Described in the 1960s, trachelectomy entails removal of the cervix entirely. Radical trachelectomy also removes the parametrial tissue. As a means of fertility preservation in patients with early-stage cervical cancer, trachelectomy should be combined with preoperative PET imaging to confirm no nodal involvement and with MRI to confirm no endocervical canal extension of tumor into the uterus. A laparoscopic lymphadenectomy should accompany the trachelectomy to confirm no nodal involvement. A nonabsorbable cerclage is placed around the uterine isthmus. Radical abdominal trachelectomy also may result in successful fertility preservation. Selection criteria for a trachelectomy include those patients requesting fertility-sparing surgery; age less than 40 years; stage IA1, IA2, or IB1 with no nodal involvement detected on MRI or PET scan; squamous cell or AC with a lesion less than 2 cm; no lymphovascular invasion on initial biopsy; and no upper endocervical involvement. The main site for recurrence is the central pelvis (average 5% risk), at the cervicouterine junction, or in the adjacent parametrial tissue. In a retrospective review of 29 patients with stage IB1 disease with tumor size 2 cm or greater treated with radical trachelectomy, patients with high-risk features were taken to immediate hysterectomy, and 21% required CRT. A total of nine patients (31%) were able to undergo a fertility-sparing procedure, with one recurrence at a median follow-up of 44 months.[116] If high- or intermediate-risk features are present (ie, presence of positive lymph nodes or positive margins) after a trachelectomy, radiation should be performed without requiring a completion hysterectomy. Leaving the uterus intact results in less small-bowel dose; radiation or CRT followed by image-based BT with an attenuated dose based

on the amount of residual disease in the uterus is feasible in order to minimize bladder and rectal dose.[117]

Types of Hysterectomy

Several types of hysterectomy are used in the management of carcinoma of the uterine cervix (Table 76.4).

TABLE 76.4 TYPES OF ABDOMINAL HYSTERECTOMY

	Intrafascial	Extrafascial Type I	Modified Radical Type II	Radical Type III-IV[a]
Cervical fascia	Partially removed	Completely removed	_____	_____
Vaginal cuff removal	None	Small rim removed	Proximal 1-2 cm removed	Upper one-third to one-half removed
Bladder	Partially mobilized	_____	_____	Mobilized
Rectum	Not mobilized	Rectovaginal septum partially mobilized	_____	Mobilized
Ureters	Not mobilized	_____	Unroofed in the ureteral tunnel	Completely dissected to the bladder entry
Cardinal ligaments	Resected medial to the ureters	_____	Resected at level of the ureter	Resected at the pelvic sidewall
Uterosacral ligaments	Resected at level of the cervix	_____	Partially resected	Resected at postpelvic insertion
Uterus	Removed	_____	_____	_____
Cervix	Partially removed	Completely removed	_____	_____

[a]Type IV, extended radical hysterectomy (partial removal of the bladder and/or ureter), in addition to type III.

Note: Line indicates that the procedure from the prior column moves forward into the next column(s) to the right.

Total (extrafascial) abdominal hysterectomy (class I) consists of removal of the cervix and adjacent tissues, as well as a small cuff of the upper vagina in a plane outside the pubocervical fascia. There is minimal disturbance of the

ureters and the trigone of the bladder. This may be the surgical treatment of choice for stage IA1 cervical cancer.

The use of an RH for cervical cancer was first described by Wertheim in 1912. In a modified radical extended hysterectomy (class II), the cervix and upper vagina are removed, including paracervical tissues, and the ureters are dissected in the paracervical tunnel to their point of entry into the bladder. Because the ureters are unsheathed and retracted laterally, parametrial and paracervical tissue can be safely removed medial to the ureter. This operation is performed with a lymphadenectomy. This is the most common surgical approach selected for stage IA2 cervical cancer.

Radical abdominal hysterectomy (class III) with bilateral pelvic lymphadenectomy consists of a wider resection of the parametrial tissues to the pelvic wall, with dissection of the ureters and mobilization of the bladder, as well as of the rectum to allow for more extensive removal of tissues. This approach was described by Meigs in 1944. In addition, a vaginal cuff of at least 2 to 3 cm is always included in the procedure, as well as the uterosacral ligaments. A bilateral pelvic lymphadenectomy is usually carried out. This operation is often referred to as the Wertheim or Meigs procedure. The extended RH (class IV) includes complete dissection of the ureter from the vesicouterine ligament, sacrifice of the superior vesicle artery, and removal of the upper three-fourths of the vagina. Because of the high rate of fistula and significant morbidity, it is rarely used. In 2007, after a consensus conference in Japan, a new classification system was released based only on the lateral extent of the resection.[118] Four levels of hysterectomy are described (A-D) and four levels of lymphadenectomy (1-4). The levels of lymph node dissection include the internal and external iliac (level 1), common iliac and presacral (level 2), aortic intramesenteric (level 3), and aortic infrarenal (level 4). The levels of primary tumor resection include the following:

Type A: Extrafascial hysterectomy, with minimum resection of the paracervix medial to the ureter and minimal vaginal resection less than 1 cm, without removal of the paracolpos

Type B: Modified RH with partial resection of the vesicouterine and uterosacral ligaments, unroofing of the ureter, transection of the parametrial tissue at the ureter, and removal of at least 1 cm of the vagina. This type is divided into B1, without removal of paracervical lymph nodes, and B2, with removal of lateral paracervical nodes.

Type C: Classic RH, variant in which the entire uterosacral and vesicouterine ligaments are removed, 1.5 to 2 cm of the vagina with paracolpos is excised, and neuronal preservation is critical

Type D: Includes the complete RH and resects tissues to the pelvis sidewall, including the hypogastric (internal iliac) vessels, and exposes the sciatic nerve (type D1). Type D2 also removes the fascial and lateral muscles, called the laterally extended endopelvic resection.

Open Abdominal Versus Minimally Invasive Approach

Historically, the standard approach for hysterectomy was open abdominal for cervical cancer. As pelvic laparoscopic surgery, with or without robotic techniques, became more prevalent, retrospective reports, prospective observational, and multicentered matched cohort studies reported comparable outcomes with the open approach.[119-121] However, the LACC trial, published by Ramirez et al,[122] which was a phase III noninferiority trial between open and minimally invasive approaches in 631 patients with early cervical cancer, showed significantly lower rates of 3-year DFS and OS (91.2% vs 97.1% and 93.8% vs 99.0%). Additional epidemiologic studies support this finding of better survival with the open approach.[123] Thus, even though minimally invasive approaches have known surgical morbidity benefits, such as reduced blood loss, shorter hospital stay, and less febrile morbidity,[119] the open abdominal approach remained the standard of care.

Pelvic Exenteration

Pelvic exenteration has been used for en masse removal of the pelvic viscera for recurrent carcinoma of the cervix. Modern RT with concurrent chemotherapy results in high complete response (CR) rates and has made residual extensive disease a rare indication for exenteration. Patients with adjacent organ invasion are given a course of primary concurrent CRT, followed by interstitial BT, with exenteration reserved for salvage.

This operation, which is not done as a palliative procedure, consists of an RH, pelvic lymph node dissection (PLND), and removal of the bladder (anterior exenteration), removal of the rectosigmoid colon (posterior exenteration), or both (total exenteration). The ileum or sigmoid has been the usual means of achieving urinary diversion. Because some patients have a pelvic recurrence after RT, the bowel is used for the urinary conduit. Proof

that there is no fixation to the pelvic wall and no extension of disease beyond the pelvis is mandatory. Metastases outside the pelvis, including those in PANs or any viscera, are absolute contraindications to the procedure. Bilateral ureteral obstruction secondary to tumor is also a relative contraindication. Patients with sacroiliac or hip pain or leg edema rarely benefit from this procedure and should be excluded on a clinical basis.

Chiantera et al[124] published a European multicenter series of 167 patients who underwent pelvic exenteration for cervical cancer from 1998 to 2011, 93 (56%) of 167 after primary or adjuvant pelvic RT, with or without chemotherapy. With a median follow-up of 68 months, the entire group's 5-year OS was 38%. Positive margins, positive lymph nodes, sidewall involvement, persistent and recurrent disease, and shorter interval from primary treatment were associated with poorer survival. Surgical complications resulted in death in 10 (6%) of 167 patients. As significant mortality and morbidity are associated with this procedure, it precludes its use as palliative therapy. Urinary diversion, either by nephrostomy or by ileal bladder, may be of palliative value in patients with either recurrent carcinoma in the pelvis or complications.

Pretreatment Surgical Nodal Assessment

Exploratory laparotomy and nodal staging to evaluate the presence of metastases to the pelvic or PAN may provide diagnostic information but have not had a demonstrated impact on survival.[125] A number of studies compared the significance of PAN metastases with other clinical and surgical findings with regard to PFS and OS. In 626 patients treated on GOG randomized studies, the RR associated with positive PAN was 11.0 for time to recurrence and 6.2 for survival time.[126] In addition to the significant increase in risk of regional relapses, patients with PAN metastasis are more likely to have extrapelvic failure.

Cosin et al[127] reviewed 266 patients with locally advanced cervical carcinoma who underwent extraperitoneal pelvic and para-aortic lymphadenectomy before RT. Patients were divided into four groups: Group A had negative lymph nodes; group B had resected, microscopic lymph node metastases; group C had macroscopically positive lymph nodes that were resectable at the time of surgery; and group D had unresectable lymph nodes. Lymph node metastases were detected in 50% of patients. All patients

received pelvic external beam radiation therapy (EBRT) (pre–intensity-modulated radiation therapy [IMRT] era) and BT; patients with lymph node metastases received extended-field irradiation. Five- and 10-year DFS rates were similar for all patients in groups B and C. All patients in group D recurred. There was a 10.5% incidence of severe radiation-related morbidity and a 1.1% incidence of treatment-related deaths.

The potential benefit of surgical nodal debulking followed by irradiation has been studied. Potish et al[128] noted that more than half of the patients with advanced cervical cancer with grossly positive pelvic nodes were debulked survived, compared with none with unresectable lymph nodes; however, this predated the ability to implement dose escalation with IMRT to the involved nodes. Nonetheless, surgical debulking of nodes decreases the dose of radiation required to these regions. The use of high-energy photon beams and limitation of the tumor dose to extended volumes in the para-aortic region for those with completely resected but positive nodes to 45 to 50 Gy decrease the probability of complications. IMRT also enhances the sparing of adjacent abdominal normal tissues. However, if node dissection is not feasible or would result in a treatment delay, patients may successfully be managed with IMRT with dose escalation to approximately 60 to 65 Gy to the grossly enlarged lymph nodes.[129,130]

Complication risk for surgical para-aortic assessment is high, particularly when patients are treated with postresection RT. Transperitoneal lymphadenectomy should be avoided.

Because of a high rate of complications, preirradiation laparotomy was discontinued in most cases. The status of the lymph nodes can be investigated with lymphangiography or PET-CT and verified when needed with percutaneous transabdominal needle biopsy. It is important though to remember that the false-negative rate of PET-CT can still be substantial. In one study, 125 patients had a PET-CT followed by para-aortic lymphadenectomy.[131] Seventeen percent had positive PAN metastases, 66% of whom had a negative PET-CT. The sensitivity and specificity of PET-CT were 33% and 94%, respectively. Morbidity of the surgery was 7%, and there was no delay in initiating CRT. Alternatively, PAN sampling may be performed through a laparoscopic approach; the procedure is well tolerated, recovery is prompt, and yield is adequate.[132]

Aside from PAN, supraclavicular metastases may rarely be involved. However, there is no indication for routine removal of the clinically negative supraclavicular nodes.

Sentinel Lymph Node Biopsy

Sentinel lymph node (SLN) studies show mixed results, with a 20% false-negative rate and a 50% incidence of other pelvic metastases.[133] However, the method allows for aborting surgery and pursuing RT instead. A seven-center prospective study analyzed 139 patients and detected 454 SLNs. Intraoperative examination did not detect micrometastasis or isolated tumor cells. Other techniques, such as molecular assays, may improve SLN assessment in the future.[134] The SENTICOL study[135] injected 145 patients with stage IA1 to IB1 cervical cancer with combined technetium-99 and patent blue. The sensitivity (92%) and lack of false-negative results were favorable, but SLN biopsy was reliable only when SLNs were detected bilaterally.

In the SENTICOL-2 trial,[136] 206 patients with early cervical cancer were randomized to SLN resection only versus SLN and PLND. Lymphatic morbidity and neurologic symptoms were significantly lower in the SLN-only arm (31.4% vs 51.5% and 7.8 vs 20.6%), but that difference became less evident after 6-month follow-up and was not significant regarding severe lymphedema. There were no false negatives found in the SLN+PLND group, and 3-year DFS was not statistically significant (92% in SLN-only vs 94.4% in the SLN+PLND group). The SENTICOL-3 trial is currently underway to further validate no difference in survival outcomes.

Ovarian Transposition

In premenopausal women, surgery and radiation may directly impact gonadal function. For women with early-stage cervical cancer who undergo an RH, ovarian function may be preserved. In patients who require postoperative radiation, transposition of ovarian tissue outside the radiation field may help preserve ovarian function, although even low doses to the ovaries may cause acute ovarian failure (Figure 76.9). In women who require radical radiation to the uterus and ovarian tissue, counseling before treatment begins with a fertility expert in reproductive endocrinology may be of benefit if an intervention such as egg retrieval is desired. Care must be taken to ensure that any potential intervention does not delay the initiation of curative treatment.

In addition, women with early-stage cervical cancer have an approximately 1% risk of ovarian metastasis. A retrospective report of 3,165 women under 50 who underwent hysterectomy with oophorectomy for early cervical cancer identified several independent risk factors for ovarian metastases—AC histology, lymphovascular space invasion (LVSI), and involvement of either the parametria, uterine corpus, or regional lymph nodes. Without any or just with AC, the risk for ovarian metastasis is 0.14% or 0.17%, respectively.[137] A combination of these risk factors can increase the risk up to 16.7%. Therefore, women should be carefully considered for ovarian preservation and counseled on its potential risks.

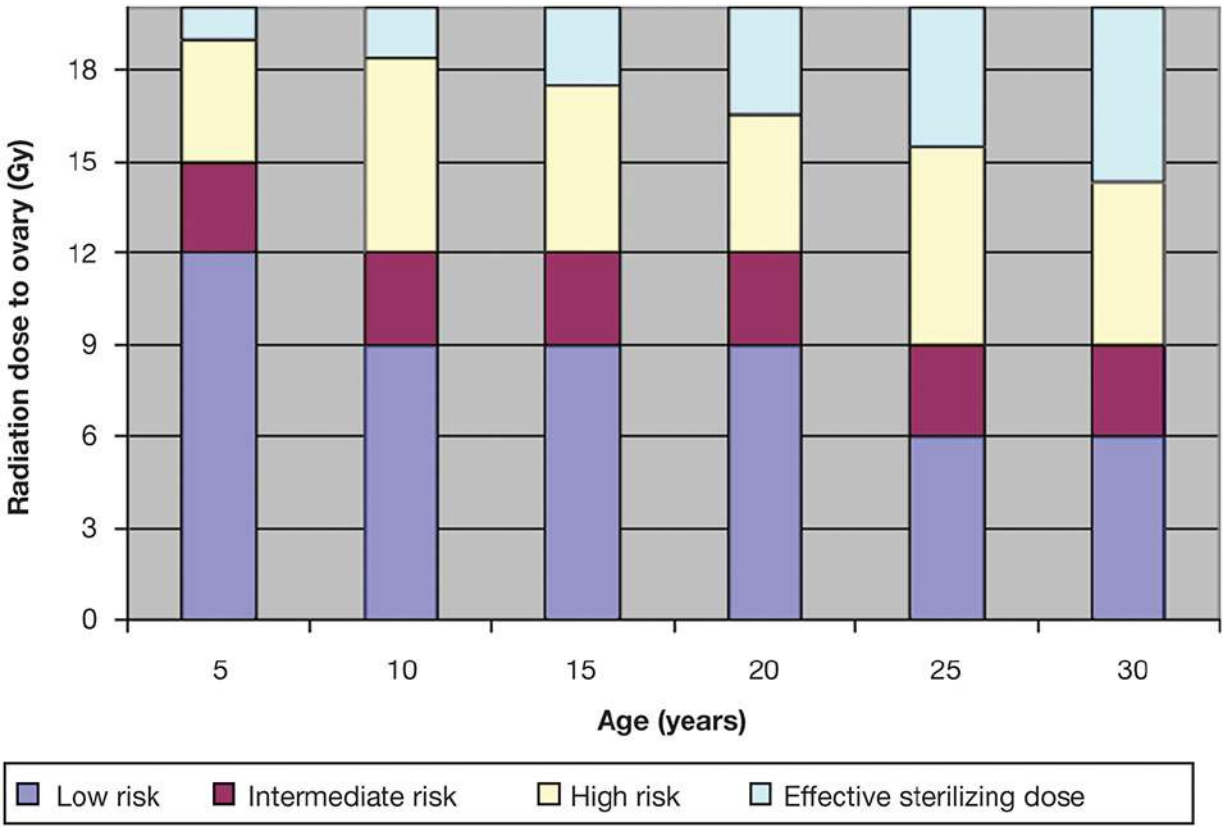

FIGURE 76.9 Risk of developing acute ovarian failure, defined as ovarian failure within 5 years, stratified by age and radiation dose to the ovary. (Reprinted from Wo JY, Viswanathan AN. Impact of radiotherapy on fertility, pregnancy, and neonatal outcomes in female cancer patients. *Int J Radiat Oncol Biol Phys.* 2009;73[5]:1304-1312. Copyright © 2009 Elsevier. With permission.)

The success rate of ovarian function preservation with ovarian transposition is affected by the treatment modalities used. A meta-analysis of 29 different

reports including 1,160 patients showed that for patients undergoing surgery alone or surgery with BT, the ovarian function was preserved in 91% and 93%, respectively. For patients treated with EBRT with or without BT and/or surgery, it was preserved in only 61%.[138] It is important to mention that the success rate was shown to diminish with follow-up period and that younger age was the most predictive factor for ovarian function preservation.

Newer techniques of radiation, such as IMRT or proton therapy, offer better ways to preserve ovarian function by lowering the dose to the transposed ovaries. Yin et al[139] reported a retrospective study of 105 patients with early cervical cancer who underwent RH and ovarian transposition before pelvic irradiation with IMRT and dose constraints on the ovary as low as possible. Ovarian function was determined 1 year after radiation with sex hormonal levels and menopausal symptoms. Ovarian function was preserved in 41 (39%) patients. The optimal cutoff for dose constraints was $V_{5.5}$ less than 29.65%.

Radiation Therapy Techniques

Since the early 1900s, radiation has been used in the curative management of cervical cancer, with a combination of external beam and BT resulting in the highest survival rates. Over the ensuing 100 years, treatment planning techniques have evolved, as has the equipment used for treatment. Several methods have been developed to aid with conformality and normal tissue sparing. External irradiation is used to treat the whole pelvis. Structures treated include the uterus and cervix or, in the postoperative cases, the tumor bed, the vagina, the parametrial tissue, and the pelvic lymph nodes, including the internal, external, and common iliac nodes. In selected cases, the PANs may be treated. In patients with locally advanced disease, in addition to external beam radiation, treatment of central disease (cervix, vagina, and medial parametria) relies heavily on dose given with intracavitary sources through BT. The techniques described apply, with some individualization, to most patients with locally advanced cervical carcinoma.

External Beam Irradiation

External beam treatments may be routinely administered to patients with cervical cancer with stages IB2 to IVA in a curative manner. Patients with stages IA to IB1 may be considered for external beam treatment if they are

deemed inoperable or prefer to avoid surgery. Patients with stage IVB disease may receive palliative radiation to the pelvis for selected indications, such as to stop vaginal bleeding, relieve pain, or alleviate urethral obstruction from extrinsic compression. External beam radiation covers the primary cervical tumor; treats any adjacent parametrial or uterosacral, uterine, or vaginal extension; and, most important, addresses microscopic disease present in pelvic lymph nodes. In treatment of invasive carcinoma of the uterine cervix, it is important to deliver adequate doses of irradiation not only to the primary tumor but also to the pelvic lymph nodes to maximize tumor control.

The initiation of external beam radiation typically precedes BT. Although BT may be interdigitated with external beam treatment, based on the desire to minimize the duration of treatment, the BT dose to the normal tissues may be better optimized after maximal tumor shrinkage; therefore, many institutions prefer to wait until the completion of 45-Gy treatment before initiating BT, particularly for patients with large tumors.

Patient Positioning

Patients may be positioned in either the supine position for stability or the prone position on a belly board. The prone position aids in shifting the small bowel out of the pelvis. In patients who have had a hysterectomy, the small bowel may drop into the pelvic area. For those patients treated for cervical cancer with an intact cervix, the small bowel often lies superior to the uterus and above the pelvic brim, creating less need to shift the bowel out of the pelvis. For patients receiving IMRT, because of stability of the pelvis, the supine position is typically preferred with immobilization devices surrounding the pelvis to ensure minimal motion during treatment. IV contrast may be helpful to localize the pelvic vessels for contouring but is not routinely used in most centers. Oral contrast delineates the small bowel. Rectal contrast and placement of a Foley catheter for bladder contrast are not considered necessary in with CT simulation because the outer wall of these normal tissue structures can be contoured without contrast on CT.

Plain X-Ray Simulation

If CT is not available, simple plain film simulation may be performed. The standard plain radiographic simulation to the pelvis with x-rays, typically using opposed anterior-posterior/ posterior-anterior (AP-PA) fields, results in

comprehensive coverage of all pelvic regions. Because of the lack of visible soft tissue detail, contrast may be placed using barium in the rectum, a vaginal tube in the vagina, and/or a wire marker over surgical scars. The superior border is set at the L4 to L5 interspace in order to cover the common iliac lymph nodes and the lateral borders 1.5 to 2 cm from the pelvic brim, and the inferior border covers at least the obturator foramen (Figure 76.10). More commonly in patients with large tumors, the inferior border extends to the ischial tuberosities. When there is vaginal involvement, the entire length of this organ should be treated down to the introitus. It is very important to identify the distal extension of the tumor at the time of simulation by placing a radiopaque clip or bead on the vaginal wall or inserting a small fiducial marker into the vagina. When the tumor involves the distal half of the vagina, the portals should be modified to cover the inguinal lymph nodes because of the increased probability of metastases (Figure 76.11).

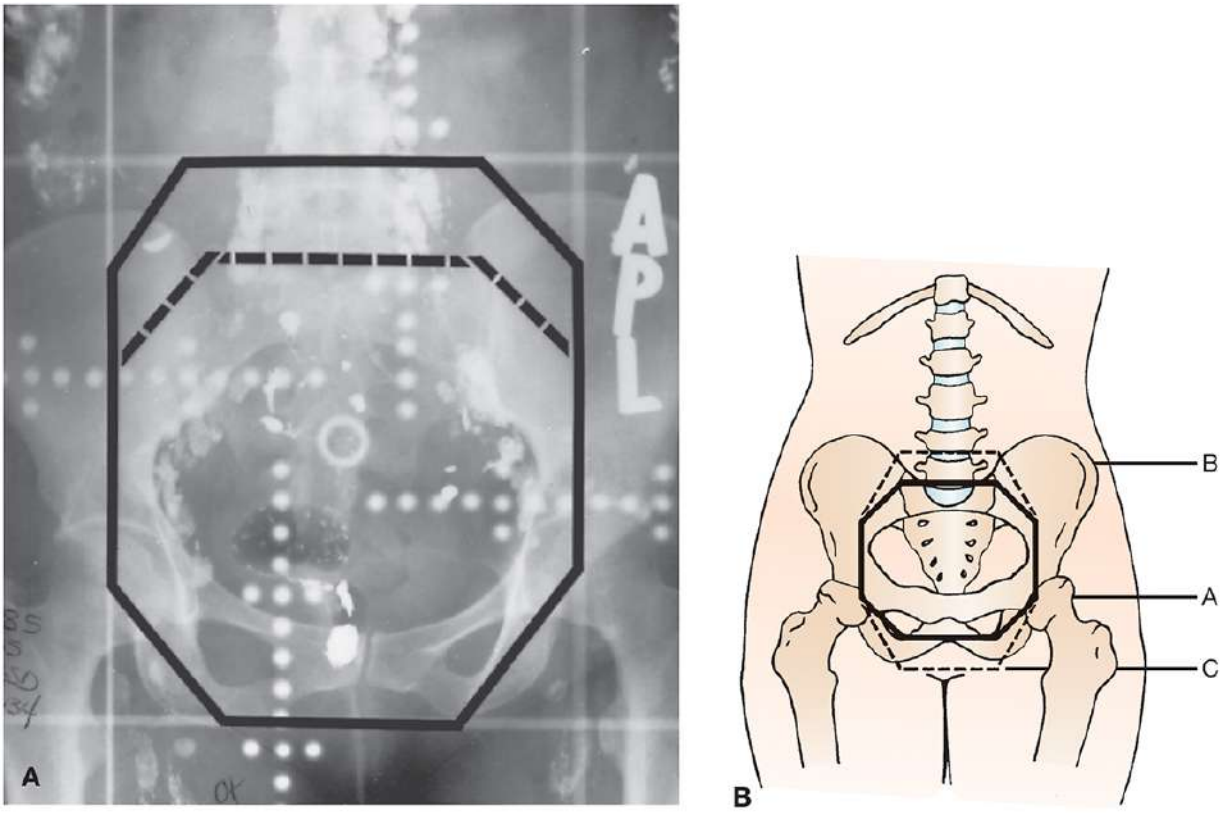

FIGURE 76.10 A. Anteroposterior simulation film of the pelvis illustrating portals used for external irradiation. The 15 by 15 cm portals at source-to-skin distance are used for stage IB (broken line), and 18 by 15 cm portals are used for more advanced disease (solid line). This allows better coverage of the common iliac lymph nodes. The distal margin is usually placed at the bottom of the obturator foramina. B. Diagram of pelvic portals used in external irradiation of carcinoma of uterine cervix. Standard portal for stage IB tumors is outlined (solid line indicated as A). When the common iliac nodes are to be covered, the upper margin is extended to the L4 to L5 space (indicated in section B). If there is vaginal tumor extension, the lower margin of the field is drawn at the introitus (indicated in section C).

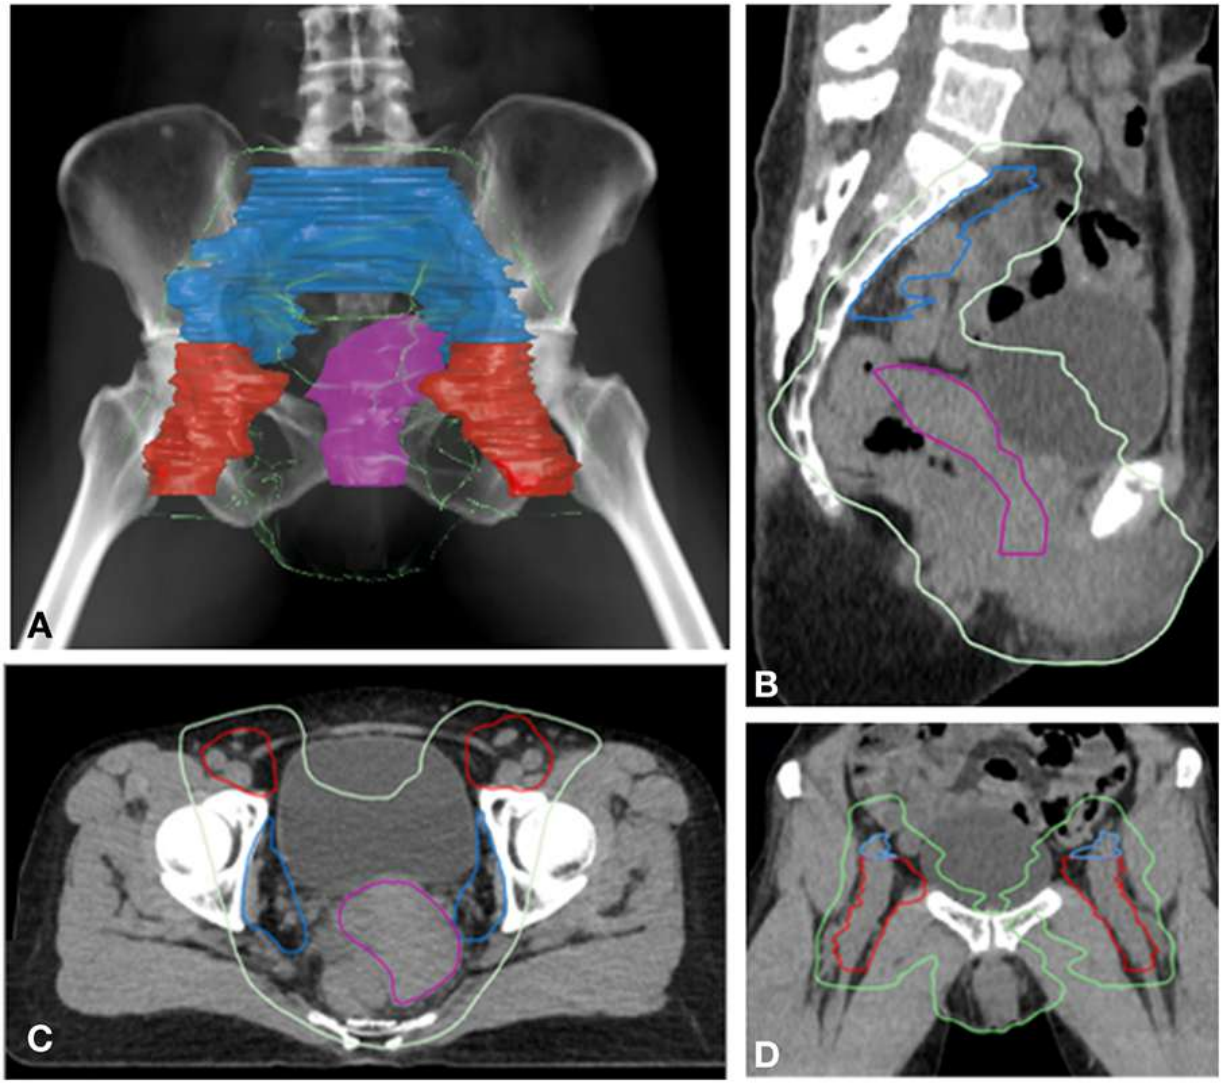

FIGURE 76.11 Pelvic (blue) and inguinal (red) lymph nodes contoured on a computed tomography scan in a patient with cervical carcinoma involving the distal vagina (purple), requiring inguinal node coverage with the 42.75 Gy (95% of elective dose). Isodose line (green). Displayed are a three-dimensional reconstruction (A), a mid-pelvic sagittal (B), axial (C), and mid-inguinal coronal (D) sections.

For the lateral field borders, in both postoperative and intact cervix settings, the posterior border must be set in such a way that the entire sacrum is covered because the uterosacral ligaments are at high risk for harboring microscopic extension. The uterosacral ligaments insert onto the sacrum, and therefore, the posterior block should ensure coverage of the entire sacrum. The anterior border on the lateral field should be set at a vertical line anterior to the pubic symphysis, because the external iliac lymph nodes must be covered.

For patients with PAN involvement, simple plain film simulation followed by AP-PA treatments to the PAN chain may overdose the kidneys, spinal cord, and small bowel. Dose escalation to para-aortic region to greater than 45 Gy is not feasible with AP-PA fields, given potential bowel complications. The use of four fields, including AP-PA and two lateral fields, is implemented as an alternative to AP-PA alone as a way to reduce some of the dose to the anterior small bowel. Patients receive oral barium approximately 30 minutes before the simulation to ensure blockage of as much small bowel as feasible superiorly. The superior border covers the renal hilum, often at the T12-L1 interspace, and the inferior borders cover the obturator foramen, unless there is distal vaginal or inguinal node involvement. For the para-aortic portion of the field, the anterior border rests 2 cm in front of the vertebral body or enlarged nodes as contoured, and posteriorly, the border bisects the mid-vertebral body. The pelvic portion mimics that described for the four-field pelvic setup. The use of lateral fields allows a decrease in dose to the small bowel, but care must be taken to include all structures of interest.

Three-Dimensional Conformal Treatment Planning

CT simulation allows direct assessment of the pelvic vessels and by adjacent location the para-aortic nodes (PANs) and pelvic nodes. Oral contrast is beneficial to identify the small bowel. Cerrobend customized blocks or multileaf collimator blocking is used on each field to block the radiation to selected areas, including the skin, muscle, soft tissue, anterior small bowel, and portions of the anus and lower rectum (Figure 76.12).

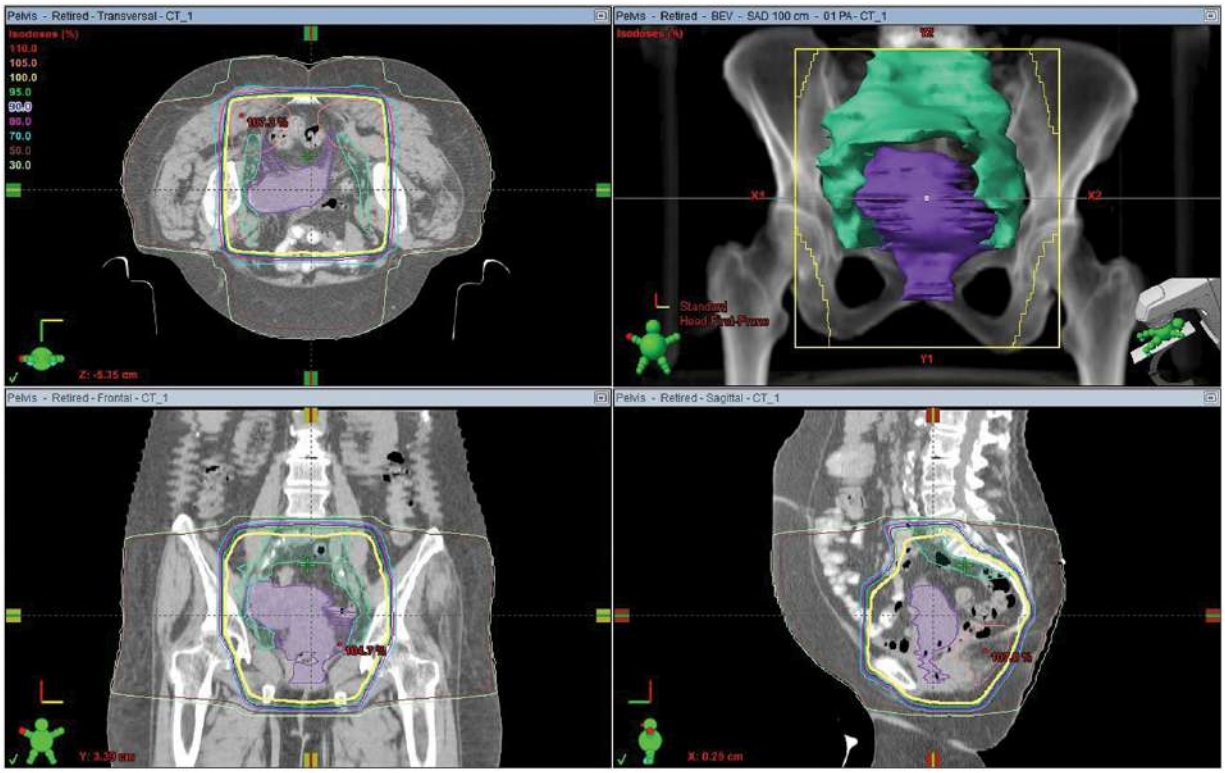

FIGURE 76.12 Anterior-posterior and lateral (4-Field) digitally reconstructed radiograph simulation film of the pelvis illustrating portals used for external irradiation with the patient in the prone position on a belly board to minimize small-bowel dose. Pelvic lymph nodes are indicated in their approximate position. The uterus, cervix, and vagina are contoured to ensure adequate coverage.

The superior border is set based on the CT-visualized bifurcation of the common iliac nodes into the external and internal iliac nodes, which may lie as high as the L3-L4 interspace. If patients have positive pelvic nodes based on PET imaging, the superior border may be shifted to either the superior border of the common iliac nodes or the superior aspect of the renal hilum to treat the PAN. In postoperative cases in which the patient has had an extensive surgical staging, the superior border may be reduced to the L5-S1 interspace. Similar to plain x-ray simulation, in patients with vaginal involvement, the inferior border is extended to cover 2 cm below the lowest extent of disease, which may lie in the vulvar tissue, and in such cases, the inguinal lymph nodes are treated, resulting in a wider AP field.

On the lateral fields, the anterior border covers the front of the pubic symphysis. Bonin et al,[140] in a review of 22 patients on whom detailed anatomic mapping of the anatomy of the pelvic lymph nodes was carried out by lymphangiography, concluded that if the criteria for adequacy of standard

pelvic fields as defined in prior clinical trials were applied (AP: 1.5-cm margin on the pelvic rim; lateral field anterior edge is a vertical line anterior to the pubic symphysis and posterior border), 10 (45%) patients would have had inadequate nodal coverage in the irradiation fields. The incompletely irradiated lymph nodes were in the lowest lateral external iliac group. However, CT simulation with contouring may prevent omission of these nodes.

For the lateral borders in postoperative and intact cervix cases, posterior coverage of the entire sacral hollow is imperative. Zunino et al[141] reviewed the appropriateness of RT box technique for cancer of the cervix in 35 sagittal MRIs and 10 lymphangiograms. If the posterior border were to be placed at the S2-S3 interspace, for 50% of the patients with FIGO IB and in 67% with stage IIA disease, the posterior border of the lateral field would not adequately encompass the planning target volume (PTV). In stage IIB, the posterior border was inadequate in eight patients (42%). In patients with stage IIB and IVA diseases, the PTV was not encompassed. Furthermore, Knocke et al[142] used standard simulator planning guided by bony landmarks for pelvic irradiation in 20 patients with primary cervical carcinoma, stages I to III, using a four-field box technique. After defining the PTV with a 3D planning system, they compared the field configuration of the simulator planning with a second one based on the defined PTV. They evaluated the ability of the PTV to encompass the treatment volume (International Commission on Radiation Units and Measurements [ICRU]). Planning by simulation resulted in 1 geographic miss, and in 10 more cases, the coverage of the PTV by the treatment volume was inadequate.

Finlay et al[143] contoured pelvic blood vessels on CT scans as surrogates for lymph nodes in 43 patients and found this to be more accurate than bony landmarks for field delineation. In total, 95% of patients planned with conventional fields had inadequate coverage of some portion of lymph node coverage, whereas 56% additional normal tissue was treated that did not require radiation. Therefore, most centers implement 3D simulation when feasible. Taylor et al[331] used MRI to outline the pelvic lymph nodes in 20 patients and noted that with margins of 10 mm, nodal coverage was 94% and with 15 mm, 99%; with a modified 7-mm margin, they ensured 99% nodal coverage with less volume of small bowel at risk.

In the postoperative setting, van den Berg et al,[144] using 47 lymphangiograms and 15 CT scans, asked radiation oncologists (n = 17) to define the CTV and PTV and to delineate on simulation films the RT treatment portals to be used after an RH with lymph node dissection for stage IB or IIA cervical carcinoma with positive iliac lymph nodes. Large variations were observed in the portals used and in treatment techniques. From the digitized films, it appeared that in 50% of the cases, the defined PTV was not covered adequately. Furthermore, 71% of the treatment plans would not cover the lateral borders of the reference PTV sufficiently. Thus, there is a need for careful adherence to standardized guidelines.

Treatment techniques may have an effect on outcome. Yamazaki et al[145] compared 34 patients with cervical cancer treated with irregularly shaped four-field whole-pelvis RT using CT simulation and 40 patients receiving whole-pelvis EBRT with parallel-opposed fields in a nonrandomized study of postoperative RT consisting of 50 Gy in 25 fractions in 6 weeks. With a mean follow-up of 60 months, the actuarial 5-year pelvic tumor control was 94% with the two-field technique and 100% for the irregularly shaped four-field technique. The incidence of grade 2 or 3 bowel complications in the irregularly shaped technique group (2.9%, 1/34) was significantly lower than that in the two-field technique group (17.5%, 7/40; $P < .05$).

Intensity-Modulated Radiation

IMRT was developed using the techniques required for inverse planning. That is, one starts with the necessary dose around the target and then works backward to develop the requisite beam intensities. IMRT spatially modulates the intensity of the beam using the motion of multileaf collimators. This allows high conformality with the target volume, while reducing the volume of normal tissue exposed to the full dose of radiation. However, it mandates a growing emphasis on imaging the pelvic anatomic structures, for both treatment planning and delivery, what is generally termed *image-guided radiation therapy* (IGRT). It is increasingly challenging to employ different imaging modalities for target volume selection as uncertainties in the definition of target volumes arise using conformal techniques. In addition, what constitutes adequate margins in different settings continues to be a matter of concern, given significant pelvic organ motion during treatment. Nevertheless, the use of IMRT has been standardized in the postoperative

setting and is more frequently used for intact cervix cases. The PARCER trial was a randomized controlled trial of IMRT versus 3D conformal adjuvant pelvic radiation in 300 patients with cervical cancer posthysterectomy.[146] It showed reduced late GI toxicity with IMRT while 3-year DFS was not significantly different (76.9% vs 81.1%, $P = .89$). In the intact cervix setting, no large-scale randomized trial comparing IMRT to 3D conformal RT was performed. A meta-analysis of six reports of a total of 1,008 patients undergoing primary CRT (only 88 of them prospectively randomized) showed no difference in OS and PFS but significantly reduced acute and chronic toxicities with IMRT.[147] In the EMBRACE registry, which accrued a cohort of 1,416 patients with locally advanced cervical cancer treated with primary CRT in multiple international centers, 40% were treated with IMRT for the EBRT part of treatment, determined by local availability. They published that IMRT use reduced the median V_{43} Gy by around 500 mL.[148] Thus, the ASTRO guidelines for the treatment of cervical cancer also strongly recommend the use of IMRT in the postoperative setting, and in the definitive setting, it recommends on the condition that IGRT is available to ensure adequate coverage of the target volumes throughout treatment.[149]

Bladder filling and rectal filling changes require accurate definition of margins for the PTV. Several reports have shown cervix motion can be up to 18 to 21 mm in all directions and that even a uniform CTV planning treatment volume margin of 15 mm would not encompass the cervical CTV in 32% of fractions.[150,151] With IMRT, there might be a need for adaptive replanning given rapid tumor regression that makes the pelvis less fixed, thus increasing internal organ motion, though the frequency for such imaging has not been clearly defined, and wide margins (≥2 cm) are indicated on the cervix in order to adequately account for organ motion. Larger margins of up to 2 to 3 cm in the AP direction and bladder volumes at 150 to 300 mL are recommended.[152]

After a CT and/or MRI scan for simulation, the images are brought into a treatment planning workstation. Contouring the gross tumor volume (GTV) on MRI may include the uterus, cervix, and/or vagina. Lim et al had 19 experts in gynecologic radiation oncology contour for a case of locally advanced cervical cancer on axial MRI of the pelvis. The sensitivity and specificity values as per Substantial Simultaneous Truth and Performance Level Estimation (STAPLE) agreement were seen for GTV delineation (0.84 and 0.96, respectively), with a kappa statistic of 0.68 ($P < .0001$). Agreement

for delineation of the cervix, uterus, vagina, and parametria was moderate. The greatest variability in physician contouring was in the parametrial tissue.[153]

The CTV for the pelvic lymph nodes was based on the Radiation Therapy Oncology Group (RTOG) atlas for the female postoperative pelvis.[154] Fiducial markers may be placed in the apex of the vagina for identification on CT scan and show up to 3.5 cm of vaginal cuff motion during treatment.[155] Therefore, for postoperative patients, the vagina is contoured using a full bladder CT scan fused to an empty bladder CT scan to account for vaginal mobility because of differences in bladder filling. This vaginal target volume has been referred to as an integrated target volume (ITV). The expansion of the CTV and/or ITV to the PTV is necessary, although, given the movement of the pelvic organ, the exact amount of margin is a matter of debate. When targeting an intact cervix, generous margins of approximately 2 to 3 cm are considered, particularly in the regions of the uterus and cervix. An example of dose distribution achieved with IMRT pelvic irradiation is illustrated in Figure 76.13. In order to cover the uterosacral ligaments, the rectum cannot be spared. Rectal filling with gas may change the position of the anterior rectal wall over 5 cm during treatment. Dose constraints required for an optimal IMRT plan have not been standardized. In the RTOG postoperative clinical trial 0921 using IMRT,[156] a PTV of 7 mm around the nodal contours is recommended, and the dose is prescribed to cover 97% of the vaginal PTV and nodal PTV. A volume of 0.03 mL within any PTV should not receive more than 110% of the prescribed dose. No more than 0.03 mL of any PTV will receive less than 93% of its prescribed dose. Any contiguous volume of 0.03 mL or larger of the tissue outside the vaginal/nodal PTVs must not receive more than 110% of the dose prescribed to the vaginal/nodal PTV; for normal tissues, the small/large bowel (30% of the entire bowel volume must not receive .40 Gy), rectum/sigmoid (60% of the rectosigmoid volume must receive ≤40 Gy), bladder (35% of the bladder volume must receive ≤45 Gy), and femoral head (15% of the femoral head volume must receive <35 Gy) constraints are being tested in RTOG 0921. Careful attention must be paid to all normal tissue organ motion because the bladder and rectum may have 3- to 5-cm shifts because of filling changes in a short time frame.

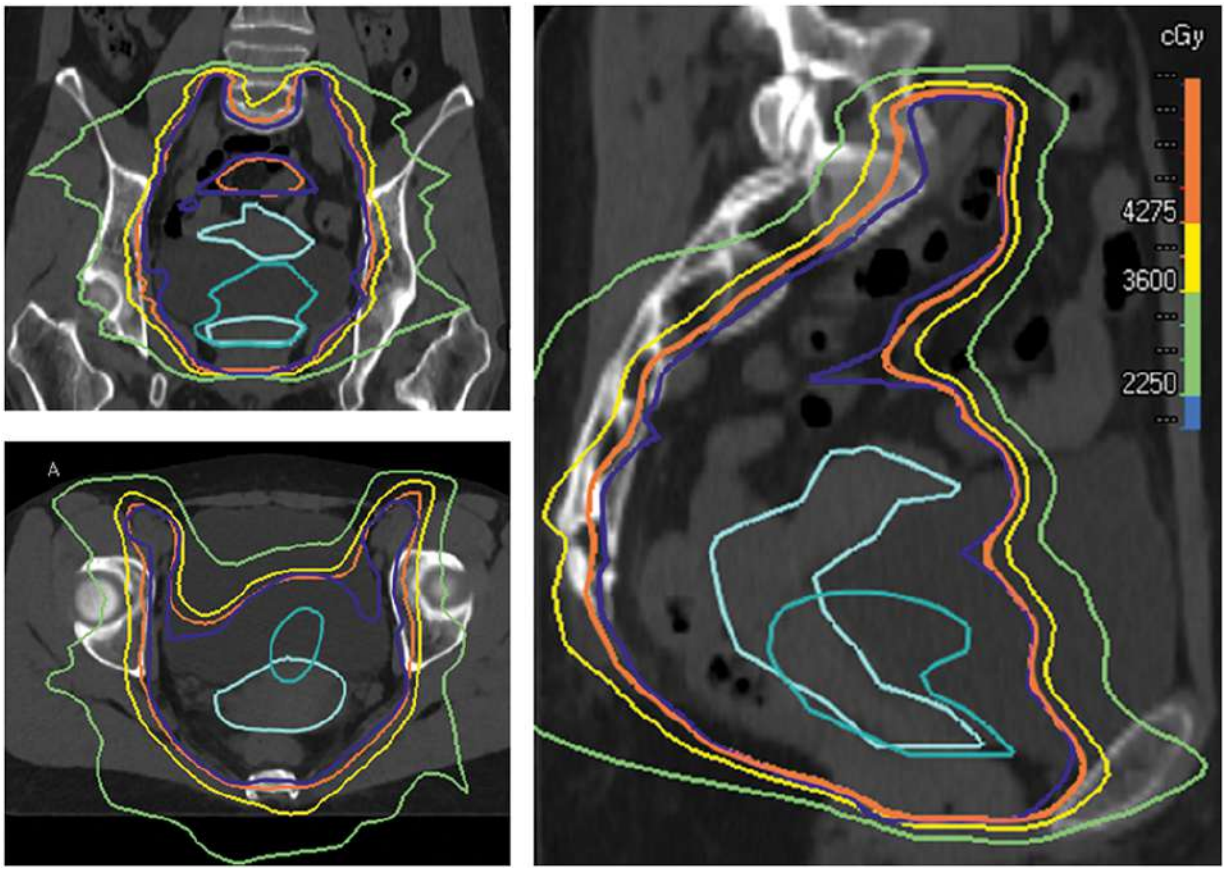

FIGURE 76.13 Intensity-modulated radiation therapy treatment plan for external irradiation of an intact cervix. The uterine motion is taken into account by contouring it with a full and empty bladder (light and dark teal) and using image guidance when delivering the dose.

For patients who have had a diagnostic PET or MRI before the simulation, these images may be registered to create a fused data set for contouring, particularly when a nodal boost is required. This allows the physician to visualize areas of PET enhancement or tumor volume, as seen on the MRI, onto the simulation films. Some recommend to use a PET-defined target volume contoured with a metabolically active tumor specified at the 40% threshold. Normal tissue structures, including the rectum, sigmoid, bladder, and small bowel, are routinely contoured for patients treated with IMRT who will be undergoing a nodal boost in order to limit the dose received primarily to the small bowel. Based on an overview of published data, the absolute volume of small bowel receiving 15 Gy or greater should be held to less than 120 mL, when possible, to minimize severe acute toxicity if delineating the contours of bowel loops themselves. Alternatively, if the entire volume of peritoneal space in which the small bowel can move is delineated, the volume

receiving greater than 45 Gy should be less than 195 mL as a starting point, though this is often not possible.[157] For the rectum, dose-volume constraints selected as a conservative starting point that have not yet been validated for 3D treatment planning include V_{50} less than 50%, V_{60} less than 35%, V_{65} less than 25%, V_{70} less than 20%, and V_{75} less than 15%.[158] No dose constraint for external beam planning for the bladder could be identified, although the limits for prostate cancer may be adopted for gynecologic IMRT, including a dose constraint of no more than 15% of the volume to receive a dose greater than 80 Gy, no more than 25% of the volume to receive a dose greater than 75 Gy, no more than 35% of the volume to receive a dose greater than 70 Gy, or no more than 50% of the volume to receive a dose greater than 65 Gy.[159]

Imaging may guide more accurate definition of lymph nodes. Portelance et al[160] carried out IMRT as well as conventional planning with two- and four-field techniques in 10 patients. Prescription was 45 Gy in 25 fractions to the uterus and the pelvic and PANs. All IMRT plans were normalized to obtain a full coverage of the cervix with the 95% isodose curve (Figure 76.14A). The volumes of the small bowel receiving the prescribed dose (45 Gy) with IMRT para-aortic–only technique were 11% with four fields, 15% with seven fields, and 13.5% with nine fields (Figure 76.14B). These dose distributions were all significantly better than with two-field or four-field conventional techniques ($P < .05$). Other works have similarly demonstrated the feasibility of escalating the dose to 60 Gy while reducing dose to the kidneys, spinal cord, small bowel, rectum, bladder, and bone marrow. However, small volume of bowel received 55 to 60 Gy with the IMRT plans.[161] Positioning the patient prone on a belly board was shown to reduce the volume of small-bowel irradiated. However, patients on a belly board may have large daily anatomic shifts that make prone IMRT unreproducible.

IMRT can be used to spare the bone marrow of patients with gynecologic tumors. If receiving concurrent chemotherapy, less grade 2 white blood cell toxicity was observed (31.2% vs 60%).[162] PET-detected bone marrow was spared using an atlas in a single-arm phase II study of 83 patients, with a median follow-up of 26.0 months; the incidence of grade 3 or higher neutropenia and clinically significant GI toxicity was 19.3% (95% CI, 12.2%-29.0%) and 12.0% (95% CI, 6.7%-20.8%), respectively. Compared with patients treated without image-guided IMRT (IG-IMRT) (n = 48), those treated with IG-IMRT (n = 35) had a significantly lower incidence of grade 3 or higher neutropenia (8.6% vs 27.1%; two-sided χ^2 P = .035), nonsignificantly lower incidence of grade 3 or higher leukopenia (25.7% vs 41.7%; P = .13), and any grade 3 or higher hematologic toxicity (31.4% vs 43.8%; P = .25).[163]

Hasselle et al[164] report on 111 patients treated with multiple different approaches, including 22 treated with postoperative IMRT, 8 with IMRT followed by intracavitary BT and adjuvant hysterectomy, and 81 with IMRT followed by planned intracavitary BT. Median follow-up time was 27 months. Acute and late grade 3 toxicity or higher was 2% (95% CI, 0%-7%) and 7% (95% CI, 2%-13%), respectively. Attempts using an IMRT simultaneous integrated boost (SIB) as an alternative to conventional whole-pelvis irradiation found that accelerated fractionation caused an unacceptably high rate of complications. A combination of an SIB to approximately 50 Gy followed by a sequential boost to 60 to 65 Gy has been shown to be feasible to both pelvic nodes and PANs. Caution in the pelvis when also administering BT is required to ensure bowel dose is limited, and in the para-aortic region, rapid shrinkage of the tumor may result in movement of bowel into the boost

field, and replanning immediately prior to beginning the sequential portion of the boost is recommended.[165]

Although IMRT has dosimetric advantages over conventional RT, IMRT exposes a greater amount of normal tissue to lower irradiation levels, which has the potential to increase the incidence of radiation-induced second cancers,[166] a phenomenon already described with conventional RT techniques.

Image-Guided Radiation Therapy

Daily cone-beam CT (CBCT) imaging for in-room IGRT permits visualization of the bladder and rectum. Particularly in cases with a large, mobile uterus, such as is seen in young women, if an extended field is used and there is concern that the uterus may be out of the field, this may be helpful to confirm full coverage of the CTV daily. Criteria for replanning were reported by Jensen et al[167] on 23 patients treated with IMRT for 45 Gy in 25 fractions and followed with daily CBCT. The CBCTs were online checked by radiation therapists and offline checked by treating MD. The report showed that in only 9.6% of CBCT, the therapists were unable to assess the coverage due to inadequate quality, and there was 99% concordance with the treating MD. Consideration of replanning was made if either the cervix went out of the PTV at least once or if the fundus went out 3 times or more. In seven patients, replanning was done, with only four gaining over 1 Gy in the underdosed area; three were in the fundus (1.2-1.8 Gy) and one in the vaginal area, with 12.7 Gy added. This highlighted the fact that a downward motion out of the field harbors more underdosing risk than an upward one, where dose to the nodal volume mitigates the lost coverage.

Another way to use IGRT to reduce coverage of normal tissue is “plan of the day” approach, where a set of plans is prepared in advance and chosen daily according to the CBCT. A study by Ghosh et al,[168] in which for each patient four plans were made (CTV-to-PTV margins of 7, 10, or 15 mm, and a robust 3D conformal plan), showed that the two larger plans were needed in only 21% of fractions and higher acute toxicity was associated with the larger plans use.

As technological advancement in auto-segmentation and auto-planning evolve, daily adaptive replanning of each pelvic fraction could potentially allow for even greater sparing of normal tissue. Some reports have already shown that with a 3-mm margin, CTVs can still be adequately covered with

improved organ at risk (OAR) dosimetry and with less than 20 minutes of extra planning time per fraction.[169]

Stereotactic Body Radiotherapy

Stereotactic body radiotherapy (SBRT) uses highly conformal treatments with large fraction sizes and, in selected cases, has been considered for a nodal boost of an isolated PAN, although care must be taken to treat the entire para-aortic chain to 45 Gy with IMRT or 4 Field prior to considering an SBRT boost in order to ensure eradication of adjacent micrometastatic disease. SBRT should not be used instead of BT, given the significant increase in normal tissue doses with SBRT compared to BT and lack of equivalent efficacy.[170] SBRT techniques should be employed for recurrences and various oligometastatic disease settings in which a focused localized approach is deemed of benefit, mainly for distant metastases in lymph nodes or solid organs or reirradiation.[171]

Midline Shielding in Anteroposterior-Posteroanterior Portals and Use of a Parametrial Boost

Depending on the institution and BT dose administered, midline shielding with rectangular or specially designed blocks has been traditionally used for a portion of the external beam dose delivered with the AP-PA ports. Midline blocks may be individualized, based on the point A isodose line or a rectangular block of approximately 4-cm width. In one series, OS and incidence of chronic complications were not related to the type of shielding. However, in the era of 3D BT planning, the use of a midline block has been questioned because it may result in tumor underdosing while still contributing significant dose to the bladder, sigmoid, and rectum.[172]

Several institutions reported placing a midline block after a full course of external beam treatment to the pelvis in order to boost the parametria or nodes for patients with persistent disease after approximately 45 to 50 Gy. When parametrial tumor persists, 50 to 60 Gy may be delivered to the parametria, with reduced AP/PA portals (8 by 12 cm for unilateral and 12 by 12 cm for bilateral parametrial coverage). However, careful estimation of dose to the small bowel, sigmoid, and rectum is needed. In the modern era, the use of highly conformal boosts with 3D planning allows an increase in normal tissue sparing. Contours on CT of the parametrial and nodal region allow more

precise tailoring of dose. For patients with enlarged nodes, when available, IMRT techniques may be best at providing conformal dose escalation to 54 to 65 Gy.

Similarly, with 3D BT and computerized optimization as available with high HDR or pulsed-dose rate (PDR) BT, the physician may cover the adjacent parametria using large enough fraction sizes that an additional external beam boost is not needed. When one prescribes HDR BT, the per fraction nodal dose is approximately 25% of prescription. In one study, the per fraction dose to the pelvic lymph nodes by HDR BT, when the HR-CTV received 5.5 Gy per fraction, was 1.4 Gy per fraction. Therefore, HDR BT may obviate the need for a parametrial boost, given the high per fraction dose to the parametria and pelvic sidewall.[172]

In a comparison of three different approaches, Fenkell et al[173] reported on parametrial boost with midline shielding in six patients with locally advanced cervical cancer (IIB-IIIB) treated with definitive CRT and MRI-guided BT. A three-phase plan was modeled: 45-Gy (1.8 Gy per fraction) four-field box, 9-Gy (1.8 Gy per fraction) midline-shielded AP/PA fields (midline-blocked boost [MBB]), and intracavitary MRI-guided BT boost of 28 Gy (7 Gy per fraction). Midline shields 3, 4, and 5 cm wide were simulated for each patient. BT and MBB plans were volumetrically summed. After a 4-cm MBB, HR-CTV D_{90} remained less than 85 Gy in all cases (mean, 74 Gy; range, 64-82 Gy). Bladder, rectum, or sigmoid D_{2cc} increased by more than 50% of the boost dose in four of six patients. The authors concluded that a midline block may not be beneficial in patients receiving 3D image-planned BT with adequate optimization of dose to the tumor and away from the normal tissues.

Para-Aortic Lymph Node Irradiation

If PAN metastases are enlarged or suspected to harbor disease, patients are treated with 45 to 50 Gy to the PAN area plus a sequential 5- to 10-Gy boost to enlarged lymph nodes through reduced lateral or rotational portals. If feasible, 3D planning with IMRT treatment is preferred to spare normal tissues, superiorly covering above the level of the renal hilum or the highest extent of disease and inferiorly covering 2 to 4 cm below the lowest extent of disease (Figure 76.15).

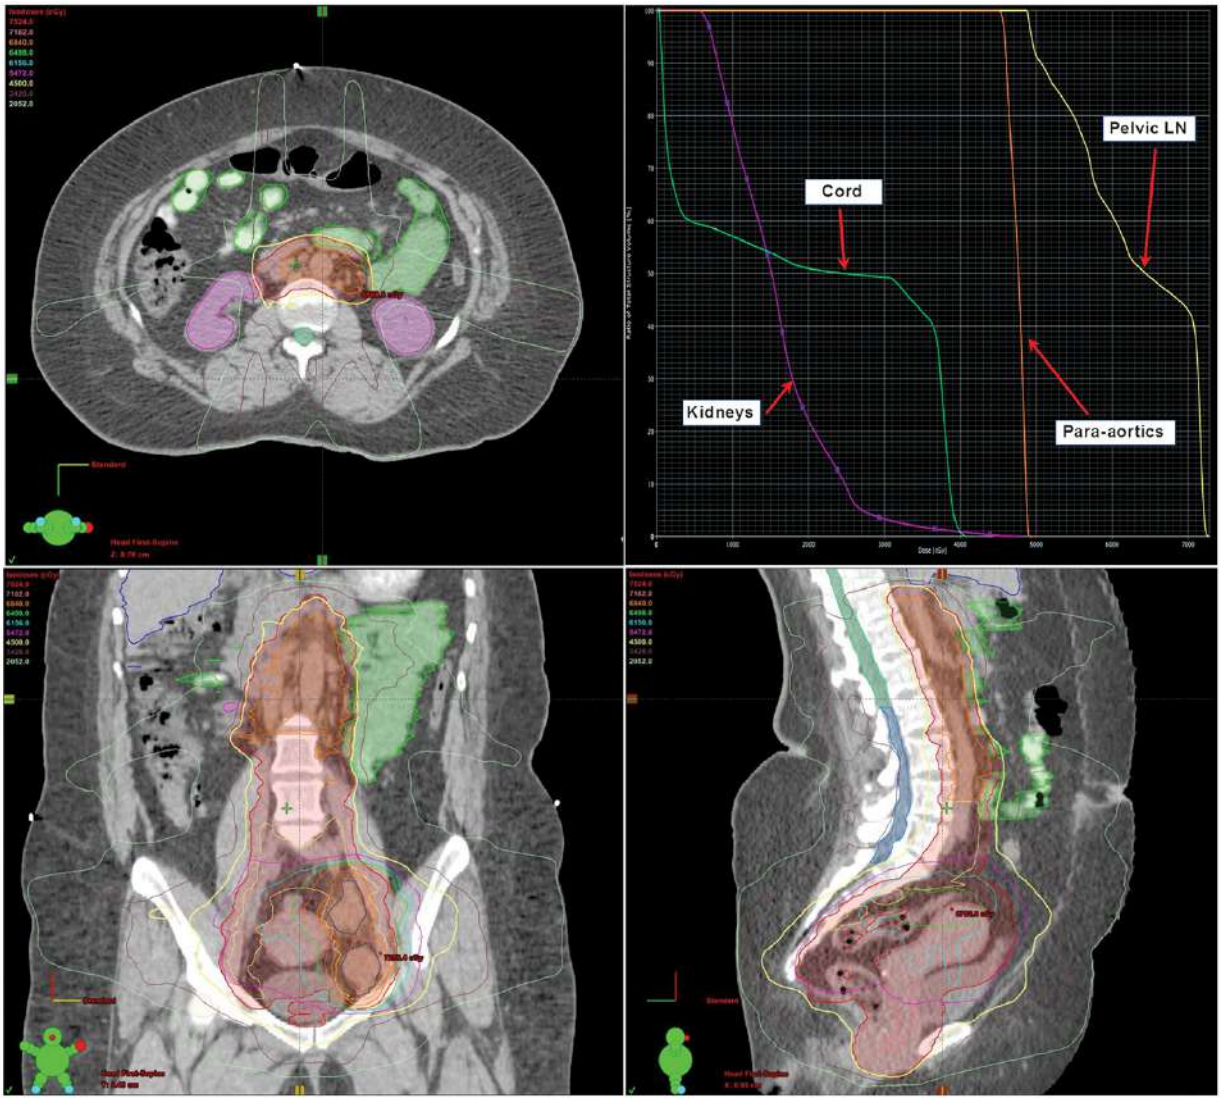

FIGURE 76.15 Extended-field intensity-modulated radiation therapy for external irradiation of the uterine cervix and pelvic and para-aortic lymph nodes (LNs). Dose-volume histogram values for the spinal cord, kidneys, para-aortic nodes, and pelvic node boost are shown for a patient who had an unresectable 4-cm pelvic LN.

The use of IMRT has allowed dose escalation to PAN, particularly unresectable nodes. Clinical reports show excellent control of disease with dose escalation, with one report demonstrating an 85% 2-year nodal control rate after IMRT with a median dose of 63 Gy.[174] Esthappan et al[129] described a technique using CT and FDG-PET to treat the PANs (50.4 and 59.4 Gy) with IMRT while treating the pelvis with 3/4 field RT, and it can be utilized if image guidance is less available. With IMRT, acceptable dose distribution of the target volumes and sparing of the spine, stomach, liver, and colon are

achievable. Sparing of small bowel can also be accomplished, but it may be limited because of overlap with the target volume. An example of IMRT use for dosing the para-aortic region up to 65 Gy while still maintaining constraints for the adjacent OARs can be seen in Figure 76.16.

FIGURE 76.16 Example of treatment plan with intensity-modulated radiation therapy for irradiation of para-aortic and pelvic lymph nodes to 65 Gy. Dose-volume histogram illustrating sparing of kidneys, spinal canal, bladder, and small intestines while achieving dose escalation to the nodal area.

IMRT also allows an integrated boost approach with doses up to 55 Gy in 25 fractions were reported with reasonable toxicity rates,[175] but controversy still remains about the increased per fraction dose and the potential for added toxicity it brings, particularly in the regions adjacent to the duodenum. A report from MD Anderson reported grade 5 toxicity with an SIB approach and therefore recommends limiting the SIB dose to 2 Gy rather than the larger 2.15 Gy or higher.[176] A combined approach of an integrated boost with an additional sequential dose up to 65 Gy was also reported, to avoid a larger per fraction dose[167] to the small bowel. Attention must be made to both the high and medium doses and the volume of bowels and kidney exposed.

When only conventional techniques are available, the PANs are irradiated either with an extended field, often using a four-field approach, that includes both the para-aortic region and the pelvis or through a separate portal (Figure 76.17). This may be done as one long field, or in cases requiring extended distance, one may instead choose to separate the pelvic and para-aortic fields.

This requires a “gap calculation” between the pelvic and para-aortic portals to avoid overlap and excessive dose to the small intestines. The upper margin of the field is at the T12-L1 interspace to reach the infrarenal hilum and the lower margin at L5-S1. The width of the para-aortic portals (in general, 8-10 cm) can be determined by CT scans, MRI, lymphangiography, FDG-PET scans, or IV pyelography outlining the ureters, with the goal to treat all tissue between the right and left psoas muscle. The spinal cord dose (T12 to L2-L3) should be kept to less than 45 Gy by interposing a 2-cm-wide five-half-value-layer shield on the posterior portal (usually after 40-Gy tumor dose) or using lateral ports and limiting the kidney dose to less than 18 Gy. A technique using four isocentric fields weighted 2:1 AP/PA over lateral portals and 1.8-Gy fractions was described to deliver high-dose therapy (56-61 Gy). Kodaira et al[177] evaluated a four-field para-aortic irradiation technique with 10-MV photons (mean, 50.4 Gy) in 97 patients with cervical cancer. The 5-year CSS rate was 32.2%. Grade 1 or 2 stomach and duodenum sequelae developed in 26.8%, grade 2 sequelae of small bowel in 3.1%, and grade 2 sequelae of bone in 3.1%. Rates of toxicity with IMRT are lower, though dose escalation with a SIB to large nodes next to the duodenum must be done with caution, given the risk of duodenal perforation.[130]

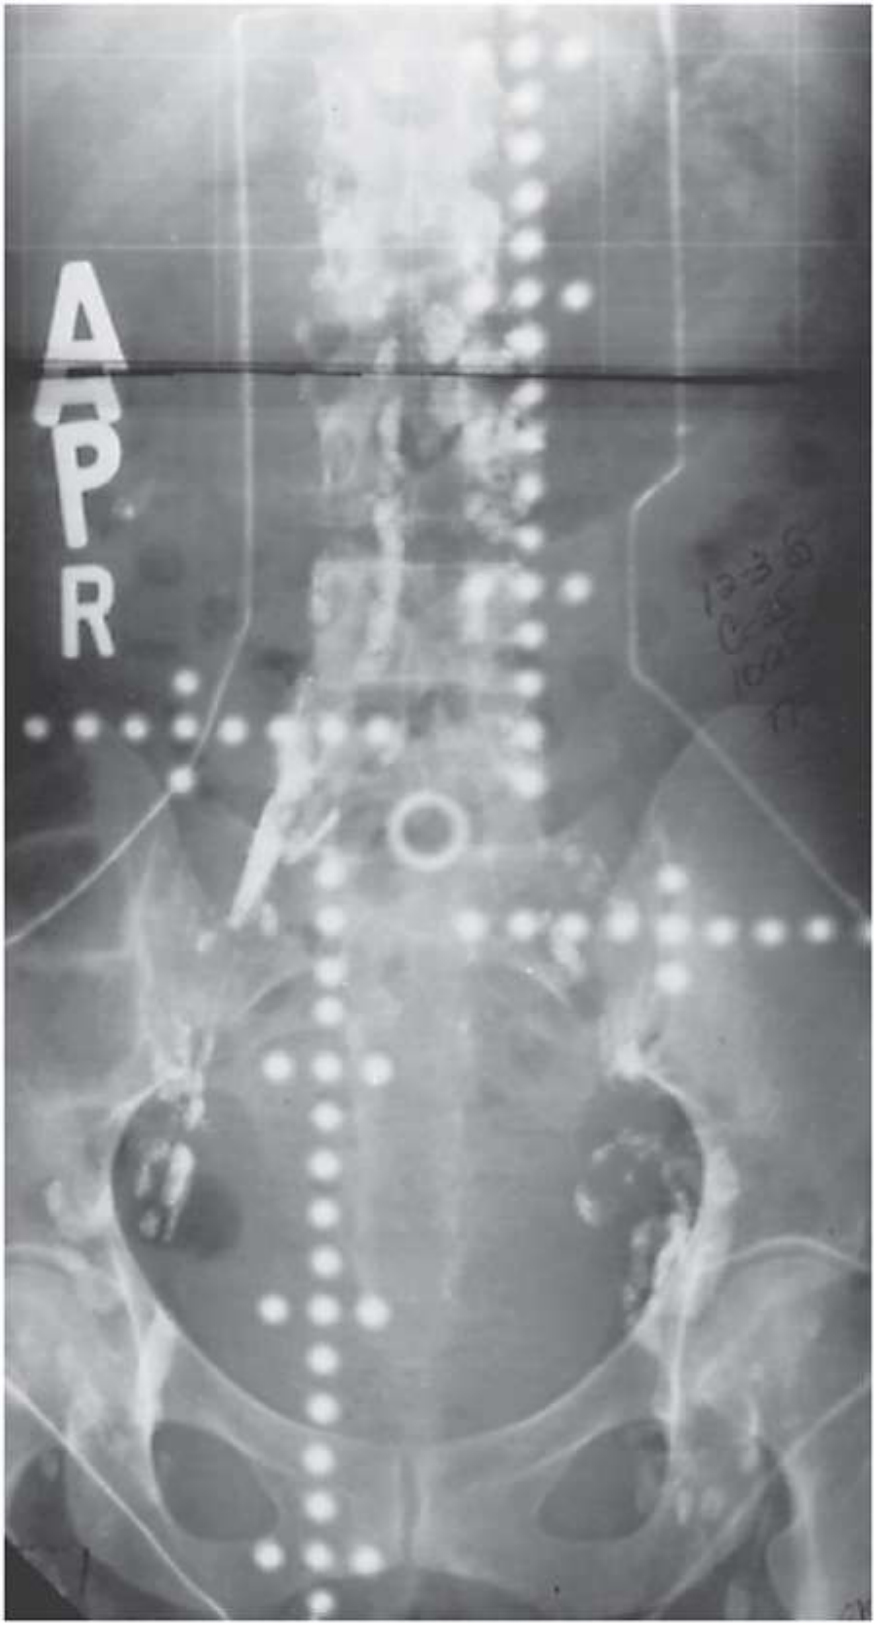

FIGURE 76.17 Extended field simulated with conventional plain films for external irradiation of pelvic and para-aortic lymph nodes.

Beam Energies

For IMRT, 6-MV energy is used to provide the most homogeneous dose. However, in conventional irradiation, because of the thickness of the pelvis, high-energy photon beams (≥10 MV) are especially suited for this treatment. They decrease the dose of radiation delivered to the peripheral normal tissues (particularly bladder and rectum) and provide a more homogeneous dose distribution in the central pelvis, which would allow more accurate combination with the BT dose (Figure 76.18). With lower energy photons (^{65}Co or 4-6 MV x-rays), higher maximum doses must be given, and more complicated field arrangements should be used to achieve the same midplane tumor dose (three-field or four-field pelvic box or rotational techniques) while minimizing the dose to the bladder and rectum and to avoid subcutaneous fibrosis. The presence of a metallic prosthesis when using lateral fields or a box pelvic irradiation technique may result in a dose decrease of approximately 2% for 25-MV x-rays and average increases of 2% for 10-MV x-rays and 5% for ^{65}Co. Better pelvic tumor control and survival and fewer complications were seen in 65 patients with stage IIB and III cervical carcinomas treated with 23-MV photons compared with 61 treated with external irradiation with ^{65}Co in addition to BT in both groups.[178] In contrast, Holcomb et al[179] compared outcome of 195 patients with stage IIB and IVA cervical carcinomas treated with ^{65}Co RT (group 1) and 53 treated with linear accelerators (group 2). There was no significant difference in OS, although there was a trend toward increasing pelvic recurrence in the ^{65}Co group (50.8%) compared with group 2 (35.8%; P = .08). Mixed beam external radiation with neutrons and photons resulted in unacceptably high toxicity rates and is not recommended. Similarly, carbon ion therapy was reported but resulted in major intestinal complications.[180]

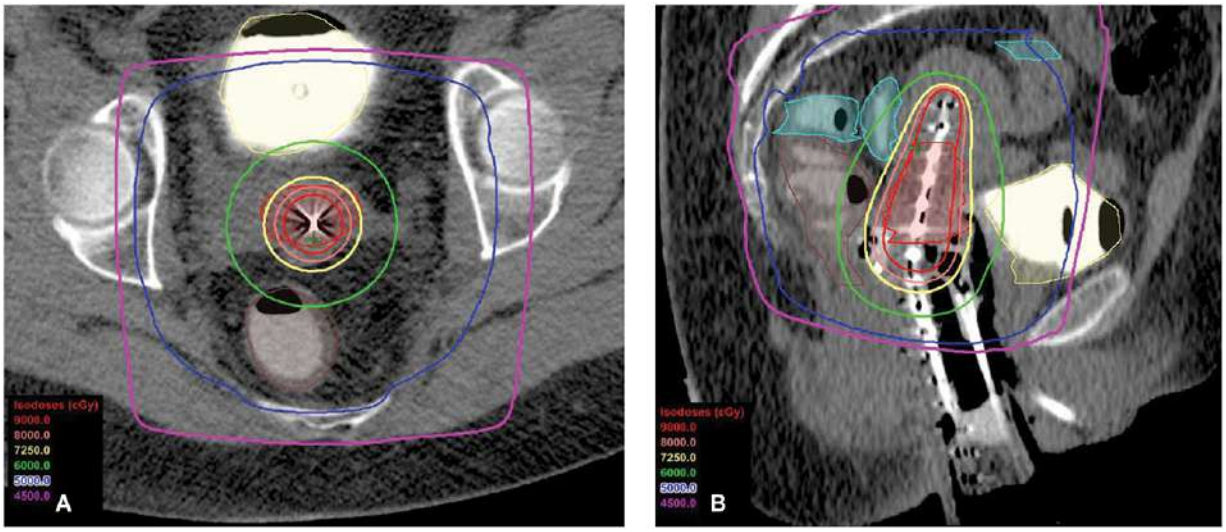

FIGURE 76.18 Example of isodose curves of 4-Field box irradiation of the pelvis with high-energy photons and computed tomography–based high-dose rate brachytherapy optimized to cover the tumor and minimize dose to the bladder and rectum. A. Axial. B. Coronal view.

Hyperfractionated or Accelerated Hyperfractionated Radiation Therapy

Studies on hyperfractionation with or without chemotherapy report comparable outcomes but higher toxicities. MacLeod et al[181] reported on a phase II trial of 61 patients with locally advanced cervical cancer treated with accelerated hyperfractionated RT (1.25 Gy administered twice daily at least 6 hours apart to a total pelvic dose of 57.5 Gy). A boost dose was administered with either low-dose rate (LDR) BT or EBRT to a smaller volume. Thirty patients had acute toxicity that required regular medication. One patient died of acute treatment-related toxicity. The overall 5-year survival was 27%, relapse-free survival was 36%, and actuarial local tumor control was 66%. There were eight severe late complications observed in seven patients, who required surgical intervention (actuarial rate of 27%). Five patients also required total hip replacement.

Another study reported on 30 patients with stage II or III cervical cancer randomized to receive either hyperfractionation (15 patients) or conventional fractionation (15 patients).[182] At 5 years, two patients in the hyperfractionation group and eight patients in the conventional treatment group had recurrent tumor (P = .04). Delayed bowel complications (grades 2 and 3) occurred in nine women in the hyperfractionation group and two patients in the conventional group (P = 0.0006).

RTOG 88-05 conducted a phase II trial of hyperfractionation (1.2 Gy to the whole pelvis twice daily at 4- to 6-hour intervals, 5 days/week) with BT in 81 patients with locally advanced carcinoma of the cervix. Comparison with historical control patients treated on other RTOG studies showed equivalent rates of pelvic tumor control, survival, and grade 3 and 4 toxicities at 3, 5, and 8 years, respectively.

Calkins et al[183] assessed the toxicities of multiple daily fractionated (twice daily, 1.2-Gy fractions) whole-pelvis radiation plus concurrent chemotherapy for locally advanced carcinoma of the cervix. In the first study (GOG 8801), for 38 patients, hydroxyurea was given orally (80 mg/kg to a maximum of 6 g) at least 2 hours before irradiation, twice every week. In the second study (GOG 8901), for 30 patients, cisplatin and 5-fluorouracil (5-FU) were used concomitantly with RT. Acute toxicity was primarily enteric and appeared to be dose related. The maximum tolerated dose of whole-pelvis radiation that could be delivered in a hyperfractionated setting with concomitant chemotherapy was 57.6 Gy in 48 fractions, followed by BT.

GENERAL MANAGEMENT

Carcinoma In Situ

Patients with persistent high-grade carcinoma in situ are usually treated with a total abdominal hysterectomy with or without a small portion of the upper vagina removed. The decision to remove the ovaries depends on the age of the patient and status of the ovaries. Occasionally, when the patient wishes to have more children, carcinoma in situ may be treated conservatively with a therapeutic conization, laser therapy, or cryotherapy. This approach should be judiciously selected when the extent of tumor allows it and the patient is reliable for continued follow-up. Conization microscopic margins are critical in decision-making regarding a conservative approach or proceeding with a hysterectomy. A therapeutic hysterectomy can be performed 6 weeks after the conization.

Irradiation may be useful for the treatment of carcinoma in situ, particularly in patients with strong medical contraindications to surgery or when there is extension of the lesion to the vaginal wall or multifocal carcinoma in situ in both the cervix and the vagina. In a group of 26 patients with carcinoma in situ treated at Washington University with intracavitary BT alone (~5,000 mgh, 45 Gy to point A with LDR) with tandem and ovoids, no recurrences

were recorded. Ogino et al[184] used HDR BT in 14 patients with grade 3 cervical, 6 with grade 3 vaginal intraepithelial neoplasia (3 with microinvasion), and 6 with recurrent CIN after hysterectomy. Seventeen patients were treated with HDR BT alone, and three in combination with EBRT without surgery. The mean dose of HDR BT was 26.1 Gy (range, 20-30 Gy) prescribed at point A for intact uterus, at 1 cm superior to the vaginal apex, or 1 cm beyond the vaginal mucosa for lesions of the vaginal stump. At a mean follow-up of 90 months, 14 patients were alive and 6 had died from intercurrent disease; none had recurrent disease. Rectal bleeding occurred in three patients and subsided spontaneously. Moderate and severe vaginal reactions were noted in two patients in whom the treatment included the entire vagina.

Invasive Disease

Based on available resources globally and the stage of disease, a debate continues among those who advocate radical surgery, those who favor radiation, and those who favor CRT for the treatment of carcinoma of the uterine cervix. Patients should be treated with close collaboration between the gynecologic oncologist and the radiation oncologist, and an integrated team approach should be vigorously pursued. In countries with access to RT facilities and financial resources to supply chemotherapy, the use of concurrent CRT represents the accepted standard for patients with stages IB3, IIA2, and IIB to IVA cervical cancer. For earlier stage patients, the use of either surgery or CRT is recommended.

A survey of patterns of RT practice documented a rise in the use of cisplatin-based concurrent CRT in patients with advanced stages, from 63% in 1999 to 74% in 2007.[185] Moreover, Barbera et al also reported a significant increase in the use of CRT in Canada after the *U.S. National Cancer Institute Bulletin* on the subject.[186] Whenever determining treatment strategy, it is important to keep in mind that almost all the trials discussed in this chapter were conducted prior to the FIGO 2018 staging system, which shifted all the node positive, less locally invasive tumors, from stages I and II to become stage IIIc. Thus, extrapolating from these data on newly diagnosed and staged patients should be done with due consideration

Carcinoma of the Cervix Inadvertently Treated With a Simple Hysterectomy

Occasionally, a simple or total abdominal hysterectomy is performed, and invasive carcinoma of the cervix is incidentally found in the surgical specimen. In general, extrafascial abdominal hysterectomy is not curative because the paravaginal or paracervical soft tissues and vaginal cuff are not removed. Furthermore, it may be technically difficult to perform an adequate radical operation after previous simple hysterectomy. If only microinvasive carcinoma is found when a total or extrafascial hysterectomy with a wide cuff is performed, no additional therapy is necessary for lesions with deeper stromal invasion; at most, one or two vaginal intracavitary insertions to deliver a 65-Gy LDR mucosal dose (or 7 Gy × six fractions prescribed at the vaginal surface or 5 Gy at 0.5 cm × six fractions with HDR BT) to the vault are sufficient. If a less comprehensive resection was carried out, it is critical that these patients receive RT immediately with or without concurrent chemotherapy, depending on the risk factors present pathologically when their postoperative status allows it because the prognosis is worse if postoperative irradiation is not administered.

In patients with fully invasive tumor, therapy consists of approximately 45 Gy to the whole pelvis with cylinder BT to the vaginal vault for an approximately 60-Gy mucosal dose. If there is gross tumor present in the vaginal vault or parametrium, the dose to the whole pelvis should be 45 Gy with concurrent weekly cisplatin chemotherapy, followed by an additional parametrial dose of 10 to 20 Gy. An intracavitary insertion should be performed. If there is gross residual tumor, an interstitial implant should be carried out to selectively increase the dose to this volume.

Several studies have reported results of postoperative external beam irradiation after conservative surgery. Münstedt et al[187] reported on 119 patients who received postoperative RT after RH and 80 who received it after simple hysterectomy. There was a trend toward better survival in the RH group, but the authors concluded that postoperative RT is a good treatment in patients with invasive cervical cancer who undergo a simple hysterectomy. In another report of 105 patients with invasive cervical carcinoma found in inadequate surgery specimens treated with postoperative RT, 5-year pelvic tumor control was 72% and the survival rate was 55%. Late rectal toxicity was 19%, bladder toxicity was 4.8%, and small-bowel toxicity was 14.3%.[188]

In a series of 147 patients treated at Asan Medical Center in Korea, 48 patients with stage IA1 lesions did not receive further treatment. Another 99 patients had stage IA2 to IIA lesions incidentally identified. Of these, 26 received no further therapy, 44 had either radiation or CRT, and 29 had a radical parametrectomy. For patients with stage IA1 disease who were observed, 0% relapsed, whereas 35% of patients with stage IA2 to IIA diseases who were observed suffered from a recurrence.[189] Either radical parametrectomy or radiation is required for patients with stage IA2 or higher cancer after a simple hysterectomy. However, these treatments increase the risk of side effects[190] including for those patients receiving robotic parametrectomy.[191]

Microinvasive Disease

The definition of microinvasive carcinoma of the cervix includes invasive carcinoma diagnosed only by microscopy, staged by the FIGO 2018 system as IA1 and IA2, according to the depth of invasion (DOI). Conization is mandatory for a more accurate diagnosis. Lesions less than 1 mm in depth can be treated with conization, provided all margins are tumor free and continued careful follow-up is instituted. Margins of 8 to 10 mm are used as guidelines for clearance in conization. Smaller margins and lymphovascular invasion in addition to DOI were prognostic factors for recurrence.

Tumor volume in the stroma may be a more reliable criterion than DOI to arrive at a definition of stage IA. Vascular space involvement does not impact stage. DOI and tumor confluence have been identified as prognostic factors that should be taken into consideration in the planning of therapy.

Early invasive carcinoma of the cervix (stage IA2) is usually treated with a total abdominal or modified RH or, in some cases, with simple conization or radical trachelectomy. When the depth of penetration of the stroma by tumor is less than 3 mm, the incidence of lymph node metastasis is 1% or less, and a lymph node dissection or pelvic external irradiation is not warranted. With more extensive lesions, an RH with bilateral pelvic lymphadenectomy (with or without sentinel mapping) is the preferred treatment. Tumor control with all treatment methods is more than 95%, with patients eventually dying of intercurrent disease. Gadducci et al[192] treated 30 patients with conization and 82 with total and 54 with RH; the recurrence rates were 10%, 4.9%, and 9.3%, respectively. None of 67 patients subjected to lymphadenectomy had

positive pelvic nodes. In 98 patients with AC of the cervix, none of 48 with DOI of ≤5 mm had involved parametria or positive nodes, in contrast to 6 (16%) of 36 with DOI of greater than 5 mm.[193]

Vaginal trachelectomy (removal of the cervix) and laparoscopic lymphadenectomy have been used to treat young patients with microinvasive carcinoma to preserve fertility. The overall incidence of central recurrence is approximately 5%. Webb et al[194] analyzed lymph node status and survival rates of women with microinvasive cervical AC (FIGO stages IA1 and IA2) from the SEER database between 1988 and 1997. Among reported cases, 131 had stage IA1 and 170 had stage IA2 disease. Simple hysterectomy was done in 54 women with IA1 and 64 women with IA2 disease and RH in 50 and 83 women. Only 1 of 140 women who had lymphadenectomy had a single positive lymph node. There were four tumor-related deaths (one with IA1 and three with IA2 disease). The survival rate was 98.7%.

Inoperable patients may be treated with intracavitary radioactive sources alone with 6,500 to 8,000 mgh, 60 to 75 Gy to point A, in two LDR insertions, respectively, or with the equivalent dose using HDR BT, approximately 10 fractions of 5 Gy per fraction. In 47 patients with microinvasive carcinoma treated at Washington University—20 with intracavitary therapy only and 27 patients with combined external irradiation and intracavitary BT—only 1 patient had a pelvic recurrence and distant metastases 10 years later; the 5-year DFS rate was 96%. Hamberger et al,[195] in patients with stage IA or IB lesions less than 1 cm in diameter treated with intracavitary therapy alone to high doses (8,640, 9,340, and 13,680 mgh), noted no failures in 41 patients with stage IA disease and only 4 (4%) of 93 patients with stage IB, small-volume disease. Only 3 (0.2%) of 151 patients in the report, which also included some larger stage IB tumors, had grade 3 complications.

Early Local Disease

This category includes nonbulky (<4 cm) tumors, confined to the uterus (stages IB1 and IB2) or limited to the upper two-thirds of the vagina (stage IIA1). The choice of definitive chemoirradiation with BT or radical surgery remains controversial, and the preference for one procedure over another depends the patient's fertility, the available resources of the treating institution, the gynecologic oncologist or radiation oncologist involved, the

general condition of the patient, and characteristics of the lesion, such as histology and size. An operation has been preferred by some in young women to preserve the ovaries, attempting to prevent premature menopause, but that should be considered against the low risk of ovarian metastases (~1%).[137] Postmenopausal or comorbid patients may benefit with CRT as they avoid operative risks. When therapeutic results in invasive carcinoma of the cervix are evaluated, a direct comparison of surgically treated or irradiated patients is fraught with many uncertainties, including patient selection, reporting of surgical cases using staging determined by laparotomy findings, and different treatment techniques. As mentioned, the introduction of the 2018 FIGO staging system, which drew out the node-positive cases from this stage group, can also complicate interpretation of older data. In particular, in the modern era when concurrent CRT is known to increase survival, and both surgical and radiation techniques have improved to cause less toxicity, a direct comparison of CRT versus surgery in early-stage cervical cancer is needed. Surgery provides an opportunity for a thorough pelvic and abdominal evaluation. However, surgical staging has not been shown to improve overall patient survival. Kupets et al[196] assessed the value of debulking large nodes and concluded that the incremental overall benefit by stage was small. In the era of MRI and PET, surgeons may rely on imaging findings to screen for operability. The impact of patient selection in results of surgical series was illustrated by Whitney and Stehman who evaluated the frequency with which intended RH for cervical cancer is abandoned and the outcomes for those selected patients.[197] In 1,127 patients with stage IB carcinoma of the cervix entered on GOG Protocol 49, 98 (8.7%) women were found at surgery to have extrauterine disease, and the proposed radical operation was abandoned. Patients had both pelvic and extrapelvic diseases, including grossly positive pelvic nodes, other pelvic implants, and gross serosal extension. Sixty-three (65%) patients subsequently underwent pelvic RT and BT. Para-aortic fields were added for eight patients who were found to have positive PANs. The DFS was longer for patients with direct pelvic extension than for those with extrapelvic disease.

However, with proper preoperative evaluation, patients with early-stage cervical cancer undergoing hysterectomy enjoy particularly good results. In the previously mentioned LACC trial,[122] which compared minimally invasive to open surgery, 92% of the 631 randomized patients had macroscopic less

than 4 cm, node-negative cancers (or FIGO 2018 stage IB1-2). The 3-year OS rates were 93.8% and 99%, respectively. Totally, only 4.3% had aborted surgery, and any adjuvant therapy was required in 28.2%.

Primary RT, using EBRT and BT without chemotherapy, is also an option for early cervical disease, if patients are deemed unsuitable for surgery or if a higher likelihood of adjuvant therapy is suspected. Randomized trials have shown similar survival outcomes to surgery and are discussed further in the next section. The importance of combining EBRT and BT to improve pelvic tumor control when treating larger localized lesions has been documented. The previously mentioned report by Hamberger et al,[195] which used intracavitary therapy alone, noted that 3 (18%) of 17 patients with over 1 cm IB lesions had regional failures. In addition, Volterrani and Lombardi[198] reported 5-year survival of 82.6% in 23 patients with occult stage IB carcinoma of the cervix treated with intracavitary ^{251}Ra only (7,500 mgh), in contrast to only 64.8% with larger stage IB tumors and 50% with stage II. Unfortunately, the authors did not report the exact location of the failures.

Concurrent chemotherapy significantly improves survival, including in stage IB to IIA diseases. In RTOG 90-01, for the subset of 272 stage IB to IIA patients, the 8-year OS was 55% with RT alone versus 78% with concurrent CRT ($P < .001$).[199] In the EMBRACE study, a total of 98 node negative, with less than 4 cm tumors, FIGO 2009 stage IB and IIA patients were included, and their 5-year OS was 88% and 85%, respectively.[200]

Randomized Studies: Surgery Versus Radiation

Few randomized trials have compared the results of RH with definitive RT, and none have compared surgery to CRT. Outcome between radiation alone versus surgery is comparable. Prospectively randomized studies reported in the 1970s on equivalent survival and pelvic recurrence rates in patients with stage IB and IIA carcinomas of the uterine cervix treated with an RH or irradiation alone.[201] Landoni et al[202] published results of a prospective, randomized trial of RT versus surgery; 469 women with stage IB and IIA cervical carcinomas were referred for treatment, and 343 were randomized (172 to surgery and 171 to RT). Postoperative irradiation was delivered after surgery for women with surgical stage pT2b or greater, less than 3 mm of cervical stromal invasion and cut-through margins, or positive pelvic nodes. Scheduled treatment was delivered to 169 and 158 women, respectively. In

the surgery group, 62 of 114 women with cervical diameters of less than 4 cm and 46 of 55 women with greater than 4 cm received adjuvant RT. After a median follow-up of 87 months (range, 57-120 months), 5-year OS and DFS rates were nearly identical in the surgery and RT groups (83% and 74%, respectively); recurrent disease developed in 86 women: 42 (25%) in the surgery group and 44 (26%) in the RT group (Figure 76.19). Forty-eight patients (28%) in the surgery group had severe morbidity, compared with 19 (12%) in the RT group (P = .0004; Table 76.5). The combination of surgery and RT had the worst morbidity, especially urologic complications.

TABLE 76.5 RANDOMIZED TRIAL OF RADICAL SURGERY OR IRRADIATION IN STAGE I TO II CERVICAL CANCERS: RELAPSES AND MORBIDITY

	Surgery							
	Surgery Only		Surgery Plus Radiation Therapy		Total		Radiation Therapy Alone	
	≤4 cm	>4 cm	≤4 cm	>4 cm	≤4 cm	>4 cm	≤4 cm	>4 cm

Of note, no randomized study has compared primary CRT to RH, although CRT has a significant survival advantage over RT alone for patients with stage IB to IIA cervical cancer. In a meta-analysis looking at the value of adjuvant cisplatin-based chemotherapy after RH, RT, or both for patients with stage IA2, IB1, or IIA cervical cancer, three randomized clinical trials were

evaluated.[203] Two of the three trials showed a significant benefit compared to adjuvant chemotherapy concurrent with radiation, with a reduced risk of death (HR = 0.56, 95% CI = 0.36-0.87). No benefit was seen when chemotherapy was given prior to RT.

NACT plus surgery does not improve survival over surgery alone.[204] In a meta-analysis of six trials, although there was an improvement in PFS with NACT (HR = 0.76, 95% CI = 0.62-0.94, *P* = .01), this did not translate into an OS benefit.

Randomized Trials of Radiation or Chemoradiotherapy After Radical Hysterectomy

Patients who have undergone RH with no preoperative RT are considered for postoperative CRT therapy if they have high-risk prognostic factors, which include positive pelvic lymph nodes, as are patients with negative nodes who have microscopic positive margins of resection or parametrial involvement.[205]

Patients with any two of deep stromal invasion, vascular/lymphatic permeation, and large tumor size are candidates for postoperative radiation.[206] These patients have an intermediate risk of failure. Whether to add concurrent chemotherapy to postoperative radiation in the intermediate-risk group is being tested in an accruing randomized trial (GOG0263).

One randomized study showed improved recurrence-free survival with postoperative pelvic irradiation (46-50.4 Gy in 23-28 fractions) after radical surgery in the presence of positive pelvic nodes or node-negative high-risk factors in women with stage IB cervical cancer treated by RH and pelvic lymphadenectomy. There were 277 eligible patients with at least two of the following risk factors: greater than one-third stromal invasion, capillary lymphatic space involvement, and large clinical tumor diameter; 137 patients were randomized to pelvic RT and 140 to no further treatment.[206] The results were updated by Rotman et al[207]; 24 (17%) patients in the irradiation group and 43 (30.7%) in the no-further-treatment group had cancer recurrences. In the RT group, 27 patients died of cancer, and in the no-further-treatment group, 40 died from cancer. There was a statistically significant reduction in risk of recurrence in the irradiation group, with recurrence-free rates at 2 years of 88% versus 79% for the irradiation and no-further-treatment groups. OS difference did not reach statistical difference (*P* = .074; Figure 76.20). Severe or life-threatening (GOG grade 3 or 4) adverse effects occurred in nine

patients (6.6%) in the RT group and three (2.1%) in the observation group. A meta-analysis of trials including stages IB1 to IIA cervical cancer found that women who received postoperative radiation had a significantly lower risk of disease progression at 5 years (RR = 0.6, 95% CI =0.4-0.9). The risk of serious adverse events was not significantly higher if women received RT rather than no further treatment, possibly because the rate of adverse events was low.[208]

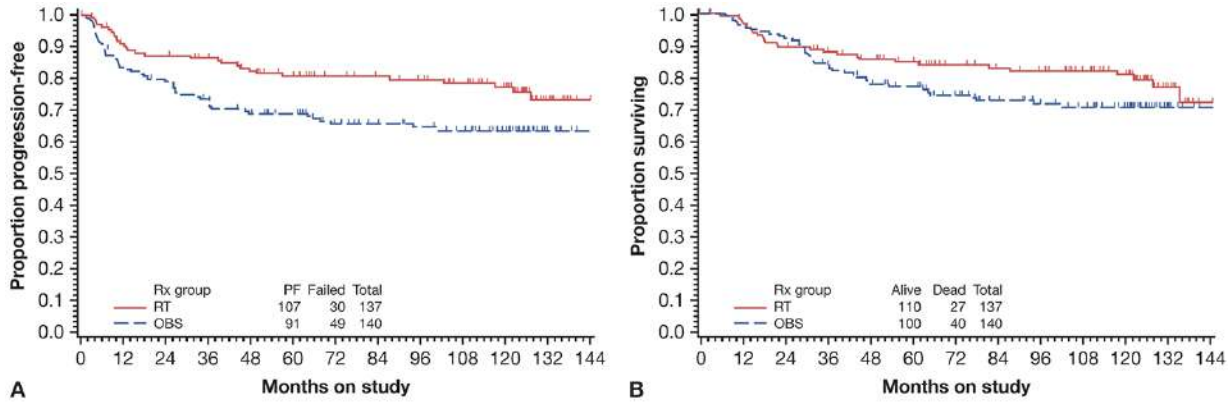

FIGURE 76.20 Recurrence-free survival (A) and overall survival (B) of patients with stage IB carcinoma of the cervix, correlated with treatment method. RT, radiation therapy. A phase III randomized trial of postoperative pelvic irradiation in patients with stage IB cervical carcinoma with poor prognostic features: follow up of a Gynecologic Oncology Group study. *Int J Radiat Oncol Biol Phys.* 2006;65[1]:169-176. Copyright © 2006 Elsevier. With permission.)

Southwest Oncology Group 8797 was a study for women with FIGO stage IA2, IB, or IIA carcinoma of the cervix with metastatic disease in the pelvic lymph nodes, positive parametrial involvement, or positive surgical margins at the time of primary RH with total pelvic lymphadenectomy. Patients had confirmed negative PANs; if the PANs were not sampled, the patients had confirmed negative common iliac lymph nodes. One hundred twenty-seven patients were randomized to treatment with pelvic EBRT with 5-FU infusion and cisplatin, and 116 were treated with irradiation alone. The 4-year PFS and OS for women on the adjuvant cisplatin/5-FU and RT arm were 80% and 81%, compared with 63% and 71% for women on the pelvic irradiation arm.[205] The difference was statistically significant.

Postoperative External Beam Radiation Dose

When metastatic pelvic lymph nodes are present, treatment has consisted of 45 Gy to the whole pelvis delivered with a four-field technique with concurrent weekly cisplatin. If gross residual disease is present, dose escalation to 54 to 65 Gy, depending on small-bowel dose limits (eg, $D_{5cc} < 55$ Gy), may be considered with a sequential IMRT nodal boost.[49] Patients with positive common iliac or PAN metastases should receive 45 Gy to the entire para-aortic region with the superior border covering the renal hilum, with consideration of a boost to the tumor bed. If gross residual nodal disease is left, a nodal boost up to 65 Gy with IMRT is particularly suited to treat these patients.[130]

In patients for whom postoperative irradiation is indicated for deep stromal invasion in the cervix or close or positive surgical margins, an alternative is to deliver 45-Gy pelvic external irradiation in combination with an intracavitary insertion (LDR, PDR, or HDR) and LDR equivalent dose of 65 Gy to the vaginal mucosa, using colpostats or a cylinder.[209] At some institutions, external irradiation alone (50 Gy to the midplane of the pelvis) with a four-field box technique has been used. Hong et al[210] recommended, for node-negative patients with high-risk factors, to irradiate only the low pelvis (median dose, 50 Gy), which resulted in a reduction of grade 3 small-bowel morbidity (3/149 = 2%) in comparison with patients treated to the whole pelvis (6/79 = 8%). Five-year DSS was 84% and 86%, respectively.

Postoperative Brachytherapy

Depending on the extent of surgical resection of the vagina, the vaginal cuff may be at risk for recurrence. There is no clear agreement on the indications for vaginal BT after RH, although adjuvant vaginal BT for cervical cancer is most commonly used as a boost after EBRT, particularly in patients with positive margins.[211] Based on the American Brachytherapy Society guidelines, vaginal cuff boost should be considered in patients with a less than RH, close or positive margins, large or deeply invasive tumors, parametrial or vaginal involvement, or extensive lymphovascular invasion.[209] Consideration of postoperative vaginal intracavitary BT after external beam therapy is recommended for patients with carcinoma at the vaginal margin of resection. If parametrial margins were close or positive, defined by either surgical clips or in the region of the surgical tumor bed, an external beam dose of at least 54 Gy for close margins and higher for positive margins is recommended.

In patients receiving postoperative irradiation, extreme care should be exercised in designing treatment techniques, including intracavitary insertions; because of the surgical extirpation of the uterus, the bladder and rectosigmoid may be closer to the radioactive sources than in the patient with an intact uterus. Furthermore, vascular supply may be affected by the surgical procedure, and adhesions can prevent mobilization of the small-bowel loops that may be fixed in the pelvis. HDR BT after surgery is particularly suited for patients with cervical cancer because it prevents the prolonged immobilization required for LDR BT. In some patients at higher risk for parametrial tumor or lymph node metastases, HDR BT is combined with external beam pelvic irradiation.

Locally Advanced Disease

Patients with stage IB3, IIA2, and IIB to IVA tumors are best treated with irradiation, including external beam and BT combined with concurrent chemotherapy. Larger tumors and tumors extending beyond the uterus are not suitable for primary surgical treatment as the need to add adjuvant RT results in higher toxicity without additional efficacy compared to primary RT.[202] In addition, NACT followed by surgery approach trials showed inferior results compared to primary cisplatin-based CRT.[212,213]

Numerous reports have been published on the concomitant use of irradiation and cytotoxic agents (hydroxyurea, cisplatin, and 5-FU, in some trials combined with mitomycin C) administered to obtain a radiosensitizing effect.[199,205,214] Cisplatin is one of the most active cytotoxic agents in SCC of the uterine cervix. When cisplatin and irradiation are used concomitantly, substantial enhancement of cell killing is observed. Suggested mechanisms for radiation enhancement by cisplatin (a) in hypoxic or oxygenated cells, free radicals with altered binding of cisplatin to DNA are formed at the time of irradiation, and (b) interaction inhibits repair of sublethal damage.

A 2005 updated meta-analysis of concomitant chemotherapy and RT by Green et al found 24 trials including 4,921 patients and concluded that CRT improves OS and PFS, whether cisplatin was used, with absolute benefits of 10% and 13%, respectively.[215] Similarly, a 2008 meta-analysis of the 13 trials that compared CRT to radiation found that there was an absolute 6% improvement in 5-year survival with concurrent CRT (HR 0.81, $P < .001$). The effect was attributed to a reduction in both local and distant recurrence.

CRT increased acute hematologic and GI toxicity, but no confirmation was made about a difference in late toxicity.[216]

Patients with stage IVA disease (bladder and/or rectal invasion) can be treated with either higher doses of external radiation to the whole pelvis with concurrent chemotherapy followed by intracavitary or interstitial insertions (total dose to point A with LDR BT about 90 Gy) and additional parametrial irradiation or with pelvic exenteration. Niibe et al,[217] in an analysis of 179 patients with stage IIIB AC, suggested that an optimal dose for large tumors was a total biologically effective dose (BED) of greater than 100 Gy.

A prospective single-arm trial, RTOG 0116, treated patients with positive para-aortic or high common iliac lymph nodes with extended-field radiation combined with cisplatin chemotherapy followed by BT.[218] IMRT was not allowed. The trial showed that this regimen is feasible, but the late grade 3 and 4 toxicity rate was 40%. There was no reduction in acute toxicity with the addition of amifostine. The use of extended-field IMRT has been shown to reduce the risk of GI toxicity in two retrospective series reports[130] and has become standard where available to patients with positive common or PANs requiring extended-field radiation with concurrent chemotherapy.

Randomized Trials of Chemoradiotherapy

Results from several randomized controlled trials demonstrated that cisplatin-based chemotherapy, when given concurrently with primary RT, prolongs survival in women with locally advanced cervical cancers, as well as in women posthysterectomy receiving adjuvant RT who have metastatic disease in the pelvic lymph nodes, positive parametrial disease, or positive surgical margins at the time of primary surgery.

The GOG conducted randomized Protocol 85, in which patients with carcinoma of the cervix, a clinical stage of IIB to IVA, and negative PAN were treated with external pelvic irradiation (51 Gy) combined with 30 Gy to point A with LDR BT.[219] One hundred twenty-seven patients received 5-FU (IV infusion, 1 g/m^2 for 4 days) and cisplatin (50 mg/m^2 IV) on days 1, 29, and 30 to 33, and 191 patients received hydroxyurea (80 mg/kg orally twice weekly). With a median follow-up for survivors of 8.7 years, the 5-year survival rate in the cisplatin/5-FU arm was 60%, compared with 47% for women in the hydroxyurea arm.

After completion of GOG 85, the group opened GOG 120[220,221] for the same patient population, which was a three-arm randomized trial comparing irradiation plus hydroxyurea versus irradiation plus weekly cisplatin versus irradiation plus hydroxyurea, cisplatin, and 5-FU. In 526 evaluable patients with a median follow-up for survivors of 106 months, the 5- and 10-year survival rates for women in both the weekly cisplatin and irradiation arm and the irradiation, 5-FU, and cisplatin arm were 60% and 53%, respectively, compared with 40% and 34% in the hydroxyurea and irradiation arm ($P \leq .01$). OS was also significantly better in the two patient groups receiving cisplatin. Hematologic toxicity was greater in the group treated with the three drugs compared with cisplatin or hydroxyurea alone.

The RTOG conducted a randomized study of 389 patients with stage IB to IIA of greater than 5 cm, proven positive pelvic lymph nodes, or stage IIB to IVA carcinoma of the cervix in which patients were treated with either pelvic and para-aortic irradiation (best arm of RTOG Protocol 79-20) or pelvic irradiation and three cycles of concomitant chemotherapy with cisplatin (75 mg/m^2) and 4-day infusion of 5-FU (1,000 mg/m^2/day). Updated results were reported by Eifel et al[199] with a median follow-up of 6.6 years for 228 survivors, the 8-year OS rate for women on the irradiation and cisplatin/5-FU arm was 67% versus 41% in the irradiation-only arm ($P < .0001$). DFS rates were 66% and 36%, respectively. There were no significant differences in late complications in the treatment groups.

In GOG 123, 369 women were enrolled. One hundred eighty-three women with bulky (≥4 cm) stage IB carcinoma of the cervix with negative pelvic nodes and PANs radiographically or surgically determined were randomized to be treated with pelvic EBRT and BT, followed by extrafascial hysterectomy, and 186 received EBRT and BT with weekly cisplatin (40 mg/m^2; total dose not to exceed 70 mg/week) followed by extrafascial hysterectomy. In an updated analysis with a median follow-up of 101 months,[222] the 6-year PFS rate for women treated with irradiation and cisplatin was 71%, compared with 60% for those treated with RT alone, after adjusting for age and tumor size ($P < .004$). The unadjusted 6-year OS rates were 78% and 64%, respectively ($P < .015$).

The results of randomized trials using concurrent CRT are summarized in Table 76.6. Curtin et al[223] completed a small phase III trial in which 89 patients with high-risk stage IB or IIA undergoing RH and pelvic node

dissection were randomized to be treated with postoperative cisplatin/bleomycin alone (44 patients) or combined with pelvic RT (45 patients). There were 9 and 10 recurrences, respectively, and survival was equivalent.

TABLE 76.6 RANDOMIZED STUDIES OF CONCURRENT CHEMOIRRADIATION IN CERVICAL CARCINOMA

On the other hand, Pearcey et al[224] reported on a Canadian randomized study in which 127 patients with stage IB to IIA of greater than 5 cm or IIB carcinoma of the cervix were randomized to be treated with cisplatin (40 mg/m^2 weekly) and RT, and 126 patients were treated with RT alone (50.4 Gy to the pelvis combined with BT). With a median follow-up of 65 months, the 5-year survival rates were 59% and 56%, respectively (P = .43). There was a somewhat greater incidence of significant late morbidity in the RT-alone group (12% vs 6%; P = .08). Possible explanations for the discrepancy in results between the five U.S. and the Canadian study were that a higher percentage of early-stage patients were accrued, who, therefore, had less of a difference in survival, given that the baseline survival rate for both arms was quite high and that treatment time was short for both arms, again minimizing the difference in improving survival in the chemotherapy arm. This was the smallest of the randomized CRT trials, and although the HR was reduced, given the factors equalizing the two arms, a larger number of patients would have possibly shown a significant difference.

In a randomized trial comparing monthly 5-FU and cisplatin versus weekly cisplatin concurrent with pelvic radiation, Kim et al[225] enrolled 158 stage IIB and IVA patients. With a median follow-up of 39 months, the acute grade 3 and 4 hematologic toxicities were significantly worse in the fluorouracil/cisplatin arm (43% vs 26%; P − .04). The trial was not powered to detect a survival difference, and no difference in the OS or PFS was noted.

As the data about the benefit of cisplatin-based CRT in patients with an advanced primary tumor were less robust, a later Indian trial randomized 850 patients with 2009 FIGO stage IIIB cervical cancer to pelvic RT and BT with or without weekly cisplatin. The results showed a significant 8% to 8.5% increase in the 5-year DFS and OS with addition of weekly cisplatin.[226]

In the United States, weekly cisplatin has become the preferred approach, with less toxicity than an every 3-week regimen and increased likelihood of completing the treatment on schedule. It is important that patients complete the full course of 45 Gy with, ideally, five to six weekly doses of cisplatin or a cumulative dose of over 180 to 200 mg/m^2. The number of completed cycles of weekly treatment was shown by Nugent et al[227] to be predictive of survival. One hundred eighteen patients with locally advanced cervical cancer (stages IB2-IVA) were treated with combination weekly cisplatin (40 mg/m^2) and radiation between 2003 and 2007. Thirty percent of patients completed fewer than six cycles of chemotherapy. In multivariate analyses, the number of chemotherapy cycles was independently predictive of PFS and OS. Patients who received fewer than six cycles of cisplatin had a worse PFS (HR = 2.65; 95% CI = 1.35-5.17; P = .0045) and OS (HR = 4.47; 95% CI = 1.83-10.9; P = .001). Advanced stage, longer time to RT completion, and absence of BT were also associated with decreased OS and PFS (P < .05). Similar results were found when analysis was conducted using a breakpoint of at least but not less than five chemotherapy cycles. The authors concluded that aggressive supportive care to minimize missed chemotherapy treatments may improve survival after CRT. A retrospective review[228] questioned whether patients with cervical cancer should receive cisplatin 20 mg/m^2 × 5 days every 21 days concomitant with RT or weekly 40 mg/m^2 weekly concomitant with RT, given that an advantage with regard to both acute toxicity and PFS was seen in the 5-day regimen.

Alternatives to Concurrent Cisplatin-Based Chemoradiotherapy

No randomized trials compared carboplatin and cisplatin as concurrent chemotherapy with RT in cervical cancer. Carboplatin is a known radiosensitizer and sometimes used as replacement for cisplatin in ineligible patients, but it should be carefully considered as the evidence for equivalence is lacking. Nam et al reported on a prospective cohort of 51 patients who were compared to historical controls treated with cisplatin and RT. No significant differences were reported in response rate, OS, PFS, or toxicity.[229] A randomized trial has shown no difference in OS and PFS with carboplatin alone or in combination with oral tegafur-uracil.[230] Katanyoo et al[231] reported 148 patients with stage IIB to IVA cervical cancers treated with concurrent weekly carboplatin (100 mg/m^2 or area under the curve 2) for a median of six

cycles and radiation. Among the 142 responders, 36 experienced recurrences: pelvic recurrences in 7 (4.7%), distant failure in 25 (16.9%), and both pelvic and distant in 4 (2.7%). The 2- and 5-year PFS rates were 75.1% and 63.0%, respectively, with the corresponding 2- and 5-year OS rates of 81.9% and 63.5%. No grade 3 or 4 hematologic and nonhematologic toxicities were observed during treatment in any patients. Late grade 3 to 4 GI or genitourinary (GU) toxicities were 10.1% and 0.7%, respectively.

A Chinese trial randomized cisplatin and nedaplatin given concurrently with RT in 160 patients. No significant differences were found in PFS and OS, with less GI and renal toxicity but higher liver toxicity in the nedaplatin group.[232]

In GOG Protocol 165, patients with stage IIB to IVA cervical cancers received either RT and concurrent weekly cisplatin (40 mg/m^2) or RT and a protracted venous infusion (PVI) of 5-FU. Lanciano et al[233] reported that the study was prematurely closed after an interim analysis showed a failure rate 35% higher and would not result in improved DFS with PVI 5-FU/RT compared with weekly cisplatin.

Mitomycin C acts as an alkylating agent and inhibits DNA and RNA synthesis. Activation of mitomycin C is increased in hypoxic conditions, and thus, it acts as a hypoxic radiosensitizer. Interstitial pneumonitis and pulmonary fibrosis are usually related to the dose of drug. The use of IV dexamethasone before administration of the drug may prevent pulmonary toxicity.

Christie et al[234] described results in three groups of patients with stage IIB and III carcinomas of the cervix treated with pelvic irradiation and an intracavitary insertion combined with chemotherapy. Group A (64 patients) received 5-FU infusion during the first and last weeks of irradiation combined with mitomycin C (10 mg/m^2 IV). Group B (29 patients) received 5-FU without mitomycin C, and group C (84 patients) received irradiation alone. With a median follow-up of 7.2 years, the 5-year survival rates were 56%, 32%, and 36%, and the local tumor control was 73%, 53%, and 50%, respectively. Toxicity was greater in group A (36% grades 3 and 4) compared with the 5-FU and irradiation group (14%) and the irradiation-alone group (20%).

Roberts et al[235] reported on a trial in which 160 patients with locally advanced cervical cancer were randomized to receive RT alone (82 patients)

or RT with concomitant mitomycin C (78 patients). The 4-year actuarial survival was 72% and 56%, respectively (P = .13), and the LR-free survival rate was 78% and 63%, respectively (P = .11). There were no treatment-related deaths. No excess in nonhematologic toxicity has been observed with combined mitomycin C and irradiation.

Several small phase II studies have been performed, showing no advantage to weekly taxanes over weekly cisplatin[236] and too high toxicity with concomitant cisplatin-paclitaxel.[237]

Older randomized trials of irradiation with concomitant hydroxyurea (HOU) in patients with cervix cancer suggested that survival was higher in the HOU group. Symonds et al,[238] in a review of seven randomized trials, found no evidence to support the use of hydroxyurea with RT in cervix cancer.

Singh et al[239] published a randomized comparison of cisplatin and gemcitabine as concurrent CRT in 60 patients with cervical cancer, showing higher hematologic toxicities with gemcitabine and higher GI toxicities with cisplatin. There was also a nonsignificant higher CR rate with cisplatin (87% vs 73.3, P = .20).

Adjuvant Chemotherapy After Chemoradiotherapy

Whether there is benefit from adjuvant chemotherapy after CRT in some patients is controversial. A randomized trial of 515 cases of stage IIB to IVA cervical carcinomas treated with concurrent gemcitabine plus cisplatin followed by adjuvant gemcitabine and cisplatin compared to standard concurrent cisplatin with radiation showed a significant 3-year PFS benefit of 74% versus 65% (P = .03) and a significant reduction of risk of death. (HR = 0.68, 95% CI = 0.49-0.65).[240] Grade 3 and 4 toxicities were higher in the extended chemotherapy arm, including two deaths. In contrast, two other randomized trials failed to show added benefit with adjuvant chemotherapy after CRT. Tangjitgamol et al[241] reported on the ACTLACC trial that randomized 259 patients after CRT to continue observation or receive three cycles of carboplatin and paclitaxel. No significant differences were found in PFS or OS, just reduced systemic recurrences in the adjuvant chemotherapy group (5.4% vs 10.1%, P = .029). The larger multinational OUTBACK trial randomized 926 patients after CRT to observation or adjuvant four cycles of carboplatin and paclitaxel and found higher toxicity but no benefit in OS after median 5 years of follow-up (72% vs 71%, P = .81).[242] About 22% of patients

in the adjuvant group did not start the adjuvant chemotherapy, which was similar to other adjuvant chemotherapy trials.

Trials of Additional Systemic Agents Concurrently With Chemoradiotherapy

Bevacizumab With Chemoradiotherapy

RTOG 0417 treated patients with once-weekly cisplatin (40 mg/m^2) chemotherapy and standard pelvic RT and BT. Bevacizumab was administered at 10 mg/kg IV every 2 weeks for three cycles. A total of 49 patients were evaluable. The median follow-up was 12.4 months (range, 4.6-31.4 months). There were 15 (31%) protocol-specified, treatment-related adverse events within 90 days of treatment start; the most common were hematologic (12/15; 80%). Eighteen (37%) occurred during treatment or follow-up at any time. An update with 3.8-year follow-up (range 0.8-6 years) showed a 3-year OS 81.3%, DFS 68.7%, and locoregional failure 23.2%, with 26.5% grade 3 adverse events (mainly hematologic) and 10.2% grade 4 events.[243]

Epidermal Growth Factor Receptor Inhibition With Chemoradiotherapy

Nogueira-Rodrigues et al[244] reported a phase I study administering escalating doses of erlotinib (50/100/150 mg) combined with cisplatin (40 mg/m^2, weekly, five cycles) and RT (external beam, 4,500 cGy in 25 fractions, followed by four fractions/600 cGy weekly of BT) in patients with SCC of the cervix, stages IIB to IIIB. Fifteen patients were enrolled, 3 at dose level (DL) 50 mg, 4 at DL 100 mg, and 8 at DL 150 mg. Three patients did not complete the planned schedule. One patient at DL 100 mg withdrew informed consent because of grade 2 rash; at DL 150 mg, one patient presented with Raynaud syndrome and had cisplatin interrupted, and another patient presented with grade 4 hepatotoxicity. The latter was interpreted as dose-limiting toxicity, and a new cohort of 150 mg was started. No further grade 4 toxicity occurred. Grade 3 toxicity occurred in six cases: diarrhea in three patients, rash in two patients, and leukopenia in one patient. Treatment did not lead to limiting in-field toxicity.

Checkpoint Inhibition and Chemoradiotherapy

As checkpoint inhibitors have shown survival benefit in patients with metastatic cervical cancer, their use in earlier stages is under active research. The CALLA trial,[245] which included 770 patients with stage IB2 to IIB, node-positive, or stage III to IVa cervical cancer, added durvalumab or placebo to CRT for up to 2 years. With a median follow-up of 18.4 months, it showed no significantly added benefit with durvalumab to 12-month PFS (76% vs 73%, HR 0.84, *P* = .17). A post hoc analysis found that in patients with high PD-L1 expression, determined as 20% and higher tumor area positivity, durvalumab slowed progression with HR 0.62 (95% CI, 0.4-0.91). The KEYNOTE-A18 trial, a similarly designed trial, randomized 1,060 patients to receive either pembrolizumab or placebo concurrently to CRT and then up to two and half years. Results have shown significant improvement in 2-year PFS with pembrolizumab (67.8% vs 57.3%, HR 0.7 [95% CI, 0.55-0.89], *P* = .002) for all comers. OS data showed a favorable trend, and grade 3 and higher adverse events incidence was reported higher with pembrolizumab (67% vs 60%).[246]

Neoadjuvant Chemotherapy

Although response rates to the chemotherapy are between 30% and 85%, none of the studies in the preconcurrent cisplatin era, comparing NACT followed by surgery or RT to primary RT alone, showed an advantage for pelvic tumor control or survival. It was hypothesized to be related to accelerated repopulation and that receiving upfront chemotherapy may compromise immune status and the patient's ability to receive definitive treatment with radiation or surgery.

As concurrent cisplatin with RT became standard, trials comparing NACT followed by CRT or surgery to CRT alone also failed to show benefit to this approach and some even showed harm. Da costa et al[247] randomized 107 patients with stage IIB to IVa cervical cancers to NACT with cisplatin and gemcitabine for three cycles followed by CRT. CR was seen in 56% of the NACT arm versus 80% in the CRT arm (*P* = .008), which translated to reduced 3-year OS (60.7% vs 86.7%, *P* = .006).

Gupta et al[212] randomized 635 patients with FIGO 2009 stage IB2, IIA, and IIB cervical cancers to receive three cycles of carboplatin and paclitaxel followed by surgery or primary CRT alone. The 5-year DFS rates were significantly higher in the CRT group (76.7% vs 69.3%, *P* = .038), and no OS difference was observed.

Kenter et al[213] randomized 626 patients with bulky stage IB and stage II cervical cancers to platinum-based NACT followed by surgery to CRT alone. Only 71% of patients in the NACT arm were able to complete therapy, versus 82% in the CRT arm. Adjuvant RT was needed in 47% of patients who underwent hysterectomy. No significant 5-year OS rate difference was seen (72% vs 76%).

The INTERLACE trial[248] randomized 500 patients with locally advanced tumors to receive either NACT of 6 weekly cycles of carboplatin and paclitaxel followed by CRT or CRT alone. We await full publication of this trial as its applicability is important for countries where a wait time for RT exists, and patients cannot immediately start concurrent CRT.

Radiation Alone With or Without Surgery

For patients unable to tolerate concurrent chemotherapy or in countries where chemotherapy is not readily available, radiation alone may be used as an alternative to CRT. Outcomes were reported in a previously mentioned meta-analysis as 60% 5-year OS, compared to 66% with CRT.[216]

Bulkier tumors can be more challenging to fully eradicate with BT; thus, they have a higher incidence of central recurrence, and regional and distant dissemination. When using plain x-ray point-based planning for BT, because of the inability of intracavitary sources to encompass the entire tumor in a high-dose volume, larger doses of external radiation to the whole pelvis, extrafascial hysterectomy, or both have been advocated to improve therapeutic results. Alternatively, the use of 3D planning for the BT component significantly improves survival, and the ability to dose escalate because of a more precise dose delivery improves LC.[249] Prior to 3D BT planning becoming widely available, primary RT with adjuvant hysterectomy was investigated as another approach to improve LC.

Eifel et al[250] evaluated 1,526 patients, of whom 371 had tumors 6 cm or greater. There were biases in treatment selection, but a statistically significantly higher 10-year survival rate was noted in patients treated with irradiation and surgery (64% vs 45%). Tumor diameter was highly significant as a prognostic factor, and the authors concluded that only patients with lesions greater than 8 cm in diameter benefited from adjuvant hysterectomy. In the same study, 98 patients with stage IB and IIB bulky endocervical carcinomas (≥6 cm in diameter) were treated with RT alone. Twenty-four

patients received less than 6,000 mgh of intracavitary treatment, and 73 received higher doses. Despite having somewhat more favorably treated tumors, patients who received less than 6,000 mgh had a higher rate of pelvic recurrence at 5 years (33%) than those who received higher doses (16%; P = .03). Actuarial 5-year survival rates were 44% and 60% for low- and high-dose groups, respectively (P = .14).

The GOG and RTOG conducted a randomized phase III clinical trial in which 282 patients with carcinoma of the cervix measuring 4 cm or greater (exophytic or barrel shaped) were treated with either external beam and intracavitary irradiation or a slightly lower dose of intracavitary irradiation and the same pelvic EBRT followed by an extrafascial hysterectomy.[251] The survival rates were 61.4% for irradiation alone and 64.4% for the combined irradiation and surgery group. The incidence of recurrences was 43.3% in the irradiation group compared to 34.5% with combined therapy (P = .081). The incidence of LRs was 25.8% and 14.4%, respectively. The incidence of grade 3 and 4 sequelae of therapy was 10.5% and 9.8%, respectively. Thus, the addition of hysterectomy to standard irradiation did not significantly affect survival, although there was a small reduction in the LR rate. When combined therapy is used, the dose of irradiation delivered to the lymph nodes, the time of the operation, and the pathologic examination of the specimens are critical in determining the presence of postirradiation residual tumor.

Chemoradiotherapy With Adjuvant Hysterectomy

Keys et al[251] reported on 183 women with bulky (≥4 cm) stage IB carcinoma of the cervix with negative pelvic nodes and PANs radiographically treated with pelvic EBRT and BT, with or without weekly cisplatin, followed by extrafascial hysterectomy. A significant survival advantage was seen with the combination of concurrent CRT. However, in comparison to other trials, the survival was not significantly improved with the addition of a hysterectomy. A subsequent reanalysis including GOG 123 and GOG 71 analyzed 464 patients allocated to pelvic radiation (75 Gy, n = 291) plus hysterectomy or to pelvic radiation (75 Gy) and cisplatin (40 mg/m^2, n = 176) plus hysterectomy. A benefit to adding cisplatin was seen only for patients who had a poor response, defined as over 10% viable tumor.[252] This suggested that whatever benefit was seen for adjuvant hysterectomy became obsolete with concurrent cisplatin in most cases, while its risks remained. Touboul et al[253] reported on

toxicities for 150 patients with stage IB2 to IVA cervical cancers treated at Institut Gustave Roussy (IGR) with extrafascial versus modified RH after CRT. After a median follow-up of 3.6 years, 15% had grade 2 or greater side effects, including lymphedema, ureteral fistula, bowel fistula, and iliac and vessel rupture. There were two postoperative deaths. Modified radical versus extrafascial hysterectomy had a higher odds ratio for complications of 2.4 (P = .04), as did the presence of residual disease.

Morice et al[254] reported a randomized trial of 61 patients treated with adjuvant hysterectomy versus none after EBRT with concurrent weekly cisplatin and vaginal BT (15 Gy to intermediate-risk CTV) for stage IB2 or II cervical cancer. Hysterectomy increased the number of deaths, with an 11% nonsignificant survival advantage in the no-hysterectomy arm (86% vs 97%). As a result of this trial, routine adjuvant hysterectomy is no longer practiced for patients who have no residual disease at 6 weeks after CRT. Therefore, patients should receive definitive doses of CRT, with hysterectomy reserved for salvage in patients with either gross residual disease or PET-positive disease that is biopsy proven at 3 months after completion of radiation.

Elective Para-Aortic Lymph Node Irradiation

Prior to the cisplatin CRT era, randomized trials have shown that in some high-risk patients with no clinical or radiographic evidence of pathologic PAN, improved local-regional control and even survival is gained with the addition of elective para-aortic irradiation to pelvic irradiation, at the cost of increased bowel toxicity.

No randomized trials of extended fields to the PAN were performed in the cisplatin CRT era.

Huang et al[255] assessed 758 patients initially treated with pelvic RT, with only 23% of them receiving two or more cycles of concurrent chemotherapy. The study reported that 38 (5%) and 42 (6%) had isolated and nonisolated PAN recurrences after a median follow-up of 50 months (range, 2-159 months), respectively. The 3- and 5-year OS rate after PAN recurrence was 35% and 28%, respectively, with those with isolated recurrences faring better than those with a nonisolated recurrence (P < .001). An SCC-Ag level of greater than 40 ng/mL (P < .001), advanced parametrial involvement (score 4-6; P = .002), and the presence of pelvic lymphadenopathy (P = .007) were independent factors associated with PAN relapse on multivariate analysis.

Subsequently, focusing specifically into the subgroup that received concurrent CRT therapy, this group identified pretreatment CEA of 10 ng/mL or higher as an additional risk factor of PAN relapse in patients with pretreatment SCC-Ag levels of less than 10 ng/mL.[256]

The multicenter EMBRACE cohort, which had varying upper field limits, showed that in the 1,338 patients included, a total of 104 any PAN recurrences were seen, 55 of which were isolated. Risk factors identified were any nodal disease and tumor width.[257]

PAN irradiation was shown to be protective from these recurrences. A risk-based algorithm was suggested and implemented in the ongoing EMBRACE II study, mandating elective para-aortic lymph nodes (PAN) irradiation in any patients with three or more positive pelvic nodes or any positive common iliac nodes, to potentially reduce these isolated recurrences.[258] Until further results are reported, the role of prophylactic para-aortic radiation, particularly in patients with large tumor size, parametrial involvement, or heavily involved pelvic lymph nodes, must be carefully weighed against the potential toxicities of para-aortic radiation.

METASTASES TO PARA-AORTIC LYMPH NODES

In the FIGO 2018 staging system, this was defined as stage IIIC2 and could be determined by either imaging or surgical assessment. This state harbors worse prognosis than patients with pelvic nodal disease, but it is still curable, especially with concurrent chemotherapy and IMRT. One retrospective report of 102 patients treated with up to 59.4 Gy to the PAN with a 3-year PFS and OS of 57% and 69%, respectively. Acute major toxicity (grade 3 and higher) was mostly hematologic (61%), with even two deaths, and to 3% GI. Late grade 3 to 4 toxicities were reported as 14% hematologic, 8% GI, and 3% GU.[259]

Toxicity to the small bowel and duodenum is important to consider when treating PANs. In 105 patients with enlarged PANs, 36% had cervical cancer; the 3-year rate of duodenal toxicity was 11.7%, with fatal events in two patients because of perforation. The recommended V_{55} less than 15 mL resulted in 7% toxicity, whereas V_{55} greater than 15 mL resulted in 48% toxicity.[260] A retrospective analysis of 103 patients with cervical cancer and PAN metastases demonstrated factors associated with improved DSS included concurrent CRT ($P = .001$), baseline PET imaging ($P = .01$), and treatment of

PANs with IMRT (P = .02). The crude rate of grade 3 or higher late treatment-related adverse effects was 17%.[176] SIB to 50 to 54 Gy followed by a sequential boost to 60 to 65 Gy has been demonstrated, with adherence to small-bowel dose constraints.[165,175]

METASTATIC, PERSISTENT, OR RECURRENT DISEASE

This category includes patients diagnosed with stage IVB at presentation, patients who recurred after local therapy, or patients whose disease did not fully respond to definitive RT. The main modality of treatment is systemic therapy, which may be combined with RT as needed.

Several chemotherapy agents were tested as monotherapies and combinations. Responses were observed for platinum agents, taxanes, camptothecin derivatives, and nucleoside, with a better response in dual platinum combination and no added benefit but higher toxicity with triple combinations. A four-arm comparison of cisplatin/paclitaxel versus cisplatin/vinorelbine, cisplatin/gemcitabine, or cisplatin/topotecan in 513 patients found that the use of cisplatin/paclitaxel remained the best option for patients with stage IVB, recurrent or persistent cervical carcinoma, with a median OS of 12.9 months.[261]

In a phase II GOG study of cetuximab 400 mg/m^2 initial dose followed by 250 mg/m^2 weekly until disease progression or prohibitive toxicity, 38 (15%) patients had no progression for at least 6 months. The median OS was 7 months. When cetuximab was combined with cisplatin, no additional benefit beyond cisplatin was identified.[262]

Antiangiogenic tyrosine kinase inhibitors pazopanib and lapatinib were tested in 230 patients with stage IVB persistent/ recurrent cervical carcinoma. An improvement in PFS and OS was seen with pazopanib.[263] Bevacizumab, a recombinant humanized anti-vascular endothelial growth factor monoclonal antibody, has shown efficacy in later lines.[264] The addition of bevacizumab to first-line chemotherapy in a median OS of 17 months compared to 13.3 months in the chemotherapy-only arm (HR 0.71, P = .004).[265] The added toxicity included hypertension (25% vs 2%) and thromboembolic events (8% vs 1%).

Immune checkpoint inhibitors have proven to be beneficial in the metastatic setting. After showing OS benefit,[109,111] the KEYNOTE-826 trial randomized 617 patients to receive either pembrolizumab or placebo to first-

line chemotherapy with or without bevacizumab. Patients were stratified according to CPS. Colombo et al[110] published the results, showing that in the CPS greater than 1 group that included 548 patients, median PFS and 2-year OS was 10.4 months and 53% in the pembrolizumab group versus 8.2 months and 41.7% in the placebo group. The main added toxicity with pembrolizumab was higher rates of hypothyroidism (18.2% vs 9.1%). The BEATcc trial, published by Oaknin et al,[266] also showed increased PFS and OS with the addition of atezolizumab, an anti–PD-L1 antibody to the first line of carboplatin, paclitaxel, and bevacizumab. The trial randomized 410 patients with metastatic, persistent, or recurrent cervical cancer, regardless of PD-L1 expression. The median OS was significantly higher with atezolizumab, 32.1 versus 22.8 months in the standard therapy group (P = .0046). Grade 3 and higher toxicity rates were similar between the groups, and grade 1 to 2 diarrhea, arthralgia pyrexia, and rash were higher in the atezolizumab groups.

Radiotherapy in Metastatic Disease

The administration of RT to the pelvis or other involved sites in patients that previously were not irradiated should be considered. Before systemic treatment was available, the RTOG 8502 trial has shown that in good performance status metastatic patients, radiation, even at palliative doses, can allow for prolonged remission with some surviving over 2 years.[267] An NCDB analysis in 2,838 patients found that the addition of definitive local treatment (either surgery and/or RT in doses over 45 Gy, with RT being given in 90% of the cases) to systemic chemotherapy was associated with better OS (HR 0.57, $P < .001$), with a median OS of 19.2 months compared to 10.1 months.[268] Perkins et al[269] reported on a multi-institutional series of 95 patients, all were treated systemically, 34 treated also with pelvic RT. The median OS was significantly longer with pelvic RT (41.6 vs 17.6 months, $P < .01$). Notably, 20 patients were also treated with bevacizumab, with higher proportion in the systemic therapy–only group (26% vs 12%). The combination of bevacizumab might increase the risk of GI bleeding and fistula formation, but pelvic toxicity rates were not significantly different between the groups. Wiley et al[270] reported on 29 patients who were all treated with a platinum doublet and at least three cycles of bevacizumab. Definitive radiation was given to 11 of them, and 9 received palliative doses. Definitive RT was

associated with longer OS, and no significant toxicity differences were seen. As systemic therapy continues to improve OS and distant metastases control, the importance of LC may become even greater.

Aggressive combined modality treatment might even be curative in some patients with limited metastatic disease. Kim et al[259] reported on 25 patients with supraclavicular metastases at diagnosis who were treated with curative intent with concurrent CRT and BT. Mean dose to the supraclavicular area was to 59.4 Gy, and 3-year PFS and OS were reported as 33% and 49%, respectively. A series of 60 patients in China with oligometastatic (up to five metastases) stage IVB disease at diagnosis were treated initially with definitive CRT to both primary and metastatic lesions using IMRT, volumetric modulated arc therapy, and BT. Ablative doses were safely achieved, and the reported outcomes were 5-year PFS and OS rates of 25.9% and 51.4%, respectively.[271] Lymphatic spread compared with hematogenous spread, lower number of metastases, and smaller primary tumor were shown to be positive prognostic factors. In a SEER database analysis looking into patients with cervical cancer with distant lymph node metastases, the utilization of BT with EBRT was associated with better CSS compared with EBRT alone.[272]

Almost all of the data described earlier are retrospective, and so it is prone to selection bias. Thus, the decision to irradiate must be carefully considered in each patient according to their specific presentation, comorbidities, availability of other therapies, and toxicity risk.

CARCINOMA OF THE CERVICAL STUMP

A supracervical hysterectomy, which removes the uterus and leaves the cervix behind, may be performed for benign conditions of the uterus. The use of subtotal hysterectomy has declined, given the persistent risk of cervical cancer arising in the remnant tissue and the difficulty of managing cancer of the cervical stump.

It is important to divide carcinoma of the cervical stump into true, when the first symptom occurs 3 years or more after subtotal hysterectomy, or coincidental, when the symptoms are noticed before the third postoperative year. This separation is important because the prognosis for true carcinoma of the stump is significantly better than for coincidental lesions, in which carcinoma was probably present when the hysterectomy was performed.

The natural history and patterns of spread of carcinoma of the cervical stump are similar to those of the cervix in the intact uterus. The diagnostic workup, clinical staging, and basic principles of therapy are the same. Treatment also follows similar paradigms. When surgery is indicated for early-stage I tumors, it may be more difficult because of the previous surgical procedures and the presence of adhesions in the pelvis. With RT, external beam treatments are identical, although small bowel may be adherent to the superior portion of the cervix because of scar tissue, and using the prone position, as well as having the patient maintain a full bladder for treatment, may aid in attempting to move the small bowel out of the radiated field. Whole-pelvic radiation is recommended, with the superior border set at the level of the bifurcation of the common iliac vessels as determined by a CT simulation, or at the L4-L5 interspace for those planned with plain film radiographs. A dose of 45 Gy in 1.8-Gy fractions over 5 weeks is the most commonly recommended dose, with concurrent weekly cisplatin at 40 mg/m^2 given for five doses. For BT, if greater than 2 cm of the endocervical canal remain, it is best to insert a short tandem surrounded by ovoids, a ring, or, if indicated because of vaginal extension or lateral extension, interstitial catheters. For LDR insertions, as many sources as technically feasible should be inserted into the remaining cervical canal. For HDR BT, the tandem should extend from the cervical os superiorly to the full extent of the canal. When there is no opportunity to insert any sources into the cervical canal, an interstitial implant to bring the tumor dose to approximately 80 to 90 Gy for BT after completing a standard dose of 45 Gy to the whole pelvis is recommended while monitoring the radiation dose to the OARs. The use of external beam radiation alone is not recommended due to the significant mobility of the cervix because of bladder motion, the low-dose tolerance of the surrounding small bowel, and the high dose of radiation necessary for cure in patients with bulky disease. Total dose (external and LDR intracavitary BT) to the upper vaginal mucosa should not exceed 150 Gy, and tolerance doses to small volumes (D_{2cc}) of the bladder (90-100 Gy) or rectum and sigmoid (70-75 Gy) should be carefully monitored.

The 5-year survival rate for carcinoma of the cervical stump treated with irradiation is similar to that reported for patients with carcinoma of the intact uterus. The anatomic sites of failure and the incidence of recurrences are

similar to those of patients in whom the uterus is intact. Distant metastases also follow the same distribution.

Hellstrom et al[273] published a retrospective study of 145 patients treated for carcinoma of the cervical stump from 1959 up to 1987, representing 2.2% of all cervical cancers. Three control cases to each case were matched from the cohort of cases with cervical carcinoma with intact uterus. The dose of irradiation from the intracavitary application given to the stump cancers was lower than for comparable cases with intact uterus. Long-term prognosis for SCC of the uterine stump was comparable to that of the ordinary cervical carcinomas. Stump ACs had a worse prognosis compared with AC of the intact uterus ($P < .07$) and with SCC stump ($P = .05$). The complication rate was higher for stump cancer cases compared with that for cervical cancers with an intact uterus. The same group published an update of this series with patients up to 2004, with similar findings.[274] Only 16 more patients were added, perhaps due to the declining prevalence of women who are postsupracervical hysterectomy. Because of the close proximity of the bladder, rectum, and small intestine to the intracavitary sources and to the often higher doses of external beam irradiation given to the whole pelvis, complications are somewhat more frequent than in carcinoma of the cervix with an intact uterus. Care in BT treatment planning, including the use of 3D-based treatment planning to minimize dose to the normal tissues, should be considered.

Wang et al[275] reported on a retrospective series of 31 patients, all treated with concurrent chemotherapy, EBRT, and BT. The 5-year PFS, OS, and LC were 69.6%, 84.9%, and 77.1%, respectively. The BT method was changed from 2D (plain radiography) to 3D (CT based) in the study period, with 14 treated with 2D BT, 5 transferred from 2D to 3D due to poor coverage, and 12 were completely 3D. LC was 100%, 91%, and 25% in the 3D, 2D, and combined groups, respectively. Toxicity was shown to be significantly lower and dosimetric parameters better in the 3D arm compared to the 2D arm.

NEUROENDOCRINE CARCINOMA OF THE CERVIX

Neuroendocrine carcinoma (NEC) of the cervix is a highly aggressive form of cervical cancer. It accounts for 1.4% of cases, with the small cell subtype being the most common, roughly 80%.[276] Like its counterparts in the lung and other anatomic locations, it has a high proliferation rate and marked

propensity for regional lymph node and distant metastases. All small cell carcinomas of the cervix are aneuploid, compared with only 30% of large cell nonkeratinizing squamous carcinomas. The incidence of lymphatic vascular space invasion is 80% to 90% and that of lymph node metastases has been reported to be 40% to 67%. Patients have extremely poor outcomes, with a Cochrane review by Tempfer et al[276] reporting that in 3,538 patients from 112 reports, the pooled median PFS and OS was 16 and 40 months, respectively. As it is a rare disease, data are mostly retrospective and consist of small series and cancer registries studies, and treatment paradigm is extrapolated from other types of cervical cancer and NEC from other locations. While it is very chemoresponsive, chemotherapy alone is rarely curative. Immune checkpoint inhibitors can be considered as they have shown benefit in NEC of the lung when combined with chemotherapy. However, their benefit alone in later stages of metastatic NEC of the cervix was minimal.[277]

These patients must be evaluated in conjunction with a medical oncologist; the workup should include a PET-CT and brain MRI if available and consider bone marrow aspiration biopsy of the iliac crest. Therapy should include radical surgery and platinum-based regimens with consideration of adjuvant RT in earlier stages, and in locally advanced disease pelvic EBRT and intracavitary BT, combined with similar systemic regimens. Chu et al[278] published a study of two cancer registries, from the United States and China, including 1,288 patients. They have shown an association of longer OS with radical surgery in FIGO 2018 stage IB3 to IIA2 disease. This may support the use of NACT and radical surgery in places with long wait times for definitive RT. If bleeding is present, prompt institution of RT with concurrent chemotherapy is necessary. Prophylactic cranial irradiation is not indicated because cervix cancer will most commonly spread first to lung and then to brain.

Patients with NEC of the cervix are treated with the same irradiation techniques and doses as outlined for other histologic varieties of cervical carcinoma in combination with multiagent chemotherapy, including external beam radiation to 45 to 50 Gy, followed by nodal boost if PET-positive nodes are identified, followed by BT. The most frequently prescribed drugs are cisplatin and etoposide (VP-16) every 3 weeks.

Hoskins et al[279] reported the outcomes of 31 patients with a multimodality regimen of combination chemotherapy (either cisplatin and etoposide or

carboplatin and paclitaxel) with concurrent involved-field RT. The 3-year OS and failure-free survival (FFS) rates were 60% and 57%, respectively. Outcome did not differ between regimens, but toxicity was lower with carboplatin and paclitaxel. Stage was the only prognostic factor with 3-year FFS of 80% and 38% for stages I to II and III to IV, respectively. Distant failure occurred in 28% and local failure in 13% of patients. Wang et al[280] published a retrospective study on adjuvant therapy after hysterectomy of 110 patients with stages I to III. Median follow-up was 39.6 months. The 5-year OS rates were 84.9%, 85.7%, and 60.9% for each stage, respectively. Longer OS was associated with patients receiving over three cycles of chemotherapy, but no significant difference was found between different platinum-based regimens or with the addition of RT.

Combined modality therapy may also have benefit in the metastatic setting. A series of 71 patients with stage IVB was reported by Salvo et al.[281] Survival outcomes were significantly superior in the 15 patients who were treated in addition to chemotherapy with pelvic RT in doses greater than 45 Gy, with 2-year PFS and OS rates of 24% and 49.2% versus 7.8% and 21.5%. In addition, a SEER database analysis by Dong et al[282] showed that adjuvant RT after radical surgery in 130 metastatic patients was also associated with a survival benefit compared to no RT (1-year OS rate of 79.3% vs 52.2%, P = .004).

ADENOCARCINOMA OF THE CERVIX

SCC accounts for 80% of cervical cancers, AC for 15%, and adenosquamous carcinoma for 3% to 5%. SEER data from 1972 to 2002 suggest that the incidence of cervical AC is rising, but based on SEER data, cause-specific mortality is not significantly different than that for SCC.[283] A separate SEER analysis of patients from 1988 to 2005 showed that patients with AC had an increased risk of dying compared to patients with SCC.[88] AC has been linked to HPV-18, which has a higher rate of nodal and distant metastases than HPV-16.[82] Despite a slower regression after irradiation, reflecting cellular kinetics and slow growth, no difference in tumor control or survival has been observed in ACs compared with SCCs, although prognosis is related to clinical stage, volume of disease, and dose of irradiation. Because of the predilection for endocervical involvement in AC, a combination of irradiation and conservative hysterectomy has been advocated by some authors, although

results are comparable with those obtained with irradiation alone. Given a lower toxicity profile with CRT, this is preferable to a planned course of RT alone followed by hysterectomy upfront. Patients who are younger had larger tumors or most importantly have residual disease after CRT may be candidates for adjuvant hysterectomy.[284]

An updated Cochrane database review[285] found only one randomized trial, the Landoni study,[202] in which a small subgroup analysis that was not powered to detect a difference showed an apparent improvement with surgery, although the majority of patients required adjuvant RT, which increases the rates of toxicity. In addition, the RT in this study was not optimal, and surgery was not compared to CRT, which is the current standard. A review of GOG prospective trial patients showed that there was no difference between AC and SCC if patients received CRT.[89]

Thus, surgery to early AC of the cervix should be pursued only after adequate staging to avoid the added toxicity of trimodal therapy. Primary CRT is considered the standard for patients with locally advanced cervical AC.

A renewed analysis of several GOG trials published by Levinson et al showed that intermediate-risk factors for recurrence for early cervical cancer after hysterectomy differed in their impact between AC and SCC, with LVSI and invasion being more pronounced in SCC compared to tumor size, which was more pronounced in AC, and histology-specific nomograms were created.[286]

Genomic profiling has also been shown to differ between AC and SCC, with the first more inclined to microsatellite instability; immunotherapy resistance–related STK11 alterations; actionable mutations, such as HER2 enrichment; and lower immune infiltration, while the latter was more inclined to high tumor mutational burden, PD-L1 expression, and higher immune infiltration.[287] As systemic therapy becomes more relevant in earlier stages of this disease, histology might play a greater role in treatment selection.

TREATMENT OF OLDER PATIENTS

Advanced age in patients with cervical cancer can impact their diagnosis and treatment. Registry studies from the United States showed that patients older than 65 had a higher stage at diagnosis and lower OS.[288] As most guidelines for cervical cancer screening recommend stopping after 65, opportunistic screening of older patients is relevant, especially in populations with lesser

access to regular screening. A SEER analysis has shown that older patients are less likely to undergo surgery, lymph node sampling, adjuvant RT, and BT and that cancer-related mortality was higher even after adjusting for treatment disparities.[289] As patients are older, rates of comorbidities, such as diabetes, hypertension, and nutritional deficits, become higher and increase the risks for complication of care.

Treatment decisions have less robust data as patients over 65 years are underrepresented in randomized data. However, retrospective data still support the use of more aggressive therapies in selected fit patients. Mitchel et al[65] reported that in a cohort of 398 patients treated with RT, 60 of them over 70 years, those receiving BT and not needing treatment breaks had similar survival to younger patients. In a Chinese report of 73 patients over 70 years, concurrent chemotherapy was a significant predictor of OS.[290] Nomograms designed for patients over 65 years from retrospective databases also showed the prognostic benefit of chemotherapy and RT. A systematic review of 24 reports on outcomes and toxicity in older patients found that when treated with adequate doses of RT with concurrent chemotherapy, equivalent or near-equivalent survival results can be achieved. Hematologic, vaginal, bone, and neurologic toxicities from CRT were reported as higher with age.[291]

As RT techniques become less toxic with IMRT and image guidance, and better support and symptoms management for older patients is available, more patients should be considered candidates for lifesaving therapy.

CARCINOMA OF THE CERVIX AND PREGNANCY

The concurrent presence of carcinoma in situ or invasive carcinoma of the uterine cervix and pregnancy, although rare, poses a therapeutic dilemma to gynecologic and radiation oncologists. Reported incidence is approximately 1 to 10 per 10,000 pregnancies.[292] In the United States, the incidence has decreased. Norstrom et al,[293] in Sweden, found that cervical cancer was diagnosed in 33 women in association with pregnancy (incidence, 11.1 cases per 100,000 deliveries and 7.5 per 100,000 pregnancies). Abnormal bleeding was the symptom that led to diagnosis in 54.5% of the women; 45.5% were asymptomatic but had an abnormal cervicovaginal cytologic test result (39.4%) or abnormal vaginal examination (6.1%) in association with pregnancy. During the follow-up, 1 of 12 women with cervix cancer in the

first trimester, 4 of 12 in the third trimester, and 2 of 9 postpartum died of the disease. Primary surgery was used more frequently than RT.

For carcinoma in situ, if the pregnancy is allowed to reach full term, confirmation of the diagnosis by colposcopy and conservative management with monthly Pap smears constitutes the best approach. Conization has frequently been performed. Punch biopsies can be obtained, but the diagnostic accuracy is less reliable. As many as 50% of the patients have residual carcinoma in situ after delivery.

In patients with invasive carcinoma, the lesion is usually clinically apparent. Multiple punch biopsies are adequate to confirm the diagnosis. Management is individualized based on tumor size and stage, patient age, and desires of the patient (or couple) regarding the pregnancy. The majority of patients with cervical cancer diagnosed during pregnancy (~75%) have stage I tumors, and prognosis is the same as in nonpregnant patients.[292] Cancer incidence is similar between the trimesters, and survival is the same, regardless of the trimester of the pregnancy in which definitive treatment is instituted.

Women with tumors diagnosed early in pregnancy are often recommended to abort the fetus. Because there is a greater need to institute therapy as soon as possible, the accepted method of treatment in patients in the first 6 months of pregnancy is to carry out definitive surgery or RT, as indicated by the stage of the disease, with resultant loss of the fetus. An abortifacient may be administered before initiating radiation to ensure fetal demise and delivery of the placenta prior to initiation of treatment. The whole pelvis is irradiated (40-45 Gy in 4-5 weeks). However, some patients will not abort spontaneously, and surgical evacuation will be required; misoprostol may be administered as an alternative to surgical evacuation after failed spontaneous abortion. After this dose of radiation, careful evacuation of the uterus and LDR (or equivalent-dose HDR) BT may be performed under general anesthesia. If an RH is performed and positive pelvic lymph nodes are found, the usual postoperative irradiation, including external beam with or without intracavitary insertion, should be carried out.

If the woman refuses abortion, serial clinical examinations and MRI scans at 2- to 3-month intervals to ensure no rapid growth or spread to lymph nodes are recommended. Small series show that delaying definitive treatment under follow-up is relatively safe, especially in early disease. Bigelow et al[294]

reported a case-control study of 28 pregnant patients diagnosed with cervical cancer, 82% were stage I. Only 7 decided to terminate, and compared to 52 matched controls, the median time from diagnosis to surgery was delayed from 7 to 20 weeks, perioperative hemorrhage was greater in the pregnant group, with no significant difference in survival. Recurrences and cancer death were only in the group that decided to terminate.

When patients are diagnosed in midpregnancy (second trimester), attempting neoadjuvant approach while carrying the pregnancy to term could be considered, especially in more advanced disease or in a rapidly growing tumor. A pooled analysis of 48 patients reported disease control rates of 96.6% with mostly cisplatin-based regimen and a median PFS of 48 months.[295] Another pooled analysis of the results of 39 reports of 84 patients treated with platinum-based regimens until delivery showed that all but 2 who miscarried were delivered at median week of 33 (range 27-38), all but 1 with cesarean surgery with a median birth weight of 2,162 g (range 1,330-2,990 g). Of the 88 neonates delivered, 80.6% had uncomplicated follow-up. The rest had transient respiratory, hematologic, and metabolic complications, and one severe bilateral hearing loss and one intraventricular hemorrhage. In a median follow-up of 17 months (range 0-150), two pediatric malignancies were noted.[296] The desire to preserve the pregnancy must be weighed by possible detriment to maternal survival and complications to the child.

Occasionally in late pregnancy (final trimester), if tumors are small and an MRI or laparoscopic sampling confirms no lymph node involvement, definitive therapy is postponed until after imminent delivery. While intentional treatment delay over 6 weeks was associated with a potential risk recurrence or death, (~5%), no recurrence occurred in proven node-negative disease.[292] In the third trimester of pregnancy, some gynecologic oncologists prefer a cesarean delivery, combined with an RH and lymphadenectomy followed by radiation for high-risk features when present. However, some authors report that vaginal delivery has no detrimental effect on the prognosis.

Patients who require high doses of pelvic irradiation should be counseled regarding the permanent loss of reproductive capability, not only because of ovarian ablation (which happens with doses of ≥8 Gy) but also as a consequence of radiation effects in the uterus.

Sood et al[297] performed a retrospective analysis of 26 women with cervical carcinoma diagnosed during pregnancy and treated primarily with RT (mean

dose, 46.7 Gy) and LDR intracavitary radiation (mean dose, 56.5 Gy to point A). These cases were matched with 26 nonpregnant control patients based on age, histology, stage, treatment, and year of treatment. There were no statistically significant differences in recurrence rates or survival between the pregnant group and the control patients. Short-term toxicity was comparable in pregnant and nonpregnant patients. Long-term complication rates were 12% in pregnant patients and 27% in control patients, but this difference was not statistically significant. Most complications were likely related to radiation techniques (particularly the predominance of ^{65}Co).

Sood et al[298] compared the prognosis of 56 women who had cervical cancer diagnosed during pregnancy and 27 who were diagnosed within 6 months after delivery. Control patients (cervical cancer diagnosed at least 5 years since last delivery) were matched one to one with cases based on age, histology, stage, treatment, and time of treatment. Among the postpartum women, 11 were treated with radical hysterectomies and 14 with RT, and 2 with stage IA1 disease were treated with vaginal hysterectomies. One of seven patients who had cesarean sections had a local and distant recurrence. In contrast, 10 (59%) of 17 patients who delivered vaginally had recurrences (P = .04). In multivariate analysis, vaginal delivery was the most significant predictor of recurrence, followed by high tumor stage. Survival for patients diagnosed in the postpartum period was significantly worse than for control patients and for those diagnosed during pregnancy. The authors concluded that pregnant women with cervical cancer should be delivered by cesarean section.

The practice popularized in the early 20th century of administering a "restraining dose of radium" and deferring definitive RT until delivery is carried out should be strongly rejected. Complications reported include infants being born with microcephaly, alopecia, facial deformity, eye damage, and chromosomal abnormalities.

BRACHYTHERAPY

After the discovery of radium in 1898 by the Curies, publications followed describing the use of the first glass radium capsule in 1904 and a metal BT applicator for cervical cancer in 1905. The incorporation of BT after external beam treatment arose from the recognition that tumor control probability correlated with radiation dose and cancer volume. Evidence confirms that BT

as used for dose escalation after external beam treatment for cervical cancer significantly improves survival. Therefore, BT is a standard part of the treatment of locally advanced (stages IB2-IVA) cervical cancer after external beam radiation; BT alone may be used as primary treatment for selected cases with early-stage (stages IA-IB1) cervical cancer. The increasing complexity of BT administration, including the use of complex imaging, mandates implementation of careful quality assurance measures and a culture of open communication to ensure safe practices in the clinic.[299]

Dose Rate

The ICRU in its Report 38 defines BT dose rate as follows: LDR, 0.4 to 2 Gy/hour; medium-dose rate (MDR) or PDR, 2 to 12 Gy/hour; and HDR, greater than 12 Gy/hour. For LDR, the most commonly used isotope is ^{144}Cs, and for PDR and HDR, it is ^{206}Ir. The use of HDR has significantly increased in the United States, from 13% in the 1996 to 1999 Quality Research in Radiation Oncology (formerly known as the Patterns of Care) survey to 62% in the 2007-2009 survey.[185] In other U.S., European, and Japanese surveys of gynecologic BT practitioners, approximately 85% state that they use HDR BT,[300] whereas in Canada, the reported use is 68% HDR, 10% PDR, and 23% LDR.[301] The dose delivered per fraction for HDR and proportion of dose delivered with external beam versus BT vary substantially in different centers around the world.[301]

Most institutions in the United States have either LDR or HDR BT available. Larger centers may have LDR, PDR, and/or HDR. Overall, outcomes are similar regardless of dose rate, with the caveat that for HDR, 3D imaging should be incorporated to ensure coverage of the tumor, particularly for large-volume disease.[302]

Biology of High-Dose Rate Brachytherapy for Cervical Carcinoma: Equivalent Dose in 2 Gy and Biologically Effective Dose

To achieve tumor control using HDR equivalent to that with LDR BT, attention to the dose/fractionation schedule and to normal tissue doses is mandatory. The linear-quadratic (LQ) model provides calculation estimates of biologically equivalent dose taking into account dose rate, dose per fraction, and OTT. For comparison of LDR to HDR, the LQ model doses are

normalized to an equivalent dose in 2 Gy (EQD2). The α/β ratio is a critical component of the LQ model. For cervix cancer, an α/β ratio of 10 Gy is used for tumor and an α/β of 3 Gy is used for normal tissues, which may have inherent inaccuracies in generalizability, although an α/β ratio of 3 Gy for the rectum has been correlated with late rectal complications.[303,304]

Spreadsheets to assist with HDR EQD2 dose conversions are available from the American Brachytherapy Society (https://www.americanbrachytherapy.org/resources/for-professionals/physics-corner/). The values derived are not actual doses but biologically effective ones that take into consideration dose rate and effect of fraction size.

Although the use of a detailed EQD2 conversion is preferred, an approximation of these values was proposed by Orton et al[305] with an LDR-to-HDR reduction factor of 0.54 to 0.6. These conversion factors are valid when three to five HDR fractions are used, but with a higher number of fractions (six to eight), the conversion factor is closer to 0.75. Therefore, the use of the EQD2 worksheet is recommended.

Figure 76.21 illustrates the late normal tissue effect, which is proportional to log cell kill, and the relationship to the number of HDR treatment fractions.[306] Each solid curve is calculated assuming the same log cell kill. Late damage rises sharply as the number of HDR fractions is decreased. When these curves are above the dashed lines that represent the maximum late effect of 70 Gy of LDR BT given at 0.5 Gy/hour, the risk of late complications increases. Displacing the bladder and rectum away from the HDR sources for the short duration of therapy may offset the radiobiologic disadvantage of using a few BT fractions.

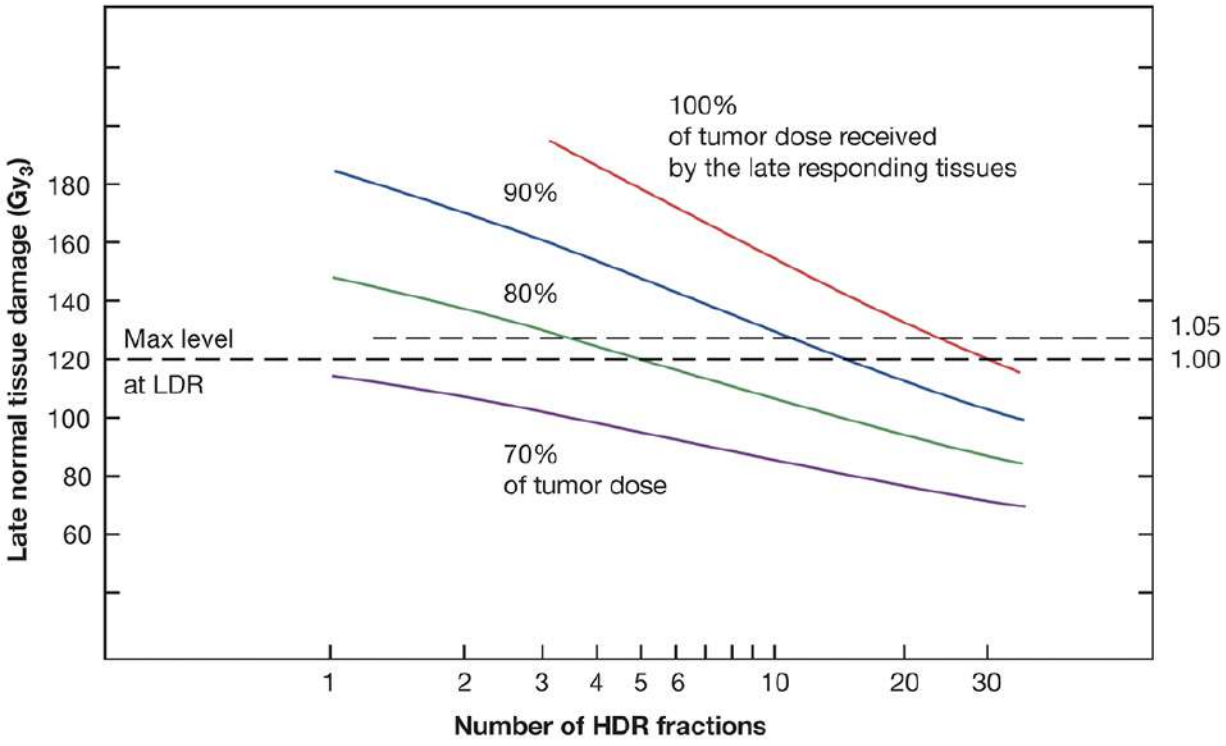

FIGURE 76.21 Relationship between number of high-dose rate (HDR) fractions and late normal tissue effects. Solid lines show the increase in normal tissue late effects as the number of HDR fractions used to treat cervical cancer decreases. Dotted lines indicate the maximum level of late damage calculated for conventional low-dose rate (LDR) brachytherapy of 70 Gy at 0.5 Gy/hour for 140 hours and an arbitrary level 5% above this. The intersection of the solid lines with the dotted lines indicates the number of HDR fractions needed to give equal late normal tissue effects. In this model, the dose to late-responding tissues should be kept at 83% of the tumor dose when treating with four to six HDR fractions. (Modified with permission from Fowler JF. The radiobiology of brachytherapy. In: Martinez AA, Orton CG, Mould RF, eds. *Brachytherapy HDR and LDR*. Nucletron International BV; 1990:121-137.)

Brachytherapy Process: Preparation and Timing

Standard procedures for pretreatment evaluation, imaging, anesthesia use, and treatment duration should follow accepted general principles in the guidelines published by the American Brachytherapy Society in 2012.[299,307,308] Planning the course of BT should begin at the time of initial presentation. An examination at diagnosis assessing disease extension and tumor size should be recorded. Periodic examinations during external beam treatment should be performed to monitor response. For patients receiving concurrent CRT, rapid shrinkage should be expected because treatment may regress the tumor to 70% to 80% of the pretherapeutic volume. Therefore, a clinical gynecologic examination at the time of BT is also important. Inserting radiopaque marker

seeds (“fiducials”) at the time of diagnosis that mark the inferior, lateral, and superior extension of a vaginal tumor may aid in identifying regions requiring dose escalation with BT, even after complete regression during external beam treatment.

Treatment schedules integrating external beam irradiation and BT were initially designed with regard to the disease stage and volume. For LDR, insertion of the applicator may be done after all external beam finishes, with the caveat that one or two insertions may be required, approximately 1 week apart. All treatments, including external beam treatment and BT, should finish 8 weeks from the initiation of radiation.

The optimal time-dose-fractionation scheme and the technique for remote control afterloading intracavitary BT for cervical cancer have yet to be established through systematic clinical trials. For HDR or PDR BT, the applicator insertion and treatment may commence after external beam treatment finishes, to ensure optimal geometry with normal tissues far from the applicator. Alternatively, the physician may choose to insert the applicator for treatment as early as during the second week of external radiation if the tumor is small enough, to minimize total treatment time. Preferably, BT and external beam treatments should not be given on the same day, and if they must, a 6 hours difference should be maintained.

Applicator Selection

The tandem and ovoid applicator provides radiation dose covering the cervix, uterus, inner parametria, and approximately 1 to 2 cm of the upper vagina. The tandem and ring applicator has a slightly narrower dose distribution, but with HDR, the dose distribution may be optimized and mimics that obtained with the tandem and ovoid applicator. For patients with a very narrow vagina because of stricturing, a tandem and cylinder applicator may be the only option available. However, this applicator provides insufficient dosing to the parametrial tissue and should be used with caution. For patients with large tumors with residual bulky disease after external beam radiation or those with vaginal extension, fistulae, or pelvic sidewall invasion, a combination of tandem/ring or ovoid with interstitial applicator or tandem/interstitial applicator alone may be inserted.

Applicator Insertion and Imaging During Insertion

General guidelines from the American Brachytherapy Society should be followed.[299] The patient receives appropriate anesthesia for pain management. In the lithotomy position, the perineum is sterilely prepped and draped. The Foley catheter is inserted into the bladder. The catheter is clamped and the bladder filled with 150 to 200 mL of saline if US is used. US with a transabdominal probe can significantly speed up the insertion process and assist with accurate placement because the uterine canal is often clearly visible after instilling fluid in the bladder (Figure 76.22). Transabdominal US can measure uterine width and height in patients who do not have large fibroids or tumor volumes that greatly distort uterine configuration. US does not define the target volume as clearly as MRI but may be used to assist with 3D-based planning when CT or MRI is unavailable.[309] Transrectal US may assist with interstitial BT when other imaging modalities are not available. For interstitial insertions, CT or MRI may be used during the insertion process either iteratively or as real-time guidance to ensure proper tumor coverage and no inadvertent insertions into the rectum or bladder. After tandem and ovoid or tandem and ring applicator placement, vaginal packing covered with lubricant gel is placed in the vagina to separate the bladder and rectum, which also helps to maintain applicator position.

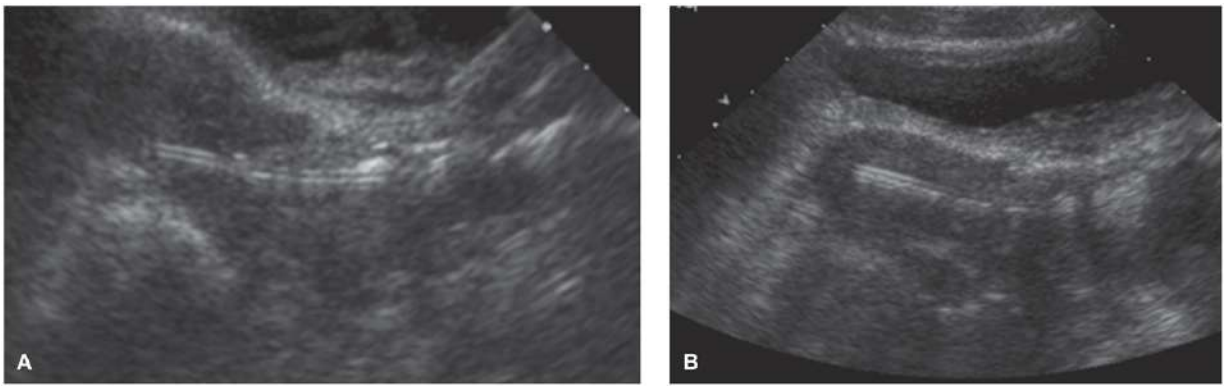

FIGURE 76.22 Ultrasound used during intrauterine tandem insertion can ensure proper placement into the intrauterine canal and shorten overall procedure time. A. Ultrasound depicts that the tandem is placed in the posterior myometrium. B. Ultrasound directs the tandem into the intrauterine canal.

Applicator Position

An experienced brachytherapist has greater familiarity with applicator insertion and evaluation. Applicator position is a critical determinant of dose

specification and pelvic control. As Fletcher emphasized, conditions for an adequate intracavitary insertion include the following:

1. The geometry of the insertion must prevent underdosing around the cervix.
2. Sufficient dose must be delivered to the paracervical areas.
3. Vaginal mucosal, bladder, and rectal tolerance doses must be respected.

For LDR Fletcher-Suit applicators, Potish et al[310] used linear least squares regression to show that although there was a moderately good correlation between the milligram-hours and dose to point A, it was markedly affected by the position of the colpostats and the tandem. A review of plain films of 808 LDR intracavitary applications in 396 patients with cervical cancer treated at MD Anderson[311] quantified acceptable implant geometry. The median distance from the tandem to the sacrum was 4 cm, or one-third the distance from the pubis to the sacrum. The distance between the vaginal ovoids and the cervical marker seeds was 7 mm, and the median distance between the tandem and the posterior edge of the ovoids was 50% of the ovoid length. In 92% of insertions, vaginal packing was posterior to or within 5 mm of a line that passed through the posterior edge of the ovoids, parallel to the tandem. The median doses to point A and rectal, bladder, and vaginal surface reference points were 87, 68, 70, and 125 Gy, respectively. Analysis of the LDR and HDR BT positions for 103 patients enrolled on RTOG trials 0116 and 0128 found that patients with unacceptable symmetry of ovoids to the tandem had a significantly higher risk of LR than patients in the acceptable group (HR = 2.67; 95% CI = 1.11-6.45; P = .03).[35] Patients with displacement of ovoids in relation to the cervical os had a significantly increased risk of LR (HR = 2.50; 95% CI = 1.05-5.93; P = .04) and a lower DFS rate (HR = 2.28; 95% CI = 1.18-4.41; P = .01). Inappropriate placement of packing resulted in a lower DFS rate (HR = 2.06; 95% CI = 1.08-3.92; P = .03).

Imaging After Insertion

For LDR BT, active sources may be inserted after the films have been reviewed and the position of the applicators judged to be satisfactory. Placing a small amount of contrast into the bladder and rectum before CT or plain film may clarify the location of these structures.

When a CT scan is obtained after applicator insertion, it also verifies proper placement (no perforation) and analyzes cervix and normal tissue location in relationship to BT dose distribution. CT provides a reasonable estimate of the location of the uterus and cervix. The CT contours of the cervix overestimate the tumor contours compared to an MRI, although the additional width contoured on a CT may not be of detriment to the patient because cervical cancer tends to spread laterally along the parametrial tissues.[312] CT depicts changes in the OAR related to tumor shrinkage, organ motion, and the location of the BT applicator in relation to the uterus. However, separating the OAR, such as the sigmoid or the small bowel from portions of the uterus or cervix, may be difficult on CT, given the lack of contrast. OAR dosimetry based on CT is similar to that based on MRI when optimized similarly. CT may not provide sufficient detail of the tumor if selected dose escalation is required, such as in cases with large residual tumors. In the vast majority of cases, however, it should suffice. The uterus and cervix cannot be distinguished as separate structures on a CT, whereas they can be on an MRI. Therefore, some CT-based contouring guidelines recommend delineating the entire cervix and uterus.[312] Other guidelines recommend using preinsertion MRI or any other clinical assessment if available, to better define the targets.[313] In a multicenter study, MRI was significantly better than CT for tumor visualization and detection of parametrial involvement.[40] Other advantages of MR include multiplanar capability and excellent soft tissue contrast resolution. The strength of a magnet in an MR scanner is expressed by a unit of measurement referred to as a tesla (T). Higher field strength produces a better overall signal-to-noise ratio and more accurate imaging.

Regardless of whether a plain film radiograph, CT, or MR is obtained after insertion to aid treatment planning, in order to properly visualize the apparatus, radiopaque markers should be inserted to identify source position to aid with dosimetric planning. Identifying the applicator using either a radiopaque marker inserted into it or for interstitial cases undergoing MR, a special 3-T MR sequence may be used to create artifact that allows the tip of the needle to appear as a balloon on the sagittal image and as a cross on the axial images.[314]

Dose Specification

Point A

Several methods for specifying dose in BT evolved over the 20th century.

Because of the limited availability of 3D imaging worldwide and a 100-year history of plain film radiography, in a survey from 2012, the majority of institutions internationally reported using point-based dosimetry based on the ICRU 38 nomenclature defining point A rather than prescribing dose to a tumor volume.[300] Other institutions use a system of milligram-hours, whereas others consider the volume of the region of interest. Based on the general principles guidelines for cervical cancer BT published by the American Brachytherapy Society and the ICRU report, the point A definition was updated in 2012.[299] To determine point A, connect a line through the center of each ovoid or the lateral most dwell position in the ring; extend this line superiorly along the radius of the ovoids (or ring), and then move an additional 2 cm superior along the tandem. From this point, extend out 2 cm on each side laterally on a line perpendicular to the tandem (Figure 76.23). For tandem and cylinders, begin at the flange or cervical marking seed and move 2 cm superiorly along the tandem and then 2 cm laterally.

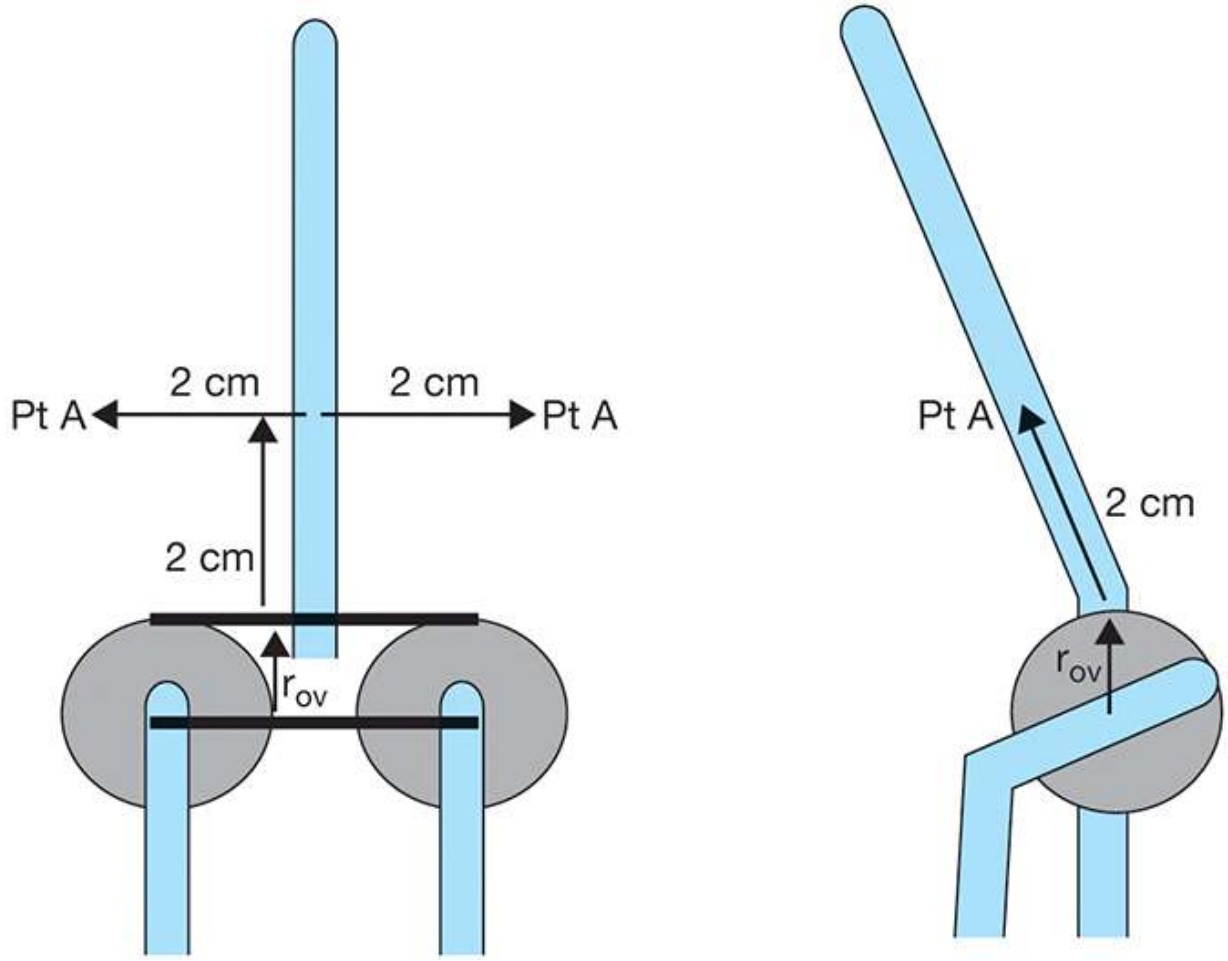

FIGURE 76.23 Definition of point A shown on a tandem and ovoid applicator based on the American Brachytherapy Society 2012 Guidelines for Cervical Cancer.

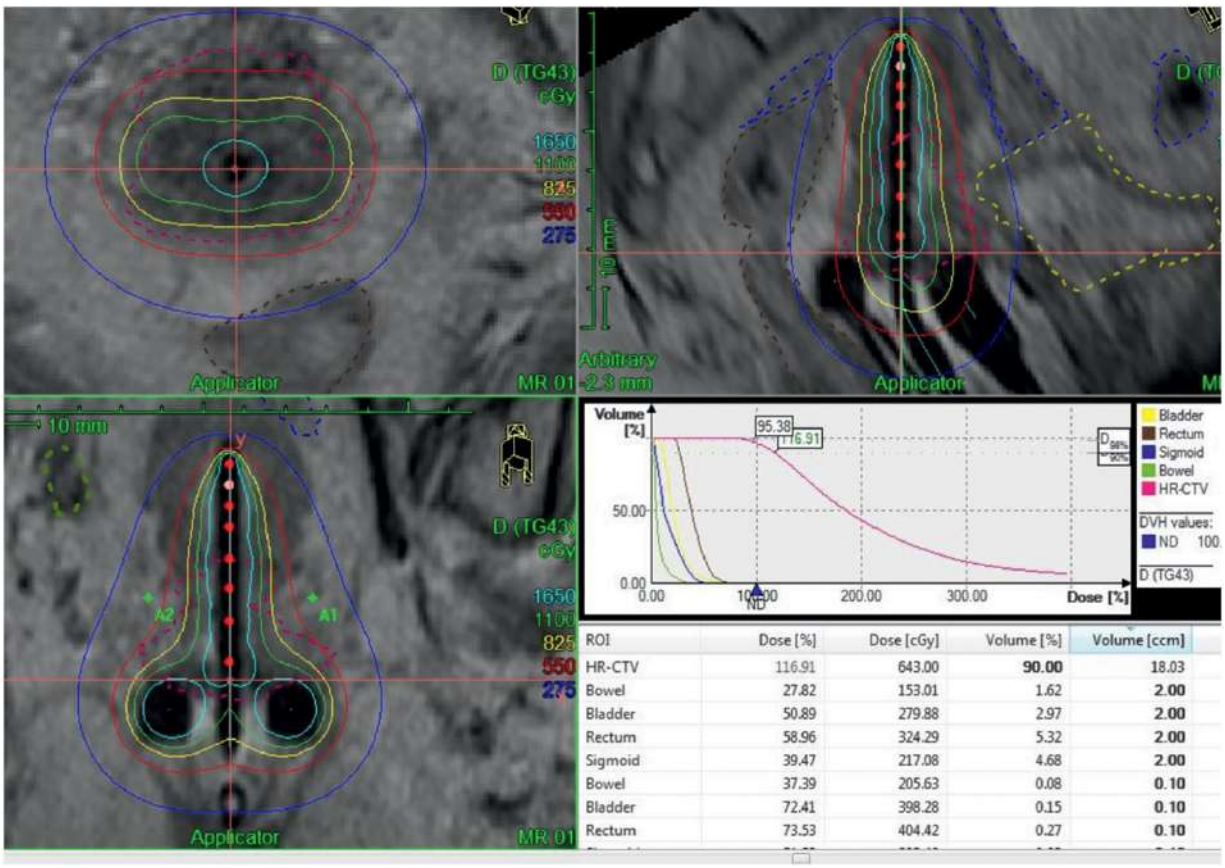
3D image-based BT treatment planning better defines the tumor and aids with the precision of radiation dose delivery, which may increase efficacy and may reduce the dose to the normal tissues and reduce toxicity.[249] In the era of increasing use of HDR BT, proper applicator placement and precise estimation of the location of the normal tissue are critical. When 3D imaging is available, point-based radiographic dosimetry has limited utility for the dose adaptation required for HDR BT because point A may overestimate or underestimate the tumor dose based on 3D imaging. Kim et al[315] found that dose to point A was significantly lower than the D_{90} for HR-CTV calculated using 3D image-based optimization. With imaging, one may visualize the tumor volume and conform dose to the volume, which may result in the dose to point A being lower than the prescription 100% isodose line (covering a smaller tumor volume) or a higher than prescription dose to point A because

of a large tumor volume extending beyond the boundaries of point A. The tumor coverage relies on tumor volume at the time of BT, with larger tumors requiring greater optimization to be adequately covered by the prescribed isodose line.

