associated OPC, this paradigm is shifting, and it may be appropriate to de-escalate RT dose to a total of 50 Gy in 2 Gy daily fractions for select patients as discussed in the section “Deintensification.”

Postoperative Radiotherapy Treatment Volume

The typical treatment volume used in PORT for HNSCC includes the bilateral neck and the primary tumor bed.[69] However, it is unclear whether both the neck and primary always need to be included in the PORT volume. In those with completely resected primary OPC with negative margins whose sole indication for PORT is pathologic cervical adenopathy, some would direct therapy only to the neck. In addition, for well-lateralized primary tumors, patterns of progression would suggest that PORT to the ipsilateral neck only may be appropriate.[70] For patients with a positive margin as the sole indication for treatment in the setting of a comprehensive neck surgery without pathologically involved cervical LNs, some would direct treatment to the primary resection bed only; indeed, there are phase II trial data in support of this practice, though this trial was limited by its relatively small size.[71]

DEFINITIVE RADIATION THERAPY

For early-stage OPC (stage I, and select stage II patients[72]), the use of RT as a single modality is associated with good outcomes and functional preservation.[73] There are additionally chemotherapy-ineligible patients with more locally advanced disease, for whom RT alone must be considered. Although there is no consensus on the optimal dose fractionation schedule for patients with OPC receiving RT alone, randomized data[74-76] and meta-analyses[77,78] support an OS benefit with the use of accelerated or hyperfractionated RT. Therefore, for patients with OPC who are treated with RT alone, consideration should be given to altered RT fractionation.

Hyperfractionated Radiation therapy

The benefit of hyperfractionated RT for patients with OPC was clearly demonstrated in EORTC 22791, in which patients with T2-3N0-1 nonbase of tongue OPC were randomized to conventionally fractionated RT at 70 Gy (2 Gy/d) or to 80.5 Gy hyperfractionated at 1.15 Gy twice daily. Hyperfractionated RT was associated with a statistically significant improvement in LRC (5-year, 59% vs 40%) without an increase in long-term toxicity. In addition, there was a trend toward improved OS (P = .06), particularly in stage III patients.[76,79] RTOG 9003 was a four-arm phase III randomized study comparing two accelerated fractionation regimens and a hyperfractionation regimen to conventionally fractionated RT for patients with stage II and IV HNSCC (~60% with OPC). Long-term follow-up of this trial confirmed that hyperfractionation (81.6 Gy/68 twice-daily fractions) was associated with significantly improved LRC and OS, compared to standard fractionation. There was additionally no difference in grade 3 or higher late toxicities among the study arms.[74]

Accelerated Radiation Therapy

Accelerated RT has also been shown to benefit patients with OPC but may depend upon the exact regimen used. For example, a randomized study that enrolled primarily patients with OPC compared an accelerated regimen of 66 to 70 Gy delivered in 2 Gy daily fractions 6 days per week to the same dose delivered 5 days per week and demonstrated improved LRC (42% vs 30%, P = .004), DFS (50% vs 40%, P = .03), and a trend toward improved OS (35% vs 28%, P = .07) with the accelerated regimen.[75] Of note, accelerated fractionation improved local control for patients with p16-positive (HR: 0.56 [0.33-0.96]) and p16-negative OPC (HR: 0.77 [0.60-0.99]).[80] EORTC 22851 compared 1.6 Gy thrice daily to 72 Gy versus 1.8 to 2 Gy daily to 70 Gy over 7 to 8 weeks in patients with locally advanced HNSCC. Patients receiving accelerated fractionation had significantly improved 5-year LRC; however, both acute and late toxicities were increased with the regimen, drawing into question its utility.[81] In addition, another study investigating an accelerated regimen of 1.8 Gy twice daily to 59.4 Gy compared to 2 Gy daily to 70 Gy in patients with stage III/IV HNSCC found no benefit in terms of LRC or OS for the accelerated regimen.[82] It is unknown if the lack of benefit seen was due to the regimen used or the eligibility criteria, as the benefit for acceleration in some randomized studies was less

significant for those with stage IV disease, as well as for patients with a larger nodal disease burden.[83]

Accelerated Versus Hyperfractionated Radiation Therapy

The Meta-Analysis of Radiotherapy in squamous cell Carcinomas of Head and Neck (MARCH) collaborative group pooled 15 randomized studies with a total of 6,515 patients with locally advanced disease (44% with OPC), comparing conventionally fractionated RT to either accelerated RT or hyperfractionated RT. Altered fractionation RT regimens were associated with a 3.4% absolute improvement in 5-year OS. Heterogeneity in patients included in accelerated and hyperfractionated trials obscures ideal direct comparison; however, hyperfractionated RT resulted in an 8.1% absolute improvement in OS at 5 years, compared to a 2% absolute benefit with accelerated RT.[78] An updated analysis in 2017 including data from 33 trials reported a 1.2% absolute benefit in 10-year OS with altered fractionation RT, with the benefit seemingly limited to those receiving hyperfractionated RT (10-year OS benefit of 3.9%; HR 0.83, 95% CI, 0.74-0.92).[84] Given the heterogeneity of the data as well as the logistical challenges associated with delivering altered fractionation regimens, there is no consensus on the optimal fractionation in the setting of definitive RT alone in the treatment of patients with OPC.

Hypofractionated Radiation Therapy

Hypofractionated RT has been investigated in the definitive treatment of OPC. Princess Margaret Hospital published their single-institution experience of treating over 2,000 patients with HNSCC, the majority of whom had OPC, with either hypofractionated RT (60 Gy/25 fractions), accelerated RT (70 Gy/35 fractions over 6 weeks), or CRT. The rates of 3-year locoregional and distant control for patients with both HPV-related and HPV-negative early-stage disease (per AJCC eighth edition) were comparable, regardless of the RT regimen utilized. Hypofractionated RT also appeared to be well tolerated. The authors thus concluded that hypofractionated RT could be considered in the definitive treatment of such patients, with obvious limitations of this study including its nonrandomized nature.[85] This approach is rather attractive given the shorter treatment timeframe, while also avoiding twice-daily treatments. Further investigation is needed to determine the optimal role for this approach, namely, by continuing to quantify both comparative efficacy and associated late toxicities.

Stereotactic body radiotherapy (SBRT) is a technique used to deliver ablative doses of external beam RT in five or fewer fractions with high accuracy and has increasingly been adopted in the definitive treatment of various malignancies, such as inoperable early-stage non–small cell lung cancer.[86] There is currently a lack of evidence to support utilization of SBRT as a primary treatment option for patients with OPC,[87] although this is an area of active investigation.

CONCURRENT CHEMORADIOTHERAPY FOR LOCOREGIONALLY ADVANCED OROPHARYNGEAL CANCER

For patients with locoregionally advanced OPC, concurrent CRT is the standard treatment. Resection when possible is generally not recommended, given the associated morbidity. In addition, adjuvant CRT is frequently necessary for these patients if surgical resection is pursued with similar morbidity to definitive CRT. Comparisons of outcomes of patients treated with RT with or without neck dissection versus surgery with or without adjuvant RT revealed higher complication rates associated with surgery.[43] With the advent of transoral and robotic surgical techniques, these findings are being reconsidered. However, as discussed above, recent trials have not demonstrated a benefit to minimally invasive surgery over definitive RT/CRT for patients with OPC.[50,52]

Evidence for Concurrent Chemoradiotherapy

The use of concurrent CRT for most patients with stage III and IV (nonmetastatic) OPC is based on the results of the meta-analysis of head and neck cancer, which demonstrated a 6.2% absolute improvement in 5-year OS with the use of concurrent CRT compared to RT alone.[88] This OS benefit was also observed specifically in the OPC subgroup of 5,872 patients (HR: 0.78, 95% CI: 0.72-0.85, $P < .0001$).[89] A benefit to cisplatin-containing and poly-chemotherapy regimens was noted, as was decreasing benefit of the addition of chemotherapy with increasing age. The updated MARCH meta-analysis additionally compared altered fractionation RT alone to conventionally fractionated CRT in patients with stage III and IV HNSCC and demonstrated that CRT resulted in significantly improved 10-year OS.[84]

Level I evidence from multiple randomized studies restricted to patients with OPC additionally supports the use of concurrent CRT for stage III/IV disease.[90,91] The Groupe d'Oncologie Radiothérapie Tête et Cou (GORTEC) compared conventional RT (2 Gy daily to 70 Gy) to RT plus three cycles of carboplatin/5-FU. A total of 222 patients (113 assigned to RT alone and 109 assigned to combined treatment) were eligible for analysis. With a median follow-up of 5.5 years, absolute 5-year OS was significantly higher in the combined modality arm (15.8% with RT alone vs 22.4% with CRT). Five-year LRC was also significantly improved with concomitant therapy (24.7% vs 47.6%, $P = .002$).[92]

Acute Toxicity of Chemoradiotherapy

For patients with OPC, a course of concurrent CRT is a life-changing event given the associated toxicities, including fatigue, nausea, emesis, thickened secretions, xerostomia, mucositis, dysphagia, odynophagia, alopecia, dermatitis, anemia, neutropenia, hoarseness, Lhermitte syndrome, and infection. Mucositis, defined as acute inflammation of the mucous membranes in the throat and mouth, is one of the most common acute toxicities of CRT, affecting approximately 70% of patients. Mucositis contributes significantly to malnutrition, dehydration, treatment breaks, hospitalization, and feeding tube placement. It is typically managed by topical (diphenhydramine-lidocaine-antacid mouthwash,

doxepin mouthwash[93]) and oral analgesics (pregabalin,[94] gabapentin[95]), although opioids are frequently necessary. Novel therapeutics to combat severe mucositis are under investigation. One promising agent is avasopasem manganese, a small molecule superoxide dismutase mimetic proposed to selectively radio-protect normal tissues. Two trials, which enrolled a total of 678 patients with locally advanced HNSCC receiving CRT, randomized patients to placebo versus avasopasem and demonstrated clinically meaningful reductions in oral mucositis (severity, incidence, duration) with the addition of avasopasem.[96,97] Dysphagia is also a significant acute complication and can contribute to poor nutritional status as well as aspiration and resultant infection. Early therapeutic intervention should be promoted and involves swallowing exercises designed to strengthen the pharyngeal musculature.[98] Patients should undergo nutritional evaluation before, during, and after treatment, particularly those who lose 5% of their body weight over 1 month. Reactive, as opposed to prophylactic, feeding tube placement is generally preferred for patients with OPC, and various guidelines and criteria can help inform clinical decision-making in this regard. Prophylactic feeding tube placement should still be considered in high-risk patients, such as those with severe pretreatment weight loss and dysphagia with significant aspiration risk.[99]

Late Toxicity of Chemoradiotherapy

Late toxicities of CRT for patients with OPC can also be quite significant and can include dysphagia, fibrosis, osteoradionecrosis, trismus, xerostomia, dental caries, feeding tube dependence, and neuritis. With modern IMRT and supportive care, grade 3 or higher late toxicities afflict roughly 20% of patients with OPC.[100] Chronic feeding tube dependence afflicts 3% to 4% of patients with OPSCC, and late cranial neuropathies can affect 4% to 5% of patients.[101,102] Lymphedema and neck fibrosis are common and can be mitigated by occupational therapy and custom compression devices. Given the increased risk for dental and oral complications, patients should be evaluated by an experienced dentist at least 2 times per year, with consultation with the treating radiation oncologist prior to any planned extractions. Pilocarpine is approved by the U.S. Food and Drug Administration as a sialagogue and can be prescribed to aid in the treatment of RT-induced xerostomia, to supplement other strategies involving salivary substitutes, dietary modification, as well as increased hydration.[103] Fluoride treatments can help reduce caries and sensitivity.[104] Trismus can be prevented and managed with custom exercises and devices. Notably, a long-term report of patients with HPV-associated OPC treated with CRT demonstrated that development of additional late toxicities beyond those present at 2 years post-CRT was rare. Furthermore, long-term QoL in all domains was similar to that seen before treatment.[105]

Alternative Concurrent Chemoradiotherapy Regimens

Bolus cisplatin at 100 mg/m^2 every 3 weeks is often cited as a standard concurrent chemotherapy regimen due to its lengthy track record in randomized trials. However, the

toxicity of bolus cisplatin has motivated evaluation of alternative regimens. Multiple randomized studies that compared RT alone to concurrent CRT using nonbolus cisplatin schedules including daily cisplatin (6 mg/m^2/d),[106] weekly cisplatin (40 mg/m^2),[107] or cisplatin (20 mg/m^2/d) on days 1 to 5 repeated every 3 weeks[108] have demonstrated comparable outcomes. Weekly cisplatin is of particular interest, given its increased tolerability and relative ease of administration. Although a recent systematic review and meta-analysis demonstrated comparable survival outcomes and toxicity in patients treated with RT with weekly cisplatin versus bolus cisplatin,[109] there are overall more high-level data in support of utilization of bolus cisplatin. Further evidence should come from an ongoing phase II/III trial through NRG (NCT05050162), which is randomizing patients with locally advanced HNSCC to RT plus weekly versus bolus cisplatin and notably has separate study arms for patients with HPV-associated OPC.

For patients who are not eligible to receive cisplatin based on medical comorbidities or performance status, there is no standard of care cytotoxic radiosensitizer. (Cetuximab is discussed in the targeted therapy section.) The aforementioned GORTEC randomized study demonstrated an OS advantage using a carboplatin/5-FU regimen specifically chosen to avoid cisplatin-related tinnitus, renal dysfunction, and emesis, although this regimen can notably result in significant mucosal toxicity. The combination of carboplatin and paclitaxel has also been trialed in a single-arm study.[110] Nonrandomized data support the use of single-agent carboplatin, specifically in place of cetuximab, for cisplatin-ineligible patients with locally advanced OPC, although selection bias is a limitation of these studies.[111,112] In addition, a recent phase II/III study randomized 356 cisplatin-ineligible patients with locally advanced HNSCC to RT alone versus RT plus concurrent docetaxel and showed significantly higher 2-year DFS (42% vs 30.3%, P = .002) and 2-year OS (50.8% vs 41.7%, P = .035) with the addition of docetaxel.[113] Any of these regimens are acceptable choices for cisplatin-ineligible patients, although the best evidence is for carboplatin/5-FU. As discussed above, if patients have locoregionally advanced OPC and are not eligible to receive any systemic therapy, then consideration for altered fractionation RT should be given. Concurrent use of targeted agents is discussed below.

Concurrent Chemotherapy and Accelerated Radiation Therapy

Two randomized studies have shown that there is no benefit to accelerated RT over conventionally fractionated RT when delivered with concurrent platinum-based chemotherapy. GORTEC 99-02 randomized patients with locoregionally advanced HNSCC to either very accelerated RT (64.8 Gy in 1.8 Gy twice-daily fractions), conventionally fractionated RT (70 Gy over 7 weeks) with concurrent carboplatin and 5-FU, or accelerated RT (70 Gy delivered in 2 Gy daily fractions to 40 Gy, then 1.5 Gy twice daily) with concurrent carboplatin and 5-FU. Outcomes in both CRT arms were similar and were superior to very accelerated RT alone, with lower rates of acute toxicity and percutaneous gastrostomy tube placement during therapy and at 5 years post-treatment.[114] RTOG 0129 randomized patients with locally advanced disease (60% with

OPC) to accelerated concomitant boost RT (72 Gy) with two cycles of bolus cisplatin (100 mg/m^2) versus conventionally fractionated RT (70 Gy over 7 weeks) with three cycles of bolus cisplatin (100 mg/m^2). Again, there was no benefit to accelerated CRT in terms of 8-year OS (accelerated 47.6% vs conventional 47.7%), locoregional progression (36.7% vs 38.5%), or grade 3 to 5 toxicity (37.9% vs 36.5%).[115] Either RT fractionation approach can thus be considered for patients with locally advanced OPC receiving concurrent systemic therapy.

Induction Chemotherapy Prior to Definitive Local Therapy

The utility of induction chemotherapy as a means to reduce the risk of distant failure and improve survival for patients with locoregionally advanced OPC was an area of active study, particularly given that the rising use of definitive CRT reduced the competing risk of locoregional failure and that the primary pattern of progression was distant metastases.[116] However, mature results from multiple randomized studies did not demonstrate significant improvement in PFS or OS with induction chemotherapy followed by concurrent CRT, and in fact reported increased associated toxicity.[117-119] Induction chemotherapy is thus not routinely recommended in the treatment of patients with nonmetastatic OPC but could be considered if there is an unavoidable delay in initiating CRT, or for rapidly growing tumors, and those adjacent to critical normal structures limiting the ability to deliver curative-intent radiation doses. Early-phase induction chemotherapy studies in the patient population with HPV-positive OPC are discussed in the section “Deintensification.”

Targeted Agents and Radiation Therapy

EGFR is commonly overexpressed in HNSCC and was thus identified as a molecular target for therapy. A randomized study compared RT (70-76.8 Gy) with weekly cetuximab, an EGFR inhibitor (loading dose of 400 mg/m^2 followed by 250 mg/m^2), to RT alone for patients with locoregionally advanced HNSCC (60% OPC). The combination therapy was found to improve LRC, DFS, and OS, independent of tumor p16 status.[120] Based on these data, it was hypothesized that the combination of cetuximab plus RT could be, at the very least, an option for cisplatin-ineligible patients and potentially even a new standard of care/less toxic regimen allowing for deintensification of treatment for HPV-associated OPC. However, data from multiple phase III randomized trials comparing cetuximab plus RT to cisplatin plus RT for mostly HPV-associated locally advanced OPC have demonstrated not only the inferiority of concurrent cetuximab to cisplatin in terms of survival and recurrence outcomes but also a lack of benefit in terms of reduced treatment-related toxicity.[100,121-123] See the section “Deintensification” for further discussion. Cetuximab should also notably be avoided in specific regions (particularly the Southeastern United States) where severe anaphylactic reactions mediated by an immunoglobulin E response to the galactose-α-1,3-galactose oligosaccharide found on the Fab portion of the cetuximab heavy chain are seen.[124] Although cetuximab has been shown

to be inferior to cisplatin in the definitive treatment setting, it remains an option for cisplatin- or otherwise chemotherapy-ineligible patients in certain geographical areas, as it has been shown to be superior to definitive RT alone.

Immune checkpoint inhibitors, which target programmed death-1 (PD-1) and PD-L1, have been evaluated in combination with RT in the definitive treatment of OPC. NRG HN004 was a phase II/III trial that randomized cisplatin-ineligible patients with locally advanced HNSCC to RT plus cetuximab versus RT plus durvalumab, a PD-L1 inhibitor. Patients with favorable-risk HPV-associated OPC were notably excluded. The study enrolled 190 patients but was closed after planned interim futility analysis due to higher rates of locoregional failure in the durvalumab arm, with no signal toward improved PFS.[125] The phase II PembroRad trial randomized 133 cisplatin-eligible patients with locally advanced HNSCC (majority with OPC) to pembrolizumab plus RT versus cetuximab plus RT and demonstrated no difference in survival outcomes between the arms, though notably less toxicity in the pembrolizumab arm.[126] Further investigation into the combination of immunotherapy and RT in the definitive treatment setting is necessary prior to integration into routine clinical practice.

Additional novel targeted agents, such as DNA-dependent protein kinase inhibitors, antagonists of inhibitor of apoptosis proteins, and second mitochondria-derived activator of caspases mimetics, have been and are being actively investigated in clinical trials in both the cisplatin-eligible and cisplatin- ineligible patient populations. These therapies have not yet been integrated into the standard of care.[127,128]

Targeted Agents in Combination With Cytotoxins and Radiation Therapy

Patients with OPC comprised 70% of those enrolled onto RTOG 0522, which compared two concurrent cycles of 100 mg/m^2 cisplatin and accelerated RT to 72 Gy with or without cetuximab. The combination of cisplatin, cetuximab, and RT did not improve LRC, DFS, or OS and was associated with increased toxicity.[129] The phase III GORTEC 2007-01 trial compared cetuximab and RT to carboplatin/5-FU plus cetuximab and RT for patients with locally advanced HNSCC (>60% OPC) and demonstrated significantly improved PFS and LRC rates at 3 years with the addition of chemotherapy. However, toxicity was increased with chemotherapy, and there was no difference in OS. No differences in outcome were seen as a function of HPV status for either of these trials. Based on these data, the addition of cetuximab to CRT in the treatment of locally advanced OPSCC is not recommended.[130]

The phase III JAVELIN Head and Neck 100 study randomized 697 patients with locally advanced HNSCC (majority with OPC) to standard CRT (70 Gy with bolus cisplatin) plus concurrent and adjuvant avelumab versus placebo. The addition of the PD-L1 inhibitor avelumab failed to improve PFS compared to placebo (HR 1.21, 95% CI 0.93-1.57, favoring placebo, P = .92). This finding was independent of HPV status.[131] KEYNOTE-412 is a similar phase III study randomizing patients with locally advanced HNSCC to CRT plus pembrolizumab versus CRT plus placebo.[132] Preliminary unpublished findings have not demonstrated a statistically significant benefit to pembrolizumab in terms of event-free survival. These findings highlight that more research into the optimal

integration of immunotherapy and other targeted agents into the definitive treatment of patients with locally advanced OPC is necessary prior to adopting them as standard therapy.

DEFINITIVE RADIATION THERAPY SIMULATION, TREATMENT PLANNING, AND TECHNIQUES

Radiation Therapy Simulation

Patients should undergo CT-based simulation to allow for optimal RT planning. Low osmolar iodinated contrast should be administered to optimize the distinction between vascular structures and LNs. Patients are positioned supine with neck gently extended, with a rigid head-holder cradling the posterior calvarium. The shoulders should be positioned as caudally as possible to allow adequate exposure of the neck. This can be achieved with either shoulder-pulls, other commercially available devices, or a combination of the two. Tongue immobilization can be useful for patients with pathologic involvement of the oral tongue. Bite-blocks are also useful as they often elevate the hard palate with its minor salivary glands. Dental amalgam can obscure the quality of the images; CT artifact–reducing algorithms can assist in this regard, as can custom dental trays or putty molds.

The head should be immobilized with a thermoplastic mask. Care should be taken to ensure that the mask is tight enough around the nose, chin, and forehead to inhibit movement. Images should be taken from above the calvarium to the carina to ensure appropriate volumes can be drawn. CT slice thickness should be no greater than 3 mm. The addition of metabolic imaging and MRI has been found to be complementary for gross tumor volume (GTV) delineation.[133]

Radiation Therapy Volumes

Definitive RT volumes for patients with OPC are based on ICRU 50. The GTV includes all known primary and cervical LN tumor extension based on clinical, endoscopic, and imaging findings. The GTV is usually expanded to include a margin for microscopic extension, forming the clinical target volume (CTV). Current international consensus guidelines specify an expansion of 5 mm from the GTV to form the high-risk CTV_primary and 10 mm to form the low-risk CTV_primary. Other anatomic areas at risk for occult microscopic spread based on the tumor location and extent are usually encompassed in the low-risk CTV_primary.[35]

Consensus guidelines for contouring the clinically node-negative neck have been published and endorsed by international head and neck cancer cooperative groups.[134] These guidelines are clinically useful aids for delineating specific nodal treatment volumes. Levels II to IV in the clinically node-negative neck would typically be covered in the low-risk CTV for patients with OPC. Similar guidelines have been proposed for clinically node-positive and postoperative patients.[69,135] A 3- to 5-mm margin on the nodal GTV, depending on the extent of adjacent structure involvement, is sufficient for the high-

risk nodal CTV. Specific recommendations for node-positive patients include coverage of the supraclavicular fossa for patients with level IV or Vb lymphadenopathy, coverage of the retrostyloid space for patients with level II lymphadenopathy, coverage of the retropharyngeal nodes in the setting of high level II lymphadenopathy and/or primary tumors extending into the nasopharynx or pterygoid region, and CTV coverage of the entire thickness of muscles invaded by pathologic lymphadenopathy. Pathologic lymphadenopathy spanning adjacent levels should trigger inclusion of the full extent of both levels in the CTV. One nodal region beyond those pathologically involved is typically included in the low-risk volume. For example, a patient with pathologic lymphadenopathy in level II would have level IB included in the low-risk treatment volume.

CTVs are expanded to account for organ motion and setup uncertainty ideally based on institution-specific data in order to form the planning target volume (PTV). For patients with OPC, movement of the base of tongue, which can be significant particularly with swallowing, should be considered when determining an appropriate PTV margin. The expansion from CTV to PTV should also account for imaging methods used to assess daily setup. In general, if more frequent image guidance is performed, less margin should be needed for setup uncertainty. A 3- to 5-mm CTV to PTV expansion, if frequent kilovolt image or cone-beam CT guidance is utilized, is relatively standard practice.[136] Representative contours for a patient with locoregionally advanced OPSCC are shown in Figure 51.1.

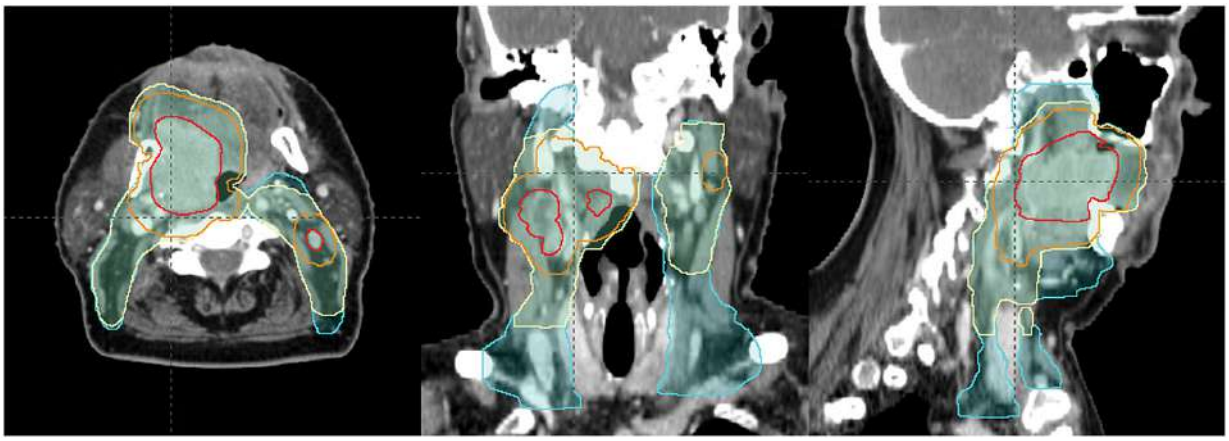

FIGURE 51.1 Representative computed tomography (CT)-based contours for a patient with cT4N2M0 human papillomavirus–related squamous cell carcinoma of the right oropharynx. Axial (left), coronal (middle), and sagittal (right) images of contrast-enhanced neck CT for radiation planning with gross tumor volume in red, low-risk planning target volume (PTV) in cyan, intermediate-risk PTV in yellow, and high-risk PTV in orange.

Indications for Ipsilateral Radiation Therapy

For well-lateralized early-stage tonsillar cancers with no involvement of the base of tongue and minimal involvement of the soft palate (>1 cm margin between the medial extent of tumor and midline), the contralateral neck can be excluded from the CTV, which

will significantly limit the exposure of the contralateral parotid, submandibular gland, and pharyngeal musculature.[32] Patients with contralateral cervical LN involvement usually have extensive involvement of ipsilateral cervical LNs[137] or tumors approaching or crossing the midline. Surgical series also demonstrate that the risk of contralateral cervical LN involvement correlates with primary tumor size and is thus more common in T3/T4 tumors.[138,139] An analysis of patients with mostly T1-2 (79%) and N0-1 (88%) tonsillar cancer who underwent resection of their primary tumors often with ipsilateral LN dissection showed that only 5% of patients progressed in the contralateral neck.[140]

A large series of patients undergoing definitive RT to a tonsil primary and only the ipsilateral neck demonstrated 0% progression in the contralateral neck in patients with T1 tumors and only 1% to 2% progression in those with T2 tumors. In the few patients with T3 tumors, contralateral nodal progression was 3% to 10%.[141,142] Further analysis of these series shows that contralateral nodal progression was associated with both base of tongue and soft palate involvement (13%), T3 stage (10%), and specifically involvement of the midline of the soft palate (16.5%). Thus, omission of RT to the contralateral neck in select patients with well-lateralized T1-2N0-1 tonsillar cancers should be strongly considered. Importantly, these excellent outcomes appear to be independent of tumor HPV status.[143]

Studies evaluating the role of ipsilateral treatment in the context of N2b disease and concurrent CRT are relatively sparse. An analysis of patients with tonsil cancer treated at MD Anderson Cancer Center from 1970 to 2007 included only 3 patients who received concurrent systemic therapy for N2b disease. In these patients, there was no contralateral neck progression.[144] An analysis of 20 patients with locoregionally advanced tonsillar cancer with N2b nodal disease, 18 of whom received concurrent CRT, demonstrated high rates of primary and nodal disease control along with a low risk of contralateral nodal progression. A caveat to this study is that all patients were staged with PET/CT and most patients underwent resection of the primary (80%) and/or neck dissection (70%).[145] Another retrospective analysis that included 41 patients undergoing ipsilateral RT for tonsillar cancer with N2b disease (88% receiving concurrent CRT and 98% staged by PET/CT) reported no contralateral neck recurrences.[146] At this time, omission of RT to the contralateral neck remains controversial in the setting of N2b or more advanced nodal disease for well-lateralized tonsillar cancer.[147]

Intensity-Modulated Radiation Therapy

IMRT has been widely adopted for the treatment of HNSCC,[148] due to its ability to minimize normal organ exposure to RT. This is particularly important for patients with OPC as pharyngeal constrictor dose and parotid dose are associated with dysphagia[149] and xerostomia,[150] respectively.

The impact of IMRT on reduction of xerostomia has been established by numerous phase II and III trials. One notable phase III randomized trial is PARSPORT, in which patients with T1-4N0-3 HNSCC (without disease involving the parotid glands) who were recommended to receive either definitive or adjuvant RT without concurrent chemotherapy were randomized 1:1 to receive either conventional RT (parallel-opposed

3D technique) or IMRT. The primary end point was the proportion of patients with grade 2 or worse xerostomia at 12 months, assessed via the late effects of normal tissues (LENT SOMA) scale.[150] Six centers in the United Kingdom recruited 94 patients (47 in each arm). Eighty-five percent of participants had OPC. IMRT significantly reduced the mean RT dose to the ipsilateral (47.6 vs 61 Gy) and contralateral (25.4 vs 61 Gy) parotid glands ($P < .0001$). At 12 months, only 38% of patients treated with IMRT had grade 2+ xerostomia compared to 74% in the conventional RT arm, independent of other treatment and clinical characteristics. Locoregional progression and OS were similar between the two arms. Other trials have reported a similar magnitude of reduction in late xerostomia with IMRT when concurrent chemotherapy is administered as well.[151] Ongoing cooperative group trials recommend limiting the mean dose to the parotids to ≤26 Gy. Furthermore, the mean dose to the submandibular gland is recommended to be limited to ≤39 Gy.

Large retrospective studies have demonstrated significant associations between treatment with IMRT and shorter duration of treatment-related feeding tube use.[152] Many studies have attempted to correlate dosimetric parameters with functional swallowing consequences following RT or CRT. Consensus on dosimetric parameters does not exist as the studies to date have all been retrospective and their findings are not completely concordant. In general, dose to the larynx and pharyngeal constrictors should be as low as possible to limit the risks of aspiration, feeding tube dependence, and stricture.

Intensity-Modulated Radiation Therapy Treatment Strategies

With the advent of IMRT, a simultaneous integrated boost (SIB) technique, whereby different doses are delivered to different targets simultaneously within the same treatment fraction, was investigated in the treatment of patients with OPC. This technique is intended to increase the specificity of tumor RT, decreasing dose to normal tissues. There can be greater heterogeneity of the dose distribution, resulting in larger hot spots. The alternative technique is sequential boost IMRT, whereby typically two plans are created, a low-dose plan that encompasses elective volumes and a high-dose plan that boosts gross disease with margin. The boost plan is typically delivered sequentially, after completion of the initial lower dose plan. In general, when treating definitively with conventionally fractionated RT, a sequential boost IMRT course involves 44 to 50 Gy in 2 Gy daily fractions to the elective lower risk volume, followed by a 20 to 26 Gy boost to the high-risk volume, to allow for a total dose of 70 Gy to gross disease. An SIB plan allows for delivery of a similar biologically effective dose (BED) to gross disease, while utilizing a range of alternative doses per fraction to elective volumes (typically 54-63 Gy as 1.6-1.8 Gy per fraction). A meta-analysis of seven trials inclusive of 1,049 patients with HNSCC demonstrated no differences in survival outcomes or grade 3 or higher toxicity in patients treated with definitive SIB-IMRT versus sequential boost IMRT plans.[153] Either of these IMRT techniques is thus appropriate, and the use depends on provider/institutional experience and preference.

Proton Beam Radiation Therapy

The use of proton beam therapy (PBT) in the definitive or adjuvant treatment of HNSCC is an area of active clinical investigation, with the relevant literature currently consisting primarily of small institutional reports and nonrandomized studies. Given its unique dosimetric characteristics, PBT is hypothesized to minimize dose to normal structures without compromising target coverage, thereby maintaining oncologic outcomes while limiting toxicity when compared to IMRT. Preliminary data are generally supportive of this hypothesis. A case-matched control analysis of patients with OPC demonstrated significantly lower doses to the oral cavity, hard palate, larynx, mandible, and esophagus in PBT plans compared to IMRT plans.[154] Various single-institution series have demonstrated decreased changes in taste and appetite, mucositis, pain, and narcotic requirements in the subacute treatment-recovery phase, as well as decreased feeding tube dependency, hospitalizations, late xerostomia, and severe weight loss in patients with OPC treated with PBT in comparison to patients treated with IMRT.[155-158] In addition, single-institution noncomparative prospective studies have demonstrated encouraging survival rates and disease control in patients with OPC treated with PBT, in both the definitive and adjuvant settings.[159,160] Currently, institutions with significant experience with PBT may consider its use for particularly challenging OPC cases when it is difficult to meet normal tissue constraints with IMRT. However, routine utilization is limited pending high-level data regarding its efficacy in comparison to IMRT. Results from prospective studies, such as a phase II/III trial at MD Anderson Cancer Center randomizing patients with stage III and IVB OPSCC to definitive PBT- versus IMRT-based CRT (NCT01893307), will help guide future management.

DEINTENSIFICATION OF THERAPY FOR PATIENTS WITH HUMAN PAPILLOMAVIRUS–POSITIVE OROPHARYNGEAL CANCER

Given the generally superior outcomes of patients with HPV-associated OPC, in combination with the potential for significant acute and late treatment-related toxicity, strategies to deintensify curative-intent treatment for patients with both early-stage and locoregionally advanced disease while maintaining favorable oncologic outcomes are being actively evaluated. Some studies have identified higher risk subgroups who may be less amenable to deintensification, given overall poorer oncologic outcomes, such as patients with a significant smoking history or patients with very advanced disease (T4, N3, matted lymphadenopathy).[161-164] With these few exceptions, many patients with HPV-associated OPC are considered potential candidates for treatment deintensification. In this regard, many different approaches have been investigated in the prospective arena with selected studies in Table 51.7.

TABLE 51.7 SUMMARY OF SELECTED RANDOMIZED THERAPEUTIC DE-ESCALATION TRIALS FOR P16-POSITIVE OROPHARYNGEAL CANCER

Trial	Patient Population[a]	*N*	Treatment Groups	Key Results
RTOG 1016[100]	cT1-T2N2a-N3M0 or cT3-T4N0-N3M0; age ≥ 18; Zubrod PS 0-1; p16+ IHC	849	Accelerated RT (70 Gy/35 fx in 6 wk) with concurrent cetuximab vs concurrent bolus cisplatin	• 5-y PFS: 63.7% (cetuximab) vs 78.4% (cisplatin); HR 1.72 (95% CI 1.29-2.29; *P* = .0002) • 5-y OS: 77.9% (cetuximab) vs 84.6% (cisplatin); HR 1.45 (1one-sided 95% upper CI 1.94; *P* = .5056 for noninferiority; one-sided log-rank *P* = .0163); failed to meet noninferiority criteria
De-ESCALaTE HPV[121]	cT3N0M0-T4N0M0 or cT1N1M0-T4N3M0; <10 pack-year smoking history; age >18; ECOG PS 0-1; p16+ IHC	334	RT (70 Gy/35 fx in 7 wk) with concurrent bolus cisplatin vs cetuximab	• 2-y recurrence: 6.0% (cisplatin) vs 16.1% (cetuximab); HR 3.4 (95% CI 1.6-7.2 *P* = .0007) • 2-y OS: 97.5% (cisplatin) vs 89.4% (cetuximab); HR 5.0 (95% CI 1.7-14.7; *P* = .0012)
TROG 12.01[122]	Stage III (excluding cT1-2N1) or stage IV (excluding T4 and/or N3 and/or N2b-c if >10 pack-year smoking history); age ≥18; ECOG PFS 0-1; p16+ IHC	189	RT (70 Gy/35 fx in 7 wk) with concurrent cisplatin (40 mg/m^2 weekly) vs cetuximab	• 3-y PFS: 93% (cisplatin) vs 80 (cetuximab); HR 3.0 (95% CI 1.2-7.7; *P* = .015) 3-y OS: 98% (cisplatin) vs 96% (cetuximab); HR 2.3 (95% CI 0.4-12.7; *P* = .32)
NRG HN002[165]	cT1-2N1-N2bM0 or cT3N0-N2bM0; ≤10 pack-year smoking history; age ≥18; Zubrod PFS 0-1; p16+ IHC	306	RT (60 Gy/30 fx in 6 wk) with concurrent weekly cisplatin (CRT) vs accelerated RT alone (60 Gy/30 fx in 5 wk)	• 2-y PFS: 90.5% (CRT) vs 87.6% (accelerated RT alone); HR 0.67 (95% CI 0.36-1.24; *P* = .20); null hypothesis of 2-y PFS ≤85% rejected • 2-y LRF: 3.3% (CRT) vs 9.5% (accelerated RT alone); HR 0.39 (95% CI 0.17-0.90; *P* = .02) • 2-y OS: 96.7% (CRT) vs 97.3% (accelerated RT alone); HR 0.95 (95% CI 0.31-2.95; *P* = .93)
ECOG-ACRIN 3311[166]	Stage III-IVA with cT1-T2 p16+ OPC amenable to TORS; age ≥18; ECOG PS 0-1; p16+ IHC	395	• Low risk: observation, no adjuvant RT • Intermediate risk (margins <3 mm, N1-N2 with ≤1 mm ENE, ≤4 LN involved): randomized to 50 Gy/25 fx (5 wk) vs.	• Low-risk 2-y PFS: 96.9% (90% CI 91.9%-100%) • Intermediate-risk 2-y PFS: 94.9% (90% CI 91.3%-98.2%) (50 Gy) vs 96.0% (90% CI 92.8%-99.3%) (60 Gy)

Trial	Patient Population[a]	*N*	Treatment Groups	Key Results
			60 Gy/25 fx (6 wk), not powered for comparison • High risk: adjuvant RT (66 Gy) with weekly cisplatin	• High-risk 2-y PFS: 90.7% (90% CI 86.2%-95.4%) • Low-risk 2-y OS: 100% • Intermediate-risk 2-y OS: 99% (90% CI 93%-100%) (50 Gy) vs 98.1% (90% CI 95.9%-100%) (60 Gy) • High-risk 2-y OS: 96.3% (90% CI 93.3%-99.3%)

CI, confidence interval; CRT, chemoradiotherapy; ECOG, Eastern Cooperative Oncology Group; ENE, extranodal extension; fx, fractions; HR, hazard ratio; IHC, immunohistochemical; LN, lymph node; LRF, locoregional failure; OPC, oropharyngeal cancer; OS, overall survival; PFS, progression-free survival; PS, performance status; RT, radiation therapy; TORS, transoral robotic surgery.

[a]All staging based on AJCC seventh edition.

One approach to deintensification, given the toxicity of cisplatin, has been to investigate alternative concurrent systemic therapy agents. Three randomized phase III trials have shown that RT with concurrent cetuximab is inferior to RT with concurrent cisplatin in the treatment of HPV-associated OPC. RTOG 1016 was a noninferiority trial that randomized 846 patients with locally advanced HPV-associated OPC to accelerated RT (70 Gy/35 fractions over 6 weeks) with concurrent cetuximab versus bolus cisplatin. The cetuximab arm not only failed to meet the criteria for noninferiority based on 5-year OS (77.9% for cetuximab vs 84.6% for cisplatin) but also had significantly worse PFS and locoregional failure rates.[100] The phase III De-ESCALaTE HPV trial randomized 334 patients with low-risk (nonsmokers or patients with <10 pack-year history) HPV-associated OPC to RT (70 Gy in 35 fractions, once daily) plus bolus cisplatin versus RT plus weekly cetuximab. Patients in the cetuximab arm had significantly lower 2-year OS (89.4% vs 97.5%, HR 5.0, $P = .001$) and higher 2-year recurrence rates (16.1% vs 6.0%, HR 3.4, $P = .0007$) and additionally did not experience reduced toxicity.[121] The TROG 12.01 trial randomized 189 patients with low-risk HPV- associated OPC to RT (70 Gy in 35 fractions, once daily) plus weekly cisplatin versus RT plus weekly cetuximab. This trial similarly demonstrated that patients receiving cetuximab had inferior failure-free survival (80% vs 93% at 3 years, $P = .015$), with no benefit in terms of reduced toxicity.[122] Cetuximab should thus not be utilized for the purpose of deintensification in the treatment of cisplatin-eligible patients with HPV-associated OPC. Nivolumab is being investigated as an alternate agent in NRG HN005, as discussed below.

Another approach under investigation is response-adapted therapy. ECOG 1308 was a single-arm study that investigated de-escalation of RT dose based on response to induction chemotherapy. Patients with a complete response to induction chemotherapy (three cycles of cisplatin, paclitaxel, and cetuximab) received 54 Gy with concurrent cetuximab and those with a partial response received 69.3 Gy with concurrent cetuximab. Patients treated with the lower dose of 54 Gy had 2-year PFS and OS rates of 80% and 93%, respectively.[167] CCRO-022 was a single-arm phase II trial with a similar study design,

namely, modifying definitive RT dose based on response to an induction chemotherapy regimen, in this case carboplatin and paclitaxel. Complete or partial responders (55%) received 54 Gy with concurrent paclitaxel and nonresponders received 60 Gy, with high 2-year PFS of 92% in the cohort.[168] Others have deintensified therapy in patients with a favorable response to induction chemotherapy by significantly shrinking or eliminating elective nodal RT volumes. In one study, following an induction regimen consisting of cisplatin, paclitaxel, and cetuximab ± everolimus, patients with >50% reduction in the sum of tumor diameters were classified as having a "good response" (GR). These patients were prescribed standard-dose CRT to gross disease only, while those with a response not meeting the predefined threshold ("nonresponse" [NR]) received standard-dose CRT to gross disease as well as the next elective nodal station at risk. There was a trend toward improved PFS in patients with GR versus NR (86% vs 68.7%, P = .086).[169] Among patients with HPV-related OPC with GR, 2-year PFS and OS were 93.1% and 92.1%, respectively, indicating that this is a potentially promising treatment strategy pending further investigation. Another phase II trial enrolling patients treated with TORS and neck dissection omitted primary site coverage for patients with favorable pathologic features, targeting only the at-risk neck, and reported excellent LRC and survival rates at 2 years, as well as promisingly low toxicity rates.[170] There are ongoing investigations into deintensification of RT dose based on mid-treatment imaging biomarkers as well, with one phase II study de- escalating patients with early-stage p16-positive OPC from 70 Gy/35 fractions to 54 Gy/27 fractions if certain interim FDG-PET parameters[171] were met. Initial acute toxicity data were promising, and we await further data on associated oncologic outcomes from this study and others utilizing novel functional imaging platforms.[172,173]

Another de-escalation strategy is simply reducing RT and/or chemotherapy dose in the setting of concurrent CRT. In a single-arm phase II study, patients with intact cT0-T3N0-N2c HPV-associated OPC were treated with definitive intent to 60 Gy with concurrent weekly cisplatin (30 mg/m^2). The primary end point was a pathologic complete response (pCR) rate, measured based on mandatory post-CRT biopsy of the primary site as well as dissection of involved LN levels, irrespective of imaging response. Remarkably, 86% of patients (37/43) had a pCR, and toxicities were decreased compared to historical controls.[174] In addition, 3-year LRC was 100%, and 3-year OS was 95%.[175] Given that a major critique of this trial was that confirmatory neck dissection could have been therapeutic, another single-arm phase II trial was initiated, testing the same de-escalation regimen of 60 Gy/6 weeks with concurrent weekly low-dose cisplatin, with a primary end point of 2-year PFS. One hundred and fourteen patients were enrolled, with excellent 2-year PFS of 86%.[176] NRG HN002 was a randomized phase II trial evaluating the efficacy of reduced-dose RT with weekly cisplatin versus accelerated reduced-dose RT without cisplatin (60 Gy/6 weeks with cisplatin vs 60 Gy/5 weeks, with 6 fractions per week RT alone) for patients with T1-2N1-N2b, or T3N0-N2b p16-positive OPC, per AJCC seventh edition staging, and a minimal smoking history (≤10 pack-years). In all, 306 patients were randomized, and the prespecified thresholds for the primary end points of 2-year PFS and swallowing function at 1 year were met by patients in the CRT arm, despite higher

associated rates of grade 3+ acute toxicity.[165] NRG HN005 was subsequently planned, randomizing a similar patient population with OPC to 70 Gy/6 weeks with bolus cisplatin versus 60 Gy/6 weeks with bolus cisplatin (winning arm of HN002) versus 60 Gy/5 weeks with concurrent nivolumab, again with co-primary end points of PFS and swallowing function. Based on the results of a scheduled interim futility analysis, experimental arm 2 (60 Gy with cisplatin) was closed due to not meeting the noninferiority threshold. Accrual to the other two arms is ongoing. Pending further randomized clinical trial data, it is not advisable to consider de-escalation of RT dose in the definitive setting for patients with p16-positive OPC unless they are enrolled in a clinical trial.

