The most important prognostic indicators reflect tumor extent. If hematogenous or transperitoneal spread is present, the outcome is, essentially, uniformly fatal. Survival rates decrease with progressive tumor extension within or beyond the gastric wall.[31,37-39] The number of involved lymph nodes also has a significant impact on survival. Lymph node involvement is important, as are the number and locations of nodes affected.[31,39-41] Minimal nodal involvement adjacent to the primary lesion only moderately affects prognosis.[37,41,42] The finding of either involved lymph nodes or complete wall penetration is usually not as ominous as the presence of both.[37,39,41,43] Additional prognostic indicators include a poor performance status, elevated alkaline phosphatase levels, and ethnicity.[44] In one study, Asian Pacific Islanders born in the United States were compared to those born abroad, finding that only foreign-born Asian Pacific Islanders had a more favorable survival compared to indigenous non-Hispanic white patients.[45] The proposed hypothesis to explain disparities in survival outcomes between Western and Asian populations includes early detection in the latter, leading to stage migration, differences in treatment policy, as well as potential differences in tumor biology. In another review, gastric cancer prognostic factors included age, type, number of positive and negative lymph nodes resected, depth of invasion, microsatellite instability, AMPHIOREGULIN (AREG), epidermal growth factor receptor (EGFR),

insulin-like growth factor-1 (IGF1R), osteopontin expression, pretreatment weight, and Maruyama Index.[46]

Flow cytometry may also be prognostically valuable; aneuploidy is associated with unfavorable tumor location, lymph node metastasis, and primary tumor invasion.[47-49] Unfavorable DNA flow cytometry correlates with a poor prognosis.[47] The prognosis is worse for cardia lesions, and flow cytometry reveals a greater incidence of aneuploidy.[49] The gross pathologic appearance of the primary lesion also reveals prognostic information, although it is not known whether this factor is independent of tumor stage. Patients with Borrmann type I and II tumors have relatively favorable 5-year survival rates, although patients with type IV (linitis plastica) fare poorly.[42,50-52]

The molecular biology of gastric cancer reflects the heterogeneity of its causes and its histologic subtypes. A detailed discussion of the molecular biology of gastric cancer is beyond the scope of this chapter and is well detailed elsewhere.[11] However, identification of the genetic and phenotypic variables existing among gastric cancers may lead to more directed therapeutic approaches and a more accurate prediction of clinical outcome. Changes that may affect the behavior of gastric tumor cells involve four major types of alterations. Loss of tumor suppressor gene function, especially inactivation of the *p53* gene, appears to play a critical role. The *p53* gene is located on the short arm of chromosome 17 and plays a key role in tumor suppression and cell cycle regulation.[53] The *p53* gene halts DNA replication and triggers programmed cell death in response to DNA damage.[54] Loss of p53 function allows malignancy to develop, affects the effectiveness of chemotherapy and irradiation, and predisposes cells to genetic instability.[55,56] The latter is particularly important because p53 mutations occur early in tumorigenesis.[57]

A second major aberration affecting gastric epithelial cells is the impact of alterations in mismatch repair genes. Two such genes, *hMSH3* and *hMLH1*, on chromosomes 2 and 3, respectively, account for replication errors throughout the genome. Mutations in these genes are implicated in cancer family syndromes and hereditary nonpolyposis colorectal cancer, which is a disease associated with an increased tendency for the development of gastric tumors.[58] Mutations in these genes generate genetic instability and have the potential to lead to further alterations in oncogenes.