Accurate delineation of the tumor and OAR is critical for precise treatment planning (Figure 76.24). Because of the rapid falloff of dose, imprecise contouring can dramatically change dosing to normal tissue structures. Formal contouring education programs reduce the variability of interobserver contours.[316] The dose to point A should still be reported to ensure consistency in terminology between centers with different capabilities. In addition, as point A reporting is not dependent on contouring, it is still a useful safety measure, and the EMBRACE II prospective trial still aims for a dose of over 65 Gy to the A point across participating centers.[258]



ROI	Dose [%]	Dose [cGy]	Volume [%]	Volume [ccm]
HR-CTV	116.91	643.00	**90.00**	18.03
Bowel	27.82	153.01	1.62	**2.00**
Bladder	50.89	279.88	2.97	**2.00**
Rectum	58.96	324.29	5.32	**2.00**
Sigmoid	39.47	217.08	4.68	**2.00**
Bowel	37.39	205.63	0.08	**0.10**
Bladder	72.41	398.28	0.15	**0.10**

FIGURE 76.24 Tandem and ring implant showing the use of three-dimensional (magnetic resonance [MR] or computed tomography) imaging to adequately cover the high-risk clinical target volume (HR-CTV) while minimizing dose to the organs at risk (OARs)—the rectum, sigmoid, and bladder. Dose-volume histograms (DVHs) record the D_{2cc} limits to the OAR. The dose at point A is recorded but varies between patients based on optimization of the HR-CTV and OAR. ROI, region of interest.

Computed Tomography Imaging for Brachytherapy Contouring

A CT scan can define a CTV with the lateral borders of the cervix and any parametrial extension defined based on suspicious regions seen on the scan. CT contouring guidelines should be followed.[312,313] Uterosacral ligaments may be visualized on CT, and if detected, they should be included in the CTV contours. No GTV may be identified on CT. The superior border of the cervix is not defined; instead, the entire tandem length is planned and the top dwell is optimized off the sigmoid to reduce bowel dose.

Magnetic Resonance Imaging for Brachytherapy Contouring

For MR-based contouring, the Groupe European Curietherapy-European Society for Therapeutic Radiation Oncology (GEC-ESTRO) guidelines can be used.[303] The recommended volumes include the GTV, including all T2 bright areas of enhancement; the HR-CTV, which is the entire cervix, any regions of high to intermediate signal intensity in the parametria, uterus, or vagina, and any residual disease detected on clinical examination at the time of BT; and the intermediate-risk clinical target volume (IR-CTV), which subtracts out the OARs but includes the tumor extension at the time of diagnosis, adding 1 cm to the HR-CTV volume. The IR-CTV defines regions with potential microscopic seeding of tumor cells (Figure 76.25).[303] Lang et al,[317] in a multicenter study, confirmed the feasibility of these recommendations, with total doses to point A from both BT and EBRT ranging from 85 to 91 Gy and to CTV from 69 to 73 cGy. Doses to OARs were comparable to those obtained with standard dosimetric methods, although they were more accurately determined with dose-volume histograms (DVHs).

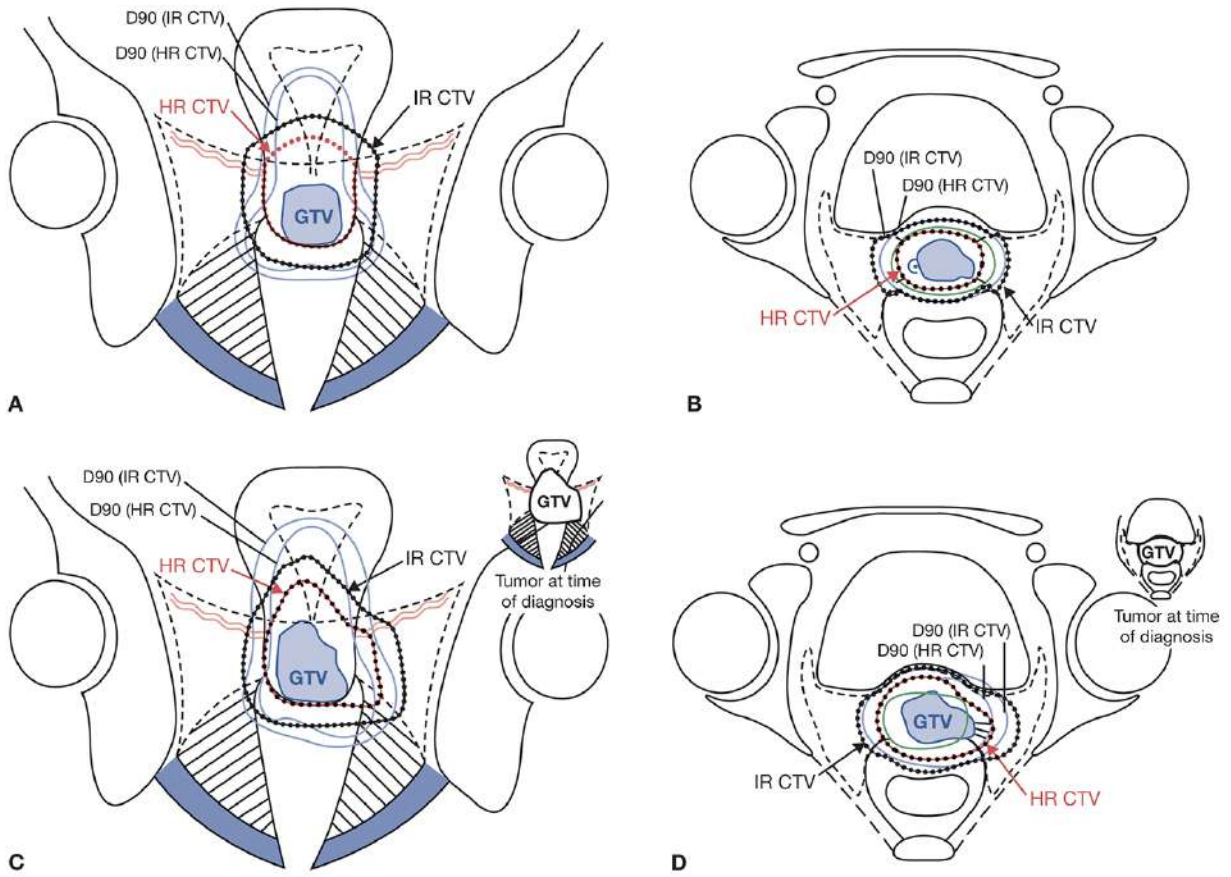

FIGURE 76.25 Diagrammatic representation of gross tumor volume (GTV) and clinical target volume (CTV) for three-dimensional treatment planning in carcinoma of the uterine cervix. Coronal (A and C) and transverse (B and D) sections for limited (A and B) and advanced (C and D) disease (gray zones in left parametrium). HR, high-risk; IR, intermediate-risk. The American Brachytherapy Society conducted a survey on the use of image-based BT in 2007 and updated this in 2014. Of 219 respondents in 2014, 13% obtain an MRI with the first fraction of BT and 7% with subsequent fractions, whereas 6% use MR for every fraction. The majority (52%) specify dose to a contoured volume rather than to point A.[318]

A panel of gynecologic radiation oncologists generated a 95% consensus volume contouring atlas to delineate the CTV in locally advanced cervical cancer. Patients with parametrial extension benefited most from MR at the time of BT, particularly those with an apparent CR.[319] The atlas is available

online at https://www.nrgoncology.org/Scientific-Program/Center-for-Innovation-in-Radiation-Oncology/GYN-Cervical-Brachytherapy.

Dose-Volume Histogram Reporting

With MR-planned BT, the most common dose-volume parameters reported for target structures of the entire cervix and any residual disease at the time of BT, the HR-CTV, are D_{90}, defined as the dose received by at least 90% of the target volume, D_{100}, and V_{100}, based on the GEC-ESTRO recommendations. The cumulative D_{90} equals the sum of D_{90} values from the individual fractions plus the dose from a homogeneous 3D conformal external beam treatment. D_{100}, the minimum target dose, may be more sensitive to inaccuracies in contouring and dose calculation. V_{100} assesses dose coverage of the whole target volume and is 100% when the entire target is covered by the prescribed dose. V_{150} and V_{200} are often reported in interstitial BT. One may report these for CT, although the dimensions of the target will differ significantly from the absolute dimensions on MR, and the CT contour of the HR-CTV will include the cervix, residual areas in the parametria or uterosacral ligaments, and part of the uterus because the superior border of the cervix is not visible. CT contours are more accurate if an MRI can be performed immediately before or with the first fraction of BT.[320] In both CT and MRI, prescribed dose is based on the physician's directive of the dose intended for the target volume, that is, the volume covered by the 100% isodose line, and point A should be recorded. Several reports have validated the use of these guidelines with HDR, LDR, or PDR BT.[200,320]

With 3D imaging, one may define the surrounding normal tissue structures as the OARs, including the rectum, sigmoid, and bladder. With 2D imaging, the ICRU 38 report requires only reporting point estimates for the rectum and bladder because the sigmoid cannot easily be visualized. However, the ICRU bladder point may underestimate maximum doses to the OAR, in particular for the bladder; it is less likely that rectal doses will be incorrectly estimated. Numerous publications correlate the ICRU point dose and the probability of late complications for bladder and rectum.[321] Nevertheless, DVH metrics may provide a more reliable predictor of long-term complications.[322]

Pelloski et al[323] compared CT-based volumetric calculations and ICRU reference point radiation doses in 60 patients with cervix cancer treated with

LDR BT. Of 118 insertions performed, 93 were evaluated, and the minimal doses delivered to 2 or 3 cm of bladder or rectum (DBV2 and DRV2, respectively) were determined on a DVH. They concluded that the ICRU dose was a reasonable surrogate for the DRV2, but not for the DBV2. Furthermore, these calculations may not be applicable to other treatment guidelines or intracavitary applicators.

Both CT- and MR-based OAR dosimetry report similar cumulative DVH parameters, including D_{2cc} and $D_{0.1cc}$. The D_{2cc} is the minimum dose received by the most exposed 2-cm^3 volume of the analyzed organ. For CT-based BT, contrast placed in the OAR may cause some artifact, resulting in some variation in contouring the wall of the organ. MR-based BT relies less on contrast because the organ wall may be more clearly visualized. Wachter-Gerstner et al[324] analyzed the correlation between DVHs for the bladder and rectum and found that D_{2cc} served as a good estimate for doses to the organ wall, whereas D_{5cc} was less reliable as it changes more based on filling status. Rectal wall thickness did not significantly affect D_{2cc}.

Based on CT dosimetry, Koom et al[325] showed that more severe rectal side effects (endoscopy score .2) occurred in patients with a higher D_{2cc}. Seventy-one patients with FIGO stage IB to IIIB uterine cervical cancers had CT-based HDR intracavitary BT. The mean values of the DVH parameters and ICRU rectal point (α/β = 3) were significantly greater in patients with a score of greater than 2 than in those with a score of less than 2 at 12 months after BT (ICRU, 71 vs 66 Gy [P = .02]; $D_{0.1cc}$, 93 vs 85 Gy [P = .04]; D_{1cc}, 80 vs 73 Gy [P = .02]; D_{2cc}, 75 vs 69 Gy [P = .02]). The probability of a score of greater than 2 was significantly correlated with the DVH parameters and ICRU rectal point (ICRU, P = .03; $D_{0.1cc}$, P = .05; D_{1cc}, P = .02; D_{2cc}, P = .02).

For MR-based dosimetry, Georg et al[322] tested the predictive value of dose-volume parameters for late effects of the rectum, sigmoid colon, and bladder using the D_{2cc}, D_{1cc}, and $D_{0.1cc}$ of these three OARs for 141 patients with cervical cancer treated with tandem and ring HDR BT after EBRT. The mean D_{2cc} values for bladder, rectum, and sigmoid were 95 ± 22, 65 ± 12, and 62 ± 12 Gy, respectively. This study confirmed that D_{2cc} was a predictor of late toxicity for the rectum and bladder. A rectoscopy study[326] was done in 35 patients in which EQD2 (α/β = 3 Gy) of the $D_{0.1cc}$, D_{1cc}, and D_{2cc} of the rectum

was recorded. After a mean follow-up time of 18 months, telangiectasia was found in 26 (74%) patients, and 5 had ulceration that corresponded to the $D_{0.1cc}$ of the anterior rectal wall. The D_{2cc} was higher in patients with rectoscopy score of greater than 3 compared to less than 3 (72 ± 6 vs 62 ± 7 Gy; $P < .001$) and in symptomatic versus asymptomatic patients (72 ± 6 vs 63 ± 8 Gy; $P < .001$).

Mazeron et al[327] described late rectal morbidity in 960 patients treated with MR-based BT in the EMBRACE study. With a median follow-up of 2 years, rectal events peaked at 2 years post-treatment. The total crude rate of events was 28%, including 18% proctitis, 16% bleeding, 1% stenosis, and 1% fistula. Rectal dose morbidity was 6% 60 Gy, 8% 65 Gy, 10% 70 Gy, and 13% 75 Gy. The authors conclude that a D_{2cc} less than 65 Gy results in a less than 10% risk of rectal toxicity.

For interstitial BT, in which a much longer portion of the anterior rectal wall is treated as part of the target volume, D_{2cc} greater than 62 Gy predicted for late toxicity.[328] The development of mucosal and clinical changes in the rectum seems to follow a clear dose effect and volume effect. For patients receiving interstitial BT who require treatment to the entire vaginal length, the dose to the rectum should be reduced as much as possible without compromising target coverage.

The dose given to the vagina is also associated with vaginal toxicity,[329] with a threshold of 108 Gy analyzed in one study.[330]

Three-Dimensional Treatment Planning for Pulsed- and High-Dose Rate Brachytherapy

Treatment planning for PDR and HDR BT can be accomplished by a variety of techniques. Treatment planning for LDR is covered in a separate chapter. For cervical cancer, customized optimization of source loading for each HDR insertion is recommended (Figure 76.26), given significant changes in tumor and OAR dosimetry between fractions. Individualized computer treatment optimization of source position and the dwell time for each position are needed. Customized planning does increase the time needed for planning and requires experience on the part of the physics and dosimetry staff.

Tandem and ring treatment plan optimized to maximize tumor coverage and minimize the dose to the organs at risk (OARs), including the rectum (brown), sigmoid (blue), and bladder (yellow). C. Sagittal CT of the standard plan at point A. D. Sagittal CT image of the optimized plan showing the reduction in OAR dose. E. Cervical stump cancer showing a magnetic resonance–planned tandem and interstitial brachytherapy implant without HDR optimization. F. Optimized tandem and interstitial plan cover the posterior border of the cervical stump while minimizing dose to the bladder and rectum..

Computed Tomography–Based Treatment Planning

Dewitt et al,[331] in 15 patients with cervical cancer, defined target and OAR for planning of HDR BT and established guidelines for volume and dose constraint parameters using image-guided inverse treatment planning.

Careful assessment of the quality of BT and dose distributions is critical. Suyama et al[332] analyzed the minimal radiation dose to the peripheral area of the cervix in relation to local tumor failure using CT images taken at the time of intracavitary BT in 80 patients with carcinoma of the cervix. After CT scanning, isodose curves were superimposed on the CT images. Histograms of both the minimum percentage peripheral dose and the dose to the cervical area showed significant correlation in the local tumor control and local failure groups ($P < .001$).

With HDR intracavitary applicators, the use of a rectal retractor has been shown to substantially reduce the rectal dose. Lee et al,[333] in a study of 15 patients, found that this reduction was significant only in the subgroup who received more than 70% of the prescription dose ($P < .05$).

Wanderas et al[334] reviewed data from 19 patients (72 fractions) retrospectively. Standard library plans were compared to individually optimized plans using a Fletcher HDR applicator. For standard treatment planning, the tolerance dose limits were exceeded in the bladder, rectum, and sigmoid in 26%, 4%, and 15% of the plans, respectively. This was observed most often for the smallest target volumes. The individualized planning of the delivered treatment gave the possibility of controlling the dose to critical organs to below certain limits. The dose was still prescribed to point A. An increase in target dose coverage was achieved when additional individual optimization was performed while keeping the dose to the OARs below predefined limits. Relatively low average target coverage was seen, however, especially for the largest volumes.

Magnetic Resonance–Based Treatment Planning

Basic principles of MRI during BT have been described.[335] Several institutions have reported the dosimetric advantages of MR-based BT, with reduction in OAR doses with optimization. Tanderup et al[336] showed that point A dose was a poor surrogate of HR-CTV dose, and MR-based planning improved target coverage and reduced OAR dose. Starting with a standard plan is important for consistency because relative uniformity of the dose distribution should be maintained.

A comparison of MR to US was reported by Van Dyk et al[309] for 71 patients, showing comparability between the two modalities in terms of target volume and rectal point dose. Mahantshetty et al[313] similarly confirmed the

feasibility of US for institutions that do not have easy access to MR or CT. One study hypothesizes that US may be more similar to MR than CT.[337]

Recommended Doses

Stage IA (microinvasive) tumors are treated with intracavitary therapy only. LDR dose is approximately 60 Gy in one insertion or 75 to 80 Gy in two insertions to point A, or with HDR an equivalent dose, with one or two fractions per week. This may be given in approximately 5 Gy per fraction for 10 fractions or other regimens based on normal tissue exposure.

For stage IB to IVA cervical cancers in the United States, the most common EBRT dose treats the elective pelvic nodes to 45 to 50 Gy given in 1.8 Gy per fraction.[299] Some institutions instead use lower doses of whole-pelvis external irradiation (20-40 Gy) in addition to parametrial doses to complete 50 to 60 Gy to the involved parametrial tissues or nodal regions for more advanced stages. BT follows, with a goal EQD2 dose of 80 to 90 Gy to point A or to the HR-CTV. For LDR, intracavitary treatment for approximately 4,000 to 5,000 mgh (36-50 Gy to point A at 60 cGy/hour) is given, depending on the tumor volume and stage and age of the patient. Fyles et al[338] identified FIGO stage as the most significant prognostic factor in 965 patients with invasive carcinoma of the cervix, followed by dose of irradiation to point A and overall time of RT. The 10-year survival rate was 62% in 743 patients receiving doses to point A of 85 Gy or higher, in contrast to 53% for 222 patients receiving lower doses.

For HDR, one study found that a dose to the HR-CTV of greater than 87 Gy resulted in an LR rate of 4% compared to 20% for D_{90} less than 87 Gy when the tumor was greater than 5 cm and using an HDR tandem/ring or tandem/ring/ interstitial approach. They concluded that LC rates of greater than 95% can be achieved for patients with a poor response after EBRT if D_{90} for the HR-CTV is 87 Gy or higher.[339] The IR-CTV intended dose should be approximately 60 Gy EQD2. In the United States, the most common regimen uses five fractions (5-6 Gy per fraction), with two fractions per week, 24 to 48 hours between fractions.

DVH constraints for both PDR and HDR are 90 Gy (EQD2) for bladder and 70 to 75 Gy (EQD2) for both rectum and sigmoid as minimal doses to the most exposed D_{2cc} of the OAR. There are no generally accepted constraints for the 0.1-cm^3 level. Given the rapid regression of the tumor and the dramatic

change in the location and size of the normal tissues, it is recommended to replan and determine the doses to the OAR with each fraction if the patient is treated on an outpatient basis.[340]

Dose Fractionation in High-Dose Rate Brachytherapy

Based on the LQ model, isoeffect tables were developed to convert traditional LDR doses and number of fractions to point A to HDR BT; depending on dose rate, different dose values can be calculated for various fractionation schedules. It was calculated using therapeutic gain ratio[341] that similar results would be obtained with BT modality with either two to four fractions of LDR or four to seven fractions of HDR. Petereit and Pearcey,[342] based on their preliminary results and published reports in the literature, recommend doses of 45 to 50.5 Gy in a 1.8-Gy per fraction external beam followed by HDR with either 5.5 or 6 Gy per fraction in the era before the standardization of CRT. Since the implementation of concurrent CRT, several institutions in the United States have standardized the use of 5.5 Gy for five fractions, given some concerns about rectal toxicity with 6 Gy per fraction.[343]

Hama et al[344] compared the effectiveness and safety of once-weekly versus twice-weekly HDR BT for cervical cancer in 124 patients treated with EBRT (50 Gy); 74 patients (group A) were treated with one HDR BT insertion weekly (three fractions of 7 Gy each to point A), and 50 patients (group B) were treated twice weekly (six fractions of 4.5 Gy each to point A). OS rates were 65.2% and 65.3%, respectively ($P = .96$). LR-free survival rates were 69% for group A and 90% for group B ($P < .001$). The rate of grade 2 (moderate) and grade 3 (severe) complications was significantly lower for group B (6%) versus 32% in group A ($P < .001$).

Mayer et al[345] compared HDR BT in two schedules used to treat 210 patients with cervix cancer—one sequential (SRT), consisting of four fractions of 8 Gy followed by EBRT, and the other continuous (CRT), consisting of five fractions of 6 Gy one session per week integrated with EBRT (four fractions per week). Total dose to point A was 68 to 70 Gy. PFS was 71% with CRT versus 56% with SRT ($P > 0.05$). Late bladder and rectal morbidity were 13% in the CRT group and 25% in the SRT group ($P = .037$), related to the higher dose per fraction (8 Gy).

The optimal time-dose-fractionation scheme for HDR BT for cervical cancer has yet to be established. In an international survey from the

Gynecologic Cancer Intergroup, 28 different fractionation regimens were used by international cooperative group members (Table 76.7); the most common was 6 Gy for five fractions after 45 Gy.[300] The American Brachytherapy Society published recommendations for HDR BT for carcinoma of the cervix.[307] Each institution should follow a consistent treatment policy, including complete documentation of treatment parameters and correlation with clinical outcome (pelvic tumor control, survival, and complications). The goals are to treat point A to at least a total LDR equivalent of 80 to 85 Gy for early-stage disease and 85 to 90 Gy for advanced-stage disease. The pelvic sidewall dose recommendations are 50 to 55 Gy for early lesions and 55 to 65 Gy for advanced ones. As with LDR BT, every attempt should be made to keep the bladder and rectal doses to less than 100 Gy and 75 Gy LDR equivalent doses, respectively. Interstitial BT should be considered when the tumor cannot be optimally encompassed by intracavitary BT. Some suggested dose and fractionation schemes for combining the EBRT with HDR BT for each stage of disease have been presented by the American Brachytherapy Society, although they have not been thoroughly tested. The responsibility for the medical decisions ultimately rests with the treating radiation oncologist. Petereit and Pearcey,[342] in a review of 24 HDR dose fractionation schedules published in the past three decades, found no dose relationship for either tumor control or late morbidity. Viswanathan et al,[300] for the Gynecologic Cancer Intergroup, found significant international variation in the HDR dose/fractionation regimens reported, but aside from Japan, where the ratio of HDR BT dose to external beam is higher, there was consistency in converted EQD2 doses administered.

TABLE 76.7 HIGH-DOSE RATE BRACHYTHERAPY DOSE AND FRACTIONATION REGIMENS WORLDWIDE

Percentage Respondents (Number)	Dose/Fraction	Number of Fractions	EQD2
Standard Fractionation for Stage IB to IIA Cervical Cancers			
18% (12)	6	5	40
15% (9)	6	4	32
12% (7)	7	3	29.75
8% (5)	5	6	37.5
8% (5)	7	4	39.7

Percentage Respondents (Number)	Dose/Fraction	Number of Fractions	EQD2
5% (3)	5	5	31.25
5% (3)	5.5	5	35.52
Standard Fractionation for Stage IIB to IVA Cervical Cancers			
23% (14)	6	5	40
10% (7)	7	4	40
10% (7)	7	3	30
8% (5)	6	4	32
7% (4)	5.5	5	35.5

5% (3)	7	6	59.5
5% (3)	6	3	24
5% (3)	8	3	36

Gynecologic Cancer Intergroup physicians worldwide who use high-dose rate (HDR) brachytherapy for cervical cancer were queried regarding the specific fractionation regimen that they routinely implement for patients with stage IB to IIA and stage IIB to IVA cervical cancers. Results are shown for regimens reported by three or more respondents. The most common external beam dose was 45 Gy in 1.8 Gy per fraction, followed by five fractions of 5 to 6 Gy per fraction. The EQD2 formula was used to convert the HDR dose and number of fractionations and does not include the external beam dose contribution.

Clinical Outcomes of Brachytherapy

Comparing High-Dose Rate to Low-Dose Rate Using Plain X-Ray Dosimetry

A meta-analysis[346] including four trials and 1,265 patients reported a pooled RR for HDR versus LDR of 0.95 (95% CI = 0.79-1.15), 0.93 (95% CI = 0.84-1.04), and 0.79 (95% CI = 0.52-1.20) for 3-, 5-, and 10-year OS rates and 0.95 (95% CI = 0.84-1.07) and 1.02 (95% CI = 0.88-1.19) for 5- and 10-year DSS rates, respectively. For LC rates, the RR was 0.95 (95% CI = 0.86-1.05) and 0.95 (95% CI = 0.87-1.05) at 3 and 5 years, respectively. For bladder, rectosigmoid, and small-bowel complications, the RR was 1.33 (95% CI = 0.53-3.34), 1.00 (95% CI = 0.52-1.91), and 3.37 (95% CI = 1.06-10.72), respectively, indicating no significant differences, except for increased small-

bowel complications with HDR (P = .04). Of note, none of the randomized studies used 3D imaging to optimize away from normal tissues.

The use of 3D imaging to guide BT treatment planning has allowed optimization of HDR and PDR BT, thereby reducing the high per fraction doses to the normal tissues that might potentially cause significant side effects. A retrospective comparison of LDR and HDR with pretreatment MRI used for tumor volume determination showed a significant reduction in complications with HDR when image-based planning was implemented. Similarly, the use of 3D imaging optimizes tumor coverage, which is critical with fractionated HDR therapy.

Prospective Data Using Point A Dosimetry

A prospective study in Japan of stage I and II cervical cancer with tumors less than 4 cm (by T2 MRI) and no lymphadenopathy treated 60 patients with whole-pelvis EBRT 20 Gy per 10 fractions with midline block followed by 30 Gy per 15 fractions and HDR 24 Gy per 4 fractions (at point A).[347] The cumulative BED was 62 Gy (α/β = 10) at point A, which is lower than that reported by any other institution worldwide. Median tumor diameter was 28 mm (range, 6-39 mm). Median OTT was 43 days. Median follow-up was 49 months (range, 7-72 months). Seven patients developed recurrences: Three patients had pelvic recurrences (two central, one nodal), and four patients had distant metastases. The 2-year DFS and OS rates were 90% (95% CI = 82%-98%) and 95% (95% CI = 89%-100%), respectively. The 2-year late complication rates (according to RTOG/EORTC grade ≥ 1) were 18% (95% CI = 8%-28%) for large intestine/rectum, 4% (95% CI = 0%-8%) for small intestine, and 0% for bladder. No cases of grade 3 or higher were observed for GU/GI late complications.

Retrospective Results Using Point A With Pulsed-Dose Rate Brachytherapy[348]

Kaneyasu et al[349] treated 419 patients with SCC of the cervix from 1969 to 1999 with LDR or MDR. LDR required overnight admission, whereas MDR was given over approximately 5 hours on an outpatient basis. The 5-year OS rates for stages I, II, III, and IVA in the LDR group were 78%, 72%, 55%, and 34% versus 100%, 68%, 52%, and 42% in the MDR group (not statistically different). The actuarial rates of late complications of grade 2 or greater at 5

years for the rectum, bladder, and small intestine in the LDR group were 11.1%, 5.8%, and 2.0%, respectively, whereas for the MDR group, they were 11.7%, 4.2%, and 2.6%, respectively (not significantly different).

Bachtiary et al[350] reported on 109 patients treated with LDR BT and 57 who received PDR BT. The 3-year OS and DFS rates were 70% and 57% for the LDR group and 82% and 70% for the PDR group, respectively (P = .25 and .19). The 3-year probability rate for late grade 3 or worse toxicity was 7.4% for patients who had LDR BT and 7.6% for those who had PDR BT (P = .69) and was 6.9% and 7.6% for concurrent chemotherapy versus none (P = .69).

Rath et al[351] reported on 48 patients treated with PDR BT (intracavitary radiation therapy) and pelvic irradiation. A single session delivered a dose of 27 Gy to point A by PDR (hourly pulse, 70 cGy). Ten patients had disease recurrence (five each in stage IIB and stage IIIB). Eight patients had pelvic failure, one had bone metastases, and one had supraclavicular node metastases. Overall, the grade III to IV late toxicity rate at 50 months was 6%. For the median follow-up period of 15 months, the actuarial recurrence-free survival in stages I to II was 82% and in stages III to IV was 78%.

Prospective Trials With Computed Tomography or Magnetic Resonance Planning

The French STIC trial[348] collected data from 20 centers prospectively and stratified to 2D versus 3D (mainly with CT) BT. Its clinical outcomes are listed in Table 76.8. A total of 705 patients with stage IB to IIIB cervical cancers were treated with one of three arms: (a) BT followed by surgery (stage IB1, 165 patients); (b) EBRT plus chemotherapy, BT, then surgery (305 patients); or (c) EBRT plus chemotherapy and then BT (235 patients). The median follow-up was 2 years. Toxicity and survival were significantly improved with 3D-based treatment planning. Detailed results are shown in Table 76.8. For the 235 patients treated with concurrent CRT and then BT, 2-year OS was 74% for 3D versus 65% for 2D (P = .27); DFS was 60% versus 55% (P = .09); local-regional relapse–free survival was 70% versus 61% (P = .001), and local-only relapse-free survival was 79% versus 74% (P = .003). Toxicity was reduced overall from 23% with 2D to 2.6% with 3D (P = .002); urinary from 9% in 2D to 1% with 3D (P = .02), GI from 9% to 0% (P = 0.17), and gynecologic from 15% to 1% (P = .01).

TABLE 76.8 TWO-DIMENSIONAL VERSUS THREE-DIMENSIONAL IMAGE-GUIDED BRACHYTHERAPY IN THE PROSPECTIVE STIC STUDY

Mode of Treatment	Number of Patients (*N* = 705)	Imaging During BT	Local Control (%)	Disease-Specific Survival (%)	Overall Survival (%)	Late Grade 3-4 Toxicity (%)
Pre-op LDR or PDR	76	X-ray	92	87	95	14.6
Pre-op PDR	89	CT	100	90	96	8.9

Data from Charra-Brunaud C, Harter V, Delannes M, et al. Impact of 3D image-based PDR brachytherapy on outcome of patients treated for cervix carcinoma in France: results of the French STIC prospective study. *Radiother Oncol*. 2012;103(3):305-313.

A meta-analysis of 24 studies, both retrospective and prospective, assessed outcomes of point A (1,538 patients) and volume-based (3,995 patients) approaches, using both CT and MRI. The 3-year DFS for point A and volume-based studies were 67% (95% CI = 60%-73%) and 79% (95% CI = 76%-82%), respectively ($P = 0.001$). Three-year LC for point A and volume-based studies were 86% (95% CI = 81%-90%) and 92% (95% CI = 91%-94%), respectively ($P = 0.01$). The difference in 3-year OS (72% vs 79%, $P = .12$) was not statistically significant. The proportion of prospectively enrolled patients was 23% for point A studies and 33% for volume-based studies. There was no difference in late grade 3 or higher GI (3% vs 4%, $P = 0.76$) and GU toxicities (3% vs 3% $P = 0.45$) between the two groups.[249]

The EMBRACE study was an international collaboration of 24 centers that set out to prospectively investigate a cohort of patients with locally advanced

cervical cancer treated with cisplatin-based CRT followed by MRI-guided adaptive BT. The focus was the standardized application of the GEC-ESTRO MRI contouring and reporting guidelines, with the aim to report outcome and toxicity in a large-scale setting. They accrued a total of 1,341 patients with data available for disease outcomes and 1,251 with sufficient data for toxicity analysis. The median HR-CTV was 28 mL (interquartile range [IQR] 20-40), and the median D90% was 90 Gy (IQR 85-94). After a median follow-up of 51 months, the 5-year LC, pelvic control, DFS, and OS rates were 92%, 87%, 68%, and 74%, respectively.[200]

Retrospective Comparison of Computed Tomography to Magnetic Resonance–Planned Brachytherapy

Three studies compared CT to MRI contouring for HDR tandem and ring BT. Wachter-Gerstner et al[324] compared MR-based plans in 15 patients to those derived with either CT or orthogonal films. CT and MR enabled higher dose to the target volume with similar OAR dosing. Viswanathan et al[312] compared CT contours to MR contours based on a standard set of guidelines; the CT contours were larger in width, but no other significant differences in DVHs were identified. Using an MR for the first fraction and CT for subsequent fractions, Beriwal et al[320] treated 44 patients with 5- to 6-Gy per fraction HDR after EBRT. Ninety-three percent had a CR by PET at 3 months. Of those with a CR, two had an LR at 6 and 8 months. With a median follow-up of 8 months (range, 2.5-38 months), 2-year LC, DSS, and OS rates were 88%, 85%, and 86%, respectively.

One study compared CT to MR interstitial-based BT for cervical cancer and showed 2-year LC rates for MR- and CT-based treatments as 96% and 87%, respectively (log-rank $P = .65$). At 2 years, OS was significantly better in the MR-guided cohort (84% vs 56%, $P = .036$). On multivariate analysis, squamous histology was associated with longer OS (HR 0.23, 95% CI, 0.07-0.72) in a model with MR BT (HR 0.35, 95% CI, 0.08-1.18). There was no difference in toxicities between CT and MR BT.[352]

Toxicities

In the Medical University of Vienna series reporting patients treated from 2001 to 2008, 73% received concurrent cisplatin chemotherapy.[353] A total of 11 grade 3 and 4 late events were recorded in 143 patients. With a median

follow-up of 3.5 years, the actuarial grade 3 and 4 late morbidity at 3 and 5 years was, respectively, as follows: GI, 4% and 4%; urinary, 2% and 3%; and vaginal, 1% and 3%. Two patients developed massive rectal bleeding requiring transfusions. Three patients required stoma (grade 4) for rectal wall ulceration, resulting in a fistula, a rectal perforation, and a rectovaginal fistula. Three patients developed grade 3 urinary frequency or urgency. Three patients experienced grade 3 or 4 coaptation of the vagina.

At IGR, of the 45 patients studied,[354] 23 and 2 developed acute grade 1 or 2 and grade 3 complications, respectively; 21 patients presented with delayed grade 1 or 2 complications. One other patient presented with a grade 3 vesicovaginal fistula. No grade 4 or greater complications, whether acute or delayed, were observed. In the IGR experience with LDR BT from 2000 to 2004, 39 late complications were reported: 13 bladder, 7 rectal, 5 small bowel, 4 urethral, 3 colic, 2 vaginal, 1 pelvic fibrosis, and 4 others. Grade 3 complications were one rectal, two bladder, and one urethral. Tan et al[355] reported on 28 patients treated with CT-guided BT for stage IB to IIIB cervix cancer. Their overall actuarial 3-year grade 3 and 4 morbidity rate was 14%. Two patients had grade 3 abdominal pain and one had a colovaginal fistula. Overall, the data indicate that a potential reduction in morbidity appears to be a benefit of image-guided BT. Advocating for contouring bowel as a separate OAR during image-based BT, a report of 32 patients showed that when bowel was present around the BT applicator, contouring the bowel reduced the D_{2cc} optimized dose.

In the EMBRACE study, of the 1,251 patients with available toxicity data from a median follow-up of 48 months (IQR, 20-62), 270 patients had 534 severe adverse events (grade ≥3). The 5-year actuarial estimate of all severe events was 26.6%. When restricted only to organ-related events (GI, GU, vaginal, or fistula), it goes down to 18.4%, broken down to 6.8%, 8.5%, 5.7%, and 3.2%, respectively. The risk for fistula was increased with stage. The most common non–organ-related events were fatigue and insomnia. Further toxicity information is displayed in Table 76.9. The 5-year cumulative actuarial risk of treatment-related death was 1.2%, mostly due to GI complications, sepsis, and GU complication.[356]

TABLE 76.9 MAIN GRADE ≥3 TOXICITY EVENTS IN PATIENTS TREATED WITH CRT AND MR-GUIDED BRACHYTHERAPY IN THE EMBRACE COHORT WITH AT LEAST 1 FOLLOW-UP (*N* = 1,251)

Event	Number (%) of Grade ≥3 events		
	At Baseline	At Follow-Up	5-Y Actuarial Estimates Grade ≥3 (95% CI)

[a]In 15 patients, the bleeding originated from the rectum.

[b]Twelve out of 36 patients had G ≥3 ureteral stricture at baseline. Among these, five patients had persistent ureteral stricture until the end of follow-up or resolution without subsequent reoccurrence, whereas in seven patients, the ureteral stricture resolved to reoccur at a later time point.

Modified from Vittrup AS, Kirchheiner K, Pötter R, et al; EMBRACE Collaborative Group. Overall severe morbidity after chemo-radiation therapy and magnetic resonance imaging-guided adaptive brachytherapy in locally advanced cervical cancer: results from the EMBRACE-I study. *Int J Radiat Oncol Biol Phys*. 2023;116(4):807-824. http://creativecommons.org/licenses/by/4.0/.

Template-Based Interstitial Brachytherapy

Interstitial implants with ^{240}Ra, ^{144}Cs needles, or ^{206}Ir afterloading plastic catheters to limited tumor volumes are helpful in specific clinical situations.

Indications include large residual bulky cervical tumors after external beam treatment, residual tumor with sidewall invasion, vaginal extension, presence of a fistula and/or adjacent organ invasion, or a prior supracervical hysterectomy (Figure 76.27). The Syed-Neblett and the Martinez Universal Perineal Interstitial applicators are the most commonly selected. Methods for insertion have been described.[299] A tandem should be inserted when a uterus is present. If the os is not visible, US guidance to determine the proper placement of the tandem is advised. Both ring- and ovoid-based applicators modified to allow simultaneous insertion of interstitial needles are available.

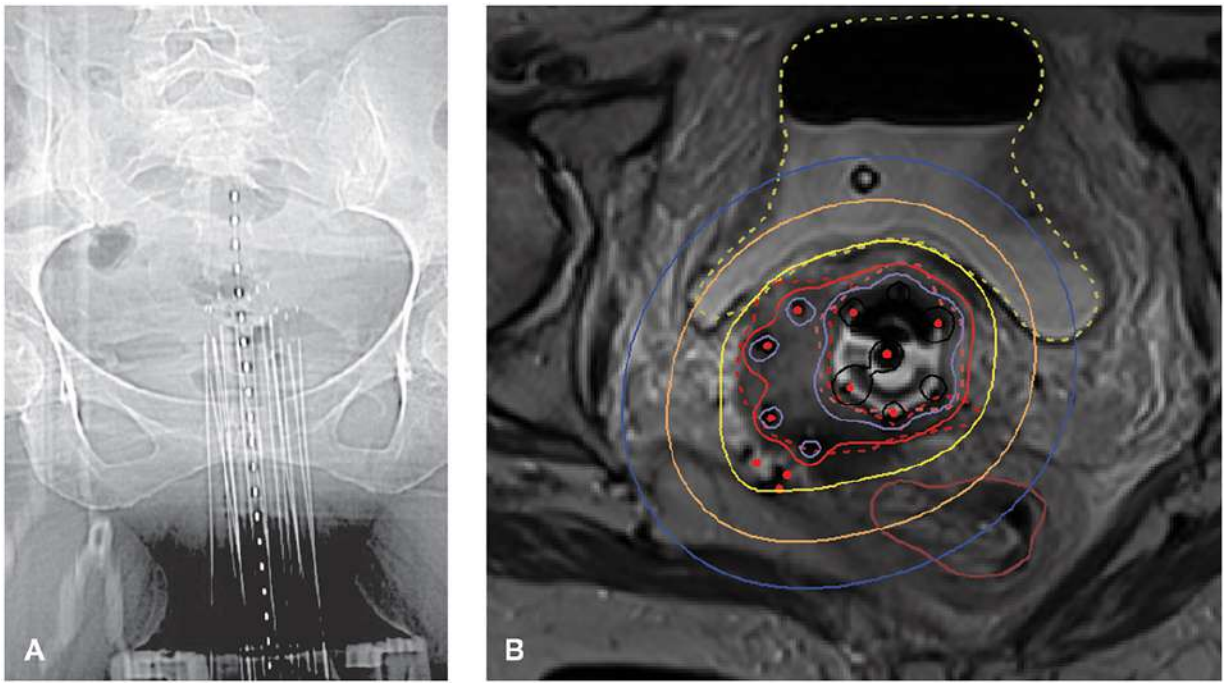

FIGURE 76.27 A. Picture of anterior scout computed tomography showing a template-based interstitial brachytherapy application. B. Magnetic resonance imaging during interstitial needle insertion in a patient with stage IIIB cervical cancer ensures proper placement of the catheters adjacent to the tandem. The 100% isodose line is in yellow.

Traditionally, plain x-ray films are used for BT treatment planning. Determination of normal tissue doses and optimization is not feasible, and the risk of complications is high. In these cases, consideration of laparoscopic approaches is recommended. Syed et al[357] reported on 185 patients with locally advanced cervical cancer treated with LDR interstitial BT from 1977 to 1997. Patients received external beam treatment to 50.4 Gy, followed by interstitial BT to 40 to 50 Gy. LC was 82%; 5-year DFS rates were 65%, 67%,

49%, and 17% for patients with stage IB, II, III, and IV diseases, respectively. Eighteen (10%) of the 185 patients developed RTOG grade 3 or 4 late complications.

Clinical outcomes using traditional techniques have been reported by several institutions.

Fallon et al[358] reported on 315 patients treated from 1992 to 2009 with interstitial BT. The 10-year LC was 87%, and late grade GU and GI toxicities were 4.8% G3 and 5.4% G4, respectively.

Recio et al[359] used laparoscopy at the time of interstitial BT in six patients with FIGO stage IIB to IVA cervical carcinomas after completion of whole-pelvis radiation; a total of 98 needles were inserted to deliver a median interstitial BT dose of 20 Gy. Eleven perforations in the pelvic peritoneum or bladder were identified during surgery in five of the six patients, leading to immediate repositioning of needles. No acute or short-term morbidity related to the procedure was noted.

Sharma et al[360] presented results on 42 patients treated from 2005 to 2007 in a prospective study of two weekly sessions of 10 Gy, 1 week after finishing external beam radiation. Median follow-up was 23 months. Delayed toxicity was 9%. The 3-year OS for all stages was 47%, and the 3-year recurrence-free survival for stages IIB, IIIB, and IVA was 67%, 34%, and 20%, respectively. Sharma et al[361] also reported on the use of transrectal US to assist with insertion of the interstitial needles.

With image-based planning including either a CT or an MRI, the physician evaluates the placement of the needles and may choose either to not treat specific catheters or to lower the dose given through catheters close to normal tissue structures. An approximate 11% rate of bowel insertion and a long-term fistula rate of 4% to 10% have been reported in studies using CT for planning after insertion. When a physician has the facility to insert the applicator in a CT or MR suite while the patient is under anesthesia, an iterative process of image-guided needle insertion ensures proper placement of the catheters and prevents an inadvertent insertion into a surrounding normal tissue structure, such as the rectum, sigmoid, or bladder.[314]

Dose optimization with either PDR or HDR may improve the normal tissue doses for interstitial therapy for some patients. The University of Pittsburgh reported on 11 patients with cervical cancer treated with CT-guided HDR interstitial BT (five fractions of 3.5 Gy per fraction).[362] From 1998 to 2004,

interstitial BT was chosen for cases with distorted anatomy or extensive vaginal disease. The 5-year actuarial LC rate was 63%. No patient had acute grade 3 or 4 toxicity. Grade 3 or 4 late toxicity occurred in one patient, with a 5-year actuarial rate of 7%. Three patients had late grade 2 rectal toxicity, and one patient had grade 2 small-bowel toxicity.

Dimopoulos et al[363] reported on the use of tandem/ring with short interstitial needles and MR-planned HDR BT for 22 patients with cervical cancer followed for a median of 20 months; no grade 3 or 4 toxicities were noted, and one patient had an LR. Nomden et al[364] described the use of tandem/ovoid application with short interstitial needles for the second insertion with MR-planned PDR BT for 20 patients with cervical cancer. They compared the first insertion with just a tandem and ovoid applicator to the second insertion, which included the addition of interstitial needles. There was an average increase in dose of 4.4 Gy (standard deviation 2.3), with better coverage of the HR-CTV with the second insertion.

A prospective cohort of MR-guided interstitial BT showed an LC rate of 96%. In a comparison of CT- to MR-based BT, no difference in toxicities was noted, whereas MR had superior outcomes.[352] A systematic review of 672 patients described an LC rate of 79% with image-based planning.[365]

As interstitial insertions are challenging to both perform and plan, keeping the applicator in place over the course of a few days and performing multiple fractions per insertion become more prevalent. Mikami et al[366] analyzed needle applicator displacement in 10 patients treated with 30 Gy HDR in five fractions and found on daily CT scans an average of 1 to 2 mm of caudal displacement. Shifts of greater than 3 mm were replanned. Shukla et al[367] presented data on 20 patients with cervical cancer treated with interstitial BT who underwent every-other-fraction CT imaging. The mean needle displacement was 2.5 (range, 0-7.4), 17.4 (range, 0-27.9), 1.7 (range, 0-6.7), 2.1 (range, 0-9.5), 1.7 (range, 0-9.3), and 0.6 mm (range, 0-7.8 mm) in cranial, caudal, anterior, posterior, right, and left directions, respectively. The mean displacement in the caudal direction was higher between days 1 and 2 than that between days 2 and 3 (13.4 vs 3.8 mm; $P = .01$). Damato et al,[368] in a study of 10 patients treated with interstitial BT, found on average that less than 1-cm displacements and deformations of the implant occurred over the course of treatment. The most significant dosimetric consequences were due to changes in organ filling rather than catheter shifts. Proper quality assurance

methodologies should be in place to detect shifts that can potentially result in inadvertent insertion into normal tissue.

Brachytherapy in the Older Patients

Magné et al[369] reported on 113 patients with a median age of 76 years (range, 70.7-94.4 years) treated by conventional LDR BT as a part of their treatment. For rectal complications, grade 1/2, 3/4, and 5 (fatal) crude incidences were 19.4% (22/113), 1.8% (2/113), and 0.9% (1/113), respectively. Acute toxicity death occurred in one patient with major diarrhea associated with a hemodynamic shock. For small-bowel complications, grade 1/2 and 3/4 crude incidences were 3.5% (4/113) and 0.9% (1/113), respectively. For urinary tract complications, grade 1/2 and 3/4 crude incidences were 11.5% (13/113) and 2.7% (3/113), respectively. With a median follow-up of 3.1 years, 10 patients developed distant metastases, and 10 others had local relapses. The 3-year specific OS rate was 88.6% (95% CI = 77-92), and the corresponding DFS rate was 81% (95% CI = 72-88). Age did not influence the effectiveness of BT in older patients, and BT should be considered whenever possible, even in older patients presenting with a cervix cancer.

Image-Guided Brachytherapy Versus Intensity-Modulated Radiation Therapy or Stereotactic Body Radiotherapy Boost

Studies of external beam treatment as an alternative boost instead of BT demonstrate significantly inferior survival rates compared to those that use BT. In a SEER analysis, 63% of 7,359 women received BT in combination with EBRT, and 37% received EBRT alone. The BT utilization rate decreased from 83% in 1988 to 58% in 2009 ($P < .001$). In a propensity score-matched cohort, BT treatment was associated with higher 4-year CSS (64.3% vs 51.5%, $P < .001$) and OS (58.2% vs 46.2%, $P < .001$). BT treatment was independently associated with better CSS (HR, 0.64; 95% CI, 0.57-0.71) and OS (HR 0.66; 95% CI, 0.60-0.74).[370] In an updated analysis, the rate of BT utilization improved further to 76% in 2018 to 2020 with still a significant effect on survival.[371] In a study of the NCDB, only 44% of patients received standard-of-care therapy; Black patients were less likely to receive any boost or BT.[372]

A phase 2 single-arm trial of SBRT as a boost after CRT in 15 patients unfit or who refused BT was reported by Albuquerque et al.[170] The trial closed early

due to poor outcomes and high toxicity. The 2-year LC, PFS, and OS were 70.1%, 46.7%, and 53.3%, respectively. Grade 3 and higher 2-year cumulative toxicity rate was 26.7%, mainly rectal bleeding/fistula.

The dosimetry of BT cannot be adequately mimicked by external beam techniques. A treatment planning report compared inversely planned EBRT with photons (IMRT/SBRT) and proton (intensity-modulated proton therapy) to 3D MRI-guided BT.[373] EBRT was planned to deliver the highest possible doses to the PTV while respecting D_{2cc} limits from BT, assuming the same fractionation. Volumes receiving 60 Gy (in equivalent dose in 2-Gy fractions) were approximately twice as large for IMRT compared with BT, and the high central tumor dose was lower than that seen with BT. Both IMRT and proton were inferior to 3D image-based BT. With IMRT, there is a need for replanning because of rapid tumor regression and an increase in integral dose, with normal tissues throughout the pelvis receiving more radiation than with BT. Given the large movement and the increased dose to the normal tissues resulting in an increase in normal tissue toxicity, highly conformal (IMRT, IGRT, SBRT) methods for boosting the cervix are not routinely recommended. Every effort should be made to use image guidance to insert a tandem into the uterus in order to provide adequate BT doses for all cervical cancer cases receiving radiation.

Occasionally, BT procedures cannot be performed because of medical reasons or unusual anatomic configuration of the pelvis or the tumor (ie, extensive lesion, inability to identify the cervical canal). These patients may be treated with higher doses of external beam irradiation alone, although survival is significantly worse than when BT is implemented and normal tissue toxicity is higher due to the excessive dose to the rectum and bowel. Therefore, every attempt to treat with BT should be made because BT moves with the patient and provides high regions of dose in the central regions of the tumor. With IMRT, a significantly higher normal tissue dose is administered, and the desired high central regions of radiation cannot safely be administered.

FOLLOW-UP

After treatment, patients should be regularly followed by both the radiation and the gynecologic oncologist. Careful history-taking and a complete physical and pelvic/rectal examination are usually performed as clinically

needed in the first 3 months after completion of irradiation, especially for toxicity management or for concerning residual disease.

A PET-CT scan performed 3 months after definitive CRT is useful in assessing response and determining prognosis. A meta-analysis including 1,104 patients in 12 cohorts was reported by Kim et al.[374] The pooled HRs for OS and PFS of patients with complete metabolic response versus partial response or progressive disease were 0.20 (95% CI, 0.12-0.34) and 0.12 (95% CI, 0.07-0.19).

Dependent on specific risk assessment, clinical evaluation should continue every 3 to 6 months for the remainder of the first year, every 4 to 8 months the second year, every 6 to 12 months during the third through the fifth year, and yearly thereafter.[375]

The use of Pap smears for cervical and vaginal cytology as a follow-up study is controversial because of postirradiation cellular morphology that renders it difficult to distinguish postirradiation changes from residual or recurrent malignant cells. DNA analysis of postirradiation cytologic smears demonstrating atypia or dysplasia may provide ancillary information.

Rintala et al[376] evaluated the reliability of cytologic analysis and atypia after RT in 89 patients treated for cervical carcinoma. A total of 697 Pap smears were taken; during the follow-up, 44 patients had recurrent disease, which was local in 17 (39%) cases. The rate of false-positive samples was only 3%. Radiation-induced atypia was detected in 28% of the Pap smears taken during the first 4 months after RT, and its incidence decreased thereafter. In 1,000 patients treated with either surgery or RT at the MD Anderson Cancer Center for stage IB cervical cancer post-treatment, Pap smears did not detect a single asymptomatic recurrence among 133 patients with recurrent disease.[377]

The presence of apparently viable tumor cells in the cytologic smear 3 months after irradiation should be evaluated with cervical biopsies, dilation and curettage, and careful EUA, as indicated.

Complete blood counts and chemistry profile tests are obtained as clinically indicated. If a known tumor marker such as SCC-AG was elevated prior to therapy, then its level afterward can be useful to detect asymptomatic recurrences. Chest radiography is commonly obtained on a yearly basis, usually for the first 5 years post-treatment, although its value to detect curable

lung metastasis is not proven. If radiographs are consistently negative, obtaining them every other year thereafter may be sufficient.

Other imaging studies, such as CT, MRI, PET scanning, or bone scans, are usually performed when clinically warranted but can be considered for routine follow-up in high-risk patients when available. PET-CT imaging in asymptomatic patients has been shown to detect recurrences amenable to curative salvage therapy.[378]

When persistent or recurrent tumor is suspected, biopsies should be obtained for histologic confirmation. If a biopsy is positive, immediate treatment should be instituted, as is discussed later.

Usually, hematometra after RT for cervical carcinoma is related to recurrent disease but occasionally may be related to estrogen replacement therapy, endometrial activity, or fibrosis and obliteration of the endocervix.

It is important to keep in mind that cervical cancer survivors are at increased risk for second malignancies from their exposure to HPV infection and/or high doses of radiation, especially as some may have decades of life ahead of them. Thus, relevant screening measures and patient education are appropriate.[379]

TREATMENT OF RECURRENT CARCINOMA OF THE CERVIX

After Previous Surgery

Radiation may salvage approximately 50% of patients with localized pelvic recurrences after surgery alone. A combination of whole-pelvis external irradiation (45-50 Gy) with concurrent chemotherapy followed by interstitial BT is recommended. If the tumor lies outside an accessible region for BT, dose escalation with conformal or IMRT techniques may be attempted, depending on the location of the tumor and the need to protect the bowel, with at least 65 to 70 Gy necessary for adequate control. In the setting of recurrent disease, the total mucosal dose from the external and BT can approach 140 Gy to the upper vagina and 95 Gy to the distal vagina without a high risk. With interstitial BT, doses of 20 to 35 Gy are administered with single, double-plane, or volume implants, for a total tumor dose of approximately 80 Gy, depending on the extent of the tumor.

Shan et al[380] retrospectively reported on 72 patients with locoregional recurrences after surgery without adjuvant RT, who underwent salvage platinum-based CRT. The 5-year PFS and OS were 57.6% and 65.9%,

respectively. Regional nodes were irradiated to 45 to 50 Gy and a boost of 18 to 30 Gy was given with BT in central recurrences or with EBRT in other locations up to 60 to 66 Gy. Better prognosis was associated with a central recurrence, fewer lesions, and regional irradiation rather than targeting only gross disease.

After Definitive Irradiation

Therapy for previously irradiated patients must be considered with caution and tailored for each specific case. It is important to analyze the techniques used in the initial treatment (beam energy, volume, doses delivered with external or intracavitary irradiation), the period of time to recurrence, its location and extent, and the general condition of the patient. Patients with longer interval and location above the field that conforms to lymphatic spread (para-aortic, left supraclavicular) can be candidates for aggressive LC with CRT. A shorter interval and larger volume might benefit more from standard first-line systemic therapy and later adding RT to involved fields in patients that achieved disease control, similar to some newly diagnosed stage IVB patients. Different uses of RT in disease recurrences are demonstrated in Figure 76.28.

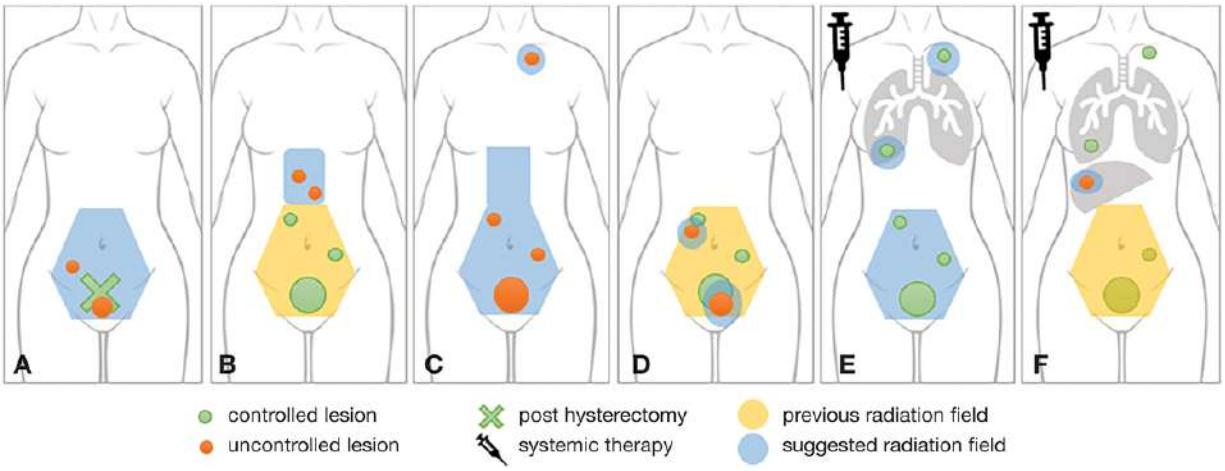

FIGURE 76.28 Recurrences and oligometastatic states. Posthysterectomy central recurrence and pelvic lymph node recurrence (A), above-the-field-recurrence with metachronous para-aortic metastases (B) and synchronous oligometastatic disease (C) are all candidates for concurrent chemoradiotherapy with curative intent. In-field recurrences (D) could also be salvaged with recurrence-directed therapy (surgery or reirradiation with external beam radiation therapy and/or brachytherapy) with or without systemic therapy. Involved-field consolidation radiotherapy (E) should also be considered in responding oligometastatic patients to prolong survival. Limited progression, or oligo-progression, under systemic therapy (F) could also benefit from local therapy such as stereotactic body radiotherapy to the progressing lesions.

Recurrences in Previously Nonirradiated Locations

"Above-the-filed" locations usually refer to upper pelvic echelons and the para-aortic regions. PAN metastases are frequently combined with distant dissemination but are clinically apparent in only 10% to 20% of patients who have recurrences. Isolated recurrences in the PANs after pelvic irradiation, now considered to be stage IIIC2, have been described in about 3% to 8% of patients and may be cured with CRT. The advent of IMRT makes treatment easier, with less morbidity. Singh et al[381] detected 14 isolated PAN metastases in 816 patients previously treated with RT; these women were subsequently treated with RT to the PANs combined with concurrent chemotherapy. Seven patients survived for 5 years.

In a review of 1,955 patients treated with RT for cervix cancer, Jhingran et al[382] identified 120 patients with recurrent tumor above the pelvic fields. Initially, 10 had common iliac and 5 had PAN involvement. In 104 patients, recurrences were immediately adjacent to the upper borders of the RT fields. In 15 patients treated with curative intent for the PAN recurrence, 5-year survival was 25%.

Niibe et al reported that from a multihospital registry of over 5,000 patients, 84 isolated PAN recurrences were identified (82% occurring after primary or adjuvant RT). Definitive treatment with RT with or without chemotherapy resulted in 31.3% 5-year OS. Shorter OS was associated with less than 50 Gy dose and with symptoms.[383]

Distant recurrences, in organs such as the liver or lung, or in distant lymph nodes, could also benefit from metastases-directed therapy, with most achieving a delay in the need for systemic therapy and some even long-term remission.[171]

Ning et al[384] reported on 38 patients with metastases to the supraclavicular or mediastinal nodes, and the lung, of whom 9 were synchronous and the rest were recurrences after CRT with BT. For nodal disease, conventional fractionation with integrated boost was given to the gross disease to a median dose of 60 Gy and the lymph node basin up to 45 to 50 Gy with the para-aortics included in supraclavicular disease. SBRT was given when feasible in pulmonary disease usually with 50 Gy in four fractions. Chemotherapy was given to 34 (89%) patients as induction concurrently or adjuvantly. Rates of 2-year PFS and OS were 48.4% and 73.5%, respectively. LC was good with only one in-field recurrence. The toxicity profile was tolerable and reflected the area treated; 13 (34%) patients experienced grade 2 esophagitis, and 5 (13%) had grade 2 dermatitis. Only one grade 3 esophagitis was reported, with a short-term feeding tube needed.

Macchia et al[385] reported a multicenter Italian cohort of 83 patients with oligometastatic, persistent, or recurrent cervical cancer treated for 125 lesions with SBRT. All patients had primary disease controlled, unfit for systemic therapy and had up to five lesions. The median dose was 35 Gy (10-60) in a median of 5 (1-10) fractions. Lesions were either nodal 54.2% or parenchymal 44.8%. Complete, partial, and stable response were achieved in 73 (58.4%), 29 (23.2%), and 16 (12.8%) lesions, respectively, and 46 (55.4%) patients gained CR. Rates of 2-year LC, PFS, and OS in patients with or without CR were 89%, 43%, and 69% versus 22%, 8%, and 43%. Toxicity was mild, with 15 (18%) and 4 (5%) patients reported as having acute and late events, respectively, and only one grade 3 pain.

Recurrence in Previously Irradiated Locations

Reirradiation is feasible, with some patients achieving long-term remission. The time between the two treatments must be taken into consideration because it is postulated that some repair of the initial damage may take place in the interval. In general, external irradiation for recurrent in-field tumor is given to limited volumes. Conventionally fractionated doses were reported, preferentially using lateral portals, but IMRT is better preferred where available. Occasionally, intracavitary or interstitial irradiation can be used to treat relatively circumscribed recurrences. Surgery could also be appropriate in select cases. Whatever the local treatment selected, systemic therapy, as discussed previously in metastatic disease, should be considered to potentially reduce the volume of the recurrence, allowing for less exposure of normal tissue to higher ablative doses of radiation or to surgical complications.

Chopra et al[386] reported on outcomes of oligorecurrences treated with varied RT techniques in 58 patients, with 30 (52%) of them as reirradiation. Median dose of reirradiation in was 44 Gy [IQR 33-68 Gy], with a cumulative dose of 116 Gy [IQR 95-148], conferring 2-year LC and OS as 74% and 61%, respectively. Crude grade 3 and higher toxicity incidence at 2 years was overall 19%, nonsignificantly higher in the reirradiation group (26% vs 11%, $P = .49$).

Kim et al[387] reported on outcomes of salvage RT in 125 patients with recurrent cervical cancer. The report included 45 patients who recurred “in field” as central lesions in 62%, pelvic and para-aortic nodes lesion in 29%, and both in 9%. Only gross disease was targeted when re-irradiating, with mostly IMRT to median 54 Gy dose or intracavitary BT to median 25 Gy. Rates of 5-year local FFS, PFS, and OS were 47.1%, 33.2%, and 66.5%, respectively. On multivariate analysis, shorter PFS was significantly associated with higher stage at initial diagnosis, non-SCC histology, and higher SCC-Ag levels at recurrence.

Ling et al[388] reported on 20 patients with 21 isolated pelvic and para-aortic recurrences, either in-field or marginal, with mixed gynecologic cancers (six with cervical cancer). All were reirradiated with SBRT to a dose of 40 to 45 Gy in five fractions, with a median BED of 82.7 Gy. Rates of 3-year LC, distant PFS, OS, and grade 2 and 3 toxicity were 61%, 44%, 51%, 38%, and 14%, respectively. This emphasizes that while some patients may gain prolonged remission with SBRT reirradiation of isolated lesions, toxicity risk must be considered.

Selected patients with limited pelvic recurrences not fixed to the pelvic wall and without evidence of extrapelvic metastases can be potentially salvaged by RH or pelvic exenteration. Selection should be based on interval from primary treatment and the ability of the patient to withstand the morbidity involved with this procedure.[124]

Intraoperative Irradiation

Intraoperative radiation therapy (IORT) has been used for the treatment of locally advanced and recurrent carcinoma of the cervix, with 3-year survival rates of 8% to 21%, respectively. Central recurrences, particularly in patients who were nonirradiated, and resection of the gross recurrent tumor in those who were irradiated improve the benefit from IORT. Significant toxicity includes peripheral nerve injury and ureteral stenosis (with doses .15-20 Gy).

IORT was used in 70 patients with pelvic recurrences in a European cooperative study.[389] Complete tumor resection was carried out in 30 patients, partial in 37, and unspecified in 3. Sixty-five patients had electron beam therapy (12-25 MeV), with mean doses of 18 Gy (10-25 Gy) after gross complete resection and 19 Gy (10-30 Gy) after partial resection. The 3-year OS rate was 8%. Grade 2 or 3 toxicity was observed in 19 (27%) of 70 patients, with 10 complications being related to IORT.

URGENT BLEEDING AND PALLIATIVE IRRADIATION

Frequently, the radiation oncologist is faced with the challenge of treating a patient with stage IVB or recurrent carcinoma requiring palliation of pelvic pain or bleeding. Tumors respond rapidly to radiation, and bleeding usually resolves within a few days of treatment. If vaginal bleeding is the main concern, several possibilities may be effective. In a descriptive review of eight papers that presented palliative treatment data,[390] five papers were found to report using 10 Gy per fraction, with the best resolution of bleeding and/or pain when each 10-Gy fraction was given at 3- to 4-week intervals for a total of three fractions. Alternatively, common palliative regimens used in other sites of the body, such as 4 Gy for 5 or 6 fractions or 3 Gy for 10 fractions, or a Quad shot regimen may be implemented. Patients who present with a new diagnosis may be treated with 3 to 4 Gy for two or three fractions, followed by standard 1.8 Gy to approximately 39.6 Gy and then BT. Alternatively, patients may receive 1 to 2 days of 1.8 Gy twice a day, switching to once-a-

day treatment with 1.8 Gy per fraction after bleeding has stopped on day 2 or 3, completing treatment after 45 Gy and then commencing routine BT.

If the situation calls for it, a single LDR intracavitary insertion with tandem and colpostats for approximately 6,000 mgh (55 Gy to point A) or the HDR equivalent may be used for palliation. If irradiation was delivered previously, lower intracavitary doses should be prescribed (4,000-5,000 mgh).

Several high-dose fractionation schedules with external beam radiation have been used. Spanos et al[391] reported on a phase II study of daily multifractionated split-course irradiation in 142 patients with recurrent or metastatic disease in the pelvis. Irradiation consisted of 3.7 Gy per fraction given twice daily for 2 consecutive days, repeated at 3- to 6-week intervals for a total of three courses, aiming at a total tumor dose of 44.4 Gy. Occasionally, this regimen was combined with an LDR intracavitary insertion (4,500 mgh), blocking the midline for the last 14.4-Gy external dose. Twenty-seven patients survived greater than 1 year. There were only two recorded cases of grade 3 toxicity (lower GI tract). This study was expanded to a phase III protocol randomizing 136 patients between a short (2 weeks) or a longer (4 weeks) rest period between the split courses of irradiation.[267] There was a trend toward increased acute toxicity in patients with shorter rest periods (5/58 vs 0/68; P = .07). Late toxicity was not significantly different in the two groups. Pelvic tumor response was comparable in both groups (34% vs 26%). The study team reported a 6% complication rate in the total 290 patients treated in RTOG Protocol 85-02. No patient receiving less than 30 Gy experienced late toxicity. There was no significant difference in the incidence of complications for patients with a 2- or 4-week rest (P = .47).

IRRADIATION AND HYPERTHERMIA

Regional hyperthermia is a treatment that applies moderate heat to tumors in an attempt to potentiate the effects of oncologic treatments and improve responses. A Cochrane database review identified six randomized controlled trials published between 1987 and 2009 comparing RT versus combined hyperthermia and RT.[392] A significantly higher CR rate (RR = 0.56, 95% CI = 0.39-0.79) and lower LR rate (HR = 0.48, 95% CI = 0.37 to 0.63) and improved OS (HR = 0.67, 95% CI = 0.45-0.99) with no difference in acute or late grade 3 to 4 toxicity were seen for patients treated with combined therapy. In the concurrent chemotherapy era, the benefit of additional hyperthermia is

less clear. A polish randomized trial in 205 patient undergoing BT with or without hyperthermia did not show improvements in outcomes.[393] In contrast, a meta-analysis of two randomized trials of the addition of hyperthermia to chemoradiation, comprising 536 patients, did show significantly higher 5-year OS with hyperthermia with an HR of 0.67 (95% CI = 0.47-0.96, P = .03).[394] The local relapse–free survival was nonsignificantly higher, and no differences were observed in toxicities. Another randomized trial in 210 patients reported by Minnaar et al[395] has shown a benefit to OS in patients with stage III disease only. Thus, along with the technical limitations in the delivery of adequate heat to large parts of the body such as the pelvis, the use of hyperthermia in the treatment of carcinoma of the uterine cervix has not been widely adopted.

SIDE EFFECTS: SURGERY AND RADIATION

Descriptions of sequelae vary among institutions because toxicity grading scales are not uniform and the scoring system for complications is not clearly stated in all reports. Surgical side effects alone depend on the extent of surgery and the amount of disease. RH alone may cause long-term side effects, such as urinary retention requiring chronic suprapubic catheter placement, sciatic nerve injury, postoperative seroma or hematoma formation, pelvic pain, or, when lymphadenectomy is performed, lifelong edema. Oophorectomy also may induce menopause; hysterectomy removes the ability to carry a pregnancy, and removal of a portion of the vagina may significantly change sexual function if vaginal shortening is severe.

With improved anesthesia, surgical techniques, and antibiotic therapy, the mortality rate for RH with pelvic lymphadenectomy has decreased to 1% or less. Open surgery is the standard due to better survival outcomes,[122] even though it is associated with more blood loss and longer hospital stay.[121] Nam et al[120] reported intraoperative complications to be comparable between approaches (6.8% and 5.7%, P = .71), but postoperative complications were significantly higher in the open surgery group (9.2% vs 21%, P < .001). The most frequent sequela after RH is urinary dysfunction as a result of partial denervation of the detrusor muscle. Patients may have various degrees of loss of bladder sensation, inability to initiate voiding, residual urine retention, and incontinence.

Patients who had a pelvic lymphadenectomy experienced a greater incidence of lower extremity lymphedema than those who did not undergo this procedure. Some loss of defecatory urge associated with chronic rectal dysfunction may occur after RH. Manometric studies suggest a disruption of the spinal arcs controlling defecation.

Other complications include ureterovaginal fistula (the incidence of which has decreased to <3%), hemorrhage, infection, bowel obstruction, stricture and fibrosis of the intestine or rectosigmoid colon, and bladder and rectovaginal fistulas. Postsurgical complications are usually more amenable to correction than late complications after irradiation.

When postoperative RT is given to selected patients, further complications of the additional therapy are expected. The main areas of side effects because of radiation are bowel, bladder, skin, and sexual function.[396] Because of intestinal adhesions to denuded surfaces in the pelvis, enteric complications, such as obstruction, fistula, or dysfunction, were observed in up to 24% of patients in the pre-IMRT era. Findings at surgery consisted of minimal incisional adhesions, but extensive matted small-bowel loops adherent to the pelvic operative sites.

Lower body mass index (BMI) is correlated with an increase in toxicity. A total of 404 patients with stage IB1 cervical cancer with positive lymph nodes or stage IB2 or higher were treated from 1998 to 2008. A BMI of less than 18.5 was associated with a decreased OS (HR = 2.37, $P < .01$). Grade 3 and 4 complications appeared to trend higher; overall, 17% versus 14%; specifically, for fistula, 11% versus 9% ($P = .05$), for bowel obstruction, 33% versus 4% ($P < .01$), and for lymphedema, 5.6% versus 1.2% ($P = .02$).[397]

The dose of irradiation, technique, and type of surgical procedure performed are important in determining the morbidity of combined therapy. A significant number of complications are associated with pretherapy staging laparotomy, particularly if irradiation (>55 Gy) is given to metastatic PANs. The incidence of complications is between 5% and 20%, depending on the extent of the PAN dissection, use of transperitoneal or retroperitoneal approach for the operation, and dose of irradiation given.

Newer techniques of RT were shown to decrease postoperative irradiation toxicity. In the phase III PARCER trial,[146] which randomized patients with posthysterectomy cervical cancer to pelvic RT with IMRT versus 3D conformal RT, toxicity was shown to be significantly lower with IMRT. The

3-year cumulative risk of grade 2 and 3 late GI toxicity was 21.1% and 2.9% versus 42.4% and 15.5% ($P < .003$). Quality-of-life questionnaires have shown that the IMRT group reported better functional scores and lower symptoms scores. Differences were not significant for late GU or acute GI toxicities.

Late Sequelae: Overall

The incidence of major late sequelae of RT for stage I and IIA carcinomas of the cervix ranges from 3% to 5% and for stages IIB and III between 10% and 15%. Injury to the GI tract usually appears within the first 2 years after RT, whereas complications of the urinary tract are seen more frequently. Actuarial estimates rather than frequency of sequelae should be reported to avoid underestimation of the risks of late morbidity after RT in long-term survivors. In fact, Eifel et al,[398] in 1,784 patients with stage IB carcinoma of the cervix, noted that the greatest risk of sequelae is in the first 3 years after therapy. The risk of rectal complications declined after the first 2 years of follow-up to 0.6% per year, whereas the risk of major urinary tract complications for survivors continued at 0.3% per year, with a 20-year actuarial risk of major complications of 14.4%.

A greater incidence of complications is associated with higher doses of irradiation. Perez et al[399] and Pourquier et al reported that with doses less than 75 to 80 Gy delivered to limited volumes, grade 2 and 3 complications in the urinary tract and rectosigmoid were approximately 5%. However, the incidence increased to more than 10% with higher doses of irradiation to these organs (Figure 76.29). Doses greater than 60 Gy were also correlated with a greater incidence of small-bowel injury (Figure 76.30). The same analysis showed that patients who experienced sequelae of therapy had slightly better survival rates than patients without any complications. This was related to improved tumor control with higher doses of irradiation.

FIGURE 76.29 Incidence of moderate or severe genitourinary (A) or rectosigmoid (B) complications in patients with carcinoma of the uterine cervix (all stages) treated with irradiation alone (external and brachytherapy). A greater frequency of complications is noted with maximum doses of .75 to 80 Gy to the bladder or rectum.

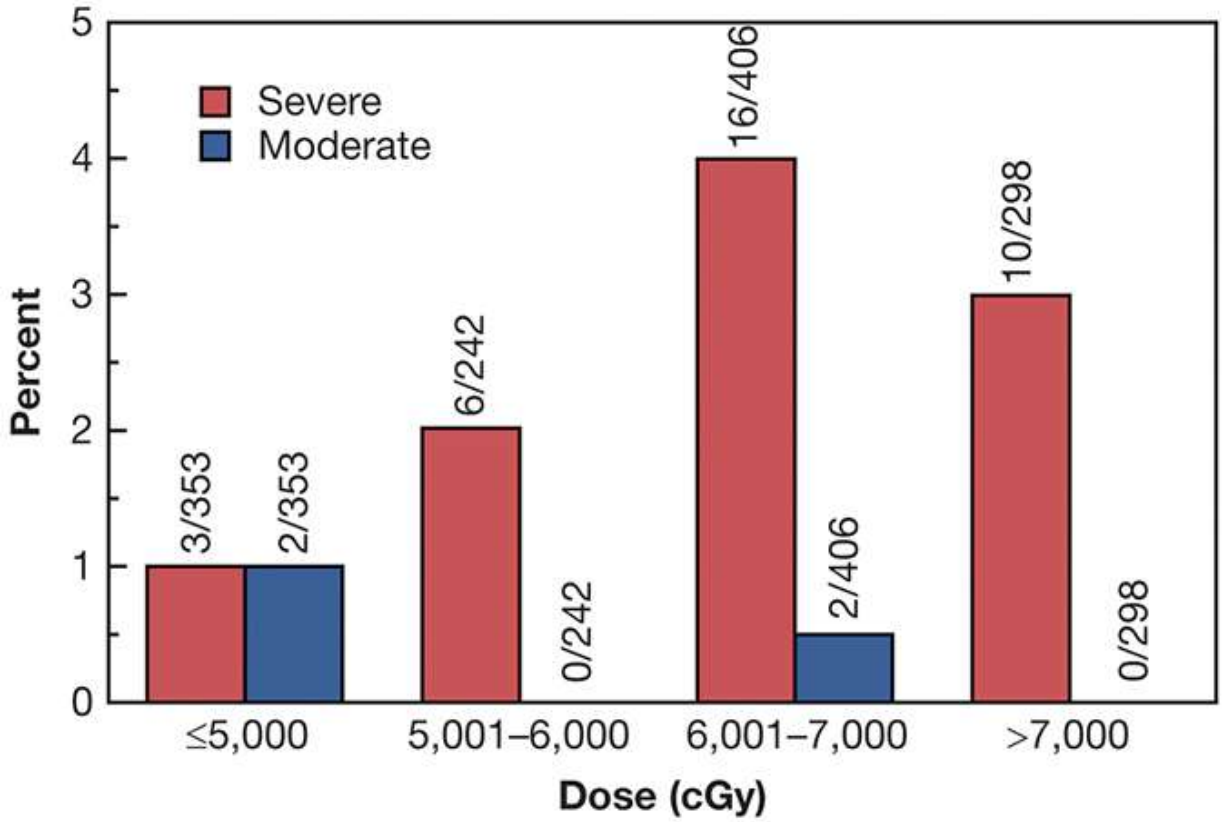

FIGURE 76.30 Incidence of moderate or severe complications in small intestine correlated with doses of irradiation.

Perez et al[399] quantitated the effect of total doses of irradiation, dose rate, and ratio of doses to bladder or rectum and point A on sequelae in 1,456 patients treated for cervical cancer with external beam irradiation plus two LDR intracavitary insertions to deliver 70 to 90 Gy to point A. Median follow-up was 11 years. In stage IB, the frequency of grade 2 morbidity was 9%, and in grade 3, it was 5%; in stages IIA, IIB, III, and IVA, the frequency of grade 2 morbidity was 10% to 12% and that of grade 3 was 10%. The most frequent grade 2 urinary/rectal sequelae were cystitis and proctitis (0.7%-3%). The most common grade 3 sequelae were vesicovaginal fistula (0.6%-2% in patients with stage I-III tumors), rectovaginal fistula (0.8%-3%), and intestinal obstruction (0.8%-4%). In the bladder, doses less than 80 Gy

correlated with a less than 3% incidence of morbidity, which was 5% with higher doses (P = .31). In the rectosigmoid, the incidence of significant morbidity was less than 4% with doses less than 75 Gy and increased to 9% with higher doses. For the small intestine, the incidence of morbidity was less than 1% with 50 Gy or less, 2% with 50 to 60 Gy, and 5% with higher doses to the lateral pelvic wall (P = .04). Multivariate analysis showed that dose to the rectal point was the only factor influencing rectosigmoid sequelae and dose to the bladder point affected bladder morbidity.

Mitchell et al[65] evaluated 398 patients with stage I to III cervical carcinomas treated with RT. Patients were divided into non-older (35-69 years of age; n = 338) and older (≥70 years of age; n = 60) groups. The frequency and severity of acute and chronic sequelae were equivalent in both groups.

The persistence of late substantial patient-reported symptoms was reported for the EMBRACE cohort.[400] Substantial symptoms were defined as whether the patient reported them as quite a bit or very much. Sufficient follow-up, meaning at least three late follow-up assessments, was available in 741 patients. This was evaluated in nine different symptoms, and across all symptoms, median persistence was 4.6%. Urinary frequency, neuropathy fatigue, insomnia, and menopausal symptoms persisted in more than 10%. Vomiting, rectal or vaginal bleeding, and urinary pain/burning were persistent in less than 1%. The occurrence of corresponding physician-assessed severe grade toxicity was apparent in only 12% of patients reporting persistent symptoms, highlighting that the sequelae of care in cervical cancer survivors can be underappreciated. Persistent symptoms were also shown to be associated with quality-of-life scores reductions, especially fatigue and pain with around 20% reductions.[401]

Gastrointestinal Toxicity

When late radiation proctitis occurs, initial treatment is the same as for acute proctitis. If the symptoms and rectal bleeding persist, laser treatment of rectal telangiectasia or ulcers is frequently beneficial. Argon plasma coagulation (APC) is the most common endoscopic method. It is a noncontact thermal method of hemostasis and thus considered to add increased safety.[402] Outpatient intrarectal application of formaldehyde 4% can also be used. If patients continue to bleed, another application 3 weeks later can be attempted. Patients are sedated, a local anesthetic block is administered, and a sponge

moistened with 4% formalin is applied for 4 minutes to each bleeding area of the rectum. Care is taken to protect the perianal skin from any caustic effects of the formalin. Complications such as burns or late stenosis of the deep layers of the rectum are extremely rare, and this technique is well tolerated. A randomized trial of APC and formalin in 30 patients did not show a significant advantage to either.[403]

Occasionally, a colostomy is necessary if conservative management fails. The importance of performing colonoscopy in patients with rectal bleeding to exclude other lesions in the colon, including polyps or cancer, is emphasized. If routine screening colonoscopy is not urgent, unless there is a medical reason, the colonoscopy may be postponed until 1 year after pelvic radiation to ensure no issues with poor wound healing, bleeding, or ulceration secondary to biopsy performed at the time of colonoscopy.

Anal incontinence is occasionally observed. This sequela must be assessed in light of a report by Nelson et al,[404] who, in a survey of 6,959 patients who were nonirradiated, identified 153 (2.2%) who reported anal incontinence, without specific etiology. Thirty percent of incontinent subjects were greater than 65 years of age, and 63% were women. Of those with anal incontinence, 36% were incontinent to solid feces, 54% to liquid feces, and 60% to gas.

Kim et al[405] investigated the effects of radiation on anorectal function using manometry in 24 patients with carcinoma of the uterine cervix who had late radiation proctitis. These data were compared with those from 24 age-matched nonirradiated female volunteers. Regardless of the severity of proctitis symptoms, 75% of patients who were irradiated exhibited abnormal manometric parameters for sensory or motor functions. Radiation damage to nerves and the external sphincter muscle was considered to be an important cause of motor dysfunction.

Perez et al[399] reported that the incidence and type of complications with interstitial therapy were approximately the same as in patients treated with intracavitary technique only. In contrast, Kasibhatla et al[406] noted 6% small-bowel obstruction in 36 women with gynecologic cancer treated with EBRT and interstitial BT, which was aggravated by previous abdominopelvic surgery. The 3-year risk of rectovaginal fistula was 18%, and it was significantly higher in patients who received total doses of greater than 76 Gy (100% vs 7%; $P = .009$).

An analysis of late GI toxicity in the EMBRACE cohort showed that in general, EBRT parameters are associated with late diarrhea and BT parameters affect rectal toxicity. Late diarrhea G1, 2, and 3 crude rates were 16%, 8.3%, and 1.5%, respectively. Patient-related risk factors were baseline diarrhea, smoking, and diabetes. Treatment-related risk factors were the prescribed elective dose (45 Gy vs 50 Gy), V_{43}, V_{57} (the nodal boost volume), and extended-field use.[401] These were also associated with other grade 3 and higher bowel toxicity.[407] Rectal toxicity was shown to be correlated to BT doses.[327] The equieffective D_{2cc} dose for a 10% probability of G2 and higher rectal toxicity was 69.5 Gy. Higher doses were associated with bleeding, proctitis, and fistula. A D_{2cc} over 75 Gy was associated with a 12.5% risk of fistula compared to 0% to 2.7% lower doses, and a D_{2cc} of less than 65 Gy is protective from proctitis. This corresponds with the soft (65 Gy) and hard (75 Gy) rectal constraints of BT planning. The 5-year actuarial incidence of severe bowel morbidity including 3 to 4 grade diarrhea, flatulence, and incontinence was 5.9% and any grade stenosis, stricture, and fistula was 2.6%.[408] Out of the 13 treatment-related deaths in the EMBRACE cohort, 8 were associated with GI morbidity.[356]

Willett et al[409] reported on 28 patients with inflammatory bowel disease (10 with Crohn disease, 18 with ulcerative colitis) who underwent external beam abdominal or pelvic irradiation. Patients were treated either by specialized techniques (16 patients) to minimize small- and large-bowel irradiation or by conventional approaches (12 patients). The overall incidence of severe toxicity was 46% (13/28 patients), and six patients (21%) experienced severe acute toxicity, necessitating cessation of RT. Late toxicity requiring hospitalization or surgical intervention was observed in 8 (29%) of 28 patients. For patients treated with conventional approaches, the 5-year actuarial rate of late toxicity was 73% versus 23% for patients treated by specialized techniques ($P = .02$). In patients with inflammatory bowel disease, abdominal or pelvic irradiation must be used judiciously.

In contrast, Song et al,[410] in a review of 24 patients with a history of inflammatory bowel disease who received RT (median dose of 45 Gy in 1.8-3 Gy fractions) to fields encompassing some portion of the GI tract, noted that 5 (21%) patients experienced acute intestinal toxicity of grade 3 or greater and 2 (8%) had grade 3 or higher late intestinal toxicity. Fifteen patients also

received concurrent chemotherapy. The authors believed that the GI toxicity in these patients was more modest than generally perceived.

Genitourinary Toxicity

Levenback et al[411] identified 116 (6.5%) of 1,784 patients with stage IB carcinoma of the cervix treated with irradiation in whom hemorrhagic cystitis developed, 23% grade 2 (repeated minor bleeding), and 18% grade 3 (hospitalization required for medical management). The median interval to onset of hematuria was 35.5 months. The risk of severe hematuria requiring surgical intervention was 1.4% at 10 years and 2.3% at 20 years. Minor episodes of hematuria are managed by antibiotic therapy. Cystoscopic, laser, or cautery treatment of bleeding points is indicated. Clot evacuation and continuous bladder irrigation are important elements in the acute management of patients with heavy bleeding. Occasionally, a urinary diversion is required for intractable severe hematuria.

Ureteral stricture at 20 years was observed in 2.5% of 1,784 patients with stage IB carcinoma of the cervix treated with irradiation (274 followed for up to ≥20 years).[412] The most common presenting symptoms were flank pain and urinary tract infection. In five patients, ureteral stricture was complicated by a vesicovaginal fistula. Seven of 43 patients who had no evidence of cancer and had hydroureter or hydronephrosis died of radiation complications. Treatment of ureteral stenosis may consist of stenting or resection of the fibrotic segment and reimplantation of the ureter with either ureteroneocystostomy or ureteroileocystostomy. In approximately half of the patients, diversion of urinary stream and ileal conduits is necessary. Occasionally, a nephrectomy is performed for removal of a nonfunctional kidney.

A pooled analysis from the EMBRACE studies, combining 1,860 patients, with a median follow-up of 34 [2-163] months, reported that 31 patients developed grade 3 to 4 ureteral stricture, amounting to a 5-year actuarial risk of 2.1%. Larger T3 to T4 tumors and hydronephrosis at diagnosis were risk factors.[413] Patients with gynecologic malignancies, including those receiving RT, are prone to the development of urinary tract infections. The most common organism isolated was *Escherichia coli*, followed by *Enterococcus* species. Appropriate urine bacterial studies and cultures are indicated in patients suspected of having superimposed urinary tract infection during the course of RT.

Parkin et al[414] reported a 26% incidence of severe urinary symptoms (urgency, incontinence, and frequency) in patients treated with irradiation alone for cervical carcinoma. They carried out urodynamic studies in 42 women and compared them with 28 women having urodynamic evaluations before and after treatment. There was no difference in the mean maximum flow rate or mean *residual* volume in the two groups. However, mean volume of full bladder sensation was significantly lower in the postirradiation group than in the pretreatment group, as was the mean maximum cystometric capacity. This same dysfunction may be noted in approximately 10% of the general female population, and the incidence increases in older women.

An analysis from the EMBRACE prospective cohort, which included 1,153 patients with median 48 [3-120] months of follow-up, reported a crude incidence of G2 and higher frequency of 13% and incontinence of 11%. Overweight and comorbidity were associated with both, older age with incontinence and IMRT use was protective for frequency. The ICRU bladder point was a stronger predictor of incontinence, with rates increasing from 11% in lower than 65 Gy to 20% in higher than 75 Gy.[415] Ureteroarterial fistula is a rare occurrence, and it is associated with a high mortality rate. When profuse urinary tract bleeding occurs in patients previously diagnosed with a gynecologic malignancy and treated with RT and extensive surgery, ureteroarterial fistula should be considered in the differential diagnoses.

Neurologic Toxicity

In the EMBRACE cohort, grade 3 to 4 neuropathy was rare, with six events amounting to a 5-year actuarial incidence of 0.6%.[356] This can be a result of both cisplatin exposure and direct pelvic radiation damage. Although extremely rare, lumbosacral plexopathy has been occasionally reported in patients treated for pelvic tumors with doses of 60 to 67.5 Gy. This syndrome was observed in 4 of 2,410 patients with cervical or endometrial carcinoma receiving 45 Gy to the PANs (without spinal cord shielding) or external pelvic irradiation (60 Gy to the parametria) and BT, with the lumbosacral plexus receiving total doses of 70 to 79 Gy.[416] Lower extremity paralysis secondary to lumbosacral plexopathy was also reported in standard doses.

Patients previously reported as having radiation myelopathy to the lumbar spine may have suffered a lumbar and sacral nerve plexopathy instead of or in addition to the spinal cord injury. The differential diagnosis of plexopathy

with recurrent tumors is sometimes difficult. Indolent leg weakness usually occurred early in radiation-induced plexopathy, whereas pain is most frequently associated with tumor plexopathy. Muscular weakness, numbness, and paresthesia are common in both situations. Electromyography may show abnormal myokymic discharges in radiation-induced plexopathy, whereas this finding was very unusual in tumor-induced plexopathy. CT is extremely helpful in the detection of pelvic masses or bone destruction caused by tumor. Although cystometrograms have demonstrated bladder atonicity in some cases, several authors have failed to observe bladder or rectal sphincter disturbances. Unfortunately, as in radiation myelopathy, the neurologic deficit is irreversible, and no effective therapy other than supportive care has been found.

Fatigue and insomnia are quite common as well in patients with cervical cancer. An analysis of the embrace cohort showed a grade 1/2 prevalence of fatigue, insomnia, and hot flushes at baseline (pretreatment) and at 3-year prevalence of 29%/6.2%, 18%/3.1%, and 7.9%/1.6% versus 29%/6.8%, 17%/4.4%, and 19%/5.9%. Rates of fatigue and insomnia were relatively stable in treatment and follow-up, and hot flushes increased after treatment. These symptoms were all observed more in younger, premenopausal patients, suggesting an association with ovarian failure.[417] Late persistent fatigue was also associated with the larger sizes volumes irradiated to intermediate and high EBRT and BT doses and other organ-related morbidity.[418]

Vaginal Toxicity and Sexual Function

Vaginal stenosis is a common toxicity of pelvic irradiation. An analysis from the EMBRACE cohort including 630 patients reported a 21% 2-year actuarial incidence for grade 2 and higher vaginal stenosis. Higher dose to the rectovaginal point with BT, higher than 45 Gy prescription dose, and tumor extension to the vagina were identified as risk factors. The risk for stenosis rose from 20% for 65 Gy to 34% at 85 Gy to the rectovaginal point.[329] Other reports found similar dose effects in other vaginal reference points and also identified age and tandem and ovoids applicator use as additional risk factors.[419]

Other clinically significant sequelae have been described. Vaginal length decreased in most patients at 24 months. This was correlated with increased

dyspareunia and with decreased frequency of sexual intercourse, desire, orgasm, and enjoyment of intercourse in 16% to 47% of patients.

Lammerink et al[420] published a systemic review of 20 studies on sexual functioning of cervical cancer survivors. Survivors had a higher rate of dyspareunia compared to controls, with pain during intercourse reported more frequently and for a longer duration of time in patients treated with RT.

An analysis of 1,045 patients with a median follow-up of 50 months from the EMBRACE cohort reported a sexual activity prevalence of 22% compared to 40% to 47% prior to treatment and on later follow-up. Vaginal issues reported were dryness, shortening, tightening, and painful intercourse in about one-fifth of patients and compromised enjoyment in 37% to 47%. Pain during intercourse was associated with tightening, shortening, dryness, and less sexual enjoyment. Regular hormonal replacement therapy (HRT) was significantly associated with less vaginal symptoms and trended to be associated to higher sexual enjoyment ($P = .062$).[421]

Regular vaginal dilation is widely recommended to maintain vaginal health and sexual functioning; however, the compliance rate with this recommendation is not consistent. In a study to test the effectiveness of an "information-motivation-behavior skills" model, the intervention improved the use of vaginal dilation after RT and decreased fear about sex after treatment.[422] There was no evidence that the experimental intervention improved global sexual health. Jensen et al[423] described persistent sexual dysfunction throughout 2 years after RT in 118 women; 85% had low or no sexual interest, 35% had lack of vaginal lubrication, and 55% had mild-to-severe dyspareunia. However, 63% of the sexually active patients before RT remained active, although with decreased frequency.

Radiation causes ovarian failure with a cessation of menses over a 6-month to 1-year period after treatment. Radiation also causes uterine fibrosis in a dose-dependent manner. The dose required for radical cervical cancer treatment causes sufficient uterine fibrosis that even if a woman were to become pregnant through embryo donation, the pregnancy terminates as a stillbirth because of insufficient uterine distensibility.

Bone Toxicity

Grigsby et al,[424] in 1,313 patients with gynecologic tumors treated with RT, identified 207 who received pelvic irradiation to the inguinal areas, including

the hips. Femoral neck fractures developed in 10 (4.8%) patients; 4 were bilateral. The cumulative actuarial incidence of fracture was 11% at 5 years and 15% at 10 years. Most of the fractures occurred in patients receiving 45 to 63 Gy, and although radiation dose could not be correlated with the occurrence of fracture, no fractures were noted in patients receiving less than 42 Gy. Cigarette smoking and osteoporosis were significant prognostic factors for increased risk of fracture.

A retrospective cohort study using SEER cancer registry data linked to Medicare claims data analyzed 6,428 women aged 65 years and above diagnosed with pelvic malignancies from 1986 through 1999 and compared the results for women who did (n = 2,855) with those who did not (n = 3,573) undergo RT.[425] Results demonstrated that women who underwent RT were more likely to have a pelvic fracture than women who did not undergo RT. The cumulative 5-year fracture rate was 8.2% versus 5.9% in women with cervical cancer; the difference was statistically significant, and most fractures (90%) were hip fractures. Concurrent chemoradiation may result in a higher risk than for patients treated with RT alone because the highest fracture rates were seen in patients with anal carcinoma treated with concurrent chemoradiation. A meta-analysis of 15 cohort studies including 3,633 patients reported a pooled estimate of pelvic insufficiency fractures of 14% [95% CI, 10-19], with higher incidence when using more advanced imaging, and with increasing age.[426]

Radiation-induced insufficiency fractures of the pelvis on MRI are characterized by edema on T1-weighted images. They may also be falsely diagnosed as metastases on PET-CT. In patients over 50 years old, a sacrum D50% reduced from 40 Gy to 35 Gy EQD2 reduced fracture risk from 45% to 22%.[427]

The most common complaint is persistent low back pain. The most common form of treatment is conservative management, followed by sacroplasty with polymethylmethacrylate. The vast majority have resolution of symptoms within less than 1 year with conservative therapy, including nonsteroidal anti-inflammatory medication and rest. However, they are associated with reduced life quality. Bye et al[428] assessed health-related quality of life (HRQoL) at 3 to 4 years after pelvic RT for carcinoma of the endometrium and cervix in 94 survivors, 79 (84%) of whom answered a survey. The treated women scored lower than the general population on role

functioning (81.5 vs 90.6; $P < .01$) and higher on diarrhea (23.8 vs 9.5; $P < .01$). Compared with pretreatment conditions, an increase in cases with pain in the lower back, hips, and thighs was seen and was associated with deterioration in HRQoL.

Toxicities Related to Brachytherapy

Descriptions of sequelae vary among institutions because toxicity grading scales are not uniform and the scoring system for complications is not clearly stated in all reports. Jhingran and Eifel,[429] in 4,043 patients with carcinoma of the cervix who had undergone 7,662 intracavitary procedures, observed 11 (0.3%) documented or suspected thromboembolisms, resulting in four deaths; the incidence of postimplant thromboembolism did not decrease significantly with the routine use of low-dose heparin prophylaxis. Other life-threatening perioperative complications included myocardial infarction (one death in five patients), cerebrovascular accident (two patients), congestive heart failure (three patients), and halothane liver toxicity (two deaths). Intraoperative complications included uterine perforation (2.8%) and vaginal laceration (0.3%), which occurred more frequently in patients aged 60 years or above ($P < .01$).

Acute GI side effects of pelvic irradiation include diarrhea, abdominal cramping, rectal discomfort, and, occasionally, rectal bleeding, which may be caused by transient enteroproctitis. Patients with hemorrhoids may experience discomfort earlier than other patients. Diarrhea and abdominal cramping can be controlled with the oral administration of diphenoxylate hydrochloride, with loperamide, atropine sulfate, or opium preparations or emollients such as kaolin and pectin. Proctitis and rectal discomfort can be alleviated by small enemas with hydrocortisone and anti-inflammatory suppositories containing bismuth, benzyl benzoate, zinc oxide, or Peruvian balsam. Some suppositories contain cortisone. Small enemas with cod liver oil are also effective. A low-residue diet with no grease or spices and increased fiber in the stool (psyllium, polycarbophil) usually help to decrease GI symptoms.

GU symptoms secondary to cystourethritis are dysuria, frequency, and nocturia. The urine is usually clear, although there may be microscopic or even gross hematuria. Methenamine mandelate and antispasmodics such as phenazopyridine hydrochloride or a smooth muscle antispasmodic such as flavoxate hydrochloride, hyoscyamine sulfate, oxybutynin chloride, or

tolterodine tartrate can relieve symptoms. Fluid intake should be at least 2,000 to 2,500 mL daily. Urinary tract infections may occur; diagnosis should be established with appropriate urine culture studies, including sensitivity to sulfonamides and antibiotics. Therapy should be promptly instituted.

Erythema and dry or moist desquamation may develop in the perineum or intergluteal fold. Proper skin hygiene and topical application of petroleum jelly, petrolatum, or lanolin should relieve these symptoms. U.S.P. zinc oxide ointment and intensive skin care may be needed for severe cases.

Management of acute radiation vaginitis includes douching every day or at least three times weekly with a 1:5 mixture of hydrogen peroxide and water. Douching should be continued on a weekly basis until the mucositis has resolved or for 2 or 3 months as necessary. Superficial ulceration of the vagina responds to topical (intravaginal) estrogen creams, which stimulate epithelial regeneration within 3 months after irradiation. The use of vaginal dilators several times daily, started during the course of treatment, prevents vaginal stenosis. Psychoeducational intervention and motivation improve the compliance in use of dilators. More severe necrosis may require debridement on a weekly basis until healing takes place. Judicious use of biopsies is recommended to rule out persistent or recurrent cancer.

Petereit et al[430] reported 16 acute events (9.5%) in 169 patients treated with HDR BT (128 with cervical cancer also receiving external irradiation and 41 medically inoperable endometrial carcinomas). The overall 30-day morbidity rate for the patients with cervical cancer was 5.5%, and the 30-day mortality rate was 1.6% (two patients; one died of pulmonary edema 12 days after first HDR insertion, and the other had enteritis and died in a nursing home).

Spontaneous intraperitoneal rupture of the urinary bladder, an extremely rare event, was reported by Fujikawa et al[431] after RT for cervical cancer in 6 of 148 patients treated with HDR intracavitary BT combined with EBRT. All six patients underwent laparotomy and repair of the perforation; however, re-rupture of the bladder occurred in three of these patients.

Hyperbaric Oxygen

Exposure of tissues harmed by radiation to hyperbaric oxygen therapy (HBOT) was shown to decrease symptoms, including in the settings of cystitis, proctitis, and soft tissue necrosis and osteonecrosis, and also reduce complication of surgical debridement.[432] HBOT entails exposure to oxygen at

2 to 2.5 atm in daily sessions of 45 to 120 minutes for 2 to 6 weeks for a total of 10 to 40 sessions. HBOT is thought to promote wound healing by temporary increasing oxygenation of tissues that had their vascular beds damaged as a result of radiation exposure. It is better to use it early when a toxicity occurs but preferably after disease remission is verified, though it is important to note that a comprehensive review of clinical and animal studies found no evidence to support HBOT has cancer growth-promoting effects.[433] The HORTIS study was a multicenter, double-blind, crossover study in 120 patients with chronic radiation proctitis. A subjective symptoms score and clinical response assessment were shown to be significantly improved in the HBOT group after 30 sessions compared to the sham group, and after crossover symptoms were reduced also in the control group, and the differences became nonsignificant.[434]

Hormonal Replacement After Treatment of Cervical Cancer

After pelvic irradiation or bilateral salpingo-oophorectomy, usually carried out with an RH in patients treated for carcinoma of the uterine cervix, symptoms of menopause may occur. They can be treated with replacement hormones, although some gynecologists have expressed reservations. HRT has been shown to reduce the risk of cardiovascular diseases, osteoporotic fractures, and colon carcinoma. In addition, better vaginal health and sexual function are associated with their use.[421] On the other hand, there is a significant increase in the risk in breast cancer with prolonged use of estrogen plus progesterone for greater than 5 years. Consideration may be given to progesterone alone, which does not increase the risk of endometrial cancer but has potential thromboembolic risks.[435]

Patients with SCCs of the cervix, vulva, and vagina are unlikely to be influenced by HRT. In a study of women aged 50 years or below with ovarian cancer, estrogen replacement therapy did not have a negative influence on DFS. Long-term HRT in women treated for a gynecologic cancer must be based on the medical history of and discussion of risk with the individual patient.[436]

Second Malignancy

The risk for induction of secondary primary cancers by pelvic irradiation is low, and many potential confounders either are unknown or may not be fully

accounted for, given the available information. Using the population-based cancer registries of Denmark, Finland, Norway, Sweden, and the United States, Chaturvedi et al[437] found a significantly increased cancer risk in both SCC and AC survivors, with standardized incidence ratio of 1.31 (95% CI = 1.29-1.34) and 1.29 (95% CI = 1.22-1.38), respectively. The risk of smoking-related lung cancer was higher in the SCC than in the AC population, whereas second malignancies of the colon, soft tissue, melanoma, and non-Hodgkin lymphoma were higher in the AC population. Similarly, 1-year survivors of cervical cancer had an increased risk of HPV-related cancers, including pharynx, genital, and anal cancers. Higher HRs for second cancer of the rectum, anus, bladder, and genital sites was seen for younger patients, with a 40-year cumulative risk of any second cancer of 22% for women diagnosed with cervical cancer before age 50 years versus 16% for those diagnosed at age greater than 50 years.

Wu et al[379] performed a SEER database study finding 23,112 patients with cervical cancer, 64% of whom were treated with RT. Second malignancies were diagnosed in 2,545 (11%) patients. After adjusting for age and using propensity score matching, RT was associated with significantly increased risk for cancer of the colon, rectum and anus (HR 1.43), lung and bronchus (HR 1.41), urinary bladder (HR 2.18), ovary (HR 2.79), and corpus uteri (HR 3.71). The risk of breast cancer was significantly decreased (HR 0.67).

In an analysis of 199,268 individuals by Wright et al,[438] the risk of secondary leukemia increased 72% in patients who received pelvic RT, with a peak at 5 to 10 years after treatment; there was no increased risk of multiple myeloma.

Second uterine corpus cancers are more likely to be with more aggressive histology.[439] Mark et al[440] identified 13 of 114 patients diagnosed with uterine sarcoma who had a prior history of pelvic irradiation (doses of 40-80 Gy). Criteria for radiation-induced sarcomas included a prior history of pelvic irradiation, a latent period of several years, development of sarcoma within previously irradiated field, and histologic confirmation of malignancy. Histologic types of tumors were mixed Müllerian in six, leiomyosarcoma in four patients, endometrial stroma sarcoma in one, fibrosarcoma in one, and angiosarcoma in one. Sarcoma developed in the uterus in 12 patients and at the vaginal cuff in one patient. Ten patients were treated with surgery and two with RT. The 5-year DFS rate after salvage therapy was 17%.

In a theoretical analysis of IMRT risk in postoperative cases relative to 3D conformal RT, the estimated increase in second cancer risk was 6% for 6-MV IMRT and 26% for 18-MV IMRT, with large increases in organs away from the primary beam and skin because with IMRT a much larger volume of skin was exposed.[441]

CHAPTER 77

Endometrial Cancer

Benjamin W. Fischer-Valuck and Yuan James Rao

ANATOMY

The uterus is a hollow, muscular organ located in the true pelvis positioned dorsocranially between the bladder and the rectum. The average adult uterus is about 8 cm long, 5 cm wide, and 2.5 cm thick. It is divided into the fundus, body (corpus), and cervix. The junction between the body and the cervix is called the isthmus. The fundus is pierced at each cornu by the fallopian tubes. The uterine surface is partially covered by the peritoneum. The uterine cavity is lined by endometrium, made up of columnar cells forming many tubular glands. The thickness of the endometrium varies during the menstrual cycle, but by the end of menstruation, it should be 2 to 3 mm in thickness. The wall of the uterus is composed of myometrium, consisting of smooth muscle fibers. The major supports of the uterus are the broad, round, uterosacral, and cardinal ligaments. The major blood supply to the uterus is the uterine artery, which enters the uterus at the isthmus after it crosses over the ureter. The lymphatic drainage for the body of the uterus is mainly to the obturator and internal and external iliac lymph nodes. The lymphatics from the fundus accompany the ovarian artery and drain into the para-aortic lymph nodes.

EPIDEMIOLOGY AND RISK FACTORS

Endometrial cancer is the most common gynecologic cancer and the fourth most frequently diagnosed cancer in women in the United States. According to 2024 cancer statistics, the estimated number of newly diagnosed cases is 67,880,[1] with a probability of 1 in every 35 women (2.8%) developing it during her lifetime.[2] Although it is a cancer that affects predominantly postmenopausal women, 14% are diagnosed in premenopausal women, with 5% being younger than 40 years.[3] The expected number of deaths from

endometrial cancer in 2024 is 13,250, making it the fifth leading cause of death from cancer in women.[1] Recent estimates on the death rate from endometrial cancer seemed to indicate that the rate is on the rise, by about 2% per year.[2] In fact, uterine cancer is the only cancer for which survival has decreased over the past four decades in the United States.[1]

The incidence of endometrial cancer is higher in more developed areas of the world (5.5%) compared to less developed countries (4.2%), indicating a possible influence of environmental factors on the incidence of this disease.[4] The exact etiology of endometrial cancer remains unknown, but several risk factors have been associated with it, chiefly unopposed estrogen. It is well established that endometrial cancer risk is increased among women who have high circulating levels of bioavailable estrogens and low levels of progesterone so that the mitogenic effect of estrogens is insufficiently counterbalanced by the opposing effect of progesterone.[5] The source of unopposed estrogen could be endogenous or exogenous. Regarding endogenous estrogen,[6] in a nested case-control study of 93,676 postmenopausal women, parent estrogens (estrone and estradiol) were positively related to endometrial cancer risk, with the highest risk observed for unconjugated estradiol (odds ratio [OR] fifth vs first quintile = 6.19; 95% confidence interval [CI], 2.95-13.03, *P* trend = .0001). The association with unconjugated estradiol was stronger for type I than type II tumors (Phet = 0.01). Lifetime cumulative number of menstrual cycles, that is, menstruation span, is associated with an increased risk of developing endometrial cancer. This is due to the fact that endometrial cell proliferation increases during the follicular phase, which is the longest in the menstrual cycle. Thus, *early age at menarche* (estimated relative risk [RR], 1.5-2) and *late age at menopause* (RR, 2-3), examples of increased menstruation span, are risk factors for endometrial cancer.[7] *Nulliparity* (RR, 3) is also associated with an increased risk of endometrial cancer[7] due, in part, to anovulatory menstrual cycles. *Obesity* is a significant risk factor for endometrial cancer, with an estimation that 38.4% of endometrial cancer worldwide could be attributed to high body mass index (BMI).[8] The increase in endometrial cancer risk is mainly through changes in endogenous hormone metabolism. After menopause, when ovarian production of both estrogen and progesterone ceases, the major source of estrogen is via peripheral conversion, mostly within adipose tissue, of

androgens that continue being produced by the adrenal glands and ovaries. Thus, with obesity, there is an increase in the amount of bioavailable estrogens in the circulation and the endometrial tissue.[5] Obesity may also influence endometrial cancer risk via chronic hyperinsulinemia, which appears to be a key factor for the development of ovarian hyperandrogenism, associated with anovulation and progesterone deficiency, especially for premenopausal women.[9] *Non–insulin-dependent diabetes mellitus* and *hypertension* (RR, 1-3) also increase the risk of endometrial cancer. This is often believed to be secondary to obesity, but there are data showing that these risk factors could be independent of obesity.[10] With regard to exogenous estrogen, it is well established that the use of *estrogen-only hormone replacement therapy* and *sequential oral contraceptives* greatly increases endometrial cancer risk, whereas combined preparations, that is, those that contain a progestogen as well as estrogen throughout the treatment period, have a protective effect (RR, 0.3-0.5).[11,12] The use of *tamoxifen* in patients with breast cancer has been associated with an increased risk of endometrial cancer. The mechanism of action of tamoxifen is in competition with that of endogenous estrogen for estrogen receptors. In premenopausal women, tamoxifen has an antiestrogenic effect, but in postmenopausal women, it has a weak estrogenic effect because of the upregulation of estrogen receptors. In a meta-analysis on adjuvant tamoxifen and endometrial cancer, for patients who were younger than 55 years of age, there was little absolute risk compared to patients aged 55 to 69 years, for whom the 15-year incidence was 3.8% in the tamoxifen group versus 1.1% in the control group (absolute increase 2.6% [standard error 0.6], 95% CI = 1.4-3.8), highlighting the influence of age and the length of its use on the risk of endometrial cancer from tamoxifen use.[13,14] Initial data seemed to indicate that the majority of endometrial cancers associated with tamoxifen use were of early stage with favorable features.[15] More recent data, however, show a change in the profile of these endometrial cancers, with a rise in the rate of serous, clear cell, carcinosarcoma, and sarcoma types.[16] It appears that most endometrial carcinomas arise as a result of a sequence of somatic DNA mutations, possibly including PTEN, mismatch repair (MMR) genes, and TP53 mutations.[17] A large proportion of cases also may progress through a premalignant phase of intraepithelial endometrial neoplasia, such as hyperplasia with atypia.[18] TP53 mutation appears to be

particularly important in serous endometrial cancer and is a marker of poor prognosis.[19] Approximately 30% of uterine serous carcinomas also overexpress HER2.[20] Inherited genetic predisposition, especially in the setting of hereditary nonpolyposis colorectal cancer (HNPCC), probably accounts for less than 5% of all endometrial cancer cases. Mutations in one of the four MMR genes *hMLH1, hMSH2, hMSH6*, and *hPMS2* have been identified in patients with Lynch syndrome. Lynch syndrome is found in approximately 3% of women with endometrial cancers and in 10% of those with tumors found to have mismatch repair deficiency (MMRd).[21] Although HNPCC is thought of primarily in terms of the risk of developing colorectal cancer, it is important to note that lifetime cumulative risk of endometrial cancer for women with HNPCC is 40% to 60%, which equals or exceeds their risk of colorectal cancer.[22] There seems to be a high rate of lower uterine segment involvement (LUSI) in patients with HNPCC-associated endometrial cancer.[23]

CLINICAL PRESENTATION AND NATURAL HISTORY

The most common presentation for endometrial cancer is postmenopausal vaginal bleeding, which is reported by 80% to 90% of patients. The incidence of endometrial cancer in women presenting with postmenopausal bleeding is only 10% to 15%. This incidence, however, could range from 1% up to 25%, depending on patient age and the presence of other risk factors. In a report of a total of 3,548 women presenting with postmenopausal vaginal bleeding, 201 (6%) had a diagnosis of endometrial carcinoma. The use of a multiple logistic regression model showed that recurrent episodes of bleeding (OR, 3.64), a history of diabetes (OR, 1.48), older age (1.06), and high BMI (OR, 1.07) increased the risk of endometrial malignancy when corrected for other characteristics.[24] Other patterns of presentations include vaginal discharge, abnormal Papanicolaou test, or thickened endometrium on routine transvaginal ultrasound. For patients with advanced disease, they may present with urinary or rectal bleeding, constipation, pain, lower extremity lymphedema, abdominal distension due to ascites, and cough and/or hemoptysis.

The International Federation of Gynecology and Obstetrics (FIGO) annual report[25] showed that the 5-year survival rate for 8,110 patients with

endometrial cancer treated between 1999 and 2001 was 80%. Such an excellent outcome is a reflection of the fact that the majority of patients are diagnosed with early-stage disease. The tumor was limited to the corpus uteri in 71% of cases, involved the cervix in 12%, and extended beyond the uterus, but short of distant spread in 13%. For patients with disease limited to the endometrium or with less than 50% myometrial invasion, the 5-year survival rate was 91%. However, the rate dropped to 66% when the disease extended to adnexa/serosa/positive peritoneal cytology, to 57% with regional lymph node involvement, to 25.5% with bladder or rectal involvement, and to 20% with distant spread. For clinically staged patients, the 5-year survival rate ranged from 67% for early-stage disease down to 15% for advanced disease. Mass screening for endometrial cancer in women at average risk or increased risk due to a history of unopposed estrogen therapy, tamoxifen therapy, late menopause, nulliparity, infertility or failure to ovulate, obesity, diabetes, or hypertension is not recommended. The American Cancer Society (ACS) recommends that women at average and increased risk should be informed about risks and symptoms (in particular, unexpected bleeding and spotting) of endometrial cancer at the onset of menopause and should be strongly encouraged to immediately report these symptoms to their physician. However, screening has been recommended by the ACS for women who carry, or are related to carriers of, the HNPCC mutation, starting at age 35 years, including annual transvaginal ultrasound and endometrial biopsy.[26] Prophylactic hysterectomy and bilateral salpingo-oophorectomy (BSO) once childbearing is completed have been shown to effectively reduce the risk of endometrial cancer in patients with HNPCC and should be strongly considered.[27]

DIAGNOSTIC WORKUP

Endometrial tissue sampling remains the gold standard by which the diagnosis of endometrial cancer is established. This is achieved via biopsy or dilation and curettage (D&C). *Endometrial biopsy*, which can be easily performed in the office with a Pipelle or similar device, is the preferred approach. Its sensitivity in detecting endometrial cancer in postmenopausal women is 99.6% compared to 91% in premenopausal women. Its specificity

is more than 98% for both groups.[28] If the patient is undergoing hysterectomy, routine D&C is not necessary after an office Pipelle sampling has documented malignancy. However, if symptoms persist, the office sampling is inadequate, or the patient is being considered for conservative fertility-sparing approaches, a D&C should be performed. In addition, D&C provides more reliable assessments of final pathologic findings in hysterectomy specimens, mainly with regard to tumor grade.[29] Given that the incidence of endometrial cancer in women with postmenopausal bleeding is only 10% to 15%, it is unclear how feasible it is to perform endometrial sampling on every patient. *Transvaginal ultrasonography* (TVU) may be considered a useful tool to assess patient's vaginal bleeding. Normal endometrium looks thin and homogeneously hyperechoic, but it is thickened and heterogeneous, with hyperplasia, polyps, and cancer[30] as shown in Figure 77.1. The consensus statement from the Society of Radiologists in Ultrasound defines an endometrial thickness of 5 mm or greater as being abnormal.[31] If the thickness of the endometrium is less than 5 mm, the risk of endometrial cancer is minimal; the false-negative rate is about 4%. If the TVU is abnormal but the biopsy is negative/nondiagnostic or the uterine cavity is inaccessible, then *saline infusion sonography* or *hysteroscopy*[32,33] should be considered to help exclude intracavitary lesions, especially polyps that might contain cancer. In addition, these methods are also helpful in premenopausal women, for whom the accuracy of TVU is limited because the endometrial thickness fluctuates, depending on the level of female hormones. The potential downside to saline infusion or hysteroscopy is that there have been reports that the insufflation of the distending medium into the canal has been associated with an increase in positive peritoneal cytology, although the prognostic implications are unclear of such positive cytology "induced" by sampling.[34] Several imaging studies are available to define the extent of disease preoperatively.[35] Good-quality pelvic *computed tomography* (CT) scans obtained with oral and intravenous contrast can demonstrate the extent of the endometrial tumor. The endometrial carcinoma is a hypodense mass relative to the normal myometrium and may be seen as a diffuse, circumscribed vegetative or polypoidal mass within the uterine cavity. CT is helpful in assessing regional and distant metastasis. *Magnetic resonance imaging* (MRI) is considered the most accurate imaging study to assess tumor extension in

endometrial cancer, especially myometrial invasion.[36,37] Dynamic contrast-enhanced and diffusion-weighted MRI are equivalent in detecting deep myometrial invasion.[38] A clear junctional zone or preservation of a sharp delineation between the tumor and the myometrium implies disease limited to the endometrium. Disease characterized by disruption of the junctional zone, increased signal intensity tumor in the inner half of the myometrium with preservation of the outer myometrium, or both correlates with superficial myometrial invasion. If there is extension of the high-signal intensity tumor into the outer myometrium with preservation of a peripheral rim of normal, intact myometrium, then that is considered deep myometrial invasion (Figure 77.2). MRI also helps to delineate tumor extension into the cervix. The normal cervical stroma is hypointense on T2-weighted images and is replaced by intermediate-signal intensity tumor in cases of invasion.[39] The reported sensitivity of MRI in detecting lymph node metastasis is on average 43.5% and the specificity is 95.9%.[37] *Positron emission tomography (PET)/CT* is also being used in endometrial cancer.[40] There seems to be little benefit in assessing the primary tumor extension. With regard to regional lymph node metastasis, the reported sensitivity is 72% and the specificity is 94%. The main advantage of PET-CT over other imaging modalities is its accuracy in detecting distant metastasis.[39] The FIGO staging for endometrial cancer is a surgical staging, and thus, preoperative imaging studies (except chest x-rays) are not part of the staging but are often acquired to assist in treatment planning; especially when nodal or distant metastatic disease is suspected. *Cancer antigen 125* (CA-125) serum levels could be elevated in patients with endometrial cancer. Kim et al[41] in a review of 413 patients found that 23.9% of patients had greater than 35 U/mL serum CA-125 levels. Hsieh et al[42] found that preoperative levels of greater than 40 U/mL correlated significantly with regional lymph node metastasis and suggested that such levels could be used as an indication for full-pelvic and para-aortic lymphadenectomy at the time of surgical staging in the absence of metastatic disease.

Pathologic Classification

Endometrial Hyperplasia

The diagnostic criterion for hyperplasia is an increase in the number and size of proliferating glands. The International Society of Gynecologic Pathologists standardized the subclassification of endometrial hyperplasia. In simple hyperplasia, there is only glandular proliferation and enlargement with increased stromal cellularity. This rarely progresses to carcinoma

(<1%). Complex hyperplasia is characterized by back-to-back proliferation of glands with intraluminal papillae, epithelial pseudostratification, and few mitotic figures. If there is no cytologic atypia, the risk of malignant degeneration is again quite low, on the order of 3%. Any proliferation demonstrating cytologic abnormalities (in cellular or nuclear morphology) is classified as atypical hyperplasia. Atypical hyperplasia has a much higher risk of progression to an invasive carcinoma—8% for simple atypical hyperplasia, increasing to 29% for complex hyperplasia associated with atypia.[18] The Gynecologic Oncology Group (GOG) conducted a prospective trial in which all patients with atypical hyperplasia of the uterus underwent an immediate hysterectomy. The rate of underlying concurrent carcinoma in the uterus was 42.6% in these patients.[43] The standard recommended treatment for atypical hyperplasia of the uterus is hysterectomy if childbearing is complete and the patient has no other contraindications to surgery. In patients who desire future fertility or have an absolute contraindication to surgery, progestational therapies may be used with caution.[44]

Carcinoma of the Endometrium

Endometrioid Carcinoma

Endometrioid adenocarcinoma is the most common endometrial carcinoma, constituting 75% to 80% of all cases (Table 77.1). The classic histologic appearance is that of marked glandular proliferation with back-to-back proliferation of glands and little intervening stroma (Figure 77.3A). The name endometrioid is derived from resemblance to proliferative-phase endometrium. Architectural grading is determined by the amount of solid mass of tumor cells compared to well-defined glands. Grade 1 is an endometrioid cancer in which less than 5% of the tumor growth is in solid sheets. Grade 2 is an adenocarcinoma in which 6% to 50% of the tumor is composed of solid sheets of cells. Grade 3 occurs when more than 50% of the tumor is made up of solid sheets. Nuclear grading is determined by the nuclear shape, size, chromatin distribution, and size of the nucleoli. The grading is primarily driven by the architectural grading, but if there is marked nuclear atypia in an otherwise grade 2 architectural grading, it should be increased to grade 3. Within endometrioid adenocarcinoma, the

subtypes are endometrioid carcinoma not otherwise specified (NOS), endometrioid carcinoma with squamous differentiation, villoglandular endometrioid carcinoma, secretory carcinoma, and a ciliated cell variant.[45] Most of the endometrioid adenocarcinomas are designated NOS. Foci of squamous differentiation are often found with endometrioid adenocarcinoma. The squamous component could be benign, with the designation of adenoacanthoma, or malignant, in which case it is called adenosquamous carcinoma. Such designations have not been very useful, however, because the degree of differentiation of the squamous component parallels that of the glandular architectural grading. Therefore, most gynecologic pathologists use the term *adenocarcinoma with squamous differentiation*. Other subtypes of endometrioid adenocarcinoma include the relatively common *villoglandular carcinoma*, which grows in a papillary manner. The prognosis of this subtype is similar to that of low-grade endometrioid cancer, and it must not be confused with serous carcinoma because of its papillary features. *Secretory carcinoma*, which represents less than 2% of all endometrial carcinomas, is characterized by a very well-differentiated glandular pattern with much intracellular glycogen, thus resembling early secretory endometrium. Although the cells have clear cytoplasm, their histologic and cytologic features are different from those of clear cell carcinoma. *Ciliated carcinoma* is a very rare subtype, characterized by the presence of ciliated cells comprising more than 75% of the tumor specimen. It is usually associated with a history of prior estrogen use, and the prognosis is quite good, because most are well differentiated.

TABLE 77.1 PATHOLOGIC CLASSIFICATION OF ENDOMETRIAL CANCERS

Endometrioid adenocarcinoma
Not otherwise specified
Villoglandular
Secretory adenocarcinoma
Ciliated carcinoma
Adenocarcinoma with squamous differentiation
Uterine papillary serous
Clear cell carcinoma
Mucinous carcinoma
Squamous cell carcinoma
Transitional cell carcinoma

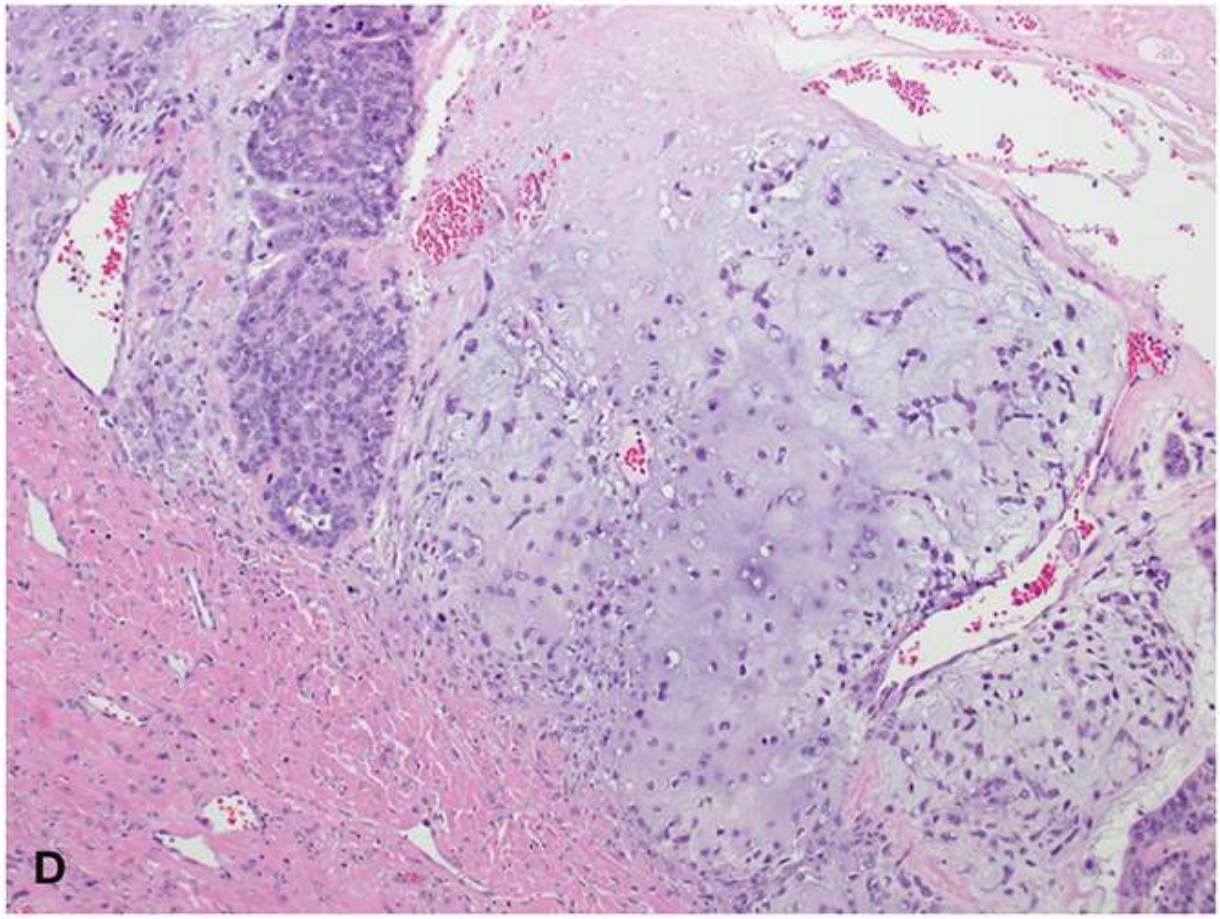

FIGURE 77.3 Different histologic types of endometrial cancer. **A.** Endometrioid. **B.** Papillary serous. **C.** Clear cell. **D.** Carcinosarcoma (heterologous; chondrosarcoma).

Mucinous Carcinoma

This designation requires more than 50% of the tumor cells to be mucinous. These cells are carcinoembryonic antigen positive and are laden with mucin, which stains positively with mucicarmine and periodic acid–Schiff stains but is diastase resistant. Because of the resemblance to endocervical adenocarcinoma, it is essential to exclude it by endocervical curettage. Mucinous carcinomas are usually well differentiated and have the same prognosis as ordinary endometrioid carcinomas.

Serous Carcinoma

Serous carcinomas, also known as papillary serous cancers, resemble ovary cancer in terms of histology and to some extent in terms of behavior. The mere presence of papillary structure is not diagnostic because other

histologic types may have papilla as well. However, the presence of marked cellular atypia in addition to papilla distinguishes serous carcinoma from others (Figure 77.3B). Psammoma bodies are found in up to 33% of cases. The incidence of serous endometrial cancer is about 11.4% that of endometrial carcinomas.[46] This is an aggressive subtype, with a high propensity for early lymphatic and intraperitoneal dissemination, often despite little myometrial penetration. In the FIGO annual report, the 5-year survival rate was 52.6% compared to 83.2% for endometrioid carcinoma.[25]

Clear Cell Carcinoma

Clear cell carcinoma of the endometrium resembles renal carcinoma, but its origin from Müllerian structures is now well established. Unlike vaginal and cervical clear cell carcinoma, it is not related to intrauterine diethylstilbestrol exposure. The microscopic structure may vary from solid patterns to glandular differentiation (Figure 77.3C). In the latter pattern, small cells resembling "hobnail" cells line spaces and glands. These are cells that extruded their cytoplasm, leaving bare nuclei that protrude into the glandular lumens. The rate of clear cell carcinoma is about 3.5% of endometrial carcinomas.[46] The prognosis of this cancer is in between that of endometrioid and serous cancer.[47] In the FIGO annual report, the 5-year survival rate was 62.5% compared to 83.2% for endometrioid carcinoma and 52.6% for serous carcinoma.[25]

Squamous Carcinoma

This type of cancer is extremely rare, and the diagnosis has to be made after the exclusion of cervical origin. The 5-year survival rate based on the FIGO report is 68.9% overall, but the prognosis is poor for patients with extrauterine disease or distant spread.[25]

Undifferentiated Carcinoma

The World Health Organization (WHO) classification system for endometrial cancer describes undifferentiated carcinomas as a rare subtype with distinct histologic features. Undifferentiated carcinomas are characterized by the absence of histologic differentiation into specific cell types, such as glandular or squamous differentiation, seen in other subtypes

of endometrial cancer. These tumors typically exhibit sheets or nests of highly pleomorphic cells with marked nuclear atypia and frequent mitotic activity.[48]

Undifferentiated carcinomas of the endometrium are considered aggressive tumors associated with a poorer prognosis compared to well-differentiated subtypes. They may be further classified based on their immunophenotypic characteristics, such as expression of certain markers like p16, p53, and MMR proteins.[48]

It is important to note that undifferentiated carcinomas are rare among endometrial cancers, comprising a small proportion of cases. Their diagnosis and management require careful histopathologic evaluation and consideration of immunohistochemical markers to distinguish them from other high-grade tumors. Some of these tumors may belong to the spectrum of gynecologic neoplasms seen in the setting of microsatellite instability and possibly Lynch syndrome.[48]

Mixed Histology

Mixed cell–type endometrial cancer composed of two or more pure types was observed in 4.5% of patients in the GOG 210 study.[46] By convention, in order to be designated as mixed, the other cell-type component has to comprise at least 10% of the tumor. Except for mixed endometrioid and serous or clear cell carcinoma, the clinical significance of mixed cell type is questionable.

Simultaneous Tumors

Occasionally identical tumor type, mainly endometrioid histology, can be discovered in the ovary and endometrium. Usually, the site of the largest tumor is assigned the primary origin, but at times, true primary endometrial and ovarian malignancies may coexist.[49] If the endometrial tumor is less than 5 cm in diameter, well differentiated, with no vascular invasion, limited to less than the middle one-third of the myometrium, and the ovarian lesions are bilateral, it is more likely that there are two concomitant primary tumors. Genetic profiling may represent a powerful tool in clinical practice for distinguishing between metastatic and dual primaries in patients

with simultaneous ovarian/endometrial cancer and for predicting disease outcome.[50]

Molecular Biology

Classically, there have been considered to be two distinct types of endometrial cancer.[51,52] In type I endometrial cancer typically considered to include tumors with endometrioid histology and grade 1 or 2, which accounts for approximately 90% of endometrial cancers, there is strong correlation with prior estrogen stimulation. The cancers in this category are often indolent in nature, with minimal myometrial invasion and low-grade histology. They affect premenopausal and perimenopausal women. Type II endometrial cancer, in contrast, is considered to include grade 3 endometrioid carcinoma or other aggressive histologies, such as serous or clear cell. It often affects postmenopausal women with no prior history of estrogen stimulation. These tumors often have deep invasion, and at a more advanced stage at the time of presentation.[3] What is intriguing is the fact that at the molecular level, the existence of two distinct types of endometrial cancer seems to be validated.[53] The most frequently altered molecular pathway in type I endometrial carcinomas is the PI3 K/PTEN/AKT pathway, which is dysregulated by oncogenic mutations, PTEN loss of function, and/or overexpression of upstream tyrosine kinase growth factor receptors, leading to uncontrolled cell proliferation and survival. On the other hand, the main pathway alterations in type II endometrial cancers involve the tumor suppressors p53.

The findings from The Cancer Genome Atlas (TCGA) have revolutionized our understanding of endometrial cancer.[54] In that study, the genomic landscape of endometrioid and serous carcinoma histologies was evaluated (Figure 77.4). Most endometrioid tumors had frequent mutations in PTEN, CTNNB1, PIK3CA, ARID1A, and KRAS; novel mutations in the SWI/SNF chromatin remodeling complex gene *ARID5B*; and few copy number alterations or TP53 mutations. Uterine serous tumors and about 25% of high-grade endometrioid tumors (serous-like) had frequent TP53 mutations and extensive copy number alterations, but few DNA methylation changes, and low estrogen receptor/progesterone receptor levels. A subset of endometrioid tumors (about 10%) that was identified had a markedly

increased mutation frequency and newly identified hot spot mutations in the exonuclease domain of DNA polymerase epsilon (*POLE*). Based on these results, endometrial cancers can be classified into four categories: POLE ultramutated, microsatellite instability hypermutated, copy number low, and copy number high. The somatic copy number alteration (SCNA) analysis showed that most endometrioid tumors have few SCNAs, whereas most serous and serous-like tumors (endometrioid) exhibit extensive SCNAs. In addition, copy number high tumors also highly correlated with TP53 mutations. Genomic analysis of clear cell carcinoma of the uterus demonstrated that, akin to endometrioid carcinomas, there are four gnomically distinct groups: POLE, MMRd tumors, copy number low, and copy number high.[55]

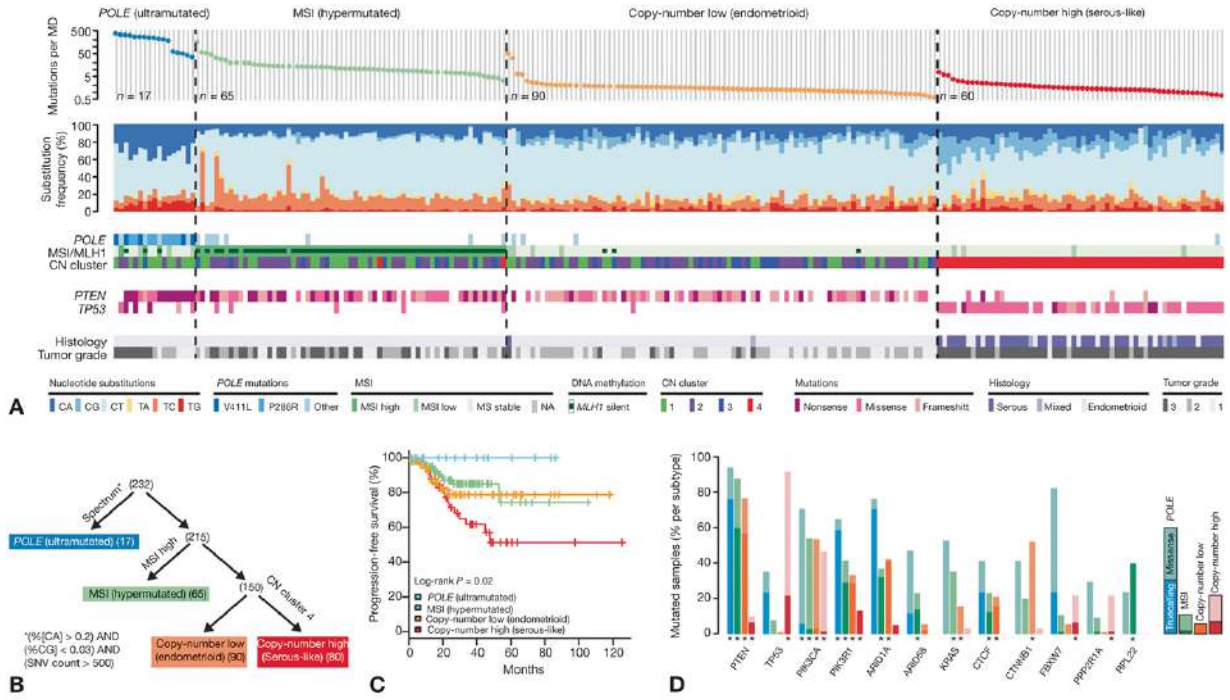

FIGURE 77.4 Genomic landscape of endometrial cancer. a, Mutation frequencies (vertical axis, top panel) plotted for each tumour (horizontal axis). Nucleotide substitutions are shown in the middle panel, with a high frequency of C-to-A transversions in the samples with *POLE* exonuclease mutations. CN, copy number. b, Tumours were stratified into the four groups by (1) nucleotide substitution frequencies and patterns, (2) MSI status, and (3) copy-number cluster. SNV, single nucleotide variant. c, *POLE*-mutant tumours have significantly better progression-free survival, whereas copy-number high tumours have the poorest outcome. d, Recurrently mutated genes are different between the four subgroups. Shown are the mutation frequencies of all genes that were significantly mutated in at least one of the four subgroups (MUSiC, asterisk denotes FDR < 0.05).

A validation study (n = 982) of these molecular subgroups of endometrial cancer was conducted in GOG 210.[56] Forty-nine percent of tumors were classified as copy number stable, 39% MMRD, 8% copy number altered, and 4% POLE mutant. Cancer-specific mortality occurred in 19% of patients with copy number–altered tumors, 7.6% with MMRD tumors, 5% with copy number–stable tumors, and 2.6% with POLE-mutant tumors.

Over time, surrogate markers that are easier to apply on formalin-fixed, paraffin-embedded tissue were developed, allowing identification of subgroups analogous to the ones described in the TCGA analysis[57] (Figure 77.5).

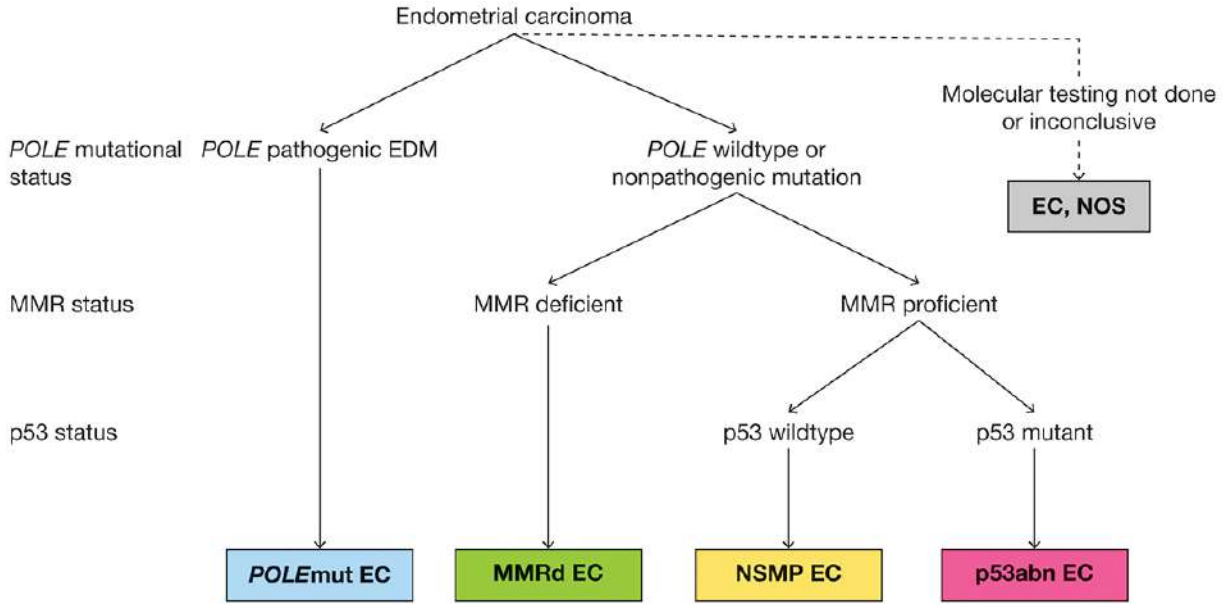

FIGURE 77.5 Diagnostic algorithm for the integrated molecular endometrial carcinoma (EC) classification. EDM, exonuclease domain mutation; MMR, mismatch repair; MMRd, mismatch repair deficient; NOS, not otherwise specified; NSMP, nonspecific molecular profile; p53abn, p53 abnormal. (Adapted from Léon-Castillo A. Update in the molecular classification of endometrial carcinoma. *Int J Gynecol Cancer*. 2023;33[3]:333-342. Copyright © 2023 IGCS and ESGO 2023. With permission.)

Specifically, sequencing may identify *POLE*-ultramutated (*POLE*mut) tumors. Loss of one or more MMR proteins defines MMRD tumors. p53 immunohistochemistry is an acceptable surrogate marker test for TP53 abnormal (p53abn) mutations. Tumors not falling within these categories are classified as having nonspecific molecular profile (NSMP). It is notable

that the p53abn and NSMP categories closely correspond to the copy number high/abnormal and copy number low/stable groups in the previous TCGA analysis.

STAGING

Radiation oncologists should be familiar with several FIGO staging systems due to the need to reference historical systems for interpreting clinical trials and for treatment planning since the newest 2023 system has not yet been fully implemented at many institutions. Although a staging system from the American Joint Committee on Cancer (AJCC) exists for uterine cancer, most clinicians around the world use the FIGO stage.

Before 1988, the staging system for endometrial cancer was clinical. The last clinical staging system was the FIGO 1971 system: Stage I was tumor limited to the uterus, with IA designation if the length was 8 cm or less and IB if it was greater than 8 cm. Stage II was for when the cervix was involved, stage III when disease extension beyond the uterus/cervix was limited to the true pelvis, and stage IV when it extended beyond the true pelvis or involved bladder or rectum (IVA) or distant spread (IVB). This system is applicable today to the few patients who cannot have surgery and are treated with definitive radiation.

In 1988, FIGO switched to a surgical staging system based on pathology findings reported after hysterectomy. Stage I was tumor limited to the uterus, with IA to the endometrium only, IB to 50% or less of the myometrium, and IC to more than 50% of the myometrium. Stage II was for cervix involvement, with IIA limited to endocervical glands, and IIB to include stromal invasion. Stage III was for extension beyond the cervix/uterus, with IIIA involving the serosa, adnexa, or having positive cytology, IIIB for the lower vagina, and IIIC for the pelvic or para-aortic nodes. Stage IV was for distant spread, with IVA for bladder or rectal invasion and IVB for distant metastatic disease.

Using the FIGO 1988 staging system, Creasman et al reported a GOG 210 study on 5,855 patients with endometrial cancer who underwent hysterectomy/BSO and peritoneal cytology.[46] During the initial phase of the study of 3,715 patients, enrollment was unrestricted, but in the later phase, enrollment was restricted to patients (n = 2,151) with adverse features, such

as nonendometrioid histologies, non-Caucasian race, and preoperative imaging suggestive of deep myometrial invasion, and such histologies were as follows: endometrioid (grade 1 was 37.8%, grade 2 was 26.3%, and grade 3 was 9.7%), serous 11.4%, clear cell 3.5%, and mixed 4.5%. The rate of positive peritoneal cytology was 8.9% and that of adnexal involvement was 8.6%. The breakdown by stage (FIGO 1988) was as follows: IA 24.8%, IB 38.4%, IC 11.2%, IIA 2.3%, IIB 4.4%, IIIA 4.6%, IIIB 0.2%, IIIC 9.8%, and IV 4.4% (Table 77.2).

In 2009, 2018, and, most recently, in 2023, the FIGO staging system was modified.[58-60] Patients who formerly were staged as IB, that is, less than 50% of myometrial invasion, were now considered IA. Patients with more than 50% of myometrial invasion are designated as stage IB. Endocervical glandular involvement no longer affects staging; only patients with cervical stromal invasion are considered stage II. Having positive peritoneal cytology no longer affects staging. Parametrial extension is now considered IIIB. Patients with stage IIIC are now subdivided into IIIC1 if pelvic nodes are involved and IIIC2 if para-aortic nodes are involved. Notably, until the update of the FIGO system in 2009, uterine sarcomas and carcinomas were staged using the same system. Thereafter, uterine sarcomas are staged using the AJCC sarcoma staging system. Carcinosarcomas remain staged with the carcinomas in the FIGO systems. Thus, stage I was tumor limited to the uterus, with IA to the endometrium only or to 50% or less of the myometrium and IB to more than 50% of the myometrium. Stage II was for cervix stromal invasion. Stage III was for extension beyond the cervix/uterus, with IIIA involving the serosa or adnexa, IIIB for the lower vagina, IIIC1 for pelvic nodes, and IIIC2 for para-aortic nodes. Stage IV was for distant spread, with IVA for bladder or rectal invasion and IVB for distant metastatic disease. Because this system has been used for the past decade, it is still the staging most familiar to currently practicing gynecologic oncologists and radiation oncologists, reported in much of the recent published literature, and is still used for treatment planning in institutions that have not yet transitioned to the FIGO 2023 system.

In addition, in the FIGO 2023 staging, the updates include the various histologic types, tumor patterns, and molecular classification to better reflect the improved understanding of the complex nature of the several types of endometrial carcinoma and their underlying biologic behavior

(Table 77.3). The reader is instructed to reference the table for detailed information. However, for clarity, major changes are described henceforth.

TABLE 77.3 2023 FIGO STAGING OF CANCER OF THE ENDOMETRIUM

Stage	Description
I	Confined to the uterine corpus and ovary[a]
IA	Disease limited to the endometrium OR nonaggressive histologic type, ie, low-grade endometrioid, with invasion of less than half of myometrium with no or focal LVSI OR good prognosis disease
IA1	Nonaggressive histologic type limited to an endometrial polyp OR confined to the endometrium
IA2	Nonaggressive histologic types involving less than half of the myometrium with no or focal LVSI
IA3	Low-grade endometrioid carcinomas limited to the uterus and ovary[a]
IB	Nonaggressive histologic types with invasion of half or more of the myometrium, and with no or focal LVSI[b]
IC	Aggressive histologic types[c] limited to a polyp or confined to the endometrium
II	Invasion of cervical stroma without extrauterine extension OR with substantial LVSI OR aggressive histologic types with myometrial invasion
IIA	Invasion of the cervical stroma of nonaggressive histologic types
IIB	Substantial LVSI[b] of nonaggressive histologic types
IIC	Aggressive histologic types[c] with any myometrial involvement
III	Local and/or regional spread of the tumor of any histologic subtype
IIIA	Invasion of uterine serosa, adnexa, or both by direct extension or metastasis
IIIA1	Spread to ovary or fallopian tube (except when meeting stage IA3 criteria)[a]
IIIA2	Involvement of uterine subserosa or spread through the uterine serosa
IIIB	Metastasis or direct spread to the vagina and/or to the parametria or pelvic peritoneum
IIIB1	Metastasis or direct spread to the vagina and/or the parametria
IIIB2	Metastasis to the pelvic peritoneum
IIIC	Metastasis to the pelvic or para-aortic lymph nodes or both[d]
IIIC1	Metastasis to the pelvic lymph nodes

Stage	Description
IIIC1i	Micrometastasis
IIIC1ii	Macrometastasis
IIIC2	Metastasis to para-aortic lymph nodes up to the renal vessels, with or without metastasis to the pelvic lymph nodes
IIIC2i	Micrometastasis
IIIC2ii	Macrometastasis
IV	Spread to the bladder mucosa and/or intestinal mucosa and/or distance metastasis
IVA	Invasion of the bladder mucosa and/or the intestinal/bowel mucosa
IVB	Abdominal peritoneal metastasis beyond the pelvis
IVC	Distant metastasis, including metastasis to any extra- or intra-abdominal lymph nodes above the renal vessels, lungs, liver, brain, or bone

EEC, endometrioid carcinoma; ESGO, European Society of Gynecological Oncology; ESP, European Society of Pathology; ESTRO, European Society for Therapeutic Radiology and Oncology; FIGO, International Federation of Gynecology and Obstetrics; ITC, isolated tumor cell; LVSI, lymphovascular space involvement; MMRd, mismatch repair deficient; NSMP, nonspecific molecular profile; p53abn, p53 abnormal; SLN, sentinel lymph node; WHO, World Health Organization.

Endometrial cancer is surgically staged and pathologically examined. In all stages, the grade of the lesion, the histologic type, and LVSI must be recorded. If available and feasible, molecular classification testing (POLEmut, MMRd, NSMP, p53abn) is encouraged in all patients with endometrial cancer for prognostic risk group stratification and as factors that might influence adjuvant and systemic treatment decisions.

[a]Low-grade EECs involving both the endometrium and the ovary are considered to have a good prognosis, and no adjuvant treatment is recommended if all the below criteria are met. Disease limited to low-grade endometrioid carcinomas involving the endometrium and ovaries (Stage IA3) must be distinguished from extensive spread of the endometrial carcinoma to the ovary (stage IIIA1), by the following criteria: (1) no more than superficial myometrial invasion is present (<50%); (2) absence of extensive/substantial LVSI; (3) absence of additional metastases; and (4) the ovarian tumor is unilateral, limited to the ovary, without capsule invasion/rupture (equivalent to pT1a).

[b]LVSI as defined in WHO 2021: extensive/substantial, 5 or more vessels involved.

[c]Grade and histologic type:

- Serous adenocarcinomas, clear cell adenocarcinomas, mesonephric-like carcinomas, gastrointestinal- type mucinous endometrial carcinoma, undifferentiated carcinomas, and carcinosarcomas are considered high grade by definition.

• Nonaggressive histologic types are composed of low-grade (grades 1 and 2) EECs. Aggressive histologic types are composed of high-grade EECs (grade 3), serous, clear cell, undifferentiated, mixed, mesonephric-like, gastrointestinal mucinous type carcinomas, and carcinosarcomas.

• It should be noted that high-grade EECs (grade 3) are a prognostically, clinically, and molecularly heterogeneous disease, and the tumor type that benefits most from applying molecular classification for improved prognostication and for treatment decision-making. Without molecular classification, high-grade EECs cannot appropriately be allocated to a risk group and thus molecular profiling is particularly recommended in these patients. For practical purposes and to avoid undertreatment of patients, if the molecular classification is unknown, high-grade EECs were grouped together with the aggressive histologic types in the actual FIGO classification.

[d]Micrometastases are considered to be metastatic involvement (pN1[mi]). The prognostic significance of ITCs is unclear. The presence of ITCs should be documented and is regarded as pN0(i+). According to TNM8, macrometastases are greater than 2 mm in size, micrometastases are 0.2-2 mm and/or greater than 200 cells, and isolated tumor cells are 0.2 mm or larger and 200 or fewer cells. *Based on staging established by FIGO and the American Joint Committee on Cancer (AJCC)*. AJCC Cancer Staging Manual. 8th ed. Springer; 2017.

For uterine/cervix-confined disease (FIGO 2023 stages I-II), it is now necessary to incorporate lymphovascular space invasion (LVSI) and histiotype with anatomic information. LVSI is subclassified according to the rules of the WHO into the following three categories: “LVSI negative” (0 vessels), “LVSI focal” (<5 vessels), or “LVSI substantial/extensive” (≥5 vessels). As for histology, nonaggressive and aggressive histiotypes are defined: Nonaggressive histologies are defined as endometrioid adenocarcinoma grades 1 to 2, while aggressive histologies are grade 3 endometrioid, clear cell, undifferentiated, mixed, mesonephric-like, gastrointestinal (GI) mucinous type, and carcinosarcomas. Stage I defines tumor confined to the uterine corpus and good prognosis, meaning limited to the endometrium or polyp (IA1), nonaggressive histiotype involving less than 50% of myometrium with no or focal LVSI (IA2), or nonaggressive

histiotype involving 50% or more of the myometrium with no or focal LVSI (IB). A unique substage is created for low-grade endometrioid carcinomas limited to the uterus and ovary (IA3). Stage II disease includes involvement of the cervical stroma (IIA), substantial LVSI (IIB), or aggressive histiotypes with myometrial involvement (IIC).

For locoregional spread of tumor (FIGO 2023 stage III), the stages are subdivided into invasion of the uterine serosa, adnexa (IIIA); spread to the vagina, parametria, or pelvic peritoneum (IIIB); or to pelvic and/or para-aortic lymph nodes (IIIC); with substages for each, which are listed in the table. Of interest for stage IIIA, spread to the ovary or fallopian tube is classified as IIIA1, except for when meeting stage IA3 criteria. In addition, metastasis to the pelvic peritoneum is now classified as stage IIIB2. For stage IIIC disease, the presence of cancer in the lymph nodes is now subclassified in the following method: Macrometastases are greater than 2 mm in size, micrometastases are 0.2 to 2 mm and/or more than 200 cells, and isolated tumor cells (ITCs) are 0.2 mm or less and 200 cells or less. Pelvic (IIIC1) and para-aortic (IIIC2) nodal involvement are subclassified by the presence of micrometastatic (1) or macrometastatic (2) disease. ITCs are not considered positive lymph nodes for FIGO staging but can be designated pN0(i+) if detected. Stage IV has been subclassified into invasion of the bladder or intestinal mucosa (IVA), abdominal peritoneal metastasis (IVB), or distant metastatic disease (IVC).

In the FIGO 2023 staging system, when molecular classification is known, the stage may be modified in certain situations. For stages I to II, POLEmut is considered a good prognostic class and the stage is modified to $IAm_{POLEmut}$, while p53abn is a poor prognostic class and the stage is modified to $IICm_{p53abn}$. MMRd and NSMP are considered intermediate prognostic classes and do not modify the FIGO stage. Molecular classification does not modify FIGO stage III or IV.

A study of three European institutions investigated changes in staging and prognosis in the FIGO 2023 versus 2009 system.[61] Stage shifts occurred in 27% of patients, with 23% increasing in stage or substage. The 5-year progression-free survival (PFS) in the 2023 versus 2009 FIGO systems were 93% versus 87% in stage I, 70% versus 71% in stage II, and 44% versus 54% in stage III.

Prognostic Factors

Several clinicopathologic factors have been identified in patients with endometrial carcinoma to help predict the prognosis and individualize the treatment plan. At Memorial Sloan Kettering Cancer Center (MSKCC), a nomogram was developed for predicting overall survival (OS) of women with endometrial cancer (n = 1,735) after primary therapy.[62] The use of five prognostic factors—age, grade, histologic type, number of lymph nodes removed, and FIGO 1988 surgical stage—predicted OS with high concordance probability. Postoperative Radiation Therapy in Endometrial Cancer (PORTEC) group also developed nomogram for predicting recurrence in FIGO stage I disease.[63]

Age

The influence of older age on worse outcome has been well established. The adverse impact of older age is often explained by pointing out that older patients tend to present with aggressive histology and more advanced disease and are generally treated less aggressively. What is intriguing, however, is that the strongest correlation between older age and poor outcome is seen in patients with otherwise favorable characteristics. Furthermore, the adverse impact of advanced age on outcome persists even when older patients are treated as aggressively as their younger counterparts.[64,65]

Race

The incidence of endometrial cancer is lower in African American than White women, yet the rate of high-risk features in this group is higher. In a GOG study, 24.3% of African Americans presented with stage III as opposed to 17.6% for White and the histology was serous in 24.4% as opposed to 11.2%. The higher recurrence rate could not be accounted for based on treatment received, indicating the need for better understanding of the biology of this disease.[66]

Histologic Subtype

According to the FIGO annual report, the 5-year survival rate was 83.2% for endometrioid adenocarcinoma, compared to 52.6% for serous cancer

and 62.5% for clear cell cancer in 8,033 surgically staged patients. Patients with endometrioid histology have surgical stage III to IV diseases only in 13.8% of patients, compared to 41.7% with serous and 33% with clear cell carcinoma, which could explain the worse outcome. However, the influence of histology was seen even in patients with surgical stage I disease (n = 5,285), for whom 5-year survival dropped from 90% for endometrioid histology to 79.9% with serous and 85.1% with clear cell carcinoma.[25]

Grade

Tumor grade is one of the most sensitive indicators of prognosis. Grade directly affects the depth of myometrial penetration and the frequency of lymph node involvement. In GOG 210 report by Creasman et al,[46] the rate of deep myometrial invasion was 15% for grade 1, 25% for grade 2, and 38% for grade 3. The rate of positive pelvic and para-aortic nodes based on the depth of invasion and histology is shown in Table 77.4. In the FIGO annual report,[25] grade 3 was an independent predictor of poor survival on multivariate analysis within each stage—stages I (hazard ratio [HR], 2.45), II (HR, 2.14), III (HR, 2.44), and IV (HR, 2.55). The recognition that about 25% of grade 3 endometrioid histology has copy number high mutations, that is, serous-like, further highlighting the impact of genomic stratification on prognosis.[54]

TABLE 77.4 RATE OF PELVIC AND PARA-AORTIC METASTASIS BASED ON HISTOLOGY AND DEPTH OF INVASION

	EG1	EG2	EG3	Serous	Clear Cell
Depth of Invasion	**Pel/PA%**	**Pel/PA%**	**Pel/PA%**	**Pel/PA%**	**Pel/PA%**
Endometrium only	0.8/0	1.6/1.1	1.7/0	7.9/4.2	1.3/0
Inner half	2.0/1.3	3.9/1.7	3.9/0.8	18.3/11.3	15.5/6.4
Outer half	15.4/6.9	16.8/8.4	29.1/14.5	44.3/32.4	40.5/28.4
Serosa	42.9/28.6	50/33.3	67.6/43.2	66.7/61.5	70/60

E, endometrioid; G, grade; PA, para-aortic; Pel, pelvic.

Myometrial Invasion

Regardless of grade, only 1.7% of tumors limited to the endometrium had lymph nodal involvement, as compared with 29% pelvic and 14.5% para-aortic involvement with deep penetration.[46] Before the 1988 FIGO staging system, the depth of invasion had been reported as none or inner, middle, or outer one-third of the myometrium. The 1988 FIGO staging system subdivided myometrial invasion into none or inner or outer half. Under that staging system, for patients with less than 50% myometrial invasion, it seems that invasion to less than versus greater than one-third is not a significant predictor of outcome.[67] In the current 2023 FIGO staging system, the depth of invasion for nonaggressive histologic types in stage I is divided into two categories: A (no or <50% myometrial invasion) and B (>50% invasion); aggressive histologic types confined to the endometrium are a third category, C 61.

Lymphovascular Invasion

In the GOG 210 study,[46] the rate of lymphovascular invasion (LVI) was 22.7%. The presence of LVI increased the rate of positive pelvic node from 4.1% to 37.5%, and para-aortic node from 2.3% to 23.8%. LVI is also associated with higher rate of relapse in the vagina[68] and a poorer outcome, especially if it was substantial.[69] The presence of LVI needs to be viewed in the context of other risk factors so that its mere presence does not trigger excessive therapy.[70]

Lower Uterine Segment Involvement

The presence of LUSI is associated with worse outcome. In a study of 481 surgically staged endometrioid endometrial cancers (FIGO stage I-II), LUSI was present in 223 (46.4%) cases and was associated with both decreased disease-free survival (P = .02) and OS (P = .01) in univariate analysis.[71] There seems to be a high rate of LUSI in patients with HNPCC-associated endometrial cancer.[72]

Cervical Involvement

In the 1988 FIGO staging system, cervical involvement was divided into IIA when limited to endocervical glandular involvement and IIB when it involves the cervical stroma. According to the FIGO report, the 5-year

survival for stage IIA was very good (89.9% for grade 1 and 83.7% for grade 2). In contrast, the corresponding figures for stage IIB were 81.2% and 76.9%.[25] This led to a change in the 2009 FIGO staging system, in which only cervical stromal invasion is considered stage II. Although the prognosis of the old stage IIA grades 1 and 2 approximated stage I rather than stage IIB, it is important to note that in the same FIGO annual report, patients with stage IIA grade 3 did not fare as well; their 5-year survival was 68.3%, which was worse than that for IC grade 3 (74.9%) and similar to that for IIB grade 3 (64.9%).

Peritoneal Cytology

In the 2009 FIGO staging, having positive peritoneal cytology is no longer considered stage IIIA. The reason for the change is due to the lack of clear correlation between positive cytology and outcome for early-stage endometrial cancer. However, the true prognostic significance of positive peritoneal cytology on outcome cannot be devoid of the influence of surgical techniques or other prognostic factors. There is some suggestion of a higher rate of positive cytology for patients undergoing laparoscopic hysterectomy, because of manipulation of the uterine cavity. In a randomized trial[73] trying to address this issue, the rate of positive cytology was 7.2% when manipulator was used compared to 1.8% when it was not, but that difference was not statistically significant (P = .147). In the GOG 210 study, positive peritoneal cytology was found in 11.3% of patients undergoing surgical staging. This was associated with 31.8% pelvic lymph node involvement and 22.7% para-aortic node involvement.[46] Histology also impacts the rate of positive cytology: 7.7% for endometrioid histology compared to 20.2% for nonendometrioid histologies.[47] In patients with early-stage disease (low-grade endometrioid histology, minimal invasion), the influence of positive peritoneal cytology on outcome is not evident.[74] In contrast, for patients with stage III disease, having positive cytology affects prognosis significantly and needs to be taken into account.[75]

Adnexal/Serosal Involvement

In the GOG 210 study,[46] the rate of positive adnexal involvement was 8.6%. The rate of positive pelvic node with such involvement is 41% and that for

para-aortic is 31.4%. Jobsen et al[76] reported on 46 patients with isolated adnexal involvement and 21 with isolated serosal involvement. There was no statistically significant difference in outcome between adnexal and serosal involvement. The 5-year disease-free survival was 76.4% versus 59.6% (P = ns), and the disease-specific survival (DSS) was 76.3% and 75.4%, respectively.

Pelvic and Para-Aortic Lymph Node Involvement

The pattern of lymphatic spread in endometrial cancer is different than that in cervical cancer. In endometrial cancer, a simultaneous spread to both pelvic and para-aortic nodes could occur, whereas in cervical cancer, the spread to para-aortic nodes is almost always secondary to pelvic lymph node involvement. Overall, about 12.6% of patients with stage I and occult stage II endometrial cancer have pelvic nodal involvement. This increases to 27.7%, 41%, and 45.7% with deep myometrial invasion, adnexal involvement, and extrauterine spread, respectively.[46] Lymph node involvement is a major predictor of outcome; the 5-year disease-free survival rates drop to 65% to 70% in patients with pelvic lymph node involvement as their only risk factor.[77] In the GOG 210 study, the rate of para-aortic nodal metastases is about 7.2%.[46] The biggest risk factor for para-aortic node involvement is the presence of pelvic nodal metastases. The 5-year disease-free survival rates drop to about 30% in this subpopulation.[77]

Molecular Prognostic Factors

In the TCGA report on endometrial cancer,[54] there was a correlation between prognosis and genomic group (Figure 77.4). In the PORTEC trials, patients with *POLE* mutations had excellent prognosis, with very low risk of recurrence, which could be attributed to its high mutational burden.[78] On the other end of the spectrum, patients with copy number high had the worst prognosis in the TCGA report.[54] The recognition that about 25% of grade 3 endometrioid adenocarcinoma (serous-like) do belong to the copy number high group (mainly serous), further highlighting the prognostic importance of genomic classifications of endometrial cancer.[56] Patients with CTNNB1 (β-catenin) mutations do significantly worse even in patients with early-

stage endometrioid histology.[79] Analysis of GOG 210 showed that in endometrioid adenocarcinoma of the uterus, the presence of MMR defects was associated with higher rate of LVI and higher grade cancers. But interestingly, MMR defects were not associated with significantly worse prognosis.[80] Based on currently available evidence, FIGO has further updated the 2023 staging guidelines to include a molecular classification. When feasible, the addition of molecular subtype evaluation to the staging criteria should be performed as it allows a better prediction of prognosis in a staging/prognosis scheme (Table 77.3).[60] The performance of complete molecular classification (*POLEmut*, MMRd, NSMP, p53abn) is encouraged in all cases of endometrial carcinoma for prognostic risk group stratification and as potential influencing factors for adjuvant or systemic treatment decisions.

SURGICAL MANAGEMENT

Surgery is the main treatment for endometrial cancer. It consists of simple hysterectomy, BSO, and inspection of the pelvic and abdominal cavities, with biopsy of any suspicious extrauterine lesions, accompanied by peritoneal washings. The FIGO staging system did not say that obtaining peritoneal washings is no longer required but only that the finding does not alter the stage. Surgical assessment of lymph nodes ranges from palpation, biopsy of suspicious nodes, to pelvic and para-aortic lymphadenectomy.

Hysterectomy

There are several approaches to simple hysterectomy, also known as extrafascial hysterectomy, but in the main, it consists of removal of the entire uterine corpus and cervix without contiguous parametrial tissue. The pubocervical fascia is entered, and the ureters are not unroofed. *Total abdominal hysterectomy/BSO* (TAH/BSO) is the most prevalent and time-tested form of simple hysterectomy in endometrial cancer. It is an abdominal approach, usually via a vertical midline incision that allows thorough exploration of intra-abdominal and pelvic cavities. The main drawback of TAH/BSO is that it is a laparotomy-based approach, in a group of patients with preexisting comorbidities such as obesity, hypertension, and diabetes. Therefore, it is not surprising that minimally invasive surgery,

whether laparoscopically or robotically, has gained a great deal of acceptance in the surgical management of endometrial cancer. In *laparoscopic vaginal hysterectomy/BSO* (LAVH/BSO), the uterus is removed vaginally rather than abdominally. The benefit of using the laparoscope is to enable the surgeon to have a thorough intra-abdominal exploration and to perform BSO, which is difficult to accomplish with just a vaginal hysterectomy. The GOG completed a trial in which patients with clinical stage I to occult IIA uterine cancer were randomly assigned to laparoscopy (n = 1,696) or open laparotomy (n = 920), including hysterectomy, salpingo-oophorectomy, pelvic cytology, and pelvic and para-aortic lymphadenectomy. The main study end points were 6-week morbidity and mortality, hospital length of stay, conversion from laparoscopy to laparotomy, recurrence-free survival, site of recurrence, and patient-reported quality of life outcomes.[81] Laparoscopy had fewer moderate to severe postoperative adverse events than laparotomy (14% vs 21%; $P <$ .0001). Hospitalization of greater than 2 days was significantly lower in laparoscopy than in laparotomy patients (52% vs 94%; $P <$ .0001). The conversion rate to laparotomy was 25.8%. With a median follow-up time of 59 months for 2,181 patients still alive, there were 309 recurrences (laparoscopy 210, laparotomy 99) and 350 deaths (laparoscopy 229, laparotomy 121). The estimated 5-year recurrence rate was 11.61% in the laparotomy arm and 13.68% for laparoscopy. The estimated 5-year OS rate was 89.8% for laparoscopy and 89.8% for laparotomy. The study demonstrated that surgical treatment of endometrial cancer can be performed laparoscopically with relatively small differences in recurrence rates (estimated difference at 3 years, 1.14%). These results, combined with improved quality of life and decreased complications associated with laparoscopy, are reassuring to patients and allow surgeons to reasonably suggest this method as a means to surgically treat and stage patients with presumed early-stage uterine cancers.[82] In recent years, *robotic-assisted hysterectomy*/BSO has emerged as an alternative minimally invasive surgery in endometrial cancer. It affords many advantages, including three-dimensional (3D) visualization, increased freedom of instrument movement, and enhanced ergonomics and surgeon comfort. The question of difference in cost is under debate debatable.[83] *Radical hysterectomy* is not routinely performed in endometrial cancer because of low incidence of

parametrial involvement. There is no evidence to show that the cure rates are any better with such radical operations. The possible exception to this might be in patients with gross cervical involvement.[84]

Surgical Assessment of Lymph Nodes

The question of which patients need routine surgical lymph nodal staging and, if so, to what extent is a matter of great debate. The uncertainty about lymphadenectomy relates to whether the benefit from it is prognostic rather than therapeutic. Those who advocate for *no lymphadenectomy* and limit nodal assessment to inspection and removal of any enlarged/suspicious pelvic or para-aortic nodes cite the lack of documented survival advantages to lymphadenectomy. Furthermore, patients who have adverse pathologic features that increase the risk of microscopic lymph node metastasis are generally offered adjuvant pelvic radiation. Advocates for *full-pelvic and para-aortic lymph node sampling* on the other end of the spectrum reason that surgical staging is the most accurate method to assess the extent of disease and that the sensitivity and specificity of palpation of lymph nodes are only 72% and 81%, respectively.[85] Lymphadenectomy in endometrial cancer includes removal of the fat pads surrounding the major vessels in the abdomen and pelvis without skeletonizing them. According to the GOG surgical guidelines, pelvic lymph nodes are to be removed from the distal one-half of the common iliac artery down to the circumflex iliac vein, and nodal tissue is to be removed anterior to the obturator nerve and surrounding the iliac arteries and vein. The para-aortic nodes include those overlying the vena cava, between the vena cava and the aorta, and to the left of the aorta. The cephalad boundary of the para-aortic specimen is generally, but not limited to, the inferior mesenteric artery, and the distal boundary is the midpoint of the common iliac artery. For the sampling to be adequate, five lymphatic stations from each side need to be removed—para-aortic, common iliac, internal iliac, external iliac, and obturator—or a total of 10 nodes.[46]

Two trials addressed the role of lymphadenectomy. The first was an Italian study[86] in which 514 eligible patients with preoperative FIGO stage I endometrial carcinoma were randomly assigned to undergo pelvic lymphadenectomy (n = 264) or no lymphadenectomy (n = 250). The

median number of lymph nodes removed was 30 in the pelvic lymphadenectomy arm. Both early and late postoperative complications occurred more frequently in patients who had received pelvic systematic lymphadenectomy (81 patients in the lymphadenectomy arm and 34 patients in the no-lymphadenectomy arm; $P = .001$). Lymphadenectomy improved surgical staging, as statistically significantly more patients with lymph node metastases were found in the lymphadenectomy arm than in the no-lymphadenectomy arm (13.3% vs 3.2%; $P < .001$). At a median follow-up of 49 months, the 5-year disease-free survival and OS rates in an intention-to-treat analysis were similar between arms (81.0% and 85.9% in the lymphadenectomy arm and 81.7% and 90.0% in the no-lymphadenectomy arm). In the second trial (Medical Research Council [MRC]/A Study in the Treatment of Endometrial Cancer [ASTEC]), patients with endometrial cancer believed preoperatively to be confined to the uterine corpus were first randomized to standard surgery consisting of hysterectomy/BSO, pelvic washing, and palpation of para-aortic nodes ($n = 704$) or to lymphadenectomy ($n = 704$). In the lymphadenectomy group, patients underwent standard surgery plus systematic dissection of the iliac and obturator nodes.[87] If the nodes could not be dissected, sampling of suspect nodes was recommended. Whether to dissect the para-aortic nodes was left to the discretion of the surgeon. After a median follow-up of 37 months, 191 women (88 standard surgery group, 103 lymphadenectomy group) had died, with an absolute difference in 5-year OS of 1% (95% CI = 4-6) and an absolute difference in 5-year recurrence-free survival of 6%. The conclusion from both trials was that pelvic lymphadenectomy significantly improved surgical staging, that is, it is a good prognosticator, but it did not improve disease-free survival or OS. *Optional lymphadenectomy* is another approach, in which preoperative tumor grading with intraoperative assessment of depth of myometrial invasion, as well as histologic subtype, is frequently used to decide whether lymph node dissection is necessary at the time of hysterectomy. With such a policy, patients with grade 3 disease or serous or clear cell histology and those with deep myometrial invasion on frozen section will undergo lymphadenectomy. Opponents of this selective lymphadenectomy approach point out that the depth of invasion on frozen section correlated with final pathology in only 67% of cases.[88] With regard to grade, preoperative FIGO

grade 1 diagnosis correlates with final grade diagnosis in only 85% of cases of endometrial cancer.[29]

As a trade-off between lymphadenectomy and no surgical assessment at all in patients with endometrial cancer, there has a growing interest in adopting a *sentinel lymph node (SLN) mapping* approach similar to that in breast cancer (Figure 77.6). In a report from MSKCC, 266 patients with endometrial cancer underwent SLN mapping. At least one sentinel node was identified in 84% of cases. Location of SLN was in the pelvis in 94% of cases, in the pelvis and para-aortic in 5%, and in the para-aortic in 1%. Positive nodes were diagnosed in 12% of patients.[89] In a recent report of a prospective study[90] of 385 patients, 86% had successful mapping of at least one SLN. Positive node rate was 12%, with nodal metastases being identified in the SLNs in 97% of these 36 patients, yielding a sensitivity to detect node- positive disease of 97.2% (95% CI = ·0-100) and a negative predictive value of 99.6% (97.9-100). It is important to note that if a patient did not have bilateral mapping, a side-specific lymphadenectomy needs to be performed on the site that failed to map, because one reason for failed mapping might be due to the presence of nodal metastasis. In addition, any suspicious node on inspection needs to be removed even if it did not map. With such encouraging results, SLN mapping is gaining more acceptance in the staging of endometrioid adenocarcinoma for sure. This approach is gaining acceptance not only in the gynecologic oncology community[91,92] but also in other histologies. In a prospective study of 123 patients with grade 3 endometrioid histology, serous, clear cell, and carcinosarcoma, all underwent sentinel node mapping followed by lymphadenectomy. Overall, sentinel node detection rate was 89%, with an overall sensitivity of 95% and false-negative rate of 5% (1/20). The rate of positive node was 23%, with only one patient having negative sentinel nodes but positive nonsentinel node.[93]

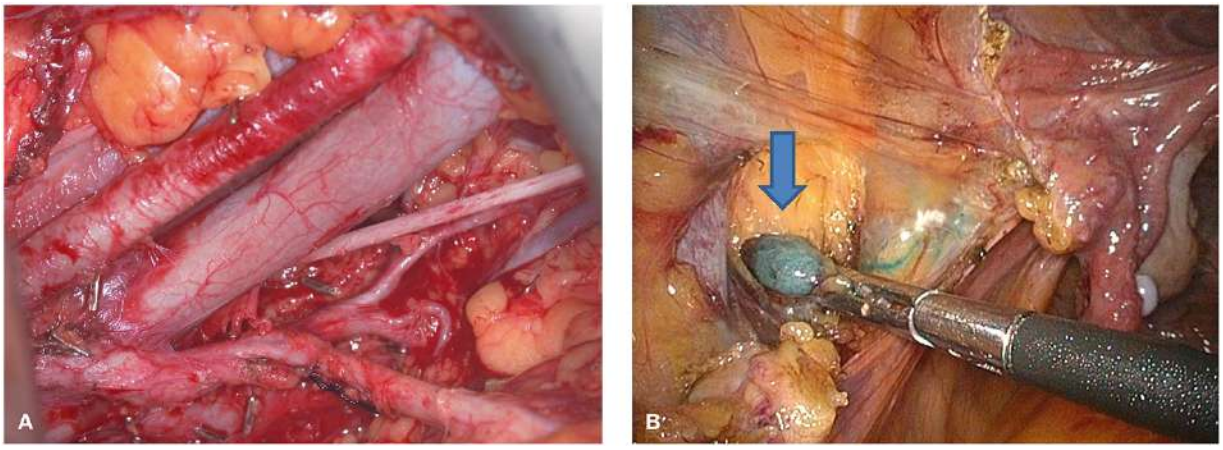

FIGURE 77.6 Comparison of nodal dissection **(A)** to sentinel node biopsy **(B)**. Solid arrow points to the blue dye in the sentinel node.

ROLE OF RADIATION

Radiation therapy (RT) plays a significant role in the management of endometrial cancer. It is often used as an adjuvant treatment after surgery (which is discussed here) or as definitive treatment for patients who are medically inoperable or with local recurrence (which is discussed later). In the past, most patients were treated with preoperative intracavitary brachytherapy (BT) with or without external beam radiotherapy (EBRT), followed by hysterectomy. This approach is not without its merit, especially in patients with gross cervical involvement. However, most patients nowadays undergo surgery first; then, depending on the prognostic features obtained from the pathology review, the need for RT is determined. In recent years, there has been a plethora of data from prospective, randomized trials addressing several aspects of the management of endometrial cancer. However, unlike in cervical cancer, for which the data from the majority of the randomized trials pointed in the same direction, that is, chemoradiation is better than RT alone, the data in endometrial cancer are less conclusive. Therefore, it is important for radiation oncologists to be familiar with the methodology of these studies so that objections to the use of any form of adjuvant RT can be addressed with facts.

Role of Radiotherapy in Stages I and II

Treatment options for patients with early-stage endometrial cancer after hysterectomy include observation, vaginal cuff brachytherapy (VCBT), or pelvic RT. At many institutions, VCBT is the preferred approach for most patients because it provides the best therapeutic ratio. As the discussion demonstrates, observation may have the best morbidity profile, but it does not provide the best therapeutic ratio because of the increased risk of local recurrence. Pelvic RT, on the other hand, although very effective in reducing recurrence, has a higher morbidity profile than VCBT. The results of prospective, randomized trials are discussed first and then treatment recommendations based on risk factors follow.

Results of Radiotherapy Randomized Trials

There are six randomized trials regarding the role of adjuvant RT in early-stage endometrial cancer, mainly pertaining to endometrioid histology and conducted in the "modern" era.

Observation Versus Pelvic Radiotherapy

Three randomized trials compared pelvic RT to observation in early-stage endometrial cancer. The first trial was the PORTEC trial, which randomized 715 patients after TAH and BSO to observation or pelvic RT.[94] Patients included were those with stage (FIGO 1988) IB grades 2 and 3 and those with IC grades 1 and 2. Those with IB grade 1 and those with IC grade 3 were excluded because it was felt that adjuvant RT was not indicated for the former and that most physicians would not omit it for the latter. No lymph node sampling was done, and the dose of pelvic RT was 46 Gy at 2 Gy per fraction. At 5 years, there was a statistically significant difference in the rates of vaginal/pelvic recurrence in favor of adjuvant pelvic RT (14% vs 4%; $P < .001$). OS, however, was not different between the two groups (81% RT vs 85% surgery; $P = .31$), and the complications with pelvic RT were significantly higher (25% vs 6%; $P < .0001$). In addition, many of the patients who relapsed locally after surgery alone were successfully salvaged with subsequent definitive RT. The second randomized trial was GOG 9996. There were 190 patients with stages (FIGO 1988) IB to IIB (grades 1-3), who all underwent TAH/BSO, pelvic washing, and pelvic/para-aortic lymph node sampling and then were randomized to observation versus

pelvic RT to a dose of 50.4 Gy at 1.8 Gy per fraction.[95] At 2 years, there was a statistically significant difference in the rates of relapse in favor of the adjuvant pelvic RT arm (3% vs 12%; $P = .007$). The 2-year estimated incidence of isolated vaginal/pelvic recurrence was 1.6% in the RT group and 7.4% in the surgery-alone group. There was, however, no significant difference in 4-year OS (92% RT vs 86% with surgery alone; $P = .557$), but there were more complications with pelvic RT. The third trial consisted of two trials with separate randomizations consolidated into one intergroup trial. One trial was conducted by the MRC and the other by the National Cancer Institute of Canada (NCIC). Furthermore, the MRC ASTEC trial in itself consisted of two trials with separate randomizations designed to answer a surgical as well as a radiation question.[96] The surgical question was discussed earlier and regarded the need for lymphadenectomy in clinical localized endometrial cancer. The radiation question was whether pelvic RT is needed. Intermediate- or high-risk early-stage patients were then randomized to observation or pelvic RT. Intermediate risk included stage (FIGO 1988) IA grade 3, IB grade 3, IC grades 1 and 2, and IIA grades 1 and 2. High risk included IC grade 3, IIA grade 3, and IA to IIA serous and clear cell tumors. Patients who had positive pelvic nodes (stage IIIC) were allowed, but not those with cervical stromal invasion (IIB). The pelvic RT was given to a total dose of 40 to 46 Gy in 20 to 25 fractions over 4 to 5 weeks. VCBT was permitted regardless of the pelvic RT randomization as long as it was the stated policy for the treating center to do so. The recommended dose was 4 Gy in two fractions prescribed to a depth of 0.5 cm treating the upper one-third of the vagina when using high-dose rate (HDR) and 15 Gy when using low-dose rate. The NCIC had a similar design but with a few exceptions. Patients with stage IIA serous or clear cell carcinoma were excluded, as were those with positive nodes. The dose of pelvic RT was 45 Gy in 25 fractions, and VCBT was permitted in accordance with local practice.