As discussed previously, minimally invasive surgical techniques such as TORS are being used increasingly for OPC. There is interest in the utilization of TORS specifically to facilitate deintensification of adjuvant RT dose. ECOG-ACRIN 3311 was a phase II study in which patients with stage III and IVa HPV-associated OPC underwent TORS followed by risk-adapted adjuvant therapy based on pathologic risk assessment. If patients met the following eligibility criteria, they were considered "intermediate risk" and randomized to 50 Gy versus 60 Gy of adjuvant RT without chemotherapy: close margins (<3 mm), N1-N2 with ≤1 mm ENE, up to four positive nodes. There were additional nonrandomized arms in the study: In the "low-risk" arm, patients with T1-T2 disease resected with negative margins (>3 mm) and N0-N1 disease without ENE were observed without further treatment. In the "high-risk" arm, patients with positive margins, >1 mm ENE, and/or >4 pathologically involved LNs received 66 Gy with concurrent weekly cisplatin (40 mg/m^2). The patients were additionally stratified based on a smoking history. The primary end point was 2-year PFS, and the investigators reported rates of 94.9% versus 96.0% for patients receiving reduced-dose (n = 100) versus standard-dose PORT (n = 108). An exploratory comparison indicated that PFS did not differ significantly between these arms, though the study was not powered for this comparison.[166] Notably, 31% of patients enrolled on this study required adjuvant CRT based on high-risk pathologic features, highlighting the importance of careful patient selection for TORS in order to avoid trimodality therapy. A phase III comparison of transoral surgery plus reduced-dose adjuvant RT versus definitive CRT for this patient population is planned.

MC1273 was a phase II trial that investigated aggressive adjuvant RT dose deintensification from 60 to 66 to 30 to 36 Gy for patients with HPV-associated OPC. Eligible patients had AJCC seventh edition stage III and IV disease and a smoking history of ≤10 pack-years. Patients had to undergo margin-clearing surgery and either a high-risk pathologic feature (ENE) or one or more intermediate-risk factors such as PNI, LVI, two or more positive LNs, ≥T3 primary tumor, or >3 cm LN. Patients without ENE received 30 Gy in 1.5 Gy fractions twice daily to the primary site and dissected and elective nodal volumes with concurrent docetaxel, while patients with ENE received an additional SIB of 36 Gy in 1.8 Gy fractions only to the nodal level with ENE. Eighty patients were enrolled, and LRF was 0% at 2 years post-treatment for patients without ENE versus 7% for patients with ENE.[177] A follow-up phase III study (NCT02908477) is underway.

While data are promising with several different approaches, therapeutic deintensification for patients with HPV-associated OPSCC remains experimental and should not be routinely considered off-trial pending results from randomized phase III trials.

POST-TREATMENT MANAGEMENT AND SURVEILLANCE

Following definitive therapy for OPC, patients should undergo routine clinical evaluation. Current guidelines recommend examination every 1 to 3 months for the first year post-therapy, every 2 to 6 months in the second year post-therapy, every 4 to 8 months in years 3 to 5 post-therapy, and annually thereafter. The frequency of follow-up within the first 2 years after completion of therapy coincides with the likelihood of recurrence within that interval. Given that a common side effect of RT to the neck is hypothyroidism, thyroid-stimulating hormone should be evaluated every 6 to 12 months in patients who have received RT to the bilateral neck. In addition, RT to the neck is associated with an increased risk of carotid artery stenosis and stroke; thus, routine carotid artery ultrasound screening for certain high-risk patients should be considered.[178,179] Speech/swallow and nutritional evaluation should be initiated or continued as clinically indicated, and smoking and alcohol consumption should be queried and addressed as needed as well.

Patients with node-positive and/or locoregionally advanced OPC should undergo imaging to assess treatment response 3 to 4 months after completion of treatment. A radiographic complete response on contrast-enhanced neck CT, defined as nonenhancing, nonnecrotic nodal tissue <1.5 cm, is associated with excellent long-term disease control in the neck, and no further therapy is needed.[180] Surveillance CT imaging of the primary site does not add additional information to physical/fiberoptic examination and should not be routinely performed.[181]

PET/CT is often the sole imaging modality utilized following the completion of RT or CRT. A prospective study by Porceddu et al helped to clarify the role of ^{18}F-FDG-PET–guided management following definitive RT/CRT for patients with node-positive HNSCC. Per the study protocol, 112 node-positive patients, based on pretreatment PET/CT (74% with OPC), underwent PET/CT approximately 12 weeks post-therapy. The results revealed that a negative PET scan at 12 weeks post-RT/CRT was associated with no isolated nodal progression, independent of the presence of residual CT abnormalities in the neck.[182] The negative predictive value (NPV) of PET was 98.1% (95% CI, 93.2%-99.8%) compared to 96.8% for CT (95% CI, 88.8%-99.6%). More importantly, however, false-positive readings were seen in only 1.8% of PET scans compared to 38% of diagnostic CT scans, resulting in a positive predictive value (PPV) of 77.8% for PET/CT and 14% for CT. When the analysis was restricted to p16-positive patients, the results were similar, with NPV of 98.2% (95% CI, 90.4%-100%) and PPV of 66.7% (95% CI, 9.4%-99.2%) for PET. Long-term follow-up of these patients demonstrated that PET-directed management resulted in >90% of patients being spared a neck dissection (previously standard of care), with only one patient experiencing a neck recurrence following initial metabolic resolution.[183] A randomized study has since been reported

comparing the utility of post-CRT PET/CT-based neck surveillance versus planned neck dissection in patients with N2 or N3 nodal disease. The trial accrued 564 patients (282 in each arm), 84% of whom had OPC with 75% of tumors tested being p16 positive. Patients assigned to the PET/CT-based neck surveillance arm had 2-year OS of 84.9% (95% CI, 80.7%-89.1%) compared to 81.5% (95% CI, 76.9%-86.3%) in the planned neck dissection group. Furthermore, there were no differences in 2-year LRC: 91.9% (95% CI, 88.5%-95.35) in the surveillance group and 91.4% (95% CI, 87.8%-95.0%) in the planned neck dissection group.[184] Finally, PET/CT-based surveillance was more cost-effective overall, with estimated savings of $2,190 per patient. This is an important consideration, given the substantial financial toxicity burden experienced by patients with OPC undergoing definitive treatment.[185] Given these data, PET/CT-guided management after definitive RT-based treatment should be the standard approach, with observation after a complete clinical response, repeat PET/CT in 4 to 6 weeks after equivocal findings, and consideration of salvage surgical resection if concern for residual FDG-avid disease. Notably, multiple prospective studies have determined that the presence of residual FDG activity can be difficult to interpret when PET/CT is obtained earlier than 12 weeks post-treatment, with treatment-related inflammation resulting in higher rates of false positivity. Therefore, careful timing of post-treatment imaging evaluation is paramount.[186] There is no clear evidence to support continued routine imaging surveillance in patients with a complete clinical response on post-treatment PET/CT; further imaging during the follow-up interval is prompted based on clinical concern and/or physical examination findings, as patients with clinically detected recurrence have been shown to have similar survival outcomes as patients with recurrences detected by subsequent surveillance imaging.[187]

Quantifying levels of plasma circulating tumor DNA (ctDNA), including circulating tumor HPV DNA (ctHPV DNA) for HPV-related disease, is a novel approach to sensitive detection of minimal residual disease and/or recurrences. Prospective studies have demonstrated high PPV and NPV for ctHPV DNA-based surveillance, with the potential for early identification of disease recurrence in patients with HPV-associated OPSCC.[188,189] While ctDNA-based surveillance is currently not standard of care, this is an area of active investigation.

TREATMENT OF RECURRENT AND METASTATIC OROPHARYNGEAL CANCER

Systemic Therapy for Recurrent and Metastatic Oropharyngeal Cancer

For many years, the standard systemic therapy for patients with recurrent or metastatic OPC was platinum-based chemotherapy. Single-agent cisplatin (100 mg/m2) has been shown to improve OS compared to best supportive care.[190] Cisplatin was also shown to be superior to single-agent methotrexate.[191] Multiple randomized studies investigated combination cisplatin-based regimens. The combination of cisplatin (100 mg/m^2) with 5-FU (1000 mg/m^2/d) demonstrated improved response rates (32% vs 17%), but not improved median survival (5.7 months) over cisplatin alone.[192] For OPC specifically, a

planned subset analysis of a phase III trial comparing cisplatin and pemetrexed to cisplatin and placebo demonstrated that patients receiving the combination regimen had improved OS (9.9 vs 6.1 months, $P = .002$) and improved PFS (4 vs 3.4 months $P = .047$).[193] The addition of EGFR inhibitors to platinum-based chemotherapy was shown in the phase III EXTREME study to improve OS (7.4 months with bolus cisplatin/5-FU or carboplatin/5-FU vs 10.1 months with the combination of platinum, 5-FU, and cetuximab); notably, a large proportion of enrolled patients had recurrent or metastatic OPC.[194] Immune checkpoint inhibitors have significantly altered the landscape for patients with recurrent and metastatic HNSCC. KEYNOTE-048 was a phase III study randomizing 882 patients with previously untreated recurrent or metastatic HNSCC (majority with OPC) to pembrolizumab alone, pembrolizumab plus chemotherapy (platinum and 5-FU), or cetuximab plus chemotherapy (per the EXTREME study). The study demonstrated improved OS with pembrolizumab plus chemotherapy versus the winning EXTREME arm (13 vs 10.7 months, $P = .003$), establishing this regimen as an appropriate first-line treatment for patients with recurrent or metastatic OPSCC. The results also supported the use of pembrolizumab monotherapy in the first-line setting for patients with PD-L1–positive tumors, based on an OS benefit in that subgroup when compared to the EXTREME arm.[195] The OS benefits of pembrolizumab with or without chemotherapy over cetuximab with chemotherapy notably persisted with long-term (4-year) follow-up.[196]

In the platinum-refractory setting, immune checkpoint inhibitors are also standard options for patients with recurrent and metastatic HNSCC. The CheckMate 141 study randomized 361 patients (35.5% with pharyngeal cancers) to nivolumab 3 mg/kg every 2 weeks or the investigator's choice of 40 to 60 mg/m^2 methotrexate, 30 to 40 mg/m^2 docetaxel, or 250 mg/m^2 weekly cetuximab after a loading dose of 400 mg/m2. Patients treated with nivolumab had significantly longer median survival (7.5 vs 5.1 months) and 1-year OS (36% vs 16.6%). In an exploratory analysis, p16-positive patients who received nivolumab had longer median survival as well (9.1 vs 4.4 months, HR 0.56, 95% CI: 0.32-0.99).[197] The phase III KEYNOTE-040 trial additionally randomized 495 patients with platinum-refractory recurrent or metastatic HNSCC to receive pembrolizumab or investigator's choice systemic therapy (methotrexate, docetaxel, or cetuximab) and demonstrated significantly improved OS in the pembrolizumab arm (8.4 vs 6.9 months, HR 0.80, $P = .016$). The results stratified based on tumor PD-L1 status revealed that the OS benefit is limited to patients with PD-L1–positive tumors.[198] Either nivolumab or pembrolizumab is thus first-line option for patients with platinum-refractory recurrent or metastatic OPC.

Reirradiation for Recurrent or Second Primary Disease

For the subgroup of patients with recurrent locoregionally confined OPC, surgical resection is recommended, although this is feasible only in a small proportion of patients.[199] Following surgery[200] in those with high-risk pathologic features or in those who are not surgical candidates,[201] a second course of full-dose CRT has been shown to result in long-term survival in approximately 20% of patients. Patients who are able to

undergo surgery prior to reirradiation and chemotherapy-naïve patients who are treated with more intensive regimens of CRT have improved outcomes. Due to the high risk of significant normal tissue toxicity (including up to a 15% risk of fatal carotid artery rupture), patients undergoing a second course of conventionally fractionated CRT should be managed at experienced centers.[202] It is unknown if a repeat course of conventionally fractionated CRT is superior to chemotherapy alone for these patients, as a phase III comparison of these modalities failed to accrue. The ongoing phase II ECOG-ACRIN 3191 study, randomizing patients with resected recurrent/second primary HNSCC with high-risk features to repeat conventionally fractionated CRT (60 Gy/30 fractions IMRT or PBT with weekly cisplatin or carboplatin) versus pembrolizumab alone will help to elucidate the benefit of local therapy in addition to modern systemic agents. This trial initially included a third arm of pembrolizumab with conventionally fractionated RT that was closed in 2023.

Stereotactic Body Radiotherapy

There are more robust data supporting the use of SBRT in the reirradiation setting of locoregionally recurrent disease than in the initial definitive treatment setting, though prospective data are still limited. This treatment approach is attractive because it entails a much shorter course compared to repeat full-dose CRT and the potential for less treatment-related toxicity. An early phase I dose escalation trial demonstrated no grade 3 or higher dose-limiting toxicities in 25 patients with previously irradiated HNSCC (24% with OPC) treated with doses up to 44 Gy/5 fractions over 2 weeks. The median time to disease progression was 4 months, and median OS was 6 months.[203] Two phase II trials[204,205] treated patients with recurrent or new primary HNSCC (most with OPC) in a previously irradiated area with SBRT (36-44 Gy/5-6 fractions over 1-2 weeks) and concurrent cetuximab. They reported low rates of grade 3 or higher acute and late toxicities, with a median OS of 10-12 months. Other trials are investigating the use of SBRT with concurrent immunotherapy[206] and/or other targeted agents in the treatment of patients with previously irradiated disease.[207] Reirradiation with SBRT is still overall associated with a relatively high risk of fatal carotid artery rupture. Factors associated with the risk of carotid artery rupture include ≥180 degrees of carotid invasion by tumor, as well as a high maximum carotid dose.[208] Overall, SBRT is a reasonable treatment option for patients with previously irradiated, recurrent OPC, but the decision to treat must be highly individualized, taking into account the location and extent of the recurrent tumor, the interval from the previous course of RT, as well as institutional expertise.

Proton Beam Therapy

As discussed previously, the unique dosimetry of PBT can result in decreased dose to normal tissues, with the Bragg peak allowing for steep dose gradients. There has thus been significant interest in utilizing PBT for reirradiation of HNSCC in an effort to reduce treatment-related toxicity. To date, only retrospective data on definitive PBT reirradiation exist, with high rates of LRC and OS, though again a significant risk of acute and late

grade 3 or higher toxicities, including grade 5 bleeding events.[209,210] An ongoing phase II trial (NCT03164460) is randomizing patients with unresectable previously irradiated recurrent or second primary HNSCC to treatment with SBRT or PBT, with a primary end point of toxicity.

Brachytherapy

Brachytherapy, the application of radioactive materials in close proximity to tumors, was primarily utilized in the pre-IMRT, preconcurrent CRT era as a means to deliver a tumoricidal dose to gross disease while minimizing dose to the mandible. The advent of improved RT planning and delivery techniques, in addition to the recognition that osteoradionecrosis secondary to brachytherapy is significantly underreported, has corresponded to a major decrease in the utilization of brachytherapy for OPC and the resultant limited availability of expertise. There are a few scenarios for which brachytherapy for OPC could be considered, namely, for recurrent disease or in other settings necessitating a highly conformal dose to a target with a very limited extent.[211]

CHAPTER 52

Hypopharynx

Matthew E. Witek, Jonathan P. Giurintano, Nitika Tripathi, and Paul M. Harari

Hypopharynx cancers are uncommon head and neck (H&N) malignancies with an annual incidence of approximately 3,000 cases per year comprising nearly 3% of all H&N cancers in the United States.[1] Hypopharynx cancer carries one of the poorest prognoses of all H&N subsites owing to patients often presenting with locally advanced disease as well as a high propensity for the development of distant metastases. Hypopharynx cancer is strongly associated with cigarette smoking, and patients diagnosed with this disease often carry significant medical comorbidities that can complicate the successful delivery of aggressive cancer therapy. Multidisciplinary management of patients with hypopharynx cancer requires the collaborative effort of H&N surgeons, radiation oncologists, medical oncologists, radiologists, pathologists, speech and swallow therapists, nutritionists, nurses, and social workers. Advances in surgical and radiation technology techniques have made organ and function preservation more amenable for selected patients with early-stage disease. Treatment of locally advanced disease has increasingly involved nonsurgical approaches with combined radiation and chemotherapy. However, laryngopharyngectomy with neck dissection and risk-adapted adjuvant therapy remains an established approach for motivated patients with very advanced disease. Notwithstanding improvements in radiotherapy (RT) and surgical techniques, new systemic agents, and supportive measures, overall survival remains poor. Future efforts to develop prognostic and predictive biomarkers to guide clinical decision-making and novel systemic agents to improve disease control are needed.

ANATOMY

The hypopharynx, sometimes referred to as the laryngopharynx, is contiguous superiorly with the oropharynx and inferiorly with the cervical esophagus (Figure 52.1). As general landmarks, the superior border of the hypopharynx is demarcated by the hyoid bone and the inferior border by the cricoid cartilage. With regard to cancer diagnosis and staging, there are three primary anatomic subsites within the hypopharynx: the bilateral pyriform sinuses, the postcricoid region, and the posterior pharyngeal wall.

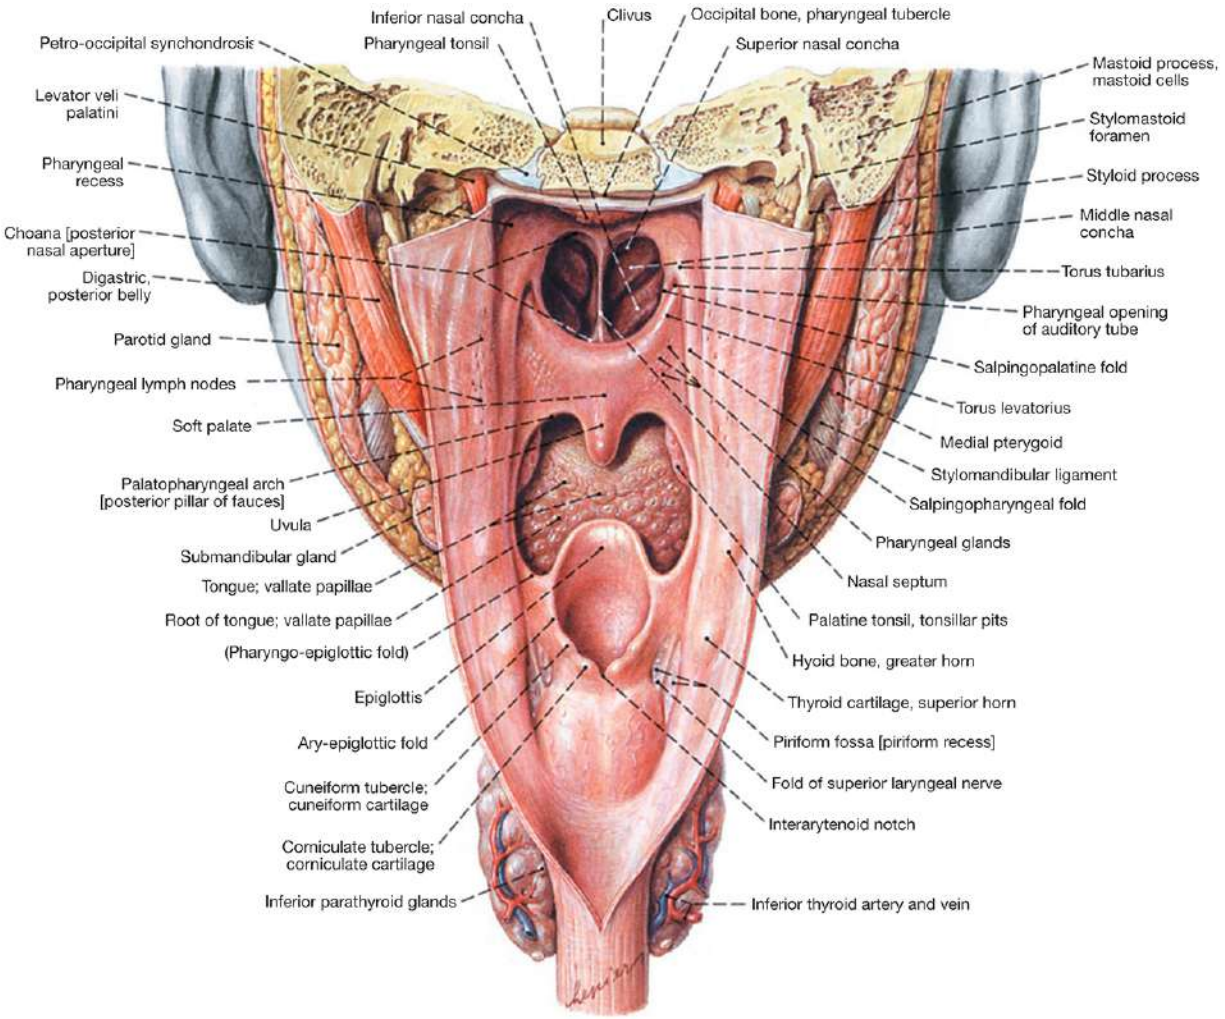

FIGURE 52.1 Posterior view of the hypopharynx shows the relationship of the pyriform sinus, pharyngeal wall, and postcricoid region within the head and neck. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figure 11.23. Copyright © 2023 Elsevier GmbH Munich. With permission.)

The pyriform sinuses are essentially inverted pyramids with the medial, lateral, and anterior walls narrowing inferiorly to form the apices. Posteriorly, the pyriform sinuses are open and contiguous with the pharyngeal walls. Superiorly, the sinuses are surrounded by the thyrohyoid membrane through which passes the internal branch of the superior laryngeal nerve. Tumor involvement of the sensory branches of this nerve can result in referred otalgia. The postcricoid region is composed of the mucosa overlying the cricoid cartilage, with the arytenoid and esophageal mucosa forming the superior and inferior borders, respectively. The posterior pharyngeal wall predominantly comprises the squamous mucosa covering the middle and inferior pharyngeal constrictor muscles and is separated from the prevertebral fascia by the retropharyngeal space. Typically, the mucosa lining the pharyngeal wall is <1 cm in thickness and provides a minimal barrier to direct tumor infiltration. The posterior pharyngeal wall is contiguous with the lateral wall of the pyriform sinus (Figure 52.2).

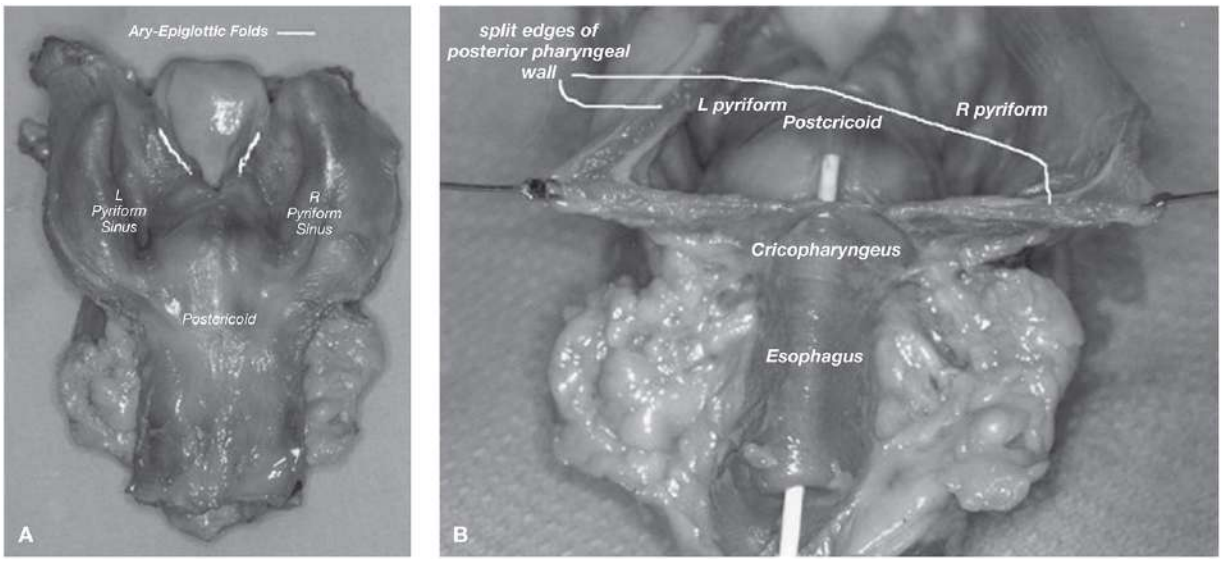

FIGURE 52.2 A. Posterior view of resected larynx and hypopharynx specimen afforded by incision through the posterior pharyngeal wall, cricopharyngeus, and cervical esophagus in the posterior midline. The aryepiglottic folds (marked) and arytenoids separate the pyriform sinuses (hypopharynx) from the larynx. B. The three primary anatomic subsites (posterior pharyngeal wall, postcricoid region, and pyriform sinuses) are revealed in this posterior view of the hypopharynx with the posterior pharyngeal wall incised.

Sensory innervation of the hypopharynx is provided by the internal branch of the superior laryngeal nerve as well as fibers deriving from the glossopharyngeal nerve. The recurrent laryngeal nerve and the pharyngeal plexus provide the primary motor supply. The arterial supply of the hypopharynx is derived primarily from branches of the external carotid artery: superior thyroid arteries, ascending pharyngeal arteries, and lingual arteries.

There is a rich network of lymphatics within the hypopharynx that drains directly through the thyrohyoid membrane and into the jugulodigastric lymph nodes, most commonly involving the subdigastric node. In addition, there may be direct drainage into the spinal accessory nodes. Tumors involving the posterior pharyngeal wall can also drain to the retropharyngeal nodes, including the most cephalad retropharyngeal nodes of Rouvière.

EPIDEMIOLOGY AND ETIOLOGY

Hypopharynx cancers are relatively uncommon. In the United States, the annual incidence is approximately 3,000 cases per year, accounting for nearly 7% of the upper aerodigestive tract.[2] Approximately three-fourths of hypopharyngeal cancers occur in men, with a mean age of 62 years.[3] Over 90% of patients with hypopharynx cancer report past cigarette use.[4] Alcohol appears to potentiate the carcinogenic effects of tobacco. In addition, alcohol consumption at medium to high levels for a long period of time can increase the likelihood of hypopharynx cancer in nonsmoking patients.[5] The index hypopharynx cancer often occurs within a field of diseased mucosa characterized by high-grade dysplasia. This “field cancerization” reflects widespread mucosal exposure to carcinogens and is responsible for the high rate of synchronous and metachronous primary tumors identified in patients with hypopharynx cancer. Successful counseling with particular emphasis on smoking cessation can enhance treatment tolerance and diminish the risk of developing subsequent cancers of the upper aerodigestive tract. Patients with occupational exposure to coal dust, steel dust, iron compounds, and fumes have also shown an increased risk for developing hypopharynx cancer.[6,7] Overall, the incidence of hypopharynx cancer has shown some gradual decline in the United States. From 1975 to 2001, the incidence

decreased by approximately 35%, perhaps as a result of smoking cessation efforts.[8] Human papillomavirus (HPV) infection is well established as a risk factor for the development of squamous cell carcinoma (SCC) of the gynecologic tract, particularly the uterine cervix. The relation between HPV and H&N cancer is now becoming much better appreciated, particularly for cancers of the oropharynx, where it may approach 60% to 70% in some series. Studies have demonstrated that approximately 20% to 25% of patients with hypopharynx cancer test positive for HPV DNA,[9,10] and seropositivity for antibodies against the HPV-16 E6 and E7 antibodies has been associated with a significantly elevated risk of hypopharyngeal cancer. The clinical implications of the presence of HPV in hypopharynx cancer are yet to be defined.

There is a recognized increased risk of developing cancers of the postcricoid region for patients with Plummer-Vinson syndrome, characterized by iron deficiency anemia, hypopharyngeal webs, weight loss, and dysphagia.[11] Favorable changes in the epidemiology of hypopharynx cancer have resulted from changes in nutrition. The addition of iron to flour has made Plummer-Vinson syndrome quite rare in the upper Midwestern United States and Scandinavian countries where it was formerly more common. An associated decrease in hypopharynx cancer involving the postcricoid region has followed.

PROGNOSTIC FACTORS

Several prognostic factors have been identified for patients with hypopharynx cancer. Age, particularly older than 70 years, has been identified as an unfavorable predictor of outcome.[11] This may simply reflect the diminished likelihood of older patients to successfully tolerate the aggressive therapy approaches required for locoregionally advanced cancers of the H&N. Women have been found to achieve somewhat improved outcomes compared to men, although this may in part be a manifestation of earlier stage disease at diagnosis.[12,13] In addition, tumor location has an impact on outcome, with cancers of the pyriform sinus generally faring better than those arising in the postcricoid or posterior pharyngeal wall regions.[12,13] As a whole, patients with hypopharynx cancer fare poorly in comparison with patients harboring tumors from other H&N sites (Figures

52.3 and 52.4).[14] To a lesser extent, tobacco, alcohol, medical comorbidities, and dietary factors may also have an impact on outcome.[15,16]

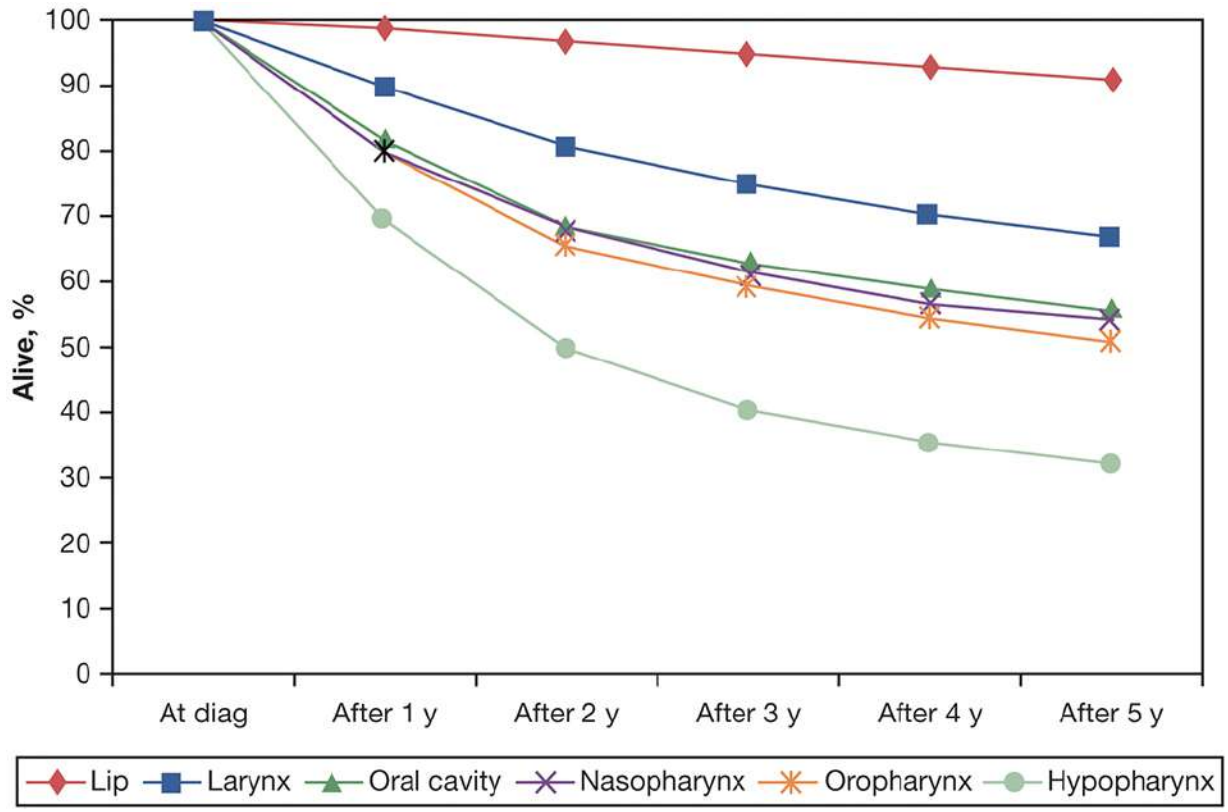

FIGURE 52.3 Five-year survival by mucosal site for head and neck cancers from 1990 to 1999 cases. (From Cooper JS, Porter K, Mallin K, et al. Staging according to the sixth edition of the *AJCC Cancer Staging Handbook*. (From National Cancer Data Base. Commission on cancer. American College of Surgeons. National Cancer Database [NCDB] survival reports. Accessed April 17, 2017. https://m.facs.org/NCDB.SurvivalDS/app/index.html?guid=8989f6dc-9809-4603-8571-7b63548ee64e, with permission from the National Cancer Data Base.)

Biologic factors have been investigated for their potential role in hypopharyngeal cancer. The presence of p53 gene mutations has been associated with bulkier tumors and younger patients along with higher expression of the epidermal growth factor receptor (EGFR). However, p53 has not shown correlation with multiple primary tumors, tumor grade, or DNA ploidy.[17,18] Further, there are conflicting data regarding the prognostic significance of EGFR expression for patients with hypopharyngeal cancer.[19] Some studies suggest EGFR overexpression portends a worse prognosis for patients undergoing (chemo)radiotherapy, but not for patients treated with primary surgical resection.[20,21]

STAGING

The primary staging system for hypopharynx cancer is the American Joint Committee on Cancer's (AJCC) 2016 eighth edition of the *AJCC Cancer Staging Handbook* and is based on a combination of clinical and radiographic data (Table 52.1).[22] There were no significant changes made between the seventh and eighth editions regarding primary tumor criteria (T-stage) and clinical stage groupings. However, in the eighth edition, the nodal group staging now incorporates extranodal extension (ENE), which constitutes N3b disease, regardless of nodal size or laterality. There were no changes to hypopharynx cancer made in the AJCC ninth edition. Although AJCC staging is a very useful tool to broadly group similar cancer types, it should not be used as a blueprint for management. Patient factors, including age, comorbid medical conditions, and motivation for organ preservation, are beyond the scope of the staging system but nevertheless represent important factors for consideration with each individual patient.

TABLE 52.1 AMERICAN JOINT COMMITTEE ON CANCER 2010 T STAGING FOR HYPOPHARYNX CANCER

T Stage	Description
T1	Limited to 1 subsite of the hypopharynx and ≤2 cm in greatest dimension
T2	Tumor invades more than 1 subsite of the hypopharynx or an adjacent site, or measures >2 cm but ≤4 cm in greatest diameter without fixation of hemilarynx
T3	Tumor measures >4 cm in greatest dimension or with fixation of hemilarynx or with extension to the esophagus
T4a	Invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue, which includes prelaryngeal strap muscles and subcutaneous fat
T4b	Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures

PATTERNS OF SPREAD

Local Extension

It is sometimes difficult to definitively assign tumor origin to a specific subsite in the hypopharynx when the tumor overlaps more than one subsite. Of the hypopharynx cancer cases recorded in the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database between 2000 and 2008, 83% of tumors with a known subsite arose in the pyriform sinus. An additional 9% arose from the posterior pharyngeal wall, and 4% originated in the postcricoid region.[5] Because of the high propensity for advanced primary disease as well as regional nodal involvement, the majority of patients with hypopharynx cancer present with stages III and IV disease. In a retrospective study from Washington University, 87% of patients with cancers of the pyriform sinus and 82% of patients with posterior pharyngeal wall tumors presented with stage III or IV disease.[23]

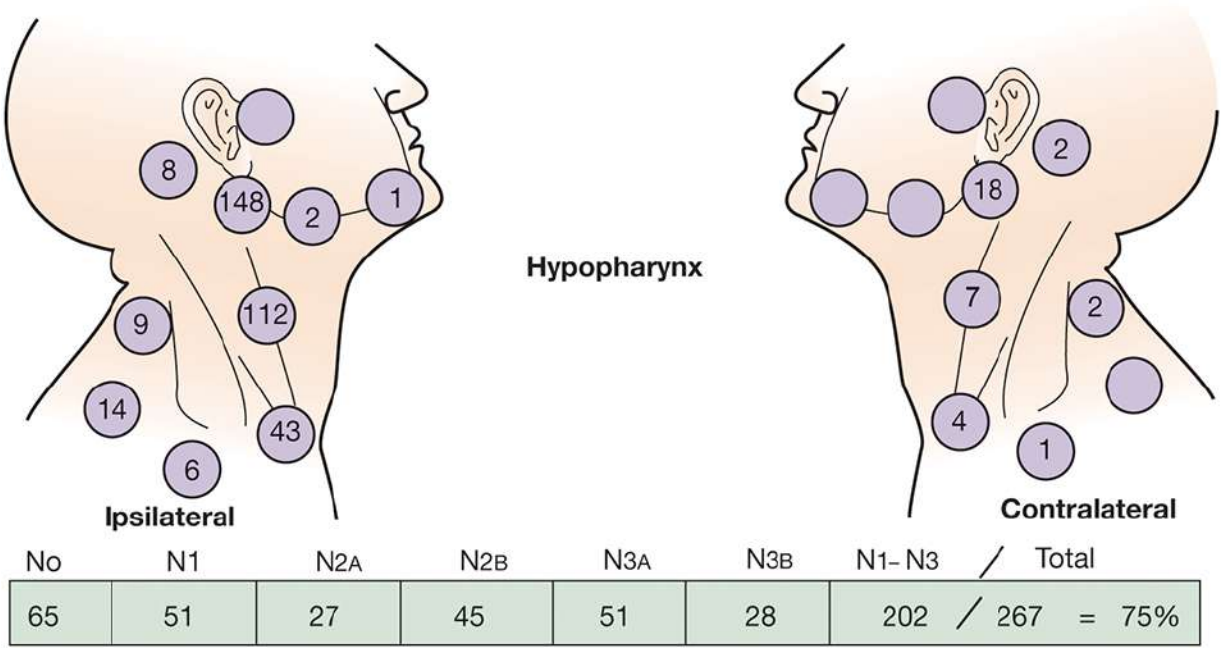
Cancers arising from the pyriform sinus may spread superiorly to involve the aryepiglottic folds and arytenoids and invade the paraglottic and preepiglottic space. Lateral tumor extension can involve portions of the thyroid cartilage, allowing entry into the lateral compartment of the neck. High-resolution computed tomography (CT) or magnetic resonance imaging (MRI) is often useful for optimal assessment regarding the extent of tumor invasion. For tumors arising from the medial wall, the most common site of involvement for pyriform sinus tumors, there is a likelihood of tumor involvement of intrinsic muscles of the larynx, resulting in vocal cord fixation. Inferior tumor extension beyond the apex can involve the thyroid gland.

Cancers arising within the postcricoid region can extend circumferentially to involve the cricoid cartilage or anteriorly to involve the larynx with resultant vocal cord fixation. Tumor involvement of the recurrent laryngeal nerve can also precipitate vocal cord fixation. Primary postcricoid tumors are often quite extensive and can involve the pyriform sinus, trachea, or esophagus. As a result, these tumors generally carry a worse prognosis in comparison to tumors from other subsites of the hypopharynx.[13] Nodal spread to the paratracheal nodes and inferior deep cervical nodes is not uncommon. Tumors arising from the posterior pharyngeal wall can extend to involve the oropharynx superiorly, the cervical esophagus inferiorly, and the prevertebral fascia and retropharyngeal space posteriorly.

Many cancers of the hypopharynx have a propensity for submucosal spread. It can, therefore, be difficult to accurately quantify the full microscopic extent of disease. This is particularly true for cancers of the posterior pharyngeal wall and postcricoid regions. Careful study through serial sectioning of surgical specimens has identified that 60% of hypopharynx cancers demonstrate subclinical spread with a range of 10 mm superiorly, 25 mm medially, 20 mm laterally, and 20 mm inferiorly.[24] This extensive pattern of tumor infiltration can present considerable challenge in the effort to achieve clear surgical margins or full dosimetric coverage with RT.

Regional Disease

Because of the rich lymphatic drainage of the hypopharynx, more than 50% of patients will manifest clinically positive cervical lymph nodes at the time of diagnosis, and ultimately, 65% to 80% of patients will have nodal involvement, as 30% to 40% of N0 necks harbor micrometastatic disease when electively dissected.[25] Jugular chain nodes, levels II to IV, as well as retropharyngeal nodes are all at high risk of harboring regional metastases in patients with hypopharynx cancer. Postcricoid tumors may also spread directly to pre- and paratracheal nodal basins. In light of cross-draining lymphatics, there is a significant risk of bilateral cervical node metastasis (Figure 52.5).[26,27]



No	N1	N2A	N2B	N3A	N3B	N1–N3 / Total
65	51	27	45	51	28	202 / 267 = 75%

FIGURE 52.5 Nodal distribution patterns for a series of 267 patients with hypopharynx cancer as summarized by admission records at the MD Anderson Cancer Center. (From Lindberg R. Distribution of cervical lymph node metastases from squamous cell carcinoma of the upper respiratory and digestive tracts. *Cancer*. 1972;29[6]:1446-1449. Copyright © 1972 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.)

Distant Metastases

The most common site for distant metastasis to develop in patients with cancer of the hypopharynx is the lung. Previously, approximately one-quarter of patients diagnosed with hypopharynx cancer presented with distant metastases, although this incidence in more recent reports is estimated at approximately 16%.[28] For those patients not rendered free of locoregional disease following initial therapy, the incidence of distant metastases increases notably with the length of time following initial treatment.[29,30]

Field Cancerization

Carcinogens can induce dysplastic changes throughout the mucosa of the upper aerodigestive tract, leading to an increased risk for field cancerization that enhances the likelihood of synchronous or metachronous secondary primary tumors. Approximately 7% of patients with hypopharynx cancer will manifest a second primary tumor at initial diagnosis, and between 10%

and 20% will develop a secondary primary tumor over time. In fact, this second tumor risk is a significant cause of mortality in patients who survive more than 2 years following initial treatment.[4]

CLINICAL PRESENTATION

In light of the nonspecific nature of early symptoms, the majority of patients with cancers of the hypopharynx present with advanced local or regional disease. Frequently, there is a delay between presentation and diagnosis as patients are often managed for presumed infectious or gastrointestinal etiology. The majority of symptoms are related to local tumor spread, including dysphagia and odynophagia. There may be frank pharyngeal obstruction, invasion of constrictor muscles, prevertebral space invasion, or strap muscle invasion. Common presenting signs and symptoms include dysphagia, sore throat, hoarseness, weight loss >10 pounds, and neck mass. The majority of patients present with more than one of these signs and symptoms.[31] Roughly, 25% of patients will present with clinical stage III disease and 50% with clinical stage IV disease; however, reflux symptoms can be a common presentation leading to diagnosis of stage I or II hypopharyngeal tumors.[4] Selected patients may first come to medical attention with complaints of unilateral ear pain (referred to as otalgia) due to tumor involvement of the visceral sensory nerves of the pharynx.

Pretreatment Evaluation and Staging Workup

A comprehensive workup for patients with cancers of the hypopharynx should include a detailed history focusing on the duration of symptoms, amount of weight loss, the presence of otalgia, changes in voice quality, and degree of dysphagia. A previous history of another upper aerodigestive tract malignancy and a history of tobacco smoking are commonly associated. The physical examination should include direct and indirect visualization of the full laryngopharyngeal axis with particular attention to the size, location, and anatomic positioning of the primary tumor as well as the mobility status of the true vocal cords. Dentition and oral health should be assessed. If the patient presents with cervical adenopathy, the size, number, location, texture, and mobility of these nodes should be documented.

Although cervical adenopathy associated with hypopharynx cancer may be analyzed with fine-needle aspiration (FNA) biopsy, there is little value in this approach, because most patients will receive advanced radiographic imaging to further define the nodal involvement. On rare occasions, FNA may be useful to help distinguish other coexisting causes of lymphadenopathy, such as lymphoma. Most patients will undergo a direct laryngoscopy under general anesthesia in conjunction with esophagoscopy. This panendoscopy allows not only biopsy confirmation of the primary tumor site but also mapping of the extent of the tumor as well as the ability to survey for synchronous primary tumors (Figure 52.6A). The use of transnasal fiberoptic techniques makes it possible for a panendoscopy to be done for selected patients without anesthesia in the clinic setting.

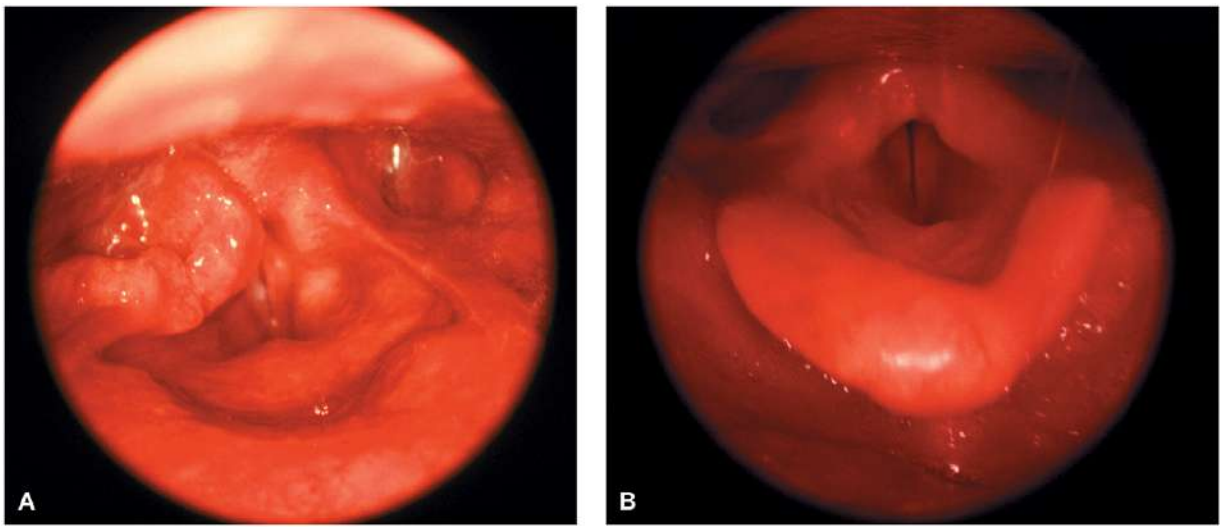


FIGURE 52.6 A. Outpatient clinic photograph taken through a rigid endoscope mounted with a 35-mm camera of a newly diagnosed exophytic T2 tumor arising from the right pyriform sinus with involvement of the adjacent aryepiglottic fold. There was no compromise of vocal cord mobility, and clinical staging of the primary lesion was T2. B. Photographic examination 1 year following 70-Gy radiation and concurrent cisplatin chemotherapy with complete tumor regression and excellent functional status of the laryngopharynx. Note mild-to-moderate mucosal edema of supraglottic structures following high-dose radiation.