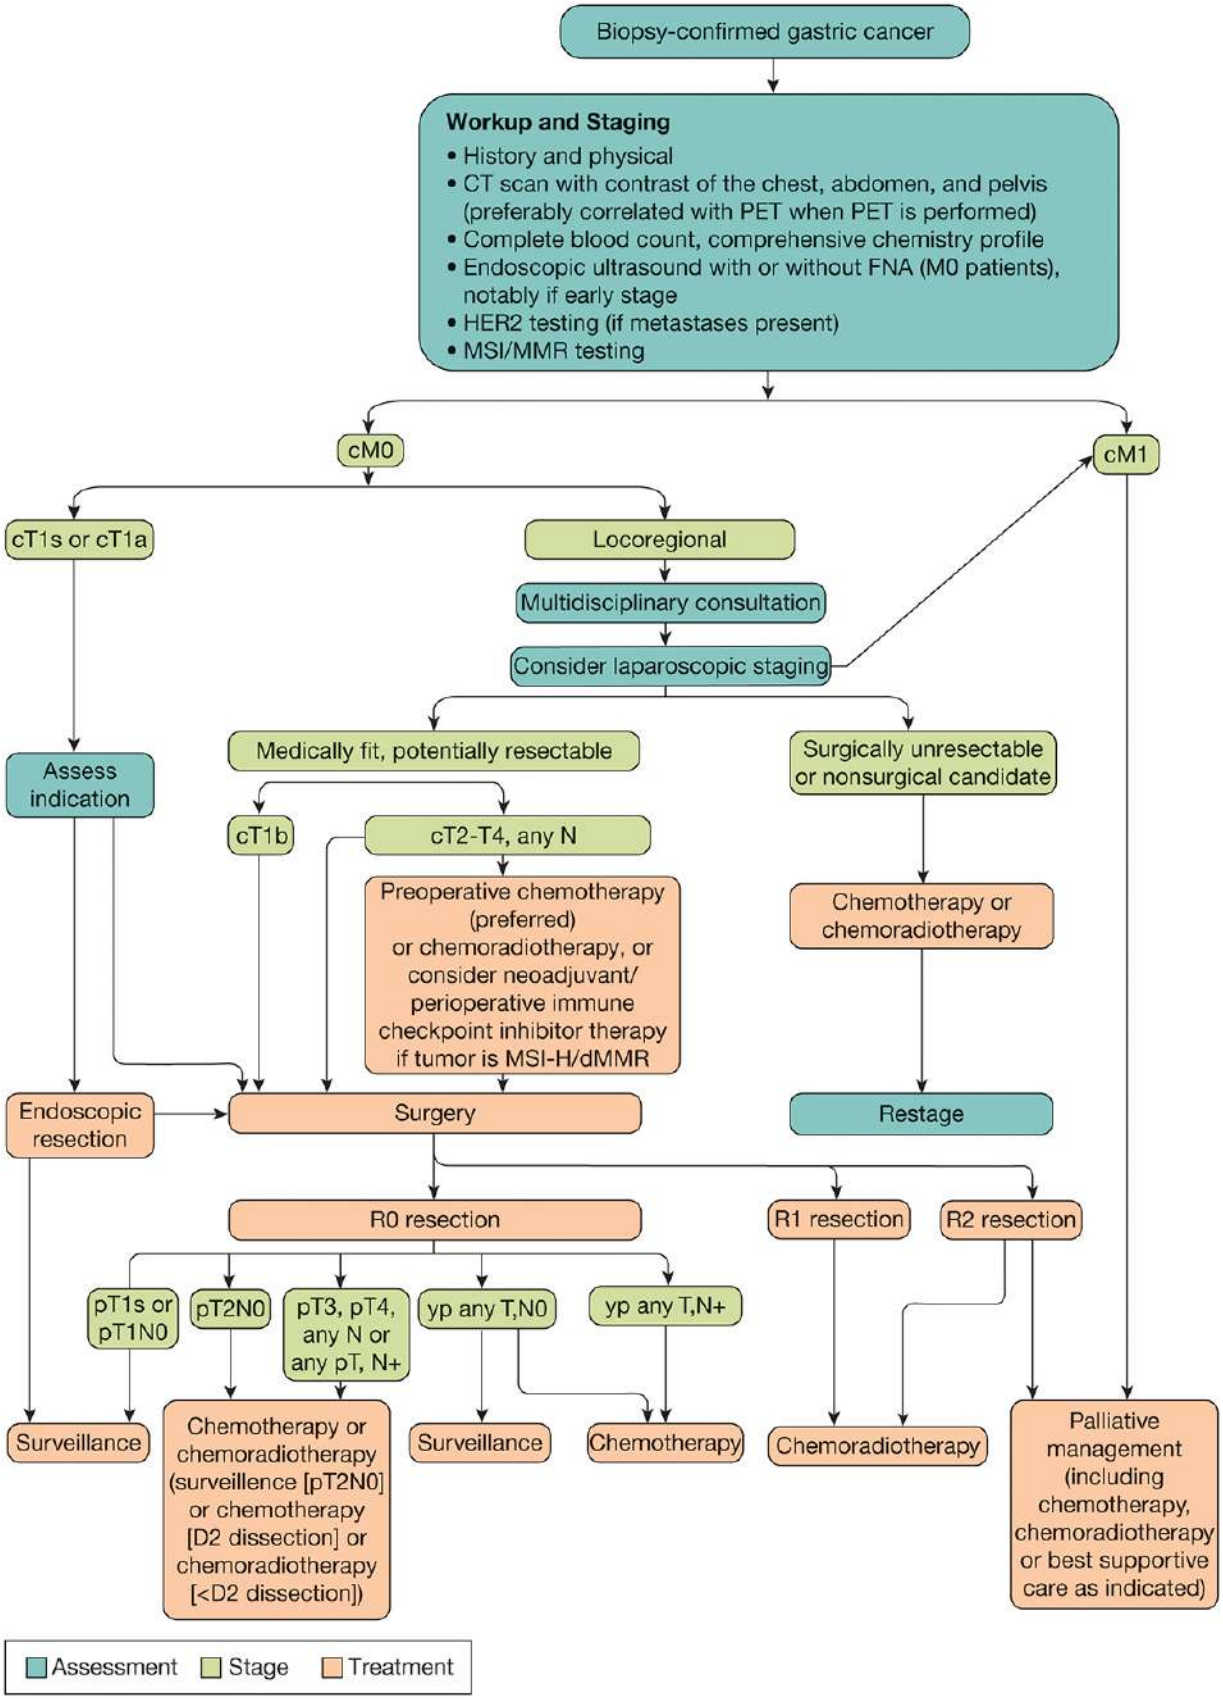
Two proto-oncogenes, *c-met* and *k-sam*, are associated with scirrhous carcinoma of the stomach. The former encodes hepatocyte growth factor, which is a potent endogenous promoter of gastric epithelial cell growth.[59] Its overexpression correlates with tumor progression and metastasis.[60] The latter encodes a tyrosine kinase receptor family.[60] In scirrhous carcinoma, *c-met* and *k-sam* amplification may occur independently. There is a tendency for *k-sam* to be activated in women less than 40 years of age and *c-met* to be amplified in men more than 50 years of age.[57,61]