Of the 905 patients (789 MRC and 116 NCIC) in the trial, 453 were randomized to observation and 452 to pelvic RT. The two arms were balanced, except for more high-risk patients (113; 25%) in the observation arm than in the pelvic RT arm (89; 20%). There were 137 (32%) patients in the observation arm in whom nodes were removed, and 5 (4%) had positive nodes. In the pelvic RT arm, 159 (38%) had nodes removed, and 6 (4%)

were positive. In the observation arm, 228 (51%) patients received intravaginal RT (IVRT), 7 (2%) received pelvic and IVRT, 3 (1%) received pelvic RT, and 3 (1%) were unknown. Only 212 (47%) received no form of adjuvant RT. Conversely, in the pelvic RT arm, 24 (5%) did not receive any adjuvant RT, 10 (2%) received VCBT, and 2 (0.4%) were unknown. Combined VCBT and pelvic RT were given to 232 (52%) patients, and only 184 (41%) received pelvic RT alone. The primary end point of this study was OS. With a median follow-up of 58 months, the 5-year OS was 84% in both arms ($P = .77$). The 5-year cumulative incidence for isolated vaginal or pelvic recurrence was 6.1% in the observation group and 3.2% in the pelvic RT group. This difference was statistically significant ($P = .2$) with an HR of 0.46 (95% CI = 0.24-0.89). The rate of any acute toxicity was 27% in the observation arm compared to 57% for pelvic RT. Similarly, late toxicity was more prevalent in the pelvic RT compared to observation (61% vs 45%).

The triad of lack of OS advantage, increased toxicity, and high salvage rate of local recurrence for patients who are observed has led some to conclude that all forms of adjuvant RT, not simply pelvic RT, should be abandoned. The morbidity of pelvic RT and the validity of omitting adjuvant RT in favor of RT for salvage policy are discussed later in the chapter. With regard to OS, it is considered the gold standard for primary end point in many randomized trials in oncology, but for early-stage endometrial cancer, it is perhaps unattainable with adjuvant RT for two reasons. First, many of the patients have other, competing causes of death such as hypertension, diabetes, and obesity. In the PORTEC trial, the 8-year actuarial rates of intercurrent death were 19.7% in the RT arm and 15.6% in the surgery-alone arm.[97] Endometrial cancer–related deaths in comparison were only 9.6% and 7.5%, respectively. Similarly, in the GOG 99 trial,[95] approximately half of the deaths were due to causes other than endometrial cancer or treatment (surgery alone, 19/36; RT, 15/30). This led the authors of GOG 99 to write, “With this number of intercurrent deaths in both arms, even if RT reduces the risk of endometrial cancer-related deaths, the size of this trial is not adequate to reliably detect an overall survival difference.” That is why OS was not the primary end point in GOG[98] but rather the disease-free interval, which was significantly different in favor of adjuvant pelvic RT over surgery alone.[95] Therefore, it is not unreasonable to conclude that neither PORTEC nor GOG 99 was large enough to conclusively show

whether adjuvant pelvic RT affected OS. The second difficult hurdle for adjuvant RT to overcome when discussing OS has to do with its localized nature. In the MRC/NCIC trial, the rate of first vaginal/pelvic recurrence was reduced from 11.4% (n = 37/453) in the observation arm to 2.8% (n = 13/452) with pelvic RT. Adjuvant pelvic RT, however, did not affect distant spread; the rate of first distant spread was 8.1% (n = 37/453) in the observation compared to 9% (n = 41/452) in the pelvic RT arm.[96] One would expect adjuvant RT to make a difference in OS only when systemic therapy has an effect on the rate of distant spread. This is exactly the story learned from postoperative chest wall irradiation in breast cancer. Because pelvic RT significantly improved local control, albeit with increased toxicity, why not replace it with VCBT rather than advocating observation for all early-stage endometrial cancer?

Observation Versus Vaginal Cuff Brachytherapy

In a trial reported by Sorbe et al,[98] 645 patients with stage (FIGO 1988) IA to IB grades 1 and 2 endometrioid adenocarcinoma were randomized after surgery to observation (n = 326) or VCBT (n = 319). Surgery consisted of TAH/BSO (laparoscopic surgery was allowed), pelvic washing, and removal of enlarged nodes. The dose and type of VCBT varied among the six centers participating in this trial, but 347 of 645 patients were treated with HDR to 18 Gy in six fractions. The proximal upper two-thirds of the vagina was treated with the dose prescribed to 0.5 cm from the surface of the cylinder. The rate of vaginal recurrence was 3.1% in the observation arm compared to 1.2% for the VCBT arm (P = .114). The rate of pelvic recurrence was 0.9% in the observation arm and 0.3% in the treatment arm (P = .326). No significance difference was seen between the two arms in terms of OS. There was significantly more grade 1 vaginal toxicity with VCBT (8.8% vs 1.5%; P = .00004). There was no significant difference in GI or genitourinary (GU) toxicity.

Pelvic Radiotherapy Versus Vaginal Cuff Brachytherapy

In the PORTEC-2 trial, 427 patients were randomized to pelvic RT (n = 214) or VCBT (n = 213).[99] Patients enrolled were those with stage (FIGO 1988) IB grade 3 and older than 60 years, IC grades 1 and 2 and older than

60 years old, and IIA grades 1 and 2 of all ages but with less than 50% myometrial invasion. During surgery, patients underwent TAH/BSO, pelvic washing, and removal of suspicious pelvic or para-aortic lymph nodes. Routine lymphadenectomy was not performed. The dose of pelvic RT was 46 Gy given in 23 fractions. VCBT was delivered using a cylinder to treat the upper half of the vagina. The dose was prescribed to 0.5 cm from the surface of the cylinder. Three types of BT were used: HDR to 21 Gy in three fractions, low-dose rate to 30 Gy at 0.5 to 0.7 Gy/hour, and medium-dose rate to 28 Gy at 1 Gy/hour. With a median follow-up of 36 months, the 3-year vaginal recurrence rates were 0.9% in the VCBT arm and 1.9% in the pelvic RT arm (P = .97). The pelvic recurrence was significantly different; the 3-year rate was 3.5% in the VCBT arm compared to 0.6% in the pelvic RT arm (P = .03). The corresponding rates of isolated pelvic recurrence, however, were not significant (0.6% vs 1.2%, P = .54). There was no significant difference in disease-free survival or OS between the two arms. The rate of grades 1 and 2 acute GI toxicity was 53% versus 12% in favor of VCBT (P < .001). This trial showed that VCBT alone is sufficient to control vaginal recurrence even in patients with intermediate- to high-risk features.[99]

In the Swedish trial reported by Sorbe et al,[100] patients with stage (FIGO 1988) I endometrioid adenocarcinoma with at least one of the risk factors grade 3, 50% or more myometrial invasion, or DNA aneuploidy were randomized to adjuvant VCBT (n = 263) or pelvic and VCBT (n = 264). Lymphadenectomy was required. There was no difference in vaginal recurrence, which was 2.7% (7/263) in the VCBT-alone arm compared to 1.9% (5/264) in the combined arm (P = .555). Pelvic recurrence rate, however, was different: 5.3% in the VCBT arm compared to 0.4% in the pelvic plus VCBT arm (P = .0006). There was no significant difference in OS between the two arms (90% vs 89%). The toxicity was significantly higher in the combined arm compared to VCBT alone.

Radiation Treatment Recommendations for Early-Stage Disease Based on Risk Factors

Based on the results of these trials in early-stage endometrial cancer, it is clear that pelvic RT is an excessive treatment for most of those patients.

Therefore, the treatment recommendations should be individualized based on risk factors. When deciding on whether to recommend observation, VCBT, or pelvic RT, the risk of vaginal recurrence and pelvic recurrence should be assessed separately. With respect to vaginal recurrence, the data from randomized trials indicate that adjuvant VCBT alone is sufficient to control potential microscopic disease in the vagina. The PORTEC-2 trial showed that VCBT is as good as pelvic RT in controlling vaginal recurrence (0.9% vs 1.9%; $P = .97$) despite the fact that patients included in this trial were at high risk for vaginal recurrence based on age 60 years or above, deep myometrial invasion, or endocervical gland involvement.[99] The data from the Swedish randomized trial further confirmed that when it comes to vaginal control, VCBT alone is sufficient.[100] The vaginal recurrence was 2.9% in the VCBT arm compared to 1.9% ($P = .555$) in the pelvic plus VCBT arm. How best to reduce pelvic recurrence is more controversial. For patients at low risk of having pelvic lymph node involvement, that is, endometrioid grade 1 or 2 with no or minimal myometrial invasion, neither lymphadenectomy nor pelvic RT is likely to be of significant benefit because of low rate of pelvic node involvement.[46] Those who are at higher risk of having lymph node involvement may need to have their lymph nodes surgically assessed to ensure that they are pathologically negative or receive pelvic RT to control potential microscopic disease. However, the two PORTEC trials, as well as the Swedish trial, showed that the risk of pelvic recurrence was only 2% to 6%, even in the absence of lymphadenectomy.[94,99,100] This low rate of pelvic recurrence, coupled with the lack of survival advantage to lymphadenectomy and pelvic RT, raises the question of whether either approach is needed for the majority of patients with early-stage endometrial cancer. In the eyes of many, having LVI is almost indicative of nodal involvement. Cohn et al[101] correlated LVI and the risk of positive pelvic nodes in 366 surgically staged patients. The rate of LVI was 25%, and the rate of positive pelvic nodes was 13%. Patients with LVI were significantly more likely to have nodal metastasis (35/92 vs 11/274; $P < .001$). However, the influence of LVI on pelvic nodal metastasis was the strongest in patients with deep myometrial invasion and high grade. Data from MSKCC on 126 patients with endometrioid FIGO (1988) stages IB to IIB and LVI also showed that the mere presence of LVI should not be a trigger for giving pelvic RT, especially when patients had

lymphadenectomy. Patients were divided into two groups: those from the old era, when treatment was often pelvic RT, and those from the modern era, when patients were more often treated with lymphadenectomy and VCBT 70. The rate of pelvic relapse for patients with LVI was 7% in the old era compared to 3% ($P = .3$) in the modern era.

No Myometrial Invasion, Grades 1 and 2

The risk of vaginal recurrence is almost negligible. Straughn et al[102] reported no vaginal recurrence in 103 such patients treated with surgery alone. Pelvic lymph nodal positivity was less than 3%. The 5-year PFS rate in this group was on the order of 95% to 98%. It is unlikely that postoperative pelvic or VCBT would add anything to the final outcome, and therefore, radiation is not routinely recommended to this group.

No Myometrial Invasion, Grade 3

In the GOG 210 study, there were only 69 patients out of 5,866 (1.1%) with disease limited to endometrium and had grade endometrioid histology, making it difficult to draw any meaningful conclusion.[46] Straughn et al[102] reported on eight patients with stage IA grade 3 disease treated with surgery alone, with two of patients developing isolated vaginal recurrence. The risk of lymph node metastasis in this group of patients is about (1.7%) in the GOG 210 study.[46] These patients are commonly offered either VCBT alone or observation.

Less Than 50% Myometrial Invasion, Grades 1 and 2

This group of patients constitutes the most common stage subgroup of all endometrial cancers. Straughn et al[102] reported a 3% (9/296) risk of vaginal recurrence when surgery alone was done. In the surgery-alone arm of the PORTEC-1 trial,[94] the 5-year vaginal recurrence rate for patients with less than 50% myometrial invasion grade 2 was 5%. In a randomized trial reported by Sorbe et al,[98] the vaginal recurrence rate was 3.1% for those in the observation arm compared to 1.2% for those in the VCBT arm ($P = .114$). The trial was designed to detect a difference of 1% versus 5% in the vaginal recurrence rate in the two groups. The data were not reported separately based on whether myometrial invasion was present, making it

difficult to determine the true impact of VCBT on the rate of vaginal recurrence in patients with myometrial invasion. Data from MSKCC on 233 patients with less than 50% myometrial invasion grade 1 or 2 showed a vaginal recurrence rate of only 1% using VCBT alone.[103,104] In addition, Sorbe et al[105] reported on 110 patients with IB grade 1 or 2 who were part of a prospective, randomized trial evaluating two different IVRT doses; the rate of vaginal recurrence was 0.9%. The risk of pelvic recurrence was only 1.8%, even though lymphadenectomy was not required. This low rate of pelvic recurrence is similar to those reported by Straughn et al[102] of 0.3% (1/296) and by Horowitz[106] of 0% (0/62) in the setting of lymphadenectomy. This indicates that pelvic RT is of limited use, and therefore, it seems reasonable to suggest that either observation or VCBT is a reasonable option for patients with grade 1 or 2 and less than 50% myometrial invasion.

However, when deciding on whether adjuvant RT is needed, it is important to address two issues. First, older patients tend to have higher rates of relapse. In the study by Straughn et al,[102] 8 of the 10 vaginal/pelvic recurrences were in patients aged 60 years or above. In the randomized trial by Sorbe et al[98] comparing adjuvant IVRT to observation, patients with vaginal recurrences were significantly (P = .018) older (mean age, 68.6 years) than patients without vaginal recurrences (mean, 62.6 years). Second, patients with LVI have a higher chance of vaginal recurrence, as demonstrated by Mariani et al[68] who reported on 508 patients with endometrial cancer limited to the corpus treated with surgery alone. The presence of LVI significantly increased the vaginal relapse rate from 3% to 7% (P = .02). The rate of vaginal relapse would have been even higher if patients without myometrial invasion (152/508) had been excluded because LVI is exceedingly rare in patients without myometrial invasion. At many institutions, patients who are older than 60 years and/or have LVI are recommended to have VCBT.

Less Than 50% Myometrial Invasion, Grade 3

Some advocate observation for patients with less than 50% myometrial invasion grade 3, yet the 5-year vaginal recurrence rate in PORTEC-1 was 14% for such patients treated with surgery alone compared to none for those

treated with pelvic RT.[94] Perhaps a better choice for those patients is VCBT. The incidence of positive pelvic lymph nodes at the time of surgery in this subset of patients is about 3.9%. In the PORTEC-1 trial, none of the 37 patients with grade 3 disease and less than 50% myometrial invasion who were treated with TAH/BSO alone relapsed in the pelvis.[94] At many institutions, VCBT is recommended for this subset of patients, irrespective of whether lymphadenectomy was performed.

Fifty Percent or Greater Myometrial Invasion, Grades 1 and 2

The risk of vaginal recurrence with surgery alone in this group of patients is not minimal. In the PORTEC-1 trial,[94] the 5-year vaginal recurrence for patients with 50% or more of myometrial invasion treated with surgery alone was 10% for those with grade 1 and 13% for grade 2. The corresponding 5-year vaginal recurrence rates for patients treated with pelvic RT were 1% and 2%. With regard to pelvic control, the 5-year pelvic recurrence for patients with more than 50% myometrial invasion treated with surgery alone was 2% for grade 1 and 6% for grade 2. The data from the PORTEC-2 trial[99] and the Swedish trial[100] in which patients with more than 50% myometrial invasion grade 1 or 2 were included indicate that the omission of pelvic RT increased the risk of pelvic recurrence. In PORTEC-2 trial,[99] the 3-year rate was 3.5% in the IVRT arm compared to 0.6% in the pelvic RT arm (P = .03). In the Swedish trial,[100] the pelvic recurrence rate was 5.3% in the VCBT arm compared to 0.4% in the pelvic plus VCBT arm (P = .0006). At many institutions, most of these patients undergo SLN mapping, and if the nodes are pathologically negative, they undergo VCBT. Pelvic RT can also be considered if age 60 years or above, grade 2, and surgical pathology has LVI.

Fifty Percent or Greater Myometrial Invasion and Grade 3

In GOG 210, the risk of finding positive lymph nodes in this group of patients was 29.147. Such patients were not enrolled in the PORTEC trials because it was felt that omitting pelvic RT when lymphadenectomy was not performed could not be justified. In the registry study reported by Creutzberg et al,[107] 99 patients with 50% or more myometrial invasion grade 3 were treated with postoperative pelvic RT. The 5-year rate of

vaginal recurrence was 5%, that of pelvic recurrence was 8%, and that of distant relapse was 31%. Very few investigators would recommend surgery alone for these patients. In fact, an argument could be made that pelvic RT might be needed even after a negative lymphadenectomy, especially for older patients and those with LVI. In the GOG 99 trial, factors associated with an increased recurrence rate (25% at 5 years) were identified using proportional hazards regression modeling of historical data from GOG 3396. These factors were increasing age, moderate to poorly differentiated tumor grade, the presence of LVI, and outer one-third myometrial invasion. From the results of that analysis, a subgroup of patients with high-intermediate risk (HIR) was defined as follows: at least 70 years of age with only one of the other risk factors, at least 50 years of age with any two of the other risk factors, or any age with all three of the other risk factors. Those on the RT arm demonstrated a somewhat lower overall death rate when compared to those on the observation arm (relative hazard [RH] = 0.73, 90% CI = 0.43-1.26) in the HIR subgroup. At many institutions, patients with deep myometrial invasion grade 3 who are HIR per GOG 99 are offered postoperative pelvic RT. If they are not HIR, which is not that common in this subset of patients, they could be considered for VCBT, but only in the setting of adequate surgical lymph node assessment.

Cervical Involvement

Gross cervical involvement increases the risk of parametrial extension as well as spread to pelvic lymph nodes in a way similar to primary cervical cancer. Such patients could undergo radical hysterectomy and pelvic lymph node dissection or preoperative radiation including pelvic radiation and intracavitary BT followed by simple hysterectomy. The FIGO 2009 staging system only recognizes cervical stromal invasion, and not endocervical gland involvement, as being stage II. However, it is important to note that patients with endocervical gland involvement were included in the POTEC-2 trial comparing pelvic RT to IVRT.

There are also emerging data on the role of IVRT alone in highly selected patients with cervical stromal invasion. Elshaikh et al reported on 27 patients treated with IVRT. There were no vaginal recurrence, and only one pelvic recurrence.[108,109] At MSKCC, patients with endocervical glandular

involvement are often treated with IVRT. For patients with cervical stromal invasion grades 1 and 2 and the depth of cervical stromal invasion less than50%, IVRT could be offered if they underwent adequate surgical lymph node assessment. For those with grade 3 or deep cervical stromal invasion, pelvic RT is recommended, irrespective of lymphadenectomy. Table 77.5 shows overall treatment recommendations for early-stage endometrioid adenocarcinoma.

TABLE 77.5 TREATMENT RECOMMENDATIONS FOR STAGE I AND II PATIENTS WITH ENDOMETRIOID ADENOCARCINOMA

FIGO Stage	Histologic Grade	Adjuvant Treatment
IA	G1, G2	Observation preferred or consider VBT if LVSI and/or age ≥60 y
	G3	VBT preferred or consider observation if no myoinvasion or consider EBRT if either age ≥70 y or LVSI
IB	G1	VBT preferred or consider observation if age <60 y and no LVSI
	G2	VBT preferred or consider EBRT if ≥60 y and/or LVSI or consider observation if age <60 y and no LVSI
	G3	RT (VBT and/or EBRT) +/− systemic therapy
II	G1-2	EBRT (preferred) and/or VBT or VBT alone if G1 or G2, <50% MMI, no LVSI, and microscopic cervical invasion
	G3	EBRT +/− VBT +/− systemic therapy

EBRT, external beam radiation therapy; LVSI, lymphovascular space invasion; RT, radiation therapy; VBT, vaginal cuff brachytherapy.

ROLE OF SYSTEMIC THERAPY IN COMBINATION WITH RADIOTHERAPY

Hormonal therapy has been used in the treatment of recurrent/advanced endometrial cancer for many years. Agents used include megestrol acetate (Megace), medroxyprogesterone acetate (Provera), and, to a lesser extent, tamoxifen.[109-111] The response rate ranges from 9% to 33%, with an OS of 6

to 14 months. In GOG 107, doxorubicin was compared to doxorubicin and cisplatin.[112] The response rate was 42% versus 25% (P = .004), and the progression-free interval was 5.7 versus 3.8 months (P = .014) in favor of combination chemotherapy. However, this did not translate into OS advantage (9 vs 9.2 months). In the GOG 177 trial,[113] doxorubicin/cisplatin was compared to doxorubicin/cisplatin/paclitaxel. The three-drug regimen was superior in terms of response rate (57% vs 34%, P < .01), progression-free interval (8.3 vs 5.3 months, P < .01), and survival (15.3 vs 12.3 months, P = .037).

However, limitations of the three-drug paclitaxel-doxorubicin- cisplatin (TAP) regimen included tolerability and cumbersome scheduling. The GOG 209 trial evaluated carboplatin plus paclitaxel as a noninferior alternative to TAP in stage III, stage IV, and recurrent endometrial cancers, who were determined to have poor potential for cure by surgery and/or RT.[114] From 2003 to 2009, 1,381 women were enrolled, of which 41% were stage III and 23% received pelvic RT. In this study, carboplatin/paclitaxel was determined to be noninferior for OS (median, 37 vs 41 months) and PFS (median, 13 vs 14 months). In addition, carboplatin/paclitaxel had a favorable toxicity profile and better quality of life. This study conclusively established carboplatin/paclitaxel as the preferred systemic therapy regimen over the past decade (prior to studies establishing the use of immunotherapy in combination with chemotherapy for advanced-stage disease).

It is important to emphasize that historically, pelvic, whole-abdomen, or volume-directed RT has been commonly recommended in the adjuvant treatment of locally advanced endometrial cancer (stages III, IVA).[115] However, with the widespread use of chemotherapy in the recurrent/advanced setting, its use in the adjuvant setting has also started to increase and challenge the role of adjuvant RT. There are several randomized trials addressing the role of adjuvant chemotherapy in combination with or as an alternative to RT in advanced endometrial cancer.

Chemotherapy Versus Radiotherapy Trials

There are three randomized trials comparing adjuvant chemotherapy to radiation. The Japanese Gynecology Oncology Group (JGOG) trial randomized 385 patients with stages (FIGO 1988) IC to III (25% with stage

III) endometrial cancer to pelvic radiation (193 patients) or to chemotherapy (192 patients).[116] The surgery was hysterectomy with optional lymphadenectomy. The dose of pelvic RT was 45 to 50 Gy using open anteroposterior/posteroanterior (AP/PA) fields. Chemotherapy consisted of cyclophosphamide (333 mg/m^2), cisplatin (50 mg/m^2), and doxorubicin (40 mg/m^2) every 4 weeks for three cycles or more. There was no significant difference in PFS (P = .726) or OS rate (P = .462) between the two groups. A trial from Italy had a similar design, in which 340 patients with stage (FIGO 1988) IC grade 3, stage II grade 3, and stage III (two-thirds of patients) were randomized to radiation consisting of 45 to 50 Gy to the pelvis or pelvis plus para-aortic fields, or to chemotherapy.[117] With a median follow-up of 95.5 months, the 5-year disease-free survival rate was 63% in both arms (P = .44) and the 5-year OS rate was 69% in the radiation arm and 66% in the chemotherapy arm (P = .77). Again, there was no significant difference in outcome despite using five cycles of Cytoxan, cisplatin, and doxorubicin. It is important to emphasize that these first two trials used pelvic or pelvic plus para-aortic RT depending on the extent of nodal involvement rather than whole-abdomen radiation.

In GOG 122, 396 patients with stages (FIGO 1988) III to IV disease were randomized to whole-abdomen radiation (n = 202) versus doxorubicin/cisplatin (n = 194) for eight cycles. PFS was the primary end point of this study. With a median follow-up of 74 months, there was significant improvement in both PFS (50% vs 38%; P = .007) and OS rate (55% vs 42%; P = .004), in favor of chemotherapy.[118] However, before concluding that chemotherapy alone is the answer, a closer examination of the data is warranted. The overall absolute rate of relapse was 54% in the radiation arm compared to 50% in the chemotherapy arm, a small difference, if any, and yet the corresponding 5-year PFS rates were 38% and 50% (P = .007). The reason for the discrepancy is that in this study, there was stage imbalance, in which there were more stage IIIA patients in the RT arm (28.2%) than in the chemotherapy arm (18%). Conversely, there were more patients with stage IIIC disease in the chemotherapy arm (51.5%) than in the RT arm (44.6%). Therefore, the 5-year disease-free survival rate for the chemotherapy arm was increased from 42% to 50%, which became significantly different than the RT arm (50% vs 38%, P = .007) rather than 42% versus 38%, which is not likely to be significant. The 5-year OS rate in

the chemotherapy arm was 55% compared to 42% for the RT arm (P = .004). What are we to make of the significant difference in OS? There were 15 deaths unrelated to endometrial cancer or protocol treatment in the radiation arm compared to only six in the chemotherapy arm, raising a question about whether the two arms of the study were truly balanced, especially because no stratification was performed in that trial.[118] The results of GOG 122 have led to the adoption of adjuvant chemotherapy as the preferred treatment for stage III endometrial cancer. It is important to note, however, that GOG 122, JGOG, and the Italian study all showed no significant difference in the patterns of relapse between RT and chemotherapy. If one were to use the unadjusted PFS from GOG 122, then all three randomized trials failed to show that adjuvant chemotherapy is superior to adjuvant RT.

Chemoradiation Versus Radiotherapy Trials

There are four randomized trials comparing adjuvant chemoradiation to radiation (Table 77.6). In the first trial from Finland,[119] 156 patients with stage (FIGO 1988) IA or IB grade 3 (n = 28) or stage IC to IIIA grades 1 to 3 (n = 128) were postoperatively randomized to receive RT (56 Gy) only (n = 72) or RT combined with three cycles of cisplatin (50 mg/m^2), epirubicin (60 mg/m^2), and cyclophosphamide (500 mg/m^2) chemotherapy (n = 84). The disease-specific overall 5-year survival was 84.7% in the RT arm versus 82.1% in the chemoradiation arm (P = .148). The second trial reported by Hogberg et al[120] is two trials (Mario Negri Gynecologic Oncology Group [MaNGO] and Nordic Society of Gynecological Oncology [NSGO]/European Organisation for Research and Treatment of Cancer [EORTC]) combined in one report. In the MaNGO trial, there were 157 patients (two-thirds were stage III); 76 were randomized to postoperative pelvic RT (45 Gy) and 80 to chemotherapy followed by pelvic RT. The chemotherapy consisted of three cycles of doxorubicin (60 mg/m^2) and cisplatin (50 mg/m^2). The 5-year PFS was 61% in the RT group compared to 74% for the chemoradiation group, but that difference was not significant (P = .1). The 5-year OS was also not significant (73% vs 78%; P = .41). In the NSGO/EORTC trial, 383 patients were randomized to RT (n = 191) versus RT and chemotherapy (n = 187). The type of chemotherapy varied,

and only a handful of patients were stage III. The 5-year PFS was better for the chemoradiation arm (79% vs 72% for RT; $P = .04$), but OS was not significantly better (83% vs 76%; $P = .1$).

TABLE 77.6 EFFECT OF CHEMORADIATION COMPARED TO RADIATION ON OUTCOME IN HIGH-RISK ENDOMETRIAL CANCER

	Finland	NSGO	MaNGO	GOG 249	PORTEC-3
PFS	↔	↑	↔	↔	↔ stage I-II ↑ stage III
OS	↔	↔	↔	↔	↔

Gynecologic Oncology Group (GOG) 249 compared chemotherapy plus intravaginal RT to pelvic RT, whereas the Finland trial, Nordic Society of Gynecological Oncology (NSGO), Mario Negri Gynecologic Oncology Group (MaNGO), and PORTEC-3 compared chemotherapy plus pelvic RT to pelvic RT.

↔, chemoradiation equivalent to pelvic RT; ↑, chemoradiation better than pelvic RT; OS, overall survival; PFS, progression-free survival.

The third trial is GOG 249, where 601 patients with stages I to II high- to intermediate-risk endometrioid adenocarcinoma and all stages I to II serous or clear cell carcinoma were randomized to either pelvic RT (45 Gy) or IVRT plus three cycles of carboplatin/paclitaxel. With a median follow-up of 53 months, the 3-year recurrence-free survival was 82% in both arms. The OS rate was 91% in the pelvic RT arm compared to 88% for the chemotherapy and IVRT arm. There was no significant difference in the rate of vaginal relapse or distant metastasis. There was a higher rate of pelvic recurrence in the chemotherapy arm compared to pelvic RT (25 vs 6 patients). Toxicity was also higher in the chemotherapy arm.[118] The fourth trial is PORTEC-3, which included stage III patients as well as high-risk early-stage disease. There were 660 patients who were randomized to either pelvic RT (46.8 Gy) or pelvic RT with concurrent cisplatin (50 mg/m^2) on weeks 1 and 4 followed by four cycles of carboplatin/paclitaxel.[121] With a median follow-up time of 60.2 months, the 5-year OS was 81.8% for chemoradiation arm versus 76.7% for RT arm (HR 0.79, 95% CI = 0.57-1.12, $P = .183$). The corresponding 5-year failure-free survival rates were 75.5% versus 68.9%, with an HR of 0.77 (0.58-1.03, $P = .078$).

Chemoradiation Versus Chemotherapy Trial

In the GOG 258 trial, 736 patients with stage III or IVA endometrial carcinoma according to FIGO 2009 staging criteria of any histologic subtype or had FIGO 2009 surgical stage I or II clear cell or serous endometrial carcinoma and positive peritoneal washings were randomized to six cycles of carboplatin/paclitaxel versus postoperative EBRT with concurrent cisplatin (50 mg/m^2) on weeks 1 and 4 followed by four cycles of carboplatin/paclitaxel.[122,123] Residual gross disease after surgery up to 2 cm was allowed. Pelvic and para-aortic lymph node biopsy or dissection was optional, but surgery to remove lymph nodes was reported in more than 94% of patients, with a median number of 13 pelvic nodes and 3 para-aortic nodes removed. The EBRT regimen was 45 Gy in 25 fractions to the pelvis, with extended fields allowed if there was evidence of para-aortic involvement. Intensity-modulated RT (IMRT) was used in 30% of cases. Vaginal BT boost was allowed for vaginal, cervix, or LUSI, or for LVSI and was administered in 201 patients. With a median follow-up of 47 months, the 5-year recurrence-free survival was about 58% in both arms. The 5-year OS was 73% in the chemotherapy-alone arm compared to 70% in the chemoradiation arm. When comparing the chemoradiation arm to chemotherapy-alone arm, there were some differences in the rates of relapse: vaginal recurrence (3% vs 7%), pelvic/para-aortic (10% vs 19%), and distant (27% vs 21%). The long-term OS outcome for this study (median follow-up of 112 months) was presented in 2023.[124] The stratified HR for death comparing chemoradiation therapy (CRT) versus CT was 1.05 (95% CI: 0.82-1.34, P = .72), demonstrating similar long-term OS. The overall conclusion from GOG 258 is that adjuvant chemotherapy should be routinely recommended in patients with stages III and IVA endometrial cancer. RT clearly decreases the incidence of locoregional recurrence but may not affect OS.

There are several important points to consider in interpreting GOG 258 as a radiation oncologist and to advocate for the benefit of RT in a multidisciplinary environment.[125] First, *RT accomplished what it set out to do*, which was to dramatically reduce locoregional recurrence. It has long been known that RT in HIR endometrial cancer improves local control, with similar OS, and an analogous outcome was demonstrated for stage III/IVA

disease in GOG 258. Second, *chemotherapy alone was insufficient to sterilize high-risk nodal basins*. The median number of dissected pelvic nodes was 13 in GOG 258, and with the increasing use of SLN mapping, future patients may have fewer dissected nodes and thus a greater burden of unresected disease, increasing the risk of locoregional recurrence even further. For instance, in the SENTOR study, a prospective study of SLN biopsy followed by lymphadenectomy, only 52% of patients with node-positive disease had metastases in the SLN specimen only, while the other patients had additional disease identified in the lymphadenectomy specimens.[126] Unresected gross disease less than 2 cm was allowed on GOG 258 (but not on PORTEC-3), and 11 of 17 of these patients later developed recurrence. While local recurrence in the vagina or nodes might be curable with salvage RT, the treatment is often more difficult and associated with greater toxicity than adjuvant RT. Third, *the increase in distant recurrence in the CRT arm was not due to RT, but possibly due to insufficient and possibly inadequately sequenced chemotherapy*. The CRT arm had four cycles of carboplatin/paclitaxel after cisplatin-based chemoradiation, while the CT arm had six cycles. The cisplatin used concurrently with radiation is not expected to be as effective as carboplatin/paclitaxel at treating occult distant disease, and therefore patients randomized to CRT may have received less treatment than necessary to reduce distant metastasis. In addition, only 75% of patients in the CRT arm received all four cycles of carboplatin/paclitaxel versus 85% of patients in the CT arm received all six cycles of carboplatin/paclitaxel. Furthermore, carboplatin/paclitaxel was delayed until after the completion of cisplatin radiation in the CRT group and recovery (5 weeks of RT plus up to 8 weeks after the end of RT), which possibly postponed the start of effective systemic therapy. In retrospective data, multiagent CT followed by RT is associated with improved outcomes compared with treatment with RT followed by CT or either treatment alone, further supporting the importance of early chemotherapy.[127] It is interesting to note that when GOG 258 was designed, there was vigorous debate about the combined modality treatment regimen, and some investigators favored a "sandwich regimen" consisting of three cycles of dual-agent chemotherapy followed by RT and then additional chemotherapy.[128] The specific CRT regimen ultimately selected (that used in Radiation Oncology Cooperative Group [RTOG] 9708) was chosen because these data were prospectively

obtained while there were less prospective data supporting sandwich therapy at the time. However, since that era, multiple studies have supported the safety and efficacy of the sandwich approach.[129,130] A randomized trial of sandwich therapy versus cisplatin chemoradiation followed by carboplatin/paclitaxel (identical to GOG 258) unfortunately failed to accrue.[131] The overall proposal from these sequence considerations is that chemotherapy should be started first and that RT may be incorporated later as a sandwich method or possibly after the conclusion of all six cycles of carboplatin/paclitaxel. Fourth, if *RT is recommended, then external radiation is an important component of treatment for locally advanced disease*. It is attractive to consider chemotherapy plus vaginal BT alone due to convenience and low toxicity, and indeed, this is likely superior to omission of RT entirely. However, the recurrence patterns from GOG 258 showed that vaginal recurrences are a minority of all recurrences and also a minority of locoregional recurrences (about one-third) and that nodal recurrence risk is an important consideration. Therefore, if the goal of RT in stage III/IVA disease is to improve local control as much as possible, then this goal would be best accomplished with external radiation, possibly with a vaginal BT boost. This argument also avoids the "cognitive dissonance" that might arise from an overall treatment strategy that involves recommending external radiation and/or vaginal BT for patients with certain early-stage endometrial cancer while omitting RT for patients with stage III/IVA, who have even higher risks of local recurrence.[126] Fifth, *external RT is likely to be better tolerated now than in GOG 258*, in which only 30% of patients received IMRT. IMRT is now a standard treatment option and has been shown in a randomized trial to decrease acute toxicity, especially diarrhea.[132] Bone marrow–sparing IMRT approaches are under active investigation to reduce hematologic toxicity and limit the impact of RT on tolerance of additional cycles of chemotherapy.[133]

After the publication of GOG 258, the radiation oncologist will be faced with the argument in multidisciplinary discussions that the role of RT in the adjuvant treatment of locally advanced endometrial cancer is settled and is now very limited. It is the authors' belief that RT still has an essential role in this setting in decreasing local recurrence, based on the abovementioned arguments, and that it is important for radiation oncologists to engage with gynecologic oncologists to optimize outcomes for patients.

Chemotherapy and Immunotherapy Trials for Advanced Disease

In 2023, two trials established the role of immunotherapy in combination with carboplatin/paclitaxel for advanced or recurrent endometrial cancer. NRG-GY018 enrolled 816 patients and evaluated standard chemotherapy with paclitaxel plus carboplatin plus either pembrolizumab or placebo in patients with advanced or recurrent endometrial cancer. Eligible patients had stage III or IVA with measurable disease or stage IVB or recurrent endometrial cancer with or without measurable disease.[134] The two treatment strategies were analyzed in two independent cohorts—patients with MMRD disease and those with MMR-proficient (MMRp) disease. The published report did not include the patient breakdown by stage. Previous RT was administered in 43% of patients in the MMRD cohort and 40% in the MMRp cohort. In the 12-month analysis, median PFS in the MMRD cohort was 74% in the pembrolizumab group and 38% in the placebo group ($P < .001$). In the MMRp cohort, median PFS was 13.1 months with pembrolizumab and 8.7 months with placebo ($P < .001$).

The RUBY trial enrolled 494 patients with FIGO stage III, IV, or recurrent endometrial cancer that was generally not amenable to curative therapy.[135] The specific eligibility criteria were complex and included stage IIIA, IIIB, or IIIC1 with measurable disease, stage IIIC1 with carcinosarcoma, clear cell, serous, or mixed histologies regardless of the presence of measurable disease, stage IIIC2 or stage IV regardless of the presence of measurable disease, and recurrent disease. Patients were randomized to dostarlimab, a programmed cell death protein 1 inhibitor, or placebo in combination with carboplatin and paclitaxel. In the trial population, 18.6% of the patients had primary stage III, 33.6% had primary stage IV, and 47.8% had recurrent disease. Previous RT was administered in 17% of patients. In the overall population, PFS at 24 months was 36.1% in the dostarlimab group and 18.1% in the placebo group ($P < .001$), while OS at 24 months was 71.3% with the dostarlimab regimen and 56.0% with the placebo regimen ($P = .0021$).

It is important to note that RT was not excluded in NRG-GY018 and RUBY and that most patients in these studies had recurrent, metastatic, or locally advanced stage with measurable disease. The addition of immunotherapy to chemotherapy is now recommended for patients who

meet entry criteria for either study. However, the implications of these studies for patients considered for adjuvant RT with locally advanced disease without measurable residual disease are debatable. It is suggested that RT, by improving local control, may complement immunotherapy, which improves distant recurrence rates and that RT can be safely delivered during immunotherapy maintenance either concurrently or between cycles.[136]

Systemic Therapy Recommendations Based on Risk Factors

When considering the use of adjuvant chemotherapy in endometrial cancer based on risk factors, one needs to pay attention to whether we are dealing with an isolated as opposed to multiple risk factors. This is particularly important when dealing with FIGO 2009 stage III disease.

Early-Stage High-Risk Endometrioid Adenocarcinoma

In the GOG 249 randomized trial[118] limited to high-risk stage I to II disease, 71% of patients had endometrioid histology. In PORTEC-3, patients with stage I (grade 3 with deep myometrial invasion and/or LVI) as well as stage II were included (55%); endometrioid histology was seen in 71% of patients.[121] In both trials, the addition of chemotherapy did not impact outcome of particularly distant metastasis, which was equivalent in GOG 249 and only slightly less in PORTEC-3 (23.1% for chemoradiation vs 29.7% for pelvic RT; $P = .077$). Therefore, routine use of adjuvant chemotherapy in addition to radiation could not be recommended for all high-risk early-stage endometrioid adenocarcinoma.

Early-Stage Serous and Clear Cell Cancer

Serous cancer and, to a lesser extent, clear cell cancer tend to spread in a way similar to ovarian cancer, with a high propensity for upper abdominal relapse. Therefore, it is important to perform comprehensive surgical staging because of the high rate of surgical upstaging. For serous endometrial cancer, the preferred approach is IVRT plus carboplatin/paclitaxel.[104,137,138] In a report from MSKCC on 41 patients with stages I to II (all had negative peritoneal cytology) treated as such, with a median follow-up time of 58 months, the 5-year disease-free survival and

OS rates were 85% and 90%, respectively.[138] The 5-year actuarial recurrence rates were 9% in the pelvis, 5% in the para-aortic nodes, and 10% at distant sites. None of the patients developed vaginal recurrence. In a subsequent report, the presence of deep myometrial invasion and/or cervical stromal invasion was associated with a higher rate of pelvic recurrence.[104] This issue raises the question of whether pelvic RT alone or in combination with chemotherapy should be considered for such a subset of early-stage serous cancers. More mature data from PORTEC-3 and GOG 249 may shed more light on the role of pelvic RT in this histology. At MSKCC, most patients with early-stage serous endometrial cancer disease who are surgically staged are treated with IVRT interdigitated with six cycles of concurrent carboplatin/paclitaxel. Treatment recommendations for clear cell carcinoma often mirror those for serous, but it is debatable if that is always warranted. At MSKCC, patients with early-stage clear cell carcinoma are treated with IVRT, with concurrent carboplatin/paclitaxel being reserved for those with deep invasion or cervical involvement.

Stage IIIA

The results of postoperative EBRT in patients with *isolated* adnexal or serosal involvement are generally good. However, the rate of distant relapse is still 26% to 33%, indicating the need for adjuvant systemic therapy.[76] Furthermore, patients with more than one site of involvement, that is, *multiple risk factors*, do worse. Jobsen et al[139] reported on 141 patients with IIIA endometrioid adenocarcinoma (patients with isolated positive peritoneal cytology were excluded) treated with postoperative RT. The risk of abdominal relapse was 12.4% (11/89) for patients with one site of involvement compared to 36.5% (19/52) for more than one site ($P < .001$). Distant metastasis rate was 23.9% (21/89) compared to 34.6% (18/52). The 5-year DSS was 70.4% for one involved site compared to 43.3% for more than one ($P = .001$). On multivariate analysis, grade 3 (HR, 2.5; $P = .045$) and more than one site involvement (HR, 2.2; $P = .012$) were independent predictors of poor DSS. In the ongoing debate on whether chemotherapy alone is better than chemoradiation in patients with stage III, it is in this group of patients with multiple sites of involvement especially with positive peritoneal cytology and/or aggressive histologies[75,140] in which

chemotherapy plus IVRT might be a better choice than combining with pelvic RT.

Stage IIIC

The outcome of patients with *isolated* lymph node involvement (especially pelvic nodes) treated with postoperative pelvic RT is relatively good.[77] Some institutions recommend external beam radiation with concurrent cisplatin followed by carboplatin/paclitaxel to try to reduce the risk of recurrence even further. Milgrom et al[141] reported on 40 patients with stage III (82% were IIIC) treated with such an approach. With a median follow-up time of 49 months, the 5-year freedom from relapse was 79% and OS was 85%. The rate of vaginal recurrence was 3%, pelvic recurrence 3%, para-aortic 11%, peritoneal 5%, and other distant 11%.

Because stage IIIC is the most common subset in stage III disease (73% of patients in GOG 258), a discussion here about how to reconcile the data from GOG 258 and those from PORTEC-3 (stage III subset 45%) is in order. In PORTEC-3, the 5-year failure-free survival was 58% for RT alone compared to 69% for chemoradiation (P = .032) in stage III patients. The corresponding rates for OS were 70% and 79%.[121] In GOG 258, the 5-year relapse-free survival was about 58% in both arms, and OS was 70% in the chemoradiation arm and 73% in the chemotherapy-alone arm.[122] The question then becomes: Why was the rate of OS and relapse-free survival of the radiation-alone arm in PORTEC-3 for patients with stage III similar to both arms of in GOG 258? The answer might be found in the different inclusion criteria: GOG 258 allowed for patients with less than 2 cm gross residual disease (17 patients with 11/17 developing recurrence), whereas POTEC-3 excluded patients with gross residual disease.

As mentioned earlier in stage IIIA, the presence of *multiple risk factors* in stage IIIC has been shown to be a predictor of poor outcome.[142] In a recent Surveillance, Epidemiology, and End Results review, Garg et al[143] showed that for patients with stage IIIC disease (n = 2,559), the 5-year DSS was 67%, which dropped to 43% when extranodal involvement (ie, positive washing, adnexa/serosal, and vaginal/parametrial involvement) was present (P < .001). At MSKCC, such patients are treated with full systemic

chemotherapy plus IVRT rather than external beam and concurrent chemotherapy.

RADIATION THERAPY TECHNIQUES

Vaginal Cuff Brachytherapy

The purpose of this treatment modality is to deliver the highest dose of radiation to the vaginal mucosa while limiting the dose to the surrounding normal structures, such as the bladder, rectum, sigmoid, and small intestines. HDR BT using ^{192}Ir sources is the preferred method of delivering VCBT. The type of applicator used is generally a cylinder. The treatment is given on an outpatient basis without the need for anesthesia and without the radiation exposure to medical personnel. Patients typically start their treatment 4 to 6 weeks postoperatively, depending on the vaginal cuff healing, and treatment should ideally be delivered no later than 12 weeks after surgery. It should be noted that it takes longer for the vaginal cuff to heal after LAVH/BSO and robotic hysterectomy than after TAH/BSO.[144] HDR BT is often delivered in multiple fractions over a short treatment period. Common fractionation schemes include 6 Gy × 4 fractions (total dose of 24 Gy) delivered twice weekly over 2 weeks, 5 Gy × 5 fractions (total dose of 25 Gy) delivered twice weekly over 2 weeks, and 7 Gy × 3 fractions (total dose of 21 Gy) delivered weekly over 3 weeks.[145] These fractionation schemes are commonly used and have been reported in various clinical studies and treatment guidelines. The American Brachytherapy Society (ABS) has made specific recommendations for applicator selection, insertion techniques, target volume definition, dose fractionation, and specifications for postoperative adjuvant VCBT.[145] The ABS recommends that applicator selection should be based on patient anatomy, target volume geometry, and physician judgment. The dose prescription point should be clearly specified. When VCBT is given with chemotherapy, it is given concurrently, but not during the week when the patient is receiving chemotherapy. When the 7 Gy × 3 fractions (total dose of 21 Gy) fractionation scheme is utilized, the dose is prescribed to a 0.5-cm depth from the mucosal surface (Figure 77.7). The treatment is usually delivered using a 3-cm diameter cylinder to treat a 3.5- to 7-cm length of the vagina, depending on the depth of invasion and tumor grade. For

patients with grade 3, serous, or clear cell carcinoma, the length of vagina treated is generally 7 cm (assuming an average length of vagina after a simple hysterectomy of about 10 cm). This is done to account for the potential submucosal extension that may lead to relapse in the distal periurethral region with these aggressive histologies. For patients with grade 1 or 2 endometrioid adenocarcinoma, the treated vaginal length increases from 3.5 cm if the myometrial invasion is less than 50%, to 5 cm for more than 50% myometrial invasion, and to 6 cm for cervical involvement. If the diameter of the cylinder is less than 3 cm, it is recommended to use a greater than three fractionation scheme (4-6 fractions). This is usually done to avoid a very high dose of radiation to the vaginal mucosa. The dose per fraction is also lowered to 4 to 5 Gy when pelvic radiation is added.

External Beam Radiation

Conventional Radiotherapy

At the time of simulation for *pelvic* RT, the small bowel is often opacified using oral contrast, a vaginal marker can be used to define the vaginal cuff, and the rectum can opacified with barium or CT-compatible contrasts. Patients are sometimes placed in the prone position to displace the small intestines from the radiation field, but supine is also acceptable. The target

volume consists of the pelvic lymph nodes, including obturator, external, internal, and lower common iliac groups and the proximal two-thirds of the vagina. The presacral nodes are not included unless patients have gross cervical involvement. High-energy linear accelerators (15 MV) are preferred because of their sparing of the skin and subcutaneous tissue. The ideal beam arrangement with conventional radiation is the four-field pelvic box technique to reduce the dose to the small intestines and, to some extent, the bladder and rectum. For AP/PA fields, the superior border is L5-S1, the inferior border is the bottom of the obturator foramina, and the lateral border is 2 cm beyond the widest point of the inlet of the true bony pelvis. For lateral fields, the anterior border is in front of the pubis symphysis and the posterior border at least at S2-S3. The superior and inferior borders are the same for the AP/PA fields. All fields are treated daily to a dose of 1.8 Gy. A total dose of 50.4 Gy is generally given when pelvic radiation is used alone, or 45 Gy when combined with VCBT.

When para-aortic nodes are involved, *extended field* RT is used, and CT simulation is crucial for accurate delineation of the kidneys, small bowel, and liver in addition to nodal target. The latter should include, in addition to the pelvic nodes, the pericaval, interaortocaval, and para-aortic areas, defined by contrast-enhanced blood vessels. The preferred approach is the four-field box technique rather than AP/PA in order to lower the dose to the small intestines. However, attention should be paid to the dose that the kidneys might receive with the four-field arrangement. The lower border is the same as in pelvic radiation, but the upper border is extended usually to the T12-L1 interspace. The typical dose is 45.0 Gy at 1.8 or 1.5 Gy if patients develop acute GI toxicity.

Intensity-Modulated Radiotherapy

At most institutions, postoperative IMRT is used for most patients with endometrial cancer who need pelvic or extended field radiation (Figure 77.8). At the time of simulation, patients are placed in the prone (pelvic) or supine (extended) position and immobilized using Aquaplast. Oral and rectal contrasts can be used to better visualize the small and large intestines. In addition, contrast is inserted into the vaginal cuff to better visualize the upper vagina. Because pelvic lymph nodes are poorly visualized by CT

when normal, they should be defined by encompassing the contrast-enhanced blood vessels. Taylor et al[146] found that a modified 7-mm margin around contrast-enhanced vessels offers a good surrogate target for pelvic lymph nodes. Small et al[147] reported on consensus guidelines for delineation of clinical target volume (CTV) for intensity-modulated pelvic RT in postoperative treatment of endometrial and cervical cancer. A modified 7-mm margin (excluding bowel and muscles) is recommended around the iliac vessels to create nodal CTV. To create nodal planning target volume (PTV), an additional expansion of 7 mm all around nodal CTV is generally recommended. At many institutions, a vaginal PTV is created by outlining the contrast-enhanced vaginal cuff and adding a 3-cm margin axially and 2 cm superior and inferior to account for the impact of bladder and rectal filling, as well as of vaginal motion.[148] An alternative approach would be to simulate patient with bladder full and bladder empty and create an internal target volume. The RTOG established dose constrains for using postoperative IMRT in endometrial cancer.[149] For bladder, less than 35% receives 45 Gy or more; rectum, less than 60% receives 45 Gy or more; small bowel, less than 30% receives 40 Gy or more; femoral heads, less than 15% receives 30 Gy or more; and any 1% or less or 1 mL or less receives more than 110% prescribed dose normal tissue.

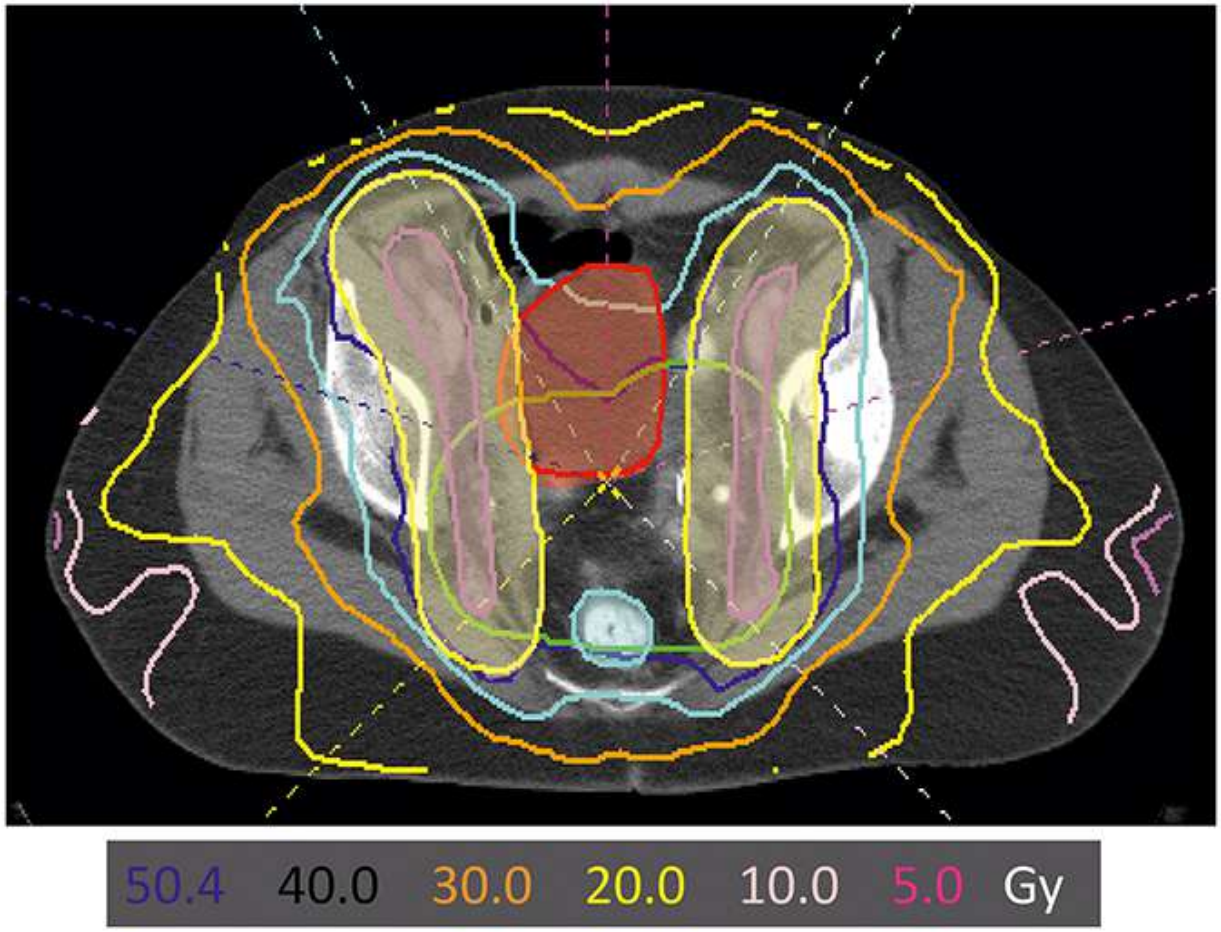

FIGURE 77.8 Pelvic intensity-modulated radiation therapy dose distribution. Outlined iliac vessels are shown in pink and nodal planning target volume in yellow.

Data on outcome with postoperative IMRT in endometrial cancer are encouraging. He et al reported on 129 patients (77% stages I to II). With a median follow-up of 57 months, the 5-year DFS in the subset of patients with stages I to II (n = 98) was 85.7% for those with low-intermediate risk and 71.6 for HIR. The corresponding rates for OS were 91.7% and 76.2%.[150] Shih et al reported on 46 patients with high-risk endometrial cancer treated with postoperative IMRT. With a median follow-up of 52 months, the 5-year disease-free survival and OS rate in stage III (n = 36) were 84% and 95%, respectively.[151]

COMPLICATIONS OF TREATMENT

Surgery

In the PORTEC-1 trial,[94] the rate of complications in the surgery-alone arm was very low (6%). Surgical toxicity data are generally collected within 30 days of surgery, that is, before patients were enrolled in the trial. Therefore, it is important to assess surgical toxicity from trials addressing a surgical question. In the GOG LAP2 trial comparing laparotomy to laproscopy,[81] the rate of intraoperative complications was 8% versus 10% ($P = .106$). More importantly, the rate of postoperative (within 6 weeks of surgery) grade 2 or greater complications was 21% for laparotomy versus 14% for laparoscopy ($P < .001$). In the Italian randomized trial comparing hysterectomy to hysterectomy and lymphadenectomy, both early and late postoperative complications occurred significantly more frequently in patients with lymphadenectomy (81/264; 30.6%) than for hysterectomy alone (34/250, 13.6%; $P = .001$). Most of the difference in morbidity was due to lymphoceles and lymphedema, which occurred in 35 patients in the lymphadenectomy arm and 4 patients in the no-lymphadenectomy arm.[85]

Radiation

Vaginal Cuff Brachytherapy

The main advantage of intravaginal BT is its ability to deliver a relatively high dose of radiation to the vagina while limiting the dose to the surrounding normal structures, such as the bowels, rectum, and bladder. In the PORTEC-2 trial, the long-term health-related quality of life analysis showed at 7 years, clinically relevant fecal leakage was reported by 10.6% in the pelvic RT group versus 1.8% for VCBT ($P = .03$), diarrhea by 8.4% versus 0.9% ($P = .04$), limitations due to bowel symptoms by 10.5% versus 1.8% ($P = .001$), and bowel urgency by 23.3% versus 6.6% ($P < .001$). Urinary urgency was reported by 39.3% of pelvic RT patients, compared to 25.5% for VCBT ($P = .05$). No difference in sexual activity was seen between treatment arms.[152] However, such a low rate of severe complications cannot be taken for granted because special attention needs to be paid to the depth of prescription, the dose per fraction, the length of vagina treated, and the diameter of the cylinder used. Sorbe and Smeds[153] reported a 15% late complication rate and a very high incidence of vaginal stenosis after postoperative HDR intravaginal irradiation. This was attributed to the high dose per fraction of 6 to 9 Gy; moreover, this dose

was prescribed at a depth of 10 mm from the surface of the cylinder, resulting in very high vaginal mucosal, bladder, and rectal doses. Adherence to vaginal dilator use[154] after VCBT as well as routine use of vaginal lubricants and moisturizers may further reduce the rate of vaginal stenosis.

In a cohort of 104 patients with early-stage endometrial cancer treated with surgery and VCBT, Female Sexual Function Index (FSFI) questionnaires were used to quantify levels of sexual functioning.[112] Sexual dysfunction defined as an FSFI score of less than 26 was reported by 81% of respondents. Multivariate analysis isolated factors associated with lower FSFI scores, including having laparotomy as opposed to minimally invasive surgery (effect size, −7.1 points; $P < .001$), lack of vaginal lubricant use (effect size, −4.4 points; $P = .040$), and short time interval (<6 months) from hysterectomy to questionnaire completion (effect size, −4.6 points; $P = .059$).

In a subsequent report[155] from MSKCC, 205 early-stage endometrial cancer survivors (>1 year from surgery) completed questionnaires containing the EuroQol (EQ5D) and the FSFI. A total of 136 (66.3%) underwent surgery alone, and 69 (33.7%) received additional VCBT. A majority of patients (80%) met criteria for sexual dysfunction by FSFI less than 26.5. The two groups were well balanced with respect to demographics, comorbidities, and baseline sexual activity. Controlling for age and surgery type (open vs minimally invasive), VCBT was not associated with poorer health state or sexual function. Receipt of laparotomy was associated with both poorer health state and sexual function ($P = .0156$ and $P = .0247$, respectively). These studies highlight the fact patients with endometrial cancer whether treated with surgery alone or with additional VCBT, when compared to the index population (healthy women ages 18-74), all scores were low.

Pelvic Radiation

In the PORTEC-1 randomized trial,[156] the overall (grades 1-4) rate of late complications was 26% in the RT group compared to 4% in the observation group ($P < .0001$). Most of the late complications in the RT group, however, were grades 1 and 2 (22%), and only 3% were grades 3 and 4. It is also important to note that many patients in this trial were treated with AP/PA

fields, for which the overall rate of complications was 30%, compared to 21% for those treated with the four-field box (P = .06). In GOG 99 when lymphadenectomy was performed, chronic lymphedema was seen in 2.5% of the patients randomized to surgery alone compared to 5% with postoperative pelvic RT.[95] There is an increased awareness of sacral insufficiency fractures (SIFs) as a potential complication of pelvic RT in gynecologic cancers. In a report from MSKCC, 222 patients were treated with postoperative pelvic RT.[157] In the subset of endometrial cancer (n = 144), the 5-year rate of SIF was 5.7%. Risk of secondary malignancies is often cited as one of the main reasons to avoid pelvic RT in patients with endometrial cancer; however, when the PORTEC-1 and PORTEC-2 trials were combined, there was no clear evidence of increased risk.[158]

The use of IMRT seems to be associated with less risk of obstruction (bowel obstruction or BO). In a report from MSKCC on 224 patients (152 with endometrial cancer) treated with postoperative radiation,[159] the 5-year rate of BO in the IMRT group was 0.9% compared to 9.3% for 3D RT (P = .006). Patients with BMI 30 kg/m^2 or higher were less likely to develop BO (2.6% vs 8.3%; P = .03). On multivariate analysis, only IMRT retained its significance as an independent predictor of less BO (P = .022).

In the PORTEC-3 trial, the addition of chemotherapy to radiation showed increased physician and patient-reported toxicities. However, by 24 months, results equalized, with the exception of persistence of patient-reported sensory neurologic symptoms in 25% of patients in the chemoradiation arm.[160]

DEFINITIVE RADIATION FOR INOPERABLE DISEASE

In medically inoperable patients with endometrial cancer, radiation is an effective alternative to surgery. These patients are usually treated in a way similar to those with cervical cancer by using intracavitary applicators with or without pelvic radiation. In a systematic review of 25 reports of patients treated with RT as single treatment, the 5-year DSS was 78.5%. EBRT combined with BT was used in 1,278 (47.4%) patients, BT alone in 1,383 (51.3%) patients, and EBRT alone in 33 (1.2%) patients. The average rate of grade 3 or worse late toxicity was 3.7% for EBRT + BT, 2.8% for BT alone, and 1.2% for EBRT alone.[161] The ABS established general guideline

recommendations regarding HDR either alone or in combination with EBRT in terms of prescription point (2 cm from the central axis at the midpoint along the intrauterine sources), number of fractions, dose per fraction, combination with EBRT, and optimization. Patients with stage IIIB disease (vaginal involvement), an uncommon presentation, are usually not surgical candidates and are also treated with definitive radiation, including a combination of EBRT and intracavitary/interstitial RT tailored to the extent of their disease.[162]

For patients with clinical stage I grade 1 or 2 and no evidence of myometrial invasion or lymph node metastasis on MRI, intracavitary BT alone is sufficient. Gebhardt et al reported on 45 patients with grades 1 to 2, clinical stage I endometrial adenocarcinoma, less than 50% myometrial invasion, and tumor 2 cm or less treated with five to six fractions HDR intracavitary BT to a median total dose of 37.5 Gy. Median follow-up among living patients was 18.6 months. The 2-year local control, cancer-specific survival, and OS rates were 90%, 86%, and 97%, respectively. No grade 3+ acute or late toxicity was observed.[163] In another report, 43 consecutive patients with endometrial cancer FIGO stages I to III were treated definitively with HDR BT with or without EBRT.[164] Mean follow-up was 29.7 months. Median BMI was 50.2 kg/m^2. The 2-year OS was 65.2%. The 2-year cumulative incidence of pelvic and distant failures was 8.3% and 13.5%, respectively. Grade 3 disease was associated with a higher risk of all failures (HR, 4.67; P = .044). The incidence of acute grade 3 GI/GU toxicities was 4.6%.

RADIATION THERAPY FOR LOCAL RECURRENCE

RT can be curative in a select group of patients with small vaginal recurrences who have not received prior radiation. Creutzberg et al reported on survival after relapse based on the PORTEC-1 randomized trial.[97] In patients who were initially randomized to surgery alone (n = 46/360), the 5-year survival after vaginal relapse was 65%. However, before adopting salvage radiation as a treatment policy for all early-stage endometrial cancer, a few aspects of this trial need to be addressed. First, the 5-year survival rate from the PORTEC trial is much higher than what is reported in the literature.[165-168] Most likely, the vaginal recurrences in this trial were

detected very early, unlike the situation for patients in the community. The extent and size of local recurrence in endometrial cancer are very significant predictors of outcome.[168] Second, this high rate of salvage pertains only to isolated vaginal recurrence. The rate of survival at 3 years for pelvic recurrence in the PORTEC-1 trial[97] was 0%. Third, although the trial does not mention any data on complications, it is not unrealistic to expect a higher complication rate than what is normally seen with adjuvant radiation. With salvage radiation, EBRT and BT are often combined, and the doses of radiation required are much higher than those used with adjuvant radiation. The study from MD Anderson Cancer Center by Jhingran et al[165] clearly highlights these issues. They reported on 91 patients who were treated with definitive radiation for isolated vaginal recurrence. The 5-year local control and OS rates were 75% and 43%, respectively. The median dose of radiation was 75 Gy, which often included external radiation and BT. The rate of grade 4 complications (requiring surgery) was 9%. Thus, when talking with a patient about adjuvant radiation versus radiation reserved for salvage, these issues need to be addressed and compared to the excellent local control and low morbidity obtained with adjuvant intravaginal BT. In a report from the University of Pittsburgh,[169] 41 patients were treated with HDR BT using image-based planning with contouring/optimization with each fraction to a median dose of 23.75 Gy in five fractions. BT was combined with pelvic IMRT in 90% of patients to a dose of 45 Gy. At a median follow-up of 18 months, the 3-year local control, distant control, recurrence-free survival, and OS were 95%, 61%, 68%, and 67%, respectively. The 3-year rate of grade 3 or higher late toxicity was 8%. This indicates that even with more modern techniques, the morbidity of salvage RT cannot be ignored.

With the increased use of IMRT, salvage rate of nodal recurrence in endometrial cancer is better. In a report by Ho et al, 38 patients with endometrial cancer who had no prior external beam radiation were treated definitively using IMRT for regionally confined pelvic or para-aortic nodal recurrences. Chemotherapy was given to 33 out of 38. The total dose of IMRT was 64.7 Gy (range 59-73 Gy). The 2-year survival was 71%. Three patients (8%) experienced grades 3 to 4 late GI toxicity.[170]

UTERINE CARCINOSARCOMA

Uterine carcinosarcoma (UCS) is no longer considered a uterine sarcoma. In GOG 210, UCS represented about 4.1 of endometrial cancinomas.[46] Molecular evaluation of UCS revealed that frequent mutations were found in TP53, PTEN, PIK3CA, PPP2R1A, FBXW7, and KRAS, similar to endometrioid and serous uterine carcinomas. The range of epithelial-to-mesenchymal transition (EMT) scores in UCS was the largest among all tumor types studied via TCGA. UCSs shared proteomic features with gynecologic carcinomas and sarcomas with intermediate EMT features.[171]

The etiology of UCS is not well established but seems to share some similarity with endometrial adenocarcinoma. History of prior pelvic radiation has been reported in some patients with carcinosarcoma.[172] These neoplasms are often bulky, necrotic, and deeply invasive. The epithelial component is generally serous carcinoma. Homologous tumors have stroma that contains cell types normally seen in the uterus, in contrast to heterologous tumors, which may contain striated muscle cells (rhabdomyosarcoma), cartilage (chondrosarcoma), and bone (osteogenic sarcoma) (Figure 77.3D).

The main treatment is surgery, and these patients should undergo comprehensive surgical staging similar to that with serous cancer. Pelvic nodal metastasis is seen in 21.1%, and in para-aortic node in 15.2% of patients.[46] For carcinosarcomas, the 2009 staging system for carcinomas of the endometrium is used, recognizing the similarity in patterns of spread.

With regard to the role of *adjuvant radiation*, the EORTC performed a prospective, randomized trial addressing the role of postoperative pelvic RT in stages I to II uterine sarcomas. There were a total of 224 patients in the trial who underwent TAH/BSO, and 166 who had peritoneal washings. Lymphadenectomy was optional. There were 91 carcinosarcomas included in that study; the rate of pelvic recurrence only was 4% in the pelvic RT arm compared to 24% for the surgery-alone arm. The corresponding rates for any local recurrence were 24% and 47%, for this subset of patients.[173]

Adjuvant chemotherapy has been evaluated mainly in carcinosarcoma. Sutton et al[174] reported on 65 patients with completely resected stage I or II carcinosarcoma of the uterus treated with adjuvant ifosfamide and cisplatin. None of the patients received adjuvant RT. Overall 5-year survival was

62%. The initial site of relapse was vaginal apex in 6 of 65 and pelvis in 4 of 64, suggesting that a combined chemoradiation approach might be ideal. GOG-150 is a phase III randomized study of whole abdominal RT versus three cycles of cisplatin, ifosfamide, and mesna. Eligible patients (n = 206) included those with stages I to IV UCS, no greater than 1-cm postsurgical residuum, and/or no extra-abdominal spread. Stage distribution was as follows: I, 64 (31%); II, 26 (13%); III, 92 (45%); and IV, 24 (12%). The estimated crude probability of recurring within 5 years was 58% for chemotherapy and 52% for RT. Adjusting for stage and age, the recurrence rate was 21% lower for chemotherapy patients than for RT patients (RH, 0.789; 95% CI = 0.530-1.176; P = .245, two-tailed test). The estimated death rate was 29% lower in the chemotherapy group (RH, 0.712; 95% CI = 0.484-1.048; P = .085, two-tailed test). The conclusion was that there was not a statistically significant advantage in recurrence rate or survival for adjuvant chemotherapy over RT in patients with UCS. However, the observed differences favor the use of combination chemotherapy in future trials. The rate of vaginal recurrence was 4 (3.8%) of 105 in the whole abdominal irradiation compared to 10 (9.9%) of 101. The corresponding abdominal relapse rates were 27.6% (29/105) and 18.8% (19/101). There was no difference in pelvic recurrence between the two arms. The rates of lung metastasis (14/105 vs 14/101) or other distant sites (13/101 vs 10/101) were similar. Analysis of the patterns of relapse from this trial also indicates the need for chemoradiation in patients with stages I to III carcinosarcoma.[175]

The use of IVRT and chemotherapy is appealing in stages I to II carcinosarcoma. Desai et al reported on 60 patients with stages I to II UCS and compared them to 112 stage I to II serous endometrial cancers.[176] Adjuvant therapy was to 90% of patients. With a median follow-up of 48 months, outcomes were better for serous versus UCS: 5-year actuarial rates of recurrence (17% vs 45%; P < .001), disease-specific mortality (11% vs 30%; P = .016), and all-cause mortality (12% vs 34%; P = .007). However, in a subgroup analysis of 111 patients (77 serous, 34 UCS) who receive IVRT and chemotherapy, UCS no longer was associated significantly with increased recurrence (29% vs 15%, P = .18), disease-specific mortality (22% vs 10%, P = .39), or all-cause mortality (22% vs 10%, P = .45). This

indicates that when early-stage UCS were treated aggressively, their outcome were not significantly different than serous endometrial cancer.

Commonly, patients with surgical stage I or II carcinosarcoma are treated with intravaginal BT and chemotherapy. Most patients with stage III are treated in a similar manner, with few exceptions when extrauterine disease is limited to nodal disease. Then, consideration is given to concurrent pelvic RT/cisplatin followed by carboplatin/paclitaxel.

UTERINE SARCOMA

Uterine sarcomas are uncommon, representing about 3% to 7% of all uterine cancers.[177] The most common histology is leiomyosarcoma (LMS), followed by endometrial stromal sarcoma (resemble proliferative-phase endometrial stroma), undifferentiated uterine sarcoma, and adenosarcoma (benign epithelial component and low-grade sarcoma). Age-related incidences vary among the histologic types. The mean age at diagnosis for endometrial stromal sarcoma is 41 years, for LMS 53.5 years, and for adenosarcoma 57.4 years. Little is known about the risk factors for uterine sarcomas. Most uterine sarcomas present with vaginal bleeding, but LMSs are more commonly discovered incidentally after simple hysterectomy for presumed uterine leiomyomata.

Pathology and Staging

Endometrial stromal sarcomas are generally divided into endometrial stromal sarcomas, which are low grade by definition, and undifferentiated endometrial sarcoma, which are high grade. Tumor cells in endometrial stromal sarcoma resemble those found in the stroma of proliferative endometrial lining. In contrast, tumor cells in undifferentiated endometrial stromal sarcoma do not resemble endometrial stroma. LMSs of the uterus have a fleshy appearance, often with areas of necrosis. They display nuclear atypia, high mitotic rates, and areas of coagulative tumor necrosis. *Adenosarcomas* have two components—a benign epithelial tumor and a malignant mesenchymal component (generally low-grade sarcoma that resembles endometrial stroma). Sarcomatous overgrowth, defined as the presence of pure sarcoma, usually of high grade and without a glandular component, occupying at least 25% of the tumor, has been reported in 33%

of uterine adenosarcomas.[177] The 2009 FIGO staging recognizes the uniqueness of each uterine sarcoma. For LMSs and endometrial stromal sarcomas, the staging system recognizes the importance of tumor size on outcome. For adenosarcomas, the new staging system recognizes the importance of depth of myometrial invasion.

Management

The main treatment for uterine sarcoma is *surgery* in a similar manner to endometrial adenocarcinoma. The extent of surgical staging varies, depending on the risk of lymph node involvement. Nodal metastases are seen in less than 5% of LMS unless there is obvious extrauterine disease.[178] For stromal sarcomas, dos Santos et al[179] reported a 19% (7/36) rate of nodal metastasis. The rate of occult metastasis was only 10%. The corresponding rates from the literature review were 10.1% and 8.1%. Thus, patients with endometrial stromal sarcomas and adenosarcomas might benefit from lymph node sampling. On the other hand, for patients with LMSs, the rate of nodal involvement is too low to justify routine lymphadenectomy.

With regard to the role of *adjuvant radiation*, the EORTC performed a prospective, randomized trial addressing the role of postoperative pelvic RT in stage I to II uterine sarcomas.[173] A total of 224 patients in the trial underwent TAH/BSO, 166 of whom had peritoneal washings. Lymphadenectomy was optional. There were 103 LMSs and 28 endometrial stromal sarcomas. The 5-year cumulative incidence of locoregional recurrence was 18.8% in the pelvic RT arm compared to 35.9% in the surgery-alone arm. That difference was statistically significant ($P = .0013$). The 5-year cumulative incidence of distant relapse was 45.3% for the pelvic RT and 33.6% for surgery alone, but the difference was not statistically significant ($P = .2569$). There was no significant difference in PFS ($P = .3254$) or OS ($P = .923$) between the two arms. For patients with LMS, the rate of pelvic recurrence only was 2% in the pelvic RT compared to 14% in patients treated with surgery alone, and for any local recurrence, it was 20% versus 24%. It is important to note that the primary end point of this trial was pelvic control, which it met ($P = .0013$). The study was not powered to detect a significant difference in PFS or OS. Sampath et al[180] performed a

retrospective review of patients with uterine sarcoma using the National Oncology Database. The impact of adjuvant radiation was assessed in patients who presented with nonmetastatic disease and underwent definitive surgery (n = 2,206). For endometrial stromal sarcoma, the rate was 97% with RT versus 93% for surgery alone (n = 252; P < .05). For LMS, it was 98% for RT (n = 131) compared to 84% with surgery alone (n = 398; P < .01).

For patients with LMSs, the main treatment is surgery, and the role of adjuvant treatment, either RT or chemotherapy, is not well defined. The high rate of distant relapse in these patients overshadows any local control benefit attained with adjuvant RT. These patients should be encouraged to participate in trials assessing the role of chemotherapy and/or targeted therapy. For patients with low-grade endometrial stromal sarcomas, observation is feasible, because most are hormonally sensitive and generally behave in an indolent manner, with long disease-free intervals. For those with undifferentiated endometrial sarcomas, adjuvant pelvic RT is reasonable. For patients with adenosarcomas, especially with sarcomatous overgrowth, adjuvant pelvic RT is also reasonable.

CHAPTER 78

Ovarian and Fallopian Tube Cancer

Christopher Weil

Ovarian neoplasms encompass a wide array of benign and malignant tumors with diverse histologic cell types, clinical features, and survival outcomes. Primary malignant tumors of the ovary include the epithelial ovarian cancers, germ cell tumors, and sex cord tumors. Low malignant potential (LMP) tumors of the ovary are noninvasive epithelial tumors often confined to the ovary, although extraovarian tumor implants may be detected. Metastases to the ovary occur from other primary malignancies, including uterine, gastrointestinal (Krukenberg tumors), and breast cancers. Primary lymphoma, sarcoma, and melanoma of the ovary are rare. Relative to its incidence, epithelial ovarian cancers have substantially high mortality because effective screening tools are lacking; only 25% are detected as stage I at diagnosis, and current therapies for advanced cancer, although improving, have approached a therapeutic plateau. Surgery is the mainstay for diagnosis, staging, and the initial treatment for ovarian cancer. Platinum-based chemotherapy, with or without anti-angiogenic therapies, are indicated for patients with high-risk or advanced disease. Poly (ADP-ribose) polymerase (PARP) inhibitors, immunotherapies, and other targeted therapies are utilized in the maintenance, recurrent, or metastatic setting. The use of whole-abdomen irradiation (WAI) or intraperitoneal (IP) radioisotopes is primarily historical, and radiation therapy now has a limited role in the management of ovarian cancer. Nonetheless, palliative radiotherapy may be of significant benefit for symptomatic disease relapse or select patients with localized recurrence.

ANATOMY

In premenopausal women, the ovaries are almond-shaped, gray-pink solid organs that measure approximately 4 × 2.5 × 1 cm^2, with an average weight of 4 to 5 g. After menopause, the ovaries atrophy and become nonfunctional

and smaller in size. When normally positioned, the ovary is attached by the mesovarium to the broad ligament that covers the uterus and fallopian tubes. The infundibular pelvic, or suspensory, ligament extends from the surface of the ovary to the lateral pelvic wall, forming the superior and lateral aspects of the broad ligament (Figure 78.1). The blood supply of the ovary is derived from the ovarian arteries, which arise from the aorta immediately below the level of the renal arteries and course through the retroperitoneum and infundibular pelvic ligaments. The venous return of the ovary empties to the renal vein on the left and directly to the venae cavae on the right. The primary lymphatic drainage of the ovary parallels the course of the ovarian veins, with secondary lymphatic flow passing through the inguinal canal and to the iliac nodal system.[1] Histologically, the outer cortex of the ovary is covered by a layer of pseudocolumnar or cuboidal epithelium, termed the *germinal epithelium of Waldeyer* or *ovarian surface epithelium* (OSE). The inner medulla consists of a superficial tunica albuginea and dense stromal tissue filled with blood vessels and spindled, “muscle-like” connective tissue. Within the medulla, maturing follicles are present throughout the various layers.

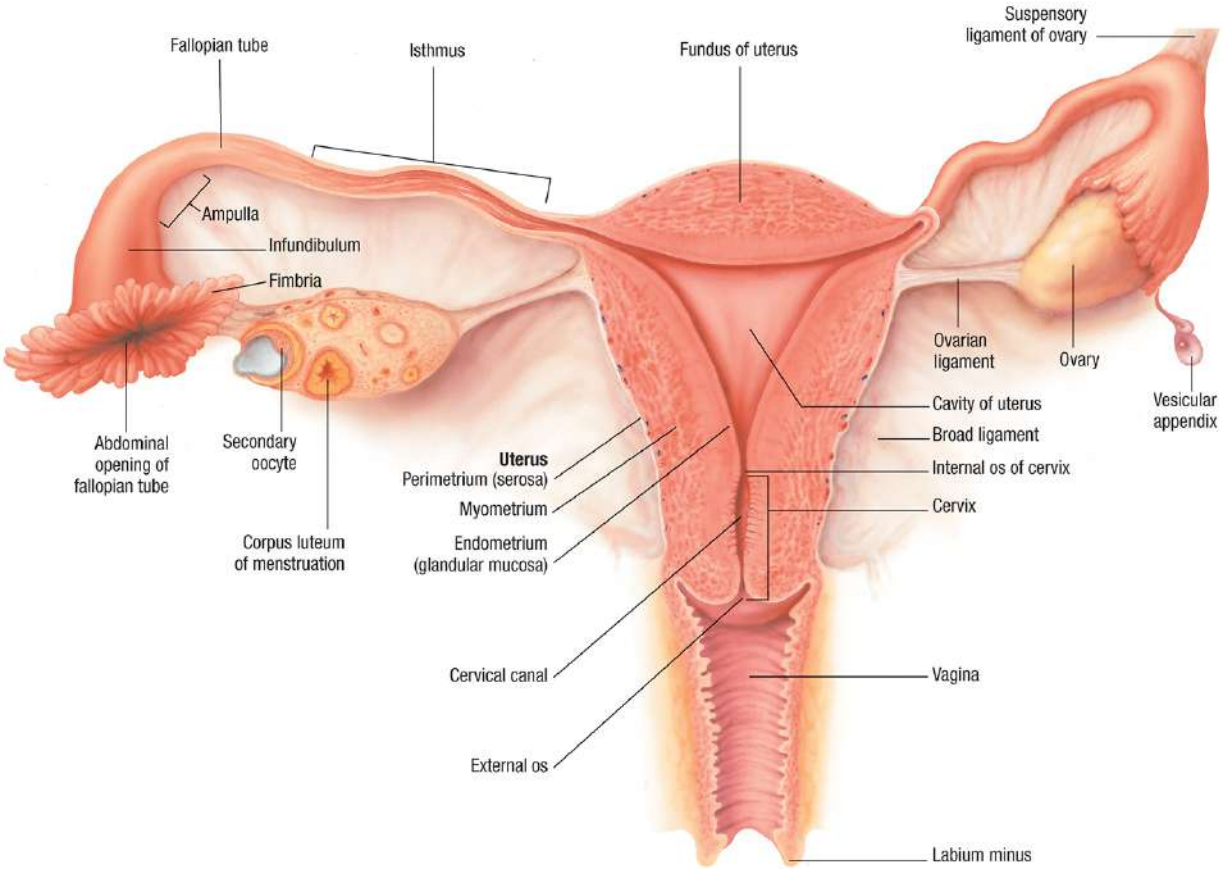

FIGURE 78.1 Anatomy of the ovary and female reproductive tract. (Asset provided by the Anatomical Chart Company.)

The fallopian tubes are positioned horizontally within the superior part of the broad ligament and extend from the superior-posterior portion of the uterine fundus to the ovaries. The fallopian tubes are hollow, muscular viscera that are in direct communication with the peritoneal cavity. The ovarian artery anastomoses with the uterine artery to supply the fallopian tube, and venous drainage is through the pampiniform plexus to the ovarian vein and uterine plexus. The mucosa of the fallopian tube contains a rich network of intercommunicating lymphatic sinusoids that anastomose with adjacent organs and drain into the ovarian lymphatics and para-aortic and iliac lymph nodes.[2] The fallopian tubes consist of four separate histologic layers: the mucosa, submucosa, muscularis (external longitudinal and inner circular layers), and outer serosal layer, which is continuous with the visceral peritoneum of the uterus. The mucosa is intricately folded, with the number of folds increasing from the interstitial portion to the ampulla. The epithelium is composed mainly of ciliated cells and secretory cells. Cyclic changes are

evident in the tubal epithelium, similar to those of the endometrium, in response to estrogen and progesterone.

EPIDEMIOLOGY

Ovarian cancer is the second most common gynecologic malignancy in the United States after endometrial cancer. An estimated 19,680 women in the United States will receive a diagnosis of epithelial ovarian cancer in 2024, and 12,740 will die of the disease[3,4] (Figure 78.2). Ovarian cancer represents the fifth leading cause of cancer-related death in U.S. women, following lung, breast, colorectal, and pancreatic cancers. The lifetime risk of ovarian cancer is approximately 1 in 77 women with a median age at diagnosis of 63 years; more than 80% of women are diagnosed after the age of 40 years.[5] The incidence of ovarian cancer rises with increasing age and peaks in the eighth decade of life. Differences in race and ethnicity are apparent in the age-adjusted annual incidence per 100,000 women, which in 2010 to 2014 was highest for White women (12.2), followed by Hispanic (10.6), American Indian/Alaska Native (9.5), Black (9.4), and Asian/Pacific Islanders (9.5).[5] The incidence of ovarian cancer also varies significantly by geography, with the highest rates in North America and northern Europe, which are 3 to 7 times higher than that observed in Japan.[6] Survival rates for ovarian cancer have been increasing in the United States since 1975, when the 5-year survival rate reported by the Surveillance, Epidemiology, and End Results program was 34%, which has increased to 47% in 2009.[5]

Primary cancer of the fallopian tube was once considered a rare disease, accounting for 0.2% to 0.5% of female gynecologic malignancies. However, the true incidence has likely been underestimated considering a large proportion of extrauterine high-grade serous carcinomas may actually originate in the fimbriated end of the fallopian tube.[7,8] Precursor lesions, known as *serous tubal intraepithelial carcinoma*s (STICs), have been detected in the fallopian tubes of prophylactic salpingo-oophorectomy specimens from high-risk patients. The model of the fallopian tube as the primary site of origin for extrauterine high-grade serous carcinoma is supported by epidemiologic, morphologic, and genetic data, as discussed later.

PATHOGENESIS

The female reproductive tract originates from the Müllerian ducts, which are paired embryologic structures of mesodermal origin that give rise to the fallopian tubes, uterus, cervix, and upper vagina. Ovarian tissue is composed

of embryonic yolk sac cells that give rise to the ova or germ cells, stromal cells that produce the steroid hormones, and mesothelium that provides the epithelial covering for the follicle cysts. These cell types give rise to germ cell tumors, sex cord-stromal tumors, and epithelial tumors of the ovary, respectively. The traditional view of ovarian cancer pathogenesis is that all tumor subtypes arise from the OSE. In the "incessant ovulation hypothesis," ovarian cancer develops from an aberrant repair process as a result of repeated rupture of the surface epithelium during each ovulatory cycle, thought to produce inflammation and scarring that serves as a nidus for carcinogenesis.[9-11] A second proposed mechanism is related to hormonal and reproductive factors such as persistent exposure to gonadotropins and elevated estradiol levels that stimulate malignant transformation.[12,13] Strong evidence exists that many borderline tumors and low-grade carcinomas of the ovary arise from cortical inclusion cysts (CICs) within the ovarian parenchyma. These benign cysts are composed of Müllerian epithelium that closely resembles the fallopian tube. CICs are thought to result from invaginations of the OSE into the ovarian stroma through repeated ovulation and aging, acquiring a Müllerian phenotype through metaplasia.[8] An alternate explanation is that remnants of Müllerian-derived epithelia from the fallopian tube may adhere to the ovarian surface and become incorporated into CICs in a process known as endosalpingiosis. Nonetheless, as a result of hormone exposure, damage repair processes, and inflammation within the ovary, neoplastic transformation gives rise to a variety of Müllerian cell type differentiations, including serous carcinomas that resemble the fallopian tube, mucinous tumors as seen in the endocervix, endometrioid tumors from the endometrium, and glycogen-rich clear cell cancers similar to secretory-phase endometrial glands.

High-grade serous ovarian carcinomas are infrequently associated with benign or borderline precursor lesions within the ovary, a contradiction of the OSE-CIC model. Furthermore, high-grade serous carcinomas of the ovary share distinct morphologic and genetic characteristics with high-grade serous carcinomas of other extrauterine sites, including serous fallopian tube carcinoma and primary peritoneal serous carcinoma. In this context, a second model of ovarian carcinogenesis has emerged with the recognition of the distal fallopian tube as the primary site of origin for many high-grade serous carcinomas. With rigorous pathologic processing, occult fallopian tube

cancer has been detected in the fimbria of prophylactic salpingo-oophorectomy specimens from high-risk patients.[14,15] Furthermore, STICs have been found in a large proportion of high-grade serous carcinomas initially designated as primary ovarian cancers.[16] An adenoma-carcinoma sequence has since been described that involves a dysplastic tubal precursor lesion with loss of p53 detectable by immunohistochemical staining ("p53 signature") with progression to a STIC characterized by increased proliferation, followed by the development of frank invasive serous carcinoma.[7,17] The concept of the fallopian tube as the primary site of high-grade serous carcinoma suggests that previously undetected serous STICs may spread to the adjacent ovary or peritoneal cavity early in the disease process of serous carcinogenesis.

In the two-pathway model of ovarian carcinogenesis, type I tumors include all major histologic subtypes (serous, endometrioid, mucinous, clear cell, and transitional) with low nuclear and architectural grade that may be linked to well-defined benign precursor lesions, and type II tumors account for the bulk of high-grade serous carcinomas (Table 78.1). The type I tumors are associated with distinct molecular alterations, such as mutations in *KRAS*, *BRAF*, and *PTEN*, which are rarely found in type II serous tumors.[18] Mutually exclusive *KRAS* and *BRAF* mutations, both of which activate the oncogenic *MAPK* signaling pathway, are observed in 65% of serous borderline tumors but are rarely seen in high-grade serous carcinomas.[19] *KRAS* mutations also occur in Müllerian histologic subtypes, including 60% of mucinous, 5% to 16% of clear cell, and 4% to 5% of endometrioid carcinomas.[18] Mutations in *PTEN*, which lead to constitutive activation of the related PI3 kinase signaling pathway, have been detected in 20% of endometrioid carcinomas,[20] whereas activating mutations in *PIK3CA* have been identified in 30% of clear cell cancers.[21] Somatic mutations in *ARID1A*, a novel tumor suppressor gene, have been identified in 46% of ovarian clear cell cancers and 30% of endometrioid cancers. *ARID1A* mutation and corresponding loss of BAF250a expression, a key component in chromatin remodeling, were also seen in preneoplastic lesions and may represent an early event in the transformation of endometriosis.[22] In contrast, type II tumors exhibit a high frequency of p53 mutation and widespread DNA copy number change. Inactivation of the BRCA pathway, a critical component of DNA repair by homologous recombination, is also a hallmark of high-grade

serous carcinomas.[23] Disruption of the BRCA pathway by germline or somatic mutation, epigenetic silencing, or microRNA regulation has been observed in more than 50% of serous cancers,[24] and functional assays show defective formation of homologous recombination repair foci following DNA damage.[25]

TABLE 78.1 TWO-PATHWAY MODEL OF EPITHELIAL OVARIAN CARCINOGENESIS

Type 1	Type 2
All Müllerian subtypes (serous, endometrioid, mucinous, clear cell, transitional)	High-grade serous carcinoma
Usually low grade	High grade
Linked to benign or borderline precursor lesions	Associated with serous tubal intraepithelial carcinomas (STICs)
KRAS or *BRAF* mutation (MAPK pathway) *PTEN* or *PIK3CA* mutation (PI3K pathway) *ARID1A* mutation, loss of BAF250a expression	Inactivation of *BRCA* pathway
Wild-type p53 status	High frequency of p53 mutation
Chromosomally stable	Widespread DNA copy number change
Frequently platinum insensitive	Usually platinum sensitive

Angiogenesis plays an important role in normal ovarian function, as heavy vascularization occurs at the beginning of each ovulatory cycle with predictable variation in the serum levels of vascular endothelial growth factor (VEGF). Epithelial ovarian cancers frequently overexpress VEGF, fibroblast growth factor, platelet-derived growth factor (PDGF), and angiopoietin.[26] In preclinical models, expression of VEGF provides a survival advantage to transformed cells of the ovary. Other studies have found an association between preoperative serum VEGF level and clinical outcome.[27] Targeting the tumor microenvironment in ovarian cancer is an attractive treatment strategy, given the inherent genomic instability of high-grade serous cancers.

RISK FACTORS

Epidemiologic studies have identified hormonal, genetic, and environmental factors that may play an important role in ovarian carcinogenesis (Table 78.2). The OSE-CIC model is consistent with well-established epidemiologic data indicating that suppression of ovulation results in a substantial reduction of ovarian cancer risk. New insights into the pathogenesis of high-grade serous carcinomas have emerged through the study of high-risk populations with a genetic predisposition for the development of ovarian cancer. Nevertheless, the pathogenic mechanisms are not well understood and likely multifactorial, associated with both patient-related and environmental factors.

TABLE 78.2 FACTORS INFLUENCING THE RISK OF OVARIAN CANCER

Factor	Estimated Risk (%)	Estimated Relative Risk
Baseline lifetime risk	1.4	1
Race		
White	12.2/100,000	—
Hispanic or American Indian	10.6/100,000	—
African American	9.4/100,000	—
Risk factors		
Family history	9.4	5-7
BRCA1 mutation	35-46	18-29
BRCA2 mutation	13-23	16-19
Lynch II/HPNCC	3-14	6-7
Infertility	–	2-5
Obesity	–	1.1-4
Nulliparity	–	2-3
Late menopause	–	1.5-2
Early menarche	–	1-1.5
Unopposed estrogen use	–	1.2-2
Protective factors		
Multiparity	–	0.4-0.6
Oral contraceptive use	–	0.7
Hysterectomy or tubal ligation	–	0.6-0.7

HPNCC, hereditary nonpolyposis colorectal cancer.

Patient-Related Factors

Risk factors associated with a higher frequency of ovulatory events, such as advancing age, low parity, infertility, early menarche, and late menopause, support the proposed mechanism of incessant ovulation.[28-31] Although infertility is associated with ovarian cancer, the use of fertility drugs has not been conclusively linked.[32-34] Suppression of ovulatory events from pregnancy, breast feeding, and oral contraceptive use may explain the observed protective benefit.[30,31,35] With oral contraceptive use for 4, 8, or 12 years, the risk of ovarian cancer is reduced by 40%, 53%, and 60%, respectively.[36] In a collaborative meta-analysis of 45 epidemiologic studies from 21 countries, the use of oral contraceptives was significantly associated with a decreased risk of ovarian cancer in every user (hazard ratio [HR] 0.73, $P < .0001$), with larger reductions observed for a longer duration of use.[37] The authors conclude that 200,000 ovarian cancers and 100,000 deaths have been prevented since the introduction of oral contraceptives 50 years ago.

Other patient-related risk factors such as polycystic ovarian disease and endometriosis may act through hormonal mechanisms attributable to elevated gonadotropins or by chronic inflammation. In a meta-analysis of eight case-control studies, women with polycystic ovarian disease had a 2.5-fold increase in ovarian cancer risk.[38] Endometriosis has been shown to be an independent risk factor for ovarian cancer with an estimated rate of malignant transformation of 2.5%.[39] Ovarian cancers that arise from endometriosis are most often low-grade tumors with endometrioid or clear cell histology and are associated with a better prognosis.[40] Altered hormonal levels such as elevated androgens may also increase risk, whereas progestins have been shown to be protective.[41] Large prospective cohort studies have demonstrated an increase in ovarian cancer risk and mortality with the use of exogenous estrogen and hormone replacement therapy.[42-44] Surgical procedures, including hysterectomy and tubal ligation, are independently associated with a 34% reduction each in ovarian cancer risk, although the protective mechanism is unknown.[29,45-47] Chronic inflammatory conditions such as pelvic inflammatory disease and tuberculous salpingitis were once believed

to be causative factors in the development of fallopian tube malignancies, although this theory remains unproven.

Genetic Factors

Heredity tumors account for 10% to 15% of all ovarian cancers, and family history is the strongest risk factor after increasing age.[48,49] The risk of developing ovarian cancer in the general population is approximately 1.4%, whereas the lifetime risk for a woman with one first-degree family member with ovarian cancer is 5% and climbs to 7% with two first-degree relatives. If a hereditary syndrome is present, the lifetime risk is on the order of 25% to 50%, with an age of diagnosis approximately 10 years younger than women with sporadic disease.[50]

Three distinct familial ovarian cancer syndromes have been identified by pedigree analysis with autosomal dominant patterns of inheritance.[51,52] *BRCA1* and *BRCA2* mutations are the most common genetic alterations, with up to 90% of all hereditary cases associated with a deleterious mutation of the *BRCA1* gene, located on chromosome 17q21, or the *BRCA2* gene, located on chromosome 13q22. The lifetime risk of ovarian cancer is approximately 40% in *BRCA1* mutation carriers and 18% in *BRCA2* mutation carriers.[53] BRCA-associated ovarian cancers are the most frequently invasive serous adenocarcinomas and less likely borderline or mucinous tumors.[54] Mutation carriers are also more likely to present with advanced-stage disease and have poorly differentiated tumors.[55] Nonetheless, *BRCA1* or *BRCA2* mutation carriers have a more favorable clinical course with a significantly longer recurrence-free and overall survival compared to noncarriers. The improved outcome appears related to a higher sensitivity to platinum chemotherapy across the first and subsequent lines of treatment.[56-60]

The importance of the fallopian tube in the pathogenesis of extrauterine serous carcinoma was initially recognized in *BRCA1* and *BRCA2* mutation carriers. In a prospective study of 483 *BRCA1* mutation carriers, the incidence of fallopian tube cancer was reported as 120 times that of the general population.[61] High-grade serous primary peritoneal carcinomas are also frequently observed in mutation carriers.[62] Further attention was focused on the fallopian tube as the primary site of origin following reports of epithelial dysplasia and occult serous carcinomas in prophylactic salpingo-oophorectomy specimens from mutation carriers.[63-66] In contrast to the

standard pathologic sampling of the ampullary region of the fallopian tube in ovarian cancer cases, more extensive complete sectioning of the tube revealed an abundance of lesions in the fimbria of the distal tube.[14-16] The detection of early serous carcinomas, or STICs, lent further support to the emerging concept of the fallopian tube as the primary site for extrauterine serous carcinoma. In this context, the national cancer guidelines recommend that any woman with a diagnosis of ovarian, fallopian tube, or primary peritoneal carcinoma be referred to a cancer genetics professional for consideration of BRCA mutation testing. BRCA screening in a population of women with nonmucinous ovarian cancer detected germline mutations in 14% of women, including 22% with high-grade serous cancer, reinforcing the importance of offering testing to all patients.[67]

Hereditary nonpolyposis colorectal syndrome, or Lynch type II cancer syndrome, is responsible for the remaining 10% of hereditary ovarian cancers.[68] In this syndrome, germline mutations of DNA mismatch repair genes lead to an increased risk of colorectal, stomach, endometrial, and ovarian cancer owing to underlying microsatellite instability. A total of seven mismatch repair genes have been identified, with mutations in *MLH1* and *MSH2* accounting for 90% of the observed mutations in Lynch syndrome families.[69,70] Mutations in *MSH6* and *PMS2* have been reported in the remaining 10% of families, whereas alterations in the remaining three identified genes are uncommonly observed. Inactivating mutations in specific genes may modify the underlying cancer predisposition. Women with *MSH6* mutations are twice as likely to develop endometrial cancer compared to carriers of *MSH2* or *MLH1* gene mutations, which are the most common alterations underlying colorectal cancer risk.[71] Women with *MSH2* gene mutations have been shown to have a risk of epithelial ovarian cancer twice that of *MLH1* carriers. In contrast to *BRCA1* and *BRCA2* mutation carriers, women with Lynch syndrome may present with a variety of nonserous epithelial tumor types, including endometrioid and clear cell histologies. Ovarian cancer associated with Lynch syndrome is more often diagnosed at an earlier stage with well- to moderately differentiated tumor grade. The lifetime risk of ovarian cancer in women with Lynch syndrome is estimated at 3% to 14% and is most commonly diagnosed in the fifth decade of life.[72] In women with a family or personal history suggestive of Lynch syndrome, tumor testing may be performed by microsatellite instability analysis or

immunohistochemical staining for mismatch repair genes. Direct sequencing of the mismatch repair genes is used for the detection of germline mutations. Other less common germline mutations have been identified by genomic sequencing and involve the following genes: *PALB2, BARD1, BRIP1, RAD51C, RAD51D, MSH2, MLH1, PMS2*, and *MSH6*.[73]

Other genetic disorders linked with nonepithelial ovarian cancers include Peutz-Jeghers syndrome, which is associated with an increased risk of sex cord-stromal tumors, and gonadal dysgenesis, associated with dysgerminomas and gonadoblastomas.

Environmental Factors

Environmental or physical causes of ovarian cancer have been investigated through numerous case-control studies. Women in developing countries have a lower incidence of ovarian cancer than those living in industrialized nations,[74] although, to date, no specific chemical carcinogens have been identified. Chronic exposure to asbestos-related products, including talc products, has long been implicated in the development of ovarian cancer.[75] The Nurses' Health Study reported a modestly elevated risk of invasive serous cancers with talc use (relative risk [RR] 1.4), although no association was detected with overall ovarian cancer risk.[76] The development of mucinous ovarian cancer has been found to be associated with cigarette smoking (RR 2-2.2), but not with other epithelial subtypes.[77,78]

Dietary and metabolic factors have also been explored in large population-based studies as possible contributors to ovarian cancer risk. To date, there have been no consistent associations of coffee or alcohol consumption with increased risk. Large epidemiologic studies also showed no relationship between consumption of animal fat and the development of ovarian cancer.[79,80] In a Swedish population–based cohort study of the effect of body mass index on cancer risk in greater than 35,000 women, a 36% higher risk of cancer was observed in obese women (body mass index $\geq$ 30) relative to women with body mass index in the normal range (18.5-25); cancer sites most strongly related to obesity were endometrium, ovary (risk for top quartile 2.09; 95% confidence interval [CI], 1.13-4.13), and colon.[81] Obesity has also been associated with increased ovarian cancer mortality in a large prospective study of adults in the United States.[82] There is no clear relationship between exercise and ovarian cancer risk.

SCREENING

In the absence of a reliable screening test, most women with ovarian cancer are diagnosed with advanced-stage disease. In contrast to women with localized disease (stage I/II) who have estimated 5-year survival rates of 70% to 90%, overall survival for women with advanced disease (stage III/IV) is poor, ranging from 20% to 45% (Table 78.3). The low sensitivity and specificity of the available screening modalities and the low prevalence of the disease in the general population have hindered the development of a robust screening test. Recent screening approaches have been associated with a low positive predictive value and unacceptable false-positive rates without impacting disease mortality in the general population or high-risk groups.

Several screening strategies have been investigated, including pelvic examination, the serum tumor marker cancer antigen 125 (CA-125), and transvaginal ultrasound (TVUS), either alone or in combination.[83] CA-125 values greater than 35 U/mL are observed in 80% of patients with epithelial

ovarian cancer, including 90% of women with advanced-stage disease, but only in 50% of early-stage patients.[84] CA-125 is nonspecific for ovarian cancer, as it can be elevated in benign gynecologic and nongynecologic conditions, including endometriosis, uterine leiomyoma, cirrhosis, pelvic inflammatory disease, the presence of pleural or peritoneal fluid, as well as endometrial carcinoma and nongynecologic cancers of the breast, lung, and pancreas. Screening with CA-125 alone has been found to lack specificity in an average-risk population of postmenopausal women. Ultrasound alone is able to detect early-stage disease in an average-risk population,[85-87] although the significant false-positive rate remains a concern. In a United Kingdom multimodality screening study, diagnostic surgeries were performed 9 times more frequently to detect one cancer in the group screened by TVUS alone compared to multimodality screening (CA-125 and TVUS).[88]

Several large screening trials currently in progress in the United States, the United Kingdom, and Japan have been designed to assess reduction in mortality with early detection of ovarian cancer. The Prostate, Lung, Colorectal, and Ovarian Cancer screening trial in the United States randomized 78,216 women aged 55 to 74 years to annual screening with CA-125 and TVUS versus usual medical care. Following baseline screening, 570 surgical procedures, including 325 laparotomies, were performed; 29 tumors were detected, 9 of which were of LMP.[89] The positive predictive value for the detection of invasive ovarian cancer was 3.7% for an abnormal CA-125, 1.0% for an abnormal TVUS, and 23.5% for both. Publication of the mortality data with 12-year follow-up showed no difference in the stage of cancer detected by screening (90% stage III or IV) and no reduction in cause-specific or overall mortality for women who underwent screening.[90] Furthermore, diagnostic evaluation for women with false-positive screening resulted in a serious complication rate of 15%.

A second trial, the United Kingdom Collaborative Trial of Ovarian Cancer Screening, has accrued greater than 200,000 postmenopausal women to evaluate multimodality screening with TVUS and serum CA-125. In the prevalence screen, the sensitivity, specificity, and positive predictive values of multimodality screening for invasive epithelial ovarian and tubal cancers were 89.5%, 99.8%, and 35.1%, respectively.[88] The initial results of baseline screening were more promising than the U.S. study, with 43% of invasive cancers detected as stage I or II, which may reflect differences in study

design and the diagnostic algorithm. However, after a median follow-up of 11 years, a significant mortality reduction with multimodality screening was not observed.[91] The multicenter, randomized Japanese study utilizes a similar screening strategy with TVUS and CA-125 and has accrued greater than 80,000 women. Unlike the U.S. and UK trials, there was a nonsignificant trend for the detection of more stage I cancers in the screened population (63% vs 38%), although mortality rates have not yet been reported.[92]

The present data do not support routine screening for ovarian cancer in the general population. All of the North American expert groups, including the U.S. Preventive Services Task Force, the American College of Obstetricians and Gynecologists, the Society of Gynecologic Oncologists (SGO), and the Canadian Task Force on the Periodic Health Examination, recommend against routine screening in asymptomatic women. The incidence of ovarian cancer is relatively low in the general population; thus, the concerns for false-positive screening and the associated risks of exploratory surgery are significant.[93] However, women at high risk for ovarian cancer with *BRCA1* or *BRCA2* mutations or hereditary nonpolyposis colorectal syndrome could potentially benefit from chemoprevention; screening with pelvic examinations, TVUS, and CA-125 on a biannual or annual basis; or prophylactic surgery.[94] Although the efficacy of screening has been disappointing in the high-risk population,[95] some physicians will follow women with high-risk factors, such as *BRCA* mutation or family history, with pelvic examination, CA-125, and TVUS. The U.S. National Institutes of Health Consensus Development Panel recommends that prophylactic salpingo-oophorectomy be considered in women with ovarian cancer syndromes at age 35 years or after childbearing is complete, as the risk reduction with salpingo-oophorectomy is 80%.[96,97] Removal of the ovaries also reduces the risk of breast cancer in BRCA mutation carriers.[98]

HISTOLOGIC CLASSIFICATION

The World Health Organization and International Federation of Gynecology and Obstetrics (FIGO) have adopted a unified classification of the common epithelial, germ cell, sex cord, and stromal tumors[99,100] (Table 78.4). Most ovarian malignancies (60%-65%) are epithelial, with germ cell tumors (20%), sex cord-stromal tumors (5%), and metastases to the ovary (5%-10%) accounting for the remainder.[101] Serous tumors are most common, comprising

50% to 60% of epithelial tumors. Other subtypes include mucinous carcinoma in 10%; endometrioid carcinoma, 8%; clear cell carcinoma, 3% to 5%; transitional, 3% to 5%; and undifferentiated carcinoma, 1%. Bilateral presentation occurs frequently in epithelial tumors, most commonly in serous tumors followed by endometrioid (15%) and mucinous tumors (5%-10%).

TABLE 78.4 WORLD HEALTH ORGANIZATION CLASSIFICATION OF OVARIAN TUMORS

Serous low-grade carcinoma
Serous high-grade carcinoma
Mucinous carcinoma
Endometrioid carcinoma
Clear cell carcinoma
Malignant Brenner tumor
Seromucinous carcinoma
Undifferentiated carcinoma
Germ cell tumors
Dysgerminoma
Yolk sac tumor
Embryonal carcinoma
Nongestational choriocarcinoma
Mature teratoma
Immature teratoma
Mixed germ cell tumor
Germ cell and sex cord-stromal tumors
Mixed germ cell-sex cord-stromal tumor, unclassified
Gonadoblastoma
Sex cord-stromal tumors
Pure sex cord tumors
Adult granulosa cell tumor
Juvenile granulosa cell tumor
Sertoli cell tumor
Sex cord tumor with annular tubules
Pure stromal tumors
Fibroma
Cellular fibroma
Thecoma
Luteinized thecoma associated with sclerosing peritonitis
Fibrosarcoma
Sclerosing stromal tumor
Signet-ring stromal tumor
Microcystic stromal tumor
Leydig cell tumor
Steroid cell tumor

Mixed sex cord-stromal tumors
Sertoli-Leydig cell tumors
Sex cord-stromal tumors, NOS
Monodermal teratoma and somatic-type tumors arising from a dermoid cyst
Struma ovarii
Carcinoid
Neuroectodermal-type tumors
Sebaceous tumors
Carcinomas
Mixed epithelial and mesenchymal tumors
Carcinosarcoma
Adenosarcoma

NOS, not otherwise specified.

High-grade serous carcinomas are often widely disseminated at diagnosis and account for most deaths from ovarian, tubal, and peritoneal cancers. In contrast, 5-year survival for low-grade serous carcinoma is 85%. Most serous tumors present as large ovarian masses and grossly appear nodular with multiple papillary projections and cysts filled with clear serous fluid. A two-tier grading system separates high-grade serous carcinomas from low-grade tumors,[102,103] which have a similar prolonged natural history to noninvasive borderline tumors, or tumors of LMP.[104] As discussed previously, there is increasing evidence that high-grade serous carcinomas originate in the fimbria of the fallopian tube and may spread rapidly to the adjacent ovary and peritoneal sites. Low-grade tumors appear to follow a stepwise progression from borderline tumor to invasive carcinoma and involve molecular pathways distinct from their high-grade counterparts.[105-107] Although treatment is similar for all serous tumors, low-grade tumors have been shown to be less responsive to chemotherapy.[104,108,109]

LMP or borderline tumors have nuclear abnormalities and mitotic activity intermediate between benign and malignant tumors of similar cell type but lack stromal invasion (Figure 78.3). Borderline tumors are a subcategory of ovarian malignancies that account for 10% to 20% of all epithelial neoplasms.[110,111] The prognosis, surgical approach, and postoperative treatment recommendations are vastly different as compared with those of their invasive counterparts. The majority of LMPs (75%) present with stage I disease, which directly contrasts with the 75% advanced stages in the invasive epithelial tumors. The 5- and 10-year survival rates for women with

LMP tumors are more than 95%. Significant heterogeneity exists in the biologic behavior of borderline tumors. Women with nonlocalized LMP tumors of the ovary have decreased survival compared to those with localized LMP tumors, but this is similar to that of women with localized, well-differentiated epithelial ovarian carcinoma.[112] Other pathologic features that affect prognosis include the cell type, tumor stage, implant type (invasive vs noninvasive), the presence of micropapillary architecture, and microinvasion. Extensive sampling of all pathologic specimens is required to firmly establish the diagnosis.

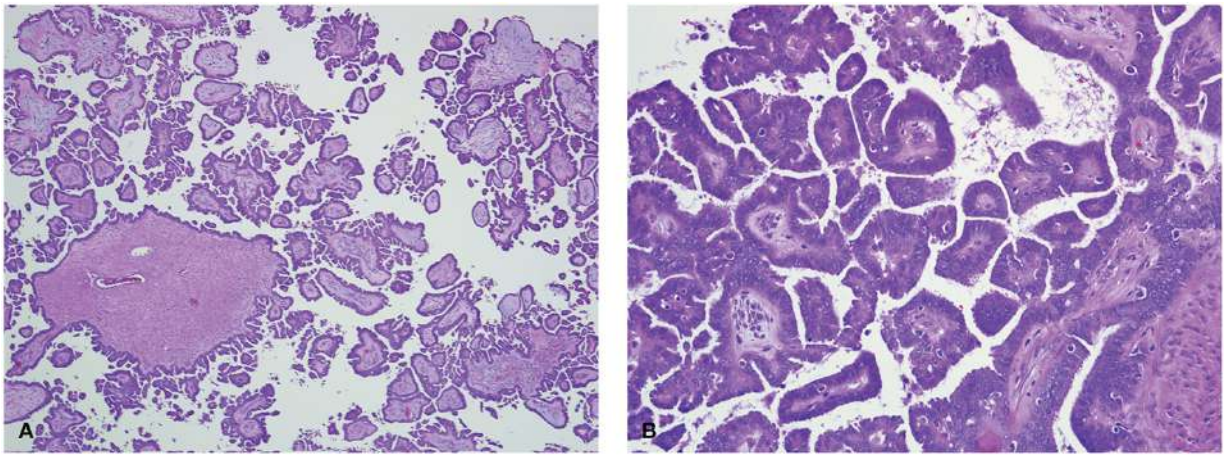

FIGURE 78.3 Serous tumor of low malignant potential of the ovary at low power (A) and high power (B). At low power, note the progressively branching papillary fronds with fibrovascular support and detached papillary clusters; at high power, note the serous epithelium with nuclear hyperchromasia and cytologic atypia. By definition, there is no destructive stromal invasion.

Most endometrioid and clear cell carcinomas arise in foci of endometriosis and follow an adenoma to borderline tumor to carcinoma sequence. Endometrioid carcinoma of the ovary resembles its endometrial counterpart (Figure 78.4), and synchronous primary cancers are detected in 10% of women with ovarian cancer and 5% of women with endometrial cancer.[113] Bilateral ovarian involvement, small multinodular ovaries, and surface and hilar spread suggest metastatic involvement from an endometrial primary, particularly if the endometrial tumor is high grade, deeply invasive, and associated with lymphovascular invasion. A large, cystic, unilateral tumor of low grade arising in a focus of endometriosis likely represents a primary ovarian tumor. Endometrioid tumors appear to have a better prognosis than

serous cancers, regardless of tumor stage.[114] Multiple synchronous primary tumors may represent a field defect related to endometriosis, which is associated with improved survival.[115]

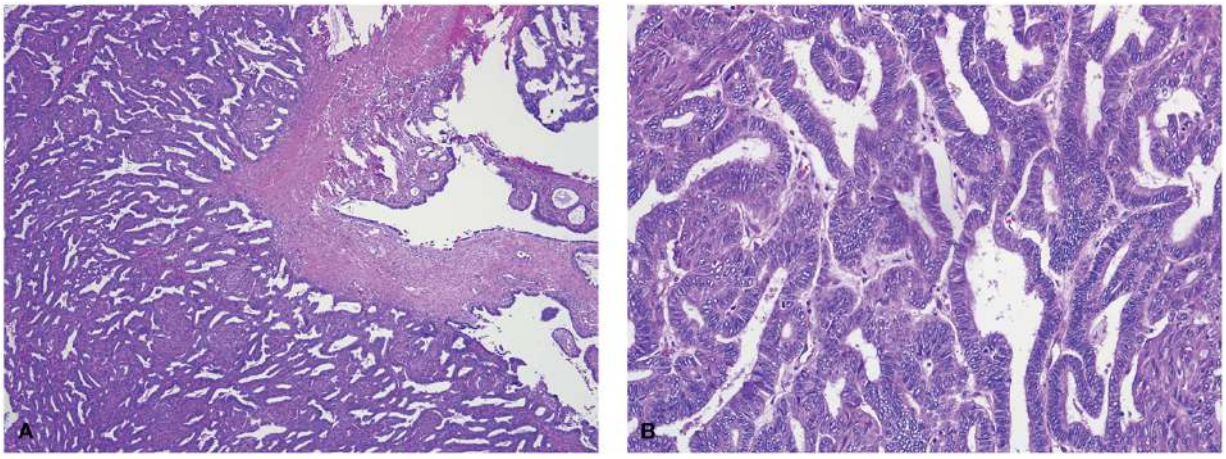

FIGURE 78.4 Endometrioid adenocarcinoma of the ovary. A. At low power, note the tumor composed of back-to-back endometrioid glands. B. At high power, note the squamous metaplasia, commonly seen in this epithelial variant. Assignment of tumor grade is based on similar criteria as for carcinomas arising in the endometrium. This tumor would qualify as well differentiated or grade 1.

Mucinous tumors follow a similar progression from cystadenoma to borderline tumor prior to invasion. All subtypes are more likely to be diagnosed when confined to the ovary. Mucinous cancers may grow to a very large size, often measuring up to 20 cm in diameter and filled with large pockets of thick, necrotic, mucinous debris.[116,117] Ovarian mucinous tumors closely resemble mucin-secreting tumors originating from other sites—most commonly the gastrointestinal tract. The pathologic distinction between primary and metastatic mucinous carcinoma may be challenging, despite the use of immunohistochemical analysis. Further clinical evaluation is often required to exclude a clinically occult nonovarian primary source. Secondary involvement of the ovary may also occur in association with pseudomyxoma peritonei arising from a low-grade tumor often of appendiceal origin.[118]

Clear cell carcinoma is characterized by clear and hobnail cells with a similar histologic appearance to clear cell carcinoma of the kidney, endometrium, and vagina. Ovarian clear cell carcinoma is often seen in association with venous thromboembolism and hypercalcemia. Although more likely to be stage I than serous carcinoma, clear cell histology is

associated with a lower response rate to platinum-based chemotherapy, higher recurrence rate, and worse survival.[119] The transitional cell tumors, including Brenner tumors, are benign in most cases (98%) and carry a favorable prognosis.

Ovarian germ cell tumors comprise less than 5% of ovarian malignancies and are classified by the World Health Organization (Table 78.4). Dysgerminomas are the most common of the germ cell tumors and occur bilaterally in 10% to 20% of cases. The other germ cell tumor types are typically unilateral. Endodermal sinus tumors, also known as yolk sac tumors, are characterized by Schiller-Duval bodies. Embryonal carcinomas are rare and tend to occur in younger populations; they may be seen with nongestational choriocarcinomas as part of mixed germ cell tumors (10% of all germ cell tumors). Immature teratomas are characterized by immature elements from the germ layers. The grade, treatment recommendations, and outcome are directed by the amount of immature neural elements.

Sex cord-stromal tumors are also classified by the World Health Organization (Table 78.4), with granulosa cell tumors being the most common (70%). Histologically, the granulosa cell tumors are composed of granulosa cells that have a pale, grooved, "coffee bean" nucleus or a rosette of cells surrounding eosinophilic material, a Call-Exner body. Thecomas (hormonally active) and fibromas (hormonally inactive) are both clinically benign tumors and are most common in middle-aged women.

The most common histopathology of primary fallopian tube malignancies is papillary serous adenocarcinoma. Other less common Müllerian subtypes include endometrioid, clear cell, and malignant mixed Müllerian tumors.[120,121] Rare reports of squamous cell carcinoma, immature teratoma, glassy cell tumor, and sarcoma have also been described. Benign tumors are found even less frequently than malignant neoplasms. Metastatic involvement of the fallopian tube is reported in up to 12% of women with uterine cancer and 4% with cervical cancer.[122,123]

PATTERNS OF SPREAD

The primary mode of spread for epithelial ovarian and fallopian tube cancers is transperitoneal, as malignant cells exfoliate into the peritoneal cavity. IP spread is favored by intestinal peristalsis and negative hydrostatic pressure below the diaphragm. The exfoliated tumor cells follow the intra-abdominal

fluid stream passing along the paracolic gutters toward the diaphragm, predominately on the right side, before implantation on any peritoneal surface.[124,125] Metastatic deposits are frequently seen in the posterior cul-de-sac, paracolic gutters, diaphragmatic surfaces, liver capsule, intestinal surfaces, and omentum. Metastases may also be found in the uterus or contralateral ovary from peritoneal spread or flow through the fallopian tubes. Dense tumor "caking" can cause infiltration into the abdominal organs creating a mass effect on the omentum, ureter, bowel, liver, pancreas, spleen, or adrenals, resulting in advanced disease stage at presentation with associated ascites.

Lymphatic drainage constitutes the second most common pattern of spread. The lymphatic capillaries of the ovary converge on the hilus and follow the ovarian blood vessels in the infundibular ligament to drain to the para-aortic nodes at the level of the renal hilum. Lymphatics also drain along the broad ligament to the hypogastric and external iliac nodes in the pelvis. Less frequently, spread can occur to the inguinal nodes via the round ligament.[126] Approximately 10% to 15% of women with disease that appears confined to the ovary have para-aortic lymph node involvement,[127] which becomes increasingly common in advanced-stage disease. Because of the rich lymphatic supply of the fallopian tubes, lymph node involvement is common, even in the absence of tubal musculature involvement.[128] Pelvic and para-aortic lymph node involvement has been reported in 10% to 30% of women with fallopian tube cancer at diagnosis.[129]

Transdiaphragmatic spread occurs in the pleural cavity and is the most common finding in stage IV disease. Hematogenous spread is infrequent at the time of presentation, with only 2% to 3% of patients with parenchymal liver or lung disease. Brain metastasis is also rare. However, more than 50% of recurrences occur both within and outside the peritoneal cavity at the time of treatment failure.

CLINICAL PRESENTATION

As ovarian cancer has insidious growth and is asymptomatic in early-stage disease, most women do not present until symptoms arise from advanced disease progression. Vague gastrointestinal complaints of dyspepsia, nausea, early satiety, bloating, constipation, or obstipation are common presenting symptoms, as are genitourinary symptoms including frequency, urgency, or

incontinence. Other ill-defined symptoms include fatigue, back pain, pain with intercourse, and menstrual irregularities. These nonspecific symptoms can be present for several months but may not trigger diagnostic evaluation until after the symptoms fail to clear with other medical therapy.[130] Detection of early-stage disease may occur by palpation of an asymptomatic adnexal mass on routine examination, although most adnexal masses require moderate size for palpation. In premenopausal women, most of these masses are benign, as ovarian cancer represents less than 5% of adnexal neoplasms. An adnexal mass in a postmenopausal woman has a higher likelihood of malignancy, and surgical exploration is often indicated. Physical examination findings such as a fixed pelvic mass, palpable upper abdominal mass, and ascites are highly suggestive of an ovarian malignancy. According to a consensus statement on the symptoms of ovarian cancer published by the Gynecologic Cancer Foundation, SGO, and American Cancer Society, new and persistent symptoms of bloating, pelvic or abdominal pain, difficulty eating, early satiety, or urinary urgency or frequency should prompt women to seek medical evaluation.

A portion of women with fallopian tube carcinoma may present with early clinical signs and symptoms. Two triads have been described as pathognomonic for fallopian tube malignancy: (a) pelvic pain, pelvic mass, and leukorrhea and (b) vaginal bleeding, vaginal discharge, and lower abdominal pain. However, the percentage of patients presenting with either triad of symptoms has been reported as low as 11%.[131] Another classic sign—hydrops tubae profluens—is a sudden emptying of accumulated fluid in the distended fallopian tube that causes profuse, watery, serosanguinous vaginal discharge. The discharge is often accompanied by a decrease in pelvic mass size on physical examination. In a meta-analysis of 122 patients with primary fallopian tube cancer, hydrops tubae profluens was a presenting sign in only 9%.[122] In other series,[125,128] it has been specifically reported that neither a triad nor hydrops tubae profluens was present in any of the patients reviewed. When clinically apparent, the fallopian tube may be dilated and mimic more benign pathologic processes such as hydrosalpinx, pyosalpinx, or hematosalpinx.[132] In more advanced disease with tubal wall invasion, extension of a necrotic mass to involve the ovary may give the initial impression of a tubo-ovarian abscess.

Germ cell and stromal cell malignancies present at an earlier stage than epithelial ovarian or fallopian tube cancers, often related to abdominal discomfort or symptoms of excessive estrogen or androgen production. Granulosa cell tumors may lead to precocious puberty in young girls, and Sertoli-Leydig cell tumors may cause virilization.

DIAGNOSTIC WORKUP

Evaluation of a pelvic mass will be influenced by the patient's age, clinical presentation, and imaging features. An ovarian mass is more likely to be a malignant neoplasm in the pediatric, perimenopausal, and postmenopausal age groups and benign during the reproductive years. Ultrasound is often the first, noninvasive step for the evaluation of a pelvic mass. Sonographic characteristics suggestive of malignancy include irregular borders, a solid component that is not hyperechoic and often nodular or papillary, Doppler demonstration of flow in the solid component, dense multiple irregular septa (>2-3 mm), and the presence of ascites, peritoneal masses, enlarged nodes, or matted bowel. Computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen and pelvis (performed with contrast) may be useful preoperatively to assess disease extent for surgical planning.[133-135] Fluorodeoxyglucose positron emission tomography CT may also be used to characterize indeterminate lesions and has increased sensitivity for the detection of occult metastatic disease when compared with CT alone or MRI, although further study is warranted.[136-138] Although limited as a screening tool, an elevated CA-125 level may suggest a more advanced or greater bulk of disease and high-grade serous histology but in general is a weak predictor of surgical resection.[139,140] Human chorionic gonadotropin (β-hCG), α-fetoprotein (AFP), total inhibin, and lactate dehydrogenase levels may aid in the diagnosis of and treatment for nonepithelial germ cell ovarian tumors, particularly in women younger than age 35 years with a pelvic mass.[141,142]

Other conditions may mimic ovarian cancer in their presentation, including colon, gastric, and appendiceal carcinomas as well as metastatic breast cancer and primary lymphoma.[143] Although ideally the primary site of disease is determined in the preoperative setting, the diagnosis often cannot be made accurately until the time of surgery, and frozen section pathologic evaluation may guide the surgical approach. Among gynecologic malignancies, primary endometrial and cervical cancer may also present with an adnexal mass, and

synchronous tumors of the ovary and endometrium have been reported in up to 10% of women, often in the setting of Lynch syndrome or an estrogen-secreting tumor.[113,115] Primary malignancies of the fallopian tube have been difficult to diagnose prior to surgical exploration, as the clinical presentation may be similar to that of salpingitis, ovarian abscess, pelvic inflammatory disease, or even ectopic pregnancy. Occult tubal primaries may be detected only by careful pathologic processing of the fimbriated tubal end.[144]

Referral to a gynecologic oncologist should be considered for any woman with a suspicious pelvic mass, family history of ovarian or fallopian tube cancer, or elevated CA-125.[145] Initial evaluation should include a thorough history and full physical and pelvic examination, laboratory studies (complete blood count, chemistries), and imaging (abdominal and pelvic CT/MRI, directed ultrasound, chest x-ray, or CT). National cancer guidelines do not recommend the use of biomarkers such as CA-125 or HE4 for determining the status of an undiagnosed pelvic mass. However, a baseline CA-125 drawn prior to surgery may be useful in follow-up to evaluate treatment response and monitor for recurrence. Further evaluation with mammography, upper gastrointestinal endoscopy, or colonoscopy may be indicated in some scenarios to exclude an extraovarian primary cancer.[146] If possible, fine-needle aspirate (FNA) for diagnostic purposes should be avoided in patients with presumed early-stage disease to prevent cyst rupture and tumor spillage, although it is often necessary in patients with bulky, nonoperable disease. Comorbid conditions may prompt additional evaluations, including cardiac risk assessment, pulmonary function testing, and nutritional evaluation.

SURGICAL STAGING

Surgical advances in staging and the therapeutic benefit of a maximal safe tumor resection have improved the progression-free and overall survival of women with ovarian cancer over the past two decades. Surgical staging for ovarian cancer is based on the FIGO staging system as shown in Table 78.5,[147] which was updated in 2024 and approved by the American Joint Committee on Cancer. The 2021 staging system combines the ovary, fallopian tubes, and primary peritoneal cancers.

TABLE 78.5 FIGO STAGING FOR OVARIAN, FALLOPIAN TUBAL, AND PERITONEAL CARCINOMA

Stage I Tumor limited to the ovaries or fallopian tube(s)
IA Tumor limited to 1 ovary; ascites and peritoneal washings negative for malignant cells. No tumor on the external surface of ovary or fallopian tube; ovarian capsule intact
IB Tumor limited to both ovaries or fallopian tubes; ascites and peritoneal washings negative for malignant cells. No tumor on the external surfaces of ovaries or fallopian tubes; ovarian capsules intact
IC Tumor stage IA or IB, and including any of the following:
IC1: Surgical spill of ovarian or fallopian tube contents
IC2: Ovarian capsule ruptured before surgery, or tumor on surface of the ovaries or fallopian tube(s)
IC3: Ascites or peritoneal washings positive for malignant cells

Stage II Tumor involving 1 or both ovaries with pelvic extension or primary peritoneal cancer
IIA Extension and/or implants on the uterus and/or fallopian tubes and/or ovaries
IIB Extension to other intraperitoneal pelvic tissues (below pelvic brim)

Stage III Tumor involving 1 or both ovaries or fallopian tubes, or primary peritoneal cancer, with pathologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal lymph nodes
IIIA1 Tumor grossly limited to the true pelvis, but with pathologically confirmed retroperitoneal lymph nodes or microscopic seeding of extrapelvic peritoneal surfaces (above the pelvic brim)
IIIA1(i): Metastasis up to 10 mm in greatest dimension
IIIA1(ii): Metastasis >10 mm in greatest dimension
IIIA2: Microscopic extrapelvic (above the pelvic brim) peritoneal sites, with or without retroperitoneal nodal involvement
IIIB Macroscopic peritoneal metastases involving extrapelvic peritoneal surfaces up to 2 cm in greatest dimension, with or without retroperitoneal nodal involvement
IIIC Macroscopic peritoneal metastases involving extrapelvic surfaces >2 cm in greatest dimension, with or without retroperitoneal nodal involvement. Tumor may extend to the capsule of the liver or spleen without parenchymal involvement.

Stage IV Presence of distant metastasis outside the peritoneal cavity
IVA: Pleural effusion with positive cytology
IVB: Parenchymal metastasis (including the liver and spleen) and metastases to extra-abdominal organs, including the inguinal lymph nodes and nodal basins outside the abdomen and pelvis

FIGO, International Federation of Gynecology and Obstetrics.

Comprehensive surgical staging is the mainstay of diagnosis and initial treatment for ovarian, fallopian tube, and peritoneal cancers. Based on

improved outcomes, surgical staging and cytoreduction should be performed by a gynecologic oncologist.[148,149] In apparent early-stage cancers, surgical evaluation is required for accurate pathologic staging to guide adjuvant treatment recommendations. In patients with advanced disease, surgery represents the initial treatment by providing optimal cytoreduction. Comprehensive surgical staging begins with an exploratory laparotomy via a vertical midline incision followed by a collection of peritoneal washings or any ascitic fluid for cytology. Select patients with early-stage disease may be candidates for minimally invasive procedures if performed by an experienced gynecologic oncologist.[150-152] The surgeon performs a thorough inspection of all visceral and peritoneal surfaces within the abdomen and pelvis, with particular attention to the intestinal serosal surfaces, mesentery, paracolic gutters, hemidiaphragms, gallbladder, and liver. Any peritoneal surface or adhesion that is suspicious for metastasis should be excised or biopsied. In the absence of suspicious areas, random peritoneal biopsies should be taken from the pelvis, paracolic gutters, and/or undersurfaces of the hemidiaphragms. Total hysterectomy, bilateral salpingo-oophorectomy, and omentectomy should be performed with intact removal of the adnexal mass when possible. National cancer guidelines state that pelvic and para-aortic nodal dissection should be performed in patients with pelvic-confined disease or extrapelvic implants measuring 2 cm or less (presumed stage IIIB disease), although recent level 1 data suggest that there is not a therapeutic benefit for lymphadenectomy in clinically node-negative patients with advanced disease.[153] Every effort should be made to achieve maximal cytoreduction of all gross disease in the pelvis, abdomen, and retroperitoneum.[154] In patients with advanced disease, bowel resection and/or appendectomy, diaphragm stripping, splenectomy, partial cystectomy and/or ureteroneocystostomy, partial hepatectomy, partial gastrectomy, cholecystectomy, and/or distal pancreatectomy may be considered. In the operative report, the surgeon should describe the following: (1) the extent of initial disease prior to cytoreduction, (2) the amount of residual disease following cytoreduction, and (3) whether a complete or incomplete resection was performed (including a description of the size and number of residual lesions).[155] In select cases, preservation of the contralateral unaffected ovary and the uterus can be achieved in young women wishing to retain fertility who have stage I (stage 1A or 1C, but not 1B) and/or low-risk tumors (early-stage, low-grade

invasive tumors, LMP/borderline lesions, or malignant stromal or germ cell tumors).[156,157] In the setting of unilateral salpingo-oophorectomy, comprehensive surgical staging should be performed to exclude occult disease. Exceptions to upfront surgical management include patients with significant medical comorbidities who are poor operative candidates and patients with a complex ovarian cyst where extraovarian disease has not been excluded. Neoadjuvant chemotherapy followed by interval cytoreduction may be considered in patients with bulky stage III or IV disease. Before initiation of neoadjuvant chemotherapy, the pathologic diagnosis should be confirmed by biopsy, FNA, or paracentesis. National cancer guidelines recommend that patients who are evaluated for neoadjuvant chemotherapy be seen by a fellowship-trained gynecologic oncologist before being deemed a nonsurgical candidate.

PROGNOSTIC FACTORS

Tumor stage, grade, histology, and optimal cytoreduction by a trained gynecologic oncologist are the most important determinants of survival for ovarian and fallopian tube cancer. Patients with FIGO stage 1A disease who have negative staging laparotomy have 5-year survival rates of 80% to 90%. If extrapelvic disease is detected at the time of surgical staging, the patient is upstaged to stage III disease with corresponding 5-year survival rates of 30% to 50%. Primary or interval cytoreductive surgery should be performed by a gynecologic oncologist based on published evidence of a 6- to 9-month median survival benefit.[148,149,158]

The volume of residual disease after primary surgery is also an important determinant of outcome.[159-164] The extent of cytoreduction may be defined as complete, no gross visible disease; optimal, residual disease that is 1 cm or less in maximal tumor diameter (Gynecologic Oncology Group [GOG] definition); or suboptimal, residual tumor nodules greater than 1 cm. Patients who have optimal cytoreduction of tumor have a 22-month improvement in median survival compared to those with suboptimal resection. In a meta-analysis of 18 studies, which included over 13,000 women with stage IIB or higher ovarian, tubal, or peritoneal carcinoma, each 10% increase in the proportion of patients undergoing complete cytoreduction showed a 2.3-month increase in median survival when compared to a 1.8-month increase for those with optimal cytoreduction.[164] Complete cytoreduction has also

been associated with improved response to chemotherapy and less platinum resistance.[163,165] Preoperative CA-125 measurement is not independently prognostic, as it likely reflects disease burden. In contrast, the half-life and nadir of CA-125 during induction chemotherapy are associated with improved outcome in ovarian and fallopian tube cancers.[121,166-170]

Although a strong correlation exists between histologic grade and stage, grade has independent prognostic significance, particularly in early-stage disease. Survival rates for stage I disease with grade 1, 2, or 3 tumors are 96%, 78%, and 62%, respectively.[171] The impact of histologic subtype on survival is less robust owing to other more important clinical variables, including stage, grade, and volume of disease. Patients with mucinous and endometrioid subtypes have improved survival rates compared to serous adenocarcinoma, predominately related to the earlier stage at presentation. Clear cell carcinomas appear to be more aggressive than other epithelial malignancies. The 5-year survival rate for stage I clear cell carcinoma is 60% and for other stages is less than 15%.[119] Younger patients also have a more favorable prognosis, as they are more likely to have tumors of lower grade and less aggressive histology, as well as better baseline performance status.[172]

MANAGEMENT OF EPITHELIAL TUMORS

Treatment for ovarian and fallopian tube cancer depends largely on the stage and grade of disease at presentation. Table 78.6 presents a general schematic for treatment recommendations for women with epithelial ovarian, fallopian tube, and primary peritoneal cancer.

TABLE 78.6 SCHEMATIC OF THE PRIMARY TREATMENT FOR EPITHELIAL OVARIAN CANCER

Low risk, early stage	
Stage IA/B, grade 1	Observation
Stage IA/B, grade 2	Observation or IV taxane/carboplatin for 3-6 cycles
High risk, early stage	
Stage IC, all grades Stage IA/B, grade 3	IV taxane/carboplatin for 3-6 cycles IV taxane/carboplatin for 3-6 cycles
Stage II	IV taxane/carboplatin for 6 cycles IP chemotherapy in optimally cytoreduced patients
Advanced stage	

Low risk, early stage	
Optimal cytoreduced stage III	IP chemotherapy IV taxane/carboplatin for 6 cycles Clinical trial
Suboptimal cytoreduced stage III/IV	IV taxane/carboplatin for 6 cycles Clinical trial Interval cytoreduction if indicated by tumor response and resectability

IP, intraperitoneal; IV, intravenous.

Early-Stage Disease

Surgical Therapy

Comprehensive surgical staging should be performed in all women with apparent early-stage disease to confirm that the cancer is confined to the adnexa. Fertility-sparing surgery with unilateral salpingo-oophorectomy may be considered in a small subset of women with stage IA disease if the contralateral ovary is normal in appearance.[173] In addition to abdominal exploration and full surgical staging, endometrial biopsy should be considered to sample the endometrium.

Postoperative Management

Early studies by the GOG and others have identified a small subgroup of patients with well- to moderately differentiated (grade 1 or 2) stage IA and IB tumors who have a low risk of relapse and may not require adjuvant therapy.[174,175] National cancer guidelines recommend that women with early-stage (FIGO IA or IB) grade 1 endometrioid carcinoma of the ovary may be treated with surgical resection and observation with expected 5-year survival rates on the order of 90%.[176] If observation is considered for women with early-stage grade 2 disease, full surgical staging should be performed.

Adjuvant Chemotherapy

Women with early-stage disease and a less favorable prognosis include patients with grade 3 tumors, clear cell histology, or disease extension beyond the ovarian capsule, positive peritoneal cytology, or pelvic extension or implants (stage IC or II). Various adjuvant treatment approaches have been investigated to improve clinical outcomes, although the optimal management

remains controversial. Few randomized trials have been conducted in this population, and they have been limited by small sample size and lack of power to demonstrate a survival advantage.

Nonetheless, two large multi-institutional trials conducted in Europe randomized women with early-stage ovarian cancer to platinum-based chemotherapy or observation following surgery (Table 78.7). The International Collaborative Ovarian Neoplasm 1 (ICON1) trial enrolled 477 women with FIGO IA-C ovarian cancer inclusive of all tumor grades and histologic subtypes.[177] Adjuvant chemotherapy consisted of six cycles of a platinum-based regimen per institutional preference. With a median follow-up of 9.2 years, 10-year recurrence-free survival was 67% for the chemotherapy arm and 57% for observation (HR 0.7, $P = .02$).[178] Overall survival also favored the chemotherapy group (72% vs 64%, $P = .06$). When stratified by histology and grade, the largest benefit for adjuvant chemotherapy was seen in patients with high-risk disease, defined as FIGO stage IA grade 3, stage IB or IC grades 2 and 3, or any clear cell histology. HRs for recurrence and death for the high-risk subset were 0.52 and 0.48, respectively (both $P < .01$). The second trial, Adjuvant Chemotherapy in Ovarian Neoplasm (ACTION), assigned 448 women with early-stage ovarian cancer to four to six cycles of platinum-based adjuvant chemotherapy or observation following surgery. Women with FIGO IA grade 2 and 3 diseases, all stages IC-IIA, or any clear cell histology were eligible for the trial. Recurrence-free survival, but not overall survival, was significantly improved in the chemotherapy group (70% vs 62% at 10 years).[179,180] The greatest benefit was seen in the subset of women with nonoptimal surgical staging. In a combined analysis of the ICON1 and ACTION trials, adjuvant chemotherapy was associated with significantly improved overall survival at 5 years (82% vs 74%) compared to observation.[181]

TABLE 78.7 RANDOMIZED STUDIES OF ADJUVANT CHEMOTHERAPY IN EARLY-STAGE OVARIAN CANCER

Trial	Stage	Study Design	Number of Patients	5-Y DFS%	5-Y OS%	Notes
Observation vs chemotherapy						
GOG (1990)	IA, IB grades	Observation	44	91	94	No survival difference; optimal staging

Trial	Stage	Study Design	Number of Patients	5-Y DFS%	5-Y OS%	Notes
	1-2					
		Melphalan	48	98	98	
ICON1 (2003, 2007)	I/II	Observation	236	62	70	Largest benefit for high-risk group; no surgical staging
		Platinum based	241	73[a]	79[a]	
ACTION (2003, 2010)	IA, IB grades 2-3	Observation	224	68	78	Optimal staging in 1/3
	IC-IIA all grades	Platinum based	224	76[a]	85	
	Clear cell					
Duration of chemotherapy						
GOG (2006, 2010)	IA, IB grade 3	3 cycles CT	232	75	81	No survival difference; greatest benefit for serous tumors
	IC-II all grades	6 cycles CT	225	80	83	
	Clear cell					

ACTION, Adjuvant Chemotherapy in Ovarian Neoplasm; CT, carboplatin and paclitaxel; DFS, disease-free survival; GOG, Gynecologic Oncology Group; ICON1, International Collaborative Ovarian Neoplasm 1; OS, overall survival.

[a]Statistically significant.

The GOG conducted a randomized trial to determine the optimal duration of adjuvant chemotherapy in women with high-risk, surgical stage I disease by comparing three versus six cycles of carboplatin and Taxol chemotherapy.[182] Rates of recurrence (25% vs 20%) and overall survival (81% vs 83%) were similar at 5 years for three and six cycles of chemotherapy, although six cycles were associated with significantly more toxicity, including neuropathy, granulocytopenia, and anemia. However, subset analysis revealed a significantly lower risk of recurrence for women with serous tumors.[183] At 5 years, recurrence-free survival for women with serous tumors was 83% for six cycles of chemotherapy versus 60% for three

cycles (HR 0.33, P = .04). Overall survival was also improved at 5 years (86% vs 73%), although not statistically significant.

Adjuvant Whole-Abdomen Irradiation

WAI was an accepted standard modality in the adjuvant postoperative treatment for completely resected ovarian cancer; however, its use declined significantly after 1975. The practical advantage of WAI was the ability to treat all of the peritoneal surfaces within the abdomen and pelvis, although the delivered dose was limited by the relatively low tolerance of the liver and kidneys. Interest in WAI was established following the publication from Princess Margaret Hospital of a randomized comparison of 147 patients with FIGO IB, FIGO II, or FIGO III debulked ovarian cancer who received WAI with a pelvic boost or pelvic radiotherapy followed by chlorambucil.[184] WAI significantly improved 10-year survival rates over limited pelvic radiotherapy and chemotherapy (64% vs 40%). The greatest magnitude of the survival benefit was observed in patients with less than 2 cm of residual disease (10-year survival 78% vs 51%). No significant benefit was observed in patients with extensive residual tumor.

Subsequent randomized studies did not find a benefit for WAI compared to combined adjuvant treatment modalities. A multi-institutional trial by the National Cancer Institute of Canada (NCIC) randomized 257 high-risk patients with stage I or optimally debulked stage II or III disease to receive melphalan, WAI, or IP phosphorus-32 (^{32}P).[185] All patients had previously received 22.5 Gy to the pelvis prior to study entry. The WAI arm delivered 22.5 Gy to the abdomen in 2.25-Gy fractions. Actuarial 10-year survival rates failed to demonstrate a statistically significant difference among all groups.[186] A second study from the Danish Ovarian Cancer Group reported similar outcomes for women who received adjuvant WAI versus pelvic radiotherapy with cyclophosphamide or melphalan (4-year survival, 63% vs 55%).[187]

WAI has also been shown to be comparable to single-agent or combination chemotherapy in the adjuvant setting. A prospective study from the MD Anderson Cancer Center randomized 149 women with stages I through III ovarian cancer and less than 2 cm of residual disease to WAI or melphalan.[188] WAI was delivered by a moving strip technique with a pelvic boost. Overall survival at 5 years was 71% for WAI and 72% for the melphalan arm. Severe late gastrointestinal toxicity requiring surgical intervention was reported in

14% of patients who received WAI, attributed to the moving strip technique that delivered excessive pelvic dose. A second prospective trial from the Northwest Oncologic Cooperative Group of Italy randomized 70 women with early-stage high-risk disease to adjuvant WAI or six cycles of cisplatin plus cyclophosphamide. Despite protocol violations in the assigned treatment groups, there was no difference in relapse-free or overall survival when analyzed by treatment received.[189] From these studies, WAI appears equivalent to chemotherapy when delivered in patients with optimally debulked disease but is no longer used. Further escalation of WAI to 27.5 Gy does not appear to provide additional survival benefit.[190]

The role of consolidative radiotherapy in patients with stage I or II disease and clear cell, endometrioid, or mucinous histology has recently been raised by population-based studies. In a multicenter retrospective study of 241 patients with stages I and II ovarian clear cell carcinoma, consolidative radiation was associated with a 20% benefit in disease-free survival at 5 years for patients with stage IC or II disease.[191] Following surgical staging, patients were treated with either three cycles of carboplatin and paclitaxel followed by WAI (45 Gy to pelvis and 22.5 Gy to whole abdomen) or six cycles of chemotherapy alone. The survival benefit was most pronounced among patients with negative or unknown peritoneal cytology. Similar results were also seen for patients with stage I or II ovarian cancer of endometrioid, clear cell, and mucinous subtypes in a larger analysis of this population-based study, which reported a 40% reduction in disease-specific mortality and 43% reduction in overall mortality with the addition of consolidative radiotherapy. A survival benefit with the addition of consolidative radiotherapy was not observed in patients with stage II disease or serous tumors.[192] However, at this time, there is no level 1 evidence to support the role of adjuvant or consolidative radiation for patients with early-stage disease and nonserous histology.

Adjuvant Intraperitoneal Phosphorus-32

IP instillation of ^{32}P was extensively studied as an alternative to external beam radiotherapy but is no longer in clinical use. In patients with high-risk, early-stage ovarian cancer, randomized trials of adjuvant IP ^{32}P versus chemotherapy from the GOG and Norwegian Radium Hospital found no significant differences in disease-free or overall survival in a population with

high-risk early-stage disease.[175,193,194] Given a higher incidence of bowel toxicity and limitations of delivery, ^{32}P has largely been replaced by platinum and taxane combination chemotherapy as the adjuvant treatment for early-stage and advanced disease.

Advanced-Stage Disease

Surgical Considerations

Optimal or complete cytoreduction is one of the most important prognostic factors for survival in patients with advanced-stage ovarian cancer. Cytoreductive surgery in advanced-stage disease may improve the patient's disease-related symptoms such as abdominal pain and early satiety and allow for the ability to maintain nutritional status. Optimal cytoreduction may also enhance chemotherapy delivery and response by the removal of large hypoxic tumor masses. Bowel resection may be required to remove metastatic implants involving the bowel mesentery or serosa. Extensive upper abdominal surgery, including splenectomy, partial hepatectomy, partial gastrectomy, partial cystectomy and/or ureteroneocystostomy, cholecystectomy, distal pancreatectomy, and/or diaphragmatic resection, also results in prolonged palliation and improved survival.[154,195,196] Select patients may be potential candidates for IP chemotherapy, as discussed later, and consideration should be given to the placement of an IP catheter at the time of surgery. Laparoscopy may be utilized to identify which patients with advanced ovarian cancer have the greatest likelihood of attaining complete cytoreduction with primary surgery.[197,198] However, based upon the evaluation of 2,655 patients in GOG 182, patients with larger tumor burden still have worse survival despite aggressive surgery attaining no residual disease.[199]

Second-look laparotomy (SLL) was introduced to assess the extent of residual disease following cytoreductive surgery and adjuvant chemotherapy. Up to 20% to 50% of patients may have residual disease after adjuvant therapy that was not detected on physical examination or by CA-125 levels or imaging. Although SLL demonstrated the prognostic importance of a pathologic remission, it was not found to have a therapeutic benefit in a GOG trial of 800 patients.[200] Therefore, second-look evaluations for the purposes of determining therapy, and not for interval cytoreduction, should be reserved for women enrolled in clinical trials.

Several studies have evaluated the importance of interval cytoreduction following an initial attempt at surgical debulking. In a randomized trial by the European Organisation for Research and Treatment of Cancer (EORTC), 319 women with suboptimally debulked disease (.1 cm residual) were assigned to six cycles of cisplatin/cyclophosphamide chemotherapy or interval cytoreduction after three cycles of chemotherapy, followed by additional three cycles.[201] Progression-free and overall survival were significantly improved with interval cytoreduction (median overall survival 26 vs 20 months, $P = .04$) without increased surgical morbidity. However, a subsequent GOG trial of 550 women failed to reproduce these results.[202] Following a suboptimal resection in the GOG trial, patients were randomized to three cycles of cisplatin and paclitaxel followed by interval debulking or chemotherapy alone for a maximum of six cycles in both arms. The absence of a survival benefit may be attributable to differences in the chemotherapy used or more aggressive initial surgical management by gynecologic oncologists in the GOG trial. National cancer guidelines state that patients should be evaluated for potential interval cytoreduction before the fourth cycle of neoadjuvant chemotherapy.

The role of neoadjuvant chemotherapy has been explored in a randomized EORTC/NCIC trial of 670 women with stages IIIC and IV ovarian, fallopian tube, or primary peritoneal cancer randomized to initial surgical debulking followed by six cycles of cisplatin-based chemotherapy or interval debulking after three cycles, followed by three additional cycles.[203] The cohort had extensive bulky disease, with more than 60% of patients with metastases greater than 10 cm. Although progression-free and overall survival were similar between the two groups, interval surgery achieved optimal cytoreduction more often (81% vs 42%) and with fewer surgical complications. A major criticism of the trial is that the median survival was significantly lower than that of recently reported U.S. trials (~30 months compared to overall survival averages of 50 months),[204,205] which may be related to selection of higher risk patients. In a retrospective analysis of the EORTC/NCIC trial, patients with stage IVB disease and bulky tumors had better 5-year survival rates with neoadjuvant therapy, whereas those with stage IIIC and less bulky tumors had a greater survival benefit with upfront surgery.[206] National cancer guidelines indicate that neoadjuvant chemotherapy may be considered for patients with bulky stage III to IV

diseases who are not surgical candidates following assessment by a gynecologic oncologist. However, more data will be necessary prior to recommending neoadjuvant chemotherapy in patients with potentially resectable ovarian cancer, as upfront debulking surgery remains the treatment of choice in the United States. In a single U.S. institutional series of 586 patients with advanced ovarian cancer, upfront debulking surgery was associated with an improved median overall survival of 72 months compared to 43 months for those selected for the treatment with neoadjuvant chemotherapy.[207]

Chemotherapy for Advanced-Stage Disease

Platinum agents are the most active class of compounds in the adjuvant treatment for ovarian cancer. Before 1980, alkylating-based regimens such as cyclophosphamide and doxorubicin were used with clinical response rates of 15% to 20%. GOG 47 demonstrated an improvement in clinical complete response rates (51% vs 26%) and progression-free survival (13 vs 8 months) with the addition of cisplatin to cyclophosphamide and doxorubicin. Cisplatin has since been used extensively in both single-agent and multidrug studies. A meta-analysis of 49 trials from the Advanced Ovarian Cancer Trialists' Group found that platinum combination chemotherapy improved survival rates over the same nonplatinum regimen (HR 0.88, 95% CI 0.79-0.98) and nonplatinum monotherapy (HR 0.93, 95% CI 0.83-1.05).[208] The women in the nonplatinum groups routinely received platinum chemotherapy at the time of relapse, likely obscuring the magnitude of the benefit. This meta-analysis also incorporated data from 11 trials that directly compared carboplatin and cisplatin, either as single agents or in combination with other drugs, which suggested no difference in efficacy between the two agents. Carboplatin clearly has fewer treatment-related side effects, including less nephrotoxicity, neurotoxicity, and emetogenic potential, and is considered standard of care. However, carboplatin does have more associated myelosuppression, primarily thrombocytopenia, which is cumulative and may be dose limiting.

In addition to platinum compounds, taxanes have become a cornerstone of the treatment schemas for women with epithelial ovarian cancer. GOG 111 was a randomized study comparing cisplatin and paclitaxel with cisplatin and cyclophosphamide in women with suboptimally debulked, large-volume

ovarian cancer. The paclitaxel-containing arm demonstrated improved clinical response rates (73% vs 60%), progression-free survival (18 vs 13 months), and overall survival (38 vs 24 months).[209] A second GOG study of 614 women with advanced disease and suboptimal resection compared single-agent cisplatin to 24-hour infusion of paclitaxel and to the combination of paclitaxel and cisplatin.[210] Either cisplatin alone or in combination with paclitaxel resulted in improved clinical response rates and progression-free survival, although overall survival was similar in the three arms. Combination chemotherapy also had lower cumulative toxicity. As several trials have demonstrated the comparable efficacy of cisplatin and carboplatin, the combination of carboplatin and paclitaxel has become the preferred first-line chemotherapy regimen. Although the standard dosing of intravenous (IV) carboplatin and paclitaxel is every 21 days, a phase III trial from Japan demonstrated significant gains in progression-free and overall survival with a dose-dense regimen of weekly paclitaxel in combination with carboplatin given every 3 weeks[211,212] (Table 78.8). Grade 3 or 4 anemia was more common in the dose-dense arm, although other toxicities were similar. In the GOG-262 trial, weekly paclitaxel was associated with an increase in progression-free survival that was 3.9 months longer than that observed with paclitaxel administered every 3 weeks among patients who did not receive bevacizumab.[213] Carboplatin and docetaxel are also an acceptable first-line alternative and may be considered for patients at high risk for neuropathy.[214] In older patients or those with poor performance status, weekly paclitaxel and carboplatin may be considered.[215] Phase III trials have failed to show a benefit for the addition of a third cytotoxic agent to the carboplatin and paclitaxel regimen. GOG 182-ICON5 was a five-arm randomized trial of 4,312 women that compared the addition of gemcitabine, liposomal doxorubicin, or topotecan to carboplatin and paclitaxel. There were no improvements in progression-free or overall survival with any experimental regimen.[216] The recommended IV regimens include (1) paclitaxel and carboplatin given every 3 weeks for six cycles, (2) dose-dense weekly paclitaxel plus carboplatin every 3 weeks for six cycles, (3) weekly paclitaxel and carboplatin for 18 weeks, and (4) docetaxel and carboplatin every 3 weeks for six cycles.

TABLE 78.8 RANDOMIZED STUDIES OF ADJUVANT CHEMOTHERAPY IN ADVANCED-

STAGE OVARIAN CANCER						
Trial	**Stage**	**Study Design**	**Number of Patients**	**Median PFS (Months)**	**Median OS (Months)**	**Notes**
GOG 172 (2006)	III	IP/IV cisplatin/paclitaxel	415	23.6	65.6	Greater toxicity in IP/IV arm
	#1 cm residual	IV cisplatin/paclitaxel		18.3[a]	49.7[a]	
Japanese GOG (2009, update 2013)	II-IV	Dose-dense CT	631	28.2	100.5	More anemia with dose-dense schedule
		CT (every 21 d)		17.5[a]	62.2[a]	
GOG 218 (2010)	III-IV	CT	1,873	10.3	39.3	Higher rates of hypertension, GI perforation, and fistula
		+ c. bevacizumab		11.2	38.7	
		+ c./m. bevacizumab		14.1[a]	39.7	
ICON7 (2010)	High risk I-II	CT	1,528	17.4	–	Greatest benefit in high-risk subset
	III-IV	+ c./m. bevacizumab		19.8[a]

[a]Statistically significant.

The role of novel biologics in the first-line treatment for ovarian, fallopian tube, and primary peritoneal cancers is under active investigation. Antiangiogenics have demonstrated activity in the recurrent treatment setting, and the addition of bevacizumab to conventional first-line chemotherapy has been tested in two randomized trials. Bevacizumab is a humanized monoclonal antibody directed against the VEGF receptor that may inhibit

tumor angiogenesis and improve chemotherapy delivery. GOG 218 reported that the addition of concurrent and maintenance bevacizumab for 15 months significantly improved progression-free survival compared to six cycles of carboplatin and paclitaxel alone (14.1 vs 10.3 months).[217] The benefit was not seen in the group who received concurrent bevacizumab without maintenance therapy. Rates of hypertension, gastrointestinal perforation, and fistula formation were higher with the use of bevacizumab. With a median follow-up of 17.4 months, overall survival was similar between the treatment arms, as was quality of life. In a subsequent analysis, women with ascites who received bevacizumab maintenance regimen had significantly improved progression-free and overall survival.[218] Long-term results with a median follow-up of 102.9 months demonstrated no disease-specific survival and no survival advantage with the addition of bevacizumab.[219] The ICON7 trial also reported a progression-free, but not overall, survival benefit with concurrent bevacizumab and carboplatin/paclitaxel chemotherapy when compared to chemotherapy alone, although the absolute benefit was modest (2.4 months).[220] The greatest benefit was observed in patients at high risk for progression, defined as FIGO stage IV or greater than 1 cm of residual disease and FIGO stage III (median progression-free survival of 16 vs 10.5 months). In an updated analysis, the addition of bevacizumab did not increase overall survival in the whole study population, although patients with a poor prognosis had a significantly longer survival time with bevacizumab (39.3 months) compared to those who received chemotherapy alone (34.5 months).[221] Concerns about cost and lack of an overall survival and/or quality of life benefit have tempered the widespread adoption of bevacizumab to the first-line chemotherapy backbone. National cancer guidelines include the addition of bevacizumab to upfront therapy with carboplatin/paclitaxel and maintenance therapy with a Category 2B recommendation.

Several VEGFR tyrosine kinase inhibitors (TKIs) have been evaluated in the concurrent and/or maintenance setting in the upfront treatment of ovarian cancer. A phase III trial of the oral antiangiogenic nintedanib (BIBF 1120) in combination with carboplatin and paclitaxel reported a significant benefit in progression-free survival (17.2 vs 16.6 months), although a higher rate of serious adverse gastrointestinal events was observed when compared to chemotherapy alone.[222] Pazopanib, a potent multitargeted TKI against VEGF receptor, PDGF receptor, and c-Kit, was evaluated as maintenance therapy

following surgical debulking and first-line chemotherapy in a randomized phase III trial of 940 patients (AGOOVAR 16 trial).[223] The addition of maintenance pazopanib resulted in a median progression-free survival benefit of 5.6 months at the expense of increased toxicity, and no overall survival difference was observed.

Intraperitoneal Chemotherapy

Because of the unique peritoneal dissemination of epithelial ovarian and fallopian tube cancer, there has been a significant interest in evaluating IP administration of chemotherapy, which allows for a several-fold increase in drug concentration compared to systemic delivery. However, penetration into tumor tissue may be limited such that therapy is best suited for patients with minimal residual disease after surgical cytoreduction. The National Cancer Institute published a consensus statement in 2006 stating that IP chemotherapy should be offered to every woman with optimally debulked advanced-stage ovarian cancer based on the findings of GOG 172 (Table 78.8), which showed a progression-free and overall survival benefit to IP chemotherapy when compared with IV therapy alone (23.6 vs 18.3 months and 65.6 vs 49.7 months).[204] In women with stage III disease, survival was significantly increased by 16 months after IP therapy using cisplatin/paclitaxel when compared to standard IV therapy (65.6 vs 49.7 months). Only 42% of patients completed all six cycles of IP chemotherapy owing to treatment-related toxicity and catheter-related complications, which included gastrointestinal events, abdominal pain, metabolic abnormalities, neuropathy, catheter infection, and blockage. Despite the higher incidence of toxicity, additional support for IP chemotherapy is derived from a meta-analysis of eight trials comparing IP to IV administration of platinum-based chemotherapy. IP delivery resulted in a 22% decrease in the risk of death, which translated into a 12-month median survival benefit.[224] With advances in IV chemotherapy and targeted therapies, IP chemotherapy is no longer part of cancer guidelines, with all IV starting with platinum-based therapy.

CONSOLIDATIVE THERAPY FOR EPITHELIAL OVARIAN CANCER

Consolidative radiotherapy was introduced in hopes of eradicating subclinical residual disease in women who remain at high risk for relapse following surgical cytoreduction and adjuvant chemotherapy. Despite a

negative SLL, 30% to 50% of women with confirmed clinical remission ultimately relapse, most commonly in the pelvis or upper abdomen. Consolidative WAI as well as IP radiocolloid have been evaluated in several studies, although randomized data are currently lacking. Radiotherapy is not currently used as a consolidative treatment for ovarian or fallopian tube carcinomas, although it may have a role in the salvage or palliative treatment of select cases.

Consolidative Whole-Abdomen Irradiation

The efficacy of WAI has been demonstrated in early-stage patients with minimal residual disease (,2 cm) after cytoreductive surgery. A few early, prospective randomized trials have evaluated the role of consolidative WAI compared to extended chemotherapy in patients with advanced-stage disease (stage III/IV) after initial surgical cytoreduction, adjuvant chemotherapy, and SLL. In all of these trials, disease-free and overall survival rates were not found to be significantly different between WAI and chemotherapy.[225-227] A possible limitation of these trials was that women with macroscopic residual disease after SLL were eligible for enrollment.

Two trials have evaluated consolidative WAI in patients with complete clinical or pathologic remission following cytoreductive surgery and adjuvant chemotherapy. A randomized study from Austria demonstrated improved disease-free and overall survival for consolidative WAI, with the greatest benefit seen in patients with stage III disease.[228] The Swedish-Norwegian Ovarian Cancer Study Group recently reported their long-term results from a randomized trial of patients with stage III disease.[229] Following primary cytoreductive surgery and four cycles of cisplatin-based chemotherapy, women with complete remission at second-look surgery were randomized to WAI, six additional cycles of chemotherapy, or observation (if pathologic remission confirmed). In the subgroup with pathologic remission, WAI improved progression-free survival compared to chemotherapy or no further therapy (56%, 36%, and 35%, respectively). Overall survival was not statistically different, although statistical power was limited because only 172 (23%) of 742 enrolled patients were randomized to consolidative treatment.

WAI does not appear to compromise the ability of patients to receive and tolerate salvage chemotherapy following relapse, as recently reported in a phase II study from Princess Margaret Hospital.[230] However, the long-term

complication rate using conventional radiotherapy techniques is significant. In a multicenter retrospective study from France with a median follow-up of 14 years, late symptomatic enteritis occurred in 20% of patients, of which 8% required surgical intervention for bowel obstruction, and death related to bowel complications occurred in 4%.[231] At this time, WAI is not included in national cancer guidelines as a treatment recommendation for initial or consolidative treatment in ovarian cancer.

Consolidative Intraperitoneal Phosphorus-32

Randomized data evaluating IP ^{32}P as consolidative treatment following SLL are limited. The Norwegian Radium Hospital randomized 50 patients with stage IA high grade and IB through III disease and negative SLL to ^{32}P versus observation and found no significant difference between the arms.[193] The GOG also conducted a prospective randomized trial of 202 patients with stage III disease with complete clinical remission and microscopically negative disease at SLL.[232] Compared with patients who received no further therapy, those who received ^{32}P (15 mCi) within 10 days of SLL did not have improved 5-year disease-free survival (36% vs 42%) or overall survival (63% vs 67%).

Recurrent Ovarian Cancer

Women in clinical remission following initial adjuvant treatment for ovarian cancer may be followed with a combination of physical examination, serial CA-125 levels, and/or abdominal and pelvic CT. Detection of early relapse by a rising CA-125 is fairly specific, although the lead time between biochemical and clinical progression may be up to 6 months. Patients should also be educated about the signs and symptoms of recurrence, such as pelvic pain, bloating, early satiety, obstruction, weight loss, and fatigue. Second-line chemotherapy is not curative; thus, the timing of salvage therapy is controversial. The EORTC conducted a randomized trial of early versus delayed treatment for relapsed ovarian cancer that showed no difference in overall survival between the arms and a decrement in quality of life.[233] These findings have not been widely adopted in the United States owing to criticisms regarding the study design, including lack of stratification by known prognostic factors and nonstandard second-line therapies. Cancer

guidelines encourage physicians to discuss the pros and cons of CA-125 monitoring with their patients and the implications regarding early treatment and quality of life.

Chemotherapy

The selection of second-line chemotherapy for recurrent ovarian cancer is based on the interval to disease relapse and the determination of platinum sensitivity or resistance. The intent of recurrence therapy is to decrease tumor burden, control symptoms, improve progression-free survival, and/or increase length or quality of life. Patients who experience an early recurrence within 6 months of the completion of initial chemotherapy, have stable disease, or progress during initial induction chemotherapy are considered platinum resistant with low likelihood of cure. Women who suffer an early recurrence do have treatment options, including second-line chemotherapy agents (topotecan, weekly paclitaxel, pegylated liposomal doxorubicin, gemcitabine, oral etoposide, docetaxel), hormonal therapies, targeted therapeutics, and the opportunity to participate in clinical trials. For women with a late recurrence, retreatment with a platinum-based combination is a reasonable option, and the longer the disease-free interval, the higher the response rate to the agents. Preferred platinum-based combinations include carboplatin/paclitaxel, cyclophosphamide/bevacizumab, carboplatin/liposomal doxorubicin, carboplatin/weekly paclitaxel, carboplatin/docetaxel, carboplatin/gemcitabine, cisplatin/ gemcitabine, or topotecan/bevacizumab, among multiple other options. With the exception of those women who have a prolonged disease-free interval, the opportunity for a meaningful second remission is low, and one needs to carefully balance quality of life, chemotherapy-related toxicity, cost, and the patient's goals of care. Several randomized phase III studies are testing the role of antiangiogenics in the recurrent setting with combination chemotherapy. The AURELIA trial evaluated bevacizumab in combination with liposomal doxorubicin, weekly paclitaxel, or topotecan compared to chemotherapy alone in patients with platinum-resistant ovarian cancer. The addition of bevacizumab resulted in a statistically significant progression-free survival benefit (6.7 vs 3.4 months) and nonsignificant overall survival benefit (16.6 vs 13.3 months) when compared to chemotherapy alone.[234] As the gastrointestinal perforation rate in the bevacizumab arm was 2.2%, these

combination regimens are contraindicated in patients at increased risk. In the OCEANS trial, the addition of bevacizumab to carboplatin/gemcitabine chemotherapy resulted in improved response rates (79% vs 57%) and progression-free survival (median 12.4 vs 8.4 months) in women with platinum-sensitive recurrent disease.[235] In the final survival analysis, there was not a significant increase in overall survival with the addition of bevacizumab when compared to chemotherapy alone (33.6 vs 32.9 months).[236] A third large multi-institutional trial of 674 women evaluated the role of secondary surgical cytoreduction and bevacizumab in women with recurrent platinum-sensitive ovarian cancer and found that the addition of bevacizumab followed by maintenance therapy until progression improved median overall survival by sensitivity analysis.[237] Phase II studies of bevacizumab have demonstrated single-agent activity in patients with platinum-resistant recurrent ovarian cancer with response rates of 15% to 20%.[238,239] However, one of these studies reported a gastrointestinal perforation rate of 11% in a heavily pretreated population. Based on the phase III trials discussed earlier, national guidelines recommend combination regimens with bevacizumab for patients with platinum-resistant recurrent ovarian cancer, although there is less consensus for those with platinum-sensitive disease.

Emerging data are confirming the activity of PARP inhibitors in select patients with recurrent ovarian cancer. This new class of targeted therapy inhibits key enzymes involved in DNA repair and has been shown to be particularly active in treating cancers in BRCA mutation carriers. In the setting of BRCA deficiency, PARP inhibition results in the accumulation of double-strand DNA breaks that are lethal to tumor cells through a mechanism known as synthetic lethality. A substantial number of patients with ovarian cancer have been found to have BRCA-deficient tumors related to germline or somatic mutation, epigenetic silencing, or alteration in microRNA levels. Olaparib has shown single-agent response rates ranging from 28% to 41% depending on dose and BRCA mutation status. In phase II of 298 patients with germline BRCA1/2 mutation and advanced cancer, olaparib resulted in an overall response rate of 31% for those with platinum-resistant ovarian cancer.[240] In the platinum-sensitive setting, olaparib maintenance therapy resulted in a progression-free survival benefit of 8.4 months compared to 4.8 months with placebo for women with relapsed ovarian cancer, although an

overall survival benefit was not observed.[241] Single-agent olaparib is now recommended as recurrence therapy for patients with advanced ovarian cancer who have a germline BRCA mutation and received three or more lines of chemotherapy. Olaparib maintenance therapy was recently granted the Food and Drug Administration (FDA) approval based on the results of the SOLO-2 trial, which showed a significant improvement in progression-free survival in patients with germline BRCA-mutated, platinum-sensitive recurrent ovarian cancer when compared to placebo.[242] Two other PARP inhibitors have also been recently granted FDA approval. In the NOVA trial, patients with recurrent epithelial, fallopian tube, or primary peritoneal cancer were stratified by germline BRCA mutation status and randomized to either niraparib or placebo following complete or partial response to platinum-based chemotherapy. Maintenance niraparib resulted in a significant improvement in progression-free survival, with the greatest benefit among patients with germline BRCA mutations.[243] Rucaparib was granted accelerated approval for patients with germline or somatic BRCA mutation who have been treated with two or more chemotherapy regimens. BRCA mutation status was determined by a next-generation sequencing diagnostic test. The overall response rate in a single-arm open-label clinical trial was 54% and ranged from 66% for patients with platinum-sensitive disease to 25% for those with platinum-resistant disease.[244]

In summary, there are four PARP inhibitors that are FDA approved for recurrent ovarian cancer that clinicians may select from[245]:

- Olaparib for patients with recurrent germline BRCA-mutated ovarian cancer who have received three or more prior lines of chemotherapy or as maintenance therapy following response to platinum therapy for those with platinum-sensitive recurrence
- Rucaparib for patients with BRCA-mutated ovarian cancer (either deleterious tumor or germline mutation) who have received at least two prior lines of chemotherapy
- Niraparib for patients with platinum-sensitive recurrent ovarian cancer as maintenance therapy following response to platinum-based chemotherapy, regardless of BRCA or tumor homologous recombination status

- Pazopanib, which showed negative results relative to paclitaxel as maintenance therapy in persistent or recurrent ovarian cancer, but is still included as an option in some cancer guidelines[245]

Further studies of PARP inhibitor agents as single agents and in combination therapy are underway in patients with platinum-sensitive and platinum-resistant disease.

A number of TKIs have been tested in the recurrent setting as single agents, with demonstrated response rates of 3% to 29%.[27,246] These agents include cediranib (targets VEGF receptor and c-Kit), sunitinib (targets VEGF receptor, c-Kit, PDGF receptor, RET, and FLT-3), sorafenib (targets VEGF receptor, c-Kit, RAF, and PDGF receptor-b), ENMD2076 (targets VEGF receptor and aurora A), pazopanib (targets VEGF receptor, PDGF receptor, and c-Kit), trebananib (inhibits binding of angiopoietins 1 and 2 to the Tie2 receptor), and cabozantinib (targets VEGF receptor and c-MET). In the phase III ICON6 trial, patients with platinum-sensitive recurrent ovarian cancer were randomized to platinum-based chemotherapy with or without cediranib as concurrent and/or maintenance therapy. The addition of maintenance cediranib showed a significant progression-free survival benefit, although at the expense of increased toxicity.[247] Trebananib has also been tested in the phase 3 setting with weekly single-agent paclitaxel and, similar to other agents in its class, resulted in prolonged progression-free survival, but with higher rates of serious adverse events, treatment discontinuation, and chronic edema.[248] Combinatorial therapy with PARP and VEGF inhibition has also been explored with promising results in a phase II study,[249] and large phase III evaluations are underway.

Palliative Surgery

Secondary cytoreductive surgery with the intent of prolonging survival may benefit a select subset of patients with a long disease-free interval, good performance status, and single or few sites of recurrence.[250,251] A recently reported phase III trial randomized 407 women with platinum-sensitive disease at the time of first relapse to cytoreduction followed by second-line chemotherapy versus chemotherapy alone. Eligible patients had an excellent performance status, volume of ascites of 500 mL or less, and complete cytoreduction at diagnosis. The median progression-free survival was 21

versus 13.9 months in favor of surgery. The primary end point of overall survival will be reported in subsequent analysis.[252] Palliative surgery may also be considered in women who present with symptomatic tumor masses or intestinal obstruction. However, the risk of perioperative mortality and reobstruction is significant, and the patient's medical condition, performance status, and anticipated life expectancy should be carefully considered before operative intervention. For patients who are not surgical candidates, percutaneous decompression and IV hydration with consideration of palliative chemotherapy and/or hospice referral may be appropriate.

Palliative Radiation Treatment

Radiation therapy may be an effective palliative treatment modality in settings where localized recurrences are causing significant symptoms that are unresponsive to systemic therapy. Symptoms such as bleeding, pain, or obstruction in the pelvis, groin, abdomen, or chest may be palliated with an abbreviated course of radiation treatment. Clinical response rates have been reported in the range of 70% to 100%, with complete clinical response rates of 30% to 70% and a median duration of 5 to 11 months.[253-257] Palliative radiotherapy is effective even in patients heavily pretreated with systemic or IP chemotherapy. Pain relief and cessation of bleeding are achieved in more than 80% of patients and symptoms from bowel or ureteral obstruction in 60% to 75%.[258] A recent report found that response rates to palliative radiation did not vary among patients with platinum-resistant versus platinum-sensitive disease either at the time of diagnosis or at the time of radiation treatment. However, patients with clear cell ovarian cancer had lower clinical response rates when compared to those with serous or endometrioid cell types, although these patients may still experience symptomatic relief with radiation.[259] When delivered locally to symptomatic sites, radiation therapy appears to be of significant and durable benefit and should be considered for palliative purposes in select patients with symptomatic relapses, particularly in those who are refractory to chemotherapy.

The role of salvage radiotherapy in select patients with isolated pelvic recurrences has been suggested by several reports. In a series by Firat and Erickson,[260] 28 patients with recurrent or persistent disease involving the vagina and/or rectum received palliative radiotherapy delivered by external

beam radiotherapy, brachytherapy, or a combination of both. Bleeding was controlled in all cases, and 79% achieved a complete symptomatic response. Of the 21 patients with no evidence of liver or extra-abdominal disease, 2-year survival was 57% compared to 0% for the seven patients with liver and extra-abdominal metastases at the time of radiotherapy. In the group of 14 patients with pelvic-confined disease, 5 patients had recurrences in the upper abdomen and 4 patients were long-term survivors greater than 5 years after radiotherapy administration. A second study by Albuquerque et al[261] evaluated the outcomes of 20 women treated with salvage radiotherapy for isolated extraperitoneal recurrence. Most recurrences were in the pelvis, although three patients had regional nodal recurrences and one patient had an abdominal wall recurrence. The median delivered dose to a tumor-directed volume was 50.4 Gy, and a brachytherapy boost was delivered in select cases. Local recurrence–free survival at 2 years was 89% for patients with optimal debulking prior to radiotherapy compared to 42% for patients with suboptimal debulking or gross residual disease. The corresponding disease-free survival rates at 3 years were 72% and 22%, and overall survival rates at 5 years were 50% and 19%, respectively. In a large single-institutional series of 102 patients with epithelial ovarian cancer who received salvage involved-field radiotherapy, 5-year rates of progression-free and overall survival were 40% and 24%, respectively, with an infield control rate of 71%. Of note, the time interval to relapse and subsequent chemotherapy was prolonged following radiation treatment compared to the time interval to relapse before radiation. Furthermore, 25 patients did not experience relapse for a median of 61 months, and patients with clear cell histology had the highest rates of progression-free and overall survival after salvage radiation therapy.[262] Another study by Corrigan, et al retrospectively evaluated the outcomes of patients who received definitive radiation therapy doses to 48 patients with oligometastatic gynecologic malignancies, of which 20 were ovarian cancer. Patients had higher rates of median disease-free survival with treatment compared with surveillance (93 vs 34 months, $p = 0.05$).[263] Given the exceptional local control rates, minimal toxicity, and long-term survival, select patients with isolated extraperitoneal recurrences may be appropriate candidates for salvage involved-field radiation treatment.

Ovarian cancer metastatic to the brain is a rare occurrence reported in less than 1% of patients in autopsy cases and in 2% of clinical series.[264,265] More

recent series have suggested an increased incidence as chemotherapy regimens have become more effective.[265] Nonetheless, long-term prognosis is poor, as brain metastases are often a late manifestation of advanced disease, with a median survival time less than 12 months. In a series of 24 patients with metastatic brain disease treated with whole-brain radiotherapy, stereotactic radiosurgery (SRS), or a combination of whole-brain radiotherapy and SRS, median survival was 8.5 months. Patients with solitary metastatic lesions had significantly improved survival compared to those with multiple metastases (17 vs 6 months).[266] Platinum sensitivity was also recently identified as an important prognostic factor in women with metastatic brain involvement from ovarian cancer. In an analysis of 4,277 women treated at six German hospitals, 74 (1.7%) patients had clinical documentation of brain metastases, of which 61 patients received either radiotherapy alone or in combination with surgical resection and chemotherapy.[267] On multivariate analysis, platinum sensitivity (HR 0.23) and good performance status (HR 0.45) were associated with improved survival, whereas multiple lesions (HR 4.4) and low tumor grade (HR 3.1) were associated with adverse outcome. Although the extent of extracranial disease was not associated with outcome in this study, it is unclear whether the prognostic importance of platinum sensitivity was related to control of intracranial or systemic disease. In a retrospective analysis from the Multicenter Italian Trials in Ovarian cancer group that included 174 women with epithelial ovarian cancer, most of which had platinum-sensitive disease, the presence of extracranial disease (HR 1.8), older age (1.7), monotherapy (HR 2.6), and multiple brain metastasis (HR 1.9) were associated with worse overall survival following a diagnosis of brain metastases.[268]

SPECIALIZED RADIATION THERAPY TECHNIQUES

Whole-Abdominal Radiation Therapy

The clinical target volume for WAI includes the entire peritoneum from the diaphragm to the pelvic floor, encompassing both the visceral and parietal surfaces and the pelvic and para-aortic nodes. Conventionally, large anterior and posterior fields have been used. The simulation technique requires attention to the excursion of the diaphragm at the superior margin during respiration to ensure appropriate coverage. The field should encompass the pouch of Douglas inferiorly as well as the lateral extent of the peritoneal

margins, which may be located outside the pelvic brim in patients who are obese. Fluoroscopy may be used to assess the range of quiet respiratory motion. Alternatively, image fusion of CT scans obtained at inspiration and expiration or throughout the respiratory cycle (four-dimensional CT) may be used to design the treatment fields. Extended source to skin distance may be required in some patients to ensure adequate coverage. Organs at risk that are dose limiting include the kidneys, liver, small and large bowel, and bone marrow. Kidney doses are limited to 15 Gy with customized blocking, and whole-liver tolerance is 30 Gy. The standard whole-abdomen dose is 30 Gy delivered in 1.2- to 1.5-Gy fractions. An additional boost may be delivered to the pelvis and para-aortic lymph nodes to 45 to 50 Gy, depending on the clinical requirements. Patients will need to be monitored for acute gastrointestinal and hematologic toxicity as well as nutritional support.