In addition to panendoscopy, patients should undergo either high-resolution CT with contrast or MRI extending from the skull base to below the clavicle to help assess the extent of the primary tumor and to quantitatively and qualitatively assess cervical adenopathy (Figures 52.7

and 52.8).[27] Although a chest x-ray has traditionally been used to assess for the presence of pulmonary metastasis, 18-fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) imaging (with accompanying CT for co-registration) is increasingly used to assess the extent of regional adenopathy and to survey for the presence of distant metastasis. FDG-PET is a valuable adjunct to CT or MRI in the radiation treatment planning process, particularly for patients treated with conformal intensity-modulated radiation therapy (IMRT), volumetric modulated arc therapy (VMAT), or tomotherapy techniques. Di Martino et al[31] compared CT, PET, color-coded duplex sonography, palpation, and panendoscopy in assessment of tumor and nodal status. Schwartz et al[32] examined the standardized uptake value (SUV) of primary and nodal metastasis in patients with H&N cancer and their relationship to clinical outcome. A primary tumor SUV >9.0 was associated with a significantly lower local recurrence-free survival and disease-free survival. However, there was no correlation between nodal SUV and clinical outcome.

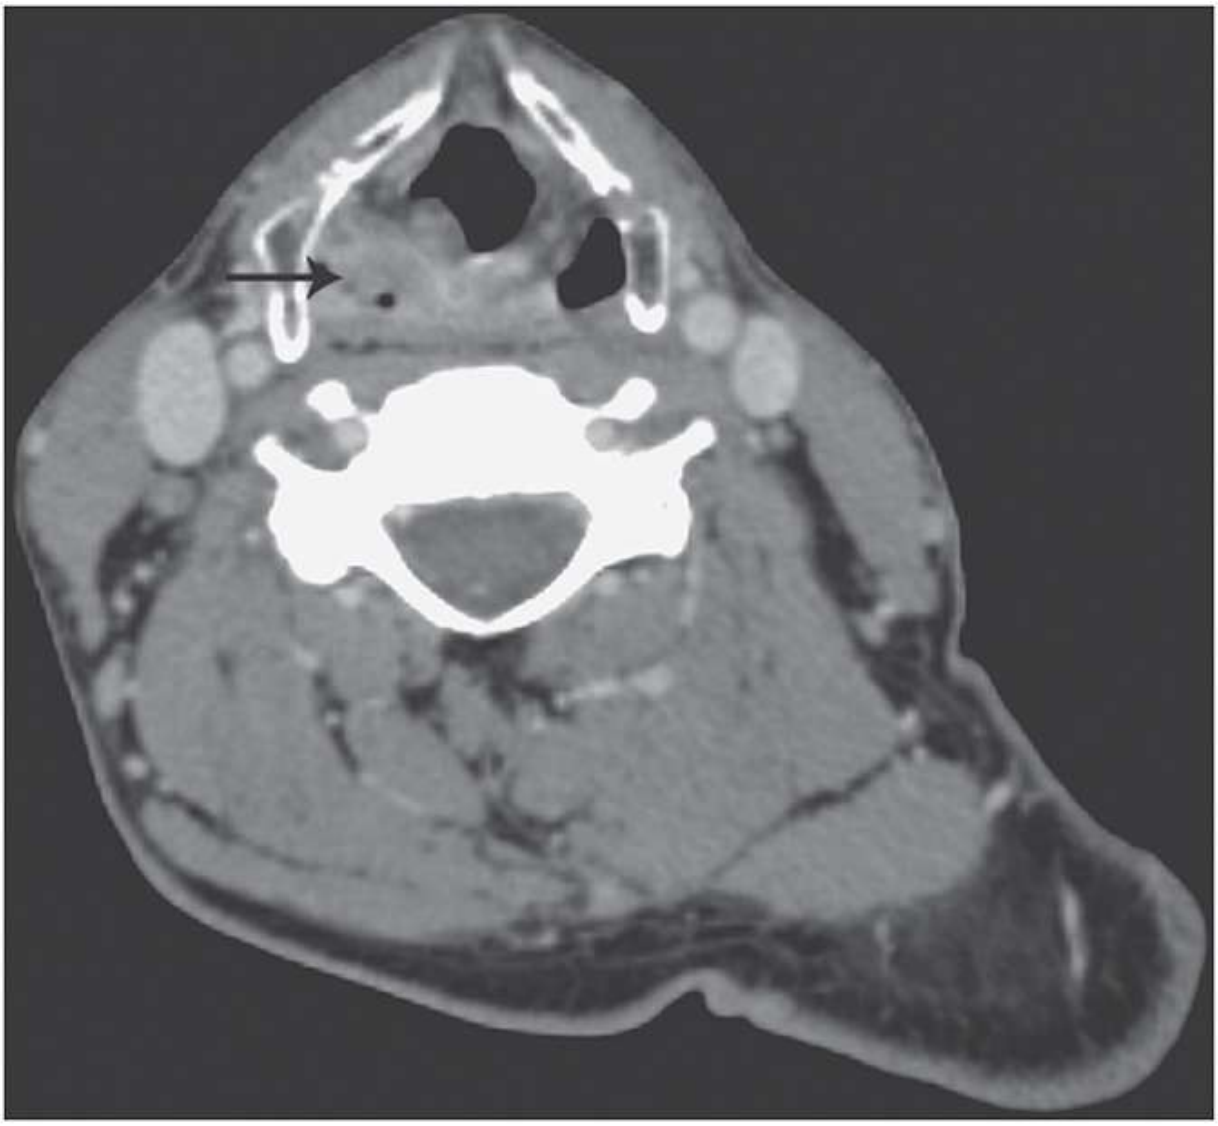

FIGURE 52.7 Axial computed tomography image from the same case as in Figure 52.6 depicting the T2 hypopharynx tumor involving the right pyriform sinus.

FIGURE 52.8 Axial gadolinium-enhanced T1-weighted magnetic resonance image scan with fat saturation depicting metastatic lateral retropharyngeal node with evidence of central necrosis and peripheral enhancement.

A recent prospective multicenter study of 233 patients with H&N SCC (including 46 hypopharyngeal cancers) highlighted the potential impact of PET imaging on H&N SCC management.[33] TNM staging and therapeutic decisions were first determined based on conventional workup and then physicians were unblinded to FDG-PET data and asked to restage the patients and reanalyze their therapeutic decisions. PET and conventional

workup revealed discordant TNM staging in 100 (43%) patients. PET was deemed significantly more accurate than conventional staging and improved the staging in 20% of patients. Incorporation of PET data ultimately impacted management in 32 (13.7%) patients (Table 52.2), supporting the use of FDG-PET in H&N SCC staging.

TABLE 52.2 IMPACT OF FDG-PET ON STAGING AND MANAGEMENT FOLLOWING CONVENTIONAL WORKUP

End Point	Impact of FDG-PET on 233 Patients
Discordant TNM stage	100 (43%)
PET accurately upstaged	30 (13%)
PET accurately downstaged	17 (7.3%)
PET inaccurately changed stage	13 (5.6%)
No confirmed gold standard TNM	40 (17%)
Impact on Patient Management[a]	
Low	188 (80.7%)
Medium	12 (5.2%)
High	20 (8.6%)

FDG, fluorodeoxyglucose; PET, positron emission tomography; TNM, tumor-node-metastasis classification.

[a]Impact ratings: low, treatment modality and delivery unchanged; medium, change within the same treatment modality (planned procedure, dose, or mode of administration changed); high, change in treatment intent or treatment modality (eg, curative to palliation, surgery to chemoradiation).

Derived from Lonneux M, Hamoir M, Reychler H, et al. Positron emission tomography with [18F]fluorodeoxyglucose improves staging and patient management in patients with head and neck squamous cell carcinoma: a multicenter prospective study. *J Clin Oncol*. 2010;28(7):1190-1195.

Many patients with hypopharynx cancer present with concurrent medical and social comorbidities that require consideration before initiating cancer-directed therapy. Commonly, there is a progressive history of dysphagia and odynophagia with associated weight loss. Whether these patients are treated with surgical or nonsurgical approaches, a gastrostomy tube may need to be considered as a temporary measure. It is important to optimize or at least stabilize the patient's nutritional status prior to initiating definitive therapy.

It is valuable for patients with hypopharynx cancer to undergo evaluation by a speech and swallow therapist to determine the degree of dysfunction prior to therapy. This may be done as a bedside study of swallowing capacity, a fiberoptic endoscopic evaluation of swallowing, or (usually preferably) through the more definitive fluoroscopic barium swallow study. This modified barium swallow study is called a cookie swallow, video pharyngogram, or oropharyngeal motility study and is most commonly done with a speech pathologist in attendance. If objective swallowing dysfunction is present, patients may be taught adaptive techniques to improve the effectiveness and safety of their oral intake. In addition, close follow-up with the same speech and swallow therapist is highly desirable during and after therapy to maximize the patient's long-term functional capabilities.

Because many patients with hypopharynx cancer have an active history of alcohol and tobacco use, it is important to counsel accordingly and encourage all patients to take advantage of methods and programs to facilitate smoking and alcohol cessation. All patients should undergo comprehensive dental evaluation and cleaning as well as basic education regarding oral hygiene. For patients treated with conventional RT techniques, there is a significant likelihood of long-term xerostomia that can promote dental decay. If existing dentition is in poor condition, dental extractions should be considered prior to therapy, particularly for teeth that will reside within the high-dose radiation region. Typically, 10 to 14 days are required following dental extractions to allow for healing prior to the initiation of RT. Custom fluoride carrier trays should be fabricated and discussed for long-term use in an effort to diminish the rate of dental decay for patients with chronic xerostomia.

Finally, many patients with hypopharynx cancer will have social issues, including lack of family support, financial limitations, transportation issues, poor nutrition, and hygiene habits that may hamper their ability to successfully receive adequate care. Often, the involvement of a case manager or social worker is of central importance to assist patients who require support both during and following cancer therapy.

PATHOLOGIC CLASSIFICATION

In SEER data from 2000 to 2008, 93.9% of hypopharynx cancers were SCC, with lymphoma, sarcoma, adenocarcinoma, and adenoid cystic carcinoma each accounting for approximately 0.5% of cases.[5] Similarly, the National Cancer Database (NCDB) Benchmark Reports evaluated 17,654 cases of hypopharyngeal cancer in the United States between the years 2000 and 2008. Over 90% of cases were SCC.[34]

Management

For patients presenting with early-stage, resectable disease, voice-preserving surgery and definitive RT alone are viable and acceptable treatment options. The vast majority of patients, however, present with stage III or IV disease and warrant multimodality treatment. Prior SEER database revealed a gradual trend away from primary surgery and toward definitive radiation without a decrement in overall survival.[35] These data suggested that primary radiation exhibited improved survival compared to surgery alone, but that combined surgery with radiation offered a survival benefit over either single modality. The use of chemotherapy in this study was unknown. Further, radiation was recorded as either received or did not receive with no mention of radiation dose raising the possibility that patients received palliative rather than curative-intent radiation doses. An updated SEER database analysis using data from 2004 to 2015 comparing more modern approaches of hypopharynx management suggested improved overall survival with surgery and adjuvant chemoradiation therapy versus chemoradiation.[3] Despite sophisticated statistical analyses, similar limitations still exist. For example, radiation dose is not specified and disease characteristics between treatment cohorts were different. Fifteen percent of patients in the chemoradiation arm had overall stage IVB disease, often uncurable, while the surgical arm included only 6%. Conversely, patients undergoing surgery were more likely to have cT4 disease compared to those receiving upfront chemoradiation. Recent results from the analysis of NCDB are similar to those proposed in the SEER analyses. After careful statistical modeling, surgery and adjuvant therapy were superior in survival compared to upfront chemoradiotherapy. However, despite less favorable disease characteristics in the surgical arm, patient selection bias has to be considered as only 12% (n = 706 of 6,055)

of patients included in the study underwent surgery.[36] Though nonrandomized, these studies provide real-world survival data estimating the overall survival risk for patients motivated to pursue the preservation of native laryngopharyngeal function through definitive chemoradiation therapy (Table 52.3).

TABLE 52.3 GENERAL TREATMENT RECOMMENDATIONS BASED ON HYPOPHARYNX TUMOR STAGE

Stage I	Radiation alone or voice preservation surgery if feasible
Stage II	Radiation alone
Stages III and IV with functional laryngopharynx	Concurrent chemoradiation followed by selective neck dissection
Stages III and IV with dysfunctional laryngopharynx[a]	Laryngopharyngectomy with adjuvant RT or CRT

CRT, chemoradiation therapy; RT, radiation therapy.

[a]Patients with bulky, destructive tumors that severely compromise the airway or destroy cartilage, bone, and deep soft tissue are often best served with immediate laryngopharyngectomy and postoperative radiation or chemoradiation.

Primary Surgery

T1 and T2 Tumors

Contemporary indications for primary surgical management of patients with early cancers of the hypopharynx include those with a history of previous H&N radiation, those in whom organ conservation approaches are deemed possible, and those who refuse radiation. Even for patients with hypopharynx cancer who will receive nonoperative treatment approaches, it remains critical for the H&N surgeon to remain actively involved. The role of the surgeon in these cases may include endoscopic biopsy with detailed assessment of tumor extent, methods to secure the airway (tracheotomy or laser debulking), and methods to ensure adequate nutrition (gastrostomy). The surgeon will also play a vital role in multidisciplinary oncologic follow-up after nonoperative treatment.

Selected T1 and T2 hypopharynx cancers may lend themselves to surgical excision. These favorable subsites include the upper pyriform sinus

and the posterior pharyngeal wall. Traditional conservation surgery for early-stage hypopharyngeal cancers consisted of an open supraglottic partial laryngectomy encompassing the aryepiglottic fold, extending the field of resection to include part of the arytenoids, the base of the tongue, and the upper pyriform sinus if necessary. With the advent of fiberoptic lasers, small cancers isolated to the posterior pharyngeal wall may be removed by endoscopic laser resection, utilizing a microscope-mounted laser delivery system or laser handpieces to precisely incise the mucosa and coagulate small vessels. Whereas minimally invasive endoscopic approaches often allow for early swallowing, if an open approach is employed, then dysphagia requiring nothing by mouth status is common in the postoperative period and temporary tracheotomy placement may be necessary, especially if reconstruction of the posterior wall is affected with an adynamic and insensate free flap. Relative contraindications to organ conservation surgery for hypopharynx cancers include cartilage invasion, vocal fold fixation (involvement of the paraglottic space), involvement of preepiglottic space, postcricoid invasion, deep pyriform sinus invasion, and extension beyond the larynx.

Innovations with free flap reconstruction have allowed retention of speech, swallowing, and breathing functions of the larynx despite extensive resection by way of a hemilaryngopharyngectomy. The temporoparietal flap and radial forearm free flap coupled with rigid cartilaginous support have been employed to retain function in patients with hypopharynx cancers without extension to the postcricoid region or apex of the pyriform sinus.[37]

In recent years, advancements in organ preservation surgery have included the use of transoral laser microsurgery (TLM) and transoral robotic surgery (TORS). For selected cases, these approaches can achieve oncologic tumor removal while limiting normal tissue disruption, thereby potentially avoiding tracheostomy and the use of feeding tubes.[38-41] This approach may involve concurrent or delayed neck dissection following transoral resection of the primary lesion (to allow for final margin assessment). The necks in some T1N0 patients may be observed with close interval follow-up CT scans. Adjuvant (chemo)radiotherapy is utilized in the majority of patients using this approach (see section “Postoperative Radiotherapy” for indications) and should generally encompass the primary tumor site as well as bilateral necks and supraclavicular fossae. Recent

results have demonstrated that appropriately selected T1 or T2 lesions can achieve negative margins by TLM or TORS.[39] Oncologic outcomes appear similar to open surgical approaches using this technique and are likely accompanied by lower rates of permanent gastrostomy tube or tracheostomy placement (Table 52.4).

TABLE 52.4 FIVE-YEAR ONCOLOGIC OUTCOMES FOR TRANSORAL MICROLASER SURGERY FOR T1 OR T2 HYPOPHARYNGEAL TUMORS

Study (Reference)	T-Stage	N	Node (+) (%)	LC (%)	DSS (%)	OS (%)	Permanent Gastrostomies (%)	Permanent Tracheostomies (%)
Martin et al[40]	pT1	20	62	84	NR	68 (stages I-II)	3.5[a]	3.5[a]
	pT2	48		70	NR

[a]Entire cohort, including T3 and T4 patients.

TORS is currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of benign and malignant tumors classified as T1 and T2, as well as benign base of tongue resection procedures. Compared to TLM, which relies on visualization of the hypopharynx with a microscope or endoscope aimed through specialized laryngoscopes, TORS has the advantage of better visualization with a three-dimensional magnified camera, the option to utilized angled endoscopes, and manipulation using "wristed" instruments, which provide the means to resect tumor en bloc. There currently exist three iterations of the da Vinci (Intuitive Surgical Inc, Sunnyvale, CA, USA) surgical robot: two multiport (MP) models, the Si and Xi, and the single port (SP) model. Whereas the MP models offered a rigid 0- or 30-degree endoscope to be used with either two or three rigid working arms, the SP robotic system employs a flexible endoscope and working arms, which are deployed through an SP. Addressing the

limitations of the MP models, including the rigid orientation of the ports and large instrument size, the SP model was developed to increase maneuverability in narrow, hard-to-access spaces (such as the hypopharynx), allowing for improved visualization in the piriform sinuses and postcricoid region and more facile use of instrumentation.[42] Traditionally, dissection is performed with a grasping instrument and monopolar cautery; however, flexible fiberoptic CO_2 laser delivery may also be utilized via the robotic instrument cart.[43] These instruments provide the means to achieve oncologic tumor removal while limiting tissue disruption, thereby avoiding tracheostomy and feeding tubes in many cases. Neck dissection can be done concurrently or in a staged manner; when neck dissection is performed, the ipsilateral superior thyroid artery is routinely ligated as it exits the external carotid artery so as to inhibit blood flow through the superior laryngeal artery, which reliably arises from the posterior aspect of the pharyngoepiglottic fold origin.[42,44]

Early studies demonstrate oncologic outcomes similar to open approaches, and a more recent study suggests that TORS may improve survival for selected patients compared to TLM and primary radiation for T1 and T2 tumors of the hypopharynx.[45,46] Finegersh et al showed that TORS hypopharyngectomy was shown to have a significantly decreased rate of positive margins compared to TLM (13% compared to 32%), and numerous studies have shown that patients undergoing TORS experience reduced postoperative morbidity and quicker recovery compared to open conservation surgery.[46-48] Existing literature supports the efficacy and safety of TORS in treating early-stage hypopharyngeal cancer and continues to demonstrate the ability to achieve negative margins in the hypopharynx for select T1 and T2 lesions, preserving the larynx and, in some cases, avoiding tracheostomy. The majority of patients in these recent series have functional swallow and voice outcomes as well.[49,50]

While TORS represents an excellent treatment option, there do exist limitations and contraindications to its use in early-stage hypopharyngeal cancers. The main limitations in TORS are determining whether the tumor is safely resectable and the ability to gain adequate exposure to visualize the extent of the tumor. Certain anatomic features, including trismus, the presence of mandibular tori, retrognathia, and a severely acute angle of the

mandibular parasymphysis, may limit transoral exposure of the hypopharynx, even with the SP robot. Contraindications to TORS include retropharyngeal course of the carotid artery, invasion of the pyriform sinus apex, vocal fold fixation, and invasion of the thyroid cartilage inner perichondrium.[42] As the technology evolves and surgeons build experience with these procedures, additional data will emerge to describe long-term outcome results for patients with early-stage hypopharyngeal cancers.[51]

T3 or T4 Resectable Tumors

Favorable T3 hypopharynx cancers that present in the upper aspect of the pyriform sinus and allow full extirpation by either an extended supraglottic laryngectomy or extended vertical partial laryngopharyngectomy with free flap reconstruction are infrequent. However, most T3 and T4 hypopharynx cancers that are treated surgically will require total laryngectomy with efforts to preserve a posterior strip of the hypopharynx spanning the oropharynx to the esophagus. This preserved posterior wall of the hypopharynx may be tubed and closed on itself in selected cases. In the past, it was common practice to accept primary reconstruction of this segment as adequate for swallowing if closure over a nasogastric tube was possible. However, with the proliferation of regional and free tissue reconstruction options, primary closure has been discouraged for cases with less than a 3- to 3.5-cm width of posterior pharyngeal wall mucosa to tube on itself. Most commonly, superior swallowing results when the anterior and lateral walls of the remaining hypopharynx are reconstructed with a pedicled or free flap.

For more bulky tumors of the hypopharynx, total laryngopharyngectomy, removal of the larynx, and the entire hypopharynx are required. This procedure creates a gap between the oropharynx and the esophagus that must be reconstructed. Historically, total circumferential laryngopharyngectomy defects were repaired with a gastric pull-up procedure, mobilizing the stomach and esophagus and pulling the stomach upward into the neck, or with a staged regional flap reconstruction, such as the Wookey flap.[52,53] With the advent of the pectoralis major myocutaneous flap, the use of the tubed pectoralis flap was pursued, though this can be technically difficult to tube in certain patients due to the bulk of fat and

muscle underlying the skin paddle. With the advent of microvascular reconstruction, the free jejunum flap and tubed free gastro-omental flap were initially popularized, though the lower morbidity, easier-to-harvest fasciocutaneous flaps, particularly the anterolateral thigh free flap and radial forearm free flap, have emerged as the predominant reconstructive methods in recent years.[54]

While microvascular techniques have seen significant advancements in recent decades, resulting in decreased operative times and increased free flap survival rates, reconstruction of total circumferential pharyngeal defects remains a challenge with numerous potential complications, including risk of free flap failure, pharyngocutaneous fistulae, and pharyngoesophageal stricture.[54]

Palliative Surgery

For patients with incurable, metastatic disease at presentation, or with symptomatic local recurrence not amenable to curative salvage therapy attempts, surgery can play an important role in palliation. If aspiration of secretions (despite nothing by mouth status and enteral feedings) persists, laryngopharyngectomy may afford a reasonable option to discuss with the patient and family members. Similarly, complete stenosis of the pharynx or upper esophagus due to tumor (or following treatment) may leave a patient with the constant need for suctioning their own secretions. In selected patients, laryngopharyngectomy with gastric pull-up may be a reasonable palliative option. Finally, gastric feeding tube placement can be considered for patients who do not wish to pursue palliative RT or surgery.

Postoperative Radiation Therapy

Most advanced hypopharynx cancers that are treated with initial surgical resection have unfavorable features that warrant the addition of postoperative RT in an effort to enhance locoregional control rates. Classic indications for postoperative radiation include T3 to T4 primary tumors, close or positive microscopic margins, cartilage or bony invasion, lymphovascular space invasion, extensive perineural invasion, more than one metastatic lymph node, or the presence of ENE. IMRT and VMAT are commonly used to enable sufficient conformal coverage of the tumor bed,

flap, and bilateral nodal regions at risk while reducing dose to adjacent organs.[55] Commonly used doses include 63 to 66 Gy in 30 to 33 fractions to areas harboring microscopic residual disease at the primary site or in regions previously containing lymph nodes with ENE. A dose of 60 Gy typically covers the tumor bed and nodal regions without positive surgical margins or ENE. Elective doses of 50 to 56 Gy are typically prescribed to elective nodal regions. Although less common, conventional therapy approaches using shrinking field techniques are adequate if more advanced conformal technologies are not available. Proton therapy can be considered in the postoperative setting, especially in patients previously treated with RT for a prior H&N cancer to avoid overdosing the spinal cord and other critical organs.[56] The Radiation Therapy Oncology Group (RTOG) and the European Organization for Research and Treatment of Cancer (EORTC) have evaluated the role of concurrent chemotherapy along with postoperative radiation in prospective randomized trials. Eligibility criteria in the RTOG trial included patients with two or more positive nodes, ENE, or microscopically positive margins. All patients received either 60 Gy alone or with concurrent cisplatin 100 mg/m^2 every 3 weeks. This trial demonstrated an improvement in locoregional control and disease-free survival for patients who received concurrent chemoradiotherapy. However, no significant benefit in absolute survival was confirmed.[57] The EORTC conducted a similar trial that included patients with stage III (except T3N0 larynx), stage IV, and patients with stage I or II with positive margins, lymphovascular invasion, and perineural invasion. All patients received either 66 Gy alone or with cisplatin at 100 mg/m^2 every 3 weeks. This trial demonstrated a significant improvement in progression-free survival and overall survival with the addition of chemotherapy.[58] A subsequently published post hoc analysis of the combined data from these trials suggested that patients with ENE and positive margins were most likely to benefit from the addition of chemotherapy, whereas those with two or more involved lymph nodes without ENE as their only risk factor did not appear to benefit from the addition of chemotherapy.[59]

Although the studies above identify that the addition of cisplatin chemotherapy to postoperative radiation can improve tumor control outcome for specific categories of high-risk patients, it is clear that this modest benefit comes at the expense of additional toxicity. Careful clinical

judgment regarding the selection of patients most likely to tolerate and thereby benefit from this approach is warranted. A recently updated meta-analysis demonstrated similar modest benefit from the addition of concurrent chemotherapy in the postoperative setting as compared to the definitive setting. However, this analysis showed that patients older than 70 years of age derive little to no benefit from the addition of systemic chemotherapy to radiation in H&N cancer.[60] Despite the lack of benefit of concurrent chemoradiation therapy in the postoperative setting for patients over 70 years of age in prior systematic analyses, additional factors, especially performance status and extent of comorbidities, should be considered in a multidisciplinary manner to finalize management. The inadvertent introduction of treatment breaks during the adjuvant radiation course can easily compromise the potential benefits of the combined modality therapy in this setting. Cooperative group studies aimed at improving clinical outcomes and minimizing toxicities using non–cisplatin-based therapies are ongoing (NCT01810913).

Definitive Radiation Therapy

T1 and T2 Tumors

Curative RT is generally the preferred treatment option for patients with T1 or T2 hypopharynx tumors (see Table 52.3). This approach affords good potential for organ preservation without compromise in clinical outcome. A classic course of RT for hypopharynx cancer lasts 6 to 7 weeks, with treatment delivered 5 days per week. A review of published clinical results of definitive RT for H&N cancer suggests a significant loss of local control with prolongation of overall radiation treatment time; therefore, interruptions in treatment once underway should be avoided whenever possible.[61,62]

IMRT/VMAT are commonly used; however, conventional treatment involving a shrinking field technique that initiates with opposed lateral fields encompassing the primary tumor and upper neck lymphatics with a matched anterior field to complete treatment of the lower neck are valid approaches (Figure 52.9; Table 52.5). One of the most common worldwide fractionation regimens involves the delivery of 2-Gy daily fractions to 70 Gy over 7 weeks. Because of the high likelihood of subclinical nodal

metastases even in the clinically N0 neck, patients traditionally receive comprehensive radiation to encompass nodal regions from the skull base to the clavicle. Because of the varying thicknesses of the H&N, custom compensators or wedges should be used for the lateral fields to improve dose homogeneity. Shrinking field techniques to spare direct spinal cord dose after approximately 45 Gy, as well as final mucosal reductions after 54 to 60 Gy, are often appropriate with posterior neck boosting, with electrons to supplement posterior chain nodal dosing without excessive dose to the spinal cord.

TABLE 52.5 GENERAL ANATOMIC LANDMARKS FOR FIELD DESIGN USING CONVENTIONAL HEAD AND NECK RADIOTHERAPY FOR HYPOPHARYNX CANCER

Border	Description
Superior	Include base of skull
Posterior	Behind vertebral spinous processes (or further if required to cover metastatic cervical lymph nodes)
Inferior	Lower aspect of cricoid cartilage unless extensive caudal tumor extension
Anterior	Flash skin at level of thyroid cartilage

For T1 lesions, classic dose is 66 to 70 Gy in 2-Gy daily fractions. For T2 to T4 lesions, consider altered fractionation regimens or concurrent cisplatin-based chemotherapy, particularly for patients over 70 years of age. Gross disease should generally receive 70 Gy with concurrent chemotherapy.

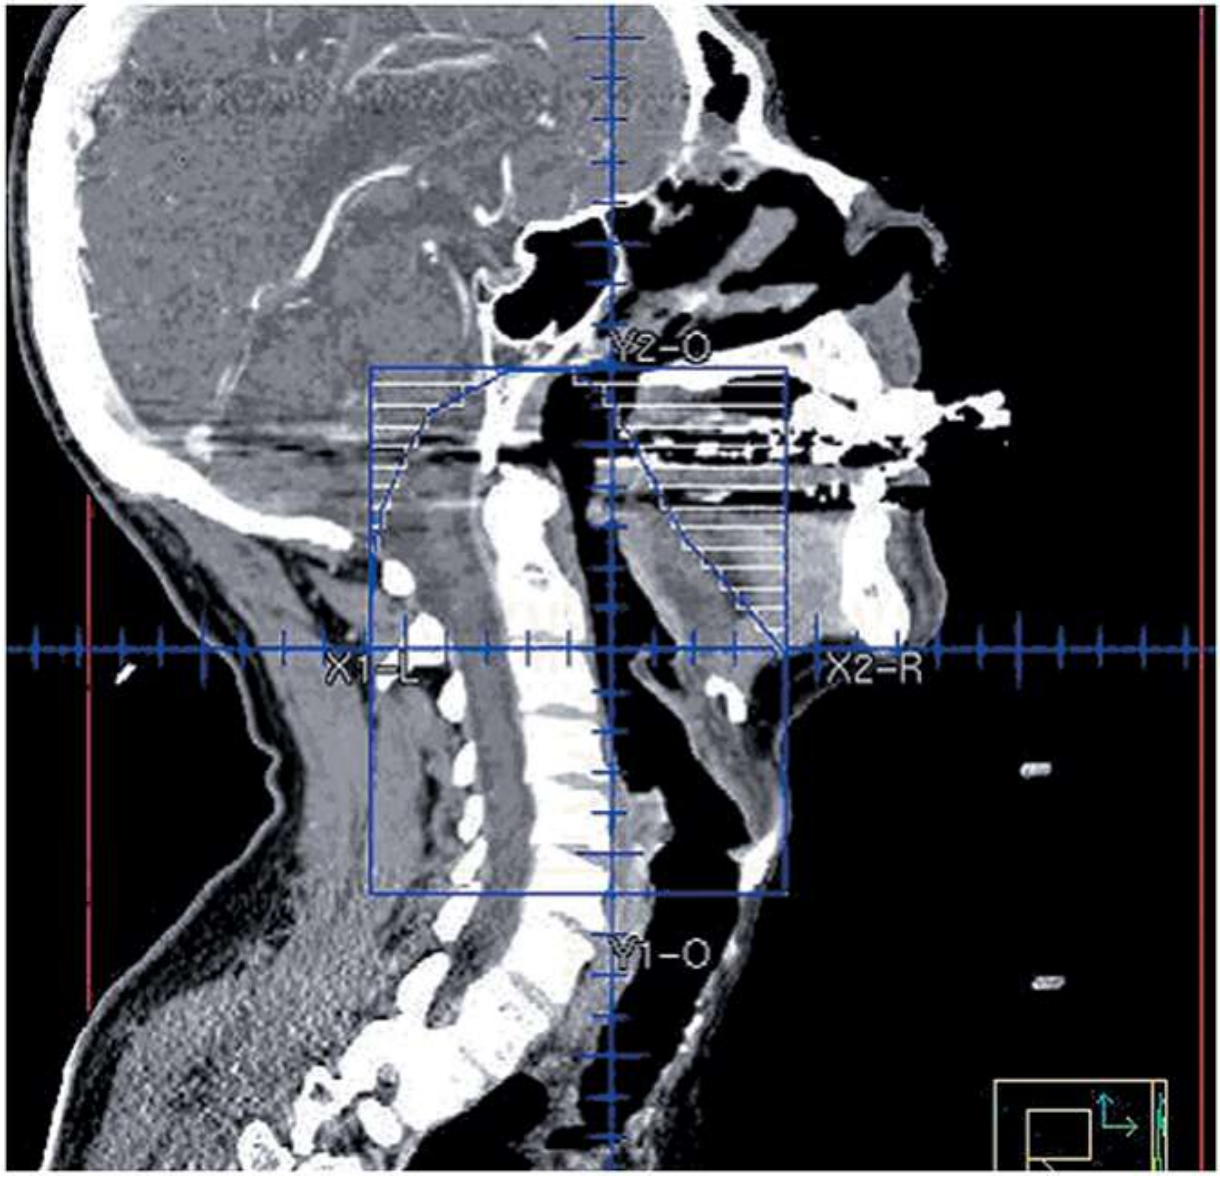

FIGURE 52.9 Digitally reconstructed radiograph depicting a classic lateral field designed to encompass the T2 pyriform sinus cancer from Figures 52.6 and 52.7 plus bilateral cervical lymphatics from skull base to cricoid, with a matching anterior low neck field to extend the lymphatic coverage to the level of the clavicle.

SCCs of the H&N are rapidly proliferating tumors. There has been significant interest over the past several decades in the use of intensified radiation fractionation schedules to counter rapid tumor cell repopulation as a means of improving outcomes in patients with H&N cancer treated with radiation alone. Altered fractionation techniques, including hyperfractionation (eg, 1.1-1.4 Gy twice daily) and accelerated fractionation

(eg, 6 fraction per week or concomitant boost regimens), have demonstrated improved locoregional control rates for patients with H&N cancer.[63-65] A meta-analysis examined 15 trials that compared conventional fractionation to altered fractionation, either hyperfractionation or accelerated fractionation. This meta-analysis demonstrated a small but statistically significant survival benefit of 3.4% at 5 years with altered fractionation. The benefit was higher with hyperfractionation compared to accelerated fractionation and was more pronounced for patients younger than age 50 (Figure 52.10).[66]

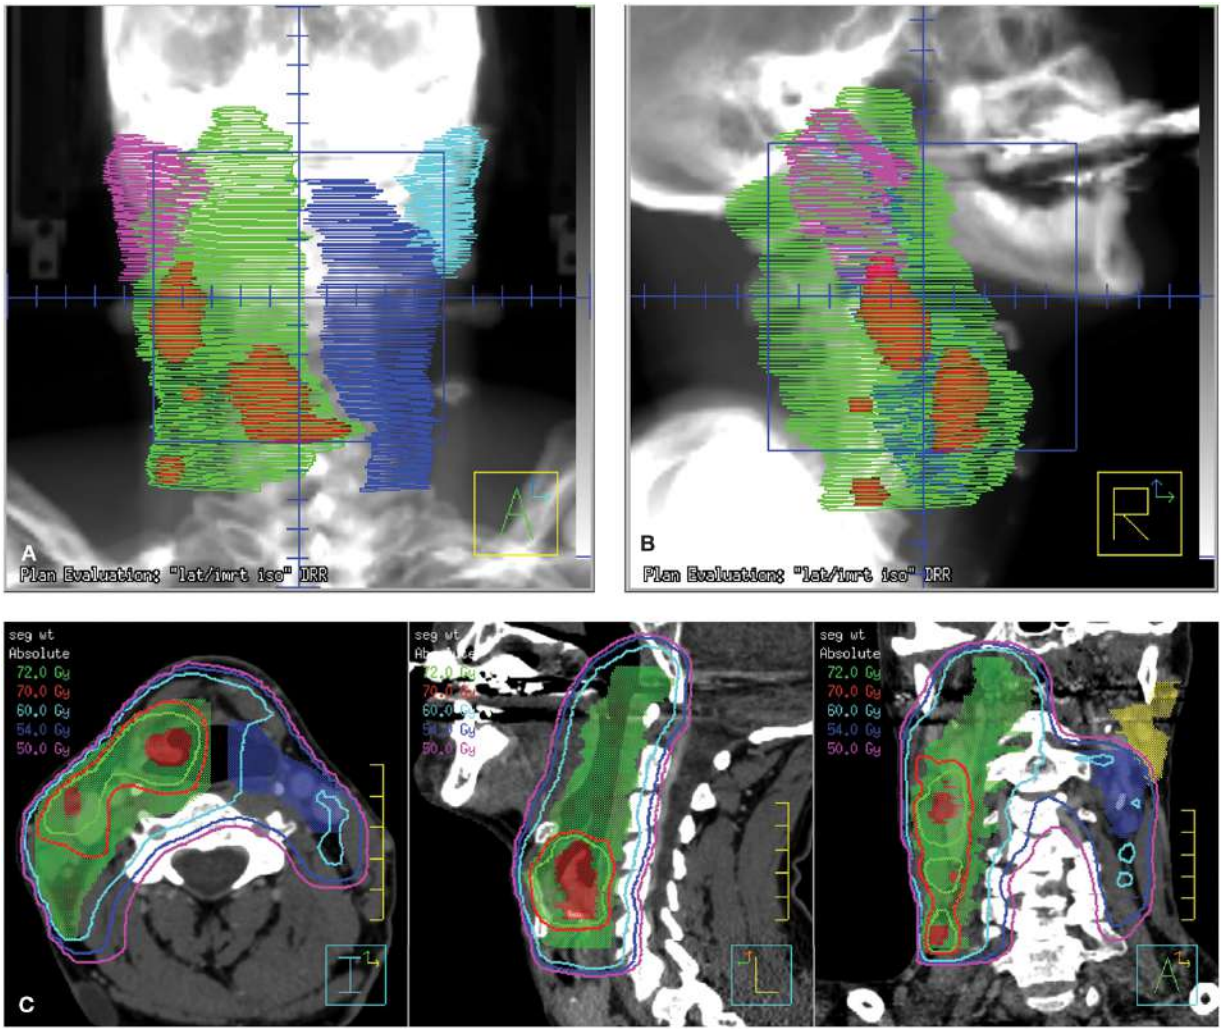

FIGURE 52.10 Beam's eye projections of intensity-modulated radiation therapy target contours for a patient with T2N2bM0 tumor of the right pyriform sinus (same case as depicted in Figures 52.6, 52.7, and 52.9). A and B. Depict anterior and lateral projections highlighting the GTV (red, 70 Gy), high-risk CTV1 (green, 60 Gy), low-risk CTV2 (blue, 54 Gy), and bilateral parotid glands. C. Demonstrates transverse, sagittal, and coronal treatment planning images depicting head and neck intensity-modulated radiation therapy isodose distributions for the same patient. The left parotid gland received a mean dose of 22 Gy. CTV, clinical target volume; GTV, gross tumor volume.

Early T-stage hypopharynx patients with N0 or N1 neck disease can be considered for treatment with either radiation alone or concurrent radiation plus chemotherapy. In this setting, gross disease should receive 70 Gy and the contralateral neck (N0) should receive 50 to 54 Gy. With T1N0 lesions, patients may achieve 5-year disease-specific survival (DSS) on the order of

90%, whereas T2N0 lesions may achieve DSS above 70% (Tables 52.6 and 52.7).[67-71]

T3 and T4 Tumors

There are several reasons why patients with hypopharynx cancer who are technically resectable may not undergo primary surgery. These include age (eg, patients over 70-80 years old), the presence of significant medical comorbidities, or patient unwillingness to accept total laryngectomy. Curative-intent radiation or chemoradiation is often pursued in these

settings. Conventional RT commonly involves a shrinking three-field technique to deliver approximately 70 Gy in 2-Gy daily fractions to areas of gross disease and 50 to 60 Gy to areas of microscopic disease. If patients are scheduled to undergo postradiotherapy neck dissection, then gross nodal disease can be limited to 60 to 63 Gy. If patients are not candidates for postradiotherapy neck dissection, then gross nodal disease should be carried to 70 Gy. Altered fractionation regimens such as hyperfractionation or accelerated fractionation should be considered for patients being treated with radiation alone, given the overall survival benefit observed with these approaches over standard fractionation in meta-analysis.[66]

In patients with adequate performance status, concurrent chemoradiation strategies using platinum-based chemotherapy should be considered. The updated meta-analysis to examine the benefit of chemotherapy in advanced H&N cancer confirms a significant survival advantage for the use of concomitant chemotherapy (6.5%), with the effect of single-agent platin significantly higher than other monochemotherapies.[60] However, this meta-analysis also confirms a steadily decreasing benefit for the use of chemotherapy with advancing patient age, such that no advantage is observed for patients over 70 years of age. This same loss of statistical benefit for patients over 70 years of age is also observed for the outcome gains derived from altered fractionation over conventional fractionation.[66] Therefore, once-daily radiation regimens without concurrent chemotherapy may be quite reasonable for patients with hypopharynx cancer over 70 years of age or for those patients with modest performance status.

Another alternative to concomitant chemotherapy or accelerated fractionation is the more recent introduction of molecularly targeted therapies in the treatment of patients with H&N cancer. The most mature clinical data set in H&N cancer involves the use of EGFR inhibitors, such as cetuximab (monoclonal antibody against the EGFR). An international phase III trial comparing high-dose radiation alone versus radiation plus cetuximab in patients with advanced H&N cancer confirmed a locoregional control improvement (10% at 5 years) and overall survival advantage (10% at 5 years) with the addition of cetuximab.[72,73] A relatively small subset of patients with hypopharynx cancer was enrolled in this study of 424 patients, and this subset did not demonstrate a clear advantage with the use of the EGFR inhibitor treatment. Ongoing trials to examine the potential value of

adding cetuximab to concurrent chemoradiation approaches in advanced H&N cancer are in progress in both the definitive and high-risk postoperative settings.

Management of hypopharynx cancer has gradually evolved over the past decades to reflect the steady advancement of nonsurgical therapy. Data from the NCDB Benchmark Reports addressing 16,136 cases diagnosed in 2000 to 2008 reveal the combination of radiation and chemotherapy to be the most common initial treatment overall for stage II (32.6%), stage III (47.8%), and stage IV (43.8%) disease (Figure 52.11).[34] Over 50% of stage III and stage IV cases received initial treatment with chemotherapy in some form—either alone or in combination with radiation or surgery. Radiation as a single-modality therapy was the most common initial treatment for stage I hypopharynx cancer (24.4%), followed by surgery alone (21.0%) as the next most common. It has been reported that approximately 35% to 45% of patients with advanced hypopharyngeal tumors treated with concurrent chemoradiotherapy utilizing IMRT can be expected to live 5 years, with laryngeal preservation in approximately two-thirds of survivors (Table 52.8).[74-76] These survival rates from single institutions utilizing IMRT should be interpreted cautiously in light of less favorable outcomes identified through a cross-sectional analysis of patients diagnosed with hypopharyngeal cancer in the United States in 2003. Review of the NCDB data identified 5-year observed survival for the majority of hypopharyngeal cancers (stage IV) to be only 19.8% (see Figure 52.4).[16]

Induction Chemotherapy and Sequential (Chemo)radiation

Recently, there has been renewed interest in the concept of induction chemotherapy approaches for patients with locoregionally advanced H&N cancer. In an effort to examine the potential for organ preservation in patients with advanced cancers of the hypopharynx, the EORTC conducted a randomized trial for patients with tumors that would require total laryngectomy as the surgical approach. This trial randomly allocated patients to induction chemotherapy with cisplatin and 5-5-fluorouracil (5-FU), followed by definitive radiation versus primary surgical resection and postoperative radiation. With a median follow-up of 10 years, this trial demonstrated no significant difference in 5- or 10-year overall survival or progression-free survival. Of note, two-thirds of living patients in the chemoradiotherapy arm were able to retain their larynx.[79] More recently, the introduction of taxane-containing regimens has been demonstrated to improve outcomes in patients receiving induction chemotherapy. Three randomized trials have been reported that compare induction 5-FU and cisplatin versus 5-FU, cisplatin, plus a taxane. The EORTC study (TAX-323) randomized patients with locoregionally advanced, unresectable disease to induction cisplatin and fluorouracil (PF) versus induction docetaxel, cisplatin, and fluorouracil (TPF), followed by definitive radiation alone.[74] Treatment with TPF improved the median overall survival from 14.5 to 18.8 months, with a 27% reduction in the risk of death. Similar results were noted in TAX-324, which utilized similar induction chemotherapy arms (TPF vs PF), followed by concurrent chemoradiotherapy with carboplatin.[75] Five-year survival in the TPF arm was 52% versus 42% receiving PF, while no increased rates of gastric feeding tubes or tracheostomies were noted between groups. A subgroup analysis of patients with larynx and hypopharynx cancer demonstrated improved survival in these patients, as well as higher rates of laryngectomy-free survival.[76]

In addition to enhanced survival outcomes, a recent randomized French study demonstrated that TPF induction chemotherapy (compared to PF induction) results in superior tumor response rates (80% vs 59%) as assessed by laryngoscopy and CT or MRI.[80] Those with response to induction chemotherapy were treated with organ-preserving

(chemo)radiotherapy, whereas nonresponders underwent laryngectomy and postoperative (chemo)radiation. The higher response rates in the TPF arm translated into higher rates of laryngeal preservation (70% vs 57% at 3 years), without a decrease in overall survival (60% at 3 years in both arms). Despite the superiority of TPF chemotherapy than PF, concerns about tolerance of postinduction chemoradiotherapy led to the TREMPLIN trial, which compared induction TPF followed by comprehensive H&N RT with either concurrent cisplatin or cetuximab.[81] Indeed, treatment compliance was challenging following completion of TPF, with only 43% of patients receiving full-dose systemic therapy on the cisplatin arm and 71% on the cetuximab arm. Patients receiving concurrent cisplatin or cetuximab had similar clinical outcomes with regard to larynx preservation at 3 months (95% and 93%, respectively), larynx function preservation (87% and 82%, respectively), and overall survival at 18 months (92% and 89%, respectively). These aggressive treatment approaches certainly warrant consideration for H&N subsites such as hypopharynx where organ preservation is desirable and overall outcomes are generally poor. Patients with good performance status, no contraindications to taxanes or platins, a high tumor burden and/or advanced nodal disease may be optimal candidates for this approach.[82] Nevertheless, these strategies are toxic and costly, and prospective data support equivalent survival outcomes for patients treated with a 7-week course of concurrent chemoradiotherapy alone.[83] Therefore, careful assessment of tumor control, survival, and long-term functional outcome dovetailed with quality-of-life (QoL) evaluation are important to place these regimens in best perspective for patients with advanced H&N cancer.