The use of intensity-modulated radiation therapy (IMRT) to deliver WAI has been proposed as a means to reduce the radiation dose to the bone marrow and kidneys to decrease the incidence of myelotoxicity and renal damage. Dosimetric analysis has demonstrated improved planning target volume (PTV) coverage and significant dose reductions to bones with equivalent kidney sparing using dynamic multileaf collimator IMRT when compared with conventional fields.[269] The PTV receiving 95% of the prescribed dose improved from 72% to 84%, and the volume of pelvic bones receiving greater than 21 Gy was reduced by a relative 60% from 86% to 35%. Dose inhomogeneity, however, increased slightly, with small regions of underdosing near the kidneys. Similar improvements in PTV dose coverage were reported in a study using IMRT arc therapy.[270] It remains to be seen whether the dosimetric advantages gained from WAI-IMRT will translate to a significant and clinically relevant benefit. Furthermore, technical considerations must be considered with great care, given the complex anatomy and delineation of the peritoneal cavity boundaries. Patient breathing motion and setup uncertainties will also need to be addressed. Early-phase clinical trials assessing the feasibility and toxicity of WAI-IMRT as consolidation following optimal cytoreduction and platinum-based chemotherapy are ongoing.[271]

Intraoperative Radiation for Ovarian Cancer

Several studies have suggested that intraoperative radiation therapy (IORT) as part of salvage surgery for locally recurrent gynecologic cancers, including ovarian cancer, may improve local-regional control and overall survival.[272-276] The largest IORT retrospective study to date that reported results of 22 patients with ovarian cancer treated with IORT (median dose, 12 Gy; range, 9-14 Gy) suggests that the addition of IORT to cytoreductive surgery may potentially improve local-regional control and achieve palliation in highly selected patients with locally recurrent ovarian cancer.[272] Various sites were treated, most commonly the pelvic sidewall. Most patients received additional treatment after IORT, including WAI, pelvic and/or inguinal radiation, and chemotherapy. Local-regional control was achieved in 68% of patients, with a median time to recurrence of 14 months and 5-year disease-free survival of 18% and overall survival of 22%. Overall treatment-related grade 3 toxicities occurred in 41%. Bowel obstruction occurred in seven patients, all of whom received postoperative WAI and two of whom also had a component of local-regional relapse. No long-term neurologic sequelae were reported.

SEQUELAE OF TREATMENT

Acute Toxicity

Acute toxicity from WAI is common but rarely severe. The use of large radiation fields that encompass multiple abdominal organs, including the liver, kidneys, gastrointestinal tract, bladder, spleen, lungs, and pancreas, contributes to the development of predictable side effects. Gastrointestinal side effects are the most common acute and subacute toxicities encountered with WAI, given the large volume of bowel within the treatment field. Up to 75% of patients treated with WAI experience mild-to-moderate diarrhea; severe diarrhea requiring hospitalization and IV hydration is seen in 10% of patients. Limiting bowel exposure through the use of shielding or appropriately timed field reductions can minimize or prevent this toxicity. Approximately 60% to 70% may also experience nausea, particularly early during treatment, although emesis occurs infrequently. Premedication with antiemetic therapy 30 to 60 minutes prior to treatment may help mitigate this side effect. Routine IV hydration to prevent dehydration is also recommended. Appetite loss accompanied by weight loss is a frequent concern. It is thus essential to closely monitor and ensure proper nutrition to

avoid malnourishment and dehydration that may result in hospitalization and treatment interruption.

Clinically significant liver damage is extremely rare with appropriate shielding.[277] Approximately 50% of patients will develop transiently elevated alkaline phosphatase levels; however, symptomatic hepatitis occurs in less than 1%.[278] Hematologic toxicity including leukopenia and thrombocytopenia occurs in 10% to 20% of patients, although significant drops in blood counts causing treatment interruption are rare. Splenic damage may occur even at low radiation doses because of the exquisite radiosensitivity of the spleen, resulting in transient reduction in platelet counts.

Urethritis and bladder spasm from pelvic irradiation may occur and should be treated symptomatically. Adequate and careful shielding of the kidneys to limit the delivered dose to less than 15 Gy is critical to minimize renal damage and failure. Stricture of the ureters or urethra is rare, occurring in less than 1% of cases and is usually not seen until 3 to 6 months postradiation. Because treatment to the entire peritoneal cavity with adequate margins requires extension of fields above the diaphragm, inclusion of the lung bases bilaterally is required. Chest radiographs may show fibrosis or bibasilar pneumonitis in 5% to 20% of patients but is generally self-limited and rarely symptomatic.

Late Toxicity

Late toxicities following WAI were more common with the moving strip technique than with the open-field technique, primarily because of the higher doses and hot spots that were generated. High radiation doses can exceed normal organ tolerances, leading to permanent organ damage and failure. Chronic gastrointestinal damage (ie, bloating, intermittent diarrhea) occurs in less than 5% of treated patients. The overall incidence of bowel obstruction has been reported to be 5% to 10% at 5 years in cases in which IP ^{32}P or WAI is used independently. Approximately 50% of these patients who develop bowel obstructions will require surgical intervention (incidence, 3%-5%); however, recent data suggest that this incidence may be higher and closer to 10% in long-term survivors at 10 years.[231] Bowel obstructions occur more frequently with doses greater than 45 Gy and in patients with gapped or abutted split fields. In addition, adhesions in the peritoneal cavity and the combination of additional pelvic radiation to ^{32}P or WAI may double the risk

of significant bowel complications up to 20% to 25%.[185,193] As with most anatomic sites, escalating doses of radiation come with an increase in rate and degree of toxicity. Major bowel complications from 10 pooled series of 1,098 patients reported an incidence of 1.4% with abdominal dose of 22.5 Gy compared with 14% with 30 Gy.[278]

MANAGEMENT OF GERM CELL TUMORS

In general, the presentation and management of nonepithelial tumors are similar to those of their epithelial counterparts, as patients usually experience vaginal bleeding, abdominal bloating, or pain and typically require surgical intervention and chemotherapy. On presentation, routine workup is identical to that for other ovarian cancers as outlined previously. Pretreatment AFP and β-hCG levels are of particular importance in diagnosis and treatment. An elevated β-hCG with a normal AFP is strongly suggestive of dysgerminoma. Lactate dehydrogenase and CA-125 levels should also be drawn, as the germ cell tumors may have several tumor markers that can be followed (Table 78.9). Variations in surgical management and adjuvant chemotherapy and radiation do exist among the nonepithelial tumors, and treatments should consider the patient's desire to maintain fertility while offering the greatest chance for cure.

TABLE 78.9 SERUM MARKERS FOR OVARIAN GERM CELL TUMORS

Tumor Type	AFP	hCG	LDH
Dysgerminoma	−	+/−	+
Choriocarcinoma	−	+	−
Endodermal sinus tumor	+	−	−
Immature teratoma	+/−	−	−
Mixed germ cell tumor	+/−	+/−	+/−
Embryonal carcinoma	+/−	+	−
Polyembryoma	+/−	+	−

AFP, α-fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

Most ovarian neoplasms diagnosed in children and adolescents are germ cell tumors, with approximately two-thirds of these tumors being malignant

at the time of diagnosis. Germ cell tumors comprise 20% of all ovarian neoplasms and 2% to 5% of all ovarian malignancies. The most common germ cell tumor is the mature cystic teratoma (also the most common ovarian neoplasm); however, fortunately, only the minority contain a malignancy or immature elements.

Dysgerminoma

Dysgerminoma is the most common of the malignant germ cell tumors and also has the highest bilaterality rate (20%), with 10% of the ovaries being grossly involved and 10% being microscopically involved. As shown in Table 78.9, dysgerminomas may secrete lactate dehydrogenase and have elevated β-hCG levels. Most women with dysgerminomas receive a diagnosis of early-stage disease, and 80% are present before the age of 30 years. In many instances, young women affected by this disease wish to maintain fertility after therapy. The high rate of contralateral disease confers a greater risk with conservative surgical therapy. Comprehensive staging is recommended as initial surgery for patients who do not desire fertility preservation, although may be omitted in children or adolescents.

Postoperative therapy for patients with dysgerminoma can be separated into those women with stage I disease and those with disease of a more advanced stage. Women with stage I dysgerminoma may be monitored closely without compromising the cure. Approximately 15% to 25% of these women will experience a recurrence, although successful salvage treatment with chemotherapy results in survival rates close to 100%. For women with more advanced-stage disease, chemotherapy with three to four cycles of BEP (bleomycin, etoposide, and cisplatin) is recommended.[279] In a report from MD Anderson Cancer Center, more than 95% of the patients with ovarian dysgerminoma were free from relapse at a median of 7 years of follow-up.[280] Of the 16 women treated with fertility-sparing surgery, 10 patients maintained menstrual function during chemotherapy and 13 patients returned to their prechemotherapy baseline. Five pregnancies were reported, and two of the women had difficulty conceiving.

Dysgerminomas are unique in that they are exquisitely radiosensitive tumors. Radiotherapy may be considered for patients who are not candidates for platinum-based chemotherapy. The appropriate radiation dose for dysgerminoma is 25 Gy in 12 to 14 fractions with a boost of 10 Gy for gross

residual disease. However, radiotherapy will affect ovarian function and fertility, which must be taken into consideration when recommending adjuvant radiation therapy in a young patient.

Other Germ Cell Tumors

Nondysgerminomas are almost always unilateral. For apparent early-stage disease, unilateral salpingo-oophorectomy appears to be as effective as more extensive surgery. Patients with stage I grade 1 immature teratomas usually require no further therapy after unilateral salpingo-oophorectomy. All others, including stage I grade 2 and 3 immature teratoma, should be treated with three or four cycles of BEP chemotherapy. Because of the low number of diagnosed cases, large-scale studies comparing adjuvant therapy are uncommon.

Extrapolation of data regarding the efficacy of chemotherapeutic regimens in the treatment of nonseminomatous testicular germ cell tumors has had a great impact on treatment in patients with nondysgerminoma ovarian germ cell tumors. Patients with less well-differentiated tumors and all those with endodermal sinus tumor, embryonal carcinoma, choriocarcinoma, or mixed germ cell tumors should receive adjuvant postoperative chemotherapy. Various regimens have been used, including vincristine, dactinomycin, and cyclophosphamide; cisplatin, vincristine, and cyclophosphamide; and cyclophosphamide, vincristine, and bleomycin. The BEP regimen was prospectively evaluated by the GOG in patients with completely resected, surgically staged I, II, and III diseases and resulted in a 96% disease-free survival rate.[281] Cancer guidelines recommend three to four courses of BEP as the standard treatment for well-staged patients with resected ovarian germ cell tumors. Six cycles of chemotherapy may be considered for patients with gross residual or stage IV disease.

Management of Sex Cord-Stromal Tumors

Sex cord-stromal tumors derive from the intraovarian matrix of mesenchymal and connective tissue elements that supports the germ cells. The most common sex cord-stromal tumors are the granulosa cell tumors, derived from the sex cord cells along with Sertoli cell tumors. The mesenchymal derivatives include fibromas, thecal cell tumors, and Leydig cell tumors.

These tumors are responsible for less than 5% of all ovarian malignancies but account for 90% of all functioning ovarian neoplasms. One-third of the tumors will produce estrogen, progesterone, testosterone, or other androgens. This hormonal expression may lead to presenting signs and symptoms such as precocious puberty, postmenopausal bleeding, hirsutism, or virilization. Sex cord-stromal tumors can develop in women of any age (with the granulosa cell tumors having a bimodal age distribution), with a peak incidence in postmenopausal women around 50 years of age. These tumors typically behave in a benign manner with LMP. Surgery remains the mainstay of treatment; however, occasionally, postoperative therapy is required, although these tumors are considered relatively insensitive.

Adult granulosa cell tumors account for 95% of all granulosa cell tumors. Most women are diagnosed after 30 years of age, with a median age of 52 years. Abdominal pain, distension, and vaginal bleeding are the most common signs and symptoms. Because of the relative state of estrogen excess produced by these tumors, 25% of women will also have concomitant endometrial pathology, such as hyperplasia or adenocarcinoma.[282] These tumors tend to be large with an average diameter of 12 cm. If a granulosa cell tumor is suspected preoperatively, inhibin A and B levels may be elevated and useful in narrowing the differential diagnosis. Ninety percent of patients present with stage I disease, and the tumors are typically unilateral in 90% of cases. Stage is the most important prognostic factor for granulosa cell tumors; other factors include tumor rupture, stage IC disease, poorly differentiated tumor, and tumor size greater than 10 to 15 cm. The 10-year survival for women with stage I disease is approximately 90%, with 15% to 25% of patients with stage I disease ultimately suffering a disease recurrence. The 10-year survival for women with advanced-stage disease is 26% to 49%.

Juvenile granulosa cell tumors are rare, although they account for 90% of the granulosa cell tumors that occur in prepubertal girls and women less than 30 years of age.[283] Similar to the adult form, the juvenile tumors may also secrete estrogen; therefore, prepubertal girls may present with isosexual precocious puberty. This may be the most dramatic presentation; however, the most common presentation is that of an abdominal mass. As with the adult variant, the juvenile variant is rarely bilateral, with bilaterality occurring in only 5% of cases. More than 90% of cases will be stage I at the time of diagnosis, and other prognostic factors apply as with the adult

variant. The 5-year survival rate is 95%, and the prognosis remains poor with advanced-stage or recurrent disease.

Most granulosa cell tumors are unilateral and can be treated with fertility-preserving therapy consisting of unilateral salpingo-oophorectomy and appropriate surgical staging. Given the rarity of pelvic and para-aortic nodal involvement, lymphadenectomy may be omitted for patients with stage IA or IC disease. Endometrial sampling should be performed in all women retaining their uterus, as these tumors may be associated with concomitant hyperplasia or adenocarcinoma. In women not wishing to preserve fertility or those who are postmenopausal, complete hysterectomy with bilateral salpingo-oophorectomy is the procedure of choice. Surgery alone is typically curative. However, risk factors for relapse that should be considered in adjuvant treatment for stage I disease include tumor rupture, stage IC disease, poorly differentiated tumor, and tumor size greater than 10 to 15 cm. Adjuvant treatment options for high-risk stage I and advanced-stage disease include observation or consideration of platinum-based chemotherapy. Radiation therapy may also be considered for patients with stage II to IV tumors and localized disease. Inhibin levels, if initially elevated, may be a useful tumor marker for the surveillance of patients under observation.[284]

FUTURE DIRECTIONS

Ovarian cancer represents a spectrum of distinct disease processes, ranging from noninvasive borderline tumors to disseminated high-grade serous carcinomas. The cell of origin may be extraovarian in a large proportion of cases, as many high-grade serous carcinomas appear to originate in the distal fallopian tube. Clear cell, endometrioid, and mucinous cancers may arise from metaplastic transformation of the OSE, although an extraovarian origin has been proposed. Recent insights from molecular and genomic studies also support the concept of distinct biologic subtypes of ovarian cancer. Gene expression profiling has revealed greater similarity between ovarian clear cell carcinoma and renal clear cell carcinoma than other ovarian subtypes.[285] High-grade serous carcinoma shares genomic and transcriptional features with the basal subtype of breast cancer, characterized by a BRCA-deficient phenotype.[23] Driver mutations that activate the PI3 kinase signaling pathway and mutations in the tumor suppressor *ARID1A* have been identified in

endometrioid and clear cell ovarian cancers, which share a strong epidemiologic link with endometriosis.

The recognition of distinct ovarian cancer subtypes has implications for prevention, early detection, clinical trial design, and the identification of new therapeutic targets, particularly for advanced-stage and recurrent disease. Results from the large screening trials of postmenopausal women in the United States, the United Kingdom, and Japan using CA-125 and TVUS do not at present support routine screening for ovarian and fallopian tube cancer in the general population. Future screening strategies may focus on women at greatest genetic risk by high-throughput sequencing and mutation testing. Genome-wide association studies have recently identified new ovarian cancer risk loci.[286,287] Novel screening strategies will also be needed to detect precursor lesions within the fallopian tube, particularly for high-grade serous carcinomas. It is not yet known whether prophylactic salpingectomy without removal of the ovaries is an acceptable prevention strategy for premenopausal women with familial ovarian cancer syndromes. Clinical trials will soon incorporate targeted therapies with blood and imaging biomarkers to assess pathway inhibition and accurately measure disease response. Trial end points should also include robust quality-of-life tools to assess the effect of palliative chemotherapy on symptom control as well as evaluation of its toxicity.

Although no longer used in the initial management of ovarian cancer, the role of radiation therapy in definitive management of isolated oligometastatic recurrences and in palliation of symptomatic recurrences remains significant, particularly for women with chemotherapy-refractory disease. To date there have been no published prospective studies on the role of radiation in these settings. Nevertheless, this remains an area of active study.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Larissa Lee, Ross Stuart Berkowitz, and Ursula A. Matulonis from the last edition. We are indebted to Larissa Lee, Ross Stuart Berkowitz, and Ursula A. Matulonis for their work and retain much of their prose in this current edition.

CHAPTER 79

Vaginal Cancer

Joanne W. Jang and Akila N. Viswanathan

ANATOMY

The vagina is a fibromuscular tube that extends from the cervix down to the vestibule, or cleft, between the labia minora. The average length of the vagina is 3 to 4 inches or 7.5 cm. It lies dorsal to the urethra and bladder base and ventral to the rectum. Embryologically, the vagina is believed to be of dual origin, with the upper third derived from the uterine canal, whereas the lower two-thirds are derived from the urogenital sinus.[1]

Proximally, the vagina joins the uterine cervix at an angle, and, as a result, the posterior vaginal wall is longer than the anterior wall (Figure 79.1). The proximal posterior vaginal wall is separated from the rectum by the rectovaginal septum or fascia. The overlying peritoneal reflection forms the posterior cul de sac, also known as the pouch of Douglas. Invaginations between the vaginal mucosa and the cervix form the anterior, posterior, and lateral fornices. Laterally, the vagina is adjacent to the pelvic fascia and levator ani muscles. Inferiorly, the vagina extends through the urogenital diaphragm to lie dorsal to the urethra and ventral to the rectum. The fibromuscular perineal body separates the vagina from the anal canal. At the introitus, the vagina has a perforated fold of thin connective tissue and mucous membrane known as the hymen.

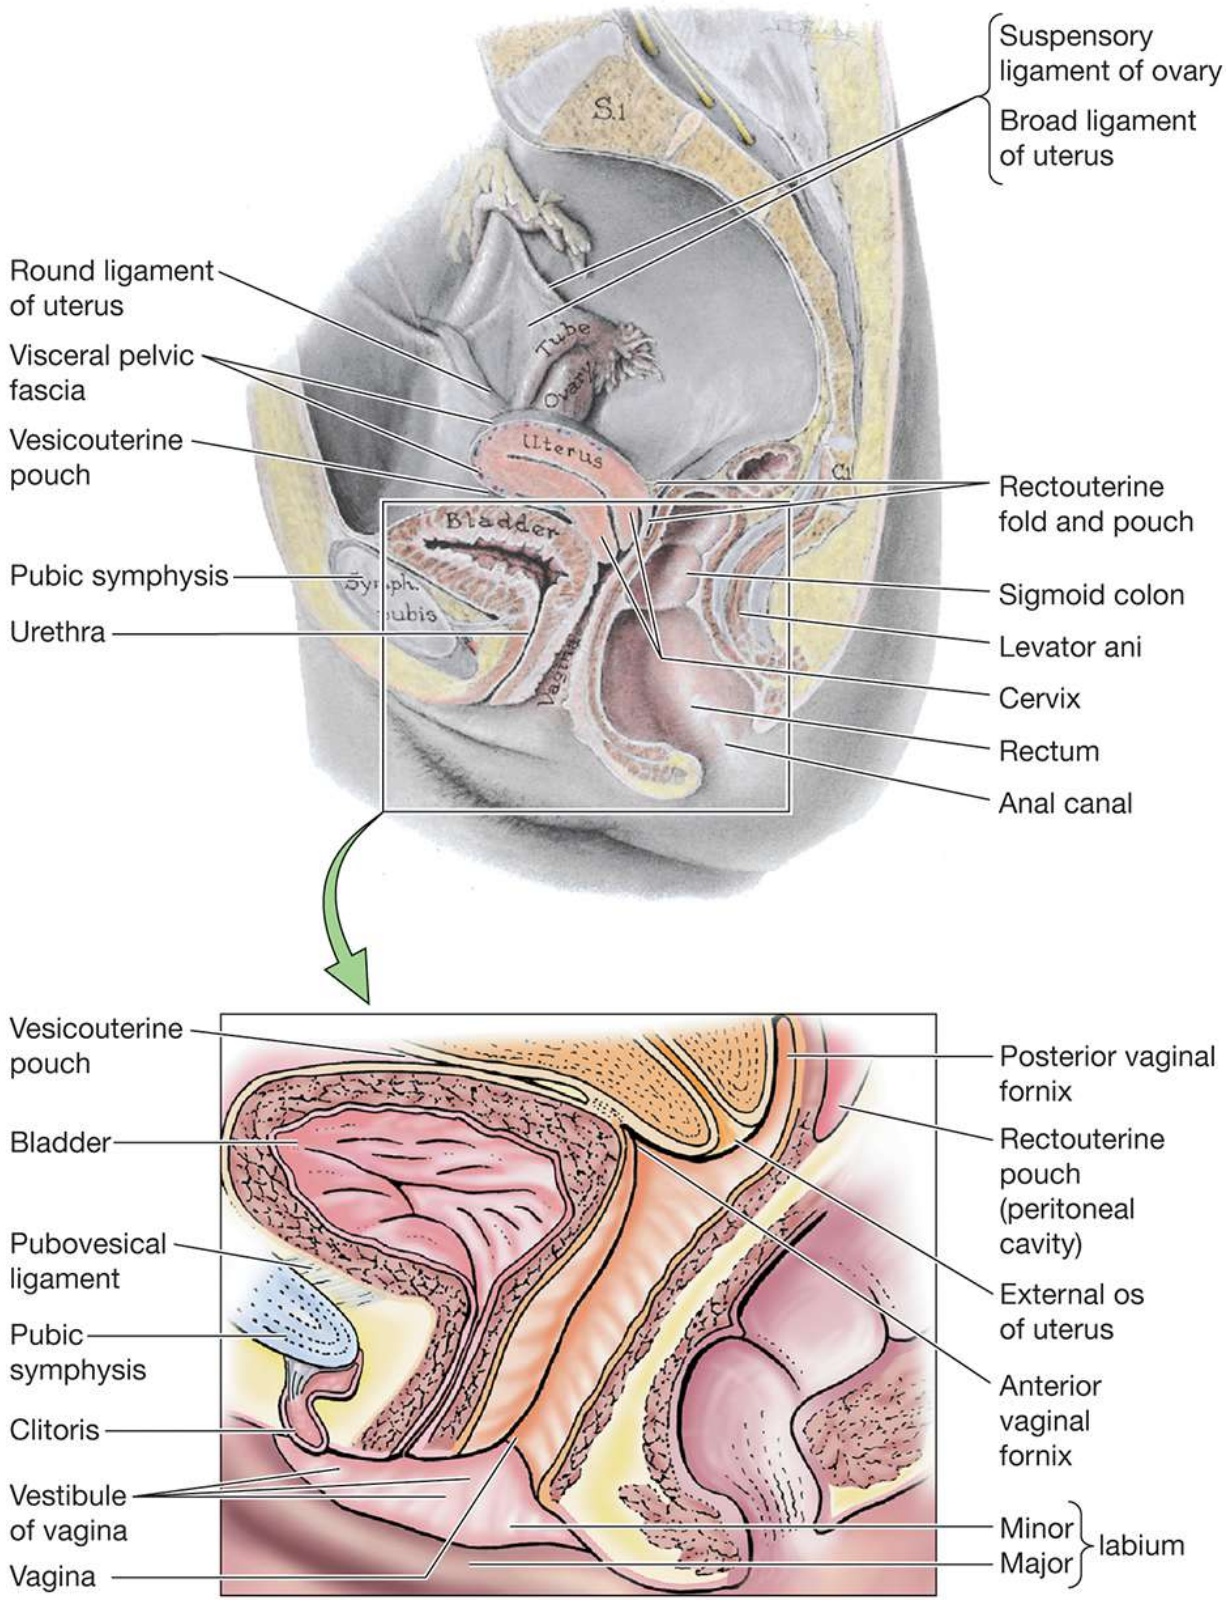

FIGURE 79.1 Anatomy of female pelvis.

The vaginal wall is composed of the mucosa, muscularis, and adventitia. The innermost lining of the vagina is formed by a nonkeratinizing, stratified squamous epithelium overlying a basement membrane. This epithelial mucosa lacks significant glandular structures and instead receives most lubrication from mucous secretions originating in the cervix. Underneath the mucosa is the connective tissue composed of elastin and a thick muscularis layer composed of two layers of smooth muscle. The inner layer is arranged circularly, whereas the outer layer is arranged longitudinally. This muscular layer is covered by the third layer, a thin adventitia that merges with neighboring organs.

The vagina has a complex, extensive network of lymphatic drainage, with vessels that course through the submucosal and muscularis layer (Figure 79.2). The proximal portion drains primarily via cervical lymphatics. The proximal anterior vagina drains along cervical channels to the internal iliac, and parametrial nodes and the proximal posterior vagina drains into the inferior gluteal, presacral, and anorectal nodes. The distal aspect of the vagina drains into the superficial inguinal nodes, and ultimately to the pelvic nodes, following drainage patterns of the vulva. Lesions in the midvagina have been shown to drain either way.[2] Lesions infiltrating the rectovaginal septum may spread to the pararectal and presacral nodes because there are multiple interconnections between the lymphatic channels, and the pattern of drainage cannot be reliably predicted based on the location of the primary tumor.

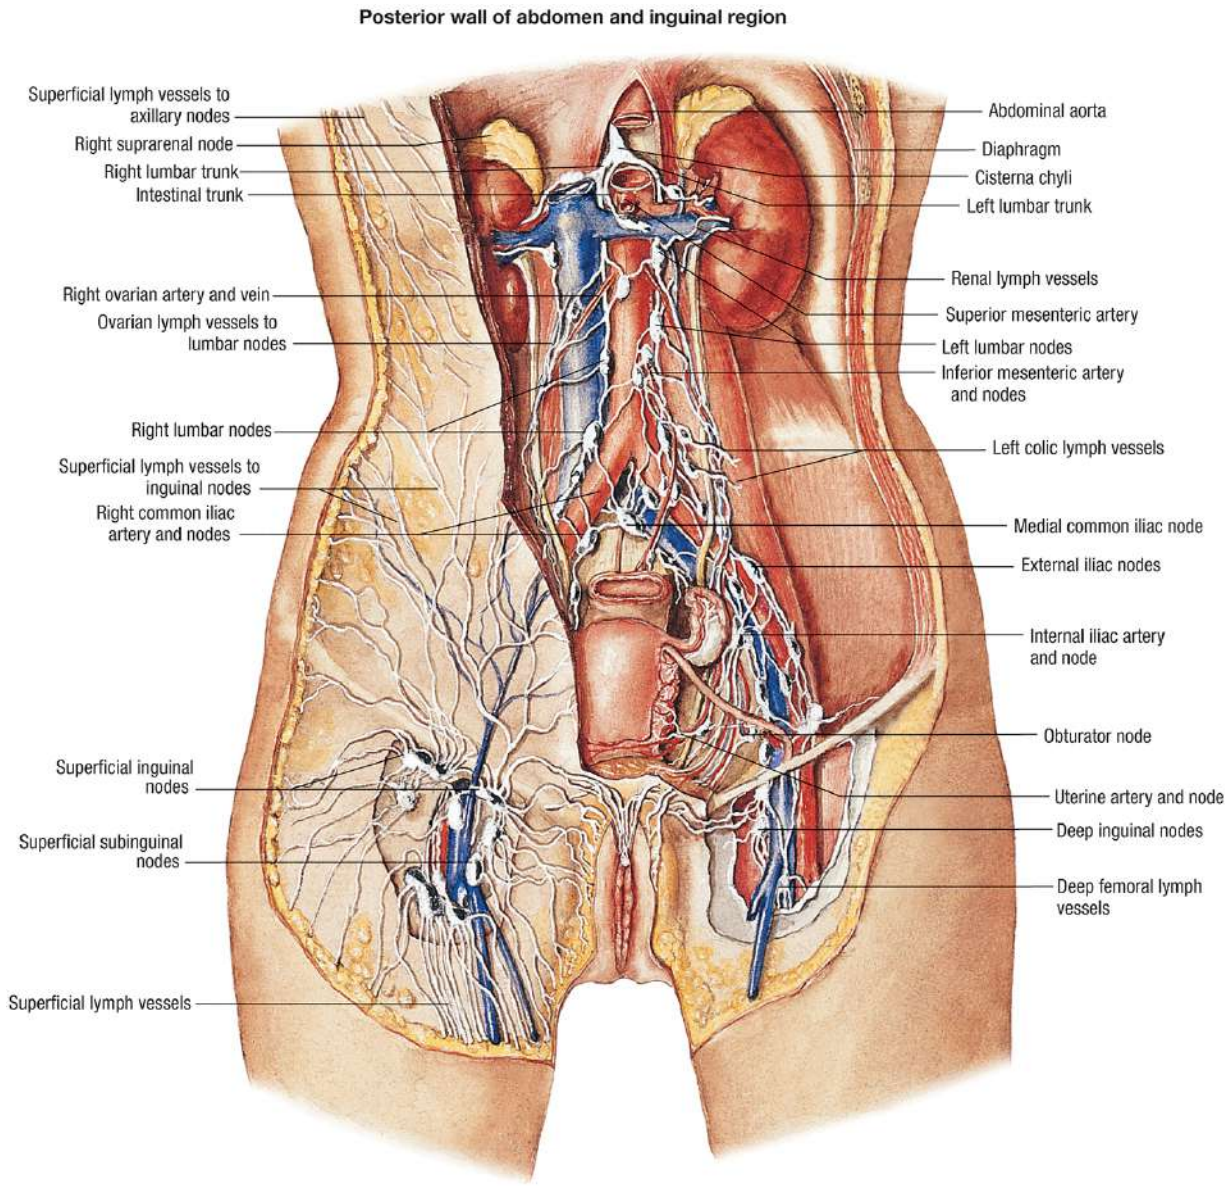

FIGURE 79.2 Lymphatic drainage of the vagina.

The vagina is supplied by the vaginal artery, which arises from the cervical branch of the uterine artery and runs lateral to the vagina until it anastomoses distally with the inferior vesical and middle rectal arteries. The venous plexus runs parallel to the arteries, draining into the internal iliac vein. The vaginal vault is innervated by the lumbar plexus and pudendal nerve, with branches from sacral roots 2 to 4.[3]

EPIDEMIOLOGY, PRESENTATION, AND MANAGEMENT

Primary vaginal cancer is a rare malignancy, constituting 1% to 2% of all gynecologic malignancies. There were approximately 8,470 new cases and 1,740 deaths from primary vaginal cancer in the United States in 2023.[4]

The majority of malignant lesions in the vagina are attributable to direct spread or metastases from other gynecologic malignancies. According to the staging system set by the International Federation of Obstetrics and Gynecology (FIGO), any tumor involving both the vagina and cervix should be classified as a cervical carcinoma. Similarly, any tumor involving both the vagina and vulva is to be classified as a vulvar carcinoma.[5] A malignant vaginal lesion in a patient with prior history of invasive cervical carcinoma within the past 5 years also excludes diagnosis as a primary vaginal cancer.[6] As a result, only a minority of vaginal carcinoma cases meet the criteria of being a primary vaginal cancer. Approximately 70% of vaginal cancers are human papillomavirus (HPV) positive.[7]

The peak incidence of primary vaginal cancer is in the sixth and seventh decades of life. According to data from the Surveillance, Epidemiology, and End Results (SEER) program,[8] 2,149 women in the United States were diagnosed with primary vaginal cancer from 1990 to 2004. The mean age at diagnosis was 65 ± 14 years, and incidence rates increased with age. There has been an overall decrease in the incidence of primary vaginal tumors, possibly secondary to earlier detection and implementation of strict exclusion criteria in the FIGO staging system.

According to the SEER study by Shah et al,[8] most women diagnosed with primary vaginal cancer are non-Hispanic Whites (66%), followed by African Americans (14%), Hispanic Whites (12%), Asian/Pacific Islanders (7%), and others (1%). Incidence rates were highest for African American women (1.24/100,000 person-years) and lowest for Asian/Pacific Islanders (0.64/100,000 person-years).

A review of five series, encompassing a total of 1,375 cases of vaginal cancer, reported a FIGO stage distribution as follows: 26% stage I, 37% stage II, 24% stage III, and 13% stage IV.[9] Consistent with this, the National Cancer Database (NCDB) review by Creasman et al, for the period of 1985 to 1994, revealed 3,244 cases of invasive primary vaginal carcinoma, with 24% of patients presenting with American Joint Committee on Cancer (AJCC) stage I disease, 20% AJCC stage II, 24% AJCC stages III to IV, and

32% unknown.[10] Most tumors were moderately (28%) or poorly (28%) differentiated at presentation.

Because of the low incidence, treatment recommendations are based on results from relatively small retrospective series comprised of heterogeneous patient populations and treatments, or extrapolated from treatment recommendations for cervical or vulvar cancer, and it remains unlikely that randomized clinical trials will be feasible.

Vaginal Intraepithelial Neoplasia

It is hypothesized that vaginal intraepithelial neoplasia (VAIN) is a precursor lesion to squamous cell carcinoma (SCC) of the vagina.[11] There has been a steady increase in the diagnosis of VAIN over the past several decades, perhaps because of a combination of increased cytologic screening, awareness, and incidence of HPV. VAIN is defined as atypia of squamous cells without evidence of stromal invasion and was first reported by Hummer and colleagues in 1933.[11]

VAIN is further classified into low grade (VAIN 1) and high grade (VAIN 2 and VAIN 3). VAIN 1 is characterized by cytomorphologic changes limited to the upper one-third of the epithelium. Such changes include nuclear enlargement, nuclear hyperchromasia, cytoplasmic halos, and occasional binucleation. VAIN 2 and VAIN 3 are characterized by cytomorphologic changes in the basal keratinocytes, including nuclear pleomorphism, nuclear hyperchromasia and crowding, and mitotic figures (including atypical forms). VAIN 2 and VAIN 3 are distinguished by the depth of cytologic change. Cytologic changes confined to the lower two-thirds of the epithelium are designated VAIN 2, whereas changes involving the full thickness of the epithelium are VAIN 3. Carcinoma in situ encompasses the full epithelial thickness and is included under VAIN 3.

The overall incidence of VAIN is estimated to be 0.2 to 0.3 cases per 100,000, with peak incidence found in women who are 40 and 60 years of age.[11] The incidence of VAIN 3, or in situ vaginal cancer, is estimated to be 0.1 per 100,000 women with peak incidence between ages 70 and 79 years, according to data from the U.S. Centers for Disease Control and Prevention's National Program of Cancer Registries and the National Cancer Institute's SEER Program.[12]

VAIN is typically asymptomatic.[13] As a result, many cases are detected after cytologic evaluation as part of surveillance in patients with a history of cervical intraepithelial neoplasia or invasive cervical carcinoma. Although the likelihood of VAIN progressing to invasive disease is difficult to predict for individual cases, multiple clinical series have demonstrated a significant overall increase in the risk of invasive vaginal cancer after a diagnosis of VAIN. Several retrospective studies have demonstrated a range of 2% to 20% of patients with VAIN progressing to invasive vaginal cancer.[13,14] The rate of occult invasive disease in patients with VAIN 3 has been reported to be as high as 28%.[15] The risk of malignant transformation in VAIN 1 and VAIN 2 is less clearly elucidated.

Risk Factors

HPV is implicated in the development of VAIN, though the relationship between HPV and the development of intraepithelial neoplasia has been best demonstrated for cervical lesions. HPV 16 and HPV 18 are the most prevalent subtypes associated with VAIN. It is estimated that HPV 16/18 is identified in 40% of VAIN 1 and 60% of high-grade VAIN 2/3 cases.[16] With the widespread implementation of HPV vaccination, it is anticipated that the incidence of VAIN will start to decline. It is predicted that HPV vaccination will ultimately prevent up to 70% of VAIN cases.[17]

The diagnosis of VAIN is often associated with prior or concurrent neoplasia elsewhere in the lower genital tract. Multiple series suggest approximately 50% to 90% of patients with VAIN have concurrent or prior history of intraepithelial neoplasia or carcinoma of the cervix or vulva.[14,18,19]

Treatment Options

In general, women with low-grade VAIN can be offered close surveillance, as lesions often regress spontaneously (Algorithm 79.1). In a study by Aho et al, 78% of patients with VAIN 1 or VAIN 2 had spontaneous regression of disease without treatment.[14] Over time, however, VAIN 1 can recur; in one series, up to 54% of patients with VAIN 1 who were observed ultimately developed recurrent, persistent, or progressive disease,[11] at a median time of 17 months. High-grade VAIN has a higher likelihood of occult invasive disease and progression to invasive disease[15,20] and is

typically treated aggressively. There is currently no consensus on optimal treatment modality for patients with high-grade VAIN. Treatment approaches include local excision, partial or total vaginectomy, laser vaporization, electrocoagulation, topical 5% fluorouracil administration, topical 5% imiquimod, and radiation.[19-27] Reported success rates for different approaches range from 48% to 100% for laser vaporization,[28,29] 52% to 100% for colpectomy,[15,20,30] 75% to 100% for topical 5-fluorouracil (5-FU),[21,31-35] 57% to 86% for topical 5% imiquimod,[27] and 83% to 100% for radiation[23,36-39] (Table 79.1). Given the breadth of available therapies, an individualized approach to patient management is advised, with consideration given to the patient's overall health, desire to preserve sexual function, candidacy for surgery, disease multifocality, and prior treatment failures.

ALGORITHM 79.1 Treatment schematic for vaginal cancer based on International Federation of Obstetrics and Gynecology classification.

Surgical and Ablative Therapies

Surgical excision for VAIN is an option in select cases, particularly for vaginal vault lesions or lesions close to the introitus. Approaches include wide local excision, partial vaginectomy, and, in rare cases, total vaginectomy for highly extensive disease, which provides the advantage of obtaining a complete pathologic diagnosis. Most resections can be performed through a transvaginal approach. Smaller lesions can be excised or ablated using a cold-knife approach, electrosurgical loop excision, laser, or via ultrasonic surgical aspiration.[50-52]

Location of VAIN in the vaginal vault or posthysterectomy suture recesses may require partial vaginectomy for complete resection, as redundancy of the vaginal mucosa makes it difficult to rule out occult disease with biopsy alone. Multifocal or extensive lesions may require a more extensive approach, such as total vaginectomy with or without skin grafting.[20]

Overall, a series looking specifically at upper vaginectomy report control rates of 68% to 88%.[15,20,30,53] Potential complications depend on the location of the lesion and the extent and method of surgical resection and range from vaginal shortening and stenosis to standard postoperative morbidity associated with abdominal procedures, such as injury to bowel or bladder. Complication rates of upper vaginectomy have been variably reported; in the series by Indermaur, there was a 9% complication rate. It should be noted that patients with a history of radiation treatment are at higher risk of postoperative complications, with a higher rate of fistula formation reported in one study.[18]

Topical Treatments

Topical treatments include topical 5-FU and 5% imiquimod cream, with response rates of 41% to 88% for 5-FU and 50% to 86% for imiquimod.[23,31-33,35,54-56] Imiquimod increases the levels of interferon-α (IFN-α), interleukin-12, and tumor necrosis factor[55] and is thought to result in immunomodulation of the vaginal mucosa. Long-term efficacy is unknown as well as response rates in immunocompromised patients.

Topical therapies have been utilized in patients with early-stage lesions, multifocal disease, or multiple comorbidities, rendering them nonideal

surgical candidates. Topical creams are favored in the management of young, HPV-positive women presenting with multifocal lesions. Topical applications have also been utilized prior to surgery to reduce lesion size and improve the stripping of neoplastic epithelial cells from the underlying stroma.[19] Side effects of topical treatments include local irritation, burning, and ulceration.[32,33]

Radiation Therapy

In general, radiation is reserved for patients who relapse after more conservative treatments, are poor surgical candidates, have extensive multifocal disease, and/or have VAIN 3, particularly if there is an in situ disease component. Numerous small series over the past 20 to 30 years have reported control rates ranging from 80% to 100%.[13,23-25,36-38,57] Drawbacks to radiation include potential undertreatment of occult invasive disease, the risk of secondary malignancy, and long-term morbidity, although there are no prospective data available regarding the impact of treatment on sexual function and quality of life. High-dose rate (HDR), medium-dose rate (MDR), and low-dose rate (LDR) techniques have been reported with acceptable results, although it is difficult to compare regimens because of small patient numbers, generally short follow-up times, and overall nonuniformity among series.

Overall, excellent local control and low toxicity have been reported for LDR brachytherapy (BT). LDR treatment is delivered with an intracavitary vaginal cylinder using cesium-137. Typically, a dose of 60 Gy is prescribed to the vaginal mucosa, but a wide range of doses, depending on the depth of dose prescription, as well as a variety of techniques, have been reported.[23,36,37,58] Chyle et al[59] prescribed 70 to 80 Gy to the vaginal surface and reported a 17% recurrence rate at 10 years in their series of 37 patients. Perez et al[58] treated patients to the vaginal surface with a dose of 60 to 70 Gy and reported one recurrence out of 20 patients. The recurrence occurred in the distal vagina and was noted to be a marginal recurrence. Blanchard et al[36] published a series on 28 patients with VAIN 3 treated at Institut Gustave Roussy from 1985 to 2008. Patients were treated with LDR BT, using a vaginal mold technique, to a dose of 60 Gy prescribed 5 mm below the vaginal surface; 18 patients received treatment to the upper half of the

vagina, 6 were treated to the upper two-thirds, and 4 were treated to the whole-vaginal length. With a median follow-up time of 41 months, the authors report only one in-field recurrence, with a 10-year local control rate of 93%. Treatment with LDR BT is overall well tolerated; in the Perez series, there was only one grade 3 urinary complication among 40 patients with VAIN 3 or stage 1 vaginal cancer treated with LDR.[58]

There are limited data on the use of MDR BT treatment for VAIN. Graham et al[25] reviewed their experience using MDR intracavitary brachytherapy (ICB) for VAIN 3 at the Beatson Oncology Centre in Glasgow, UK. Using an MDR Selectron, 48 Gy was prescribed 0.5 cm lateral to the ovoid surface (point Z) over two insertions, spaced 1 week apart. Ovoids were chosen over vaginal cylinder placement in order to adequately cover epithelium sutured into the superolateral vagina at hysterectomy. With a median follow-up duration of 77 months, recurrent/residual VAIN 3 was documented in three patients, and two of these patients subsequently developed invasive or microinvasive vaginal carcinoma. One other patient developed late progression 14 years after treatment.

Several series have reported promising results for HDR BT, with disease-free survival (DFS) rates of 90% or greater. Ogino et al[38] reported their experience treating six patients with VAIN 3 at Kanagawa Cancer Center from 1983 to 1993, with a mean dose of 23.3 Gy (range, 15-30 Gy); most treatments were delivered in five fractions using two ovoids, with dose calculated to a point 1 cm superior to the vaginal apex. Lesions distal to the vaginal vault had doses calculated 1 cm beyond the plane of the vaginal cylinder in order to deliver adequate dose to the entire vagina. The median follow-up was 90.5 months, with no evidence of disease recurrence in the treated patients. MacLeod et al[39] reviewed their experience treating 14 patients with VAIN 3 from 1985 to 1995. Total dose was 34 to 45 Gy to the vaginal surface, in 8.5-Gy fractions delivered twice a week, or 4.5-Gy fractions delivered 4 times a week. One patient developed invasive cancer, and one patient had persistent VAIN 3. There were no major acute toxicities, and two patients developed late grade 3 vaginal atrophy and stenosis. According to one study that evaluated toxicity after the use of HDR BT for VAIN in 20 patients, with utilization of the CTCAE scale, a biologically equivalent dose of 70 Gy or greater results in significantly

greater toxicity. The most commonly seen toxicities were decreased libido, vaginal discharge, dryness, mucositis, stenosis, and vaginitis.[60]

Squamous Cell Carcinoma

Clinical Presentation

Symptoms

Up to 20% of women are asymptomatic at the time of diagnosis,[61] with lesions detected via cytologic screening or by speculum examination. SCC accounts for 65% to 85% of vaginal cancer cases,[8] and the greatest proportion of women present with stage I disease (36%). Up to 65% of patients with vaginal cancer present with irregular vaginal bleeding as their primary symptom.[61,62] Vaginal discharge is the second most common symptom, occurring in 10% to 15% of patients. Less frequent symptoms, associated with locally advanced disease, include the presence of a mass; pain; urinary symptoms including frequency, dysuria, or hematuria; or gastrointestinal complaints, such as tenesmus, constipation, or melena. Because of the proximity of anterior wall lesions to the urethra and bladder, urinary symptoms can be seen more commonly in vaginal cancer than in cervical cancer.

Location

Vaginal cancer most frequently involves the superior one-third of the vaginal canal, with series reporting 50% to 83% of cases occurring in this region.[53,63-66] There is approximately equal involvement of the middle and inferior thirds,[53] although some studies suggest that involvement of the lower third is more common than involvement of the middle third.[61,63] The lateral walls are less frequently involved. Tumors may exhibit an exophytic or ulcerative, infiltrating growth pattern.

A high proportion of patients have a history of prior hysterectomy. Involvement of the cervix (if present) or vulva at the time of diagnosis excludes classification as a primary vaginal cancer. Lesions can extend radially, either into the lumen to form exophytic masses or through the vaginal wall to invade surrounding musculature and organs. Anterior wall lesions can infiltrate the vesicovaginal septum, urethra, and/or bladder. Posterior wall lesions can infiltrate the rectovaginal septum and involve the

rectal mucosa. Advanced disease can extend laterally toward the parametrium and paracolpal tissues or into the urogenital diaphragm, levator ani muscles, or pelvic fascia and eventually to the pelvic side wall.

Advanced or recurrent disease can present with distant metastases. The most frequent site of hematogenous metastasis is the lung, with less commonly noted sites being liver and bone.[59] In a series by Perez et al,[67] the incidence of distant metastasis was 16% for stage I, 31% for stage II, 46% for stage IIB, 62% for stage III, and 50% for stage IV. Some histologies may have a higher likelihood of distant metastases than others. Chyle et al[59] noted a higher incidence of distant metastases in patients with adenocarcinoma (48%) than in those with SCC (10%), with correspondingly lower 10-year survival rates (20% vs 50%).

Histopathology

Grossly, SCC of the vagina can present as nodular, ulcerated, indurated, exophytic, or endophytic lesions. Histologically, tumors are graded as well, moderate, or poorly differentiated and have been described as keratinizing, nonkeratinizing, basaloid, warty, or verrucous. The majority of these lesions are nonkeratinizing and moderately differentiated.[68] It is not possible to histologically distinguish a primary vaginal SCC from recurrent cervical or vulvar carcinoma.

Verrucous carcinoma is a distinct histologic variant of vaginal SCC[69] that typically presents as a well-circumscribed, soft, cauliflower-like mass that is microscopically well differentiated, with a papillary growth pattern and acanthotic epithelium. There is surface maturation with parakeratosis or hyperkeratosis without koilocytosis. This variant of SCC exhibits less aggressive behavior and rarely metastasizes.[69] Given the extremely low incidence of these cancers, it has been difficult to evaluate therapeutic efficacy; while case reports from other sites question the utility of radiation, there is no clear evidence of resistance of transformation to a more aggressive histology in the more modern literature.

Sarcomatoid SCC is a rare subset of vaginal SCC, comprising 2% of all cases. It is characterized by spindle-shaped neoplastic cells that can initially be mistaken for sarcoma. However, positive stains for cytokeratin help

distinguish sarcomatoid SCC as a poorly differentiated variant of vaginal SCC.[70]

Patterns of Lymphatic Drainage

The vagina has a complex pattern of lymphatic drainage, with multiple interconnections. The upper vagina drains to the obturator and hypogastric nodes, similar to the cervix. The lower vagina drains to the inguinal, femoral, and external iliac nodes, and posteriorly situated lesions can drain to the inferior gluteal, presacral, or perirectal nodes. Lymphatic channels in the mucosa run parallel to networks of channels in the submucosa and muscular layer, ultimately converging to form trunks at the vaginal wall periphery, which subsequently drain into major pelvic nodal groups.

Because of considerable crossover drainage, the location of the primary tumor is not a reliable indicator of drainage site. Frumovitz et al utilized lymphoscintigraphy to determine patterns of lymphatic drainage in 14 women diagnosed with primary vaginal cancers[71] and found a substantial degree of anomalous drainage, resulting in a change in radiation treatment for 33% of patients. For example, among four women with lesions located in the upper third of the vagina, which is predicted to drain along the cervical lymphatic chains to the pelvis, two (50%) were found to have a sentinel node in the inguinal region. Among five women with lesions located at the vaginal introitus, a location predicted to drain along the vulvar lymphatic chains to the inguinal triangle, three (60%) were found to have a sentinel node in the pelvis.

The risk of nodal involvement increases significantly with stage. At diagnosis, up to 20% of patients have clinically positive inguinal nodes, with reported ranges of 5.3% to 20%.[58,67] Sparse data on nodal metastases are derived from a series in which exploratory laparotomies and lymphadenectomies were performed.[72] However, the true incidence of positive lymph nodes is difficult to determine because most patients receive treatment with radiation therapy (RT) and do not undergo surgical lymphadenectomy. The incidence of lymph node involvement has been reported to be 0% to 14% in stage I and 21% to 32% in stage II disease.[72-74] The incidence of nodal involvement in stages III and IV has been reported to be as high as 78% and 83%, respectively.[63]

The risk of nodal failure increases significantly if there is local recurrence. Chyle et al[59] reported 10-year inguinal and pelvic failure rates of 16% and 28%, respectively, in patients with local recurrence, in contrast to 2% and 4%, respectively, in patients without local recurrence.

Staging

The AJCC[75] and FIGO[5] systems are used to stage vaginal cancer (Tables 79.2 and 79.3). Neither system incorporates computed tomography (CT), positron emission tomography (PET), or magnetic resonance imaging (MRI) findings, though these are recommended where available to provide enhanced information about sites of disease spread. Primary vaginal melanomas and lymphomas are staged according to the AJCC staging systems for melanomas and lymphomas, respectively.[75]

TABLE 79.2 INTERNATIONAL FEDERATION OF GYNECOLOGY AND OBSTETRICS STAGING SYSTEM FOR CARCINOMA OF THE VAGINA

Stage	Description
Stage I	Carcinoma is limited to vaginal wall.
Stage II	Carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	Carcinoma has extended to the pelvic wall.[a]
Stage IV	Carcinoma has extended beyond the true pelvic or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV.
Stage IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis.

[a]Pelvic wall is defined as muscle, fascia, neurovascular structures, or skeletal portions of the bony pelvis.

TABLE 79.3 AMERICAN JOINT COMMISSION ON CANCER STAGING OF VAGINAL CANCER, SEVENTH EDITION

Primary Tumor (T)

Tx	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis/0	Carcinoma in situ
T1/I	Tumor confined to the vagina.
T2/II	Tumor invades paravaginal tissues but not to the pelvic wall.
T3/III	Tumor extends to the pelvic wall.[a]
T4/IVA	Tumor invades the mucosa of the bladder or rectum and/or extends beyond the pelvis (bullous edema is not sufficient to classify a tumor as T4).
Regional Lymph Nodes (N)	
Nx	Regional lymph nodes cannot be assessed.
N0	No regional lymph nodes
N1/IVB	Pelvic or inguinal lymph node metastasis
Distant Metastasis (M)	
Mx	Distant metastasis cannot be assessed.

[a]Pelvic wall is defined as muscle, fascia, neurovascular structures, or skeletal portions of the bony pelvis.

From Brierley JD, Gospodarowicz MK, Wittekind C, eds. *TNM Classification of Malignant Tumours*. 8th ed. Wiley-Blackwell; 2017:165-166; Copyright © 2017 UICC. Reprinted by permission of John Wiley & Sons.

For patients with a prior gynecologic malignancy, a 5-year period free of disease is generally considered adequate to allow for distinction between

recurrent disease and a new primary vaginal cancer. FIGO no longer recognizes carcinoma in situ as stage 0.

Stage I disease is defined as limited to the vaginal wall, and stage II disease involves subvaginal tissue without extension to the pelvic wall. Discriminating between stages I and II can be subjective; thin tumors less than 0.5 cm are generally classified as stage I, with thicker infiltrating tumors or those with paravaginal nodularity classified as stage II. Perez et al proposed a modification to the FIGO system in 1973, distinguishing tumors with paravaginal submucosal extension only (stage IIA) from tumors with parametrial infiltration (stage IIB).[58] The study reported a 20% 5-year survival difference (55% vs 35%) between stages IIA and IIB. This modification has not been adopted into FIGO staging. However, some investigators consider the distinction to be prognostically relevant.[67,76] Stage III disease extends to the pelvic sidewall, has caused hydronephrosis, extends to the lower third of the vagina, or involves lymph nodes. Stage IVA disease reflects spread to the bladder or bowel, while stage IVB disease indicates spread to distant sites.

Diagnostic Workup

The diagnostic workup should start with a thorough history and physical examination. During speculum examination, the speculum blades can obscure the anterior and posterior walls, so it is essential to rotate the speculum for visualization of all four walls from the introitus to the apex. Bimanual and rectovaginal examinations, with careful digital palpation, should be performed, assessing for parametrial and pelvic sidewall involvement and invasion of tumor to the rectal mucosa. Complete assessment of tumor extent and assessment of vaginal walls are facilitated by examination under anesthesia.

Inguinal nodes should be palpated for disease involvement, particularly if the primary lesion is situated in the lower portion of the vagina, as 5% to 20% of patients have been reported to have involved inguinal nodes at presentation.[58,67] Suspicious nodes usually warrant a biopsy. Laboratory tests include a complete blood count with differential and assessment of renal and hepatic function.

A definitive diagnosis is achieved with biopsy of suspected lesions, which can present as an exophytic mass, plaque, or ulcer. If a lesion is not visible in the setting of abnormal cytology, colposcopy with acetic acid, followed by Lugol iodine stain, can be conducted, along with biopsies of any white epithelium or atypical vascularity. Iodine will identify Schiller-positive regions, which are nonstaining and should correspond with areas identified following application of acetic acid. Adequate biopsies should include the cervix, if present, to rule out a cervical primary. Patients can present with multiple regions of abnormality.

FIGO staging of vaginal cancer is clinical and allows chest x-ray, intravenous pyelography (IVP), barium enema, cystoscopy, and proctosigmoidoscopy. FIGO encourages the utilization of more advanced imaging modalities, such as CT imaging, MRI, and PET, as guidance for treatment, though imaging findings cannot be used to reassign stage.[77] Cystoscopy or proctosigmoidoscopy may be necessary in patients with symptoms suggestive of bladder or rectal infiltration. CT of the pelvis can be obtained in place of IVP to assess the renal parenchyma and also to obtain information on the extent of local disease and lymph node status. MRI can provide salient treatment planning information by characterizing the extent of invasion and differentiating malignant tumor, which is isointense to muscle on T1, and hyperintense on T2, from normal structures and/or fibrosis.[78] Advantages of MRI over other imaging modalities include superior soft tissue contrast resolution, allowing accurate assessment of tumor volume and extent of local invasion and accurate assessment of pelvic nodal involvement. In general, MRI is regarded as superior to CT for staging of gynecologic malignancies and should be obtained when available.

PET has shown efficacy in detecting the extent of primary tumor and abnormal lymph nodes in vaginal cancer with higher sensitivity than CT (Figure 79.3), as is the case with cervical carcinoma.[79,80] Primary vaginal carcinoma and metastatic lesions demonstrate avid uptake of 2-[fluorine 18] fluoro-2-deoxy-D-glucose (FDG). In one study, 23 patients with primary vaginal carcinoma received both PET and CT during staging. CT identified the primary tumor in only 43% of patients, whereas PET identified the tumor in 100%. PET identified suspicious uptake in groin and pelvic nodes

in 8 of 23 patients, compared to 4 of 23 with CT. Treatment planning was modified in 14% of patients because of findings from PET, and the authors concluded that PET detects primary tumor and abnormal lymph nodes more often than CT.[79] Another series compared detection of suspicious lymph nodes using PET/CT versus MRI and CT; PET/CT outperformed both MRI and CT, resulting in a change in management in 36% of cases.[80] It is important that the patient have an empty bladder prior to imaging, as physiologic FDG activity in a filled bladder can potentially interfere with accurate estimation of vaginal involvement. In practice, most patients undergo planning for radiation treatment with multiple imaging modalities.[81]

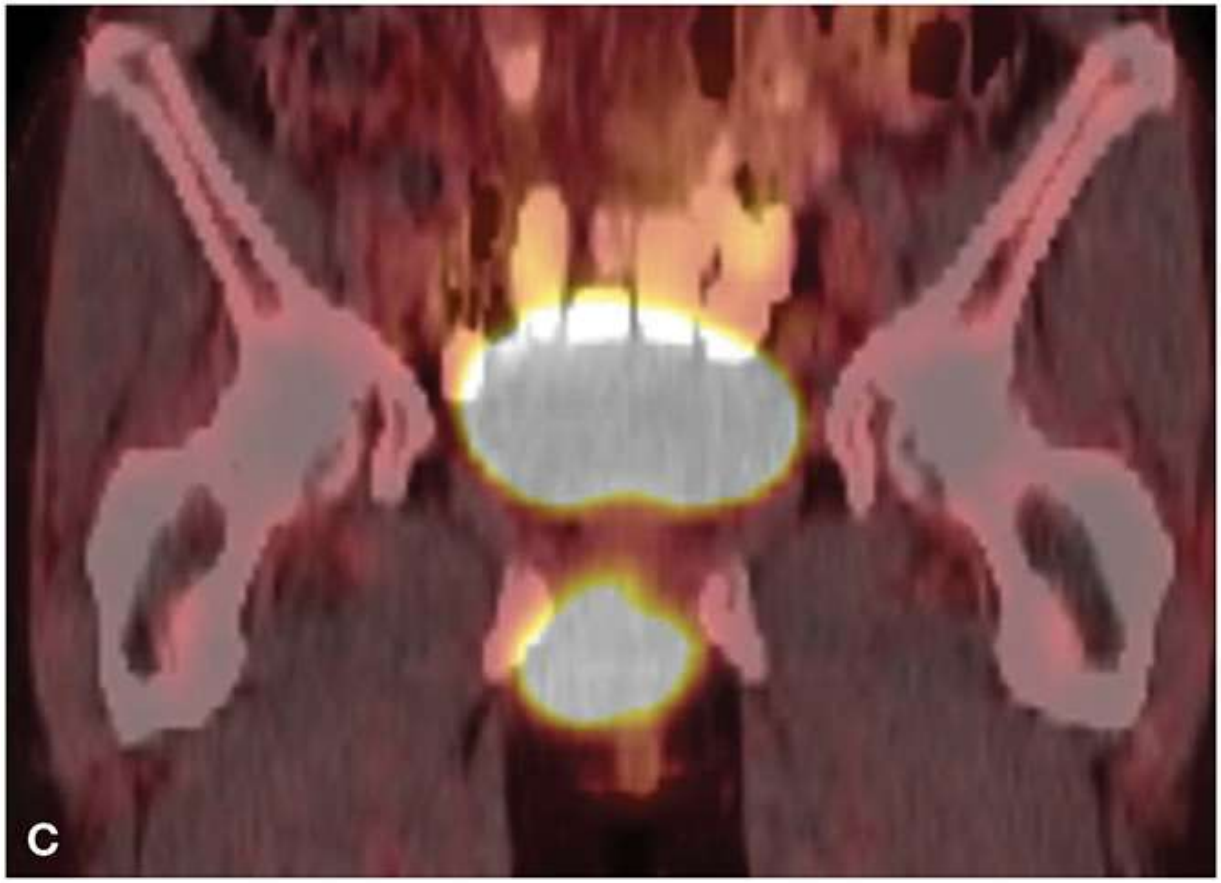

FIGURE 79.3 A. T2-weighted axial magnetic resonance imaging (MRI) of the pelvis showing a low pelvic mass arising in the vagina and spreading to the urethra and abutting the vulva. MRI is able to delineate individual anatomic structure and can assist in tumor segmentation for treatment planning. B. Fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) axial image showing hypermetabolic activity to identify the region but with less precision than MRI. C. Coronal FDG-PET showing a distinct region separating the vagina from the bladder.

The European Society for Radiotherapy and Oncology (ESTRO), European Society of Gynaecological Oncology (ESGO), and European Society for Paediatric Oncology (SIOPe) have developed joint evidence-based guidelines that include the workup of vaginal cancers, which concur with these recommendations.[81]

Risk Factors

Risk factors for primary vaginal SCC are similar to VAIN and cervical neoplasia. Commonly cited factors include HPV infection and/or history of

cervical or vulvar intraepithelial neoplasia, immunosuppression, multiple sexual partners, smoking, and early age at first intercourse.

It is believed that majority of cases of vaginal cancer can be attributed to HPV infection. According to a meta-analysis composed of 14 studies, the overall HPV prevalence was 70% for vaginal carcinomas, with the most common subtypes as follows: HPV 16 (53.7%), HPV 18 (7.6%), and HPV 31 (5.6%). Multiple subtypes of HPV were identified in 3.4% of vaginal carcinoma cases.[82] In a population-based case-control study of 156 women with VAIN or invasive cancer, HPV DNA was detectable in 80% of patients with in situ disease and 60% of those with invasive disease, and 30% of patients reported a history of treatment for invasive malignancy, most commonly cervix, or in situ anogenital neoplasia.[83]

Patients with a history of cervical cancer have a significantly higher risk of developing in situ as well as invasive carcinoma of the vagina. Studies suggest that 10% to 50% of patients with a history of VAIN or invasive carcinoma of the vagina have undergone treatment for in situ or invasive cervical carcinoma,[13,59,61,67,84-88] with the interval from the treatment of cervical disease to the development of vaginal carcinoma averaging approximately 14 years.[61,72] Early hysterectomy appears to be a risk factor in some studies, if performed for malignant or premalignant disease.[83,89]

The role of ionizing radiation to the pelvis in the development of vaginal carcinoma is unclear, with conflicting reports. According to one study that analyzed 1,200 patients treated over a 20-year period for carcinoma of the cervix, prior RT was not shown to result in increased secondary pelvic neoplasms.[90] A second study by Boice et al,[91] however, reported a 14-fold increased risk of vaginal cancer in women with a history of pelvic irradiation before the age of 45, with a significant dose-response relationship.

Another potential risk factor is chronic irritation of the vaginal mucosa, resulting in chronic inflammation, hyperkeratosis, thickening, and acanthosis,[92] with subsequent metaplastic and dysplastic changes; however, this is not proven. Although older studies showed that more vaginal cancers arise from the posterior vaginal wall, other studies report approximately equal distribution of invasive carcinomas on the anterior and posterior walls,[53,61,63,64,93] arguing against the theory that pooling of irritating substances in the posterior fornix contributes to the development of vaginal

cancers, particularly on the posterior wall. Chronic irritation from the use of vaginal pessaries has also been implicated as a contributor in vaginal cancer development.[94]

Other, lesser reported risk factors include low socioeconomic status, history of genital warts, and vaginal trauma.[95] A larger case-control study of 36,856 women found an increased risk of vaginal cancer in alcoholic women, likely associated with a higher incidence of lifestyle factors, such as promiscuity and smoking, which are also associated with a higher incidence of HPV infection. HIV-infected and other immunocompromised women are at higher risk of developing vaginal carcinoma, which tends to behave more aggressively than in the immunocompetent patients.[92]

Prognostic Factors

Stage at the time of presentation is the most significant prognostic factor.[8,58,86,96] According to an NCDB study by Creasman et al, 5-year survival rates are as follows: 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stage III/IV disease.[10]

The series by Shah et al,[8] based on SEER data for women diagnosed between 1990 and 2004, also reveals the correlation between stage and outcome, with 5-year disease-specific survival rates of 84% for stage I, 75% for stage II, and 57% for stage III/IV; the adjusted hazard ratio (HR) for mortality, on multivariate analysis, was 4.67. In the Perez et al series,[67] 165 patients with primary vaginal cancer were treated with definitive RT and had 10-year actuarial DFS rates of 94% for stage 0, 75% for stage I, 55% for stage IIA, 43% for stage IIB, 32% for stage III, and 0% for stage IV.[97]

The size of the initial lesion is a prognostic factor that has shown significance in several series. The SEER database study,[8] which included 2,149 women with primary vaginal cancer, noted a significantly lower 5-year survival rate in women with tumors 4 cm or larger than in women with tumors smaller than 4 cm (65% vs 84%); however, size information was missing for 52% of women. After multivariate analysis, the women with the larger tumors had an adjusted HR of 1.71 for mortality. Chyle et al,[59] in their review of 301 patients treated at MD Anderson Cancer Center (MDACC) from 1953 to 1991, found that women with lesions larger than 5 cm in maximum diameter had a significantly higher 10-year local

recurrence rate than those with smaller lesions (40% vs 20%). The series by Hellman et al,[96] with 314 patients treated at the Karolinska University Hospital from 1956 to 1996, found only three factors to independently predict for poor survival on multivariate analysis: advanced age, tumor size 4 cm or larger, and advanced stage. Tumors comprising two-thirds or more of the vagina and tumors growing circumferentially were associated with an extremely poor prognosis. The series by Tran et al,[98] which reviewed records of 78 patients with SCC treated at Stanford University Medical Center from 1959 to 2005, also found size to be a prognostic factor for DFS on multivariate analysis, along with stage, prior hysterectomy, and pretreatment hemoglobin level. Smaller series by Tjalma et al[99] and Kirkbride et al[86] also describe adverse outcomes with larger tumor size. Other series have failed to show significance, but likely are hindered by small numbers, difficulties in accurate assessment of size, and treatment heterogeneity.

Extent of vaginal canal involvement has also been examined and found to be significant, perhaps because it is a surrogate for tumor size. In a series by Stock et al,[64] which examined 100 cases of primary vaginal carcinoma treated at Magee-Women's Hospital from 1962 to 1992, patients with involvement of one-third of the vaginal canal or less had a significantly higher 5-year DFS rate (61%) than patients with more extensive involvement (25%).

Several studies suggest HPV status is an indicator of a favorable prognosis. Fuste et al found a trend toward longer survival in women with HPV-positive tumors in their series of 32 patients, with median survival times of 113.9 versus 19.7 months for women with HPV-positive and HPV-negative tumors ($P = .15$).[100] Alonso et al evaluated 57 total patients, of whom 70.2% had evidence of high-risk HPV.[101] On multivariate analysis, HPV-positive status was a favorable prognostic variable for overall survival (OS) (HR 0.35, $P = .038$). Brunner et al,[102] evaluated 35 patients with primary invasive SCC of the vagina. Using in situ hybridization, HPV was detected in 51.4% of cases. There was no significant influence on clinical stage, grade, or tumor size, nor did prognosis differ between HPV-positive and HPV-negative tumors. However, in a subset of patients with FIGO stage III or higher disease, HPV positivity was found to correlate with improved DFS and OS, with *P* values of .004 and .023, respectively.

There is conflicting evidence on the impact of lesion location on prognosis; it has been noted in some,[59,65,103] but not all,[66,67] reports. In an analysis of 110 patients by Kucera et al,[104] 5-year survival rates were 60% for lesions of the upper third of the vagina, 37.5% for lesions of the middle third, and 37% for the lower third. Chyle et al[59] noted a 17% rate of pelvic relapse in patients with tumors in the upper third of the vagina, 36% for patients with tumors in the middle or lower third, and 42% for patients with whole-vaginal involvement. Lesions in the posterior wall were also noted to be associated with a worse prognosis than lesions involving the anterior vaginal wall,[59] with 10-year recurrence rates of 32% versus 19% on univariate analysis ($P < .007$). The Hellman series,[96] however, found no difference in prognosis between the anterior and posterior tumors. Similarly, histologic grade has been found to be an independent significant predictor of survival in several series,[65,86,103] but not others.[96] Hellman et al[96] evaluated the impact of tumor grade and other histopathologic variables (mitotic activity, koilocytosis, growth in vessels, lymphocytic reactions) and found no correlation with survival.

Several series suggest there is a correlation between older age and decreased survival.[11,96,103] For example, age was also noted to be a significant prognostic factor in the Urbanski et al series,[103] with 5-year survival rates of 83% for patients younger than 60 years compared to 25% for those aged 60 years or above ($P < .0001$). Age greater than 60 years was negatively associated with survival in the series by Gunderson et al, which examined a total of 110 patients (HR 2.16; $P = .0339$). Other series have failed to demonstrate the statistical significance of age.[58,105]

For patients treated with radiation, treatment time may be a significant factor impacting tumor control.[106,107] Overall treatment time of 9 weeks or less was associated with a pelvic tumor control rate of 97% as compared to 57% for treatment time greater than 9 weeks ($P < .01$).[121] Pingley et al also noted a correlation between treatment time and outcome; patients receiving BT within 4 weeks of external beam radiation therapy (EBRT) had a 5-year DFS rate of 60%, compared to a 30% rate in patients who had an interval greater than 4 weeks.[106]

Other possible prognostic factors include hemoglobin levels, prior hysterectomy, and smoking status. A hemoglobin level less than 12.5 g/dL prior to definitive treatment was prognostic for worse pelvic control and

disease-specific survival on multivariate analysis, along with prior hysterectomy, stage, and tumor size. Prior hysterectomy was a favorable prognostic factor on multivariate analysis.[98] This may reflect more rigorous surveillance in posthysterectomy patients, resulting in tumors discovered at an earlier stage, or may be a reflection of less overall vaginal tissue as a substrate for tumorigenesis. Two subsequent studies have identified hysterectomy as a significant prognostic factor, but only in univariate analysis.[59,96]

Treatment Options

Surgery

For most patients with invasive vaginal cancer, surgery has a limited role and radiation is the treatment of choice (see Algorithm 79.1). Because of the rarity of these lesions and the required individualization of treatment, it is recommended that patients are referred to a tertiary center with experienced practitioners. In general, surgery is considered beneficial only in carefully selected patients. Typically, amenable lesions are small, superficially invasive and well demarcated, and localized to the upper vagina. For patients who have previously undergone hysterectomy, a radical upper vaginectomy and pelvic lymphadenectomy can be considered. If the uterus is present, a radical hysterectomy (which include upper vaginectomy and radical parametrectomy) with lymph node assessment could be considered, particularly for patients with a lesion in the posterior proximal vagina.[6] Regardless of surgical procedure, wide negative margins are necessary.

Older surgical series often required pelvic exenteration in 40% to 50% of cases to obtain negative margins.[63,72] Invasive anterior wall lesions may require anterior exenteration, which removes the vagina, urethra, and bladder. Posterior exenteration for posterior vaginal wall lesions requires resection of the vagina and rectum. Deeply invasive, circumferential lesions may require a total exenteration in order to achieve clear margins. If there are positive margins, adjuvant radiation should be offered. Lesions that extend to the inferior vagina require a total vaginectomy with radical hysterectomy, pelvic lymphadenectomy, and, possibly, vulvovaginectomy and inguinofemoral lymphadenectomy.[61,63,64,85] It is not uncommon for

relatively small lesions to invade the rectum or urethra early in the disease course, given the close proximity of the vagina to these structures. Many of these exenterative surgeries also require plastic surgery reconstruction.

Extrapolating from the more robust evidence for cervical cancer, combining both surgery and radiation would likely increase toxicities. Given the similar survival outcomes with surgery alone and radiation alone for vaginal cancers, as well as the potentially devastating functional results associated with radical surgery, definitive radiation is the treatment of choice for most patients with invasive vaginal cancer and has largely replaced surgery as the primary therapeutic modality.

Exenterative surgical procedures can be considered for previously irradiated patients with a pelvic confined tumor who cannot receive further radiation.

Patients with advanced disease are typically not candidates for curative-intent surgery because of difficulty achieving negative margins, morbidity of resection, and metastatic disease.

Reported 5-year OS rates for stage I vaginal cancer treated with surgery range from 75% to 100% (Table 79.4).[10,64,72,85,99,108] The distinction between stages I and II disease is made clinically, based on physical examination, and can be subject to variability. The NCDB review for cancers of the vagina noted superior survival rates in patients treated with surgery,[10] though this likely reflects selection of healthier patients with good performance status for radical surgery. A more recent analysis utilizing the SEER database[8] found women with stage I disease treated with surgery only to have a lower risk of mortality than those treated with radiation only, combined modalities, or no treatment; however, this difference did not reach statistical significance. For patients with stage II vaginal cancer, there was a similar trend toward increased mortality in women who did not have surgery alone as their primary treatment modality, but values once again did not reach statistical significance in their multivariate-adjusted model.

TABLE 79.4 OUTCOMES AFTER PRIMARY SURGERY IN EARLY-STAGE VAGINAL CANCER

Series	Stage	# of Pts	Outcomes	Comments
Jain et al (2010-2015)[109]	I	10	1 y DFS 89%	6 pts received adjuvant treatment for + margins/nodes.
	II	1	1 y OS 100%	2 RV; 5 TV; 4 PV
Tjalma et al (1974-1999)[99]	I	26	5 y OS 91%	4 pts received adjuvant RT. 5 LE, 19 HTX, 2 EXT
Creasman et al (1985-1994)[10]	I	76	5 y OS 90%	
	II	34	5 y OS 70%	
Otton et al (1982-1998)[108]	I	8	5 y OS 100%	6 PV; 2 HTX + removal of vaginal cuff
Stock et al (1962-1992)[64]	I	17	5 y DFS 56%	6 LE, 7 PV, 4 RV
	II	33	5 y DFS 68%	6 EXT, 17 RV, 8 PV, 2 LE
Davis et al (1960-1987)[72]	I/II	52	5 y OS 85%	21 EXT
Rubin et al (1957-1980)[63]	I/II	9	5 y OS 75%	
Ball and Berman (1947-1978)[85]	I	19	5 y OS 84%	4 EXT
	II	8	5 y OS 63%	1 EXT

DFS, disease-free survival; EXT, exenteration; HTX, hysterectomy; LE, local excision; OS, overall survival; pts, patients; PV, partial vaginectomy; RV, radical vaginectomy; TV, total vaginectomy.

Ling et al, in a small series consisting of four patients with stage I disease, report their experience using laparoscopic radical hysterectomy with vaginectomy and reconstruction of the vagina.[110] With follow-up times ranging from 40 to 54 months, they report all patients to be free of disease, with satisfactory sexual function. The authors suggest that laparoscopic surgery can be an option for select patients with early-stage disease, with good outcomes.

Other series also report excellent results with primary surgical therapy, though authors acknowledge bias resulting from the selection of healthier patients with less extensive disease for primary surgery over radiation. In a review of 100 cases by Stock et al,[64] with 85 SCC cases, surgical treatment was noted to be a significantly favorable prognostic factor for DFS (63%), compared to treatment with radiation alone (26%). This benefit appears to skew from the advanced-stage patients and potentially, therefore, with a selection bias. For stage I patients, DFS rates were 56% and 80% for patients treated with surgery versus radiation. For stage II patients, survival rates were 68% and 31% after surgery and radiation, respectively, though this likely reflects selection bias, with patients with more extensive involvement offered radiation. Overall 5-year survival was 47%. Stock et al concluded that surgery consisting of radical hysterectomy, pelvic lymphadenectomy, and upper vaginectomy could be reasonable for stage I lesions and select stage II lesions, with radiation being the preferred primary modality for patients with stage IIB disease. It should be noted, however, that 23 (70%) of 33 stage II patients treated with surgery required a total vaginectomy or exenterative procedure, which carries significant morbidity and functional impairment.

Smaller series also support the use of surgery in select patients with early-stage disease. Tjalma et al[99] reported on 55 cases of primary vaginal SCC. Of 27 patients with stage I disease, 26 received surgery, with 4 subsequently receiving some form of adjuvant radiation. With a median follow-up time of 45 months, 5-year survival was reported to be 91%. Otton et al,[108] in their retrospective review of 70 patients with stages I to II vaginal carcinoma, treated at Queensland Centre for Gynaecological Cancer between 1982 and 1998, report that patients treated with surgery alone or a combination of surgery and radiation had significantly longer survival times than patients treated with radiation alone. The authors suggest that surgery may be effective in a select subset of patients with small, localized tumors that permit clear surgical margins. Peters et al[66] reviewed records of 86 patients with vaginal carcinoma, including 68 SCC cases, treated at University of Michigan Medical Center. Twelve selected patients had surgery as primary therapy, with a 75% survival rate. Similarly, Rubin et al[63] reported on eight patients with stage I or II disease who received surgery as primary treatment; 5-year survival was 75% and the overall local

control rate for the stage I patients was 80%, suggesting that highly selected patients can achieve excellent outcomes with surgery. Davis et al[72] reported on 89 patients with vaginal carcinoma, treated primarily at the Mayo Clinic from 1960 to 1987. A total of 52 patients were treated with surgery as primary therapy, with 5-year survival of 85%, compared to 65% for patients who received radiation alone. In the stage II patients, the 5-year survival rates were 49%, 50%, and 69% for surgery, radiation, and combined treatment with surgery and radiation, respectively. However, treatment modalities cannot be effectively compared using retrospective series, given selection biases.

Neoadjuvant chemotherapy is not recommended, given limited data and risk of progression during chemotherapy. A case report documented the use of neoadjuvant chemotherapy consisting of bleomycin and cisplatin, followed by radical surgery, for one patient with stage II SCC of the vagina. The patient was free of disease, with satisfactory sexual function, at 30 months.[111] Results on 11 patients with stage II SCC of the vagina,[112] treated with three cycles of neoadjuvant paclitaxel and cisplatin followed by surgical resection, showed that 27% achieved a complete response. All patients had disease-free resection margins after surgery, and only one patient had positive lymph nodes. At a median follow-up time of 75 months, 10 (91%) of 11 patients were alive, and of those, 8 (73%) were free of disease. Postoperative complications were mild. However, more series and larger numbers of patients treated with this approach, with longer follow-up, are necessary to further evaluate the feasibility of this treatment.

Advanced vaginal cancers are generally treated with definitive radiation in combination with chemotherapy. The use of combined modality treatment is imputed from the cervical cancer literature. Several series report their experience using surgery for advanced stages III or IV patients, with most cases requiring radical excision, typically pelvic exenteration.[61,63,64,85] Control rates, at best, are around 50%, even with highly selected patients.

Radiation

For most patients, radiation is the treatment of choice given the desire for organ preservation and the significant morbidity that may be incurred by

exenterative surgery. It is important to individualize RT techniques based on the size, depth, and location of the lesion. The outcomes of the retrospective series on the use of radiation for vaginal cancer are summarized in Table 79.5 and in detail later.

TABLE 79.5 OUTCOMES BY STAGE FOR VAGINAL CANCER TREATED WITH PRIMARY RADIATION WITH OR WITHOUT CHEMOTHERAPY

Series	Outcome	Stage I (%)	Stage II (%)	Stage III (%)	Stage IV (%)	Treatment	Notes

BT, brachytherapy; CRT, conformal radiation therapy; CSS, cause-specific survival; DFS, disease-free survival; DSS, disease-specific survival; EBRT, external beam radiation therapy; HDR, high-dose rate; LC, local control; OS, overall survival; PC, pelvic control; RT, radiotherapy; S, surgery.

[a]Outcomes for stages IVA, IVB, respectively.

[b]Outcomes for stages IIA, IIB, respectively.

Stage I. For very small, superficial tumors, BT alone can be considered, but appropriate patient selection is critical. Reported local control rates range from 62% to 100.[62,65,67,87,93,93,117,118] Perez et al[58] reported pelvic tumor control of 88% in patients with stage I disease who received BT alone, using a dose of 60 to 70 Gy, prescribed 5 mm beyond the plane of the implant or vaginal mucosa, with a vaginal surface dose of 80 to 120 Gy. Notably, tumor control in stage I vaginal carcinoma was similar to BT alone, versus BT plus EBRT. This observation is consistent with reports from some groups,[58,104,119] but not others.[62,118] Other series suggest high locoregional failure rates with BT alone. Kanayama et al report three out of eight (38%) patients with stage I vaginal cancer, treated with BT alone, developed lymph node recurrence.[118] Frank et al[62] reported on 21 patients with stage I disease who were treated with local radiation only, without regional node coverage. Nine received BT alone, 11 received EBRT with or without BT, and 1 received local EBRT using a transvaginal orthovoltage cone. Three of nine patients treated with BT alone developed recurrent

disease in the pelvis, resulting in a 10-year pelvic disease control rate of 67%. Patients who received EBRT with or without BT did not have pelvic recurrences. A pelvic relapse rate of 18% at 10 years was noted by Frank et al,[62] with all pelvic failures occurring in patients treated with BT alone. Overall, results suggest caution should be taken when BT alone is used without prophylactic lymph node irradiation, given fairly high rates of lymph node recurrence. Appropriate patient selection is critical when utilizing BT alone as primary treatment, particularly since the distinction between stages I and II is based on clinical examination and can vary between providers.

With LDR, treatment can be delivered in two applications, with the first designed to treat the entire vaginal wall and a second application to cover the tumor volume. When HDR BT is the primary treatment, the entire length of the vagina is typically treated to a mucosal dose of 60 to 65 Gy, with an additional mucosal dose of 20 to 30 Gy delivered to the area of tumor involvement.[120] Treatment can be delivered with a shielded vaginal cylinder or with a multichannel HDR cylinder to treat the tumor with a 2-cm margin and block uninvolved mucosal surfaces.[121] HDR can also be used to treat superficial lesions.

The use of a multichannel HDR cylinder is an alternative technique with favorable local control and low toxicity. The standard multichannel HDR cylinder is composed of a central channel with 6 to 12 peripheral channels, allowing preferential dosing to the target while decreasing dose to normal structures. Vargo et al reported their outcomes for 41 patients with vaginal cancer treated with this technique to median EQD2 (equivalent dose in 2-Gy fractions) of 77.1 Gy.[122] Definitive treatment consisted of EBRT followed by BT. The majority (71%) of patients had FIGO 1 disease. At 2 years, there was 93% local control and 4% overall late grade 3 or higher toxicity, demonstrating comparable results to historical treatments. A tumor thickness cutoff of 5 mm for the apex and posterior vagina and 7 mm for other locations was utilized.

Guidelines from the American Brachytherapy Society, as well as the ESTRO/ESGO/SIOPe guidelines, recommend a cumulative D_{90} (dose to 90% of volume) EQD2 of 70 to 85 Gy prescribed to the vaginal tumor.[81,123] Various regimens can be utilized to achieve this dose, with commonly

utilized schedules of 45 Gy in 25 fractions EBRT followed by HDR BT in 5 fractions of 4.5 to 5.5 Gy (EQD2 = 71.4-79.8 Gy) or 9 to 10 fractions of 3 Gy (EQD2 = 73.5-76.8 Gy).

Poorly differentiated or extensively infiltrating stage I lesions should be treated with a combination of EBRT and BT. Given a possible underestimation of submucosal disease and/or nodal disease, resulting in a potentially high likelihood of recurrence with BT alone, some groups recommend incorporating EBRT into the treatment of all stage I patients, except for those with very small, superficial lesions.[62,118] Damast et al reported outcomes for early-stage vaginal cancer treated with a combination of EBRT and MRI-based ICB between 1998 and 2008.[124] With mean EBRT dose of 45, followed by HDR-ICB, 5-year OS, disease-specific survival, and local failure-free survival were 67%, 80%, and 90%, respectively. Notably, 60% of patients had a complete response after EBRT; of this group, there were no recurrences. Concurrent cisplatin was used as a radiosensitizer in 40% of patients.

Actuarial 5-year survival rates for stage I disease range from 60% to 85%.[8,62,67,98] Disease-specific survival rates for stage I disease, treated with definitive radiation, range from 75% to 95%.[58,59,88] The 10-year pelvic relapse rate, composed of local, pelvic nodal, and inguinal nodal failures, was noted to be 16% by Frank et al for stage I patients.[62] Most failures are locoregional. Distant metastases are uncommon and occur in about 5% of patients.[58,72,117]

Stage II. Stage II vaginal carcinoma involves the subvaginal tissue but does not extend to the pelvic side wall. The primary treatment for stage II disease is radiation, most commonly as a combination of EBRT followed by vaginal BT; chemo therapy is typically considered. Outcomes with BT alone have been poor; thus, this approach is not recommended. With BT alone, Perez et al[58] noted a 36% pelvic tumor control rate in stage II patients, compared to 67% in patients treated with a combination of EBRT and BT. The benefit of combining EBRT and BT, as opposed to using either alone, has been shown in other series as well.[59,64]

During EBRT, the pelvis generally receives 45 to 50.4 Gy in 1.8-Gy fractions, with consideration of a parametrial boost if there is extensive primary infiltration or high suspicion of nodal disease. Inguinal lymph

nodes are included in a modified whole-pelvic field for lesions involving the distal one-third of the vaginal canal.

Subsequent BT should be carefully delivered to ensure adequate coverage of tumor volume. An interstitial technique, ideally with three-dimensional (3D) imaging for treatment planning, is required for tumors greater than5 mm in depth.[87] Image-guided adaptive brachytherapy (IGABT) is highly recommended, preferably with the use of MRI.[81] Using IGABT, local control rates are high with acceptable morbidity. In a series of patients treated only using IGABT, Westerveld et al report 5-year local control rates of 85% for stage I to II tumors.[125]

Extensive tumors, or deeply infiltrating tumors with non distinct margins, may be poor candidates for BT.[81] In such cases, boosting tumors with conformal techniques or intensity- modulated radiation therapy (IMRT) can be considered and may yield better outcomes than suboptimal BT. The tumor volume should receive a minimum of 75 to 80 Gy using combined EBRT and BT. Fleming et al[126] and Puthawala et al[127] both report improved outcomes with higher doses of 80 to 100 Gy. The 5-year survival rate for patients with stage II disease treated with RT alone ranges from 35% to 70% for stage IIA and 35% to 60% for stage IIB.[30,128,129] Pelvic relapse at 10 years has been reported to be 25% by Frank et al, consistent with recent series reporting 5-year pelvic control rates ranging from 76% to 84%.[62,98] The likelihood of distant metastasis is higher for stage IIB lesions compared to stage IIA,[67,119] with overall reported rates ranging from 22% to 46%.[67,72]

Stages III and IVA. Locally advanced vaginal cancer is treated with a combined modality approach of radiation and chemotherapy, extrapolating from favorable outcomes with use of conformal radiation therapy (CRT) in patients with cervical cancer, and endorsed by the ESTRO/ESGO/SIOPe vaginal cancer guidelines.[81,130,131] Radiation is delivered as pelvic EBRT, followed by an additional parametrial boost when warranted. If adequate tumor coverage can be achieved without undue toxicity, interstitial BT is employed to deliver a minimum tumor dose of 75 to 80 Gy. If BT is not feasible because of extensive tumor infiltration of the rectovaginal septum or bladder, a shrinking field technique or IMRT has been used to deliver additional dose to the primary lesion.[132,133] The overall cure rate for patients with stage III disease ranges from 30% to 50%. Stage IVA carries a worse

prognosis. In highly selected patients with small-volume stage IV disease, pelvic exenteration can yield good long-term control; however, in practice, EBRT remains the primary treatment.[8,10,58,62-64,103]

Five-year actuarial survival rates for women with stage III disease range from 25% to 58%,[8,10] with local failure rates of 30% to 75%.[62,67,98] Outcomes for stage IV disease are worse, with survival rates of 0% to 40%.[59,64,134] Despite treatment with EBRT and BT, only 20% to 30% of patients with stages III to IV disease achieve local control. Pelvic recurrences occur more often than distant recurrences.[62]

However, with the use of IGABT, 5-year local control rates approach 75%, and there is some suggestion that there is improved local control in advanced stage II to IV tumors if the primary tumor receives more than 80 Gy.[125] In these patients, pelvic recurrences are roughly equal to distant recurrences, given the improved rates of local control. In general, lymph node involvement is a poor prognostic factor for DFS.[125]

Role of Combined Chemotherapy and Radiation

Chemotherapy has been incorporated with radiation for the treatment of vaginal cancer, extrapolating from studies in cervical cancer showing improved progression-free survival and OS when cisplatin is added to RT.[58,130,131,135,136] Given rarity of vaginal cancer, there are no randomized trials comparing radiation alone to radiation plus chemotherapy.

Retrospective series are limited by small numbers or inclusion of other cancers, such as cervical and vulvar carcinomas. Nonetheless, the majority of retrospective studies suggest that a combined modality approach is feasible and may yield improved outcomes. These studies are summarized in Table 79.6.

TABLE 79.6 OUTCOMES AFTER COMBINED CHEMORADIATION IN VAGINAL CANCER

AC, adenocarcinoma; AWD, alive with disease; B, brachytherapy; cis, cisplatin; CRT, conformal radiation therapy; DID, died of intercurrent disease; DOD, died of disease; EBRT, external beam radiation therapy; FU, fluorouracil; 5-FU, 5-fluorouracil; LC, local control; PFS, locoregional progression-free survival; MMC, mitomycin-C; NED, no evidence of disease; OS, overall survival; SCC, squamous cell carcinoma; MR-BT, MR-guided brachytherapy.

An NCDB study identified 13,689 women with primary vaginal cancer treated between 1998 and 2011 and explored the impact of concurrent chemoradiation on survival.[138] Median survival with chemotherapy and radiation was significantly longer, compared to radiation alone (56.2 vs 41.2 months, $P < .0005$). It was noted that only 48.6% of all patients received chemotherapy, but there was a consistent trend toward increased use of concurrent chemoradiation from 20% to 59.1% between 1998 and 2011.

Ghia et al[139] published a retrospective patterns-of-care analysis using the SEER database, analyzing data from women with primary vaginal cancer treated with EBRT and/or BT between 1991 and 2005. Of the 326 women in the study cohort, 80.4% had SCC. It was noted that CRT was used in 7.5% of patients treated before 1999 compared to 36.1% of those treated afterward ($P < .001$). Cisplatin was the most frequently utilized agent, accounting for 59% of CRT treatments. Chemotherapy was significantly less likely to be used in conjunction with radiation for women older than 80 years; otherwise, there was no difference for race, stage, grade, histologic diagnosis, comorbidities, or BT use. On multivariate analysis, CRT was not found to correlate with improved cause-specific survival or OS.

In a retrospective analysis of 71 patients with primary vaginal cancer treated from 1972 to 2009, 51 patients were treated with radiation alone and 20 were treated with CRT and RT.[136] Of the patients treated with chemosensitization during radiation, 85% of patients received weekly cisplatin chemotherapy, whereas the remainder received either carboplatin or 5-FU. Three-year actuarial OS and DFS was 56% for the RT-alone group, compared to 79% for the CRT group ($P = .01$). Three-year DFS was 43% for the RT-alone group, compared to 73% for the CRT group ($P = .01$). At a median follow-up of 3 years, tumor relapse was seen in 15% of patients treated with CRT compared to 45% of patients treated with radiation alone ($P = .03$). On multivariate analysis, the addition of chemotherapy was a significant predictor of DFS (HR 0.31).

Evans et al[140] reported the use of radiation with 5-FU and mitomycin-C (MMC) in seven patients with vaginal cancer. Four out of seven patients were free of disease with follow-up times ranging from 19 to 39 months. Roberts et al[141] reported results for seven patients with vaginal cancer treated with concurrent 5-FU, cisplatin, and radiation. Three patients received interstitial BT after EBRT, and two patients received ICB after EBRT. Eighty-five percent of patients achieved a complete response initially. Ultimately, 61% recurred, with a median time to recurrence of 6 months. There were three local recurrences and one distant metastasis, and the 5-year OS rate was 22%. Kirkbride et al[86] reported on the use of concurrent 5-FU, with or without MMC, in 26 of 153 patients with vaginal carcinoma treated at Princess Margaret Hospital. Seventy-seven percent of the patients had stage III/IV disease. Radiation was EBRT followed by

interstitial BT or ICB to a total dose of 62 to 74 Gy. The 5-year survival rate was 50%. Dalrymple et al[142] reported results using 5-FU–based chemotherapy in combination with radiation for the treatment of primary SCC of the vagina. Thirteen of 14 patients (93%) had stage I or II disease. The median dose of radiation was 63 Gy, achieved using EBRT alone or EBRT with ICB. The 5-year survival rate was 86% for all patients, and nine patients were free of disease with a median follow-up time of 100 months, suggesting that good local control can be achieved despite the use of lower radiation doses. There was a 31% rate of severe bowel complications reported, with two deaths as a result of bowel obstruction.

A retrospective series from MDACC by Frank et al[62] included nine patients with stages II to IVA SCC of the vagina treated with RT and concurrent cisplatin-based CRT. With a mean follow-up time of 129 months, improved local control with the use of chemotherapy was noted, with 44% of patients treated with concurrent CRT remaining free of disease. Samant et al published a review of 12 patients with stages II to IVA vaginal cancer treated with concurrent weekly cisplatin at a dose of 40 mg/m^2 for 5 weeks.[143] Patients received concurrent EBRT to a median dose of 45 Gy, with LDR interstitial BT or an HDR-ICB boost of median dose 30 Gy. Six patients had stage II disease, four had stage III disease, and two had stage IVA. Ten of 12 patients (83%) had SCC; the other two had adenocarcinoma. Overall, treatment was well tolerated, with 92% of patients completing therapy as prescribed. Two of 10 patients who received interstitial BT required surgery for fistula repair. The 5-year OS, progression-free survival, and locoregional progression-free survival rates were 66%, 75%, and 92%, respectively, supporting the use of concurrent weekly cisplatin therapy. A small series of six patients treated with CRT at the University of the Ryukyus was reported by Nashiro et al[144] All patients received EBRT to 50 Gy, followed by either a boost with shrinking fields (n = 4) or ICB (n = 2). Radiation was delivered with two to three cycles of cisplatin. Two patients had stage II, one had stage III, and three had stage IVA disease. All six achieved a complete response, and four of six patients remained free of disease at follow-up times of 18 to 55 months.

Outcomes

In general, the rate of locoregional recurrence ranges from 10% to 20% for stage I and 30% to 40% for stage II. Patients with advanced disease often have persistent disease despite treatment. In a series by Dixit et al,[105] 68% of failures in stage III patients were due to persistent disease. Most treatment failures occur within 5 years, with a median time to recurrence of 6 to 12 months,[62,146] and local recurrence is the most common pattern of treatment failure in the majority of published series. Extravaginal recurrences in the pelvic lymph nodes are less common. The reported rates of distant metastasis vary, ranging from 7% to 33% and usually occur later in the course of disease, with approximately half of all distant metastases presenting at the time of local recurrence.[67,87,105,147]

According to SEER-based data, outcomes for vaginal cancer may be improving. A recent study by Shah et al[8] analyzed records from the SEER database of 2,149 women diagnosed with primary vaginal cancer between 1990 and 2004. The risk of mortality is noted to have decreased over time, with a 17% decrease in the risk of death for women diagnosed after 2,000 relative to those diagnosed between 1990 and 1994. The authors reported 5-year disease-specific survival rates of 84% for stage I, 75% for stage II, and 57% for stages III to IV. An older study by Creasman et al[10] focused on 4,885 women diagnosed with vaginal cancer between 1985 and 1994 and reported 5-year survival rates of 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stages III to IV, with 85% of invasive cases being SCC, MR-guided brachytherapy resulted in 2y LC 93% after RT and weekly cisplatin.[145]

Melanoma

Vaginal melanomas constitute approximately 4% of all primary vaginal cancers,[9] with just over 100 new cases of vaginal melanoma reported each year in the United States. Melanomas arising from the vaginal mucosa are thought to originate from mucosal melanocytes in regions of melanosis or from atypical melanocytic hyperplasia.

The incidence of vaginal melanoma has remained stable and is reported to be approximately 0.26 per million.[148] The majority of reported cases are in Caucasian women; one study of 37 women with primary melanoma of the vagina reported 84% of patients to be Caucasian, and only 3% African

American.[149] According to a report by Hu et al[150] analyzing SEER data from 1992 to 2005 on 125 cases of vaginal melanoma with known race/ethnicity, there is no significant difference in incidence rate of vaginal melanoma between Caucasian and African American women, with a White/Black ratio of 1.02 after age adjustment. In the report by Creasman et al,[10] most patients were of advanced age at presentation, with only 23% of patients diagnosed before the age of 60; 28% were diagnosed between the ages of 60 and 69 years, 28% were diagnosed between the ages of 70 and 79 years, and 22% were diagnosed at age 80 years or above.

Grossly, melanoma of the vagina tends to be pigmented and may present as a dark mass, plaque, or ulceration; multifocal presentation is also common. In a case series of 37 women with primary vaginal melanoma reported by Frumovitz et al,[149] median tumor size at presentation was 3 cm (range, 0.4-5 cm), with median depth of invasion of 7 mm (range, 1-21 mm). Twenty-one percent of patients presented with multifocal disease. Twenty-four patients (65%) presented with lesions in the distal third of the vagina or introitus. The most common appearance is polypoid-nodular.[151] The most common location at presentation is the anterior vaginal wall and lower one-third of the vagina.[149]

Microscopically, tumors may be composed of epithelioid, spindle, or nevus-like cells, with variable morphology, and stain frequently positive for S-100 protein, HMB-45, and Melan A. When S-100 is negative or only focally positive, tyrosinase and MART-1 are useful markers. Poorly differentiated tumors may be difficult to distinguish from carcinomas or sarcomas. Tumor thickness correlates with prognosis and is measured by the methods of Breslow.[152]

Vaginal melanoma is a high malignant disease with a propensity for early hematogenous spread. The most common presenting symptoms reported have been slight vaginal bleeding and vaginal discharge, which is usually blood tinged, foul smelling, or purulent.[153] Reid et al reviewed 115 patients with primary melanoma of the vagina and found depth of invasion and lesion size greater than 3 cm to be negative prognostic factors.[154] Stage was not found to be prognostic for outcome, but only 42 of the 115 patients had this information available. Compared to women with SCC, patients with vaginal melanoma have a significant 1.5-fold increased risk of mortality.[8]

Treatment Options

Primary vaginal melanoma is uncommon, and treatment outcomes for only a small number of patients have been reported.[149,153,155-158] As a result, it is difficult to make definitive treatment recommendations. Treatments used in published series include wide local excision, radical surgery, radiation, chemotherapy, immunotherapy following principles from skin melanoma, or a combination of modalities.

Some authors advocate incorporation of radical surgical resection into the treatment paradigm, when feasible.[159,160] The rationale for favoring surgery over radiation is based upon the observation that melanoma tends to be radioresistant. Geisler et al[159] recommend primary pelvic exenteration for vaginal melanomas with greater than 3 mm invasion, reporting a 5-year survival rate of 50% if pelvic nodes are free of disease. Morrow and DiSaia,[161] in their review of gynecologic melanoma, recommend radical surgery based on a review of the literature revealing 3 out of 19 long-term survivors after exenteration with wide local excision. Chung et al[155] reviewed 19 cases of primary vaginal melanoma treated between 1934 and 1976. All patients who received wide local excision developed recurrence. Five-year survival was only 21%. Miner et al[162] reported on 35 patients treated at Memorial Sloan-Kettering Cancer Center from 1977 to 2001. Sixty-nine percent underwent surgery, which was either en bloc removal of the involved pelvic organs, wide excision, or total vaginectomy, with elective pelvic lymph node dissection in 74% of cases. Thirty-one percent of patients received definitive radiation. Primary surgical therapy was significantly associated with a longer OS time (25 vs 13 months). Recurrence-free survival was not found to correlate with surgical extent. A study by Huang et al found 5-year OS to be 32% but as high as 47% in patients who underwent surgical treatment.[163]

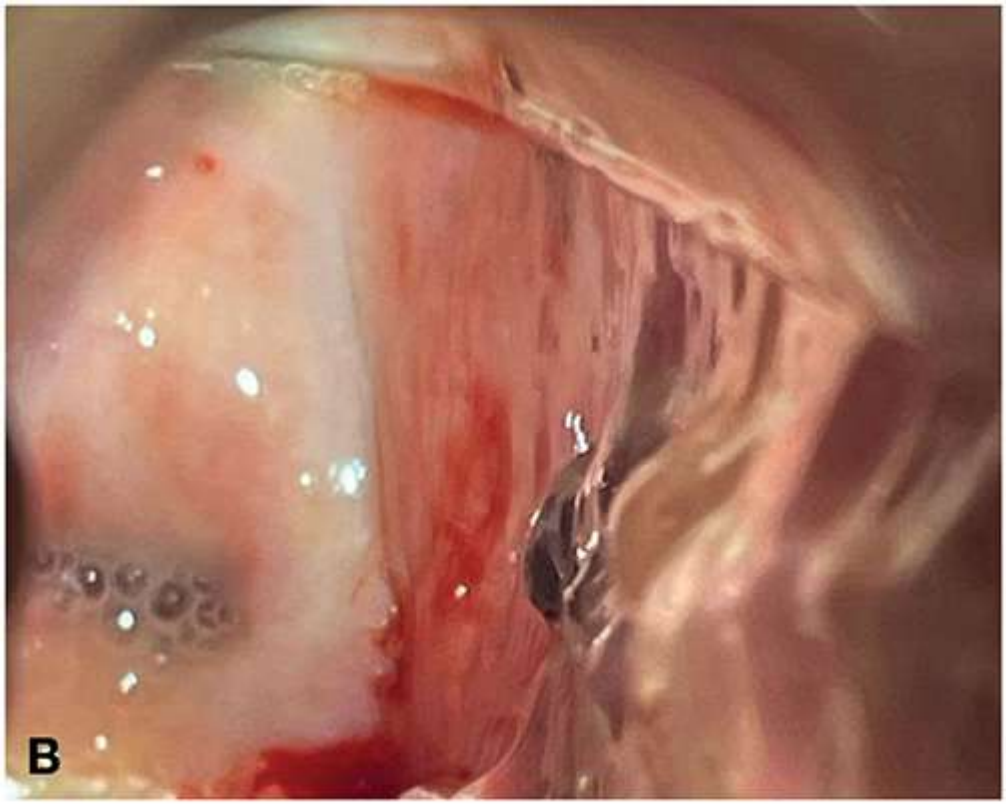
The goal of surgical excision should be complete resection with a negative margin. Drawing on the general melanoma guidelines this would be between 0.5 and 2 cm depending on the Breslow thickness of the primary tumor. Given the close proximity of the bladder and rectum, a wide local excision can rarely achieve this. Due to the risk of metastatic disease and the aggressive nature of the tumor, however, several series comparing radical surgery and local excision find equivalent outcomes.[153,156,164,165]

The role of surgical lymphadenectomy, lymph node sampling, or sentinel lymph node mapping is not established in vaginal cancer, given the vast variability in lymphatic drainage and substantial morbidity in the form of lymphedema that could result from sampling of both the inguinal and pelvic nodal basins. Lymphadenectomy could be considered in patients with nodal disease with the goal of locoregional control.

The use of wide local excision followed by postoperative EBRT and BT has been proposed. Bonner et al[166] reported on nine cases of vaginal melanoma. Three patients were treated with wide local excision, and six underwent radical surgery. All nine patients developed locoregional recurrence. As a result, the authors suggest adding pelvic RT to improve local control. A more recent review by Frumovitz et al[149] reported that radiation after wide local excision can reduce local recurrences. However, most patients develop distant metastases, most commonly in the lungs and liver. New advances in immunotherapy hold promise for changing the outcomes of patients and evolving the management of patients with melanoma. There is no general recommendation for the treatment of primary vaginal melanoma. When radiation is administered, vaginal melanoma is treated similarly to vaginal carcinoma, with volumes and doses ranging from 50 Gy for subclinical disease to 75 Gy for gross tumor.

Retrospective data suggest that radiation may improve local control for vaginal melanoma.[153,167] Among the few long-term survivors reported in the literature are a handful of patients who were treated with radiation. Harwood and Cummings[168] described a complete response in four patients with vaginal melanoma treated with radiation, although two subsequently relapsed. Rogo et al,[169] in their series of 22 cases of vulvovaginal melanoma, reported comparable results for surgery and radiation, with eight patients (36%) alive 5 years after treatment. Petru et al,[167] in their series documenting 14 patients treated for primary malignant melanoma of the vagina, noted that three of nine patients treated with radiation, either as primary treatment (n = 2) or in the postoperative setting (n = 1), survived longer than 5 years. The median OS for all patients was 10 months, with a 5-year DFS rate of 14% and an OS rate of 21%. Figure 79.4 shows a vaginal melanoma lesion treated with five-fraction stereotactic body radiation therapy (SBRT) that had a rapid regression of disease.

A



B

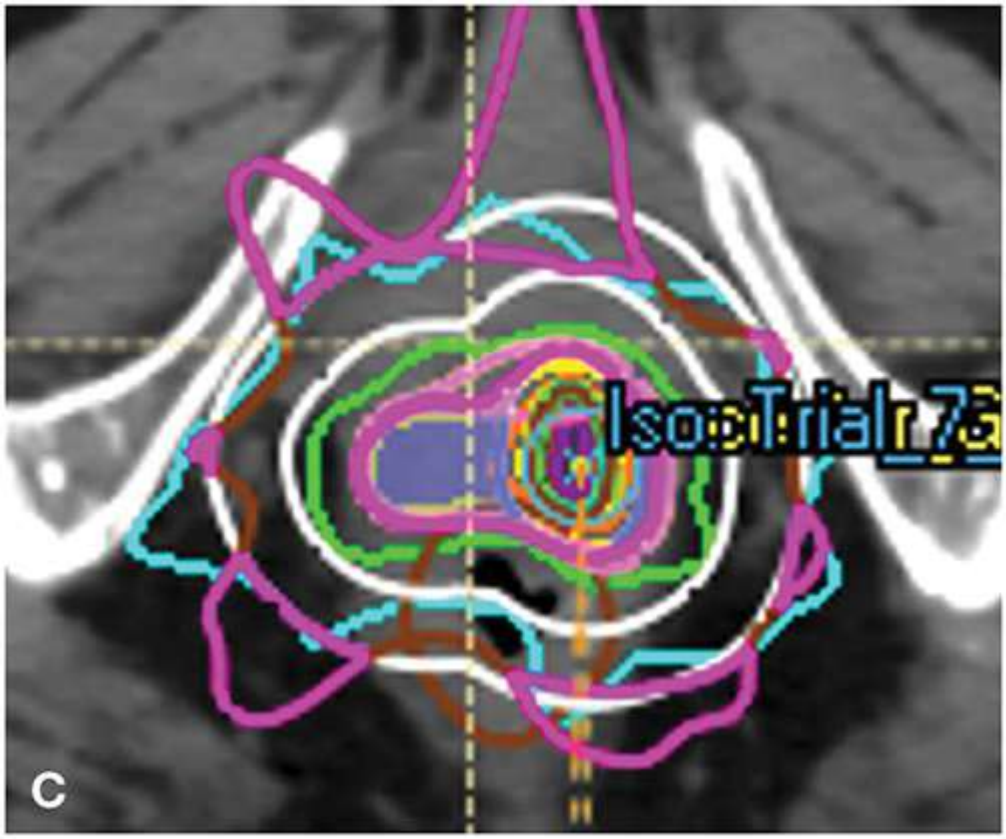


FIGURE 79.4 Vaginal melanoma treated with stereotactic body radiation therapy (SBRT) using 8 Gy for five fractions to the mass defined on a magnetic resonance (MR) simulation and 6 Gy for five fractions to the rest of the vaginal mucosa. Fiducial markers were placed surrounding the mass before the magnetic resonance imaging (MRI) and used for set up daily. A. Mass at diagnosis presenting as a pedunculated 2-cm mass. B. Flattened mass 3 months after SBRT. C. SBRT simultaneous integrated boost of the gross tumor volume (GTV) and the vaginal clinical target volume (CTV).

Frumovitz et al,[149] in their review of 37 women with stage I melanoma of the vagina treated at MDACC between 1980 and 2009, report very poor prognosis even in this group of patients with localized disease, with a 5-year OS rate of 20%. In that study, 10% of patients received nonsurgical treatment with radiation, chemotherapy, or both. Patients treated surgically had significantly longer survival times compared to those treated nonsurgically. Radiation delivered after wide local excision reduced local recurrence and demonstrated a trend toward longer survival times, from 16.1 to 29.4 months.[170] A study by Xia et al evaluated 44 women, diagnosed and treated for vaginal melanoma between 2002 and 2011.[158] There was no difference in OS between local excision and radical surgery. However, the

authors note increased progression-free survival with the addition of adjuvant chemotherapy and radiation (8.6 vs 16.0 months, $P = .038$). Given the high rates of distant metastases, chemotherapy has been used, either alone or in conjunction with radiation.[149,171] Other reports have described the use of immunotherapy after surgery.[163]

Recommendations for the use of adjuvant chemotherapy for vaginal melanoma derive from the general melanoma literature where multiple agents have been the focus of investigation. One of the first drugs used was IFN-α, which was been found to bring an improvement in recurrence-free survival with no OS benefit. More recently in a phase II study, patients treated with surgery followed by adjuvant temozolomide in combination with cisplatin were noted to have a 48.7-month OS, superior to IFN-α (40.4 months) or observation (21.2 months) ($P < .01$). Further studies are ongoing.[172]

The effectiveness of targeted molecular therapies and immunotherapy in cutaneous melanoma has significantly expanded the options for patients with advanced melanoma. Approved therapies for advanced, unresectable melanomas include ipilimumab (antibody against cytotoxic T-lymphocyte–associated protein 4), nivolumab (inhibitor of programmed cell death 1 [PD-1] protein), pembrolizumab (PD-1 inhibitor), vemurafenib (B-raf proto-oncogene serine/threonine kinase [BRAF] inhibitor), dabrafenib (BRAF inhibitor), and trametinib (mitogen-activated protein kinase inhibitor). However, it is difficult to extrapolate the effectiveness of these therapies for cutaneous melanoma to vaginal melanoma, and there are no specific trials that have validated the efficacy of these regimens in vaginal melanoma. Testing of tumors for BRAF, NRAS, and c-KIT can be used to guide therapy. There appear to be high levels of PD-1 and PDL-1 expression in both vaginal and vulvar melanomas, suggesting utilization of immunotherapy may have efficacy for this disease.[128]

Regardless of primary treatment, outcomes have been disappointing. Overall prognosis is poor, with historic 5-year survival rates ranging from 5% to 30% regardless of treatment modality or extent of surgical resection.[154,155,157] There is a high rate of distant metastases, ranging from 66% to 100%.[155,173]

Sarcoma

Sarcomas represent 3% of all primary vaginal cancers.[10] In a report based on data from the NCDB between 1985 and 1994,[10] there were 135 cases of primary vaginal sarcoma of heterogeneous histologies and varying age. Twenty-two percent of patients were under 14 years of age, with a median age at presentation of approximately 50 years. Consistent with this, a recent analysis of the SEER database identified 221 patients with primary vaginal sarcoma, diagnosed between 1988 and 2010, with mean age of 54.9.[174] Compared to other vaginal cancers, sarcomas tended to be larger, with decreased likelihood of lymph node involvement, and more likely to be treated with primary surgery without radiation. It was estimated that, after adjusting for other variables, vaginal sarcomas had a 69% greater risk of cancer-related mortality when compared to SCC.

Vaginal sarcoma most frequently presents as an asymptomatic vaginal mass.[175] In one series, this was the most frequent symptom, found in 35% of patients, followed by vaginal, rectal or bladder pain (26%), bleeding or serosanguinous discharge from the vagina or rectum (18%), leucorrhea (9%), dyspareunia (7%), or difficulty in micturition (7%).

Leiomyosarcoma is the most common histology in adults, representing up to 65% of all vaginal sarcoma cases; however, overall numbers are very small, with less than 150 published reports in the literature.[175] Vaginal leiomyosarcomas not only originate from the smooth muscle of the vaginal wall but may also develop from smooth muscle cells in tissues adjacent to the vagina. Leiomyosarcomas have a predilection for the posterior vaginal wall, with published reports suggesting approximately 43% to 45% in the posterior vagina, 17% to 21% anteriorly, and 34% to 39% laterally.[175,176]

Grossly, patients present with a palpable submucosal nodule, although advanced tumors may demonstrate palpable necrosis or exophytic polypoid tissue.[177] Criteria to distinguish between benign leiomyoma and leiomyosarcoma include the mitotic index, cytologic atypia, and coagulative tumor necrosis.[178] Because of considerable variation in smooth muscle tumors from area to area, adequate sampling is recommended to achieve an accurate diagnosis. Microscopically, leiomyosarcomas demonstrate interlacing bundles of spindle-shaped cells, with blunt-ended nuclei and fibrillar cytoplasm.[153,179] Leiomyosarcomas are also aggressive;

they undergo early hematogenous dissemination, recur locally,[10,175] and demonstrate pulmonary metastases.[180]

Other less common histologies include endometrial stromal sarcoma and angiosarcoma.[181,182] Fewer than 10 cases of angiosarcoma of the vagina have been reported in the literature.[183,184] A history of pelvic radiation is a risk factor for pelvic sarcomas, particularly angiosarcoma.[185] In the pediatric population, embryonal rhabdomyosarcoma/sarcoma botryoides is the most common histology,[185] with 90% of cases occurring in children younger than 5 years.[186]

Prognostic Factors

Review of the literature indicates that vaginal sarcomas undergo early hematogenous dissemination as well as frequent local recurrence. Pulmonary metastases are common.[175,176] Adverse prognostic factors for vaginal sarcoma include high histologic grade, stage, size greater than 3 cm, infiltrative borders, and cytologic atypia.[180]

Treatment Options

Despite surgery and the use of adjuvant RT in select cases, patients with sarcoma sustain poor outcomes because of a high incidence of local recurrence and distant metastasis. Locoregional control is especially important for vaginal leiomyosarcoma. The addition of systemic treatment, typically with doxorubicin, is standard for leiomyosarcoma.[187] Postoperative RT has been used to manage soft tissue sarcomas in other sites, to reduce locoregional recurrence rates.[188] Results from adjuvant radiation for high-grade sarcoma in other regions of the body have been extrapolated to vaginal cancer. In patients with involved margins, high doses above 62.5 Gy are generally required to achieve local control.[189]

A series by Peters et al[190] reported on 17 cases, composed of 10 patients with leiomyosarcoma, 4 with MMT, and 3 with other types of sarcomas. There were only three patients alive and free of disease with follow-up times of 84 to 161 months. All three patients had undergone pelvic exenteration. Patients who received other forms of primary therapy all died of recurrence, with the pelvis as the first site of recurrence in all cases. In 50% of cases, the pelvis was the only site of failure, stressing the

importance of local treatment. OS of 8 and 10 years following wide local excision have been reported.[176]

Outcomes

In the SEER analysis, 5-year survival was 89% for stage I and under 50% for stage II vaginal sarcomas of all types.[174] Other series describe similarly poor outcomes. A 5-year survival was 36% for patients with leiomyosarcoma in the Peters et al's series.[190]

Malignant Mixed Müllerian Tumors

Mixed Müllerian tumors (MMT), also called carcinosarcomas, are highly aggressive, biphasic neoplasms composed of an epithelial component as well as a sarcomatous component. The epithelial component in vaginal MMT is most often SCC.[181] The sarcomatous component can be composed of fibroblasts and smooth muscle, or include cartilage, striated muscle, bone, and other heterologous tissues. The metaplastic carcinoma theory suggests that there is a common cell of origin for MMT, with carcinoma giving rise to the sarcomatous component via metaplasia.[191] The most common differential diagnosis is sarcomatoid carcinoma. The spindle and carcinomatous components are positive for cytokeratin in sarcomatous carcinoma, whereas MMT demonstrates a sarcomatous component that is positive for vimentin, with the carcinomatous component positive for cytokeratin.[181] The first case of vaginal MMT was described in 1975 by Davis et al,[192] since then, only 11 cases have been reported in the literature, with age ranging from 57 to 74 years.[181,193,196] At least one case report of MMT of the vagina detected high-risk HPV in both the carcinomatous and sarcomatous components, suggesting that some vaginal MMTs may be related to HPV.[193]

The survival rate for patients with MMT was even lower, at 17%. There are only a few case reports and small series detailing treatment of primary vaginal MMT. Neesham et al[195] published a case report of a 74-year-old patient treated with wide local excision and radiation for a 5.5-cm stage I MMT. The patient developed distant metastases within 6 months of local therapy. Analysis of patterns of failure suggests that local therapy does not have a significant impact on survival because of early distant spread. For

that reason, chemotherapy is typically administered after surgery for MMT in other sites and should be considered for primary vaginal lesions, along with adjuvant radiation as warranted. Platinum-based chemotherapy has been used for MMT occurring elsewhere in the pelvis. It has not yet been determined whether platinum agents are best administered either alone or in combination with other agents. Combination regimens include a paclitaxel with either ifosfamide or a platinum agent.[197-199]

Clear Cell Adenocarcinoma

Epidemiology

Clear cell adenocarcinoma of the vagina was first reported in 1971 by Herbst and Scully,[200] who documented six cases of primary vaginal clear cell carcinoma in patients aged 15 to 22 years: five of the six had been exposed to the synthetic estrogen diethylstilbestrol (DES) in utero during the first trimester. This was the first report suggesting that in utero exposure to DES, prescribed during the mid-1940s to 1960s for high-risk pregnancies, could result in an increased risk of clear cell adenocarcinoma. DES-related clear cell adenocarcinoma presents at a young age, with studies documenting median age at presentation to be within the second or third decade of life.[200]

Studies suggest that there is a bimodal distribution for clear cell adenocarcinoma of the vagina, with the first peak containing young women with a mean age of 26, most of whom were exposed to DES in utero, and a second peak containing women with a mean age of 71 years, not exposed to DES.[200] The majority of patients present with stages I to II disease.[200,201] DES-related clear cell adenocarcinoma is rarely seen today, as DES is no longer administered to pregnant women.

Risk Factors

In 45% to 95% of cases, clear cell adenocarcinoma of the vagina is associated with vaginal adenosis, defined as the abnormal presence of glandular epithelium in the vagina.[170,202] Vaginal adenosis has three patterns: endocervical, tuboendometrial, and embryonic.[170,203,204] Grossly, vaginal adenosis appears as red, velvety, grapelike clusters in the vagina. Glandular columnar epithelium of Müllerian type either appears beneath the squamous

epithelium or replaces it, undergoing progressive squamous metaplasia.[205] Vaginal adenosis is believed to be a precursor lesion to clear cell adenocarcinoma of the vagina. It is a common histologic abnormality in women who have been exposed to DES in utero, presenting in up to 95% of such women.[170,202]

The risk of developing clear cell adenocarcinoma in DES-exposed women is estimated to be 1 in 1,000,[201] suggesting that there are multiple factors contributing to pathogenesis. However, it is not strictly confined to this population; there are rare, sporadic cases of primary adenocarcinoma of the vagina that is not associated with DES exposure.[206]

Histopathology

Clear cell adenocarcinoma of the vagina is most often located in the upper third of the anterior vagina and can vary greatly in size. Grossly, they exhibit exophytic growth and are superficially invasive.[207] Microscopically, they are composed of vacuolated, glycogen-rich cells, hence the term *clear cell carcinoma*. The most common histologic pattern is tubulocystic, although solid, papillary, and mixed cell patterns have also been described.[74,208] Cells are cuboidal or columnar in shape, with large, atypical protruding nuclei, rimmed by a small amount of vacuolated cytoplasm.

Clinical Presentation

Patients with clear cell adenocarcinoma most often present with abnormal vaginal bleeding,[200] which is found in 50% to 75% of cases. Cytology is not reliable, revealing abnormalities in only 33% of cases; therefore, careful assessment of the entire vaginal vault to assess for submucosal irregularity is recommended, in addition to four-quadrant cytologic assessment.[209] The cervix should be carefully inspected, as clear cell adenocarcinoma can arise from this region as well. Abnormal discharge, urinary symptoms, and lower gastrointestinal complaints can also be noted, particularly in advanced cases. The differential diagnosis of vaginal adenocarcinoma is often challenging, because it must be distinguished from metastases from distant sites.

Prognostic Factors

Prognostic variables associated with worse survival include advanced stage, nontubulocystic pattern of histology, size greater than 3 cm, and depth of invasion greater than 3 mm.[207] A study of 21 women with clear cell carcinoma of the vagina and cervix reported overexpression of wild-type p53 to be associated with a more favorable prognosis.[210] Primary adenocarcinoma of the vagina not associated with DES exposure is extremely rare, with poor outcomes. In a review of 26 such cases by Frank et al, 5-year OS was 34%, worse than in patients with SCC.[211] A recent series described five cases of clear cell adenocarcinoma in patients without prior DES exposure, treated between 1990 and 2013.[212] Patients were all older than 40 years. There was high incidence of distant spread, especially to the lungs. OS at 5 years was 55%.

Treatment Options

The optimal management of clear cell adenocarcinoma is unclear. There are several published series on DES-related clear cell adenocarcinomas[74,129,207,213,214] using conventional treatments similar to those used for SCC of the vagina for stages I and II disease, including surgery with radical hysterectomy, vaginectomy, and lymphadenectomy with construction of a neovagina or definitive radiation with consideration of radiosensitizing concurrent chemotherapy.[215,216] In these series, there has been an emphasis on preservation of ovarian and vaginal function, because of the earlier age at diagnosis in DES-exposed patients. According to data from the United States Registry for Research on Hormonal Transplacental Carcinogenesis, approximately one half of all vaginal clear cell adenocarcinoma cases were treated with radical surgery alone as primary therapy.[217]

Wharton et al report the use of intracavitary or transvaginal irradiation for early-stage disease, with excellent tumor control and preservation of ovarian function.[218] Herbst et al[219] reported on 142 cases of stage I clear cell adenocarcinoma. For the 117 patients treated with radical surgery, there was an 8% risk of recurrence and 87% OS. For patients treated with radiation, there was a 36% risk of recurrence. The authors acknowledge that it is difficult to compare surgery to radiation, as radiation was most likely used in patients with larger lesions less amenable to resection.

A series by Senekjian et al[214] reported on 219 cases of stage I clear cell vaginal adenocarcinoma. Forty-three patients received local therapy alone, consisting of vaginectomy, local excision, or local irradiation with or without excision, and the rest had conventional radical surgery. At 10 years, the actuarial survival rates were equivalent (88% vs 90%) for patients who received local therapy only and those treated conventionally. However, the actuarial recurrence rate was significantly higher (40% vs 13%) with local excision alone. Patients who received local irradiation, with or without local excision, had decreased local recurrence compared to those treated with excision alone ($P < .03$).

A subsequent series by Senekjian et al reviewed 76 cases of stage II clear cell adenocarcinoma.[74] The 10-year OS rate was 65%. The 5-year survival rates were 80% for patients treated with surgery, 87% for patients treated with radiation, and 85% for patients treated with both. The authors advocate treatment with a combination of EBRT and BT for stage II disease, with surgery reserved for smaller, more easily resectable lesions in the upper vagina. The use of pelvic exenteration for primary and recurrent lesions has been reported by Senekjian et al.[129] Survival outcomes were comparable to those of patients treated with other modalities. Thus, to minimize morbidity and preserve quality of life, exenterative approaches are advocated only for patients with disease recurrence after radiation. The 5-year survival rate after pelvic relapse is reported to be 40% by Herbst et al.[213]

Most recurrences occur within 3 years of therapy, although recurrences occurring 10 to 20 years after treatment have been reported.[220] Most recurrences are local or locoregional, with approximately one-third detected at distant sites, most commonly in the lungs or extrapelvic lymph nodes, although there have been rare cases of central nervous system metastases manifesting years after treatment.[221] The 10-year actuarial survival rate for clear cell adenocarcinoma of the vagina is 79%. For stages I and II disease, survival rates are 90% and 80%, respectively.

Other Adenocarcinomas

The majority of adenocarcinomas that present in the vagina are attributed to metastatic spread from other sites. Vaginal metastases from adenocarcinoma of the breast, kidneys, or other gynecologic primary sites have been

described.[222-224] Primary non–clear cell adenocarcinoma of the vagina is extremely rare and occurs predominantly in postmenopausal women. Histologic variants include endometrioid, mucinous, mesonephric, and papillary serous adenocarcinoma. Vaginal endometrioid adenocarcinoma is the most common non–clear cell subtype and presents most often in women with a history of endometriosis. Only a handful of case reports or series have been published in detail about endometrioid adenocarcinoma of the vagina.[225-229] In one series of 18 cases of primary vaginal endometrioid adenocarcinoma,[225] 10 cases arose from the apex. Fourteen out of 18 cases had vaginal endometriosis, important in indicating a primary vaginal tumor rather than secondary spread from the endothelium. The median age at presentation was 57, with a range from 45 to 81 years. There have been case reports of mucinous adenocarcinoma of the vagina,[230-232] with at least one arising from a focus on endocervicosis.[233]

On gross examination, endometrioid adenocarcinomas can be polypoid, papillary, rough, granular, fungating, exophytic, or flat, and most arise from the superior aspect of the vagina. Microscopically, tumors display a predominant component of typical endometrioid carcinoma, with tubular glands lined by columnar cells with moderate amounts of eosinophilic cytoplasm and large elongated nuclei. Only a handful of cases of mucinous adenocarcinoma have been described,[223,230-232] including rare cases arising in neovaginas[234] or arising from endocervicosis.[233] Mesonephric adenocarcinoma arises from mesonephric duct remnants situated in the lateral vaginal wall.[235,236] Primary papillary serous adenocarcinoma of the vagina has rarely been reported.[237]

Lymphoma

Lymphomas of the female genital tract are rare, accounting for only 1% of all primary extranodal lymphomas.[238] Lymphomas of the vagina are exceedingly uncommon, with fewer than 30 cases reported in the literature thus far.[239-252] In one review from the Armed Forces Institute of Pathology, only 4 of 9,500 cases of lymphoma were determined to originate from the vagina.[253] Diffuse large B-cell lymphoma is the most common histology, though there have also been reports of lymphoplasmacytic, Burkitt, and mucosa-associated lymphoid tissue lymphomas.[244]

On examination, tumor is typically palpable, with infiltrative thickening and/or ulceration of the vaginal wall.[251] Immunohistochemical analyses are valuable techniques for confirming the diagnosis, with tumors typically expressing CD20.[245,252] The most common symptom at presentation is vaginal bleeding. Leukemic infiltrates may be difficult to distinguish from lymphoma; therefore, chloroacetate esterase or myeloperoxidase staining may be useful. Though there is no established treatment protocol for primary lymphoma of the vagina, it seems reasonable to extrapolate from results for extranodal lymphomas elsewhere in the body and to use similar chemotherapeutic and response-based radiation regimens. For patients wishing to retain fertility, chemotherapy alone may be an option in select cases.

If diagnosed at an early stage, the prognosis for vaginal lymphoma is excellent, with 5-year survival rates ranging up to 90%. Of 10 cases reported in the literature between 1994 and 2007, all patients, except one, were cured of disease after treatment with chemotherapy or a combination of radiation and chemotherapy.[243,245,249,250,254-257] Follow-up periods for these 10 case reports ranged from 6 to 120 months, and one patient died from other causes. Eight patients had Ann Arbor stage IEA disease, one had IIEA, and one did not have stage reported. The most common chemotherapy regimen was cyclophosphamide, doxorubicin, vincristine, and prednisone. Complete remission was also achieved using methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin in one patient. Half of the patients did not receive radiation because of an excellent response with chemotherapy alone.

Small Cell Carcinoma of the Vagina and Other Rare Histologies

Primary small cell carcinoma of the vagina is an exceedingly rare entity, with fewer than 25 cases reported in the literature.[258] The mean age at diagnosis is 59 years, with poor outcome due to early widespread dissemination. Eighty-five percent of patients die within 1 year of diagnosis.[259,260] Neuroendocrine differentiation is often manifested by secretory granules, argyrophilia, and expression of neuroendocrine markers,[261,262] staining positive for cytokeratin, neuron-specific enolase, chromogranin A, and serotonin. Thyroid transcription factor-1 can also be

positive and should not be used to differentiate primary from metastatic disease.[263] Microscopically, it is indistinguishable from that of the lung. These tumors can occur in pure form or be associated with squamous or glandular elements.[259,261] Ectopic Cushing syndrome has been documented to occur in primary small cell carcinoma of the vagina.[262] Treatment typically follows general principles for small cell carcinomas of the cervix, with aggressive therapy, including combination cisplatin-based chemotherapy, RT, BT, and surgery if feasible indicated.

Vaginal paraganglioma is a rare neuroendocrine tumor, with less than 10 cases reported in the literature in younger women, with median age at presentation of 31 years.[264-266] It is thought to be an indolent tumor, managed surgically. The tumor can manifest with catecholamine secretion, similar to paragangliomas elsewhere in the body.[264]

Adenosquamous carcinoma of the vagina is also uncommon. Microscopically, tumor cells are composed of glandular and squamous elements. One case report described adenosquamous carcinoma associated with small cell carcinoma of the endometrium in a 64-year-old female.[267] Treatment similarly follows general approaches for SCC of the vagina, including consideration of combination chemoradiation for patients with gross disease.

RADIOTHERAPY TECHNIQUES

Definitive treatment of primary vaginal cancer with radiation typically involves a combination of EBRT and BT. The use of 3D-based imaging to guide BT treatment planning is evolving, and recent results for vaginal cancer show excellent outcomes.[81,268,269] Because of advances in CRT, tumor dose can be escalated, whereas the dose to surrounding normal structures, such as small bowel, rectum, bladder, urethra, and the femoral heads, can be minimized. BT can be delivered via intracavitary or interstitial approaches, using LDR or HDR techniques.

External Beam Radiotherapy

In general, when radiation is delivered as primary therapy, EBRT is prescribed prior to or, in rare select cases, without BT for a subset of patients with stage I and all patients with stages II to IVA disease. The

treatment technique, dose prescription, and selection of the appropriate energy level must be individualized for each patient.

At the time of simulation, it may be helpful to identify the distal tumor margin with a radiopaque marker. Unless contraindicated, the use of oral and intravenous contrast can be helpful, allowing delineation of vascular structures and facilitating the contouring of the bladder, small bowel, and rectum. CT simulation allows the contouring of vessels as a surrogate for lymph node localization, allowing more precise and individualized field delineation relative to pelvic bony anatomy.[270] When available, the fusion of diagnostic pelvic MRI or PET-CT to the treatment planning CT can assist in defining the tumor (Figure 79.3). If inguinal nodes are to be treated, a "frog-leg" position to expose the groin region can be considered.

Three-Dimensional Conformal Treatment

The use of 3D imaging for treatment planning has increased dramatically over the past two decades and is currently used at almost all centers for simulation and treatment planning. This allows treatment fields to be tailored to a patient's specific anatomy.

The target volume for EBRT is influenced by diagnostic imaging results and the stage of disease. Treatment fields are designed to ensure coverage of the vagina and internal iliac, external iliac, and obturator lymph nodes. Coverage of the common iliac, para-aortic, and inguinal lymph nodes can be considered depending on the extent of disease and the location of the tumor. A standard field has the L5 to S1 interspace as the superior border, which ensures coverage of retroperitoneal nodes that lie caudal to the common iliac bifurcation.[271] However, because many initial failures occur predominantly in the vagina, paracolpos, and parametria, some authors suggest setting the superior border 1 to 2 cm superior to the inferior margin of the sacroiliac joints in patients with negative imaging of regional nodes, in order to minimize treatment toxicity.[272] If there are positive pelvic lymph nodes, the superior border should be raised to the L4 to L5 interspace or higher in order to cover the common iliac nodes. The inferior border lies at the introitus to ensure coverage of the entire vagina or 4 cm distal to the most caudal aspect of the vaginal tumor. Lateral borders are 1.5 to 2.0 cm lateral to the pelvic brim. Lateral fields, when utilized, should extend

anteriorly to the pubic symphysis and posteriorly to the junction of the S2 to S3 interspace. The border should be extended accordingly to include the inguinal nodes, if warranted. The dose to the inguinal nodes should be calculated during treatment planning, to ensure appropriate coverage. When designing treatment fields, the interconnectivity of vaginal lymph node drainage should be kept in mind. Unexpected nodal drainage is possible and should be considered. In a study of 14 women with vaginal cancer who received pretreatment lymphatic mapping with sentinel lymph node identification, two out of four women with a lesion in the upper one-third of the vagina were found to have a sentinel lymph node in the inguinal region.[71]

Several techniques can be considered when treating the inguinal region, to minimize dose to the femoral heads. An electron boost can be used to raise the inguinal dose to appropriate levels. Alternately, unequally weighted beams (2:1, anteroposterior:posteroanterior [AP:PA]) or a combination of low- and high-energy photons (4-6 MV AP; 15-18 MV PA) can be used. Another method uses a wide AP and a narrow PA field, with a daily photon boost to the inguinal nodes delivered with asymmetric collimator jaws.[273]

The gross tumor volume (GTV) is defined as the extent of gross disease found on clinical examination, as well as palpable lymph nodes and suspicious lymph nodes and regions seen on CT, MRI, and/or PET. The GTV is expanded by 1 to 2 cm to form the clinical target volume (CTV), which also includes the entire length of the vagina, paravaginal tissue up to the pelvic sidewall, and bilateral pelvic lymph nodes. Visualization of vessels allows approximation of lymph node locations. The pelvic nodal CTV can be defined as a 1- to 2-cm margin around blood vessels and should include the common iliac, external iliac, internal iliac, obturator, perirectal, and presacral lymph node regions. For distal vaginal involvement, inguinal lymph nodes are commonly included, with the inferior border set at the lowest aspect of the ischial tuberosity or lesser trochanter. The CTV is expanded by 1 cm to form the planning target volume (PTV). The small bowel, bladder, and rectum are contoured and doses to normal structures calculated.

Standard dose to the pelvis is 45 to 50.4 Gy in 1.8-Gy fractions, followed in select cases by a parametrial boost ranging from 50 to 65 Gy. Elective

nodal irradiation of the inguinal nodes may be delivered to 45 to 50 Gy. Gross nodal disease should receive 60 to 65 Gy, if feasible, using conformal therapy. For clinically palpable inguinal nodes, this can be achieved with reduced portals, using low-energy photons or electrons.

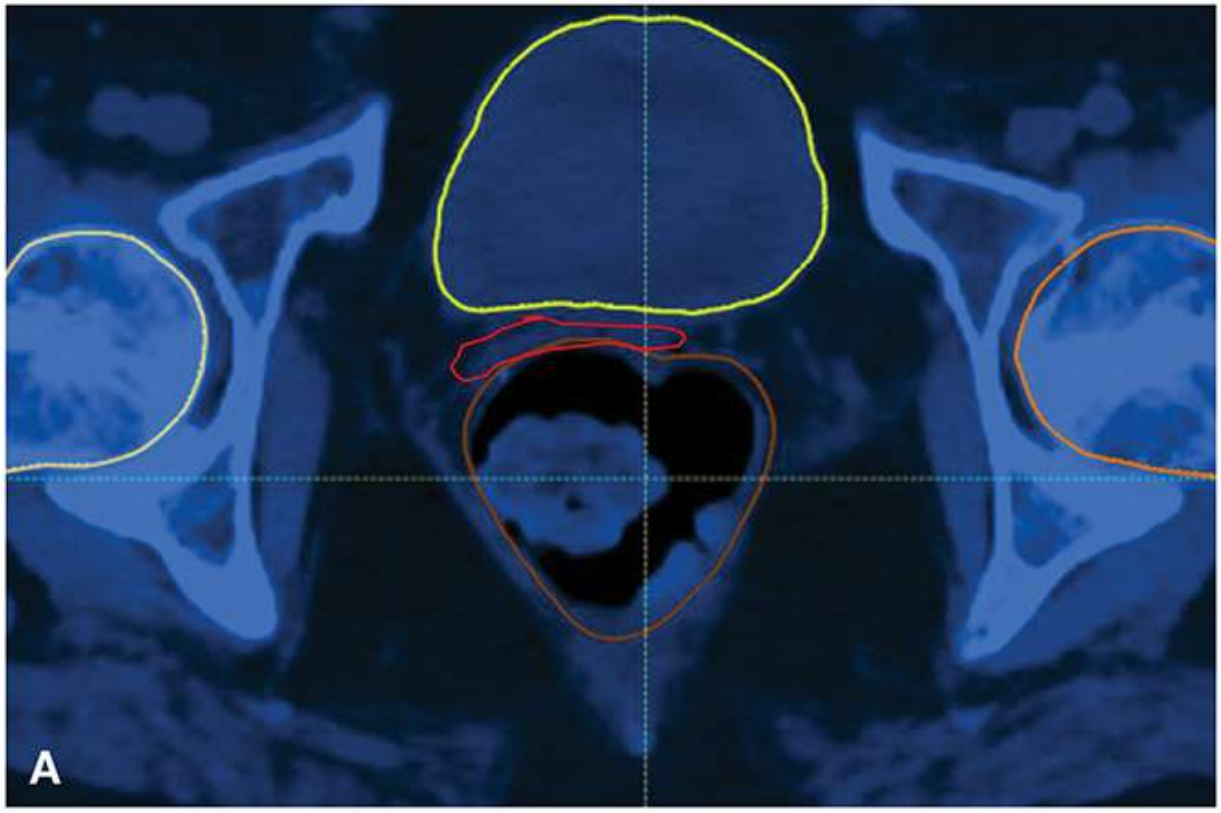
The location of the tumor, size, and extent of disease and treatment response are factors to be taken into consideration when individualizing treatment for each patient. After EBRT to the pelvis, tumors of the vaginal apex greater than 0.5 cm in depth should be considered for interstitial BT or external beam boost; tumors less than 0.5 cm should be treated with ICB. Depending on location, tumors of the midvagina can be treated with external beam boost or considered for freehand interstitial BT, particularly if they are located anteriorly or laterally. Tumors of the distal vagina are also amenable to treatment with interstitial BT, especially if the tumor is relatively confined. In general, BT is delivered upon completion of EBRT and allows dose escalation to the vaginal tumor to 70 to 80 Gy.

Intensity-Modulated Radiation Therapy

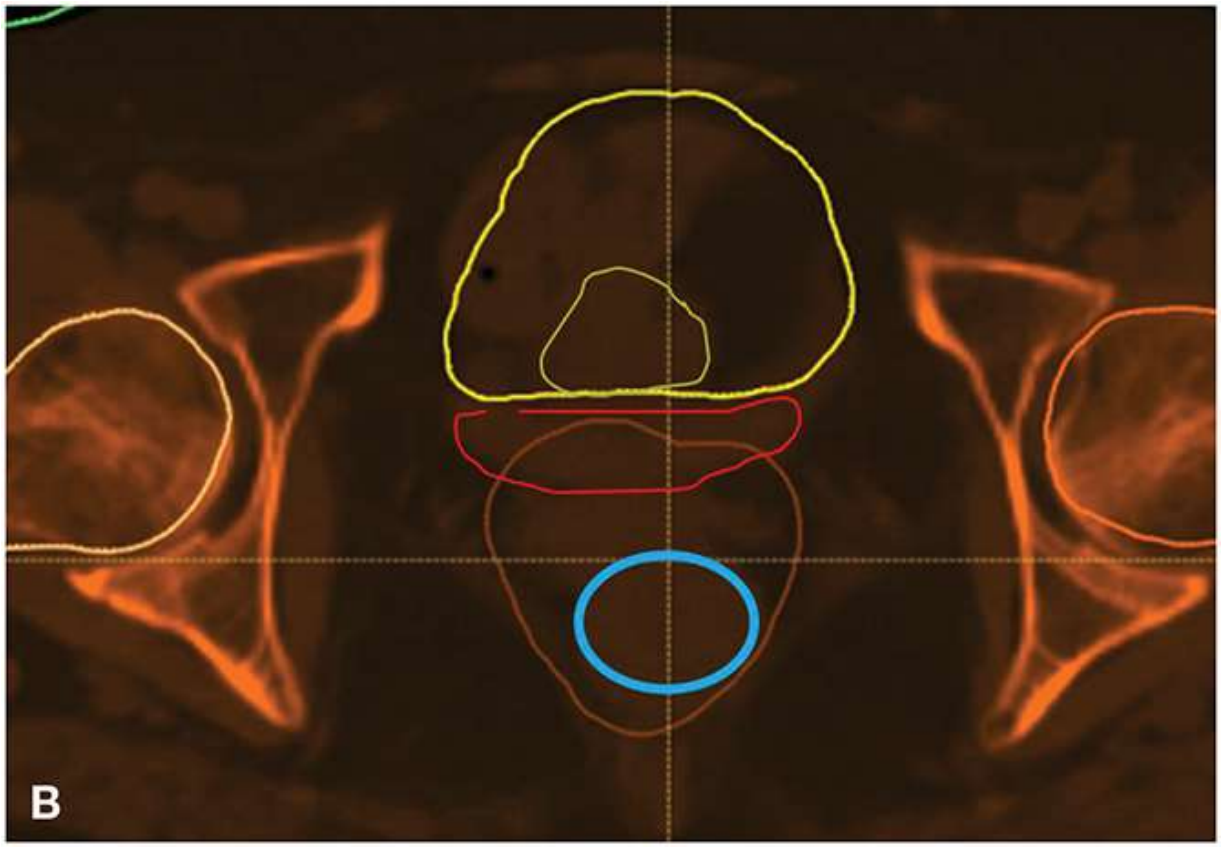
IMRT, which includes volumetric arc therapy, may allow dose escalation to gross disease in areas such as inguinal or pelvic lymph nodes, diffusely infiltrative disease, or sidewall tumors inaccessible to BT. Shrinking field techniques, or IMRT, can be used for dose escalation if BT is not feasible.[274,275] In such circumstances, a total dose of 70 to 75 Gy minimum should be delivered to gross disease. Higher doses are difficult to achieve without substantially increasing the risk of toxicity to adjacent normal tissues, such as the urethra, bladder, and rectum. IMRT input parameters include 30% or less of the bowel to receive 40 Gy or less; 35% or less of the bladder to receive 40 Gy or less; 60% or less of the rectum and sigmoid to receive 40 Gy or less; and the femoral heads 15% to receive 35 Gy or less. The IMRT plans are optimized to minimize the volume of PTV that receives more than 110% of the prescribed dose.[276]

When utilizing IMRT technique, it is important to take into account the possibility of significant shifts in tumor position because of constant normal tissue changes and rapid tumor regression. As a result, we recommend contouring an integrated vaginal volume, which reflects the CTV volume, paying close attention to rectal and bladder filling, and contouring the

position of the vagina with both bladder full and bladder empty (Figure 79.5).[277] A PTV margin of 1 to 2 cm is recommended, given the degree of motion and uncertainties in target definition.



A



B

FIGURE 79.5 A. Bladder and rectum full scan. B. Depiction of the original full contours on the bladder and rectum empty scans showing the movement of the vagina into the rectal volume. Margins of more than 2 cm are required on the vagina to cover the organ when bladder and rectal filling change.

Image-guided RT is also widely used to ensure proper patient and organ positioning, which is particularly useful when treating with IMRT. X-rays prior to each radiation fraction can assist with lining up the patients according to bony anatomy, allowing patients to be shifted in the right-to-left (X), anterior-to-posterior (Y), and superior-to-inferior (Z) dimensions, minimizing the impact of daily patient setup differences. Low-dose cone-beam CTs prior to each radiation fraction can take full advantage of the six degrees of freedom on modern radiation tables, which include yaw, pitch, and roll shifts, in addition to the traditional X-Y-Z shifts. In addition, the use of cone-beam CT during treatment can validate that organ motion has not inadvertently shifted the target outside the treatment volume.

Brachytherapy

The utilization of BT should be considered for all patients with vaginal cancer who are undergoing radiation, unless they are unable to tolerate the procedure. According to a SEER database analysis spanning the years 1974 to 2011, the use of BT as a boost or definitive treatment provided a disease-specific survival and OS benefit across all FIGO stages of primary vaginal cancer.[278] An NCDB study spanning 2004 to 2011 found the use of BT as a boost in vaginal cancer has been declining, however, from 87.7% in 2004 to 68.4% in 2011 ($P < .001$), with an increase in the use of IMRT boost from 4.5% to 23.5%.[279] Treatment at a high-volume facility predicted for greater likelihood of BT as a boost. Given the mobility of the organ during treatment, SBRT is recommended only in the most rare of circumstances, requiring careful placement of fiducials and daily imaging with adaptive planning.

ICB as monotherapy can be considered for patients with VAIN and highly selected patients with minimally invasive stage I disease. In most cases, BT is offered after EBRT to boost the cumulative dose to a minimum of 70 to 80 Gy. Tumor response to EBRT is used to assess suitability for ICB or interstitial BT. In general, patients with superficial disease that is 5

mm in thickness or less can receive intracavitary treatment, whereas thicker lesions require interstitial BT in order to achieve adequate dose coverage. Image-based interstitial BT technique should be utilized to optimize target dose delivery and minimize dose to organs at risk; this has been shown to maximize disease control compared to non–image-based techniques.[280]

Intracavitary Brachytherapy: Low-Dose Rate

ICB can be delivered with LDR or HDR technique. LDR-ICB is most commonly performed using a vaginal cylinder loaded with cesium-137 radioactive sources. LDR remote control afterloading can be utilized to minimize radiation exposure to hospital personnel.

A variety of vaginal applicators are available, such as Burnett, Bloedorn, Delclos,[281] or MIRALVA.[282,283] Some cylinders have lead shielding to protect regions of the vagina, bladder, and rectum. Most applicators come in different diameters, and the largest diameter cylinder that can be comfortably accommodated by the patient should be used to improve the ratio of mucosa to tumor dose.

Typically, two to three cesium sources are placed along the central tandem of the cylinder, and labia are sutured closed to secure the implant during the treatment. To minimize skin toxicity, it is important to avoid placing a source over the vulva. With appropriate selection of dose specification points, a uniform dose distribution can be achieved over the entire length of the vagina. In cases where disease is localized to the upper vagina or vaginal fornices, an intrauterine tandem can be used to anchor the vaginal cylinder or be used with vaginal colpostats. Vaginal colpostats alone can be used to treat the upper vagina. Some institutions report good results using custom vaginal molds.[284]

A retrospective series by Pingley et al[106] reported their experience treating 134 women with primary vaginal cancer ranging from stage I to IV; ICB was delivered using the LDR technique. Only the 75 patients who completed treatment were analyzed. Most patients received EBRT to 50 Gy, and 59 of 75 patients received subsequent BT (30 with LDR-ICB, 29 interstitial). The 5-year DFS rate was 53% for patients treated with LDR-ICB and 30% for patients who did not receive BT. Patients who received BT within 4 weeks of EBRT had a DFS rate of 60%, compared to 30% in

those who did not, suggesting that a shorter interval between EBRT and BT is preferable.

Intracavitary Brachytherapy: High-Dose Rate

HDR-ICB is typically performed using iridium-192, with applicators that are similar to those described for LDR. HDR-ICB delivers treatment over a span of several minutes and has the potential advantages of limiting exposure to caregivers, as well as the ability to optimize dose distribution through varying dwell times.[285,286] The largest cylinder that a patient can comfortably tolerate should be selected.

Compared to LDR radiation, there is theoretically less potential sublethal damage repair and thus an increased likelihood of normal tissue toxicity. However, this has not been demonstrated in vaginal cancer, nor in cervical cancer, where multiple prospective and retrospective studies have failed to note any significant difference in local control, survival, or toxicity outcomes between HDR BT and LDR BT.[287]

Several single-institution studies have reported their outcomes for HDR BT. The largest series of HDR BT for vaginal cancer is from Vienna by Mock et al[57] and reported on 86 patients. Patients with stage 0 to stage II disease received treatment with HDR-ICB alone (n = 26). Prescribed dose per fraction ranged from 5 to 8 Gy, with a mean dose of 7 Gy, and the number of insertions ranged from 2 to 6, with a median of 5. In that series, the 5-year recurrence-free survival rates were 100%, 77%, and 50% for stages 0, I, and II, respectively. The authors noted similar local failure rates for HDR BT administered with or without EBRT, for both stage I and II diseases. Treatment was well tolerated.

Kucera et al[288] described their experience with 80 patients who received treatment with HDR-ICB, with or without EBRT. Compared to a historical group of patients treated with LDR-ICB, with or without EBRT, no significant differences were noted for local and distant recurrences or rate of complications. Three-year actuarial OS and disease-specific survival rates were 51% and 61%, respectively. Three-year disease-specific survival rates for stage I and stage II patients were 83% and 66%, respectively.

Stock et al[93] reported results for 49 patients treated with primary carcinoma of the vagina. Of this group, 15 patients were treated with EBRT

and HDR BT for vaginal carcinoma, with dose per treatment ranging from 3 to 8 Gy. The total median dose delivered via HDR was 21 Gy, and the total median tumor dose overall was 63 Gy. No significant difference in outcome was noted between patients treated with LDR versus HDR. Five-year actuarial survival was reported to be 50% in the HDR BT group. In comparison, the 5-year survival rate for patients who received EBRT alone ($n - 11$) was 9% ($P < .001$), with a higher rate of stage IV disease in the EBRT-alone group (36%) compared to the BT group (5%).

The use of image-based HDR-ICB was reported by Vargo et al,[122] in a series of 41 patients with vaginal cancer treated with chemotherapy and definitive radiation with image-based multichannel vaginal cylinder HDR BT. CT (41%) or MRI (59%) was used for each fraction, and high-risk CTV (HRCTV) drawn. The median dose to 90% of the HRCTV was 77.1 Gy (equivalent dose of 2 Gy per fraction), and outcomes were favorable, with 2-year local, regional, and distant control of 93%, 100%, and 81%, respectively. There was 4% grade 3 or higher toxicity at 2 years.

Among 148 patients with vaginal cancer from five separate institutions reported by Westerveld et al, 67 of these patients had ICB using image guidance with MRI or CT, with the remainder receiving interstitial BT.[125] For the entire cohort, the median dose to 90% of the CTV was 80 Gy (equivalent dose of 2 Gy per fractions), with 5-year local and pelvic control of 83% and 79%, respectively, and 5-year DFS and OS of 66% and 68%, respectively.

Interstitial Brachytherapy

According to the American Brachytherapy Society Consensus Guidelines for interstitial BT for vaginal cancer, any lesions greater than 5 mm in thickness after EBRT should be considered for interstitial BT, and image guidance is recommended to minimize dose to normal organs and optimize dose to the target volume.[123] Any paravaginal extension at the time of diagnosis, regardless of treatment response, merits consideration of interstitial BT, as a vaginal cylinder is unable to deliver sufficient coverage to this region. Other candidates for interstitial BT include patients with lesions thicker than 5 mm, distal vaginal extension, or those with a vagina that is unable to accommodate standard intracavitary applicators. When

possible, image-based interstitial BT should be utilized, as outcomes are superior to non–image-based techniques.[280] Further details of the procedure and planning are detailed later.

Preoperative Assessment

When determining tumor thickness, MRI is superior to other imaging modalities. T1 with gadolinium and T2-weighted MRI should be obtained if possible after EBRT to assess residual disease.[121] Contrast, such as ultrasound gel placed to distend the vagina, may also aid in visualization of the tumor. Clinical examination provides an imprecise estimate of tumor thickness. An examination under anesthesia can be performed after EBRT; placement of gold fiducial markers can be considered to mark the proximal and distal end of residual disease. The use of a radiopaque marker in the vagina placed at the time of diagnosis and after external beam will facilitate assessment of the lesion on CT imaging.

The patient should be assessed for general, epidural, or spinal anesthesia. When feasible, a combination of general anesthesia during the insertion followed by an epidural patient-controlled anesthesia approach that continues during the entire inpatient hospitalization maximizes pain relief. Epidural anesthesia allows the patient to control the degree of pelvic anesthesia while avoiding the systemic effects, somnolence, and potential mental status changes that may occur with a peripheral patient-controlled anesthesia device. Patients with a history of laminectomy, significant degenerative disease, or labile blood pressure are suboptimal candidates for epidural anesthesia.

Patients on anticoagulation with medications such as warfarin should switch to low-molecular-weight (LMR) heparin approximately 1 week prior to the procedure, and LMR heparin may be discontinued 24 to 48 hours prior to insertion time and be withheld during the duration of the implant, though subcutaneous heparin for thrombosis prophylaxis may be initiated after the procedure is completed. The need for therapeutic levels of anticoagulation may also play a role in deciding if patients can receive epidural or spinal anesthesia.

Particularly if patients receive concurrent chemotherapy prior to their implant, it is important to monitor their blood counts, particularly their

absolute neutrophil count and platelets. As with other procedures and surgeries, it is preferable to have an absolutely neutrophil count greater than 500/μL and platelets greater than 40,000/μL in order to minimize the risk of infection or bleeding. Patients may have a gentle bowel preparation orally or an enema before the procedure.

Applicator Selection

Template systems are available to secure the position of the needles in the target volumes and include the Syed-Neblett template, the modified Syed-Neblett, and the Martinez Universal Perineal Interstitial Template.[289] These systems consist of a perineal template, a vaginal cylindrical obturator, and hollow guides for loading radionuclide sources. The perineal template requires suturing to the perineal skin. The vaginal obturator allows for the placement of a tandem, making it possible to combine interstitial with intracavitary treatment if desired. Lower vaginal tumors may be suitable for freehand technique, if the mass can be readily visualized and palpated.

Procedure

The insertion procedure is performed with the patient in a dorsal lithotomy position. A sterile setup is used at the time of insertion. A Foley catheter is placed for bladder drainage. A digital and speculum examination allows assessment of vaginal width, tumor size and location, amount and thickness of residual parametrial or paravaginal disease, and presence of any fistulas. For patients with an intact uterus, a central tandem may be inserted to anchor the applicator. A vaginal central plastic cylinder is placed over the tandem and secured. The template, which contains multiple openings through which needles can be inserted, is placed onto the perineum. The tumor volume is implanted by inserting the needles through the holes of the template, with the goal of covering the GTV with a 1- to 2-cm margin, utilizing 3D imaging afterward to confirm proper needle location and uniform dose distribution around the tumor volume. Generally speaking, needles should extend approximately 5 to 10 mm past the disease, with 5 to 10 mm between each needle.[121] The physician should be mindful that slight needle displacement can occur when legs are lowered back to the supine position.

When possible, utilizing image guidance to perform implants is ideal in order to improve target localization and guide needle placement. Available modalities include laparoscopic guidance, ultrasound, CT, and MRI. The results with these various techniques are summarized below.

Several investigators have used laparoscopic guidance or laparotomy[290-292] to improve the accuracy and safety of interstitial implant placement. With open laparotomy, the bladder and urethra can be visualized during needle placement. The bladder and rectum can be protected either by using slings or tissue expanders or by lysis of adhesions. Disaia and Creasman[293] described the creation of an "omental carpet," where a section of omentum is placed along the descending colon into the pelvis in order to separate the bladder and rectum from the implant and prevent small-bowel adhesions. If laparotomy is performed in a two-application course of treatment, it is typically done for the first application only. As expected, there is higher associated morbidity with the use of laparotomy compared to other techniques, as a result of increased operative time, longer postoperative recovery, risk of bleeding, and ileus.

Laparoscopic visualization is an alternative to open laparotomy that has also been reported. Though laparoscopy is less invasive, both laparoscopic approaches and open laparotomy are limited by an inability to visualize extraperitoneal structures, such as parts of the bladder, uterus, and cervix, as well as the vagina and paravaginal tissues. However, these techniques can be considered when CT or MRI is not available during BT, to avoid needle insertion through the small bowel and sigmoid.

Stock et al reported results using real-time transrectal ultrasound as visualization.[290] The ultrasound probe was brought into close proximity to the vagina, parametria, and cervix, and the longitudinal mode of the ultrasound probe was useful in determining the optimum depth of needle insertion. Transverse imaging was utilized during the procedure to ensure coverage of the target area and avoid entry into the bladder, rectum, or small bowel. Using this technique, invasive laparotomy or laparoscopy was able to be avoided.

In general, temporary implants are preferred to permanent implants because of their relative safety/simplicity, cost-effectiveness, easy applicability, readily controlled distribution of sources, and easier modification of dose distribution. HDR interstitial BT has the advantage of

limiting exposure to caregivers and visitors and offers the ability to optimize dose distribution using 3D image-based treatment planning.[268,286] The use of permanent radioactive implants using gold-198 or iodine-125 has also been reported for smaller volume disease[294] and can be considered for select patients; reports suggest long-lasting control can be achieved with appropriate selection of patients.

Image-Guided Brachytherapy

The use of 3D imaging during HDR BT has increased with the rise of CT and MR availability and has been a favored approach when available because of lower morbidity and invasiveness compared to historical approaches.[295] Only a few institutions have access to real-time image guidance during BT[145,296]; most scan patients after insertion is complete, with subsequent readjustment as needed. It is not feasible at many institutions to obtain an MRI at the time of BT. A diagnostic MRI obtained after EBRT prior to BT can be used instead to assist with treatment planning. MRI provides superior tumor delineation, whereas CT images can cause overestimation of tumor extension.[297]

The integration of 3D imaging during the BT procedure allows determination of depth and location of insertion and enables repositioning if perforation into the bladder or rectum is detected. Treatment planning based on 3D imaging allows high dose to be delivered to the tumor volume while sparing critical adjacent organs. The use of 3D image–based HDR BT has been shown to improve local control and decrease treatment-related toxicities.[125,280,298] There are fewer published reports on 3D HDR BT for primary vaginal cancer, but results suggest similar outcomes.[269,280]

Dosimetry

Given the close proximity of the rectum and bladder, it is important to minimize treatment toxicity by avoiding overdose of critical normal structures. However, underdosing the target volume is also a serious risk; thus, it is critical to optimize target localization and needle placement.[299]

Vaginal cancer with gross residual disease at the time of BT is prescribed a cumulative EQD2 dose of 70 to 90 Gy, with 60 Gy prescribed to the entire vaginal surface. Special care should be taken to minimize the dose to the

bowel, which often lies in close proximity to gross disease. Image-based planning software, when available, allows the dose to conform to the target areas while avoiding organs at risk. As a result, optimal dose distribution can be achieved. Image-guided technique should be utilized when possible to reduce toxicity and improve local control.

Proposed dose schedules for HDR interstitial BT, depending on dose of initial EBRT, have been released by the American Brachytherapy Society[123] (Table 79.7). The number of fractions ranges from 3 to 10, with the goal of delivering a total EQD2 of over 70 Gy to the CTV. Given the difficulty of insertion, physicians may insert the applicator once and treat patients over a several-day inpatient hospitalization. Twice-a-day (BID) regimens range from 9 to 10 fractions of 200 to 300 cGy per fraction, BID, or 3 to 6 fractions, ranging from 450 to 650 cGy, BID, with at least 6 hours between fractions. It is also feasible to perform two separate insertions with two hospitalizations required.

TABLE 79.7 DOSE SCHEDULES FOR HDR INTERSTITIAL BRACHYTHERAPY IN COMBINATION WITH EBRT, AS PROPOSED BY THE AMERICAN BRACHYTHERAPY SOCIETY CONSENSUS GUIDELINES FOR INTERSTITIAL BRACHYTHERAPY FOR VAGINAL CANCER

EBRT		HDR		EQD2
Total Dose (Gy)	**# Fx**	**Dose per Fx (Gy)**	**# Fx**	**CTV**
36[a]	18	5.0	6	72.9
		5.5	6	87
39.6[a]	22	5.0	6	76.4
		5.5	6	81.5
45	25	3.0	9	73.6
		3.0	10	76.8
		4.5	5	71.5
		5.0	5	75.5
		5.5	5	79.8
		7.0	3	74.1
50.4	28	4.0	5	72.9

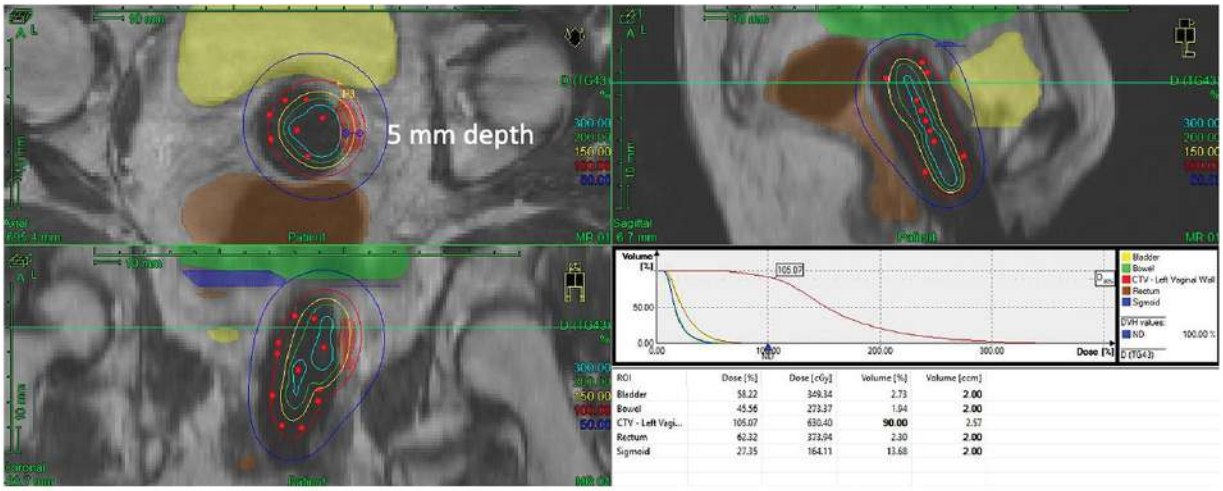
EBRT		HDR		EQD2
Total Dose (Gy)	# Fx	Dose per Fx (Gy)	# Fx	CTV
		4.5	5	76.8
		5.0	5	80.9
		7.0	3	79.4

CTV, clinical target volume; EBRT, external beam radiation therapy; EQD2, equivalent dose in 2-Gy fractions; fx, fractions; HDR, high-dose rate.

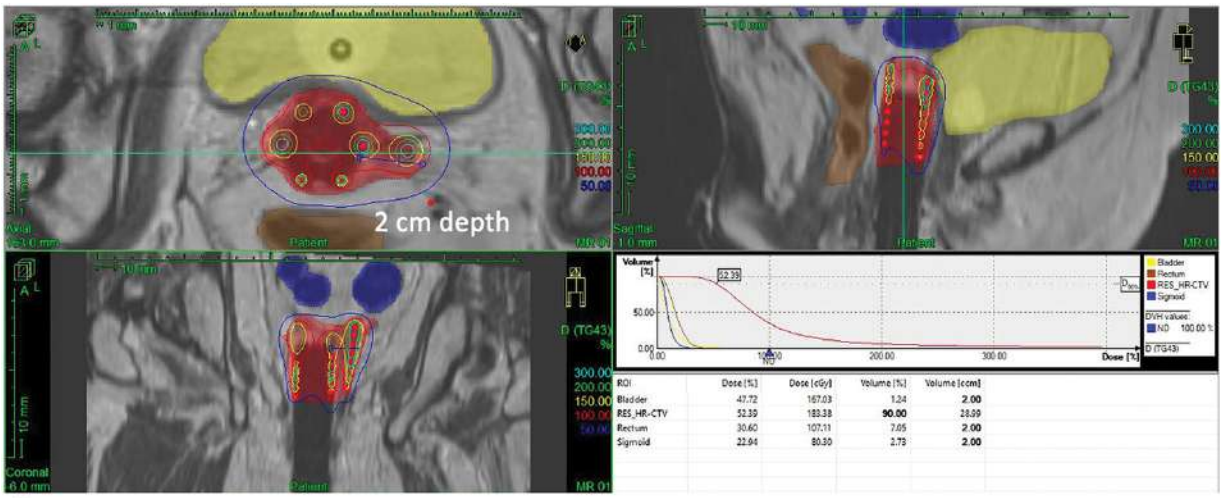
[a]Assumes midline block after 36 to 39.6 Gy, with total pelvic dose to 50.4 Gy.

Modified from Beriwal S, Demanes DJ, Erickson B, et al. American Brachytherapy Society consensus guidelines for interstitial brachytherapy for vaginal cancer. *Brachytherapy*. 2012;11(1):68-75. Copyright © 2012 American Brachytherapy Society. With permission.

For CT- or MRI-based 3D treatment planning, the D_{90}, D_{100}, V_{100}, V_{150}, and V_{200} are parameters used to describe tumor volumes and the doses to those volumes. D_{90} and D_{100} are defined as the minimum dose delivered to 90% and 100% of the volume, respectively. V_{100}, V_{150}, and V_{200} are defined as the volumes receiving 100%, 150%, and 200% of the prescribed physical dose, respectively.[300] Figure 79.6 depicts a representative isodose distribution comparing multichannel vaginal cylinder for a lesion less than 5 mm in depth versus interstitial BT for a mass greater than 5 mm in depth.



A



B

FIGURE 79.6 Comparison of a multichannel vaginal cylinder versus interstitial implant for vaginal cancer in the upper one-third of the vagina. A. Gross tumor volume (GTV) in red at less than 5-mm depth covered with 100% isodose whereas the entire vagina receives 50% of prescription. B. GTV in red with disease in the left fornix extending over 2 cm and inferiorly to the upper one-third of the vagina. The entire vagina is covered with 50% of the prescribed dose.

When MRI-guided adaptive BT is utilized, the HRCTV is defined as a clinically palpable disease, plus any residual disease seen on MRI, and the entire circumference of the adjacent vagina at the level of the residual tumor. The intermediate-risk CTV (IRCTV) includes the region of initial tumor extension and the remaining vagina, in order to encompass potential submucosal tumor spread. The low-risk CTV (LRCTV) is the remaining vagina.

The bladder, rectum, sigmoid, urethra, and small bowel are contoured as volumes at risk, and the D_{2cc} and $D_{0.1cc}$ are calculated.[317] The recommended maximum EQD2 D_{2cc} to the rectum and sigmoid is 65 to 75 Gy and should be less than 65 Gy when feasible.[143] Maximum EQD2 D_{2cc} for the bladder should be 80 to 90 Gy based on cervical cancer dose limits. There are no dose-volume histogram parameters specific to the female urethra, but in general, the D_{2cc} should be comparable to the parameters for the bladder and rectum. The small-bowel dose can be limited with the use of a full bladder; some institutions limit the EQD2 maximum point dose to 60 to 65 Gy.[141] The actuarial rates of grade 3 to 4 complications at 2 years were 20% gastrointestinal, 9% vaginal, 6% skin, 3% musculoskeletal, and 2% lymphatic in 51 women undergoing HDR 3D-planned interstitial BT,[136] with median D_{2cc} for the bladder, rectum, and sigmoid were 64.6, 61.0, and 51.9 Gy, respectively. The D_{2cc} for the rectum was significantly higher in patients with grade 2 or more gastrointestinal toxicity.

Precautions for Interstitial Patients

Appropriate measures should be taken to reduce the likelihood of needle displacement during hospitalization. Patients should be instructed to remain in bed, with head of the bed raised no more than 15 degrees. To ensure there has been no needle displacement between fractions, the needle length protruding the template can be measured and validated prior to every treatment.

Skin care is also critical. Given the risk of decubitus ulcer, it is advisable to utilize an air mattress, when available. Careful rolling of the patient and placement of foam or pillows to change contact points with the mattress can be used to decrease the risk of pressure ulcers. To minimize skin abrasion, gauze or Duoderm can be placed between the template and perineal skin.

To prevent the development of a deep vein thrombosis, patients should receive subcutaneous heparin and pneumoboots.

Patients should be seen in follow-up 2 to 4 weeks after implant removal for a skin check, then at 3-month intervals up to a year, and then every 6 months. Dilute hydrogen peroxide douching is advised for patients with tissue necrosis development. Antibiotics with anaerobic coverage are

recommended if a malodorous discharge accompanies the necrosis. Hyperbaric oxygen should be considered for those that have been proven on biopsy not to have recurrent disease.

Outcomes With Interstitial Technique

There are only a handful of series describing outcomes for vaginal cancer treated with interstitial BT. They are summarized later.

The use of MRI-guided adaptive BT in locally advanced vaginal cancer was reported by Dimopoulos et al[301] with excellent outcomes, supporting the use of the following parameters for IGABT: for HRCTV, D_{90} of 85 Gy or more; for IRCTV, D_{90} approximately 60 Gy; and for LRCTV, D_{90} of approximately 50 Gy. Thirteen patients with stages II to IV disease were treated. Mean D_{2cc} doses to the bladder, urethra, rectum, and sigmoid colon were 80, 76, 70, and 60 Gy, respectively. Toxicity was acceptable, with two fistulas reported and one case of periurethral necrosis. The 3-year local control and OS rates were 92% and 85%, respectively, with a mean D_{90} to the HRCTV of 86 (±13) Gy. Consistent with these promising outcomes, image-guided interstitial BT results were reported by Manuel et al,[280] with 2-year local control, DFS, and OS of 93%, 86%, and 82%, respectively, in their cohort of 72 patients. Patients were treated with image-guided (n = 50) or non–image-guided (n = 25) technique treated during the time period of 1973 to 2014.[269] With the use of image-guided technique, there was a trend toward improved DFS (2-year DFS 77% vs 42%; P = .072), improved OS (84% vs 47%; P = .26), and decreased gastrointestinal and genitourinary toxicity, supporting the incorporation of CT and/or MRI as image guidance when available.

Kushner et al[302] reported outcomes of HDR BT in 19 patients with primary vaginal cancer. 2D treatment planning was performed, with interstitial BT delivered to eight patients at a median dose of 23 Gy in four fractions. The 2-year OS rate for patients for all patients was 66.1%. Three patients (15.8%) had serious late effects, including ureteral stenosis, vaginal necrosis, and small-bowel obstruction; two of these patients were treated with interstitial BT.

A series by Tewari et al[303] reviewed long-term results using interstitial BT, with or without EBRT, in 71 patients with primary vaginal cancer. A

Syed-Neblett template was used with an interstitial iridium-192 after loading technique. Patients received a minimum of 20 Gy via implant, with a total tumor dose of approximately 80 Gy. With a median follow-up time of 66 months, 5-year DFS rates were reported to be 100%, 60%, 61%, 30%, and 0% for stages I, IIA, IIB, III, and IV patients, respectively. Significant complications were noted in 13% of patients and included necrosis, fistula, and small-bowel obstruction. Overall, 75% of patients achieved local control.

Beriwal et al describe results using 3D image–based HDR interstitial BT[268] at the University of Pittsburgh Cancer Institute. A total of 30 patients with primary vaginal cancer (n = 17) or recurrent gynecologic cancer to the vagina (n = 13) were treated using the Syed-Neblett template, with a CT scan done after the placement of needles for confirmation and treatment planning. Of the subset of 17 patients with primary vaginal cancer, the number of patients with stage I, II, III, and IVA disease were 2, 9, 5, and 1, respectively. Fifty-three percent of patients received concurrent chemotherapy with weekly cisplatin at 40 mg/m^2, and apical lesions had laparoscopic guidance during needle placement. The CTV and organs at risk were contoured on a CT scan for treatment planning after the placement of needles. Most patients (93.3%) received EBRT to a median dose of 45 Gy, followed by HDR interstitial BT at 3.75 to 5 Gy per fraction in five fractions to a median dose of 21.3 Gy. Overall median D90 to the HRCTV was 74.3 Gy, and median D_{2cc} to the bladder, rectum, and sigmoid were 58.5, 57.2, and 50 Gy, respectively, showing excellent sparing of critical organs. At a median follow-up time of 16.7 months, the 2-year locoregional control and OS rates were 78.8% and 70.2%, respectively, suggesting good local control. Overall, the treatment was fairly well tolerated. There were no grade 3 or higher gastrointestinal complications. One patient developed late grade 3 vaginal ulceration, and another had grade 4 vaginal necrosis.

Westerveld et al reported 148 patients with vaginal cancer of all stages from five institutions, of which 81 received interstitial BT as part of their treatment.[125] The vast majority (145 patients) had EBRT prior to BT, and 64% had concurrent cisplatin. For the entire cohort, the median dose to 90% of the CTV was 80 Gy (equivalent dose of 2 Gy per fractions), with 5-year local and pelvic control of 83% and 79%, respectively, and 5-year DFS and

OS of 66% and 68%, respectively. Morbidity was acceptable, with 25 patients developing grade 3 or higher toxicity, including one grade 4 event, which was a life-threatening vesicovaginal fistula in the setting of reirradiation. There were no grade 5 toxicities.

Brachytherapy Versus External Beam Boost

In select circumstances when patients are not appropriate candidates for BT, IMRT can be considered an alternative for boost to residual gross disease. A retrospective dosimetric analysis from Princess Margaret Hospital[304] reported data comparing IMRT boost treatment plans with conventional and four-field radiation boost plans for 12 patients with cervical (n = 8), endometrial (n = 2), or vaginal (n = 2) cancer. IMRT conferred a significant improvement in dose conformity, with an overall improvement in rectal and bladder dose-volume distributions, relative to conformal radiation, though inferior to BT. However, when comparing an ideal photon or proton external beam boost to BT, BT provided the best coverage and normal tissue sparing.[305]

Barraclough, et al[306] used an EBRT boost in 21 patients with cervical cancer who could not undergo ICB. A 3D conformal boost was used to deliver a total dose of 54 to 70 Gy. With a median follow-up time of 2.3 years, 48% of patients had recurrent disease, with central recurrence in 16 of 21 patients, significantly higher than 3% to 4% local recurrence rates reported with MR-planned BT. These results are dramatically inferior to those reported with BT, suggesting that external beam boosts should only be considered an alternative when BT is not feasible.

SBRT is a relatively newer treatment modality with very little data to support its use. A review by Higginson et al[307] reported on two patients with vaginal cancer treated with an SBRT boost instead of BT. Fiducials were placed into the paravaginal, parametrial, or cervical tissues during outpatient clinical examination. The two patients with vaginal cancer received 40 to 45 Gy EBRT followed by 25 Gy in five fractions of SBRT; one patient had a local recurrence at 5 months, and another developed distant disease 17 months post-treatment. Toxicity included one acute grade 2 cystitis and one late grade 3 rectal bleeding.

Treatment Toxicity and Management

Acute Toxicity

The bladder and rectum are located in close proximity to the vagina, and it is common for patients to develop acute bowel and urinary toxicity during treatment.[308] Increased urinary frequency, urgency, and dysuria can be managed with phenazopyridine, a urinary tract analgesic, as well as oral anticholinergic and antispasmodic medications. Antidiarrheal medications such as loperamide, or in more severe cases, tincture of opium, should be prescribed for symptom management early in the development of symptoms. Irritation of the anal mucosa can cause exacerbation of hemorrhoids and occasional hemorrhagic spotting and discomfort with defecation; topical hemorrhoidal ointments or suppositories can be used.

Acute irritation of the vaginal mucosa can be managed symptomatically through hygiene, recognition and treatment of infection, and pain control. Sitz baths and topical ointments may be useful for radiation dermatitis, and both topical and oral analgesics can be prescribed for mucositis and general discomfort during radiation and immediately thereafter. As *Candida* can exacerbate vaginitis, there should be a low threshold for starting antifungal medications.

Late Toxicity

Late toxicity after radiation can manifest as rectovaginal or vesicovaginal fistulas, strictures in the rectum or vagina, premature menopause from radiation exposure to the ovaries, or cystitis, proctitis, or necrosis of the soft tissue or bone.

Clinically, vaginal stenosis and shortening can manifest several months after radiation, although presentation as late as 15 years post-treatment has been documented.[309] Pathologic changes in the vaginal mucosa after radiation treatment include marked mucosal atrophy with epithelial thinning and loss of the overlying stratified squamous layer. There can be hyalinization and collagenization of submucosal connective tissues, with fibrosis of the muscular layer and vasculature. Such changes result in compromised oxygenation of injured tissues, promoting ulceration and fistula formation. It is common to find cytologic abnormalities within the first 6 months after radiation, and it is important to distinguish postradiation

atypia from new or recurrent malignancy during post-treatment follow-up.[310]

Regular use of a vaginal dilator to decrease stenosis and shortening should be recommended shortly after completion of radiation treatment, as it is difficult to reverse stenosis and shortening once fibrosis has ensued. Without the use of a vaginal dilator, complete agglutination or vaginal obliteration can occur. Topical estrogen, applied 3 times a week for 6 to 9 months after radiation, was shown in a randomized controlled trial published in 1975 to reduce the incidence of stenosis, dyspareunia, and cytologic changes in vaginal epithelium.[311] However, due to a small potential for systemic absorption with untoward effects on endometrial proliferation, the use of topical estrogens is not favored for patients.

Radiation necrosis can be conservatively managed with local debridement, peroxide douches, antimicrobials, and estrogen. There is some evidence that hyperbaric oxygen can facilitate healing, with a more than 50% reduction in vaginal ulceration noted in one series.[312] Fistulas present more of a treatment challenge. Despite the use of interventions such as urinary or fecal diversions, additional surgical correction is often required for effective management, particularly in the case of rectovaginal fistulas.[313]

PATTERNS OF FAILURE

Most treatment failures occur within 5 years, with a median time to recurrence of 6 to 12 months,[62,146] and local recurrence is the most common pattern of treatment failure in the majority of published series. Extravaginal recurrences in the pelvic lymph nodes are less common.

Overall outcomes, by stage, are shown in Table 79.5. In general, the rate of locoregional recurrence ranges from 10% to 20% for stage I and 30% to 40% for stage II. Patients with advanced disease often have persistent disease despite treatment, up to 68% according to one series.[105] The reported rates of distant metastasis vary, ranging from 7% to 33%, and usually occur later in the course of disease, with approximately half of all distant metastases presenting at the time of local recurrence.[67,87,105,147]

GENERAL MANAGEMENT, TREATMENT OPTIONS, AND OUTCOMES: SPECIAL SCENARIOS

The Posthysterectomy Patient

Approximately 60% of patients with primary vaginal cancer have had a prior hysterectomy. This likely reflects patients with a history of cervical neoplasia and carcinoma requiring surgical management.[314,315] Finding methods to improve target positioning during EBRT becomes especially important as treatment delivery becomes increasingly more conformal.

After hysterectomy, the small bowel tends to fall lower into the pelvis, increasing the likelihood of it being irradiated during treatment. There is also daily variation in vaginal vault position. A study by Jhingran et al[277] evaluated the variations in vaginal vault position and bladder and rectal volumes in posthysterectomy patients undergoing IMRT and found significant variations in the position of the vaginal vault depending on bladder and rectal filling. Patients were instructed to have a full bladder prior to radiation treatment; however, the study showed a median difference of 247 mL despite this. It is likely that bladder movement impacts vaginal position. For patients with fiducial markers placed in the vagina, the median movement during treatment was 0.59 cm in the right-left direction, 1.46 cm in the AP direction, and 1.2 cm in the superior-inferior direction. Thus, it is important to be mindful of target movement when delineating the treatment volume.

To minimize uncertainly, the treating physician can fuse planning CT scans taken with full and empty bladder in order to estimate the potential range of target volume positions during treatment. Another approach, though less practical, is to fill the bladder with a fixed volume of saline using a Foley catheter immediately prior to treatment or to utilize fiducial markers for daily localization.

History of Prior Pelvic Radiation

Up to 10% to 50% of patients with VAIN or invasive carcinoma of the vagina have a previous diagnosis of cervical carcinoma,[13,59,61,67,84-88] with average time interval of 14 years between diagnosis of cervical disease to the development of vaginal carcinoma.[61,72] As a result, a proportion of patients with vaginal cancer have a history of prior pelvic radiation. Reirradiation can be considered in this setting, but there is an increased risk of toxicity, particularly radionecrosis and fistula formation. Xiang et al[316]

published a series on 73 patients with a history of radiation treatment for cervical carcinoma who received a second diagnosis of vaginal malignancy 5 to 30 years later. All patients received EBRT and BT for the treatment of their initial cancer. Reirradiation for the vaginal malignancy was planned according to the site and volume of the vaginal tumor and the location and dose of the prior radiation. Patients received BT, using either radium delivered to the tumor base (30-40 Gy in three to five fractions) or HDR with cobalt-60 to the tumor base (20-35 Gy in three to five fractions), followed by a dose to 0.5 cm below the vaginal mucosa at 20 to 30 Gy in four to six fractions delivered using a vaginal mold. For involvement of the vulva or groin, patients additionally received EBRT to a dose of 30 to 40 Gy. Most patients received radiation alone; 11 also received chemotherapy, most typically cisplatin based. The 5-year survival rate was 40.3%, and three patients survived more than 15 years. There were significant side effects with reirradiation: 18 of 73 patients developed radionecrosis. Other side effects included one (1.4%) vesicovaginal fistula and eight (11%) rectovaginal fistulas, hematuria (12.3%), and moderate-to-severe rectal sequelae (13.6%).

Beriwal et al reported on the use of HDR interstitial and ICB for five patients with recurrent vaginal cancer with a history of prior pelvic radiation.[317] Significant grade 3 or higher toxicities were noted in patients who received a total EQD2 dose above 140 Gy. The median time from prior radiation to recurrence was 4 years (range, 6 months to 18 years). The recurrence was within 2 cm of the prior field in two patients and within the previous field in four patients. All patients received EBRT to a median dose of 45 Gy, followed by BT. For the four patients with prior overlapping fields, the cumulative EQD2 to the vaginal mucosa ranged from 120.7 to 154.54 Gy. Of these patients, one developed a rectovaginal fistula 2 years after treatment, and another developed chronic vaginal ulceration with vaginal shortening to 2 cm; the EQD2 values were 142.98 and 154 Gy, respectively.

Carcinoma of the Neovagina

The neovagina is a surgically constructed vaginal canal, typically described in patients with congenitally deformed or absent genitalia or patients

desiring reconstruction of a functional vaginal after surgery for gynecologic malignancy. Various methods have been utilized for neovaginal construction, including split-skin grafts, myocutaneous flaps, and the formation of an artificial canal between the rectum and the vagina.[318] Given its overall rarity, there are very few reports of in situ or invasive carcinoma arising in the neovagina.

A review of published literature reveals six published reports of carcinoma in situ.[319-324] The period of development of carcinoma in situ ranged from 6 months to 20 years after constructive surgery. Invasive carcinoma of the neovagina tends to be poorly differentiated, and the majority of reported cases have been SCC. All reported patients have presented with large tumor masses and evidence of rapid progression, with poor overall outcomes.[234,325,326]

Treatment options include radiation, with or without an attempt at radical resection, and, in select cases, lymph node dissection. Of 16 reported cases from a review by Steiner et al,[318] nine received primary radiation alone, one received radiation followed by exenteration and intraoperative radiation, and four underwent exenteration. Recurrence status was not documented for all patients. Three were found to have rapid disease recurrence within several months. Two patients were free of disease at 10 and 18 months, respectively. One patient had a recurrence-free interval of 3 years but died a year later from disease.

Though there is no optimal treatment, resection followed by consideration of adjuvant radiation is preferable to definitive radiation alone, as surgery can offer a full pathologic diagnosis. The extent of disease, patient characteristics, and treatment goals should be used to guide the choice of treatment.

Salvage Therapy for Recurrent or Persistent Disease

For patients with recurrent or persistent disease, it is important to determine whether there is a reasonable chance of cure with salvage treatment or whether the primary goal is palliation. Thus, multiple factors, including histology, sites and extent of recurrence, disease-free interval, patient age, comorbidities, and overall performance status, must be considered.

Early-stage lesions that recur after RT can be surgically salvaged. A retrospective review of pelvic exenteration for recurrent gynecologic malignancies at University of California Los Angeles Medical Center from 1956 to 2001 reported survival rates for patients with recurrent cervical and vaginal cancer to be 73% at 1 year and 54% at 5 years.[327]

Patients with tumor persistence or recurrence after limited surgical procedures can be considered for more extensive surgery. If not, systemic chemotherapy and/or radiation can be administered.

Recurrent disease in advanced-stage patients is more challenging to treat. Most patients have received prior EBRT and thus have options limited to radical surgery or, in patients with localized disease, reirradiation. For patients with small pelvic recurrences, reirradiation with ICB or interstitial BT has been reported, with control rates between 50% and 75% and grade 3 or higher complication rates between 7% and 15%.[316,317,328-331] Beriwal et al[317] evaluated HDR BT for primary and recurrent vaginal malignancy. In the subset of patients with a previous malignancy, crude local control rates were 100% for patients without prior radiation and 67% for patients with a history of radiation.

Palliative Therapy

Local treatment can provide symptomatic benefit for patients with advanced disease, who have no curative options. Advanced disease can result in vaginal bleeding, pelvic pain, lymphedema, and visceral obstruction. Vaginal bleeding is a common symptom, which can become brisk if tumor erodes into a larger vessel. Large fractions of radiation delivered initially during the treatment course may be useful in achieving hemostasis for such cases. Other options include embolization, infusion of vasopressin, and balloon catheterization for severe hemodynamic losses.

FOLLOW-UP

Recommendations for post-treatment surveillance are based on Society of Gynecologic Oncologist (SGO) guidelines for gynecologic malignancies.[332] Patients with early-stage lesions, treated with surgery alone, can be followed every 6 months for 2 years, then annually thereafter. Patients with more advanced lesions are at higher risk of recurrence and are

recommended follow-up every 3 months for the first 2 years, then 6 months for the next 3 years, and annually thereafter.

There is insufficient evidence to support the use of regular cervical or vaginal cytology to detect cancer recurrence. However, the SGO recommends annual cytology as surveillance to detect lower genital tract dysplasia. The routine use of CT or PET as surveillance is not recommended.

SUMMARY

Vaginal cancer is a rare disease, accounting for 1% to 2% of all gynecologic malignancies. Treatment options depend on stage. For early-stage disease, definitive surgery and radiation are efficacious; more advanced disease is generally managed with a combination of chemotherapy and radiation.

CHAPTER 80

Female Urethral

Benjamin D. Hopkins and Tony Y. Eng

Primary urethral carcinoma is an infrequent neoplastic entity, accounting for less than 1% of all malignancies. While data derived from the Surveillance, Epidemiology, and End Results (SEER) study suggest a predominance of primary urethral cancer in males as compared to females,[1,2] the management of female urethral cancer presents heightened complexity due to the peculiarities of its anatomic location and its rarity within the clinical landscape. Given the absence of prospective studies, the optimal approach to addressing female urethral cancer is predicated upon retrospective data analysis, with key determinants encompassing the clinical staging tumor localization, extent of nodal involvement, the patient's overall health status, and individualized treatment preferences.

ANATOMY

The female urethra is approximately 3 to 4 cm long and 0.6 cm in resting diameter. It is located in the anterior vaginal wall behind the pubis symphysis, extending inferiorly and anteriorly from the urinary bladder through the urogenital diaphragm to the vestibule, where it forms the urethral meatus. Because of the proximity of the pubic symphysis, a small curve is formed with an anterior concavity. The lower distal half of the urethra is considered the anterior urethra, and the upper proximal half is considered the posterior urethra. Figure 80.1 illustrates the urethra and adjacent organs in the female pelvis.

FIGURE 80.1 Magnetic resonance T1-weighted sagittal image of the female pelvis.

The wall of the urethra consists of three layers. The muscular layer is continuous with that of the bladder. At the vesicular end of the urethra, this muscular wall forms the internal sphincter. The voluntary urethral sphincter is located at the plane of the urogenital diaphragm. A thin layer of erectile tissue consisting of a plexus of veins and muscle fibers, forms the middle layer of the wall. The inner layer is the mucous membrane, which is continuous with the bladder proximally and with the vulva distally. This membrane consists of transitional epithelium near the bladder but distally changes to nonkeratinizing stratified squamous epithelium and pseudostratified columnar epithelium. The distal urethra also contains small mucous recesses and periurethral or Skene glands, most of which are located in the region of the meatus.

The lymphatic drainage of the distal urethra and urethral meatus parallels that of the vulva to the superficial and deep inguinal and external iliac lymph nodes. The primary

drainage of the posterior or entire urethra is mainly to the obturator and internal and external iliac nodes.

EPIDEMIOLOGY AND ETIOLOGY

From 2004 to 2016, the SEER database identified a total of 1,907 individuals afflicted with primary urethral cancer. Notably, age-standardized incidence rates per 1,000,000 were found to be notably higher in males (2.70) as opposed to females (0.55).[2]

The overall annual incidence for women stood at 1.5 per million, whereas for men, it was 4.3 per million. Although prior observations had indicated a higher prevalence of this malignancy among White women compared to Black women,[3,4] SEER data reveal an increased incidence among Black women, which exhibits a progressive rise with advancing age. Given the rarity of carcinoma of the urethra in women, major cancer centers only encounter a limited number of cases annually.[5-7] Carcinoma of the female urethra constitutes a mere 0.02% of all malignancies in women and contributes to approximately 0.1% of the broader spectrum of gynecologic cancers.[8,9] The average patient age at the time of diagnosis is 60 years, with most patients between 50 and 80 years of age.[1-12]

While various hypotheses have been put forth, the precise etiology of female urethral cancer remains enigmatic. Unlike other forms of transitional cell carcinoma within the urinary tract, there is no documented correlation between cigarette smoking and the incidence of urethral carcinoma. A study by Weiner and Walther[13] delved into the analysis of archival surgical specimens obtained from women diagnosed with urethral carcinoma. This examination unveiled the presence of human papillomavirus (HPV) in 10 out of 17 patients afflicted with invasive disease, with HPV type 16 identified in eight of these cases. Eight women presenting with squamous cell carcinoma and two with transitional cell carcinoma were also found to harbor HPV infections. Furthermore, there exists a potential association between female urethral cancer and the presence of urethral diverticula,[14-16] as depicted in Figure 80.2, which illustrates carcinoma originating within a urethral diverticulum.

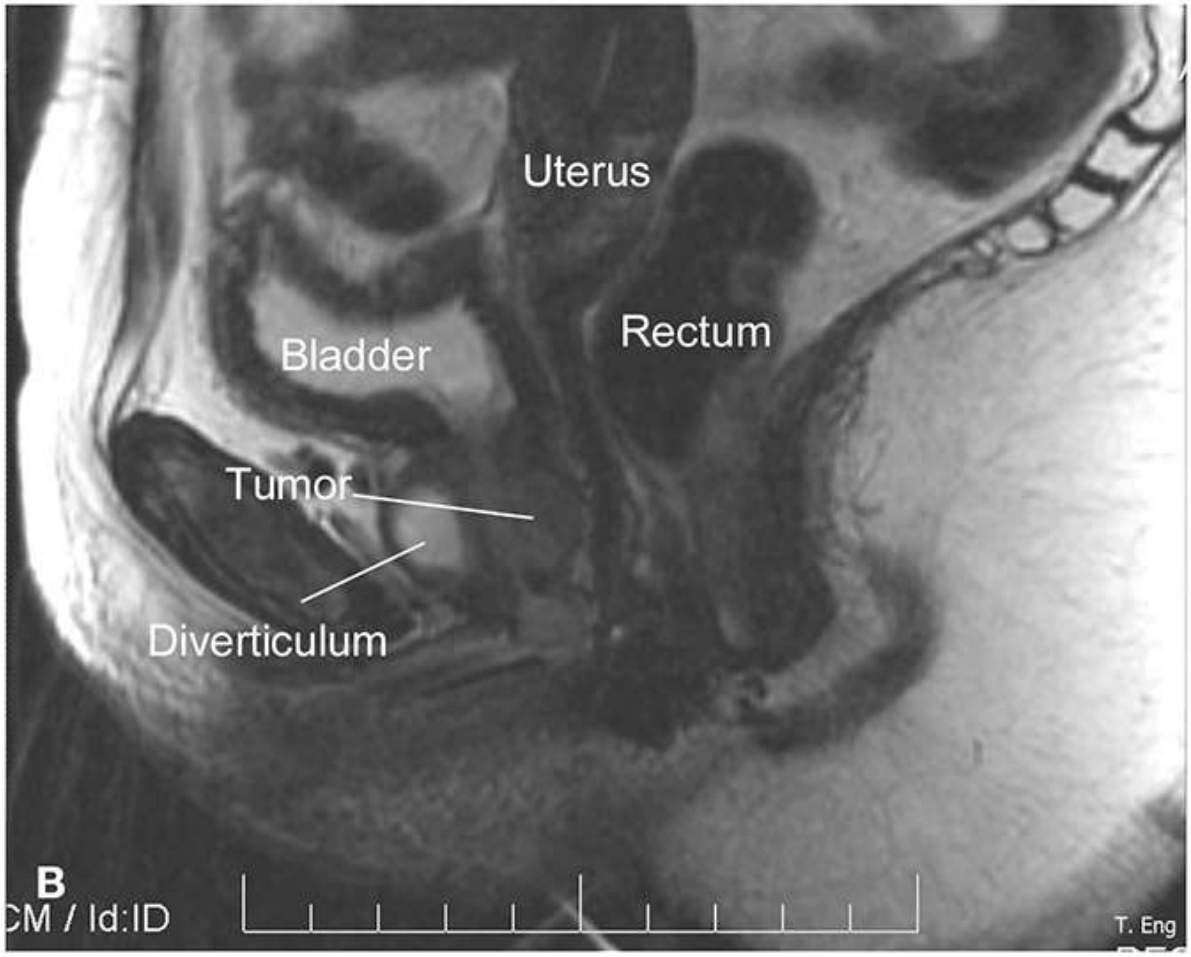

FIGURE 80.2 Coronal (A) and sagittal (B) T2-weighted magnetic resonance images demonstrate a large diverticulum surrounding the urethra with a tumor mass arising within the confines of the diverticulum posteriorly that results in an impression at the vagina.

Notably, patients diagnosed with transitional cell carcinoma of the bladder, particularly those involving the bladder neck, may carry an elevated risk of developing urethral cancer either synchronously or metachronously.[17,18]

NATURAL HISTORY

Most urethral cancers are clinically aggressive and historically carry a poor prognosis. During the later stages, cancers of the middle or posterior urethra tend to extend proximally into the urinary bladder, distally to invade the remainder of the urethra, and posteriorly into the vaginal mucosa. Lesions involving the anterior urethra account for approximately 30% of all cases.[10,19]

Regional lymph node involvement is uncommon in early tumors (stage 0) of the urethral meatus. Advanced tumors (stages II and III) of the urethra have been associated with a 35% to 50% incidence of inguinal or pelvic lymph node

involvement.[7,11,20-22] Bilateral nodal involvement occurs in approximately one-third of patients with positive nodes. Grabstald[10] confirmed nodal involvement in 24 of 25 patients with clinically palpable nodes. In his series of patients with advanced disease, 26 underwent pelvic lymph node sampling and 13 (50%) had nodal involvement.

Distant metastases are found in approximately 10% of patients at presentation, and approximately 30% to 50% ultimately die of distant disease. The most common sites of metastasis are the lung, liver, bone, and brain.[10,23]

CLINICAL PRESENTATION

A majority of patients with urethral cancer present with some degree of irritative or obstructive urethral symptoms.[24] Bleeding (hematuria) or spotting is the prevailing presenting sign in 50% to 60% of patients.[3,25,26] Approximately 30% to 50% of patients experience pain or irritative symptoms, difficulty urinating, and frequent micturition. Urinary retention and overflow incontinence may occur in advanced cases. Less frequently cited signs and symptoms are a mass in the introitus (10%-20% of patients), dyspareunia, perineal pain, and inguinal lymphadenopathy.[21,23] Urethrovaginal and vesicovaginal fistulas may develop in advanced, neglected cases.

Small tumors involving the urethral meatus are often mistakenly diagnosed as urethral caruncle, a benign, inflammatory lesion, or a prolapse of the mucosa through the urethral orifice. As the lesion progresses, it enlarges and eventually ulcerates.[23] Tumors may arise in a urethral diverticulum.[16,27,28] Larger lesions of the distal urethra are readily identified on inspection (Figure 80.3). Tumors occupying the proximal urethra may produce a fusiform enlargement that can be palpated during pelvic examination.

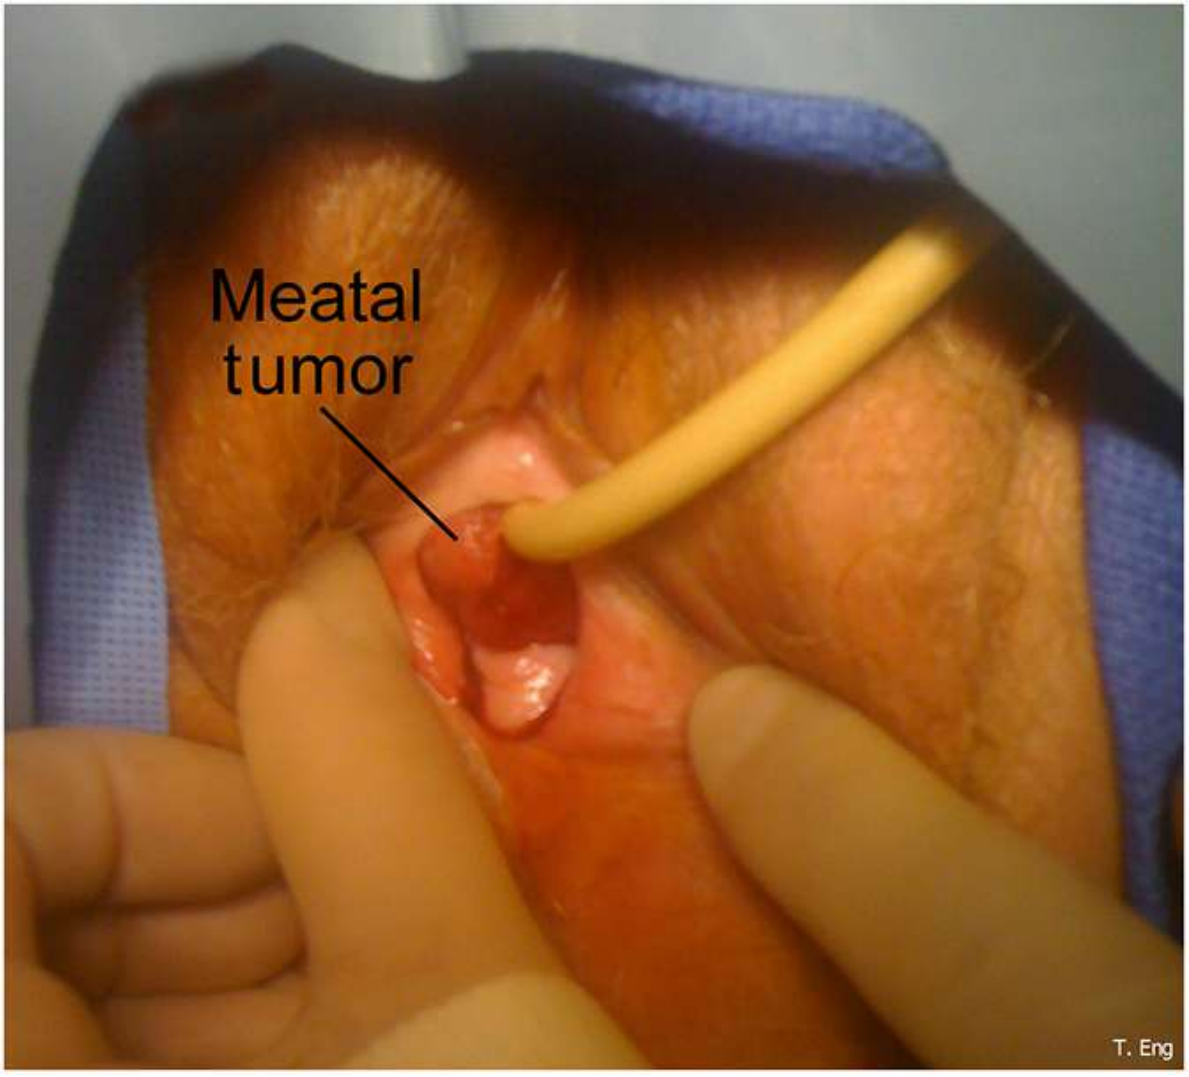

FIGURE 80.3 A meatal carcinoma of the urethra in a 68-year-old White woman presenting with hematuria.

DIAGNOSTIC WORKUP

An outline for the diagnostic workup for carcinoma of the female urethra is presented in Table 80.1. A routine history and general physical examination should be performed for all patients. A detailed pelvic examination under anesthesia is necessary to fully evaluate the clinical extent of the disease. This examination can be performed at the time of urethroscopy and cystoscopy. Urine cytologic analyses have a high false-negative rate.[29] The definitive diagnosis is made by punch or incisional biopsy.

TABLE 80.1 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE FEMALE URETHRA

General
History

Physical examination, including detailed pelvic examination under anesthesia
Special procedures
Punch biopsy
Urethroscopy
Cystoscopy
Rectosigmoidoscopy (advanced stages or if symptomatic)
Radiographic evaluation
Standard:
Computed tomography scan (chest, abdomen, and pelvis)
Magnetic resonance imaging Intravenous urography
Complementary:
Bone scan (if symptomatic or elevated alkaline phosphatase)
Barium enema (if symptomatic or advanced stages)
Ultrasound
Urethrography
Laboratory evaluation
Complete blood count
Chemistry profile
Urinalysis

Routine radiographic evaluation should include an intravenous urogram and a computed tomography (CT) scan of the chest, abdomen, and pelvis[30,31] (Figure 80.4A). Sometimes, a positron emission tomography (PET)-CT may be helpful (Figure 80.4B). Barium enema can be cost-effective for patients with symptoms of advanced disease. Magnetic resonance imaging of the pelvis helps delineate the tumor extent, especially when an endourethral coil is used (see Figure 80.2). It provides a discrete view of the muscular layers of the urethra.[32,33] Additional complementary studies include interactive virtual urethrography and ultrasonography that can help detect a urethral diverticulum without contrast agent filling.[34] Multidetector CT voiding urethrography yields real-time urethral images during micturition.

FIGURE 80.4 Transaxial computed tomography (A) and positron emission tomography/computed tomography (B) images of a patient with urethral cancer illustrating the periurethral and anterior vaginal

wall expansion and deviation of the urethra (arrow).

There are no studies addressing the role of PET-FDG (fluorodeoxyglucose) scan in urethral cancer. Perhaps, some genitourinary tumors do not accumulate sufficient FDG, which may not be a useful tracer for the detection of primary genitourinary tumors because of its physiologic excretion in the urine.[35] However, PET scans may potentially be useful for identifying nodal and distant sites of disease, especially in patients with equivocal findings on conventional imaging.[36-38]

STAGING SYSTEMS

Clinical staging is based on findings on physical examination, chest X-ray, and CT scan of the abdomen and pelvis. Many attempts have been made to formulate a staging system for carcinoma of the urethra. Urethral tumors can be classified into two groups: those involving the distal half of the urethra and those located in the proximal or entire urethra. Most authors have found that this classification correctly depicts the feasibility of treatment and the prognosis. A staging system based on location has been proposed by Prempree et al[39] (Table 80.2). The current TNM staging system of the American Joint Committee on Cancer[40] is shown in Table 80.3.

TABLE 80.2 PROPOSED CLINICAL STAGING SYSTEM FOR CARCINOMA OF THE FEMALE URETHRA

Tumor Stage	Characteristics
I	Disease limited to distal one-half of urethra
II	Disease involving entire urethra, with extension to periurethral tissues, but not involving vulva or bladder neck
III	
A	Disease involving urethra and vulva
B	Disease invading vaginal mucosa
C	Disease involving urethra and bladder neck
IV	
A	Disease invading parametrium or paracolpium
B	Metastasis
B1	Inguinal lymph nodes
B2	Pelvic lymph nodes
B3	Para-aortic nodes
B4	Distant metastasis

TABLE 80.3 TNM CLASSIFICATION OF CARCINOMA OF THE URETHRA (MALE OR FEMALE)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue.
T2	Tumor invades any of the following: corpus spongiosum, periurethral muscle.
T3	Tumor invades any of the following: corpus cavernosum, anterior vagina.
T4	Tumor invades other adjacent organs (eg, invasion of the bladder wall).
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Single lymph node metastasis in the inguinal region or true pelvis [perivesical, obturator, internal (hypogastric), and external iliac] or presacral lymph node
N2	Multiple regional lymph node metastasis in the inguinal region or true pelvis [perivesical, obturator, internal (hypogastric), and external iliac] or presacral lymph node
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

PATHOLOGIC CLASSIFICATION

As the urethra is lined by transitional cells proximally and stratified squamous cells distally, transitional cell carcinoma occurs typically in the proximal urethra, whereas squamous cell carcinoma occurs frequently in the distal urethra. The SEER data report the most common histologic type is transitional cell carcinoma, followed by squamous cell and adenocarcinoma.[1,2] However, most published series suggest that squamous cell carcinoma is the most common histologic type in cancer of the female urethra, representing more than 50% of all cases, whereas transitional cell carcinoma and adenocarcinoma represent approximately 15% to 20% and 10% to 15%, respectively.[15,41,42] The remainder of the histologic types includes adenoid cystic

carcinoma, melanoma, clear cell adenocarcinoma, anaplastic tumors, Kaposi sarcoma, lymphomas, and metastatic lesions.[6,36,43-46]

PROGNOSTIC FACTORS

Conventional prognostic factors such as grade and histology have not been consistently predictive for recurrence or survival of female urethral cancer. In the literature, some of the most important factors in determining prognosis and survival are stage, depth of invasion, tumor size, and anatomic location.[3,15,21,29,47,48] The 1983-2008 SEER database shows that advanced age, T stage, node positivity, nonsquamous histology, and Black race were associated with reduced cause-specific survival.[49] Dalbagni et al[3] showed that the primary stage was one of the major independent predictors of survival in 72 female patients with a 5-year survival of 83% for low-stage tumors and 33% for high-stage tumors.

Lesions located in the meatus or distal urethra tend to be superficial, with a better prognosis. Lesions in the posterior urethra are often deeply invasive and tend to have a worse prognosis.[9] Most investigators found that patients with advanced-stage disease do poorly, often irrespective of their treatment.[3,24,48,50]

Grigsby and associates[25,51] demonstrated a worsening prognosis with increased tumor size. The 5-year progression-free survival was 81% for patients with lesions <2 cm, compared with 37% for those with lesions 2 to 4 cm and 7% for patients with lesions >4 cm ($P = .0001$). For lesions confined to the proximal urethra, local control was observed in all four patients. However, patients with tumors involving the distal urethra had a 5-year progression free survival rate of 69%, and there was a 12% survival rate for those with involvement of the entire free urethra ($P = .0001$). Patients with meatal tumors, if diagnosed early and treated appropriately, can achieve an 80% to 90% survival rate (Figures 80.5 and 80.6).[25] Bladder neck involvement, parametrial extension, and inguinal lymph node involvement have been identified as poor prognostic factors.

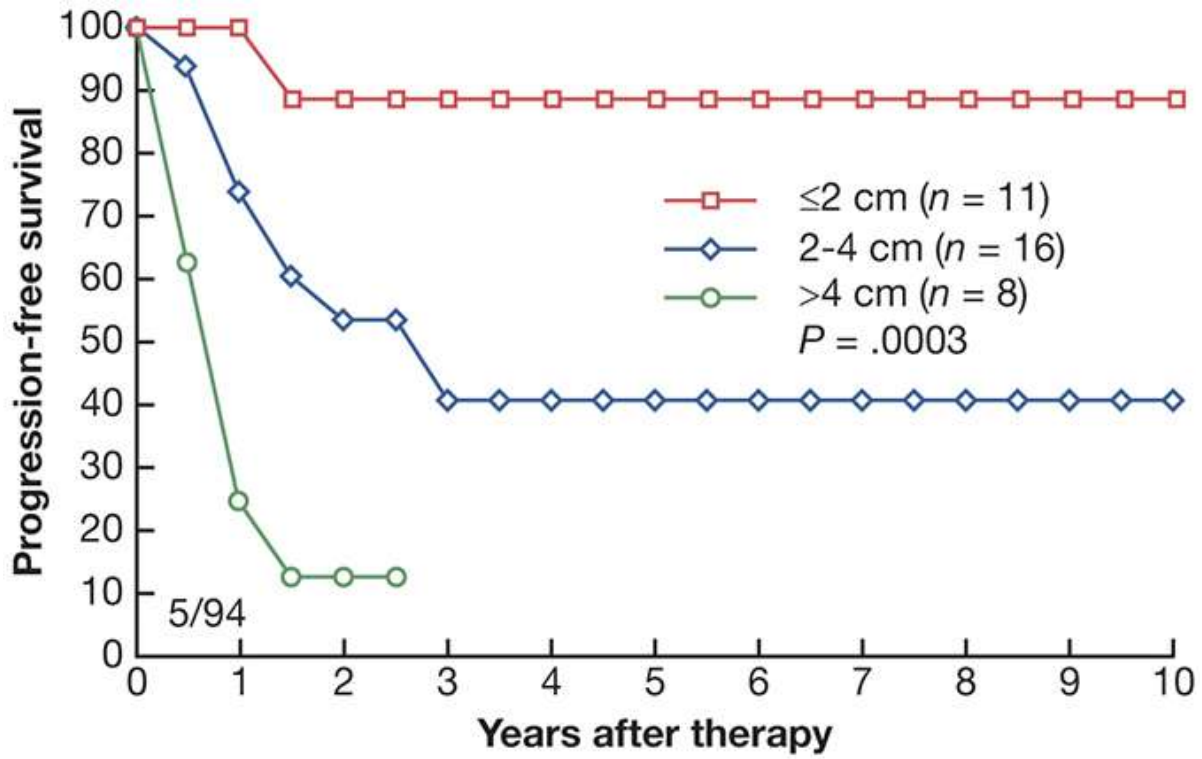

FIGURE 80.5 Progression-free survival correlated with tumor size. (Reprinted with permission from Grigsby PW, Herr HW. Urethral tumors. In: Vogelzang NJ, Scardino PT, Shipley WU, Coffey DS, eds. *Comprehensive Textbook of Genitourinary Oncology*. Williams & Wilkins; 1996:1117-1123.)

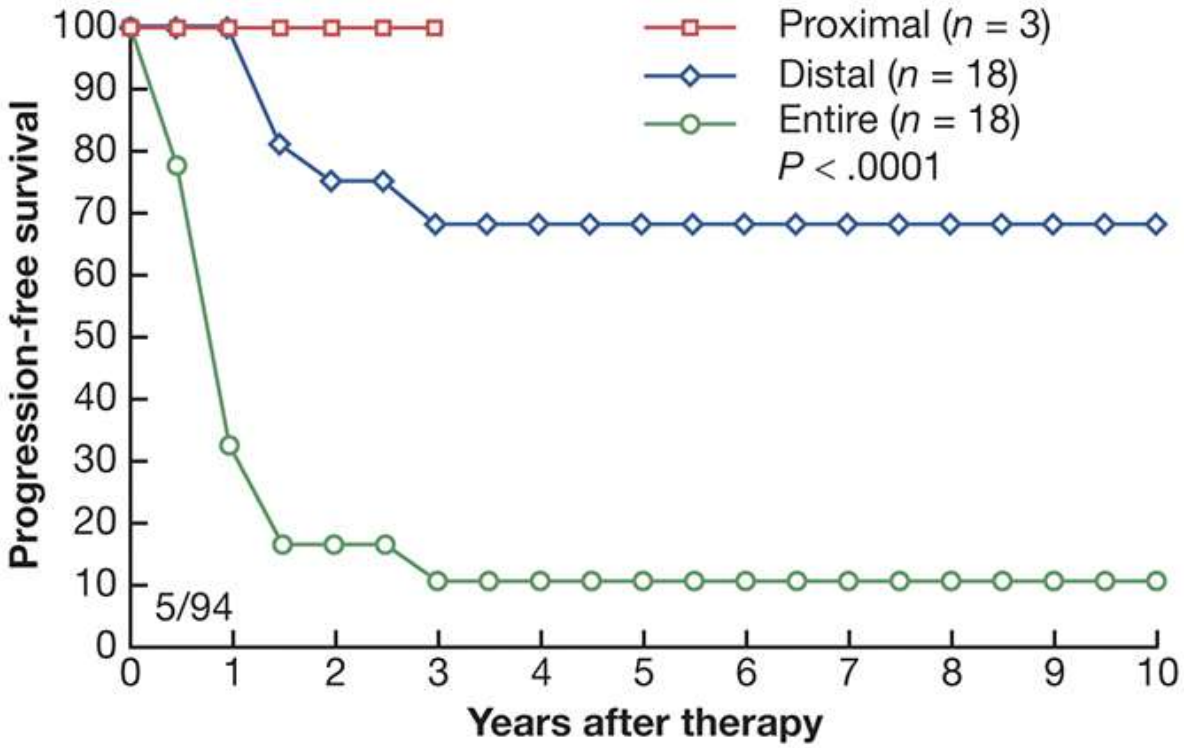

FIGURE 80.6 Progression-free survival correlated with tumor location. (Reprinted with permission from Grigsby PW, Herr HW. Urethral tumors. In: Vogelzang NJ, Scardino PT, Shipley WU, Coffey DS, eds. *Comprehensive Textbook of Genitourinary Oncology*. Williams & Wilkins; 1996:1117-1123.)

The histology of the primary lesion appears to be less important as a prognostic factor in determining response to therapy and survival. Most studies have shown no difference in survival among patients with adenocarcinoma, squamous cell carcinoma, and transitional cell carcinoma.[10,14,39,47] Grigsby[25] found a worse prognosis in patients with adenocarcinoma, with 0 of 13 treated patients with this histology alive at 5 years, although this trend has not been maintained in more recent registry trials.[52,53] It has been described that adenocarcinoma has a proclivity to present as more advanced disease, which may explain observed survival differences in prior small series.[54] Primary melanoma of the urethra, although rare, has a very poor prognosis.[55-57]

GENERAL MANAGEMENT

Although various therapeutic approaches have been advocated for the management of carcinoma of the female urethra, there are no established therapeutic guidelines. The variety of treatments reflects the dimensions and locations of the disease and the approaches of the treating physicians.[4] In general, surgical resection is the primary mode of treatment.[58] Radical urethral resection with urinary diversion and pelvic lymphadenectomy are commonly performed for lesions not involving the bladder neck. However, early-stage lesions of limited extent may be amenable to organ-

sparing radiation therapy or conservative surgical management, with or without adjuvant radiation therapy to minimize the morbidity associated with surgical intervention. Surgical approaches include neodymium:yttrium-aluminum-garnet (Nd:YAG) laser coagulation,[59] Mohs micrographic surgery, and partial or total urethrectomy.[42] Radiation therapy may include external beam radiation, interstitial brachytherapy, or a combination of these treatments.[60] For patients who are medically nonsurgical candidates because of potential risks of anesthesia, outpatient high-dose rate (HDR) intracavitary and intraluminal brachytherapy may be an option.[61,62]

Multimodality Therapy

For patients with locally invasive urethral carcinoma, anterior exenteration may be required. Although most available data are insufficient, in patients with more advanced disease, some authors have advocated adjuvant radiation therapy and/or combined irradiation and chemotherapy including 5-fluorouracil, cisplatin, vinblastine, epirubicin, carboplatin, bleomycin, methotrexate, or mitomycin C after surgical extirpation.[58,63-66] A subgroup of patients with positive nodes may also benefit from preoperative cisplatin-based chemotherapy.[67]

Multimodality therapy is associated with better overall results, even though patients who receive combined modality tend to have more advanced disease. Although most studies included a small number of patients, those patients who received combined therapy seem to have better disease-free survival.[15,48,50] Unfortunately, National Cancer Database (NCDB) studies suggest that the majority of patients with locally advanced disease do not receive multimodality care.[52] Combination therapy often consists of either chemotherapy with radiotherapy or radiotherapy with surgery. Combined chemotherapy and radiation therapy for locally advanced urethral cancer has shown a reasonable response in several reports.[48,50,63,65,68]

Anterior (Distal) Urethral Cancer

For stage 0 and I (Ta, Tis, or small T1) lesions, open excision, electroexcision, fulguration, and laser (Nd-YAG or CO_2) coagulation are possible for tumors at the meatus or with in situ involvement of the distal urethra (stage 0). For larger and more invasive lesions (stages T1 and T2), surgical resection of the distal third of the urethra is often adequate. Alternatively, interstitial irradiation or a combination of interstitial and external beam irradiation can be considered. For T3 to T4 or recurrent anterior urethral lesions previously treated by local excision or radiation therapy, anterior exenteration and urinary diversion may be curative. Adjuvant radiation therapy may be required, depending on surgical findings.

If a limited number of inguinal nodes are involved, ipsilateral node dissection or irradiation is indicated because cure is still achievable. If no inguinal adenopathy

exists, node dissection is not recommended, but prophylactic groin irradiation is recommended for patients with invasive lesions.[6,47]

Posterior (Proximal) Urethral Cancer

Cancers of the posterior or entire urethra are usually associated with invasion of the bladder, a high incidence of inguinal and pelvic lymph node metastases, and a worse prognosis. For lesions <2 cm, radical resection, definitive radiation therapy, or combined treatment may provide adequate control.[51] However, for larger lesions or locally advanced disease, the best results have been achieved with preoperative irradiation, exenterative surgery, and urinary diversion. Pelvic lymphadenectomy is performed and inguinal node dissection may be indicated if the inguinal nodes are involved. In selected patients, it is possible to remove part of the pubis symphysis and the inferior pubic rami to maximize the surgical margin. A transpubic approach has been advocated by Golimbu et al[69] Perineal closure and vaginal reconstruction can be accomplished with the use of myocutaneous flaps. Hedden et al[70] have advocated the use of bladder-sparing surgery with or without irradiation.

Recurrent Urethral Cancer

In most cases, locally recurrent urethral cancer after surgery alone should be considered for combination radiation therapy and wider surgical resection. Locally recurrent urethral cancer after radiation therapy should be treated by surgical excision. For those who are not surgical candidates, local reirradiation (i.e., hyperfractionated intensity-modulated radiation therapy [IMRT] or brachytherapy) may be considered if radiation tolerance has not been exceeded. Patients with metastatic urethral cancer should be considered for investigational chemotherapy protocols. Palliative radiation therapy may provide good symptomatic relief.

RADIATION THERAPY TECHNIQUES

Small meatal and distal urethral lesions are curable with limited therapy. Interstitial implants have been the usual method for treating meatal carcinomas. Radioactive needles, forming a double-plane or a volume implant, have been used (Figure 80.7). Both low-dose rate (LDR) and HDR afterloading implants using ^{192}Ir have replaced radium.[8,61,62] For early localized disease without involvement of adjacent organs, a volume implant composed of 8 to 12 needles arranged in an arc around the urethral orifice is used (Figure 80.8). Radiographs may be used to verify needle placement (Figure 80.9). Computer planning with CT-based simulation and three-dimensional (3D) treatment planning should be the standard of care to spare the adjacent normal organs. A dose of 60 to 70 Gy (LDR) should be given in 6 to 7 days (0.4-0.5 Gy/hour to the target volume) when an implant alone is used.

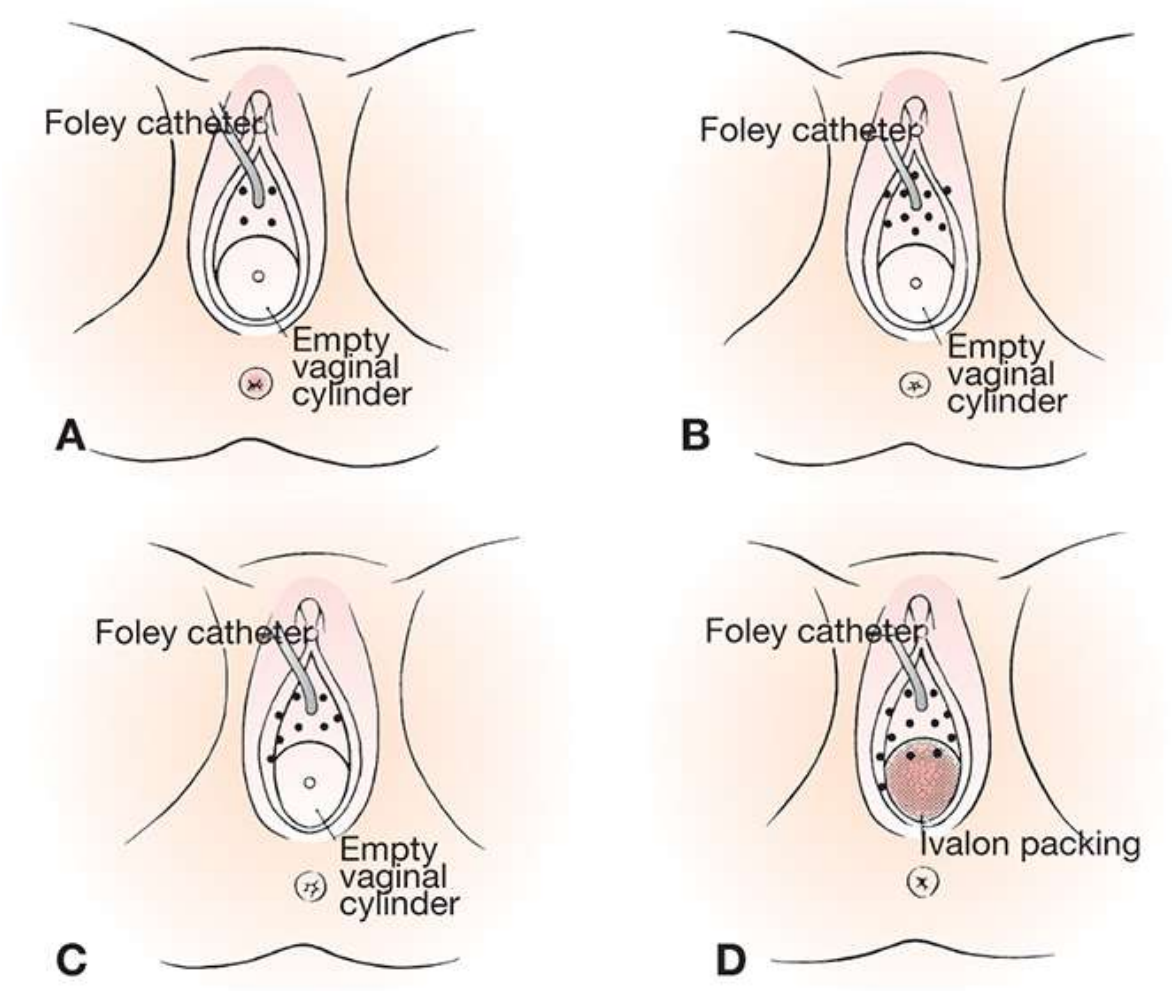

FIGURE 80.7 Diagrams of implants. A. Tumor limited to the urethra. B. Tumor extending to the periurethral tissues or originating in the periurethral glands. C. In: Johnson DE, Boileau MA, eds. *Genitourinary Tumors: Fundamental Principles and Surgical Techniques*. Grune & Stratton; 1982:275-286. Copyright © 1982 Elsevier. With permission.).

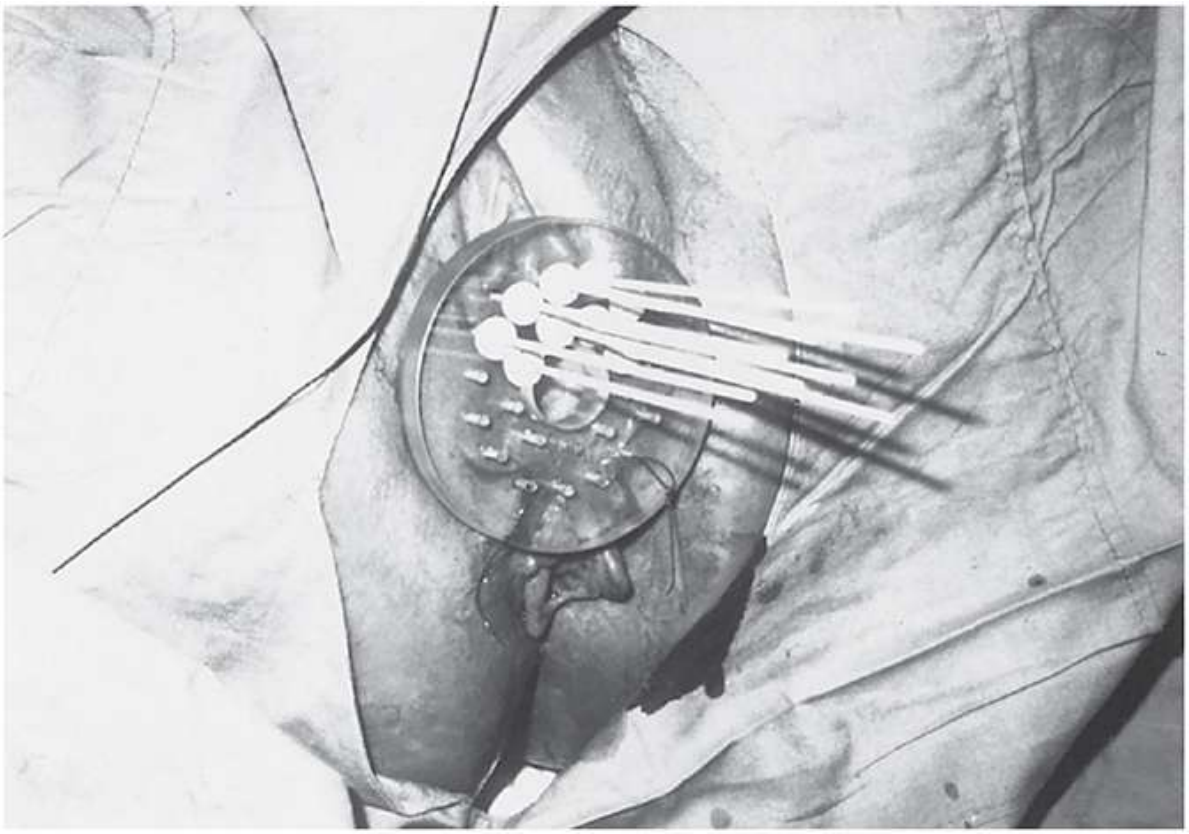

FIGURE 80.8 A template used for a curved, double-plane implant that surrounds the urethra. The closed-end flexible catheters inserted in the periurethral or vaginal tissues are glued to the template, which is sutured to the skin. The catheters are afterloaded with ^{192}Ir.

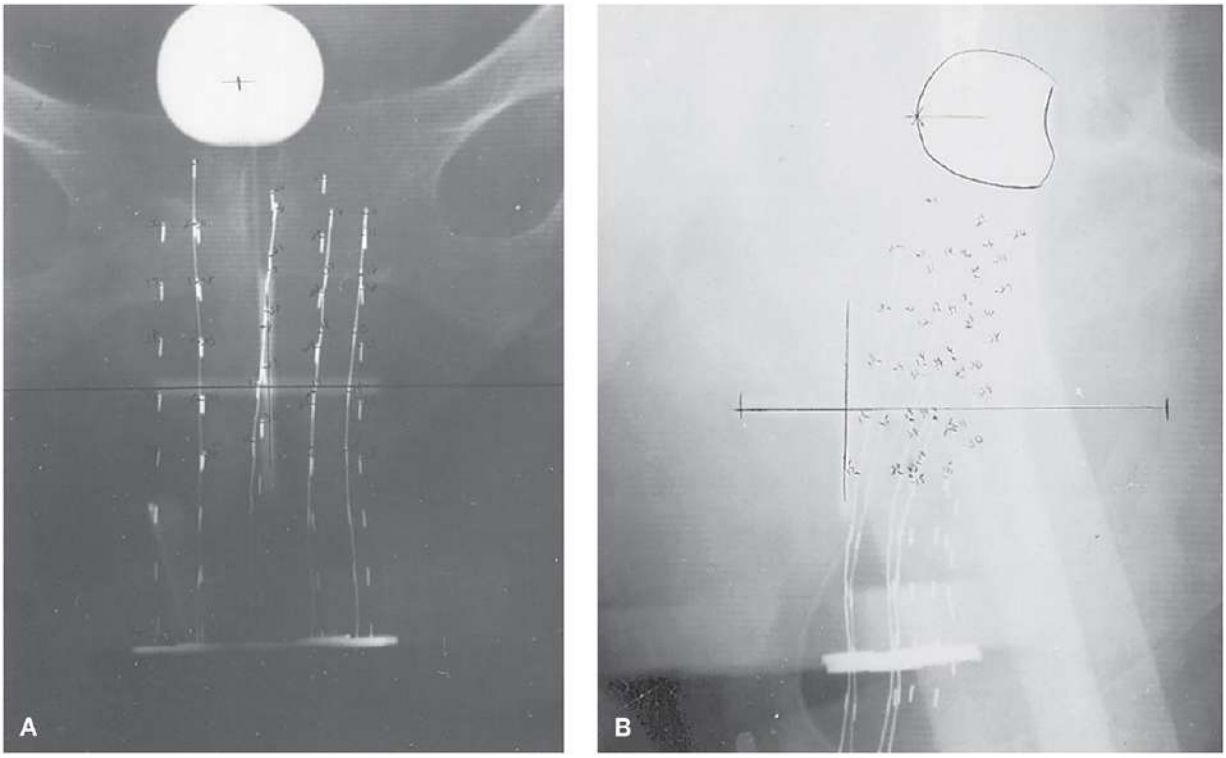

FIGURE 80.9 Anteroposterior (A) and lateral (B) simulation radiographs with dummy seeds in place. Contrast material is used to inflate the balloon of the urinary catheter, which is used to localize the bladder.

Alternatively, in patients with small localized disease receiving radiation therapy alone, noninvasive intracavitary or intraluminal HDR brachytherapy without sedation or anesthesia after pelvic external beam radiation has been used.[48,62] Figure 80.10 illustrates an intraluminal HDR brachytherapy using a Foley catheter. The resultant conformal radiation dose covers the periurethral tissue well while sparing the surrounding normal structures. At the Emory University Winship Cancer Institute in Atlanta, we deliver 5 to 6 Gy twice a week, 3 days apart, to a total dose of 24 to 25 Gy with a good response.

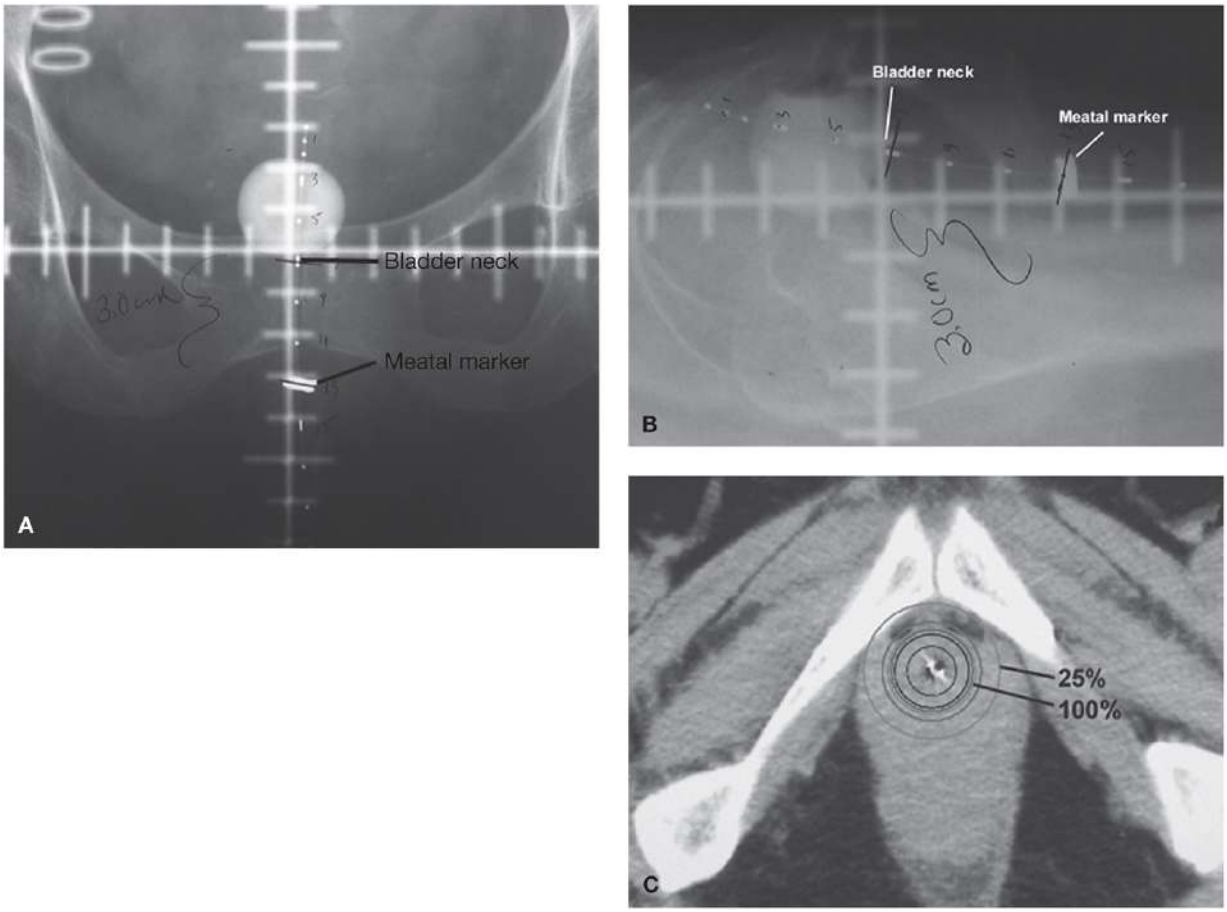

FIGURE 80.10 High-dose rate brachytherapy with a Foley catheter. Anteroposterior (A) and lateral simulation films (B) and transaxial computed tomography image with isodose plan (C). The resultant uniformed, steep isodose lines cover the periurethral tissue well.

Large tumors or advanced disease extending into the labia, vagina, entire urethra, or base of the bladder should not be treated with an implant alone. For these patients, a combination of external beam irradiation and implant is recommended.[62,71,72] The external beam portal should flash the perineum to cover the entire urethra. The conventional portal should be wide enough to cover the inguinal nodes and should extend cephalad to the L5-S1 interspace to include the pelvic nodes (Figure 80.11).[73] A bolus, appropriate for the photon energy used, should be added to the groin when inguinal nodes are positive. This technique minimizes the hazard of groin failure due to underdosing of gross tumor. Hahn et al[74] have demonstrated the importance of treating the inguinal lymph nodes in all patients. The whole pelvis is treated to a dose of 45 to 50 Gy. A boost of 10 to 15 Gy is delivered to positive groin nodes through reduced anteroposterior fields.

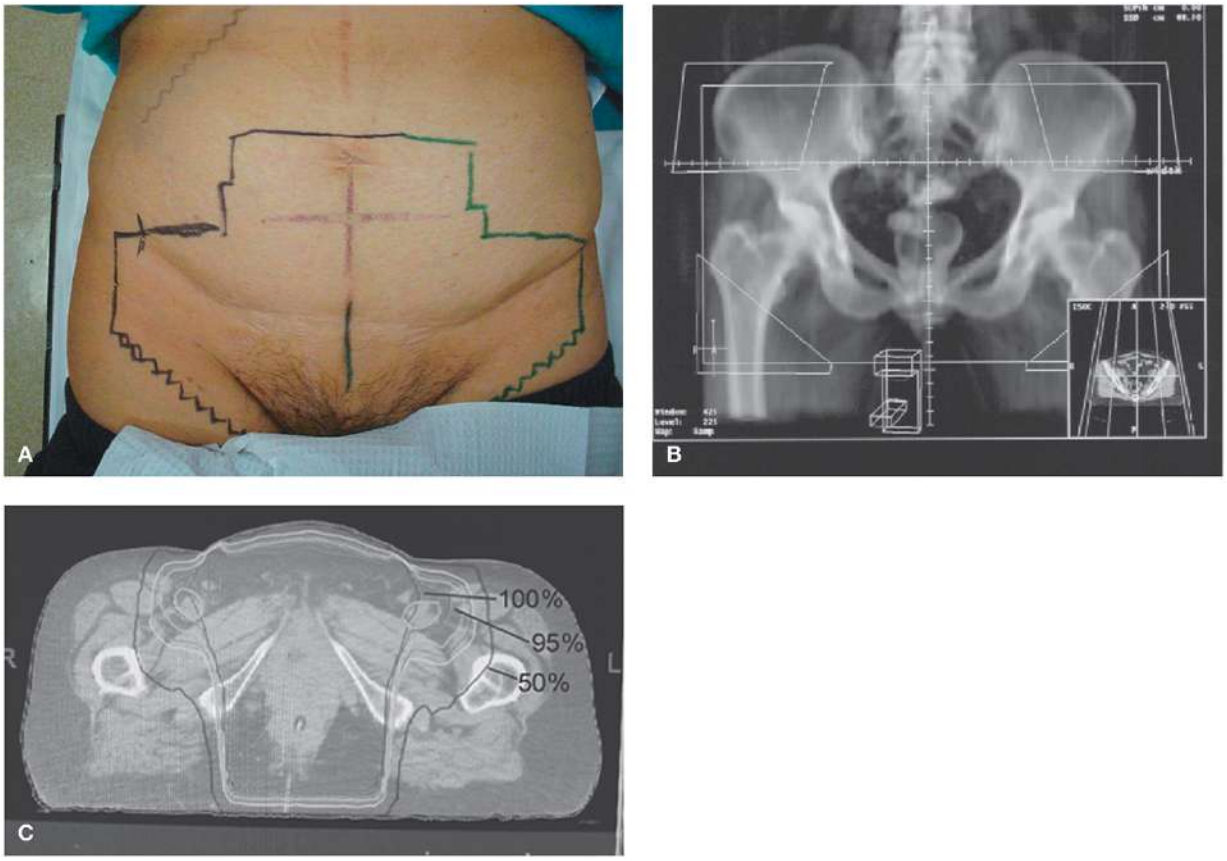

FIGURE 80.11 Whole pelvis and inguinal field. External skin marking (A) and anteroposterior simulation film (B) of a pelvic portal showing the lateral extension to cover the inguinal lymph nodes and the isodose plan (C).

After pelvic radiation therapy, the primary tumor can be treated with a vaginal cylinder to bring the dose to the entire urethra to approximately 60 Gy. An interstitial implant is administered to raise the total tumor dose to 70 to 80 Gy. For patients undergoing postoperative therapy, the tumor bed is treated after pelvic radiation therapy with an additional 10 to 15 Gy using interstitial brachytherapy.[61] Intracavitary irradiation with the vaginal cylinder and an interstitial implant are almost never used simultaneously because of the resultant HDR at the vaginal mucosa interface of the intracavitary and interstitial implant fields. A vaginal cylinder with partial shielding posteriorly can be used in select patients. Gerbaulet et al[75] have demonstrated the use of a catheter or a vaginal mold applicator for intraluminal/intracavitary brachytherapy and needles or guide gutters for interstitial brachytherapy.

At the Emory University Winship Cancer Institute in Atlanta, we commonly deliver external beam therapy, 45 to 50.4 Gy, to the primary tumor and pelvic lymphatics using IMRT technique with CT image guidance (Figure 80.12). This is followed by interstitial HDR brachytherapy, 5 to 6 Gy twice a week, 2 days apart. A vaginal cylinder is always employed to provide spatial protection of the posterior vagina and

rectum. The HDR brachytherapy is repeated in 1 week to achieve a total dose of 20 to 24 Gy (Figure 80.13). The major advantage of interstitial HDR brachytherapy is geometric or volume optimization by changing the dwell time and dwell position of the radioactive source along the afterloading catheter so that the target volume is well covered with good conformity while the doses to the vaginal mucosa and surrounding structures are kept below their tolerances. Modification of dose and fractionation may be made depending on the tumor size and response to external beam therapy. The HDR brachytherapy is performed as an outpatient treatment.

One of the limiting factors in the use of external beam irradiation is the tolerance of the perineal and vulva skin (i.e., confluent moist desquamation). Extensive disease combined with advanced age can be a formidable obstacle to completing the irradiation course. Proper radiation therapy techniques and diligent personal hygiene and individualized skin care during and after treatment are necessary if patients are to complete the course of treatment.

RESULTS OF THERAPY

The 1983-2008 SEER database identified 722 women with urethral cancer.[49] The median overall survival was 42 months, and the 5- and 10-year overall survival was 43% and 32%, respectively. The median cause-specific survival was 78 months, and the 5- and 10-year cause-specific survival was 53% and 46%, respectively. A subsequent NCDB analysis published by Son et al in 2018 identified 2,614 patients treated for primary urethral cancer.[53] Three-year overall survival was found to be 54%. Furthermore, a benefit was found with the addition of radiation to surgery compared to surgery alone (hazard ratio 0.77, $P \leq .01$). Table 80.4 summarizes the recent treatment results from various institutions. Depending on the various prognostic and

treatment factors, the 5-year overall survival and cause-specific survival rates range from 32% to 59% and 40% to 61%, respectively. The recurrence rates range from 58% to 64%.

recurrence-free survival; RT, radiation therapy; surg, surgery; UTHSCSA, University of Texas Health Science Center at San Antonio.

Surgery

There is a paucity of long-term outcome data. In general, female urethral cancers are clinically aggressive with high recurrence and poor survival rates.[3,10,15,22,50] DiMarco et al[24] reviewed 53 female patients with primary urethral carcinoma undergoing partial urethrectomy or radical extirpation. The estimated 10-year cancer-specific survival was 60%. In a study of 72 patients treated at Memorial Sloan-Kettering Cancer Center between 1925 and 1994, the 5-year disease-specific survival was 89% for low-stage tumors and 33% for high-stage tumors.[3] The overall survival was 78% and 22%, respectively, as shown in Table 80.4.

Five of seven patients with early meatal tumors were cured of disease in the series reported by Grabstald[10] after partial urethrectomy. In the remaining two patients, both local recurrences and distant metastases developed. Bracken et al[47] reported local control in just one of four patients treated with local excision only for distal urethral lesions. Peterson et al[23] reported on two patients in whom squamous cell carcinomas were excised successfully. In the same series, a patient with adenocarcinoma treated with local excision had a local recurrence and left inguinal adenopathy developed 4 years later.

Grabstald et al[21] performed radical surgery on 15 patients with advanced disease; there were only three survivors at 5 years. Peterson et al[23] performed radical surgery on seven patients, three of whom were alive at 5 years. Primary radical cystectomy with anterior vaginectomy and total urethrectomy was performed on eight patients by Mayer et al.[79] Three of these patients were free of disease at 1, 4, and 11 years.

Radiation Therapy

A study published by DiMarco et al[24] in 2004 found that adjuvant radiation did not improve local control or survival in the study of 53 female patients with urethral carcinoma, although treatment selection bias may have played a role as the higher stage tumors tended to receive adjuvant radiation therapy. Eng et al[48] reported only one of six patients with low-stage disease was referred for adjuvant radiation therapy, whereas four of five patients with advanced disease received radiation therapy. The one who did not receive radiation died 10 months after surgery. A case review of early-stage urethral cancer treated with external beam radiotherapy, brachytherapy, or a combination of both seems to have equivalent results as surgery alone.[60,61,68,73] More recently, multiple series have now found that multimodality therapy with the addition of adjuvant radiation confers a survival benefit.[52,53]

Control of tumors of the urethral meatus or the distal urethra with irradiation alone is often satisfactory. Early meatal tumors have cure rates of 70% to 90%.[39] Chu[20]

reported a 5-year progression-free survival rate of 64% for 11 patients with tumor involvement of the anterior urethra treated with irradiation alone. Prempree et al[39] treated three patients with stage I disease with interstitial irradiation alone (50-65 Gy) and achieved local control in all three. In the same series, two of four patients with stage II disease achieved local control and were alive 5 years after treatment. Weghaupt et al[9] reported a 5-year survival rate of 71% for 42 patients with cancer of the anterior urethra. Their doses ranged from 55 to 70 Gy from intracavitary and external irradiation. Princess Margaret Hospital reported an 87% relapse-free survival rate in patients with stage I or II disease.[72] The majority of patients with small primary tumors received brachytherapy as a component of their treatment. Patients receiving brachytherapy and external beam radiation therapy had a median total dose of 65 Gy.

Tumors of the proximal urethra or the entire urethra are more difficult to treat. The overall local control rate is 20% to 30%. Bracken et al[47] treated 81 patients, and the 5-year survival rate was approximately 25% for patients with stage III and 20% for those with stage IV disease. Princess Margaret Hospital reported stage III and IV tumors to have cause- specific survival rates of 26% and 16%, respectively.[41] Weghaupt et al[9] reported a 5-year survival rate of 50% among 20 patients with tumor involvement of the posterior urethra who received irradiation alone or preoperative irradiation and surgery. Garden et al[4] treated 86 patients with irradiation only after excision or biopsy of the primary lesion. Radiation doses ranged from 40 to 106 Gy (median, 65 Gy). The 5-year disease-specific survival rate was 49%, and the 5-year local control rate was 64%. Preoperative irradiation combined with radical surgery is an approach used by Klein et al[22] They treated five women in this manner and achieved a 5-year survival rate of 40%. Dalbagni et al[61] used anterior pelvic exenteration with intraoperative tumor bed interstitial brachytherapy using ^{192}Ir, followed several weeks later by pelvic external beam radiation therapy. A variety of chemosensitizing agents were used. The median brachytherapy dose was 15 Gy, and pelvic radiation therapy dose given was 45 Gy. Local control was achieved in four of six women with T2 and T4 disease.

Several investigators have found that the use of brachytherapy improves local control and further enables organ preservation.[61,72,80] Milosevic et al[72] reported that patients who were treated with external beam therapy only were 4.2 times more likely to recur locally independent of other prognostic factors, compared with those who received brachytherapy as a component of management. Similarly, in a study of six patients with locally advanced urethral carcinoma, Dalbagni et al[61] noted that high-dose intraoperative brachytherapy followed by external beam radiation appeared to improve local control.

Chemotherapy and Multimodality

Dayyani et al[67] reported a response rate of 72% in 36 patients with locally advanced urethral cancer who had received definitive or preoperative platinum-based chemotherapy. The median overall survival was 25.6 months. Gheiler et al,[50] reported a disease-free survival rate of 60% in selected patients with advanced T3 or higher disease treated with a multimodality regimen consisting of neoadjuvant chemotherapy and radiation therapy. A phase 2 study has shown the combination of ifosfamide, paclitaxel, and cisplatin used in 45 patients with advanced transitional carcinoma of the urothelial tract is well tolerated and results in a median survival of 20 months.[81] Similar encouraging results have been reported in patients with advanced urethral cancer receiving concomitant fluorouracil, mitomycin C, and radiation therapy.[63,64,82] While immunotherapies have begun to be used in bladder cancer and other cancers of urothelial origin, there have not been data reported on their use in urethral cancers, which warrants future investigation.

SEQUELAE OF THERAPY

Complications as a result of surgery, irradiation, or combined-modality therapy vary greatly, from 0% to 42%, because of different tumor stages, the extent of surgery, and various irradiation doses.[11,20,25,70,83] In general, more aggressive treatment is expected to result in a higher complication rate. Garden et al[4] reported that 27 (49%) of 55 patients achieving local control had complications, including urethral stenosis, fistula, necrosis, cystitis, and hemorrhage. Urethral strictures develop in some patients, necessitating dilation or urinary diversion. Others may experience incontinence, cystitis, and vaginal stenosis. Severe complications include fistula formation, bowel obstruction, and, occasionally, operative death. In the case of advanced neoplasms, fistula formation may be unavoidable because of tumor erosion of adjacent organs and subsequent tumor necrosis. Unlike the male counterpart, the physical loss of the female urethra is not uniformly associated with sexual impotence; nevertheless, the associated treatment side effects and negative self-image may affect sexual function and quality of life.

FUTURE DIRECTION

Early detection and intervention provide the best chance of organ preservation and cure. Although most clinical information comes from retrospective case series accumulated over a long span of time using various treatment modalities, multimodality shows encouraging results and should always be considered, especially in patients with locally advanced or metastatic disease. Clinical trials are clearly needed to obtain prospective data. Improved knowledge of tumor and normal tissue radiobiology, along with continued technological advances in external beam radiation

therapy and brachytherapy delivery will maximize organ preservation and minimize some of the treatment-related complications.

CHAPTER 81

Carcinoma of the Vulva

Diandra N. Ayala-Peacock, Mary Katherine Anastasio, and Junzo P. Chino

ANATOMY

Vulva

The vulva is composed of the mons pubis, clitoris, labia majora and minora, vaginal vestibule, and their supporting subcutaneous tissues. The vulva blends with the urinary meatus anteriorly and with the perineum and anus posteriorly. The mons pubis consists of prominent tissue located anteriorly to the pubic symphysis. The labia majora are two elongated skin folds that course posteriorly from the mons pubis and blend into the perineal body. The skin of the labia majora is pigmented and contains hair follicles and sebaceous glands. The labia minora are a smaller pair of skin folds located medial to the labia majora. Anteriorly the labia minora separates into two components that course above and below the clitoris, fusing with those of the opposite side to form the prepuce and frenulum, respectively. The skin of the labia minora contains numerous sebaceous glands but no hair follicles and has no underlying adipose tissue. The clitoris is 2 to 3 cm anterior to the urethral meatus and is supported externally by the fusion of the labia minora.

The vaginal introitus is demarcated laterally by the labia minora and posteriorly by the perineal body. Anteriorly numerous small vestibular glands are located beneath the mucosa and open onto its surface adjacent to the urethral meatus. The Bartholin glands (or greater vestibular glands) are two small mucous-secreting glands situated within the subcutaneous tissue in the posterior aspect of the labia majora. The ducts of the Bartholin glands open onto the posterolateral portion of the introitus. The Skene glands (or paraurethral glands) open in the anterior aspect of the introitus but can be variable in location. The perineal body is a 3- to 4-cm band of skin that separates the vaginal introitus from the anus and forms the posterior margin of the vulva with the fusion of the labia minora, the fourchette.

Lymphatic Drainage

The inguinofemoral nodes are located within the triangle formed by the inguinal ligament superiorly, the border of the sartorius muscle laterally, and the border of the adductor longus muscle medially. There are superficial inguinal lymph nodes (LNs)

that lie along the saphenous vein and its branches between Camper fascia and the cribriform fascia overlying the femoral vessels. There are usually three to five deep nodes, the most superior of which (Cloquet node) is located under the inguinal ligament. Lymph drains from these nodes into the external and common iliac pelvic LNs.

Lymphatic drainage is specific to the location of a vulvar lesion. Labial lesions drain into the superficial inguinal and femoral LNs, then penetrate the cribriform fascia and reach the deep femoral nodes. Lesions of the fourchette and perineum follow the lymphatics of the labia. Lymphatic drainage from the glans clitoris or perineal body enters either unilateral or bilateral superficial femoral nodes or the deep femoral and pelvic LNs. Some lymphatics originating in the clitoris enter the pelvis directly, bypassing the femoral nodes to connect with the obturator and external iliac LNs, though, in practice, the pelvic LNs are rarely involved without synchronous involvement of the inguinal nodes (Figure 81.1).

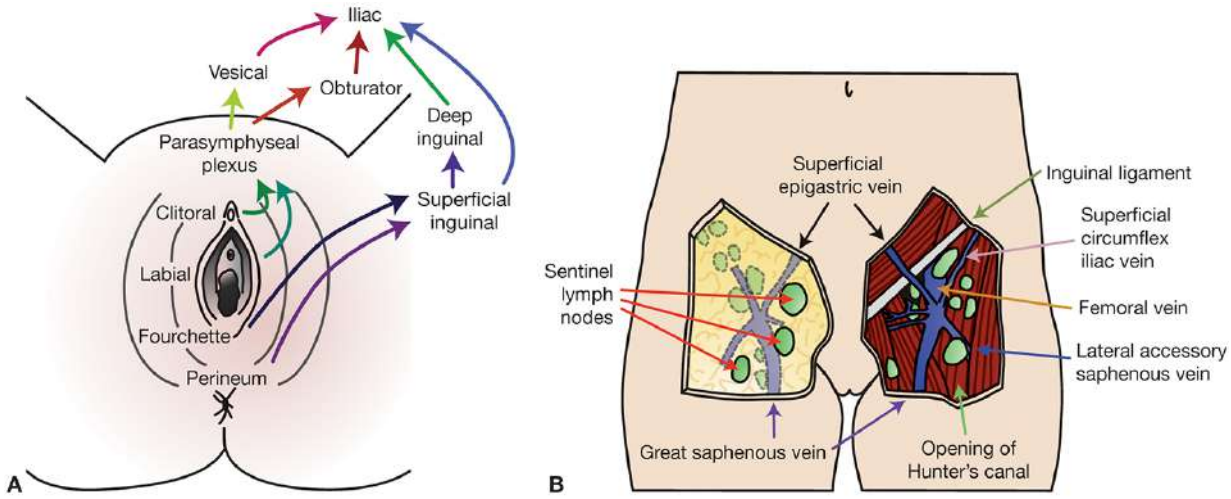

FIGURE 81.1 A. The lymphatic drainage of the vulva initially flows to the superficial inguinal nodes and then to the deep femoral and iliac group. Drainage from midline structures may flow directly beneath the symphysis to the pelvic nodes. B. Anatomic relation of inguinal lymphatics. EPIDEMIOLOGY

Vulvar cancer is a rare malignancy representing less than 1% of all cancers diagnosed in women and less than 4% of all gynecologic neoplasms.[1] In the United States, there were an estimated 6,470 new cases in 2023 with an estimated 1,670 deaths—both representing approximately 0.3% of all new cancer cases and cancer deaths, respectively. There are two primary mechanisms believed to be involved in

carcinogenesis: human papillomavirus (HPV) or vulvar dystrophy, including lichen sclerosus (LS) and squamous hyperplasia. HPV DNA can be identified in approximately 30% to 40% of invasive vulvar cancers, with serotypes 16, 18, and 33 being the predominant subtypes.[2] As HPV infection is related to numerous other cancers of the anogenital region (eg, cervical cancer and anal canal cancer), the risk factors for HPV-related vulvar cancers are similar: previous diagnosis of genital warts, multiple sexual partners, smoking history, previous abnormal Papanicolaou test, and immune suppression.[3] However, vulvar dysplasia such as LS is often associated with HPV-negative cancers, although there is no histopathologic evidence of direct transformation.[4] Women with existing LS have a 5% to 7% risk of developing invasive disease, with risk increasing with older age and concurrent differentiated vulvar intraepithelial neoplasia (dVIN), up to a 19% risk of invasive cancer at 10 years.[5,6] In 2019, the incidence for women of age greater than 75 in the United States was 15.0 per 100,000 women in contrast to the incidence of 2.6 per 100,000 women for all ages.

The evidence for VIN as an obligate precursor to invasive vulvar disease is less compelling than that established between cervical intraepithelial neoplasia and cervical cancer. Only one-third of vulvar cancers have an associated VIN-3 lesion, and only 5% to 7% of women with an existing VIN lesion will subsequently be diagnosed with invasive disease.[7]

VIN may be divisible into two general types, depending on the lesion association with HPV (Table 81.1).[8] Usual type vulvar intraepithelial neoplasia (uVIN) is associated with HPV in 70% to 90% of cases and occurs in younger women with HPV risk factors. The aforementioned dVIN arises in the setting of LS and other chronic inflammatory processes and is associated with older age. These differing precursor lesions may then transform into two distinct classifications of squamous carcinoma: keratinizing squamous carcinomas (KSCs) arising from HPV-independent dVIN and basaloid squamous carcinomas (BSCs) arising from HPV-associated uVIN,[9] with KSC as the more common of the two (representing 60%-80% of cases). p53 mutations may also play a role in pathogenesis in a subset of these neoplasms, with some KSCs staining positive for p53. In contrast, p16 is rarely positive in KSCs, indicating a lack of association with HPV.[10,11] The less common BSCs (20%-40% of cases) often stain negative for p53 but are often p16 positive due to their association with HPV. Similar to findings related to HPV-related cancers in other sites, HPV-driven lesions (uVIN and BSC) portend a better prognosis.[12] Overexpression of p16 may also be associated with an improved prognosis, even when high-risk HPV DNA is not detected.[13]

TABLE 81.1 HISTOPATHOLOGIC PATTERNS OF SQUAMOUS CELL CARCINOMAS OF THE VULVA

	Keratinizing Squamous Carcinoma	Basaloid Squamous Carcinoma
Prevalence	More common (60%-80%)	Less common (20%-40%)
Age	Older age	Younger age
Distribution	Usually unifocal	Can be multifocal
Morphology	Keratinizing	Warty
Association with VIN	Uncommon: Differentiated type (dVIN)	Common: Usual type (uVIN)
Association with HPV	No	Yes (serotypes 16, 18, 31, 33)
Association with vulvar dystrophy	Common	Rare
Immunohistochemistry	p53: May be positive or negative p16: Negative or focally positive at stromal interface	p53: negative p16: positive

HPV, human papillomavirus; VIN, vulvar intraepithelial neoplasia.

PATHOLOGY

Squamous Carcinoma

Eighty to 90% of invasive disease of the vulva is squamous cell carcinoma (Figure 81.2), arising within the squamous epithelium, within or adjacent to areas of epithelial abnormalities or of premalignant conditions such as LS, erythroplasia of Queyrat, and Bowen disease.[14] The depth of invasion (DOI), critical for appropriate staging and management, previously defined as the distance from the epithelial-stromal junction of the most *superficial* adjacent dermal papillae to the deepest point of invasion has undergone revision since 2015. Current recommendations are to measure from the basement membrane of the *deepest* adjacent, dysplastic, tumor-free rete ridge or peg to the deepest point of invasion, resulting in a lesser depth in many cases.[15] Tumor thickness is measured from the overlying surface epithelium, or the bottom of the granular layer if the surface is keratinized, to the deepest point of invasion.

FIGURE 81.2 Squamous cell carcinoma of the vulva. A. Squamous cell carcinoma with ulceration, arising from the right labia minora. This older woman had no apparent predisposing disease. B. Photomicrograph of invasive keratinizing squamous cell carcinoma of the vulva. Note the keratin pearls. (Courtesy of Dr. Stanley Robboy, Duke University Medical Center, Durham, NC.)

There are three recognizable types of growth pattern of squamous carcinoma: confluent, compact, and spray or finger-like growth. Confluent growth is defined as a tumor mass composed of interconnected tumor greater than 1 mm in dimension. This type of growth is characteristic for being deeply invasive with associated stromal desmoplasia. Compact growth is associated with well-differentiated tumors, which maintain continuity with the overlying epithelium, infiltrating as a well-defined and circumscribed tumor mass, which rarely invades the vascular space. Histologically, the tumor cells resemble squamous cells of adjacent and overlaying epithelium. The spray or finger-like growth pattern is characterized by a trabecular appearance with small islands of poorly differentiated tumor cells found within the dermis or submucosa, deeper than the main tumor mass. This growth pattern is often associated with desmoplastic stromal response and a lymphocytic inflammatory infiltrate. Vascular space involvement is seen more commonly with this growth pattern than with tumors with a compact pattern.[16]

Uncommon Histologic Types and Management

Melanoma

Malignant melanoma of the vulva accounts for approximately 10% of all primary tumors of the vulva. It occurs more commonly in White women (incidence ratio 3:1 White/Black), with a peak incidence in the sixth and seventh decades (Figure 81.3).[17,18] Melanomas may arise in preexisting pigmented lesions; the differential diagnosis includes benign vulvar melanosis and pigmented VIN. Vulvar melanomas can be subclassified into three specific categories: superficial spreading malignant melanoma, nodular melanoma, and acral lentiginous melanoma. As is the case for

melanomas arising in other mucosal sites, the level of invasion, tumor thickness, and nodal evaluations dictate the therapy and determine the prognosis.[19] Compared to nongynecologic melanomas, BRAF and KIT mutations are more frequently detected in vulvar and vaginal melanomas, and programmed death-ligand 1 (PD-L1) and programmed cell death protein 1 (PD-1) may be more frequently expressed, having implications for targeted therapies and immunmodulation.[20]

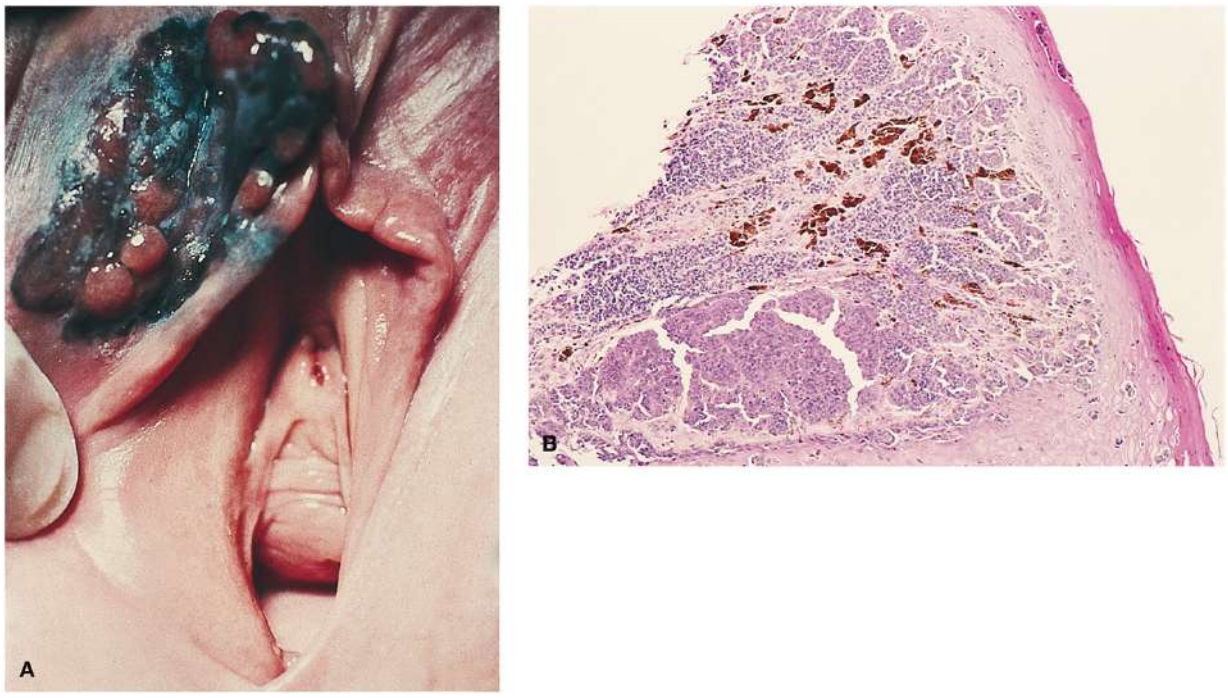

FIGURE 81.3 Melanoma of the vulva. A. A nodular, elevated, and darkly pigmented lesion arising from the right labia majora. B. Photomicrograph of invasive melanoma, with melanin apparent in portions of the tumor. (Courtesy of Dr. Stanley Robboy, Duke University Medical Center, Durham, NC.)

The prognosis is worse than with squamous cell carcinoma, with a 5-year overall survival (OS) of approximately 35%, particularly in those with deep invasion, ulceration, nodular growth pattern, epithelioid cell type, and high mitotic rate.[21,22] The prognosis is also worse in older patients. Primary surgical excision with nodal evaluation is preferred if possible, with adjuvant radiotherapy (RT) for nodal disease or close margins at the primary site. In a study of 32 patients treated at the Royal Marsden Hospital in London, there was no difference in the outcome between patients treated with wide local excision and those treated with more radical surgical procedures.[23] Radiation may be considered for patients with positive margins, positive LNs, or for palliation of symptoms. As with other mucosal melanomas, there is a high incidence of distant metastasis.

Adenocarcinoma

Adenocarcinomas of the vulva arise predominantly in the Bartholin glands, although apocrine, eccrine, and Skene glands can also be the site of origin. In the rare instances when adenocarcinomas arise in the absence of glandular tissue, they may be of cloacogenic origin. Carcinoma of Bartholin gland is seen more frequently in older women and is often solid and deeply infiltrative. The overlying epidermis or mucosa may remain intact, leading to misinterpretation as a benign process. Other histopathologic types are mucinous, papillary, mucoepidermoid, adenosquamous, and transitional. Adenocarcinomas often present with more locally advanced disease and metastases to the inguinal-femoral LNs.

The general approach to treatment, however, follows squamous cell carcinomas, with initial surgery followed by tailored adjuvant RT for resectable disease, and multimodality therapies for advanced stages. Survival after treatment is comparable to stage-matched squamous cell cancers.[24] The role of radiation for Bartholin gland carcinoma has been studied by Copeland et al and Leuchter et al.[25,26] These two studies suggest that adjuvant radiation to the vulva and regional nodes after conservative surgery may decrease local recurrence, with 7% recurrence with radiation and 27% recurrence without it in the Copeland et al's study. Five-year survival of 67% was reported by Cardosi et al in patients who were found to have close margins and were treated with primary surgery and adjuvant radiation.[27]

Paget Disease of the Vulva

Paget disease of the vulva (intraepithelial adenocarcinoma) is seen most often in postmenopausal, older White women. The disease varies in appearance, but most often, it presents as an eczematoid, red, and/or weeping lesion, and it can be mistakenly diagnosed as eczema or contact dermatitis (Figure 81.4). The lesion may be flat, raised, or ulcerated and may appear whitish (leukoplakia), red (erythroplastic), or hyperpigmented. This condition has a typical histologic pattern and often immunohistochemically positive for carcinoembryonic antigen. Vulvar Paget disease is associated with invasive carcinoma in 10% to 20% of the cases.[28,29] The associated invasive disease may be an underlying adenocarcinoma of the apocrine or Bartholin glands, or it may be an adenocarcinoma arising elsewhere in the anogenital region. Management is generally focused on maximal safe resection, though RT is an effective therapy for recurrent or unresectable disease.[30] Topical imiquimod also shows promise as an effective nonoperative therapy.[31] HER2 may be overexpressed in 15% of extramammary Paget disease, and anti–HER2-directed therapy may have clinical activity in these cases.[32,33]

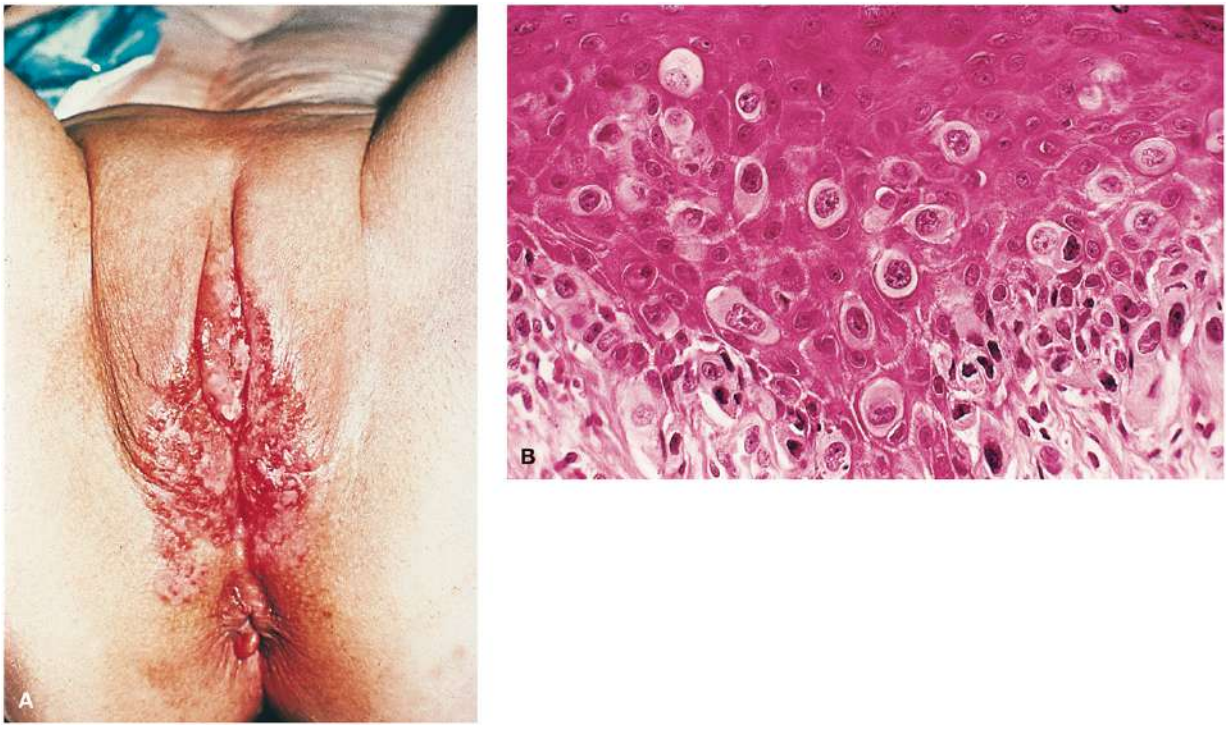

FIGURE 81.4 Paget disease of the vulva. A. Photo of extensive perineal disease, extending to the perianal skin. B. Photomicrograph of intraepithelial Paget cells, with copious pale cytoplasm, occurring singly or in small clusters, and appearing slightly larger than neighboring squamous cells. (Courtesy of Dr. Stanley Robboy, Duke University Medical Center, Durham, NC.)

Verrucous Carcinoma

Verrucous carcinomas of the vulva are uncommon, usually diagnosed in the fifth or sixth decade of life. They are locally invasive tumors that present as fungating, ulcerative masses. Histologically, these tumors are often well differentiated and have a low incidence of metastasis to LNs. In the early stages, excellent results are obtained with radical wide excision.[34] Inguinofemoral dissections are not recommended routinely due to the rarity of nodal metastases.

The literature regarding vulvar verrucous carcinomas consists largely of case reports, with the exception of the series by Japaze et al.[35] This study was based on 24 patients, 17 of whom were treated with surgery only and 7 of whom were treated with surgery and radiation. In the surgery group, only one patient developed recurrence and died as a result of it. In the radiation group, four patients developed recurrence, and all died from the disease. Although it is difficult to draw conclusions from this small series, there are no convincing data to recommend the routine use of RT for this disease. However, there is also no sufficient evidence to support the notion that radiation induces anaplastic transformation.[36]

Other Histologies

Other vulvar malignancies arising from epidermal cell types are rare. Merkel cell tumors (neuroendocrine carcinomas) are aggressive locally, have a high incidence of distant metastasis, and carry a poor prognosis. Basal cell carcinomas, on the other hand, seldom spread to LNs and are appropriately treated with wide excision alone.[37] Transitional cell carcinomas may arise from the Bartholin glands or may represent metastasis from the bladder and/or lower urinary tract.

Leiomyosarcomas are the most common subtypes of vulvar sarcoma, followed by undifferentiated pleomorphic sarcomas, epithelioid sarcomas, and rhabdomyosarcomas. Rhabdomyosarcomas of the vulva require combination therapy, chemotherapy, and radiation, as per rhabdomyosarcoma protocols of other sites. Results of treatment with other sarcomas of the vulva are variable; wide resection and/or radical RT should be considered, given the relative inactivity of chemotherapy.

CLINICAL PRESENTATION

Vulvar pruritus is the most common presenting symptom, often associated with bleeding, pain, or discharge. If there is a visible lesion on physical examination, a biopsy is required to distinguish it from other vulvar lesions, such as dystrophia, benign condylomata, and VIN. Presenting symptoms may also be related to the invasion of regional structures, including difficulty with urination or defecation. Metastatic disease is an uncommon presenting symptom because the primary lesion is usually much more problematic, although consequences of groin and distant disease may also be seen at presentation.

PATTERNS OF DISEASE AND SPREAD

Primary Site

Approximately 70% of vulvar malignancies arise in the labia majora and minora, 15% in the clitoris, 5% in the perineum and fourchette, 5% in the prepuce Bartholin glands and urethra, and 5% are too extensive at presentation to classify.[38]

Lymphatic Spread

High-grade tumors with “spray” growth pattern and lymphatic space invasion have a proclivity to spread to the regional lymphatic nodes. The superficial inguinofemoral LNs are the first echelon, followed by the deep inguinofemoral nodes. For well-lateralized lesions, metastasis to the contralateral inguinal or pelvic LNs is unusual in the absence of ipsilateral inguinofemoral node involvement. Lesions of the clitoris or urethra are occasionally noted to directly metastasize to pelvic LNs, although this is rare without inguinal node involvement.[39,40]

The frequency of inguinal LN metastasis in surgically staged patients ranges from 6% to 50%, depending on tumor invasion and extent of disease (Table 81.2).[41-45] Physical examination alone is inaccurate to assess LN involvement: Plentl and Friedman reported a 62% incidence of LN metastases in patients with clinically palpable adenopathy and 35% involvement in patients without clinically palpable adenopathy.[38] In the Gynecologic Oncology Group (GOG) protocol 36, 24% of the patients with clinically negative inguinal nodes were found to have nodal metastasis on final pathology. When the LNs were clinically suspicious, 76% had histologically positive nodes.

TABLE 81.2 INCIDENCE OF LYMPH NODE INVOLVEMENT CORRELATED WITH PRIMARY TUMOR SIZE AND EXTENT

Primary Tumor Size and Depth of Invasion	Number of Patients	Number of Patients With Positive Lymph Nodes (%)
Depth		
<1 mm	120	0 (0)
1.1-2 mm	121	8 (6.6)
2.1-3 mm	97	8 (8.2)
3.1-4 mm	50	11 (22)
4.1-5 mm	40	10 (25)
Size		
>5 mm	32	12 (37.5)
>2 cm	168	77 (45.8)
Any size of primary tumor extending beyond the vulva	70	38 (54.2)

Multiple clinical and histologic features of the primary tumor are associated with nodal metastasis, including tumor thickness, histologic grade, capillary-like space involvement, DOI, location of the tumor, and tumor size.[46,47] Rutledge et al. also described the adverse effect on local control and survival based on tumor size, clinical stage, positive inguinal or pelvic nodes, and positive margins at the primary site.[47] When the tumor thickness is 1 mm or less, the probability of nodal metastasis is 3% or less, but with tumor a tumor thickness 5 mm or larger, the probability increases to 33.3%. DOI of 1, 2, and 3 mm corresponds to a 4.3%, 7.8%, and 17% incidence of nodal involvement. It should be noted that the thickness of the epithelium in the vulva varies significantly from one area to another, in some areas being greater than 0.8 mm thick, which can influence the relative value given to

tumor thickness and DOI. Measuring tumor thickness in superficially ulcerated tumors can be misleading and may lead to underestimating the DOI. Perineural invasion correlates strongly with LN metastasis.[48]

In an analysis of the GOG database on carcinoma of the vulva, several clinical and histologic tumor characteristics were identified as predictors of nodal involvement. In order of importance, these are clinical node status (palpable vs nonpalpable), grade, capillary-lymphatic space involvement, tumor thickness, and patient's age.[46,49,50] There is also a correlation between the size of the primary tumor and the involvement of the LNs. In Donaldson et al.'s series of 66 patients, the probability of having positive inguinal nodes rose from 18.9% for patients with lesions less than 3 cm to 72.4% for patients with primary tumors 3 cm or more.[42] In a GOG study of 267 patients with superficial vulvar cancer reported by Sedlis et al, the frequency of positive inguinal nodes was 18.1% for patients with lesions up to 3 cm in size and 29.3% for patients with lesions 3 cm or more.[46] Extension of the primary tumor to the urethra, vagina, and anal area is associated with an increased incidence of nodal involvement and worse prognosis.

Inguinal nodal involvement is a strong predictor for pelvic nodal disease. In a GOG study of patients with positive inguinal nodes, the incidence of pelvic node involvement was 28%.[51] Due to the rarity of isolated pelvic nodal metastasis, the status of the inguinal nodes often determines the management of the pelvic nodes. Although pelvic node involvement is currently staged as IVB disease, many are still potentially curable, and definitive local therapy remains indicated. In a series from MD Anderson, 5-year OS for women with involved pelvic nodes was 43% when treated with aggressive local therapy.[52]

Distant Metastases

Hematogenous dissemination generally occurs late in the natural history of the disease, with the most common sites being the lungs, liver, and bones. The OS is limited in these cases to a median of approximately 6 months.[53]

PROGNOSTIC FACTORS

LN metastasis is the most important prognostic factor in patients with vulvar cancer. The presence of inguinal node metastases is accompanied by a 50% reduction in long-term survival.[54] LN extracapsular tumor extension has been noted in several series to impact disease recurrence and all-cause mortality.[55] Origoni et al evaluated the significance of the size of the metastases in the LNs, the number of positive LNs, and extracapsular extension (ECE) of the disease and found that the presence of any one of these factors worsened the prognosis.[56] Extracapsular tumor extension as an independent adverse prognostic factor on survival was also described by van der

Velden et al.[57] Pelvic nodal metastasis has an even more profound negative effect on survival, though as noted earlier, definitive local therapy can still result in long-term survival.[58]

In an analysis of formalin-fixed tissue specimens, a UCLA series reported a sharp rise in the incidence of local recurrence for tumors with close microscopic surgical margins (48% if <8 mm, with no local recurrences if >8 mm).[59] This corresponds to a margin of 1 cm in fresh, unfixed tissue. In addition to margin status, DOI was reported as an important prognostic factor, with 30% of patients with 10 mm or more DOI experiencing recurrence, in contrast to 0 of the 52 patients with less than 2.5 mm. Although the frequency of local recurrences correlated with the adequacy of the margins of the surgical resection, larger or thicker tumors, or when those that involve midline structures, adequate surgical margins may be difficult to obtain.

Faul et al published a retrospective series evaluating the role of adjuvant radiation for close and positive surgical margins in which a 5-mm margin of excision was a predictor for local recurrence (58% if observed).[60] More modern series, however, have put into question the relationship between surgical margins and recurrence, with a 2019 series from the Netherlands suggesting that locoregional recurrence did not correlate with pathologic tumor-free margins, but rather the presence of precursor lesions at the surgical margin, such as LS, dVIN or both.[61]

Kurzl and Masserer analyzed 124 patients with various stages of vulvar carcinoma treated with simple vulvectomy alone and local/inguinal irradiation.[62] They found that age, disassociated growth, lymphatic spread, thickness, and ulceration of the primary tumor were important prognostic factors. In a detailed analysis of a GOG clinicopathologic study of 558 women with vulvar cancer, two significant risk factors were identified that predispose for recurrence in the vulva: tumor size greater than 4 cm and capillary-lymphatic space involvement.[49] If either of these factors was present, the risk of local recurrence after radical vulvectomy was 21% versus 9% without. In this study, the DOI did not predict for vulvar failure.

INITIAL EVALUATION

A thorough examination of the genitourinary system is warranted in all those with vulvar cancer to evaluate for multifocal disease. Examination of the vagina, cervix, perianal skin, and anal canal is of particular importance in order to delineate the extent of disease and to identify synchronous lesions, particularly in the setting of HPV-mediated disease. Special attention as well is paid to the inguinofemoral basins for clinical detection of lymphatic spread, though clinical negative groin examinations have a 25% to 30% false-negative rate, as noted earlier.

Imaging studies may not be necessary in early lesions that may be approached with surgery as the first treatment modality. However, imaging in women with

locally advanced disease or with clinically suspicious LNs help the clinician select the most appropriate treatment. Computed tomography (CT) scans can identify suspicious lymphadenopathy in the inguinofemoral chains, pelvis, or para-aortic regions.[63] Contrast-enhanced magnetic resonance imaging (MRI) is also helpful to delineate the primary lesion and contributes to the evaluation of inguinal LNs, with a sensitivity of 80% and a specificity of 88%.[64] Clinically or radiographically detected inguinal nodes may be evaluated with ultrasound-guided fine-needle aspiration, though a negative result does not rule out involvement.[65] Fluorodeoxyglucose (FDG) positron emission tomography (PET) has been used to evaluate the groin prior to surgical evaluation, with a sensitivity of 67% and a specificity of 95%.[66] FDG-PET at diagnosis may change the prior clinical impression in up to 50% of cases.[67] However, the sensitivity of all imaging modalities available remain insufficient to omit surgical evaluation in women with a high risk of nodal involvement.

STAGING

The most recent Federation of Gynecology and Obstetrics staging revision was performed in 2021 (Table 81.3).[68] The definition of DOI is now defined as the measurement from the basement membrane of the deepest, adjacent, dysplastic, tumor-free ridge to the deepest point of invasion. Stage III is divided into three substages with changes based on nodal involvement. Stage IIIA involves tumor extension to the upper urethra, upper vagina, bladder or rectal mucosa, or regional (inguinal and femoral) nodal metastases 5 mm or less, whereas nonosseous organ extension was previously stage IVA. Stage IIIB includes regional nodal metastases greater than 5 mm, and stage IIIC involves nodal metastases with extracapsular spread. Stage IVA includes disease fixed to the pelvic bone or fixed regional LN metastases, and stage IVB is defined by distant metastases. The presence of pelvic nodal metastases remains stage IVB disease.

TABLE 81.3 VULVAR CANCER: 2009 AJCC STAGING AND CORRESPONDING 2021 FIGO STAGING

2009 AJCC			2021 FIGO
Tis	Carcinoma in situ		–
T1a	Confined to vulva/perineum, size ≤2 cm, stromal invasion ≤1 mm	N0	IA
T1b	Confined to vulva/perineum, size >2 cm, or stromal invasion >1 mm	N0	IB
T2	Adjacent spread to distal 1/3 urethra and/or vagina or anus	N0	II
T3	Extension to proximal 2/3 urethra and/or vagina, bladder/rectal mucosa		IIIA
N1a, N2a	Regional (inguinal and femoral) nodal metastases ≤5 mm		IIIA
N1b, N2b	Regional lymph node metastases >5 mm		IIIB

2009 AJCC		2021 FIGO

MANAGEMENT OVERVIEW

Many factors make the treatment of carcinoma of the vulva challenging. Many women with this disease are older and have comorbidities. The tumor, by virtue of its location, can easily involve adjacent organs such as the urethral meatus and anal canal, and the frequency of nodal involvement is high. Because of the relatively low incidence, most published reports consist of small and heterogeneous groups of patients. Management of carcinoma of the vulva is further complicated by the major impact on genitourinary function that the disease itself and its treatment can have on patients.

The management of vulvar carcinoma has evolved significantly in the past decades. En bloc resection of the primary tumor and a full inguinal node dissection are no longer routinely utilized, replaced by multimodality therapy, with surgery being more tailored to the extent of the disease. This change is in large measure due to the recognition of the morbidity associated with radical surgery and improving results achieved with multimodality therapy.[69-71] The likelihood of controlling the primary tumor with surgery largely depends on the adequacy of the margins of resection, and it is not necessary to remove the entire vulva. A clear margin of greater than 8 mm in all directions is sufficient to achieve a high rate of local control of the primary tumor.[59]

There have been refinements in the surgical technique that have made the procedures more tolerable. Examples of such improvements include primary closure of the perineal wound, the use of myocutaneous flaps to close the surgical defect in the inguinal area, and the use of separate incisions for the resection of the primary tumor and the inguinal nodes. These developments have resulted in a decrease in operative mortality and morbidity.

There have been also significant advances in all aspects of RT that apply to the treatment of carcinoma of the vulva. The technical resources available now make it

possible to deliver effective doses of radiation to the vulvovaginal and inguinal regions with less acute and late morbidity. With high photon energy units, well-collimated fields, multileaf collimators, electron beams of different energies, and intensity- modulated radiation therapy (IMRT), radiation is now delivered to the primary disease and LNs with precise account of the differences in contour, tissue thickness, and extent of the disease. It is possible to tailor the treatment to the specified treatment volume while keeping the dose to the normal tissues within acceptable limits of tolerance. In particular, IMRT has allowed for dose escalation to involved sites of disease for locally advanced vulvar cancers. This has resulted in higher response rates in more modern series such as GOG 279 (71% clinical complete response [CCR]) when compared to the response rates observed in GOG 101 (48% CCR) and GOG 205 (48% CCR).[72] In very select cases, brachytherapy (BT) may also be used as either primary treatment or in combination with external beam to bring the dose higher to limited volumes. Chemotherapy, radiation, and surgery in sequence and/or in combination lessen the impact of any one modality and can lead to functional organ preservation with comparable or improved local tumor control and survival (Figure 81.5).

SURGERY

Wide Local Excision, Radical Vulvectomy, Exenteration

In the past, even patients with early-stage IB disease were considered to have diffuse disease, and a radical vulvectomy was considered the standard of care, yielding 90% survival rates but with considerable long-term sequelae. While there is a lack of prospective data comparing radical local excisions versus more extensive radical vulvectomies, several retrospective studies reveal no difference in recurrence or survival outcomes.[73] For T1 and smaller T2 lesions (<4 cm) with 1 mm or less invasion, a wide local excision is recommended without inguinofemoral node evaluation, given the risk of nodal involvement in these cases is less than 1%.[74] For tumors with greater than 1 mm invasion, an inguinofemoral groin node evaluation is recommended. If these tumors are well lateralized (>2 cm from the midline), only an ipsilateral groin evaluation is necessary; however, for midline lesions, bilateral groin node evaluation is recommended.

At surgical resection, the depth of the excision should be to the deep perineal fascia or periosteum of the pubis for more anterior lesions. Excision of 2-cm margins of grossly normal-appearing tissue is recommended when possible, with a goal of obtaining at least 1-cm microscopic margins in fresh tissue, and greater than 8 mm following tissue processing. If the tumor involves or abuts the clitoris, preservation of this structure may not be possible. Positive margins can also be considered for reresection, if there are no other indications for postoperative therapy, and critical structures can be preserved.

Radical vulvectomy is reserved for patients with large or multifocal lesions in whom preservation of normal vulvar tissue is not possible or would not serve a functional or reconstructive benefit. When the anus, vagina, or urethra is involved by malignancy, extended radical vulvectomy or pelvic exenteration is required to clear the disease surgically.[75,76] However, surgery alone for patients with advanced disease yields disappointing long-term results, stimulating interest in multimodality treatment in the mid- to late 1980s.[77,78]

Surgical Evaluation of Inguinofemoral Lymph Nodes

Attention to risk factors for nodal involvement is critical as inguinal recurrences are very difficult to treat and a full inguinofemoral node dissection can be morbid. The main complications of groin surgery are wound breakdown, infection, and lower extremity lymphedema. Although wound breakdown will often heal successfully by secondary intention, chronic lower extremity edema is very difficult to deal with and can lead to significant disability. To reduce the frequency and severity of these complications, efforts have been made to identify patients in whom the extent of the node dissection can be decreased or eliminated altogether without compromising the likelihood of control of the disease.

As mentioned previously, patients with small (<2 cm diameter) superficial squamous cell carcinomas with a DOI 1 mm or less and no lymph vascular invasion have a very low risk of nodal involvement, and the groin dissection may be omitted.[79] For lesions with greater than 1-mm invasion, groin node assessment should be performed in the form of superficial inguinal lymphadenectomy or sentinel node procedure. Small (<4 cm), lateralized lesions (>2 cm from the midline) may be treated by unilateral groin evaluation, whereas for midline and clitoral lesions, both groins should be assessed. For patients undergoing primary surgery, palpable inguinal nodes should be removed if present.

The need to perform bilateral inguinal node dissection in patients with unilateral vulvar lesions, as well as the need to dissect the deep nodes whenever a superficial node dissection is carried out, has been reexamined in light of the additive morbidity of each procedure. When bilateral superficial and deep inguinal node dissections are

performed, the potential for wound breakdown and lower extremity lymphedema increases. When a unilateral dissection is indicated and nodes are found to be negative, a contralateral node dissection is not required due to the low likelihood of contralateral metastasis.[80,81] The deep inguinal node dissection is usually omitted, based on the fact that if the superficial nodes are free of tumor, the deep nodes are rarely involved.[82] However, control of the disease in the LNs is of utmost importance as groin recurrences can be difficult to treat.[83]

Women with fixed or ulcerated inguinal nodes are rarely curable with surgery alone. These patients should have a biopsy to document the nodal involvement and should be treated with combined radiation and chemotherapy, either primarily or in a preoperative manner as discussed later.

Sentinel Lymph Node Dissection

Sentinel nodal procedures have become a standard of care for the assessment of inguinal disease. In the multicenter Groningen International Study on Sentinel Nodes in Vulvar Cancer (GROINSS-V), a sentinel node procedure using radioactive tracer and blue dye was performed in 623 groins and resulted in a 2.3% groin recurrence rate following a negative sentinel node.[84] This compares favorably to the 5% ipsilateral groin recurrence rate following negative full superficial inguinal dissection in a prospective GOG study of low-risk vulvar cancer.[83] Patients who underwent a sentinel node dissection had significantly lower groin wound breakdown when compared to full dissections (12% vs 34%). Long-term follow-up of the GROINSS-V trial demonstrated 5- and 10-year overall recurrence rates of 24.6% and 36.4% for sentinel node–negative patients versus 33.2% and 46.4% in patients who had positive sentinel nodes with subsequent completion inguinofemoral node dissection.[85] Optimal lesions for sentinel node procedures are those with small (<4 cm) unifocal lesions. If a sentinel node approach is undertaken, it is recommended that the sentinel nodes be evaluated prior to vulvar resection to avoid disruption of lymphatic channels emanating from the tumor. If no sentinel node is found, a full inguinofemoral lymphadenectomy is still recommended.

The GOG 88 protocol tested whether RT alone could supplant nodal dissections after vulvectomy.[86] Women with clinically negative nodes after radical vulvectomy were randomized between 50 Gy to the bilateral inguinal regions or an LN dissection with selective radiation delivered to those with positive nodes. The radiation-alone arm had increased recurrences within the inguinal regions (at 2 years: 32% RT alone vs 6% nodal dissection, $P = .033$), with an associated decrement in OS (59% RT alone vs 90% nodal dissection, $P = .035$). A critique of this trial is whether the prescribed radiation treatment depth to the inguinal nodes provided adequate coverage, which may have accounted for the difference in local control and

survival.[87] Ultimately, the study does suggest that 50 Gy alone is not sufficient for elective control of subclinical nodal disease.

Intraoperative diagnosis of inguinal node metastasis necessitates further diagnostic or therapeutic procedures. The GROINSS-V II/GOG 270 study evaluated inguinofemoral RT versus inguinofemoral lymphadenectomy in patients with vulvar cancer and a metastatic sentinel LN.[88] Among patients with sentinel node micrometastases (≤2 mm) who received inguinofemoral RT, the ipsilateral isolated groin recurrent rate was 1.6% at 2 years. Among those with sentinel node macrometastases (>2 mm) or ECE, isolated groin recurrences remained unacceptably high, with a rate of 22% with RT versus 6.9% with completion inguinofemoral lymphadenopathy. Thus, similar to GOG 88, 50 Gy alone is not a safe alternative to inguinofemoral lymphadenectomy in patients with sentinel node macrometastases. Drawing on the response rates seen in locally advanced vulvar cancers with combination chemoradiation, the ongoing GROINSS-V III study is evaluating the safety of replacing inguinofemoral lymphadenectomy with a higher dose of 56 Gy and concurrent weekly cisplatin for early-stage vulvar cancer with sentinel node macrometastasis (>2 mm) and/or ECE.

Pelvic Lymph Nodes

Patients with clinically or pathologically positive groin nodes are at risk for having contralateral groin and pelvic nodal involvement. Thus, the status of the groin nodes is to be taken into consideration when determining the management of the pelvic nodes. Radiation to the pelvic nodes is generally preferred to surgery as women in need of treatment to the pelvis often also require radiation to the primary and/or inguinal nodes.

ADJUVANT RADIATION THERAPY

In the setting of early invasive disease treated with wide local excision, radiation to the tumor bed may be advised to prevent local recurrence. More modern series have highlighted the importance of local control at the primary site, including the long-term follow-up GROINSS-V I data that demonstrated a significant detriment to disease-specific survival at 10 years in the case of vulvar local recurrence (90.4% vs 68.7%).[85] As noted previously, pathologic features associated with higher risk of local recurrence at the primary site include lymphatic-vascular invasion (LVI), DOI greater than 5 mm, margins less than 8 mm, and microscopically positive margins.[59] Faul et al reported a retrospective study of 62 patients with close (≤8 mm) or positive surgical margins and found that local recurrence was significantly reduced from 58% with observation to 16% with postoperative radiation.[60] Although postoperative radiation reduces the incidence of local recurrence, some may be successfully treated

with repeat surgery or chemoradiation. In the absence of randomized trials, women with positive margins, margins less than 8 mm, deep invasion, and/or LVI should be considered for adjuvant radiation in a multidisciplinary discussion.

The role of radiation in the management of inguinal and pelvic nodes was evaluated in the GOG 37 trial reported in 1986.[51] In this trial, women underwent bilateral inguinal lymphadenectomy, and those with positive groin nodes were randomized to either pelvic lymphadenectomy or radiation to the pelvis and bilateral groins. The radiation group had significantly lower groin recurrence rate of 5%, compared to 24% for the group that did not receive radiation. This translated into a 2-year significant survival benefit of 68% versus 54% ($P = .03$) in favor of the group that received postoperative radiation. Subgroup analysis of this study identified that the benefit was seen primarily in patients with more than one pathologically positive node. An update of this trial suggested that if the ratio of involved nodes to submitted nodes was more than 20%, there were increased rates of contralateral LN metastases, relapse, and cancer-related death. This suggests that more than 20% positive inguinal nodes may be an alternative definition of a cohort that may benefit from radiation.[89] An analysis of the Surveillance, Epidemiology, and End Results databases in patients with one node positive revealed a significant survival difference in patients with less than 12 nodes submitted, supporting the hypothesis that the benefit of radiation may be greater in patients with an insufficient nodal dissection.[90] However, based on the entry criteria for the GOG 37 study, adjuvant radiation to the pelvis and both groins can be considered for all patients with nodal involvement.

All women with ECE of tumor in the nodes or with residual disease in the inguinal areas should receive postoperative radiation to the pelvis and inguinal areas, due to the increased risk of recurrence at the primary site and the LNs.[57] When the surgical margins are clear and there is no pathologic indication to treat the vulva, vulvar sparing to avoid acute and late effects is controversial. A series from Dusenberry et al found the probability of vulvar recurrence to be 48% when the vulva was excluded. In contrast, the vulvar recurrence rates in GOG 37 and GOG 88, where the vulva was similarly excluded from the treatment field, were only 4% to 9%.[51,86,91] Given these conflicting data, vulvar sparing should be carefully considered, balancing the risks of recurrence versus acute and late effects.

Historically, adjuvant radiation to the primary site was delivered with either photons or en face electrons with bolus. When treating a large area of the vulva and groins, anteroposterior/ posteroanterior (AP/PA) photon fields were previously used. However, in modern practice, IMRT has become the preferred method of delivery. There is now sufficient data suggesting the use of IMRT may be equally effective with much less morbidity. This delivery approach has also allowed for further dose escalation, associated with increased response rates while mitigating toxicity.[72,92]

Further details in regard to treatment planning may be found later in the chapter. The elective volume (grossly uninvolved nodal basins) can be treated to 45 to 50.4 Gy. When microscopic disease in the primary tumor area is suspected, a dose of greater than 56 Gy is recommended.[93] When there is ECE of tumor in the LNs, the dose to the groins can be carried up to 60 Gy. If there is gross residual disease postsurgery, the dose to the area should be brought to a minimum of 65 to 70 Gy, as for definitive therapy.

The GOG 37 study required treatment to both groins; however, in the dissection arm of GOG 88, only the ipsilateral groin and hemipelvis were treated, suggesting that with well-lateralized lesions, ipsilateral-only treatment may be effective. In a small series of 20 women undergoing ipsilateral radiation alone (44 Gy in 2 Gy fractions), no contralateral recurrences were observed.[94] In fact, although there were no contralateral recurrences, the *ipsilateral* recurrence rate was quite high (45% crude rate), suggesting that 44 Gy is an insufficient dose. The decision to treat unilateral or bilateral groin/pelvis remains an active clinical question with the current GROINSS-VIII study, which offers ipsilateral groin and pelvic RT. For well-lateralized, low-risk lesions unilateral radiation may be appropriate in the postoperative setting.

The use of adjuvant chemotherapy with RT, either sequentially or concurrent, has not been tested prospectively. A National Cancer Database (NCDB) study found that adjuvant chemotherapy has been used more frequently since 1999 (11% in 1998 to 41% in 2006) and that the use of chemotherapy was associated with improved OS (hazard ratio [HR] 0.62, 95% confidence interval 0.48-0.79).[95] In extrapolation from cervix cancer, the most common concurrent regimen is cisplatin at 40 mg/m^2 weekly for women with higher risk of recurrence (≥2 nodes positive). However, in lack of higher quality evidence, the use of chemotherapy in this setting remains controversial.

PREOPERATIVE RADIATION THERAPY WITH CONCURRENT CHEMOTHERAPY

For locally advanced vulvar cancer, multimodality therapies have become the standard of care.[96] When a preoperative approach is used, after concurrent chemoradiation is complete, the response to the therapy at the primary site and the LN is assessed. If there is complete clinical regression of the disease at the site of the primary, one option is to perform biopsies of the primary site, foregoing resection if there is a pathologic complete response (pCR).[97] In the case of persistent clinical or pathologic disease, vulvectomy with or without nodal dissection is considered if possible.

Preoperative chemoradiation was tested in the phase II GOG 101 trial for patients with advanced primary and/or nodal disease.[96,97] Radiation treatment consisted of 170 cGy twice daily on days 1 to 4 and 170 cGy once a day on day 5 and days 8 to 12, for a dose of 2,380 cGy. Cisplatin, 50 mg/m^2, was given on day 1, and 5-fluorouracil (5-FU), 1,000 mg/m^2 by a 24-hour infusion, daily on days 1 to 4. The combined cycle of chemotherapy and radiation was repeated after a 2-week break, thus delivering a total radiation dose of 4,760 cGy. In the locally advanced cohort, the pCR rate was 34% and R0 resections were possible in 77% of subjects. In all, 55% were alive and without disease at the last follow-up. In the group of women with advanced nodal disease, the nodes became resectable in 83%, with a pCR rate of 40% in those who underwent surgery, with 43% of the patients being alive and disease free at the last follow-up.

The follow-up phase II GOG 205 study enrolled women with T3 or T4 tumors, treated with a total dose of 5,760 cGy (180 cGy/fraction) and weekly cisplatin (40 mg/m^2), with no planned treatment breaks.[98] In all, 69% of women were able to complete the protocol per plan, 64% achieved a complete response, and 50% had a pCR. OS at 2 years (estimated from curves provided in the manuscript) was 40% for those with no or partial clinical response, 62% for those with a complete clinical response, and 81% for those with a pCR.

GOG 279 was recently reported, utilizing a combination of gemcitabine at 50 mg/m^2 and cisplatin at 40 mg/m^2 weekly with IMRT.[72] The vulva was treated to 64 Gy, with varying groin doses according to LN status. The reported pCR rate of 73.1% and CCR rate of 71.2% was superior to prior GOG studies. The progression-free survival (PFS) rate at 12 months was 74%. It is uncertain if these encouraging results were a result of a higher radiation dose (64 Gy), better radiation delivery (via IMRT), the addition of gemcitabine, or a combination of these factors. Final publication of this trial is pending as of this writing, but this treatment protocol is likely to become part of the standard of care.

DEFINITIVE RADIATION THERAPY

The standard of care for early lesions is surgical resection; however, selected patients with small central lesions may be considered for definitive radiation, particularly when the lesions are in close proximity to the urethra, clitoris, or anus. There are few published series of radiation alone used as definitive therapy for vulvar cancer.[99-101] The reported series include patients with recurrent disease postsurgery and patients who are not medically suitable for surgery or have declined it. In Ellis's series of 65 patients treated with BT and or external beam, the crude 5-year survival rate was 23%, with crude local control in 40%.[99] Slevin and Pointon reported on the results of 58 patients treated also with BT and/or external beam, depending on the extent of the

disease.[101] The crude 5-year survival rate was 26% with a similar local control rate of 40%. These series reflect the difficulty of achieving appropriate curative doses for gross disease with radiation alone in the pre-IMRT era.

BT has been used for inoperable vulvar cancer and as a boost to the primary tumor and/or to the LNs. The efficacy of this treatment is difficult to evaluate due to small numbers and heterogeneity in the reported populations. A series from the Centre Alexis Vautrin Institute in France describes 34 patients, 21 with primary and 13 with recurrent disease, treated with BT only.[100] The median dose was 60 Gy, with a range of 53 to 88 Gy. In the group of 21 patients who underwent BT as primary treatment, 3 patients developed locoregional recurrence, for a 5-year local control rate of 80% and a disease-specific survival of 70%. In the group of 13 patients who were treated for recurrence, 8 developed local recurrence, with or without disease at other sites, for a local control rate of 19%. Of the entire group of 34 patients, 5 developed vulvar necrosis. This relatively low complication rate most likely reflects that extensive experience and high quality of the BT carried out in this institution. Similarly, Tata Memorial published on their institutional outcomes with high-dose rate BT for vulvar cancer. Treatment was delivered at 3.4 to 4 Gy per fraction at 2 fractions per day at least 6 hours apart to a total of 4 to 5 fractions as boost or 10 to 13 fractions if BT monotherapy alone. Five-year local control rate for the entire cohort was 77%: 100% for patients treated with radical BT and 68% for those treated with the combination of external beam radiation therapy (EBRT) and interstitial BT boost. The 5-year disease-free survival (DFS) and OS for the entire group were 51% and 82%, respectively, with the data favoring better DFS and OS outcomes for those treated with radical BT as compared to combination EBRT and BT boost. Nonetheless, due to the risk of necrosis, the use of BT should be limited to selected cases and performed by experienced practitioners.

DEFINITIVE CHEMORADIATION THERAPY

Definitive chemoradiation is used for patients with advanced tumors considered unresectable at presentation or for patients who are medically inoperable (Table 81.4). This may be used when the tumor does not become resectable in the midst of preoperative-intent chemoradiation or as an upfront alternative to surgically based treatment. Elective pelvic and inguinal volumes are treated to 45 to 50.4 Gy, while the primary and involved nodes are boosted to 60 to 70 Gy. The total dose to certain areas is dependent upon the location and extent or bulk of the disease, the response to the therapy, and the estimated tolerance of the area requiring the high radiation dose. Often, it is the tolerance of normal tissue that limits the dose to 65 or less to 70 Gy. The use of simultaneous integrated boosts to the primary should be used with caution due to the risk of vulvar necrosis. Selected patients at low risk of having nodal

involvement (<1 mm invasion, or negative LN dissection or sentinel node biopsy) may be treated to the vulvar area alone. Bolus material should be used also to avoid underdosing the surface of the tumor.

[a]Includes patients treated for recurrent disease.

There are no prospective comparative trials for chemotherapy selection with concurrent treatment; however, a retrospective series from Dana-Farber/Brigham and Women's Cancer Center and Massachusetts General Hospital does shed some light.[102] In this series of 44 women, 24 of whom were treated definitively without surgery, 16 received weekly platinum-based regimens and 28 received a 5-FU–based regimen every 3 to 4 weeks. The 2-year OS (74% platinum, 70% 5-FU), DFS (62% platinum, 56% 5-FU), and locoregional recurrence (31% platinum, 33% 5-FU) were not significantly different. The grade 3 or higher skin toxicity was higher with weekly platinum (62% platinum, 32% 5-FU), but the nonskin toxicity was higher with 5-FU (13% platinum, 46% 5-FU). Given these data and the positive results of GOG 205 (discussed earlier), weekly cisplatin at 40 mg/m^2 is a reasonable option for concurrent treatment.[98] Pending the publication of GOG 279, it remains uncertain if a new standard will be established with combination of cisplatin and gemcitabine.

There are no prospective data comparing chemoradiotherapy alone and combined with surgery; however, an NCDB study has examined survival after both strategies have been reported.[103] In the overall cohort, women undergoing primary radiation had OS at 3 years of 42% compared to 57% with radiation plus surgery. However, when limiting the definitive cohort to those who received concurrent chemotherapy and radiation to doses greater than 55 Gy, the survival was 57%, comparable to preoperative approaches. While there are multiple possible confounders that affect NCDB analyses, this suggests that initial radiation and concurrent chemotherapy may be considered, with surgery reserved for persistent or recurrent disease.

TREATMENT VOLUME AND TECHNIQUE

Simulation and Target Delineation

Appropriate identification of the targets of treatment is a challenging but critical process in vulvar cancer. CT- or MR-based three-dimensional planning is essential to establish the location, extent, and depth of the inguinal and pelvic nodal basins, as well as the primary site.

At the time of simulation, markers should be placed on the primary site, the LNs, and scars from previous surgery to document the extent of the disease. “Frog-leg” positioning may be used to reduce skin folds in the inguinal regions, though this may be less important if IMRT is used. Radio-opaque markers at natural anatomic landmarks such as the introitus and anus may also be useful in outlining treatment fields. Advanced immobilization devices such as a cradle can be considered, though, for some, the cradle itself may become uncomfortable during treatment due to the expected skin reaction. Bubble wrap or bariatric slings may also be used to reduce skin folds, particularly in patients with a pronounced panniculus. Bolus is often critical over the vulva and groins, which may be applied at the time of simulation, or applied “virtually” at the time of treatment planning. Obtaining good contact against the skin at all points to eliminate significant air gap is challenging but critical. The use of wet gauze, towels, or impregnated gauze may be necessary. Placement of bolus should be confirmed at the time of treatment, either through direct inspection of setup or through the use of onboard imaging such as a cone-beam CT. Verification of dose at the surface is also an important evaluation and can be achieved with dosimeters such as OSLDs (optically stimulated luminescent dosimiters) or TLDs (thermoluminescent dosimeters) at the start of treatment.

The primary vulvar lesion (primary gross tumor volume) may be hard to identify on CT imaging alone, making the use of radio-opaque markers critical. MRI and PET imaging, if available, may also aid in the identification of the primary lesion. When defining a primary planning target volume (PTV), ample margins (1.5-2 cm) should be placed to account for microscopic spread of disease and the potential variations in daily setup. Additional clinical tumor volume (CTV) coverage of the vagina should be added for lesions that involve the introitus or distal vagina. The uterus, if present, is not usually targeted.

The nodal targets include the inguinal basins, which should be defined based on anatomic compartment; symmetric margins around the vessels are inadequate, leading to undertreatment medially and overtreatment to deep structures (Figure 81.6).[104] This compartment is defined by:

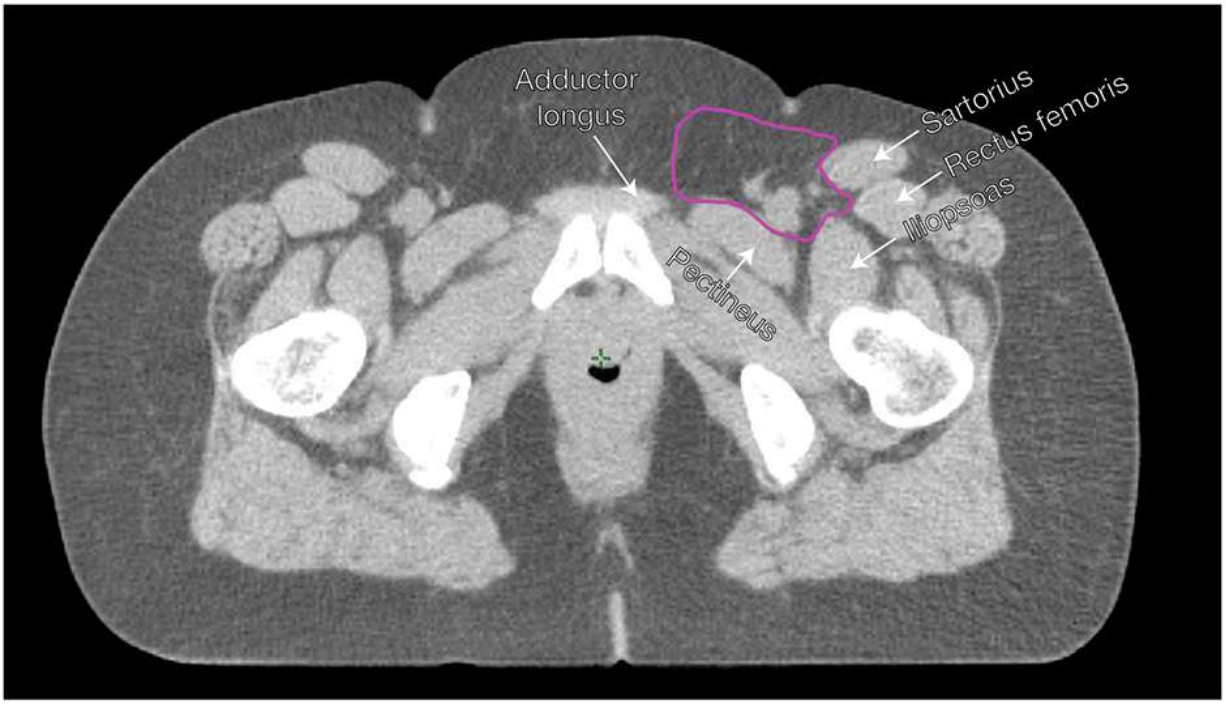

FIGURE 81.6 Example of a clinical tumor volume (CTV) for inguinal treatment (purple contour). The lateral border is the medial edge of the iliopsoas. The medial border is the lateral extent of the adductor longus or medial end of pectineus. The posterior border is bounded by the iliopsoas muscle laterally and anterior aspect of the pectineus muscle medially. The Anterior border is carried over from the anterior edge of sartorius muscle. All benign-appearing nodes also should be included, and the inferior extent should extend 1 to 2 cm below the vulva and perineum.

Lateral: The medial border of the iliopsoas

Medial: The lateral border of adductor longus or medial end of pectineus

Posterior: The iliopsoas muscle laterally and anterior aspect of the pectineus muscle medially

Anterior: The anterior edge of sartorius muscle

The pelvic nodes are often also targets of treatment and include the obturator, external, and internal iliac chains, defined in a manner similar to uterine or cervical disease. Common iliac nodes or para-aortic basins may be added if there are nodes positive in the more distal pelvic echelons. Presacral basins are usually not target, unless there is involvement of the anal canal or rectum. Consensus contours are now available to guide treatment and may be very helpful, particularly when more conformal techniques such as IMRT are used.[105]

Historical Two- and Three-Dimensional Conformal Treatments and the Transition to Intensity-Modulated Radiation Therapy

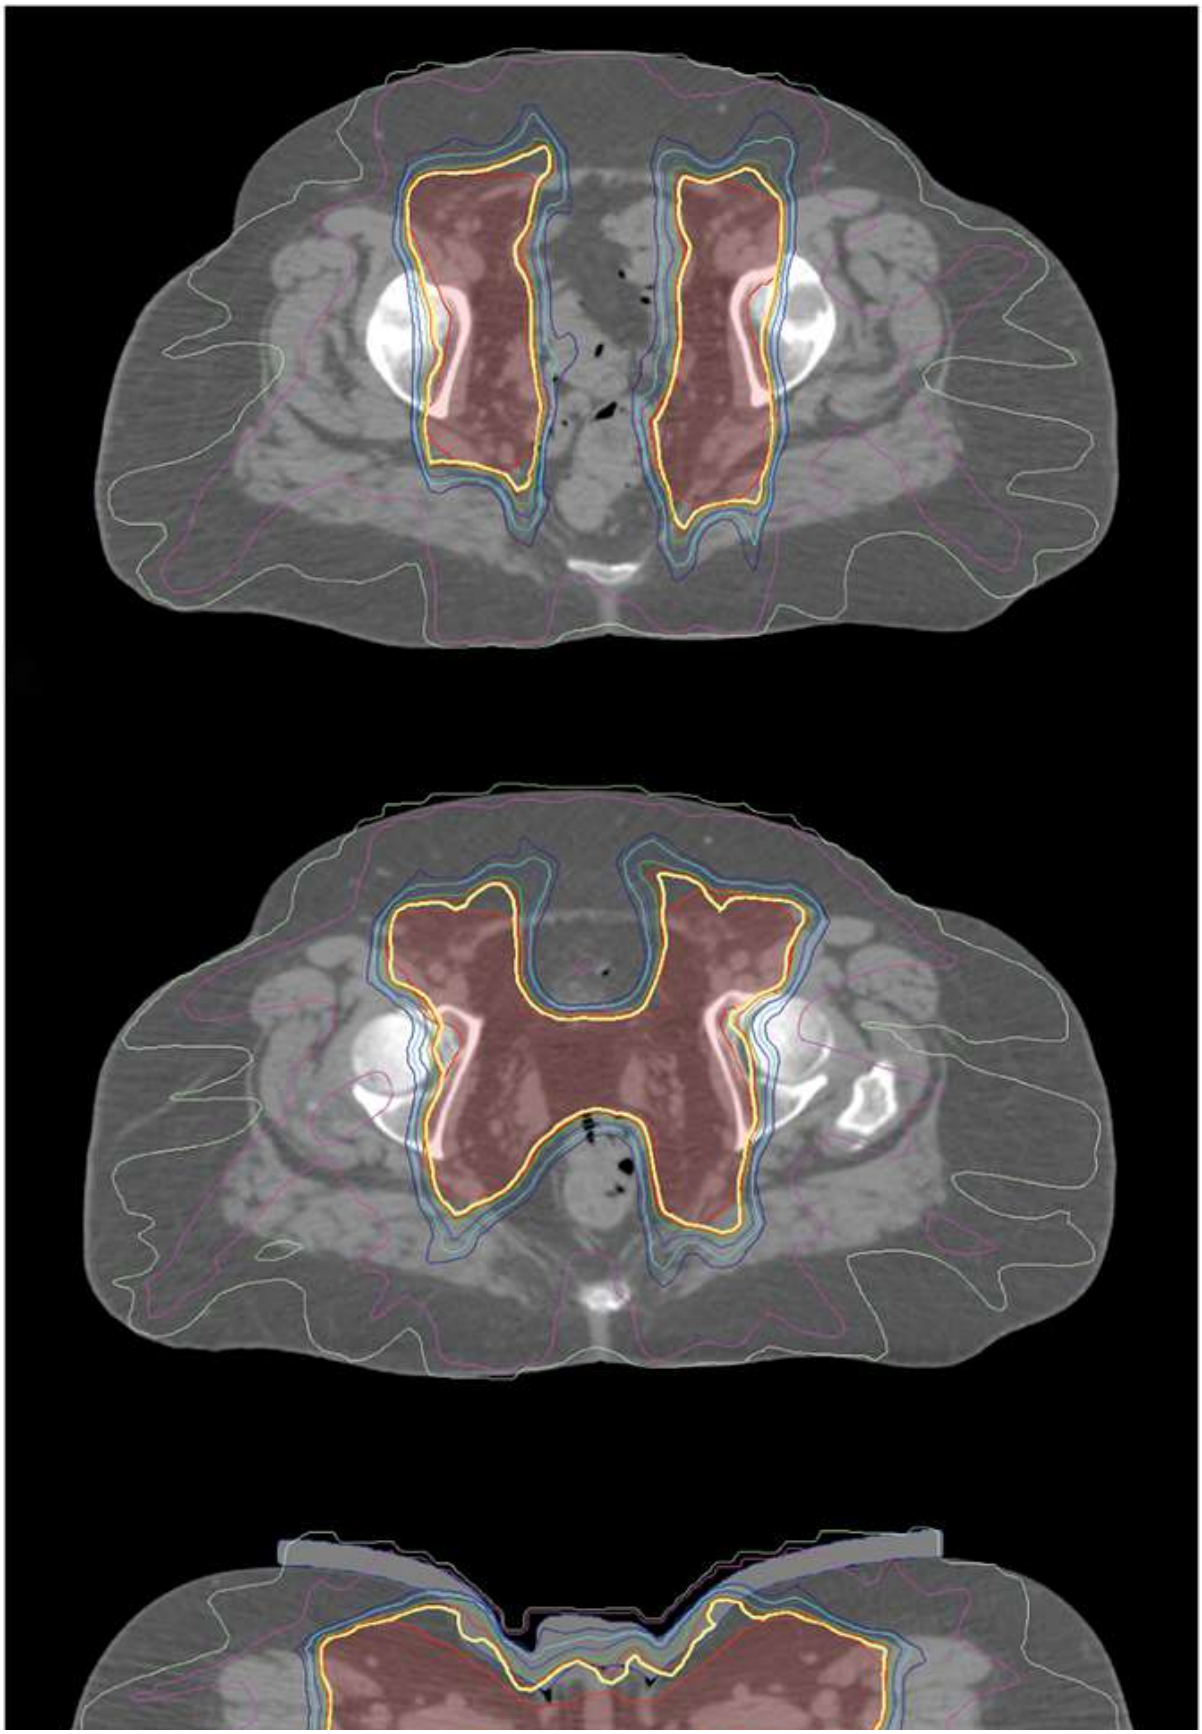
IMRT has replaced 2D/3D delivery techniques in this disease site due to improved conformality and capacity for dose escalation. Historically, 2D/3D techniques employed an AP/PA beam arrangement in which a wider AP field was paired with a narrower PA field in order to encompass the inguinal LNs in the anterior approach, while allowing for traditional midline prescription of the pelvic nodal coverage using AP/PA beams. This technique would spare additional posterior dose to the femoral heads. The photon fields were weighted equally, and the inguinal dose was then supplemented by separate anterior electron patch fields, matched to the pelvic field.

A derivation of this method consisted of using an AP/PA approach to the primary and pelvis while utilizing anterior electron fields alone for the inguinal nodes. Although this approach had the advantage of a simpler treatment setup, ensuring adequate dose at the inguinal electron-photon match line could be challenging in the setting of gross nodal disease, and significant late skin changes were associated with electron fields carrying the entire dose.

Alternatively, a wide AP field was again paired with a narrow PA field, with a partial transmission block placed in the central portion of the AP field. The desired dose at a specified depth was delivered to the inguinal nodes through the AP field.[106] The degree of central anterior beam attenuation was calculated so that the midpoint of the pelvis received equal doses from the AP and PA beams. This technique eliminated the dosimetric problems of photon/electron field matching, as well as the potential for daily setup variation, but the design of a precise partial transmission block remained difficult.

A growing body of literature has supported the substitution of these techniques with IMRT.[107-109] Early in its adoption, Beriwal et al reported 15 patients treated with IMRT using a median of seven fields.[107] The CTV was defined as a 1- to 2-cm margin around bilateral external iliac, internal iliac, and inguinofemoral nodes, as well as a 1-cm margin around the entire vulvar region. Gross tumor was also expanded by 1 cm for the CTV. The planning treatment volume was defined as 1-cm margin beyond the CTV, and the prescription dose was 43 to 48 Gy for preoperative treatment and 50 Gy for postoperative treatment, delivered partly on a twice-daily schedule. This early experience yielded excellent clinical response, with 13 of 15 patients having no evidence of disease at the last follow-up. This technique also resulted in improved dose conformality and lower doses to normal structures, including rectum, bladder, small bowel, and femoral heads. The most recent update of this series found a pCR rate of 48%, 3-year OS of 61%, and 3-year local recurrence-free survival of 66%.[109] These results were comparable to the GOG 101 results and resulted in less acute skin toxicity than 2D or 3D techniques. IMRT was prospectively allowed on the GOG 279 trial, allowing dose escalation to 64 Gy with cisplatin and gemcitabine, resulting in a pCR of 73.1%, confirming the benefits of this approach.[72]

Careful quality assurance is required when using IMRT. In particular, care should be placed to ensure that the surface of the vulvar tumor receives adequate dose. This may be accomplished by creating a “virtual flash” during treatment planning, where the PTV is expanded out of the skin by 1 to 2 cm, with additional placement of virtual tissue equivalent to allow for dose buildup. This protects against underdosing the tumor surface if there is superior displacement of the patient during treatment. Again, placement of thermoluminescent dosimetry chips or similar in the inguinal and perineal regions is recommended to confirm adequate dose to the skin and target areas (Figure 81.7).



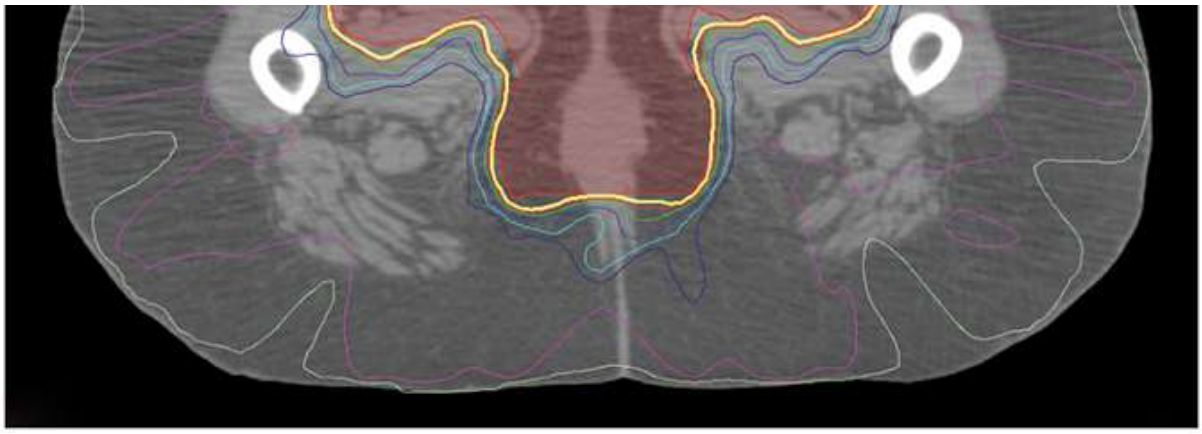


FIGURE 81.7 Intensity-modulated radiation therapy for vulvar cancer. This patient had a lesion of the posterior portion of the labia minora, involving the fourchette and the distal vagina. Three axial views are shown of the conformality of the 100% isodose line (yellow) and the planning treatment volume contour (shaded red volume). The central dose in the middle axial level is the superior margin for the vagina, added in this case due to the distal vaginal involvement.

Border definition is of understandable paramount in either delivery approach, with special attention paid to target delineation given the conformality that IMRT provides. External and internal iliac nodal coverage would correspond to a superior border along the middle of the sacroiliac joints with a 2D technique. However, if the patient has internal or external iliac node involvement, the superior border should be raised to the L3/L4 interspace to provide coverage to the common iliac nodes. Inferior borders should cover the entirety of the vulva and the most superficial inferior inguinal nodes. Laterally, the pelvic field would extend 2 cm laterally using 2D/3D techniques in order to encompass the widest point of the pelvic inlet. Although there are no data regarding scar recurrences, it is common practice to include the inguinal node dissection scars in the radiation field.

CHEMOTHERAPY

The use of chemotherapy alone is usually reserved for patients having advanced, inoperable, or recurrent disease. Even in the setting of advanced distant disease, however, radiation is often recommended for locoregional control and/or palliation of symptoms. With regard to systemic therapy as monotherapy for stage IV disease beyond the pelvis, there are limited data, given the rarity of this tumor type. Many of the recommended treatment regimens are in extrapolation from regimens studied in advanced cervical cancer, and reports of treatment regimens are generally small, single-institution studies. Current common treatment regimens include cisplatin and paclitaxel combination therapies. To date, there is no standard systemic therapy regimen for those with advanced, metastatic, or recurrent disease.

Single-Agent Chemotherapy

There is limited experience with single-agent chemotherapy for the treatment of vulvar cancer (Table 81.5). The single agents cisplatin, piperazinedione, mitoxantrone, and etoposide have all been evaluated prospectively by the GOG with disappointing results.[110-112] In a prospective study of patients with stage III/IV disease, single-agent adjuvant cisplatin resulted in 3-year OS and PFS rates of 86% and 71%, respectively; however, this was in fully resected patients.[113] Paclitaxel has moderate activity, with a 14% response rate described in a phase II trial of the European Organisation for Radiation Therapy and Chemotherapy (EORTC).[53]

Multiagent Regimens

Combination chemotherapy regimens have previously included bleomycin, which is associated with considerable pulmonary toxicity.[114] The Gynecological Cancer Cooperative Group of the EORTC conducted two phase II studies using neoadjuvant regimens of bleomycin, vincristine, mitomycin-C, and cisplatin and bleomycin, methotrexate, and lomustine.[115,116] The overall response rate (ORR) was between 55% and 65%, with a complete response rate of 8% to 11%. Unfortunately, the toxicity was high with treatment-related death in four (7.5%) patients and frequent withdrawals due to toxicity. A group of prospective studies evaluated cisplatin, bleomycin, and methotrexate in the neoadjuvant setting and reported a 10% response rate for the primary tumor but a 67% response rate for nodal disease after two cycles of treatment.[117] A more recent multicenter study evaluated cisplatin-based neoadjuvant chemotherapy in patients with locally advanced vulvar cancer and

reported a 5-year survival rate of 92%.[118] Compared to bleomycin-containing regimens, cisplatin may exhibit improved response rates and reduced toxicity.

In other small series, combinations of cisplatin with a second agent such as vinorelbine or 5-FU showed significant activity.[119,120] In a small report of neoadjuvant chemotherapy with cisplatin and 5-FU, at least a partial response was observed in all 10 patients. Of interest, three patients were treated with cisplatin alone in the same series with no responses.[120]

Biologic Agents

Biomarker-directed therapy has increasingly become an area of focus for the management of vulvar cancers. PD-1 is an immune checkpoint protein that promotes antitumor activity, and many tumors overexpress PD-L1. KEYNOTE-158 was a phase 2 multicenter study of pembrolizumab monotherapy in patients with advanced solid tumors and included 101 patients with heavily pretreated vulvar squamous cell carcinoma.[121] The ORR was 10.9% among all patients with vulvar cancer, 9.5% among those with PD-L1–positive tumors, and 28.6% among those with PD-L1–negative tumors. The median duration of response was 20.4 months. Prospective biomarker analyses of the KETNOTE-158 study found that patients with a high tumor mutational burden or DNA mismatch repair deficiencies/microsatellite instability had a more robust response to pembrolizumab.[122,123] The efficacy of nivolumab, a PD-1 immune checkpoint inhibitor, was evaluated in five patients with recurrent or metastatic vaginal/vulvar cancer in the phase I/II CheckMate 358 trial. The ORR in the vaginal/vulvar cohort was 20.0%, with a median duration of response of 5.0 months.[124] Thus, immunotherapy may be useful for managing vulvar cancer and is subject to ongoing investigation.

The epidermal growth factor receptor (EGFR) is a tyrosine kinase overexpressed in many squamous cell carcinomas of the vulva.[125] Erlotinib, an EGFR inhibitor, was reported to have significant activity in a case report, leading to the development of a phase II trial of this agent for women with lesions amenable to surgery or chemoradiation (cohort 1) or metastatic measurable disease.[126] The overall clinical benefit rate was 67.5%, with 27.5% experiencing partial responses and 40% with stable disease. Responses, however, were of short duration. Rare but significant grade 3 to 4 toxicities included diarrhea/electrolyte abnormalities, ischemic colitis, and renal failure.[127] In one other case report, the EGFR inhibitor cetuximab elicited a partial response when administered in combination with cisplatin.[128] Further studies may elucidate the role of EGRF-targeted agents and other biologics in the treatment of this disease.

Bevacizumab was studied in combination with cisplatin/carboplatin and paclitaxel or topotecan in the GOG 240 study for metastatic and/or recurrent cervical cancer,

resulting in improved OS (HR, 0.77, P = .007).[129] While these regimens have not been studied prospectively in vulvar cancer, they have been incorporated into some vulvar cancer guidelines by analogy.

In conclusion, single-agent cisplatin shows activity against advanced vulvar cancer. Combination chemotherapy regimens, particularly those including cisplatin and 5-FU, yield improved response rates, but they are associated with significant toxicity. In the recurrent or metastatic setting, the choice of regimen requires consideration of single agents with modest activity and low toxicity versus combination regimens that carry both higher response and toxicity rates. Targeted therapies are increasingly being investigated and utilized for the treatment of vulvar cancer and may have a significant effect on the future of vulvar cancer management. They may also have a role in combination with RT in the perioperative or definitive settings; however, this is as of yet unstudied.

TREATMENT SEQUELAE

The adverse effects of treatment can be classified as acute or chronic and depend on the treatment modality or modalities used, as well as the intensity of the treatment. With early-stage disease and more limited surgery to the primary site, the acute surgical complications are often minor, such as the development of wound infection and hematomas. With more extensive surgery, the frequency and degree of the complications can be more significant. With single "longhorn" or "butterfly" incisions for bilateral inguinal lymphadenectomies and for resection of the primary lesions, wound infection, necrosis, and breakdown occurred in 50% to 85% of the cases. Since the use of separate incisions was adopted, the incidence of groin wound infection, necrosis, and breakdown has decreased to nearly 15%.[43,130] Other potential complications or surgery include wound infections, seromas, hemorrhage, deep vein thrombosis, pulmonary embolism, osteitis pubis, and loss of sensory perception in the anterior aspect of the thigh secondary to femoral nerve injury.

The most significant chronic surgical complication is edema of the lower extremities. Lymphedema is related to the extent of the lymphadenectomy, and it is, therefore, more likely to occur with a deep inguinal node dissection, with a risk of approximately 30%.[130,131] Lymphedema can be progressive and very difficult to manage. Early referral for physical therapy is indicated to prevent progression and stimulate regression of symptoms. Other chronic complications reported are chronic cellulitis of the inguinal areas, stenosis of the introitus, femoral hernias, and rectovaginal or rectoperineal fistulas.

The most significant acute morbidity of radiation, either alone or in combination with chemotherapy, is the mucocutaneous reaction in the vulva, perineum, and inguinal folds. The severity of the reaction depends upon the radiation fractionation

schema used and the type of chemotherapy employed. The degree of reaction may result in treatment interruptions; frequent assessments of the treatment area are necessary for early supportive interventions. Topical agents, such as zinc oxide preparations, may be helpful; however, these preparations must be off the skin during radiation treatment because they can exacerbate the skin reaction. Sitz baths with sodium bicarbonate may also aid in the cleansing and soothing of the affected skin. In cases with excessive moist desquamation, astringents such as aluminum acetate solution may be applied. Narcotic pain medications are often required in the final weeks of treatment.

Treatment of candidal infections with appropriate antifungal agents should be provided as required. These can mimic radiation-associated desquamation, and topical or oral agents (such as fluconazole) should be considered if the degree of desquamation is beyond that expected with the current accumulated dose. These may be more frequent in those receiving concurrent chemotherapy or steroids or are otherwise immune suppressed.

Acute hematologic toxicity is common and depends upon the type and intensity of the chemotherapy used. Decreased leukocytes may be managed well with colony-stimulating factors, and blood transfusions may be necessary for anemia. Chemotherapy dose adjustments or interruptions are sometimes required. Severe hematologic toxicity can lead to septicemia, with fatal consequences in some instances.[96,132]

The late complications of radiation include telangiectasias, atrophy of the skin and mucosa of the vulva, dryness of the vaginal/vulvar mucosa, and narrowing of the vaginal introitus. Avascular necrosis of the femoral head is possible, though rare. In the GOG combined-modality study for patients with advanced disease, only one patient developed avascular necrosis of the femoral head, even though the femoral heads were fully treated in the inguinal fields.[96] In this study, there were two instances of injury to the femoral artery. In one patient, necrosis of the femoral artery occurred immediately following surgery and was fatal. The second patient required femoral artery angioplasty.

Besides the generally recognized complications seen with surgery, radiation, and/or chemotherapy, the treatment of carcinoma of the vulva has significant psychosocial and sexual health consequences.[133] In a study by Andersen et al. of 42 patients, most of whom were treated with conservative surgery, with wide local excision in 32 patients and simple vulvectomy in 10, there was a 2- to 3-fold increase in the frequency of sexual dysfunction from the pretreatment level.[134] In this study, 30% of the patients were sexually inactive at follow-up. Andersen and Hacker also reported that vulvar surgery has a significant impact on sexual functioning and body image, even when intercourse remains possible.[135] As might be expected, after pelvic exenteration, patients also experience significant sexual dysfunction, even when a

neovagina is created. Ostomies necessitated by exenteration have a significant detrimental impact on quality of life.[136]

RT is also associated with sexual dysfunction due to narrowing of the introitus, vulvar edema, decreased vaginal lubrication, injury to the bulboclitoris, and premature menopause due to ovarian dose. While data specific to vulvar cancer are sparse, there is growing literature related to dysfunction after radiation for anal canal cancer.[137] The bulboclitoris is an erectile organ, which is a key anatomic structure for arousal and orgasm; proposals for sparing this organ have been proposed for anal canal cancer, though this is not feasible for vulvar cancers.[138] Dilator therapy to limit stenosis is indicated, similar to recommendations in uterine and cervical cancer, as well as early referral to sexual health physical therapy. Hormone replacement should also be offered as it is associated with improved sexual function when hormonal function is compromised by treatment.[139]

PART J

Adrenal and Retroperitoneal Tumors

CHAPTER 82

Retroperitoneum

Meng Xu-Welliver, Eric D. Miller, Joel L. Mayerson, Brian A. Van Tine, and Jeffrey C. Buchsbaum

Primary tumors of the retroperitoneum are rare and account for 0.1% to 0.2% of all malignancies,[1-3] with up to 80% of lesions being malignant.[4] A retroperitoneal lesion was first reported by Morgagni in 1761 following an autopsy,[5] with additional work by Pack and Tabah demonstrating the variety of histologies that can originate from the retroperitoneum.[3] This chapter focuses on lesions that primarily arise from tissues in the retroperitoneum.

ANATOMY

The anatomy of the retroperitoneum has been described in detail by Burkill and Healy[6] and reviewed by Osman et al[7] and shown in Figure 82.1. In summary, the anterior border of the retroperitoneal compartment is the posterior parietal peritoneum, and the posterior border is the transversalis fascia. Superiorly, it extends to the diaphragm and inferiorly to the superior aspect of the pelvic diaphragm formed by the levator ani and coccygeus muscles. The retroperitoneum can be divided into three compartments: the anterior pararenal, the perirenal, and the posterior pararenal spaces. The anterior pararenal compartment is bordered anteriorly by the posterior parietal peritoneum, posteriorly by the anterior renal fascia, and laterally by the lateroconal fascia and contains the ascending and descending colon, the pancreas, and the second portion of the duodenum. The perirenal compartment is located between the anterior and posterior renal fascia and

contains the kidneys and adrenal glands. It is shaped like an inverted cone and superiorly abuts the bare liver on the right and the subdiaphragmatic space on the left. The posterior pararenal compartment is located between the posterior renal fascia and the transversalis fascia and contains fat without any visceral organs. Below the level of the kidneys, the anterior and posterior pararenal compartments combine to form the infrarenal retroperitoneal space, which communicates with the pelvis inferiorly.[4] The aorta and inferior vena cava are contained within the great vessel space that is a primarily fat-containing region immediately anterior to the vertebral bodies and psoas muscles.[4]

EPIDEMIOLOGY

The population incidence of retroperitoneal tumors is based on two population studies and is estimated to be 3 per million persons.[1,2] The age range of patients varied between 3 and 83 years, with half of the patients diagnosed between the ages of 60 and 80. There was no significant difference in frequency observed between males and females.[2]

The age at diagnosis of several large series of patients with primary retroperitoneal tumors is shown in Figure 82.2.[1-3,8,9] Two peak age periods are seen, with the first peak occurring during the first decade of life generally caused by neuroblastoma or germ cell tumors and a second peak occurring during the sixth decade generally caused by mesenchymal lesions. These histologies are outlined in Figure 82.3. Lawenda and Johnstone performed a comprehensive review of the Surveillance Epidemiology and End Results (SEER) public use registry focusing on retroperitoneal tumors.[10] As seen in the results of this review in Table 82.1, soft tissue sarcomas (STSs) constitute a major portion of retroperitoneal tumors. However, in general, retroperitoneal sarcomas (RPSs) are uncommon representing approximately 15% of all STSs,[11] with an average estimated annual incidence of 2.7 cases per million persons.[12] Most of this chapter is focused on the diagnosis and management of RPSs.

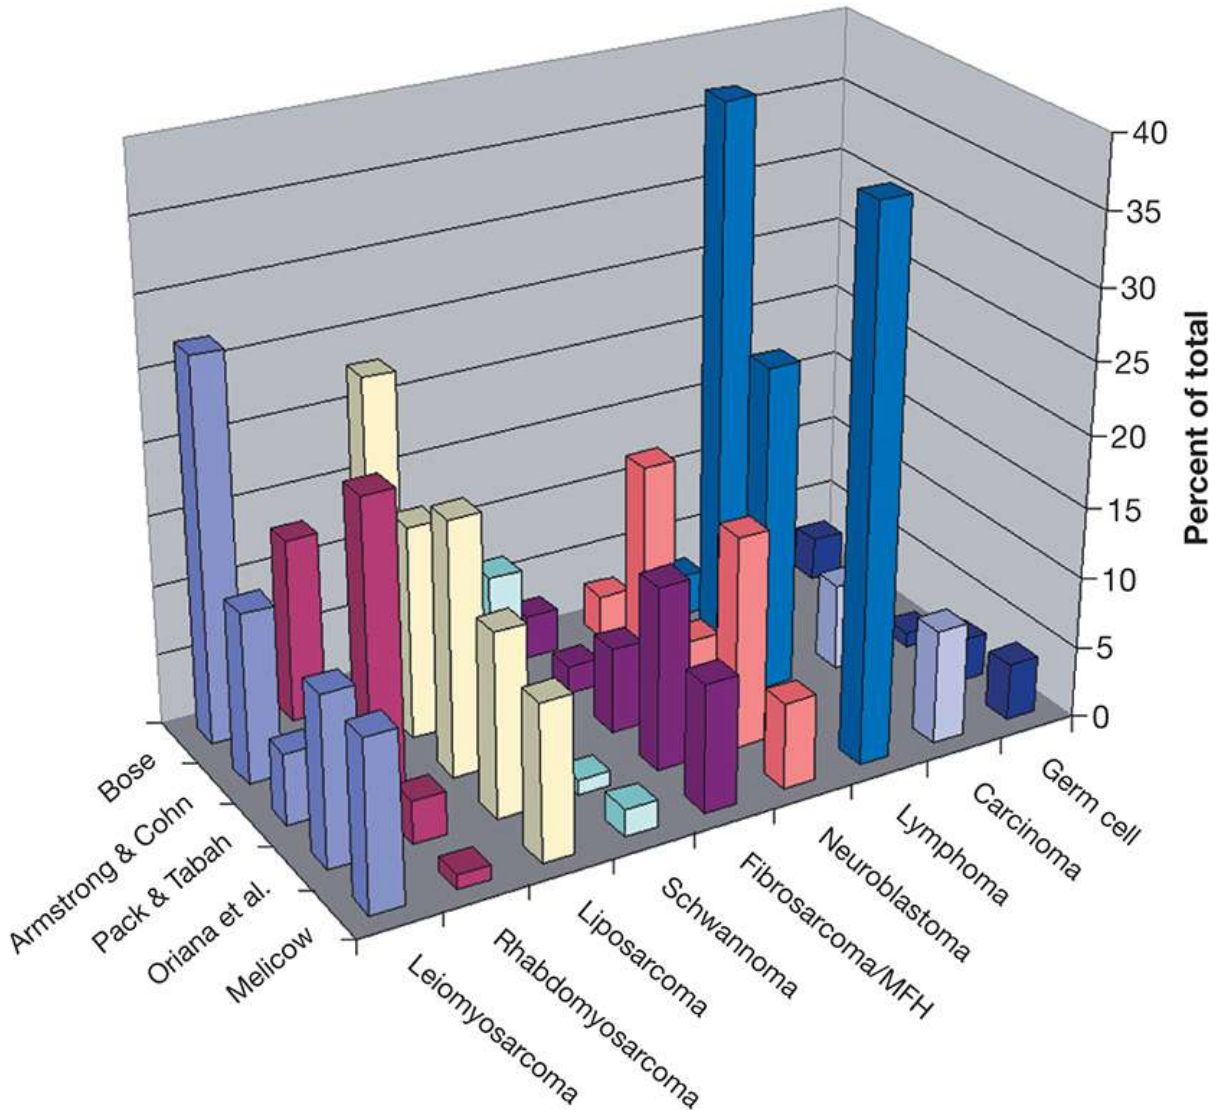

FIGURE 82.3 Percentage of retroperitoneal lesions by histology (pooled data from multiple published series).

NATURAL HISTORY

With such varied neoplasms occurring in the retroperitoneum, the natural history is primarily dependent on histology. As the retroperitoneum is a potential space, neoplasms in this region can become quite large, weigh over 50 kg, and cause displacement or compression of adjacent organs prior to diagnosis.

CLINICAL PRESENTATION

Table 82.2 outlines pooled data regarding signs and symptoms at presentation of retroperitoneal tumors. In general, presentation involves a mass or abdominal pain in most cases.

TABLE 82.2 PRESENTING COMPLAINTS (%) OF PATIENTS WITH RETROPERITONEAL LESIONS

NS, not stated.

[a]Indicates all patients with pain as presenting sign.

DIAGNOSTIC WORKUP

Retroperitoneal tumors include a diverse group of both benign and malignant neoplasms that may be primary or secondary in origin.[7] Imaging serves an important role in differentiating retroperitoneal masses, with computed tomography (CT) and magnetic resonance imaging (MRI) serving as the primary imaging modalities. Although the differential diagnosis is broad, certain imaging characteristics such as fat content, necrotic changes, contrast enhancement, presence of calcifications and/or cysts, and appearance on T1- and T2-weighted images all provide clues to narrow the differential diagnosis.[4] For example, in retroperitoneal liposarcoma (LPS), the most common subtype,[13] tumors appear as a hypoattenuating lesion on CT because of the fat content and are indistinguishable from a benign lipoma.[4,7] On MRI, a well-differentiated LPS demonstrates high-signal intensity on T1, intermediate signal on T2, and loss of fat signal intensity on fat-suppressed images and may be contrast enhancing.[4,7] However, in a dedifferentiated LPS, both fat and solid

components are observed with occasional associated calcifications.[4] Leiomyosarcomas (LMSs), the second most common subtype,[13] appear on CT as homogeneously solid, but larger tumors may develop areas of necrosis and hemorrhage.[4] On MRI, these tumors demonstrate low T1 signal intensity and intermediate to high T2 signal intensity depending on the presence of necrosis with peripheral and heterogeneous contrast enhancement.[4,14] In general, retroperitoneal neoplasms can be divided into either solid or cystic tumors based on their imaging appearance.[7] Solid tumors fall into three main categories, including mesodermal, neurogenic, or extragonadal germ cell origin, whereas cystic tumors include cystic changes in solid neoplasms as well as cystic lymphangioma, cystic teratoma, cystadenoma, cystadenocarcinoma, and cystic mesothelioma.[7]

As part of the primary workup, in addition to imaging the primary tumor with a CT of the abdomen/pelvis with intravenous (IV) contrast, a CT of the chest should also be obtained to evaluate for the presence of metastatic disease. Arterial phase CT imaging can be helpful for operative planning. MRI of the abdomen/pelvis with and without IV contrast can also be considered to further classify the lesion and evaluate the extent of disease. Imaging with 18-fluorine-labeled 2-deoxy-2-fluoro-D-glucose ([18]F-FDG-PET) is not routinely performed for RPSs but may be useful for evaluating the extent of distant metastasis during initial staging if the primary lesion is PET avid in the first place.[15]

Functional assessment of the contralateral kidney is necessary if ipsilateral kidney may be removed along with the primary retroperitoneal tumor. This may be achieved using CT with IV contrast or pharmacologic renal scan with radioisotope (differential renal scan).[16]

A definitive diagnosis is obtained with a biopsy and should be performed unless preoperative treatment is not planned. Image-guided core needle biopsy is recommended with multiple cores obtained for histologic and molecular subtyping.[17] Both fine-needle aspiration and laparotomy with open biopsy should be avoided. Ideally, biopsy of a solid, well-perfused portion of the tumor should be performed rather than an area of necrosis.[17]

RETROPERITONEAL SARCOMA GENERAL MANAGEMENT

The first decision point is determining whether the patient is resectable or unresectable.[18] Surgical resection is the primary treatment for RPS and is the only potentially curative option for localized and resectable disease. Criteria for unresectable tumors may include extensive major vessel involvement, including the root of the mesentery, spinal cord involvement, peritoneal implants, and distant metastasis.[18] Achieving an R0 resection of a RPS is often challenging due to the size and anatomic location of the tumor. Based on a review by Mendenhall et al,[13] which includes data from four large institutional series, the rate of complete resection, which includes R0 and R1 resections, was 50% to 67%. Patients who have an R1 resection are at increased risk of local recurrence,[19,20] with recent data from the National Cancer Database (NCDB) suggesting inferior survival as well.[21] Surgical resection often involves resection of adjacent organs to achieve complete extirpation of the tumor. Liberal visceral en bloc resections may increase morbidity but also have been associated with higher rates of local control and potentially an improvement in overall survival based on retrospective data, although this practice has not yet been widely adopted.[21,22]

Because of the rarity of RPS, patients should be evaluated and managed at high-volume centers with expertise in sarcoma by a multidisciplinary team, including surgical oncology, radiation oncology, and medical oncology.[17] Management of this rare disease in high-volume sarcoma centers is strongly recommended: It is associated with reduced early postoperative morbidity, reduced risk of postoperative mortality, reduced risk of relapse, reduced death rates from sarcoma, and, most importantly, improved long-term overall survival.[23-27]

PERIOPERATIVE RADIOTHERAPY

The efficacy of radiotherapy (RT) for RPS has been controversial, substantiated primarily by its well-established role in extremity sarcoma. Local control remains a challenge for RPS, due largely to the anatomic constraints of the retroperitoneum. Incomplete resection (R1 or R2) and subsequent locoregional failure have been reported in up to 50% of patients who undergo surgery with curative intent.[28]

Two cohort studies utilizing publicly available registry data have compared survival outcomes for patients with resectable RPS receiving

surgery alone to outcomes for patients receiving perioperative RT or chemotherapy.[29,30] The first study performed two case-control, propensity score-matched analyses of NCDB, which included adult patients with RPS who were diagnosed from 2003 to 2011. Both preoperative RT (hazard ratio [HR] 0.70, 95% confidence interval [CI] 0.59-0.82; $P < .0001$) and postoperative RT (HR 0.78, 0.71-0.85; $P < .0001$) were significantly associated with improved overall survival compared with surgery alone.[30] The second study compared survival outcomes in patients with primary resectable RPS diagnosed between 2006 and 2015.[29] On multivariable analysis adjusted for facility type, age, sex, income, Charlson-Deyo comorbidity score, histologic characteristics, tumor grade, tumor size, surgical type, surgical margin, and postoperative inpatient duration, addition of preoperative radiation was associated with improved overall survival (HR, 0.88; 95% CI, 0.77-0.99; $P = .03$), while the addition of preoperative chemotherapy was associated with lower overall survival (HR, 1.54; 95% CI, 1.27-1.88; $P < .001$).[29]

Despite the abovementioned NCDB studies as well as several nonrandomized prospective studies, and retrospective studies evaluating the role of perioperative RT in resectable RPS,[31-36] there has been no evidence to support such a treatment approach from any randomized studies. In the United States, the only randomized controlled trial addressing the use of perioperative RT for RPS did not accrue enough patients for completion (ACOSOG Z90312, NCT00091351). The European Organisation for Research and Treatment of Cancer (EORTC) conducted a prospective, randomized phase III study in patients with RPS comparing patients treated with surgery alone to patients treated with preoperative RT followed by surgery (EORTC 62092-22092), known as the STRASS trial.[37] Between January 2012 and April 2017, 266 patients were enrolled in this study and randomized to one of the two arms: preoperative RT plus surgery versus surgery alone. RT was delivered as 50.4 Gy in 28 daily fractions, either with three-dimensional (3D) conformal RT or intensity-modulated radiotherapy (IMRT). Surgery was defined as a macroscopically complete resection of the tumor mass with en bloc organ resection as necessary. Primary end point was abdominal recurrence-free survival (ARFS) as assessed by the investigator. With median follow-up of 43.1 months, median ARFS was not different between the two groups (4.5 years in the RT plus surgery group

and 5.0 years in the surgery-only group [HR 1.01, 95% CI 0.71-1.44; log-rank P = .95]). While no difference in primary end point was observed, twice as many local relapses were observed in the surgery group than in the RT plus surgery group, possibly related to RT, specifically in the LPS cohort. In fact, in the subgroup analyses exploring patients with LPS only, there was a 10% absolute ARFS benefit in favor of the RT plus surgery arm.[37] This is consistent with a prior multicenter study from the Trans-Atlantic Australasian Retroperitoneal Sarcoma Working Group, which showed that intra-abdominal local recurrence was the predominant pattern of failure for LPS, whereas distant metastasis was the principal pattern of failure for LMS.[38]

The STRASS trial was the first successfully completed randomized phase III study comparing preoperative RT plus surgery to surgery alone, and its results suggested that preoperative RT should not be considered as standard-of-care treatment for every patient with RPS; rather, RT should be considered on a case-by-case basis.[37] National guidelines suggest the use of neoadjuvant RT in selected cases, where tumors are at high risk for local recurrence, with or without intraoperative RT (IORT) boost. If neoadjuvant RT is anticipated, IMRT and other advanced image-guided radiation techniques are recommended.

For patients with unresectable or borderline resectable tumors, downstaging can be attempted using preoperative chemotherapy, RT, or chemoradiation. Repeat imaging with CT of the chest/abdomen/pelvis with or without MRI of the abdomen/ pelvis should then be performed to evaluate the treatment response and to verify that the patient has not developed metastasis. If the tumor progresses or the patient develops metastatic disease, palliative care can be considered, which may involve any combination of chemotherapy, RT, surgery to help control symptoms,[39] or other supportive care. In patients with unresectable tumors, particle therapy may provide durable local control.[40]

Following preoperative RT in the definitive setting, surgical resection is typically delayed 3 to 8 weeks with radiographic restaging performed to assess for metastases and treatment response. In the setting of a positive microscopic margin (R1 resection) following preoperative RT, a postoperative external beam RT (EBRT) boost can be considered but is discouraged. In general, postoperative RT is discouraged in favor of

observation following surgical resection with consideration of preoperative EBRT in the event of a local recurrence. However, postoperative EBRT should be considered when a local recurrence would cause significant morbidity because of a critical anatomic location. For patients who undergo a resection where gross residual disease is present (R2 resection), reresection should be discussed, if possible.

Unlike extremity sarcomas, where the most first recurrences are distant, RPSs tend to fail locally with a 5-year local control of approximately 50%.[13] In the setting of recurrent disease, patients who did not receive prior RT can be considered for preoperative radiation. Repeat resection should be offered, if possible, as patients who completed resection for recurrent disease had improved survival based on a large retrospective study from the Trans-Atlantic Retroperitoneal Sarcoma Working Group.[41] IORT can also be considered in an attempt to improve the chances of local control in the recurrent setting.[42-44]

Patients who present with or develop metastatic disease should be managed on a case-by-case basis. Any combination of chemotherapy, RT, surgery to palliate symptoms, and other supportive care is appropriate.[18]

Following definitive treatment, patients should undergo physical examination with imaging every 3 to 6 months for the first 2 to 3 years.[18] For the next 2 years, the patient should undergo physical examination and imaging every 6 months, and then annually after that. Imaging should include CT or MRI of the abdomen/pelvis with a chest x-ray or CT of the chest also included.

A histology-based RPS prognostic system identifies RPS into three prognostic groups, and it can be used in both primary and recurrent RPS. Distinct risk stratification is necessary for specific assessment of prognosis and decision regarding individualized adjuvant therapy.[45] Some authors recommend the formulation of an LPS-specific postoperative nomogram based on histologic subtypes, which provides more accurate survival predictions for patients with primary RPS.[46,47] Well-differentiated and dedifferentiated LPSs differ significantly in their biologic behavior and are treated by different surgical approaches at the MD Anderson.[48] Researchers at the center recommend that the American Joint Committee on Cancer STS staging system needs to incorporate the primary site, histologic subtype, margin status, and recurrence to further shed light on prognosis.[49]

CHEMOTHERAPY

Adjuvant chemotherapy is controversial in the management of adult patients with macroscopically completely resected retroperitoneal STSs. Retrospective analysis of both preoperative[50] or postoperative[18,51-53] chemotherapy has yet to demonstrate overall survival benefit. In a National Cancer Institute trial, patients with STSs were randomized to chemotherapy or observation following resection; some patients had postoperative irradiation.[54] Among patients who were assigned to chemotherapy, survival was favorably affected in those with extremity tumors. However, patients with head and neck and truncal lesions (including RPSs) did not benefit; the 5-year survival rate was approximately 40% in both arms. Similar findings were reported in a large meta-analysis of patients with STS.[55]

The use of neoadjuvant or adjuvant chemotherapy is not standard in the management of nonmetastatic adult retroperitoneal STSs. Neoadjuvant chemotherapy has been primarily studied in the setting of high-grade, extremity STSs. Pisters et al[56] demonstrated feasibility of using preoperative concurrent doxorubicin and EBRT (18-50.4 Gy), followed by resection and IORT (15 Gy) in patients with RPS. An R0 or R1 resection was possible in 90% of the patients who went to surgery (83%). Newer studies have shown that doxorubicin-based adjuvant chemotherapy significantly improves local and distant recurrence in localized resectable STS.[57] Newer agents, such as olaratumab,[58] are currently being tested in the neoadjuvant setting to see if overall survival can be improved.

Overall, treatment with chemotherapy is not recommended outside clinical protocols. Currently, EORTC EA7211/STRASS 2, a randomized study investigating preoperative chemotherapy followed by surgery versus surgery alone in patients with high-risk RPS, is ongoing. Patients will include those with localized resectable high-risk LMS or LPS (NCT04031677).

RADIATION THERAPY TECHNIQUES

External Beam Radiation Therapy

In patients for whom RT is recommended, preoperative RT is the preferred approach. Treatment guidelines based on the consensus of an international expert panel for preoperative RT of RPS have been published by Baldini et

al[59] Suitable candidates for preoperative RT include patients with unifocal or localized tumors that are amenable to an R0 resection and where delivery of 50 to 50.4 Gy to the tumor while meeting the dose objectives for the adjacent normal structures is feasible. Patients with symptoms requiring urgent surgical intervention should not be considered for preoperative RT. Prior to any therapy, the surgical and radiation oncologist should work together to develop a consensus plan. In the setting of kidney or liver involvement where surgical resection may involve either a nephrectomy or partial hepatectomy, or where RT may result in impaired function of one kidney, preliminary studies need to be performed to ensure adequate function in the remaining kidney or liver. Further, in the setting of a nephrectomy or partial hepatectomy, care should be taken to minimize the radiation dose to the remaining kidney and/or liver. Kidney function can be evaluated using a renal perfusion study, whereas the liver can be evaluated using serum liver chemistries.

CT simulation should be performed with the patient in the supine position with suitable custom immobilization device to allow reproducible setup during treatment. Both oral and IV contrast should be considered for the simulation scan to better delineate the tumor and adjacent normal structures including bowel. A 4D CT should be performed to evaluate tumor motion during the respiratory cycle with more motion anticipated in superiorly located tumors in the abdomen.[60] For patients with more than 1 cm of motion, motion management techniques should be considered, such as active breathing control, respiratory gating, or end-expiration breath-hold. To aid with target and organ at risk of delineation, registration of the free-breathing planning CT with diagnostic studies should be performed. Useful diagnostic studies may include a diagnostic CT and/or T1-weighted postcontrast MRI. Data on the use of [18]F-FDG-PET in the staging of RPS and for use in RT treatment planning are currently limited, with more data likely to emerge in the coming years. Proton therapy (especially intensity-modulated proton therapy) may allow dose escalation to the targets while sparing normal tissues, including liver, small bowel, and large bowel.

Target Delineation/Organs at Risk

Target volumes for RPSs are included in the international expert panel consensus guidelines from Baldini et al[59] For upper abdominal tumors where a 4D CT simulation is performed, the gross tumor volume (GTV) is delineated, and an internal gross tumor volume (iGTV) is made based on the motion of the GTV throughout the respiratory cycle. The internal target volume (ITV) is made using a 1.5-cm uniform expansion of the iGTV edited off uninvolved bone, kidney, and liver. The ITV should expand 5 mm into the bowel and any air cavities and should be cropped away from uninvolved skin per institutional guidelines. If the tumor extends into the inguinal canal, the inferior expansion of the iGTV to make the ITV should be 3 cm. For an upper abdominal tumor where a 4D CT simulation is not performed, the GTV should be expanded by 2 to 2.5 cm in the superior-inferior direction and 1.5 to 2 cm radially. The CTV should be edited off the interfaces in the same manner as the ITV in the upper abdomen case where a 4D scan is obtained. For tumors below the level of the iliac crest, the GTV can be expanded 1.5 cm uniformly and edited off the interfaces as mentioned above to create the CTV. In all cases, the planning target volume, which accounts for setup error and patient movement, should be based on imaging frequency and institutional guidelines. The standard preoperative dose is 50.4 Gy in 1.8-Gy fractions or 50 Gy in 25 fractions. The delivery of a boost dose to the areas considered to be at high risk for a positive margin has been reported.[61] However, this approach remains experimental and is the subject of a currently accruing phase I/II trial at Massachusetts General Hospital.[35] In the setting of a positive surgical margin following preoperative EBRT, a postoperative EBRT boost may be considered; however, it is considered controversial.

In the postoperative setting, the treatment volumes are generally larger, with a larger volume of normal tissue in the treatment field as the bowel and other organs initially displaced by the tumor fall into the resection cavity. Temporary tissue expanders have been used in a limited number of studies to displace bowel and other organs at risk out of the treatment volume.[62,63] Target delineation in the postoperative setting is challenging, and no consensus guidelines exist. Therefore, adjuvant RT following surgery is generally discouraged for retroperitoneal/intra-abdominal sarcoma. If RT is not delivered prior to surgical resection, consider follow-up with possible neoadjuvant RT at the time of localized recurrence.

Adjacent organs at risk include liver, stomach, bowel including duodenum, small and large bowel, kidneys, spinal cord, testicles, ovaries, bladder, rectum, and femoral heads. To aid in normal organ contouring, consensus guidelines and an atlas are available from the Radiation Therapy Oncology Group.[63] Again, the consensus guidelines for preoperative RT for RPS include a summary of constraints for organs at risk primarily derived from Quantitative Analysis of Normal Tissue Effects in the Clinic data.[59,64] In brief, no more than 100% of the stomach should receive ≥45 Gy, the mean bilateral kidney dose is 15 to 18 Gy, and no more than 15% of the remaining kidney should receive >18 Gy if one kidney is removed. For the small/large bowel contoured as the peritoneal cavity, no more than 195 cm^3 should receive >45 Gy. The mean residual liver dose should be limited to <26 Gy, and the spinal cord dose should be <50 Gy.

Treatment Planning and Delivery

For RT planning using photons, IMRT is preferred to 3D conformal radiation because of increased conformality with decreased dose to adjacent organs at risk.[65] Swanson et al[65] determined the optimal RT technique for the treatment of RPSs by comparing plans prepared using 3D conformal proton RT, IMRT, and 3D conformal photon RT. The IMRT and conformal proton plans were more conformal than the 3D photon plans. Furthermore, the IMRT and proton plans provided a lower bowel and kidney dose than the 3D photon plans.

Based on the results of Wong et al, which demonstrated volumetric changes and significant interfraction displacement during preoperative RT for RPS, daily image-guided RT should be considered where soft tissue is clearly visible, such as cone-beam CT.[59,60] Prophylactic antiemetics should be considered for the patient depending on the location of the tumor.