Postradiotherapy Neck Dissection

Patients with hypopharynx cancer also require careful evaluation regarding regional nodal metastases. For N0 or N1 patients treated with primary radiation or chemoradiation approaches, adjuvant neck dissection is generally unnecessary. However, for patients presenting with N2 or N3 neck disease, careful evaluation of tumor response in the neck is important to help gauge the potential value of adjuvant neck dissection following radiation or chemoradiation. An increasing number of reports suggest that

detailed imaging of the neck 12 weeks postradiation with FDG-PET can serve as a valuable guide to help select those patients warranting adjuvant neck dissection. One such study from the University of Iowa assessed the value of a postradiation FDG-PET to help select those patients who might benefit most from subsequent neck dissection. For complete clinical responders, the Iowa study concluded that FDG-PET in this setting has a very high negative predictive value. The authors suggest that FDG-PET may be a valuable tool to help determine which patients should undergo adjuvant neck dissection versus observation following the completion of H&N radiation or (chemo)radiotherapy.[84] In a multi-institutional study comparing PET-CT surveillance versus neck dissection, at a median follow-up of 36 months, PET-CT–guided surveillance resulted in fewer neck dissections than the planned neck dissection cohort without impacting overall survival.[85] It should be noted that patients with hypopharynx cancer only comprised 10% of the total patient population. Despite these emerging data, many institutions mandate adjuvant neck dissection for all patients presenting with N2 or N3 neck disease in an effort to maximize regional disease control.[86-88] Both approaches are readily defendable at present. If neck dissection is performed, this provides an opportunity for the surgeon to reassess the primary tumor site under anesthesia with directed biopsy if suspicious for residual disease. If residual disease at the primary site is highly suspected or confirmed by biopsy several months following completion of radiation or chemoradiation, this will prompt consideration regarding the feasibility and advisability of salvage surgery options.

Palliative Radiotherapy

The management of patients with unresectable locoregional disease without distant metastases is dependent on patient performance status. A patient with a good performance status may be offered definitive RT, concurrent chemoradiotherapy, or induction chemotherapy with sequential (chemo)radiotherapy, as discussed above. However, patients with poor performance status who are not considered candidates for aggressive radiation or chemoradiation approaches should be managed with palliative intent. This may include short-course radiation regimens such as 4 to 5 Gy in 5 fractions over 1 to 2 weeks with consideration of the same scheme 3

weeks later if the regimen is tolerated and a favorable response is achieved. A recent study suggests using a 3.7-Gy fraction twice daily × 2 consecutive days for three cycles every 2 to 3 weeks, as described in RTOG-85-02, may have similar palliative efficacy with less toxicity as compared to other palliative regimens.[89] Other approaches described include 50 Gy in 16 fractions[90] and 30 Gy in 5 fractions, 2 fractions per week.[91] Systemic chemotherapy alone can be considered, although, for poor performance status patients, best supportive care with medical therapy and airway control may also be appropriate.

Palliative Chemotherapy

As many as one-quarter of patients with hypopharynx cancer will develop metastatic disease at some point in their clinical course. In this setting, treatment is palliative and should be delivered to maximize or help maintain QoL. If patients are having difficulty with local pain, bleeding, or swallowing, palliative short-course RT can be delivered, as described above. Surgery may also provide a reasonable palliative option for selected patients who have incurable disease but significant symptoms related to their localized disease, as described above. Many patients in this setting will benefit from narcotic analgesics for pain management.

Patients with adequate or good performance status should be considered for palliative chemotherapy. Median overall survival for patients with metastatic disease is 6 to 10 months.[92] Single-agent cisplatin is usually the first regimen, as it has been shown to improve overall survival.[93] Combinations of cytotoxic chemotherapies have demonstrated improved response rates over cisplatin alone, but have not improved survival and are accompanied by increased toxicity[94] and, therefore, are uncommonly utilized. However, recent randomized studies have shown efficacy of the anti-EGFR monoclonal antibody cetuximab. In combination with cisplatin as first-line treatment, cetuximab improved overall survival from 7.4 to 10.1 months over cisplatin alone.[92] As second-line therapy in patients who have progressed through platinum-based chemotherapy, cetuximab also has demonstrable activity as either monotherapy[95] or in combination with platinum-based chemotherapy.[96]

COMPLICATIONS

Surgery

The complications from surgery generally fall within the confines of bleeding, infection, reaction to the anesthesia, and damage to structures around or in the field of surgery. The damage to the laryngopharynx that occurs in the course of removing those tissues involved by cancer necessarily interferes with key laryngeal functions: breathing, swallowing, and speaking.

If an effort is made to preserve laryngeal function, some compromise may be required. A long-term tracheotomy, nothing by mouth status with the use of gastrostomy feedings, and significant dysphonia are not uncommon for patients with hypopharynx cancer treated with conservation laryngeal surgery. These same complications may attend the more comprehensive laryngopharyngectomy as well. Stenosis of the neopharynx, difficulty with alaryngeal speech, and stomal stenosis may compromise the same functions ordinarily ascribed to the larynx. For all open surgical approaches, the risk of a salivary fistula is greatest for those patients previously treated with radiation. More recent literature has advocated for the use of either pedicled or free tissue reconstruction in all cases of salvage laryngectomy when feasible, with meta-analysis showing incidence of pharyngocutaneous fistula at 37% in salvage laryngectomy with primary closure compared to 19% after flap closure ($P < .01$).[97] Although salivary fistulas are rare with endoscopic approaches, they have occurred in cases requiring aggressive laser resection.

Radiation Therapy

During a course of H&N RT, there are predictable side effects that are experienced by the majority of patients: mucositis, fatigue, loss of taste acuity, radiation dermatitis, and xerostomia. Typically, patients will begin to experience mucositis during the third week of RT. This initially manifests as mucosal blanching within the treatment field but can progress to patchy or confluent mucositis. Initially, patients can be treated with an over-the-counter pain reliever, but once patients develop grade II or III mucositis, they will commonly require narcotic analgesics for adequate pain control. The combination of dysphagia and mucositis can result in significant

nutritional compromise, necessitating intravenous hydration and parenteral nutritional supplementation. Nausea associated with treatment can also further complicate the nutritional status. These acute toxicities can become particularly pronounced in the setting of intensified radiation fractionation schedules or combined chemoradiotherapy. Patients may require prophylactic antiemetics. In patients receiving concurrent RT and platinum-based chemotherapy, there is clear potential for myelosuppression; therefore, blood counts should be monitored regularly. Signs or symptoms of infection should be addressed promptly. Finally, xerostomia can become problematic during the course of radiation. Ultimately, patients can be reassured that most of these side effects, with the exception of xerostomia, are temporary and will resolve several weeks to months following completion of therapy.

As noted, one of the acute side effects of RT that can become permanent is xerostomia. Chemical and physical modifiers of the radiation response have been utilized to reduce long-term xerostomia. The free radical scavenger amifostine has the potential to reduce radiation effects on normal tissues if administered just prior to each radiation fraction. A randomized phase III trial demonstrated a reduction in the severity of the acute and chronic grade 2 or higher xerostomia in patients who received amifostine during RT.[98] Dose-limiting toxicities commonly include hypotension and nausea. There has been concern over possible tumor-protective effects of amifostine, but a recent meta-analysis does not suggest this.[99] However, data supporting the use of amifostine to reduce xerostomia have been generated in the setting of conventional radiation, and the magnitude of benefit on xerostomia of parotid-sparing IMRT appears greater than that of amifostine.[55,100] Therefore, the ultimate value of amifostine in patients with advanced H&N cancer, especially in the setting of IMRT, has been called into question.[101] Currently, there is no universal standard recommendation across treatment centers for the use of this radioprotector.

In some cases, patients with hypopharynx cancer who complete a course of RT will be noted to have persistent laryngeal edema on subsequent follow-up visits. Although in the early post-treatment phase (in fact up to 24 months), significant or newfound edema should raise suspicion regarding the possibility of persistent or recurrent disease. The majority of patients who receive high-dose radiation across major segments of the larynx and

hypopharynx will manifest some degree of edema, mucosal congestion, and eventual fibrosis (see Figure 52.6B). Generally, this collateral damage is a tolerable chronic toxicity with modest impact on patient QoL. However, in approximately 10% to 15% of patients, this edema is severe enough to cause significant airway and swallow function compromise requiring tracheostomy. Rarely, more significant complications such as osteoradionecrosis (ORN) of the cervical spine may occur. In this setting, patients can present with persistent neck pain prompting imaging and biopsy. Most cases can be managed conservatively; however, progression to serious complications including epidural abscess, radiculopathy, and myelopathy has been described. Once neurologic symptoms emerge, they can progress rapidly, indicating the need to maintain vigilance in patients with cervical spine ORN.[102-104]

LONG-TERM FOLLOW-UP

Regardless of whether patients undergo primary surgery or RT, there is value in close post-treatment surveillance by H&N surgeon and radiation oncologist in a multidisciplinary manner. Follow-up care is designed initially to survey for recurrence. As duration from time of intervention to clinic visits lengthen, the focus shifts to surveillance for second primaries (ie, lung), to address morbidity from treatment, and to provide generalized support.

Although there are limited data to guide surveillance, commonly, during the first 6 months after treatment, patients should be followed every 4 to 6 weeks with clinical examination, including fiberoptic nasopharyngoscopy. Recommended guidelines include a follow-up visit every 1 to 3 months during the first year, every 2 to 4 months for the second year, every 4 to 6 months for years 3 through 5, and every 6 to 12 months thereafter. In addition, if the patient received comprehensive H&N radiation, the serum thyroid-stimulating hormone level should be measured every 6 to 12 months. Imaging evaluation of the neck, most commonly with CT or MRI scan, is obtained at 3- to 6-month intervals during the first 2 years or as indicated based on clinical findings. Functional imaging with ^{18}FDG-PET can sometimes prove valuable to help differentiate post-treatment fibrosis from persistent or recurrent disease.

A study by Hermans et al[105] examined findings on CT scan of the neck 3 to 4 months following completion of RT for patients with larynx or hypopharynx cancer to examine correlation with long-term outcome. The authors suggest that in patients achieving complete radiographic resolution of all pretreatment disease, the likelihood of subsequent local failure is very small. These patients might, therefore, undergo routine clinical examination, with repeat imaging reserved for instances where the clinical examination becomes suspicious for recurrence. For patients who achieved <50% reduction in tumor volume or retained a mass 1 cm or larger on the post-treatment imaging study, the likelihood of local failure was 100% and 30%, respectively. In these patients, repeat CT at 3 to 4 months, FDG-PET, or biopsy is, therefore, recommended. Preliminary reports indicate that the results of the first post-RT FDG-PET scan may be a strong predictor of developing locoregional disease recurrence.

In the post-treatment setting of patients with hypopharynx cancer, the involvement of an experienced H&N radiologist is highly desirable for optimal interpretation of imaging results. Soft tissue changes following ablative surgery and reconstruction, or following high-dose radiation or chemoradiation with resultant edema and fibrosis, can be very difficult to differentiate from tumor, particularly for the inexperienced reader.

MANAGEMENT OF RECURRENCE

After completion of treatment, patients should be followed closely for signs of recurrent or persistent disease. If recurrence is suspected, this should be confirmed by biopsy. If biopsy is confirmatory, then the patient should undergo complete restaging to assess the extent of disease. In the setting of local or regional disease alone, patients treated with initial radiation or chemoradiation can be considered for surgical salvage therapy. Although salvage surgery following comprehensive H&N radiation and chemotherapy presents several resection and reconstructive healing challenges for the surgeon, selected patients may still derive long-term benefit from this approach. Select patients with low-volume localized disease may be candidates for TLM for recurrent disease following radiation.[106] Recurrent patients who initially received comprehensive H&N radiation have traditionally not been considered good candidates for repeat

high-dose radiation in light of normal tissue tolerances. However, two recent prospective RTOG studies have demonstrated that reirradiation to the H&N is feasible.[107,108] With the advent of highly conformal radiation delivery techniques, selected patients may benefit from reirradiation approaches in conjunction with systemic chemotherapy.[109] A retrospective study from Memorial Sloan-Kettering Cancer Center has suggested that IMRT is beneficial for local control in this setting,[110] and a recent prospective trial of reirradiation utilizing IMRT suggests long-term disease control can be achieved in select patients with tolerable toxicity.[111] The use of stereotactic body radiosurgery is becoming more common in the management of patients with H&N cancer who manifest locoregional recurrence. Recent data suggest that patients with laryngeal and hypopharyngeal primaries exhibit significantly more late toxicities compared to those with oral cavity and oropharyngeal primaries, likely related to cartilage in the retreatment region. Therefore, careful consideration should be given to patient performance status, preexisting organ dysfunction, and goals of care prior to delivering ablative doses of RT in the laryngopharynx.[112] Many patients with recurrent disease, however, are not good candidates for aggressive surgery or salvage RT and are best served with systemic chemotherapy or best supportive care approaches.

QUALITY OF LIFE

Assessment of parameters, including functional status, organ preservation, treatment cost, and patient assessment of QoL, plays an increasingly important role in the evaluation of overall treatment efficacy. For patients with larynx and hypopharynx cancer, a focus of contemporary clinical investigation has been the study of treatments designed to preserve laryngeal function for patients traditionally treated with total laryngectomy. A frequently cited but somewhat controversial study by McNeil et al[113] employed a questionnaire administered to healthy individuals and concluded that some might forgo total laryngectomy in favor of alternative therapy, even if this choice diminished their ultimate chance for cure. A more recent report by El-Deiry et al[114] evaluated long-term QoL in a matched pair analysis comparing the surgical and nonsurgical treatment of patients with advanced H&N cancer involving the oropharynx,

hypopharynx, and larynx. Although patients in the surgery arm demonstrated worse speech outcomes than those treated with chemoradiation, this difference did not carry over to the overall QoL score. These investigators concluded that, although it seems reasonable that organ preservation (nonsurgical) treatment will uniformly result in a higher QoL, the complexities of human adjustment and multitude of potential treatment effects render this assumption invalid for many patients. Alternatively, a study from the Medical University of South Carolina compared swallow-related QoL after surgery or RT for H&N cancer using a dysphagia symptom survey, the MD Anderson Dysphagia Inventory (MDADI). They found significantly better scores on the emotional and functional components of the MDADI for patients undergoing chemoradiation compared to those undergoing surgery followed by radiation.[115] There have been relatively few prospective assessments of QoL following treatment for H&N cancer. In a subset of locally advanced patients requiring radical surgery, such as total laryngectomy and partial pharyngectomy, the functional deficits are predictable. However, for patients undergoing organ preservation with either radiation alone or in combination with chemotherapy, it can be difficult to assess the true extent and quality of organ preservation. Regardless of the primary treatment approach, these patients often require long-term speech, swallow, and dental rehabilitation. A study from Meyer et al[116] retrospectively assessed speech intelligibility and QoL in survivors of H&N cancer. A total of 64 patients were enrolled; 31 underwent RT alone, 5 underwent surgery alone, and 28 received both. All patients underwent comprehensive subjective and objective testing of speech function and QoL. They found significant subjective and objective deficits in speech and QoL, even 5 years after completion of therapy. Terrell et al[117] reported the results of a self-administered health survey of 570 patients at a Veterans' Administration hospital that demonstrated that the single most notable event having a negative impact on QoL was placement of a feeding tube. This was followed by medical comorbid conditions, presence of a tracheotomy tube, chemotherapy, and neck dissection.

A prospective study on QoL utilizing the EORTC QLQ-C30 and QLQ-H&N35 questionnaires was conducted in Sweden on 357 patients. This study found that QoL issues were significantly associated with the site of origin, with stage at diagnosis being the most important predictor. In

addition, patients with hypopharynx cancer exhibited the poorest QoL.[118] Similarly, another study prospectively examining swallow function in patients with H&N cancer demonstrated that worse swallowing was associated with hypopharyngeal tumor sites.[119] Although the use of IMRT can have a significant impact on xerostomia and QoL measures in patients with H&N cancer,[120,121] the intimate approximation of hypopharyngeal tumors to pharyngeal constrictor musculature does not allow for sparing of these structures vital to long-term swallow function, likely contributing to the poorer QoL of patients with hypopharynx cancer in comparison to patients with other H&N cancer.[122]

CONCLUSION

Patients with cancers of the hypopharynx commonly present with advanced disease associated with varying degrees of compromise in speech or swallow function. Many patients with hypopharynx cancer also carry significant medical and social comorbidities. Typically, small T1 or T2 lesions can be managed with either primary radiation or surgery, with similar clinical outcome. For intermediate-stage disease that would require laryngopharyngectomy for the surgical approach, an increasingly preferred treatment option is combined chemoradiation. For bulky hypopharynx tumors with significant airway compromise, laryngeal distortion, and cartilage destruction, it is generally best to proceed with definitive surgery with postoperative radiation or chemoradiation.

Despite an aggressive approach in the overall management of patients with hypopharynx cancer, ultimate cure rates remain quite poor. There are relatively few early-stage patients; and for many advanced-stage patients, it is difficult to achieve long-term control. Even for those patients with excellent response to therapy, there exists a continuous risk for the development of second malignancies, particularly of the upper aerodigestive track with long-term follow-up. Post-treatment patients often require aggressive speech and swallow therapy to maximize their functional outcome. There is significant interest in the incorporation of molecularly targeted therapies in combination with traditional cytotoxic therapy and radiation in an effort to improve outcomes.

CHAPTER 53

Laryngeal Cancer

William M. Mendenhall, Anthony A. Mancuso, Rui P. Fernandes, and Peter T. Dziegielewski

ANATOMY

The larynx is divided into the supraglottis, glottis, and subglottis. The supraglottis consists of the epiglottis, false vocal cords, ventricles, aryepiglottic folds, and arytenoids. The glottis includes the floor of the ventricle, interarytenoid area, true vocal cords, and the anterior commissure. The subglottis is located below the vocal cords (Figures 53.1 and 53.2).[1]

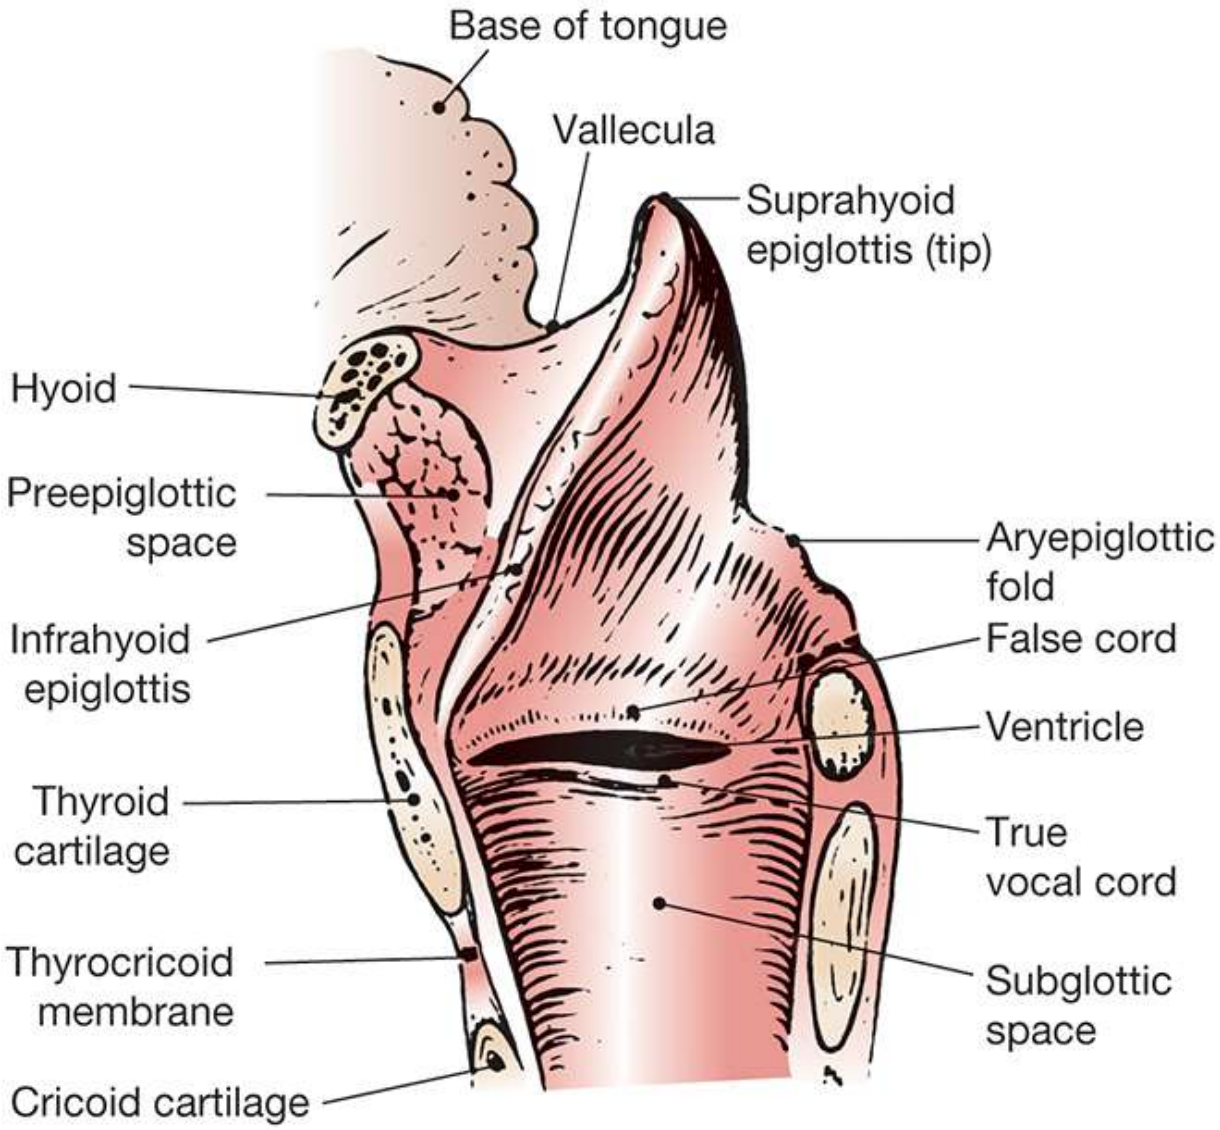

FIGURE 53.1 Diagrammatic sagittal section of the larynx. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figure 11.49. Copyright © 2023 Elsevier GmbH Munich. With permission.)

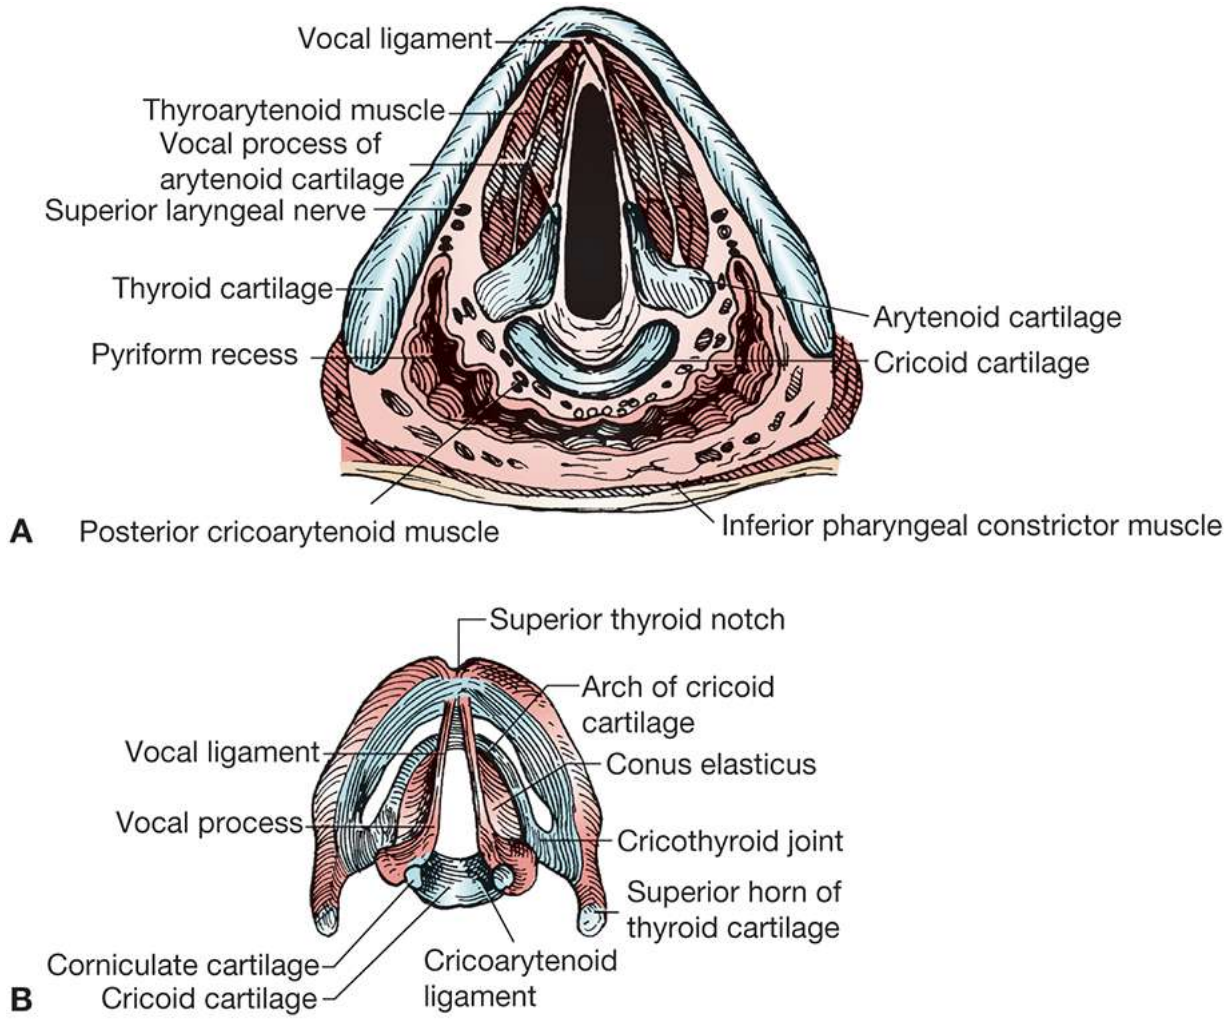

FIGURE 53.2 A. Cross section of the larynx at the level of the vocal cords. B. Framework of the larynx. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figures 11.63 and 11.40. Copyright © 2023 Elsevier GmbH Munich. With permission.)

The axial line of demarcation between the glottic and supraglottic larynx is the apex of the ventricle. The demarcation between the glottis and the subglottis is ill-defined, but the subglottis is considered to extend from a point 5 mm below the free margin of the vocal cord to the inferior border of the cricoid cartilage or 10 mm below the apex of the ventricle.

The vocal cords vary from 3 to 5 mm in thickness and terminate posteriorly with their attachment to the vocal process or the arytenoid cartilage. The posterior commissure is the mucosa between the arytenoids (interarytenoid area).

The shell of the larynx is formed by the hyoid bone, thyroid cartilage, and cricoid cartilage; the cricoid cartilage is the only complete ring of the upper airway. The more mobile interior framework is composed of the heart-shaped epiglottis and the arytenoid, corniculate, and cuneiform cartilages. The corniculate and cuneiform cartilages produce small, rounded bulges at the posterior end of each aryepiglottic fold.

The thyroid and the cricoid cartilage and a portion of the arytenoid cartilage are hyaline cartilage and may ossify with age, particularly in men. The epiglottis is elastic cartilage; ossification does not occur, and even focal calcification is rare.[2]

The external laryngeal framework is linked together by the thyrohyoid, the cricothyroid, and the cricotracheal ligaments or membranes (Figures 53.3 and 53.4).[1]

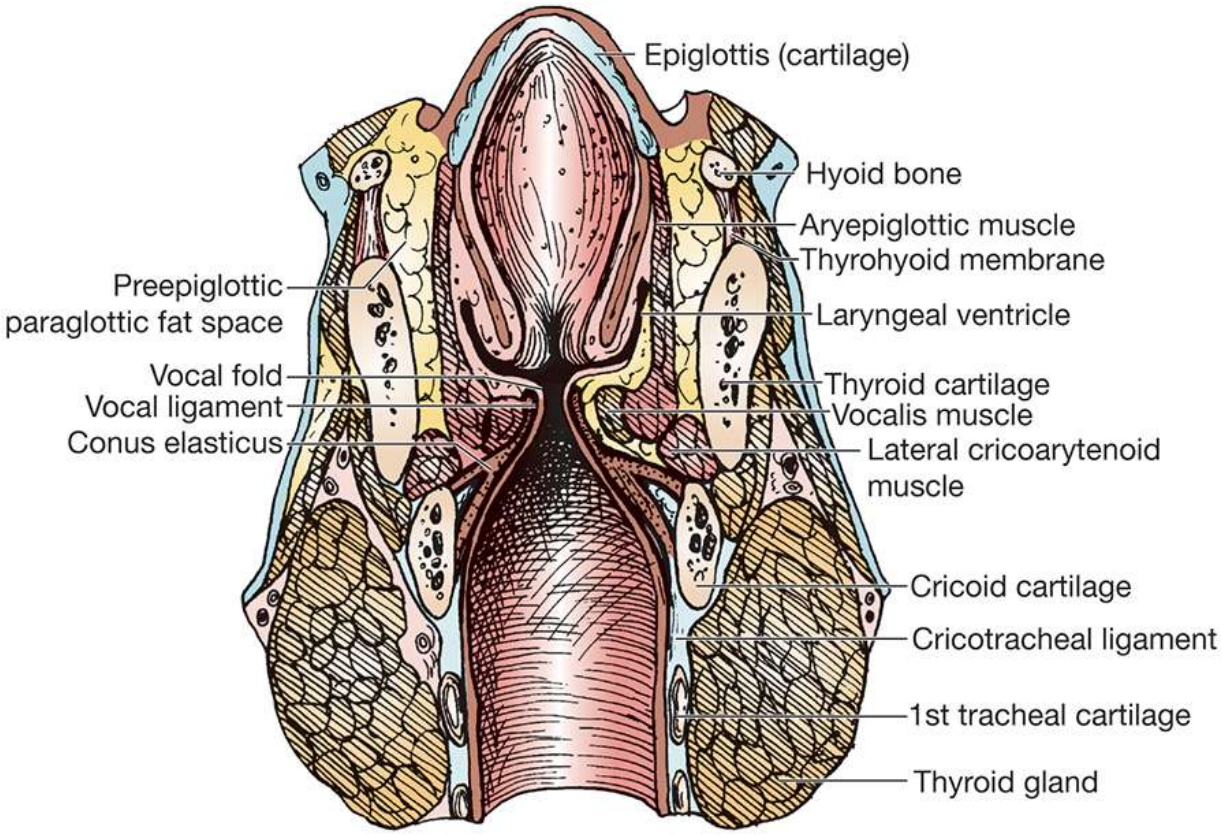

FIGURE 53.3 Diagram of the coronal view of the larynx. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figure 11.66. Copyright © 2023 Elsevier GmbH Munich. With permission.)

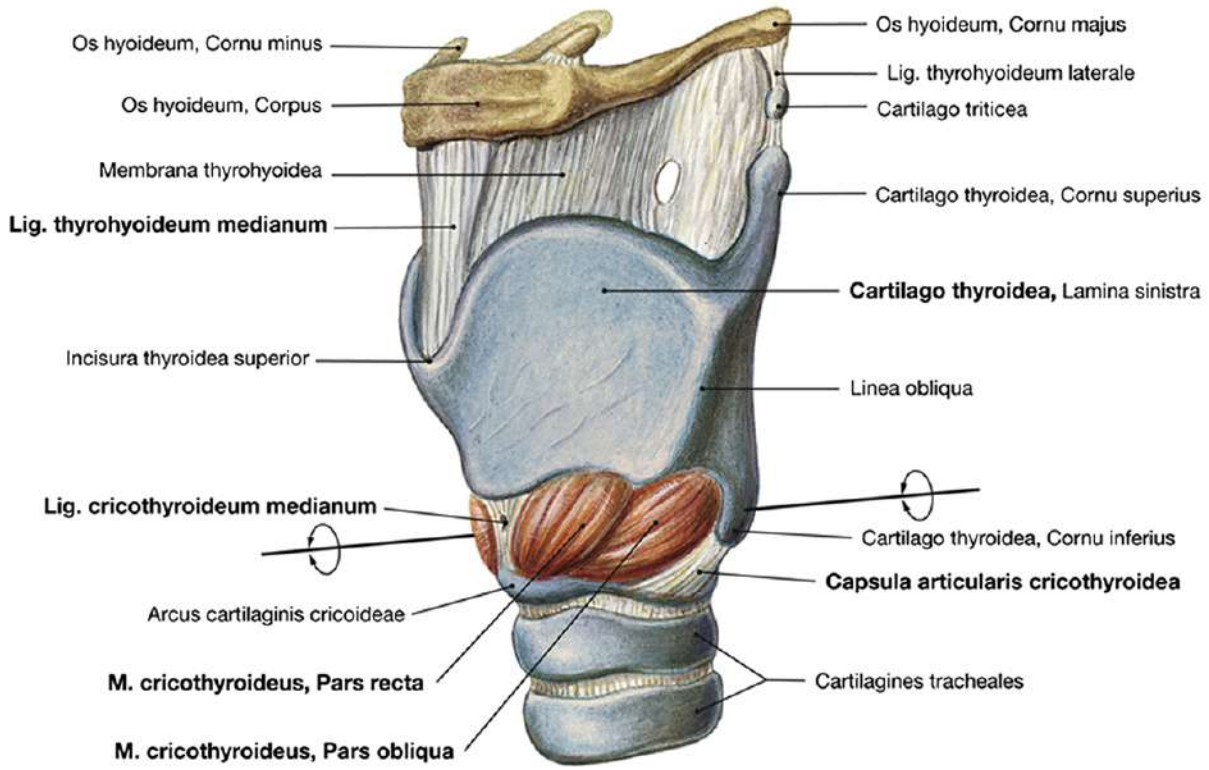

FIGURE 53.4 External view of the larynx. (Reprinted from Paulsen F, Waschke J. *Sobotta Atlas of Human Anatomy*. 17th ed. Urban & Fischer; 2023, Figure 11.41. Copyright © 2023 Elsevier GmbH Munich. With permission.)

The epiglottis is joined superiorly to the hyoid bone by the hyoepiglottic ligament. The epiglottis is joined to the thyroid cartilage by the thyroepiglottic ligament at a point just below the thyroid notch and above the anterior commissure. This area of attachment is the *petiole* of the epiglottis. The arrangement of the ligaments that connect the cricoid and arytenoid cartilages and form the vocal ligaments is shown in Figure 53.2B.[1] The conus elasticus (cricovocal ligament) is the lower portion of the elastic membrane that connects the inferior framework. It connects the upper surface of the cricoid, the vocal process of the arytenoid, and the lower thyroid cartilage; its free border is thickened into the vocal ligament. The quadrangular membrane is the upper portion of the elastic membrane that connects the superior framework. It connects the false vocal cords, aryepiglottic folds, and the epiglottis.

The vocal ligaments and thyroarytenoid/vocalis muscle complex attach to the vocal process of the arytenoid posteriorly and the thyroid cartilage

anteriorly. The intrinsic muscles of the larynx, which primarily control the movement of the cords, are presented in Figures 53.2 and 53.3.[1] The extrinsic muscles are concerned primarily with swallowing. The cricothyroid muscle draws the larynx anteriorly and inferiorly when contracting. The consequence is increased vocal cord tension, leading to increased pitch of the voice. It is innervated by the external branch of the superior laryngeal nerve (Figure 53.4).[1] The intrinsic muscles of the larynx are innervated by the recurrent laryngeal nerve.

The preepiglottic and paraglottic fat spaces are essentially one contiguous space lying between the external framework of the thyroid cartilage and hyoid bone and the inner framework of the epiglottis and intrinsic muscles. Lam and Wong[3] showed that there are thin membranous septa between the paraglottic and preepiglottic spaces, which produce a barrier to tumor spread to a limited degree. The space is traversed by blood and lymphatic vessels as well as nerves. Because few capillary lymphatics arise in this area, invasion of the fat space seldom leads to lymph node metastases. The fat space is limited by the conus elasticus inferiorly; the thyroid ala, thyrohyoid membrane, quadrangular membrane, and hyoid bone anterolaterally; the hyoepiglottic ligament superiorly; and the fascia of the intrinsic muscles medially. Posteriorly, it is adjacent to the anterior wall of the pyriform sinus.

The laryngeal surface of the epiglottis and the free margin of the vocal cords are squamous epithelium, and the remaining mucosa is usually pseudostratified ciliated columnar epithelium. Beneath the epithelium of the free edge of the vocal cord is the lamina propria, which can be divided into three layers. There is no true submucosal layer along the free margin of the vocal fold.[4] The laryngeal arteries are branches of the superior and inferior thyroid arteries.

The supraglottic structures have a rich capillary lymphatic plexus; the trunks pass through the preepiglottic space and the thyrohyoid membrane and terminate mainly in the jugulodigastric (level II) lymph nodes; a few drain to the middle internal jugular chain (level III) lymph nodes.

There are essentially no capillary lymphatics of the true vocal cords; as a result, lymphatic spread from glottic cancer occurs only if tumor extends to supraglottic or subglottic areas.

The subglottic area has relatively few capillary lymphatics. The lymphatic trunks pass through the cricothyroid membrane to the pretracheal (Delphian) lymph nodes in the region of the thyroid isthmus. The subglottic area also drains posteriorly through the cricotracheal membrane, with some trunks going to the paratracheal (level VI) lymph nodes and others continuing to the inferior jugular (level IV) chain.

EPIDEMIOLOGY AND RISK FACTORS

Cancer of the larynx represents about 2% of the total cancer burden and accounts for 0.3% of all cancer deaths. It is the second most common head and neck mucosal cancer. In 2023, in the United States, there will be approximately 12,380 new cases of cancer of the larynx (9,900 men and 2,480 women) and about 3,820 deaths from laryngeal cancer.[5] Based on 1973-1998 U.S. data, at diagnosis, about 51% of the cases remain localized, 29% have regional spread, and 15% have distant metastases.[6] The ratio of glottic to supraglottic carcinoma is approximately 2:1.

Cancer of the larynx is strongly related to cigarette smoking. The risk of tobacco-related cancers of the upper alimentary and respiratory tracts declines among former smokers after 5 years and is said to approach the risk of nonsmokers after 10 years of abstention.[7] The role of alcohol in provoking laryngeal cancer remains unclear.[8] Some evidence exists that heavy marijuana smoking may be associated with laryngeal cancer in young patients.

PATTERNS OF SPREAD

Local Spread

Although supraglottic and glottic lesions tend to remain confined to their original compartments, there is no anatomic barrier to growth from one area to the next. Glottic lesions tend to be slow growing, but as they increase in size, they extend to the supraglottic and subglottic areas. Supraglottic lesions do not often start near the vocal cords. Involvement of the cords on their external epithelial surface is a late phenomenon, but submucosal extension by way of the paraglottic space occurs earlier.

The fat space is an important avenue of submucosal tumor spread for infrahyoid epiglottis, false cord, and true vocal cord lesions. As the false cord and the true vocal cord lesions penetrate anteriorly and laterally, they quickly encounter the tough perichondrium of the thyroid cartilage and may eventually be shunted by the conus elasticus (lateral cricothyroid membrane) out of the larynx via the cricothyroid space. Thyroid cartilage invasion usually occurs in the ossified section of the cartilage, commonly in the region of the anterior commissure tendon or the junction of the anterior one-fourth and the posterior three-fourths of the thyroid lamina.[9]

Fixation of the vocal cord from laryngeal cancer is usually caused by invasion or destruction of the vocal cord muscle, invasion of the cricoarytenoid muscle or joint, or, rarely, invasion of the recurrent laryngeal nerve. Perineural spread is uncommon.

Supraglottic Larynx

Suprahyoid Epiglottis

A lesion of the suprahyoid epiglottis may produce a large exophytic mass with little tendency to destroy cartilage or spread to adjacent structures. Other lesions may infiltrate the tip and destroy cartilage. The destructive lesions tend to invade the vallecula and preepiglottic space, the lateral pharyngeal walls, and the remainder of the supraglottic larynx.

Infrahyoid Epiglottis

Lesions of the infrahyoid epiglottis tend to produce irregular tumor nodules and simultaneously invade the porous epiglottic cartilage and thyroepiglottic ligament into the preepiglottic fat space and extend toward the vallecula and base of the tongue. The thick hyoepiglottic ligament is an effective tumor barrier. However, the tumor may present in the vallecula and base of the tongue without involving the suprahyoid epiglottis.

Lesions of the infrahyoid epiglottis grow circumferentially to involve the false cords, aryepiglottic folds, medial wall of the pyriform sinus, and the pharyngoepiglottic folds. Invasion of the anterior commissure and cords and anterior subglottic extension usually occur only in advanced lesions. Infrahyoid epiglottic lesions that extend onto or below the vocal cords are at high risk for thyroid cartilage invasion, even if the cords are mobile.[10]

False Cord

Early false cord carcinomas, which are usually submucosal with little exophytic component, are difficult to delineate accurately. They involve the paraglottic fat space early in their development and may spread a considerable distance beneath the mucosa without producing physical signs. These carcinomas extend to the perichondrium of the thyroid cartilage quite early, but cartilage invasion is a late phenomenon. Extension to the lower portion of the infrahyoid epiglottis and invasion of the preepiglottic space are common. Submucosal extension involves the true vocal cord, which may appear normal. Vocal cord invasion is often associated with thyroid cartilage invasion. Submucosal extension to the medial wall of the pyriform sinus occurs early.

Aryepiglottic Fold/Arytenoid

Early lesions of the aryepiglottic fold/arytenoid are usually exophytic. It may be difficult to decide whether the lesion started on the medial wall of the pyriform sinus or on the aryepiglottic fold. As the lesions enlarge, they extend to adjacent sites and eventually cause fixation of the larynx, which is usually a result of involvement of the cricoarytenoid muscle or joint or, rarely, invasion of the recurrent laryngeal nerve. Computed tomography (CT) may distinguish the cause of fixation. Advanced lesions invade the thyroid, epiglottic, and cricoid cartilages and eventually invade the pyriform sinus and postcricoid area.

Glottic Larynx

Most lesions of the true vocal cord begin on the free margin and upper surface of the cord. When diagnosed, about two-thirds are confined to the cords, usually one cord. The anterior portion of the cord is the most common site. Anterior commissure involvement, which is common, is said to occur when no tumor-free cord can be seen anteriorly; if the lesion crosses to the opposite cord, anterior commissure invasion is certain. Small lesions isolated to the anterior commissure account for only 1% to 2% of cases. Extension to the posterior commissure is uncommon, occurring only in advanced lesions.

Tumors at the anterior commissure may extend anteriorly via the anterior commissure tendon (Broyles ligament)[11] into the thyroid cartilage. Kirchner,[12] using whole-organ sections, showed that such extension is unusual unless the tumor extends off the vocal cord onto the base of the infrahyoid epiglottis and suggested that the tendon serves as more of a barrier than an avenue of tumor spread. Early subglottic extension is also associated with involvement of the anterior commissure, and tumor may grow through the cricothyroid membrane.

Lesions that arise on the posterior half of the vocal cord tend to extend along the submucosa toward the medial side of the vocal process and invade the cricoarytenoid joint and posterior commissure; this spread is difficult to appreciate by clinical examination.

Subglottic extension may occur by simple mucosal surface growth, but it more commonly occurs by submucosal penetration beneath the conus elasticus. One centimeter of subglottic extension anteriorly or 4 to 5 mm of subglottic extension posteriorly brings the border of the tumor to the upper margin of the cricoid, exceeding the anatomic limits for conventional hemilaryngectomy. Lesions may spread beneath the epithelium along the length of the vocal cord within Reinke space.[13]

As vocal cord lesions enlarge, they extend to the false cord, vocal process of the arytenoid, and subglottis. Infiltrative lesions invade the vocal ligament and muscle and eventually reach the paraglottic space and the perichondrium of the thyroid cartilage. Advanced glottic lesions eventually penetrate through the thyroid cartilage or via the cricothyroid space to enter the neck, where they may invade the thyroid gland. Lesions involving the anterior commissure often exit the larynx via the cricothyroid membrane after they extend subglottically.[13]

A fixed cord that is associated with a lesion having <1 cm of subglottic extension and no false cord involvement does not ordinarily indicate invasion of the thyroid cartilage.[12] If the false cord is also involved, cartilage invasion is likely.

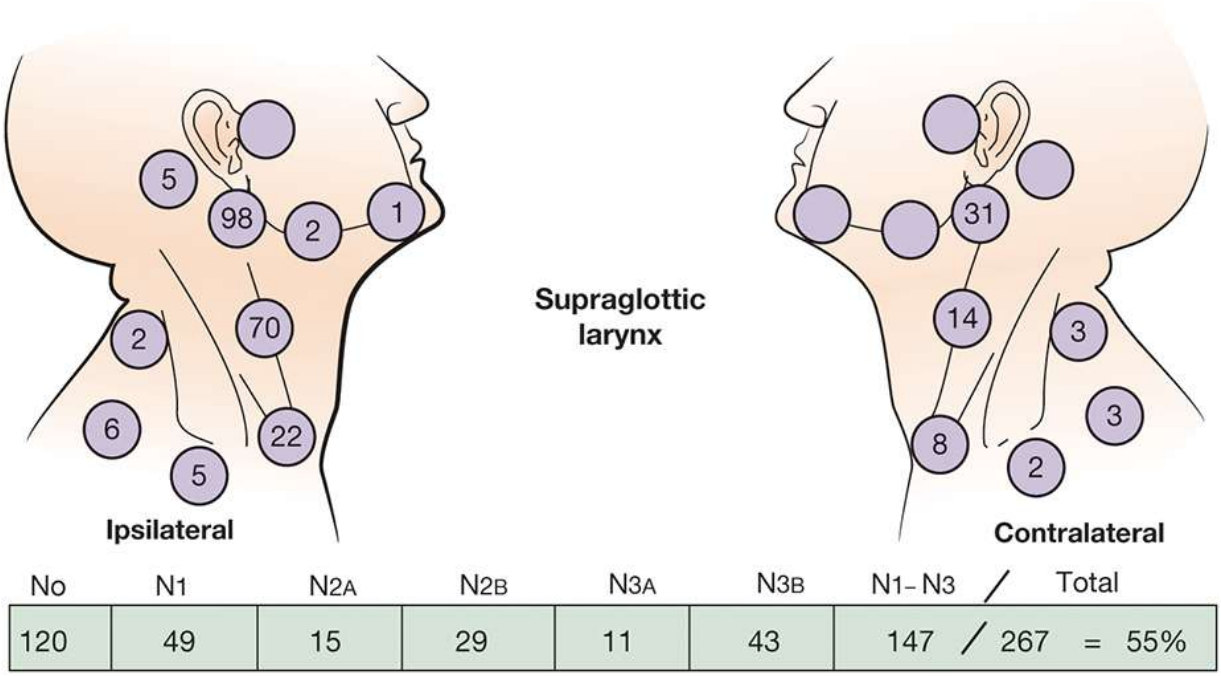
Subglottic Larynx

Subglottic cancers are rare.[14] Most involve the inferior surface of the vocal cords by the time they are diagnosed, so it is difficult to know whether the

tumor started on the undersurface of the vocal cord or in the true subglottic larynx. Because early diagnosis is uncommon, most lesions are bilateral or circumferential at discovery. They involve the cricoid cartilages in the early stage because there is no intervening muscle layer. Partial or complete fixation of one or both cords is common; misdiagnosis or diagnostic delay is frequent.