Additional Radiation Techniques

IORT refers to the delivery of either brachytherapy or external beam irradiation to a target area, whereas the area is exposed during surgery. IORT is typically used to deliver a focal boost to areas of concern, such as close or positive margins. The advantages of IORT include the ability to directly visualize the area of concern and manually remove normal tissues

from the field or shield them prior to treatment delivery. When electron beams are used (intraoperative electron radiation therapy [IOERT]), typical doses range from 10 Gy for completely resected tumors with negative margins, 12.5 to 15 Gy for positive microscopic margins, and 15 to 20 Gy for gross residual disease.[66] Typical electron energies range from 9 to 15 MeV based on the desired depth of penetration.

IORT can also be delivered using high-dose rate intraoperative irradiation (HDR-IORT) as previously described in detail by Harrison et al.[67,68] For HDR-IORT, following displacement of normal tissue from the field of interest, a Harrison-Anderson- Mick (HAM) applicator (an array of catheters spaced 1 cm apart in a silicone rubber pad) is secured in the target region, and a dose of 10 to 20 Gy at a tissue depth of 5 to 10 mm is typically delivered.[66] Following delivery of IORT, the applicators are removed from the target region, and the surgeon continues with the case. The advantages and disadvantages of each IORT technique have been previously summarized.[66] HDR-IORT allows for delivery of more conformal treatments along curved surfaces secondary to the flexible nature of the HAM applicator, the ability to treat large fields without field matching, and the ability to deliver RT to areas that may not necessarily be accessible with IOERT. HDR-IORT is limited to treating target areas ≤0.5 cm thick. IOERT can treat both superficial and deeper targets by varying the electron energy employed for treatment. Treatment with IOERT is also generally shorter than HDR-IORT, thus decreasing the overall procedure time.

RESULTS OF THERAPY

Surgical resection remains the only curative treatment for patients with RPSs, although local control rates with resection alone remain poor. Because of both the size and proximity of RPSs to critical organs, margin-negative resections are difficult to achieve. Locoregional failure is the predominant pattern of failure,[13,69] and failure to achieve local control is the major cause of death in patients with RPS.[70] A large retrospective series from Memorial Sloan Kettering reported on 231 patients with primary RPS that was resectable.[71] Of the 231 patients, 185 (80%) were able to undergo a gross total resection. Patients with a gross total resection were found to

have a statistically significant increase in survival compared to those who underwent incomplete resection (103 vs 18 months). No difference in survival was observed between patients with unresectable disease and patients who underwent incomplete resection. For patients with localized, completely excised RPS, 5-year overall survival is 49% to 70%, with selected studies summarized in Table 82.3. Preoperative RT potentially could improve local control; however, the STRASS study did not demonstrate this in all comers, but only in patients with LPS. Additional prospective randomized studies with more sophisticated RT techniques and/or biomarker-informed systemic therapies are needed.

Patients with positive microscopic margins are at increased risk of local recurrence[75] based on retrospective data, with a recent study from the NCDB demonstrating a survival advantage in patients able to achieve an R0

resection versus R1 resection (92 and 70 months, respectively).[19] As part of the analysis, preoperative RT was associated with an increased probability of R0 resection. A number of retrospective studies demonstrate an improvement in local control with postoperative RT, with select studies summarized in Table 82.4. In the report by Stoeckle et al,[22] patients with complete excision had a significant reduction in local recurrence risk when treated with received postoperative RT (median dose = 50 Gy) compared to those not treated with adjuvant RT (relative risk, 3.36; $P = .0021$). However, no improvement in overall survival on multivariate analysis was observed. Catton et al[69] found that adjuvant RT for patients who had a complete resection increased the time to locoregional relapse, from 30 (no radiation) to 103 months ($P = .06$). Again, radiation did not have an impact on survival.

LRF, locoregional failure.

IORT is used by some centers to deliver a boost to the resection cavity to improve local control. A prospective randomized trial was performed by the National Cancer Institute to evaluate the benefit of gross total resection with IORT followed by postoperative EBRT compared to gross total resection and postoperative EBRT alone.[71,76] IORT was delivered with electrons with an energy of 11 to 15 MeV delivered in a single dose of 20 Gy. For patients treated with IORT, the postoperative EBRT dose was 35 to 40 Gy delivered in 1.5 to 1.8 Gy fractions. For patients treated with postoperative EBRT alone, the dose was 50 to 55 Gy delivered in 1.5 to 1.8 Gy fractions. For patients treated in the IORT arm, significantly fewer locoregional

recurrences were observed compared to the postoperative EBRT-alone arm. No difference in survival was observed between the two arms. Additional nonrandomized studies summarized in Table 82.5 have demonstrated excellent local control with the use of IORT and EBRT with acceptable toxicity.

CE, complete excision; GI, gastrointestinal; gross, gross residual disease; HDR, high-dose rate; LC, local control; micro, microscopic residual disease; NR, not reported; OS, overall survival.

Patients with unresectable disease have a poor prognosis. Surgery may be considered to palliate symptoms. A retrospective study from Memorial Sloan Kettering was performed to evaluate patients with RPS who underwent palliative procedures.[77] Patients most frequently underwent a procedure because of gastrointestinal (GI) symptoms (44% of patients). Overall, about 50% of patients were symptom free at 100 days postprocedure, but only 23% of patients with GI obstructive symptoms were symptom free at 100 days. The postoperative morbidity was 29%, and the postoperative mortality was 12%. Particle therapy can also be considered for patients with unresectable disease. Serizawa reported on a small series of patients with unresectable RPS treated with carbon ion RT.[40] The patient cohort included both primary and recurrent diseases, with doses ranging from 52.8 to 73.6 GyE in 16 fractions. The local control rates at 2 and 5 years were 77% and 69%, respectively, with a 2- and 5-year overall survival of 75% and 50%, respectively. No grade ≥3 toxicities were observed.

Recurrence is common, and there are minimal data to guide management in the recurrent setting.[41] A large retrospective series from the Trans-Atlantic Retroperitoneal Sarcoma Working Group evaluated postrelapse

outcomes in 408 patients.[41] For patients with a local recurrence only, the median time from initial resection to recurrence was 23 months. Repeat resection was performed in 48% of patients with chemotherapy and RT given to 31% and 18% of patients, respectively. Following local recurrence, the median overall survival was 33 months and the 5-year overall survival was 29%, with repeat resection and longer time interval to recurrence found to be significant predictors for survival. Treatment with RT trended for significance. The 5-year overall survival for patients who underwent repeat resection was 43% versus 11% for those not able to undergo repeat resection. The 5-year overall survival for patients with distant metastasis and those with local recurrence and distant metastasis was 20% and 14%, respectively. For patients with distant metastasis only, resection of the distant metastasis was found to be a significant predictor of improved disease-specific survival. For patients with both a local recurrence and distant metastasis, patients who completed resection of the recurrent disease had longer survival than those who did not.

TREATMENT SEQUELAE

Acute symptoms from EBRT of the retroperitoneum include fatigue, radiation dermatitis, nausea, vomiting, and diarrhea. For large radiation fields where the adjacent spine is included, a significant portion of bone marrow may also be included, and anemia, neutropenia, and thrombocytopenia may occur. At minimum, weekly monitoring of vital signs should be performed, and monitoring of blood counts should be considered. Reported postoperative complications include bleeding, impaired wound healing or dehiscence, infection, myocardial infarction, and death.[33,77]

Late toxicities of surgery and radiation include small bowel enteritis, stricture, perforation, fistula, and obstruction. Development of nephritis is possible after radiation doses >30 Gy with resultant hypertension. Late complications are associated with the number of laparotomies to which the patient has been subjected and with the radiation dose and volume.[78,79] A lower incidence of enteritis has been reported with the use of EBRT and an IORT boost compared with EBRT alone, as the bowel is able to be moved from the field, resulting in a lower radiation dose[63] (Table 82.5). Overlap of

adjacent IORT fields can increase the risk of neuropathy and ureteral injury.[33,77] As discussed previously, preoperative RT is the preferred approach to postoperative RT because of a more favorable toxicity profile and ease of target delineation.[59] Proton therapy may also allow a decreased dose to the bowel, resulting in a decrease in acute and late toxicity.[80]

Callegaro et al[80] performed a cross-sectional study to assess the long-term morbidity of patients treated for RPS. Patients were evaluated for lower limb function using the Lower Extremity Functional Scale (LEFS) and pain was assessed using the Brief Pain Inventory—Short Form, both self-report questionnaires. RT and chemotherapy were used in 28.8% and 51.4% of patients, respectively. Overall, sensory impairment of the limbs was reported in 76% of patients with a median LEFS score of 60 out of a maximum of 80 (high function), indicating overall good motor function. Mean pain scores varied from 1.23 to 2.68 out of a maximum of 10 (bad pain), indicating mild pain overall. No difference in median creatinine levels on multivariate analysis was observed in patients requiring nephrectomy compared to those who did not.

LYMPHOMAS

Lymphomas frequently involve the retroperitoneum, with the predominant histologic variant being non-Hodgkin lymphoma. Workup generally includes CT and/or MRI and ^{18}F-FDG-PET. On CT, lymphomas appear as a homogeneous mass that generally spreads between normal structures occasionally causing displacement, but generally not resulting in compression.[4] On MRI, lymphomas are isointense on T1 and iso- to hyperintense on T2-weighted images with patchy contrast enhancement.[4] PET imaging is also generally used with FDG avidity dependent on histologic subtype.[81] A definitive diagnosis requires a tissue biopsy that can be difficult in the retroperitoneum. An image-guided needle biopsy is to be used over fine-needle aspiration for diagnostic purposes if no other superficial lymph nodes are accessible and also because sarcoma is in the differential.[82] Flow cytometry and immunohistochemical stains are used to confirm the diagnosis of lymphoma. The diagnosis, staging, and management of retroperitoneal lymphoma are similar to that of other lymphoma sites and are discussed elsewhere in this text. As with all

retroperitoneal tumors, radiation doses and treatment volumes may be limited by adjacent normal tissues.

OTHER LESIONS

Neuroblastoma is the most common solid extracranial tumor in children and the most common cancer in infants younger than 12 months, though this can occur rarely in adults.[83] In the United States, approximately 650 new cases are diagnosed per year,[84] with a prevalence of 1 case per 7,000 live births and an incidence of 10.54 cases per 1 million per year in children younger than 15 years.[83] Ninety percent of cases are diagnosed in children <5 years of age, with about 37% diagnosed as infants.[83] Neuroblastoma accounts for approximately 15% of all pediatric cancer fatalities. This tumor is extraordinarily uncommon in adults, with an estimated incidence of 0.2 per million population in those aged 30 to 39.[85] The paradigm for the treatment of neuroblastoma includes combination therapy with chemotherapy, surgery, and RT in advanced-stage disease, which is most commonly found in adults.[86]

Wilms tumor (WT) or nephroblastoma is the most common intra-abdominal malignancy of childhood, with an incidence of 7.1 cases per 1 million children younger than age 15 years, with approximately 650 cases diagnosed in the United States each year.[83] It is the second most common extracranial solid neoplasm of childhood and the most common renal malignancy in children.[87] In contrast, it is an uncommon malignancy in patients ≥16 years of age, with an estimated incidence of 0.2 per million population.[88,89] Adults frequently present with flank pain and painless hematuria,[90] whereas children are more likely to present with painless hematuria and/or a palpable abdominal mass.[83] The treatment and outcomes of patients with adult Wilms tumor (AWT) remain controversial, with no standard therapy yet developed.[91] Kalapurakal et al[92] reported the outcomes of 23 adults (>16 years of age) treated on Children Oncology Group (COG) protocols (National Wilms Tumor Study Group; NWTS 4 and NWTS 5) and found no difference between the adults and their pediatric counterparts. Similarly, the International Society of Pediatric Oncology (SIOP) published results from an SIOP retrospective review of 30 patients with AWT >16 years of age with comparable results between adults and children.[90]

Conversely, Izawa et al[93] reported on 128 patients with AWT from SIOP as well as individual institutional reports and concluded that the outcomes in adults were inferior to that of children. A SEER study by Ali et al[94] concluded that the outcome in 152 patients with AWT was worse than in children. Overall survival at 5 years was 69% in AWT versus 88% in children ($P < .001$). On multivariate analysis, adult status (≥16 years), SEER stage, treatment era (before 1990), and lack of surgical staging of lymph nodes were significant prognostic factors in this cohort. A consensus statement by an international group of childhood renal experts was published that recommends adoption of the pediatric paradigm for the treatment of patients with AWT, including surgical resection, chemotherapy agents depending on stage and histologic subtype, and local therapy with irradiation depending on the stage of disease.[91] Furthermore, patients <30 years old are included on the current COG WT studies. The toxicities of treatment (severe acute neuropathy, grade 4 hematologic toxicity) in patients with AWT may be somewhat higher than in the pediatric population but are thought to be reasonable in view of the high response rates.[90]

Retroperitoneal schwannomas are a rare tumor, accounting for approximately 4% of retroperitoneal tumors, but are the most common benign tumor found in this location.[95,96] They belong to the family of peripheral nerve sheath tumors, which, in addition to schwannomas, includes neurofibromas, solitary circumscribed neuromas, and perineuriomas.[97] Schwannomas may occur in any nerve trunk in the body, with the exception of cranial nerves 1 and 2 (which are not covered by Schwann cells), and are most commonly found at peripheral nerve sites of the upper extremities and cranial nerves, with only 0.3% to 3.2% of all schwannomas occurring in the retroperitoneum.[97] Benign schwannomas are associated with neurofibromatosis 2 (NF2) in approximately 5% to 18% of patients with NF2, presenting most commonly between 20 and 50 years of age.[98] They are slow-growing nonaggressive tumors that displace rather than invade normal tissues and often form large, well-circumscribed masses.[96,97] They may display cystic degeneration, calcification, hemorrhage, and hyalinization on imaging studies. In several moderate to large series, there appears to be a slight female patient propensity, and the tumors are often diagnosed incidentally during radiologic examinations for unrelated symptoms.[99,100] Bone changes may occur in tumors adjacent to the

spine with invasion into nerve roots or the spinal canal, which may lead to neurologic symptoms, including paresthesias, weakness, and pain. MRI examinations are the preferred method of imaging these soft tissue neoplasms, although CT scanning may be necessary to better visualize potential bone abnormalities, particularly in the spine. Because these tumors are frequently quite vascular, some investigators do not recommend the use of CT-guided biopsies because of the risk of hemorrhage.[101] Whenever feasible, complete surgical resection with negative margins is the treatment of choice, although adjuvant RT may be necessary for incompletely excised sacral schwannomas.[102] Patients with NF1 have a particularly high risk of developing STS, particularly malignant peripheral nerve sheath tumors, often with an aggressive clinical presentation and poor outcome.[103]

Aggressive fibromatosis, also referred to as desmoid tumors, is a rare fibroblastic neoplasm that arises from deep musculoaponeurotic connective tissue and has an incidence of 2 to 4 cases per million population,[104] occurring either sporadically or associated with familial adenomatous polyposis (FAP).[105-108] Ten to 30% of patients with FAP eventually develop desmoid tumors, with most occurring in either the extremities or abdomen/retroperitoneum.[109-111] They occur slightly more frequently in women than in men.[112] Although benign in nature, they are locally aggressive and may infiltrate critical structures. Complete surgical resection is the mainstay of treatment, but because the local recurrence rate and morbidity from resection can be high, some patients are now managed with observation and close clinical radiologic follow-up per the National Comprehensive Cancer Network guidelines. Local recurrence is common, even in the setting of a wide local resection in up to 40% of patients depending on the series.[113-116] Postoperative RT and/or chemotherapy may be indicated when a complete surgical resection is not achieved or is not feasible or in multiple recurrent disease, though some institutions have been adopting a watch-and-wait approach to the treatment of desmoids as they are an indolent disease. The data are variable regarding the dose and treatment volumes for this disease; however, most reported series suggest that a dose of 50 to 60 Gy with margins of 5 to 7 cm is appropriate.[116,117] Doses >56 Gy may not be necessary to control gross disease.[117] A meta-analysis by Nuyttens et al, which included data from 22 studies, suggested that local control was improved with adjuvant RT compared to surgery

alone; local control after surgery alone was 72% (R0) and 41% (R1 and R2) compared to 94% (R0) and 75% (R1 and R2) after surgery and adjuvant radiation.[116] In patients with unresectable disease, RT alone is effective in providing long-term local control in up to 80% of patients.[116,118] Systemic therapy may also play a role in unresectable, incompletely resected, or recurrent disease. Systemic therapy options include both cytotoxic and noncytotoxic agents, including anthracyclines, hormonal therapy, nonsteroidal anti-inflammatory drugs, imatinib, and clinical trials with agents like sorafinib.[119]

Extragonadal germ cell tumors (EGCTs) account for approximately 1% to 5% of all germ cell tumors and occur in the retroperitoneum as the second most common extragonadal site in adults after the mediastinum.[120] Primary retroperitoneal germ cell tumors account for approximately 5% of all primary malignant retroperitoneal tumors in adults.[121] It is believed that these tumors arise from primordial germ cells, which are displaced during their migration along the urogenital ridge to the gonads.[120] When they occur in the retroperitoneum, they are considered to be metastases from an occult or "burned out" gonadal primary until proven otherwise. EGCTs are most typically found in children or young adults and mostly arise in midline locations. Most of these tumors occur in young men, and most are nonseminomatous germ cell tumors (NSGCTs) rather than seminomatous germ cell tumors (SGCTs).[120] In young women, the histologic varieties are dysgerminomas and nondysgerminomas. NSGCTs include the following histologies: teratoma, embryonal carcinoma, endodermal sinus tumor (yolk sac tumor), choriocarcinoma, and mixed histologies. Any proportion of nonseminomatous component is enough to classify a tumor as an NSGCT. NSGCTs generally have a much more aggressive course than do SGCTs. Serum markers, although nonspecific, may help to categorize the histology and can be useful for following both response to therapy and the presence of recurrence. β-Human chorionic gonadotropin is elevated in choriocarcinoma and embryonal carcinoma and in approximately 10% to 15% of SGCTs.[122] Serum α-fetoprotein is elevated in endodermal sinus tumors and embryonal carcinomas. These tumors often present as large masses in the retroperitoneum and frequently displace, compress, or encase abdominal vessels. There are no distinguishing features by imaging to differentiate germ cell tumors from other retroperitoneal masses; thus,

image-guided biopsy is necessary. Gonadal primaries must be ruled out using high-resolution ultrasound.[123] A biopsy of the gonads appears to be unnecessary in the presence of a negative ultrasound. Common sites of metastases are liver, bone, brain, and lungs. The prognosis of retroperitoneal SGCTs and their mediastinal counterparts is similar; however, retroperitoneal NSGCTs actually have a better prognosis than those occurring in the mediastinum.[120]

The treatment for EGCTs has evolved over past 10 to 15 years from the use of primary RT for SGCTs to the more commonly recommended treatment of platinum-based chemotherapy regimens.[120] Treatment paradigms for early-stage SGCT and NSGCT are covered elsewhere in this book. The International Germ Cell Cancer Collaborative Group established a classification system for assessing prognosis in NSGCT and SGCT[124] (Table 82.6), which is used to guide treatment decisions. For patients with a retroperitoneal SGCT, the preferred treatment approach is systemic chemotherapy using a cisplatin- based regimen similar to a patient with advanced testicular SGCT. In an international retrospective review of EGCTs, patients with retroperitoneal SGCTs had an overall survival of approximately 90%, with most patients treated with chemotherapy alone.[120] Patients treated with primary RT had an inferior progression-free survival compared to patients treated with either chemotherapy alone or chemotherapy plus RT.[120] For retroperitoneal NSGCTs, the preferred treatment is also cisplatin-based chemotherapy as in a testicular NSGCT, with the number of cycles dependent on if the patient is in the good or intermediate/poor prognosis group (Table 82.6). Residual masses should then be resected. In the international retrospective review of EGCTs, patients with retroperitoneal NSGCTs were primarily treated with primary chemotherapy, with 45% of patients undergoing a secondary surgery for residual disease.[120] The 5-year overall survival for patients with retroperitoneal NSGCTs was 62%.[120]

TABLE 82.6 THE INTERNATIONAL GERM CELL CANCER COLLABORATIVE GROUP CLASSIFICATION SYSTEM FOR ASSESSING PROGNOSIS IN NSGCT AND SGCT

Tumor	Good Prognosis	Intermediate Prognosis	Poor Prognosis
NSGCT	• Testis/retroperitoneal primary, no	• Testis/retroperitoneal primary, no	• Indicated by any of the following:

Tumor	Good Prognosis	Intermediate Prognosis	Poor Prognosis
	nonpulmonary visceral metastases, AFP <1,000 ng/mL, β-hCG <1,000 IU/L, and LDH <1.5 × upper limit of normal • 5-y PFS, 89% • 5-y survival rate, 92%	nonpulmonary visceral metastases, AFP >1,000 ng/mL and <10,000 ng/mL and/or β-hCG 5,000-50,000 IU/L and/or LDH > 1.5 × normal to 10 × normal • 5-y PFS, 75% • 5-y survival rate, 92%	mediastinal primary, nonpulmonary visceral metastases or AFP >10,000 ng/mL, β-hCG >50,000 IU/L, or LDH > 10 × normal • 5-y PFS, 41% • 5-y survival rate, 48%
Seminoma	• Any primary site, no nonpulmonary visceral metastases, normal AFP, any β-hCG, any LDH • 5-y PFS, 92% • 5-y survival rate, 88%	• Any primary site, nonpulmonary visceral metastases, normal AFP, any β-hCG, any LDH • 5-y PFS, 67% • 5-y survival rate, 72%	• No patients classified as having poor prognosis

AFP, α-fetoprotein; β-hCG, β-human chorionic gonadotropin; NSGCT, nonseminomatous germ cell tumor; LDH, lactate dehydrogenase; SGCT, seminomatous germ cell tumor.

CONCLUSION

The retroperitoneum is a challenging space for clinicians with a wide variety of possible histologies and adjacent normal tissues limiting therapeutic options. Advances in imaging have improved the ability to characterize these lesions, although, ultimately, a histologic diagnosis is necessary. In general, treatment is driven by histology. For most neoplasms in the retroperitoneum, evaluation by a multidisciplinary team is necessary. RT technology advances, including the use of IMRT and particle therapy, have improved the ability to deliver a therapeutic radiation dose to the tumor in this challenging space while sparing abutting organs at risk. Although much progress has been made with advances in surgery, systemic

therapy, and RT, patient outcomes remain poor; thus, additional advancements need to be made, including more prospective multi-institutional studies.

CHAPTER 83

Adrenal Cancer

Filip T. Troicki

ANATOMY

The paired suprarenal (adrenal) glands are located between the superomedial aspects of the kidney and the diaphragmatic crura. They are surrounded by connective tissue containing perinephric fat. The glands are enclosed by renal fascia but separated from the kidneys by fibrous tissue. The triangular right gland relates to the diaphragm posteriorly and the inferior vena cava and liver anteriorly. The semilunar left adrenal gland is positioned in the middle of the left crux of the diaphragm. The omental bursa separates it from the stomach. It is also related to the spleen and pancreas.[1]

The endocrine function of the adrenal glands necessitates an abundant blood supply. The superior suprarenal arteries are derived from the inferior phrenic artery, the middle suprarenal arteries from the abdominal aorta near the origin of the superior mesenteric artery, and the inferior suprarenal arteries from the renal artery. A large central vein leaves the anterior surface of the gland at the hilum. The shorter right suprarenal vein drains into the inferior vena cava, and the longer left suprarenal vein drains into the left renal vein.[1]

The lymphatic drainage follows the arterial supply and is predominantly to lumbar lymph nodes. The superior lymphatic trunks end in aortocaval lymph nodes located near the origin of the celiac plexus. The inferior lymphatic trunks end in lateral aortic nodes above the renal pedicle. Some trunks may pass through the diaphragm, following the splanchnic nerves, ending in retroaortic nodes in the posterior mediastinum. On the right, some lymphatic trunks may penetrate the liver.[2]

The adrenal gland is composed of a central catecholamine-producing medulla enveloped by the steroid-secreting cortex. Although they are in

intimate contact, they represent two functionally separate organs with different embryologic origins.

EPIDEMIOLOGY

Adrenal Cortical Tumors

Adrenocortical carcinomas (ACCs) are rare. Benign tumors are more common, occurring in 1% to 8% of the general population, and are typically discovered incidentally in up to 4% of abdominal imaging studies.[3] The incidence of carcinoma is approximately 1 per million population in the United States.[4,5] There are approximately 75 to 115 new cases per year.[6] Adrenal cortex carcinoma deaths account for 0.2% of all yearly cancer deaths. There is a bimodal age distribution with disease peaks before the age of 5 years and in the fourth to fifth decades of life.

Overall, ACC is slightly more common in women than in men. Nonfunctional carcinomas occur in an older age population (>30 years old) and are more common in men (3:2 male-to-female ratio), although functional tumors are more common in women (7:3 female-to-male ratio) and younger patients. As they frequently present with symptoms related to hormone production, typically symptomatic cortisol hypersecretion, functional tumors are usually detected at an early stage.

Although most cases of ACC are sporadic, it has been described as a component of several hereditary cancer syndromes, including Li-Fraumeni syndrome (breast cancer, soft tissue and bone sarcoma, brain tumors, and ACC), Beckwith- Wiedemann syndrome (Wilms tumor, neuroblastoma, hepatoblastoma, and ACC), multiple endocrine neoplasia type I (MEN-I) (parathyroid, pituitary and pancreatic neuroendocrine tumors, and adrenal adenomas and carcinomas), and sarcoma, breast, lung, ACC, and other tumors.[7-10] A role for p53 mutations in sporadic ACC is suspected.

Adrenal Medulla Tumors

Ganglioneuromas are rare, benign tumors of the adrenal medulla seen in children and young adults.[11,12] Neuroblastoma is the most common malignant tumor of the adrenal gland in children, accounting for 90% of all cases.[4,13]

Pheochromocytomas and functional ganglioneuromas (or extra-adrenal pheochromocytomas) are rare tumors that arise from chromaffin cells in the adrenal medulla and elsewhere. They secrete catecholamines and cause intermittent, episodic, or sustained hypertension. Pheochromocytomas have an estimated prevalence of 0.1% in patients with hypertension.[14] In autopsy series, there is a 0.01% to 0.1% prevalence of unsuspected pheochromocytomas. Extra-adrenal tumors are more commonly malignant.[15] Estimates of the incidence of malignancy in pheochromocytoma range from 5% to 46% in different series.[16,17] Approximately 400 new cases of malignant pheochromocytomas are expected each year in the United States.[18,19]

Pheochromocytomas may be associated with a variety of endocrine and nonendocrine inherited disorders. Bilateral pheochromocytomas are a component of multiple endocrine neoplasia type IIA (MEN-IIA) syndrome (pheochromocytoma, medullary thyroid carcinoma, and parathyroid hyperplasia) or MEN-IIB syndrome in which they are associated with marfanoid habitus, mucosal neuromas, and medullary thyroid carcinoma. Pheochromocytomas occur in 25% of patients with von Hippel-Lindau syndrome and <1% of patients with neurofibromatosis and von Recklinghausen disease.[20,21]

NATURAL HISTORY

Fifty-nine percent of adrenal cortex tumors are functional, the left-to-right ratio is approximately 1:1, and 2.4% are bilateral.[22] Unless bothersome symptoms prompt a rapid workup, diagnosis is frequently delayed because of the rarity of the disease and the deep retroperitoneal location of the adrenal glands.[23]

Nonfunctioning ACCs are typically large, often >6 cm, whereas functioning tumors are smaller because they tend to be discovered at an earlier stage (for tumor, node, metastases [TNM] staging, see Table 83.1). Incidentally discovered adrenal masses <4 cm are rarely malignant. In fact, a study from the National Italian Study Group on Adrenal Tumors found that 90% of adrenal carcinomas found incidentally were >4 cm in diameter.[24] ACC is an aggressive malignancy that frequently violates the tumor capsule and invades surrounding tissues. It metastasizes early to

lungs, liver, brain, and regional lymph nodes. Many patients present with widespread metastasis; most of these patients die within 6 months of diagnosis. This situation is especially common in the pediatric population. For all stages, the 5-year overall survival (OS) is only 20% to 25%.[23]

Malignant pheochromocytomas not only exhibit a similar pattern of spread but also metastasize to bone. They are equally common in men and women. The average age of presentation is 40 to 50 years old, but these carcinomas may also occur in children.

CLINICAL PRESENTATION

Functional adrenocortical tumors most frequently secrete cortisol and androgens, resulting in Cushing syndrome, virilization, and hypertension. Estrogen or aldosterone production is less common. It is estimated that up to 10% of adult patients with Cushing syndrome have adrenal adenomas. Approximately 60% of ACCs are functional. In a child, virilization is the most common symptom of ACC, and Cushing syndrome is relatively uncommon. By contrast, adults usually present with either Cushing syndrome alone or mixed with virilization. Patients with nonfunctioning

tumors present with nonspecific symptoms related to tumor burden, including abdominal fullness, early satiety, pain, weight loss, weakness, fever, or an abdominal mass. Nonfunctioning ACCs are more common in older patients and tend to progress more rapidly. An increasing number of adrenal tumors are incidentally discovered during abdominal imaging in the absence of any symptoms.

Pheochromocytomas arising in the setting of an inherited disorder occur in the adrenal medulla in 90% of cases, as compared with 75% of sporadic pheochromocytomas. When associated with MEN-II syndromes, 80% are bilateral. A tumor >4 cm more commonly has a malignant course than a smaller lesion. Serum catecholamines and urinary metanephrine and vanillylmandelic acid levels are elevated in 90% of pheochromocytomas. These patients present with a range of symptoms from mild labile hypertension to sudden cardiac death secondary to hypertensive crisis, myocardial infarction, or cerebrovascular accident. The classic triad of symptoms consists of episodic headaches, diaphoresis, and tachycardia.[9,25] About half of patients have paroxysmal hypertension, and others have sustained hypertension. Pheochromocytomas may also present with normal blood pressure in 5% to 15%. Other symptoms may include pallor, palpitations, panic attack symptoms, or generalized weakness. Orthostatic hypertension may occur in association with hypovolemia.

DIAGNOSTIC WORKUP AND STAGING

Patients with adrenal gland tumors should be evaluated for other primary tumors. Metastases to the adrenal gland, typically from lung, breast, skin, kidney, thyroid and colon, are far more common than primary adrenal gland tumors.[26] In metastatic tumors that are not adrenal in origin, a biopsy is recommended. Prior to obtaining a biopsy, however, pheochromocytomas must be ruled out by measuring the fractionated plasma-free metanephrine, as well as the 24-hour urine fractionated metanephrines and catecholamines. Low suspicion for pheochromocytoma either clinically or biochemically should steer providers toward obtaining an adrenal biopsy. Furthermore, any patient with a suspected adrenal tumor should be screened for hormonal hypersecretion, including cortisol, aldosterone, and catecholamine secretion (Table 83.2). As hypercortisolism is the most

frequent abnormality, serum cortisol, a 24-hour urinary cortisol, and an overnight dexamethasone suppression test should be obtained.

TABLE 83.2 DIAGNOSTIC WORKUP FOR ADRENAL TUMORS

CT, computed tomography; MRI, magnetic resonance imaging.

Morphologic evaluation of the adrenal glands with computed tomography (CT) of the abdomen should be performed as per adrenal protocol. CT of the abdomen with thin cuts through the adrenal gland is the imaging test of choice for the evaluation of adrenal tumors. Carcinomas can mimic adenomas but are characterized by larger size, irregular margins, and heterogeneous enhancement. They may also demonstrate tumor necrosis and cystic degeneration. Local invasion, tumor extension into the vena cava, as well as lymph node or other metastases are often seen in advanced ACC. Magnetic resonance imaging (MRI) is useful in the evaluation of adrenal tumors (Figure 83.1). ACC and pheochromocytomas are hyperintense on T2-weighted images, and venous invasion is better imaged on MRI. If there is still question of vascular invasion, an angiographic study can be performed preoperatively, either selective arteriography or vena cavography. Fluorodeoxyglucose positron emission tomography may be useful in differentiating benign from malignant lesions. It may also serve as an additional staging study for patients with known ACC. A chest CT should also be obtained.

FIGURE 83.1 T2-weighted magnetic resonance image of a 35-year-old woman with a left adrenal carcinoma.

Evaluation of the patient's adrenal function is indicated if there is no suspicion of adrenal metastasis. Workup for hyperaldosteronism, Cushing syndrome, and pheochromocytoma should be performed when clinically indicated. The diagnosis of pheochromocytoma is confirmed by measurements of urinary and plasma fractionated metanephrines and catecholamines. Medication-induced elevation of metanephrine levels is common and should be evaluated prior to initiating further costly workup. Levels of metanephrine 4 times the normal limit are diagnostic of pheochromocytoma, and biochemical confirmation of disease is followed by imaging to locate the tumor. Other scans, including the OctreoScan

(Mallinckrodt Inc) and a bone scan, may be indicated if metastatic disease is suspected.

Levels of plasma aldosterone (high) and renin (low) activity should be assessed when suspecting primary aldosteronism (hyperaldosteronism). The ratio of aldosterone to renin above 30 is suggestive of hyperaldosteronism and should be confirmed with saline suppression or salt loading tests, and electrolytes should be measured. Although malignant hyperaldosteronism is rare, these patients require an open adrenalectomy (OA) to prevent tumor rupture. In benign cases of hyperaldosteronism, adrenal vein sampling for aldosterone is considered standard of care.

Patients with Cushing syndrome require an evaluation of serum levels of corticotropin, cortisol, as well as the sex steroid dehydroepiandrosterone sulfate. If cortisol levels are elevated, a confirmatory test with dexamethasone suppression is recommended. It is important to remember that elevated corticotropin levels do not indicate adrenal origin, and further workup is necessary to look for primary causes of increased corticotropin. Benign adrenal tumors can be removed laparoscopically. Patients who present with Cushing syndrome in the presence of large (>4 cm), inhomogeneous, or invasive masses should be suspected to have malignant tumors, and imaging of the chest, abdomen, and pelvis is warranted to look for metastasis.

Pathologic Classification

Tumors <6 cm are more likely adenomas, although some smaller tumors may be malignant (Table 83.3). In order to establish stability of an adrenal mass, imaging should be repeated in 6 to 12 months for benign-appearing adenomas measuring <4 cm, and 3 to 6 months for larger lesions up to 6 cm. Hemorrhage and necrosis may be observed macroscopically in carcinomas. Numerous mitotic figures and cellular undifferentiation are common microscopic findings. Larger size, vascular invasion, or invasion of surrounding tissues and numerous mitotic figures are poor prognostic features.[27]

Fibrosarcoma

Pheochromocytomas have malignant features in <10% of cases. Macroscopically, they tend to be encapsulated with areas of cystic change, hemorrhage, and necrosis. The capsule is frequently invaded, but that does not constitute malignant change. Benign and malignant pheochromocytomas may appear identical histologically. A fine-needle aspiration cannot be utilized to differentiate between a benign or malignant adrenal tumor, but it can be used when a metastatic adrenal lesion is suspected.[10] A pheochromocytoma must be ruled out with biochemical testing before any biopsy is attempted in order to avoid a potentially devastating hemorrhage, hypertensive crisis, or capsular rupture.[28] Histologically, cell size, nuclear size, and arrangement of cells are variable. A twisted cell cord pattern, basophilic or cytophilic staining with fine intracytoplasmic pigment granules, and periodic acid-Schiff staining of secretory droplets aid in the diagnosis.

GENERAL MANAGEMENT

The most important prognostic factors that predict outcomes in patients with ACC are stage and extent of resection. Benign tumors are nonfunctioning and are most often found incidentally. After the benign nature of these tumors is confirmed, small tumors can be left untreated and can be followed up by repeat imaging 6 to 12 months after diagnosis to confirm their stability. Larger tumors (>4 cm) should be followed up with

imaging in 3 to 6 months after diagnosis. A small benign mass that grows at the rate of >1 cm/y can be removed electively, but any significant growth of a larger mass should alert the clinician to a potentially malignant nature of the tumor and adrenalectomy is recommended in that case.

Nonfunctioning adrenal tumors that are >4 cm, are heterogeneous, or have irregular margins are suspicious for adrenal carcinomas. Surgery with removal of adjacent lymph nodes is the primary and only potentially curative treatment for ACC, especially in stage I and II patients.[29] Complete resection is the only treatment that offers long-term disease-free survival, but it is not always feasible.[30] Although minimally invasive adrenalectomy (MIA) has been pursued at some institutions, data regarding the management of MIA are limited, and as of this publication, OA remains the gold standard. For patients with a macroscopically complete resection, a margin-free resection is a strong predictor for survival. Efforts to avoid tumor spillage are warranted, and the tumor capsule should remain intact. Invasion or adherence of adjacent structures often necessitates en bloc resection of the kidney or spleen, partial hepatectomy, or pancreatectomy. The presence of tumor thrombus in the renal vein or vena cava does not preclude resection. A lymphadenectomy is often included. An extensive regional lymph node dissection has not been shown to have any impact on OS or disease-specific survival.[31] For patients with localized disease who have high-risk features, such as positive margins, rupture of capsule, high grade, or large size, postoperative radiation should be considered. The role of tumor debulking in the presence of metastatic disease is not clear. Incomplete resection of the primary tumor or metastatic disease not amenable to surgery is associated with a poor prognosis. Still, tumor debulking may help control hormonal oversecretion or relieve local symptoms in certain cases. Neoadjuvant chemotherapy to facilitate surgery is not a standard approach, although cisplatin-based treatments have been shown to have a cytoreductive effect in some patients.[32] Even with a complete resection, local recurrence and metastatic disease are common. For isolated distant metastases and locally unresectable disease, cytoreductive resection with or without radiation is recommended.

Adjuvant therapies typically depend on factors that affect recurrence risks. Patients with low recurrence risk include those who are early stage and underwent a complete resection of the tumor (R0). Proliferation marker

Ki67 below 10% has been shown to be another favorable feature after an R0 resection of ACC.[33] Low-risk patients can be typically observed postoperatively. High-risk patients have a higher risk of recurrence and typically require some form of adjuvant treatment.

Mitotane, a chemical congener of the insecticide dichlorodiphenyltrichloroethane, is an adrenolytic compound with specific activity on the adrenal cortex. It is the chemotherapeutic agent most commonly used in the management of ACC. In patients with measurable disease, overall response rates of 14% to 36% have been reported, but most studies have reported no significant survival benefit.[34] The largest retrospective study from Italy and Germany that included 177 patients with resected ACC (stages I-III) showed improvements in disease- free survival and OS.[35] Unfortunately, responses are usually partial and transient, with only an occasional complete remission.[22] The role of mitotane as adjuvant therapy after complete surgical resection is questionable. Despite limited supporting data, it is frequently employed in this setting, given the high rates of locoregional and distant recurrence. Serum levels of mitotane are monitored in order to optimize therapy because objective response in the metastatic setting was associated with higher serum levels (>14 mg/L). Unfortunately, increased toxicity is also associated with higher serum levels. Side effects are predominantly gastrointestinal, particularly nausea, but anorexia and diarrhea also occur. Although less common, central nervous system toxicity can include lethargy, somnolence, ataxia, dizziness, or confusion.

Single-agent chemotherapy has proven disappointing in the management of ACC. Doxorubicin and cisplatin have both been evaluated as either single-agent therapy and in combination with mitotane. Neither drug was efficacious.[36] Multiagent chemotherapy has shown more promise. A multicenter phase II study by the Italian Group for the Study of Adrenal Cancer demonstrated 49% overall response rate using a regimen of etoposide, doxorubicin, and cisplatin in combination with mitotane. The regimen was well tolerated. The most common side effects were gastrointestinal. The time to progression in responding patients was 2 years.[7] Inclusion of mitotane in a multidrug regimen is rational as ACCs are prone to multidrug resistance mediated by the multidrug resistance-1/P

glycoprotein drug pump, whose mechanism is inhibited by mitotane. This multidrug regimen is worthy of further study.

The role of radiation in the management of ACC is not well defined. Adjuvant radiation in patients with stages I and II ACC who underwent a complete resection is typically discouraged. Radiation has been proposed as adjuvant therapy in patients with stage III disease, as well as those with high-grade adrenal carcinoma, and those who underwent an R1 or Rx resection or had tumor spillage during surgery. Although the benefits of adjuvant radiation are in local control, one series reported a 10-year crude survival rate of 33% for surgical resection followed by adjuvant radiation.[37] Previous beliefs that ACC is radioresistant have been challenged with a significant response of tumor cells when utilizing modern radiation techniques. External radiation results in good response rates and effective palliation in patients with residual macroscopic disease or bone or nodal metastasis.[19,38]

Surgical resection is the definitive management of pheochromocytoma, but it is a high-risk procedure. Cardiovascular and hemodynamic parameters must be monitored closely. Preoperative medical therapy is aimed at controlling hypertension and expanding intravascular volume. Preoperative pharmacologic preparation typically includes combined α- and β-adrenergic blockade.

In patients with undiagnosed pheochromocytomas who undergo surgery for other reasons, surgical mortality rates are high because of lethal hypertensive crisis and multiorgan failure.[39] In the largest series of 147 patients undergoing surgery for pheochromocytoma, perioperative mortality and morbidity rates were 2.4% and 24%, respectively.[40] Although it results in rapid symptomatic control, surgical removal of a pheochromocytoma does not always lead to a long-time cure. In a large series of 176 patients, pheochromocytoma recurred in 16% of patients. Half of these recurrences were malignant.[41] In patients with bilateral pheochromocytomas, usually in the setting of an inherited syndrome, bilateral adrenalectomy is recommended. Hormone replacement is required in this setting. Although not curative, debulking surgery for control of symptoms is the primary therapy for malignant pheochromocytoma.

The radioisotope iodine-131 metaiodobenzylguanidine (^{131}I-MIBG) has been used as a therapeutic agent in malignant pheochromocytomas that

demonstrate avid uptake of the agent. Investigators have reported partial responses, based on biochemical response as well as decreased tumor volume, ranging from 18% to 82%.[42-44] Symptomatic improvement was observed in responding patients with regard to both painful metastases and manifestations of increased catecholamine levels. Partial remissions are usually temporary, with some patients relapsing between doses of MIBG. In other patients, sustained partial remissions have been noted with durable palliation extending 2 to 3 years.[43,45] Prolonged survival has been associated with measurable responses and higher administered doses of MIBG (>500 mCi).[46] Toxicity includes bone marrow toxicity (particularly thrombocytopenia), nausea, and vomiting.

Combination chemotherapy with cyclophosphamide, vincristine, and dacarbazine has shown efficacy in a small study. In 14 treated patients, the clinical and biochemical response rates were 57% and 79%, respectively. Response was associated with objective improvement in performance status and blood pressure, and treatment was well tolerated.[47]

RADIATION THERAPY TECHNIQUES

The role of radiation in the management of ACC is controversial. Locoregional disease control remains a major problem in this disease, and some reports suggest that external radiation may reduce recurrence rates.

In the primary management of ACC, external radiation may play a role preoperatively for unresectable tumors, postoperatively for patients with residual disease or high risk of local failure, or as definitive therapy for patients who are medically unfit for surgery. In a recent large retrospective review, the time to tumor progression in advanced ACC has been significantly improved with conventional and stereotactic radiation.[48] Radiation is also effective in the palliative setting for bone and nodal metastases.

For patients with macroscopic or unresectable disease, doses of 50 to 60 Gy delivered during 5 to 6 weeks should be considered. Adjuvant radiation should be started within 12 weeks post-op. Initial fields should encompass the gross tumor with adequate margins as well as the regional lymph nodes, which should include the contralateral para-aortic and inter-aortocaval lymph nodes. Dose to regional nodes can be limited to 45 Gy when they are

not macroscopically involved. Care should be taken to limit dose to the spinal cord, kidneys, liver, and small bowel. Avoiding adjacent organs at risk is vital in treating adrenal cancers and intensity-modulated radiation therapy or volumetric modulated arc therapy should be considered standard. For patients receiving postoperative treatment for high-risk or microscopic disease, doses of 45 to 54 Gy are appropriate. The role of stereotactic body radiotherapy (SBRT) for primary adrenal tumors has not been established, although it is now a common practice for oligometastatic disease to the adrenal gland. A handful of case series have shown potential efficacy of SBRT for primary adrenal tumors that are unresectable because of comorbidities or patient preference. The popularity of SBRT for metastatic lesions is mainly based on results of case series and retrospective reviews, which show good local control rates ranging from 60% to 70% at year 1 and between 40% and 50% at year 2.[49] No prospective randomized trials are available to compare the efficacy of SBRT against a surgical resection. SBRT doses typically range from 30 Gy in 3 fractions to 50 Gy over 5 fractions for both primary and oligometastatic adrenal tumors.

In the palliative setting, doses of 30 to 40 Gy given during the course of 2 to 3 weeks are reasonable. In patients with painful bone metastases, hypofractionated regimens should be considered for patients with poor performance status or otherwise limited life expectancy.

External beam radiation is limited to a palliative role in the management of pheochromocytomas.

FOLLOW-UP

Patients with pheochromocytomas should have frequent follow-up that includes a thorough history and physical examination with an evaluation of vital signs and plasma markers. This should be done every 6 months for the first 3 years starting around 3 months postsurgery and annually thereafter. Advanced or persistent disease may require more frequent follow-up and symptom management.

PART K

Lymphoma and Hematologic Tumors

CHAPTER 84

Hodgkin Lymphoma

Bradford S. Hoppe, Omran Saifi, and Richard T. Hoppe

The management of Hodgkin lymphoma (HL) continues to evolve. Since the last edition of this text, initial treatments have become more refined, relying on interim or end of systemic therapy response assessments to adapt therapies. The role of radiation therapy (RT) for early, intermediate, and advanced stages has become better defined. Targeted systemic therapy (brentuximab vedotin [BV]) has been introduced in all stages of disease, and immunotherapy with nivolumab and pembrolizumab has shown significant benefit in advanced and relapsed disease and is being explored in early stage, as well. Large prospective, randomized clinical trials have allowed us to refine treatments, and data regarding late effects continue to influence the development of management approaches.

ANATOMY

HL almost always begins in the lymph nodes. Over 80% of patients present with cervical lymph node involvement, and over 50% have mediastinal disease. Disease can extend into extralymphatic sites, such as lung, pericardium, and soft tissue, but solitary extralymphatic involvement without nodal disease is rare.

EPIDEMIOLOGY AND RISK FACTORS

The reported incidence of HL is 2.3 per 100,000, with a slight male predominance (1.2:1). It accounts for 0.51% of all cancers diagnosed. The death rate decreased from 0.7 per 100,000 per year to 0.1 per 100,000 per year between 1975 and 2020.[1] Although HL is rare in children older than 10 years, it is the fourth most commonly diagnosed malignancy among individuals younger than 20 years.[1] The median age of patients at the time of diagnosis is 26 years. Its incidence shows a bimodal peak as a function of age.[1] The early peak, from ages 20 to 24 years, shows an incidence

of approximately 4.1 per 100,000 per year. A second peak, from age 80 to 84 years, shows a similar incidence (4.4/100,000 per year).[1]

Geographic clusters of patients with HL have been reported, but these are likely coincidental.[2] Inherited risk has also been reported among first-degree relatives.[3] A relation between HL and previous infection with Epstein-Barr virus (EBV) has been proposed.[4] Components of the EBV genome have been identified in the cellular DNA of Reed-Sternberg (R-S) cells in lymph nodes involved by HL. The risk for the development of HL is 2.55 times higher among individuals with a history of infectious mononucleosis than among noninfected control subjects. Several series have demonstrated an association between EBV infection and mixed cellularity HL (MCHL), especially among children in developing countries. However, the precise relationship between EBV infection and the development of HL remains undefined.[5] The coexistence of EBV and human immunodeficiency virus (HIV) infections may account for the higher risk of HL in the acquired immunodeficiency syndrome population. Studies attempting to link occupational exposures or other etiologic factors with the development of HL have been inconclusive or contradictory.[2]

NATURAL HISTORY AND CLINICAL PRESENTATION

Patients with HL usually present with painless lymphadenopathy. Some note systemic symptoms such as unexplained fevers, drenching night sweats, weight loss, generalized pruritus, fatigue, and alcohol-induced pain in tissues involved by HL. Still, other patients are diagnosed after the detection of a mediastinal mass on a routine chest radiograph.

Sites of involvement are typically contiguous, although occasional skip areas occur.[6,7] The theory of contiguity of spread and the development of treatment programs with radiation that included treatment of uninvolved sites were important conceptual advances in the treatment of HL in the latter half of the 20th century.

HL can extend from the lymph nodes to adjacent organs, as when it spreads from enlarged mediastinal or bronchopulmonary (pulmonary hilar) nodes directly into the pulmonary parenchyma. It can also be hematogenous, as with nodular disease in the liver or multiple bony sites. Involved bones can undergo blastic changes, especially those in the vertebrae (creating the classic “ivory vertebra” on plain radiographs), pelvis, sternum, or ribs.

The likelihood of disseminated disease, including bone marrow and liver involvement, increases with splenic involvement.[8,9] HL rarely involves the Waldeyer lymphoid region or the gut-associated lymphoid tissues, such as Peyer patches. It also rarely involves the upper aerodigestive tract, central nervous system, and skin.[6]

The rapidity of HL’s growth and spread varies. Disease can evolve over several years, as demonstrated on serial radiographs or suspected by clinical history, and it

is uncommon to document progression during evaluation and staging.

Three "B symptoms" are included as part of the staging system for HL (see later discussion): fever, drenching night sweats, and significant weight loss (10% of baseline weight). One-third of patients present with one of these symptoms. Fevers may present in the classic waxing-and-waning Pel-Ebstein pattern. Drenching night sweats may require a change of bedclothes and/or sheets. The B symptoms can occur even in patients with relatively limited disease (stage II), but they are uncommon in stage I disease.

Historically, children fare better with treatment than adults, so different treatment strategies have been developed for children (see Chapters 97).[10,11] Yet, recent pediatric approaches in North America are utilizing adult systemic therapy backbones. Older adults (>60 years) have a worse prognosis, often secondary to intercurrent illness or an inability to tolerate standard therapies, especially bleomycin, anthracyclines, and extended-field RT.[12] The risk of bleomycin lung toxicity is especially increased in older patients.

If HL is diagnosed during pregnancy, special treatment considerations are warranted; however, no evidence exists that pregnancy affects the natural course of the disease. Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine (ABVD) may be administered safely after the first trimester of pregnancy.[13] Many women become pregnant after successful treatment. Among patients infected with HIV type 1, HL tends to behave differently, with a poorer prognosis.[14]

DIAGNOSTIC WORKUP

Diagnostic and staging procedures commonly used for HL are listed in Table 84.1. Patient age and intercurrent disease may influence the selection of staging studies.[15,16]

TABLE 84.1 DIAGNOSTIC AND STAGING PROCEDURES FOR HODGKIN LYMPHOMA

History
Systemic B symptoms: unexplained fever, drenching night sweats, weight loss >10% of body weight in the last 6 mo
Other symptoms: alcohol intolerance, pruritus, respiratory problems, fatigue
Physical Examination
Palpable nodes (note number, size, location, shape, consistency, mobility)
Palpable liver or spleen
Laboratory Studies
Complete blood count, differential, platelets

ESR
Serum albumin, lactate dehydrogenase, liver function studies
Blood urea nitrogen, creatinine
If indicated:
Pregnancy test in women of childbearing age
Pulmonary function studies
Cardiac ejection fraction
HIV testing
Imaging
Chest radiograph: posterior-anterior and lateral
Integrated PET-CT scan (skull base to midthigh) (or integrated PET-MRI scan)

CT, computed tomography; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging; PET, positron emission tomography.

Hematologic evaluation may reveal anemia, leukocytosis, lymphopenia, or thrombocytosis, common paraneoplastic effects stimulated by cytokines. Anemia, lymphopenia, leukocytosis, and hypoalbuminemia are adverse prognostic factors, especially in patients with advanced disease (stages III-IV).[17] The serum alkaline phosphatase level can serve as a nonspecific marker of tumor activity or hepatic, bone marrow, or bone disease. The erythrocyte sedimentation rate (ESR) is a prognostic factor for patients with limited disease (stages I-II).[18] Other useful markers include lactate dehydrogenase and β_2-microglobulin levels.

Radiographic evaluation with posterior-anterior (PA) and lateral chest radiographs is helpful for the stratification of patients in clinical trials. Mediastinal adenopathy can be measured by dividing the maximum width of the mediastinal mass by the maximum intrathoracic diameter (near the level of the diaphragm) on a standing PA chest radiograph. When this ratio exceeds 1:3, the disease is defined as bulky, which affects assignment to many clinical trials. Other definitions of bulky mediastinal adenopathy include a mass greater than 10 cm and a ratio of mediastinal mass to the chest diameter at T5-T6 exceeding 0.35 (employed in European Organisation for the Treatment of Cancer [EORTC] clinical trials). Contrast-enhanced (diagnostic) computed tomography (CT) scans of the chest, abdomen, and pelvis may reveal adenopathy or organ involvement but rarely identify disease beyond that detectable by an integrated positron emission tomography (PET)-CT scan. Lymph nodes larger than 1.5 cm on a CT scan are considered enlarged.[16] Although splenomegaly or hepatomegaly alone do not suggest involvement of HL (in the absence of confirmatory findings on a contrast-enhanced CT scan or 2-

fluoro-2-deoxy-D-glucose [FDG]-PET scan), a spleen over 13-cm long is considered likely involved per the current staging system.[16]

PET using FDG with fused CT images (PET-CT scan, subsequently abbreviated as PET) is essential to staging HL. Omitting PET as part of staging can negatively influence outcomes, especially as they pertain to designing radiation treatment fields.[19] Tissues affected by HL are intensely FDG avid, and FDG-PET is more sensitive than CT for detecting disease. FDG's uptake pattern in bone defines whether bone or bone marrow is involved, obviating the need for a bone marrow biopsy.[20] The overall incidence of bone marrow involvement in HL is only approximately 5%.

PET is also an essential study for response assessment, is particularly useful for evaluating residual masses detected by CT scanning, and can be a useful prognostic indicator when repeated after some chemotherapy (CT) has been administered (vide infra interim PET).[15,16] The 5-point Deauville visual score is used to evaluate the degree of response to therapy, based on the comparison of FDG activity in initial disease sites to background levels in the liver and mediastinal blood pool (Table 84.2).

TABLE 84.2 DEAUVILLE FIVE-POINT SCALE FOR ASSESSING TREATMENT RESPONSE ON PET-CT

Score	PET-CT Scan Result
1	No uptake
2	Uptake # mediastinum
3	Uptake > mediastinum but #liver
4	Uptake moderately higher than liver
5	Uptake markedly higher than liver and/or new lesions
X	New areas of uptake unlikely to be related to lymphoma

PET-CT, positron emission tomography-computed tomography.

Although not widely used, magnetic resonance imaging (MRI) is an alternative to chest or abdominal-pelvic CT scanning for initial staging. Its main value is in the staging evaluation of children and pregnant women (without contrast). Furthermore, it can be incorporated with FDG-PET to generate fused PET-MRI scans.[21]

Staging

The Ann Arbor staging system for HL, used since 1971, was modified in the Cotswolds, England, in 1989,[22] and in Lugano, Switzerland, in 2014[16] (Table 84.3).[23] The lymphoid regions as defined in the Ann Arbor staging system are shown in

Figure 84.1. Although somewhat arbitrary in their anatomic borders, these definitions reliably describe the extent of disease and help to define clinical risk groups for clinical trial assignment. Defining the "E" lesion has always been a challenge. The Cotswolds system attempts to clarify it as a direct disease extension from any nodal site that can be encompassed by a radiation field; however, some scenarios are more complex.[24] The final stage reflects the distribution of disease as observed on physical examination and imaging studies, with or without B symptoms.

TABLE 84.3 THE ANN ARBOR STAGING CLASSIFICATION FOR HODGKIN DISEASE

Stage I	Involvement of a single lymph node region
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm (IIE)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which can be accompanied by involvement of the spleen (IIIS) or by localized involvement of an extralymphatic organ or site (IIIE) or by both (IIISE)
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without associated lymph node involvement

The absence or presence of fever, night sweats, and/or unexplained loss of 10% or more body weight in the 6 months before diagnosis is denoted by the suffix letter A or B, respectively. The Cotswolds system used X to designate bulky disease, variably defined, but including a mediastinal mass width exceeding one-third of the thoracic ratio at the T5-T6 interspace and any disease >10 cm.[25] The Lugano system recommended deleting X and instead noting the size of the largest node.[26]

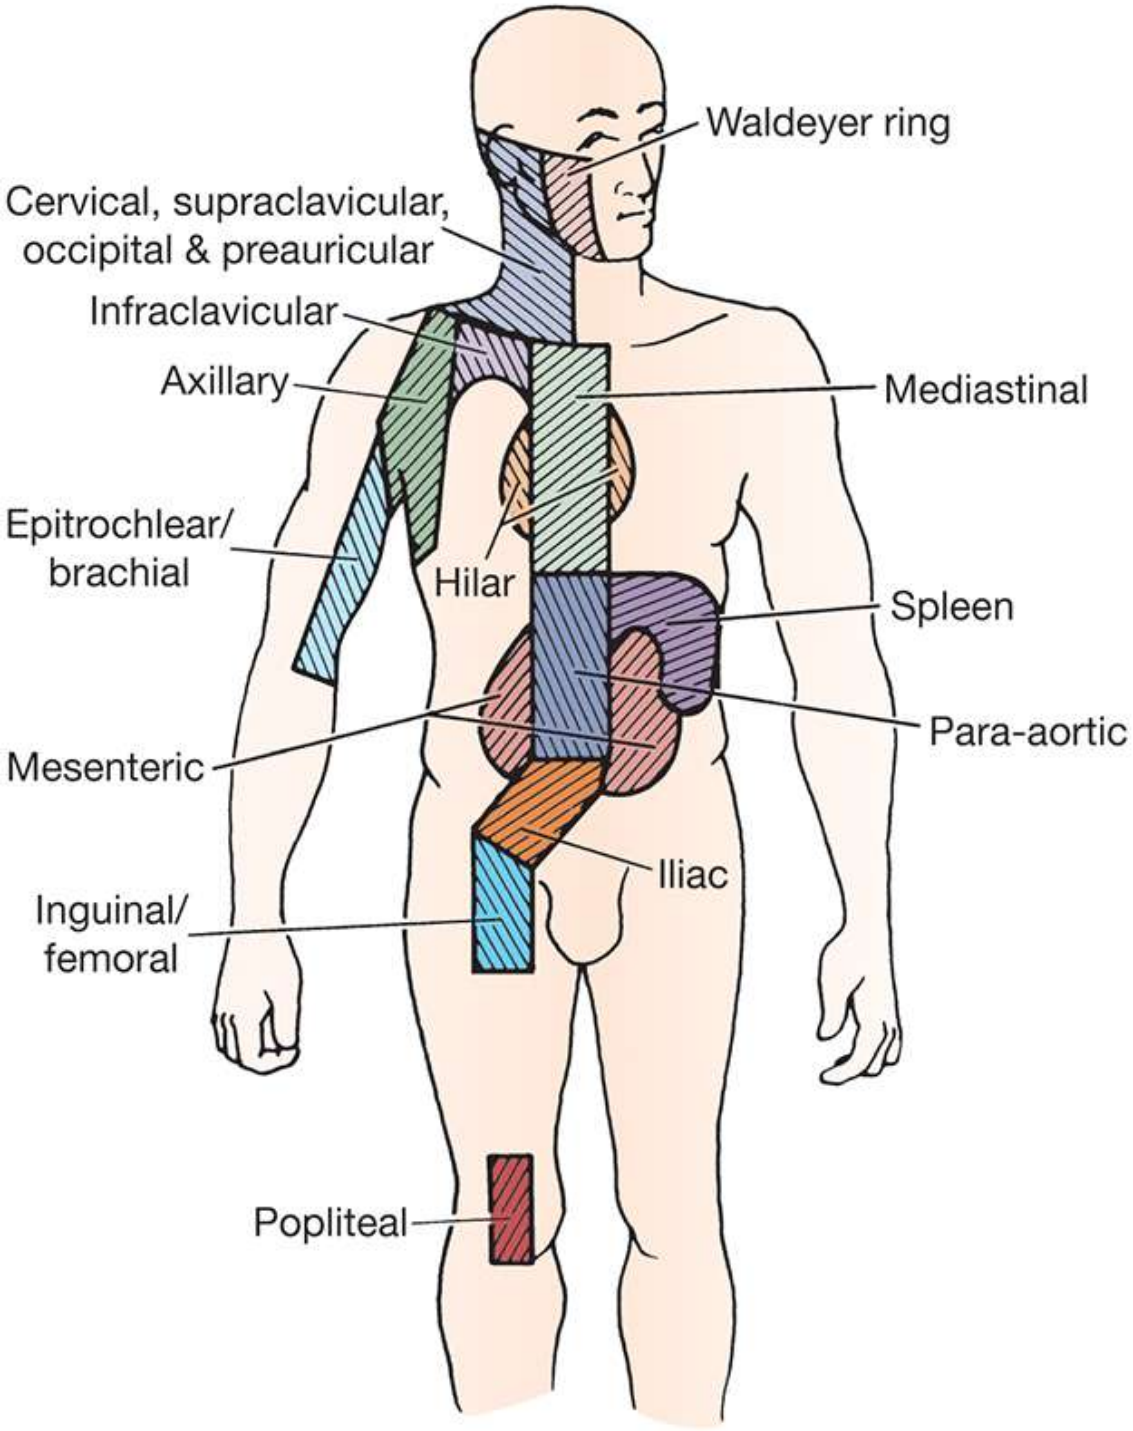

FIGURE 84.1 The lymph node regions are defined in the Ann Arbor staging system. Note that the ipsilateral supraclavicular, cervical, preauricular, and occipital nodes are defined as a single region. The mediastinum and pulmonary hila are defined as separate regions. The infraclavicular region corresponds to the subpectoral nodes. The GHSG and EORTC define the lymph node regions slightly differently. Both combine the hilar and mediastinal regions. The GHSG also combines subpectoral with cervical, whereas the EORTC combines subpectoral with axilla. EORTC, European Organisation for the Treatment of Cancer; GHSG, German Hodgkin Study Group. non-Hodgkin's lymphomas: pathology, staging, treatment. *Curr Probl Cancer*. 1987;11[6]:364-434. Copyright © 1987 Elsevier. With permission.)

Pathologic Classification

The World Health Organization (WHO) defines two major categories of HL: classic HL (cHL) and nodular lymphocyte–predominant HL (NLPHL).[27] At the same time, the WHO acknowledges that NLPHL might be more accurately termed "nodular lymphocyte–predominant B-cell lymphoma." The Clinical Advisory Committee prefers the later term, recognizing its origin as a mature B-cell neoplasm.[26]

cHL is characterized by its signature neoplastic cell, the R-S cell. Morphologically, the R-S cell is binucleate with a prominent, centrally located nucleolus in each nucleus, a well-demarcated nuclear membrane, and eosinophilic cytoplasm with a perinuclear halo. R-S cells usually account for less than 1% of the cells in a lymph node involved by HL. The components of the microenvironment include lymphoid cells, eosinophils, plasma cells, and other normal inflammatory cells.[28]

R-S cells likely originate from B-lineage cells at various stages of development, including pre–B-cell and germinal center B-cell origin. Interactions of these cells with the cells of the microenvironment are complex.[5] In most instances, the R-S cells stain positively with the lymphocyte activation marker CD30, with PAX5 (dimly), and with variable expression of the antigranulocyte monoclonal antibody CD15. CD20, a marker of mature B cells, is expressed on some tumor cells with variable intensity in as many as 40% of cases. They stain negatively with CD45, ALK, and J-chain. Nearly all R-S cells express the PD-1 ligand.[29] The expression of CD30 and PD-L1 open opportunities for targeted therapy of cHL.

cHL is divided into four histologic subtypes. *Nodular sclerosis HL* (NSHL) is the most common histologic subtype diagnosed in developed countries. Involved nodes often have a thickened capsule and are traversed by broad bands of birefringent collagen that surround nodules of cells consisting of lymphocytes, eosinophils, plasma cells, and tissue histiocytes intermixed with a variable proportion of atypical mononuclear cells, inflammatory cells, and R-S cells. The syncytial variant of NSHL refers to cases of prominent cellular aggregates of atypical cells and histiocytes. Patients with NSHL typically present in the clinic with mediastinal involvement, and one-third have B symptoms. It is more common among women, especially young ones. The natural history of NSHL is favorable.

MCHL is characterized by lymph nodes that are diffusely effaced by lymphocytes, eosinophils, plasma cells, inflammatory cells, and relatively abundant atypical mononuclear and R-S cells. Adult patients with MCHL usually present with

advanced disease and tend to be slightly older than those with NSHL. The natural history of MCHL in adult patients is less favorable than that of NSHL.

Lymphocyte-rich Hodgkin lymphoma (LRHL)[30] typically has a nodular growth pattern but may be diffuse. In the past, many cases of LRHL were confused with lymphocyte- predominant HL (LPHL); however, the staining characteristics of the malignant cells in LRHL are consistent with those of cHL. The clinical characteristics of patients affected by LRHL resemble those of NLPHL: early stage, absence of B symptoms, and excellent prognosis.

Lymphocyte-depleted Hodgkin lymphoma (LDHL) varies in its microscopic appearance but reveals a paucity of normal-appearing cells and an abundance of abnormal mononuclear cells, R-S cells, and R-S variants. Differentiating LDHL from anaplastic large cell lymphoma is sometimes challenging, especially because both are CD30 positive. It is an exceedingly uncommon subtype of HL. It tends to occur in older patients and is more likely to be associated with advanced disease and B symptoms. It has the worst prognosis of all histologic subtypes of HL.[31]

NLPHL has recently been subdivided into six immunoarchitectural patterns based on morphology and immunohistochemistry characteristics termed *typical and variant histologies*.[32,33] Unlike the other subtypes of HL, the abnormal cells ("L and H cells" or "popcorn cells"), which are few in number, are strongly reactive for CD20, CD45, CD79a, and PAX5 and negative for CD15 and CD30.[27] NLPHL is usually diagnosed in early-stage disease, often in a single peripheral nodal site. Systemic symptoms are uncommon (<10%). The natural history is the most favorable of the histologic subtypes. Some patients demonstrate a pattern of late relapse but good survival, resembling that observed in the follicular (B-cell) lymphomas. In as many as 14% of patients, NLPHL will transform into an aggressive B-cell lymphoma as part of its natural history.[25,34] Patients with a variant histology, versus those with typical NLPHL, are at greater risk for transformation[33,34] and are also more likely to present with advanced disease and experience disease relapse. A reactive process termed *progressive transformation of germinal centers* may be observed either before, with, or after the diagnosis of NLPHL.[35,36]

PROGNOSTIC FACTORS AND THERAPEUTIC IMPLICATIONS

In HL, prognostic factors are important for defining therapy and predicting outcome. Histologic subtypes now have little impact on therapy, except for the identification of NLPHL, for which different treatment algorithms apply. Although large series report a slightly worse outcome for men than women,[1] gender influences treatment selection primarily because of potential reproductive complications (see section "Sequelae of Treatment").

Ann Arbor stage is the primary determinant of therapy. Stage has a marked impact on prognosis, although current management programs blur its influence. For many patients, disease bulk influences treatment selection, especially bulky mediastinal disease. Combined modality therapy historically was the preferred option for patients with bulky disease; however, those with a complete response (CR) by interim PET may do similarly well with CT alone.[37]

An important international study evaluated a series of prognostic factors among 5,141 patients with advanced-stage HL (Table 84.4).[17] Seven factors were identified, each of which had an independent yet similar effect on prognosis. Unfavorable factors included male gender, age greater than 45 years, Ann Arbor stage IV, hemoglobin level less than 10.5 g/dL, white cell count greater than 15,000/mL, lymphocyte count less than 8% or absolute lymphocyte count less than 600, and albumin less than 4 g/dL. Note that neither bulk, ESR level, presence of B symptoms, nor histology was important factor. The International Prognostic Score (IPS) is now used to assign patients to clinical trials. Patients with three or more adverse risk factors are often considered to be in an unfavorable prognostic group for stages III to IV HL. Recently, the HOLISTIC group developed the Advanced-stage classic Hodgkin Lymphoma International Prognostication Index calculator based on greater than 5,000 diagnosed with advanced-stage HL between 1996 and 2014, which includes age, sex, stage, bulky absolute lymphocyte count, hemoglobin, and albumin with Kaplan-Meier estimators of 0.77 for 5-year progression-free survival (PFS) and 0.92 for 5-year overall survival (OS).[38]

TABLE 84.4 INTERNATIONAL PROGNOSTIC SCORE FOR ADVANCED HL[17]

Factor	Unfavorable Covariate
Serum albumin	<4 g/dL
Hemoglobin	<10.5 g/dL
Sex	Male
Age	≥45 y
Stage	IV (Ann Arbor)
Leukocyte count	≥15,000/mm^3
Lymphocyte count	<600/mm^3 or <8% of white count

HL, Hodgkin lymphoma.

Patients with stage I or II diseases often have only one or two adverse factors based on the IPS. Other factors, such as the number of sites of disease, age, ESR, bulky disease, and the presence of B symptoms, can help stratify these patients with

early-stage disease by prognosis and are often used for assignment to clinical trials. Unfortunately, the criteria for defining "unfavorable" presentations of stage I to II diseases vary among clinical trial groups. The German Hodgkin Study Group (GHSG) includes any of the following: ESR 30 mm or higher with any B symptoms or 50 or higher without B symptoms, bulky disease based on mediastinal mass ratio (MMR) greater than 0.33, more than two nodal regions (defined by GHSG), or any E lesion. The EORTC criteria include age 50 or above, ESR 30 mm or higher with any B symptoms or 50 or higher without B symptoms, bulky disease defined by mediastinal thoracic ratio (MTR) 0.35 or greater, or more than three nodal regions (defined by EORTC).

The reliable FDG-avidity of HL has enabled the study of PET metrics as correlates of prognosis. One of these is the baseline metabolic tumor volume (MTV) or total MTV (TMTV). The TMTV is calculated by summing the metabolic volumes of all involved nodal and extranodal tissues, using a maximum standardized uptake value (SUV). A high MTV was shown to be an important prognostic factor in the EORTC H10 trial.[39] Total lesion glycolysis measured by the total body MTV multiplied by the SUV_{mean} of that MTV has been shown to be prognostic in pediatric HL.[40] Another PET metric is the D_{max}, a measure of the distance between the lesions that are the greatest distance apart. The D_{max} has been shown to have prognostic significance in diffuse large B-cell lymphoma but has not yet been tested in HL.[41]

In NLPHL, yet another IPS, the lymphocyte-predominant IPS has been proposed for all stages.[42] This includes the following adverse risk factors: age greater than 45 years, stage III to IV, hemoglobin less than 10.5, and splenic involvement.

GENERAL MANAGEMENT

Radiation Therapy

RT is the most effective therapeutic agent for treating HL and has been used in its management for over a century.[43] The optimal RT technique includes meticulous pretreatment evaluation of disease sites, precise simulation and immobilization, individually contoured treatment volumes according to the location of a patient's tumor configuration, radiation exposure to all adjacent organs at risk (OARs) that is as low as reasonably achievable (ALARA), an adequate target dose, a multifield fractionated regimen, and image guidance during therapy. Outcomes are best maximized and risks minimized through scrupulous attention to every detail of therapy.[44]

Chemotherapy

The standard drug combinations in use worldwide for the primary treatment of HL are ABVD[45,46] and bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP).[47]

Targeted Therapy

New systemic agents have been approved by the Food and Drug Administration for the treatment of HL. These include BV and the checkpoint inhibitors (CPIs) nivolumab[48] and pembrolizumab.[49] BV is an anti-CD30 monoclonal antibody linked to an antitubulin agent. BV has demonstrated efficacy in $CD30^+$ lymphomas, including HL and anaplastic large cell lymphoma. It is approved for pediatric and adult patients with advanced-stage disease and in those in the relapse or refractory settings.[50,51] Because of overlapping pulmonary toxicity, however, bleomycin is removed from any drug combination that includes BV, so trials of primary therapy with an ABVD backbone typically incorporate BV-doxorubicin, vinblastine, and dacarbazine (BV-AVD). Owing to the ETHERA trial, BV has been approved as a maintenance therapy following autologous hematopoietic cell transplant.[52] Pembrolizumab and nivolumab are both approved for patients with disease that is chemoresistant or has relapsed. Based on encouraging results from the S1826 study in pediatric and adult patients with advanced-stage disease, we may see nivolumab in conjunction with AVD (N-AVD) approved in the up-front setting for these high-risk patients.

Combined Modality Therapy

Combined modality therapy has become the most common form of general management for patients with HL. Modern treatment protocols can include RT of all initially involved sites, bulky sites only, slowly responding sites, or sites of incomplete response to CT. In general, RT of all initially involved sites is indicated when combined with abbreviated CT in early-stage HL. Treatment of just high-risk areas, such as bulky disease, slowly responding disease, or incompletely responding disease, is reserved for more advanced-stage disease treated with definitive CT (ie, six cycles of ABVD, BV-AVD, or escalated BEACOPP [eBEACOPP]).

RADIATION THERAPY TECHNIQUES

The principal objective of RT in HL is to treat regions at high risk for containing disease to a dose associated with a high likelihood of tumor eradication, meanwhile keeping the dose to adjacent tissues and organs ALARA. Thoughtful evaluation of all imaging studies, especially diagnostic CT and integrated PET scans; precise simulation with appropriate immobilization and consideration of organ motion;

detailed treatment planning; and effective and conformal treatment delivery, including image guidance, treatment verification, and appropriate quality assurance measures are requisite to achieving the best outcomes.[44]

Simulation

Patient positioning for simulation must allow for patient comfort, daily reproducibility, displacement of OARs (such as breasts) beyond the treatment field, impact of positioning on target delineation, and feasibility of treatment delivery. For patients with low neck and mediastinal involvement, a headrest with a face mask that extends the head can help pull the chin superiorly and beyond the radiation field. However, a headrest and face mask can also introduce uncertainties when fusing with the baseline staging PET scan, which is often done with the head flexed on a pillow for comfort. Arm position, in general, is more comfortable at the patient's side or slightly akimbo and affects whether breast tissue falls inferior/laterally or beyond the field, especially when combined with an inclined board and immobilization bag. Conversely, patients with axillary, infraclavicular, or subpectoral involvement may have smaller target volumes with less uncertainty when their arm position resembles that in the baseline PET scan because defining the target is challenging after systemic therapy. In these circumstances, the best position in which to treat the patient may be with arms above the head in an immobilization bag, which helps with reproducibility and with reducing the dose to the lungs. Occasionally, the prechemotherapy CT imaging is performed with arms up, whereas the PET scan is performed with arms down, providing both options to optimize treatment.

With proton therapy, some immobilization devices can hinder the path of the particle beam and compromise beam selection, a concern that should be evaluated with physics and dosimetry before simulation.

Simulation should be done with intravenous contrast to help define the interface between normal soft tissues and residual disease. Furthermore, it can be helpful in identifying the cardiac substructures.

Motion Management

Patients with mediastinal involvement and certain abdominal locations (eg, spleen) must undergo motion management strategies with the use of a four-dimensional (4D) CT scan or deep inspiration breath-hold (DIBH) technique.

4D CT scans acquire imaging throughout the full 10 phases of the respiratory cycle, allowing us to assess the margin to add to the clinical target volume (CTV) that will account for normal respiratory motion. This internal treatment volume

(ITV) margin can be an expansion of the CTV on the average scan of the 4D CT scan or independently drawn as the ITV, ensuring coverage of all 10 phases of the scan. In some cases, respiratory gating can be used to minimize the ITV margin.

Alternatively, DIBH is a technique that results in reduced doses to the lungs and may also reduce dose to the heart for patients with mediastinal involvement.[53] DIBH can spare additional volume of the lungs when treating superior mediastinal disease. In addition, DIBH pulls the heart medially and down, away from mediastinal disease located above the heart. In most cases, DIBH is likely to reduce the lung and heart doses, but in cases with extensive lower mediastinal involvement including cardiophrenic nodes, the relative benefit of DIBH for sparing the heart may diminish.[54]

Various techniques of DIBH have been described.[55-57] Important concepts to consider with DIBH include breath-hold reproducibility, the patient's ability to maintain the breath-hold or multiple breath-holds during treatment, and the breath-hold's impact on contouring. Our practice is to perform three DIBH scans at the time of simulation to assess reproducibility of the target across the three different breath-holds.

Involved-Node and Involved-Site Radiotherapy

The classic field configurations for HL treatment with RT alone have included the mantle and inverted Y. However, clinical trials have shown the equivalence of "involved-field radiotherapy" (IFRT) treatment with "extended-field" or "subtotal lymphoid" RT as part of combined modality therapy programs; thus, IFRT was adopted as the standard for combined modality therapy in clinical trials.[58-60] Field reductions and 3D target volume definitions comprise the loosely described techniques for "intelligent-field RT" and "modified IFRT." The more clearly defined "involved-node radiotherapy" (INRT)[61] and "involved-site radiotherapy" (ISRT)[44] have become the standard of care (SOC) in clinical practice and more recent clinical trials. INRT, as defined by Girinsky et al for the EORTC-GELA Lymphoma Group, requires baseline diagnostic CT and PET imaging with the patient in the treatment position, postchemotherapy contrast-enhanced CT simulation, and fusion of the baseline and postchemotherapy images.[61-63] The fields are designed to treat only the initially involved nodes with some modifications to avoid OARs. This gross tumor volume (GTV) then becomes the CTV, and a 1-cm expansion of the CTV defines the planning target volume (PTV).

When components of this planning process are missing—perhaps the pretreatment PET scan was not done in the treatment position, there is poor registration between scans, or the CT simulation scan was done without intravenous

contrast—it may be impossible to treat such strictly defined INRT fields. However, field reduction is still possible to what has been termed *involved-site radiotherapy*.[44]

ISRT volumes will vary depending on the clinical situation and treatment protocol. In general, because of the use of abbreviated chemotherapy (ie, 2-4 cycles of ABVD), patients with favorable early-stage HL receive ISRT to all initial sites of disease after completing chemotherapy.

For patients treated with RT alone (ie, NLPHL), the ISRT CTV should be increased to include sites of potential subclinical disease. In practice, this would mean an additional 2- to 5-cm margin within the lymphatic stations superior and inferior to the initially involved disease on PET imaging, taking into account the OARs.[64]

Among patients with unfavorable early-stage HL, ISRT to all sites of disease should be used when abbreviated chemotherapy has been delivered; however, for those who receive more intensive chemotherapy (such as six cycles of ABVD), certain complete responding areas that could result in an unacceptable dose to an OAR if included could be omitted (ie, cardiophrenic nodes or axillary lymph nodes in a young woman could be omitted if they have had a CR by CT scan). Patients with stage III/IV diseases previously received ISRT to sites of initially bulky disease, but recent data have questioned its benefit in the era of PET response assessment.[65,66] PET-directed RT (PD-RT) may still be used in patients with stage III/IV diseases to sites of slow or incomplete response to chemotherapy.

Design of Involved-Site Radiotherapy Fields

Many descriptive guidelines for ISRT and atlases exist.[67,68] The prechemotherapy GTV is based on localizing the initially positive lymph nodes (and extranodal sites) on the staging PET scan fused to the treatment planning CT. The postchemotherapy GTV is based on the anatomic residual disease observed at the time of CT simulation. When RT is the sole treatment modality, it is simple to identify the GTV, especially after PET simulation. This may be the case for treating patients with primary RT for NLPHL.[44]

For the more common situation of combined modality treatment, the CTV includes the postchemotherapy GTV and also the entire initial disease volume but is modified (reduced) to exclude uninvolved normal organs (eg, lungs, bones, muscles, great vessels) and to accommodate shrinking lymph node masses following chemotherapy, especially in the chest. The CTV can be expanded based on the quality of the initial imaging or owing to concerns of subclinical disease. For initially large mediastinal masses, the postchemotherapy treatment fields should conform to the width of only the residual disease (absent any pulmonary parenchymal extension), and the superior and inferior field margins should

encompass the initial extent of disease with the margin previously noted (Figure 84.2).[44] Adjacent organ dose constraints may also mean reducing the CTV. The PTV is an expansion of the CTV based on day-to-day setup uncertainties.

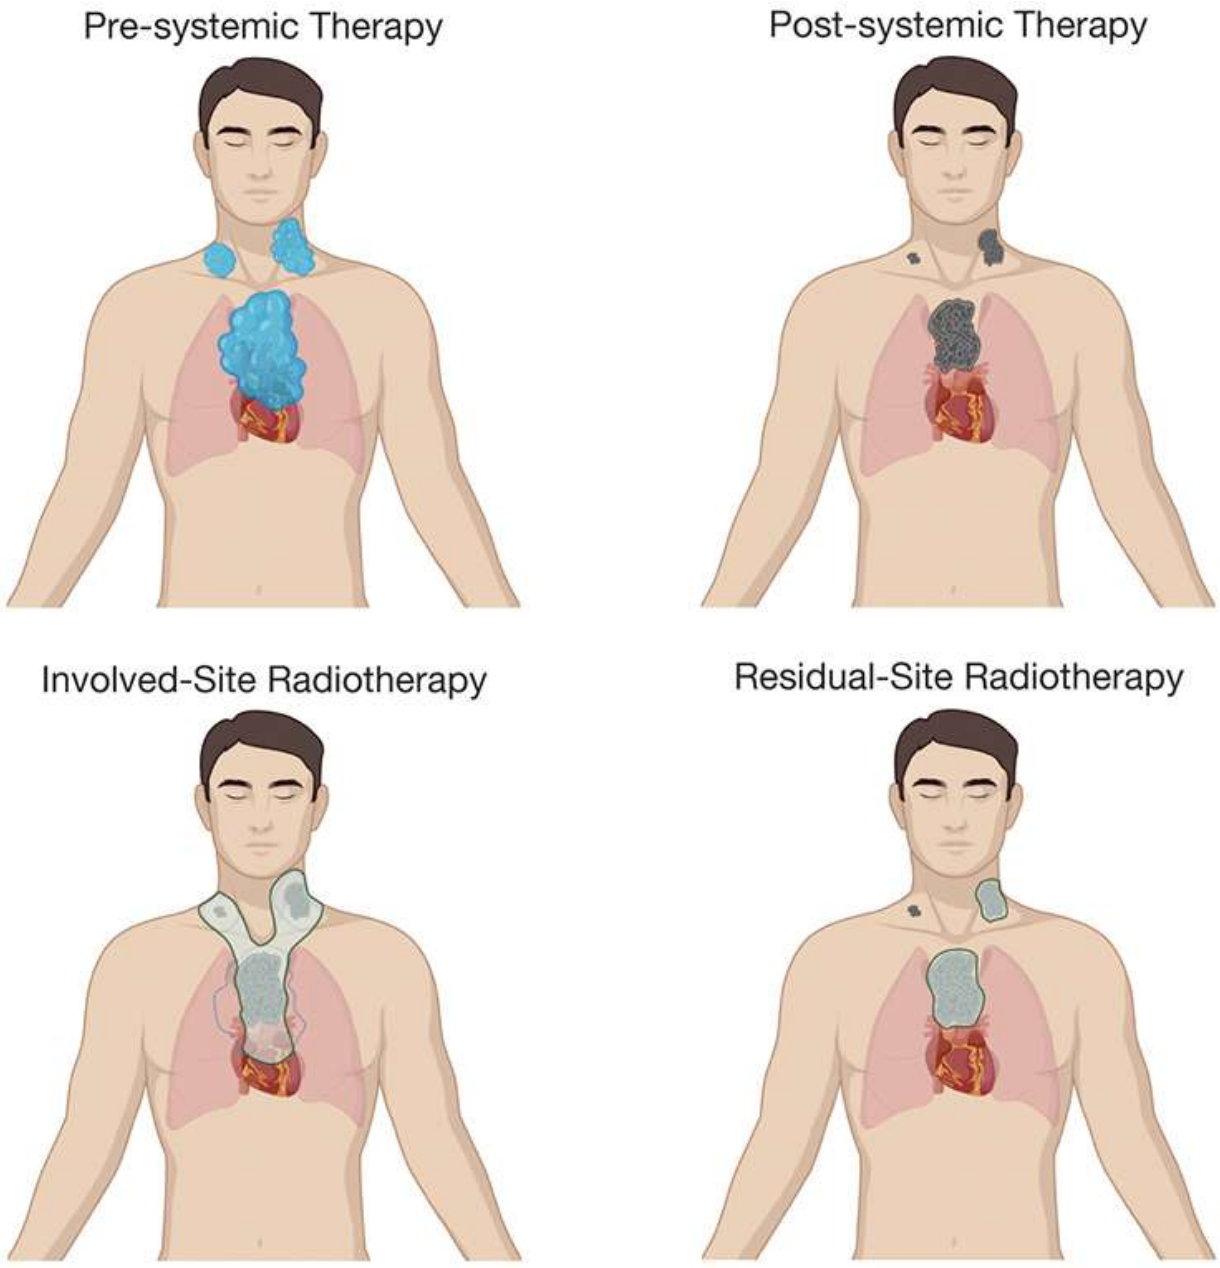

FIGURE 84.2 Involved-site and residual site radiotherapy volumes (green contours) in a patient with Hodgkin lymphoma involving the bilateral neck and mediastinum (blue masses) who achieved partial response following systemic therapy with residual computed tomography anatomic disease (black-gray masses) ≥1 cm in the left neck and mediastinum.

Contemporary Radiation Fields Beyond Involved-Site Radiotherapy

ISRT was developed to replace 2D era IFRT, while providing a more pragmatic field design compared to INRT. Yet, ISRT volumes can be interpreted and translated quite differently depending on the accuracy of pretreatment and simulation scans fusion, suspicion of subclinical disease involvement, and dose constraints of OARs. As such, several groups have begun to research smaller treatment volumes based on the postchemotherapy extent of disease, residual site radiotherapy (RSRT). While ISRT includes the prechemotherapy extent of disease in the cranial-caudal dimension, taking into account the postchemotherapy anatomic changes in the axial dimension, RSRT includes only the postchemotherapy anatomic extent of disease that is greater than a certain size cutoff (per protocol) as visualized on the contrasted CT simulation[69,70] (Figure 84.2). The RSRT volume may be much smaller than the ISRT volume and is very similar to the ISRT postchemotherapy gross tumor volume ($GTV_{postchemo}$) with a PTV margin. For patients with advanced-stage disease, the use of comprehensive RT to all sites of initial involvement is rarely employed, due to the significant amount of tissue irradiation. Instead, for advanced-stage disease, ISRT or RSRT can be restricted to areas at high risk of relapse, such as initially bulky sites, as per AHOD 1331[50] or based on interim or end of systemic therapy PET response as per S1826.

PET imaging is prognostic and can help identify disease sites at high risk of relapse, which may further direct the delivery of RT.[71] Negative interim and end of systemic therapy PET scans yield excellent outcomes regardless of receipt of RT.[65,66,72] This has restricted the use of RT on contemporary HL clinical trials to patients with positive PET/CT imaging. Thus, the NRG Hematologic Malignancies Working Group has provided consensus on the nomenclature of PD-RT that utilizes the interim and/or end of systemic therapy PET scans to better define sites at high risk of relapse, which may benefit from the addition of radiation or escalating the dose. Regardless of the initial presystemic therapy sites of disease, PD-RT would target only sites that are Deauville 4-5 on interim PET (if performed and indicated) and sites with partial or no response on end of systemic therapy PET scan. PD-RT can be used either alone or as a boost in combination with ISRT/RSRT based on patient's disease stage and treatment setting on current National Clinical Trials Network (NCTN) clinical trials (eg, AHOD 2131: NCT05675410).

PD-RT includes PET-directed involved-site radiotherapy (pISRT), PET-directed residual site radiotherapy (pRSRT), and PET-directed residual PET RT (pRPRT) (Table 84.5) (Figure 84.3). pISRT target volume includes the presystemic therapy involved lymph node site(s) that continue(s) to harbor PET-avidity on the interim and/or end of systemic therapy PET scan. pISRT may be used in noncontiguous early-stage or advanced-stage disease to identify areas at highest risk of relapse that warrant local therapy and was used in the AHOD 1331 trial.[50] pRSRT target volume

includes the postsystemic therapy CT anatomic residual mass that contains the PET-avid lesion on the interim and/or end of systemic therapy PET scan without covering/including all the initial extent of involved lymph node site(s). pRSRT can be used as a boost following ISRT as done for patients younger than 15 years on the AHOD 2131 trial, or for consolidation/salvage of residual disease in the up-front setting as per S1826 trial or relapsed/refractory setting. pRPRT target volume includes only the PET-avidity. It is very similar to pRSRT in cases where the residual CT anatomic mass is fully avid. However, it differs from pRSRT in cases where there is a large residual CT anatomic mass (pRSRT volume), with only a small focus of residual PET-avidity (pRPRT volume) as seen in patients with large bulky mediastinal mass who achieve partial response to systemic therapy. pRPRT is mostly used as a boost following ISRT, RSRT, or PD-RT as it is in S1826.

TABLE 84.5 CONTEMPORARY TUMOR VOLUMES AND TARGET DELINEATION DEFINITIONS

Gross Tumor Volumes (GTVs)	Clinical Tumor Volumes (CTVs)
$GTV_{prechemo}$ = Disease prior to any treatment based on the baseline PET/CT or PET/MRI scans	CTV_{ISRT} = lymph nodes/tissues originally involved with lymphoma (ie, $GTV_{prechemo}$) + a margin of 1.0 cm above and below $GTV_{prechemo}$
	CTV_{pISRT} = lymph nodes/tissues originally involved with lymphoma (ie, $GTV_{prechemo}$) that still contain PET-avidity on iPET and/or EST-PET ± a margin of 1.0 cm above and below $GTV_{prechemo}$
$GTV_{postchemo}$ = Residual CT anatomic mass ≥ 1 cm[a] on EST ± interim scans	$CTV_{RSRT} = GTV_{postchemo}$
GTV_{PET+} = PET-avid lesion on iPET and/or EST-PET	CTV_{pRSRT} = CT anatomic mass that contains GTV_{PET+}
	$CTV_{pRPRT} = GTV_{PET+}$

CT, computed tomography; EST-PET, end of systemic therapy positron emission tomography; iPET, interim positron emission tomography; ISRT, involved-site radiotherapy; MRI, magnetic resonance imaging; PET, positron emission tomography; pISRT, PET-directed involved-site radiotherapy; pRPRT, PET-directed residual PET radiotherapy; pRSRT, PET-directed residual site radiotherapy; RSRT, residual site radiotherapy.

[a]$GTV_{postchemo}$ size cutoff might be different based on protocol.

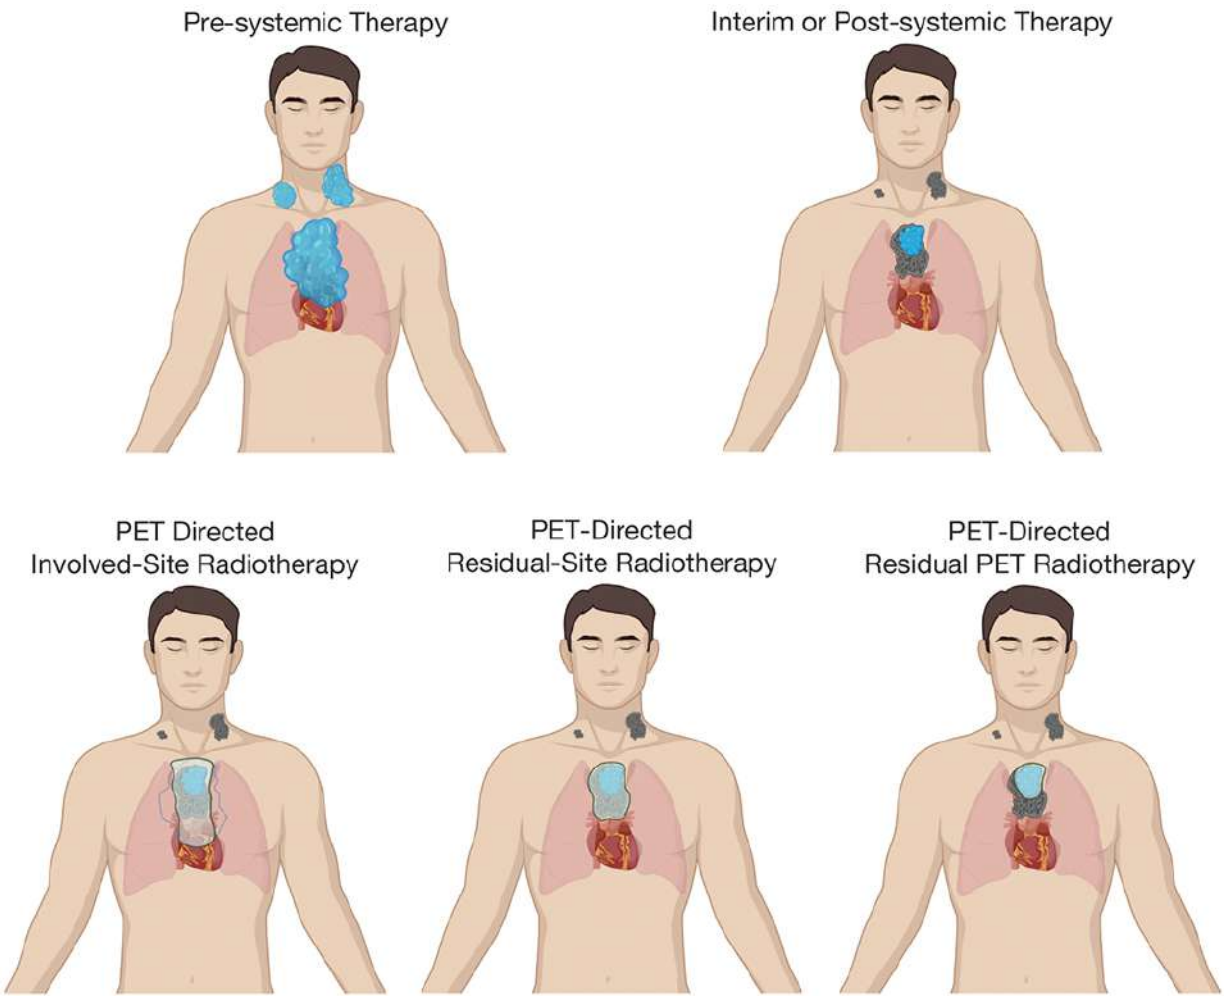

FIGURE 84.3 Positron emission tomography (PET)–directed radiotherapy volumes (green contours) in a patient with Hodgkin lymphoma involving the bilateral neck and mediastinum (blue masses) who achieved partial response following systemic therapy with residual PET-avidity (blue mass) in the mediastinum only, and non–PET-avid lesions (black-gray masses) in the bilateral neck.

Radiation Dose

In the uncommon scenario that RT alone is used for the treatment of HL (most commonly for NLPHL), national consensus guidelines recommend a dose of 30 to 36 Gy to involved sites and 25 to 30 Gy to sites of potential subclinical involvement, delivered in 1.5- to 2-Gy fractions. More commonly, however, RT is as a component of a combined modality approach, with chemotherapy expected to eradicate subclinical disease, and radiation playing a role in eradicating disease in involved sites. Doses vary considerably among trials, depending on the prognostic category of patients, disease bulk, and chemotherapy regimen. The dose ranges considered acceptable per national consensus guidelines are 20 to 30 Gy for nonbulky and 30 to 36 Gy for bulky sites, delivered 1.5 to 2 Gy per fraction.

Patients with incomplete metabolic response (Deauville 4, 5) following chemotherapy can receive higher doses (36-45 Gy).

Radiation Delivery

Historically, RT was delivered after 2D or 3D treatment planning, typically with opposed anterior-posterior (AP)/PA treatment fields. Over the past 20 years, however, with more refined radiation fields and 3D target delineation, modern radiation delivery systems have helped to reduce the radiation dose to the OARs. Such techniques require photon-based systems (intensity-modulated RT [IMRT], volumetric modulated arc therapy [VMAT], tomotherapy) and proton-based systems (3D and intensity-modulated proton therapy [IMPT]) with passive scatter, uniform scanning, and pencil beam scanning. The benefit of each treatment type depends on various factors, including disease distribution relative to the OARs, patient age and comorbidities, and type of prior chemotherapy. An example of the dose distributions achieved with 3D conformal radiotherapy (CRT), IMRT, and proton therapy for a patient is shown in Figure 84.4.[73]

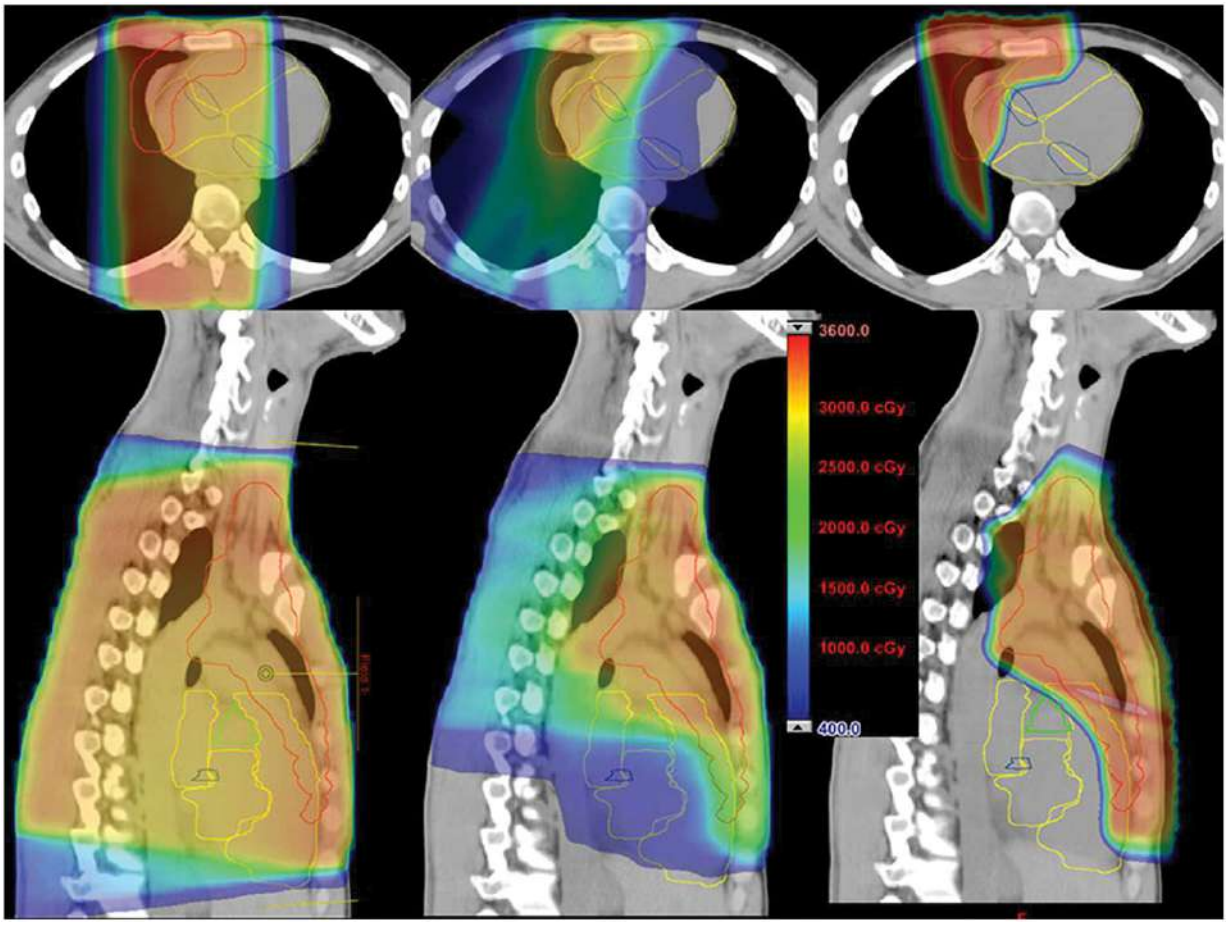

FIGURE 84.4 Involved-site radiotherapy axial and sagittal color wash isodose plans for a Hodgkin lymphoma patient with three-dimensional conformal radiation therapy (left), intensity-modulated radiation therapy (middle), and proton therapy (right). Cardiac chambers are outlined in yellow, cardiac valves are outlined in blue, and the planned target volume is outlined in red. (Reprinted from Hoppe BS, Flampouri S, Su Z, et al. Effective dose reduction to cardiac structures using protons compared with 3DCRT and IMRT in mediastinal Hodgkin lymphoma. *Int J Radiat Oncol Biol Phys*. 2012;84[2]:449-455. Copyright © 2012 Elsevier. With permission.)

In general, when comparing IMRT with 3D CRT plans, IMRT delivers a more conformal dose distribution in the high-dose region, but less conformality in the low-dose region and the creation of a "low-dose bath." Conversely, when comparing proton therapy techniques with 3D CRT, protons deliver a more conformal dose distribution in both the high- and low-dose ranges.

Among patients with high cervical disease, IMRT or protons can be useful in reducing the radiation dose to the parotid glands and oral cavity. But the radiation dose to the thyroid warrants consideration because the low-dose bath of IMRT can increase its exposure to radiation compared with conventional 3D CRT.

For most patients with involvement of the mediastinum and/or axilla, IMRT can improve dose-volume histogram (DVH) criteria for the heart, coronary arteries,

esophagus, and lungs, compared with 3D CRT. Yet, the low-dose bath from IMRT puts larger volumes of normal tissue at risk for the development of secondary cancer,[74,75] such as the breasts or pneumonitis,[76] although this may be overshadowed by the significant sparing of the heart and coronary arteries with the IMRT plan. Proton therapy allows for a reduced dose to the heart, lungs, breast, and body compared with either IMRT or 3D CRT techniques[75,77,78] without generating a low-dose bath.

Infradiaphragmatic radiation may also benefit from the use of IMRT or proton therapy, especially when the spleen is irradiated, to help minimize the radiation dose to the heart, stomach, pancreas, and left kidney.[79,80]

IMRT and proton therapy are also useful in patients reirradiated for relapsed disease close to or within a previously treated area.[81]

Clinical results using these modern radiation technologies are beginning to emerge, but, thus far, they only demonstrate clinical effectiveness in regard to disease control and acceptable rates of acute toxicities. Investigators at three centers have reported their experiences using IMRT for HL (N = 40-60 patients), observing excellent relapse-free survival (~95%).[63,82,83] Similar results have been found by investigators at proton therapy centers, some of whom conducted a small prospective clinical trial. In a combined analysis of academic and community proton centers where patients received consolidative proton therapy, the 3-year event-free survival rate was approximately 95% for patients with a CR before radiation.[84,85] The true benefit of these technologies will not be realized for at least two decades, when late toxicities become apparent. Some data are already emerging from large cancer registries. Xiang et al compared second cancer development among patients within the National Cancer Database receiving 3DCRT, IMRT, and proton therapy and found significantly fewer second cancers among patients receiving proton therapy compared with IMRT.[86] Consequently, radiation oncologists should utilize all tools available to them to minimize the dose to the OARs and, therefore, minimize acute and late toxicities.

Intensity-Modulated Radiation Therapy, Volumetric Modulated Arc Therapy, and Tomotherapy for Mediastinal Disease

Various techniques exist for delivering IMRT, VMAT, and tomotherapy.[82] Cella et al reported comparison planning using forward-planned IMRT wherein the treatment fields were chosen to mimic an AP/PA field arrangement and then compared with a seven-field IMRT plan or tomotherapy. The forward-planned IMRT was better at reducing the radiation dose to the lungs and breast, but the seven-field IMRT plan and the tomotherapy plan were better at sparing the heart. Accordingly, the optimal treatment approach should be individually tailored to address potential toxicities.

Proton Therapy

Several techniques exist for delivering proton therapy, including passive scatter, uniform scanning, and pencil beam scanning with single-field optimization or multifield optimization. Several important factors should be considered when proton therapy is employed.[75] DIBH may be combined with proton therapy to further improve doses to the heart and lung. In addition, DIBH in combination with IMPT can provide meaningful dose reduction to the cardiac substructures, more than what can be achieved with IMRT.[87,88] In general, multiple fields are encouraged to spread out the relative biologic effectiveness uncertainties within the distal edge (2-3 mm) of the spread-out Bragg peak.

Organs at Risk

The dose range used for HL (20-36 Gy) is below the threshold tolerance for most organs; however, intrathoracic structures can be affected by these doses, and careful review of DVHs is warranted to minimize both acute and late effects. ILROG and other consensus guidelines have provided guidance on dose constraints to the OARs.[89]

With respect to carcinogenesis, because data indicate that lung cancer risk increases after doses as low as 5 Gy, it is reasonable to define and minimize the lung V_5 if multiple plans are reviewed, taking into account potential toxicity to other organs.[90] The lung cancer risk is also increased by the use of alkylating agent chemotherapy or procarbazine.[91,92]

In women, given the excess risk of secondary breast cancer for doses as low as 4 Gy, it is reasonable to track the breast V_4 and keep the volume as small as possible, especially for women younger than 30 years.[93] A less rigorous constraint is to keep the mean breast dose less than 4 Gy. When calculating the V_4 and mean breast dose, only the glandular tissue of the breasts should be contoured, not the anatomic structures.

The criteria for cardiac dose tolerance are less well defined. Tolerances are influenced by lifestyle; comorbidities such as diabetes mellitus, hyperlipidemia, and hypertension; family history; and prior treatment with cardiotoxic drugs like doxorubicin. In a large analysis of Dutch patients treated before 1996 (with lymphoma radiation fields and doses that are no longer employed), patients who received mediastinal RT had a 4- to 6-fold increased standardized incidence ratio of cardiovascular disease.[94] In a more detailed comparison of coronary heart disease and mean heart dose (MHD), the excess relative risk (ERR) was 7.4% per Gy of MHD.[95] The ERR was negligible with an MHD less than 5 Gy and was approximately 2 for an MHD of 12 Gy, a dose that should be achievable in most

patients with contemporary treatment techniques. Although the MHD has been used as a surrogate for the likelihood of developing secondary cardiac effects, the dose to individual subunits of the heart is more likely to define the true cardiac risks. Therefore, effort should be made to contour all of the cardiac subunits using one of the standard cardiac atlases as a guide.[96] It is likely the dose to the left anterior descending coronary artery and left ventricle is the most important; however, it is only recently that the dose to these structures has been contoured and measured, so limited retrospective data are available regarding acceptable threshold doses. The best approach is to keep the dose ALARA. With respect to valvular disease, the ERR is increased only minimally for valve doses up to approximately 20 Gy, but with a steep increase in risk thereafter.[97] Congestive heart failure risk is demonstrable when the left ventricular mean dose exceeds 15 Gy, or V_{30} is 50% or greater, but the greatest increase in risk for congestive heart failure is associated with the use of anthracycline-based chemotherapy.[98] Acute pericarditis, an occasional risk following treatment with classic mantle field RT that includes large parts of the pericardium treated to doses greater than 30 Gy, has essentially disappeared with current standard radiation treatment techniques.

Treatment techniques such as IMRT may help reduce the cardiac dose but increase the V_5 to the lungs or V_4 to the breasts, potentially resulting in a higher risk for secondary cancer in those organs. This is not a problem when using proton therapy.[75]

In treating retroperitoneal nodes or the spleen, the organ at greatest risk is the left kidney. QUANTEC data recommend that the mean kidney dose (bilateral) should be less than 18 Gy, which should always be achievable in the context of treating HL.[99] In women who require pelvic nodal RT, the dose to the ovaries must be considered, as they are near the iliac nodes. Occasionally, an oophoropexy is necessary to provide sufficient ovarian protection. If an oophoropexy is performed, the surgeon should clip the superior and inferior poles of the ovary for precise localization on simulation scans. The menopausal effect of RT on the ovaries is dependent upon a woman's age. At age 20, the mean sterilizing dose is 15 Gy, but it drops to 12 Gy at age 30 and 8 Gy at age 40.[100] Alkylator agent chemotherapy, such as is in BEACOPP, will induce menopause in more than 50% of women, also correlating with age.[101] Among men, the possibility of inadvertent testicular RT is most likely to occur when the inguinal-femoral nodes are treated.[102] This dose can be readily reduced 3- to 10-fold by use of a "clamshell" testicular shield.

Hypothyroidism is a common complication following cervical/ supraclavicular node RT, as the thyroid cannot be spared completely because of the involvement of those nodes. Data regarding dose-volume risks are limited. One analysis showed

that the risk of developing hypothyroidism is only 11.5% if the V_{30} is 62.5 or less and 70.8% if the V_{30} is greater than 62.5.[103]

RESULTS OF THERAPY

HL is responsive to both RT and chemotherapy, and a variety of regimens can achieve similar survival rates. However, significant differences in freedom from relapse rates and potential complications of therapy can occur. The results described in the following sections emphasize treatment programs that adhere to national consensus guidelines. Clinical trial results that have helped define the current standards are shown in Tables 84.6 and 84.7.

TABLE 84.6 SELECTED CLINICAL TRIALS IN STAGE I TO II FAVORABLE AND UNFAVORABLE HL

Interim Positron Emission Tomography

The utility of PET imaging as a prognostic indicator after two cycles of chemotherapy was first demonstrated in patients with stages III to IV HL.[104] Patients with a positive interim PET study had a significantly higher risk for relapse than patients with a negative study, regardless of their initial IPS.[105] An interim PET has become standard for all stages of disease in most recent clinical trials, as well as in clinical practice, allowing for potential de-escalation of treatment if the interim PET is negative or escalation of treatment if it is positive. Yet, the value of an interim PET scan among patients receiving CPIs, such as nivolumab or pembrolizumab, is still unclear, due to the phenomena of pseudo-progression with CPIs.

Favorable Prognosis Stage I to IIA Classic Hodgkin Lymphoma

In favorable prognostic groups, patients are treated with either chemotherapy alone or combined modality therapy (Table 84.6). Prospective randomized clinical trials often show a significant advantage for combined modality therapy (2-3 cycles of ABVD followed by 20-30 Gy IFRT/ISRT/INRT) with respect to PFS (absolute differences of 6.3%-11.9% at 3-5 years) but no differences in OS compared to two to four cycles of ABVD alone.[106-108] As a result, treatment selection is often based upon factors including patient age, gender, and sites of disease that would influence the risk for both early and late complications of therapy. This is important, as none of the prospective trials in the modern era have a duration of follow-up that allows for true comparison of late effects. Late effects may be reflective of initial radiation treatment or salvage therapy required for relapse. Nevertheless, the smaller radiation fields and lower doses now used compared to historical experience should result in a lower risk of radiation-related late effects.[109-111] Selecting the right treatment for these patients depends on many variables, and patient education and engagement are encouraged. For example, a young woman with mediastinal and axillary node involvement might choose the greater risk of relapse with ABVD alone over the risk of breast cancer from combined modality therapy. The opposite may be true for a patient with neck and superior mediastinal involvement, for which the heart and breasts would receive little radiation exposure.

According to the GHSG HD10 and HD16 trials, patients with favorable disease (per GHSG criteria) can be treated effectively with just two cycles of ABVD followed by 20-Gy ISRT.[108,112] For patients who do not fit all of these criteria, standard combined modality therapy programs can include four cycles of ABVD followed by 30-Gy ISRT, per the GHSG HD14 trial[113] or, if the interim PET is negative (Deauville 1 or 2), three cycles of ABVD followed by 30-Gy ISRT, per the UK RAPID trial or the EORTC H10F trial.[106,107]

If the interim PET is positive following two cycles of ABVD, and absent progressive disease, additional treatment can include two to four additional cycles of ABVD (total 4-6) plus 30-Gy ISRT or INRT, per the UK RAPID or EORTC H10 trials,[106,107] or treatment escalation to two cycles of eBEACOPP followed by 30-Gy ISRT.[107] Outcomes for any of these approaches are excellent (Table 84.6).

Unfavorable Prognosis Stage I to II Classic Hodgkin Lymphoma

This category includes a diverse patient group (Table 84.6). A commonly used treatment for stage I or II HL with large mediastinal adenopathy is combined modality therapy with four cycles of ABVD plus 30-Gy ISRT. The reported 5-year PFS was 89.1% and 10-year PFS 83.9%.[113,114] Four cycles of ABVD is sufficient in the combined modality setting, as the EORTC H9U study showed no significant benefit to six cycles compared with four cycles of ABVD[115] when given with RT. An

essential concern with this treatment program is the potential for overlapping toxicities of radiation with doxorubicin, bleomycin, and RT (ie, cardiac and pulmonary effects).

The EORTC H10U trial evaluated the use of interim PET to define a group of patients who might be treated effectively with ABVD alone.[107] In this trial, 40% of patients had bulky mediastinal disease (mediastinal-thoracic ratio ≥0.35 at the T5-T6 interspace) and 39% had B symptoms. Patients with a negative interim PET were randomized to four additional cycles of ABVD or two cycles of ABVD plus INRT. Among the patients randomized to treatment with six cycles of ABVD alone, the 10-year PFS rate was 86.5% versus 91.4% with combined modality therapy. No subset analysis was performed to analyze the impact of specific unfavorable characteristics. Although noninferiority of the six cycles of ABVD versus standard combined modality therapy could not be demonstrated, the rather similar 5-year PFS rates (P = .7) justify a consideration of six cycles of chemotherapy alone for these patients.

In the H10 trial, if the interim PET was positive (Deauville 3-5), long-term data demonstrated no benefit to escalating treatment to eBEACOPP followed by INRT.[107] Patients whose treatment was escalated had a similar 10-year PFS compared to those who continued ABVD plus INRT (85.1% vs 79.2%, P = .18). The OS difference (92% vs 90.4%) was also not statistically significant (P = .18).

The RATHL UK trial for advanced disease included 41.6% of patients with stage II disease and unfavorable characteristics, often large mediastinal adenopathy.[116] Following two cycles of ABVD and a negative interim PET (Deauville 1-3), patients were randomized to an additional four cycles of ABVD or four cycles of AVD. The AVD option was noninferior to ABVD, and the deletion of bleomycin led to a lower risk for adverse respiratory events. The 3-year PFS for patients with stage II disease and bulk was 91.5% on this study.

In summary, patients with unfavorable early-stage HL can be successfully treated with ABVD × 4 cycles with 30 Gy of ISRT if they have a negative interim PET (Deauville 1-3). Alternatively, if significant amounts of the heart or breasts (females) are within the RT field, a chemotherapy alone approach with two cycles of ABVD followed by four cycles of AVD could be considered. For patients with a positive interim PET (Deauville 4-5), patients should be treated with another four cycles of ABVD or eBEACOPP followed by ISRT.

Infradiaphragmatic Stage I to II Classic Hodgkin Lymphoma

Infradiaphragmatic involvement is seen in fewer than 10% of patients with stage I or II HL. These patients may have more adverse risk factors such as older age, a greater number of disease sites, male predominance, or worse performance status

and may require more intensive initial therapy.[117-119] Patients with bulky abdominal presentations or those with involvement of the spleen are typically treated according to guidelines for "unfavorable" stage I or II disease or for stage III to IV diseases.

For more favorable patients with infradiaphragmatic disease in whom disease is nonbulky and limited to pelvic lymph nodes with or without extension into the lower para-aortic nodes, the same general treatment principles apply as for supradiaphragmatic disease. In general, the outcome of treatment for these more favorable patients resembles that of patients with supradiaphragmatic disease.

Use of Novel Agents in Stage I to II Classic Hodgkin Lymphoma

Although novel agents such as BV and the CPIs have been incorporated into standard management programs in the primary treatment of advanced disease (vide infra), these agents have been utilized only in phase 2 clinical trials for stage I to II diseases.

Abramson et al have reported two trials utilizing BV in conjunction with other drugs for limited-stage nonbulky HL. One included BV-AVD[120] and the other included just doxorubicin and dacarbazine (BV-AD).[121] In the first study, 34 patients received four to six cycles of BV-AVD, depending upon the results of an interim PET following two cycles of BV-AVD. The 3-year PFS was 94%; however, the toxicity was significant. There was 79% peripheral neuropathy (24% grade 3-4), neutropenia 76% (62% grade 3-4), and 35% febrile neutropenia. In the second study, 34 patients were treated with BV-AD for four to six cycles, depending on the results of the interim PET. The 5-year PFS was 91%. With the deletion of vinblastine, the rate of peripheral neuropathy was reduced to 59%, all grade 1 to 2. There was no grade 4 neutropenia or neutropenic fever.

Kumar et al, treated 117 patients in four cohorts using four cycles of BV-AVD followed by RT.[70] In cohort 1, RT was 30-Gy ISRT, in cohort 2 20-Gy ISRT, in cohort 3 30-Gy RSRT, and in cohort 4 no RT. This series included 86% of patients with bulk and 39% of patients with B symptoms. The combined 2-year PFS was 94%, ranging from 90% to 97%. Adverse events included 54% peripheral neuropathy (3% grade 3-4), 44% neutropenia (39% grade 3-4), and 8% febrile neutropenia.

The LYSA-FIL-EORTC BREACH trial randomized patients to four cycles of BV-ABVD plus 30-Gy INRT versus four cycles of ABVD plus 30-Gy INRT.[122] In all, 55% of patients had bulky mediastinal disease and 39% had B symptoms. The complete metabolic response by interim PET after two cycles of chemotherapy was 82.3% versus 75.4%. The 2-year PFS was 97.3% and 92.6%. Patients with a high TMTV at the outset (30% of the patients) seemed to benefit the most, with 2-year

PFS of 90.9% and 70.7%. This study suggests that just a limited subset of patients with stage I to II diseases may benefit from the inclusion of BV in primary therapy.

The main clinical trial that has incorporated a CPI in the treatment of stage I to II diseases is the GHSG phase 2 NIVAHL trial.[123] This trial for patients with unfavorable disease characteristics compared sequential versus concomitant nivolumab (nivo) combined with AVD. All patients were then treated with 30-Gy ISRT. In all, 21% of patients had B symptoms and 20% of patients had a large mediastinal mass. With a median follow-up of 41 months, the 3-year PFS was 98% and 100% in the two arms of the study.

A multicenter, phase 2 study of sequential pembrolizumab and AVD (4-6 cycles) was studied among 30 patients with unfavorable early-stage or advanced-stage disease without any RT. The 3-year PFS and OS were 100%.[124]

An international study was conducted in patients with early-stage nonbulky disease incorporating both nivo and BV in addition to doxorubicin and dacarbazine.[125] A total of 154 patients were treated with four cycles of systemic therapy. With a median follow-up of 15.2 months, three patients had progressive disease, but there were no deaths.

Stage I to IIA Nodular Lymphocyte–Predominant Hodgkin Lymphoma

In contrast to the standard therapy for cHL, patients with limited presentation of NLPHL can achieve long-term disease-free survival after treatment with limited RT alone.[126-129] The appropriate treatment volume is ISRT, but ISRT is defined somewhat differently than in cHL where typical treatment is with combined modality therapy. The CTV expansion in NLPHL treated with ISRT must account for possible microscopic spread beyond the lymph nodes clinically observed on PET imaging. For example, in a patient who presents with unilateral cervical level I or IIA disease, the CTV should be expanded to include ipsilateral levels IIB, III, and even IV. For a femoral node presentation, the CTV should include an approximately 5-cm extension along the lymphatic chains superiorly and a 2-cm extension inferiorly.[64] The usual dose for NLPHL is 30 to 36 Gy. Doses as low as 4 Gy have been evaluated, but responses have not been as durable as with conventional doses.[130]

Retrospective data from the GHSG show a 4-year PFS rate of 93.2% and an 8-year OS rate of 99% for patients with stage I NLPHL treated with IFRT.[128] There was no benefit from extending the radiation fields or adding chemotherapy. Single-institution results for treatment of stage I to II diseases with RT alone include a 10- to 15-year PFS rate of 75% to 82% and 10-year OS rate of 83% to 100%.[126,127,131,132]

At some treatment centers, management resembling that for cHL is preferred, utilizing combined modality therapy.[132,133] With combined modality therapy, the

chemotherapy delivered can be ABVD (with or without rituximab), but patients may also be treated effectively with alkylator-based chemotherapy.[134]

A recent international multi-institutional analysis included 559 adult patients with stage I to II NLPHL.[34] The 5-year PFS was 91.1% after RT alone treatment (89.8% in stage I and 93.9% in stage II). Adverse risk factors among these patients on a multivariable analysis were a variant immunoarchitectural pattern and more than two nodal sites of disease. In the combined modality treatment group, the only factor impacting PFS was the presence of B symptoms. The overall 5-year survival was 99.4% following either RT alone or combined modality therapy. The absolute risk of transformation to an aggressive B-cell lymphoma was 3.8% (3.3% 5-year actuarial risk). The risk for transformation was also associated with more than two sites of disease and a variant immunoarchitectural pattern.

In the GHSG HD16 trial following ABVD, patients had a PET scan. Those with negative PET imaging were randomized with or without 20-Gy IFRT. Patients with NLPHL treated with chemotherapy alone had an inferior 5-year PFS compared to those treated with combined modality therapy (83% vs 100%, $P = .05$).[133]

Based on these data, European Society for Medical Oncology and other national consensus guidelines reflect a preference for ISRT alone in stage I disease and, per NCCN, contiguous stage II disease.[37] For other patients with stage II disease, combined modality therapy (including rituximab) is preferred. Attention is also brought to the potential importance of a variant immunoarchitectural pattern and the risk for transformation, mandating rebiopsy at the time of relapse.

Stage III to IV Classic Hodgkin Lymphoma

Systemic therapy is the mainstay of treatment for patients with stage III to IV HL (Table 84.7). Six cycles of ABVD was first established as the SOC among patients with advanced-staged disease in the landmark clinical trial conducted by the Cancer and Leukemia Group B.[46]

The value of a PET/CT response-based treatment approach has been evaluated in advanced disease. Both the RATHL study[135] and the SWOG S0816[136] trial used eBEACOPP for patients with PET-positive (Deauville 4-5) disease following two cycles of ABVD. Although eBEACOPP improved patient outcomes, neither trial had a comparison arm for continued treatment with ABVD. An important conclusion of the RATHL study was that patients with a negative interim PET scan could have bleomycin removed from cycles 3 to 6 of ABVD without compromising outcomes.

Based on encouraging results of BV in the relapse and refractory setting, the ECHELON-1 study investigated BV-AVD × 6 cycles versus ABVD × 6 cycles among adults with stage III or IV cHL. This study first demonstrated a significant

improvement in 2-year modified PFS with BV-AVD (82.1% vs 77.2%),[137] which ultimately translated into an improvement in OS at 6 years (93.9% vs 89.4%, P = .009)[51] and established BV-AVD as the new SOC in North America for advanced-stage disease.

Following the success of the ECHELON-1 study, the SWOG S1826 study, an NCTN study that included pediatric and adult patients with cHL, reported early PFS outcomes comparing BV-AVD × 6 cycles with N-AVD × 6 cycles with pRSRT for both groups based on the end of chemotherapy PET scan. The results demonstrated with a median follow-up of 12 months that N-AVD had a superior PFS to BV-AVD (94% vs 86%) without significantly higher rates of toxicity.[138] While these results are encouraging, longer follow-up is needed to confirm the difference in outcomes.

Role of Radiotherapy in Stage III/IV Classic Hodgkin Lymphoma

Bulky disease historically was thought to be a poor prognostic factor for patients with advanced-stage disease and as such was often a target of consolidative RT in this patient cohort. However, two recent studies have demonstrated minimal value to adding RT to sites of bulky disease among patients receiving six cycles of ABVD with a Deauville 1-3 response after two cycles. These studies include the GITIL/FIL HD0607[66] study and FIL HD0801 study.

On the other hand, RT may be valuable for patients with a positive interim PET regardless if they have bulky disease. While the ECHELON-1 study did not incorporate a PET response-based treatment approach, an interim PET was conducted after two cycles of systemic therapy. Patients with a PET2+ (Deauville 4-5) had significantly worse 3-year PFS in both arms than PET2− (Deauville 1-3), including after ABVD (79.5% PET2− vs 51.5% PET2+) and BV-AVD (85.8% PET2− vs 67.7% PET2+). Understanding the pattern of relapse on this study with respect to PET2+ sites of disease could help inform us whether a role of RT to PET2+ sites would be helpful. Nevertheless, trials of systemic therapy for advanced disease continue to include the selective use of consolidative RT.[139-141]

In summary, N-AVD × 6 cycles appears to be the new SOC treatment for patients with stage III/IV disease, while ABVD and BV-AVD could be considered in certain circumstances. The role of RT has diminished in advanced-stage disease and should be reserved for sites of partial response at completion of systemic therapy and also possible to sites of partial response after two cycles of systemic therapy.

Pediatric Patients

The management of pediatric patients with cHL is evolving and synergizing in some regard with adult patients, as seen with inclusion of both pediatric and adult patients

on recent NCTN HL studies (S1826 and AHOD 2131). More discussion can be found in the pediatric HL chapter.

Older Adult Patients

Treating HL in older patients (>60 years) is challenging because they often have less favorable histologies and a worse performance status.[142-144] They are also more likely to have intercurrent disease that compromises the aggressive management programs used for younger patients. Overall outcomes for patients older than 60 years are comparably poor.[142] Chemotherapy programs must often be modified to minimize cardiac or pulmonary toxicity, and the hematologic reserve in older patients requires dose reductions or premature discontinuation.[145] Bleomycin should be avoided, and eBEACOPP should not be used in patients over 60 years old.[146] Drug combinations better tolerated by older adults include ChlVPP;[147] procarbazine, Alkeran, and vinblastine;[148] and vinblastine, bleomycin, and methotrexate (used primarily for stages I-II).[149] More recently combinations of novel therapeutics including BV plus dacarbazine and BV plus nivolumab have demonstrated encouraging results.[150] Patients receiving RT may require slower fractionation programs and must be observed carefully for signs of weight loss or general decline in performance status. Extended fields are more difficult to tolerate than limited ones.[151]

Treatment for Relapse

Treatment for relapse must be individualized. Initial disease characteristics, initial treatment and response duration, relapse sites, and general patient status must be considered in developing an effective secondary treatment program. The conventional salvage therapy for most patients who were treated initially with either chemotherapy alone or combined modality therapy is high-dose chemotherapy followed by autologous hematopoietic cell transplantation, which is effective in approximately 50% of patients.[152,153] Allotransplantation is not used often for relapsed HL but can be considered after an unsuccessful autotransplant or when disease is refractory to both conventional chemotherapy and biologic agents. Reduced-intensity conditioning regimens appear to be safer than myeloablative regimens.[154]

An increasing dilemma is the management of patients who present with stage I to II diseases and are treated with abbreviated chemotherapy only, such as three to four cycles of ABVD. In these patients, relapse may be restricted to initial sites of disease.[155] The Checkmate 744 study recently reported on a small cohort of 28 patients who met a strict criterion for low-risk relapse disease and went on to

receive BV plus nivolumab with additional bendamustine for patients who were only partial responders. All patients were then treated with ISRT to 30 Gy and had a 3-year PFS of 95%.[156] While the study was small, the results are encouraging and could help establish a growing role of using RT in the second-line treatment in place of high-dose chemotherapy and autologous stem cell transplant. Although more evidence is needed to define the best "salvage" regimens for these patients, it has become apparent that autologous transplant can be avoided in many situations.

The Role of Radiation Therapy in Hematopoietic Cell Transplantation

RT can be incorporated into high-dose therapy/hematopoietic cell transplantation programs for relapsed or refractory HL. Fractionated total body irradiation is sometimes used, but its value is debatable. Often, relapse is locoregional rather than systemic. Data suggest that RT doses resembling those used for total body RT (12-15 Gy) are likely to eradicate disease in only approximately 20% of treated sites.[6] Thus, radiation should be limited to sites of failure or sites at high risk for disease, such as initially bulky ones.

Other considerations relevant to the issue of RT are its timing (pretransplant or post-transplant), field design, and dose. The advantages of using RT as cytoreductive treatment before high-dose therapy are that it can effectively reduce the tumor burden before high-dose treatment and the risk of interruption or delay of the locoregional RT is minimal. The primary disadvantages include potential delay of the high-dose therapy and the potential overlapping toxicities of the locoregional RT and high-dose therapy, including mucositis and pneumonitis.[157]

Many published series of high-dose therapy for HL have included locoregional RT in selected patients, usually after transplant.[158] The range of intervals from transplant to RT varies from 1 to 4 months. Often, the fields treated include sites of bulky disease (variably defined) at the time of relapse or sites that remain positive on PET imaging before the transplant. Some fields included all sites involved at the time of relapse.

In these studies, radiation doses ranged from 18 to 40 Gy. In general, lower doses were employed when initially nonbulky disease was included in the treatment or when there was a CR to high-dose therapy.

The use of locoregional RT in high-dose therapy programs can alter disease patterns and reduce the failure risk. At Stanford University, 49 patients with relapsed stage I to III diseases underwent high-dose therapy and received IFRT as a component of their salvage treatment.[159] Investigators observed 3-year freedom from relapse, OS, and event-free survival rates of 100%, 85%, and 85%, respectively, compared with only 67%, 60%, and 54%, respectively, for patients who received high-dose chemotherapy alone. The difference in freedom from

relapse was statistically significant (P = .04). The same was observed in a cohort of patients who received transplants at several centers.[160,161] The International Lymphoma Radiation Oncology Group has developed radiation treatment guidelines for patients undergoing hematopoietic cell transplantation.[162]

FOLLOW-UP

All studies that initially yielded abnormal results (eg, blood work and imaging) should be repeated upon completing therapy to document the patient's response to treatment. The Lugano response criteria mandate PET imaging immediately following therapy for this purpose.[15,16] Earlier challenges with interpreting residual mediastinal abnormality after therapy have been obviated by the adoption of FDG-PET imaging as a post-treatment assessment tool, so concern can be limited to those patients with residual PET activity.[163]

The follow-up interval is typically every 3 to 6 months during the first 2 years and every 6 to 12 months thereafter. The most important component of follow-up is an interim history and physical examination, which help identify two-thirds of relapses.[164] Relapses can be detected by enlarged nodes or when the initial symptoms return, such as night sweats, pruritus, or alcohol intolerance. If ESR, serum albumin, and other serum marker studies were abnormal at presentation, they can be repeated, although they rarely suggest disease recurrence without clinical symptoms or physical findings.[165] Given the effectiveness of primary therapy for HL, the low rate of relapse, the risk for "false-positive" imaging studies, and the expense to the health care enterprise, the value of routine imaging has become debatable and guidelines remain nonspecific.[164,166,167] National consensus guidelines endorse up to three CT scans in the first 2 years after therapy.[168,169] Surveillance PET imaging is not indicated because of the high likelihood of false-positive findings, radiation exposure, and economic costs.[170-172]

In virtually every case, the first episode of relapse should be documented by biopsy. Inflammatory disease, especially following the use of CPIs; progressive transformation of germinal centers; or the rebound growth of the thymus in young patients are other reactive processes that can be confused with recurrent HL. All of these processes can be FDG avid on PET imaging.

Long-term follow-up helps detect late effects and ensures health maintenance. Serum thyroxine (T_4) and sensitive thyroid-stimulating hormone (TSH) levels should be obtained at least annually in patients who received radiation to the neck to detect subclinical hypothyroidism.

Cardiovascular risk factors should be managed aggressively, especially for patients exposed to thoracic radiation or doxorubicin chemotherapy. National consensus guidelines recommend annual fasting blood sugar and biannual lipid

panels and a stress echocardiogram, and carotid ultrasound should be done 10 years after treatment. Women exposed to thoracic radiation should initiate routine mammographic screenings starting at age 25 or 8 years after radiation, whichever occurs first. Also, women treated before 30 years old should undergo both routine mammography and magnetic resonance mammography annually. Surveillance for other malignancies should conform to the American Cancer Society guidelines. Annual immunization against influenza is recommended.

SEQUELAE OF TREATMENT

Depending on the fields treated, the acute side effects of RT can include mild skin reactions, sore throat, an altered sense of taste, dysphagia, reflux symptoms, dry cough, nausea, occasional vomiting, diarrhea, and blood count suppression. Most of these sequelae can be managed symptomatically. Complications that arise in the early phase of the follow-up program can include mild radiation pneumonitis, radiation pericarditis, hypothyroidism, herpes zoster, Lhermitte sign, and xerostomia.

Subclinical hypothyroidism develops in as many as half of patients who receive doses above 30 Gy to the neck.[173] It can be detected by elevated TSH levels even in the presence of a normal T_4 level. Thyroid replacement therapy with L-thyroxine is recommended, with an initial dose of up to 0.1 mg/d. The T_4 and TSH values are monitored regularly to adjust dose. Evidence suggests that thyroid replacement therapy in this setting reduces the risk of developing benign thyroid nodules.[174] It is likely that newer treatment techniques with lower doses and better shielding of the thyroid gland will result in decreased risk.

Herpes zoster can occur either during or within the first few years of HL treatment in 10% to 15% of patients.[175] Acyclovir can limit the duration and intensity of the infection and decrease the likelihood of cutaneous or visceral dissemination. Currently, zoster vaccine immunization is not recommended for patients treated for lymphoma (www.cdc.gov/vaccines).

Significant xerostomia can follow RT of the Waldeyer lymphoid region or the bilateral submandibular regions, which is rarely necessary, and permanent attention to dental care is required for these patients. Frequent dental prophylaxis and use of fluoride supplements are recommended.

An uncommon but potentially serious complication is overwhelming sepsis after splenectomy or splenic RT.[176,177] The most serious infections occur with Gram-positive organisms, including *Streptococcus pneumoniae*, meningococci, and *Haemophilus* strains. Immunizing against these organisms minimizes risk. Patients can be immunized upon diagnosing the HL. Recommendations vary for the immunization of patients who have been previously treated, but not immunized.

Recent data suggest that patients can develop adequate antibody titers to *Haemophilus influenzae* type b-conjugate, four-valent meningococcal polysaccharide vaccine, and 23-valent pneumococcal polysaccharide vaccine 2 after treatment.[178] Reimmunization is recommended for every 5 to 7 years. Fortunately, sepsis has become even more rare with the declining use of staging laparotomy and splenic RT.

An uncommon but significant treatment complication is the "dropped-head syndrome" secondary to cervical muscle atrophy that occurs in just some patients treated with high-dose RT (>36 Gy) to the neck.[179] This is a late risk, not usually apparent until greater than 10 years after therapy. Management of this problem is challenging, with varying responses to physical therapy and use of a "soft collar." Surgical intervention has been attempted in some patients.[180] The use of contemporary therapies should obviate this risk.

Long-term follow-up is essential to identifying significant adverse late treatment complications in all patients.[181-184] The most important long-term concerns are secondary malignancies[92] and cardiovascular disease.[95]

Secondary malignancies include leukemia, lymphoma, and solid tumors. In a large series by Schaapveld et al, the standardized incidence ratio for developing a second malignancy after treatment for HL was 4.6, with 121.8 excess cancer cases per 10,000 patients per year.[92] Breast cancer was the greatest contributor to excess risk, followed by lung cancer, gastrointestinal tract cancers, and non-HLs. The highest (relative) risks were for thyroid cancer, soft tissue sarcoma, mesothelioma, and non-HL. Patients were also at an elevated risk of developing esophageal, gastric, pancreatic, and lung cancers as well as leukemia. These data were gathered in an earlier era of larger radiation fields, higher doses, and alkylating agent chemotherapy; therefore, risks are likely much lower now with the current management programs.[74,185-187] Secondary solid tumors, which have a latency of at least 7 to 10 years, are largely attributable to RT, although chemotherapy plays a part, especially with secondary lung cancers and gastrointestinal tract cancers.[91,92,188]

Secondary lymphomas are usually of the diffuse large cell B-cell type. The latent interval is typically over 5 years. The relative risk is 13.4, and the absolute excess risk is 16.0.[92] The development of secondary lymphomas does not seem to be related to any specific component of therapy but can be related to underlying immunosuppression.

A recent study of more than 1,000 women below age 51 years when treated for HL reported a 5.6-fold increased risk of developing invasive breast cancer compared with the general population of women (absolute excess risk, 57 cases per 10,000 persons per year).[186] The increased risk was primarily among women younger than 40 years at the time they were treated, and the risk was greater for

women treated to a full mantle field compared with mediastinal RT only. The risk can also be related to radiation dose. Travis et al[93] reported that doses exceeding 4 Gy were associated with an increased risk for developing a secondary cancer. Recently, there is reported to be an increased risk of secondary breast cancer following the use of doxorubicin without radiation.

The lung cancer risk after RT exposure is also dose related, with an increased risk for lung cancer following doses as low as 5 Gy.[90] In addition, it has been clearly demonstrated that the lung cancer risk is extraordinarily high among irradiated patients who continue to smoke after treatment.[189] Because of this inordinately high risk for lung cancer, patients who continue to smoke after treatment should be urged to stop and enter smoking cessation programs.

Potential cardiac complications following treatment for HL include pericarditis (which can occur during therapy), valvular dysfunction, conduction abnormalities, coronary artery disease, and ventricular dysfunction.[95] Radiation pericarditis is a potential risk if a large portion of the pericardium is treated, which is uncommon in the current management programs; it presents as an acute febrile syndrome associated with chest pain and friction rub, an asymptomatic pericardial effusion diagnosed by chest radiograph or echocardiogram, or constrictive pericarditis or tamponade. Mild manifestations can be managed with conservative medical treatment, including analgesics and nonsteroidal anti-inflammatory agents; it usually clears within a few weeks. Although rare, tamponade or constrictive pericarditis is the most serious and can require surgical intervention.

Long-term cardiovascular sequelae result in increased morbidity and mortality.[95] Coronary heart disease for patients increases 2.5-fold for those who receive an MHD of 20 Gy. The use of doxorubicin did not increase this risk, although it did increase the risk for congestive heart failure nearly 3-fold.[98] Compared with the general population, the risk for cardiac morbidity requiring hospitalization is 2.77-fold for patients treated with both mediastinal RT and doxorubicin and 1.82-fold following mediastinal RT alone.[190] Screening studies have shown a significant risk of asymptomatic coronary artery disease, although optimal screening guidelines for patients after mediastinal RT have not been clearly defined.[191] Aggressive management of hypertension, diabetes, and serum lipid abnormalities is recommended for all patients.[192]

Another group of sequelae involves psychosocial problems, fatigue, marital difficulties, and employment issues.[193-195] Identifying these problems can promote the development of rehabilitation programs to anticipate and deal with these issues early in the course of treatment.

CURRENT CLINICAL TRIALS

In North America, the NCTN is currently enrolling patients in AHOD 2131 for pediatric and adult patients with early-stage cHL. Following two cycles of ABVD, patients undergo PET response assessment, and patients with a rapid early response, defined as a Deauville 1-3, go on to be randomized between SOC with additional A(B)VD chemotherapy (two more cycles of ABVD if favorable risk per EORTC guidelines; four cycles of AVD if unfavorable risk) versus four cycles of experimental treatment of BV plus nivolumab. Patients with a slow early response, defined as a Deauville 4 to 5, are randomized between SOC with eBEACOPP × 2 cycles followed by ISRT versus experimental treatment with four cycles of BV and nivolumab followed by ISRT.

CHAPTER 85

Non-Hodgkin Lymphomas

Christopher R. Kelsey, Edina Wang, Alex J. Gooding, and Leonard R. Prosnitz

Non-Hodgkin lymphomas (NHLs) are a heterogeneous group of malignancies of the lymphoid system characterized by an abnormal clonal proliferation of B cells, T cells, or NK (natural killer) cells. Significant molecular and immunobiologic advances over the past several decades have inevitably led to evolving classification systems as well as novel therapies for NHL, with chemotherapy, immunotherapy, cell-based therapy, and radiation therapy (RT) all playing important therapeutic roles.

There are currently approximately 47 distinct mature B-cell entities and approximately 34 mature T-cell and NK cell entities within the 2022 World Health Organization (WHO) classification.[1] A second classification system, the International Consensus Classification (ICC) from the Clinical Advisory Committee, has also been described, which categorizes some entities slightly different than the WHO.[2] A description of all the varieties of NHL is not practical and beyond the scope of this chapter. We focus on the most common diseases encountered by radiation oncologists including diffuse large B-cell lymphoma (DLBCL) along with several other large cell lymphomas, follicular lymphoma (FL), marginal zone lymphomas (MZLs), mantle cell lymphoma (MCL), and various peripheral T-cell lymphomas (PTCLs), including extranodal NK/T-cell lymphoma, nasal type. Other entities less frequently encountered by radiation oncologists are also briefly discussed.

EPIDEMIOLOGY

The U.S. age-adjusted incidence rate for NHL was 19.3 per 100,000 between 2015 and 2019, with a projected 80,550 new cases in 2023 (4.1% of new cancer diagnoses) and 20,180 estimated NHL-associated deaths in

2023.[3] With worldwide incidence rates of NHL totaling only 5.9 per 100,000, the United States, along with Europe and Australia/New Zealand, has the highest rates of NHL, while Asian and African populations are least likely to be diagnosed.[4]

Following a doubling in incidence rates of NHL between 1975 and 2000, a rise thought to be attributable to various factors including advancing molecular diagnostic techniques, immunosuppression from human immunodeficiency virus (HIV), environmental factors, and an aging population, new cases peaked at 21.3 per 100,000 in 2010[5] and have since been relatively stable. The U.S. NHL mortality rate rose from 5.6 per 100,000 to 8.2 per 100,000 between 1975 and 2000. Despite only a slight decrease in incidence rates since 2000, NHL mortality rates have nearly halved from a peak of 8.9 per 100,000 in 1997 to 4.9 per 100,000 in 2020, reflecting advances in NHL therapies.[3]

ETIOLOGY

Several genetic diseases, environmental exposures, and infectious agents have been associated with the development of lymphoma. In addition, a family history of NHL is naturally associated with an increased risk of all forms of NHL, most notably in PTCL, chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), and MCL.[6]

Immune Disorders

The frequency of NHL is greatly increased in immunocompromised patients and predominantly manifested in patients who are HIV infected and solid organ transplant recipients.[7,8] Between 1996 and 2009, HIV-infected individuals experienced a 4.5% incidence of NHL (the highest of any malignancy), most commonly DLBCL, Burkitt lymphoma (BL), and primary central nervous system lymphoma (PCNSL).[9] While the introduction of highly active antiretroviral therapy has resulted in the decline in NHL incidence and mortality among those infected with HIV, HIV-associated NHL typically exhibit more aggressive clinical behavior and can be refractory to standard therapeutic regimens.

Immunosuppression caused by organ transplantation and end-stage renal disease is also associated with an increased risk of NHL. A large registry

study of 221,962 American transplant recipients between 1987 and 2014 revealed that NHL incidence increased approximately 8-fold post-transplant and led to 5,430 life-years lost over this time frame, contributing to 15% of all cancer-related deaths among these transplant recipients, second only to lung cancer.[10] In addition, those with rare inherited immunodeficiency disorders such as X-linked lymphoproliferative syndrome, common variable immunodeficiency, Wiskott-Aldrich syndrome, and ataxia-telangiectasia, experience up to a 7% lifetime risk for the development of NHL.[11]

NHL is more common among those with certain autoimmune diseases. Sjögren disease is strongly associated with increased incidence of MZL.[12] Sjögren disease is also associated with DLBCL, as are other B-cell–activating autoimmune diseases such as autoimmune hemolytic anemia, systemic lupus erythematosis, and rheumatoid arthritis.[13-15] T-cell–activating autoimmune disorders such as celiac disease, psoriasis, bullous pemphigoid, and atopic dermatitis are associated with an increased frequency of T-cell lymphomas.

Infectious Agents

Infectious exposures have long been associated with the pathogenesis of several forms of NHL. For example, Epstein-Barr virus (EBV) and human herpes virus 8 are thought to be causal in BL, human T-cell lymphotropic virus type 1 conveys a 5% lifetime risk of developing adult T-cell leukemia/lymphoma, and chronic hepatitis C virus (HCV) is associated with a 2- to 10-fold increased incidence of DLBCL, lymphoplasmacytic lymphoma, and MZL.[16]

Of particular relevance to radiation oncologists is the association of MZL with localized bacterial infections, most notably *Helicobacter pylori* and the development of gastric mucosa-associated lymphoma tissue (MALT). Infection with this organism is found in over 90% of patients with gastric MALT.[17] Successful eradication of *H. pylori* with antibiotic therapy in localized gastric MALT results in complete remission in more than 80% of patients.[18]

The role of other bacterial infections in nongastric MALT is controversial. Several studies document, for example, an association

between *Chlamydia psittaci* and ocular adnexal MALT, *Borrelia burgdorferi* and cutaneous MZL, and *Campylobacter jejuni* with MZL of the small bowel and responses to antibiotics have been reported, particularly for orbital MZL. However, the association with infectious agents varies widely depending on geographic locale. At present, there is no established role for the use of antibiotics in the treatment of nongastric MZL. Antivirals are recommended in patients who are seropositive for the HCV with splenic MZL.

Environmental and Occupational Exposures

Many occupations have been associated with a higher risk of developing NHL. A comprehensive pooled analysis from the InterLymph Consortium demonstrated a 1- to 2-fold increased incidence of NHL in populations exposed to various pesticides and solvents, including farmworkers, women's hairdressers, charworkers/cleaners, spray painters, and carpenters.[19] Despite occupational associations and litiginous pursuits, conclusive evidence establishing a causal relationship between individual pesticides and the development of lymphoma has remained elusive.[20] Ionizing radiation exposure is associated with the development of leukemia and many solid tumors, but the link to the development of NHL is tenuous. Large analyses of atomic bomb survivors, radiologic technologists, and those who have received therapeutic radiation have not detected a definite association with NHL. Other studies, however, have shown an increased risk of developing NHL among those who underwent therapeutic radiation for Hodgkin lymphoma (HL).[21] This is probably related to the increased susceptibility of young patients to the development of radiation-induced second malignancies, compared with an older population.

PATHOLOGY

NHL comprises numerous disease entities with intricate and frequently evolving histopathologic subtleties, which often complicate the process of establishing a specific diagnosis. Over the past two decades, the WHO classification system has stood as the lone international standard for diagnosing and classifying lymphoid neoplasms. A wide array of novel molecular, clinical, and immunophenotypic data have been implemented

into the fifth edition of the WHO classification, released in 2022.[1] The exhaustive nature of the WHO classification system renders a comprehensive discussion of its components beyond the scope of this chapter. Table 85.1 lists the disease entities most commonly encountered by a radiation oncologist and discussed within this chapter. Key updates in the WHO include adherence to a more clearly defined hierarchical classification system extending most broadly from lymphoid neoplasm category (eg, mature B cell), to family/class (eg, large B-cell lymphoma), to entity/type (eg, DLBCL, not otherwise specified [NOS]), to the most granular specification-subtype (eg, DLBCL, NOS, germinal center B cell [GCB] like). Furthermore, molecular diagnostic advances have led to the identification of several entities not previously recognized (eg, B-lymphoblastic leukemia/lymphoma with TCF3.HLF fusion) and have allowed for more diagnostic certainty (eg, removal of "provisional" classifiers).

ALK, anaplastic lymphoma kinase; CNS, central nervous system; ICC, International Consensus Classification; MALT, mucosa-associated lymphoid tissue; NOS, not otherwise specified; WHO, World Health Organization;

Notably, the WHO has recently been joined by an influential companion lymphoid neoplasm classification system, the ICC.[2] Finalized in 2022, the ICC closely mirrors the WHO classification yet harbors several subtle distinctions (eg, preservation of "provisional" classifiers in ICC, more granular DLBCL subtype delineation, and substantial genomic refinement of multiple myeloma subtypes), sparking concerns that clinicians and pathologists may no longer have a unifying approach to the diagnosis of lymphoid neoplasms.[22] Nevertheless, the classification of NHL types is generally concordant. Table 85.1 provides specific comparisons between the WHO and ICC classifications for the NHL entities discussed within this chapter.

CLINICAL FEATURES AND EVALUATION

Clinical Presentation, Evaluating, and Staging

NHL has a slight male preponderance (~55% male) and is predominantly a disease of older adults, in contrast to HL, with a median age at presentation of approximately 68 years.[3] Over the past several decades, the ratio of NHL cases to HL has increased from approximately 3:1 to 10:1. The clinical features differ widely depending on the histology and location of disease involvement. NHL may involve lymph nodes in almost any area of the body, but a typical presentation is an asymptomatic lump in the neck or inguinal-femoral region. Most nodal presentations of NHL are asymptomatic as B symptoms are much less frequently encountered than in HL, are not prognostic, and usually do not influence the choice of

treatment. For these reasons, it is unnecessary to add "A" or "B" designation to the numerical stage of a patient with NHL. Extranodal involvement is common in DLBCL (eg, ~50% of patients with early-stage disease and ~70% of all patients)[23] with symptoms related to the organ involved. Extranodal disease is relatively rare with FL.

Initial evaluation includes a complete physical examination with particular attention to node-bearing areas and other sites depending upon the specific disease entity (eg, parotids and orbits in MZL). Positron emission tomography-computed tomography (PET-CT) is now the imaging procedure of choice as the great majority of NHLs are fluorodeoxyglucose (FDG) avid. The Lugano classification is used for staging (Table 85.2). Tumor bulk is no longer considered because of the lack of consensus as to what constitutes bulky disease as well as the uncertain influence of bulk on prognosis in the current therapeutic era. Routine bone marrow biopsy has been standard in lymphoma evaluation for many years, but the high negative predictive value of PET-CT for bone marrow involvement in DLBCL allows for consideration of omitting this procedure in the setting of a negative PET-CT.[24] Similarly, bone marrow biopsy should typically be deferred if PET-CT indicates marrow involvement in DLBCL, given high positive predictive value. There are considerably less data, however, for other histologies, particularly FL where bone marrow biopsy remains standard of practice and is particularly important in patients with ostensible stage I or II disease being considered for definitive RT.

TABLE 85.2 REVISED STAGING SYSTEM: THE LUGANO CLASSIFICATION

Stage[a]	Involvement	Extranodal (E) Status[b]
Limited		
I	One node or a group of adjacent nodes	Single extranodal lesion without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	Stage I/II by nodal extent with limited contiguous extranodal involvement
II bulky	II as above with "bulky" disease[c]	NA
Advanced		

Stage[a]	Involvement	Extranodal (E) Status[b]
III	Nodes on both sides of the diaphragm; nodes above the diaphragm with spleen involvement	NA
IV	Additional noncontiguous extralymphatic involvement	NA

[a]Note, for non-Hodgkin lymphoma, A and B subtypes have been dropped because of the infrequency of systemic symptomatology, the unclear influence on prognosis, and the usual lack of relevance for management decisions.

[b]Tonsils, Waldeyer ring, and spleen are considered nodal tissue.

[c]Definition of bulky disease in diffuse large B-cell lymphoma is not consistent across studies, most recently considered to be 7 to 7.5 cm, but 6 to 10 cm also generally accepted.

Recommendations for initial evaluation, staging, and response assessment of Hodgkin and non-Hodgkin lymphoma: the Lugano classification. *J Clin Oncol*. 2014;32(27):3059-3068. Copyright © 2014 by American Society of Clinical Oncology.

As discussed earlier, the initial diagnosis of NHL based on WHO or ICC criteria is dependent on morphology, immunohistochemistry, flow cytometry, and molecular studies. An incisional or excisional biopsy is strongly preferred for diagnosis, though a core-needle biopsy is acceptable in difficult-to-access sites. Fine-needle aspirate rarely provides sufficient tissue to perform the studies necessary for a detailed classification. Additional laboratory procedures include complete blood count (CBC), metabolic panel, lactate dehydrogenase (LDH), β2-microglobulin (B2M), and hepatitis B, C, and HIV antibodies in selected patients.

Response Assessment

Response assessment should include a clinical evaluation with interval history and physical examination, laboratory evaluation (eg, CBC, LDH), and repeating any positive pretreatment imaging studies, most commonly PET-CT, as it is the most accurate imaging modality for response assessment. Responses may be divided into complete, partial, no response or stable disease, and progressive disease. For PET-CT, this is currently based on the five-point scale of the Lugano response criteria.[25,258] A complete response (CR) is defined as a score of 1, 2, or 3; a partial response (PR) is defined as a score of 4 or 5 but with reduced uptake compared with

original scans; no response or stable disease is defined as a score of 4 or 5 with no significant change in FDG uptake from baseline; progressive disease is scored when the intensity of uptake has increased from baseline and/or new lesions have developed. Definitions of PET-CT scores (Deauville criteria) are listed in Table 85.3.

TABLE 85.3 DEAUVILLE CRITERIA (PET-CT 5-POINT SCALE)

Score	Definition
Deauville 1	No uptake above background
Deauville 2	Uptake ≤ mediastinal blood pool
Deauville 3	Uptake > mediastinal blood pool but ≤ liver
Deauville 4	Uptake moderately increased compared to liver
Deauville 5	Uptake markedly increased compared to liver or new sites of disease

PET-CT, positron emission tomography-computed tomography.

A Deauville 4 treatment response can be quite variable ranging from a dramatic decrease in size of a large tumor mass but with a small focus of residual FDG uptake slightly above liver, to a minimal response in size of a mass with intense residual FDG uptake. Clinical judgment is required to determine if the response to systemic therapy was satisfactory in these settings. If so, proceeding with consolidation RT, often to a slightly higher dose, is often justified. The use of RT in the event of PR is discussed in the individual disease sections. If the response to initial therapy is judged inadequate and a major change in therapy is planned, it is often advisable to confirm the persistence of active disease with repeat biopsy.

In some NHL subtypes, imaging response assessment is often carried out midway through the course of therapy, the so-called interim PET-CT imaging. Many studies of interim PET-CT have been carried out, particularly in DLBCL, suggesting that an interim positive PET-CT (Deauville 4 or 5) predicts for a worse outcome. Modifying treatment based

on interim PET-CT in DLBCL and other NHLs requires further studies to understand how this is best accomplished.

Follow-Up and Routine Surveillance

Follow-up procedures and routine surveillance studies have been infrequently addressed in the literature, but consensus guidelines suggest a history and physical and routine laboratory assessment every 3 to 6 months for 5 years and then annually or as clinically indicated thereafter. There is no clear consensus on the role of surveillance imaging in NHL as the great majority of relapses are associated with clinical symptoms or abnormal physical findings and studies have not generally demonstrated a benefit for intense surveillance programs.

Detection of relapse is most relevant for diseases where curative therapy is available, such as chimeric antigen receptor (CAR) T-cell therapy or autologous stem cell transplantation (ASCT). For many histologies, particularly FL, the detection of recurrence is less relevant. Generalized FL is still regarded as incurable (in contrast to localized FL). Relapse after treatment of localized FL is almost always generalized, and because generalized FL is often observed without treatment until specific criteria for initiating therapy are met, there is little rationale for aggressive attempts at early detection of relapse in an asymptomatic patient with a normal examination.

LARGE B-CELL LYMPHOMAS

The fifth edition of the WHO classification lists 18 entities under the category "Large B-cell lymphomas."[1] The most common diseases encountered by radiation oncologists in this category (and reviewed in this chapter) include DLBCL NOS, high-grade B-cell lymphoma, NOS (HGBL NOS), DLBCL/HGBL with *MYC* and *BCL2* rearrangements, primary mediastinal (thymic) large B-cell lymphoma (PMBCL), T-cell/histiocyte-rich large B-cell lymphoma, mediastinal gray zone lymphoma (MGZL), and primary testicular DLBCL (included in the category of primary large B-cell lymphoma of immune-privileged sites by the WHO). PCNSL and primary cutaneous DLBCL, leg type are discussed elsewhere. With minor

exceptions that are noted, RT recommendations are similar across large B-cell lymphoma entities and are discussed under DLBCL NOS.

DIFFUSE LARGE B-CELL LYMPHOMA, NOT OTHERWISE SPECIFIED

Pathology

DLBCL is a neoplasm of large, transformed B cells with a diffuse growth pattern that totally or partially effaces the nodal architecture. The proposed normal counterparts are peripheral B cells of either germinal center or post–germinal center (activated B-cell [ABC]) origin. DNA microarray analyses using fresh frozen tissue show that unique molecular subgroups exist, which include a GCB subgroup and an ABC subgroup.[26,27] Algorithms utilizing immunohistochemistry to identify molecular subgroups, using formalin-fixed, paraffin-embedded tissue, have also been developed.[28] No single algorithm using immunohistochemistry is perfect in regard to predicting gene expression profiling results, though each divides patients into groups with different survival outcomes. Treatment tailored to molecular subclassification of this disease is currently being evaluated in prospective studies and remains investigational.

DLBCLs express one or more pan B-cell markers (CD19, CD20, CD22, and CD79a) and often surface and/or cytoplasmic immunoglobulin.[29] *MYC*, *BCL2*, and/or *BCL6* gene rearrangements are present in a minority of patients with DLBCL. Large cell lymphomas with gene rearrangements of *MYC* (a potent oncogene) together with a translocation of *BCL2* (an antiapoptotic gene) are now referred to by the WHO as DLBCL/HGBL with *MYC* and *BCL2* rearrangements (double-hit lymphoma). Similarly, other patients, typically with an ABC-like subtype, have overexpression by immunohistochemistry of MYC and BCL2 and/or BCL6, without the accompanying gene rearrangements. Such DLBCLs are referred to as double or triple expressors. Such patients also have a worse prognosis, though more favorable than double-hit lymphomas.[30]

Clinical Presentation

DLBCL is primarily a disease of older adults, with a median age of 64 years and a slight preponderance of men (55%). B symptoms are present in approximately one-third of patients but are not prognostic.[25] Just over half of patients (55%) have localized disease (stage I or II). About half of patients with stage I or II DLBCL present with extranodal disease, as opposed to localized FL where nodal presentation predominate. Patients with primary nodal disease most often present with an enlarging peripheral nodal mass.

Prognostic Factors

The International Non-Hodgkin's Lymphoma Prognostic Factors project examined data on 2,031 patients, all with aggressive histology NHL.[31,32] Two indices were developed, the international prognostic index (IPI) and the age-adjusted international prognostic index, because age was found to be a highly significant prognostic variable (>60 vs ≤60 years). For the IPI, five prognostic variables were found to be significant: age, performance status, stage, number of extranodal sites, and LDH (Table 85.4). The relative risks of these factors were low, ranging from 1.47 for stage to 1.96 for age. Five-year survival was 73%, 51%, 43%, and 26% when 0 to 1, 2, 3, and 4 to 5 risk factors were present. When patients were divided by age, three factors remained independently significant: performance status, stage, and LDH.

TABLE 85.4 PROGNOSTIC INDICES: DIFFUSE LARGE B-CELL LYMPHOMA AND FOLLICULAR LYMPHOMA

Prognostic Index	Risk Factors	Score (Number of Factors)	Outcome
Diffuse Large B-cell Lymphoma[a]			
IPI[31]	Age >60 y Performance status ≥2 Stage III-IV Elevated LDH >1 extranodal site	Low (0-1) Low intermediate (2) High intermediate (3) High (4-5)	73% (5-y survival) 51% 43% 26%
Follicular Lymphoma			

Prognostic Index	Risk Factors	Score (Number of Factors)	Outcome
FLIPI[33]	Age ≥60 y >4 nodal sites Elevated LDH Stage III-IV Hemoglobin <12 g/dL	Low (0-1) Intermediate (2) High (≥3)	71% (10-y survival) 51% 36%
FLIPI-2[34]	Age >60 y B2M elevated Hemoglobin <12 g/dL BM involvement Nodal diameter >6 cm	Low (0) Intermediate (1-2) High (≥3)	80% (5-y PFS) 51% 19%

β2M, β2-microglobulin; BM, bone marrow; FLIPI, follicular lymphoma international prognostic index; IPI, international prognostic index; LDH, lactate dehydrogenase; PFS, progression-free survival.

[a]Developed in the pre-rituximab era.

The IPI was designed in the pre-rituximab era. In the past 10 to 15 years, multiple randomized studies have shown that rituximab significantly improves survival when combined with standard combination chemotherapy.[35-37] Using data from three prospective trials, the German High-Grade Non-Hodgkin's Lymphoma Study Group found the IPI to retain prognostic significance in the rituximab era.[38] Adding approximately 10% survival to each IPI subgroup approximates outcomes when rituximab is added to combination chemotherapy.

As mentioned previously, several pathologic factors carry prognostic implications. The GCB subtype has a more favorable prognosis compared with the ABC subtype (defined using gene expression profiling) or non–GCB-like subtype (defined using immunohistochemistry).[26,39] Additional molecular signatures that appear to influence tumor behavior have also been proposed.[27]

Both interim and postchemotherapy PET-CT assessment also carry prognostic importance. At present, the five-point scale (Deauville criteria) should be utilized to interpret interim and post-treatment PET-CTs.[25] In numerous studies, residual PET-positive disease (Deauville 4-5) after the completion of chemotherapy alone in aggressive NHLs (mostly DLBCL) is associated with a high risk of disease progression.[40-43] For example, in the

setting of advanced DLBCL with PET-positive disease after chemotherapy without rituximab, the risk of progression was 100% in a series by Mikhaeel et al (n = 9)[41] and Spaepen et al (n = 26).[40] Similarly, poor outcomes have been noted when a post-treatment PET-CT is still positive after R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone).[44] Outcomes appear to be much better when RT is administered in this clinical setting.[45-47]

Achievement of a negative PET-CT early in the course of therapy (after 2-3 cycles) is generally associated with improved outcomes.[48] For example, in a study by Safar et al, 3-year progression-free survival (PFS) and overall survival (OS) were 84% and 88%, respectively, in patients achieving a negative PET-CT after two cycles of chemotherapy plus rituximab.[49] This compared with 47% and 62%, respectively, in patients who were still PET positive. Although the negative predictive value of interim PET-CT is high, the positive predictive value is relatively low. When compared with interim response assessment, postchemotherapy PET-CT response appears to be more prognostic, particularly in terms of the positive predictive value.[50]

Clinical Management

Chemoimmunotherapy, with or without consolidation RT, is standard in all stages of DLBCL. The most widely used drug combination is R-CHOP. R-CHOP is administered every 3 weeks in the outpatient setting.

DLBCL expresses the B-cell antigen CD20. Rituximab, an anti-CD20 antibody, improves survival in all stages of DLBCL when combined with chemotherapy.[35,36] A recent randomized trial demonstrated that R-CHOP was just as effective as the more aggressive regimen DA-EPOCH-R (dose adjusted, etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin, rituximab).[51] Thus, R-CHOP remains the standard regimen for DLBCL NOS.

Stage I and II Diffuse Large B-Cell Lymphoma

Historically, stage I and II DLBCL was often managed with RT alone. This strategy proved successful in approximately 40% to 45% of patients. Outcomes were better for those with stage I, compared with stage II, disease. Though rarely employed today, definitive RT is an appropriate

treatment option for patients with localized disease who are not candidates for, or refuse, chemoimmunotherapy. It can also be considered as an option for select patients with localized disease who do not respond to induction chemoimmunotherapy. A dose of approximately 40 Gy is recommended to the involved site(s) without any elective coverage.

Definitive RT as the preferred treatment for early-stage DLBCL was abandoned in the 1980s after randomized studies demonstrated that RT plus chemotherapy was superior to RT alone.[52-55] Chemotherapy became the foundational treatment, and RT transitioned to a consolidation modality. After improved outcomes were seen with the addition of rituximab to CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone), the need for consolidation RT has been called into question. Multiple randomized studies in early-stage DLBCL have been conducted comparing chemotherapy with a combined modality program (Table 85.5).[56-61] Interpretation of the trials can be challenging, given their individual peculiarities. A brief summary of the key trials follows.

TABLE 85.5 SELECT RANDOMIZED TRIALS IN EARLY-STAGE DLBCL

Study	*n*	Disease Characteristics	Randomization	Progression-Free Survival[a]	Comments
Pre-Rituximab/PET-CT era					
SWOG[59,62]	401	I II (nonbulky)	CHOP × 8 CHOP × 3 + RT	64% 77% (*P* = .03)	No difference with long f/u
ECOG[57]	172	I (high risk) II	CHOP × 8 CHOP × 8 + RT	56% 73%[b] (*P* = .05)	Only patients in CR by CT randomized
GELA 93-4[56]	576	I-II (without risk factors)	CHOP × 4 CHOP × 4 + RT	61% 64% (*P* = .6)	Only patients ≥60 y old
Rituximab/PET-CT era					
LYSA/GOELAMS[63]	301	I-II (nonbulky)	R-CHOP × 4-6 R-CHOP × 4-6 + RT	89% 92% (*P* = .18)	In PET-CT CR
FLYER[64]	592	I-II (nonbulky)	R-CHOP × 4 + 2R	96%	No risk factors

Study	*n*	Disease Characteristics	Randomization	Progression-Free Survival[a]	Comments

[c]3 years.

Pre-Rituximab/Positron Emission Tomography-Computed Tomography Era: Key Prospective Trials

The SWOG S8736 study evaluated the feasibility of replacing a significant number of chemotherapy cycles with consolidation RT. Three cycles of CHOP chemotherapy plus RT (40-55 Gy) was compared with a more extended CHOP regimen (eight cycles) without RT.[59] Unexpectedly, both PFS (77% vs 64%) and OS (82% vs 72%) at 5 years were improved in the combined modality arm with less toxicity. However, after a median follow-up of almost 18 years, no significant differences were apparent, in part because of a higher risk of late systemic relapses in the arm with only three cycles of CHOP.[62] A follow-up phase II study demonstrated 4-year PFS of 88% with three cycles of R-CHOP plus RT.[65] However, long-term data from both studies demonstrated a continuous risk of relapse over time.[62] Thus, three cycles of CHOP, or even R-CHOP, may provide insufficient systemic treatment for some patients with early-stage DLBCL.

The Eastern Cooperative Oncology Group (ECOG) 1484 study evaluated whether consolidation RT (30 Gy), after achievement of a CR by CT imaging, would reduce the risk of relapse in the setting of extended chemotherapy (eight cycles of CHOP in this case).[57] The primary outcome was PFS, which was significantly improved with the addition of RT (73% with consolidation RT vs 56% with observation at 6 years) (P = .05). No difference in OS was noted, though the study was not powered to evaluate

this. This study suggests that consolidation RT provides benefit even after an extended course of chemotherapy.

The Groupe d'Etudes des Lymphomes de l'Adulte (GELA) 93-4 enrolled older patients (>60 years) with early-stage disease without adverse risk factors.[56] Crude rates of local failure were less with RT (18% vs 7%). However, neither PFS nor OS was improved with consolidation RT (40 Gy) after four cycles of chemotherapy. This study suggests that older patients, especially those with favorable prognostic factors and/or medical comorbidities, may derive less benefit from consolidation RT.

Rituximab/Positron Emission Tomography-Computed Tomography Era: Key Prospective Trials

The Lymphoma Study Association/Groupe Ouest-Est des Leucémies et des Autres Maladies du Sang (LYSA/GOELAMS) trial enrolled 319 patients with nonbulky (<7 cm), stage I and II DLBCL.[63] Patients were randomized to four to six cycles of R-CHOP-14 with or without consolidation RT (40 Gy). Only patients in CR by PET-CT after four cycles (n = 281) proceeded with treatment according to their random assignment. The study was designed as a noninferiority study. By intention-to-treat analysis, 5-year event-free survival (EFS) was 89% with R-CHOP versus 92% with R-CHOP plus RT (P = .18). Crude rates of local failure were 4% (5/137) versus 0% (0/144).

Several nuances of this study deserve attention. First, 62 (~20%) patients had a negative staging PET-CT after diagnostic excisional biopsy. This would significantly dilute the effect of consolidation RT. Further, eight patients randomized to receive consolidation RT arm declined treatment. Since nonadherence to an allocated treatment in noninferiority studies will bias results in favor of the investigational arm, a per-protocol analysis is typically standard with such trial designs. Yet, no per-protocol analysis was reported for this trial. Finally, 94% of patients had a very favorable modified IPI (MIPI) score (0-1).

The FLYER study did not directly examine the role of RT in early-stage DLBCL.[64] Patients (n = 558) aged 60 years or below, with nonbulky (<7.5 cm) DLBCL and HGBL, without risk factors such as elevated LDH or poor performance status, were randomized to four cycles of R-CHOP with two

additional cycles of rituximab or six cycles of R-CHOP. PET-CT imaging was not standardized within the protocol. PFS at 3 years was no different between arms (96% vs 94%) in the intention-to-treat analysis. A per-protocol analysis (n = 482) was performed given the noninferiority study design and showed similar findings (98% vs 94%). The investigators concluded that young patients without risk factors can be successfully treated with four cycles of R-CHOP with two additional cycles of rituximab.

The Intergroup National Clinical Trials Network Study S1001 did not specifically investigate the role of consolidation RT in early-stage DLBCL.[66] In this randomized phase II trial, patients with nonbulky (<10 cm), stage I and II, ECOG performance status 0-2, DLBCL or HGBL with or without gene rearrangements, were eligible. Patients received three cycles of R-CHOP and then underwent an interim PET-CT. Those with a negative PET-CT (Deauville 1-3) received an additional cycle of R-CHOP without consolidation RT. Patients with a positive PET-CT (Deauville 4-5) received both consolidation RT (36-45 Gy) and ibritumomab tiuxetan. In general, patients in the S1001 study had more risk factors than those on the LYSA/GOELAMS or FLYER studies but were still relatively low risk (stage-modified IPI 0-1 in 70%). All gross disease was resected in 10% of patients before initiating systemic therapy. A CR by PET-CT was achieved in 110 (86%) of 128 patients after three cycles of R-CHOP. Among patients with a negative interim PET-CT who received four cycles of R-CHOP, 5-year PFS and OS were 89% and 91%, respectively. Among the 14 patients with a positive interim PET-CT, all but one received consolidation RT. With the addition of RT, 5-year PFS was 86%, similar to that among patients who had a negative interim PET-CT. Only two of these patients relapsed, one of whom refused RT and one received only one cycle of chemotherapy before going off treatment.

In conclusion, for patients with stage I and II nonbulky DLBCL with 0-1 IPI risk factors, four cycles of R-CHOP (FLYER, LYSA/GOELAMS, S1001) or three cycles of R-CHOP plus RT (SWOG S0014) are reasonable options. Patients with early-stage DLBCL with an IPI of 2-3, underrepresented in the modern trials, may be considered for consolidation RT depending upon distribution of disease, response to therapy, and risks of

RT. Consolidation RT is recommended in patients with bulky disease (variably defined in randomized studies, most commonly >7.5 cm).

At present, a dose of 30 Gy is standard. A prospective study by the International Lymphoma Radiation Oncology Group (ILROG) is assessing whether 20 Gy is sufficient in the setting of a CR by PET-CT (Deauville 1-3). In the setting of a PR (Deauville 4), a higher dose of RT would be appropriate (40-44 Gy).

Stage III and IV Diffuse Large B-Cell Lymphoma

The mainstay of treatment of advanced DLBCL is systemic chemoimmunotherapy, typically R-CHOP, with 5-year survival of approximately 60%.[35] Many strategies have been explored to improve upon R-CHOP, including more chemotherapy cycles,[67] dose-dense chemotherapy,[68,69] more intensive chemotherapy regimens,[70,71] maintenance rituximab,[37] and high-dose chemotherapy and ASCT.[72] None have consistently improved survival compared with standard R-CHOP.

Several retrospective studies have suggested a benefit for consolidation RT in advanced DLBCL.[73-75] One rational for the use of consolidation RT is the tendency of patients with advanced lymphoma to relapse at sites of original involvement and, in particular, sites of original bulk.[74,76,77]

The RICOVER-60 and RICOVER-noRTh trials primarily enrolled patients with advanced disease (50% and 60%, respectively).[78] The original RICOVER-60 trial was a randomized study that investigated different chemoimmunotherapy regimens in older adults (ages 61-80) with both early and advanced DLBCL. Those with bulky (≥7.5 cm) or extranodal disease were to receive RT to those areas if a CR or PR was achieved by CT imaging. PET-CT imaging was not utilized in this trial. The treatment arm yielding the best outcomes consisted of six cycles of dose-dense R-CHOP (administered every 2 weeks) with two additional cycles of rituximab and RT to bulky or extranodal sites of disease. The RICOVER-noRTh trial was an amendment to the original trial in which this same regimen was administered but without RT to bulky or extranodal disease. Comparing outcomes from the two studies, the risk of relapse in patients with bulky disease achieving a CR was higher when RT was not administered (22% vs 4%, $P = .007$). A per-protocol analysis of all patients with bulky disease

revealed improved PFS in patients receiving RT (88% vs 62%, $P < .001$). Of course, these were not randomized comparisons but suggest that RT improves outcomes in the setting of bulky disease. A limitation of this study was the lack of PET-CT imaging.

The UNFOLDER trail enrolled younger patients (≤60 years) with high-grade NHLs including DLBCL presenting with an age-adjusted IPI (aaIPI) of 1 or aaIPI of 0 with bulky disease (≥7.5 cm).[79] Patients were randomized to R-CHOP14 or R-CHOP21 with a secondary randomization to consolidation RT or observation. PET-CT imaging was not utilized. A planned interim analysis demonstrated a significantly better 3-year EFS for patients randomized to RT (84% vs 68%, $P = .001$), in part because patients randomized to observation who only achieved a PR (by CT imaging) to chemotherapy proceeded to RT and were scored as an event. This study is still only published in abstract form.

Several retrospective studies have shown that consolidation RT, in the setting of a PR to systemic therapy, provides long-term disease control in a significant proportion of patients.[80-82] A recent retrospective study from British Columbia reporting their institutional experience in advanced DLBCL is illustrative.[47] Patients with advanced DLBCL were initially treated with at least six cycles of R-CHOP. Only patients who were PET positive at the completion of chemoimmunotherapy received consolidation RT. Time to progression at 3 years was 83% in the cohort who achieved a CR by PET-CT to R-CHOP alone. Notably, patients who were PET positive at the completion of chemoimmunotherapy and received consolidation RT had similar outcomes to the PET-negative cohort and far better outcomes than those who were PET positive but did not receive RT.

In addition to bulky disease and PRs, other circumstances that may warrant consideration of consolidation RT include limited skeletal disease[83] and disease in sensitive locations where achievement of local control is critical (eg, spinal canal, cavernous sinus).

Relapsed and Refractory Diffuse Large B-Cell Lymphoma

Until recently, high-dose chemotherapy followed by ASCT was the preferred salvage regimen for patients with relapsed or refractory (R/R) DLBCL. In a phase III trial from the Parma group, patients with DLBCL

who had relapsed following initial CHOP chemotherapy and were responsive to a salvage regimen (dexamethasone, cisplatin, cytarabine-DHAP) were then randomly assigned to receive either four additional cycles of DHAP or high-dose chemotherapy followed by ASCT.[84] Those receiving ASCT had a markedly improved PFS (46% vs 12%) and OS (53% vs 32%), compared with those receiving conventional chemotherapy. Note that in both arms of this trial, RT to original bulky sites of disease (≥5 cm) was utilized (35 Gy in 20 fractions in the conventional chemotherapy arm and 26 Gy in 1.3 Gy fractions bid in the ASCT arm). All patients in the Parma trial were younger than 60 years of age. It is important to recognize that only patients with chemotherapy-sensitive disease (those who achieve a CR or PR by CT imaging to salvage chemotherapy) are candidates for ASCT. More recently, PET-CT imaging is the preferred method to define response. Those with a persistently positive PET-CT after a salvage program (Deauville 4) do poorly with ASCT.[85,86]

The role of RT in patients undergoing ASCT is not well defined due to the lack of prospective studies. The ILROG has published detailed guidelines regarding RT in the setting of ASCT.[87] We generally recommend post-ASCT RT for patients with bulky and/or localized disease at the time of relapse. A dose of 30 Gy is recommended in the setting of a CR with higher doses reserved for PRs.

However, recent randomized studies have shown that CAR T-cell therapy, described later, provides superior outcomes, compared with ASCT, in patients with refractory DLBCL or who relapse within 12 months of completing therapy.[88,89] Thus, ASCT is now primarily pursued for patients with late relapses.

In 2017, the U.S. Food and Drug Administration approved CAR T-cell therapy, a novel treatment for R/R DLCBL. CAR T cells are a type of immunotherapy, consisting of autologous T cells that are harvested from a patient and genetically engineered to express CAR molecules that target a specific antigen of interest on malignant cells. CD19, a transmembrane protein expressed on all B cells, has proved to be an ideal target for DLBCL. In a typical course, patients undergo leukapheresis, wait a minimum of 2 weeks for the CAR T-cell production process, and are then treated with lymphodepleting chemotherapy several days prior to infusion of the autologous CAR T-cell product. This allows for optimal CAR T-cell

survival, expansion, and tumor cell killing upon reinfusion. The genetic engineering breakthrough of CAR T cells, which combine the exquisitely specific antigen-recognition capabilities of antibodies with the downstream cytotoxic effector functions of T cells, has proved to successfully lead to long-term remissions in patients with refractory disease. Three phase II clinical trials (JULIET, ZUMA-1, and TRANSCEND) demonstrated overall response rates between 52% and 82% and CR rates between 40% and 54%, with sustained PFS at approximately 40% following a single infusion of the engineered cellular product.[90-92]

Given the delay between apharesis and infusion of the final CAR T-cell product, bridging RT is often employed. Bridging RT is ideal for patients with symptomatic disease or rapidly progressing disease, to maintain performance status and control pain and other symptoms, which will help the patient better tolerate the CAR T-cell procedure. The optimal RT schedule, timing, and other such issues remain to be clarified. In regard to timing, it seems advisable to delay RT until after apheresis has taken place. Even with low RT doses and minimal bone marrow exposure, circulating lymphocytes within the bloodstream remain susceptible to RT. Prior studies primarily treated patients after apheresis (84% for Moffit, 65% for MDACC, 100% for University of Pennsylvania).[93-95] Such concerns must be counterbalanced against the need to treat patients with symptomatic disease awaiting insurance approval. The optimal dose for bridging RT is also uncertain. In some circumstances, the dose is limited by logistical timing of the CAR T-cell schedule. While many patients have been treated with palliative doses (20-30 Gy), at least one study suggests that “definitive” doses may be ideal. Sim et al demonstrated that local control was 100% in patients who received at least an EQD2 dose of 39 Gy.[96] The utility of higher doses and prolonged fractionation schemes must be weighed against the putative benefits of shorter RT courses, allowing more prompt CAR T-cell infusion.[80]

For patients with localized presentations that can be safely encompassed in RT fields, we recommend comprehensive treatment, ideally to definitive doses (eg, ~40 Gy). This can often be accomplished in a hypofractionated manner (eg, 3 Gy per fraction) to expedite treatment and minimize reinfusion delays. If definitive doses are not feasible or practical given the circumstances, a total dose of 20 to 30 Gy in 2 to 4 Gy fractions could be

pursued. For patients with more extensive disease who present with bulky tumors, symptomatic disease, or lymphoma in sensitive locations (eg, spinal cord, airway), we suggest localized irradiation of select sites to a dose of 20 to 30 Gy. Hypofractionation is often feasible.

Palliation

For patients with relapsed/refractory disease, RT is an effective modality to achieve palliation of symptomatic disease. While doses of 24 to 30 Gy, typically administered in a hypofractionated manner, are most commonly utilized, low-dose RT (2 Gy × 2) may be reasonable in select circumstances. Response rates of 50% to 80% have been reported with 2 Gy × 2, with a median time to progression of about 1 year.[81,97] Larger and more durable responses are likely achieved with more traditional dosing schemes.