Lymphatic Spread

The location and stage of neck nodes detected on admission for previously untreated patients with squamous cell carcinoma of the supraglottic larynx are given in Figure 53.5.[15] The disease spreads mainly to the level II nodes. The level Ib nodes are rarely involved, and there is only a small risk of level V lymph node involvement. The incidence of clinically positive nodes is 55% at the time of diagnosis; 16% are bilateral.[15] Elective neck dissection shows pathologically positive nodes in at least 16% of cases; observation of initially node-negative necks eventually identifies the appearance of positive nodes in 33% of cases.[16,17] Spread to the pyriform sinus, vallecula, and base of the tongue increases the risk of lymph node metastases. The risk of late-appearing contralateral lymph node metastasis is 37% if the ipsilateral neck is pathologically positive, but the risk is unrelated to whether the nodes in the ipsilateral neck were palpable before neck dissection.



No	N1	N2A	N2B	N3A	N3B	N1–N3 / Total
120	49	15	29	11	43	147 / 267 = 55%

FIGURE 53.5 Nodal distribution on admission, MD Anderson Cancer Center, 1948-1965. (From Lindberg R. Distribution of cervical lymph node metastases from squamous cell carcinoma of the upper respiratory and digestive tracts. *Cancer*. 1972;29[6]:1446-1449. Copyright © 1972 American Cancer Society. Reprinted by permission of John Wiley & Sons.)

The incidence of clinically positive lymph nodes at diagnosis for vocal cord carcinoma approaches zero for T1 lesions and is ≤6% for T2 lesions.[18] The incidence of neck metastases increases to 20% to 30% for T3 and T4 lesions. Glottic spread is typically associated with metastasis to the level II nodes. Anterior commissure and anterior subglottic invasion are also associated with involvement of the midline pretracheal lymph node (level VI).

Lederman[19] reported a 10% incidence of positive lymph nodes in 73 patients with subglottic carcinoma.

CLINICAL PRESENTATION

Carcinoma arising on the true vocal cords produces hoarseness at a very early stage. Odynophagia, otalgia, pain localized to the thyroid cartilage, and airway obstruction are features of advanced lesions.

Hoarseness is not a prominent symptom of cancer of the supraglottis until the lesion becomes extensive. Odynophagia, usually mild, is the most frequent initial symptom, often described as a sore throat. Some patients report a sensation of a "lump in the throat." Pain is referred to the ear by way of Arnold branch of the vagus nerve. A neck mass may be the first sign of a supraglottic cancer. Late symptoms include weight loss, halitosis, dysphagia, and aspiration.

DIAGNOSTIC WORKUP

Physical Examination

Flexible fiberoptic endoscopes provide the best view of the larynx, hypopharynx, and posterior oropharynx. The scope is inserted through the nasal passage and passed over the nasopharyngeal side of the soft palate to provide a "bird's-eye" view of the larynx. The mucosal surfaces of the base of tongue, posterior pharyngeal wall, vallecula, hypopharynx, supraglottis, glottis, and subglottis are examined. Vocal cord mobility is determined by asking the patient to say "ee" (adduction) and sniff in (abduction). Subtle distinctions between paresis and paralysis may require multiple examinations or stroboscopy.

Ulceration of the infrahyoid epiglottis or fullness of the vallecula is an indirect sign of preepiglottic space invasion. Palpation of diffuse, firm fullness above the thyroid notch with widening of the space between the hyoid and the thyroid cartilages signifies invasion of the preepiglottic space. The preepiglottic fat space is a low-density area on the CT scan, and changes resulting from tumor invasion are easily seen.

Postcricoid extension may be suspected when the laryngeal click disappears on physical examination. Postcricoid tumor may cause the thyroid cartilage to protrude anteriorly, producing a fullness of the neck. Invasion of the thyroid cartilage remains a difficult clinical diagnosis. Localized pain or tenderness to palpation or a small bulge over one ala of the thyroid cartilage is suggestive.

Radiographic Studies

CT scan with contrast enhancement is often the method of choice for studying the larynx (Figure 53.6).[20] The CT scan should be performed before biopsy so that abnormalities that may be caused by the biopsy are not confused with tumor. CT is preferred to magnetic resonance (MR) imaging because the longer scanning time for MR results in motion artifact.[21] CT slices 1 to 2 mm thick are obtained at 1- to 2-mm intervals through the larynx and at 3-mm intervals for the remainder of the study. Thinner sections (1-2 mm through the larynx) facilitate high-quality multiplanar reformations. The gantry is angled so that the scan slices are parallel to the plane of the true vocal cords. It is also necessary to obtain a CT scan of the entire neck to detect positive, nonpalpable lymph nodes. Positive retropharyngeal nodes may be present at diagnosis in patients with laryngeal cancer who have advanced neck disease.[22] Retropharyngeal adenopathy will not be apparent on physical examination but is usually appreciated on CT scan. Contrast enhancement helps to outline the blood vessels and the thyroid gland. Tumor is often enhanced, probably because of reactive inflammatory changes.

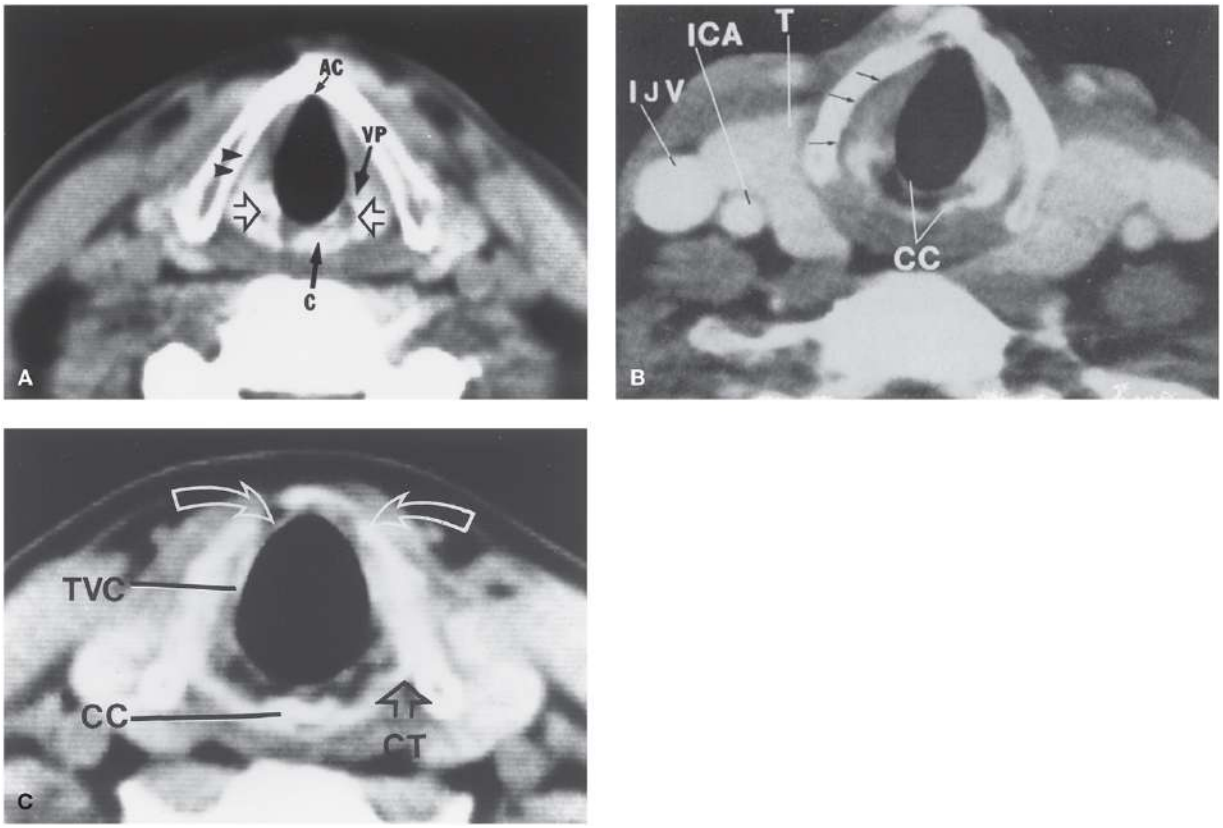


FIGURE 53.6 A. Normal computed tomography anatomy of the midplane of the true vocal cords. Open arrows indicate arytenoid cartilages. The top of the cricoid cartilage (C) is partially visualized at this level. The vocal process of the left arytenoid cartilage is demonstrated. A narrow, low-density plane is seen between the right true vocal cord and the thyroid lamina (arrowheads); this is the inferior part of the paraglottic fat space. Note the complete lack of tissue at the anterior commissure. Any tissue here density should be considered abnormal. B. Normal computed tomography anatomy just below the midplane of the vocal cords. Arrows indicate low-density lower paraglottic fat space. The fibrofatty tissue in this space facilitates separation of the vocal cord and the adjacent thyroid lamina. If this clear space is maintained in the face of the thyroid lamina irregularity adjacent to the tumor, the lamina abnormality can be attributed to uneven calcification rather than tumor destruction. The posterior portion (lamina) of the cricoid cartilage (CC) is seen. The outer and inner cortex of the cartilage is calcified; an intervening marrow space has a lower density. The vertical height of the lamina is 2 to 3 cm. There is incomplete calcification of the thyroid cartilage anteriorly. C. Normal computed tomography anatomy 5 mm below the free margin of the true vocal cord. The vocal cord appears thin because of abduction during scanning. There is incomplete bilateral paramedian calcification and thinning of the thyroid lamina (arrows). Notice the normal lack of tissue density between the airway and the anterior arch of the thyroid cartilage. CT, cricothyroid joint; ICA, internal carotid artery; IJV, internal jugular vein; T, thyroid gland. (Reprinted with permission from Million RR, Cassisi NJ. Larynx. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach*. J.B. Lippincott; 1984:315-364.)

The value of MR imaging includes defining subtle exolaryngeal spread or early cartilage destruction as well as the extent of tracheal invasion and esophageal invasion. Sagittal MR may also be useful in detecting early invasion of the base of the tongue.

Vocal Cord Carcinoma

Although the CT scan does not show minimal mucosal lesions and is generally not helpful for well-defined, easily visualized T1, or early T2 vocal cord carcinomas, it is almost always obtained. CT is excellent for determining subglottic extension and is often used in selected T1 and most T2 lesions for this reason alone. CT scanning is useful in the diagnosis of moderately advanced and advanced lesions; it is excellent for demonstrating extension outside the larynx into the soft tissues of the neck and has the potential for determining thyroid or cricoid cartilage invasion, which tends to occur at the edges of the cartilage rather than on the faces. Early cartilage involvement is difficult to detect with axial scans, but it may be demonstrated by coronal or sagittal scanning techniques. If the low-density plane of the paraglottic space is intact, cartilage is probably not invaded by tumor.

Archer et al[23] correlated CT findings with the incidence of cartilage or bone invasion on whole-organ sections. For 12 of 14 patients with pathologic evidence of cartilage invasion, the average diameter of the tumor in two dimensions was >16 mm, and the lesion was located below the top of the arytenoid. Lesions in which the maximum diameter lay above the top of the arytenoid had a low incidence of cartilage invasion.[23]

Supraglottic Carcinoma

The CT scan provides an excellent means for viewing the preepiglottic and paraglottic fat spaces. Soft tissue extension into the neck or base of the tongue can also be seen. The CT scan is also useful for determining extension to the subglottis.[2]

Diagnostic procedures for laryngeal cancer at the University of Florida are summarized in Table 53.1.[24] A CT scan is usually performed for all patients; MR is obtained in a small subset of patients with questionable findings on CT. Positron emission tomography (PET) is not routinely

obtained; although it may be useful to evaluate suspicious lymph nodes, it would change the treatment. Chest CT is usually obtained to detect pulmonary metastases, particularly in patients with positive cervical nodes. It may also be useful to identify the occasional synchronous lung cancer. Direct laryngoscopy and biopsy with frozen section are usually performed with the patient under general anesthesia. The ventricles, subglottis, apex of the pyriform sinus, and postcricoid area must be carefully examined because these areas are not consistently seen by indirect examinations. Fiberoptic telescopes (0° and 30°) are introduced through the laryngoscope for inspection of these areas. A generous biopsy specimen is taken from the obvious lesion; additional biopsy specimens may be obtained from suspicious areas and from areas grossly involved. The mucosa of the margin of the cord may be stripped to provide adequate tissue if the lesion is distributed superficially along the cord and is not obviously a carcinoma.

STAGING

The 2017 American Joint Committee on Cancer (AJCC)[25] staging system for laryngeal primary cancer is listed in Table 53.2. T2 glottic cancers are stratified into those with normal (T2A) and impaired (T2B) vocal cord mobility. For lesions arising in the supraglottis, the sites of origin include false cords, aryepiglottic folds, suprahyoid epiglottis, infrahyoid epiglottis, pharyngoepiglottic folds, and arytenoids. Only in the early T stages can one identify the specific site of origin with certainty. As the lesion enlarges, the site of origin is often an educated guess based on the location of the greatest tumor bulk/density. The major difference between the 1998 and 2010 staging systems is that a glottic cancer that invades the paraglottic space is upstaged to T3 in the latter system, even with mobile vocal cords, resulting in significant stage migration.[26] In addition, T4 has been stratified into T4A and T4B, based on resectability.

TABLE 53.2 STAGING OF LARYNGEAL CANCER

Supraglottis	
TX	Primary tumor cannot be assessed.
Tis	Carcinoma in situ
T1	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (eg, mucosa of base of the tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx.
T3	Tumor limited to larynx with vocal cord fixation and/or invades any of the following area: postcricoid space, preepiglottic space, paraglottic space, and/or inner cortex of thyroid cartilage.
T4	Moderately advanced or very advanced
T4a	Moderately advanced local disease; tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (eg, trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus).
T4b	Very advanced local disease; tumor invades prevertebral space, encases carotid artery, invades or mediastinal structures.
Glottis	
TX	Primary tumor cannot be assessed.
Tis	Carcinoma in situ

Supraglottis

T1	Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T1a	Tumor limited one to vocal cord
T1b	Tumor both involving vocal cords
T2	Tumor extends supraglottis and/or subglottis and/or with impaired vocal cord mobility.
T3	Tumor limited to the larynx with vocal cord fixation and/or invasion of paraglottic space and/or inner cortex of thyroid cartilage
T4	Moderately advanced or very advanced
T4a	Moderately advanced local disease; tumor invades through the outer cortex of the thyroid cartilage and/or invades beyond tissues beyond the larynx (eg, trachea, cricoid cartilage, soft tissues of neck including deep extrinsic muscle the of tongue, strap muscles, thyroid, or esophagus).
T4b	Very advanced local disease; tumor invades prevertebral space, encases carotid artery, invades or mediastinal structures.

PATHOLOGIC CLASSIFICATION

Nearly all malignant tumors of the larynx arise from the surface epithelium and, therefore, are squamous cell carcinoma or one of its variants.

Carcinoma in situ occurs frequently on the vocal cords. Differentiating among dysplasia, carcinoma in situ, squamous cell carcinoma with microinvasion, and true invasive carcinoma is a problem that the pathologist and the clinician frequently confront.

Most vocal cord carcinomas are well or moderately well differentiated. In a few cases, an apparent carcinoma and sarcoma occur together, but most of these are actually a spindle cell carcinoma (ie, squamous cell carcinoma with a spindle cell stromal reaction).

Verrucous carcinoma occurs in 1% to 2% of patients with carcinoma of the vocal cord. The histologic diagnosis is difficult and must correlate with the gross appearance of the lesion.

Small cell neuroendocrine carcinoma is rarely diagnosed in the supraglottic larynx, but it should be recognized because of its biologic

potential for rapid growth, early dissemination, and responsiveness to chemotherapy.[27,28]

Minor salivary gland tumors arise from the mucous glands in the supraglottic and subglottic larynx, but they are rare.[29] Even rarer are paragangliomas, carcinoids, soft tissue sarcomas, malignant lymphomas, and plasmacytomas. Benign chondromas and osteochondromas are reported, but their malignant counterparts are rare.

PROGNOSTIC FACTORS

The extent of the primary lesion and neck disease are the major determinants of prognosis. The likelihood of local control is determined primarily by T stage; there are conflicting data pertaining to a possible inverse relationship between N stage and local control. The likelihood of local-regional control is affected primarily by the overall AJCC stage, which accounts for both T stage and N stage. AJCC stage and N stage are the major determinants of cause-specific survival. Primary tumor volume predicts for local control and survival for patients with advanced glottic carcinomas treated with curative-intent radiotherapy (RT) and chemotherapy.[30] In addition, within each N stage, patients with positive nodes in the low neck below the level of the thyroid notch tend to have a lower cause-specific survival rate than those with disease confined to the upper neck. Human papillomavirus status may be a prognostic factor for patients with advanced laryngeal treated with chemoradiation.[31] In general, women tend to have a better prognosis than men.

TREATMENT OF VOCAL CORD CARCINOMA

Selection of Treatment Modality

In treating vocal cord carcinoma, the goal is cure with the best functional result and the least risk of a serious complication. Patients may be considered to be in an early group if the chance of cure with larynx preservation is high, a moderately advanced group if the likelihood of local control is 60% to 70% but the chance of cure is still good, and an advanced group if the chance of cure is moderate and the likelihood of laryngeal preservation is relatively low.[32] The early group may be treated initially by

RT or, in selected cases, by transoral laser microsurgery (TLM) or transoral robotic surgery (TORS).[33] The moderately advanced group may be treated with either RT with laryngectomy reserved for relapse or by total laryngectomy with or without adjuvant postoperative RT. The obvious advantage of the former strategy, which is used at the University of Florida, is that there is a fairly good chance that the larynx will be preserved.[34-36] Although some patients may be rehabilitated with a tracheoesophageal puncture after laryngectomy, only about 20% of patients use this device long term, and the majority use an electrolarynx.[37] The advanced group is treated with total laryngectomy and neck dissection with or without adjuvant RT or by RT and adjuvant chemotherapy.[38] Data suggest that if patients whose tumors show a partial or complete response to two to three cycles of neoadjuvant chemotherapy are then given high-dose RT, the cure rates are comparable with those obtained with initial total laryngectomy.[39] Another less expensive and less toxic method to select patients likely to be cured by RT alone is to calculate the primary tumor volume on pretreatment CT or MR. Data indicate that primary tumor volume is inversely related to the probability of local control after irradiation.[40,41] Recent data indicate that whereas induction chemotherapy probably does not improve the likelihood of local-regional control and survival, concomitant chemotherapy and RT result in an improved likelihood of cure compared with RT alone.[42-44] There is a subset of patients with high-volume (>3.5 mL), unfavorable, advanced cancers who may be cured by chemoradiation but have a useless larynx and permanent tracheostomy and/or gastrostomy.[40] These patients are best treated with a total laryngectomy, neck dissection, and postoperative RT.[45]

Carcinoma in Situ

Lesions diagnosed as carcinoma in situ can be treated with TLM. However, it is difficult to exclude the possibility of microinvasion on these specimens. Recurrence is frequent if the patient continues to smoke and the cord may become thickened and the voice hoarse with repeated treatments.

Early RT for carcinoma in situ often means a better chance of preserving a good voice, especially since many patients with this diagnosis eventually receive this treatment.[42]

Many patients with a diagnosis of carcinoma in situ have obvious lesions that probably contain invasive carcinoma. We have often proceeded with RT rather than put the patient through a repeated biopsy procedure.

Early Vocal Cord Carcinoma

In many centers, RT is the initial treatment prescribed for T1 and T2 lesions, with surgery reserved for salvage after RT failure.[18,46,47] However, TLM and TORS have shown comparable cure rates with the possibility of using RT for recurrences.[46,48,49] Supracricoid laryngectomy, as reported by Laccourreye et al,[50] is a procedure designed to remove moderate-sized cancers involving the supraglottic and glottic larynx. The larynx may be removed with preservation of the cricoid and the arytenoid with its neurovascular innervation; the defect is closed by approximating the base of the tongue to the remaining larynx. The oncologic and functional results of this procedure in selected patients are reported to be excellent. TLM may also provide high cure rates for select patients with small, well-defined lesions limited to the mid one-third of one true cord.[51-55] A small subset of TLM surgeons successfully use this technique for moderately advanced cancers.[46] The major advantage of RT compared with partial laryngectomy is better quality of the voice. The advantages of surgical treatments include avoidance of RT, single treatment, and cost-effectiveness. However, if voice quality is important for the patient, surgery should be avoided. Open partial laryngectomy finds its major use as salvage surgery in suitable cases after RT failure. Even if the patient has a local recurrence after salvage partial laryngectomy, there is a third chance with total laryngectomy, which may still be successful.

Verrucous lesions have the reputation of being unresponsive to RT and, in some instances, converting into invasive, often anaplastic, metastasizing lesions. Partial laryngectomy is recommended for early verrucous carcinoma of the glottis, but RT is recommended if the alternative is total laryngectomy. We have observed typical verrucous lesions that have disappeared with RT and not recurred. O'Sullivan et al[56] also made this observation. In addition, a variety of tumors that recur after unsuccessful treatment (with surgery, RT, and/or chemotherapy) are more likely to exhibit more aggressive behavior.

Moderately Advanced Vocal Cord Cancer

Fixed-cord lesions (T3) may be subdivided into relatively favorable or unfavorable lesions. Patients with unfavorable lesions usually have extensive bilateral disease with a compromised airway and are considered to be in the advanced group. Patients with favorable T3 lesions have disease confined mostly to one side of the larynx, have a good airway, and are reliable for follow-up. Some degree of supraglottic and subglottic extension usually exists. The extent of disease and tumor volume (≤3.5-4 mL), in particular, are related to the likelihood of control after RT.[40]

The patient with a favorable lesion is advised of the alternatives of RT with surgical salvage or immediate total laryngectomy. Recent data suggest that the likelihood of local- regional control is better after some altered fractionation schedules compared with conventional once-daily RT.[44,57] Follow-up examinations are recommended every 4 to 6 weeks for the first year, every 6 to 8 weeks for the second year, every 3 months for the third year, every 6 months for the fourth and fifth years, and annually thereafter. The patient must understand that total laryngectomy may be recommended purely on clinical grounds without biopsy-proven recurrence and that the risk of laryngeal osteochondronecrosis is about 5%.

Evaluation of cord mobility after 50.4 Gy or at the end of RT has not been helpful in predicting local control.[41] Some patients in whom the vocal cord remained fixed have had local tumor control of the disease for 2 years or longer after RT.

The major difficulty in using RT for the more advanced lesions is distinguishing radiation edema from local recurrence during follow-up examinations.[58] Progressive laryngeal edema, persistent throat pain, or fixation of a previously mobile vocal cord frequently signifies recurrent disease in the larynx, although a few patients with these findings remain disease-free with long-term follow-up.

Extended hemilaryngectomy has been used by a few surgeons in the treatment of well-lateralized fixed-cord lesions. A permanent tracheostomy is usually required because a portion of the cricoid is resected, but a useful voice may be retained.[59]

Advanced Vocal Cord Carcinoma

Advanced lesions usually show extensive subglottic and supraglottic extension, bilateral glottic involvement, and invasion of the thyroid, cricoid, and/or arytenoid cartilages.[9,23] The airway is compromised, necessitating a tracheostomy at the time of direct laryngoscopy in approximately 30% of patients. Clinically positive lymph nodes are found in about 25% to 30% of patients.

The mainstay of treatment is total laryngectomy, with or without adjuvant RT. The most frequent sites of local failure after total laryngectomy are the tracheal stoma, the base of the tongue, the neck lymph nodes, and/or or soft tissues of the neck. If the neck is clinically negative before surgery and if postoperative RT is planned, neck dissection may be withheld, and RT may be used to treat both sides of the neck.[60] However, in practice, most surgeons prefer to perform elective bilateral selective (levels II-IV) neck dissections in conjunction with a total laryngectomy for T3 N0 or T4 N0 laryngeal cancer, even if postoperative RT is planned. If the lymph nodes are clinically positive, a therapeutic neck dissection is performed at the time of laryngectomy.

The indications for postoperative RT include close or positive margins, significant subglottic extension (1 cm or more), cartilage invasion, perineural invasion, lymphovascular space invasion, extension of the primary tumor into the soft tissues of the neck, multiple positive neck nodes, and extracapsular extension.[61,62] Preoperative RT is indicated for patients who have fixed neck nodes, have had an emergency tracheotomy through tumor, or have direct extension of tumor involving the skin.

Definitive RT is prescribed for the patient who refuses total laryngectomy or is medically unsuitable for major surgery.

As previously stated, there is evidence that two to three cycles of induction chemotherapy followed by RT in patients obtaining at least a partial response may provide a moderate likelihood of larynx preservation without compromising cure.[39] Data suggest that concomitant chemotherapy and RT are more efficacious than RT alone or induction chemotherapy followed by RT.[42,43] The optimal combination of concomitant chemotherapy and irradiation is unclear.[44]

A randomized intergroup trial (Radiation Therapy Oncology Group [RTOG] 91-11) compared three treatment arms: arm A, three cycles of induction cisplatin and fluorouracil followed by RT in complete and partial

responders; arm B, RT and concomitant cisplatin (100 mg/m^2 on days 1, 22, and 43 of RT); and arm C, once-daily RT (70 Gy in 35 fractions over 7 weeks) alone.[42] Five hundred forty-seven patients were randomized and followed for a median of 3.8 years; 518 patients were evaluable. The rates of larynx preservation were as follows: arm A, 72%; arm B, 84%; and arm C, 67%. The rates of larynx presentation were significantly improved for arm B; there was no significant difference between arms A and C. The 5-year survival rates were similar for the three treatment groups: arm A, 55%; arm B, 54%; and arm C, 56%. The likelihood of developing distant metastases was lower for the two groups of patients who received adjuvant chemotherapy.

Surgical Treatment

Cordectomy is an excision of the vocal cord and may be performed by a TLM or TORS approach or externally by a thyrotomy. Its use is usually confined to small lesions of the middle one-third of the cord. After cordectomy, a pseudocord is formed, and the patient has a useful, if somewhat harsh, voice.

Vertical partial laryngectomy (ie, hemilaryngectomy) allows removal of limited cord lesions with preservation of voice. One entire cord with as much as one-third of the opposite cord with the adjacent thyroid cartilage is the maximum cordal involvement suitable for surgery in men; women have a smaller larynx, and usually only one vocal cord may be removed without compromising the airway. Partial fixation of one cord is not a contraindication to hemilaryngectomy; a few surgeons perform a hemilaryngectomy for selected fixed-cord lesions. The maximum subglottic extension suitable for hemilaryngectomy is 8 to 9 mm anteriorly and 5 mm posteriorly; this limit is necessary to preserve the integrity of the cricoid. Tumor extension to the epiglottis, false cord, or both arytenoids is a contraindication to hemilaryngectomy.

Supracricoid partial laryngectomy is used for selected T2 and T3 glottic carcinomas and entails removal of both true and false cords and the entire thyroid cartilage. The cricoid is sutured to the epiglottis and hyoid (cricohyoidoepiglottopexy).

Total laryngectomy with or without neck dissection is the operation of choice for advanced lesions and as a salvage procedure for RT failures in lesions that are not suitable for conservation surgery. The entire larynx is removed, and the pharynx is reconstructed. A permanent tracheostomy is required. Speech may be reconstituted with a prosthesis or with an electrolarynx. One hundred four (63%) of 166 patients entered into the surgery and postoperative irradiation arm of the Veterans Affairs Laryngeal Cancer Study Group randomized trial were evaluable for voice rehabilitation at 2 years after treatment.[63] Ninety-six patients had undergone a total laryngectomy and communicated as follows: tracheoesophageal, 27 (28%); esophageal, 5 (5%); artificial larynx, 47 (50%); nonvocal, 7 (7%); and no data, 10 (10%).[63] One hundred seventy-three patients underwent total laryngectomy and postoperative RT at the University of Florida, and 69 patients were evaluable for 5 years or longer.[37] Voice rehabilitation was accomplished as follows: tracheoesophageal, 19%; electrolarynx, 57%; esophageal, 3%; nonvocal, 14%; and no data, 7%.

Radiation Therapy Technique

RT for T1 or T2 vocal cord cancer is delivered by small portals covering only the primary lesion.[47] The cervical lymph node chain is not electively treated. For T1 lesions, RT portals extend from the thyroid notch superiorly to the inferior border of the cricoid and fall off anteriorly. The posterior border depends on the posterior extension of the tumor.[21] For T2 tumors, the field is extended depending on the anatomic distribution of the tumor. The field size ranges from 4×4 cm^2 to 5×5 cm^2 (plus an additional 1.0 cm of "flash" anteriorly) and is occasionally 6×6 cm^2 for a large T2 lesion. Portals larger than this increase the risk of edema without improving the cure rate. Intensity-modulated RT (IMRT) may be considered for T1-T2 glottic cancers to reduce the dose to carotid arteries.[47] The potential advantages of this technique must be weighed against the potential increased likelihood of a marginal miss.

A commonly used dose fractionation schedule at many institutions is 66 Gy for T1 lesions and 70 Gy for T2 cancers, given in 2-Gy fractions. Evidence suggests that increasing the dose per fraction may improve the likelihood of local control.[64-68] Ample data suggest that 1.8 Gy once daily

results in significantly lower local control rates compared with 2.0 Gy once daily.[65] Yamazaki et al[69] reported a prospective trial in which patients with T1 N0 squamous cell carcinoma of the glottic larynx were randomized to definitive RT at 2.0 or 2.25 Gy per fraction. The 5-year local control rates were 77% after 2.0 Gy per fraction and 92% after Gy per fraction (P = .004); there was no difference in either acute or late toxicity. Patients with T1 or T2 vocal cord cancer treated with once-a-day fractionation at the University of Florida are irradiated with 2.25-Gy fractions; the dose fractionation schemes used are as follows: Tis-T2 A, 63.0 Gy in 28 fractions, and T2B, 65.25 Gy in 29 fractions. Concomitant weekly cisplatin 30 ng/M^2 is considered for patients with T2 B cancers.

At the University of Florida, patients are treated in the supine position; the field borders for a patient with a T1 N0 cancer are depicted in Figure 53.7.[21] A three-field technique, using 4- or 6-MV x-rays, is used to deliver approximately 95% of the dose through opposed lateral wedged fields weighted to the side of the lesion; the remaining dose is delivered by an anterior field shifted 0.5 cm toward the side of the lesion (Figure 53.8).[21] The tumor dose is usually specified at the 95% normalized isodose line.

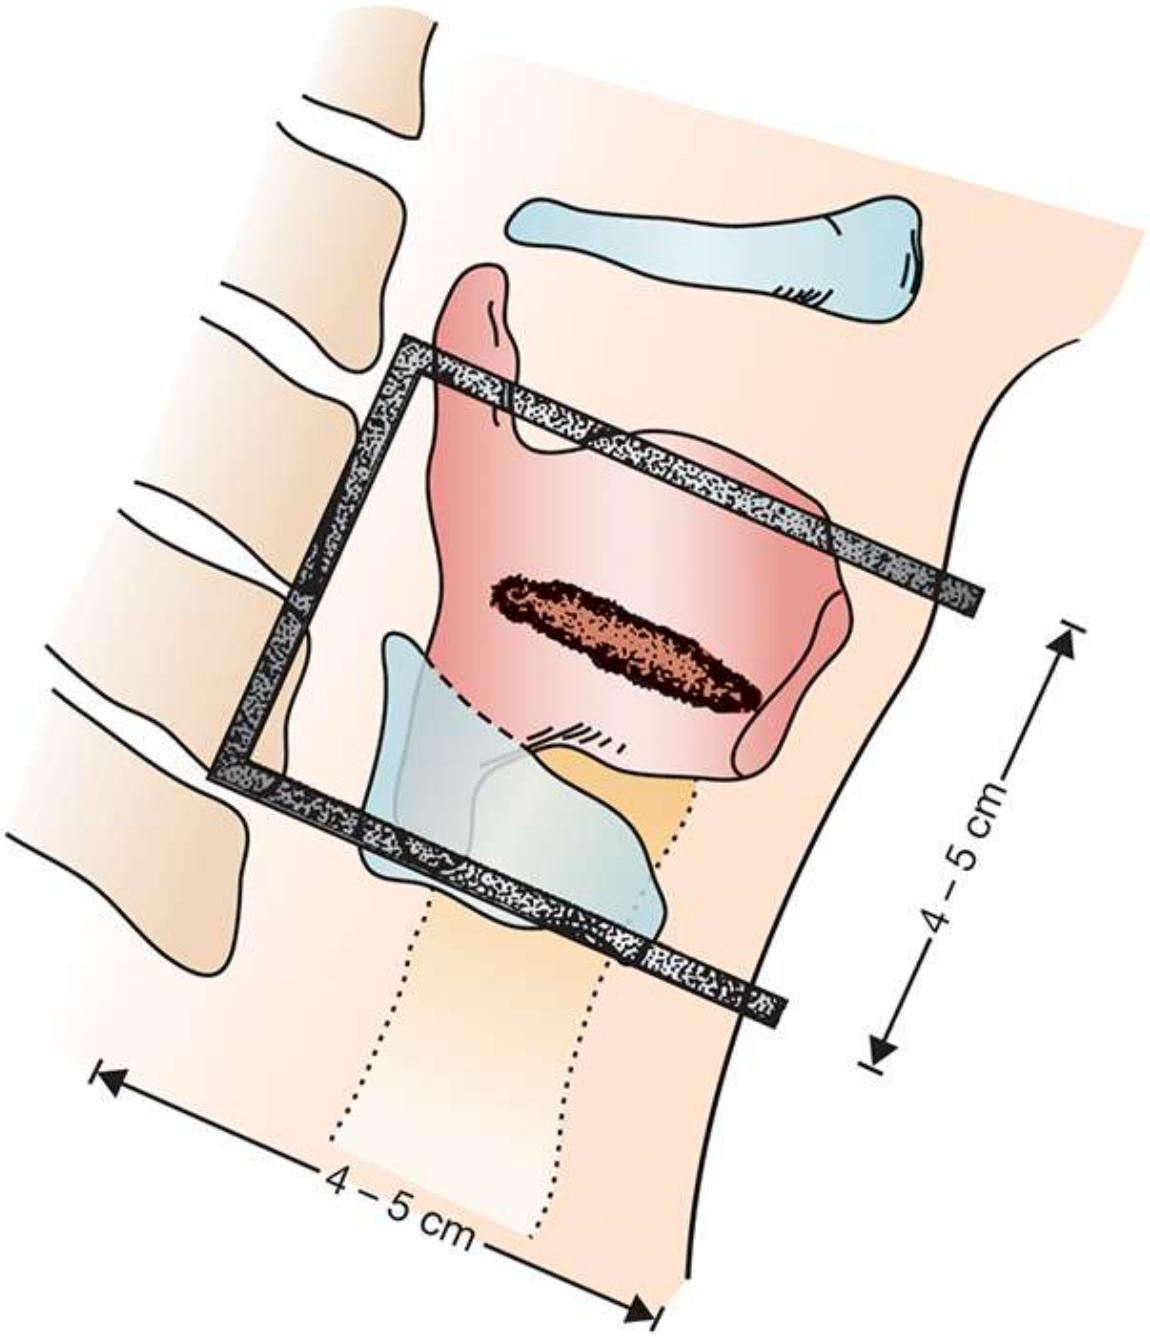

FIGURE 53.7 Treatment portal for early glottic carcinoma. The top border is adjusted according to the lesion. The middle of the thyroid notch is the landmark for very early lesions, and the top of the notch is the marker for larger lesions or those with minimal supraglottic extension. The posterior border is 1 cm posterior to the back edge of the thyroid cartilage if the lesion is confined to the anterior two-thirds of the vocal cord; if the posterior one-third of the vocal cord is involved, the posterior border is placed 1.0 to 1.5 cm behind the cartilage. The inferior border is placed at the bottom of the cricoid cartilage if there is no subglottic extension. (Reprinted with permission from Million RR, Cassisi NJ. Larynx. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach*. 2nd ed. J.B. Lippincott; 1994:431-497.)

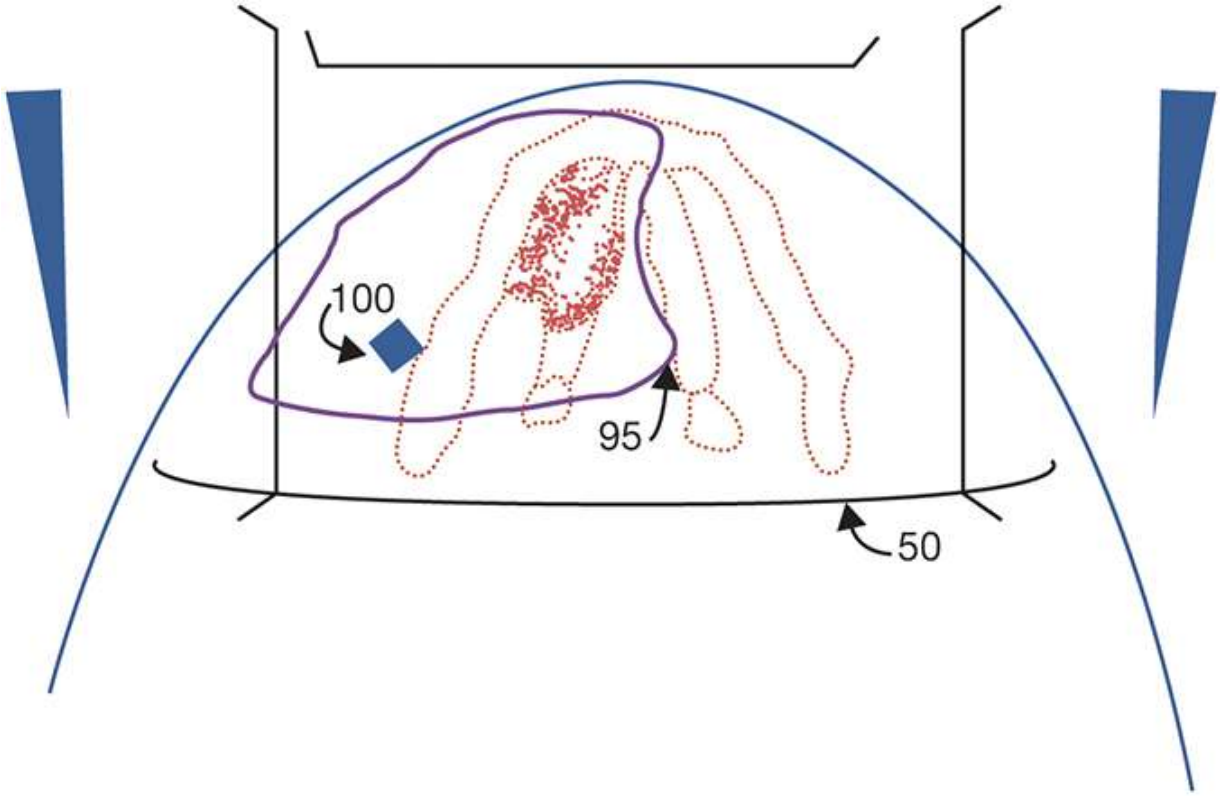

FIGURE 53.8 Normalized isodose distribution for three-field technique for the treatment of a tumor involving the anterior two-thirds of one true vocal cord. The dose is specified at the 95% isodose line. (Reprinted with permission from Million RR, Cassisi NJ. Larynx. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach*. 2nd ed. J.B. Lippincott; 1994:431-497.)

RT of T3 and T4 lesions requires larger portals, which include the levels II and III lymph nodes (Figure 53.9).[20,70] The level IV lymph nodes are included in a separate low neck portal. Patients treated at the University of Florida are irradiated in a continuous course twice daily at 1.2 Gy per fraction to a total dose of 74.4 Gy. The portals are reduced after 50.4 Gy in 42 fractions; the reduced portals cover only the primary lesion.

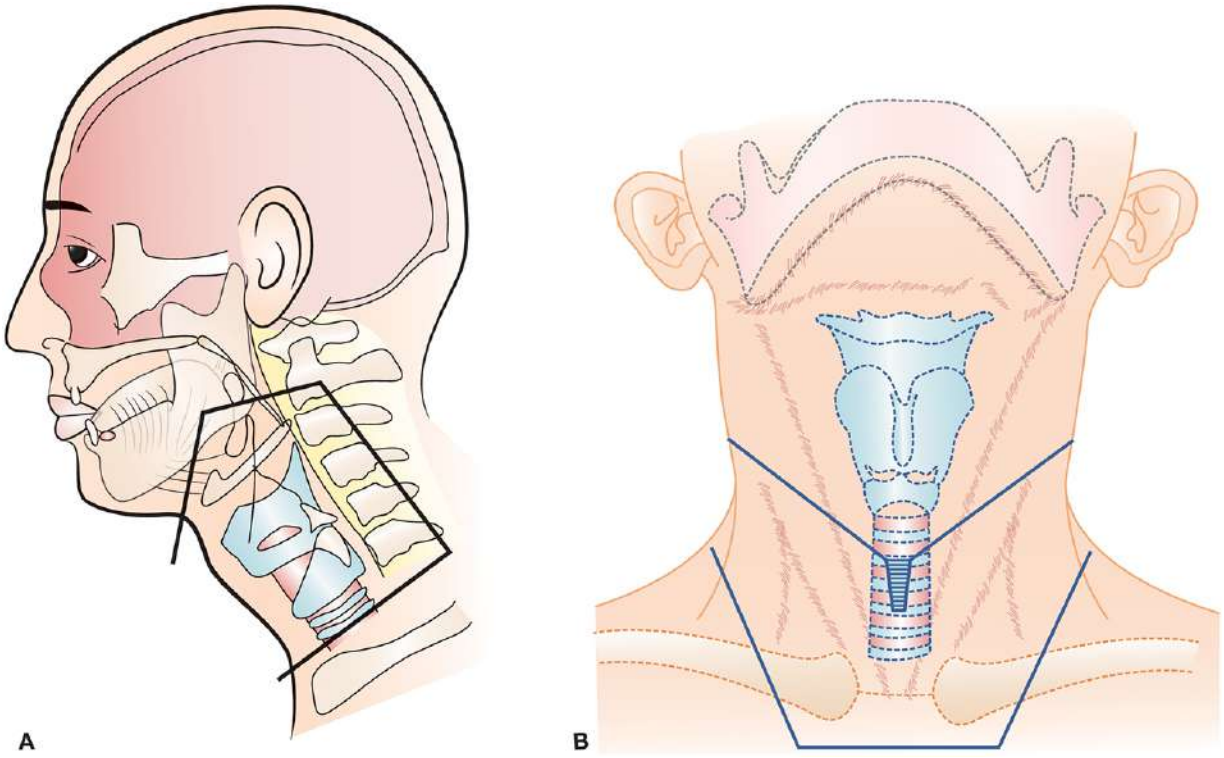

FIGURE 53.9 A. Radiation treatment technique for carcinoma of glottic larynx, stage T3-T4 N0. The patient is treated supine, and the field is shaped with Lipowitz metal. Anteriorly, the field is allowed to fall off. The entire preepiglottic space is included by encompassing the hyoid bone and epiglottis. The superior border (just above the angle of the mandible) includes the jugulodigastric lymph nodes. Posteriorly, a portion of the spinal cord must be included within the field to ensure adequate coverage of the midjugular lymph nodes; spinal accessory lymph nodes themselves are at little risk of involvement. The lower border is slanted to facilitate matching with the low neck field and to reduce the length of spinal cord in the high-dose field. The inferior border is placed at the bottom of the cricoid cartilage if the patient has no subglottic spread; in the presence of subglottic extension, the inferior border must be lowered according to the disease extent. B. Example of a low neck portal for T3 N0 glottic carcinoma. The main nodes at risk are the low jugular and lateral paratracheal. The Delphian node would be in the primary portal. A very narrow and short midline shield is used. (A. From Parsons JT, Mendenhall WM, Mancuso AA, Cassisi NJ, Stringer SP, Million RR. Twice-a-day radiotherapy for T3 squamous cell carcinoma of the glottic larynx. *Head Neck*. 1989;11(2):123-128. Copyright © 1989 Wiley Periodicals, A Wiley Company. Reprinted by permission of John Wiley & Sons. B. Reprinted with permission from Million RR, Cassisi NJ, Mancuso AA, et al. Management of the neck for squamous cell carcinoma. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach*. 2nd ed. J.B. Lippincott; 1994:75-143.)

IMRT is used if there is a clear advantage associated with this technique. Disadvantages associated with IMRT include increased dose inhomogeneity, increased total body dose, and increased labor and

expense.[71] The most common indications for IMRT for laryngeal cancers would be the occasional patients with a node-positive T3-T4 cancer, where the retropharyngeal nodes would be electively irradiated and the dose to the contralateral parotid gland reduced, and/or a difficult low match between the lateral fields used to treat the primary site and upper neck and the anterior low neck field in a patient with a short neck and large shoulders. In the latter instance, IMRT could be used to encompass the entire target volume and avoid the problem of field junctioning entirely. IMRT is especially useful for patients with extensive subglottic invasion, where achieving an adequate inferior margin with conventional lateral portals may not be possible.

Evidence from both retrospective and randomized trials points to improved therapeutic ratios with altered fractionation schedules.[44] Given that RT is effective treatment for head and neck primary squamous cell carcinoma, it should not be surprising that higher doses of RT given more intensively would be more effective at providing tumor control. Because most observers have noted no increase in late toxicity with the various regimens, it generally is concluded that these schedules yield an improved therapeutic ratio. A recently updated RTOG 90-03 trial reported on 1,073 patients who were randomly selected to receive one of four fractionation schedules[57,72,73]:

1. Standard fractionation: 2 Gy per fraction, once a day, 5 days a week, to a total dose of 70 Gy in 35 fractions over 7 weeks
2. Hyperfractionation: 1.2 Gy per fraction, twice daily (≥6 hours apart), 5 days a week, to a total dose of 81.6 Gy in 68 fractions over 7 weeks
3. Accelerated fractionation with split: 1.6 Gy per fraction, twice daily (≥6 hours apart), 5 days a week, to a total dose of 67.2 Gy in 42 fractions over 6 weeks, including a 2-week rest after 38.4 Gy
4. Accelerated fractionation with concomitant boost: 1.8 Gy per fraction, once a day, 5 days a week to a large field, plus 1.5 Gy per fraction once a day to a boost field given 6 hours or more after treatment of the large field for the last 12 treatments days, to a total dose of 72 Gy in 42 fractions over 6 weeks

The 5-year local-regional failure rates were as follows: standard fractionation, 59%; hyperfractionation, 51%; accelerated split course, 58%; and concomitant boost, 52%. Both the hyperfractionation and concomitant schedules boost yielded local-regional control rates that were significantly better than those with standard fractionation. There was a trend toward improved overall survival with hyperfractionation, but no difference in cause-specific survival. Acute toxicity was increased with all three altered fractionation schedules; there was a modest increase in late effects with the concomitant boost schedule.

The treatment technique used for postoperative RT after total laryngectomy is depicted in Figure 53.10.[61] The treatment technique for preoperative RT is essentially the same as that used for RT alone. Alternatively, IMRT may be employed for the indications discussed previously.

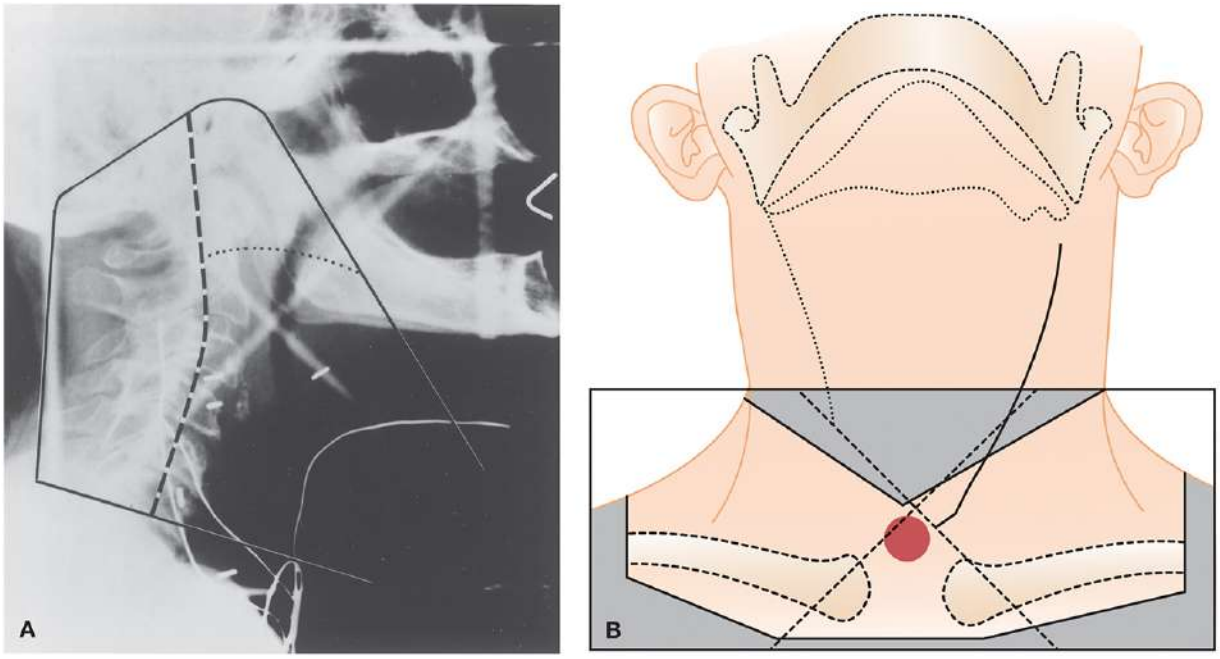

FIGURE 53.10 A. Typical simulation film for postoperative treatment of advanced cancer of the laryngopharynx. If the neck is pathologically negative, the superior field border is lowered to 2 cm above the angle of the mandible. The initial "off-cord" reduction (50 Gy) (broken line) and the final reduction (dotted line) are indicated. Wires mark the surgical scars and stoma. The slanting line used on the lower border reduces the length of spinal cord treated by the primary field, allows better caudal coverage of the mucosal surfaces while simultaneously bypassing the shoulders, and facilitates matching of the low neck field. B. Schematic diagram of the low neck field. The rectangle (solid line) represents the light field. The shaded areas represent the blocked portions of the field (stacked lead blocks). The superior border of the neck field is the inferior border of the primary field. The actual line is treated only in the primary field. The upper border of the low neck field assumes a V shape. In the midline of the patient, the apex of the V generally is at or close to the central axis (broken lines) so that the portal that treats the spinal cord is not divergent in its upper portion and diverges away from the primary fields in its lower portion. At the junction of the three fields, a short (2-3 cm) segment of spinal cord remains untreated by any of the three fields. Treatment of Recurrence

Most recurrences appear within 18 months, but late recurrences may appear after 5 years. The latter are likely second primary malignancies. The risk of metastatic disease in lymph nodes increases with local recurrence.[18]

Recurrence After Radiation Therapy

With careful follow-up, recurrence is sometimes detected before the patient notices a return of hoarseness. There is often minimal lymphedema for 1 to 2 months after RT, which usually subsides or stabilizes. An increase in edema, particularly if associated with hoarseness or pain, suggests recurrence, even if there is no obvious tumor. Fixation of a previously mobile vocal cord usually implies local recurrence, but we have occasionally observed a patient who has experienced a fixed cord with an otherwise normal-appearing larynx and who has not shown evidence of recurrence.

It may be difficult to diagnose recurrence if the tumor is submucosal. Generous, deep biopsies are required. If recurrence is strongly suspected, laryngectomy may rarely be advised without biopsy-confirmed evidence of recurrence. PET may be useful to distinguish recurrent tumor from necrosis.

RT failures may be salvaged by cordectomy, hemilaryngectomy, supracricoid partial laryngectomy, or total laryngectomy. Biller et al[74] reported a 78% salvage rate by hemilaryngectomy for 18 selected patients in whom RT failed; total laryngectomy was eventually required in two patients. Only two patients died of cancer. These investigators offered guidelines for using hemilaryngectomy: contralateral vocal cord is normal, arytenoid is not involved, subglottic extension does not exceed 5 mm, and vocal cord is not fixed. In our experience, 14 patients irradiated for T1 or T2 vocal cord cancers underwent a hemilaryngectomy after local recurrence, and 8 were successfully salvaged.[18]

Recurrence After Surgery

The rate of salvage by RT for recurrences or new tumors that appear after initial treatment by hemilaryngectomy is about 50%. Lee et al[75] reported seven successes among 12 patients; one lesion was later controlled by total laryngectomy. Total laryngectomy can be used successfully to treat hemilaryngectomy failures not suitable for RT. RT rarely cures patients with recurrence in the neck or stoma after total laryngectomy.

TREATMENT OF SUPRAGLOTTIC LARYNX CARCINOMA

Selection of Treatment Modality

Patients with supraglottic laryngeal carcinoma may be considered to be in an early or favorable group suitable for RT or conservation laryngectomy or an unfavorable group often requiring total laryngectomy.

Early and Moderately Advanced Supraglottic Lesions

Treatment of the primary lesion for the early group is by RT or supraglottic laryngectomy, with or without adjuvant RT.[76] TLM or TORS[77] is effective in experienced hands for small, selected lesions.[52] Total laryngectomy is rarely indicated as the initial treatment for this group of patients and is reserved for treatment failures. RT and supraglottic laryngectomy are highly successful modes of therapy for early lesions.[76]

The decision to use RT or supraglottic laryngectomy depends on several factors, including the anatomic extent of the tumor, medical condition of the patient, philosophy of the attending physician(s), and inclination of the patient and family. Overall, about 80% of patients are treated initially by RT. Approximately half of the patients seen in our clinic whose lesions are technically suitable for a supraglottic laryngectomy are not suitable for medical reasons (eg, inadequate pulmonary status or other major medical problems); these patients are treated with RT.

Analysis of local control by anatomic site within the supraglottic larynx shows no obvious differences in local control by RT for similarly staged lesions. Invasion of the preepiglottic space is not a contraindication to supraglottic laryngectomy or RT. Primary tumor volume based on pretreatment CT is inversely related to local tumor control after RT.[40] A large, bulky (>6 mL) infiltrative lesion, especially one with extensive preepiglottic space invasion, is a common reason to select supraglottic laryngectomy.

The status of the neck often determines the selection of treatment of the primary lesion. Patients with clinically negative neck nodes have a high risk for occult neck disease and may be treated by RT or supraglottic laryngectomy and bilateral selective neck dissections (levels II-IV).

If a patient has an early-stage primary lesion but advanced neck disease (N2b or N3), combined treatment is frequently necessary to control the neck disease.[38] In these cases, the primary lesion is usually treated by definitive RT, with surgery added to the treatment of the involved neck

site(s). If the same patient were treated with supraglottic laryngectomy, neck dissection, and postoperative RT, the portals would unnecessarily cover the primary site and the neck. If the patient has early, resectable neck disease (N1 or N2a) and surgery is elected for the primary site, postoperative RT is added only because of unexpected findings (eg, positive margins, multiple positive nodes, or extracapsular extension). We prefer to avoid routine high-dose preoperative or postoperative RT in conjunction with a supraglottic laryngectomy because the lymphedema of the remaining larynx may be considerable, although it eventually subsides. However, Lee et al[78] from the MD Anderson Cancer Center reported excellent results with combined supraglottic laryngectomy and postoperative RT for moderately advanced lesions.

Advanced Supraglottic Lesions

Although a subset of these patients may be suitable for a supraglottic or supracricoid laryngectomy, total laryngectomy is the main surgical option. Selected advanced lesions, especially those that are mainly exophytic, may be treated by RT and concomitant chemotherapy,[43] with total laryngectomy reserved for RT failures.

For patients whose primary lesion is to be treated by a total or partial laryngectomy and who have resectable neck disease, surgery is the initial treatment, and postoperative RT is added if needed. If the neck disease is unresectable, preoperative RT is used. The indications for preoperative and postoperative RT have been previously outlined.

Surgical Treatment

Supraglottic Laryngectomy

Supraglottic laryngectomy is voice-sparing surgery that can be used successfully for selected lesions involving the epiglottis, a single arytenoid, the aryepiglottic fold, or the false vocal cord. This can be performed via TLM or TORS.[33] Extension of the tumor to the true vocal cord, the anterior commissure, or both arytenoids, fixation of the vocal cord, or thyroid or cricoid cartilage invasion precludes supraglottic laryngectomy. The supraglottic laryngectomy may be extended to include the base of the tongue if one lingual artery is preserved.

All patients have difficulty swallowing, with a tendency to aspirate immediately after surgery, but almost all learn to swallow again in a short time; motivation and the amount of tissue removed are key factors in learning to swallow again. Preoperatively, adequate pulmonary reserve is evaluated by blood gas determinations, function tests, chest roentgenography, and a work test involving walking the patient up two flights of stairs to determine tolerance to pulmonary stress. The voice quality is generally normal after supraglottic laryngectomy.

Supracricoid Laryngectomy

This procedure is an option for lesions extending from the supraglottis into one or both vocal cords. However, vocal cord fixation is a relative contraindication. At least one arytenoid must be preserved for successful decannulation and phonation. Extension to the cricoid and thyroid cartilage destruction also preclude its use. Phonation and respiratory function are reconstituted by approximating the cricoid to the hyoid (cricohyoidopexy).

Wide-Field Total Laryngectomy

Total laryngectomy is performed as previously described.

Radiation Therapy

The primary lesion and both sides of the neck are treated with opposed lateral portals; wedges are used to compensate for the contour of the neck (Figure 53.11).[21] The lower neck nodes are irradiated through a separate anterior portal. IMRT may be employed to spare one or both parotids and to avoid a low match line in the occasional patient with a short neck and large shoulders. We currently use either hyperfractionation or simultaneous integrated boost. The latter schedule delivers 70 Gy in 35 fractions over 30 treatment days in 6 weeks with 1 twice-daily fraction during the last 5 weeks (with a minimum 6-hour interfraction interval). The high-risk clinical target volume (CTV) encompasses the gross disease, the intermediate-risk CTV receives 63 Gy at 1.8 Gy per fraction, and the standard-risk CTV receives 56 Gy at 1.65 Gy per fraction.

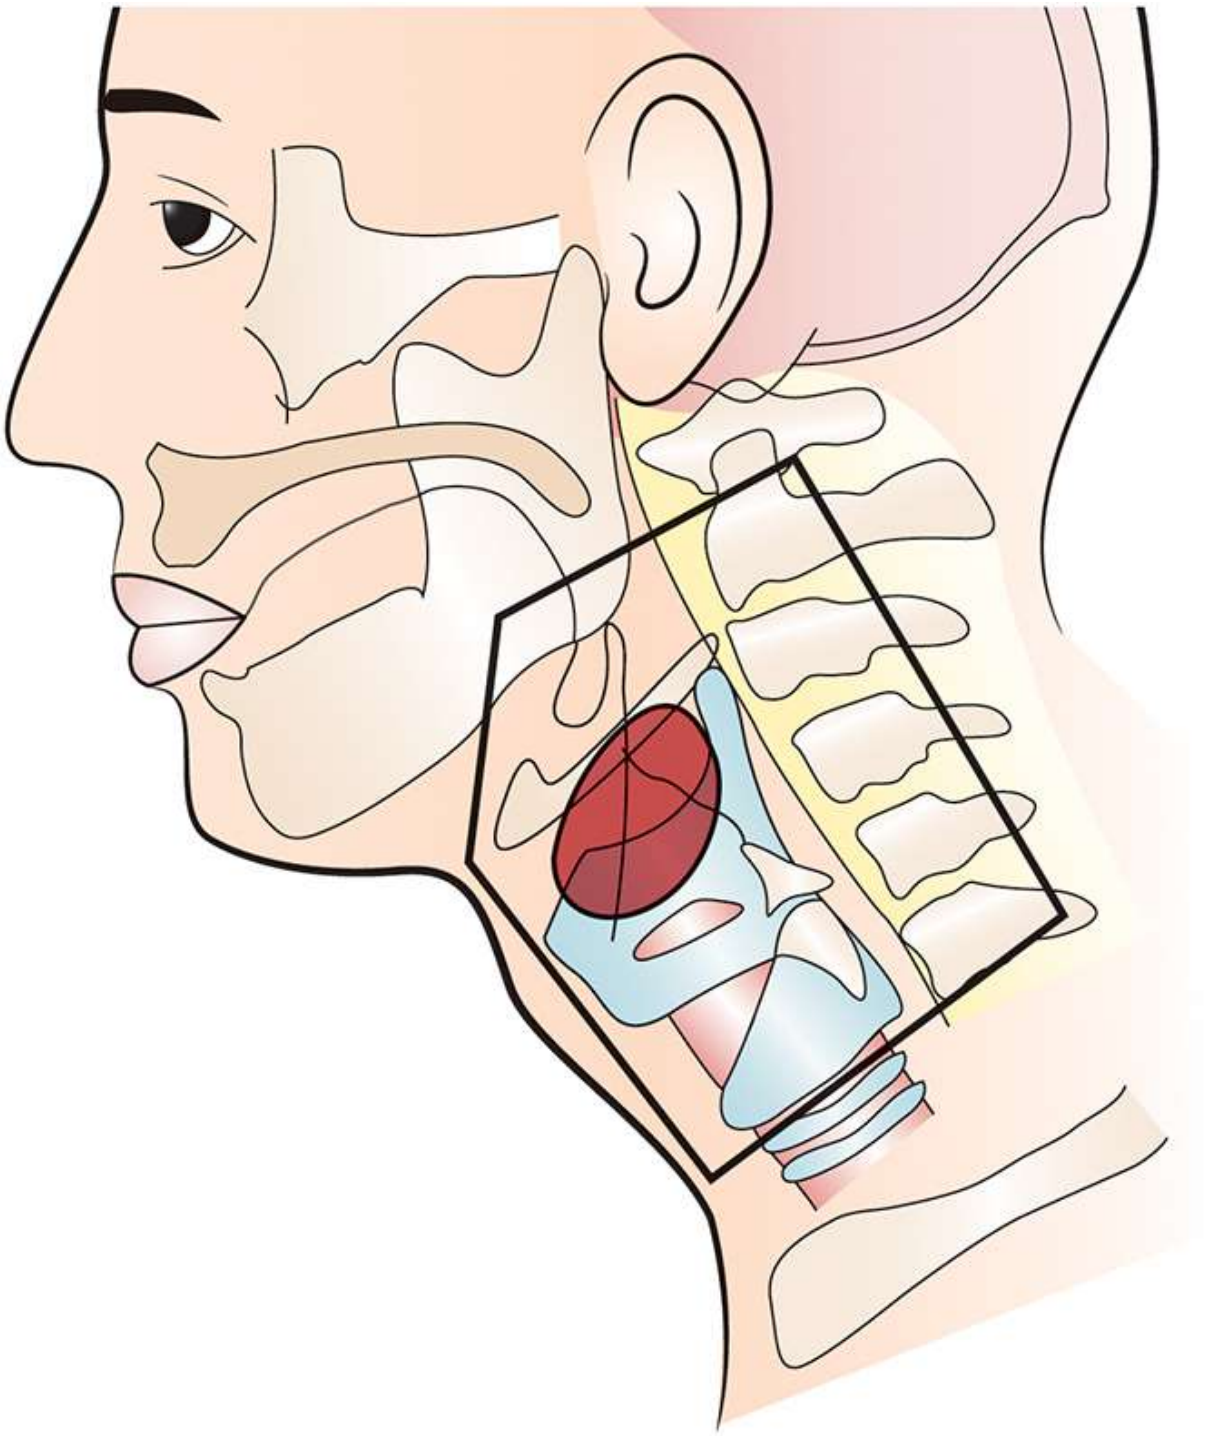

FIGURE 53.11 Example of the portal for a lesion of the lower epiglottis or false vocal cord and a clinically negative neck. The subdigastric nodes are included, but not the junctional nodes. Depending on the anatomy and tumor extent, the anterior border may fall off (ie, "flash") or a small strip of skin may be shielded. (Reprinted with permission from Million RR, Cassisi NJ, Mancuso AA, et al. Management of the neck for squamous cell carcinoma. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach*. 2nd ed. J.B. Lippincott; 1994:75-143.)

In the case of clinically positive nodes, an electron beam portal may be used to increase the dose to the posterior cervical nodes after the fields are reduced to avoid the spinal cord at 45 Gy if parallel opposed fields are employed. CT is obtained 4 weeks after completing RT, and a neck dissection is added if the residual cancer in the nodes is believed to exceed 5%; otherwise, the patient is observed, and a CT is repeated in 3 months.[38] Alternatively, a PET-CT is obtained at 3 months, and a neck dissection is added if persistent positive nodes are observed.

Patients experience a sore throat, loss of taste, and moderate dryness during RT. Edema of the arytenoids may occur and give a sensation of a lump in the throat. Tracheostomy is rarely necessary, even for bulky lesions.

Edema of the larynx may persist for several months to a year. Patients who continue to smoke heighten the side effects of dryness, dysphagia, and hoarseness.

Preoperative and Postoperative Treatment Technique

If total laryngectomy is required and the lesion is resectable, postoperative RT is preferred because there is no evidence that preoperative RT produces any better local-regional control or survival rates than surgery and postoperative RT. Irradiation is added for close or positive margins, invasion of soft tissues of the neck, significant subglottic extension (1 cm or more), thyroid cartilage invasion, multiple positive nodes, and extracapsular extension. The high-risk areas are usually the base of the tongue and the neck.

The dose for postoperative RT as a function of known residual disease is as follows: negative margins, 60 Gy in 30 fractions; microscopically positive margins, 66 Gy in 33 fractions; and gross residual disease, 70 Gy in 35 fractions. All patients are treated with a continuous course, one fraction per day, 5 days per week. The lower neck is treated with doses of 50 Gy in 25 fractions at D_{max}. If there is subglottic extension, the dose to the stoma is boosted with electrons (usually 10-14 MeV) for an additional 10 Gy in five fractions. The treatment technique is shown in Figure 53.10.[61] If postoperative RT is added after supraglottic laryngectomy, dose is lowered to 55.8 Gy given in 1.8-Gy fractions. This dose produces acceptable rates of local control and laryngeal edema.[78]

The treatment technique used for preoperative RT is essentially the same as that used for patients treated with RT alone, using doses of 50 to 60 Gy at 1.8 to 2.0 Gy per fraction. Thereafter, the dose is boosted to areas of unresectable disease (usually the neck) to total doses ranging from 66 to 70 Gy.

Treatment of Recurrence

Failures after supraglottic laryngectomy or RT can frequently be controlled by further treatment; therefore, recognition of recurrence should be vigorously pursued.[76] Salvage of patients with recurrence after combined total laryngectomy and RT is uncommon. Stomal recurrences are occasionally controlled by RT or surgery; however, the average lifespan after stomal recurrence is 6.3 months.[79]

RESULTS OF TREATMENT

Vocal Cord Cancer

The local control and survival rates after treatment of early-stage glottic carcinoma are depicted in Tables 53.3 to 53.6.[46] Mendenhall et al[80] recently reported on 50 patients treated at the University of Florida with definitive RT for carcinoma in situ and observed the following 5-year outcomes: local control, 91%; ultimate local control with larynx preservation, 93%; and ultimate local-regional control, 100%. Chera et al[47] reported on 585 patients at the University of Florida for T1-T2 N0 glottic carcinoma and observed the following 5-year local control rates: T1 A1, 95%; T1 B, 94%; T2 A, 81%; and T2 B, 74%. The local control and survival rates are similar for transoral laser excision, open partial laryngectomy, and RT. Larynx preservation rates are also comparable. Voice quality depends on the amount of tissue removed with partial laryngectomy and is probably similar for patients with limited lesions treated with laser to those undergoing RT and poorer for patients undergoing open partial laryngectomy.[46]

Foote et al[81] reported on 81 patients who underwent laryngectomy for T3 cancers at the Mayo Clinic between 1970 and 1981. Seventy-five patients underwent a total laryngectomy and six underwent a near-total laryngectomy; 53 patients received a neck dissection. No patient underwent adjuvant irradiation or chemotherapy. The 5-year rates of local-regional control, cause-specific survival, and absolute survival were 74%, 74%, and 54%, respectively. The results of definitive RT patients with T3 glottic carcinoma are depicted in Table 53.7[70] and are similar to the surgical outcomes reported by Foote et al.[81]

The survival and control rates of patients with T3 fixed-cord lesions treated at the University of Florida are presented in Table 53.8.[82] There was no relationship between subsequent local control and whether the vocal cord remained fixed or became mobile during irradiation. The incidence of severe complications, including those after the initial treatment and any later salvage procedures, was 15% after RT alone and 15% after surgery alone or combined with adjuvant irradiation. The vocal quality varied from fair to nearly normal. Hinerman et al[34] recently reported an update on the University of Florida experience treating fixed-cord T3 glottic cancers with definitive RT and reported a 5-year local control rate after RT of 63%.

TABLE 53.8 T3 GLOTTIC CARCINOMA TREATED AT THE UNIVERSITY OF FLORIDA, 1965-1988: 5-YEAR RESULTS

Parameter	Radiotherapy Alone (53 Patients)	Surgery With or Without (65 Adjuvant Radiotherapy Patients)
Local-regional control (%)	62	75
Ultimate control local-regional (%)	84	82
Absolute survival (%)	55	45
Cause-specific survival (%)	75	71

The results of treatment of T4 vocal cord carcinoma in four surgical series and two radiotherapy series are summarized in Table 53.9.[64] Hinerman et al[34] observed an 81% 5-year local control rate in 22 selected patients with favorable T4 cancers treated with definitive RT at the University of Florida.

Parsons et al[83] reviewed the literature and reported a local control rate of 62% in a series of 87 patients treated with RT alone for T4 glottic carcinoma.

Supraglottic Cancer

The proportion of patients suitable for a supraglottic laryngectomy is depicted in Table 53.10.[76] Depending on the referral patterns, a modest subset of patients is suitable for this operation. The extent of neck disease for patients treated with either surgery or RT is shown in Table 53.11.[76] In general, patients treated with supraglottic laryngectomy appropriately have earlier stage neck disease and would be anticipated to have a lower risk of distant failure and improved survival. The local control rates after transoral laser, RT, and supraglottic laryngectomy are summarized in Tables 53.12 to 53.14.[76] In general, the local control rates after transoral laser excision are fairly good for patients with T1-T2 tumors and tend to deteriorate for those with more advanced disease. The local control rate for patients selected for supraglottic laryngectomy is excellent. However, the incidence of severe

complications tends to be higher after supraglottic laryngectomy compared with RT and transoral laser excision (Table 53.15).[76,84]

LARYNGECTOMY VERSUS ORGAN PRESERVATION

Treatment of advanced laryngeal cancer carries significant morbidity with deteriorations in quality of life. Thus, many centers and patients have elected to pursue organ preservation strategies. The first major breakthrough in organ preservation came with the Department of Veterans Affairs Laryngeal Cancer Study Group Trial ("The VA Trial").[39] Stage III and IV patients were randomized to total laryngectomy followed by RT versus RT or induction chemotherapy + RT. The conclusion was that induction chemotherapy + RT produced equivalent survival to total laryngectomy + RT. In 2003, the RTOG 91-11 study randomized patients to organ preservation modalities and found that concurrent chemotherapy and RT (CCRT) produced superior survival outcomes. Following these studies, the employment of CCRT for advanced laryngeal cancer has risen significantly.

In 2006, Hoffman et al[85] used the National Cancer Database and found that of all cancers in the United States, laryngeal cancer is the only one with a declining survival rate. While early-stage cancer maintains high survival outcomes, patients with advanced disease have a declining lifespan. This pattern coincides with the trend of increased use of organ preservation and decreased use of total laryngectomy for advanced laryngeal cancers.

Over the past 15 years, there has been great interest in reexamining the optimal treatment for advanced laryngeal cancers. In 2007, Chen and Halpern[86] analyzed 10,590 patients from the late 1990s and found that total laryngectomy had superior survival outcomes compared to RT or CCRT. In 2009, Gourin et al[87] analyzed a population of patients treated between 1985 and 2002 and found that patients with stage IV disease had improved 5-year survival compared to organ preservation. In 2012, Dziegielewski et al[88] performed a population-based analysis of survival from 1998 to 2008 and found that T3 and T4a laryngeal cancers treated with total laryngectomy + RT had improved overall and disease-free survival. The 5-year survival rates for T3 cancers treated with total laryngectomy + RT, RT, and chemoradiotherapy (CRT) were 70%, 18%, and 52%, respectively. For T4a disease, these figures were 49%, 5%, and 16%. In 2014, Megwalu and Sikora[89] found similar survival outcomes using the Surveillance, Epidemiology, and End Results database to analyze 5,394 patients with

stage III and stage IV laryngeal carcinomas treated between 1992 and 2009. Disease-specific survival rates for surgically treated patients at 2 and 5 years were 70% and 64% versus organ preservation strategies, which yielded rates of 55% and 51%. Multivariate analysis, accounting for the year of diagnosis, stage, age, sex, subsite, race, and marital status, continued to show improved disease-specific and overall survival for patients receiving primary surgery.

Since the initial VA trial, advanced laryngeal cancer survival outcomes have deteriorated, prompting debate on whether the results of the trial can be widely applied to all advanced laryngeal cancer.[90] Population-based studies have shown that treatment strategies need to be tailored to the patient and that T stage is a better determinant of survival than the overall stage.[87,88] It has become widely accepted that the majority of patients with T4a cancer will experience better survival and functional outcomes when treated with laryngectomy versus organ preservation.[87-89] However, the debate over which T3 tumors can be optimally treated with CRT continues.[91]

FOLLOW-UP POLICY

Follow-up of patients with early lesions is planned for every 4 to 8 weeks for 2 years, every 3 months for the third year, every 6 months for years 4 and 5, and then annually for life.

Follow-up of patients with vocal cord or supraglottic larynx lesions treated by RT or conservative surgery is almost more important than the treatment itself because early detection of recurrence usually results in salvage that may include cure with voice preservation.

If recurrence is suspected but the biopsy is negative, patients are reexamined at 2- to 4-week intervals until the matter is settled. The value of follow-up CT scans for detecting early local recurrence is investigational.

Wagenfeld et al[92] studied 740 cases of glottic larynx cancer treated from 1965 to 1974 to determine the incidence of second respiratory tract malignancies. There was a minimum follow-up of 5 years. There were 48 second respiratory tract malignancies, although only 14 were expected. Twenty-five were in the lung, and 23 were scattered among other head and neck sites. Only 7 of the 23 second head and neck primary lesions resulted

in death; these second lesions were frequently diagnosed in an early stage during routine follow-up for the glottic lesion.

Because the risk of a lethal lung primary lesion is nearly as great as that of dying of an early glottic carcinoma, it makes sense to obtain annual chest roentgenograms. Approximately 50% of patients who receive moderate- to high-dose RT to the entire thyroid gland will develop hypothyroidism within 5 years, and so thyroid functions are checked every 6 to 12 months and thyroid replacement is initiated if the thyroid-stimulating hormone level begins to rise.[93]

SEQUELAE OF TREATMENT

Surgical Sequelae

Neel et al[94] reported a 26% incidence of nonfatal complications for cordectomy. Immediate postoperative complications included atelectasis and pneumonia, severe subcutaneous emphysema in the neck, bleeding from the tracheotomy site or larynx, wound complications, and airway obstruction requiring tracheotomy. Late complications included granulation tissue that had to be removed by direct laryngoscopy to exclude recurrences, extrusion of cartilage, laryngeal stenosis, and obstructing laryngeal web.

The postoperative complications and sequelae of hemilaryngectomy include chondritis, wound slough, inadequate glottic closure, and anterior commissure webs.[95] The complications associated with supraglottic laryngectomy and total laryngectomy for supraglottic carcinomas include fistula (8%), carotid artery exposure or blowout (3%-5%), infection or wound sloughing (3%-7%), and fatal complications (3%).[95] The risk of complication increased if tumor margins were involved by tumor; there was no change in risk associated with age, sex, race, laryngeal site, stage of primary tumor, size of primary tumor, use of low-dose preoperative RT, or status of the positive nodes.

The incidence of complications after treatment of supraglottic carcinoma is given in Table 53.15.[76]

Radiation Therapy Sequelae

The acute reactions from the treatment of early vocal cord cancer using a tumor dose of 2.25 Gy per day to administer a total dose 63 Gy (4- or 6-MV photons, five fractions per week) are relatively mild. During the first 2 to 3 weeks, the voice may improve as the tumor regresses. The voice generally becomes hoarse again because of RT-induced changes, even though the tumor continues to regress. A mild sore throat develops beginning at the end of the second week, but medication is usually not required. The voice begins to improve approximately 3 weeks after completion of treatment, usually reaching a plateau in 2 to 3 months. Patients with extensive lesions often recover a normal voice, although not as frequently as those with small tumors.

Edema of the larynx is the most common sequela after RT for glottic or supraglottic lesions. The rate of clearance of the edema is related to the RT dose, volume of tissue irradiated, addition of a neck dissection, continued use of alcohol and tobacco, and size and extent of the original lesion. Edema may be accentuated by a neck dissection and may require 6 to 12 months to subside.

Soft tissue necrosis leading to chondritis occurs in <1% of patients, usually in those who continue to smoke. Soft tissue and cartilage necroses mimic recurrence, with hoarseness, pain, and edema; a laryngectomy may be recommended as a last resort for fear of recurrent cancer, even though biopsy specimens show only necrosis.

Corticosteroids such as dexamethasone (Decadron) have been used to reduce RT-induced edema after recurrence has been ruled out by biopsy. If ulceration and pain occur, administration of an antibiotic such as tetracycline may help. Of 519 patients with T1 N0 or T2 N0 vocal cord cancer treated at the University of Florida, 5 (1%) experienced severe complications,[18] including total laryngectomy for a suspected local recurrence (1 patient), permanent tracheostomy for edema (3 patients), and a pharyngocutaneous fistula after a salvage total laryngectomy (1 patient).

In patients irradiated for supraglottic carcinoma, sore throat persists 1 to 2 months after completion of treatment. There is an associated dry mouth from RT of the salivary and parotid glands, a loss of taste, and a sensation of a lump in the throat. It is unusual for patients to require a tracheotomy before RT unless severe lymphedema develops at the time of direct laryngoscopy and biopsy. However, in patients who have recovered from

the direct laryngoscopy and biopsy without obstruction, a tracheotomy has rarely been required during a fractionated course of RT.

Patients treated twice a day with 1.2-Gy fractions (continuous- course technique) to a total dose of 74.4 Gy usually have more brisk acute reactions than those treated once a day with 2-Gy fractions. Approximately 30% treated with twice-a-day RT require temporary gastrostomy feeding tubes because they have difficulty in swallowing.[96]

Examples of acute chondritis requiring discontinuation of treatment have not been seen, although most epiglottic lesions exhibit cartilage invasion.

The epiglottis, both suprahyoid and infrahyoid portions, remains thicker than normal for long periods of time, but this is not often associated with difficulty in swallowing, respiratory obstruction, or aspiration. The patient is cautioned to eat and drink slowly until the edema resolves. The false cord and arytenoids may develop some edema.

Lesions of the suprahyoid epiglottis frequently destroy the tip of the epiglottis, and it may require some time for the exposed cartilage to heal. Successful RT of infrahyoid epiglottis tumors is not associated with a high rate of necrosis, even though most of these lesions penetrate the porous epiglottic cartilage.

The incidence of severe late complications in 274 patients treated with RT alone or combined with neck dissection at the University of Florida was 4%.[76]

ACKNOWLEDGMENTS

We thank the research support staff of the Department of Radiation Oncology for their help with statistics, editing, and manuscript preparation.

CHAPTER 54

Unusual Nonepithelial Tumors of the Head and Neck

Adam L. Holtzman and Daniel M. Trifiletti

PARAGANGLIOMAS

Anatomy

Paragangliomas (PGs), previously called glomus tumors, are neuroendocrine tumors (NETs) found in the peripheral nervous system. Whereas adrenal tumors are referred to as pheochromocytomas, extra-adrenal tumors are termed *paragangliomas* and are commonly found in the head and neck (H&N). They are often located in the jugular bulb and along the tympanic (Jacobson) and auricular (Arnold) branches of the tenth nerve in the middle ear or in other anatomic sites (Figure 54.1). Depending on the location, PGs are classified as tympanic (middle ear), jugular, carotid, or vagal or designated as originating from other locations, such as the larynx, adventitia of thoracic aorta, abdominal aorta, or the surface of the lungs (Figure 54.2).[1]

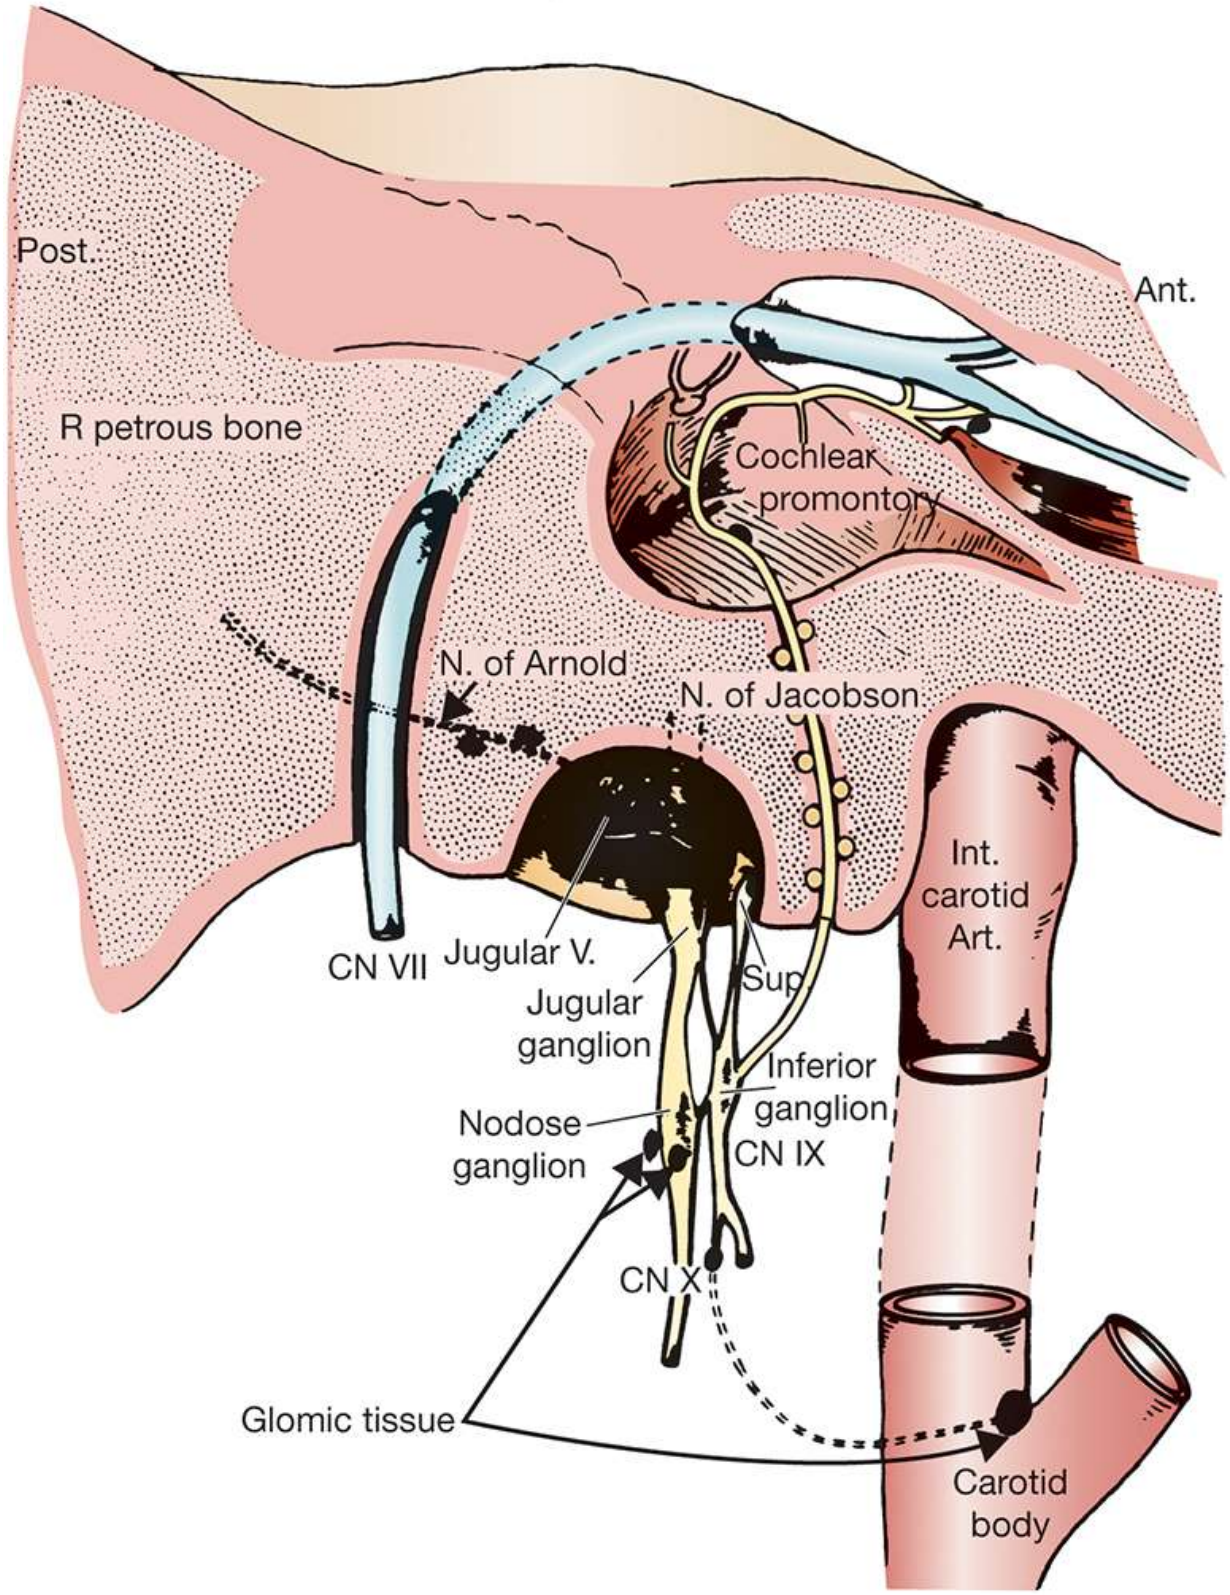

FIGURE 54.1 Anatomy of the region of jugular paragangliomas. CN, cranial nerve. (From Hatfield PM, James AE, Schulz MD. Chemodectomas of the glomus jugulare. *Cancer*. 1972;30[5]:1164-1168. Copyright © 1972 American *Cancer* Society. Reprinted by permission of John Wiley & Sons.)

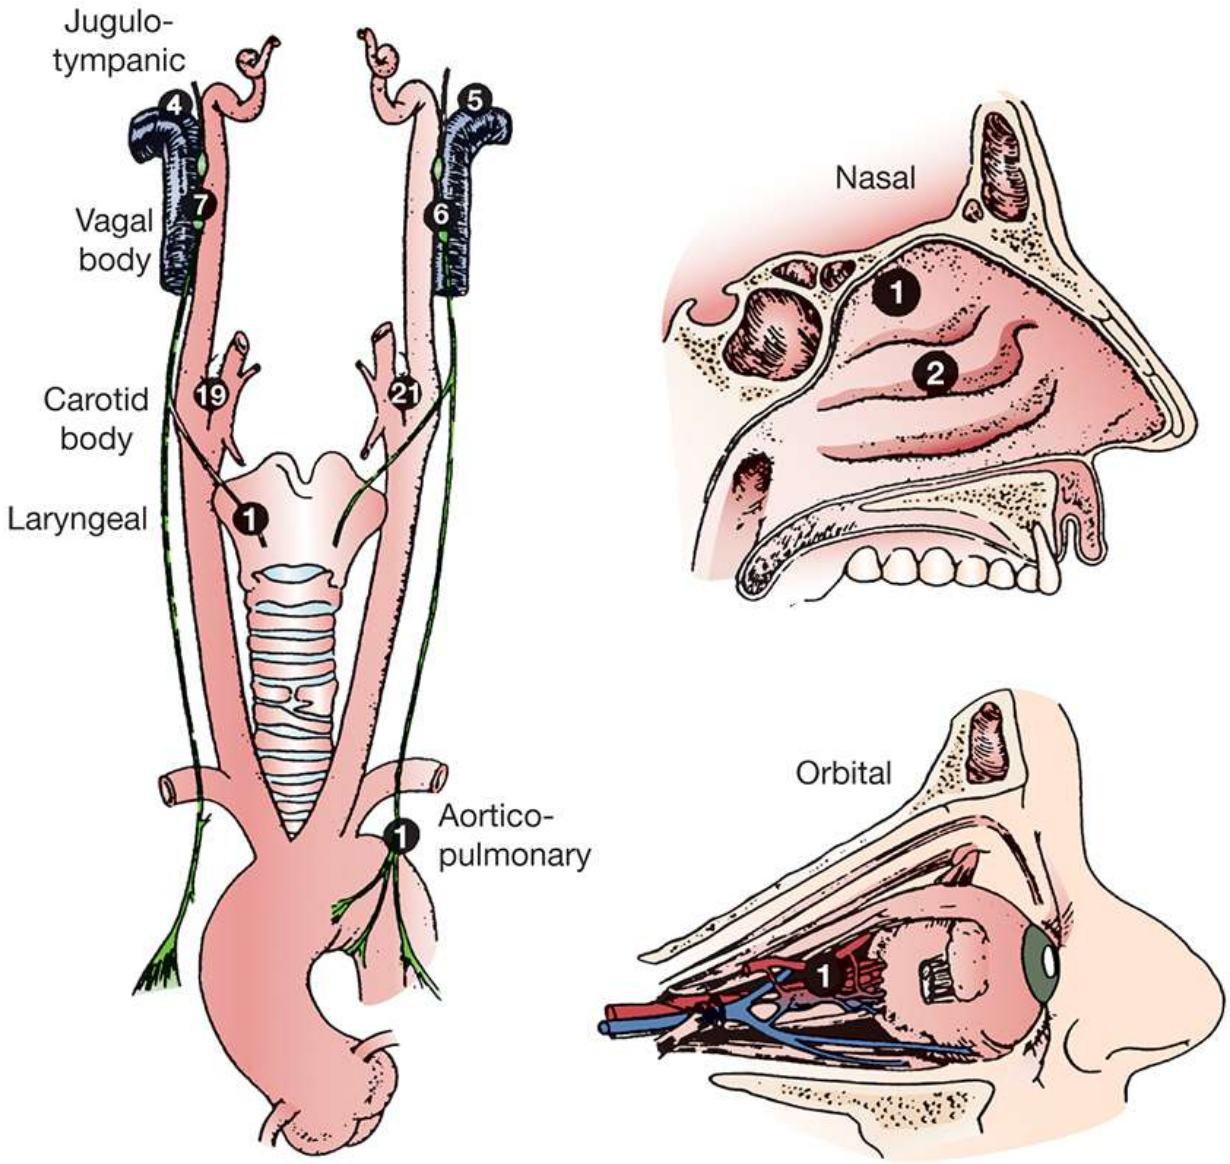

FIGURE 54.2 Distribution of paragangliomas of the head and neck region. Laterality was not specified in three patients with carotid body paragangliomas. The diagram does not include one left carotid body paraganglioma that was found incidentally at autopsy and a left vagal body paraganglioma that presented in a patient who had two other paragangliomas. (From Lack EE, Cubilla AL, Woodruff JM, Farr HW. Paragangliomas of the head and neck region: a clinical study of 69 patients. *Cancer*. 1977;39[2]:397-409. Copyright © 1977 American Cancer Society. Reprinted by permission of John Wiley & Sons.)