Radiation Therapy Dose and Field Design

The dose of RT in a combined modality treatment program depends principally on the response to chemotherapy. For patients with stage I and II diseases, the standard dose is 30 Gy when a CR (Deauville 1-3) has been achieved by PET-CT after chemoimmunotherapy. A British National Lymphoma Investigation randomized study showed no difference in freedom from local progression, PFS, or OS between 30 and 40 to 45 Gy.[98] Local control is approximately 95% if RT is given in the setting of a CR to systemic therapy.

Even smaller doses may suffice with more effective systemic therapy, including rituximab-based regimens. A phase II study from Duke University demonstrated a 98% freedom from local recurrence with R-CHOP or R-EPOCH followed by 20 Gy of RT in DLBCL and PMBCL.[99] A confirmatory study by the ILROG has completed accrual.

For patients who respond favorably but not completely to chemoimmunotherapy (Deauville 4), higher doses of consolidation RT may be required to achieve optimal local control (≥40 Gy)[45,46] (Figure 85.1). In refractory localized DLBCL (Deauville 4-5), primarily those with stage I disease, salvage RT (≥40 Gy) may be a reasonable option, reserving CAR T-cell therapy if RT unsuccessful. In the unusual circumstance when RT

alone is pursued for patients with localized disease, a dose of 40 Gy is recommended. There is little evidence for doses above 40 Gy.

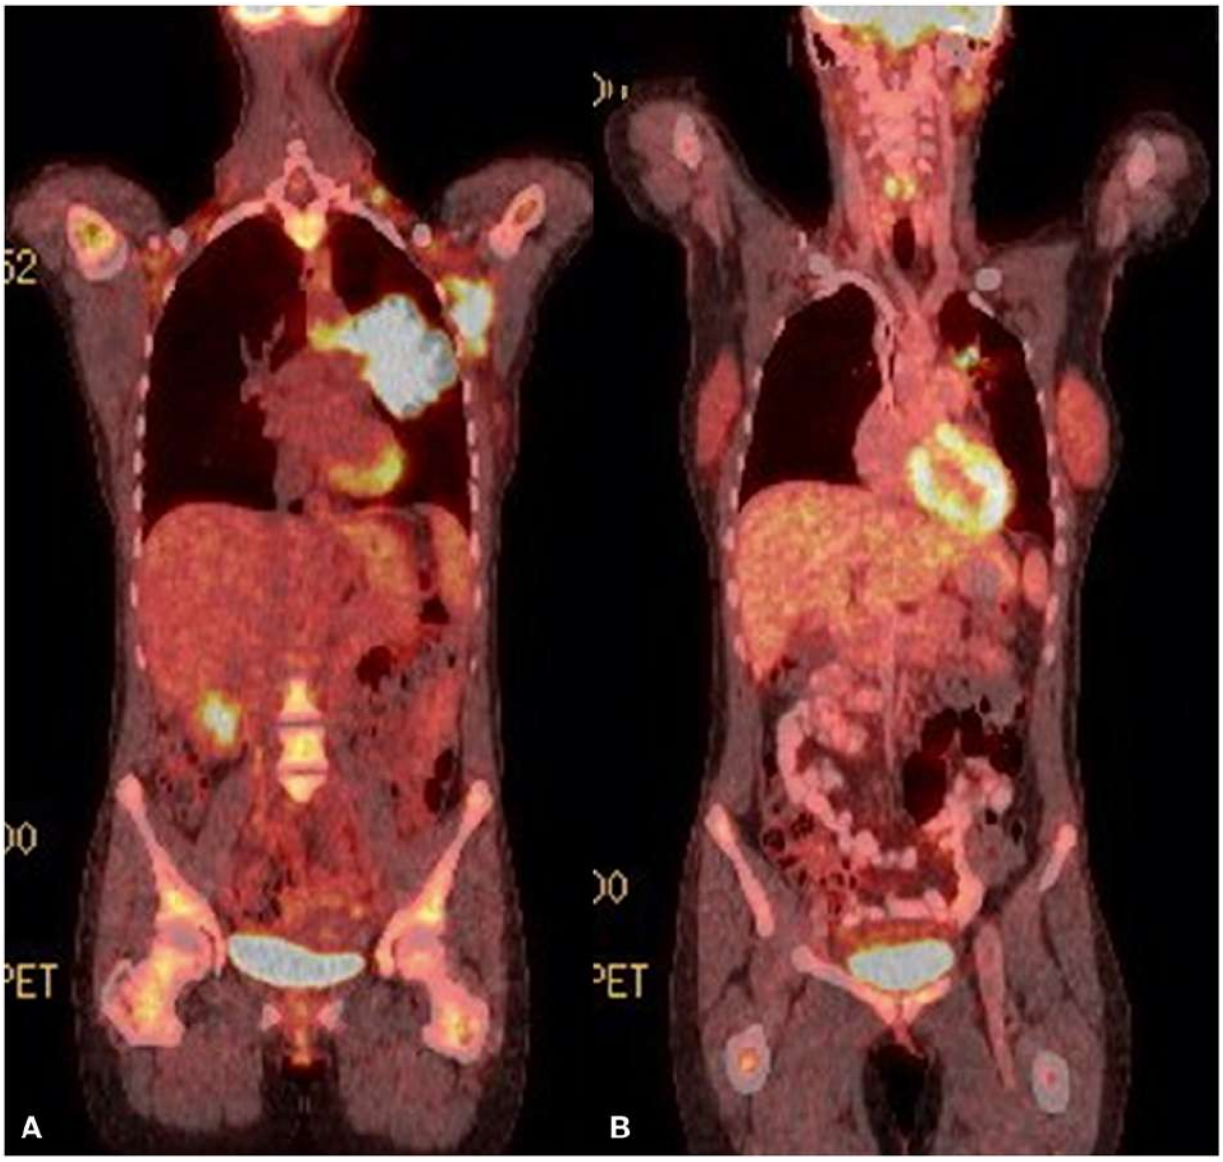

FIGURE 85.1 Fused coronal positron emission tomography-computed tomography (PET-CT) im ages of a patient with diffuse large B-cell lymphoma before (A) and after (B) chemoimmunotherapy. The postchemotherapy PET-CT was scored as a Deauville 4 (uptake above liver) in the left hilum. Biopsy confirmed persistent disease.

In advanced DLBCL, a dose of 20 to 30 Gy is appropriate in the setting of a CR to systemic therapy (Deauville 1-3). We prefer 20 Gy as patients with advanced DLBCL receive a full course of chemoimmunotherapy (six cycles) and are dependent upon an excellent response to such for low-dose

consolidation RT to be of effect. In patients who achieve a good, but not complete (Deauville 4), response to chemoimmunotherapy, with localized persistent FDG-avid disease, consolidation RT to higher doses (≥40 Gy) can be considered.[47]

In regard to field design, detailed guidelines from the ILROG are available.[100,101] These guidelines recommend treatment using "involved-site" principles. Involved-site radiation therapy (ISRT) involves creating a clinical target volume (CTV) that consists of the prechemotherapy extent of disease, adjusted to exclude uninvolved normal tissues after chemotherapy, and expanded to account for uncertainties in recreating the prechemotherapy extent of disease (anatomic changes, patient positioning differences between diagnostic PET-CT and planning CT scan, imaging uncertainties, etc) (Figure 85.2). A planning target volume (PTV) is then created to account for setup variation and potential organ motion.

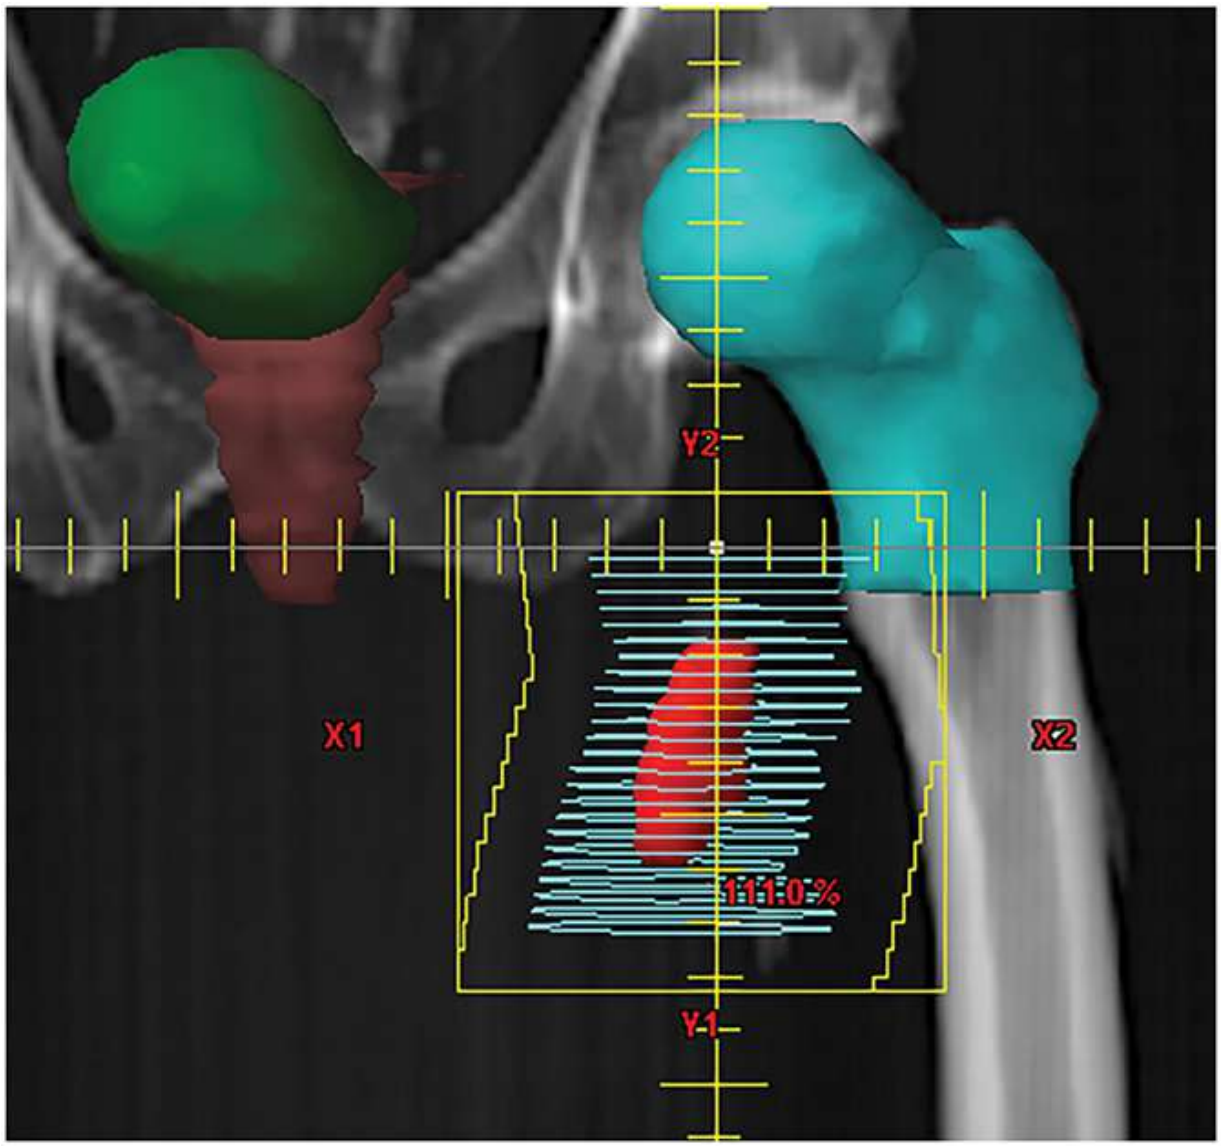

FIGURE 85.2 Stage I diffuse large B-cell lymphoma of the L inguinal region s/p three cycles of rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone followed by radiation therapy (30 Gy). The original extent of disease was recreated on the planning computed tomography scan (red structure). The clinical target volume is represented by the aqua contours.

Such recommendations are supported by prior studies, demonstrating that the dominant pattern of failure after combined modality therapy is usually disseminated disease, with a small percentage with local failure.[59] On the other hand, after chemotherapy alone, more local failure occurs.[59,102] Failure in nodal areas adjacent to the original disease is uncommon.

For patients with localized disease (stages I-II), all sites of original involvement should be treated. For patients with advanced disease (stages III-IV), treatment fields should be customized. In those with reasonably limited presentations, consolidation of all sites of original involvement can be considered. When this is not practical, treatment of select sites may be more prudent. This may include original sites of bulk, limited skeletal involvement, or a site that failed to achieve a CR to chemotherapy.

RT delivery techniques should be customized to the site being treated, proximity of critical normal organs, dose of RT being prescribed, and treatment intent. In many cases, three- dimensional conformal RT (3D-CRT) is appropriate. For example, if administering consolidation RT to a CTV within the axilla, anteroposterior/posteroanterior (AP/PA) fields using 3D-CRT techniques to avoid the lung is very reasonable. On the other hand, intensity-modulated RT (IMRT) may be selected to treat CTVs in close proximity to the parotid gland, heart, kidneys, or other critical structures (Figure 85.3). In some cases, protons, if available, may be advantageous over IMRT. Simpler techniques are often sufficient when treating in a palliative fashion. Radiation oncologists should choose the modality that provides clinically meaningful avoidance of critical surrounding structures to limit both acute and long-term toxicity.

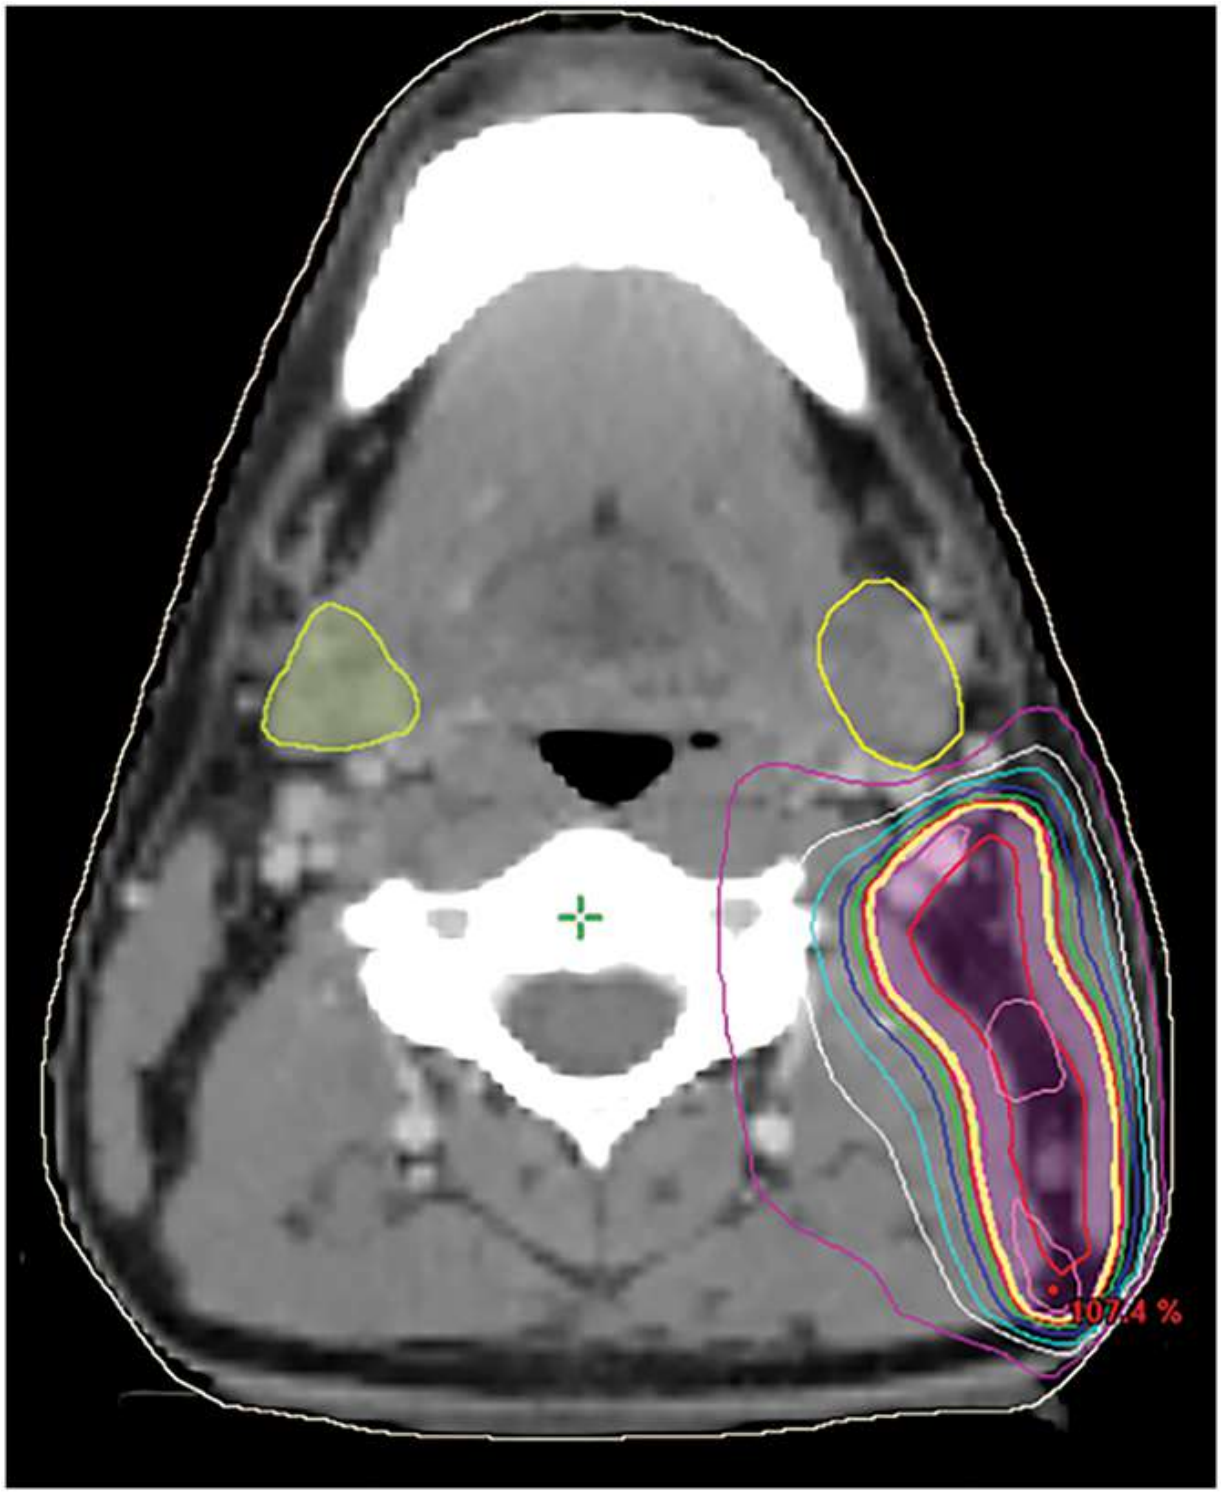

FIGURE 85.3 Stage I diffuse large B-cell lymphoma of the L neck s/p three cycles of rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone followed by radiation therapy (30 Gy). Note ability of intensity-modulate radiation therapy to avoid left submandibular gland (yellow contour).

HIGH-GRADE B-CELL LYMPHOMAS

HGBL is a distinct entity within both the WHO and the ICC classification systems and is closely related to DLBCL. HGBL NOS is an aggressive mature B-cell process, typically composed of intermediate-sized or blastoid cells, that does not fit into other well-defined entities, such as DLBCL. HGBL with *MYC* and *BCL2* and/or *BCL6* gene rearrangements, often referred to as "double-hit" or "triple-hit" lymphomas, can also contain large cells. Approximately 5% to 10% of patients with large B-cell lymphoma have double-hit or triple-hit genetics, which carries a particularly poor prognosis, despite the fact that the molecular subgroup is typically GCB like.[103]

These patients generally present with advanced disease with a high IPI score and are at higher risk of central nervous system (CNS) involvement. Given the higher risk of relapse in the setting of *MYC* and *BCL2/BCL6* gene rearrangements, more aggressive chemotherapy regimens are often utilized, such as DA-EPOCH-R.[104] R-CHOP may be suitable for patients presenting with early-stage disease with a low-risk IPI score. Regardless of which chemoimmunotherapy therapy is pursued, consolidation RT is recommended in patients with early-stage double-hit or triple-hit lymphoma.[105] R-CHOP is often recommended for HGBL NOS.

PRIMARY MEDIASTINAL (THYMIC) LARGE B-CELL LYMPHOMA

PMBCL comprises about 10% of all large cell lymphomas and is believed to arise from thymic medullary B cells. Although the histologic appearance can vary, compartmentalizing alveolar fibrosis is a common feature. PMBCL expresses pan B-cell antigens, including CD20, but is negative for surface immunoglobulin. CD30 is present in a majority of patients but stains weaker than classic HL.[106] PMBCL also has a unique molecular signature that closely resembles classic HL.[107] The disease affects primarily young women (median age 37) with prominent anterior mediastinal disease, generally with stage I and II presentations. When grouped according to the IPI, the prognosis is similar to that of DLBCL generally, perhaps a bit more favorable[108,109] with a plateau observed in the PFS curve after 18 to 24 months.[108]

PMBCL is typically managed with more intensive chemotherapy (DA-EPOCH-R) without RT, less commonly standard chemotherapy (R-CHOP), with or without consolidation RT (30 Gy).[110,111] Omission of RT with DA-EPOCH-R is primarily based on phase II[112] and retrospective data,[111,113] and more studies are needed. The failure of DA-EPOCH-R to improve outcomes compared with R-CHOP in DLBCL NOS should temper enthusiasm of this regimen in PMBCL until more data are available.[71] Preliminary results from a randomized trial (IELSG-37, NCT01599559) suggested that RT can be omitted in patients achieving a CR (Deauville 1-3) using more standard regimens such as R-CHOP.[114] In this study, PFS at 30 months was 96% with chemoimmunotherapy alone. Notably, only 50% of patients achieved a CR and were randomized to observation or RT. It should be noted that it is common for patients with PMBCL to have residual FDG uptake (Deauville 4) in the anterior mediastinum after completing chemotherapy. If the residual uptake is mild, albeit above liver background, observation with serial PET-CT studies is appropriate as most patients will not relapse, even without RT.[115] Thymic rebound may be explanatory. When consolidation RT is pursued, dose and field recommendations are the same as DLBCL NOS.

T-CELL/HISTIOCYTE-RICH LARGE B-CELL LYMPHOMA

T-cell/histiocyte-rich B-cell lymphoma consists of large malignant B cells with a florid background of inflammatory T cells, with or without histiocytes. Clinically, it occurs in a younger population compared with DLBCL, generally with a male predominance.[116,117] This entity is also more likely to present with B symptoms and involves the spleen, liver, and bone marrow. Treatment recommendations are similar to DLBCL NOS.

MEDIASTINAL GRAY ZONE LYMPHOMA

MGZL is a B-cell lymphoma with features that overlap classic HL and PMBCL. This disease typically affects young adults, generally with involvement of the anterior mediastinum. The histologic appearance and immunophenotype are aberrant. For example, cases that appear histologically to resemble classic HL may show strong CD20 and CD79a expression. On the other hand, cases that resemble PMBCL histologically

may lack B-cell antigens, such as CD20. MGZL generally exhibits an aggressive course with inferior outcomes compared with classic HL or PMBCL. Combined modality therapy is generally recommended, typically employing B-cell chemotherapy regimens such as R-CHOP or DA-EPOCH-R, with RT for patients with stage I and II presentations or bulky disease.[118]

PRIMARY TESTICULAR DLBCL

Included in the category of primary large B-cell lymphoma of immune-privileged sites, primary testicular DLBCL deserves special attention. Patients typically present with a painless testicular mass with the diagnosis established after orchiectomy. The majority (~80%) of patients have stage I or II disease. Even with chemotherapy, there is a high risk of failing in the contralateral testicle (~40%). Prophylactic scrotal irradiation significantly reduces this risk (<10%) and is associated with improved survival.[119] Patients are also at risk of CNS failure, most commonly in the brain parenchyma necessitating some form of CNS prophylaxis. An international phase II trial demonstrated good outcomes with R-CHOP chemotherapy, intrathecal methotrexate, and prophylactic scrotal irradiation with consolidation RT to regional lymph nodes in the setting of stage II disease.[120] A variety of RT techniques can be employed to treat the testicles (PMID 22836054). We utilize a single superior-anterior-oblique 6X photon field setup clinically using 1.5 cm of bolus. A dose of 26 to 30 Gy in conventional fractionation is recommended.

FOLLICULAR LYMPHOMA

FL is the second most common NHL in the United States and western Europe, comprising approximately 20% of cases. It is the most common “indolent” lymphoma.

Pathology

FL is a tumor of follicle center B cells (centrocytes and centroblasts) with a follicular (nodular) pattern that morphologically is similar to normal germinal centers. The neoplastic follicles may be present in the entire

tumor, or the lymphoma may contain a diffuse component as well. In the WHO classification, the number of large cells per high-power field is used to assign grades (0-5, 5-15, >15 for grades 1-3, respectively). Grade 3 is further subdivided into 3A and 3B, with the latter characterized by an absence of centrocytes and replacement by sheets of centroblasts. Grades 1, 2, and 3A FL are all closely related with similar biologic behavior and response to therapy. FL grade 3B, however, has a clinical course very similar to DLBCL and is usually managed as such.[121] Any area of DLBCL in an FL, irrespective of grade, suggests the disease is DLBCL and should be managed as such.

The tumor cells of FL are usually surface immunoglobulin positive, express pan B-cell–associated antigens (CD19, CD20), CD21, and CD10 (60% of the time), but lack CD5. Most cases are BCL-2 positive; nuclear BCL-6 is expressed by at least some of the neoplastic cells. The (14;18) translocation is characteristic for FL and, together with the *BCL-2* rearrangement, is present in approximately 85% of cases. It is frequently absent, however, in FL grade 3B, further supporting the biologic distinctiveness of this category.

Clinical Presentation

FL primarily affects older adults (median age 65 years). There is a slight female preponderance. Most patients present with painless peripheral lymphadenopathy involving cervical, axillary, or inguinal/femoral regions. There may often be a history of spontaneous waxing and waning of lymph node size. Constitutional B symptoms of fever, sweats, or weight loss are uncommon. In contrast to DLBCL, approximately 80% of patients present with generalized disease, most often with stage IV disease. The bone marrow is the principle extranodal organ involved.

In contrast to DLBCL, localized extranodal presentation of FL is uncommon, reported in only 6% of the International Lymphoma Study Group (ILSG) series.[122] A unique but uncommon variant of FL is extranodal presentation in the intestinal tract, usually the duodenum, usually stage I.[123] Duodenal FL, which generally arises in the second portion of the duodenum and is often not FDG avid, seems to have a lower propensity to fail at systemic sites after definitive local therapy.

The principle indicated imaging study is the PET-CT scan. Although FL is typically less FDG avid than DLBCL, increased uptake is still seen in about 90% to 95% of cases.[124] Bone marrow biopsy should be performed in all patients thought to have early-stage disease, given the high incidence of involvement. PET-CT is less accurate in detecting bone marrow involvement than in DLBCL. For patients with advanced disease, a bone marrow can be pursued if the results will change clinical management.

Large cell transformation to DLBCL occurs in approximately 30% of patients with FL at a rate of approximately 2% per year.[125] This should be suspected if LDH levels are rising, B symptoms develop, extranodal sites become involved, disproportionate growth occurs, or high SUVmax is observed (>10).[126] The prognosis after transformation is generally not good but better in the rituximab era, with a median survival of 50 months following transformation. The outlook is better with an increasing interval between FL diagnosis and the occurrence of transformation.

Prognostic Factors

Subsequent to the development of the widely used IPI for DLBCL, attempts were made to apply it to FL, but here it was less useful because most patients fell into a favorable prognostic category. Additional efforts to address this problem led to the development of the follicular lymphoma international prognostic index (FLIPI)[33] (Table 85.4). The initial database included 4,167 patients with FL diagnosed between the years 1985 and 1992 (the pre-rituximab era). Five adverse prognostic factors were identified on multivariate analysis, age (>60 vs <60 years), stage (I/II vs III/IV), hemoglobin level (<12 vs ≥12 g/dL), number of nodal areas (>4 vs ≤4), and elevated serum LDH. Low-risk patients had 0 to 1 adverse factors, intermediate risk 2 factors, and poor risk 3 or more. Patients were divided approximately equally between the three groups with good separation in terms of OS (Table 85.4).

The FLIPI was subsequently modified to take into account the advent of rituximab leading to the FLIPI-2 categorization.[34] That index identified age, elevated B2M, hemoglobin, bone marrow involvement, and lymph node diameter greater than 6 cm as independent risk factors for PFS (OS data not as yet available) (Table 85.4).

Recently, a third prognostic index is under development utilizing genetic risk factors as well and is known as the M7-FLIPI.[127] This model integrates the mutational status of seven genes known to be important in FL.

As with DLBCL, post-treatment PET-CT response appears to have prognostic significance.[128,129] Limited studies on interim PET scanning have suggested no benefit from this.[129,130]

Clinical Management

The majority of patients with FL present with advanced-stage disease. Advanced FL is still considered incurable despite advances in chemoimmunotherapy in the past several years, with resulting prolongation of both PFS and OS. For the minority (20%-25%) of patients who present with localized disease, local RT has curative potential.

Stage I to II Follicular Lymphoma

A large number of retrospective studies have shown a high rate of local disease control, greater than 90%, with approximately 50% of patients achieving long-term survival without relapse in early-stage FL. Selected series are shown in Table 85.6.

TABLE 85.6 RADIOTHERAPY FOR STAGE I/II FOLLICULAR LYMPHOMA

Study	Year	Number of Patients	Radiation Fields	Radiation Dose (Gy)	Failure-Free Survival % (10 y)	Overall Survival % (10 y)
Vaughan Hudson et al[131]	1996	208	NS	35	47	71-84[a]
Mac Manus and Hoppe[132]	1996	177	IF, EF, TNI	34-55	44	64

EF, extended field; IF, involved field; IN, involved nodal; NS, not specified; TNI, total nodal irradiation.

[a]Overall survival and cause-specific survival.

Several comments about the series listed in Table 85.6 are listed in the following in order:

1. Most of the studies shown are older, which gives them the advantage of long follow-up but the disadvantage of lack of modern staging, notably the absence of PET-CT studies. Further, most of the series included some patients with low-grade lymphoma histologies other than FL, although the great majority were FL.
2. The radiation doses used varied widely from 16 to 50 Gy, although most patients received in the neighborhood of 30 Gy. None of the series report detailed dose response data. In general, there appeared to be no dose response demonstrated, with greater than 90% local control with doses in the 30 Gy range.
3. The field sizes also varied considerably with somewhat different definitions than are now used. In brief, involved-field radiation, in which the nodal area in question was treated with a generous margin, appeared to be as effective as larger fields.
4. Ten-year PFS is remarkably close to 50% in all of the series. There was more variation in the OS, which generally ranged from about 60% to 80% depending on whether lymphoma-only deaths were counted or all deaths due to any cause. In general, the risk of a patient with stage I/II

FL treated with radiation alone *dying of lymphoma* at 10 years was approximately 20%.

5. As can be inferred by the high local control rate of approximately 90%, the great majority of relapses were at distant sites from the original disease, not adjacent nodal areas. This has led directly to the practice of irradiating only the involved nodal site with a generous margin. Importantly, few relapses were observed after 10 years with a general flattening of the PFS curve.

The largest series in the literature is the report from Pugh et al[137] The Surveillance, Epidemiology, and End Results (SEER) database forms the basis of this study. In all, 6,558 patients were identified from 1973 to 2004 with localized FL. Of these patients, 2,222 (34%) were treated with initial RT. No details as to radiation fields or dose are available. Compared with patients from the SEER database who received no RT, cause-specific survival was improved in the radiation group at 10 years from 65% to 79%. Survival at 10 years was 60% in the radiated patients and 50% in those not receiving RT.

A recent multi-institutional study from the ILROG addressed the issue of whether the results would be improved in patients with localized disease who underwent modern staging with PET-CT.[140] In all, 512 patients were included, all of whom were staged with PET-CT. The majority (80%) were stage I. Bone marrow biopsies were not done in about one-third of patients. Five-year OS and freedom from progression (FFP) were 96% and 69%, respectively. FFP was 74% for stage I and 49% for stage II. Local control was 97%, with 1.6% true in-field failures and 0.9% marginal recurrences. In the great majority of recurrences, these results suggest a better outcome for the treatment of localized disease when patients have been staged with contemporary techniques outside the radiation field. There was no effect of field size on the outcome, with comparable results achieved with either involved-field radiation therapy (IFRT), ISRT, or involved nodal RT (INRT), with some variation, however, in how these fields were defined. There were several predictors of a worse outcome, including BCL-2 expression and early relapse within 12 months of completion of treatment. FFP at 10 years was approximately 50%, similar to historical series. Compared to historical controls, these results suggest a better outcome for

the treatment of localized disease when patients have been staged with contemporary techniques but longer follow-up is needed.

On the basis of these studies, RT remains the standard of care for early-stage FL. Most of the patients in these series had stage I disease or contiguous stage II disease. For noncontiguous stage II disease, the data are sparse. Many centers individualize the treatment of such patients rather than automatically treating with RT.

Small series of patients with localized disease have been observed without treatment with apparently favorable results.[141] Experience with this approach, however, is quite limited. National consensus guidelines recommend RT as the standard approach for localized disease with observation reserved for selected patients in whom there might be a concern for the ability to tolerate RT.

Despite the abovementioned data and European Society for Medical Oncology[142] and other national consensus guidelines endorsing RT as the preferred initial management, the use of radiation in patients with early-stage FL continues to decline. In the Pugh study, only 24% of patients with localized disease received RT as initial treatment.[137] In the National LymphoCare study, 23% of patients with stage I FL received RT alone.[143] The remainder of the patients were treated in a variety of ways, including rituximab plus chemotherapy (30%), rituximab alone (13%), and observation (29%). OS at 5 years was approximately 90% in all treatment groups.

Adjuvant systemic therapy after definitive RT in early-stage FL has been investigated in an attempt to prolong PFS and ultimately OS. In the pre-rituximab era, four randomized trials (three of which included a small number of patients with FL as part of larger DLBCL trials) showed no benefit for adjuvant systemic therapy.[52,53,144,145]

A recent multicenter prospective phase III trial randomized 150 patients with limited-stage FL to RT alone or with the addition of systemic therapy (cyclophosphamide, vincristine, and prednisone [CVP] ₊/− rituximab [R-CVP]).[82] Of the 75 patients randomized to the latter, only 31 received rituximab with a benefit in PFS seen in this group only. No OS benefits were seen. Given the rapidly evolving area of innovative systemic agents,

this remains under active investigation, but outside of a clinical trial, this approach cannot be recommended.

For patients with localized FL treated with definitive RT (with or without adjuvant systemic therapy), the optimal surveillance approach is not well defined. In the asymptomatic patient with a negative physical examination, PET-CT at regular intervals will lead to early detection of recurrent disease. However, such recurrences are usually disseminated disease, generally considered incurable, with little suggestion of benefit for early initiation of therapy in the absence of symptoms. We recommend focusing subsequent imaging on the symptomatic patient or one with abnormal physical examination findings.

Stage III and IV Follicular Lymphoma

Advanced FL is still considered an incurable disease with survival curves that never become parallel to that of the corresponding normal population. The clinical course, however, is often prolonged with multiple effective therapeutic agents available. Because of the relatively indolent nature of advanced FL, a strategy of initial observation without therapy was introduced first at Stanford University.[146] It was later confirmed in randomized trials that this approach did not adversely affect long-term survival.[147] Note that these trials were performed in the pre-rituximab era. Nonetheless, the strategy of "watchful waiting" has gained widespread acceptance. The decision to pursue treatment is generally based on GELF criteria in which any one of the following may be an indication to begin active therapy: (1) three distinct nodal sites, each ≥3 cm; (2) a single nodal or extranodal site ≥7 cm; (3) splenomegaly; (4) organ compression or compromise; (5) pleural effusions or ascites; (6) B symptoms; (7) leukemia (>5 × 10^9/L malignant cells); or (8) cytopenias.[148]

A recent report from the National LymphoCare Study compared outcomes in 386 patients initially managed with observation, rituximab alone (296 patients), or rituximab combined with chemotherapy (1,072 patients).[149] OS rates were approximately 70% in all three groups.

One recent treatment algorithm divides patients with advanced-stage disease into four categories depending upon symptoms and tumor burden. For asymptomatic patients with a low tumor burden, the proposed

therapeutic strategies are either observation or treatment with single-agent rituximab, with observation being preferred. For asymptomatic patients with a high tumor burden, proposed therapeutic choices are observation or chemotherapy along with rituximab. For symptomatic patients with low tumor burden, treatment choices include single-agent rituximab or in combination with chemotherapy. For high tumor-burden symptomatic patients, the preferred strategy is rituximab-containing chemotherapy with maintenance rituximab. In this decision-making process, there is room for considerable individualization with consideration for the patient's age, comorbidities, predicted life expectancy, and general patient preference.[150] For select patients with generalized disease but with a problematic localized area of lymphoma, ultra-low-dose RT (4 Gy) constitutes very effective palliation with almost no toxicity.

The majority of patients for whom systemic therapy is desirable will receive rituximab in combination with chemotherapy. In the past two decades, the addition of rituximab to chemotherapy constitutes a major therapeutic advance. Its use has been associated with increased response rates, duration of response, and improvement in PFS at a minimum. One recent meta-analysis suggests a benefit in OS as well, although longer follow-up is needed.[151]

Multiple chemotherapy combinations have been studied in combination with rituximab, including CHOP, CVP, and fludarabine. In brief, no one drug program when combined with rituximab has demonstrated superior OS over another. Recently, however, the alkylating agent bendamustine has been introduced for the therapy of FL in combination with rituximab. A phase III trial from the Study Group Indolent Lymphoma compared bendamustine-rituximab (BR) to R-CHOP and demonstrated increased efficacy and reduced toxicity with the BR combination.[152] This improved efficacy was manifested by prolongation of PFS and improved response rates, but, as is so often the case with FL, no differences in survival were found. A second study, a randomized phase III noninferiority trial (BRIGHT study) indicated the equivalence of BR to R-CHOP or R-CVP with, however, somewhat different toxicity profiles.[153] Since the BR combination appears to be generally significantly less toxic, this has led to the rapid adaptation in North America of BR as first-line systemic therapy for patients with advanced-stage FL who require treatment.

Another novel strategy for first-line treatment has involved combining rituximab with the immunomodulatory agent lenalidomide. Among patients with previously untreated advanced FL, rituximab plus lenalidomide was as efficacious as rituximab plus chemotherapy in a randomized trial.[154] This regimen provides a chemotherapy-free treatment option for symptomatic patients with advanced FL.

The use of maintenance rituximab after chemoimmunotherapy has gained widespread acceptance following a large phase III intergroup trial (PRIMA study).[155] In this trial, patients with previously untreated FL who had responded to chemoimmunotherapy were randomly assigned 2 years of maintenance with rituximab or placebo. With short follow-up, the 2-year PFS in the rituximab maintenance arm was 75% compared with 58% in the observation arm. There was a slight increase in adverse events in the maintenance arm. There was no difference in OS. Thus, the benefit of rituximab maintenance is unclear but is being increasingly employed.

Treatment of Relapsed, Refractory, or Transformed Follicular Lymphoma

Patients who relapse after initial therapy of localized FL almost always have generalized disease, even if the area of relapse is ostensibly localized. These patients should be reevaluated in a similar manner to those who present with advanced disease, as has been already discussed. Similarly, patients who presented with advanced disease and relapse after initial therapy should be reevaluated in a similar manner as they were at the time of diagnosis. Are they symptomatic, what is the extent of the tumor burden, do they meet the GELF criteria for treatment, what is the goal of therapy, what are the patient preferences, and, finally, what is the patient's overall medical condition? Answers to these questions will guide the therapeutic choices.

At the time of relapse, biopsy of a new disease site is appropriate to rule out transformation to a more aggressive histology. Restaging is usually appropriate as well with the procedures mentioned earlier, including routine blood studies, LDH, B2M, and PET-CT scan. A bone marrow examination is less important in the presence of known generalized disease.

For patients relapsing with a limited extent of disease, low-dose palliative RT, to 4 Gy total, should be strongly considered. Such low doses have been found to be remarkably effective (see later). Side effects are minimal, with 1% grade III to IV toxicity. Unfortunately, low-dose palliative RT is often overlooked in the management of generalized disease.

For patients with generalized disease who do require systemic therapy, the choice of agents is greatly influenced by what prior therapy the patient has received. For example, if the initial systemic therapy was BR, it would be logical to proceed with R-CHOP or vice versa. A new anti-CD20 antibody, obinutuzumab, may be employed.[156] A number of other agents are also available for relapsed FL.

Finally, stem cell transplantation (SCT) has been extensively studied in FL, both autologous (ASCT) and allogeneic. In the only phase III trial to compare ASCT to conventional chemotherapy in relapsed FL, patients appeared to demonstrate a higher PFS and OS when treated with ASCT.[157] However, the procedure is not believed to be curative for relapsed disease, in contrast to the situation with DLBCL. Allogeneic transplantation may have curative potential, but its use has been hindered by the high treatment-related mortality of approximately 40% at 3 years for a full myeloablative transplant and a treatment-related mortality of up to 20% even for the reduced-intensity conditioning transplant, as well as the logistical difficulties of finding a matched donor. In a recent retrospective analysis, however, 3-year OS for allogeneic SCT versus ASCT was 87% versus 61%.[158] It should be noted that neither ASCT nor allogeneic SCT has any proven role in the initial treatment of generalized FL, such as consolidation therapy for patients in first remission.

Histologic transformation to DLBCL occurs in approximately 2% to 3% of patients per year and historically has been associated with a poor clinical outcome. The prognosis directly relates to the number of prior therapies the patient has received with a much poorer outlook in those with multiple prior therapies. Aggressive chemotherapy has most often been employed in this situation. In selected patients in a Canadian trial, treated after transformation by induction chemotherapy followed by high-dose chemotherapy and ASCT, a 5-year survival of 65% has been reported.[159]

Radiation Dose and Field Size

As can be seen from Table 85.6, the dose of RT employed in older retrospective studies varied widely from approximately 20 to 44 Gy, with local control being achieved in over 90% of patients irrespective of dose. Retrospective dose analyses reported from the Princess Margaret Hospital and the University of Florida suggested local control rates over 90% with doses in the range of 25 to 35 Gy at the Princess Margaret[160] and 30 Gy at the University of Florida.[161]

These discrepancies led to the performance of a large prospective trial by the British National Lymphoma Investigation comparing 24 to 40-45 Gy.[98] This is one of the few prospective phase III trials of different RT doses in any disease. In brief, no differences were observed in any measured outcome, either local control, PFS, or OS between the two different doses employed. This study made no mention of bulk of disease. Such patients appeared to have been included. There is no information as to whether their outcome was any different from those with small-volume disease.

This study has led to the widespread adoption of 24 to 30 Gy as the appropriate dose for curative treatment of FL and other so-called indolent lymphomas. Phase III data suggest 24 Gy is sufficient, but there is a large historical experience with 30 Gy and little increase in toxicity in many instances. Many centers would probably give 30 Gy for bulk disease (variably defined).

Even lower doses (4 Gy) have been found to be quite effective in the palliation of advanced FL. Response rates of 80% to 90% have been reported with a median duration of response ranging from 22 to 45 months.[162-164] These data have led some to propose the use of very low doses of 4 Gy as appropriate for curative treatment of limited-stage FL, leading to a randomized trial involving 548 patients who were prospectively allocated to receive either 4 or 24 Gy.[163] In 40% of these patients, the treatment was curative in intent, 60% palliative. PFS at 2 years was superior in both the curative and palliative cases for the 24 Gy dose. Thus, 24 to 30 Gy remains the standard dose for curative therapy of localized FL, with 4 Gy reserved for palliation of advanced disease. This issue is discussed further in the following section on MZL.

The choice of an appropriate radiation field size for localized FL is more complex. Prospective randomized trials addressing this issue do not exist. The field sizes used in the studies in the table were highly variable, with no suggestion of a different outcome related to field size. Almost none of the studies employed modern imaging techniques in either the initial diagnosis or subsequent therapy. CT-based 3D treatment planning was carried out in almost none of these studies. The only trial that looked at INRT or ISRT and compared it with larger fields was the Campbell trial from British Columbia.[138] This trial had a relatively large number of patients. No difference was observed in the treatment outcome depending on field size. Additional evidence for small fields derives from the patterns of failure in patients with limited-stage FL treated with RT alone. Most recurrence are at distant sites, either nodal, extranodal, or both, very seldom at adjacent nodal areas or within the radiation field.

Extensive guidelines for both radiation field size and target definition as well as radiation doses have been developed by the ILROG[101] (Figure 85.4). Most patients with FL will not have received preradiation systemic therapy, but for those who may have, the target volume is still the initial extent of disease prior to any therapeutic intervention. Modern imaging techniques should be used to define the extent of gross disease (gross tumor volume [GTV]), preferably a PET-CT scan. As stage I FL is generally treated with RT alone, the CTV will consist of the GTV plus lymph nodes in the immediate vicinity at risk of harboring microscopic disease (typically a 3-4 cm expansion along the lymph node chain). The CTV expansion is highly dependent on the clinical situation. For example, the margin may be reduced when the GTV is close to important normal organs or tissues. A final PTV margin will account for day-to-day setup variation.

FIGURE 85.4 Stage I follicular lymphoma of a right inguinal lymph node treated with radiation therapy alone using involved-site principles. The gross tumor volume is contoured in red. The clinical target volume (orange) includes the immediate area at risk of harboring microscopic disease. The planning target volume (purple) includes a small margin to account for daily setup error.

Most patients with localized FL have peripheral nodal areas involved, such as neck or inguinal-femoral regions. Often relatively simple field arrangements such as AP/PA will suffice, but 3D planning or IMRT should be considered depending on individual circumstances.

MARGINAL ZONE LYMPHOMAS

MZL accounts for approximately 8% to 10% of all cases of NHL. MZL entities traditionally included nodal MZL, splenic MZL, and extranodal MZL of MALT. Primary cutaneous MZL was recently added as a distinct entity by the WHO. The classification of pediatric MZL is uncertain and is considered by some to be a subset of pediatric FL. MALT is the most frequent MZL entity encountered in clinical practice and is the focus of the following section. A brief synopsis of the other varieties of MZL is also included (primary cutaneous MZL is reviewed in Chapters 86).

Pathology

MALT lymphoma is characterized by a polymorphous infiltrate of marginal zone (centrocyte-like) B cells, small lymphocytes, monocytoid B cells, and plasma cells, as well as rare large basophilic blast cells (centroblast or immunoblast like). In epithelial tissues, the marginal zone B cells typically infiltrate the epithelium, forming lymphoepithelial lesions defined by invasion and partial obstruction of mucosal glands by tumor cells.[165] Although transformed large cells are typically present, they are in the minority. If present in large numbers, a diagnosis of DLBCL is warranted.

The tumor cells express pan B-cell–associated antigens, including CD19, CD20, CD22, and CD79a, but there is no specific marker for MALT at present. However, lack of CD5 (positive in CLL/SLL and MCL), CD10 (positive in FL), and cyclin D1 (positive in MCL) expression helps distinguish MALT from other small B-cell lymphomas.[166]

Clinical Presentation

Two-thirds to three-fourths of patients have stage I or II diseases, usually stage I. The most common locations for MALT lymphoma are the stomach, orbit, and skin.[167] Other less common anatomic sites include the parotid, breast, thyroid, and lung. Involvement of paired organs simultaneously, or less commonly two distinct extranodal sites, is occasionally encountered. With such scenarios, it best to stage each site separately as opposed to making a stage IV designation. Such patients may be treated with local RT to both extranodal sites with long-term disease control.[168]

The most common site of MALT is the stomach. A unique feature of gastric MALT is the association with *H. pylori* infection. *H. pylori* can be identified in up to 92% of patients.[17] Lymphoid tissue is not normally present in the stomach, but in response to an antigenic stimulus brought about by *H. pylori*, normally present T cells in the gastric mucosa attract a B-cell population, giving rise to lymphoid follicles and, after prolonged antigenic stimulation, lymphomas.[169]

An association with bacterial infection for MALT at sites other than the stomach has been described.[170] *C. psittaci* has been found in some cases of ocular adnexal lymphoma. In addition, *B. burgdorferi* and *C. jejuni* have been associated with MZL arising in the skin and small intestine,

respectively.[170,171] There is a wide geographic variation of these associations, however, which have not generally been observed in cases in the United States. Accordingly, while there are some reports of antibiotic efficacy for MALT at sites other than the stomach, the standard initial treatment remains local RT with very high rates of CR and local control in excess of 90%, similar to what has been reported for gastric MALT.[172,173]

Patients with orbital MALT typically present with mass lesions in the bulbar or palpebral conjunctivae, described in the literature as "salmon pink" in color. Tumors of the retrobulbar region may present with swelling, proptosis, double vision, and/or other associated disturbances in function of the extraocular muscles. Bilaterality is not unusual, occurring in 10% to 15% of cases. Similar to salivary gland and skin tumors, this does not adversely affect prognosis.

Prognostic Factors

The primary prognostic factor is disease site. MALT arising in paired organs (eg, orbit or salivary gland) appears to have a higher risk of relapse compared with that arising in a single organ (eg, stomach or thyroid).[167,172,174] Relapse after RT for cutaneous MZL is also rather frequent.[175] Such relapses, however, are almost always distant from the initial RT field and usually amenable to a second course of RT.

Treatment of gastric MALT with antibiotics is a special consideration. Predictive factors associated with a lower chance of achieving and maintaining a CR after antibiotic therapy include deep gastric wall invasion,[176-178] nodal involvement,[178,179] and the translocation t(11;18).[18,180]

Clinical Management

First-line treatment for localized MZL should be RT, with the exception of *H. pylori*–positive gastric MALT lymphoma. MZL is extremely radiosensitive. CR rates approach 100%, with doses approximately 24 to 30 Gy.[174] Local failure is rare.[167] The overall prognosis of patients with localized MZL treated with RT is generally excellent, with more than 90% 5-year survival and more than 80% 10-year survival, although relapses occur in approximately 25% of patients.[167,173,174] Relapses seldom develop within nodal areas but rather at sites prone to MZL development. Many

such relapses are localized, often in the contralateral paired organ, and after appropriate treatment, often further RT alone, long-term survival is excellent.

For patients with gastric MALT lymphoma, antibiotic treatment is indicated in the presence of *H. pylori* infection. Eradication of *H. pylori* is near universal after antibiotics. A frequently recommended combination is omeprazole, metronidazole, and clarithromycin.[181] A CR is achieved in approximately 80% of patients, though this may take up to 2 years or longer to achieve.[18] As long as the lymphoma is regressing on serial endoscopy, a watch-and-wait policy is appropriate. The t(11;18) translocation, however, is predictive for failure to respond to antibiotics.

Of patients achieving a CR to antibiotics, less than 10% will relapse clinically. Some patients will be found to have microscopic foci of disease on random biopsies performed during upper endoscopy. Continued observation and monitoring is preferred for these patients as many will subsequently revert to a histologic CR.[18,182]

For patients who are *H. pylori* negative and who do not respond to or relapse clinically after antibiotics, the treatment of choice is RT. Long-term PFS and OS exceeds 90%.[174] Interestingly, the original B-cell clone is also detected frequently after RT for gastric MALT lymphoma but without an associated risk of relapse.[183]

Because of the efficacy of RT in controlling MZL locally with minimal side effects, there is little indication for surgical resection, with a few possible exceptions such as involvement of spleen (rituximab-refractory splenic MZL), small intestine, or lung. In particular surgical resection for gastric MALT, although often practiced historically, is to be avoided.

Radiation Dose and Field Design

Detailed radiation field and dose guidelines for extranodal lymphomas, including MALT, have recently been published.[100] For MALT lymphoma, particularly gastric MALT, local control rates of 95% to 100% are achieved with doses of approximately 24 to 30 Gy.[174,184] Similar results, although in smaller numbers, are available for MZL at sites other than the stomach.[172,185] A small number of patients with MALT were included in the randomized British National Lymphoma Investigation demonstrating similar clinical

outcomes with 24 Gy compared to 40-45 Gy.[98] With modern treatment techniques and doses of 24 to 30 Gy, long-term RT complications are very infrequent, with the exception of the eyes where post RT cataracts are common and some degree of dryness may result. Very modest doses of RT (2 Gy × 2) have been demonstrated to be effective palliation for FL and MZL, leading some centers to recommend a 4-Gy dose for curative treatment of orbital MZL.[186,187] Preliminary results are quite encouraging, but follow-up is short. A randomized British trial, however, comparing 24 versus 4 Gy for the treatment of indolent NHL demonstrated superior local control with the higher dose (~90% freedom from local progression at 5 years vs 70%).

Thus, in general, a dose of 24 Gy is recommended for localized MZL. A trial of 4 Gy may be appropriate for select patients with orbital disease (and possibly parotid presentations), given the risk of long-term side effects with 24 Gy. However, this response-adapted approach requires careful monitoring with ophthalmology, including surveillance imaging if appropriate for nonconjunctival presentations, with a plan for salvage therapy (typically a definitive course of RT) should the disease persist or progress after 4 Gy. This approach is not recommended for most other sites, given the limited risk of long-term toxicity.

For disease involving the palpebral and/or bulbar conjunctiva alone, a single en-face electron field is preferred. Given the multifocal nature of extranodal MZL, we prefer treatment of the entire conjunctiva, which is set up clinically with 1 cm of overlying bolus and treated using a 6-MeV beam prescribed to 90%. While some institutions utilize a hanging lens shield, at our institution, we have not pursued this, given the concern for shielding potential disease and the ease in which cataracts can be addressed. For disease confined to the lacrimal gland, a conformal IMRT plan is very reasonable. For patients with disease involving the posterior orbit, where the disease is often not well circumscribed, a wedged-pair photon beam arrangement treating the entire bony orbit is preferred.

For stage IE gastric MALT lymphoma, the entire stomach should be included in the CTV. Both 3D and IMRT can be utilized to minimize dose to the heart, liver, and kidneys. Clinicians must be mindful of several characteristics of the stomach that can make IMRT problematic. First, the shape and position of the stomach in the upper abdomen often changes from

day to day. The patient should fast for 3 to 4 hours before simulation and treatment. Daily cone-beam CTs with soft tissue matching can be helpful in some situations, but in others, the CTV from the planning CT scan simply cannot be matched to the stomach as visualized on the cone-beam CT due to these variations. Second, the stomach typically moves significantly during the respiratory cycle, necessitating some form of active respiratory management, ideally deep-inspiratory breath-hold, especially if IMRT is utilized.

One helpful 3D approach is to use a single isocenter, half-beam block technique with the isocenter position at the top of the kidneys. AP/PA (or slightly oblique) fields are utilized superiorly to treat the upper stomach (while avoiding almost all of the liver), with more oblique fields (sometimes very close to laterals) utilized inferiorly to avoid the posteriorly positioned kidneys. When treating the entire stomach, 1.5-Gy daily fractions with prophylactic antiemetics are helpful to minimize nausea.

For conjunctival MALT, a single en-face electron field provides appropriate coverage of the conjunctiva while minimizing the dose to the lacrimal gland and posterior globe. It is usually appropriate to treat the entire conjunctiva. A lens shield is occasionally used to prevent cataracts but may increase marginal misses. We generally do not use one. Well-circumscribed orbital lesions elsewhere can be managed with either a 3D or IMRT approach. Target volumes are somewhat controversial. Some authors suggest the entire orbit be treated to avoid marginal misses.[188,189] Depending on the size and location, partial orbit coverage may also be reasonable. With doses of 24 Gy, cataract formation is the principle risk, occurring in 20% to 30% of patients,[189] which, however, can be easily corrected surgically. Some dryness may result from inclusion in the field of a portion of the lacrimal gland and meibomian glands. These side effects are avoided with the lower dose of 4 Gy.

As mentioned, orbital MZL may involve both eyes at presentation. Under these circumstances, RT alone remains the treatment of choice, with careful attention to treatment planning and prescribed dose to minimize eye complications. For MALT lymphomas of the thyroid and parotid, treatment of the entire gland is generally advisable, given the multifocality of the disease.

In the unusual circumstance of disseminated MALT lymphoma, treatment generally follows the guidelines for advanced FL. Chemotherapy is palliative and reserved for patients with generalized disease who are symptomatic. MALT lymphomas also respond well to rituximab.[190] Asymptomatic individuals with generalized disease should be considered for observation, similar to patients with generalized FL, since the course is so often indolent. Patients with generalized disease with symptoms due to a localized tumor mass may be easily palliated with modest doses of RT (eg, 2 Gy × 2) to the mass in question. That approach is often superior to systemic chemotherapy. There is no established role for chemotherapy or rituximab in localized disease.

Splenic Marginal Zone Lymphoma

Splenic MZL is a rare subset of MZL constituting less than 10% of all MZL and less than 1% of all NHL. The diagnosis is often difficult since definitive tissue diagnosis requires splenectomy. It is often made by examination of bone marrow histology and correlation with clinical findings. Patients usually present with splenomegaly.[191-193] Almost all have stage IV disease, principally because of bone marrow or blood involvement. The disease is relatively indolent with three-quarters of patients alive at 5 years, but a more aggressive subset does exist. Observation is typically pursued for asymptomatic patients. When symptomatic, splenectomy and rituximab with or without chemotherapy are all options. There is virtually no literature regarding splenic irradiation, but it is a consideration in patients with symptomatic splenomegaly in whom splenectomy is contraindicated and/or does not respond to chemoimmunotherapy. Modest doses should be utilized (4-20 Gy) depending on clinical response. As with other varieties of MZL, an association with an infectious agent (HCV, in this case) has been reported, and clinical responses to antiviral treatment in seropositive patients have been observed.

Nodal Marginal Zone Lymphoma

This entity is rare as well, comprising about 10% of all MZL and less than 2% of all NHL. Patients generally present with disseminated lymphadenopathy. Bone marrow involvement is common, observed in

about one-third of patients. B symptoms are uncommon. The clinical course and outcome are similar to that of other indolent nodal lymphomas, in particular FL. In the uncommon event of localized nodal MZL, RT has curative potential, although clinical data are sparse. For localized disease, we recommend ISRT with doses of 24 to 30 Gy. As with FL, the FLIPI may distinguish patients with different outcomes. Also similar to FL, chemoimmunotherapy has not proven curative. Accordingly, some asymptomatic patients with disseminated disease may be observed without treatment. If HCV is demonstrated, however, antiviral therapy is appropriate and will result in tumor regression in most patients. Overall, 5-year survival ranges from 70% to 90%, higher for cause-specific survival. If systemic therapy is advisable, the choice of agents generally follows the recommendations for FL. Indeed, data for the response of MZL to chemotherapy almost always derive from the inclusion of such patients in a larger series of patients with FL. Patients with disseminated disease with a problematic local lesion may be very effectively palliated with ultra-low-dose RT (4 Gy).

MANTLE CELL LYMPHOMA

MCL was first distinguished in the 1980s by Weisenburger et al,[194] who described a type of FL in which there were wide mantles of malignant cells around apparently benign germinal centers. It was thought to represent a variant of FL and was classified under the Working Formulation as a low-grade lymphoma. Its behavior, however, is more characteristic of aggressive disease.

Pathology

MCL is a neoplasm of small- to medium-sized B cells with irregular nuclei that resemble the cleaved cells (centrocytes) of germinal centers. The morphologic pattern may be diffuse, nodular, a mantle zone, or some combination thereof.[195] Tumor cells are typically CD5 positive, CD23 negative, CD20 positive, and CD10 negative. A characteristic cytogenetic abnormality is t(11;14) involving the *BCL-1* gene and resulting in the overexpression of cyclin D1. The product of the cyclin D1 gene can be detected in paraffin-embedded tissue sections with the immunoperoxidase

technique and is useful in distinguishing MCL from other lymphoma variants.[196,197]

Immunophenotyping studies are useful in confirming malignancy (light-chain restriction) and in excluding other B-cell histologies, such as CLL ($CD5_+$, $CD23_+$, and $CD200_+$) and FLs ($CD10_+$).[166]

Clinical Presentation

MCL accounts for approximately 3% to 7% of patients with NHL, with approximately 70% of all cases in men.[198,199] The median age at diagnosis is 68 years. Stages I and II MCL are rare. Most cases of MCL present with an aggressive natural history. More than 75% of patients have stage III or IV disease at onset. IPI scores are high, with 23% of patients with a score of 4 or 5, 54% 2 or 3, and only 23% 0 or 1. In common with FL, the organ most likely to be involved is the bone marrow, which is positive in two-thirds of patients at the time of diagnosis. Gastrointestinal tract involvement is frequent as well.[200] CNS involvement is occasionally encountered, particularly in those with blastoid histology or elevated LDH.[201]

Prognostic Factors

Although originally classified among the low-grade/indolent lymphomas, the clinical course for MCL is unfavorable in the great majority of patients. The 5-year survival rate in the ILSG project was only 27%, with a PFS rate of 11%.[122] This PFS rate is, in fact, among the worst for virtually any type of lymphoma. The survival pattern of MCL resembles advanced FL in its response to therapy and PFS (ie, no plateauing of the PFS curve and thus no indication of cure), but DLBCL in its OS (ie, much shorter than FL).[202-205] A proportion of patients with MCL have a more indolent course, but identifying these patients prospectively can be challenging. They are usually asymptomatic with small-volume nodal disease.

TP53-mutated MCL is associated with inferior outcomes, and more aggressive regimens, in appropriate patients, are recommended. In addition to TP53, a simple prognostic scoring has continued utility: the MIPI or MCL IPI.[206] This index uses four parameters: age, performance status, LDH, and leukocyte count. The MIPI score allows discrimination into three

prognostic subgroups: low risk (MIPI ≤5.7), intermediate risk (MIPI >5.7 and ≤6.2), and high risk (MIPI >6.2). The MIPI score was created using the data from 455 patients with advanced-stage MCL treated within three clinical trials. The median survival was not reached in the low-risk group (5-year OS of 60%). The intermediate- and high-risk groups had a median OS of 51 and 29 months, respectively. The 5-year OS was approximately 40% and approximately 15% months in the intermediate- and high-risk groups, respectively. The MIPI has been prospectively validated, and multiple reports have shown consistent reliability of the MIPI prognostic scoring that has had independent significance over pathologic, molecular-based, and clinical/therapeutic predictors.[207,208] The Ki-67 index has also been combined with the MIPI to estimate prognosis in trials as a biologic MIPI.[209]

Clinical Management

Chemoimmunotherapy is the standard initial treatment for all stages of MCL. Rituximab is generally combined with chemotherapy regimens as it is CD20+. There is no standard treatment regimen for MCL. The choice of chemotherapy regimen is often guided by age and performance status. There are several options for both “aggressive” and “less aggressive” regimens. High-dose chemotherapy and ASCT are often pursued in patients who achieve a CR to initial therapy. Maintenance rituximab with or without ibrutinib is generally recommended.[210] Patients with MCL seldom achieve a cure.

Patients presenting with localized MCL (stage I or II) are rare. A small series from British Columbia suggested that RT was an integral treatment component in localized disease.[211] Of 26 patients reviewed, 17 received RT with or without chemotherapy and 9 patients received chemotherapy or were observed. RT was associated with improved PFS (68% vs 11%, P = .002). This finding was corroborated by the large National Cancer Database and SEER database analyses.[212,213] Thus, for early-stage disease, we recommend a combined modality approach.

RT should be considered in salvage settings of a localized relapse since MCL is radiosensitive and palliation can resolve symptoms even in patients who have received multiple lines of systemic therapy. RT is also very

effective for palliation for patients with advanced disease.[214] Modest doses (4-10 Gy) are typically sufficient in the palliative setting.

Radiation Dose and Field Design

For patients presenting with localized (stages I-II) disease, we recommend consolidation RT after chemoimmunotherapy. In the setting of a CR by PET-CT, a dose of 30 Gy is appropriate. Treatment of the original site of disease with a margin, following involved-site principles, is recommended.

PERIPHERAL T-CELL LYMPHOMAS

The PTCLs are the group most confusing to clinicians. The term *peripheral T-cell lymphoma* is often misinterpreted. It refers not to the anatomic distribution of the lymphomas but to their origin, from the so-called peripheral or mature T cells outside the thymus, as opposed to thymic (precursor) T lymphocytes. The T-cell and NK lymphomas collectively make up approximately 10% of all NHL.[215] Their frequency is quite different, however, by geographic locale, with a roughly 5% to 10% incidence of PTCL in North America compared with 15% to 20% in Asia.[216] They are a diverse group that includes nearly 30 distinct entities (Table 85.1).[1,2]

Pathology

PTCL NOS typically contains a mixture of small, medium, and/or large cells with many mitotic figures. The architectural pattern is diffuse. T-cell–associated antigens (CD2, CD3, CD4) are variably expressed, and oftentimes the T-cell antigens CD5 and CD7 are lost. A CD4+/CD8− phenotype is typical in nodal cases. B-cell–associated antigens are lacking. The T-cell receptor (*TCR*) genes are usually, but not always, rearranged. TCR β-chain is typically expressed distinguishing PTCL from NK cell lymphomas and γ-Δ T-cell lymphomas.

A special variant of PTCL is anaplastic large cell lymphoma (ALCL).[217,218] In the ILSG project, this comprised 2% of all NHL.[219] The tumor is usually composed of large cells with round, pleomorphic, or horseshoe-shaped nuclei with single or multiple prominent nucleoli and

abundant cytoplasm, giving the cells an epithelial or histiocyte-like appearance. The cells express CD30 (Ki-1) and usually express CD25 and either T-cell or null lineage–specific antigens.[218] CD30 was originally recognized on HL cells. In some cases, there may be confusion between ALCL and HL, but distinction between the two on the basis of immunophenotyping and morphology is usually possible.

The WHO recognizes two distinct entities anaplastic lymphoma kinase (ALK)-positive ALCL and ALK-negative ALCL, with the former characterized by overexpression of ALK-1 protein, typically from a chromosomal translocation [t(2:5)].[220] Approximately 60% of cases overexpress the ALK protein; such cases have a better prognosis than ALK-negative cases (except primary cutaneous ALCL, which is invariably ALK negative but has an excellent prognosis).

Extranodal NK/T-cell lymphomas are characterized by a diffuse lymphomatous infiltrate with an angiocentric pattern. The cells are variable in morphology and can be of any size. Necrosis is common and attributed to vascular obstruction by lymphoma cells, though chemokines and cytokines may also be contributory. CD56, though not specific for NK cells, is generally expressed with extranodal NK/T-cell lymphoma. Cytotoxic molecules including granzyme B and perforin are also positive. EBV analyses, preferably in situ hybridization, are mandatory and should be positive. No specific translocations have been observed for this disease.

Clinical Presentation

The most common T-cell lymphoma in North America is PTCL NOS, accounting for about one-third of cases (vs ~20% in Asia).[221] The median age at diagnosis is 62 years. Both nodal and extranodal diseases are common in a similar manner to B-cell lymphoma. In contrast to DLBCL, however, the great majority of patients (~70%) have stage III or IV disease at diagnosis, and overall, the outlook is considerably worse. The International T-Cell Lymphoma Project reported 10-year survival in the range of 20%.[221]

ALCL consists of both a systemic malignancy, typically presenting with widespread involvement of lymph nodes and extranodal sites, and a type limited to the skin (primary cutaneous ALCL).[218,222-226] The systemic type

may in turn be separated into those patients who are ALK positive and those who do not overexpress this protein. The clinical features and prognosis differ widely among these two categories. Patients with ALK-positive ALCL are predominantly young men and, despite advanced-stage disease, respond well to combination chemotherapy with 10-year survival rates of approximately 70%.[220] ALCL in children/young adults is usually ALK positive.[211] Patients who are ALK negative, in contrast, tend to be older, with a more nearly equal male/female ratio and a long-term OS of approximately 20%.

Cutaneous ALCL constitutes a special situation.[222] It is almost invariably ALK negative but carries an excellent prognosis. It is often difficult to distinguish from benign lymphomatoid papulosis. The latter may spontaneously remit and tends to run a benign clinical course over many years. ALCL of the skin is quite responsive and highly curable with localized RT[227] (see Chapters 86). Chemotherapy generally has no role.

Extranodal NK/T-cell lymphoma is a T-cell lymphoma of special interest. It is much more frequent in Asia (about 22% of T-cell lymphomas) than in the United States and associated with EBV.[228] There is a male-to-female ratio of 2:1. In contrast to most lymphomas, tissue destruction of the nasal, paranasal sinuses, and/or facial area is common. Patients can also present with epistaxis and nasal obstruction. Lymph nodes may also be involved. Extranodal sites outside the head and neck region may be manifest, with or without nasal involvement. The International Peripheral T-Cell Lymphoma Project reported superior OS in nasal type (5-year OS 42% with an apparent plateau) compared to extranasal cases (5-year OS 9%).[221] The response to chemotherapy and RT is variable and slow, in contrast to the usual rapid response observed in most other lymphomas. The disease appears to progress primarily locally with only a small predilection for regional or systemic failure.[229]

A unique entity in the WHO classification is breast implant– associated ALCL. It is thought to develop in the setting of chronic inflammation induced by textured surface implants and often presents as an accumulation of fluid between the implant and the fibrous capsule. Given the rarity and recent identification of this presentation, the optimal management remains largely unknown, though capsulectomy removal of the breast implant and removal of any disease mass appear to be essential.[230] Surgery alone may be

sufficient for those with disease confined within the fibrous capsule.[231] Adjuvant RT to the breast may be appropriate after incomplete resection.

Prognostic Factors

Two prognostic scores are commonly utilized for PTCL NOS—the IPI and the prognostic index for PTCL-unspecified (PIT). The IPI, primarily utilized for DLBCL, has also been shown to be prognostic in PTCL. The PIT identified four factors on multivariate analysis including three that are also contained in the IPI: age 60 years or above, elevated LDH, and ECOG performance 2 or higher. The novel factor was bone marrow involvement.[232] Using this prognostic model, patients with no adverse factors had a 5-year OS rate of approximately 63%. Patients with 1, 2, or 3 to 4 of the adverse prognostic factors had 5-year OS rates of approximately 53%, 33%, and 18%, respectively. Patients with stages I to II disease, although quite uncommon, also appear to have a more favorable prognosis.[233]

In ALCL, the prognosis can vary considerably. Several studies have shown that survival is significantly better with ALK-positive ALCL compared with ALK-negative ALCL.[220,234-236] The International Peripheral T-cell Lymphoma Project demonstrated that ALK-positive ALCL has the most favorable prognosis among all T and NK histologies, followed by ALK-negative ALCL.[221] The heterogeneity and complexity of ALCL well illustrate past difficulties of attempting to group lymphomas in categories of low grade, intermediate, and high grade; indolent or aggressive; and favorable or unfavorable, on the basis of histologic appearance alone, since all ALCL appears aggressive histologically. There remains some uncertainty on whether ALK expression is independently prognostic or simply correlates with other favorable factors (eg, young age). IPI score has also been found to be a predictor of outcome in patients with ALCL. Other factors that have been found prognostic for OS and predictive of inferior outcomes include an elevated B2M and older age (≥40 years).[234]

For extranodal NK/T-cell lymphomas, age 60 years or above, stages III to IV disease, distant lymph node involvement, and non–nasal-type disease have been identified as unfavorable prognostic factors. There are several prognostic models that have been used. The Prognostic Index of Natural Killer Lymphoma (PINK) stratifies patients into low-, intermediate-, and

high-risk cohorts with 0, 1, or 2 or higher risk factors.[237] In an analysis of 527 patients, the low-, intermediate-, and high-risk groups had a 3-year OS of 81%, 62%, and 25%, respectively. Detectable EBV DNA in the circulating blood at diagnosis also appeared to be a negative prognostic factor for OS in the subset of patients who had EBV DNA data. The EBV DNA data are incorporated into the PINK-E prognostic scoring system.

Clinical Management

For PTCL NOS and ALCL, CHOP is probably the most commonly employed regimen in the United States. For younger patients, the addition of etoposide (CHOEP) can be considered.[238] Since this is a T-cell lymphoma, there is no role for rituximab. For the minority of patients who present with stages I to II PTCL[239,240] or ALCL,[241] consolidation RT after chemotherapy is recommended. Three-year PFS and OS were 50% and 33% in early-stage PTCL NOS with combined modality therapy versus 23% and 15% with chemotherapy alone, in one small series.[240]

The optimal treatment of localized NK/T-cell lymphoma, nasal type is not established. Treatment approaches have consisted of RT alone, chemotherapy alone, and the two combined.

The contribution of chemotherapy to the management of NK/T-cell lymphoma is unclear. When treated initially with CHOP-like regimens, CR occurs in only a minority of patients,[242-245] in contrast to the results seen with most other lymphomas. Japanese and Korean investigators have reported the use of concurrent chemotherapy and radiation with encouraging results.[246,247] The Japanese Clinical Oncology Group study (JCOB0211) used concurrent chemoradiation therapy that consisted of dexamethasone, etoposide, carboplatin, and ifosfamide with a dose of 50 Gy of RT. The CR rate was 77% and the 2-year survival was 78% compared with historical controls of 45%.[241] In an updated analysis, the 5-year PFS and OS were 67% and 73%, respectively.[248] The Korean series employed concurrent cisplatin and RT (40-50 Gy), followed by three cycles of cisplatin, dexamethasone, ifosfamide, and etoposide. The CR rate was 83%, and the 3-year survival was 86%.[247] In both series, the number of patients was small (33 and 30 patients, respectively), but the results were quite promising and worthy of further study.

Combined modality therapy options include not only concurrent chemoradiation but also sequential and sandwich approaches. There are a variety of sequential chemoradiation regimens using pegaspargase, which can be considered (eg, dexamethasone, methotrexate, ifosfamide, L-asparaginase, etoposide, and gemcitabine, dexamethasone, cisplatin). There are no data, particularly from the United States, to recommend one regimen over another at this point.

In a cohort of 240 patients with early-stage extranodal NK/T-cell lymphoma from the China Lymphoma Collaborative Group, the addition of RT to chemotherapy significantly improved OS, disease-free survival (DFS), and local-regional control (LRC), even after achieving a CR after asparaginase-containing chemotherapy.[249] The 5-year OS, DFS, and LRC rates were 85%, 76%, and 85% for RT and chemotherapy, compared to 59%, 44% and 62%, respectively, for chemotherapy alone. In patients with stages I to II disease in the United States, the omission of RT or the use of a suboptimal RT dose has been found to be associated with a worse OS.[250]

In stage III or IV extranodal NK/T-cell lymphoma, nasal type, chemotherapy with or without RT is the primary treatment. Non–anthracycline-based regimens have also been shown in retrospective analyses to have a survival benefit compared to anthracycline-based regimens.[251] In a retrospective study, consolidative RT was found to improve survival among patients with stage III or IV disease who exhibit complete or partial remission after initial chemotherapy.[252] Relapsed and refractory disease management is informed by prior therapy and can include salvage chemotherapy regimens, immunotherapy, reirradiation, and hematopoietic SCT.

Radiation Therapy Dose and Field Design

Doses and field sizes of RT for PTCL NOS and ALCL should approximate those for DLBCL. For extranodal NK/T-cell lymphomas, nasal type, higher doses of RT are generally employed. It has been found that radiation dose and target volume are associated with LRC and OS. For patients with early-stage disease receiving RT, higher doses of RT (≥50 Gy) were associated with significantly better 5-year LRC (85% vs 73%), PFS (61% vs 50%), and OS (70% vs 58%) than lower doses of RT (<50 Gy).[253] With RT alone

as primary treatment, the recommended tumor dose is 50 to 56 Gy. When RT is given with concurrent or sequential chemotherapy, doses of 45 to 56 Gy can be considered due to radiosensitization and/or cytoreduction. In palliative settings, doses of 20 to 36 Gy seem reasonable.

Physical examination and endoscopic examination should be considered in defining radiation target volumes of lesions in aerodigestive tract sites and particularly in lesions that cannot be identified well on imaging. Basic involved-site principles apply for extranodal NK/T-cell lymphomas. However, the CTV may be larger than other more chemosensitive lymphomas due to both the uncertain effect of chemotherapy and the submucosal infiltration of the tumor that is beyond the apparent initial macroscopic disease. The CTV is also dependent on the location of primary tumor, involved lymph nodes, and the pattern of microscopic spread. The value of prophylactic cervical lymph node RT is controversial. IMRT is often, but not always, required, given the proximity of the tumor to critical structures such as the optic apparatus, parotid glands, and brain and brainstem (Figure 85.5). The relevant critical structures are determined mainly by the location of the primary disease.

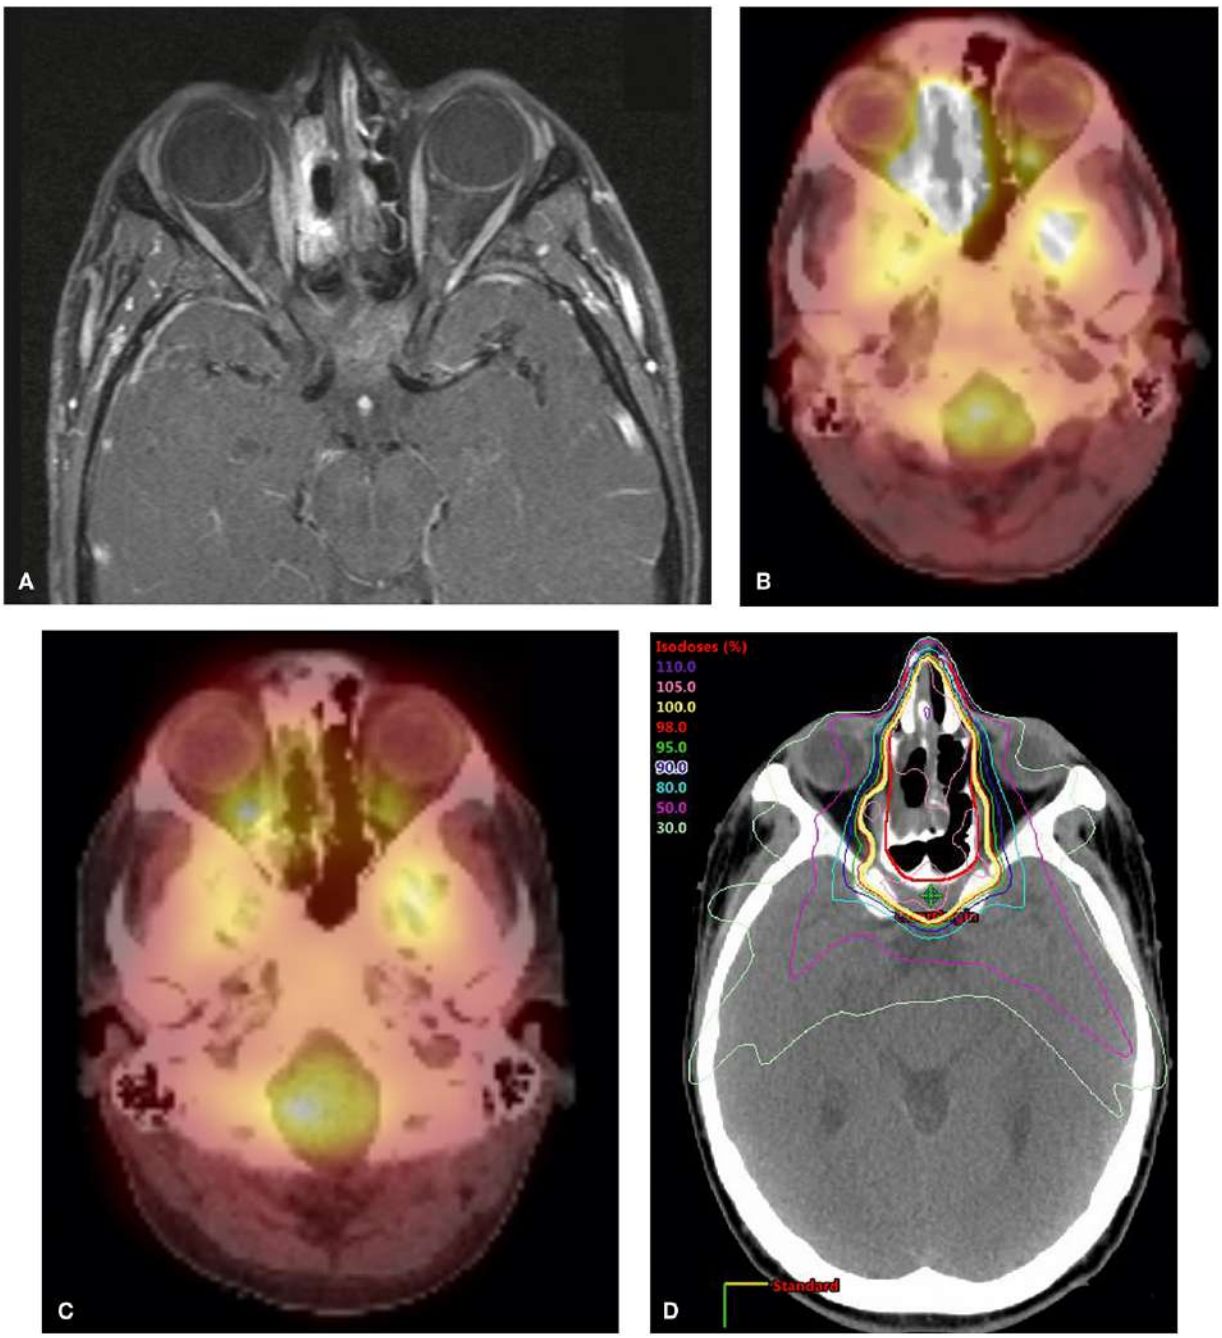

FIGURE 85.5 IE natural killer/T-cell lymphoma of the left nasal cavity and ethmoid sinuses on magnetic resonance imaging (A) and positron emission tomography-computed tomography (PET-CT) (B). The patient achieved a complete response (C) by PET-CT (Deauville 2) after dexamethasone, methotrexate, ifosfamide, pegaspargase, etoposide chemotherapy. He then received consolidation radiation therapy (D) to 50 Gy. The clinical target volume (red contour) included bilateral nasal cavities and ethmoid sinuses.

In general, adhering to published protocols, in relation to both dose and field, is prudent, given the rarity of this disease. More detailed

recommendations have been published by the ILROG.[100]

LYMPHOID PROLIFERATIONS AND LYMPHOMAS ASSOCIATED WITH IMMUNE DEFICIENCY AND DYSREGULATION

The number and success of solid organ transplants have increased substantially over the past several decades. Unfortunately, with long-term immunosuppression, post-transplant lymphoproliferative disorders (PTLDs) are being increasingly diagnosed. The WHO currently describes four distinct entities under the category "Lymphoid proliferations and lymphomas associated with immune deficiency and dysregulation" depending upon the pathologic findings and underlying disease. For simplicity, we refer to them collectively as PTLD.

EBV is implicated in the majority of cases (50%-80%), especially if PTLD occurs within 2 years of transplantation. During the diagnostic workup, infection with lymphoplasmacytic infiltrations, graft rejection, graft-versus-host disease, and/or recurrence from a previous lymphoma should be ruled out.

The prognosis of PTLD is poor compared to immunocompetent counterparts with similar histologies. Five-year OS ranges from 40% to 60%. The IPI can be used in patients with PTLD to predict outcomes. Other various prognostic indices have been developed as well but ultimately are fraught with validation inconsistencies. Still, older age, advanced disease, poor Karnofsky Performance Status, elevated LDH, and CNS involvement are consistently associated with inferior outcomes.[254]

Management can be variable depending on clinical presentation and pathology. In solid organ PTLD, reduction of immunosuppression should be considered, which can lead to responses in about 10% of people within a matter of weeks. Caution should be taken to prevent graft rejection or graft-versus-host disease. If no response is achieved with immunosuppression reduction, rituximab can be considered for $CD20_+$ PTLDs. Overall response rates are approximately 40%, and CR rates can be almost 30%, with little risk of treatment-related mortality.[255] Chemotherapy can also provide good responses but is associated with increased toxicity. A phase II study demonstrated that the combination of rituximab and CHOP is an effective,

with up to a 90% response rate and a 68% CR rate.[256] Mortality from chemotherapy remains a significant risk in PTLD.[256,257]

Radiation is reserved for localized disease (consolidation after chemotherapy or as a definitive modality) or in palliative situations. Involved-site radiation principles with appropriate doses depending on the underlying histology are recommended.

CHAPTER 86

Primary Cutaneous Lymphomas

Tarsheen K. Sethi, Youn H. Kim, Lynn D. Wilson, and Richard T. Hoppe

Primary cutaneous lymphoma is defined as an accumulation of malignant lymphoid cells in the skin without evidence of extracutaneous disease at the time of diagnosis. The distinction between a primary cutaneous lymphoma and a nodal lymphoma with secondary cutaneous involvement is important and markedly impacts evaluation, staging, prognosis, and therapeutic management. The term *primary cutaneous lymphoma* encompasses a heterogeneous group of extranodal non-Hodgkin lymphomas, and in 2005, the World Health Organization (WHO) and European Organisation for Research and Treatment of Cancer (EORTC) endorsed a consensus classification system that defines three categories of primary cutaneous lymphomas: cutaneous T-cell (CTCL) and natural killer (NK) cell lymphomas, cutaneous B-cell lymphomas, and precursor hematologic neoplasms/immature hematologic malignancies (Table 86.1).[1] This chapter reviews the primary cutaneous lymphomas in the context of this consensus system. A slightly modified classification system was updated by the WHO in 2022.[2]

TABLE 86.1 WHO-EORTC CLASSIFICATION

Cutaneous T-cell and NK/T-cell lymphomas
Mycosis fungoides and variants (folliculotropic mycosis fungoides, pagetoid reticulosis, and granulomatous slack skin)
Sézary syndrome
$CD30^+$ lymphoproliferative disorders (primary cutaneous anaplastic large cell lymphoma and lymphomatoid papulosis)
Extranodal NK/T-cell lymphoma, nasal type
Subcutaneous panniculitis-like T-cell lymphoma
Primary cutaneous peripheral T-cell lymphoma, unspecified
Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma (provisional)

Primary cutaneous γ/Δ T-cell lymphoma
Primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-lymphoproliferative disorder (provisional)
Cutaneous B-cell lymphomas
Primary cutaneous marginal zone lymphoma
Primary cutaneous follicle center lymphoma
Primary cutaneous diffuse large B-cell lymphoma, leg type
Primary cutaneous diffuse large B-cell lymphoma, other
Precursor hematologic neoplasm
$CD4^+/CD56^+$ hematodermic neoplasm (blastic NK cell lymphoma)

EORTC, European Organisation for Research and Treatment of Cancer; WHO, World Health Organization.

Adapted from Willemze R, Jaffe ES, Burg G, et al. WHO-EORTC classification for cutaneous lymphomas. *Blood*. 2005;105(10):3768-3785. Copyright © 2005 American Society of Hematology. With permission.

CUTANEOUS T-CELL AND NK CELL LYMPHOMAS

CTCL is the most common primary cutaneous lymphoma. In the United States, 71% of the 3,884 cases of primary cutaneous lymphoma diagnosed during 2001 to 2005 were CTCLs.[3] Similarly, 78% of primary cutaneous lymphoma diagnoses recorded in the Dutch and Austrian Cutaneous Lymphoma Group registry over 1986 to 2002[1] and 85% of diagnoses in the Central Cutaneous Lymphoma Registry of the German Society of Dermatology over 1999 to 2004 were CTCLs.[4]

CTCL subtypes include mycosis fungoides (MF); $CD30^+$ lymphoproliferative disorders; extranodal NK/T-cell lymphoma, nasal type; subcutaneous panniculitis-like T-cell lymphoma; adult T-cell leukemia/lymphoma; and primary cutaneous peripheral T-cell lymphomas. MF is the most common CTCL, responsible for 54% of CTCL diagnoses in the United States over 2001 to 2005.[3] $CD30^+$ T-cell lymphoproliferative disorders and cutaneous peripheral T-cell lymphomas represent the majority of the remaining cases of CTCL. The remaining CTCL subtypes are extremely rare and represent <1% of primary cutaneous lymphomas.

Mycosis Fungoides

MF is the archetype cutaneous lymphoma. The first case of MF was reported in 1806 by the French dermatologist Jean-Louis-Marc Alibert in his atlas of dermatoses, *Descriptions des maladies de la peau* (Figure 86.1). After Alibert released his depiction of MF, approximately 300 similar cases were reported over the next decade, and in modern times, approximately 1,500 new cases of MF were diagnosed during 2001 to 2005.[3] MF is a disease of skin-homing $CD4^+$ T-helper cells[5] and is more commonly diagnosed in men (male/female ratio of 1.6-2.0:1), with a median age at diagnosis of 55 to 60.[1] Significant advances in MF therapy have been made over the past 200 years, but the precise etiology responsible for the development of MF remains elusive.

FIGURE 86.1 Pian fungoide, from Jean-Louis-Marc Alibert's atlas of dermatoses, *Descriptions des Maladies de la Peau*.

Cutaneous Disease

Pruritus, either diffuse or localized to areas of involved skin, is the most common symptom associated with MF. Ulcerated lesions may also cause patients significant pain. Cutaneous lesions in classic (or Alibert-Bazin) MF follow a predictable evolutionary course, and a consensus statement from the International Society for Cutaneous Lymphomas (ISCL), U.S. Cutaneous Lymphoma Consortium (USCLC), and EORTC defines the lesions found in distinct phases of MF.[6] In the *premycotic phase*, a small number of red, scaled, macular or patch-like lesions develop in sun-shielded

areas of the skin, such as the trunk, pelvis, and extremities. These early lesions are unstable and usually regress, followed by the development of new lesions. Biopsies of premycotic lesions are rarely diagnostic due to a paucity of malignant lymphocytes in the lesion. With an increased deposition of malignant T cells in the skin, the lesions become increasingly durable, and persistent cutaneous patches are characteristic of the *patch phase*. The ISCL/USCLC/EORTC consensus definition of an MF patch is "any size lesion without induration or significant elevation above the surrounding uninvolved skin: poikiloderma may be present."[6] As the lesions become more densely infiltrated by both malignant and reactive lymphocytes, they evolve into plaques with thickened and raised borders in the *plaque phase* of classic MF. Plaques are defined by the ISCL/USCLC/EORTC as "any size lesion that is elevated or indurated: crusting or poikiloderma may be present."[6] Plaques may evolve into cutaneous tumors, which the ISCL/USCLC/EORTC defines as "any solid or nodular lesion ≥1 cm in diameter with evidence of deep infiltration in the skin and/or vertical growth." The presence of cutaneous tumors designates the tumor phase of MF. MF may also progress to or present with erythroderma, in which a diffuse erythema involves >80% of the skin surface area.[6] Representative images of patches, plaques, tumors, and erythroderma are shown in Figure 86.2.

Diagnosis, staging, and prognosis. *Oncology (Williston Park)*. 2003;17[9]:1281-1288; permission conveyed through Copyright Clearance Center.)

Leukemic Cutaneous T-Cell Lymphoma and the Sézary Syndrome

In rare CTCL cases, circulating malignant T cells are identified in the peripheral blood. This phenomenon, sometimes referred to as leukemic CTCL or the Sézary syndrome (SS), most commonly occurs in association with erythroderma but may occur in patients with minimal cutaneous disease.[1] The circulating malignant T cells (also called Sézary cells) are atypical T cells with hyperconvoluted nuclei seen at the analysis of peripheral buffy coat smear. The circulating atypical T cells most commonly possess a $CD4^+/CD7^-$ or $CD4^+/CD26^-$ immunophenotype, and flow cytometry allows for quantification of the proportion of circulating malignant T cells. In addition, the presence of a dominant circulating malignant clone may be demonstrated by evaluation of the T-cell receptor

(TCR) by polymerase chain reaction (PCR) or next-generation sequencing (NGS). The degree of tumor burden in the peripheral blood is denoted as B0 (atypical T cells <250 Sézary cells/mm^3 by flow cytometry), B1 (atypical T cells >250 Sézary cells/mm^3 but not meeting B2 criteria), or B2 (combination of the presence of a dominant T-cell clone in the peripheral blood identified by routine PCR or TCR NGS and ≥1,000 Sézary cells/mm^3).[7] If peripheral blood is evaluated for a circulating clone by PCR or Southern blot, B0 or B1 disease may be stratified into B0a or B1a (absence of circulating clone) or B0b or B1b (presence of circulating clone). The mechanism responsible for the development of leukemic disease in MF is unknown and, in some cases, may simply reflect disease progression. In other cases, erythroderma and circulating cell disease develop simultaneously, which has historically been referred to as SS. The distinction between SS and erythrodermic MF with leukemic involvement (or SS syndrome preceded by MF) has been a point of controversy, and it remains unclear whether the two diseases are distinct or merely variants of one another. At present, SS is specifically defined as the combination of erythroderma with B2 disease.[6]

Extracutaneous Disease

In advanced stages of disease, MF may progress to involve regional or distant lymph nodes or extracutaneous organ systems (most commonly the lungs, oral cavity, pharynx, or central nervous system), and these sites may cause patients significant pain or functional impairment.[8] Of note, in advanced cases of MF, the extent of cutaneous or extracutaneous disease may vary significantly in patients of the same clinical stage. Clinical trials that report results by stage alone may, therefore, be difficult to interpret. The ISCL/USCLC/EORTC consensus statement on clinical end points and response criteria should facilitate improved communication of the degree of disease and response to treatment in future clinical trials.[7]

Molecular and Cellular Pathophysiology

Examination of early-phase MF lesions by hematoxylin and eosin staining commonly reveals epidermotropism, a profound infiltration of lymphocytes into the epidermis. As the lesions progress and become thickened,

epidermotropism is gradually lost as the lymphocytes begin to localize more diffusely in the skin. Only a fraction of the skin-homing lymphocytes in MF are malignant, and the malignant T cells may be identified by visualization of their small- to medium-sized hyperconvoluted (or cerebriform) nuclei and surrounding lacunae, which give them the impression of being surrounded by a halo. Pautrier microabscesses (Langerhans cell surrounded by atypical T cells in the epidermis) are less common, but a pathognomonic histologic finding associated with MF is common.[1,5] The malignant cells in MF are $CD4^+$ T-helper cells, which most commonly express a $CD3^+$, $CD4^+$, $CD45RO^+$, CLA^+, and $CCR4^+$ immunophenotype. Evaluation of the TCR profile of malignant T cells in MF reveals a predominant TCR rearrangement, indicative of clonal dominance in a majority of cases.

The specific stimuli and molecular events responsible for the activation and development of clonal dominance of a specific T cell are unknown. Genetic profiling studies have identified a number of chromosomal deletions and duplications associated with MF/SS, and microRNA profiling may reveal distinct molecular profiles associated with different phases of MF. More recently, whole-exome/genome sequencing of leukemic CTCL cells revealed mutations of interest involving 17 genes associated with a range of cellular functions, including TCR and NF-κB signaling and T-cell activation and survival pathways, chromatin remodeling, and DNA repair. In addition to any molecular aberrations intrinsic to the malignant T cells, the cutaneous microenvironment is also likely to play a key role in the development and maintenance of disease.[5,9-14]

Diagnosis and Evaluation

Evaluation of a patient with suspected or recently diagnosed MF should include a comprehensive history/physical examination, biopsy of cutaneous lesion(s) and suspicious lymph nodes, and appropriate laboratory and imaging studies. The ISCL has designed a diagnostic algorithm for early-stage MF (not applicable to MF variants) (Table 86.2),[15] and specific recommendations for patient evaluation have been released by the ISCL/EORTC.[16,17]

TABLE 86.2 DIAGNOSTIC CRITERIA FOR EARLY-STAGE MYCOSIS FUNGOIDES[A]

Clinical

Persistent and/or progressive patches and plaques plus:
Non–sun-exposed location
Size/shape variation
Poikiloderma
Scoring: 2 points if two or more criteria met; 1 point if only one criterion met

Immunopathologic

CD2, 3, 5 <50% of T cells
CD7 <10% of T cells
Epidermal discordance from expression of CD2, CD3, CD5, or CD7 on dermal T cells
Scoring: 1 point if any criterion met

Molecular/biologic

Clonal TCR gene rearrangement
Scoring: 1 point if present

Histopathologic

Epidermotropism without spongiosis
Lymphoid atypia
Scoring: 1 point for each

TCR, T-cell receptor.

[a]Not applicable to mycosis fungoides variants. Diagnosis made with 4 points or more.

Adapted from Pimpinelli N, Olsen EA, Santucci M, et al. Defining early mycosis fungoides. *J Am Acad Dermatol*. 2005;53(6):1053-1063. Copyright © 2005 American Academy of Dermatology, Inc. With permission.

History and Physical Examination

The duration of symptoms, evolutionary course of cutaneous disease, and presence or absence of B symptoms should be determined. The percentage of body surface area involved by disease and the presence or absence of cutaneous tumors should be documented, and a thorough evaluation of the lymphatic system should be performed. Appropriate images of cutaneous lesions should be recorded so that disease progression or response to therapy may be monitored.

Skin Biopsy

Biopsies should be taken from a minimum of two distinct sites of disease. Lesions of the greatest induration will be most likely to yield a diagnosis

due to greater numbers of malignant cells. However, scaled lesions are more likely to show epidermotropism. Tissue should be evaluated with hematoxylin and eosin staining, immunostaining for surface marker expression profiles (including CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30, CD26, CD56, TIA1, granzyme B, βF1), and routine PCR or TCR NGS for clonal TCR rearrangement. Slides should be reviewed by a dermatopathologist.

Excisional biopsies of enlarged or otherwise suspicious lymph nodes (fixed or matted lymph nodes, or lymph nodes ≥1.5 cm or ≥1 cm in the head and neck) should be evaluated as described previously. When multiple suspicious lymph nodes are encountered, the choice of lymph node to be excised should be based on size, fluorodeoxyglucose avidity, and location, with priority given to the largest lymph node draining an affected area of skin or the lymph node with the highest standardized uptake value on positron emission tomography (PET) scan. If all other factors are equal, priority should be given first to cervical nodes, followed by axillary and then inguinal nodes.[16,17]

Laboratory and Imaging Studies

Laboratory studies should include a complete blood count, chemistry panel, liver function tests, and lactate dehydrogenase (LDH). Examination of the peripheral blood for circulating disease by PCR and flow cytometry should also be considered, particularly for patients with erythroderma, nodal, or extracutaneous disease. Bone marrow biopsy should be considered if peripheral blood or extracutaneous organs are found to harbor disease.[16,17] Computed tomography (CT) of the chest, abdomen, and pelvis is recommended in the evaluation of all patients with MF, with the exception of patients with patch/plaque disease limited to 10% or less of the body surface area. In these cases, a chest x-ray or nodal ultrasound may suffice. PET scanning was shown to be more sensitive than CT in identifying involved lymph nodes, and the role of PET in MF continues to evolve.[18]

Staging and Prognosis

MF is presently staged using the modified TNMB system proposed by the ISCL/EORTC (Table 86.3).[15] Based on a review of 525 patients with MF

(staged using the previous 1979 TNMB system), the majority of patients present with early-stage disease (30% IA, 25% IB, 11% IIA, 16% IIB, 3% IIIA, 8% IIIB, 6% IVA, and 1% IVB). Only 7% of patients presented with peripheral blood involvement. [8] Similar results were obtained in a validation study of the current staging system.[19] Of note, stage IA MF is not associated with any increase in mortality risk in comparison to an age- and ethnicity-matched control population and is associated with only a 16% rate of disease progression at 20 years of follow-up.[8] Benton et al proposed a cutaneous lymphoma international prognostic index (CLIPi) for both early- and late-stage MF/SS that is based on the presence of certain adverse features identified in a multivariate analysis, including "male gender, age >60, plaques, folliculotropic disease and stage N1/Nx for early-stage disease, and male gender, age >60, stages B1/B2, N2/3 and visceral involvement for late-stage disease."[20] The CLIPi then stratifies patients into low- (0-1 risk factors), intermediate- (2 risk factors), and high- (3-5 risk factors) risk groups.[20] A report from Emory University indicates that the CLIPi successfully stratified patients with early-stage, but not late-stage, MF/SS.[21] The Cutaneous Lymphoma International Consortium conducted a multi- institutional and international study of potential prognostic factors in advanced stage (IIB-IV) MF/SS and has proposed an alternative prognostic index based on the presence of four risk factors (stage IV disease, age>60, elevated LDH, and large cell transformation in the skin). Based on these factors, patients are stratified into low- (0-1 risk factor; 67.8% 5-year survival), intermediate- (2 risk factors; 43.5% 5-year survival), or high- (3-4 risk factors; 27.6% 5-year survival) risk groups.[22] Overall, these studies underscore the complexities and difficulties inherent to developing accurate prognostic indices for such rare disease entities.

TABLE 86.3 ISCL/EORTC REVISIONS TO MYCOSIS FUNGOIDES STAGING

T Stage
T1: Limited patches, papules, and/or plaques covering <10% of the skin surface. May further stratify into T1a (patch only) vs T1b (plaque/patch)
T2: Patches, papules, or plaques covering ≥10% of the skin surface. May further stratify into T2a (patch only) vs T2b (plaque/patch)
T3: One or more tumors (≥1-cm diameter)
T4: Confluence of erythema covering >80% body surface area

M Stage

M0: No visceral organ involvement
M1: Visceral involvement (must have pathology confirmation and organ involved should be specified)

N Stage

N0: No clinically abnormal peripheral lymph nodes; biopsy not required
N1: Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 1 or NCI LN0-2 (N1a: clone negative, N1b: clone positive)
N2: Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 2 or NCI LN3
N3: Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 3 or 4 or NCI LN4; clone positive or negative
NX: Clinically abnormal peripheral lymph nodes; no histologic confirmation

B Stage

B_0 = <250/μL of $CD4^+/CD26^-$ or $CD4^+/CD7^-$ cells,
B_1 = does not meet criteria for B_0 or B_2, and
B_2 = ≥1,000/μL of $CD4^+/CD26^-$ or $CD4^+/CD7^-$ cells or other aberrant population of lymphocytes identified by flow cytometry.

Staging Groups

IA: T1 N0 M0 B0-1
IB: T2 N0 M0 B0-1
IIA: T1-2 N1-2 M0 B0
IIB: T3 N0-2 M0 B0-1
IIIA: T4 N0-2 M0 B0
IIIB: T4 N0-2 M0 B1
IVA1: T1-4 N0-2 M0 B0-2
IVA2: T1-4 N3 M0 B0-2
IVB: T1-4 N0-3 M1 B0-2

Treatment

Skin-Directed Therapy

MF is not generally considered to be curable, although extended periods of disease-free survival after treatment have been reported. Efforts to treat MF are primarily focused on preventing progression and ameliorating symptoms. In early-stage disease, a number of skin-directed treatments are effective and should be considered as first-line therapy. Topical therapies include corticosteroids (complete response [CR] rates of 63% for T1 and 25% for T2 disease),[23] nitrogen mustard (CR rates of 76%-80% for stage IA and 35%-68% for stage IB),[24] carmustine (CR rates of 86% for T1 and 47% for T2 disease),[25] and bexarotene gel (CR rate of 21% in early-stage MF).[26] Phototherapy with narrow-band ultraviolet B (NB-UVB) (54% CR in stage IA or IB)[27] or psoralen + UVA (PUVA) (CR rate of 65%)[28] is also frequently used. However, the most effective skin-directed therapy for MF is ionizing radiation.

Ionizing radiation is well suited to the treatment of cutaneous lymphoma. Lymphocytes are highly radiosensitive, and radiation doses may be effectively limited to the epidermis and dermis by appropriate selection of photon or electron energies. Options for irradiation include local superficial irradiation or irradiation of the entirety of the skin via total skin electron beam therapy (TSEBT). The International Lymphoma Radiation Oncology Group (ILROG) has suggested guidelines for field and dose selection.[29]

Local Superficial Irradiation

A small portion (5%) of patients with stage IA MF present with “minimal” disease, defined as a solitary lesion or two to three MF lesions clustered sufficiently close to one another that they are amenable to treatment with a single or abutting radiation field.[30] For these patients, treatment with local superficial irradiation may be considered. Treatment fields should be designed to encompass the entirety of the lesion (determined by visual inspection, palpation, and/or appropriate imaging) with a 1- to 2-cm margin, with the use of a lead or Cerrobend cutout to conform field borders to the anatomy of the cutaneous lesion. Skin collimation can also be incorporated. Treatment is most commonly provided with electrons, with energies (usually 6-16 MeV) carefully selected to optimize dose penetration. The EORTC recommends that the 80% isodose line is set at the deep border of the dermis,[31] which is commonly at a depth of approximately 4.5 mm.

Local superficial radiation is very effective in generating a CR for patients with "minimal" stage IA MF. In a review of 21 patients with "minimal" stage IA MF treated with local superficial radiation (superficial or orthovoltage x-rays or megavoltage electrons) to doses ranging from 20 to 40 Gy in four to five or 10 to 15 fractions, Wilson et al[30] found a CR rate of 97%. Importantly, a review of the recurrence rates associated with different total doses of local superficial radiation revealed a 25% local recurrence rate (2/8 fields) with treatment to 20 Gy and an 8% local recurrence rate (2/25 fields) with treatment to 20 to 40 Gy. Similarly, Cotter et al[32] reported a local recurrence rate of 42% for fields treated to 10 Gy or less, but 0% for fields treated to >30 Gy. Based on these studies, it is recommended that "minimal" stage IA (ie, unilesional or up to three closely approximated sites) MF lesions are treated to a dose of at least 24 Gy, With respect to palliative treatment of individual lesions, Patel et al reported on 225 lesions irradiated in 41 patients with 4, 8, or 12 Gy.[33] The response rates ranged from 82.2% to 91.5%. The response rates for 4 versus 8 Gy were 82.2% and 91.5%, respectively (P = .057). The higher dose also achieved more durable control. Treatment with a dose as low as 8 Gy in a single fraction is now considered standard as a palliative treatment. Side effects of local superficial radiation are usually limited to mild dermatitis, local alopecia, and pigmentation changes.

Total Skin Electron Beam Therapy

Technique

TSEBT is technically challenging and should be attempted only in centers with special expertise in its provision, including skilled physics support. EORTC recommendations regarding the technical aspects of TSEBT are presented in Table 86.4. Modern TSEBT is usually accomplished with 6- to 9-MeV electrons generated by a medical linear accelerator directed at a patient standing behind a polycarbonate screen, 3.8 m from the linear accelerator head. The polycarbonate screen scatters the incident electron beam and contributes to an improved surface dose. Treatment is often provided in "cycles," with one cycle composed of treatment of the patient in six different positions (Figure 86.3A) over 2 days (three positions each day). Typically, a dose of 2 to 3 Gy is provided to the entirety of the skin

during one cycle, and two cycles are usually administered per week. Treatment in six positions optimizes dose distribution at the skin surface (Figure 86.3B). At Yale and Stanford, the anterior, right posterior oblique, and left posterior oblique positions are treated on cycle day 1, and the posterior, right anterior oblique, and left anterior oblique positions on cycle day 2.[34,35] When the patient stands in a treatment position, a dual-field technique is used to deliver treatment to a superior and inferior field by angling the gantry 16° to 17.5° above and below horizontal, respectively, with the specific angle dependent upon individual machine characteristics (Figure 86.4). Treatment to the six positions using the dual-field technique, which is in use at Yale and Stanford, delivers maximum dose to a depth of 1 mm, 80% dose to 6 to 7 mm, and 20% dose to 12.5 mm.[34,35]

TABLE 86.4 EORTC TECHNICAL RECOMMENDATIONS FOR TSEBT

The primary target in TSEBT is the epidermis, adnexal structures, and dermis.
The goal of treatment (either by primary or supplemental treatments) is to deliver a dose of 26-28 Gy to a depth of 4 mm below the skin surface, which usually translates to a truncal dose of 31-36 Gy.[a]
Treatment should be provided in 30-36 fractions (1-1.2 Gy/fraction) over 6-10 wks. Fraction sizes should not exceed 2-2.5 Gy due to increased acute and late side effects.
The 80% isodose line should extend to 4 mm below the skin surface, the dose 20 mm deep to the skin must be <20% of the maximum dose at skin, and the dose at curved skin sites must not exceed 120% of the prescribed skin dose.
Patient positioning is critical, and patients must be positioned in a manner to maximize unfolding of the skin. A minimum of six treatment positions is recommended.
The optimal source-to-patient distance is 3-8 m, and dose should be homogeneous to within 10% across the entire vertical and lateral dimensions of the beam at the patient's surface.
The globe of the eye must be limited to <15% of the maximum skin dose, and photon contamination at the bone marrow must be limited to <0.7 Gy.

EORTC, European Organisation for Research and Treatment of Cancer; TSEBT, total skin electron beam therapy.

[a]Lower doses of 10-12 Gy are now most commonly used.

Dose and Fractionation

Sublethal damage repair does not appear to be a major factor in determining the response of MF to ionizing radiation,[36] and modern TSEBT is provided

with a relatively protracted course. The classic approach delivered 36 Gy to the skin surface in 9 to 10 weeks. The total radiation dose appears to be directly associated with CR rates, with 18% CR with treatment to <10 Gy, 55% CR with treatment to 10 to 20 Gy, 66% CR with treatment to 20 to 25 Gy, 75% CR with treatment to 25 to 30 Gy, and 94% CR with treatment to 30 to 36 Gy.[37] However, lower doses yield impressive rates of overall response (defined as a >50% reduction in cutaneous disease), overall survival, progression-free survival, and relapse-free survival rates. Relapse rates are relatively high even in patients in which a CR is obtained, and the absolute benefit of a CR relative to the increased side effects at higher doses of TSEBT is unclear. This has led to the use of reduced-dose TSEBT (10-20 Gy) in combination with additional therapies and has become preferable to the use of higher doses of TSEBT.[38-40] These studies consistently show overall excellent outcomes with reduced toxicity, allowing TSEBT to be repeated as necessary for a patient's disease.

Supplemental Treatments

The six treatment positions in TSEBT maximize unfolding of the skin and exposure of the skin surface to the incident electron beam, but areas such as the soles of the feet, perineum, and scalp remain obscured and require supplemental doses to ensure that a minimum of 20 Gy is administered to a depth of approximately 4 mm. Supplemental treatment to these areas may be accomplished by the use of 120-kV superficial photons with half-value layer 4.2-mm or low-energy (6 MeV) electrons with 1-cm bolus to treat the soles of the feet (1 Gy per fraction) and the perineum (1 Gy per fraction). In some setups, the scalp is treated by placing an angled electron reflector above the patient,[34] but supplemental boosting is an alternative approach that is incorporated in some centers. Additional areas that may need supplemental dose include thick cutaneous tumors and skin folds secondary to body habitus, and the need for a supplemental dose to such areas is based on the judgment of the radiation oncologist.[34,35]

Side Effects

In a review of perceptions of MF therapy, patients overall considered high-dose TSEBT to be a more difficult treatment to endure as compared to other

treatments,[41] and it is important that patients are advised that symptoms such as pruritus and cutaneous erythema may be exacerbated during therapy. Additional acute side effects that commonly occur after high-dose TSEBT include xerosis, dry desquamation, extremity edema, blister/bullae formation over the lower extremities, alopecia (including hair of the scalp, eyebrows, eyelashes, and body), and nail changes (nails may ultimately be lost but usually regrow). Hypohydrosis secondary to damage to sweat glands may occur. Similarly, dryness and irritation of the nasal mucosa may result in nosebleeds. Gynecomastia is a rare occurrence. Following lower doses of TSEBT (~12 Gy), all of these effects are diminished. Dryness, xerosis, and alopecia (temporary) may still occur, but nail changes and hypohydrosis are notably less. Late/chronic side effects are minimal and dose related but may include cataract formation, chronic xerosis, persistent alopecia, dystrophic nails, telangiectasia, and secondary skin cancers, including squamous and basal cell carcinomas and melanomas. Clinicians should be vigilant for the possibility of active cutaneous infection during the course of therapy.[31,42-46]

In an effort to minimize side effects, areas that are most sensitive to TSEBT such as the eyes, lips, hands, fingernails, feet, and testes may be blocked completely or during certain cycles of treatment. Shielding of the eye and lens may be accomplished by a combination of internal/external shields, selected based upon the proximity of clinical disease. Usually, if internal eye shields are used, they are used for only a portion of the therapy (7-20 Gy). The lips, hands, and fingernails may be blocked by lead mitts or fingernail shields as clinical circumstances warrant. The feet may be blocked by footboards for a portion of the treatment. A testicular shield may be used during TSEBT or perineal boost treatments.[34] The scalp may be shielded if there is no nearby disease.[47]

Clinical Efficacy

TSEBT is very effective, particularly for early-stage disease. TSEBT yields a CR rate of >90% with a 15-year relapse-free survival of 40% in patients with T1 disease, although it is no longer recommended for such limited disease.[37] Of note, patients with recurrent disease after a course of TSEBT most commonly have disease restricted to <5% of the skin surface area, and

these recurrences are, therefore, amenable to local salvage therapy with topical therapy or limited superficial radiation. When successful salvage of such limited recurrences is taken into account, relapse-free survival improves to 70% at 15 years.[48-50]

In T2 disease TSEBT is similarly effective, with a CR rate of 76% to 90% and a 50% relapse-free survival rate at 5 years and 10% at 10 years. Relapse-free survival is significantly improved by the addition of adjuvant PUVA or nitrogen mustard. Specifically, adjuvant PUVA improves 5-year relapse-free survival to 85%, and nitrogen mustard improves 10-year relapse-free survival to 40%.[31,50-52]

When cutaneous tumors are present (T3 disease), TSEBT is less effective but still yields an impressive CR rate of 44% to 54% of patients, much greater than any other single modality. Adjuvant treatment is indicated, and retrospective studies suggest that nitrogen mustard, PUVA, low-dose methotrexate, interferon (IFN), or acitretin may increase the durability of response. Alternatively, a combination of topical therapy and local superficial radiation may be considered for tumors localized to a small percentage of the skin surface.[50,51,53] Supplemental boosts should be considered for patients with tumors, and such boost treatment should be provided concomitantly with the initiation of TSEBT or prior to its initiation. The purpose of the boost is to diminish the thickness of the lesion so that electrons from TSEBT can effectively penetrate the entire depth of the lesion.

In erythrodermic MF (T4 disease), TSEBT yields a 70% to 100% response rate (for patients with T4N0 disease) and 5-year progression-free survival of 25% to 69%. When disease involves the peripheral circulation or extracutaneous sites, TSEBT is less effective and response and progression-free survival rates decrease to 74% and 36%, respectively. TSEBT appears to be synergistic with extracorporeal photopheresis (ECP), and the combination of TSEBT and ECP is associated with improved disease-specific survival and decreased levels of circulating malignant cells.[53-56] Occasional patients with erythroderma have exquisitely sensitive skin, necessitating the use of lower daily doses of TSEBT.

Palliative Radiotherapy

Symptomatic nodal or visceral disease may be effectively palliated by a brief course of localized radiotherapy, usually to a total dose of 12 to 30 Gy. If this treatment is given in conjunction with a course of TSEBT, a similar dose may be used. In the subset of patients who develop extensive recurrence of cutaneous disease after a previous course of TSEBT, additional courses of TSEBT to lower total doses can be considered and have proven effective in studies at Yale and Stanford.[57,58] This is especially appropriate when lower initial doses of TSEBT have been used.

Systemic Therapy

Skin-directed therapy should be attempted first for patients with early-stage disease, but in patients with advanced or refractory disease, systemic therapy should be considered. Common options for systemic therapy have included oral bexarotene (response rate up to 54% in refractory CTCL at a dose of 300 mg/m^2, and bexarotene may be used in combination with other therapies)[59,60] and histone deacetylase inhibitors (such as vorinostat and romidepsin, 30% response rate in refractory CTCL).[61,62] One of the most effective systemic therapies is brentuximab vedotin (BV). In the ALCANZA study, patients with MF were randomized to treatment with BV or physician choice (methotrexate or bexarotene). The global objective response lasting at least 4 months was 56.3% in the BV group and only 12.5% in the control group. The likelihood of grade 3 to 4 events was similar in both groups, but the risk for peripheral neuropathy was much higher in the BV group (67% vs 6%).[63] Another novel effective therapy is mogamulizumab (moga), a monoclonal antibody directed against C–C chemokine receptor 4. In the MAVORIC study, moga was compared to vorinostat in previously treated patients. The progression-free survival was 7.7 months in the moga group versus only 3.1 months for vorinostat.[64] Other systemic options include alemtuzumab (a monoclonal antibody targeted against the CD52 surface marker with a 38% overall response rate in relapsed or refractory CTCL and 86% response rate in SS),[65,66] INF-α2a (a biologic modifier with a response rate of 40%-80% in CTCL as a single agent and with synergistic activity with other MF therapies),[67-69] ECP (associated with improvement in peripheral blood and skin involvement, especially in those with T4 disease),[70] and pembrolizumab (38% overall

response rate in heavily pretreated patients with advanced disease).[71] With respect to cytotoxic chemotherapy, single-agent treatment with agents such as purine or nucleoside analogs, liposomal doxorubicin, and antifolate agents, including methotrexate and pralatrexate, is preferred because no distinct advantages have been identified with the use of multiagent regimens.[72-76]

Autologous or Allogeneic Stem Cell Transplant

Patients with MF/SS refractory to other therapies may be considered for stem cell transplant. Autologous stem cell transplantation is ineffective, but greater success has been achieved with allogeneic stem cell transplants. Additional studies are necessary to fully define the role of allogeneic transplantation, but this approach may prove to be a valuable option for patients with refractory disease.[77-81]

Treatment Recommendations by Stage

Treatment recommendations for MF/SS are presented by stage in Table 86.5.[82]

TABLE 86.5 RECOMMENDATIONS FOR TREATMENT OF MF BY STAGE

Stage	First-Line Therapies	Options for Refractory or Relapsed Disease
"Minimal" IA	Local superficial irradiation Topical corticosteroids	Consider standard-stage IA first-line therapies
IA, IB, IIA	Expectant observation (for stage IA) Topical therapies (corticosteroids, nitrogen mustard, bexarotene) Phototherapy (PUVA, NB-UVB) TSEBT (consider adjuvant PUVA or nitrogen mustard) Oral retinoids Methotrexate	Second-course TSEBT Oral bexarotene (or other retinoids) IFN-α Low-dose MTX Vorinostat Brentuximab vedotin Clinical trials NOTE: Chemotherapy is not Recommended.
IIB	TSEBT (consider boosts to cutaneous tumors and adjuvant	Second-course TSEBT Oral bexarotene

Stage	First-Line Therapies	Options for Refractory or Relapsed Disease
	PUVA IFN-*α* Brentuximab vedotin (esp if LCT)	Vorinostat Romidepsin Pralatrexate Pembrolizumab Clinical trials Chemotherapy Allogeneic stem cell transplant in R/R cases, LCT
IIIA, IIIB, leukemic CTCL or SS	TSEBT + ECP ECP alone IFN-*α* PUVA + IFN-*α* MTX Oral retinoids Mogamulizumab (esp in those with high Sézary burden)	Second-course TSEBT Oral bexarotene Mogamulizumab Vorinostat Romidepsin Pembrolizumab Alemtuzumab Clinical trials Chemotherapy Allogeneic stem cell transplant
IVA (1-2), IVB	Chemotherapy TSEBT for palliation Oral bexarotene IFN-*α* Brentuximab vedotin Pralatrexate Pembrolizumab Vorinostat Romidepsin Clinical trials	Liposomal doxorubicin Gemcitabine Combination chemotherapy (esp if bridging to allogeneic HSCT) Allogeneic stem cell transplant

BCNU, *bis*-chloroethylnitrosourea; CTCL, cutaneous T-cell lymphoma; ECP, extracorporeal photopheresis; IFN-*α*, interferon-alpha; MTX, methotrexate; NB-UVB, narrow-band ultraviolet B; PUVA, psoralen plus ultraviolet A; SS, Sézary syndrome; TSEBT, total skin electron beam therapy.

Transformed Disease

In some cases, large cell transformation of MF may occur, which is identified on biopsy by >25% large cells in the sample. Large cell transformation may be associated with decreased survival rates and occurs in 8% to 39% of cases. Patients with advanced stage or high levels of β_2-microglobulin or LDH are at the greatest risk of large cell transformation.

Treatment options include BV, systemic chemotherapy, stem cell transplant, and consolidative or local radiation for localized disease.[79,63]

Variants of Mycosis Fungoides

Variant forms of MF that share histologic and clinical features with classic MF but exhibit distinct clinical behavior have been recognized and include folliculotropic MF, Woringer-Kolopp disease, granulomatous slack skin (GSS), and hypopigmented MF.

Folliculotropic MF is characterized by a folliculotropic pattern of cutaneous infiltration of malignant T cells. Folliculotropic MF lesions present as patches, plaques, or tumors or may manifest in an acneiform pattern. Lesions primarily develop over the head and neck and are rarely found over the trunk. Localized alopecia secondary to the folliculotropic pattern is common. Folliculotropic MF is associated with a 15-year survival of 41% for early-stage disease. Early-stage disease may be treated with PUVA combined with bexarotene or IFN-α. Local radiation therapy may be advantageous because it can effectively treat to deeper depths of involvement seen in this variant. Advanced-stage disease is minimally responsive to cytotoxic chemotherapy, and alternate options such as irradiation or allogeneic stem cell transplant should be considered.[1,83,84]

Woringer-Kolopp disease (pagetoid reticulosis) is characterized by a solitary erythematous and scaling cutaneous patch on an extremity. Biopsy results are similar to classic MF, and the malignant T cells commonly carry a $CD3^+/CD4^+/CD8^-$ or $CD3^+/CD4^-/CD8^+$ immunophenotype. If $CD8^+$ disease is identified, it is important to consider the alternative diagnosis of $CD8^+$ aggressive peripheral CTCL, and the distinction between these diagnoses is made by the aggressiveness of disease. Specifically, as compared to $CD8^+$ aggressive peripheral CTCL, Woringer-Kolopp disease is very slowly progressive and carries an excellent prognosis. Treatment options include skin-directed therapies, such as corticosteroids, nitrogen mustard, resection, or local irradiation. Local radiation may be very successful in achieving long-term local control, even in locally very advanced disease. In rare cases of diffuse or refractory disease, irradiation is also recommended.[1,85]

GSS is an extremely rare variant of MF, with <100 cases reported in the literature. It is characterized by cutaneous infiltration of a clonal population of malignant T cells coupled with a granulomatous infiltration. The granulomatous infiltrate ultimately causes destruction of local elastin fibers and impairs the structural integrity and elasticity of the skin, which results in loose or "slack" skin. This loosening of the skin is most commonly observed in the axilla, groin, neck, and breast. Although GSS is itself an indolent disease, it is associated with an increased incidence of secondary lymphomas, most commonly Hodgkin lymphoma or MF. Given the rarity of this disease, it is difficult to make definitive recommendations regarding therapy, but surgical resection or local superficial radiation may be effective.[1,86]

Hypopigmented MF presents at an earlier age (childhood or adolescence) than classic MF and is characterized by the development of hypopigmented patches frequently over the trunk or extremities. In contrast to classic MF, the malignant T cells are often $CD8^+$. Treatment and disease course are otherwise similar to classic MF.[87,88]

NON–MYCOSIS FUNGOIDES CUTANEOUS T-CELL LYMPHOMA

Staging

In 2007, the ISCL and EORTC presented a new TNM staging system for non-MF/SS cutaneous lymphomas (Table 86.6).[89]

TABLE 86.6 ISCL/EORTC TNM CLASSIFICATION OF CUTANEOUS LYMPHOMA OTHER THAN MYCOSIS FUNGOIDES/SÉZARY SYNDROME

T Stage

T1: Solitary skin involvement
T1a: A solitary lesion <5 cm in diameter
T1b: A solitary lesion >5 cm in diameter
T2: Regional skin involvement: multiple lesions limited to 1 body region or 2 contiguous body regions
T2a: All disease encompassing in a <15-cm-diameter circular area
T2b: All disease encompassing in a >15- and <30-cm-diameter circular area
T2c: All disease encompassing in a >30-cm-diameter circular area
T3: Generalized skin involvement
T3a: Multiple lesions involving 2 noncontiguous body regions
T3b: Multiple lesions involving and ≥3 body regions

N Stage

N0: No clinical or pathologic lymph node involvement
N1: Involvement of 1 peripheral lymph node region that drains an area of current or prior skin involvement
N2: Involvement of 2 or more peripheral lymph node regions or involvement of any lymph node region that does not drain an area of current or prior skin involvement
N3: Involvement of central lymph nodes

M Stage

M0: No evidence of extracutaneous non–lymph node disease
M1: Extracutaneous non–lymph node disease present

CD30-Positive Lymphoproliferative Disorders

A review of the Surveillance, Epidemiology, and End Results registry identified 268 cases of primary cutaneous $CD30^+$ lymphoproliferative disorders recorded between 1974 and 2004 (58% male and 42% female patients). The median age of diagnosis was 61, and population-matched 3-year relative survival was 87%, with 5-year disease-specific survival of 92%. Localization of disease in the head and neck appears to be a negative prognostic factor.[90] The primary cutaneous $CD30^+$ lymphoproliferative disorders recognized by the WHO/EORTC are primary cutaneous anaplastic large cell lymphoma (PC-ALCL) and lymphomatoid papulosis (LyP).[1] These cannot be differentiated histologically. It is essential to take a careful clinical history to document the distribution of lesions and their clinical course (eg, history of spontaneous regression). The diagnosis is clinicopathologic. The EORTC, ISCL, and USCLC have provided consensus recommendations regarding the evaluation and treatment of primary cutaneous $CD30^+$ lymphoproliferative disorders.[91]

Primary Cutaneous Anaplastic Large Cell Lymphoma

PC-ALCL is characterized by the development of cutaneous plaques, nodules, or tumors that are usually solitary or clustered into a localized area. Multifocal disease is uncommon (occurring in only 20% of patients), and lymph nodes are involved in only 10% of cases. Nonnodal extracutaneous disease is rarely found. PC-ALCL is most commonly diagnosed in males, with a male:female ratio of 2 to 3:1. When disease is localized to the skin and regional lymph nodes, prognoses are excellent, with anticipated 5-year overall survival and 10-year disease-specific survival rates of 90%. Progression to extracutaneous disease affects overall survival, and extensive limb disease (defined as "initial presentation or progression to multiple skin tumors in one limb or contiguous body regions")[92] impacts disease-specific survival. Biopsies of PC-ALCL lesions reveal a diffuse infiltration of large anaplastic $CD4^+$ T cells, and at least 75% of these anaplastic T cells express CD30. Similar to MF, clonal dominance is frequently detected by PCR evaluation for TCR rearrangement.[1]

Limited resection or local superficial irradiation is very effective in controlling localized cutaneous disease, and BV or low-dose methotrexate may be considered when widespread cutaneous disease precludes simple resection or irradiation. Local superficial radiation to a dose of 34 to 44 Gy was associated with a 100% CR rate,[93] but more recent data suggest that lower doses such as 20 Gy may be adequate.[94] In rare cases in which extracutaneous disease is found, treatment with BV should be considered in limited regional lymph node involvement with a potential role for local radiation in addition. Anthracycline-based combination chemotherapy is reserved for systemic ALCL. Of note, prior to initiating therapy, it is critically important to verify that PC-ALCL has been correctly distinguished from the more common systemic ALCL. Molecular studies to evaluate the presence of the (2:5) (p23;q35) chromosomal translocation and expression of anaplastic lymphoma kinase (ALK) or epithelial membrane antigen (EMA) are useful in making this distinction, because the (2:5) translocation and expression of ALK and EMA are found in systemic ALCL but rarely found in PC-ALCL.[1,95]

Lymphomatoid Papulosis

LyP carries an excellent prognosis, with a 5-year overall survival rate of 100%. However, 15% to 20% of patients with LyP will develop MF, PC-ALCL, or a Hodgkin lymphoma. LyP is characterized by the development of violaceous papular or papulonodular lesions over the trunk or extremities, which typically regress after 3 to 12 weeks, often leaving a residual scar. Biopsy of LyP cutaneous lesions reveals epidermotropic atypical $CD3^+/CD4^+/CD8^-$ lymphocytes, and clonal TCR rearrangement is identified in 60% to 70% of cases. Three distinct histologic subtypes are recognized: LyP A, LyP B, and LyP C. LyP A (characterized by large multinucleated $CD30^+$ cells intermixed with an inflammatory infiltrate) and LyP C (characterized by large $CD30^+$ cells with minimal inflammatory infiltrate) represent 90% of cases. In contrast to types A and C, atypical lymphocytes in LyP B are $CD3^+/CD4^+/CD30^-$, reminiscent of MF.[1]

Aggressive therapies such as chemotherapy should be avoided in LyP. In the rare patient with a large cutaneous burden of disease, skin-directed therapy with PUVA or a topical chemotherapy agent may be considered. In addition, low-dose oral methotrexate or BV may be effective in suppressing the development of new lesions and may be considered if previous LyP lesions caused significant scarring.[1]

Extranodal NK/T-Cell Lymphoma, Nasal Type

Extranodal NK/T-cell lymphoma, nasal type most commonly arises in the nasal cavity and nasopharynx but, in select cases, may present with cutaneous plaques or tumors over the extremities and trunk and is, therefore, included in the WHO/EORTC classification of cutaneous lymphomas. Biopsy of a cutaneous lesion reveals a dense lymphoid infiltrate, which may exhibit an epidermotropic component. The malignant cells are most commonly NK in origin with a $CD3^-/CD2^+/CD56^+$ immunophenotype, but on occasion, the malignant cells are derived from cytotoxic T cells. Epstein-Barr virus (EBV) is directly associated with disease development, and cutaneous lesions are nearly always EBV^+. Consistent with an EBV-mediated pathophysiology, the disease occurs more commonly in geographic distributions in which EBV is endemic (Central America, South America, South Asia). The TCR usually remains in germline configuration when the malignant cells are of NK cell origin, but

clonal TCR rearrangement may be observed in cases in which the malignant cells are derived from cytotoxic T cells. Optimal treatment regimens for cutaneous extranodal NK/T-cell lymphoma, nasal type have not yet been determined. Treatment with radiotherapy to a median dose of 50 Gy yields a CR rate of 95.4% in early-stage disease, but local or distant recurrences are common and adjuvant therapy with L-asparaginase- based chemotherapy regimens should be considered. Advanced-stage disease is treated primarily with chemotherapy; recently, checkpoint inhibitor pembrolizumab was shown to be active in NK/T-cell lymphoma.[1,96-99]

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma presents with subcutaneous nodules and/or plaques, which are commonly localized over the legs or trunk. Biopsy reveals a lymphoid infiltrate composed primarily of malignant cytotoxic $CD8^+$ T cells. Prior to the establishment of the WHO/EORTC classification system, α/β and γ/Δ T-cell forms of disease were each recognized as subcutaneous panniculitis-like T-cell lymphoma. However, γ/Δ T-cell lymphoma is now recognized as a distinct, more aggressive disease and is categorized as a primary cutaneous peripheral T-cell lymphoma. The 5-year survival of the less aggressive α/β disease approaches 80%, and treatment involves combinations of corticosteroids and radiation, and potentially chemotherapy for refractory or aggressive disease.[1] The more aggressive γ/Δ type requires intensive therapy that may include allotransplantation with radiation for local control.[100] The presence of the hemophagocytic syndrome predicts a worse prognosis.

Adult T-Cell Leukemia/Lymphoma

Infection with the human T-lymphotropic virus 1 (HTLV-1) may result in adult T-cell leukemia/lymphoma in approximately 1% to 5% of individuals, and patients may develop associated cutaneous disease, characterized by papules, plaques, and tumors. In smoldering disease, cutaneous lesions may be the only sign of pathology. Chemotherapy is often the primary initial therapy for acute adult T-cell leukemia/lymphoma, with recent studies also showing the efficacy of agents such as moga. Smoldering cases may be treated with skin-directed therapies.[1]

Primary Cutaneous Peripheral T-Cell Lymphoma

Additional CTCLs that do not fit into the previously discussed categories are grouped as "primary cutaneous peripheral T-cell lymphomas," and provisional subsets of this category described by the WHO/EORTC include primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T-cell lymphoma (characterized by cutaneous papules/plaques, nodules, and tumors with ulceration and a propensity for extracutaneous spread of disease; of note, it has recently been proposed that $CD8^+$ should be removed from the naming of this disease entity in order to allow inclusion of diseases of similar behavior that are $CD8^-$ or have variability in TCR expression status),[101] cutaneous γ/Δ T-cell lymphoma (most commonly characterized by subcutaneous plaques or tumors in the extremities), primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma (usually presents as a single cutaneous plaque or tumor on the head and neck or upper trunk and has an indolent clinical behavior), and primary cutaneous peripheral T-cell lymphoma, unspecified (most commonly presents as solitary or generalized nodules). The primary cutaneous peripheral T-cell lymphomas are primarily treated with chemotherapy or allogeneic stem cell transplantation, with the exception of primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma, which may be treated with local resection or radiation.[1]

PRIMARY CUTANEOUS B-CELL LYMPHOMAS

Classification

Primary cutaneous B-cell lymphoma (PCBCL) was first recognized as a distinct clinicopathologic entity in 1981 and accounts for 29% of the 3,884 cases of primary cutaneous lymphoma diagnosed in the United States during 2001 to 2005.[3] The WHO/EORTC classification system recognizes three primary categories of CBCL: primary cutaneous marginal zone B-cell lymphoma (PCMZL), primary cutaneous follicle center B-cell lymphoma (PCFCL), and primary cutaneous diffuse large B-cell lymphoma, leg type (PCDLBCL-LT).[1] In a large Dutch series of PCBCL, 57% were PCFCL, 24% were PCMZL, and 19% were PCDLBCL-LT.[102]

Primary Cutaneous Marginal Zone B-Cell Lymphoma

PCMZL commonly presents with isolated or multifocal red or violaceous papules, plaques, and/or nodules on the trunk or extremities. The malignant cells are marginal zone B cells with a $CD20^{+}/CD79a^{+}/CD5^{-}/CD10^{-}$ immunophenotype. Biopsies reveal an infiltrate composed of numerous lymphoid cells, including marginal zone B cells, lymphoplasmacytoid cells, plasma cells, centroblast- and immunoblast-like cells, reactive T cells, and reactive germinal centers. The prognosis for patients with PCMZL is excellent, and extracutaneous disease is rarely seen. Five-year overall survival rates of approximately 99% are expected, and cutaneous disease is very responsive to therapy. Cutaneous relapses are common but do not predict decreased survival.[1]

Primary Cutaneous Follicle Center Lymphoma

In contrast to PCMZL, PCFCL frequently presents with solitary or clustered plaques and tumors on the scalp, forehead, and trunk. Biopsy reveals a nodular or diffuse lymphoid infiltrate containing varying proportions of centrocytes, centroblasts, and reactive T cells growing in patterns ranging from follicular to diffuse. Similar to PCMZL, the malignant cells in PCFCL are of a $CD20^{+}/CD79a^{+}$ immunophenotype. Clonal rearrangement of immunoglobulin genes is usually observed. Importantly, the chromosomal translocation *t*(14:18) is infrequent in PCFCL, and therefore, detection of this translocation should prompt consideration of a nodal or systemic follicular lymphoma. Similar to PCMZL, cutaneous lesions respond well to treatment. Extracutaneous disease is detected in 5% to 10% of patients, and bone marrow biopsy is an important component of evaluation. The 5-year overall survival rate for PCFCL is estimated at 95%.[1]

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

PCDLBCL-LT usually presents with violaceous cutaneous tumors over the lower extremities. It is most common in older females. Despite the nomenclature, anatomic restriction to the legs is not a requirement, and in rare cases, PCDLBCL-LT may be found in other cutaneous sites than the leg. The disease is characterized by diffuse lymphoid infiltrates with a predominance of centroblasts and immunoblasts, with the absence of any significant number of centrocytes being a key distinguishing feature from

PCFCL. A $CD20^+$, $CD79a^+$, Bcl-$6^{+/-}$, $CD10^-$, Bcl-2^+, MUM-1^+, $FOXP1^+$, and MYD-88 immunophenotype is usually observed. In contrast to PCMZL and PCFCL, both cutaneous relapses and the development of extracutaneous disease are common, and the 5-year overall survival is only about 50%. A very small subset of PCLBCL (such as intravascular PCLBCL or anaplastic or plasmablastic PCLBCL) is categorized as PCLBCL, other.[1]

Diagnosis and Evaluation

Evaluation of patients with suspected PCBCL should follow the basic protocol recommended by ISCL/USCLC/EORTC previously discussed.[7] A thorough skin and lymph node examination and a PET/CT are warranted.[103] In addition, a bone marrow biopsy is needed for PCBCL-LT and should be strongly considered in PCFCL (rate of bone marrow involvement may be as high as 11%). In other cases, the need for bone marrow biopsy is left to the discretion of the treating physician. A further component for the evaluation of PCBCL in Europe includes evaluation for *Borrelia burgdorferi* infection.[1,104] The *Borrelia* subspecies *Borrelia afzelii* that appears to be the causative organism is not found in the United States.[105]

Staging and Prognosis

PCBCLs should be staged in accordance with the ISCL/EORTC staging system for non-MF/SS cutaneous lymphomas (Table 86.6). In 2011, the International Extranodal Lymphoma Study Group released the CLIPi for indolent CBCL. Independent prognostic factors associated with progression-free survival included serum LDH, morphology (nodule vs other), and number of distinct cutaneous sites of disease (greater than two). One point is scored for each factor, and patients are grouped into low risk (score 0), intermediate risk (score 1), and high risk (score 2 or 3), with associated 5-year progression-free survival rates of 91%, 64%, and 48%, respectively.[106] The clinical utility of this prognostic system in determining risk-adapted therapy remains unclear.

Treatment

No prospective randomized clinical trial data are available to help guide treatment decisions, but the ISCL/EORTC recently performed an extensive survey of the literature pertaining to the treatment of the PCBCLs and published consensus recommendations. The ILROG has also published treatment guidelines for the use of radiation therapy in the B-cell cutaneous lymphomas.[29]

Primary Cutaneous Marginal Zone B-Cell Lymphoma and Primary Cutaneous FollicleCenter B-Cell Lymphoma

PCMZL and PCFCL are not expected to be associated with decreased survival relative to control populations (although PCFCL arising in the leg may have a worsened prognosis under the WHO/EORTC classification), and therefore, side effects of proposed treatments should be carefully considered. Treatment options include local superficial irradiation, surgical excision, intralesional IFN-α, local and systemic rituximab, antibiotics (where *B. burgdorferi* is endemic), and chemotherapy.

Local Superficial Irradiation

In the ISCL/EORTC literature review, 132 patients with PCMZL treated with local superficial irradiation were identified, and a 99% CR rate was observed. Doses ranged from 30 to 45 Gy, and field margins ranged from 1 to 5 cm. Although cutaneous relapse of disease occurred in 46% of patients, extracutaneous progression occurred in only 2% of patients. For PCFCL, 460 patients treated with radiation were reviewed, and the CR rate was 99% with a 30% relapse rate. Doses ranged from 20 to 54 Gy, and margins were 0.5 to 5+ cm. National guidelines recommend a definitive dose of 24 to 30 Gy. Local superficial irradiation to 4 Gy in two fractions has been shown to yield a 72% CR rate for PCMZL and PCFCL and is recommended as a palliative dose.[27,107]

Surgery

Excision is associated with a 99% CR rate and 43% cutaneous relapse rate in PCMZL and a 98% CR rate and 40% cutaneous relapse rate in PCFCL.[107]

Rituximab

Systemic rituximab (monoclonal antibody targeted against CD20) has proven effective as a treatment for non-Hodgkin lymphomas and has been applied to the treatment of PCBCL. In a review of five patients with PCMZL treated with systemic rituximab, the overall response rate was 60%, and in 10 patients with PCFCL treated with systemic rituximab, a 100% overall response rate and 80% CR rate were observed. Intralesional rituximab may also be effective, with a reported CR rate of 89% in nine patients with PCMZL, but with a high relapse rate of 62%. Twelve patients with PCFCL treated with intralesional rituximab had a CR rate of 83% with 40% relapse.[108] In general, rituximab is most useful for a patient who has multiple symptomatic sites of disease.

Chemotherapy

Chemotherapy is appropriate only for patients with symptomatic disease who have failed prior therapy, including rituximab. Single-agent treatment with chlorambucil was evaluated in 14 patients with PCMZL, and a CR rate of 64% with a 33% relapse rate was observed. Multiagent chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) was also evaluated in 33 patients with PCMZL, and an 85% CR rate with a 57% relapse rate was observed. In 104 patients with PCFCL treated with CHOP or CHOP-like regimens, an 85% CR rate with a 48% relapse rate was reported.[107]

International Society for Cutaneous Lymphomas/European Organisation for Research and Treatment of Cancer Recommendations

For patients who have only one or a few lesions clustered in one region, radiation (30 Gy or more) using a margin of 1 to 1.5 cm is highly effective. Patients presenting with a single small lesion may be treated with resection alone. Scattered lesions that cannot easily be encompassed in one or a few radiation fields may be carefully observed, with treatment reserved for only the most concerning or symptomatic sites. In the setting of diffuse disease, systemic rituximab should be considered. Of note, cutaneous relapses are common, and relapsed disease often responds to retreatment and does not predict for worsened overall survival rate.[107]

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

PCDLBCL-LT is a significantly more aggressive entity in comparison to PCMZL and PCFCL. It is managed similarly to systemic DLBCL (R-CHOP), with radiation usually employed for local control.

Local Superficial Irradiation

The ISCL/EORTC literature review found 101 patients with PCDLBCL-LT treated with radiation. In contrast to the more indolent lymphomas in which CR rates were close to 100%, the CR rate for PCDLBCL-LT was lower at 88%. The rate of cutaneous relapse rate was high (58%), and even more concerning, 30% of patients were found to have extracutaneous progression of disease. Generally, higher doses are used for this entity (24-36 Gy), depending upon the response to chemotherapy.

Rituximab

Systemic rituximab in PCDLBCL-LT has been investigated (dose 375 mg/m^2 weekly for 4-8 weeks) and yielded a CR rate of 38%. Relapse rates are as yet unknown, and additional follow-up is necessary.[107] However, single-agent rituximab should only be used with palliative intent. Primary treatment should include a combination of rituximab and chemotherapy.

Chemotherapy

Multiagent chemotherapy regimens have been tested in PCDLBCL-LT, and in 32 patients treated with CHOP or CHOP-like regimens, an 81% CR rate has been observed. However, despite aggressive therapy, relapse rates remain high at 54%.[107]

International Society for Cutaneous Lymphomas/European Organisation for Research and Treatment of Cancer Recommendations

Based on the aggressive nature of PCDLBCL-LT and its propensity to develop extracutaneous disease, the recommended treatment in patients able to tolerate multiagent chemotherapy is R-CHOP, with the likely addition of local superficial radiation to distinct cutaneous lesions. In the subset of patients unable to tolerate a multiagent course of chemotherapy, systemic

rituximab may be considered. Alternatively, an aggressive course of radiation to all cutaneous sites of disease may be considered, but relapse is likely.[107]

PRECURSOR HEMATOLOGIC NEOPLASMS

The third category of cutaneous lymphomas in the WHO/EORTC system is precursor hematologic neoplasms/immature hematologic malignancies. At present, this category primarily references $CD4^{+}/CD56_{+}$ hematodermic neoplasm (also referred to as blastic NK cell lymphoma or blastic plasmacytoid dendritic cell neoplasm), which is characterized by the development of red or violaceous cutaneous nodules. Biopsy reveals cutaneous infiltration of abnormal cells with an appearance reminiscent of lymphoblasts and myeloblasts. The origin of the tumor cells in $CD4^{+}/CD56^{+}$ hematodermic neoplasm is unclear. Immunohistochemistry indicates that the tumor cells lack CD3 and CD8 and express both CD4 and CD56. The expression of CD56 initially led investigators to believe these cells were of NK origin. However, the concomitant expression of CD4 and CD56 is unusual, and further exploration led to the identification of expression of CD123 and TCL1 in these tumor cells, which suggests a possible origin in plasmacytoid dendritic cells. Examination of TCR status in these cells indicates it remains in germline configuration, providing further support for the notion that these cells are not derived from a B- or T-cell lineage. $CD4^{+}/CD56^{+}$ hematodermic neoplasm is an aggressive malignancy, and it is common for patients to harbor nodal or systemic disease at diagnosis. Due to the propensity for systemic spread of disease, skin-directed therapies are usually unlikely to control disease, and chemotherapy is often necessary. Although chemotherapy may induce remission of disease, the duration of remission is typically relatively brief, and median survival is only 14 months.[1]

SUMMARY

The primary cutaneous lymphomas are a diverse group of extranodal non-Hodgkin lymphomas, each with distinct a biologic activity. A correct histopathologic diagnosis is critical to the determination of appropriate

management. Although significant advances in therapy have been made since the recognition of MF in 1806, numerous questions remain unanswered regarding the pathophysiology and optimal treatment of the cutaneous lymphomas. Advances in genomic profiling of the cutaneous lymphomas may yield greater insight into the molecular bases of these diseases and help identify better and more individualized therapies. Recent efforts to develop improved prognostic indices and uniform criteria for the classification of disease and response to treatment should facilitate ongoing international collaborations. Due to the rarity of these diseases, large multi-institutional collaborative efforts are critical to the advancement of our understanding of primary cutaneous lymphomas.

CHAPTER 87

Leukemia

Timothy J. Robinson, Kenneth B. Roberts, Scott Huntington, Jessica M. Stempel, and Nikolai Podoltsev

The leukemias are a group of neoplastic disorders of the hematopoietic system, characterized by aberrant or arrested differentiation that results in unlimited proliferative potential of cells within the hematopoietic lineage (Figure 87.1). Leukemias are not only typically highly radiosensitive but also widely disseminated with respect to anatomy (ie, the entire bone marrow and blood compartment), with limited settings in which radiation can be used to help improve outcomes. The role of radiotherapy (RT) in up-front curative treatment is largely to deliver central nervous system (CNS) treatment in combination with systemic therapy for patients with acute lymphocytic leukemia (ALL) with evidence of CNS involvement. While the role of CNS prophylaxis in childhood ALL has declined over the past 15 years because of toxicity concerns, it remains an important component of therapy for high-risk patients. Radiation oncologists must also be familiar with certain palliative situations unique to the leukemias, including myeloid sarcomas (macroscopic tumors composed of leukemic cells also known as extramedullary acute myeloid leukemia [eAML] tumors), splenomegaly (due to direct involvement with leukemic cells or extramedullary hematopoiesis [EMH]), and chemotherapy-refractory CNS recurrence. Lastly, radiation oncologists must be at least peripherally familiar with total body irradiation (TBI) (discussed elsewhere), as the latter is often part of an allogeneic hematopoietic stem cell transplant (allo-HSCT) program.

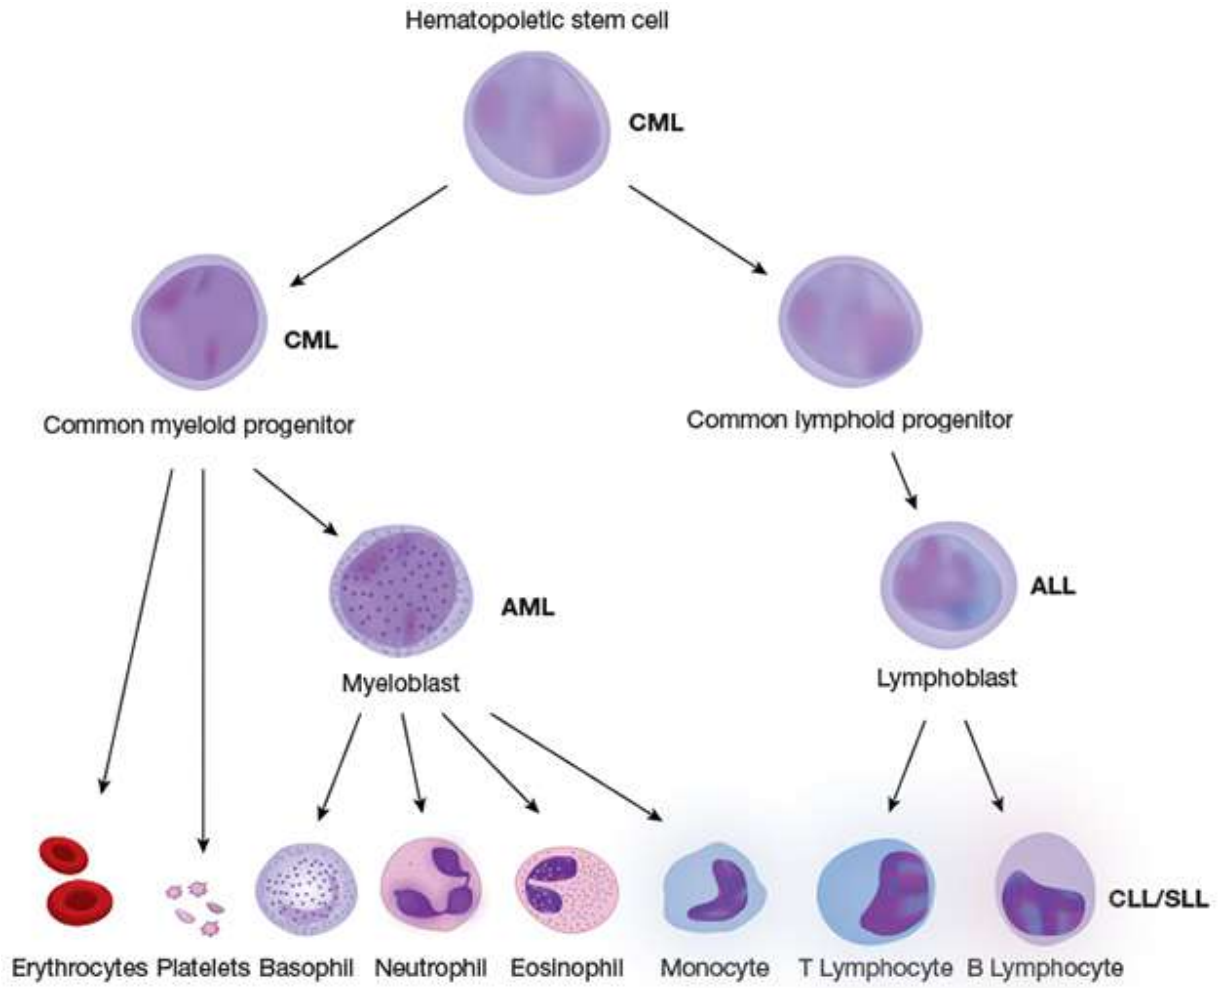

FIGURE 87.1 Hematopoietic stem cells naturally divide into common myeloid (marrow) and lymphoid progenitors. These subsequently differentiate into immature, rapidly growing blast cells, which then undergo additional differentiation into mature, functionally normal components of the blood. Acute myeloid (AML) and acute lymphoid leukemias (ALL) are characterized by an excess of blasts (myeloblasts and lymphoblasts, respectively), reflecting their relatively undifferentiated and rapid disease course. At the other extreme, CLL/SLL reflects mature lymphoid cells. CML can include not only multiple cell histologies ranging from the common myeloid progenitors to differentiated myeloid cells but can also lymphoblasts. Thus, it is shown in both locations on the diagram (common myeloid progenitor as well as hematopoietic stem cell). CLL, chronic lymphocytic leukemia; SLL, small lymphocytic lymphoma.

Cure rates of childhood ALL have improved from approximately 10% in the 1960s to over 90% with modern treatment,[1] with frontline Children's Oncology Group (COG) trials from 1996 to 2014 reporting 12% relapse rates,[2] improved from the 20% relapse rate reported by COG in 2008.[3] Initial remissions generally occurring in about 90%.[1,4-6] In adults, initial

remission rates are generally equally high, but cure rates are only in the 30% to 45% range.[7] In contrast to the situation in pediatric ALL, pediatric AML generally fairs less well, with 60% cure rates, although this represents a marked improvement since the 1970s when cure rates were roughly 20%.[6] Adult AML cures are less frequent in the overall population, in large part a reflection that this disease principally afflicts older individuals. About 20,000 new cases are diagnosed per year in the United States, with 11,000 patients dying from the disease.[8] Allo-HSCT has specifically targeted refractory/recurrent ALL and AML. Reduced-intensity transplants are being used to address the needs of high-risk older patients with acute leukemia.

A notable recent addition to the armament in systemic therapies for B-cell ALL includes chimeric antigen receptor T-cell (CAR T) therapy. CAR T therapy involves harvesting a patient's T cells (ie, "apheresis"), genetically engineering them to express a recombinant T-cell receptor that targets a protein that is highly expressed on the surface of B-cell malignancies (CD19), and then reinfusing these cells into the patient after lymphodepleting therapy. CAR T therapy in B-cell ALL has been associated with long-term durable remissions,[9] with 55% to 59% of patients remaining disease free a year after treatment.[10] The use of radiation in combination with CAR T therapy has not been reported in patients with leukemia. However, studies of patients receiving CAR T therapy for lymphoma or multiple myeloma suggest no evidence of increased toxicity in patients receiving RT immediately prior to or following CAR T.[11-15]

Chronic myelogenous leukemia (CML) and chronic lymphocytic leukemia (CLL) are primarily diseases of adults and have natural histories measured in years to decades. While both chronic leukemias can transform into more aggressive diseases, CML can progress to a more acute disease or blast crisis in its terminal phase. Allo-HSCT is associated with a high cure rate for patients with CML if conducted early in the chronic phase of the disease. However, due to the widespread use of the BCR-ABL tyrosine kinase inhibitors (TKIs), the use of allo-HSCT for CML has declined dramatically over the past two decades.[16]

CML, ALL, and AML, but not CLL, have all been associated with exposure to ionizing radiation, with at least one study reporting a risk with exposures of even less than 1 Gy in atomic bomb survivors,[17] an estimated 2.5-fold increased risk of following therapeutic thyroid cancer treatment

with I-131,[18] and at least one report observing that radiation-related leukemia may be more resistant to treatment compared with nonradiation cases.[19]

A BRIEF HISTORICAL PERSPECTIVE OF LEUKEMIA CLASSIFICATION

The term *leukemia* comes from the Greek word roots meaning "white blood" with early variants of the term including the more precise *leukocythemia* or "white cell blood" (WBC).[20] All leukemias were initially bundled under this single entity, characterized as a fatal condition in adults who presented with general ill health and a range of potential symptoms that could include frequent hemorrhage, abnormally thickened blood, lymphatic masses, and/or splenomegaly. At this time in the mid-1800s, clinical microscopy was in its infancy and was only able to distinguish normal red blood cells from nonred (clear, ie "white") cells. Leukemia was, therefore, characterized by a reversal of the roughly approximately 300:1 red-to-white cell ratio seen in the blood of healthy patients. During the latter half of the 1800s, it was discovered that blood was formed within the bone marrow from ancestral (ie, stem) cells, that leukemia was in fact a disease of the bone marrow, and that bone marrow biopsies could be used to aid in diagnosis.[21]

The introduction of triacid stains enabled the ability to further distinguish between subtypes of WBCs as granulocytes versus lymphocytes. Granulocytes were known to come from the bone marrow, whereas lymphocytes arose from lymphoid tissues. Leukemias were thus able to be classified into myelogenous (from the Greek for "originating in the bone marrow") versus lymphoid (from the Greek for "resembling lymph tissues") subtypes. By 1900, the primitive precursor myeloblasts and lymphoblasts had been identified as hallmarks of rapidly progressive disease, and the presence of blast cells was used to further distinguish acute (vs chronic) leukemias. Diagnosis of both AML and ALL, for example, to this day in some circumstances requires that 20% or more blast cells (myeloblasts and lymphoblasts, respectively) be present among nucleated cells (ie, not red blood cells) within the bone marrow or peripheral blood.

Further clinical experience and advances in histology led to the French-American-British (FAB) morphologic criteria, which remained in use until the turn of the 21st century. In this system, AML and its subtypes were identified microscopically by morphologic features including the presence of Auer rods, and cytochemistry staining for myeloperoxidase or monocyte-associated esterases, and other markers. Certain genetic abnormalities, particularly translocations, were also found to be common to each AML subtype. The FAB assignment of subtypes was replaced by the World Health Organization (WHO) in 2002[22] and most recently updated in the 2022 classification.[23,24] Most of these entities previously covered by the FAB morphologic criteria, with the exception of Burkitt, which is classified as lymphoma, fall under the category of precursor lymphoid neoplasms.[23]

ACUTE LEUKEMIAS

Current Classification Systems and Risk Stratification

The WHO classification scheme for myeloid neoplasms was most recently updated in 2022 (fifth edition).[24] The competing International Consensus Classification was released in 2022 as well.[25] The new acute leukemia subgroups have been developed to highlight meaningful biologic and genetic differences between disease entities with differing prognoses and clinical behavior. The latest WHO classification creates two key subgroups for AML: AML with defining genetic abnormalities (including with *RUNX1::RUNX1T1* fusion due to t(8;21), *CBFB::MYH11* fusion due to inv(16) and acute promyelocytic leukemia (APML) with *PML::RARA* fusion due to t(15;17), among others); AML defined by differentiation (similar to previous FAB subgroups; Table 87.1). For ALL, the WHO 2022 subcategorizes disease into B-cell lymphoblastic leukemia/lymphoma, not otherwise specified (NOS); B-cell leukemia/lymphoma with recurrent genetic abnormalities; and T-lymphoblastic leukemia/lymphoma, NOS; and early T-precursor lymphoblastic leukemia/lymphoma (ETP-ALL).[23] Acute lymphoblastic leukemia and lymphoblastic lymphoma are considered the same disease with latter predominantly affecting extramedullary sites, including lymph nodes, liver, and spleen. In this chapter, both conditions are abbreviated as ALL (Table 87.2).

TABLE 87.1 2022 WHO CLASSIFICATION OF AML

AML with defining genetic abnormalities
Acute promyelocytic leukemia with *PML::RARA* fusion
AML with *RUNX1::RUNX1T1* fusion
AML with *CBFB::MYH11* fusion
AML with *DEK::NUP214* fusion
AML with *RBM15::MRTFA* fusion
AML with *BCR::ABL1* fusion
AML with *KMT2A* rearrangement
AML with *MECOM* rearrangement
AML with *NUP98* rearrangement
AML with *CEBPA* mutation
AML, myelodysplasia related
AML with other defined genetic abnormalities
AML, defined by differentiation
AML with minimal differentiation
AML without maturation
AML with maturation
Acute basophilic leukemia
Acute myelomonocytic leukemia
Acute monocytic leukemia
Acute erythroid leukemia
Acute megakaryoblastic leukemia

AML, acute myeloid leukemia; WHO, World Health Organization.

TABLE 87.2 2022 WHO CLASSIFICATION OF SELECT B- AND T-CELL LYMPHOID MALIGNANCIES

Precursor lymphoid neoplasms
• B-cell lymphoblastic leukemias/lymphomas

- B-lymphoblastic leukemia/lymphoma, not otherwise specified (NOS)
- B-lymphoblastic leukemia/lymphoma with high hyperdiploidy
- B-lymphoblastic leukemia/lymphoma with hypodiploidy
- B-lymphoblastic leukemia/lymphoma with iAMP21
- B-lymphoblastic leukemia/lymphoma with *BCR::ABL1* fusion
- B-lymphoblastic leukemia/lymphoma with *BCR::ABL1*-like features
- B-lymphoblastic leukemia/lymphoma with *KMT2A* rearrangement
- B-lymphoblastic leukemia/lymphoma with *ETV6::RUNX1* fusion
- B-lymphoblastic leukemia/lymphoma with *ETV6::RUNX1*-like features
- B-lymphoblastic leukemia/lymphoma with *TCF3::PBX1* fusion
- B-lymphoblastic leukemia/lymphoma with *IGH::IL3* fusion
- B-lymphoblastic leukemia/lymphoma with *TCF3::HLF* fusion
- B-lymphoblastic leukemia/lymphoma with other defined generic abnormalities

- T-cell lymphoblastic leukemia/lymphoma
  - T-lymphoblastic leukemia/lymphoma, NOS
  - Early T-precursor lymphoblastic leukemia/lymphoma

Mature lymphoid neoplasm

- Mature B-cell neoplasms
  - Chronic lymphocytic leukemia/small lymphocytic lymphoma
  - Splenic B-cell lymphomas and leukemias
  - Lymphoplasmacytic lymphoma
  - Marginal zone lymphoma
  - Cutaneous follicle center lymphoma
  - Mantle cell lymphoma
  - Transformations of indolent B-cell lymphomas
  - Large B-cell lymphomas
  - Burkitt lymphoma
  - KSHV/HHV8-associated B-cell lymphoid proliferations and lymphomas
  - Lymphoid proliferations and lymphomas associated with immune deficiency and dysregulation
  - Hodgkin lymphoma
- Mature T-cell neoplasms
  - Mature T-cell and NK cell leukemias
  - Primary cutaneous T-cell lymphomas
  - Intestinal T-cell and NK cell lymphoid proliferations and lymphomas
  - Hepatosplenic T-cell lymphoma
  - Anaplastic large cell lymphoma
- Nodal T-follicular helper cell lymphoma
  - Peripheral T-cell lymphomas
  - EBV-positive NK/T-cell lymphomas

- EBV-positive T- and NK cell lymphoid proliferations and lymphomas of childhood

EBV, Epstein-Barr virus; NK, natural killer; WHO, World Health Organization.

Adpated from Alaggio R, Amador C, Anagnostopoulos I, et al. The 5th edition of the World Health Organization classification of haematolymphoid tumours: lymphoid neoplasms. *Leukemia*. 2022;36(7):1720-1748. http://creativecommons.org/licenses/by/4.0/.

As may be apparent from the previous discussion of the transition from the FAB to the WHO criteria for categorization, immunophenotyping, cytogenetic, and molecular markers have become very important in the classification of leukemia. Flow cytometry with specific monoclonal antibodies can be used to assay for a panel of antigens, often known as *cluster of differentiation (CD) molecules*, that define leukocyte maturation. For instance, CD19 and cytoplasmic CD79a define B-cell lineage, whereas cytoplasmic or surface CD3 defines T-cell lineage. Myeloid cells are correlated with positivity for CD13 and CD33, but cytoplasmic myeloperoxidase is required to definitively assign the cell to myeloid linage. The common ALL antigen (CALLA, CD10) is expressed in about 85% of ALL cases. With other markers defining different degrees of differentiation and maturation, ALL is conventionally divided into T-cell and B-cell lineage. T-cell ALL can be further characterized based on immunophenotype as ETP-ALL, which is associated with a worse prognosis.

Cytogenetic or chromosomal abnormalities occur in up to 90% of ALL cases. Of these, roughly two-thirds are nonrandom, falling into distinct patterns. Specific cytogenetic abnormalities have important prognostic and therapeutic implications in ALL. Chromosomal translocations occur in approximately 15% of pediatric ALL, and a bit higher in adult cases. The oldest known is the *BCR::ABL1* fusion due to t(9;22), which forms the Philadelphia (Ph) chromosome. This translocation is associated with a higher risk of CNS involvement and overall poorer prognosis. Adult and childhood forms of ALL have distinctly different patterns of genetic abnormalities as well as immunophenotyping. This may partially explain the poorer prognosis in older patients. For example, *BCR::ABL1* fusion occurs in 4% of childhood ALL cases compared to about 25% in adults; moreover, this genetic lesion now represents an important therapeutic target with the development of TKIs, which led to improved outcomes in this

disease. On the other hand, a new subtype of B-cell ALL with *BCR::ABL1*-like features in the setting of multiple genetic aberrations including ABL-class fusions involving *ABL1, ABL2, CSF1R*, and *PDGFRB* that phenocopy *BCR::ABL1* and alterations of *CRLF2, JAK2*, and *EPOR* that activate JAK/STAT signaling are associated with poor prognosis.[26] In addition to specific genomic alterations, abnormal DNA ploidy is extremely common, with two noted patterns that seem to be clinically important. Hyperdiploidy with greater than 51 chromosomes per cell (or DNA index ≥1.6) occurs in 25% of children with ALL. Although there is some association with favorable clinical factors (age >10 years and low presenting leukocyte counts), hyperdiploidy is an independent favorable factor; however, in adults with ALL, outcomes are poor, even in the presence of hyperdiploidy. In childhood ALL, the most common trisomies involve chromosomes 4, 10, and 17 and are associated with a good prognosis. Conversely, hypodiploidy of less than 45 chromosomes is associated with a more unfavorable outcome.

The aforementioned laboratory assessment and clinical disease features have led to distinct risk stratification categories, at least as far as childhood ALL is concerned. Clinical prognostic features of B-cell leukemias have been commonly used to place patients into risk groups. Using the National Cancer Institute's risk classification scheme, standard risk includes patients (two-thirds of pediatric patients with B-cell ALL) whose age at diagnosis is between 1 and 10 years as well as a presenting leukocyte count of less than 50,000/μL, in the absence of CNS involvement, was historically associated with an 80% 4-year disease-free survival (DFS).[27] High-risk patients—defined as a high WBC count, age below 1 year or above 10 years, or CNS involvement at diagnosis—had a corresponding 65% 4-year DFS. T-cell phenotype occurs in 12% to 15% of pediatric ALL cases and is thought to convey a poorer prognosis due to numerous unfavorable clinical correlations, including older age, male sex, elevated WBC count, extensive extramedullary disease including mediastinal and peripheral adenopathy or hepatosplenomegaly, and a higher tendency for relapse in the CNS and testes in males.[28] Current clinical practice is for T-cell leukemias to be treated on different protocols than B-lineage ALL. However, when one factors out unfavorable clinical features, the prognostic difference between T- and B-cell ALL is difficult to discern. In regard to B-cell ALL, current

protocols assign patients to low, standard, and high risk. Low-risk patients are operationally defined by age (1-10 years old) and standard-risk features along with anticipated rapid early response to induction chemotherapy.[29] Apart from this, the intensity of the treatment program is of importance as shown by the fact that adolescents and young adults treated on pediatric leukemia regimens have had better outcomes than those treated on adult programs.[30]

The response to induction chemotherapy has also been proven to be an extremely important prognostic category. In pediatric ALL, the concept of measurable (previously called minimal) residual disease (MRD) detected by flow cytometry or polymerase chain reaction (PCR) of postinduction peripheral blood or marrow aspirates has led to critical prognostic stratification that cannot be underestimated as it is a single most important prognostic factor for patients with ALL (hence the name change from "minimal" to "measurable"). A new method to identify the presence of MRD using next-generation sequencing techniques with the depth of MRD detection at 10^{-6} (superior to PCR and flow cytometry) is increasingly being used.[31] From the assessment of MRD, the concept of risk-adapted therapy has allowed for improved outcomes with the intensification of therapy, including allo-HSCT in those patients who continue to have detectable lymphoblasts after initial chemotherapy (Figure 87.2).

Assessment of CNS involvement at diagnosis in ALL is critical for risk stratification, which is of particular importance to the radiation oncologist. Unfortunately, despite low sensitivity and specificity, cerebrospinal fluid (CSF) cytospin smear analysis and cytology remain the primary means of determining CNS involvement at diagnosis. In addition to CSF, clinical CNS involvement may be detected clinically through the presence of

neurologic symptoms, magnetic resonance imaging (MRI) findings, or slit-lamp examination (in the setting of visual symptoms). Emerging technologies such as quantitative flow cytometry,[32,33] clone-specific PCR, or other CSF-based cytokines or microRNAs may offer improved detection but are not widely available or routinely used at present.[34] Unequivocal CNS involvement (CNS-3) is defined by a CSF leukocyte count of 5 WBC/μL or greater along with either blast cells on cytospin, the presence of cranial nerve (CN) palsy, gross disease by MRI of the brain or spine, or fundoscopic findings. CNS-1 is defined as no blast cells on CSF cytology, whereas CNS-2 is less than 5 WBC/μL with blast cells present. Clinical data are conflicting as to the prognostic importance of CNS-2, reflecting the fact that CNS involvement is not simply a distinction of being present or absent, but that it has also been associated with improved control with more intensive systemic and intrathecal (IT) therapies.[35,36] Traumatic lumbar puncture at diagnosis has been associated with a worse prognosis.[37] Patients with CNS-3 disease who have more intensive IT chemotherapy along with cranial radiation within the first year of therapy have similar event-free survival (EFS) as patients with CNS-2. COG stratification of CNS involvement has added complexity, taking into account a correction formula for traumatic lumbar punctures (the so-called Steinherz-Bleyer algorithm; Table 87.3).[38-41] CNS-2 and CNS-3 are further subgrouped. Regardless, patients with CNS-3 disease are allocated to high-risk treatment protocols.

TABLE 87.3 ASSIGNMENT OF CNS STATUS AT DIAGNOSIS OF PEDIATRIC ALL[42]

CNS-1	In CSF, absence of blasts on cytospin preparation, regardless of the number of WBCs
CNS-2	In CSF, presence of <5/μL WBCs and cytospin positive for blasts, or ≥5/μL WBCs but negative by Steinherz-Bleyer algorithm[a]
CNS-2a	<10/μL RBCs; <5/μL WBCs and cytospin positive for blasts
CNS-2b[b]	≥10/μL RBCs; <5/μL WBCs and cytospin positive for blasts
CNS-2c[b]	≥10/μL RBCs; ≥5/μL WBCs and cytospin positive for blasts but negative by Steinherz-Bleyer algorithm
CNS-3	In CSF, presence of ≥5/μL WBCs and cytospin positive for blasts and/or clinical

	signs of CNS leukemia
CNS-3a	<10/μL RBCs; ≥5/μL WBCs and cytospin positive for blasts
CNS-3b[b]	≥10/μL RBCs; ≥5/μL WBCs and positive by Steinherz-Bleyer algorithm
CNS-3c	Clinical signs of CNS leukemia (such as facial nerve palsy, brain/eye involvement, or hypothalamic syndrome)

ALL, acute lymphocytic leukemia; CNS, central nervous system; CSF, cerebrospinal fluid; RBC, red blood cell; WBC, white blood cell.

[a]The Steinherz-Bleyer algorithm provides a method of evaluating initial traumatic lumbar punctures (TLPs): If the patient has leukemic cells in the peripheral blood and the lumbar puncture is traumatic and contains ≥ 5 WBC/μL and blasts, the following algorithm should be used to distinguish between CNS-2 and CNS-3 disease:

CSF WBCx/CSF RBCx > 2× blood WBCx/blood RBCx.

A patient with CSF WBC ≥ 5/μL blasts, whose CSF WBC/RBC is 2 times greater than the blood WBC/RBC ratio, has CNS disease at diagnosis.

[b]CNS status that can be assigned after a TLP with blasts.

AML patient risk stratification is based on cytogenetic and molecular characteristics, de novo versus secondary nature of the disease (Table 87.4). The presence of complex karyotype abnormalities, FLT3-ITD, and TP53 mutations, among others, may justify a more aggressive treatment approach. In addition, the presence of MRD after induction chemotherapy in certain subtypes of AML including with *NPM1* mutation and with *RUNX1::RUNX1T1*, *CBFB::MYH11* fusion considered a good prognosis based on European Leukemia Net criteria is associated with a significant risk of relapse and may dictate the need for allo-HSCT rather than chemotherapy consolidation.[41] Selecting treatment for older patients with AML should take into consideration not only disease characteristics but also patient's characteristics such as age, comorbidities, and performance status with induction chemotherapy reserved for fit patients and less intense regimens aimed at preserving the quality of life for others.[43]

TABLE 87.4 2022 EUROPEAN LEUKEMIA NET RISK CLASSIFICATION OF AML BY GENETIC ABNORMALITIES IDENTIFIED AT THE TIME OF DIAGNOSIS

Favorable risk

- t(8;21)(q22;q22.1)/*RUNX1::RUNX1T1*

Treatment of Acute Myeloid Leukemias

Classic induction therapy for AML consists of an anthracycline on days 1 to 3 along with cytarabine (cytosine arabinoside, ara-C) for 7 days. APML represents an exception to this rule. In many cases, the coagulopathy predisposing to severe bleeding including intracranial and pulmonary hemorrhage as well as associated *PML::RARA* fusion in APML are best managed with a combination of all-*trans*-retinoic acid and arsenic trioxide, which promote differentiation and apoptosis of malignant promyelocytes.[44,45] Patients with high-risk APML defined by WBC greater than 10,000/μL are treated with the combination of differentiating agents and chemotherapy including CD33 antibody-drug conjugate gemtuzumab ozogamicin and anthracyclines.[46] For the remainder of the AML subtypes, daunorubicin and idarubicin are the anthracyclines most commonly used in

induction chemotherapy regimens. Remission rates vary from 50% to 80% depending on patient age, karyotype, and subtype of AML.

Patients younger than age 60 have complete remission (CR) rates of 70% to 80%, whereas older patients tend to have lower CR rates of 50% to 60%. Patients who develop secondary AML following chemotherapy for other cancers have CR rates in the 40% to 50% range. Some induction regimens in children have added other drugs, such as etoposide. Adding other chemotherapy drugs to anthracycline and cytarabine was evaluated in many studies without convincing survival benefit for AML induction in adults[47] until the addition of midostaurin in patients with previously untreated *FLT3* mutation-positive (FLT3+) AML, for which a randomized trial of 717 patients demonstrated an improvement in overall survival (OS) compared with placebo (hazard ratio [HR] 0.77, $P = .016$).[48] The Food and Drug Administration (FDA) approved midostaurin for the treatment of adult patients with newly diagnosed AML who are *FLT3* mutated in combination with standard cytarabine and daunorubicin induction and cytarabine consolidation (RATIFY). Midostaurin approval in 2017 opened the gate for multiple additional drug approvals by FDA in AML (11 drugs in total between 2017 and 2023) including another FLT3 inhibitor quizartinib in combination with 7+3 based on the results of the QuANTUM-First trial.[49] In addition, multiple other targeted agents were approved including IDH1 and IDH2 inhibitors in the second-line setting.[50]

Adults older than 60 years with AML and intermediate- or adverse-risk disease who are not candidates for allo-HSCT are generally considered suitable for treatment with low-intensity palliative therapies, such as low-dose subcutaneous cytarabine and DNA hypomethylating agents (HMAs) (azacitidine, decitabine).[43] Since FDA approval in 2018, most of these patients received treatment of intermediate intensity with HMAs in combination with bcl-2 inhibitor (venetoclax). VIALE-A randomized placebo-controlled phase 3 trial showed improved survival among older patients “unfit” for induction chemotherapy treated with azacitidine and venetoclax when compared to azacitidine and placebo with a median OS of 14.7 versus 9.6 months. Treatment was complicated with febrile neutropenia in 49% versus 19% of patients.[51]

Once remission is achieved, the need for additional therapy has been well documented in large randomized trials due to high rates of subsequent

relapse in the absence of further treatment. Current data suggest that optimal postremission consolidative therapy begins with high-dose ara-C for up to four cycles.[52] Alternatively, additional cycles of anthracycline for 2 days along with conventional-dose cytarabine for 5 days have been used in both younger and older individuals with AML. With the utilization of new drugs, AML outcomes are improving, but cure rates still remain suboptimal (10%-20%) for older patients with intermediate- and adverse-risk diseases, especially if not treated with allo-HSCT. High-dose ara-C has considerable CNS toxicity in older patients and has also been avoided in pediatric protocols. Other drugs used for consolidative treatment or for second-line induction therapy combinations include anthracyclines mitoxantrone, etoposide, fludarabine, and clofarabine, but no one regimen is clearly advantageous. Lower intensity therapies for older patients include FLT-3 inhibitor gilteritinib, IDH1 inhibitors (ivosidenib, olutasidenib), and IDH2 inhibitor (enasidenib), among others (Table 87.5).[53]

TABLE 87.5 NEW DRUGS FOR AML: 2017-2023

Drug (Brand Name)	FDA Approval	Indication	Schedule
Midostaurin (Rydapt)	4/28/17	New dx FLT3-mut AML with 7+3 induction and HiDAC consolidation	PO BID
Enasidenib (Idhifa)	8/1/17	R/R IDH2-mut AML	PO daily
Liposomal daunorubicin and cytarabine (CPX-351, Vyxeos)	8/3/17	New dx therapy-related AML or AML with MDS-related changes	IV days 1, 3, and 5
Gemtuzumab ozogamicin (Mylotarg)	9/1/17	• CD33+ AML in adults • R/R CD33+ AML in adults and children	IV days 1, 3, and 8
Ivosidenib (Tibsovo)	5/3/18 5/2/19 5/25/22	• R/R IDH1-mut AML • Frontline: ≥75 y or ineligible for intensive chemotherapy • Frontline: combination with azacitidine	PO daily

Drug (Brand Name)	FDA Approval	Indication	Schedule
Venetoclax (Venclexta)	11/21/18	New dx AML > 75 yo or ineligible for chemo with azacitidine, decitabine, or low-dose cytarabine	PO daily
Glasdegib (Daurismo)	11/21/18	New dx AML > 75 yo or ineligible for chemo with low-dose cytarabine	PO daily
Gilteritinib (Xospata)	11/28/18	R/R FLT3-mut AML	PO daily
Oral azacitidine (Onureg)	9/1/20	Maintenance for AML in CR1	PO daily, 2 wk on 2 wk off
Olutasidenib (Rezlidhia)	12/1/22	R/R IDH1-mut AML	PO BID
Quizartinib (Vanflyta)	7/20/23	New dx FLT3-mut AML with 7+3 and as maintenance monotherapy following consolidation chemotherapy	PO daily ×2 wk for induction and consolidation; dose for maintenance based on QTcF

AML, acute myeloid leukemia; BID, twice daily; chemo, chemotherapy; CR, complete remission; dx, diagnosis; FDA, Food and Drug Administration; HiDAC, high-dose ara-C; MDS, myelodysplastic syndrome; mut, mutant; PO, oral; R/R, relapsed/refractory.

The Role of Up-front Radiation in Routine Treatment of Acute Myeloid Leukemias

Historically, prophylactic cranial radiation has been used to decrease the risk of CNS and overall recurrence rates following initial therapy for high-risk AML, particularly with CNS-3 disease. However, CNS prophylaxis is no longer routinely used for AML in the setting of low CNS relapse rates (5%-10%), improved systemic and IT up-front prophylactic regimens, reasonably effective salvage therapy options, and, most importantly, the potential for late effects, particularly in the pediatric population. Patients without neurologic symptoms who have a high WBC count (>40,000/μL) at diagnosis, extramedullary involvement, high-risk APML, mixed phenotype acute leukemia, or monocytic variants of AML are believed to have a higher risk for CNS involvement and screening CSF evaluation with prophylactic IT chemotherapy administration may be considered at the end of induction.