Ninety-five percent of PGs of the H&N are nonchromaffin, nonsecretory benign tumors. Clinically, they are divided into benign and, very rarely, malignant neoplasms. Malignancy, in contrast to most other tumors, is defined by clinical behavior such as the development of metastases, rather than from histologic evaluation.[2] The incidence can vary based on tumor location, with up to 15% of the carotid body and vagal lesions being malignant.[3,4]

PGs consist of large epithelioid (smooth muscle) cells with fine granular cytoplasm embedded in a rich capillary network and fibrous stroma with reticulin fibers, which derive from embryonic neural crest cells. Although histologically benign, they may extend along the lumen of the vein to regional lymph nodes, but rarely to distant sites. These tissues are responsive to changes in oxygen and carbon dioxide tensions and pH.

Epidemiology

The mean age at diagnosis has been reported to be 45 years for carotid body tumors and 52 years for tympanic PG.[5] These tumors occur 3 or 4 times more frequently in women than in men, suggesting a possible estrogen influence.[3,5,6] PG tumors may be familial; they occur in multiple sites in 10% to 20% of patients.[7] Incidence may be influenced by hereditary syndromes, including Paraganglioma Syndromes 1 to 5 (PGL1-5), Multiple Endocrine Neoplasia Type 2 (MEN2), and Neurofibromatosis Type 1 (NF1).

Recent advances in genetics identified three loci associated with hereditary PGs, and genetic screening may detect affected patients.[8] Multiple PGs of the H&N are rare, with an incidence of 10% of all patients, but in familial cases, it increases up to 35% to 50%. In the H&N region, while several susceptibility genes have been identified, they are most commonly caused by the *SDHD* gene and present with bilateral carotid body tumors or carotid body tumors associated with tympanic-jugular tumors.[7]

Clinical Presentation

PGs may arise along the nerve roots. In the middle ear, they may initially cause earache or discomfort. As they expand, eventually, they produce pulsatile tinnitus, hearing loss, and, in later stages, cranial nerve paralysis resulting from invasion of the base of the skull in 10% to 15% of patients. If the tumor invades the middle cranial fossa, symptoms may include temporoparietal headache, retro-orbital pain, proptosis, and paresis of cranial nerves V and VI. If the posterior fossa is involved, symptoms may include occipital headache, ataxia, and paresis of cranial nerves V to VII, IX, and XII; invasion of the jugular foramen causes paralysis of nerves IX to XI. Carotid body PG usually presents as a painless, slowly growing mass in the upper neck. Occasionally, the mass may be pulsatile and may have an associated thrill or bruit. As it enlarges, the mass may extend into the parapharyngeal space and be visible on examination of the oropharynx.

Diagnostic Workup

Diagnostic evaluation for PGs is outlined in Table 54.1. In the majority of tympanic PGs, physical examination demonstrates a red, vascular middle ear mass, although, occasionally, it may be bluish or white (the latter resembling a cholesteatoma).[5] Figure 54.3 demonstrates an example of the clinical and radiographic appearance of a tympanic PG. Audiography may demonstrate conductive hearing loss in the ear involved by tumor as noted in 33 of 49 patients evaluated by Larson et al[5]; 4 of 33 patients with conductive deficits also exhibited tympanic pulsations. Examination of the neck may occasionally

demonstrate a mass in the neck that may be pulsatile or have a bruit or regional lymph node metastases, although exceedingly rare.

TABLE 54.1 DIAGNOSTIC WORKUP FOR HEAD AND NECK PARAGANGLIOMA

General
Clinical history
General physical examination
Ear, nose, and throat examination
Radiographic Studies
Computed tomography scan (with contrast) to define tumor extent and possible central nervous system involvement)
Magnetic resonance imaging with gadolinium
Arteriography to determine bilateral involvement and collateral cerebral blood flow (optional)
Jugular phlebography (optional)
Laboratory Studies
Complete blood cell count
Blood chemistry profile
Urinalysis (optional)
Special Tests
Audiograms to establish baseline hearing loss
Histologic staining to determine the presence of catecholamines

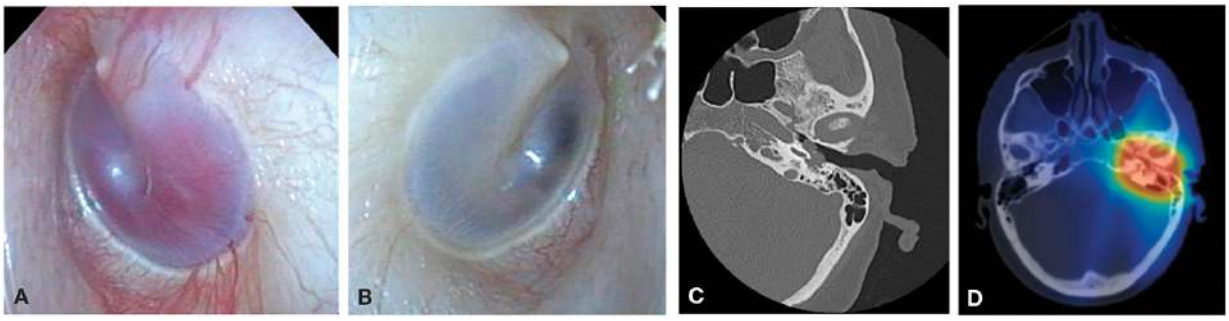

FIGURE 54.3 A. Tympanic paraganglioma involving the left middle ear with the left tympanic membrane demonstrating a bulging, pulsatile, purple-red mass. B. As compared to the right ear of the same patient serving as a normal examination control. C. The tumor within the left ear canal is shown on high-resolution, bone-windowed computed tomography. D. Representative intensity-modulated radiation therapy plan fused to a color wash dose distribution being treated to 45 Gy at 1.8 Gy per treatment.

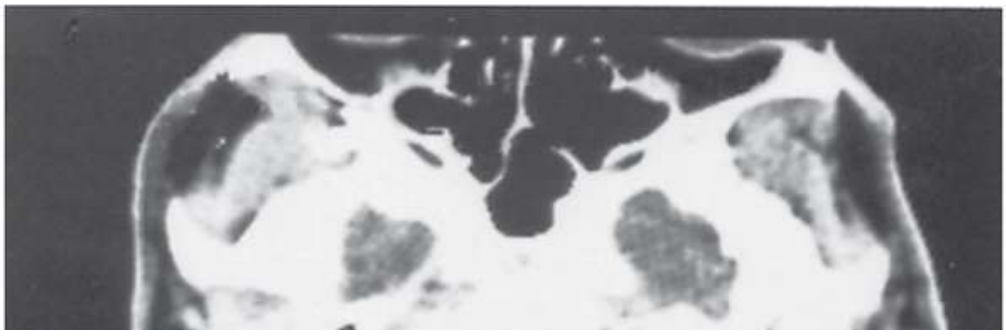
High-resolution computed tomography (CT) with contrast has a degree of sensitivity and specificity to diagnose this tumor when located in the middle ear or jugular bulb; masses as small as 3 mm have been demonstrated. Tumor enhancement is similar to that of

the temporalis muscle (Figure 54.4).[5] In 46 patients with glomus tympanicum, there were no instances of local bony erosion; instead, the tumors engulfed the ossicular chain, bulged or protruded through the tympanic membrane, filled the middle ear, or extended into the eustachian tube orifice or aditus ad antrum. This pattern is in contrast to cholesteatomas or even other malignancies such as endolymphatic sac tumors (ELSTs), which typically destroy adjacent bony landmarks, including the ossicles, and progressively erode the petrous bones as they enlarge.[5] Distinction from ELST, while rare and less than 300 cases reported in the literature, is important as this locally aggressive malignancy (Figure 54.5) necessitates carcinoma-type dosing of 66 Gy or higher to gross disease to achieve durable tumor control.[9]

A



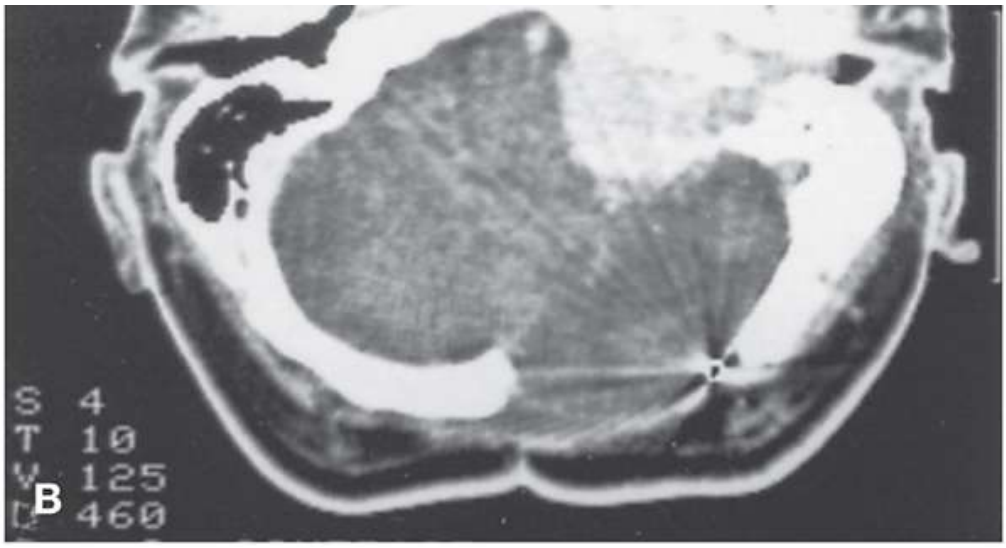


FIGURE 54.4 A. Late-phase arteriogram illustrating large jugular paraganglioma with extension into the neck. B. Computed tomography scan with contrast enhancement showing intracranial component of lesion.

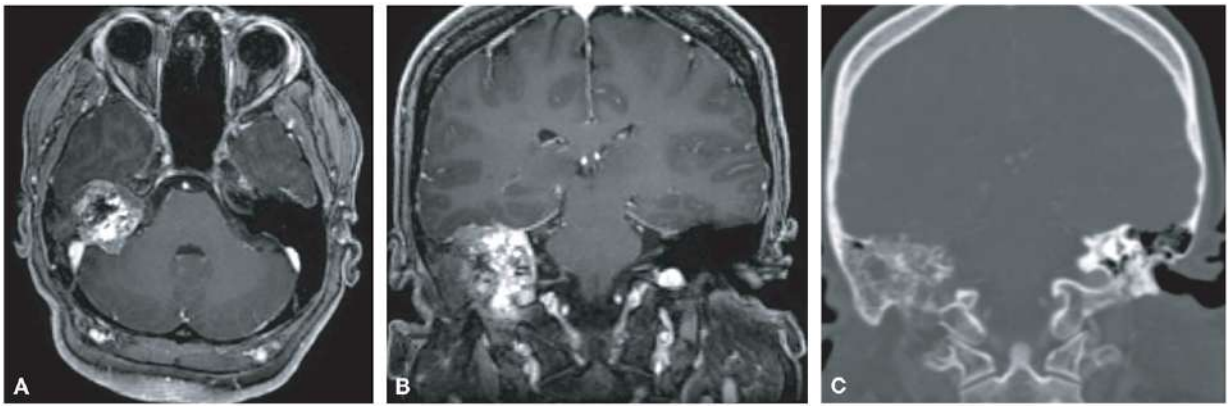

FIGURE 54.5 Axial (A) and coronal (B) T1-weighted three-dimensional magnetic resonance imaging (MRI) fused to coronal computed tomography (CT) of the head (C) with bone windowing demonstrating an endolymphatic sac tumor (ELST). Less common in jugulotympanic paragangliomas, ELST is associated with osseous erosion including involvement of the semicircular canals and jugular plate as shown by CT. MRI demonstrates a lobular enhancing mass arising from the right mastoid and petrous temporal bone with peripheral areas of intrinsic T1 hyperintensity. There is an extension through the tegmen mastoideum superiorly, jugular plate laterally, into the right internal auditory canal and cerebellopontine angle medially, and slightly through the right mastoid bone and base of skull inferiorly. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Magnification angiography is a sensitive and specific means of detecting tympanic PGs. This procedure is performed after high-resolution thin-section CT scan (with contrast material), only when there is a question regarding the nature of the lesion or the location of the carotid canal. Findings include a hypervascular middle ear mass that first appears in the middle to late arterial phase, persists through the capillary phase, and quickly disappears in the venous phase without demonstrably early draining veins. Diagnosis is made clinically and radiographically, and treatment with radiotherapy (RT) without a

tissue diagnosis is accepted practice. Biopsy of an aberrant internal carotid artery can result in major neurologic sequelae or death.

Vogl et al[10] reported on 40 patients with PGs of the skull; diagnostic interpretations were correlated with histologic examination, digital subtraction angiography, CT, and clinical follow-up. Sixteen of 18 proven tumors were detected with spin-echo images alone. Although four high-flying jugular bulbs were misinterpreted as tumors because of similar signal intensity, combined evaluation allowed differentiation between tumor and sinusal blood flow in all cases.

Drapé et al[11] described magnetic resonance imaging (MRI) findings in 31 patients with a clinical suspicion of PG; gadoterate meglumine was injected into 19 patients. Twenty-seven of 28 pathologically confirmed PGs were detected with MRI; a peripheral capsule was present in most tumors. The investigators were able to differentiate three subtypes of PGs (vascular, solid, and myxoid) on the basis of relaxation times and enhancement characteristics. Multidetector CT angiography was found to be more accurate in the diagnosis of six PGs, with enhancement in the arterial phase, when compared with MRI.[12]

As PGs show high levels of somatostatin receptor (SSTR) subtypes 2 and 5, fluorine-(^{18}F)-octreotate positron emission tomography (PET) may be useful for diagnostic purposes in a semiquantitative manner and for improving target volume delineation in RT planning. Astner et al[13] noted that preliminary findings with two different PET tracers for SSTR imaging have been reported: Gallium-68 (^{68}Ga)-DOTATOC (DOTA-D-Phe(1)-Tyr(3)-octreotide [somatostatin analog]) PET was shown to detect SSTR expressing tumors with high sensitivity and specificity. A second PET tracer, Gluc-Lys(^{18})F-TOCA, allows fast, high-contrast imaging of SSTR-positive tumors with superior biokinetics and diagnostic performance as compared with indium-111 (^{111}In)-diethylenetriamine pentaacetic acid-octreotide and—as far as can be determined from the literature—comparable to[14] Ga-DOTATOC.[15-17]

Cytochemical techniques demonstrate increased levels of serotonin, epinephrine, and norepinephrine in normal tissue of the carotid body. Histologic staining techniques, including chromaffin and argentaffin reactions, identify patients with hormonally active tumors. This is important because the PGs may coexist with a pheochromocytoma, which requires special preoperative preparation of the patient. Biopsy of PGs should be avoided as they can result in severe hemorrhage.

Staging

The prognosis of these tumors is closely related to the anatomic location and the volume of the lesion, which is reflected in the Glasscock-Jackson classification,[18] and an alternative system proposed by McCabe and Fletcher[14] is presented in Table 54.2.

TABLE 54.2 MODIFICATION OF MCCABE AND FLETCHER CLASSIFICATION OF PARAGANGLIOMA

Group I: Tympanic Tumors
Absence of bone destruction on x-rays of the mastoid bone and jugular fossa

Absence of facial nerve weakness
Intact eighth nerve with conductive deafness only
Intact jugular foramen nerves (cranial nerves IX, X, and XI)
Group II: Tympanomastoid Tumors
X-ray evidence of bone destruction confined to the mastoid bone and not involving the petrous bone
Normal or paretic seventh nerve
Intact jugular foramen nerves
No evidence of involvement of the superior bulb of the jugular vein on retrograde venogram
Group III: Petrosal and Extrapetrosal Tumors
Destruction of the petrous bone, jugular fossa, and/or occipital bone on x-rays
Positive findings on retrograde jugulography
Evidence of destruction of the petrous or occipital bones on carotid arteriogram
Jugular foramen syndrome (paresis of cranial nerve IX, X, or XI)
Presence of metastasis

General Management

Li et al[15] published a historical perspective of various treatment modalities used to treat PGs over the past 60 years.

Surgery

Surgery is generally selected for small tumors that can be completely excised. Tympanic PGs are particularly well managed with excision via tympanotomy or mastoidectomy. Percutaneous embolization of a low-viscosity silicone polymer has been used, frequently as preoperative preparation of the tumor embolization of feeding vessels allows meticulous microsurgery with virtually complete hemostasis.

Surgical treatment of a PG arising in the jugular bulb, however, often consists of piece-by-piece removal accompanied by significant intraoperative bleeding with damage to adjacent neurovascular structures and requires more complex surgical approaches involving the base of the skull. Preoperative embolization via a transarterial approach has proved beneficial but is often limited by vascular anatomy and unfavorable locations. Abud et al[16] reported experience with preoperative devascularization using direct puncture and intralesional injection of cyanoacrylate (acrylic glue) under fluoroscopic guidance in nine patients with H&N PGs. Ozyer et al[17] performed devascularization with intralesional injection of *N*-butyl cyanoacrylate (seven carotid and three jugular PGs). The tumors were subsequently surgically removed.

The local tumor control rate with surgery alone (SA) is only about 60%, and there is a significant risk of morbidity, particularly cranial nerve injury and bleeding based on the location and extent of the tumor.

In a retrospective review of all skull base surgery cases treated at Baylor University, 175 jugulotympanic PGs and 9 (5.1%) malignant cases were identified.[2] The 5-year survival rate was 72%.

Radiation Therapy

RT is frequently used in the treatment of PGs, particularly for those in the tympanic and jugular bulb locations where gross total removal may result in significant morbidity, including cranial nerve dysfunction or risk of hemorrhage. Tumors with destruction of the petrous bone, jugular fossa, or occipital bone or patients with jugular foramen syndrome are more reliably managed with irradiation.[5,6,19,20] While in the past there were questions on the effectiveness of RT in the treatment of PG because of histologic sections, obtained even many years after irradiation, it is possible to find chromophilic cells remaining in the tumor.[18] Suit and Gallager,[21] however, demonstrated in a murine mammary carcinoma model that morphologically intact cells may have lost their reproductive ability after irradiation, which is the ultimate end point of cell killing. Furthermore, it is extremely unusual to observe clinical regrowth of a glomus tumor after irradiation, even if they do not regress completely as is common in most benign diseases treated with RT. Mendenhall et al,[4,22] updated the University of Florida experience in a total of 149 patients with 176 benign PGs treated with curative-intent RT. The 15-year overall local control (LC) was 95% with a median dose of 45 Gy in 25 treatments. No patient developed a moderate or severe complication, including radiation-induced second tumors or malignant transformation of the benign PG demonstrating the long-term efficacy and safety of RT.

Radiation Therapy Techniques

RT techniques are determined by the resectability, patient symptoms, location, and extent of the tumor.[20,23,24] Treatment is given at the rate of 1.8 to 2 Gy per day with five treatments per week for a total tumor dose of 45 to 50.4 Gy in 5 weeks or 12.5 to 15 Gy in a single fraction with stereotactic-ablative radiotherapy (SABR). Image-guided (IG), intensity-modulated radiation therapy (IMRT) is a highly desirable technique to treat these tumors, with a representative isodose dose distribution for single fraction SABR (Figure 54.6). Table 54.3 summarizes the doses of irradiation recommended by several investigators and the probability of tumor control for each.[20,24,25] Of note, there is no convincing evidence that dose escalation above 50 Gy improves tumor control for benign PG.[4,22]

TABLE 54.3 LOCAL CONTROL WITH RADIATION THERAPY FOR TEMPORAL BONE PARAGANGLIOMA OF THE TEMPORAL BONE (TYMPANIC AND JUGULAR)[24,26]

Institution (Reference)	Local Control	Nominal Dosage Schedule
Princess Margaret Hospital[20]	42/45[a]	35 Gy/3 wk

Institution (Reference)	Local Control	Nominal Dosage Schedule
Queen Elizabeth Hospital, Birmingham[27]	19/20[b]	45-50 Gy/4-5 wk
University of Washington[28]	10/13	8-65 Gy/4-7 wk
Rotterdamsch Radio-Therapeutisch Instituut, Netherlands[29]	19/19	40-60 Gy/4-6 wk
University of Minnesota[30]	13/14	30-60 Gy/3.5-7.5 wk
University of Virginia[31]	14/17	40-50 Gy/4-5 wk
Total	117/128 (91%)	

[a]Two patients listed as failures were salvaged with further treatments.

[b]One patient listed as a failure was salvaged with further radiation therapy.

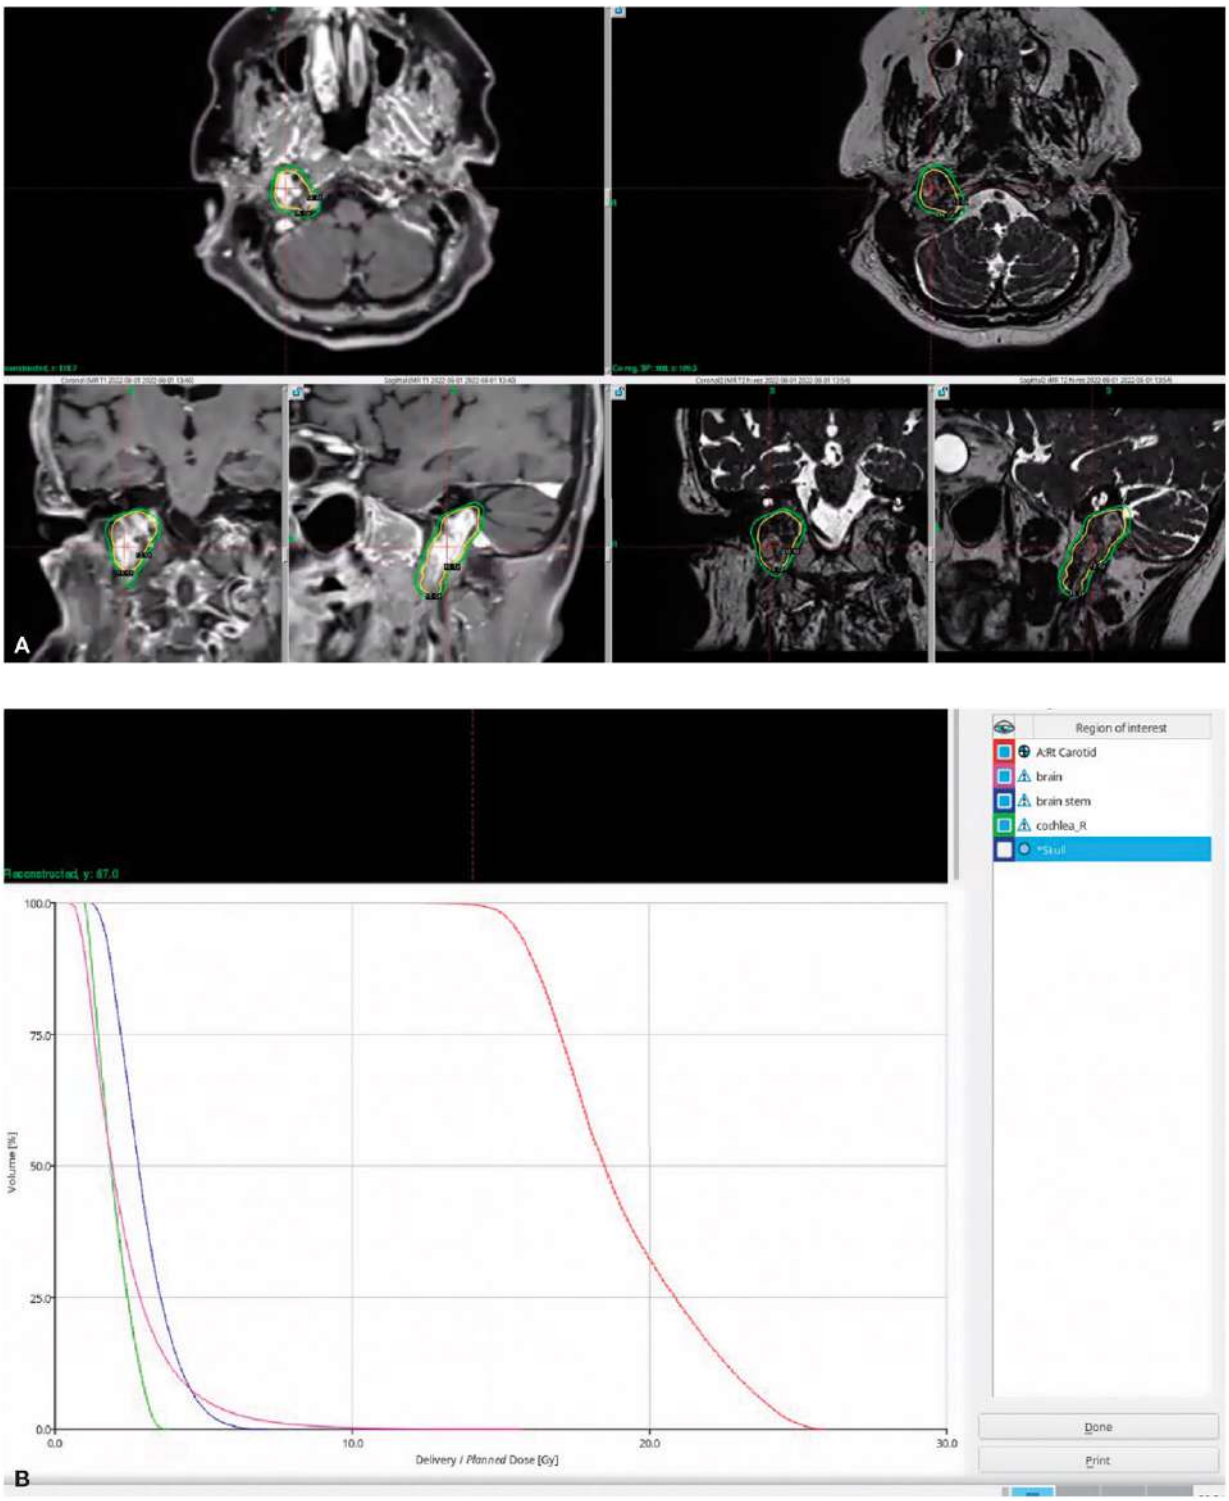

FIGURE 54.6 A. T1- and T2-weighted magnetic resonance images showing the dose distribution with stereotactic radiation therapy (radiosurgery) for right jugulotympanic paraganglioma. This patient received 15 Gy in 1 treatment with Gamma Knife, with the yellow line representing the 100% isodose line. B. In the dose-volume histogram, the red line represents the coverage of the gross tumor volume, the green line shows the cochlea, and the purple line shows the dose to the brainstem. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

van Hulsteijn et al[25] performed a meta-analysis of 283 jugulotympanic PGs in 276 patients. Pooled regression proportions for initial, combined, and salvage treatment were, respectively, 21%, 33%, and 52% in radiosurgery studies and 4%, 0%, and 64% in external beam RT studies. Pooled LC proportions for RT as initial, combined, and salvage treatment ranged from 79% to 100%.

RT for jugulotympanic PGs results in excellent local tumor control. The effects of RT on regression of tumor volume remained ambiguous, although the data suggest that complete regression can be achieved in some patients.

Leber et al[32] reported on 13 patients with PGs treated with radiosurgery in 6, because of recurrences after surgical removal. Histology was not available in seven patients; diagnosis was made from neuroradiologic features only. With a mean follow-up of 42 months (range 14-72 months), there was no tumor progression and no clinical deterioration in any patient; 64% of the patients had improvement of symptoms, and in 36%, the volume of the lesion decreased in size. There was no radiation-related morbidity. There have been an increasing number of reports of PG <3 cm treated with SABR, with tumor control over 80% and relatively minimal morbidity. The mean single dose is about 16 Gy (range 13-20 Gy).[33-38]

A report on fractionated stereotactic irradiation (6-MV x-rays) of 17 patients has been published, with a dose of 57 Gy.[39] Pollock[40] reported on 42 glomus tumors (19 primary treatment and 23 recurrences after initial surgery) treated with Gamma Knife (Elekta Corp, Stockholm) stereotactic radiation (12-24 Gy single dose at 50% isodose, depending on tumor size). Twelve lesions (31%) decreased in size, and 26 were unchanged. The most common complication was hearing loss (19%). Wegner et al[41] treated 18 patients with carotid or jugular lesions with fractionated stereotactic CyberKnife (Accuray). Fifteen (83%) patients had single jugular tumors, and three patients had bilateral jugular tumors. Ten tumors were previously untreated, and eight were persistent after previous surgical resection. The median prescribed dose was 20 Gy in three fractions (range: 16-25 Gy in 1-5 fractions). The median prescription coverage of the tumor was 93.6% (range: 83%-98.72%). Median follow-up was 22 months. All the patients were alive at the time of the last follow-up with imaging available for review. The tumor was stable in 17 patients and decreased in size in one patient—yielding an LC rate of 100%. No patients experienced any new or worsening treatment-related neurologic deficits.

Results of Therapy

The postirradiation change in tumor size is slow, with an increase in proliferative and perivascular fibrosis and minimal alterations in the chief epithelial cells. Histologic evaluation of tumor cell viability is not reliable.[21] Despite the persistence of tumor both clinically and angiographically, amelioration of symptoms, absence of disease progression, and occasional return of cranial nerve function have been reported. Sixteen patients were treated for tympanic PGs tumors at Washington University.[3] In five patients, initial treatment consisted of irradiation alone, and all were tumor free at the last follow-up (4.5 years in one patient) or at death. Seven of eight patients irradiated for surgical recurrence

were free of disease 4.5 to 19 years after irradiation. The remaining four patients were treated preoperatively or postoperatively; only one had recurrence and was salvaged surgically and tumor free 10 years later. Of six patients with glomus jugulare lesions treated with irradiation, two with extensive lesions died of their disease, whereas the glomus tumor was controlled in four, including two patients with intracranial extension. Irradiation doses ranged from 46 to 52 Gy, with 86% to 100% tumor control with doses over 46 Gy and 50% (two of four) with doses below 46 Gy.

Wang et al[26] reported on 32 patients with tympanic PGs; 13 are treated with SA, 15 with irradiation alone, and 4 with a combination of both modalities. The initial tumor control rate was 46% with SA; ultimately 84% of patients were tumor free after salvage with additional surgery. Although 78% survived 10 years, 31% developed complications. Of the patients treated with irradiation, 84% had initial local tumor control; 77% survived 10 years, and only 11% developed complications. The doses of irradiation used were slightly higher than those reported by others (mean 58.3 Gy). However, no improvement in tumor control was noted with higher doses. Complications occurred in two patients receiving 66 Gy.

Zabel et al[42] described results in 22 patients with large PGs of the skull base (8 after primary surgery and 4 after embolization), treated with fractionated stereotactic irradiation (median total dose 57 Gy with median fraction dose 1.8 Gy). With a median follow-up of 5.7 years, 5- and 10-year actuarial tumor control was 90%, with 7 (32%) patients having a partial response and 13 patients with (59%) stable tumors. No patient developed new neurologic deficit.

Powell et al[19] reported on 84 patients with PGs of the H&N, 46 of which were either jugular or tympanic locations, treated with irradiation alone (45-50 Gy in 25 fractions). LC of the lesion was 73% at 5 years. Thirty patients were treated with surgery after irradiation with no recurrences (median follow-up of 9 years). Four patients, treated with SA, developed recurrences by 7 years. Four carotid body and vagal tumors treated with irradiation were locally controlled at 1, 2, 8, and 11 years, respectively. In 13 patients treated with SA, the 15-year LC rate was 54%.

Hinerman et al[43,44] updated a previous report with 104 patients who had 121 PGs of the temporal bone, carotid bone, or vagal treated with RT alone in 104 patients or subtotal resection with or without RT (17 tumors). There were six tumor recurrences, with a local tumor control of 95%. No severe treatment complications were noted. As aforementioned, Gilbo[4] and Mendenhall et al[22] updated the series in 2014 and 2019, showing continued high control even at 15 years after therapy.

Ivan et al[45] published a meta-analysis based on 869 patients in 46 studies reported with PGs, with follow-up ranging from 6 to 256 months. The tumor control rates were, for subtotal resection 69%, gross tumor resection (GTR) 86%, subtotal resection and radiosurgery 71%, and stereotactic radiosurgery (SRS) alone 95%. Post-treatment cranial nerve deficit was observed in 26% to 40% of patients treated with GTR and in about 10% of the SRS group. Guss et al[46] reported on a meta-analysis of 19 studies (335 patients) with glomus tumors treated with stereotactic radiotherapy (SRT) (radiosurgery), eight

publications with a median follow-up of 36 months; tumor control (unchanged or reduced tumor volume) was 95% to 96%, with various RT techniques.

In 29 patients with postsurgical recurrent PGs (16 jugular, 7 carotid, 5 tympanic, and 1 thyroid), Elshaikh et al[47] reported a 5-year tumor control of 100% in 12 treated with RT and 62% in 17 treated surgically.

Cheesman and Kelly[48] emphasized the importance of evaluating preoperatively the swallowing function of patients with jugular PGs undergoing surgery, as it is common for these patients to develop postsurgical dysphagia.

The results of primary treatment for temporal bone PGs are summarized in Table 54.4.

SOLITARY FIBROUS TUMORS

Solitary fibrous tumors (SFTs), also termed *hemangiopericytomas* (HPCs) when they refer to lesions within the central nervous system (CNS), are mesenchymal, nonmeningothelial soft tissue neoplasms that account for 3% to 5% of all soft tissue sarcomas and 1% of all vascular tumors. Lesions of the H&N were also previously described as giant cell angiofibromas and orbital fibrous histiocytoma (OFH), which are all now recognized within the spectrum of SFT.[57] Approximately 15% to 30% of all SFTs occur in the H&N, and of these, approximately 5% occur in the sinonasal area. While vagal PGs originate within the first 2 cm of the extracranial stretch of the vagus nerve and are associated with the inferior ganglion,[58] SFTs are believed to originate from the pericytes of Zimmerman extravascular cells, morphologically resembling smooth muscle, found around the capillaries or from primitive mesenchymal cells. The function of the pericyte is uncertain but is believed to provide mechanical support for the capillaries having contractile function.[59]

SFTs of the H&N are uncommon. Lesions previously diagnosed in the H&N as HPCs, giant cell angiofibromas, and OFHs are now recognized as within the expanded spectrum of SFTs.

Epidemiology

SFTs represent approximately 1% of all vascular neoplasms; it occurs in both genders with equal frequency and is found primarily in adults. In the H&N, the most common sites are the nasal cavity and the paranasal sinuses and, less frequently, the orbital region, the parotid gland, and the neck.[60-62] HPCs represent 3% to 4% of all meningeal and <1% of CNS tumors.

Pathology

SFTs are composed of a proliferation of tightly packed pericytes around thin-walled endothelial-lined vascular channels, ranging from capillary-sized vessels to large, gaping sinusoidal spaces.[63] The tumor has a tendency to grow slowly and invade locally into adjacent structures.[60,64] Although they are always well circumscribed and partially or completely surrounded by a pseudocapsule, benign tumors may be difficult to differentiate

from malignant tumors. However, prominent mitoses (>4 per high-power field), foci of necrosis, and increased cellularity are suggestive of malignancy; the definitive sign is local recurrence or development of metastases. In general, tumors of the CNS, lower extremity, and mediastinum tend to be more malignant, with local recurrence occurring in up to 50% of cases.[63]

Kowalski and Paulino[65] reviewed 12 cases of SFTs. The mitotic index per 10 high-power fields varied from 0 or 1 to 15. Proliferation indices using MIB-1 (Ki-67) ranged from 2.6% to 52.5%. Clinical follow-up showed three cases with recurrence all possessing proliferation indices of approximately 10%, indicating a more aggressive subset of SFTs. Vuorinen et al[66] found proliferation index to be a poor predictor of prognosis for intracranial HPC.

Clinical Presentation

Soft tissue SFT is a firm, painless, slowly expanding mass that is often nodular and well localized. The skin overlying the mass does not have any discoloration or redness to indicate its vascular origin because the capillaries are emptied of the blood by compression of massive numbers of pericytes surrounding them.[63] In the H&N, the tumor may constitute a polypoid, soft gray or red mass that grows slowly and may cause nasal obstruction. Epistaxis and nasal obstruction are common symptoms. Orbital SFTs account for 3% of orbital malignancies and most frequently occur with painless proptosis.[67] SFT rarely originates in the lacrimal sac. When present, however, it occurs in a younger age group than that of other locations.[68]

HPC may occur intracranially. When it arises in the brain, it is a solid mass attached to the meninges that grossly resembles a meningioma. These intracranial HPCs carry a high risk of local failure (80%), as well as a higher potential for dissemination. Meningeal HPCs almost always recur, despite seemingly complete removal, because of infiltrative properties of HPC cells and not just higher proliferation potential. The mean time for local recurrence is 75 months.[69] For more specifics regarding intracranial HPC, refer to Chapters 40.

The incidence of metastasis, which depends on the site of origin, can be 50% to 80%. Late metastases occurring 10 years after diagnosis are not uncommon.

On CT imaging, the SFT appears as a well-circumscribed, homogeneously and intensely enhancing mass. On MRI, the mass is isointense to slightly hyperintense to muscle on T1- and T2-weighted imaging. Multiple, branching flow voids are typically seen within the tumor on both T1- and T2-weighted images. On T2-weighted imaging, the punctate black flow voids in cross section within the relatively bright tumor, creating a characteristic "salt-and-pepper" appearance in tumors >2 cm in diameter. In addition, flow voids of large feeding arteries are seen at the periphery of the mass. Angiography demonstrates the characteristic appearance of a vascular tumor, with large feeding arteries, intense tumor stain, and early draining veins.[58] On arteriography, according to Yaghmai,[70] SFT is the only vascular tumor that has radially arranged or spiderlike branching vessels around and inside the tumor and a long-standing, well-demarcated tumor stain. Intracranial tumors typically

have arterial blood supply from both meningeal and cerebral connections, with one to three main feeders supplying many small corkscrew-like vessels.[69] The most distinctive and constant feature of this tumor is its hypervascularity, which may be demonstrated with contrast-enhanced CT.[61] Intracranially, the diffusely enhancing tumor may closely resemble a meningioma on CT. However, some CT signs may suggest HPC rather than meningioma, such as a lack of calcification, scarce surrounding edema, and ringlike enhancement. Both CT and MRI scans are of special value in the delineation of the full extent of the tumor.

General Management

Complete surgical resection, if possible, combined with preoperative embolization of the tumor, is the treatment of choice. More extensive surgery is required in tumors that show features of malignancy. Many patients undergo surgical treatment after embolization of the feeding artery(ies).

For incompletely resected tumors, postoperative RT is used.[71,72] The role of chemotherapy in this tumor is not well determined; a few reports have described partial tumor regression in some lesions treated with cytotoxic agents. Doxorubicin, either alone or in combination drug regimens, is the most effective agent for metastatic SFT, producing complete and partial remissions in 50% of cases. Other drugs prescribed when metastasis occurs are cyclophosphamide, dacarbazine, vincristine, and actinomycin D.[73] Park et al[74] reported on 14 patients with soft tissue HPC treated with temozolomide 150 mg/m^2 orally on days 1 to 7 and days 15 to 21 and bevacizumab 5 mg/kg intravenously on days 8 and 22, repeated at 28-day intervals. The median follow-up period was 34 months. Eleven (79%) patients achieved a partial response, with a median time to response of 2.5 months. Estimated median progression-free survival (PFS) was 9.7 months, with a 6-month progression-free rate of 78.6%. The most frequently observed toxic effect was myelosuppression.

Radiation Therapy Techniques

The role of RT alone in the management of SFT is controversial. The main role of irradiation is as an adjuvant after complete excision of the lesion or postoperatively for minimal residual disease.[62,75,76] The tumor has been considered relatively radioresistant. Preoperative doses of 45 to 50 Gy and postoperative doses of 50 to 65 Gy at 1.8 to 2 Gy per treatment are indicated for local tumor control based on the extent of resection and if residual disease is present.[71,72]

The fields of irradiation should be wide to encompass the tumor bed with a margin of at least 3 to 5 cm edited to boundaries of anatomic tumor spread similar to those used in the treatment of other soft tissue sarcomas discussed in the ensuing section near the end of this chapter.

Results of Therapy

Billings et al[77] reported on 10 patients with SFT of the H&N: 7 tumors arose from soft tissue sites and 3 from the mucosa. All patients underwent wide excision of the primary lesion with a local recurrence rate of 40%. Three patients developed metastatic lung disease 0 to 8 years after initial diagnosis. Each patient who developed metastatic disease had abundant mitoses on pathologic review compared with rare or absent mitoses in the lesions that took a more benign course.

Spitz et al[62] published a report on 36 patients with SFT. The median follow-up was 57 months. Twenty-eight (78%) patients underwent complete and potentially curative resection. Of the nine (32%) patients who had local recurrences, four (44%) had epidural tumors and three (33%) had retroperitoneal tumors, but none had extremity tumors. Ten patients had recurrences at distant sites. Of the 13 patients who experienced any form of disease recurrence, four had recurrences after a disease-free interval of more than 5 years. The 5-year actuarial survival rate for the entire group of 36 patients was 71%.

Carew et al[78] reviewed the records of 12 patients with SFT: 5 had high- or intermediate-grade lesions and 7 had low-grade lesions. Nine patients were treated with curative intent; they underwent a variety of surgical resections dictated by the tumor location and size. Four patients received postoperative RT, to a median dose of 60 Gy, for positive surgical margins (two patients), high-grade histology (one patient), or a recurrent lesion (one patient). The 5-year overall survival (OS) rate for patients treated surgically was 87.5%. A single mortality occurred in a patient with a recurrent high-grade lesion who failed at local, regional, and distant sites.

Staples et al[79] reported on 12 patients with localized SFT, 7 treated with SA (only 1 had long-term tumor control and 2 were salvaged with RT), 4 with resection and postoperative irradiation (all with long-term tumor control), and 1 with surgery and chemotherapy. Local tumor control was achieved at all sites treated with doses >55 Gy. Mitotic activity was not a reliable predictor of biologic behavior.

Shaigany et al[80] reported on a study of the Surveillance, Epidemiology, and End Results (SEER) database (1973-2012) encompassing 121 cases of SFT of the H&N and compared results with 510 of other body sites. H&N SFTs were most commonly located in the connective and soft tissue (18.4%), followed by the nasal cavity and paranasal sinuses (8.5%). H&N sites were smaller than other extracranial locations and more likely to be of lower histologic grade, and the primary treatment modality was SA for 95.8% of cases. The 5-, 10-, and 20-year disease-specific survival (DSS) for were 84.0%, 79.4%, and 69.4%, respectively. Higher histologic grade and the presence of distant metastases were poor prognostic factors. Adjuvant radiotherapy (ART) did not appear to confer a survival benefit.

Bishop et al[71] reviewed the outcomes of 31 patients treated for SFT with surgery and RT. The most common sites of involvement included the H&N (n = 9, 29%), trunk (n = 10, 32%), and lower extremities (n = 9, 29%). Nearly half the cases were treated with postoperative RT (45%) to a median dose of 58 Gy, and the other half received preoperative therapy. The 5-year rates of LC and distant metastatic-free survival were 100% and 92%, accordingly. There were no regional failures.

BASE OF SKULL CHORDOMA

Anatomy

Chordomas are rare neoplasms of the axial skeleton that arise from the remnant of the primitive notochord (chorda dorsalis). About 50% arise in the sacrococcygeal area; 35% arise from the skull base, where they typically involve the clivus, and the remaining 15% occur in the midline along the path of the notochord, primarily involving the vertebrae of the mobile spine.[81]

Epidemiology

Chordomas are more common in patients in their 50s and 60s but can occur in all age groups. In children and young adults, the prognosis and long-term survival appear to be better than in older patients. No risk factors have been identified. Male predominance is reported at a 2:1 to 3:1 ratio.

Natural History

Although slowly growing, chordomas are locally invasive, destroying bone and infiltrating soft tissues. The lethality of these tumors rests on their critical location, aggressive local behavior, and extremely high local recurrence rate. The incidence of metastasis, which has been reported to be as high as 25%, may be related to the long clinical history and identification of high-grade variants. The lungs are the most common site for distant disease (>50%), followed by the liver and bone. Factors associated with the development of metastatic disease include age <25 years and local recurrence at the primary site. Lymphatic spread is uncommon.[82]

Pathology

Chordoma is a soft, lobulated tumor that may have areas of hemorrhage, cystic changes, or calcification. It is frequently encapsulated but may be nonencapsulated or pseudoencapsulated. Histologically, it is composed of cords or masses of large cells (physaliferous cells) with typical vacuoles and granules of glycogen in the cytoplasm and abundant intercellular mucoid material. Usually, there are few mitotic cells.[83] Pathologic variants include conventional, dedifferentiated, and poorly differentiated histology. Chondroid is a subtype of conventional, and dedifferentiated may have a high-grade sarcomatous component and occur more commonly at sites of previously treated chordoma.[84] Poorly differentiated tumors tend to occur more commonly in younger patients and are characterized by the loss of INI1 (SMARCB1). It is associated with higher local and distant progression and may be more responsive to chemotherapy.[85] Brachyury expression has been shown to be a histologic marker for chordoma. Gene duplication has been shown to confer increased susceptibility to familial chordoma.[86] Aside from the previously mentioned histologic variants, the prognostic factors that most influence the choice of treatment are the tumor location and local extent of disease.

Clinical Presentation

Regarding the skull base, chordomas tend to originate midline from along the spheno-occipital synchondrosis where the basisphenoid and basiocciput bones joined to form the clivus. This contrasts with chondrosarcomas that occur paramedian along the petroclival cartilage-producing cells in areas of enchondral ossification of the temporal bone.[81] Figure 54.7 shows an example schematic of a sagittal rendering of the clivus. Clinical symptoms vary with the location and extent of the tumor. In the head, extension may be intracranial or extracranial, into the sphenoid sinus, nasopharynx, clivus, and sellar and parasellar areas, with a resultant mass effect. In chordomas of the spheno-occipital region, the most common presenting symptom is headache. Other presentations include symptoms of pituitary insufficiency, nasal stuffiness, bitemporal hemianopia, diplopia, and other cranial nerve deficits. Volpe et al[87] reviewed the clinical features of 48 patients with chordoma and 49 patients with low-grade chondrosarcoma of the skull base. Twenty-five (52%) patients with chordoma and 24 (49%) patients with chondrosarcoma had ocular symptoms (diplopia or visual impairment) as the initial manifestation of the disease. Of the 59 patients (both groups) with diplopia, it was initially intermittent in 25 (42%). Headache and diplopia from abducens nerve palsy occurred in 22 (46%) patients with chordoma and 23 (47%) with chondrosarcoma. While often grouped together for largely historic purposes, these are two distinct clinical entities and should be demarcated as such for clinical and research purposes.

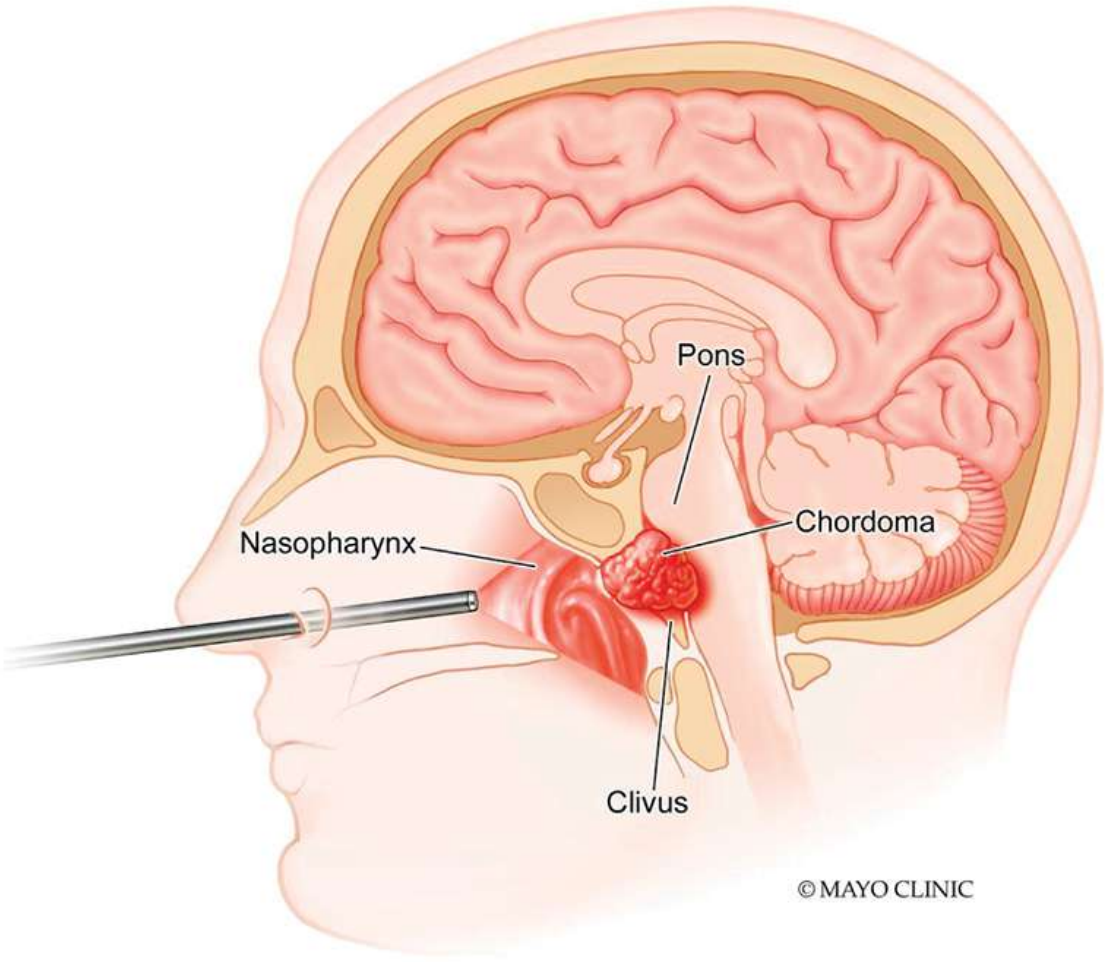

FIGURE 54.7 Sagittal anatomic rendering of the clivus. From a surgical standpoint, the clivus is divided into three anatomic divisions. There are slight differences in the description of the boundaries based on surgical techniques and authors. Simply, they are divided into the upper, middle, and lower clivus, which is demarcated by the floor of the sella and the sphenoid. This separates into a sellar, sphenoidal, and nasopharyngeal division. Tumors such as the one represented in the image are referred to as craniocervical junction chordomas because it involves the lower one-third of the clivus. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Diagnostic Workup

The diagnostic workup varies with the primary location of disease. Most patients have significant bony destruction, intracranial, and soft tissue extension; hence, CT and MRI are necessary for proper diagnosis and management decisions (Table 54.6).[81,88,89] In most cases, the soft tissue component is much more extensive than initially appreciated, and a CT scan and MRI with contrast enhancement can identify these findings. High-resolution bone CT can help demonstrate bony destruction and intratumoral calcification.[89] MRI with high-resolution T2-weighted sequences with steady-state sequences is essential for treatment planning. Figure 54.8 shows an axial T2 MRI preoperatively and

postoperatively and highlights the importance of 3D T2-weighted imaging for treatment planning of chordoma.

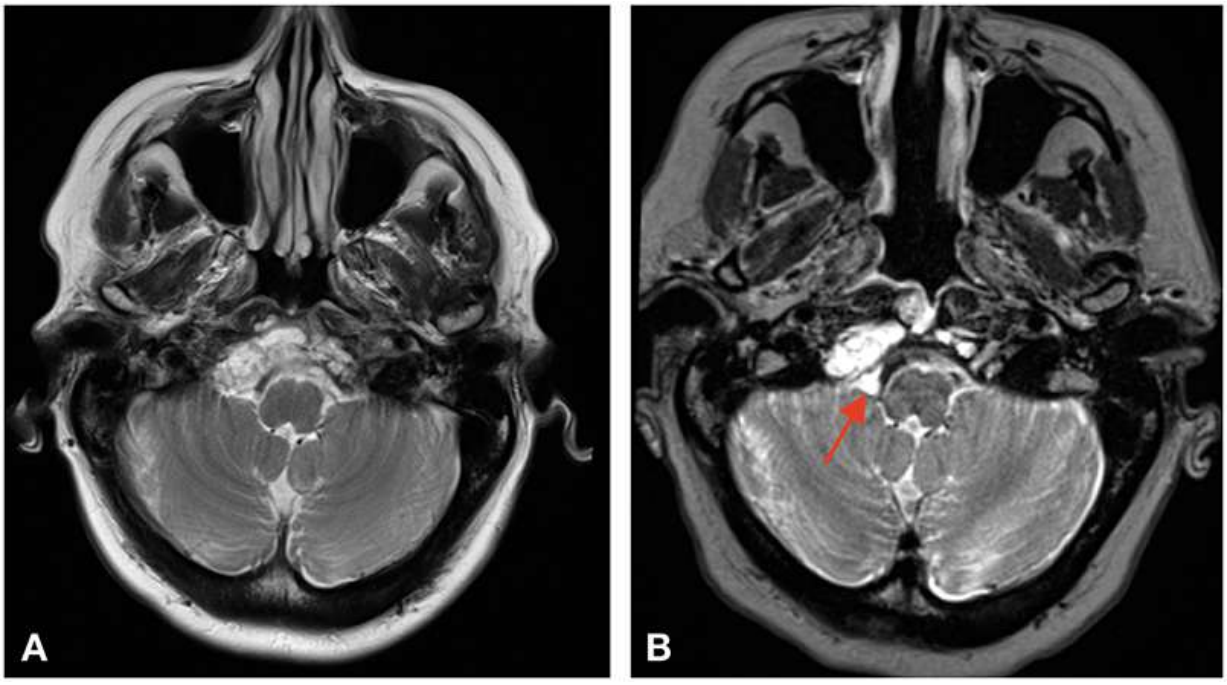

FIGURE 54.8 Chordoma of the clivus showing preoperative and postoperative T2-weighted magnetic resonance images (MRIs). A. A low-resolution preoperative MRI. B. A high-resolution, fusion planning MRI used for radiation treatment planning. Not only is the residual tumor in the bilateral occipital condyles more easily determined, but there is also a small focus of residual tumor near the brainstem that abuts the V1 segment of the vertebral artery (red arrow), which was not definitively distinguishable without the improved resolution. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Reliable signs of chordoma of the skull base are posterior extension to the pontine cistern; a lobulated, “honeycomb” appearance after gadolinium; the swollen appearance of the bone in the early stages; bone erosion on CT; and frequent extension to critical structures such as the circle of Willis, cavernous sinuses, and brainstem.[90]

General Management

Because of their surgical inaccessibility and relative resistance to RT, clival chordomas represent a formidable therapeutic challenge. The general management of the patient is dictated by the anatomic location of the tumor and the direction and extent of spread. Upfront maximal safe resection is the primary treatment option.[81] The exception is in poorly differentiated subtypes, in which some groups propose upfront chemotherapy, followed by RT and/or surgery based on response.[85] Most modern surgical techniques include anterior endoscopic endonasal approaches (EEAs). Open craniotomy is typically reserved for staged resections in combination with EEA such as when or if the primary is not entirely accessible to an endonasal approach because of the location or extent of disease. Because of the high incidence of local recurrence, combined surgical excision and irradiation is frequently used. Figure 54.9 shows an example of a craniocervical junction chordoma, which is often a difficult location to achieve gross total resection. While erlotinib is used in the palliative setting, no effective chemotherapeutic agent or combination of drugs has been identified. The development of systemic therapies including immunotherapy, tyrosine kinase inhibitors, brachyury vaccines, and enhancer of zeste homolog 2 inhibitors such as tazemetostat are currently in the investigational stage.[91]

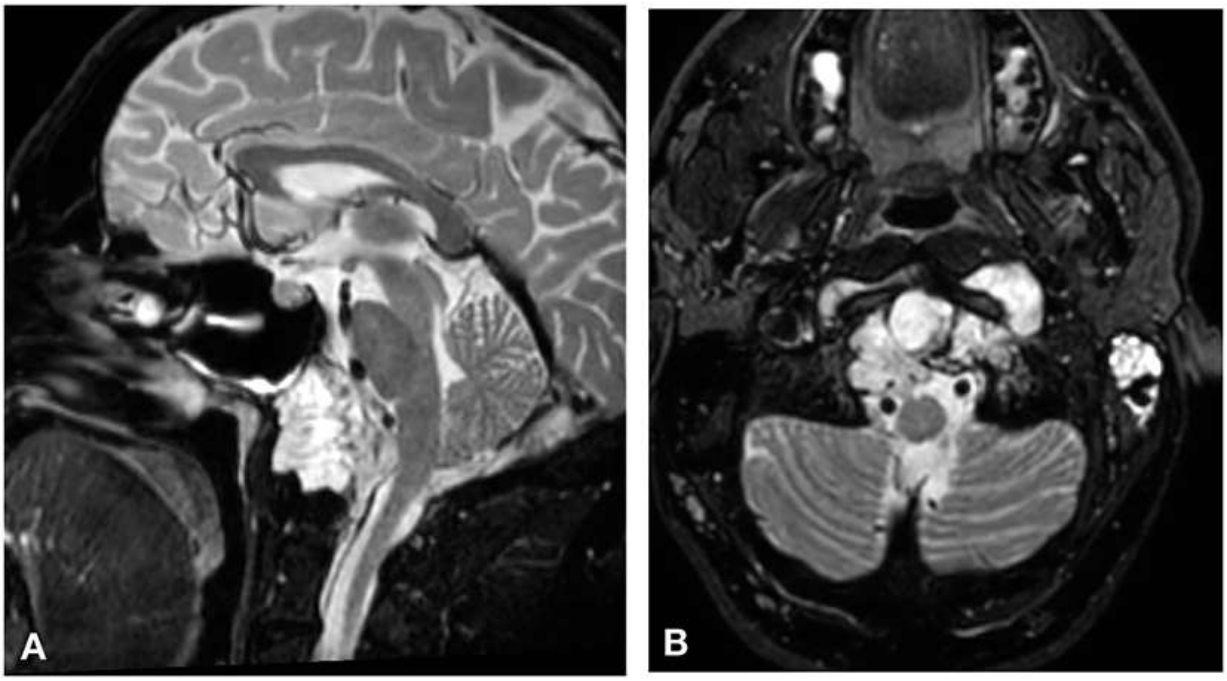

FIGURE 54.9 Sagittal (A) and axial (B) T2-weighted magnetic resonance imaging showing a T2 bright craniocervical junction chordoma. This tumor involves lower one-third of the clivus. Tumors of this area often present in a tent-like manner with both a prevertebral and posterior dural component draping over the dens. Chordomas of this location have the lowest rates of gross total resection compared to sphenoidal and sellar clival lesions and higher local recurrence rates. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Radiation Therapy Techniques

Irradiation techniques vary considerably, depending on the location of the tumor along the craniospinal axis; however, highly conformal techniques with both photons or protons have become a mainstay in therapy. Precision RT planning, using CT and MRI, is required because high doses of external beam RT are needed.

The tumor usually surrounds the brainstem, optic apparatus, and spinal cord and infiltrates vertebral bones. For skull base tumors, IMRT, radiosurgery, and proton therapy (PT) are used. In the treatment of chordomas surrounding the spinal cord, PT can provide high-dose homogeneity and planning target volume (PTV) coverage. In addition to maximal safe resection, tumor decompression and removal can provide optimal target dosimetry to allow for safe dose escalation around sensitive organs at risk (OARs) (Figure 54.10). Dose levels are typically prescribed using a sequential boost with an initial volume to 50 to 60 GyRBE (Gy radiobiologic equivalent) and a boost to 70 to 74 GyRBE or higher based on the extent of resection.[81,92-97] Example target definitions and OAR dose constraints are also provided in Table 54.7. PTV expansions are based on specific institutional guidelines but are typically 2 to 3 mm with thermoplastic immobilization and daily image guidance. Of note, these OAR constraints provided were used for series with adult patients. Pediatric patients have more stringent guidelines for dose constraints and recommendations to follow institutional or cooperative group protocols for those cases.[72,96]

Treatment to high doses should be conducted at high-volume centers with experience with dose escalation, given the associated risks of CNS necrosis.[98,99] For skull base chondrosarcoma, target coverage is typically compromised to meet more conservative dose constraints of the brainstem and optics as studies show no difference in ultimate tumor control.

TABLE 54.7 SUMMARY TREATMENT VOLUME DEFINITIONS AND ORGAN AT RISK DOSE CONSTRAINTS FOR ADULTS WITH SKULL BASE CHORDOMA

ICRU-62 Volume	Dose	Definition
GTV		Gross residual and/or tumor bed
CTV low	50-60 GyRBE at 1.8/2 GyRBE	GTV expanded for preoperative and high-risk subclinical extent of disease
CTV high	>70 GyRBE at 1.8/2 GyRBE	GTV
PTV	CTV plus 3 mm based on institutional practice and daily CBCT image guidance	

Organ	Dose constraint (GyRBE)
Brainstem D (0.1 mL)	<55, 64
Brainstem core[a] D (0.1 mL)	<50, 60
Spinal cord D (0.1 mL)	<50, 55
Optic chiasm D (0.1 mL)	<55, 60
Optic nerves D (0.1 mL)	<55, 60
Retina D (0.1 mL)	<50 Gy
Cochlea (D_{max})	<36, 45
Temporal lobe (V20)	<10%
Temporal lobe (V60)	<6 mL
Temporal lobe (V70)	<1.5 mL
Hippocampus (mean)	<5, 20
Pituitary gland (mean)	<30

Mayo Clinic Florida target volume definition and dose constraints for skull base tumors in adult patients (age >22 years). The listed constraints represent two dose levels; this represents primary and secondary priorities. The constraints for the optic chiasm and optic nerve, retina and brainstem, the secondary constraints represent absolute, hard constraints with few exceptions. Note that these constraints may differ significantly from pediatric constraints and are best conducted at high-volume skull base centers.

CBCT, cone-beam CT; CTV, clinical tumor volume; D(0.1 mL), maximum dose to 0.1 mL; D_{max}, maximum dose; GTV, gross tumor volume; PTV, planning tumor volume.

[a]Brainstem core is a 3-mm anisotropic subtraction structure 3 mm in all directions, except superior and inferior.

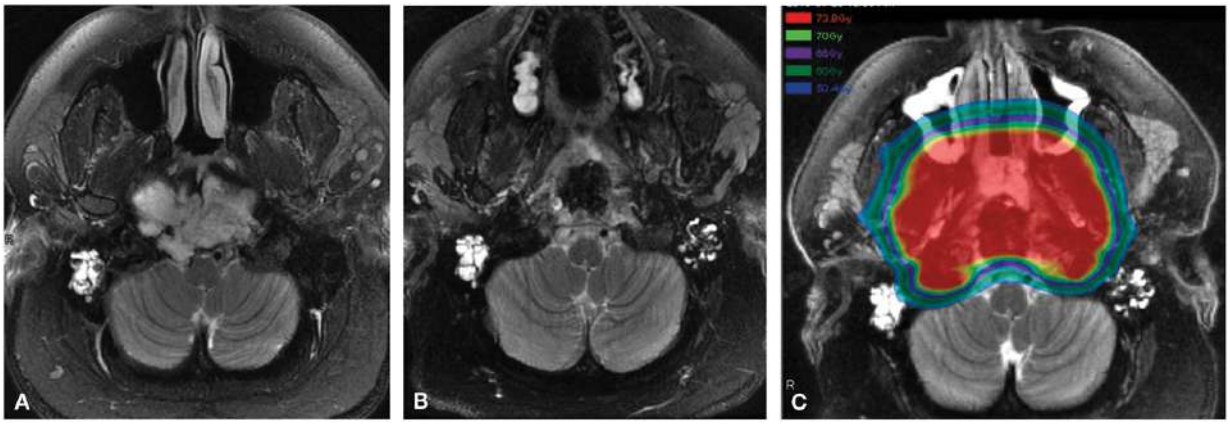

FIGURE 54.10 Axial T2-weighted magnetic resonance imaging showing preoperative (A), postoperative (B), and fused color wash (C) dose distribution of a near-totally resected clival chordoma. Preoperatively, there was gross tumor abutting the brainstem, and by decompressing the tumor via an endoscopic endonasal technique, this created a 2- to 3-mm space between the brainstem and the postoperative resection bed. This allowed for full-dose escalation to 73.8 GyRBE to be delivered in the adjuvant setting with proton therapy without compromising target coverage at the interface between a critical organ at risk. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Of note, one issue when planning for chordomas that involve the spine includes the introduction of titanium hardware often used for spinal stabilization. This may cause significant image artifacts on image registration, target delineation, and dose calculation. More recently, carbon fiber–reinforced polyetheretherketone low-density implantable material has been used to improve robustness for treatment planning with particle therapy (Figure 54.11).[100]

FIGURE 54.11 A. Cervical-thoracic spinal chordoma showing axial magnetic resonance imaging (MRI) on presentation with cord compression. B. The postoperative hardware is shown on sagittal computed tomography (CT). Because it is carbon fiber, low-density material, there is little image artifact. Not only does this improve treatment plan robustness for planning with particle therapy, but also as shown greatly reduces CT- and MRI-based artifact. This improves visualization of the tumor bed and avoidance structurs, such as the spinal cord, that are often being treated to their normal tissue tolerance. C. Postoperative radiotherapy following decompressive surgery showing the planning target volume (lime green) being treated using a mixed proton-photon in a 2:1 ratio technique to a total dose of 75.6 GyRBE. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Because of the slow proliferative nature of chordomas, high linear energy transfer (LET) may prove useful in their management, as discussed later.

Results of Therapy

Photons

Although survival in some patients with chordoma may be long term, the salient feature of this unusual neoplasm is local recurrence with eventual death. The course may be indolent, with multiple treatments for recurrences, but the overall 5-year disease-free survival rate is <10% to 20%. Catton et al[101] analyzed the long-term results of treatment for patients with chordoma of the sacrum, base of the skull, and mobile spine treated predominantly with postoperative photon irradiation. In 20 base of skull chordomas, most of them were irradiated with conventionally fractionated radiation to a median dose of 50 Gy in 25 fractions for 5 weeks (range 25-50 Gy), and the median survival was 62 months (range 4-240 months) from diagnosis with no difference between clival and nonclival presentations. There was no survival advantage to patients receiving radiation doses >50 Gy (median 60 Gy) compared with lower doses <50 Gy (median 40 Gy). Hyperfractionation regimens did not influence the degree or duration of symptomatic response or PFS. Median survival after retreatment was 18 months. Of note, modern series now treat patients to doses of 70 Gy or higher in the primary and adjuvant setting for residual disease.

Forsyth et al[102] reported on 51 patients with intracranial chordomas (19 classified as chondroid) treated surgically (biopsy in 11 patients and subtotal removal or greater in 40); 39 patients received postoperative irradiation. At the time of the analysis, 17 patients were alive. The 5- and 10-year survival rates were 51% and 35%, respectively; 5-year survival was 36% for biopsy patients and 55% for those who had resection. Patients who underwent postoperative irradiation tended to have longer disease-free survival times.

Gay et al[103] analyzed the outcome of 46 patients with cranial base chordomas and 14 with chondrosarcomas after extensive surgical resection, with 50% of them treated previously and 20% received postoperative irradiation. Nine patients with chordomas and two with chondrosarcomas died during the postoperative follow-up period. The 5-year recurrence-free survival (RFS) for all patients was 76%. Chondrosarcomas had a better prognosis than chordomas (5-year RFS of 90% and 65%, respectively; $P = .09$). Patients who had undergone previous surgery had a greater risk of recurrence than did those who had not undergone previous surgery (5-year RFS rates of 64% and 93%, respectively; $P < .05$). Those with total or near-total resection had a better 5-year RFS rate (84%) than did patients with partial or subtotal resection (64%; $P < .05$). Postoperative leakage of cerebrospinal fluid was the most frequent complication (30% of patients) and was found to increase the risk of permanent disability. Patients who had undergone previous irradiation had a greater risk of death in the postoperative period (within 3 months of operation) and during follow-up.

Tai et al[104] reviewed the results of irradiation combined with surgery, irradiation alone, and SA in 159 patients reported in the literature. An analysis of the optimal biologically equivalent dose was performed using the linear-quadratic formula on 47 patients. With conventional photon irradiation, no dose-response relationship was shown. Survival improved in patients undergoing surgery followed by irradiation.

Keisch et al[105] reported on 21 patients with chordoma treated at the authors' medical center: 5 had clival tumors, 2 had nasopharyngeal tumors, and 1 had a lumbar spine tumor. Nine patients were treated with SA, eight had subtotal resection and postoperative irradiation, and four received irradiation alone after biopsy. The 5- and 10-year actuarial survivals were significantly better in patients treated with SA or surgery and irradiation than in those treated with RT alone (52%, 32%, and 0%, respectively; $P = .02$). Disease-free survival of patients with base of skull tumors was not significantly different among the treatment groups.

Kim et al[106] reported 14 clivus chordomas undergoing postoperative IMRT simultaneous integrated boost (SIB). Total and near-total resections were achieved in 11 (78.6%) patients and partial in 2 (14.3%) patients, and 1 (7.1%) patient received RT for recurrent tumor after total resection. A moderate hypofractionation schedule was used: Doses to PTV1, PTV2, and PTV3 were 3.9, 3.15, and 2.8 Gy through 15 fractions for the first two patients, and the rest received 2.5, 2.2, and 1.8 Gy through 25 fractions, respectively. The biologically equivalent dose in 2-Gy fractions (EQD2) was 65 to 68 Gy for PTV1, 52 to 56 Gy for PTV2, and 44.3 to 44.8 Gy for PTV3. The median follow-up was 41 months. Eight patients were free of disease for a median of 42.5 months (range 23-91 months), four patients had stable disease for a median of 60.5 months, and 1 patient showed partial response for 38 months after RT. Estimated 5-year PFS and OS rates were 92.9%. IMRT-SIB was well tolerated without lasting toxicity.

Debus et al[107] reported on 45 patients treated for chordoma or chondrosarcoma with postoperative fractionated 3D SRT. The median dose at isocenter was 66.6 Gy for chordomas and 64.9 Gy for chondrosarcomas. All chondrosarcomas achieved and maintained local tumor and recurrence-free status at 5 years of follow-up. LC rate of chordomas at 5 years was 50%, and survival was 82%. Clinically significant late toxicity developed in only one patient.

Den et al[108] described a multi-institutional study of 31 patients, of whom 28 with clivus chordoma or chondrosarcoma, treated with various photon techniques (single-dose stereotactic, fractionated 3D chemoradiation therapy [CRT], IMRT). The median fractionated total dose was 65 Gy. Actuarial 3-year local tumor control was 68%, and OS was 63%. Patients receiving 65 Gy or a higher dose had a 5-year tumor control of 78% and OS of 90%. No grade 2 or greater toxicity was observed.

Muthukumar et al[109] published a report on 15 patients with skull base chordoma and chondrosarcoma treated with SRT (13 had previous surgical resection). The median minimum marginal tumor single dose was 18 Gy (12-20 Gy), and the number of isocenters ranged from 1 to 10 (average, 4). Dose to the optic nerve or chiasm was ≤9 Gy. With a median follow-up of 40 months, eight patients had clinical improvement, three were stable, and four had died. No significant morbidity was noted.

Sahgal et al[110] reviewed 24 patients treated with skull base chordoma with IG-IMRT to a median dose of 76 Gy at 2 Gy per treatment. The 5-year OS and LC rates were 85.6% and 65.3%, respectively. Radiation toxicities were limited despite treating to high doses to the optic chiasm, nerves, and brainstem.

Particle Therapy

Successful results have also been demonstrated with surgical resection followed by high-dose particle irradiation.[111] A representative summary of studies evaluating PT for skull base chordoma in adult patients is shown in Table 54.8. Berson et al[112] described 45 patients with chordomas or chondrosarcomas at the base of the skull or cervical spine treated by subtotal resection and postoperative irradiation. Twenty-three patients were treated definitively by charged particles, 13 patients with photons and particles, and 9 were treated for recurrent disease. Doses ranged from 36 to 80 Gy equivalent (GyE). There appeared to be significant benefit for patients with smaller tumor volumes (80% vs 33% actuarial survival rate at 5 years). Patients treated for primary disease had a 78% actuarial local tumor control at 2 years versus 33% for recurrent disease.

TABLE 54.8 LITERATURE SUMMARY OF REPRESENTATIVE PROTON THERAPY STUDIES FOR SKULL BASE CHORDOMA

Author (Reference)	Patients (*n*)	Median Dose (GyRBE)	Follow-Up Median (Years)	Local Control

NR, not reported.

Austin et al[117] evaluated 141 patients with chordoma and chondrosarcoma of the base of skull and cervical spine treated with proton and photon irradiation. The local disease was controlled in 111 patients. They reviewed 26 patients who had recurrent disease (21 nonchondroid chordomas, 2 chondroid chordomas, and 3 chondrosarcomas). The prescribed doses ranged from 67 to 72 GyRBE. Approximately 25% (6/26) of the cases failed in the prescribed dose region. More than half (15/26) failed in regions where tumor dose was limited by normal tissue constraints. Approximately 10% of the patients recurred in the surgical pathway, and 10% were judged to be marginal misses. Overall, 75% of the patients failed in regions receiving less than the prescribed dose. All tumors that failed in the high-dose region had recurrences (10/26) and larger tumors (average volume of 102 mL) than those with base of skull disease (16/115), with an average volume of 63 mL.

O'Connell et al[118] reported on 62 patients with base of skull chordomas treated with proton beam irradiation (65-73.5 GyE); 29 patients (19 women and 10 men) experienced local failure, and 14 women (48%) and 7 men (21%) died of disease. On histologic analysis, the presence of >10% necrosis, prominent nucleoli, and tumor >70 mm were

significant predictors of short-term DSS. Chondroid chordoma and conventional chordomas had equivalent outcomes.

Fagundes et al[119] reviewed the Massachusetts General Hospital experience with 204 patients treated for chordoma of the base of the skull or cervical spine. Sixty-three (31%) patients had treatment failures, which were local in 60 (29%) patients and the only site of failure in 49 patients. Two patients had regional lymph node relapse, and three developed surgical pathway recurrence. Thirteen patients relapsed in distant sites (especially lungs and bones). The 5-year actuarial survival rate after any relapse was 7%. Terahara et al[120] reported on 132 patients with skull base chordoma treated with combined photon and proton irradiation; in 115 patients, dose-volume data and follow-up were available. The prescribed doses ranged from 66.6 to 79.2 GyRBE (median 68.9 GyRBE). Dose to the optic structures (optic nerves and chiasm), the brainstem surface, and the brainstem center was limited to 60, 64, and 53 GyRBE, respectively. Local failure developed in 42 of 115 patients, with the actuarial local tumor control rates at 5 and 10 years being 59% and 44%, respectively. In a Cox multivariate analysis, the model's equivalent uniform dose suggested that the probability of recurrence of skull base chordomas depends on gender, target volume, and target dose inhomogeneity; equivalent uniform dose was shown to be a useful parameter to evaluate dose distribution for the target volume.

Hug et al[114] analyzed efficacy of fractionated proton RT for 33 skull base chordomas and 25 chondrosarcomas. Following various surgical procedures, residual tumor was present in 91% of patients; 59% demonstrated brainstem involvement. Target doses ranged from 64.8 to 79.2 GyRBE (mean 70.7 GyRBE). The range of follow-up was 7 to 75 months (mean 33 months). In 10 (17%) patients, the treatment failed locally, resulting in LC rates of 92% (23/25 patients) for chondrosarcomas and 76% (25/33 patients) for chordomas. All tumors with volumes of ≤25 mL remained locally controlled compared with 56% of tumors >25 mL (P = .02). Of patients without brainstem involvement, 94% did not experience recurrence, whereas with brainstem involvement (and dose reduction because of brainstem tolerance constraints), the tumor control rate was 53% (P = .04). Actuarial 5-year survival rates were 100% for patients with chondrosarcoma and 79% for patients with chordoma. Grade 3 and 4 late toxicities were observed in four (7%) patients and were symptomatic in three (5%).

Ares et al[121] treated 42 patients with chordomas and 22 with chondrosarcomas of the skull base using spot scanning protons (median doses 73.5 and 68.4 Gy, respectively, at 1.8-2.0 GyRBE). With a median follow-up of 38 months, 5-year tumor control was 81% and 94% and OS 100% and 91%, respectively. Late toxicity consisted of one grade 3 and one grade 4 unilateral optic neuropathy and two patients with grade 3 CNS necrosis. No patient experienced brainstem toxicity.

Noël et al[122] reported on 49 chordomas and 18 chondrosarcomas treated with high-energy photons (two-thirds of dose) and 201-MeV protons (one-third of dose). The median total dose was 67 GyRBE (60-70 GyRBE). With a median follow-up of 32 months, 3-year local tumor control was 71% for chordomas and 85% for chondrosarcomas and 4-year OS was 88% and 75%, respectively. Fourteen tumors (21%) failed locally.

Weber et al[95] reported on 71 patients with chordoma who received pencil-beam scanning PT at a typical dose of 74 GyRBE. The estimated 7-year LC and OS rates were 70.9% and 81.7%, accordingly. On multivariate analysis, optic apparatus and/or brainstem compression, histology, and GTV were independent prognostic factors for LC and OS.

Holtzman et al[92] reported on 112 patients treated with PT to a median dose of 73.8 GyRBE. At 5 years after RT, the actuarial OS, DSS, and LC rates were 78% (n = 87), 83% (n = 93), and 74% (n = 83), respectively. LC and DSS by resection status were 95% versus 70% (P = .28) and 100% versus 80% (P = .06) for gross total versus subtotal, resection or biopsy alone.

Indelicato et al[96] reviewed 29 patients treated with passively scattered PT, the majority of which involved the base of skull or cervical spine to a median dose of 73.8 GyRBE. The 5-year LC, PFS, and OS were 85%, 82%, and 86%, respectively. Excluding three patients with dedifferentiated/not otherwise specified chordoma, the 5-year LC rate increased to 92%. Serious grade 3 or higher toxicity included three patients with hardware failure or related infection requiring revision surgery; however, no patient experienced CNS toxicity including brainstem injury, myelopathy, vision loss, or hearing loss after radiation.

In a prospective trial of 20 patients treated with PT with chordoma/chondrosarcoma published by Baumann et al, 3-year LC was 86%, with two patients with acute grade 3 toxicity (fatigue) and one patient with late grade 3 toxicity (osteoradionecrosis).[123]

In the largest pediatric chordoma study to date, Ioakeim-Ioannidou et al[94] reviewed 204 pediatric patients with base of skull tumors treated with proton-based RT to a median dose of 76.7 GyRBE to GTV. Ten- and 20-year OS and PFS rates were 78% and 69% and 64% and 64%, respectively. Multivariable actuarial analyses showed poorly differentiated subtype, radiographical progression prior to RT, larger treatment volume, and lower clivus location to be prognostic factors for worse OS, PFS, and LC. RT late toxicity was acceptable with 12% of patients with late toxicities, including 2% who developed second malignancy.

Tobert et al[124] reviewed impact of proton-based RT following surgery for 67 patients with spinal or sacral chordoma. Stratified by if patients received >70 GyRBE, OS was greater for the patients who received 70 Gy or higher (5-year OS 82% vs 63%, P = .001).

Palm et al[98] reviewed 715 patients with chordoma treated with PT or conventional RT from the National Cancer Database (NCDB) patients. In patients with chordoma, PT was associated with improved OS at 5 years in a multivariate analysis (100% vs 34.1%; P = .031), and a high dose for chordoma was significant for improved OS in a univariate analysis with both definitive (79.0% vs 54.1%; P = .027) and perioperative (83.3% vs 77.4%; P = .007).

Benk et al[125] described results in 18 children with base of skull or cervical spine chordomas who received fractionated high-dose postoperative irradiation using mixed photon and 160-MeV proton beams. Median tumor dose was 69 GyRBE, with a 1.8-GyRBE daily fraction. With a median follow-up of 72 months, the 5-year survival was 68%, and the 5-year disease-free survival rate was 63%. Patients with cervical spine

chordomas had a worse survival rate than did those with base of skull lesions (P = .008). Treatment-related morbidity was acceptable: Two cases of growth hormone deficit corrected by hormone replacement, one temporal lobe necrosis and one fibrosis of the temporalis muscle, improved after surgery.

A report on PT for base of skull chordoma published by the Royal College of Radiologists[126] concluded that outcome after proton irradiation is superior to that reported for conventional photon irradiation; however, a Cochrane library review[97] noted that there is a lack of published evidence to confirm a clinical difference between modalities. In summary, RT schedules involving a mixed regimens of either and including both protons and photons have achieved an approximately 60% to 80% local tumor control rate at 5 years and 50% to 60% at 10 years.

Recently, heavy particles have been used to treat some of these patients.[111,112,127] While PT has the ability to reduce low and moderate doses of RT, both proton and photon modalities are limited in the potential to biologically intensify therapy beyond physical dose deposition alone (Figure 54.12). Because carbon exhibits a higher LET than photons and protons, this leads to a higher RBE, where damage caused by carbon ions is clustered in the DNA, overwhelming the cellular repair systems.[128] Ongoing studies regarding LET optimization with protons are underway, both protons and photons are considered low LET. A representative summary of studies evaluating carbon ion RT (CIRT) for skull base chordoma is shown in Table 54.9.

TABLE 54.9 CARBON ION RADIOTHERAPY LITERATURE SUMMARY FOR SKULL BASE CHORDOMA

Author, Reference, Institution	LOE/Study Design	Number of Patients	Median Total Dose and/or Dose Range, GyE	Total Fractions	Median Follow-Up, Months (Range)	Local Control Rate	Overall Survival Rate	Grade 3+ Toxicity or Other QoL Outcome

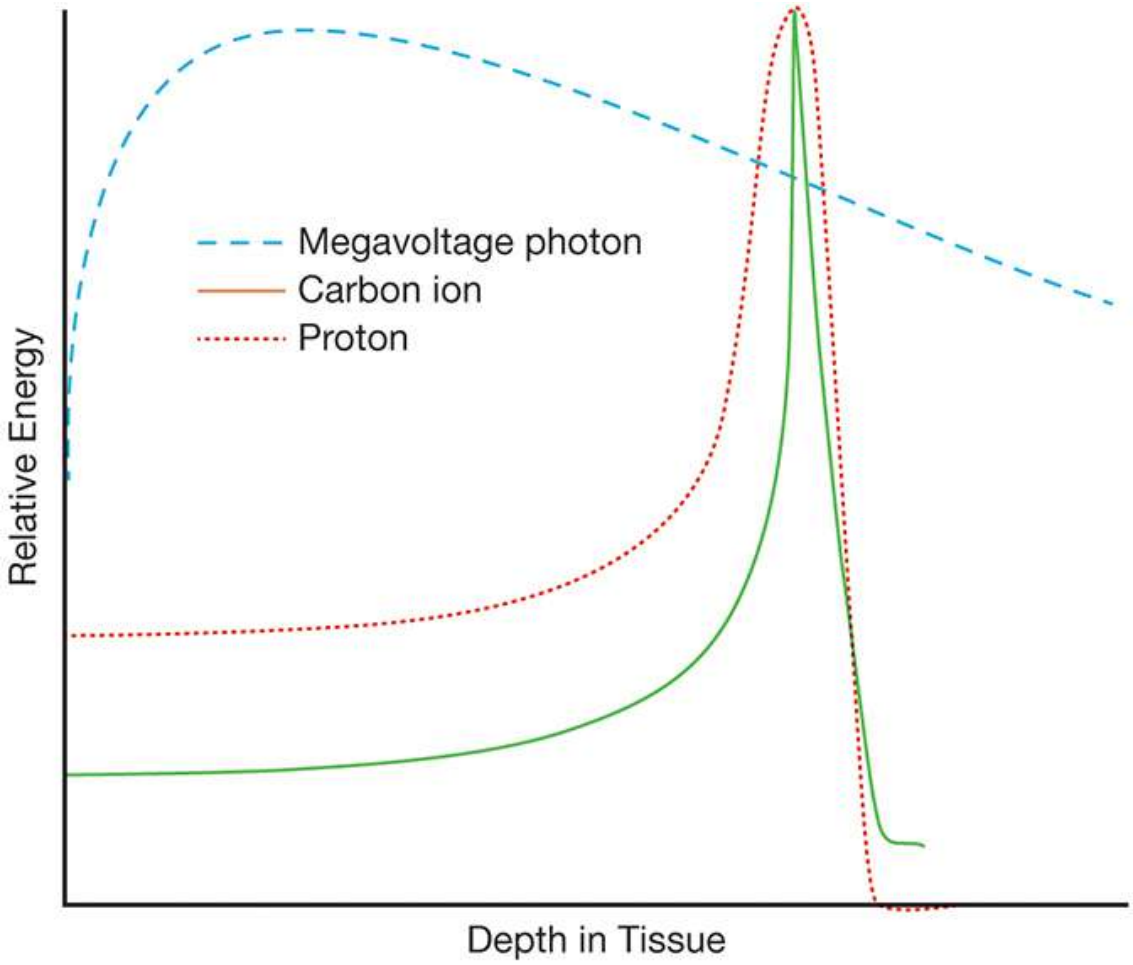

FIGURE 54.12 Dose deposition at depth for 6-MV photons, protons, and carbon ions. Carbon ions exhibit a characteristic energy distribution in depth, known as the "Bragg peak," where low levels of energy are deposited in tissues proximal to the target, and the majority of energy is released in the target. Distal tissues receive little energy, although, unlike protons, there is energy deposited distally due to nuclear fragmentation. (Reprinted from Malouff TD, Mahajan A, Krishnan S, Beltran C, Seneviratne DS, Trifiletti DM. Carbon ion therapy: a modern review of an emerging technology. *Front Oncol*. 2020;10:82. http://creativecommons.org/licenses/by/4.0/.)

Hasegawa et al[136] reported on 54 patients with skull base or paracervical tumors (31 with chordomas) treated with carbon ions (escalating doses from 48 to 60.8 GyE in 16 fractions over 4 weeks). In the 31 patients with chordoma, 5-year local tumor control and OS were 78% and 85%, respectively. Patients were divided into two groups: a low-dose group (n = 10) irradiated with doses ranging from 48 to 57.8 GyE and a high-dose group (n = 21) irradiated with 60.8 GyE. The 5-year local tumor control was 60% for the low-dose group and 93% for the high-dose group, and the OS was 90% and 84%, respectively. One late grade 2 brain sequela was noted in a patient treated with 60.8 GyE.

Likewise, Schulz-Ertner et al[121] treated 24 chordomas and 13 chondrosarcomas with 3D planning carbon ions (median dose 60 GyE). With a mean follow-up of 13 months, local tumor control at 2 years was 90%. PFS was 83% for chordomas and 100% for chondrosarcomas. No significant toxicity was observed.

Mattke et al[127] reviewed the outcomes of patients treated with either carbon or PT for skull base chordoma. With a median follow-up over 4 years, no significant differences between protons and carbon ions were observed regarding LC, OS, or overall toxicity. The 5-year LC rates were 61% for protons and 65% for carbon.

Holtzman et al[137] performed a systematic review that reviewed the quality of evidence and identified 24 papers published on skull base chordoma treated with CIRT. Two systematic reviews were identified. Lu et al reported the LC incidence at 1-, 5-, and 10 years following carbon therapy were 99%, 80%, and 56%, respectively.[129] The incidence of severe early and late toxicity ranged from 0% to 4% across all study groups. Dong et al identified nearly 900 patients with skull base sarcomas who received CIRT, 526 had chordoma, and 255 had chondrosarcoma. The LC rate at 5 and 10 years in these studies was 74.3% and 64.7%, respectively. The incidence of acute grade 3 toxicity was 3.2% to 3.8%, and late grade 4 was 2.1% to 8.0%.[138]

Sequelae of Treatment

While highly conformal external beam RT has been used to mitigate acute and late effects following therapy, in patients treated with high irradiation doses, there is an increasing probability of sequelae, including brain damage (Figure 54.13A), brainstem (Figure 54.13B) and spinal cord injury, optic pathway toxicity (Figure 54.13C), bone or soft tissue necrosis, and xerostomia.[139]

FIGURE 54.13 Representative toxicities following high-dose complications from radiotherapy. A. Left temporal radionecrosis as shown on T1-weighted magnetic resonance imaging (MRI) with contrast (red arrow). B. T1-weighted brain MRI showing axial slice illustrating enhancement in the right pons consistent with clinically asymptomatic brainstem necrosis (red arrow). C. Bilateral enhancement on coronal brain MRI showing bilateral optic nerve enhancement (red arrows). This patient developed bilateral grade 4 vision loss. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Regarding the temporal lobe, several groups have evaluated clinical outcomes following PT. McDonald et al[140] in 2014 published the outcomes on 66 patients with skull base tumors treated with uniform scanning 3D conformal PT to a median dose of 75.6 GyRBE. The 3-year estimate of any grade temporal lobe radiation necrosis was 12.4%, and they illustrated that only the dose-volume relationship was associated with the risk of radiation necrosis. They modeled a 15% 3-year risk of any grade temporal lobe radiation necrosis

when the absolute volume of a temporal lobe receiving 60 GyRBE exceeded 5.5 cm^3, or V70 >1.7 cm^3. In regard to the clinical implications and determination of RBE and LET for PT, this is still a debate. Clinical evidence shows that the RBE for protons may in fact be higher than as reported as 1.1. While the incidence of temporal lobe epilepsy and grade 3 complications are rare, more work into RBE optimization and understanding its clinical effects is ongoing. Zhang et al reviewed 566 patients treated with double-scattering PT or IMRT. The reported dose tolerance at D1% was 58.6 Gy for protons and 69.1 Gy for photons, with the calculated RBE for temporal lobe enhancement being 1.18.[141]

Schröder et al[142] evaluated nearly 300 patients with a median radiologic follow-up of over 4.5 years. They showed that not only clinical dose but also age, V40Gy, hypertension, and dose to at least 1 mL (D1cc) in the temporal lobe were associated with grade 2 necrosis or greater. This was cross-valuated and used to develop an age * prescription-dose * D1cc (Gy) * hypertension patient-wise model to predict the risk of radionecrosis following PT.

In patients receiving high-dose PT for clivus tumors, Slater et al[143] observed a 26% incidence of endocrine abnormalities at 3 years and 37% at 5 years, with hypothyroidism being the most frequent sequela. The dose to the pituitary in patients with abnormalities ranged from 63.1 to 67.7 GyE.

Weber et al[95] reviewed in a series of 222 patients with skull base chordoma and chondrosarcoma treated to a median dose of 72.5 GyRBE with pencil-beam PT. In total, there were 25 events (≥grade 3 toxicity): 5 (25%) patients with grade 3 unilateral optic neuropathy, 2 (8%) patients with grade 4 bilateral optic neuropathy, 13 (56%) patients with grade 3 temporal lobe necrosis, 1 (8%) with cerebellum brain parenchyma grade 3 necrosis, 1 (8%) patient with a grade 4 spinal cord necrosis, and 3 (12%) patients with grade 3 unilateral hearing loss. Of note, no patient experienced brainstem toxicity nor grade 5 toxicity or treatment-related secondary malignancies were observed. The estimated 5- and 7-year high-grade (≥grade 3 toxicity) toxicity-free survival was 87.2 (95% confidence interval [CI] 82.4-92.3). A summary of brainstem toxicity is provided in Table 54.10.

TABLE 54.10 REPRESENTATIVE LITERATURE SUMMARY OF BRAINSTEM NECROSIS IN SKULL BASE TUMOR SERIES

Author (Reference)	Size (n)	Follow-Up	Brainstem Dose (GyRBE)	Brainstem Complications
Holtzman et al[144]	163	Median—47 mo	D(0.03 mL) 63.5 D_{max} 65.7	1.3% grade 2+
Weber et al[95]	222	Mean—50 mo	NR Mean prescribed dose 72.5	No events
Sahgal et al[110a]	42	Median—36 mo	D_{max} 67.6	1 brainstem glioma
Feuvret et al[145]	159	Median—77 mo	D_{max} <64	1 brainstem glioma
Debus et al[146]	367	Mean—42.5 mo	D_{max} 63	4% grade 2+

All series included used proton-based techniques with the one noted exception.

[a]Intensity-modulated radiotherapy.
D(0.03 mL), maximum dose to 0.03 mL; D_{max}, maximum dose; NR, not reported.

Chhabra et al[93] reported the clinical outcomes and toxicities of 100 patients treated with PT for chordoma on the proton collaborative group prospective registry to a median dose of 74 GyRBE. Acute grade 3 toxicity consisted of common pain (n = 3), radiation dermatitis (n = 2), fatigue (n = 1), insomnia (n = 1), and dizziness (n = 1). No grade ≥ 4 acute toxicities were reported nor grade ≥ 3 late toxicities.