At least one study of childhood AML demonstrated a lower systemic relapse rate after cranial radiation.[54] This observation has been replicated in the Berlin-Frankfurt-Münster (BFM) group, which has studied the role of prophylactic cranial RT in childhood AML in a similar manner to their ALL studies described later. In combination with increasing intensity of induction therapy emphasizing anthracycline chemotherapy and cytarabine IT chemotherapy, cranial irradiation has helped to reduce the risk of CNS relapse, Results from study AML-BFM 87 including nonrandomized patients showed an increased risk of mainly bone marrow relapses in nonirradiated patients. Five-year DFS for patients who received cranial radiotherapy (CRT) was 69% compared to 46% for those not receiving RT. In later studies (AML-BFM 98 and 2004), randomized evidence indicated that 12 Gy resulted in the same relapse rate as 18 Gy.[55] At present, most AML study groups (including BFM-AML 2012)[56] do not include prophylactic CNS-directed RT due to concerns for late effects observed in ALL studies.[57] Although no randomized data have compared the efficacy of radiation versus systemic and IT prophylaxis, triple IT chemotherapy (cytarabine, methotrexate [MTX], and steroids) has demonstrated a lower rate of CNS failures than cytarabine monotherapy and has been a common standard in children in CNS-negative AML.[57]

The radiation oncologist may be called on to treat tissue-based eAML tumor, also known as myeloid or granulocytic sarcoma or chloroma is subtype of AML per WHO, which may predate a diagnosis of leukemia or be a harbinger of systemic relapse, and is typically associated with systemic AML: About 75% to 90% of patients with isolated myeloid sarcoma will develop metachronous intramedullary AML with a median latency period ranging from 4 to 12 months. Myeloid sarcomas may also be seen with other myeloid neoplasms transforming to AML.[58] These solid masses of leukemic infiltrates are responsive to modest doses of RT. The name chloroma derives from the fact that myeloid cells contain myeloperoxidase, which manifests a greenish color on gross inspection. These may occur in all varieties of extramedullary sites, including periosteum, skin, conjunctiva, testicles, soft tissues, gastrointestinal tract, the spine, and epidural spaces or meninges.[58] Pathologic misclassifications are common, as this is a rare clinicopathologic disorder. Based on various case reports in the literature, symptomatic problems from myeloid sarcomas may be

readily relieved with doses of 10 to 24 Gy. The fractionation and total dose need to take into consideration any normal tissue toxicities, and the potential for future TBI should the patient be a potential candidate for an allo-HSCT. Recent reviews and commentary have suggested a prescription dose of 24 Gy in 12 fractions for most patients.[59,60] However, it should be noted that leukemias are at least in principle thought to be more radiosensitive than indolent lymphomas, in which a shift toward ultra-low dose of 4 Gy in two fractions has been adopted, particularly in palliative settings. Anecdotally, ultra-low doses of RT can be highly effective in AML, but little has been published in the way of formal reports. Although OS may be better for isolated myeloid sarcomas as compared with systemic AML, due to high co-incidence of medullary and extramedullary disease, long-term disease control requires similar systemic therapy as is used for systemic AML.[61-64] Outcomes among patients with myeloid sarcomas are defined by cytogenetic and molecular testing results, and selection of systemic treatment strategy should be similar to other patients with AML.[58]

Treatment of Acute Lymphoblastic Leukemia/Lymphoblastic Lymphoma

The approach to the treatment of ALL is based on disease Ph chromosome status (Ph-positive or negative), phenotype (T or B cell), and patient's age (children, adolescents and young adults, adults and older adults). Multiagent regimens are usually used to treat this disease. The four components of ALL therapy are typically (1) induction of remission, (2) intensification and/or consolidation, (3) maintenance therapy, and (4) CNS prophylaxis. Duration of treatment is about 2 to 3 years, including more intense up-front treatment periods and a 2-year period of prolonged low-intensity maintenance at the end. It is significantly longer than chemotherapy for AML, which typically includes induction and up to four cycles of consolidation spanning 6 to 7 months. In the 1960s, the problem of CNS recurrence was addressed with CNS radiation and IT chemotherapy. Subsequent improvements in ALL cure rates over the past two to three decades have resulted from improved risk stratification of patients with more effective, tailored multidrug regimens. As discussed in the following text, the late sequela of 24-Gy cranial irradiation was recognized in the

1980s and 1990s, leading to the elimination of CRT in favor of intermediate- or high-dose MTX in all but high-risk patients or those with CNS-3 disease. While not a standard worldwide, investigators at St Jude Children's Research Hospital (SJCRH) have completely eliminated the use of up-front CRT in their protocols of pediatric ALL, accepting a small incidence of CNS relapse even in their high-risk patients.[65] In addition, with the improvements in systemic therapy, testicular relapse in males has become a rare event.[66] Testicular irradiation is rarely necessary, except in the setting of testicular relapse or bone marrow transplantation.

Current induction therapy for pediatric and young adult patients with ALL as a minimum typically includes a glucocorticoid, anthracycline, vincristine, and L-asparaginase.[67] Other four or greater multidrug regimens have been used, all of which have resulted in initial remission rates of 95% to 99% in children and 75% to 90% in adults. Dexamethasone is now the preferred systemic steroid treatment as suggested in two clinical reports comparing it to prednisone, with dexamethasone reducing both CNS and systemic relapse in pediatric ALL.[68,69] This may be related to dexamethasone's better penetration into the CSF and longer half-life, providing enhanced protection against CNS relapse.[70]

Following induction and achieving CR, patients then receive intensification therapies that have been developed by cooperative groups in the United States and Europe.[71,72] This may consist of high doses of antimetabolites, such as MTX, ara-C, and L-asparaginase. It is believed that high-dose MTX helps control CNS disease, which has allowed for less use of cranial radiation. After intensive therapy, patients undergo a phase of prolonged maintenance treatment with agents such as monthly vincristine, a short course of steroid, weekly low-dose MTX, and daily mercaptopurine, which appear to be quite important, albeit for unclear reasons.

For ALL in adults, patients have experienced improved CR rates (>90%) with multiagent induction regimens similar to pediatric protocols but with decreased exposure to certain medications (eg, steroids, L-asparaginase), which are not well tolerated by this patient population. The issue for these groups is preventing relapse and accomplishing cure, which has been suboptimal among adults at around 30% to 40% but is improving to about 60% to 70% with the use of pediatric- inspired regimens, especially among

adolescents and young adults.[73] Survival of older patients with ALL who are not able to tolerate pediatric-inspired treatment approaches remains poor.

Ph-positive B-cell ALL had been considered prognostically poor with universal indication for allo-HSCT frontline consolidation for fit patients who were able to accomplish remission with a multiagent regimen until the introduction of BCR::ABL1 TKIs. The use of third-generation TKI ponatinib together with a multiagent regimen hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) led to CR in all 68 patients enrolled in a phase 2 trial. Twenty patients (23%) underwent allo-HSCT. With a median follow-up of 80 months (range, 16-129 months), the estimated 6-year EFS rate was 65% and the OS rate was 75%. There was no difference in outcome by the performance of allo-HSCT in the first CR.[74]

Patients with T-cell ALL receive multiagent regimens as patients with B-cell ALL with some modifications based on the recently completed large COG study (AALL0434), which showed that lower dose but more frequent administration of MTX (Capizzi-Style) was superior to high-dose MTX. The 5-year DFS rate was 87.4% and OS 90.5% versus 70% and 79.1%.[75] Introduction of nucleoside analog nelarabine approved in the second-line setting to the frontline led to improved DFS (4-year DFS of 88.9% vs 83.3%, $P = .0332$) with significant reduction of CNS relapse incidence (0.3% vs 4.3%, $P = .0009$) based on the same study.[76] Finally, the study showed similar EFS and OS among patients with ETP and near-ETP versus patients with non-ETP, albeit with decreased CR rate in the ETP-/near ETP-ALL group.[77]

For relapsed ALL, the traditional treatment has included a second induction that generally consists of multiple drugs similar to frontline regimes. If the CNS is involved, IT treatment is given along with RT.[78] If testicular relapse occurs, bilateral testicular irradiation is administered. When isolated CNS or testicular relapse develops, systemic therapy is indicated along with local RT.[79] If a second remission develops, as occurs in 70% to 90% of cases, subsequent treatment includes either allo-HSCT or consolidative chemotherapy.[79,80] There are no randomized trials to indicate which is better, but comparative analysis suggests that survival is improved with allo-HSCT, particularly in patients with ALL who had brief initial remissions.[80,81]

Treatment approaches for relapsed ALL have begun to undergo a paradigm shift in treatment thanks to the recent influx of immune-modulating and other targeted agents in oncology. These include bispecific T-cell engagers (BiTEs), which are monoclonal antibodies designed to link CD3-positive host T cells to leukemic cells (eg, via CD19 expressed in >90% of patients with B-cell ALL). The CD3-CD19 BiTE blinatumomab, for example, has been shown to be safe and effective in the up-front treatment of infant ALL[82] and high-risk relapsed ALL.[83] Blinatumomab was approved for Ph-negative and positive, CD19-positive B-cell ALL in relapse as well as for patients with positive MRD and serves as a bridge for curative allo-HSCT in some patients.[84,85] Antibody-drug conjugate inotuzumab ozogamicin, which targets CD22 expressed in 80% of B-cell ALL, has been approved for the management of relapsed/refractory disease but should be used with caution prior to allo-HSCT due to high incidence of veno-occlusive disease.[86] Both drugs are currently investigated in the frontline setting with successful outcomes already reported in a few studies with the anticipated approval for use in the frontline setting.[87-89] Additional advances in salvage therapies include CD-19–directed CAR T therapy, which has shown remarkable efficacy in multiply relapsed/refractory (third-line or greater) patients with B-cell ALL, with 48% of patients remaining disease free at 3 years.[90] CAR T therapy is associated with unique toxicity profiles, including cytokine release syndrome in most patients and immune effector cell–associated neurotoxicity syndrome in over one-third of patients.[10] There are numerous immune-modulating and targeted agents under active investigation, which will likely continue to impact relapsed management options;[67] however, none of these have yet made it into first-line standard-of-care therapy for childhood ALL.

The Role of Radiation Therapy in Acute Myeloid Leukemia and Acute Lymphoblastic Leukemia

As noted earlier, the use of prophylactic CNS radiation has been largely removed from the up-front treatment of pediatric leukemias due to advances in alternative systemic therapies and an increasing appreciation for the potentially devastating and lifelong consequences of brain radiation in these patients. The data surrounding this evolution are described in the next

sections. However, there still remains a role for RT in patients with highly selected leukemia, particularly adults, in which palliation of local disease or CNS salvage remains important, potentially life-saving treatment options. The local-only progression of leukemias, which was previously a relatively uncommon phenomenon, has become more prevalent as systemic therapies have improved.

Radiotherapeutic Emergencies

The radiation oncologist will be called on to assist with certain emergencies when the patient first presents with leukemia or at the time of relapse. Mediastinal adenopathy causing airway compression or spinal cord compression from epidural disease is clear indication for emergent RT. Generally, only one to three 1.5- to 2.0-Gy fractions are required while the diagnosis is being established and systemic therapy is being initiated (Figure 87.3). Glucocorticoids are an important adjunct to CNS RT but can produce rapid lysis of some lymphoblastic lymphomas/leukemias, which may hamper diagnostic evaluation. In the presence of CN palsies at diagnosis, some radiation oncologists recommend 10 to 15 Gy to the base of skull early in the treatment course to try and reverse the neurologic deficits.[91,92] However, it should be noted that larger retrospective studies of isolated CNS leukemia relapses have observed increased rates of CNS failure with base of skull alone, and therefore, any curative treatment, particularly in adults, should consider larger treatment fields with whole brain or even craniospinal irradiation (CSI) in selected cases (isolated CNS failure with no evidence of marrow disease).[93] CN palsies can improve rapidly after initiation of radiation (within two fractions),[94] but complete neurologic recovery may take weeks or months if it happens at all. Extreme leukocytosis with blast counts over 75,000 to 100,000/μL is a concern with myeloid leukemia, as leukostasis may occur, particularly in the vessels of the brain or lung. Lymphoid blasts are less adhesive to vessel walls, and blast counts of up to 400,000/μL or more are often well tolerated. In decades past, RT directed at the whole brain was employed using low doses on the order of 6 to 10 Gy in various fractionations. However, the role of RT in this setting has been questioned[95-97] but may be considered when leukophoresis is contraindicated or unavailable. Nevertheless, one recent

report suggests reconsideration of the role of CRT for leukostasis. Eighteen patients received whole-brain RT in one to three fractions for a mean total dose of 5.63 Gy (range 2-9 Gy). Thirteen patients were treated to control neurologic symptoms rather than in a preventive manner, resulting in 92% achieving prompt resolution of symptoms during RT or immediately thereafter. There was no toxicity above grade 2. Two (6%) patients developed an intracranial bleed following therapy from underlying leukostasis, while historically, this leukostasis syndrome has been associated with a 20% acute mortality rate from stroke or heart failure.[98]

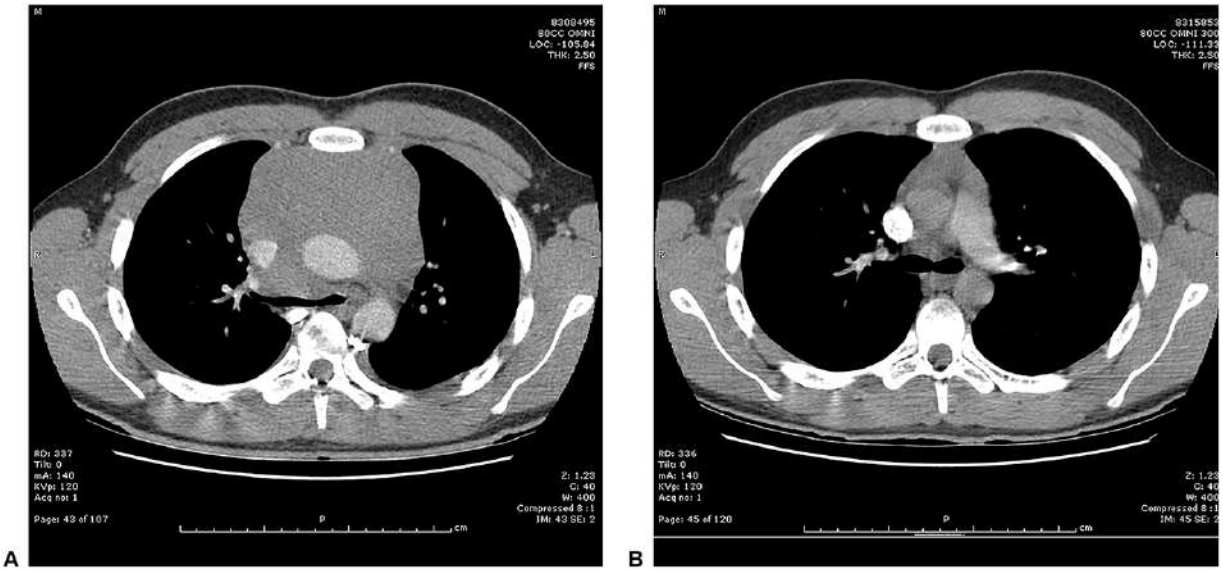

FIGURE 87.3 Computed tomography scans of chest before (A) and after (B) palliative radiotherapy (RT) for mediastinal mass associated with T-cell acute lymphocytic leukemia. A 16-year-old boy presented with dyspnea and chest pain. A chest x-ray showed a mediastinal mass, while blood counts revealed a lymphocytosis. Diagnosis was established by flow cytometry of blood. Initial treatment with steroids, doxorubicin, vincristine, and methotrexate failed to produce immediate response. Megavoltage RT with anterior and posterior opposed beams for 6 Gy in three fractions was administered, subsequently relieving acute symptoms and allowing for general anesthesia to take place without risk for complete airway obstruction in order for central line placement and lumbar puncture to be performed.

Central Nervous System Prophylaxis of Acute Leukemia

Patients with AML, except for specific subtypes such as monocytic variants, are not generally treated with prophylactic cranial radiation at the present as the risk for CNS relapse is less than 5%. The risk of CNS relapse

is dramatically higher for ALL, however, which is the focus of the remainder of this section.

The Historical Role of Prophylactic Central Nervous System–Directed Radiotherapy in Acute Lymphoblastic Leukemia

As investigators in the 1970s began producing remissions in childhood ALL, CNS relapse became the next hurdle to long-term cure, with historical chemotherapy regimens (ie, without CNS prophylaxis associated with rates of up to 67% CNS relapse).[99] The CNS was thus recognized as a sanctuary site, protected from chemotherapy by the blood-brain barrier. In addition, it was observed that CNS recurrences invariably led to systemic recurrence, suggesting that CNS disease was capable of reseeding the blood and marrow.

This observation led to a long series of CNS preventive therapy trials in pediatric ALL, which initially utilized CSI. For instance, studies V and VI in 1962 to 1967 from SJCRH established that CSI to 24 Gy in 15 to 16 fractions reduced the isolated CNS relapse rate from 67% to 4%.[100,101] Concerns that full-dose spinal RT would be associated with more acute myelosuppression, late musculoskeletal hypoplasia, as well as the technical difficulties of CSI led to the subsequent investigation of prophylactic cranial irradiation (PCI) without the treatment of the spine and lower doses of radiation. Important milestones and lessons learned ensued. Early lessons of toxicity came from the SJCRH study VII, in which 24-Gy cranial radiation with concurrent MTX resulted in a 55% rate of leukoencephalopathy, characterized by a disabling syndrome of lethargy, seizures, spasticity, paresis, and ataxia.[102] In contrast, no such toxicity was observed in patients treated sequentially with cranial radiation followed by maintenance oral MTX and mercaptopurine, in which only 1.5% of patients experienced CNS relapse. To this day, intravenous (IV) MTX and cranial radiation in close temporal proximity are avoided, with at least 2 weeks of washout for MTX provided prior to CNS radiation whenever feasible in both periods.

Further cooperative group trials have refined the efficacy of CNS-directed therapies within patient groups stratified by risk. Several trials have compared CRT with intermediate- or high-dose IV MTX along with IT

chemotherapy (some with the addition of IT hydrocortisone and ara-C to MTX known as "triple" IT therapy).[66,103,104] The essential findings have been that in patients with low- or standard-risk ALL (eg, age 3-6 years and WBC count <10,000/μL) who are managed without cranial radiation by substituting IT MTX throughout induction, consolidation, and maintenance therapy, CNS relapse rates have remained at a low level of 5% or less.[105-107] In addition, with triple IT chemotherapy, there was a trend toward fewer systemic failures as well as excellent CNS control when given throughout consolidation and maintenance therapy. This may be at the expense of increased neurotoxicity, however, when given in conjunction with intermediate-dose IV MTX.[107] A meta-analysis of 65 randomized trials of pediatric ALL worldwide initiated prior to 1993 that evaluated the role CRT concluded that in the vast majority of patients, CRT may be avoided with the use of extended IT therapy.[108] One notable exception to the conclusions of aggregated trials of this meta-analysis was the CCG-105 trial of intermediate-risk ALL,[109] in which patients treated with standard (ie, nonintensified) chemotherapy without cranial radiation experienced a CNS recurrence rate of 20%. Thus, more intensive systemic therapy can lower CNS recurrence rates, abrogating any benefit to cranial irradiation. As a result, the vast majority of patients with ALL are treated without RT in the up-front setting.

The Current Role of Prophylactic Central Nervous System–Directed Radiotherapy in Acute Lymphoblastic Leukemia

The use of PCI in pediatric ALL is undergoing continued restriction and even abandonment due to concerns for limited efficacy due to improved alternative systemic and CNS-directed therapies, as well as a growing body of evidence that many CNS relapses are harbingers of systemic relapse. Any benefit of PCI must be weighed against a historical body of evidence for musculoskeletal, neurocognitive, endocrine, and secondary tumor toxicities associated with RT. Conversely, adverse effects of radiation on IQ are known to be particularly pronounced in very young patients (under age 2) and comparisons that exclude these very young patients (as is routinely done in all modern trials) suggest that the neurocognitive impact of CRT compared with non-RT regimens may be far less pronounced than was

previously thought.[110,111] These data support that while the avoidance of RT is preferred wherever possible, RT may not add significant risk of neurotoxicity when therapeutically necessary.

The most sweeping assessment of PCI use came from a group of international investigators in 2016, in which they performed a detailed meta-analysis of PCI use from 10 cooperative groups involving 16,623 patients aged 1 to 18 years with newly diagnosed ALL treated between 1996 and 2007.[112] The proportion of patients eligible for PCI varied from 0% to 33% by trial, unrelated to eligibility for allo-HSCT in the first CR. A meta-analysis using PCI as a dichotomous covariate compared EFS and cumulative incidence of isolated or any CNS relapse and isolated bone marrow relapse in high-risk subgroups of patients who either did or did not receive PCI. Results showed that only a small subgroup of patients with overt CNS disease at diagnosis had a plausible benefit from RT, with a significantly lower risk of isolated CNS relapse of 4% with PCI compared to 17% who did not receive RT (P =.02); moreover, there was a trend toward lower risk of any CNS relapse (7% with PCI vs 17% without, P = .09). These investigators, however, still questioned the role of PCI even in this or other high-risk groups of pediatric ALL receiving contemporary risk-adapted therapy as systemic relapse and death were equally high occurring in roughly one-third of patients, regardless of RT usage.

At present, only patients who are at the highest risk for CNS relapse receive RT as part of their CNS prophylaxis, with some groups such as SJRCH forgoing RT in all up-front cases including those with CNS-3 disease. In all practicality, decisions made regarding CNS prophylaxis and/or TBI in the context of leukemia are typically made by the managing leukemia oncologist or transplant team member within the context of tertiary cancer centers. The role of the radiation oncologist, therefore, is primarily to be (1) familiar with subsets of patients for which CNS prophylaxis may be recommended and is appropriate, (2) understand the appropriate dose of radiation and associated toxicities, and (3) be proficient in the modern technical delivery of CNS-directed therapy. Therefore, in this section, we highlight current practices with a focus on which patients receive prophylactic CNS-directed therapy.

At one extreme is the St Jude's group, which has become particularly concerned about the late effects of 24 Gy to the brain in terms of

neurocognitive disabilities, hypothalamic/pituitary dysfunction, and secondary malignancies. With risk-adapted intensification of chemotherapy, Pui et al have reported favorable results with the complete elimination of CRT in all patients with newly diagnosed ALL.[65] In their St Jude Total XV trial, 498 patients were treated without CRT, yielding an 86.6% 5-year EFS, which was comparable to their prior studies that had included CRT. CNS-directed therapy used five cycles of high-dose MTX including, as part of induction therapy, dexamethasone, and extended IT chemotherapy. High-risk patients with ALL received up to 16 to 25 IT chemotherapy sessions, whereas low-risk patients received 13 to 18 doses of IT chemotherapy. Patients who were at increased risk of CNS relapse were those who had positive CSF cytology (CNS-2 or CNS-3) or T-cell ALL. Moreover, a relatively high 7% of patients in the first remission went on to undergo an allo-HSCT correlating with high-risk features of MRD and adverse cytogenetic markers. An additional 598 patients were treated on Total XVI, which not only randomized the dosage of PEG-asparaginase but also omitted RT, reporting 5-year EFS of 88.2%, with a cumulative risk of any CNS relapse (isolated or combined) of 1.5%. In patients with features associated with CNS relapse (eg, T-cell phenotype), the 5-year rate of any CNS relapse was lower than that seen in Total XV (1.8% vs 5.7%).[113]

Elsewhere worldwide, the philosophy on the use of CRT in pediatric ALL has been to use it judiciously in high-risk patients while also reducing radiation doses to address the concerns about late effects. The European BFM-ALL trials since 1990 have reduced the cranial radiation dose to 12 Gy with their risk-adapted intensification schemes, although those with CNS-3 disease received 24 Gy in their BFM-90 trial and 18 Gy in the more recent BFM-95 trial. The recent Intercontinental BFM 2009 has similarly employed a dose of 12-Gy cranial radiation for high-risk prophylaxis, in which 13% of patients received CRT.[114]

Currently, the COG has followed suit with a reduction in both the utilization and intensity (ie, dose) of cranial radiation in its current ALL trials. One of the largest reductions in utilization has been for T-ALL, where T-cell subtype is a known substantive risk factor for CNS and overall relapse. In the COG ALL1231 trial of patients with T-ALL, RT was given to only 9.5% of patients (very high risk or CNS-3) compared with the precursor ALL0434, in which 90.8% of patients received CRT. No

statistically significant differences in EFS or OS were observed between matched patients who did versus did not receive CRT, suggesting that up to 90% of patients with T-ALL can safely forgo RT.[115]

In the AIEOP-BFM ALL 2009 study, approximately 10% of patients receive PCI. In the current COG studies, prophylactic CRT is given only to the 2% to 3% of patients with CNS-3 status and approximately 10% of patients with T-ALL with high levels of MRD after 3 months of therapy. Bcr-abl mutations and other high-risk molecular markers are no longer an indication for PCI by itself. In the current DFCI Consortium study, approximately 20% of patients (all patients with T-ALL and patients with B-cell precursor ALL with CNS-3, high level of MRD at the end of remission induction, MLL rearrangement, or low hypodiploidy) receive PCI. But, in the upcoming DFCI study, only CNS-3 status will be used as a criterion for PCI for patients with B-cell ALL. In the current Cooperative Acute Lymphoblastic Leukemia 08-09 study, PCI 12 Gy is given to approximately 6% of the patients. Only patients with CNS-3 status receive PCI in the current trial of the Japanese Pediatric Leukemia/Lymphoma Study Group. Of note, several groups have completely omitted PCI, including the Dutch group, the Nordic Society of Hematology and Oncology, the European Organisation for Research and Treatment of Cancer (EORTC), the UK ALL group, and the SJCRH.[112]

Meningeal Leukemia at Diagnosis

At the time of diagnosis of ALL, approximately 3% to 5% of patients will present with clinically detectable CNS involvement (ie, CNS-3 disease). Meningeal leukemia at diagnosis is typically managed as high-risk leukemia with CRT. The St Jude investigators may disagree with the use of RT even here, but their results of the Total XV protocol included nine patients with CNS-3 disease whose 5-year EFS was only 43%.[65] These high-risk patients receive chemotherapy programs that include dose-intensive therapy with agents that penetrate the blood-brain barrier as well as IT therapy. Cranial radiation doses may vary from 18 to 25 Gy. Historically, CSI has been used, but modern practice has dispensed with the spine fields as the IT and systemic chemotherapy programs appear to be effective in assisting with CNS control. In children with ALL, meningeal

involvement no longer carries a dire prognosis, as 5-year DFS rates approaching 70% are commonly seen.[116]

Delay in CRT or craniospinal RT up to 12 months has been found to be safe as long as intensive chemotherapy is being given first.[117,118] This avoids the marrow compromise that could potentially occur with early spine irradiation. In addition, with doses less than 16 Gy to the spine, myelosuppression has not been a major problem. Musculoskeletal hypoplasia would not be expected to be a significant problem for long-term survivors. The sequencing of RT *after* rather than *before* potentially neurotoxic drug therapy such as MTX may theoretically result in a lower incidence of cognitive dysfunction or encephalopathy. Some pediatric protocols will also tailor the dose to the brain based on patient age. For instance, the ALL-BFM 90 protocol, which utilizes cranial rather than CSI, avoids any RT for those younger than 1 year of age, 18 Gy for ages 1 to 2 years, and 24 Gy for older patients. In this large multicenter trial, 54 patients presented with CNS-3 disease and achieved a 48% 6-year EFS.[119] Arguably, this is inferior to protocols that use CSI, such as those reported by the CCG.[116] However, in the ALL-BFM 95, there were 64 patients with CNS-3 disease who had a 6-year EFS of 57.7% in which therapy included cranial radiation to 18 Gy without irradiation of the spine.

Some investigators in addition to those at SJCRH continue to try to avoid CRT in all cases, including those with CNS-3 disease. The Dutch Childhood Oncology Group (DCOG) and the EORTC have omitted cranial radiation by also using more high-dose MTX during postinduction consolidation and by an increased frequency of IT chemotherapy. The SJCRH study also included higher cumulative doses of anthracycline than on COG trials, and frequent vincristine/dexamethasone pulses and intensified dosing of L-asparaginase, while the EORTC trials included multiple doses of high-dose cytarabine, during postinduction treatment phases for patients with CNS-3. On the DCOG-9 trial, 21 patients with CNS-3 treated without cranial radiation had a 5-year EFS of 67% ± 10%. On the EORTC trial, the 8-year EFS of 49 patients with CNS-3 treated without cranial radiation was 68%. The cumulative incidence of isolated CNS relapse for those patients was 9.4%. This CNS-3 subgroup is relatively

uncommon, and further studies will be required to see if CNS irradiation can be safely eliminated.[120,121]

Cranial Radiation Dose

To reduce the toxicity of prophylactic cranial radiation, several investigations have explored a reduction in radiation dose. In earlier, circa 1981 trials, the use of 18 Gy in 9 or 10 fractions along with IT MTX yielded comparable disease control rates as 24 Gy.[122] Although there were some initial reports of reduced cognitive dysfunction even with such a dose reduction,[123] this issue is by no means completely settled.[124-126] The Dana Farber Cancer Institute ALL Consortium has studied the role of hyperfractionated cranial radiation (0.9 Gy twice daily) compared to standard daily fractionated treatments (1.8 Gy daily) to 18 Gy in high-risk patients.[127,128] Results from Dana Farber ALL 87-04 show excellent CNS control rates with both the standard or hyperfractionated treatments. Late neurocognitive sequela has been similar in which systemic therapy emphasizes L-asparaginase and omits high-dose MTX. A follow-up Dana Farber ALL trial 95-01 compared hyperfractionated 18-Gy CRT to extended IT chemotherapy without CRT. The interesting finding here is that quantitative measurements of neurocognitive function were similar in both groups.[111] The German-Austrian-Swiss ALL-BFM Study Group has further reduced the radiation dose to 12 Gy, initially in a selected group of standard-risk pediatric patients.[106] With modern chemotherapy regimens as opposed to the older SJCRH experience, this further reduction in radiation dose was associated with excellent CNS control. Moreover, the ALL-BFM 90 protocol stopped using CRT in low- or standard-risk patients, but both the medium- and high-risk patients received 12-Gy prophylactic cranial radiation, resulting in CNS recurrence rates well below 5%.[119] For the ALL-BFM 95 trial, CRT was deleted for the patients with intermediate-risk B-cell ALL. This has resulted in a small increased risk for CNS relapse, which is considered clinically acceptable in order to avoid the late effects of such RT.[129] Specifically comparing intermediate-risk BFM 90 to BFM 95 patients, the isolated CNS relapse rate at 6 years is 0.5% versus 1.9% ($P <$ .01). The 6-year “any CNS” relapse rate was also statistically different at 2.2% versus 4.4%. Further follow-up and additional experience within the

COG with this lower cranial radiation dose will be of interest in the years to come, hopefully seeing a reduction in late toxicity without compromising efficacy as CRT continues as used in a subset of high-risk pediatric patients with ALL.

For adults with ALL, various protocols have used 24 Gy, whereas others employ 18 Gy.[124,125,130] Recent studies have explored even lower doses, including 6 Gy, with no evidence of neurocognitive toxicity and a suggestion toward improved local control and may warrant future study.[131] Some programs such as hyper-CVAD omit the use of CRT in the face of high-dose MTX and ara-C, which effectively penetrate the blood-brain barrier.

Summary of Cranial Radiotherapy for Initial Acute Lymphoblastic Leukemia Management

In summary, CRT may be used to prevent CNS relapse of leukemia. From a historical perspective that considered the brain as a sanctuary site, CRT has been well documented to improve outcomes for selected patients with pediatric ALL. With concerns about late sequela and improvements in systemic therapy including agents that can better penetrate the blood-brain barrier, CRT is used much less frequently in the up-front management of ALL. Overall, only 15% to 20% of pediatric patients with ALL who have high-risk features require CRT currently. In current practice, cranial radiation is employed selectively in patients with high-risk ALL. Although the definition of high risk has been shifting, one needs to take into account the intensity and specifics of risk-adapted chemotherapy. Nevertheless, patients with ALL who benefit from CRT include older age (eg, older than 10 years of age, and probably increasing benefit at ages older than 13 years); T-cell phenotype, especially in older patients with high presenting WBC over 100,000; and risk groups CNS-2 or CNS-3 by CSF findings. In addition, among B-cell patients, those with MRD and adverse cytogenetics should be strongly considered for CRT. Moreover, a recent meta-analysis supports the concept that a relatively small cohort of high-risk pediatric patients with ALL require CRT as part of initial CNS-directed therapy.[132] All adults with ALL may be considered to be at high risk for CNS relapse, but there are no standard recommendations on CRT. Unless otherwise

indicated, in a specific treatment protocol, the radiation prescription for prophylactic cranial radiation to prevent ALL relapse is 18 Gy in 9 or 10 fractions. When BFM-type chemotherapy programs are used, the radiation dose has been reduced to 12 Gy with favorable outcomes. The spinal region is specifically treated by IT chemotherapy rather than RT, although an open question is whether there would be an incremental benefit to low radiation doses to the spine with meningeal leukemia at diagnosis.

Therapeutic Central Nervous System Irradiation for Meningeal Relapse

With modern chemotherapy programs incorporating CNS-directed treatment, CNS relapse rates are typically less than 10%. As in overt CNS leukemia at diagnosis, RT has a central role. Formally, CNS relapse was thought to have a poor prognosis. Studies in the 1970s and 1980s describe disease control rates of 25% to 50%.[133-139] More recent trials, however, utilizing more intensive chemotherapy as well as RT, have reported ALL 5-year survivals of 50% to 70%.[118,140-143] Almost all trials have employed RT; the debate has been between CRT alone or CSI. Doses used have generally been approximately 24 Gy to the brain and 10 to 15 Gy to the spine. Most comparisons have not been randomized, but superior outcomes seem to be achieved with CSI.[119,118,140-143] One small phase III trial did show superiority for CSI compared to CRT.[140]

Although CNS relapse may ostensibly occur without overt systemic disease, the latter is viewed as inevitable without additional systemic therapy. Therefore, intensive chemotherapy is an essential component of the treatment of meningeal relapse.[120,144]

Several prognostic factors have been found to be of importance in the setting of CNS relapse.[145-147] Patients who were originally deemed at diagnosis to be at low risk for CNS relapse by virtue of a low initial leukocyte count (<20,000/μL), who originally did not receive cranial irradiation, or whose CNS relapse occurred at a relatively long period after the original diagnosis have a better prognosis after CNS recurrence. An isolated CNS relapse has generally been more prognostically favorable compared to combined CNS and systemic relapse. After completing chemotherapy, those children with CNS relapse have better outcomes with

longer disease-free intervals. For instance, experience within the Pediatric Oncology Group (POG) with isolated CNS relapse of ALL in which RT used a cranial dose of 24 Gy and a spine dose of 15 Gy. The 4-year EFS was 71%. Those patients who presented with greater than an 18-month disease-free interval prior to CNS relapse had a 4-year EFS of 83% compared to 46% for those with shorter initial remission durations.[118] This has led subsequent POG and COG trials that omit RT to the spine if there is a long disease-free interval, but if the disease-free interval is less than 18 months, 24 Gy is given to brain while 15 Gy is delivered to the spine. Whether the omission of spinal RT in this favorable subgroup is detrimental is unclear. However, high-dose ara-C has generally been added to the management of CNS relapse of ALL. With this agent, Morra et al[148] reported a favorable 63% complete response rate. These concepts have been maintained with current COG trials for CNS relapse of ALL, but with intensification of systemic therapy, spinal RT has been proposed to be dropped even for short disease-free intervals, while the brain is treated to 18 Gy. As for adults with CNS leukemia, most of the published experience and commentary from medical oncologists has been opposed to the use of CSI mainly for fear of excessive myelosuppression.[124] Cranial irradiation is relatively standard, however. Quite possibly, the avoidance in treating the entire CNS is detrimental, although admittedly this is not a settled issue. Modern CSI techniques using either protons or photon-based approaches that spare the vertebral bodies may be able to reduce the risk of myelosuppression compared with historical three-dimensional (3D)-based approaches.[149]

Selected high-risk patients with CNS relapse may be candidates for allo-HSCT. TBI is often a component of the preparative regimen. One function of the TBI is to specifically treat the CNS burden of disease. Because doses on the order of 12 to 15 Gy are employed here, it makes sense to boost the head prior to TBI to bring total doses to the cranium to 18 to 25 Gy. Investigators at Stanford have evaluated the neurocognitive effects of this practice of boosting the CNS in conjunction with TBI. Forty-one pediatric patients with relapsed ALL undergoing TBI-based allo-HSCT had the brain boosted to a total mean dose of 24 Gy. In 18 patients, the spine was also boost to a total cumulative dose of 18 Gy. Five-year DFS for all patients was 67% for this high-risk group. Patients with isolated CNS disease before

transplant had a trend toward superior DFS (HR 3.64, $P = .11$, 5-year DFS 74%) compared with those with combined CNS and bone marrow disease (5-year DFS 59%). Neurocognitive testing revealed a mean post-SCT overall intelligence quotient of 103.7 at 4.4 years. While relative deficiencies in processing speed and/or working memory were noted in 6 (38%) of 16 tested patients, the pre- and post-transplant neurocognitive testing revealed no significant change in intelligence quotient. At a mean of 12.5 years after transplant, 11 (85%) of 13 long-term survivors had completed some college-level coursework.[150]

Considerations for Adult Central Nervous System Leukemia Salvage

Adult patients with CNS relapse leukemia, particularly those with isolated CNS failure after prolonged disease-free intervals, may benefit from consideration of comprehensive CSI and do not face the same concerns as pediatric populations regarding developmental delays and secondary radiation-induced malignancies. Secondary therapeutic cranial radiation-induced CNS malignancies are strongly age dependent, are difficult to detect at the population level after age 18, and may take 20 to 25 years to manifest in adults, assuming there is any increased risk at all.[151] Current International Lymphoma Radiation Oncology Group guidelines recommend doses of 18 to 24 Gy.[152] These data stem from evidence of long-term disease control in some adult patients with CSI, which is highly effective at eliminating CNS disease. One retrospective review of 16 patients (ages 16-58) described a mix of CNS leukemia recurrences from AML, ALL, and one patient in CML blast crisis.[153] A median dose of 24 Gy to cranium and 18 Gy to the spine was used with median fraction sizes of 1.8 and 1.5 Gy, respectively, and 15 also received IT chemotherapy. CNS clearance was shown to be effective, with 13 of 16 patients achieving clearance of CNS disease with no evidence of disease at the time of death or last follow-up, with two patients experiencing greater than 5-year DFS. Eleven patients experienced bone marrow failure, which continued to drive overall outcomes.

A second, larger series of 163 adults treated between 1996 and 2012 examined patients with CNS leukemia treated with base of skull (29%), whole brain (41%), and CSI (29%). Common symptoms included headache

and CN deficits (ie, facial, optic, oculomotor, or abducens). Among patients with neurologic deficits, two-thirds experienced improvement or resolution with RT. Base of skull radiation, as opposed to whole brain or spine radiation, was associated with worse 12-month CNS progression-free survival (51% vs 77%). Patients with isolated CNS involvement benefited the most from comprehensive radiation fields, suggesting that "aggressive" comprehensive CSI may be capable of achieving cure in these cases. Although not formally examined in these studies, patients with a longer bone marrow–free disease interval (ie, at least 6 months) who present with isolated CNS leukemia are thought to stand the most to benefit from curative-intent CSI.[93] Technical considerations related to CSI delivery are discussed later in this chapter.

Testicular Relapse

In boys with ALL, particularly those with T-cell subtype, testicular involvement was once a common problem. Overt testicular involvement by leukemia at diagnosis occurs in approximately 2% of males with ALL and is a particularly poor prognostic situation. Microscopic burden in the testes is estimated to be higher at 5% to 15% based on biopsy data and the historic risk for testicular relapse. With modern chemotherapy, especially the use of intermediate- to high-dose MTX, testicular relapse is now rare. Similar to the experience with CNS relapse, there once was speculation as to whether the testes acted as a sanctuary site due to a physiologic blood-testes barrier. In 1980, a trial of prophylactic testicular irradiation significantly reduced the risk of testicular relapse but did not improve survival.[154] Modern risk-adapted chemotherapies as promulgated by SJCRH investigators no longer require testicular RT in the up-front management of patients presenting with testicular involvement as there is no reduction in relapses nor improvement in OS or EFS.[155]

In cases of testicular relapse, systemic and/or CNS relapse usually follows.[156] Both intensive systemic therapy and local RT are indicated. Doses less than 12 Gy are generally thought to be suboptimal, whereas doses of 24 to 26 Gy over 2.5 to 3.5 weeks are considered standard. Case reports of local recurrences despite adequate RT have led some to suggest higher doses. When only one testis is clinically involved, imaging or biopsy

of the contralateral testes frequently reveals bilateral disease. Similarly, unilateral irradiation or orchiectomy as local management is felt to be associated with a significant risk of contralateral testicular relapse, justifying treatment directed at both testes for leukemia management, despite the expectation of infertility from RT. Data from CCG and POG studies suggest that local irradiation and intensive systemic therapy result in prolonged EFS in roughly 50% to 65% of patients.[79,157] Where allo-HSCT is indicated, TBI is often part of the conditioning regimen. One retrospective series from the Memorial Sloan-Kettering Cancer Center suggests that for TBI/cyclophosphamide preparative regimens, the risk of testicular relapse is significantly reduced with a local boost to the scrotum of 4 Gy to bring the total testicular dose to 16 to 20 Gy.[158] However, a retrospective study from Stanford did not observe any improvement associated with testicular boost with respect to leukemia control and was associated with worse gonadal function.[159] There is not universal agreement about the need for a testicular boost in this setting, and most transplant programs have stopped the practice of prophylactic testicular boost with TBI.

Ocular Relapse

Historically, choroidal recurrence of leukemia was sometimes associated with inadequate coverage of the optic nerve and posterior globe with CRT. This has led to practice patterns in which the posterior eye is included in standard cranial fields. Even so, isolated relapse in the eye is rarely seen and may even occur in the anterior chamber. RT is often used as part of retrieval therapy analogous to relapse in the brain or testes. The best report of the incidence and management of this situation comes from the United Kingdom Medical Research Council leukemia clinical trial experience.[160] Investigators found a 2.2% incidence of eye relapse in their Leukaemia XI and ALL97 trials between 1991 and 2001. There were 17 patients who had ocular leukemia as a first relapse, either in isolation or combined with relapse at another site, and three occurred as a poor prognosis second relapse event. Among the patients with ocular relapse as a first site of recurrence, 11 patients were long-term survivors with disease control who were treated with a full chemotherapy relapse protocol along with local RT. Disease tended to not be controlled when chemotherapy was of reduced

intensity; again, a lesson that isolated leukemia recurrences is a harbinger of systemic relapse. From this limited experience and from other cooperative groups, there is a sense that posterior eye relapse should direct the RT volume to include not just the eye but also the CNS comprehensively. Radiation doses to the eye ranged from 10 to 24 Gy, mostly using 24 Gy as a cumulative dose that might have also entailed TBI or CRT/craniospinal RT volumes with differential dosing. An isolated relapse in the anterior chamber is felt to have less risk for occult CNS involvement and may be managed with electron beam RT rather than photons just to the eye along with intensive chemotherapy.

THE CHRONIC LEUKEMIAS

Chronic Myelogenous Leukemia

CML is a chronic myeloproliferative disorder arising from clonal expansion of the hematopoietic stem cell. CML involves both mature and precursor myeloid, erythroid, megakaryocytic, and, sometimes, lymphoid elements. It is the first neoplastic process to be characterized by a specific cytogenetic marker, the Ph chromosome, t(9;22) described in 1960.[161] This is detectable by cytogenetics in 90% to 95% of patients and by molecular analysis in most other patients.[162] This translocation results in a BCR::ABL1 fusion protein that has tyrosine kinase activity critical for leukemic transformation. CML, the subject of this chapter, is not to be confused with chronic myelomonocytic leukemia (CMML) or atypical CML (myelodysplastic syndrome/myeloproliferative neoplasm [MDS/MPN] with neutrophilia per WHO 2022 classification). These latter two entities are both classified under MDS/MPNs, characterized by defective bone marrow hematopoiesis, and are not associated with the Ph chromosome that is characteristic of CML. CMML is associated with excess monocyte production and atypical CML with excess neutrophil proliferation and myeloid left shift. CMML, atypical CML, and other myeloid disorders beyond AML and CML are not separately covered in this text, as RT is not a direct component of their treatment. However, MDs/MPNs and MPNs are still relevant to radiation oncologists in that any form of aberrant hematopoiesis can also result in splenomegaly and other foci of aberrant hematopoiesis (discussed more in the splenomegaly section), which can be palliated with RT. Any myeloid

malignancy can be complicated by the development of myeloid sarcoma, which has been previously discussed.[58]

Clinically, CML can manifest several phases: If untreated, an initial chronic indolent phase of 3 to 4 years will progress to an accelerated phase for about 6 months and finally will transform into blast phase with a survival of 3 to 6 months. As the disease advances, the accelerated phase is characterized by increasing difficulty in controlling the peripheral WBC count, increasing splenomegaly, increasing blasts in the peripheral blood and bone marrow, and increasing basophilia and eosinophilia. The blast crisis resembles acute leukemia with more than 20% blasts in blood or bone marrow with symptoms such as bone pain, sweats, fever, anorexia, or weight loss. Anemia, thrombocytopenia, and extramedullary disease involving bones, skin, CNS, and lymph nodes are common. In about 20% of cases, blasts are lymphoid by phenotype. Historically, prognostic factors for CML have included age, splenic size, platelet count, percent of basophils in blood, and marrow. Factors associated with a poor prognosis include age greater than 60 years, spleen greater than l0 cm below the left costal margin, more than 3% blasts in blood or marrow, basophilia more than 7% in blood or marrow, and platelets greater than 700,000/μL.[163] More recently, the prognostic scoring system has been updated (European Treatment and Outcome Study (EUTOS) Long-term Survival score) but still uses the same parameters, including age, spleen size by palpation below the costal margin, and blast and platelet count in peripheral blood.[164] High-risk patients are usually managed with second-generation TKIs rather than imatinib as discussed in the following section.

Therapy of Chronic Myelogenous Leukemia

The first effective therapy for chronic leukemias was RT to the spleen and sometimes the liver, initiated in 1902 by Pusey[165] and assessed in 1924 by Minot et al.[166] Today, RT is primarily used in a palliative setting to relieve painful splenomegaly or other extramedullary sites when indicated. In some centers, TBI plays an important role in allo-HSCT. The use of the latter is now quite limited in CML management due to successful management with TKIs.

There is a long history of treating CML in the chronic phase with alkylating agents, hydroxyurea, cytarabine, and interferon-α, which is beyond the scope of this chapter. Since the approval of the first-generation TKI, imatinib, in 2001, such therapies, as well as allo-HSCT, have largely been relegated to the salvage setting. Multiple ABL TKIs effective in inducing and maintaining long-term remissions in CML without cumulative toxicities have been approved for use in first-, second-, and third-line settings in the past 20 years.[167,168] Imatinib is a relatively well-tolerated oral medication that has been shown to be effective in CML in both chronic and accelerated phases.[169,170] This agent has been a paradigm for molecularly targeted therapies and is now used as up-front therapy for CML.[171] Second-generation TKIs such as dasatinib, nilotinib, and bosutinib may be used for patients with resistance to imatinib or with poor prognostic features.[172,167] The potent third-generation TKIs ponatinib and asciminib are available for use in the relapsed and/or refractory setting, as well as for patients with a T315I *ABL1* gatekeeper mutation, which confers resistance to earlier generation TKIs.[167] Approximately one-third of patients with chronic-phase CML who have been treated with TKIs for over 3 years and achieved a deep molecular response for over 2 years may be eligible for treatment discontinuation. Roughly half of those patients can successfully maintain treatment-free remission with close monitoring of the BCR::ABL1 transcript level in blood, which is essential for the successful management of CML. For a minority of patients who do not respond adequately to the TKIs or who lose response, allo-HSCT remains an important option.[173,174] About 70% of favorable-risk patients achieve long-term DFS.[175] Allo-HSCT and TBI are further discussed in Chapters 15.

Palliative RT may be of benefit in those patients with massive splenomegaly with responses seen with low doses (<20 Gy) and is discussed further in the splenomegaly treatment section.

Chronic Lymphocytic Leukemia and Small Lymphocytic Lymphoma

CLL/SLL (small lymphocytic lymphoma) is an indolent leukemia of B-cell origin and is characterized by the accumulation of clonal, functionally incompetent mature B lymphocytes. It is the most common leukemia in the

Western world, and the course of the disease demonstrates marked variability. While some patients live a normal lifespan and never require therapy, others progress rapidly despite treatment. The usual course is characterized by gradual progression from incidentally found lymphocytosis to lymphadenopathy, splenomegaly, to anemia and thrombocytopenia due to progressive bone marrow involvement and/or autoimmune phenomena. Nonlymphoid organ involvement may occur with advanced stage of disease. CLL/SLL is often diagnosed following an elevated WBC discovered during a routine office visit. In symptomatic patients, 80% present with lymphadenopathy and 60% with splenomegaly. Other signs and symptoms include "B" symptoms of lymphoma, hepatomegaly, or skin lesions. Patients may also present with complications associated with CLL/SLL, including thrombocytopenia, anemia, and infections, which are usually indicative of advanced disease. Workup for CLL/SLL should include history (with specific inquiry into the presence of B symptoms) and physical examination (with focus on node-bearing areas, liver, and spleen). Imaging with a computed tomography (CT) of the chest/abdomen/pelvis may be helpful to characterize the extent of disease, but positron emission tomography (PET)/CT is typically not recommended in CLL unless Richter transformation is suspected.

It should be noted that *CLL and SLL* are terms used to describe different patterns of gross anatomic behavior of the same underlying pathology, in which CLL refers to a predominantly leukemic process (ie, high blood lymphocyte counts), and SLL refers to a predominantly lymphatic process (ie, lymphadenopathy or splenomegaly). A diagnosis of CLL requires the presence of greater than 5.0×10^9/L monoclonal B cells in the peripheral blood with or without lymph node/splenic involvement, while a diagnosis of SLL is made when lymph nodes and/or spleen are infiltrated with mature B cells in the absence of a lymphocytosis greater than 5.0×10^9/L.[176] Diagnosis of CLL is made by flow cytometry of peripheral blood, which should confirm a monoclonal B-cell population. A typical immunophenotype of CLL is $CD5^+$, $CD10^-$, CD20 dim, and $CD23^+$. Fluorescence in situ hybridization analysis for t(11:14) is helpful to distinguish it from mantle cell lymphoma, which is included in the differential diagnosis of $CD5^+$ B-cell neoplasms. If analysis of peripheral blood confirms CLL, a bone marrow biopsy is typically not required. A

diagnosis of SLL can similarly be made with flow cytometry of a biopsied lymph node or with immunohistochemistry for the abovementioned cell surface markers. Histologically, CLL cells have a similar appearance to mature lymphocytes with scant cytoplasm, a dense nucleus, and no discernable nucleoli.[177] Although there are likely underlying additional clinical nuances and genomic or molecular features that vary between CLL and SLL, they remain somewhat interchangeable terms that reflect the same basic underlying pathology, often referred to as CLL/SLL.

Occasionally, patients with CLL/SLL develop transformation to an aggressive large B-cell lymphoma referred to as *Richter syndrome*.[178] Its incidence ranges from 3% to 5% of CLL cases.[179] It may arise in the setting of active disease or during a remission. It is characterized by an abrupt onset of asymmetric adenopathy, splenomegaly, B symptoms, and elevated lactate dehydrogenase. Other transformations include evolution to prolymphocytic leukemia with the development of progressive refractory disease and a majority of prolymphocytes in the blood. Rarely, ALL or myeloma develops in the course of CLL.[180,181] The fundamental process of transformation can occur because CLL/SLL reflects a more mature cell type. When additional genomic alterations occur, the differentiation can be blocked and the disease phenotype can suddenly revert to an earlier precursor, characterized by a more primitive (de-differentiated) and rapidly growing entity with aggressive clinical behavior.

There have been many staging systems proposed, but the most widely used are those modified by Rai et al[182] and Binet et al,[183] the former used in the United States and the latter in Europe (Table 87.6). Clinical stage is the most important predictor of survival in patients with CLL. Numerous other factors have been reported to have an impact on survival and include age, sex, lymphocyte doubling time, pattern of marrow involvement, β-2 microglobulin levels, and immunophenotype of malignant cells.[184] Cytogenetic and molecular abnormalities have more recently emerged as powerful predictors of outcome and may impact treatment decisions.[185] For example, deletion of chromosome 17p or p53 mutation confers both an inferior OS and resistance to purine analog and alkylator-based therapy.

TABLE 87.6 CHRONIC LYMPHOCYTIC LEUKEMIA STAGING SYSTEMS

Staging System	Clinical Features	Median Survival (y)
Rai staging		
Low risk		>10
0	Lymphocytosis of blood and marrow	
Intermediate risk		7
I	Lymphadenopathy	
II	Splenomegaly	
High risk		2-4
III	Anemia, Hgb <10 g/dL (unrelated to hemolysis)	
IV	Thrombocytopenia <100,000 platelets/μL	
Binet staging		
A	<3 Areas of lymphadenopathy	12
B	≥3 Involved nodal areas	7
C	Anemia and/or thrombocytopenia	2

Hgb, hemoglobin.

Asymptomatic early-stage patients are typically followed without therapy ("watch-and-wait" or "active surveillance" approach). About 20% of such patients will continue to have an indolent course and never require therapy. Of the remaining patients, the decision to intervene therapeutically is often challenging. The International Workshop on CLL has established guidelines for the initiation of treatment, which include constitutional symptoms ("B symptoms") due to CLL, symptomatic lymphadenopathy and/or hepatosplenomegaly, anemia (hemoglobin <10 g/dL), thrombocytopenia (platelets <100,000/μL), and refractory autoimmune disease.[186] The absolute lymphocyte count should not be used as an indication for treatment, as symptoms associated with marked lymphocytosis due to leukocyte aggregation do not typically occur in patients with CLL.

For many years, the standard treatment for CLL included single-agent chlorambucil with or without prednisone.[187] The newer purine analogs, 2-deoxycoformycin, fludarabine, and 2-chloro-2′-deoxy-*b*-D-adenosine (cladribine or 2-CDA), have been tested in CLL, and, of these, fludarabine has shown a high response rate in combination with the anti-CD20

antibody, rituximab.[188] In a phase III trial comparing fludarabine to chlorambucil, the complete response rate with chlorambucil was 4% and with fludarabine 20%.[189] Overall response rates (ORRs) were 37% with chlorambucil and 63% with fludarabine. The median survival was 66 months (fludarabine) versus 56 months. For these reasons, fludarabine was a standard backbone of therapy for CLL for much of the late 20th century. More recently, a combination of fludarabine, cyclophosphamide, and rituximab, has resulted in a very high CR rate of 70% in patients with CLL, with a median time to progression of 80 months.[190] Moreover, when compared to fludarabine and cyclophosphamide, the addition of rituximab led to a survival benefit, which made this the regimen of choice in the up-front treatment of the young and fit.[191]

For patients who are older than 65 years, have comorbidities, and/or decreased renal function, bendamustine plus rituximab has been used traditionally, given the increased risk for adverse events including infectious complications.[192] This regimen has a relatively low toxicity mainly confined to a mild to moderate degree of reversible myelosuppression.[193]

However, the past decade has been revolutionized with the advent of targeted therapies, which have demonstrated superior efficacy and safety compared to chemoimmunotherapy in CLL. Ibrutinib—a selective irreversible inhibitor of Bruton tyrosine kinase, part of the B-cell receptor signaling cascade—was the first FDA-approved novel orally administered agent for the up-front treatment of older patient with CLL based on the results of the RESONATE-2 trial.[194] This was an open-label, randomized phase 3 trial, which compared ibrutinib and chlorambucil, in previously untreated older patients with CLL or SLL, and resulted in a higher ORR (86% vs 35%, $P < .001$), longer progression-free survival (median, not reached vs 18.9 months), and OS, with a relative risk of death that was 84% lower in the ibrutinib group than in the chlorambucil group (HR 0.16; $P = .001$). Ibrutinib has also been FDA approved for patients with relapsed/refractory CLL and for the up-front treatment of patients with CLL harboring a deletion in chromosome 17p or a deletion on p53 who have historically a poor response to traditional chemoimmunotherapy.[195,196]

More recently, ibrutinib with or without rituximab was found to have improved clinical outcomes and favorable safety when compared in large,

randomized trials to either standard chemotherapy with R-bendamustine or fludarabine, cyclophosphamide, and rituximab (FCR).[197,198] The role of targeted Bruton tyrosine kinase inhibitors (BTKi) was further advanced with the development of second-generation molecules with fewer off-target inhibition, including the approval of zanubrutinib and acalabrutinib for the treatment of CLL following head-to-head trials against ibrutinib that showed at least equivalent efficacy, but more favorable safety profile compared to ibrutinib.[199,200]

While BTKi have remarkable activity against CLL/SLL, they typically require continuous therapy for years until toxicity or intolerance. Acute toxicities may be less when compared to chemoimmunotherapy; however, cumulative toxicities such as cardiovascular, bleeding, and myalgias/arthralgias can limit long-term administration.[201] Fortunately, a second class of targeted orally administered medications targeting BCL2 have been shown to be highly efficacious against CLL/SLL and allow for a time-limited treatment over 12 to 24 months. Here, venetoclax was first shown to have efficacy in relapsed CLL, including with 17p deletion, and has a low toxicity profile, except for a propensity to cause tumor lysis syndrome due to its high response rate.[202] Impressively, it has led to an ORR of 79%, with a 20% CR, which is highly unusual in this heavily pretreated patient population. Based on these results, it had an initial FDA approval for patients with CLL with 17p deletion after at least one prior line of therapy. Subsequent large-scale randomized trials have established that venetoclax combined with anti-CD20 therapy (obinutuzumab in first line or rituximab in relapsed/refractory) has superior efficacy over prior standard chemoimmunotherapy.[203,204]

Modern CLL/SLL management in both the first-line and relapsed settings is typically without any chemotherapy, instead relying on sequential use of BTKi followed by venetoclax-based therapies or vice versa. However, recent trials that combine orally administered BTKi with venetoclax has also been shown to be safe and may provide durable remissions following time-limited therapy.[205]

Given the availability of highly active orally administered targeted therapies for CLL/SLL, there has been a dramatic shift away from traditional chemoimmunotherapy in the past decade. However, for younger patients with high-risk CLL, refractory disease may still occur. Here, allo-

HSCT has been employed with the recognition of graft-versus-leukemia effects and the advent of reduced-intensity conditioning. Earlier studies of allografting showed promising results in young patients with regard to disease control at the expense of significant treatment-related toxicity.[206,207] Several groups have reported favorable disease control and survival in high-risk patients with reduced-intensity conditioning regimens that are fludarabine or low-dose TBI based. Of note, patients with chromosome 17p deletion appear to respond as well to allografting as those without 17p deletion.[208,209] Indications for consideration of allografting have been proposed by the European Group for Blood and Marrow Transplantation and include early relapse following chemoimmunotherapy, resistance to fludarabine, chromosome 17p deletion, and Richter transformation.[209] The use of CAR T therapy may also be a viable option in the near future for multiply relapsed CLL/SLL refractory to BTKi and BCL2-based therapy.[210]

The Role of Radiotherapy in Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

RT was historically a very effective initial therapy for CLL. Prior to the plethora of modern chemotherapeutics, ultra-low-dose TBI was used without stem cell support decades ago for CLL, given its extraordinary radiosensitivity. This historical use of TBI used roughly 3 to 12 rad or 0.03 to 0.12 Gy per fraction several times a week titrated to response, but total doses in the range of 1 to 4 Gy,[211-214] But, RT is now almost entirely relegated to a palliative role for CLL, for instance, used in the management of painful splenomegaly or occasionally for cytopenias associated with splenomegaly when splenectomy is not an option. It is also indicated in instances of unresponsive disease to alleviate symptomatic adenopathy or nonlymphoid organ involvement. Remarkably, low doses on the order of 4 Gy in one to two fractions can be effective for palliation as used with low-grade B-cell lymphomas, although fractionated doses up to 20 Gy are also reasonable for more definitive local control.[215-217]

Localized SLL (stage I) is seldom encountered, but when it is, RT is the treatment of choice. In a series of 54 patients with SLL, including 14 patients with stage I or II disease who were treated with RT alone (40-44 Gy), the 10-year freedom from relapse for the patients with stage I and II

diseases treated with RT was 80% and 62%, respectively.[218] Radiation dose and field size are similar to that of other indolent non-Hodgkin lymphomas. The recommended total dose is 24 to 30 Gy; treatment volumes should follow involved-site principles similar to follicular lymphoma (FL). Like FL, RT can be used to palliate symptomatic lymphadenopathy in CLL/SLL. A small series of 14 patients with symptomatic SLL were treated with 2 Gy × 2 with involved-field radiation, resulting in an ORR of 85% with a median time to local progression of 14 months.[219] The regimen can be safely repeated if symptoms recur.

IRRADIATION TECHNIQUES

Anatomic Considerations

The radiation oncologist must be knowledgeable about the anatomy of the CNS, particularly the meninges (Gk. "membranes," ie, dura mater, arachnoid, and pia mater) and subarachnoid space for the proper design of CNS-directed radiation treatments. The epidural space lies between the periosteum and the dura, whereas the potential space between the dura and the arachnoid is called the *subdural space*. The pia and arachnoid are often described as a combined membrane called the *leptomeninges* (Gk. lepto, "thin" or "peel"). Between the arachnoid and pia is the subarachnoid space, which is filled with CSF. The pia hugs the surface of the brain, extending into sulci, fissures, and the internal cavities or ventricles, while the bulk of the arachnoid follows along the dura, except for the fine trabeculations, and into some of the major fissures of the brain. Arachnoid sheathes both nerves and blood vessels penetrating the pia and exiting the CNS, creating relatively short segments of subarachnoid space, which is of particular anatomic importance in the vertebral column. In the design of the inferior aspect of craniospinal radiation fields, the subarachnoid space extends laterally to the spinal ganglia, which are located within the intervertebral foramina.[220,221] Thus, coverage of the entire sacroiliac joints in such spinal field design is excessive. The caudad extent of the subarachnoid space is variable within the sacrum.[222] Clinically, the end of the thecal sac is now routinely determined on MRI scanning. A large retrospective study of 502 children (ages 1 month to 19 years) with nonpathologic MRI of the spine demonstrated that the mean level of thecal sac termination lies around the

level of mid-S2, with 90% ending at S2 or higher. All patients terminated between S1 and S3. For this reason, if MRI is not available, coverage through S3 can be used to ensure the entire sac is covered.[223] Pathologically, CNS leukemia originates as a perivascular infiltrate along the subpial blood vessels. As this progresses, the leukemia infiltrates preferentially into the subarachnoid space as well as into the brain parenchyma.[224]

Base of skull anatomy is also of importance to the radiation oncologist in the design of lateral cranial fields. The middle cranial fossa and temporal lobe project over the sphenoid sinuses on lateral radiographs. The cribriform plate projects along the roof of the orbit along an imaginary line that connects to the inferior aspect of the frontal sinuses. Several radiologic-anatomic studies have pointed out how the eye's lens in this "beam's-eye view" is less than 1 cm away from the cribriform plate, having implications in field design. Insuring coverage of the entire subarachnoid space should supersede the concerns of radiation-induced cataracts as this is a readily manageable complication.[225,226] Moreover, because subarachnoid space extends as a sheath along the optic nerve, it is standard to include the posterior half of the eye globes within cranial radiation fields by using the anterolateral aspect of the bony orbit as an anatomic landmark, as it typically lies along a line that roughly bisects the eye[226] (Figures 87.4 and 87.5).

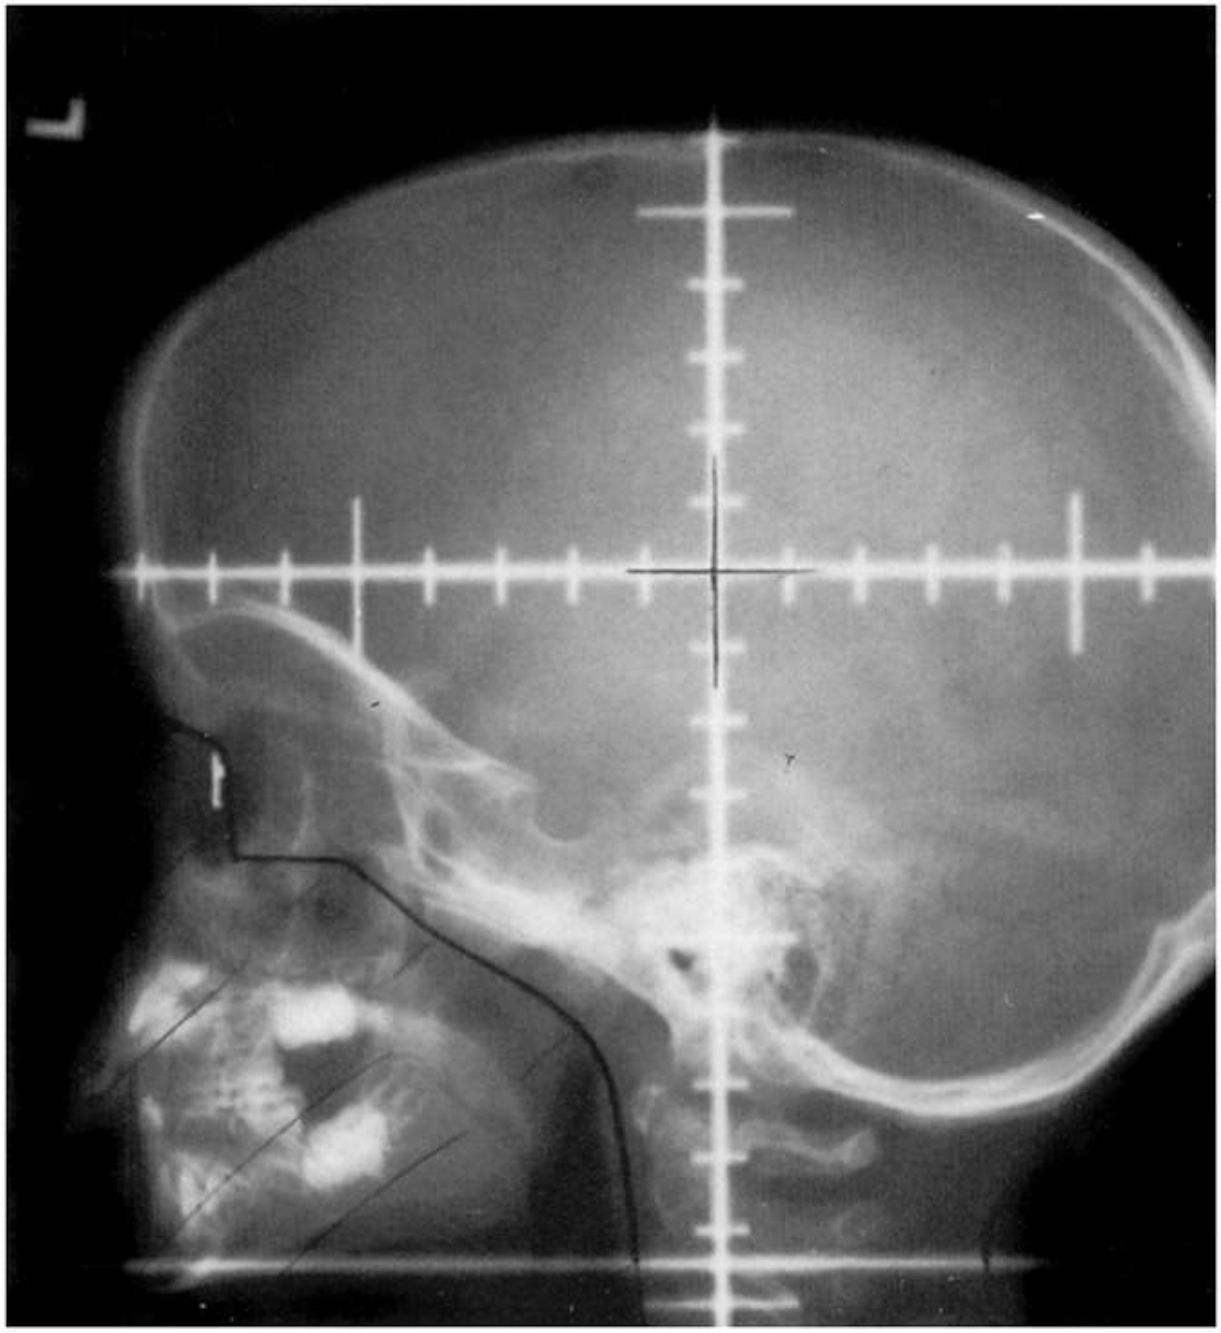

FIGURE 87.4 Cranial irradiation field outlining treatment that encompasses the entire cranial subarachnoid space. The radio-opaque markers outline the anterior aspect of the bony orbit to demarcate inclusion of the posterior aspect of the eye within the treatment fields.

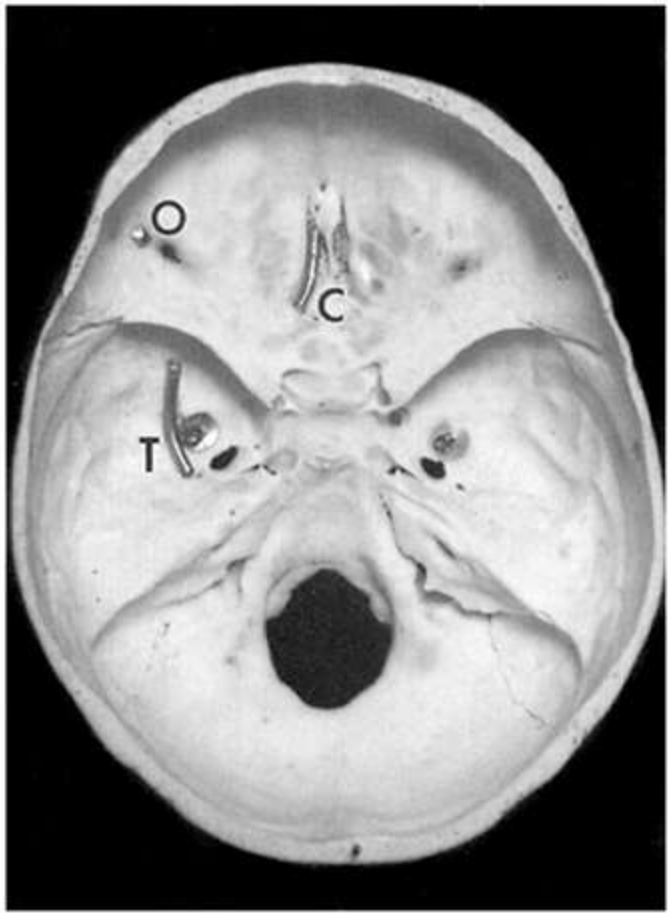

A

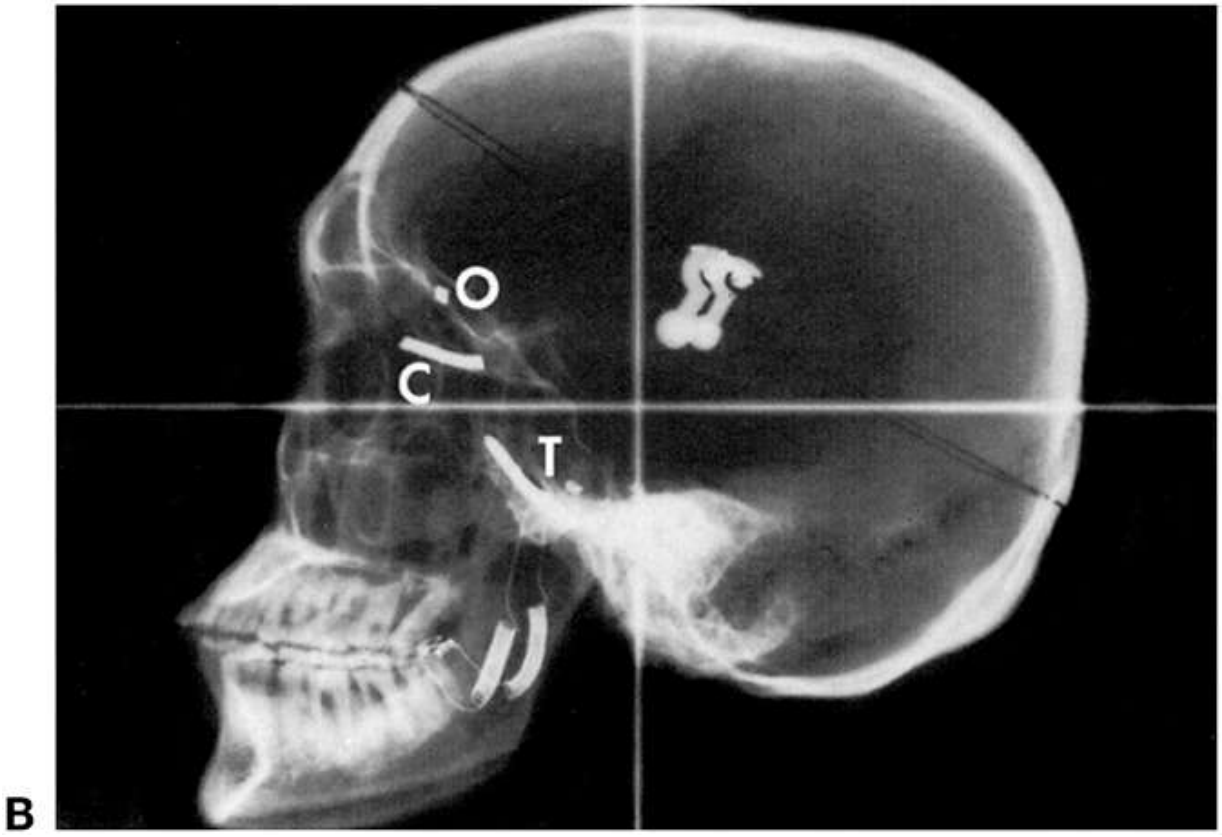

FIGURE 87.5 Skull views outlining anatomic limits of the base of skull for inclusion of the cranial subarachnoid space. A. Radio-opaque markers have been placed at the cribriform plate (C), roof of the orbit (O), and the temporal fossa (T). B. Plain lateral radiograph shows the projection of the cribriform plate, orbital roof, and temporal fossa.

To compensate for the blood-brain barrier, certain drugs are administered directly into the subarachnoid space either via lumbar puncture or via an intraventricular reservoir (eg, an Ommaya reservoir). IT drugs distribute unevenly, however, throughout the subarachnoid space.[227,228] This is not surprising, given the knowledge of brain anatomy and CSF circulation. CSF is mainly formed in the brain ventricles by the choroid plexuses, which are specialized capillary-rich tufted structures. This fluid then flows through the intraventricular foramina and the cerebral aqueduct of the midbrain into the fourth ventricle, from where it communicates with the rest of the subarachnoid space. CSF is resorbed principally in the dural sinuses via button-like projections called *arachnoid villi*. Thus, IT therapy theoretically undertreats the ventricular spaces and cerebral/cerebellar sulci as well as any gross disease extending into the brain substance. This concern has led

to the concept of combining CRT with IT chemotherapy; the latter to cover the spinal subarachnoid space. Similarly, when CSI is needed to treat a higher burden of CNS leukemia, IT therapy allows the spine to be treated at a lower dose than the brain.

Cranial Radiation

The volume of treatment must include the subarachnoid space within the cranial vault. The inferior margin has by historical convention extended to the bottom of the second cervical vertebra and includes the whole vertebral body. This may facilitate the matching of potential future treatment fields to the spine but is less of a practical concern with modern RT techniques. Limiting inferior coverage to C1 may better reduce incidental parotid irradiation,[229,230] while extending to C2 may offer a theoretical benefit of fully covering the inferior aspect of the dura within the brain as is used for primary CNS lymphoma and leptomeningeal disease. The inferior most point of the fourth ventricle, the obex, should be included in the field. Regardless, current COG protocols and practice have consistently used C2 as the inferior border for cranial fields.[231] Traditional field boundaries typically involve "flashing" over the scalp. However, it should be noted that this flashing also results in a hot spot of radiation dose within the vertex scalp using legacy 2D treatment planning techniques, responsible for much of the permanent alopecia seen in this location following cranial radiation at doses exceeding 20 to 24 Gy. Modern "scalp-sparing" techniques using nonflashed block edges or even modern conformal ("field-in-field" compensation) techniques. Higher energy radiation (10-15 MV) can be used to reduce scalp and follicle doses without underdosing the brain itself and has been described in adult patients with brain metastases from solid tumors.[232,233] However, these matters are largely cosmetic and should be placed in the context of the patient's clinical situation. Therefore, these approaches may not be appropriate for urgent cases of relapsed/refractory CNS leukemia or for patients for which on-treatment setup may be challenging due to altered mental status or young age may far outweigh long-term cosmetic outcomes. With regard to blocking the anterior facial structures, attention must be given to the base of skull anatomy to adequately cover the cribriform plate and the middle cranial fossa. The

cribriform plate is somewhat variable as a function of the age of the patient but is generally in line with the bottom of the frontal sinuses extending posteriorly for several centimeters and can also be identified via the use of standard CT simulation. The middle cranial or temporal fossa projects on lateral radiographs over the sphenoid sinuses. Figure 87.5 shows plain radiographs of an adult skull with radio-opaque markers at various anatomic landmarks. The posterior globe of the eye is included, given concerns of leukemic relapse in the posterior retina near where there is subarachnoid space extending along the optic nerves. Radio-opaque markers on the anterior aspect of the bony orbit are generally a good anatomic landmark that bifurcates the globe.

Figure 87.3 shows an example of conventional lateral fields used to treat a patient with ALL. Head immobilization with Aquaplast or similar thermoplastic material facilitates a high degree of treatment position reproducibility. Accounting for setup variation and beam penumbra leads to field design that clearly must encroach on the eye. With a forward gaze of the eyes, this would imply that the superior half of the lens is within the dose build-up region of the treatment fields. With the exception of very young children who cannot cooperate, voluntary rotation of the eye downward ("looking toward one's toes") would theoretically reduce the risk of cataracts. It should be noted that cataract repair surgery has become a commonplace safe and effective outpatient procedure, making cataracts a far less concerning potential side effect than it has been historically. However, it should be noted that the lens dose and downward rotation may also protect the central cornea and eyelid margins. Decreased dose to the cornea may reduce corneal irritation and sensitivity. Decreased dose to the Meibomian glands and accessory lacrimal glands located within the eyelids themselves is critical for preventing dry eye.[234] The Meibomian glands are critical in this respect, as they secret a lipid-based additive to tears that reduces tear evaporation,[235] in addition to other properties that help promote a functional tear film.[236] Contrary to common teachings in radiation oncology, the major lacrimal gland's primary role is largely for bolus tear secretion in response to emotional responses (ie, crying) or flushing out foreign bodies from the eye. and its role in basal eye lubrication, critical for maintaining quality of life, is a matter of debate.[237] Another important caveat in the treatment technique to minimize dose to the anterior portion of

the eyes is the alignment of the anterior beam edge divergence. Figure 87.6 depicts this concept of angling the gantry 3° to 5° to achieve a parallel anterior beam margin behind the lens, bisecting the eye and producing a relatively tight radiation dose gradient.

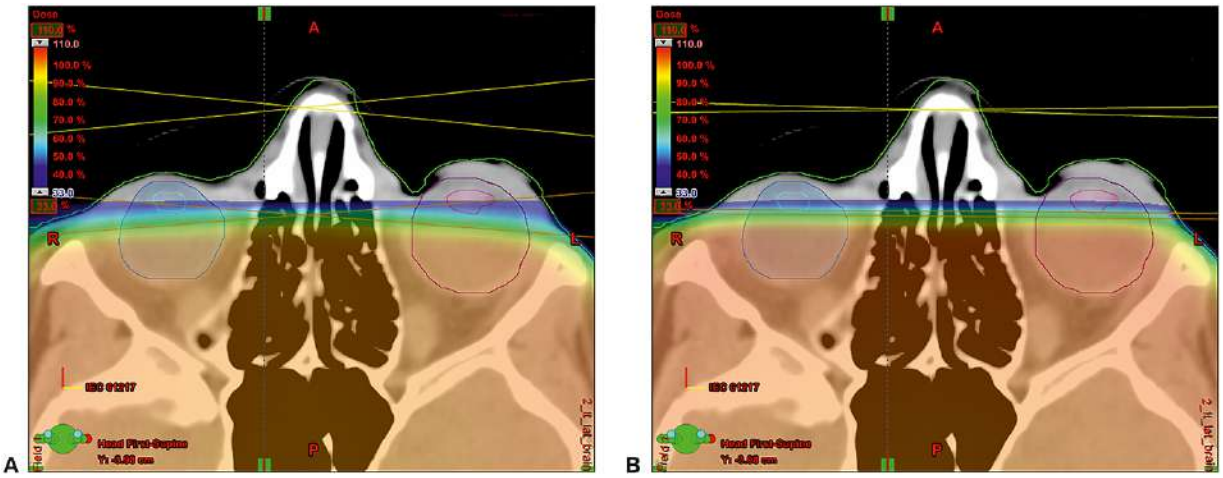

FIGURE 87.6 An 8-year-old boy with T-cell acute lymphoblastic leukemia, central nervous system type 3 at diagnosis, requiring cranial radiotherapy to 18 Gy in 12 fractions after remission from systemic therapy. Alignment of anterior divergence of lateral cranial fields showing beam edge and color wash of radiation dose superimposed on axial computed tomography scan at level of eyes. A. Parallel opposed fields result in widened dose gradient within anterior aspect of eyes. B. Gantry angle of 3° to 5° results in alignment of anterior margin beam divergence from lateral fields and tighter dose gradient.

Some radiation oncologists prefer to simply place the isocenter of the treatment beam just posterior to the lens so that the anterior eye is protected by a modified "half-beam block." With the advent of CT simulators, alignment of beam divergence can be performed graphically, also correcting for any head rotation with immobilization without the need for trigonometric calculations. The standard radiation dose for prophylactic cranial radiation in pediatric ALL is 18 Gy in 9 to 10 fractions, but protocol-driven use of 12 to 15 Gy in 8 to 10 fractions is based on evolving experience, with selected patients being treated with BFM-type ALL programs. Although this is a reasonable dose for adults, some protocols still continue to utilize 24 Gy in 12 fractions or even 23.4 Gy in 13 fractions.

Craniospinal Radiation and Therapeutic Cranial Radiation for Central Nervous System Leukemia

Historical, photon-based 3D techniques of cranial spinal radiation involved precise matching of beam divergence between a PA spine field and lateral parallel opposed cranial fields. Additional details of this technique are discussed in detail in the previous edition of this textbook in the chapter on medulloblastoma (see Chapters 90). Limitations of 3D craniospinal, photon-based radiation include the creation of hot- and cold-matched spots, limited forgiveness at the matched junction of each field, and the need to shift or "feather" the match junction by 1 to 2 cm once or twice during the treatment course (resulting in essentially two additional plans). When CSI is indicated, referral to a proton center may be considered if it is logistically feasible in order to decrease anterior structure (lungs, heart, liver, abdomen, kidneys, bowel, etc). However, given the current and likely ongoing scarcity and cost associated with proton beam centers in many areas, volumetric modulated arc radiotherapy (VMAT)-based approaches may offer a feasible and acceptable alternative.[238] VMAT-based treatment planning uses two to three isocenters (based on patient height), one for the brain and then one to two for the upper and lower spine. Gradients or "auto-feathering" is used to create gradual gradients of several centimeters (eg 6-8 cm) to minimize the impact of minor daily variations in setup. However, robust coordination of isocenters in CSI remains critical and is required for proper dosimetry for both photon and proton-based CSI treatment. Critically, VMAT-based CSI can be used to spare anterior structures, dramatically reducing the radiation dose to the heart, lungs, liver, bowel, and esophagus. Recent "vertebral body–sparing" approaches, in which the vertebral bodies themselves are spared, have been reported and found to be associated with marked reductions in cytopenias.[149] This is particularly critical in relapsed and/or refractory adult CNS leukemia cases, where severe or persistent life-threatening cytopenias caused by disease and prior chemotherapy can be exacerbated by large-volume CSI and lead to life-threatening complications. Acute drops in platelet counts at 7 to 10 days following initiation of CSI of approximately 75% are common and correlate roughly with the anatomic distribution of bone marrow residing in the adjacent cervical spine (~4%), thoracic spine (~18%), lumbar spine (~15%),

sacrum (~8%), and partial pelvis (~23%).[239] In patients without preexisting cytopenias, marrow recovery is typically rapid and complete following CSI. However, in patients with previously existing severe cytopenias, CSI can exacerbate these further and contribute to mortality from complications related to profound persistent cytopenias.

Radiation doses for overt CNS leukemia are 16 to 30 Gy to the cranium in 1.5- to 1.8-Gy fractions. The authors recognize that it is increasingly rare that overt CNS leukemia for children or adults be treated with craniospinal fields, but there can be clinical circumstances where this may still be rational. In such cases, along with the administration of IT chemotherapy, the spine may be treated to lower doses than the brain to total doses of 6 to 15 Gy depending on individual circumstances. However, salvage CSI for patients with isolated CNS relapse with a long (>6 months) disease-free interval may be curable with definitive intent CSI as mentioned earlier (Figure 87.7). Plans for possible TBI must be taken into account. This part of the preparative regimen for an allogeneic transplant can be conceptualized as being in part CNS therapy.

FIGURE 87.7 Example of salvage VMAT CSI case. Sagittal and selected axial views are shown with percent doses (50%-110%) of the prescribed 21 Gy in 1.5-Gy fractions. The patient was a 39-year-old female with acute myelogenous leukemia who completed fludarabine/busulfan induction therapy followed by allogeneic hematopoietic stem cell transplant. One year later, she developed midback pain with magnetic resonance imaging evidence of bulky recurrent disease at T6-7 with enhancement of the right-sided nerve roots and deformation of the spinal canal. Cerebrospinal fluid was positive for malignant cells, which progressed on intrathecal therapy after a brief initial response. She completed urgent radiotherapy to T5-7 paraspinal nerve roots to 4 Gy over two fractions treated with anteroposterior/posteroanterior fields. She then underwent CSI with curative intent to a dose of 21 Gy in 1.5 Gy per fraction to the entire neuroaxis with coverage of adjacent peripheral nerve roots with the involved thoracic paraspinal nerve roots (second axial image from the top right). CSI was accomplished using a VMAT approach using a multiple isocenter "auto-feathering" (ie, gradient match) technique with an overlap of 3 cm. Acutely, she developed G2 oral mucositis and G2 nausea. Long-term toxicities included generalized fatigue, which ultimately resolved, and dry eyes. Her malignancy-related back pain completely resolved. She was in remission without evidence of disease at her last follow-up 2.6 years after CSI. CSI, craniospinal irradiation; VMAT, volumetric modulated arc radiotherapy.

Testicular Irradiation

For the management of leukemic infiltration of the testes, both gonads and the scrotum can be irradiated with either electrons or photons. With the patient in a "frog-leg" position and the penile shaft taped onto the abdomen, an anterior inferior oblique photon field works well. Attention to the cremaster reflex and potential ascent of the testes into the inguinal canal is important so as to avoid a geographic miss. For megavoltage photon beams, bolus is often required to avoid superficial underdosing. An anterior wedged pair beam arrangement often works well. In young boys where the scrotum/testes thickness is under 2 cm, 250-kV orthovoltage x-rays may also be used. Alternatively, direct en face electron beams of appropriate energy work adequately. Though there are considerable dose inhomogeneities in treating such a curved surface with electrons, the relatively low doses employed in this setting translate into relatively low risks related to skin and subcutaneous soft tissue reactions. Radiation doses typically used are 24 to 26 Gy in 1.5- to 2.0-Gy fractions. When a testicular boost is given in conjunction with TBI for an HSCT, the dose is either 4 Gy × 1 fraction or 2 Gy × 2 fractions.

Splenic Irradiation

Massive splenomegaly may be seen with CML, CLL, hairy cell leukemia, and splenic marginal zone lymphomas where the spleen can extend into the pelvis. Significant splenomegaly may also occur with prolymphocytic leukemia, myeloproliferative disorders such as CMML, polycythemia vera or essential thrombocytosis, or myelofibrosis. One type of myelofibrosis called *agnogenic myeloid metaplasia* is characterized by progressive bone marrow failure, splenomegaly, and EMH. It is therapeutically important to recognize which conditions of splenomegaly are due to EMH rather than leukemic infiltration as whole-spleen RT with modest radiation doses can result in severe, long-lasting pancytopenia when the spleen is the primary hematopoiesis site.[240] Splenic hematopoiesis can also occur with late stages of CML, myeloproliferative disorders, and hairy cell leukemia. Extreme care is required to proceed slowly with RT in these circumstances.

Historically, splenic RT was commonly employed for palliation, but it is now uncommon, as more effective systemic treatments have been developed. Nevertheless, the radiation oncologist is called on to assist with the management of symptomatic splenomegaly from these hematologic disorders from time to time, often with excellent results.[241] Symptomatic problems include pain, early satiety, diaphragmatic irritation, and bleeding risk related to sequestration of platelets. Leukemic infiltration of the spleen responds to relatively low doses of radiation.[242] Particularly in an older patient with other comorbidities, palliative splenic RT can offer significantly less risk than splenectomy.[243] Splenic irradiation has been reviewed by Weinmann et al.[244]

Anterior and posterior opposed portals for photon treatments are generally employed. In cases of leukemic infiltration, standard practice is to treat the whole spleen in 0.25- to 1.0-Gy fractions either daily or once to 3 times a week with doses titrated to response and hematologic tolerance.[245] As the spleen responds, one may progressively shrink the treatment fields accordingly. Generally, it is prudent to start treatment very conservatively. Blood counts may need to be monitored several times a week. Total radiation dose delivered is determined clinically by when palliation is achieved. Total doses are typically in the range of 4 to 10 Gy with usually no more than 20 Gy required. Occasionally, a large spleen that is

extensively fibrotic will not respond to RT. CLL and prolymphocytic leukemia are particularly radiosensitive, with occasional abscopal effects seen with splenic irradiation. One trial of CLL and splenomegaly successfully used 1.0 Gy a fraction once a week for an average of seven treatments, yielding good palliation including complete normalization of blood counts in 44% of patients.[246]

In patients with EMH, the potential for severe neutropenia or thrombocytopenia is very high with even modest radiation doses. Dose per fraction may need to be as low as 0.1 to 0.5 Gy treating several times a week to avoid severe and protracted myelosuppression. Another strategy in this situation is to treat only half of the spleen. For myelodysplastic conditions or EMH/intrasplenic hematopoiesis, total doses of 1 to 9 Gy are usually adequate.

With splenic irradiation, nausea is uncommon with these low-dose fractions but can be readily managed with antiemetics if necessary. As there can be rapid cell lysis, allopurinol to prevent uric acid nephropathy is advised. Cumulative dose to the left kidney should be monitored, especially as retreatment in the future may be required, but it is rare for doses beyond 20 Gy to be required.

SEQUELAE OF THERAPY IN PEDIATRIC PATIENTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Somnolence Syndrome

Approximately 1 month following cranial radiation, up to 40% to 50% of patients may develop lethargy, irritability, anorexia, and even fevers. This has been termed *somnolence syndrome*. It has been associated with electroencephalographic abnormalities and CSF pleocytosis.[247,248] This syndrome is self-limited and typically reverses within 1 to 3 weeks. Glucocorticoids in acute management may be helpful. Two reports suggest that the incidence of this syndrome is reduced if patients receive steroids during CRT.[117,249]

Pituitary Dysfunction

Hypothalamic-pituitary irradiation can impact endocrine function in a dose- and age-dependent manner. For the doses used in leukemia management, growth hormone (GH) deficiency is the most common abnormality observed. Age younger than 5 years at the time of RT is associated with particular susceptibility to the development of GH deficiency. Higher radiation doses as well as younger age correlate with an increased incidence of GH deficiency and a shorter time period for its clinical manifestations.[250] It is more common after 24 Gy than 18 Gy.[251,252] Up to 22% of adult survivors of pediatric ALL who have received CRT may have diminished GH responses to provocative testing.[253] Precocious puberty has been reported with radiation doses to the hypothalamic-pituitary region as low as 18 Gy, although it seems to be more prevalent in females who receive doses of 24 Gy or higher.[254] Doses less than 35 to 40 Gy are rarely associated with other pituitary hormone deficiencies or abnormalities. Thus, patients receiving CRT for leukemia, particularly in childhood, require regular follow-up of their linear growth and sexual development. Abnormalities should then lead to appropriate endocrinologic evaluation so as to determine the need for therapy with either GH replacement or gonadotropin-releasing hormone agonists.

Cognitive Dysfunction

Intellectual and psychological impairments from the treatment of leukemia have received wide attention. Evidence that RT is to blame has been a major impetus in investigations aimed at lowering the dose delivered to the brain or eliminating it completely. Increasingly, however, there is evidence that chemotherapy may also be causing similar detriments. Objective measures of cognitive function and social functioning are inherently difficult. Nevertheless, a variety of assessment tools, intelligence quotients, or scales have been verified as useful measures of language, reasoning, and performance skills. Other descriptive measures of lowered school achievement have also been reported. Cognitive dysfunction is thought to be the result of white matter injury causing deficits in the speed of information processing.[255] These effects are most pronounced in children younger than age 5 years and probably most pronounced in those younger

than 3 years of age when the brain is still undergoing growth and development, especially with myelinization.

Some reports have suggested a gender difference in susceptibility to radiation injury, with females more likely than males to develop intellectual impairments, although this has not been consistently reported.[256,257] The Dana Farber group has suggested that the reduction in IQ seen in girls was the result of an interaction between high-dose MTX and cranial radiation.[258] Moreover, an impairment in verbal memory observed in both boys and girls was independent of cranial radiation, suggesting toxicity from systemic therapy.[258]

A reduction in radiation dose from 24 to 18 Gy has not consistently been reported to result in lower cognitive difficulties.[123,124,126] Further reduction to 12 Gy is under study. Overall, for these radiation doses, the cognitive deficits have been arguably small, with average full-scale IQ measures decreasing by no more than 10%, while other studies fail to show measurable changes. Perhaps a more important statistic is the proportion of patients with significant reductions, say greater than 15 points in IQ scales; the SJCRH group has reported that up to 22% to 30% of children have such deficits after 18 Gy, 24 Gy, or no CRT.[257] One hypothesis is that a component of cognitive difficulties is related to chemotherapy rather than RT. Regardless, a recent report from the Dana Farber group suggests that in patients with high-risk ALL receiving 18-Gy cranial radiation, neurocognitive function many years after therapy is not significantly different from that of the general population.[127] Importantly, this was a group of patients who experienced a favorable 5-year DFS of 75% with a 1% CNS relapse rate. The Dana Farber group has been investigating hyperfractionated cranial radiation for CNS prophylaxis (0.9 Gy twice daily vs 1.8 Gy daily to a total dose of 18 Gy). There are no obvious differences between standard or hyperfractionated RT in terms of late neurotoxicity reported thus far, although there are numerous methodological problems inherent in such a comparison.[111,127,128] An emerging experience suggests that stimulants such as methylphenidate may be of help in managing treatment-related cognitive problems, particularly some attentional or social deficits.[259]

Leukoencephalopathy

Some early prophylactic cranial radiation studies for childhood ALL showed a significant incidence of profound encephalopathy occurring months after irradiation.[144,260] The highest incidence was seen when cranial radiation with doses as low as 24 Gy were combined with IV MTX. Leukoencephalopathy is thought to represent a demyelinating condition that may be initiated by endothelial damage and a subsequent cytokine cascade with ischemic microinfarcts.[261] While concomitant IV MTX seems to be a significant synergistic factor, leukoencephalopathy has been observed at low incidence rates with RT alone at doses greater than 30 to 35 Gy, with IT MTX, or in conjunction with other chemotherapy agents. High-dose chemotherapy alone is becoming increasingly recognized as causing similar dementia-like syndromes. One should also remember that after CRT, the blood-brain barrier is thought to be more permeable, which may contribute to chemotherapy effects on cognitive function.[262] Regardless, the risk of leukoencephalopathy is decidedly rare after doses of less than 20 Gy.

Secondary Malignancies

One of the larger single-institution series of pediatric ALL with extended follow-up of 2,169 patients from SJCRH treated between 1962 and 1998 reported that the cumulative incidence of secondary cancers was 4.2% and 10.9% at 15 and 30 years, respectively.[263] The incidence does not appear to plateau, although second malignancies occurring after 20 years tend to be lower grade malignancies that include meningiomas and basal cell skin cancers. The Childhood Cancer Survivor Study (CCSG) has also documented an elevated risk for nonmelanoma skin cancers in pediatric ALL survivors, with a cumulative incidence of 10% at 30 years.[264] Cranial MRI surveillance may also increase the detection of asymptomatic radiation–associated meningiomas, estimated to have an incidence of 15% at 20 years and which may sometimes be multifocal.[265] Other secondary cancers attributable to RT include gliomas, parotid gland tumors, thyroid cancers, and sarcomas (bone and soft tissue).[263,266-268] The types of secondary brain tumors from RT tend to be evenly split between meningiomas and high-grade gliomas.[263] In an earlier report from the CCSG of 9,720 patients treated for ALL, 43 secondary cancers were observed after a mean follow-

up of 6 years.[268] Of these, 24 were CNS tumors in patients who had previously received 24-Gy CRT. All but one of these patients with CNS tumors had been younger than 5 years of age at diagnosis of their acute leukemia, suggesting an age-related susceptibility. Additional data from the CCSG suggest that the risk of gliomas and meningiomas both have a linear radiation dose-response relationship.[268,269] The CCSG has now extended additional long-term follow-up of patients with ALL in different treatment eras using various radiation dose prescriptions to more definitely observe that lower doses of cranial irradiation correlate with lower risk for meningiomas.[270] Age of exposure to radiation is also a significant determinant of meningioma risk as lower aged patients have higher risk. On multivariable modeling, there is an increase in HR of 1.12 per 5 Gy of CRT exposure. While there is hope that a reduction in cranial radiation doses to as low as 12 Gy may reduce the incidence of secondary tumors, the German BFM group has observed in the long-term follow-up of their ALL-BFM 90 trial a 3.4% actuarial incidence of secondary brain tumors at 16 years of follow-up.[129] In comparison, for those children with ALL not receiving CRT, the incidence of subsequent brain tumors was 1.2% at 15 years.[266] In a review of 3,182 children treated by an allogeneic bone marrow transplant, 25 solid tumors were observed compared to an expected incidence of one case.[271] Most of these cancers originated in the CNS or thyroid gland. Moreover, most of these patients had received TBI as part of their preparative regimen before transplant.

Testicular Effects From Radiotherapy

Gonadal dysfunction is quite rare from CRT for leukemia management unless patients undergo retreatment that results in high cumulative doses. Direct effects from testicular irradiation, however, are very common. Doses as low as 1 Gy, even from scattered dose from adjacent external beam fields, will cause transient oligospermia or azoospermia. Higher doses, particularly those used in TBI or therapeutic testicular radiation, would be expected to cause permanent infertility. Leydig cell function, on the other hand, is more radioresistent.[272] Low serum testosterone levels or delayed puberty is unusual with doses less than 29 Gy to the testes. One report of 60 male survivors of ALL showed significant germ cell dysfunction as

manifested by increased follicle-stimulating hormone levels and testicular atrophy in 55% of patients treated with testicular RT and in 17% treated with craniospinal RT. The incidence of Leydig cell dysfunction was very low.[272]

CHAPTER 88

Plasma Cell Neoplasms: Multiple Myeloma and Solitary Plasmacytomas

Belinda A. Campbell, Sarah A. Milgrom, Andrea Lo, Amit Khot, Richard Bakst, and Joseph Mikhael

EPIDEMIOLOGY AND ETIOLOGY

Plasma cell neoplasms are a rare and heterogeneous group of diseases, usually associated with the presence of a monoclonal (or myeloma) protein (M protein) or free light chain. The majority of plasma cell neoplasms are multiple myeloma (approximately 95%), with solitary plasmacytoma (SP) and plasma cell leukemia occurring less commonly.[1] Myeloma, the second most common hematologic malignancy, currently accounts for approximately 14% of hematologic malignancies.[2]

The incidence of myeloma varies significantly across the world. Reported by the International Agency for Research on Cancer, an estimated 176,404 people worldwide were diagnosed with myeloma in 2020, with age-standardized (world) incidence rate (ASR) of 1.8 per 100,000 and a worldwide annual mortality rate of 1.1 per 100,000.[3] Per 100,000, the ASRs vary: from 1.1 in Asia, to 2.9 in Europe, to 4.7 in North America.[3] Data from the Surveillance, Epidemiology, and End Results database indicates the rate of new myeloma diagnoses in the United States was 7.1 per 100,000 per year during the period 2016 to 2020, with a lifetime risk of 0.9%.[4] For 2023, it is estimated that there will have been 35,730 new cases (constituting 1.8% of all new cancer diagnoses) and 12,590 deaths (representing 2.1% of all cancer deaths) due to multiple myeloma in the United States.[4] Internationally, cancer registry data suggest that the incidence of multiple myeloma is gradually increasing.[1,2,4]

The incidence rises with advancing age, with a median age at diagnosis of 69 years, and only 3% of all cases diagnosed in those younger than 45 years.[4] There is a male predominance, with a male:female ratio of

approximately 1.5:1.[3] For African Americans, the incidence and mortality rates are approximately double that of Hispanic and White people.[4] An increase in prevalence is also contributed to by the availability of effective treatment options. The observed 5-year relative survival rates of patients with multiple myeloma have increased over time, from 26% in 1975 to 34% in 2000, and rising more steeply to 62% in 2015.[4]

There is limited information about the cause of multiple myeloma; however, environmental exposures and genetic events may be the risk factors. There are studies reporting an association with certain chemicals, such as petroleum products.[5,6] Familial clustering has been observed; however, consistent predisposing germline mutations have not yet been uncovered.[7]

It is clear that multiple myeloma evolves from precursor conditions of smoldering myeloma and monoclonal gammopathy of unknown significance (MGUS). A recent large population-based study reports a prevalence of smoldering myeloma of 0.53% in individuals aged 40 years or above.[8] Comparatively, MGUS is a more common condition, with incidence increasing from <2% below the age of 50 to >10% in the ninth decade of life.[9] Annual risks of progression from smoldering myeloma and MGUS are 10% and 1%, respectively.[7,10-12] Further risk stratification is possible on the basis of clinical and genetic criteria,[7] but the precise mechanisms for progression to symptomatic myeloma are not presently clear.

PATHOPHYSIOLOGY

Myeloma arises from malignant transformation of post–germinal center B cells, which are committed to terminal differentiation to plasma cells. One of the earliest genetic events is the illegitimate switch recombination of partner oncogenes into the immunoglobulin heavy chain (IgH).[13] The result of these genetic abnormalities is the development and propagation of a clonal population of B cells within the bone marrow; this, however, is common and can be seen in up to 5% of the general population over the age of 70 (MGUS).[14] However, the vast majority of those with MGUS will not go on to develop myeloma. The subsequent pathogenesis of multiple myeloma is complex with high heterogeneity, and the development of the

disease is a multistep process requiring the activation of oncogenes or mutations in tumor suppressor genes. These secondary events may include *RAS* mutations, chromosome 13 deletions, *MYC* translocations, and increasing genomic instability.[13] This progression results in the proliferation of the malignant plasma cells in the bone marrow microenvironment, which provides a protective niche for myeloma cells and is responsible for many of the unique features of the disease. The contribution of the bone marrow microenvironment to the pathogenesis is a focal area of research, resulting in current and potential future therapeutic targets. Established myeloma is sustained by a number of microenvironment features, including the bone marrow stroma itself and the cytokines interleukin-6, vascular endothelial growth factor, and insulin-like growth factor-1.[13] The slow accumulation of these malignant cells gradually results in the characteristic clinical features of myeloma: anemia, bone resorption, hypercalcemia, renal failure, and immunodeficiency. Myeloma-induced bone destruction is a result of the imbalance between osteoblast and osteoclast activation, leading to osteoporosis and osteolytic bone lesions, primarily by amplification of the RANK pathway and the inhibition of the Wnt signaling pathway.[13]

CLINICAL PRESENTATION

Plasma cell neoplasms have a wide clinical spectrum, ranging from asymptomatic MGUS and smoldering myeloma, to SP, symptomatic slowly progressive myeloma or Ig light chain amyloidosis, and aggressive plasmablastic disease and plasma cell leukemia (Table 88.1).[14,15,41] In all cases, the existing plasma cell clone usually secretes either a monoclonal IgG/IgA paraprotein or κ/λ free light chains (light chain myeloma). The interaction of the malignant plasma cells with the bone marrow environment or the monoclonal light chains with other organs is the source of organ damage in patients with this illness.[13] Significant interpatient and intrapatient heterogeneity in clinical presentations is demonstrated by these disorders, which raises many challenges in diagnosis and patient management. These concepts have become particularly important, as the molecular mechanisms by which the disease progresses through these "stages" provide essential information that may help us to better understand the disease and its potential therapies.

TABLE 88.1 THE SPECTRUM OF MYELOMA[14,41]

	MGUS	Smoldering Multiple Myeloma	Multiple Myeloma[a]	Plasma Cell Leukemia
Clinical	No organ damage	No myeloma-defining events[b] or amyloidosis	One or more myeloma-defining events[b]	Organ damage, leukocytosis, high tumor burden, and high proliferation rate
Marrow disease/M protein features	<10% clonal plasma cells	10%-60% clonal plasma cells and/or M protein ≥30 g/L (or urinary M = protein ≥500 mg per 24 h)	≥10% clonal plasma cells or biopsy-proven plasmacytoma[a]	Plasma cells in peripheral blood ≥2 × 10^9/L or ≥20%. Immature plasma cells in bone marrow
Management	Monitor	Close follow-up	Chemotherapy	High-dose chemotherapy
Transformation rate	0.5%-1% per year	10% per year	—	—

CT, computed tomography; MGUS, monoclonal gammopathy of unknown significance; MRI, magnetic resonance imaging; PET, positron emission tomography.

[a]Multiple myeloma can be diagnosed when (a) clonal bone marrow plasma cells ≥10% or biopsy-proven bone or extramedullary plasmacytoma is present, plus (b) any one or more myeloma-defining events as outlined below.[b] Alternatively, without the presence of myeloma-defining events, the presence of (a) any one or more of the following biomarkers of malignancy also satisfies the diagnosis of multiple myeloma: clonal bone marrow plasma cell percentage ≥60%, involved:uninvolved serum light chain ratio ≥100, or >1 focal lesions on MRI (each focal lesion must be 5 mm or more in size).[13] This is also known as the SLiM (Sixty percent, Light chains, MRI) criteria.

[b]Myeloma-defining events: end-organ damage attributed to myeloma: hypercalcemia (calcium >2.75 mmol/L); renal insufficiency (creatinine >177 μmol/L or creatinine clearance <40 mL/min); anemia (hemoglobin <10 g/dL or >20 g/L below the lower limit of normal); and bone lesions (one or more osteolytic lesions on x-rays, CT, or PET scan).

Monoclonal Gammopathy of Unknown Significance

MGUS has traditionally been considered a benign or a premalignant condition, in which a small proportion of patients will ultimately progress to multiple myeloma or related diseases (Table 88.1). There are three distinct clinical types of MGUS: light chain MGUS, IgM MGUS (rarest

subtype, subdivided into plasma cell type and not otherwise specified type), and non-IgM MGUS (IgG, IgA, or IgD MGUS).[16] Non-IgM MGUS is the commonest subtype; light chain Ig MGUS represents 20% of cases.[12,15] Diagnostic criteria for MGUS include all of the monoclonal proteins <3 g/dL, bone marrow clonal plasmacytosis <10%, and no related organ damage. This condition is likely much more common than initially thought, as it has been documented in 3% of the population and 5% in those over the age of 70 and 7.5% of those over the age of 85.[17] The risk of transformation to myeloma and related diseases (such as amyloidosis, indolent lymphoproliferative disorders, or Waldenström macroglobulinemia) has been estimated at 1% per year, based on a 30-year follow-up of 1,384 patients at the Mayo Clinic.[12] Further risk stratification based on the level and subtype of the paraprotein and alteration of the free light chain ratio can be used to determine the risk of progression.[18] Most individuals present to attention when an M protein is detected as an incidental finding on protein electrophoresis performed as part of an evaluation for one of a wide variety of clinical symptoms and disorders. By definition, individuals with MGUS have no symptoms of myeloma; surveillance, based on the risk of progression, is the only management required.

Smoldering Myeloma

Smoldering myeloma represents an intermediate stage between MGUS and symptomatic multiple myeloma. In this precursor form of myeloma, patients meet serologic monoclonal IgA/IgG protein levels ≥3 g/dL or urinary protein >500 mg per 24 hours and/or bone marrow clonal plasma cell infiltration of 10% to 60%,[14] with the absence of myeloma-defining events or amyloidosis (Table 88.1). These patients are not significantly anemic, do not have hypercalcemia or renal insufficiency, and do not have bony disease. The risk of transformation to multiple myeloma is high: approximately 10-fold higher than in MGUS (approximately 10% per year).[15] However, 30% of patients will remain asymptomatic without significant progression to multiple myeloma at 10 years.[15] Further stratification based on clinical and biochemical parameters segregates groups into those with the highest risk (50%) of progression over 2 years.[19,20] This group is the subject of previous and ongoing trials for early

intervention, which have demonstrated a benefit for progression-free survival (PFS) from immunomodulatory- based treatment. Most patients with smoldering myeloma are managed by close surveillance and do not require active treatment; however, some guidelines recommend that established risk models are used to identify those who may benefit from early implementation of therapy despite not yet fulfilling the criteria for symptomatic myeloma.[19-21]

Solitary Plasmacytomas

Two forms of SP are recognized according to the site of origin: SP of bone (SBP) and solitary extraosseous/extramedullary plasmacytoma (SEP).[16] SPs are rare, with SBP accounting for 4% to 5% of all plasma cell neoplasms and SEP accounting for 1% to 3% of all plasma cell neoplasms.[15] The median age at diagnosis of SP is 55 to 65 years, on average about 10 years younger than patients with multiple myeloma.[22-25] Males are affected predominately (male-to-female ratio 2:1).[22,23] A diagnosis of SP is made if all the following criteria are satisfied at presentation: a histologically confirmed single lesion (arising in bone or extramedullary tissue) with negative skeletal imaging outside the primary site, normal bone marrow biopsy (<10% monoclonal plasma cells), and no myeloma-related organ dysfunction.[14] A monoclonal protein is present in 30% to 75% of cases (particularly for an osseous presentation), and the level is usually minimally elevated (IgG < 3.5 g/dL, IgA < 2.0 g/dL, and urine monoclonal κ or λ < 1.0 g per 24 hours).[26-28]

SPB are more common, constituting 70% to 80% of SP.[23] Such cases are considered stage I multiple myeloma according to the original Durie Salmon staging system.[29] The most common location is the vertebra.[22,23] Most patients present with skeletal pain or a pathologic fracture of the affected bone. On imaging, a lytic lesion is typical, with or without adjacent soft tissue mass. SEPs are less common (20%-30% of all SPs) and commonly present with local compressive symptoms, for example, a mass in the upper aerorespiratory passages may present with dyspnea and cough.[22-24,30]

Histologically, both SBP and SEP are characterized by monotonous proliferations of mostly mature plasma cells with light chain restriction.[15]

The histologic diagnosis of SEP can be difficult in the presence of an accompanying neoplastic B-cell population, with the main differential diagnosis being extranodal marginal zone lymphoma (mucosa-associated lymphoid tissue type), where there can be extensive infiltration by plasmacytoid cells.[31,32] Anaplastic SEPs may show plasmablastic cytology, raising the differential diagnosis of an aggressive B-cell lymphoma with plasmablastic differentiation, and can arise in the context of immunosuppression and Epstein-Barr virus infection.[33,34]

Multiple Myeloma

By definition, a diagnosis of multiple myeloma involves end-organ damage or imminently anticipated damage. These myeloma-defining events are described by the mnemonic CRAB (*C*alcium elevation, *R*enal insufficiency, *A*nemia, and *B*one disease).[13,14] Recent modification added additional features when CRAB findings are absent, to include the SLiM criteria of 60% or more clonal plasma cells in bone marrow (*S*), light chains (*Li*) involved:uninvolved ratio >100, or magnetic resonance imaging or MRI (*M*) detected number of bone lesions >1, measuring at least 5 mm in size for the diagnosis of multiple myeloma.[35]

Patients with multiple myeloma usually present with signs or symptoms related to the infiltration of plasma cells into the bone or other organs, or secondary to kidney damage from Ig deposition. Bone pain and symptoms of anemia, such as easy fatigability, are the most common.[36] Because of the myriad effects of the disease, other insidious symptoms can result from a combination of hypercalcemia, renal impairment, infection, neurologic compression, and, occasionally, hyperviscosity. Bone disease manifesting as generalized osteopenia and multiple lytic bone lesions can frequently lead to pathologic fractures. In the vertebral column, this may often result in diminished height. Sclerotic lesions at presentation are rare and can be a manifestation of a related disorder, POEMS syndrome. Amyloidosis, a disorder related to the deposition of misfolded light chains in various organs, can occur as a secondary manifestation in some cases of multiple myeloma. Another important manifestation of the disease can be major or recurrent infection due to hypogammaglobulinemia, which is especially prominent in patients with relapsed and refractory disease.

Laboratory evaluation generally confirms anemia, high erythrocyte sedimentation rate, and a variable degree of granulocytopenia and thrombocytopenia. An abnormal monoclonal Ig (M protein) in the blood or urine is characteristic,[13,36] most commonly IgG or IgA. Biclonal disease is also recognized, and, rarely, nonsecretory disease in approximately 3% of cases. In up to 20% of cases, only monoclonal light chains are detected. It is important to assess for hypercalcemia, renal dysfunction, and integrity of the skeleton because these complications require appropriate management. A constellation of polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes characterizes a rare plasma cell dyscrasia known as POEMS syndrome.[37,38]

Plasma Cell Leukemia

Plasma cell leukemia is a relatively rare variant of multiple myeloma, where the proliferation of plasma cells is not confined to the bone marrow but may be detected in the peripheral blood. Plasma cell leukemia is defined as ≥5% circulating plasma cells in the peripheral blood smears of patients with symptomatic myeloma.[39] Although recent studies suggest that even 1% to 2% circulating plasma cells confer a prognosis similar to plasma cell leukemia,[40] presenting signs and symptoms can include those seen in multiple myeloma and other leukemias such as anemia, thrombocytopenia and infections. It carries a very poor prognosis, with a median survival of <1 year, and shorter when occurring as secondary plasma cell leukemia.[41-43] There is currently no standard therapy for this condition, but patients are usually treated with high-dose, multiagent chemotherapeutic regimens or with experimental therapies, followed by autologous stem cell transplant (ASCT).[41]

DIAGNOSTIC WORKUP AND STAGING

The recommended tests for the diagnosis of plasma cell neoplasms are outlined in Table 88.2. The most important components relate to the measurement and quantification of the M protein on serum electrophoresis, bone marrow examination with flow cytometry and cytogenetic studies, serum β_2 microglobulin and albumin, and diagnostic imaging.[44]

Quantification of the monoclonal Ig with immunofixation techniques is also acceptable and especially useful if the M component is at a low level. Assays for free light chains should be performed in the serum and the urine (Bence Jones proteinuria).

TABLE 88.2 DIAGNOSTIC WORKUP FOR PLASMA CELL NEOPLASMS

General

History and physical examination
Complete blood count and blood smear, chemistry panel including calcium and creatinine

Standard Laboratory Tests

Bone marrow aspirate and trephine biopsy or biopsy of mass if solitary lesion (clonality, immunophenotype, and cytogenetic studies [both conventional cytogenetics and fluorescence in situ hybridization], and plasma cell labeling index)
Serum β_2 microglobulin, albumin, C-reactive protein, and lactate dehydrogenase
M component measurement:

- Serum protein electrophoresis and immunofixation for quantification of immunoglobulins
- Urine protein electrophoresis
- Serum-free light chain measurements

Imaging Studies

Skeletal survey
Computed tomography and magnetic resonance imaging (eg, detailed assessment of local disease extent and bulk, visualize soft tissue tumor, and assess vertebral column for occult disease, compression fractures, or spinal cord compression)
Fluorine-18-fluorodeoxyglucose positron emission tomography or magnetic resonance imaging to detect and quantify occult disease

Imaging is essential for diagnosis, staging, and treatment planning. The traditional imaging modality is the plain x-ray skeletal survey. However, this lacks the sensitivity of more modern imaging modalities.[45] Radionuclide bone scan has limited value in myeloma due to low sensitivity.[19] For structural assessment, both computed tomography (CT) and MRI are useful. CT is a fast and convenient modality for the detection and assessment of lytic bone lesions and extramedullary disease in three dimensions but lacks the sensitivity of MRI. MRI has higher sensitivity for earlier detection of marrow infiltration by direct visualization of the disease within the bone marrow, rather than the myeloma-related secondary effects on cortical bone that are seen on CT.[46] MRI of the axial skeleton is

recommended as a sensitive screening tool to rule out occult vertebral lesions (eg, for patients with SP) and to evaluate for the presence of spinal cord or nerve root compression.[46] MRI is also useful to assess the extent of infiltration of SP (eg, in the head and neck region), providing valuable information to guide radiotherapy (RT) planning.[25] 18-Fluorine (^{18}F)-fluorodeoxyglucose positron emission tomography (FDG-PET)/CT combines the complementary information of the metabolic activity of the disease with the spatial resolution of CT. FDG-PET/CT has recognized the value in the detection of additional plasmacytomas as well as diffuse and variegated marrow infiltration that cannot be appreciated on other imaging modalities; however, false positives can occur secondary to infection or inflammation (eg, postsurgery, post-RT), and false negatives may occur in patients with diabetes or receiving steroid therapy.

For patients with presumed SP or smoldering myeloma, the use of more sensitive studies (flow cytometry of the bone marrow, cytogenetics, and sensitive whole-body imaging such as MRI and PET/CT) as part of the diagnostic workup is strongly recommended to rule out subclinical multiple myeloma.[47] In a consensus statement from the International Myeloma Working Group (IMWG), whole-body MRI or FDG-PET/CT is mandatory for patients with suspected SP.[48] Similarly, whole-body MRI or FDG-PET/CT is also strongly recommended to distinguish between smoldering myeloma and active multiple myeloma.[48]

The staging criteria for the historical Durie Salmon staging system are detailed in Table 88.3.[29] The newer revised International Myeloma Staging System (R-ISS) is simple, validated, and of importance particularly for present and future clinical trials (Table 88.4).[49] It incorporated important cytogenetic abnormalities (eg, del[17p], t[4;14], and t[14;16]) into the staging system. Criteria for the diagnosis of MGUS and smoldering myeloma have been recently updated by the World Health Organization and the IMWG.[16,21]

TABLE 88.3 DURIE AND SALMON SYSTEM FOR STAGING OF MULTIPLE MYELOMA

Clinical Stage	Description
Stage I	All of the following: • Hemoglobin >10 g/dL

Clinical Stage	Description
	• Serum calcium normal • Normal bone structure or solitary plasmacytoma only • Low M component (IgG < 5 g/dL, IgA < 3 g/dL, and urine light chains <4 g/24 h)[a]
Stage II	Fitting neither stage I nor stage III
Stage III	One or more of the following: • Hemoglobin <8.5 g/dL • Serum calcium >12 mg/dL • Advanced lytic bone lesions • High M component (IgG > 7 g/dL, IgA > 3 g/dL, and urine light chains >12 g/24 h)
Subclassified	
A	Relatively normal renal function (serum creatinine <2 mg/dL)
B	Abnormal renal function (serum creatinine ≥2 mg/dL)

IgG, immunoglobulin G.

[a]For solitary plasmacytoma: IgG < 3.5 g/dL and IgA < 2 g/dL.

From Durie BG, Salmon SE. A clinical staging system for multiple myeloma correlation of measured myeloma cell mass with presenting clinical features, response to treatment, and survival. TABLE 88.4 ISS AND R-ISS STAGING OF MULTIPLE MYELOMA

Stage	Description	Median Survival
International Staging System (ISS)[72]		
ISS stage I	Serum β_2 microglobulin <3.5 mg/L and serum albumin ≥35 g/L	62 mo
ISS stage II	Neither I nor III ie, β_2 microglobulin <3.5 mg/L, with albumin <35 g/L, or β_2 microglobulin 3.5-5.5 mg/L	44 mo
ISS stage III	Serum β_2 microglobulin ≥5.5 mg/L	29 mo
Revised International Staging System (R-ISS)[49]		

Stage	Description	Median Survival
R-ISS stage I	ISS stage I and standard risk chromosomal abnormalities[a] (by iFISH) and normal LDH	Not reached[b]
R-ISS stage II	Neither R-ISS stage I nor III	83 mo
R-ISS stage III	ISS stage III and either high-risk chromosomal abnormality[a] (by iFISH) or high LDH	43 mo

iFISH, interphase fluorescent in situ hybridization; LDH, lactate dehydrogenase.

[a]High-risk chromosomal abnormalities are any one of Del(17p), translocation t(4;14), or translocation t(14;16).

[b]Median follow-up 46 months.

PROGNOSTIC FACTORS

Solitary Plasmacytoma

For patients with SP, several factors have been associated with the risk of progression from SP to myeloma. Many of these factors reflect the presence of subclinical myeloma and were derived from early patient cohorts that predate the highly sensitive staging investigations that are mandated in modern practice. Bony presentation has been consistently demonstrated to have a significantly higher risk of progression to myeloma, with a 10-year rate of 76% observed in earlier cohorts, compared with an extramedullary presentation that has a 10-year rate of 36%[23,50] (Figure 88.1). Subclinical bone disease that may be detected radiographically as generalized osteopenia[51] or abnormal MRI scan of the spine[46,52-54] predicts for rapid progression to symptomatic multiple myeloma. Therefore, in the updated IMWG criteria for the diagnosis of multiple myeloma, MRI detection of more than one focal lesion in bone, of 5 mm or more in size, is recognized as multiple myeloma.[14] Furthermore, careful evaluation of the bone marrow using flow cytometry identifies clonally related plasma cells in some patients treated for presumed SBP, and this occult bone marrow disease is highly predictive of progression to myeloma and of major prognostic value.[15,47,55,56] In addition, suppression of the normal Ig classes correlates with a higher risk of progressing to myeloma.[51,57] The presence of low-level M protein prior to RT is extremely common and is not associated with a

higher risk of progression to multiple myeloma; however, its persistence following RT is highly predictive of subsequent systemic failure.[28,47,58-60] In addition, the presence of anaplasia (ie, a higher histologic grade)[61] or high-grade angiogenesis[62] in the tumor sample is associated with a poor outcome. The prognostic value of age remains uncertain; older age has been identified as a risk factor for progression to myeloma and poor prognosis in some series,[58,63-66] but not in others.[23,67-71]

Multiple Myeloma

Analysis of over 1,000 patients evaluated at the Mayo Clinic revealed the following adverse prognostic risk factors: Eastern Cooperative Oncology Group performance status 3 or 4, serum albumin <3 g/dL, serum creatinine

≥2 mg/dL, platelet count <150,000/μL, age ≥70 years, β_2 microglobulin >4 mg/L, plasma cell labeling index ≥1%, serum calcium ≥11 mg/dL, hemoglobin <10 g/dL, and bone marrow plasma cell percentage ≥50%.[36] The International Staging System (ISS)[72] and the R-ISS[49] have been validated to assist in prognostication. For the original ISS, over 10,000 patients were evaluated, and the three-stage system was developed based on two variables: serum albumin and β_2 microglobulin. In the R-ISS, cytogenetic abnormalities associated with a worse prognosis were also incorporated[68] (Table 88.4). The definition of high-risk disease continues to evolve. To risk-stratify patients with myeloma at initial diagnosis, fluorescence in situ hybridization studies are performed on the bone marrow for t(4;14), t(14;16), t(14;20), gain/ amp 1q, del 1p32, and del 17p13 with biallelic TP53 inactivation and/or multiple cytogenetic aberrations.[73] The presence of certain clinical features such as extramedullary disease, plasma cell leukemia, primary refractoriness to treatment, or early relapse within 18 months is also classified as high-risk disease.[74]

MANAGEMENT OF SOLITARY PLASMACYTOMA

Confirming the true solitary nature is critical for accurate diagnosis of SP. For all patients with presumed or suspected SP, full evaluation is mandatory to exclude occult myeloma (see section “Diagnostic Workup and Staging”).

Solitary Bone Plasmacytoma

Radiotherapy

Localized RT is the standard of care for SBP, achieving long-term remissions and potential for cure. Early patient data demonstrate high rates of local control following RT for SBP; however, long-term overall survival (OS) rates were more modest due to the high risk of progression to multiple myeloma[23,28,51,57,59,63-65,67,75-78] (Table 88.5). As shown in Table 88.5, rates of progression to myeloma vary across the published literature, likely reflecting the less sensitive staging investigations used in earlier patient cohorts to exclude sites of subclinical involvement. In the largest series of 206 patients with SBP diagnosed from 1977 to 2001, the multicenter Rare

Cancer Network reported the 10-year rate of progression to myeloma to be 72%, with higher annual risk occurring within the first 3 years of diagnosis.[23] This finding suggests that subclinical myeloma may have existed in a proportion of patients at the time of initial diagnosis with SBP. However, in modern practice, the use of more sensitive imaging and bone marrow evaluations upfront are more likely to identify patients with occult myeloma.[56] For example, studies have documented that 29% to 50% of patients with apparent SP had multiple asymptomatic lesions detected in the spine on MRI.[44,46,52,54,79] With increasing availability of whole-body MRI and FDG-PET/CT, "stage migration" is a likely phenomenon, with a proportion of patients with presumed SP being upstaged following the detection of additional sites of disease by MRI or FDG-PET/CT.[80-82] This "Will Rogers phenomenon"[83] is likely to contribute to an observed increase in myeloma-free survival rates for patients with SP in studies where more sensitive staging investigations are employed. A recent multicenter study of 54 patients diagnosed with SBP from 2000 to 2019, and in whom 55% had either staging MRI or FDG-PET/CT, revealed a relatively lower risk of progression to myeloma and excellent survival, with myeloma-free survival rate of 69% and OS rate of 95%, at 5 years.[84] Details regarding RT dose and technique are discussed later in this chapter.

Surgery

For patients with mechanical bone instability or rapidly progressive neurologic compromise such as spinal cord compression, urgent surgery should be considered.[26] For those with gross tumor resection of SBP, postoperative RT is indicated because of a high likelihood of residual microscopic disease.[47] Surgery alone, without RT, leads to an unacceptably high local recurrence rate[23] and is generally not recommended.

Adjuvant Systemic Therapy

Arguably, for patients at high risk of occult systemic disease, management approaches that incorporate systemic therapy may be of theoretical appeal to eradicate subclinical disease and prevent the development of myeloma.[85] However, the role of adjuvant systemic therapy in accurately staged SBP is a highly contentious area of debate.[47] By definition, true SBP represents localized disease with the absence of occult systemic disease on highly sensitive staging modalities, in which case the addition of adjuvant systemic therapy may be of questionable value and remains to be proven in the modern era. Published in 1996, one randomized trial suggested a benefit from adjuvant melphalan and prednisone (MP) given for 3 years after RT: With median follow-up of 8.9 years, patients treated with adjuvant chemotherapy had a myeloma progression rate of 12%, compared to 54% in those treated with RT alone.[86] However, this was a small study that used less sensitive staging investigations coupled with outdated systemic therapies and RT techniques; furthermore, the risk of diminishing stem cell reserve and/or inducing leukemia makes the prolonged use of alkylating agents an undesirable treatment option for most patients. The use of adjuvant novel agents, such as proteasome inhibitors (PIs) (eg, bortezomib) or immunomodulatory drugs (IMIDs, eg, lenalidomide), may be more theoretically attractive. Pilot data indicate feasibility of combining novel agents with RT,[87] and this approach is under active investigation. In the United Kingdom, a multicenter, phase III clinical trial is underway to examine the potential role of adding lenalidomide and dexamethasone (LD) to definitive RT (NCT02544308). A phase III study is underway in China to compare RT alone to RT combined with bortezomib, lenalidomide, and dexamethasone for SP (NCT05248633). In Alaska, USA, a phase III study is investigating the addition of adjuvant ixazomib, lenalidomide, dexamethasone, and zoledronic acid, to adjuvant zoledronic acid alone, after definitive RT for patients with SBP (NCT02516423). And, a single-arm pilot study from Memorial Sloan Kettering in the United States is investigating checkpoint blockade therapy (durvalumab, anti–PD-L1 [Programmed Cell Death Ligand 1]) plus definitive RT on the development of multiple myeloma in patients with SBP with limited clonal bone marrow plasmacytosis (NCT03196401).

Solitary Extramedullary Plasmacytoma

Radiotherapy

Localized RT is associated with high rates of long-term disease control and is the standard of care for patients with SEP.[47] In contrast to SBP, SEP is generally associated with a lower risk of progression to myeloma and improved prognosis.[47] In the reported literature, the long-term outcomes for patients with SEP vary widely, with 10-year OS rates ranging from 43% to 89% and progression to myeloma rates ranging from 7% to 44%[23,24,58,61,69,77,84,88-97] (Table 88.6). Older studies utilizing less sensitive staging modalities should be interpreted judiciously. Two of the more recently published series, with patients diagnosed no earlier than 2000, report myeloma-free survival rates of 76% to 88% and OS rates of 81% to 88% at 5-years.[84,97] Details regarding RT dose and technique are discussed later in this chapter.

Surgery

Although complete surgical excision may have curative potential for small SEP,[98] most patients present with larger lesions or with tumors that are not amenable to complete excision. Postoperative RT is indicated for all incompletely excised lesions due to unacceptably high rates of local recurrence from surgery alone.[25,47]

MANAGEMENT OF MULTIPLE MYELOMA

For patients with myeloma of all ages, survival outcomes have continued to improve over recent decades following the development of effective chemotherapy combinations, including PIs, IMIDs, monoclonal antibodies (MoAbs), and high-dose chemotherapy with ASCT.[7,99-101] These agents have been used sequentially in induction, consolidation, and maintenance strategies, resulting in the majority of patients achieving minimal residual disease (MRD)-negative status with a resultant PFS of >60 months in both

transplant eligible and nontransplant eligible patients.[102,103] In the past decade, advances in immunotherapy including T-cell redirecting therapies such as bispecific antibodies (BsAbs) and chimeric antigen receptor T-cell (CAR-T) therapy have shown high levels of efficacy in relapsed/refractory multiple myeloma with deep and durable responses.[35] A list of approved agents is summarized in Table 88.7. Choice of therapy is significantly determined by access to treatments in different geographical, regulatory, and resource-limited environments; these are major considerations for decision-making in addition to routine clinical factors.[104-110] Despite these therapeutic advances, disease progression presently remains the most common cause of death, highlighting the ongoing need for more effective and more accessible treatment strategies for patients with multiple myeloma.[111]

TABLE 88.7 SYSTEMIC TREATMENT OPTIONS FOR RELAPSED/REFRACTORY MULTIPLE MYELOMA

Conventional therapy	Low-dose alkylators: melphalan, cyclophosphamide Corticosteroids: dexamethasone, prednisolone
Combination chemotherapy	DTPACE (dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, and etoposide)/DCEP High-dose cyclophosphamide
Autologous stem cell transplantation	High-dose melphalan 140-200 mg/sqm conditioning
Novel agents	Proteasome inhibitors: bortezomib, carfilzomib, ixazomib Immunomodulatory agents (IMIDs): thalidomide lenalidomide, pomalidomide Monoclonal antibodies: anti-CS1—elotuzumab; anti-CD38—daratumumab, isatuximab Histone deacetylase (HDAC) inhibitors: panobinostat XPO1 inhibitor: selinexor Bispecific antibodies: CD3 B-cell maturation antigen (BCMA)—teclistamab, elranatamab; CD3/GPRC5D—talquetamab Chimeric antigen receptor T (CAR-T) cell therapies: anti-BCMA—idecabtagene vicleucel, ciltacabtagene autoleucel
Agents targeting bone disease	Bisphosphonates: pamidronate, zoledronic acid Anti-RANKL: denosumab

DCEP, dexamethasone, cyclophosphamide, etoposide, and cisplatin.

Initial Treatment of Symptomatic Multiple Myeloma

Patients who have symptomatic multiple myeloma require treatment of the malignant plasma cell clone. Once the decision is made to treat, however, the first step is to determine eligibility for high-dose chemotherapy and ASCT.[13] This modality has become the standard of care for patients <65 years of age, with fit patients up to 75 years also being considered for transplant in many treating centers. It is necessary to stratify patients early so that the ability to collect stem cells is not compromised by some types of induction therapy.[112]

Patients Eligible for Autologous Stem Cell Transplantation

In patients who are candidates for ASCT, various regimens can be used to induce response prior to stem cell collection. Historical regimens included combinations of chemotherapeutic agents, such as alkylators, anthracyclines (vincristine, adriamycin, dexamethasone or VAD), and corticosteroids.[113,114] Since the turn of the century novel agents, IMIDs, PIs, and MoAbs have been used in combination for induction therapy, with significantly superior results for depth of response and PFS and OS.[102,115]

Bortezomib

Bortezomib was the first PI to be used in clinical trials and has demonstrated efficacy and safety in frontline therapy, when used in combination with alkylators, anthracyclines, or IMID. Indeed, response rates have dramatically improved when compared with VAD or dexamethasone alone. A randomized comparison of bortezomib plus dexamethasone (BD) versus VAD as induction therapy before ASCT showed that BD produced superior complete response (CR) or near-CR rate (14.8% vs 6.4%), at least very good partial response (PR) rate (37.7% vs 15.1%), and overall response rate (ORR) (78.5% vs 62.8%), as compared to VAD. Median PFS was 36.0 months (BD) versus 29.7 months (VAD; P = .064).[116] Even as a single agent, with dexamethasone or doxorubicin, bortezomib has remarkable efficacy and safety in initial therapy.[117] Bortezomib is often the preferred agent in patients with renal insufficiency and high-risk disease. The greatest challenge, however, remains neuropathy, occurring in 9% to 13% of patients at ≥grade 3 in initial trials[118]; this may

be mitigated by early recognition and dose reduction strategies and by using weekly dosing schedules[119] or subcutaneous route of delivery.[120]

Lenalidomide

Lenalidomide is an IMID derived from thalidomide that has also been shown to be effective, both as upfront therapy and in relapsed disease. It is most commonly used in combination with low-dose dexamethasone. A phase III trial of lenalidomide with low-dose dexamethasone versus lenalidomide with high-dose dexamethasone found that despite a higher rate of CR or PR with high-dose therapy, 1-year OS was 87% in the high-dose group versus 96% in the low-dose group ($P = .0002$), largely because of the significant toxicity of the former.[121] As a result, the trial was stopped and patients on high-dose therapy were crossed over to low-dose therapy. Three-year OS rates in both arms were 75%.[122] This has resulted in the extensive use of this combination in upfront myeloma.

Lenalidomide has also been used in combination with conventional chemotherapy and most recently with bortezomib. This has resulted in even higher ORRs of >90% and near-CR rates of >50%.[115,123] The combination of lenalidomide, bortezomib, and dexamethasone (RVD) gave a CR/very good PR rate of 77% and is considered to be the current standard of care for induction.[115] The post-transplant MRD-negative rate for this combination is 54%, which translates to a median PFS of 67 months.[102]

Thalidomide

Early reports indicate that thalidomide and dexamethasone yield a response rate of 64% (similar to VAD), without compromising the ability to collect stem cells, but with a rate of deep vein thrombosis of 12%.[124] The Medical Research Council Myeloma IX trial compared cyclophosphamide-thalidomide-dexamethasone (CTD) with cyclophosphamide-VAD as induction before ASCT: The CR rate was 20.3% after CTD and 11.7% after cyclophosphamide-VAD,[124] lower than other regimens cited above. Thus, preferred initial regimens include bortezomib- and/or lenalidomide-based combinations, whereas thalidomide or doxorubicin is very infrequently used in current practice.

Daratumumab

The addition of anti–CD38-directed antibody therapy with daratumumab to the standard of care of bortezomib, lenalidomide, and dexamethasone (D-RVD) has been demonstrated to further improve the depth of response for transplant-eligible, newly diagnosed patients with myeloma. In the phase III GRIFFIN study, stringent complete response (sCR) rates and PFS were greater for D-RVD than RVD: sCR 62% versus 45%, and 2-year PFS 96% versus 90%.[125] In the recently published phase III PERSEUS study, CR rates were 88% versus 70% and 4-year PFS rates were 84% versus 68% for D-RVD versus RVD groups.[126] Quadruplet therapy is likely to be the new induction therapy of choice.

Patients Not Eligible for Autologous Stem Cell Transplantation

In patients who will not be undergoing a transplant, often because of a combination of advanced age, comorbidities, and unfit health status, there are various options available for initial therapy.[13,127] Treatment decision-making is based on frailty assessment and ability to tolerate triplet versus doublet therapy. Geriatric assessment with a recognized scoring system is an important part of patient evaluation for those over the age of 65 and with comorbidities or physical and/or cognitive impairment, as patients who are frail have lower tolerance of treatment and poorer prognosis.[128]

Historically, most transplant-ineligible patients received MP, which produced partial remissions in approximately 55% of patients, with the occasional CR.[129] Several therapy options have been shown to improve outcomes for patients who will not proceed to ASCT. In a phase III study, 682 patients were randomized to receive either nine 6-week cycles of MP or the same chemotherapy with bortezomib: The addition of bortezomib increased the proportion of patients achieving CR (30% and 4%, $P < .001$) and improved median duration of response (19.9 vs 13.1 months), time to progression (24 vs 17 months; hazard ratio 0.48, $P < .001$), and the risk of death (hazard ratio 0.61, $P = .008$).[130] The addition of thalidomide to MP (MPT) also improves outcome compared with MP alone: The median PFS was 21.8 months for MPT and 14.5 months for MP ($P = .004$); however, thromboses were more common with thalidomide (12% vs 2% in the MP group).[131,132] A meta-analysis of MP versus MPT concluded that MPT

increases response rates and OS but with increased toxicity, such as thrombosis and somnolence.[133] In the FIRST randomized trial, LD when used continuously (until disease progression) gave a better median PFS (25.5 months) when compared with MPT (median PFS 21.2 months, $P <$ .001), and 4-year OS was also improved (LD regimen 59%, MPT regimen 51%, $P = .02$).[134] A randomized phase III study demonstrated the benefit of adding bortezomib to LD (median PFS, 41 vs 29 months, hazard ratio 0.74, $P = .003$).[135] The addition of the anti-CD38 MoAb daratumumab to IMID and PI backbones provides further benefit in this patient cohort: This was demonstrated in the phase III MAIA study, in which the triplet combination of daratumumab, lenalidomide, and dexamethasone (D-Rd) was associated with a median PFS of 62 months (vs 34 months for LD doublet therapy, hazard ratio 0.55, $P <$ .00001), which is close to expected outcomes in the transplant-eligible cohort of patients.[136] Presently, several treatment strategies exist for the initial therapy of patients who will not proceed to ASCT, with preference for a lenalidomide-based regimen approach and elimination of alkylator (melphalan) therapy altogether.[134,137]

Autologous Stem Cell Transplantation

ASCT has become the standard of care for eligible patients, as it has been demonstrated in multiple trials to improve the likelihood of CR, prolong disease-free survival, and extend OS.[13,62,115,138] ASCT is still important even with highly effective induction therapy consisting of RVD regimen, as shown in a phase III trial of comparing RVD (eight cycles) with RVD (three cycles) followed by ASCT and then two further cycles of RVD.[115] Treatment-related mortality rates are now standardly <2%, and often, the transplant can be performed entirely as an outpatient.[115,139] Melphalan 200 mg/m^2 is the most commonly used conditioning regimen; doses may be reduced in older/less fit patients or patients with renal insufficiency.

Tandem Transplantation

Tandem or double transplantation refers to a planned second ASCT after the patient has recovered from the first. A phase III trial in France evaluated tandem transplant versus single ASCT and demonstrated superior OS in the tandem ASCT group.[140] On further analysis, the patients who benefited most

from the second transplant were those who did not achieve a very good PR after the first ASCT;[140] therefore, it may be more prudent to consider tandem transplantation only in patients whose response to the first ASCT is suboptimal. Also, the results of the phase 3 EMN02/HO95 study suggest that tandem ASCT may be beneficial in the cohort of patients with high-risk cytogenetics.[141]

Allogeneic Stem Cell Transplantation

Myeloablative allogeneic stem cell transplant was previously considered the only current potential curative option for patients with myeloma, as the graft is not contaminated with tumor cells and may produce a graft versus myeloma effect.[142] However, its use is very limited because of the lack of donors, age restriction, high treatment-related mortality, and graft versus host disease. Reduced intensity nonmyeloablative allogeneic transplant following ASCT has also been investigated as a means of inducing a graft versus myeloma effect. In one study of 102 patients undergoing nonmyeloablative transplant, 5-year OS and PFS were 64% and 36%, respectively, although the 5-year rate of nonmyeloma mortality was 18%.[143] Recent pooled and retrospective data suggest that the long-term potential for cure of myeloma following allogeneic stem cell transplant is low, with 8- to 10-year PFS of around 10% to 18%.[144,145]

Maintenance Therapy

The use of maintenance therapy post-ASCT to prolong remission and survival has been extensively investigated. Two large randomized trials used maintenance lenalidomide versus placebo, with prolongation of PFS by approximately 20 months.[146,147] OS was similar in the European trial,[146] whereas the U.S. trial showed a statistically improved survival with lenalidomide maintenance (3-year survival 85% vs 77% with placebo).[147] Post- autograft maintenance therapy with low-dose lenalidomide is now considered to be current standard of care, with a meta-analysis of three large randomized phase 3 trials demonstrating a consistent benefit for improvement in median PFS of >50 months.[148] Further trials are now exploring the benefit of adding other agents to lenalidomide, especially in high-risk patients.

Treatment of Relapsed/Refractory Multiple Myeloma

The general approach to myeloma after failure of frontline therapy is influenced by a number of factors, including patient fitness, agents used in initial therapy, prior toxicities, duration of prior response, treatment goals, and patient priorities regarding quality of life. The plethora of complex factors, which influence decision-making in this setting, means that a one-size-fits-all approach is not feasible.[104]

Patients generally receive sequential lines of treatment of combination regimens and monotherapies, balancing the needs for improving depth of response to prolong the period of disease control against tolerability and quality of life. The armamentarium of effective therapies available has expanded considerably over the past 10 years, contributing to a significant prolongation of the median survival of patients with myeloma (Table 88.7). These include PI (carfilzomib and ixazomib), IMID (pomalidomide), and MoAb (elotuzumab, daratumumab, and isatuximab), which can be used in doublet or triplet combination regimens. Carfilzomib is an irreversible PI with significant activity in relapsed myeloma. Pomalidomide is an IMID that has demonstrated efficacy in relapsed myeloma, in patients who are refractory to both bortezomib and lenalidomide.[149,150] Elotuzumab and daratumumab/isatuximab are MoAbs targeting a glycoprotein SLAMF-7[151] and CD38,[152,153], respectively, both showing activity as single agents and in combination with IMIDs/PIs and dexamethasone.[154] Another novel agent recently approved for the management of heavily pretreated myeloma is the selective inhibitor of nuclear export XPO1 inhibitor, selinexor, which is used in combination with corticosteroids and bortezomib.[155]

Bispecific Antibody and Chimeric Antigen Receptor T-Cell Immunotherapies

The single biggest recent advance in the management of myeloma is the development of immunotherapeutic options of highly effective T-cell redirecting therapy with BsAbs and CAR-T cells. These agents have demonstrated unprecedented efficacy in patients with heavily pretreated myeloma.

BsAbs are engineered antibodies designed to simultaneously bind to two antigens, CD3 on T cells and a target moiety on myeloma cells, for

example, B-cell maturation antigen (BCMA), G-protein coupled receptor family C group 5 member D (GPRC5D), and Fc receptor homolog 5 (FcRH5). The resulting immune synapse causes T-cell activation and proliferation and leads to tumor cell lysis. Teclistamab and elranatamab, which target BCMA, have been approved for the treatment of myeloma with four prior lines of therapy on the basis of the phase 1/2 MajesTEC-1 (ORR 61%) and MagnetisMM-3 (ORR 57%) studies, along with talquetamab, which targets GPRC5D on the basis of the MonumenTAL-1 (ORR 73%) study.[156-158] There are significant risks for infections during treatment for this class of agents, along with early risks for cytokine release syndrome (CRS).[156-158]

CAR-T cells are genetically modified, most commonly using lentiviral or retroviral vectors, autologous or allogeneic cells, with a specific tumor-targeted receptor against antigens, such as BCMA, GPRC5D, and FcRH5. The CAR consists of a single chain variable fragment (scFv) with specificity for the target antigen, a transmembrane domain CD8α and an intracellular co-stimulatory domain, 4-1BB or CD28, co-stimulatory domain linked to the T-cell activation domain CD3ζ. The currently approved CAR-T cells are generated from autologous mononuclear cells collected from the patient by a steady-state apheresis procedure. These are enriched for T cells that undergo modification to express the desired scFv, which recognizes BCMA, by viral transduction. These cells are then expanded before reinfusion into the patient, after prior lymphodepletion chemotherapy. Two agents are currently approved for the treatment of relapsed and refractory myeloma after four prior lines of therapy, idecabtagene vicleucel and ciltacabtagene autoleucel, on the basis of the phase 1/2 trials, KarMMa (ORR 72%, CR 33%)[159] and CARTITUDE-1 (ORR 97%, sCR 67%),[160] respectively. Important adverse events noted included CRS, immune effector cell–associated neurotoxicity syndrome, macrophage activation syndrome, myelosuppression, and infections.

While the response rates to these therapies are high, disease progression continues to be a significant issue; hence, future areas for research include combinations with established antimyeloma therapies and concurrent or sequential targeting of different antigens.

Supportive Care

A description of therapy for multiple myeloma would not be complete without addressing the need to treat not only the disease itself but also the complications of this disease. Many of these complications are treatable, allowing an improved quality of life for patients with myeloma. Patients with symptomatic hypercalcemia require immediate treatment with hydration, glucocorticoids, bisphosphonates, and/or hemodialysis/calcitonin. Red blood cell transfusion should be considered for patients with significant symptoms of anemia. Erythropoietic agents may assist in the management of chemotherapy-induced anemia, leading to reduced transfusion requirements. Osteoclast inhibitor with bisphosphonate or denosumab therapy is critical to the optimal therapy of bone disease and has been demonstrated to improve OS in patients with the initial diagnosis of myeloma, with the benefit being seen irrespective of overt bone lesions.[161-163] In patients with skeletal lesions, osteoclast inhibitors reduce vertebral fractures, skeletal-related events, and associated pain,[164] with an observed reduction of the use of RT from 50% to 34% in one study.[165] Local RT remains a highly effective, local therapy for painful bone lesions and for debulking of symptomatic or threatening plasmacytomas. Surgical pinning of high-risk long bones may avoid the morbidity of pathologic fracture. Surgical techniques such as vertebroplasty and kyphoplasty may be beneficial in improving back pain and spinal symptoms in patients with vertebral disease.[166]

RADIATION THERAPY OF MULTIPLE MYELOMA

Local External Beam for Palliation

The most common use of RT in the management of multiple myeloma is for palliative treatment of bony disease and relief of compression of the spinal cord, cranial nerves, or peripheral nerves. The proportion of patients with myeloma in whom RT would be recommended at some time point during the course of their disease has been estimated to be 45%.[167] In practice, however, the actual RT utilization rate is lower, varying from 11% to 34% of patients with myeloma in cancer registry data.[168-171] A recently published review from the prospective Connect Multiple Myeloma Registry in the United States of 3,011 patients with myeloma demonstrated an RT

utilization rate of 30%.[168] Taken together, these data suggest that RT is underutilized in the management of myeloma, with a gradual decline in utilization rates observed over time.[169]

Palliative RT is highly effective in patients with myeloma, with high rates of local symptom relief reported[67,172-175] (Figure 88.2). In a recently published, retrospective study of 312 patients with myeloma with 577 lesions, 206 lesions were treated with RT alone and achieved a pain control rate of 83% at the end of treatment, which increased to 98% at 1 month, 99% at 3 months, and 94% at 6 months; the radiologic response rate following RT alone was 90% (CR 12%, PR 63%, stable disease 15%) at 6 months.[175] Patient-reported outcome data have shown that delivery of palliative RT in patients with myeloma is associated with approximately 5-fold lower total symptom scores compared to patients who did not receive RT.[176] Significant improvements were seen in pain (odds ratio [OR] 1.6, P = .031), breathing (OR 4.47, P = .022), depression (OR 17.4, P < .001), anxiety (OR 19.0, P < .001), overall well-being (OR 3.6, P = .24), spiritual well-being (OR 10.4, P = .008), and constipation (OR 4.14, P = .024).[176]

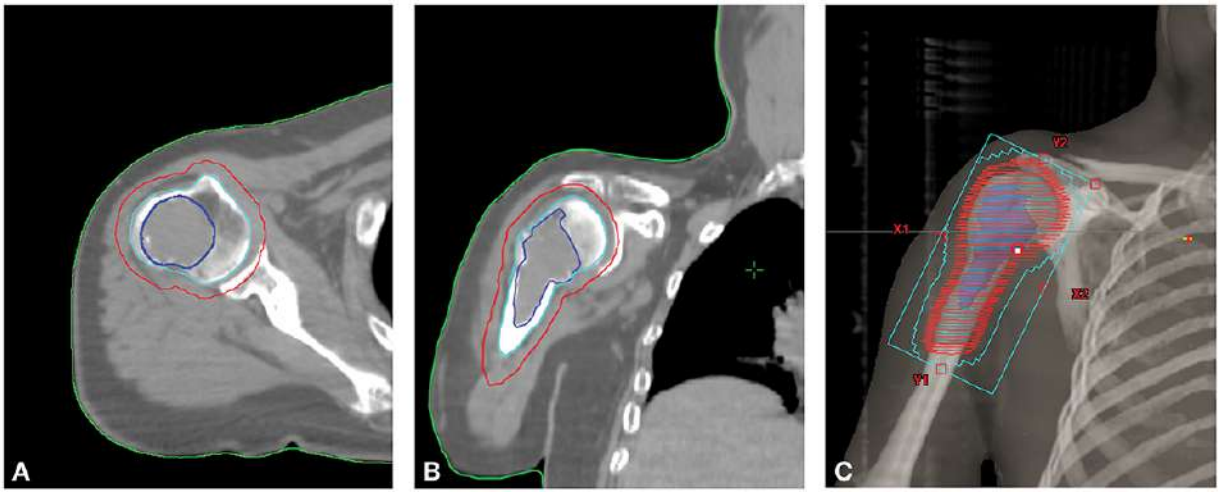

FIGURE 88.2 Radiotherapy treatment plan for a patient with multiple myeloma, presenting with severe pain in the right shoulder. The patient was treated with palliative radiotherapy to the symptomatic lytic lesion in the proximal right humerus, with 8 Gy in one fraction. Gross tumor volume (blue), clinical target volume (aqua), and planning target volume (red) are displayed on an axial slice (A) and a sagittal slice (B) of the computed tomography simulation scan, with beam's-eye view (C) of the right anterior oblique field from a parallel-opposed beam arrangement. Excellent symptomatic relief was achieved, allowing for complete cessation of opioid medications.

For patients with malignant spinal cord compression, RT is an effective, noninvasive treatment modality. In a large retrospective series of 238 patients with multiple myeloma with malignant spinal cord compression, excellent outcomes were observed after RT alone, with an overall high response rate of 97% (53% motor improvement, 44% no further progression); following RT, 88% of patients were able to walk, including the 64% of nonambulatory patients who regained the ability to ambulate.[177] In a second retrospective series of 172 patients with myeloma receiving RT for malignant spinal cord compression, improvement in motor function was experienced in 52% of patients overall, but with significantly greater frequency in patients receiving longer courses (10 × 3 Gy, 15 × 2.5 Gy, 20 × 2 Gy) of RT than shorter courses (1 × 8 Gy, 5 × 4 Gy) from 1 to 18 months following RT.[178] A dose-response was also seen in a retrospective series of 162 patients with myeloma with severe spinal cord compression, with the highest rate of good outcomes (defined as American Spinal Injury Association [ASIA] score E or improvement to ASIA score D) observed in patients who received doses ≥30 Gy.[179] Published in 2018, the International Lymphoma Radiation Oncology Group (ILROG) guidelines for RT for myeloma recommend 30 Gy in 10 to 15 fractions for patients with malignant spinal cord compression.[25] Glucocorticoids are also recommended for patients with nerve root or spinal cord compression (eg, dexamethasone 4 mg qid, prednisone 50-75 mg bid, or equivalent).[25] Upfront decompressive surgery may also be considered for malignant spinal cord compression, extrapolating from randomized evidence in nonhematologic malignancies showing a higher chance of ambulation after surgery plus RT compared to RT alone.[180]

Palliative RT to the spine may also reduce the incidence of future vertebral fractures or the appearance of new lesions. In a small study of patients with myeloma prospectively followed with MRI following localized spinal RT, low rates of fracture (5% vs 20%) and new focal lesions (4% vs 27%) revealed in the irradiated vertebrae compared to nonirradiated vertebrae.[181] However, the role of RT in preventing impending pathologic fracture is unclear; in general, lesions at high risk for pathologic fracture should be referred for surgical stabilization, with RT administered after surgery for control of residual disease at the local site. Similarly, surgical intervention (decompression with or without stabilization) is

indicated in patients who have structural compromise because of vertebral disease, for example, a bone fragment displaced into the spinal canal and/or vertebral instability. Surgery is usually performed first, with RT considered in the postoperative period usually 4 to 6 weeks after surgery to allow for adequate healing.

It is unclear if pain relief is improved if RT is given concurrently with systemic therapy. An earlier retrospective study of 70 patients with myeloma reported complete pain relief in 80% of patients receiving RT with chemotherapy (melphalan and prednisolone), compared to only 40% among those who received RT prior to chemotherapy, with an association seen between RT dose and the duration of pain control.[182] In contrast, other studies have not found an impact on pain control from the delivery of concurrent systemic therapy.[172,175].

With the increasing availability of novel systemic therapies, the effects of drug-radiation combinations are a topical concern in current clinical practice. To date, most series demonstrate that RT with concurrent systemic therapy (either chemotherapy or biologic agents) is well tolerated with low rates of high-grade toxicity.[175,183-185] In a study of 312 patients treated with a mix of RT alone (38%), RT with concurrent chemotherapy (13%), or RT with concurrent biologic treatment (48%), concurrent systemic therapy was associated with increased toxicity; however, high-grade (grades 3-4) toxicities were rare (<4%) across every subgroup.[175] In a study of 55 patients, 64 sites were irradiated within 3 weeks of receiving dexamethasone, cyclophosphamide, etoposide, and cisplatin +/− other agents (35% PI, 18% additional cytotoxic chemotherapy, and 5% immune checkpoint inhibitors): Overall, concurrent therapy was well tolerated, with a nonsignificant increase in grade ≥ 3 hematologic toxicity observed from 21% prior to RT to 35% during RT (P = .13), which subsequently decreased to 12% at 3 to 6 months after RT (P = .02).[183] In a study of 130 patients treated with RT to a median dose of 20 Gy in 10 fractions +/− concurrent biologic agents (42% bortezomib, 23% carfilzomib, 15% daratumumab, and 20% other), no grade ≥ 3 toxicity was noted in the entire cohort, and no significant difference in toxicity was observed between patients who received versus who did not receive biologic agents concurrently with RT.[184] On the other hand, other reports suggest a significant risk of high-grade toxicity after RT plus concurrent PI, especially with higher radiation

doses.[186-188] In a report of 82 patients with myeloma treated with RT with a median dose of 40 Gy +/− concurrent systemic therapy (with 68% including a PI), 45% of patients experienced at least one high-grade (grade III/IV) toxicity; after RT, a significant increase in the rate of high-grade toxicities was observed in the group who received combined modality therapy (49% vs 17%, $P = .018$).[186] Furthermore, case reports of bortezomib and spinal radiation (30 Gy in 10 fractions and 20 Gy in 8 fractions) given concurrently have been reported to result in severe enteritis.[187,188]

Hemibody Radiotherapy

Diffuse bone pain involving wide areas of the skeleton can be effectively palliated by half-body RT with single doses of 5 to 8 Gy.[189-193] However, this technique is rarely used now due to the ready availability of other effective systemic therapy options. The main toxicity risk is myelosuppression; growth factor support may be helpful, and transfusions of blood products should be given as needed. In hemibody RT, the bone marrow in the unirradiated half body serves as a stem cell reserve and will slowly repopulate the irradiated marrow after treatment. The use of hemibody RT must be carefully considered in patients heavily pretreated with chemotherapy who may have lesser marrow reserve. For the upper half body, the hemibody RT dose should not exceed 6 to 8 Gy because of the risk of radiation pneumonitis following larger single doses to lung.[191]

The sequential hemibody RT technique has also been investigated as a consolidation treatment to control myeloma.[194] In the South West Oncology Group phase III trial, patients were first treated with combination chemotherapy with complete responders randomized to consolidation with sequential hemibody RT (7.5 Gy in five fractions, upper hemibody, followed 6 weeks later by lower hemibody) or a further 12 months of chemotherapy; however, relapse-free survival and OS were significantly inferior in those receiving RT and with significantly worse myelosuppression compared to those receiving chemotherapy.[194] For patients with myeloma, there is presently no standard role for sequential or concurrent combination therapy with hemibody RT outside a clinical trial.

Total Body Irradiation and Total Marrow Irradiation

Some high-dose chemotherapy protocols for multiple myeloma incorporate total body irradiation (TBI) into the conditioning regimen. Because of toxicity concerns (mucosal and hematologic) with TBI, many programs use chemotherapy alone, most commonly melphalan. A phase III French study (Intergroupe Francophone du Mye'lome trial 9502) examined melphalan 200 mg/m^2 alone (M200) versus melphalan 140 mg/m^2 with TBI, 8 Gy in four fractions (M140/TBI), and found that patients in the M140/TBI-containing arm suffered more grade 3 or 4 mucosal toxicity, heavier transfusion requirement, longer hospitalization stay, and higher toxic death rate (3.6% vs 0% for the M200 arm).[195] Although the event-free survival was no different between the two treatments, the 45-month OS favored the M200 arm (M200: 65.8%; M140/TBI: 45.5%; $P = .05$).[195] TBI is now rarely used in conditioning regimens for ASCT, unless in the context of a clinical trial.

Emerging prospective studies suggest that total marrow irradiation (TMI) may be a feasible alternative to TBI associated with lesser toxicity.[196-202] A phase I trial was designed to determine the maximum tolerated dose (MTD) of TMI in 13 patients with myeloma treated with melphalan 140 mg/m^2 combined with TMI followed by ASCT as consolidation: Four TMI dose levels were investigated (8, 10, 12, and 14 Gy), with only one dose-limiting toxic event observed at 12 Gy, while the one patient treated at 14 Gy had no adverse events.[196] The CR and very good PR rates were 30.8% and 38.5%, respectively, and acute toxicity rates were low, with only 38% experiencing grade 3 and 4 diarrhea, mucositis, or unexplained fever.[196] In a phase I-II trial of 54 patients, TMI was investigated as the sole ablative modality during the second cycle of tandem ASCT: TMI doses were escalated from 10 to 18 Gy in 2-Gy increments, and 55.6% received the MTD of 16 Gy.[198] Very good PR and CR were achieved in 48.1% and 22.2% of patients, respectively, after ASCT and maintenance, and the treatment was well tolerated.[198] Further research is needed to investigate incorporating TMI as a conditioning regimen in the context of modern induction and maintenance therapies.

Radioimmunotherapy Approaches

Bone-seeking radiopharmaceuticals targeting the bone marrow have been studied as an alternative to TBI. Typically, a β-emitting isotope is conjugated to a phosphonate complex, such as samarium-153-ethylene diamine tetramethylene phosphonate (^{153}Sm-EDTMP or Quadramet). The isotope also emits a γ-ray, permitting scanning to locate areas of uptake, and for use in the palliation of bone metastasis.[203] Other bone-seeking pharmaceuticals include holmium-166-DOTMP (^{166}Ho-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetramethylene- phosphonic acid) and rhenium-118-labeled anti-CD66 antibodies. Compared to ^{153}Sm, holmium-166-DOTMP and Re-188-anti-CD66 have higher energy β emission (maximum energy 1.85 and 2.12 MeV, respectively) and shorter $T_{1/2}$ (26.8 and 16.9 hours, respectively).[204,205] ^{153}Sm-EDTMP, holmium-166-DOTMP, and Re-188-anti-CD66 all have a γ emission (81-155 keV) suitable for imaging. With the ability to deliver much higher doses to the bone marrow than TBI, in the range of 30 to 60 Gy, yet sparing the dose-limiting normal tissues such as the lung, mucosa, and kidneys, the concept of targeted radiation therapy is tantalizing. Small series investigating radiopharmaceuticals prior to stem cell transplantation have reported on the feasibility, tolerability, and promising outcomes of this approach.[206,207] However, there remains a problem of heterogeneity of uptake in the skeleton, and the dosimetric variation may be even larger at a microscopic level because of the limited range of the β particle. Whether this approach will have a more favorable therapeutic ratio than standard conditioning regimens in the transplant setting awaits larger scale phase II and phase III trials.

Bridging Radiotherapy to Chimeric Antigen Receptor T-Cell Therapy

CAR-T therapies are promising new therapies for patients with relapsed/refractory hematologic malignancies. Current research is investigating the potentiation effects of bridging RT before CAR-T infusion. Early data suggest that bridging RT prior to B-cell maturation (BCMA)-targeted CAR-T is safe and feasible in patients with myeloma.[208,209] In a report of 25 patients undergoing CAR-T BCMA for relapsed/refractory myeloma, those who received bridging RT after

apheresis and ≤35 days before CAR-T infusion (N = 4) had qualitatively lower rates of hematologic toxicities and neurotoxicity, compared to those who received RT within 1 year before apheresis (N = 18) and those with no RT within 1 year before apheresis (N = 13).[209] Interestingly, RT administered within 1 year (P = .002) and within 100 days (P = .069) before apheresis was associated with lower in vitro proliferation during manufacturing; however, in vivo CAR-T BCMA expansion appeared similar across the patient groups.[209] Further clinical research is required to investigate the safety and optimal timing of bridging RT prior to CAR-T therapy for patients with multiple myeloma. Presently, equitable access to CAR-T therapy is challenged by geographic, socioeconomic, and racial factors, with opportunities for health services research and implementation science to reduce this disparity.[210,211]

RADIATION THERAPY TECHNIQUES

Delineation of Target Volumes

There are few data to support specific guidelines regarding RT treatment volumes. To improve uniformity of practice, ILROG published contouring guidelines specific to myeloma and SP, in 2018.[25] Accurate delineation of tumor extent is important for the irradiation of plasma cell neoplasms, especially for the radical treatment of SP. MRI is useful to evaluate the extent of disease infiltration. This is particularly true for the paranasal sinuses, where inflammatory changes may be difficult to distinguish from tumor on CT imaging. FDG-PET/CT provides complimentary detail, distinguishing between active and inactive disease (Figures 88.3A and 88.4A).

FIGURE 88.3 Radiotherapy treatment plan for a patient with solitary plasmacytoma of the sternum who presented with a 1-year history of a painless, enlarging chest wall mass. The patient was treated with definitive radiotherapy, 45 Gy in 25 fractions. (A) Staging positron emission tomography/computed tomography (CT) scan demonstrated a single plasmacytoma arising in the manubrium. (B) Gross tumor volume (blue), clinical target volume (aqua), and planning target volume (red) on a sagittal slice of the CT simulation scan. (C) Dosimetry from a conformal volumetric modulated arc therapy plan with isodose lines displaying 50%, 80%, 90%, 95%, 100%, and 110% of the prescription dose. (D) Dose-volume histogram of heart (green) and bilateral lungs (purple).

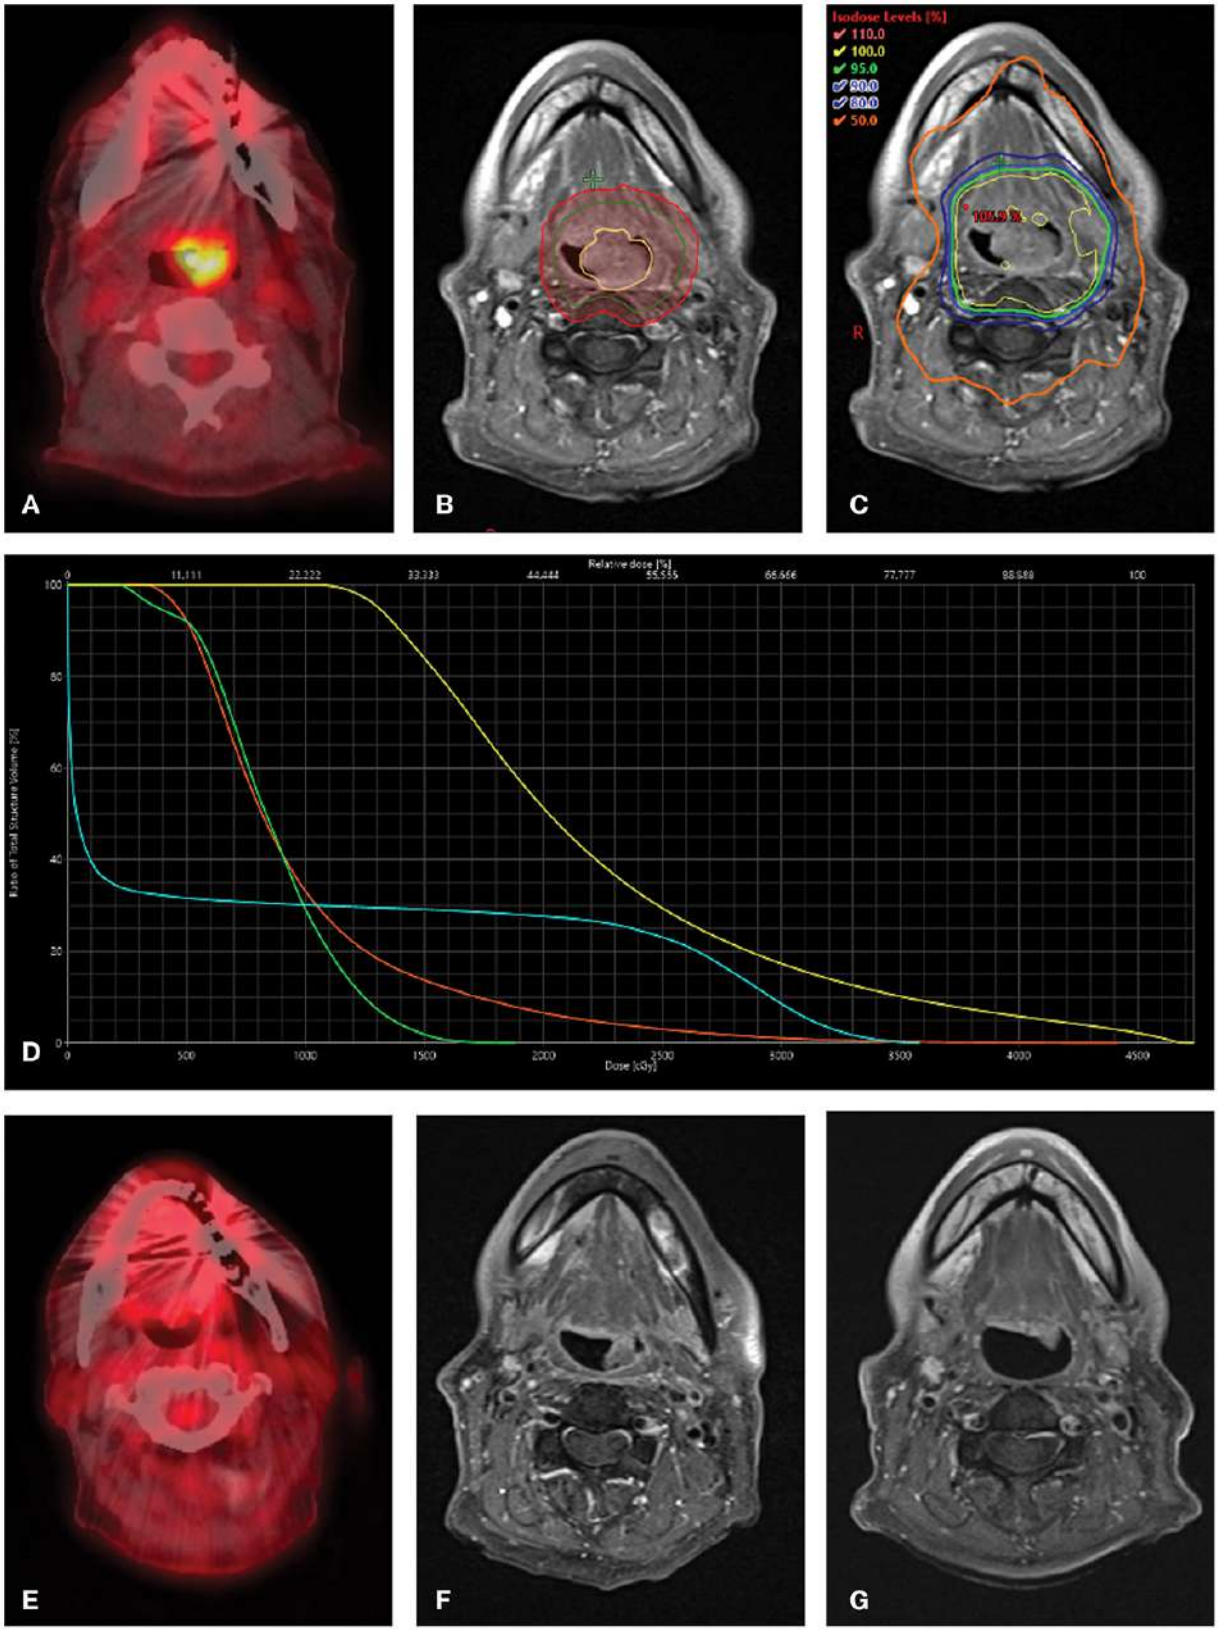

FIGURE 88.4 Radiotherapy treatment plan for a patient with solitary extramedullary plasmacytoma of the base of tongue who presented with 6-month history of dysphagia and

hoarseness. The patient was treated with definitive radiotherapy, 45 Gy in 25 fractions. (A) Axial image from Staging positron emission tomography (PET) scan. (B) Magnetic resonance imaging (MRI) fused to the computed tomography simulation scan to aid contouring of gross tumor volume (yellow), clinical target volume (green), and planning target volume (red), as depicted on this axial slice. (C) Dosimetry from a conformal volumetric modulated arc therapy plan with isodose lines displaying 50%, 80%, 90%, 95%, 100%, and 110% of the prescription dose. (D) Dose-volume histogram of the right parotid gland (green), left parotid gland (orange), oral cavity (yellow), and spinal cord (aqua). (E) PET to assess metabolic response approximately 3 months after radiotherapy showing a partial metabolic response. (F) MRI to assess structural response at 3.5 months postradiotherapy showing partial response. (G) Follow-up MRI 24 months postradiotherapy showing further interval improvement. The patient remains disease free.

In modern RT, "involved field RT" is no longer the preferred terminology, and the "involved site RT" concept should be adopted, as described in the ILROG guidelines.[25] Three- dimensional (3D) planning should always be used (except for a small skin lesion that can be treated with superficial x-rays or high-energy electrons guided by clinical examination). Field placement based on anatomic landmarks should no longer be used and should be replaced by volumetric delineation;[25] for example, the historical practice of inclusion of two vertebral bodies above and below the grossly involved vertebra(e) should be abandoned.

For defining gross tumor volume (GTV), the primary imaging (ie, CT, MRI, and PET) of the untreated lesion should be outlined on the simulation scan, with fusion of the primary imaging to the simulation scan if helpful (Figures 88.2A-B, 88.3B, and 88.4B). Clinical target volume (CTV) should encompass probable routes of microscopic spread, recognizing that barriers to the extension of local disease will vary according to anatomic location, as will the morbidity of treating adjacent normal tissues. In determining the CTV, using the GTV plus a margin of 0.5 to 3 cm is reasonable (depending on the site) respecting anatomic boundaries (Figures 88.2A-B, 88.3B, and 88.4B). In soft tissues, GTV to CTV expansion of 0.5 to 1 cm in the axial plane may be appropriate for covering potential microscopic extension, for example, in the head and neck area (Figure 88.4B). For a long bone site (eg, the humerus), the proximal and distant expansion should be increased to 2 to 3 cm (Figure 88.2B).[25] Coverage of the entirety of an involved long bone is no longer considered necessary as smaller, localized RT fields are associated with good palliation of symptoms and allow for greater marrow

sparing[212] (Figure 88.2C). Adjacent normal structures that are clearly uninvolved or at low risk of microscopic disease should not be included in the CTV.

Elective regional lymph node RT for SBP or SEP is generally not recommended by ILROG, with the exception being in the situation of convincing clinical evidence of a high risk of nodal involvement (eg, bulky primary disease in proximity to the drainage lymph node station where nodal coverage will not increase the treatment toxicity in a significant way).[25]

When physiologic movement could affect the CTV, an additional margin, ideally based on 4D CT simulation, should be added to the CTV to create an internal target volume (ITV). Planning target volumes (PTV) account for day-to-day setup variation and will typically add 5 to 10 mm around CTV volumes depending on the immobilization technique employed (Figures 88.2A-B, 88.3B, and 88.4B).

Radiation Therapy Techniques

In current practice, CT-based planning and conformal RT techniques are essential to reduce toxicity risks and improve the therapeutic ratio for patients with SP. The steeper dose gradients of intensity-modulated RT and volumetric modulated arc RT are especially useful when the PTV is adjacent to critical structures, for example, for SP of the head and neck, conformal techniques are important to reduce dose to the adjacent organs at risk, including optic structures and salivary glands (Figures 88.3C-D and 88.4C-D). Other highly conformal techniques, including stereotactic body radiation therapy (SBRT) and proton therapy, are presently investigational. A preliminary, prospective report of five patients with SBP treated with hypofractionated SBRT suggests the technique is safe and feasible[213]; however, further robust data are required. To date, the published experience of proton therapy for SP is limited to case reports only, but the sharp dose fall-off profile of proton therapy is attractive in the treatment of SP with proximity to dose-limiting critical organs (eg, an SP in the base of skull).[214]

Radiation Therapy Dose

Solitary Plasmacytoma

Studies evaluating RT dose-response in SP have produced differing results. However, these published data are largely limited to retrospective series, which may be confounded by selection bias (eg, higher doses prescribed to bulkier tumors) or limitations in surveillance imaging. For SP treated with RT, durable local control has been demonstrated from RT doses of 35 to 50 Gy.[30,63,75,215] For SP measuring <5 cm in size, data suggest excellent local control can be achieved by 35 Gy.[63] However, SP ≥5 cm is associated with inferior local control and may benefit from higher RT doses.[23,63,69,216] For SEP, some published studies report greater local control following doses of ≥40 Gy.[24,30,78] The current ILROG guidelines for clinical practice recommend doses of 35 to 40 Gy for SBP <5 cm and 40 to 50 Gy for SBP ≥5 cm or SEP.[25] However, one should be reminded that the quality of evidence supporting the use of higher RT doses is limited and that local failures are occasionally observed even after doses of 50 Gy or higher.[23,58,63]

Multiple Myeloma

For multiple myeloma, the most commonly used doses range from 8 to 30 Gy, resulting in excellent ORRs, although the pain relief is often partial.[172,174,175,217] Response rates exceed 80%, with complete pain relief in approximately 30%.[59,172,174] In a large study of 772 patients with myeloma and 1,513 irradiated sites (the most common biologic equivalent dose [BED] was 20-25 Gy in 43%), only 2.6% of sites required reirradiation, with the most common indications being persistent pain and radiographic progression.[217] Higher rates of pain control have been demonstrated from BED_{10} >38 Gy and lower rates associated with BED_{10} <15 Gy.[101] However, the cost of increased toxicity from higher doses is important to consider, as BED_{10} >38 Gy is associated with higher rates of grade 1 toxicity[207] and BED_{10} >36 Gy is associated with scarce bone marrow recovery.[218] Published in 2018, the ILROG guidelines recommend a hypofractionated regimen to a total dose of 8 to 30 Gy, with a single 8 Gy fraction preferred for bone disease in patients with poor prognosis.[25] However, more recent studies suggest that low-dose RT regimens are a feasible alternative. In a retrospective study of dose-response from palliative RT for uncomplicated myeloma osseous lesions (ie, without impending risk of pathologic fracture, prior orthopedic fixation, or spinal lesions with malignant epidural

involvement), there was no significant difference in duration of pain response after an equivalent dose in 2 Gy fractions <12 Gy versus ≥ 12 Gy.[219] An ongoing prospective multi-institutional study is investigating the use of a 2 × 2 Gy for painful myeloma lesions, including quality of life assessment (NCT03858205).[220] Recent publications suggest that RT regimens involving fewer fractions are being increasingly favored over time in the treatment of multiple myeloma. A population-based analysis in Australia found that the proportion of RT courses given over 2 to 5 fractions increased from 48% in 2012 to 60% in 2017, with a corresponding decrease in the use of 6 to 10 fractions from 26% in 2012 to 20% in 2017 (*P*-trend = .003).[221]

Assessment of Response and Follow-Up

Response assessment is indicated following RT for SP, with re-imaging best performed 3 to 6 months after therapy, as recommended by ILROG.[25] Following RT, bony destruction caused by the tumor can produce persistent abnormalities on CT and x-ray; and it is common for a residual soft tissue abnormality to persist on follow-up imaging (Figure 88.4F, G). Periodic reimaging may be required every 4 to 6 months until any residual mass disappears or remains stable on consecutive scans. For patients with persistent structural abnormalities seen on CT or MRI, FDG-PET/CT is a powerful tool to distinguish between active and nonactive sites of disease and to assess response to treatment.[47] FDG-PET/CT is the preferred functional imaging modality of the IMWG for evaluation of response to treatment.[48] As metabolic changes precede structural changes, FDG-PET/CT may also allow for earlier response assessment.[45,48] Repeated surveillance imaging is not considered beneficial in the context of a stable radiologic abnormality; however, reimaging should be considered in the context of persistent, deteriorating, or new symptomatology.

Follow-up procedures include clinical assessment plus serum and urine testing for any persistent M protein on a regular basis (eg, every 6 months).[29] Repeat measurement of the M protein often detects the onset of systemic disease prior to the development of symptoms and may be used as an indicator of disease burden.[28,222] A complete blood count, serum chemistry (calcium and creatinine), and episodic skeletal survey are

common practices for surveillance of myeloma. The development of new symptomatology necessitates further investigation and workup, including imaging as appropriate.