Peptide receptors, including estrogen receptors and EGFRs, are associated with adverse prognoses.[62,63] EGF receptors and levels correlate with higher rates of primary tumor infiltration, poorer histologic differentiation, and linitis plastica.[64] The pathophysiologic relation between these peptide receptors and their association with poor prognoses is not well understood.

Modern molecular biology observations confirm the heterogeneity of human gastric cancer. Genetic alterations detected and potentially associated with a worse prognosis include CD44 expression; telomerase reactivation; *p53* gene inactivation; dysfunction of repair genes such as *hMSH3* and *hMLH1*; overexpression of proto-oncogenes such as *erb-B2*, *bcl-2*, *c-met*, and *k-sam*; estrogenic receptor expression; and presence of viral genomes.[65] Gastric cancers with class II major histocompatibility complex antigen expression have a better prognosis; however, the loss of expression is not an independent prognostic factor.[64] Illustrating the importance of understanding and potential exploitation of these genetic alterations, a randomized study was conducted in patients with human epidermal growth factor receptor 2 (HER2) overexpression. Patients with locally advanced or metastatic gastric or GE cancer (the ToGA trial) were randomized to determine whether trastuzumab (an antibody against the *HER2* gene product/receptor) enhanced treatment efficacy when added to cisplatin and 5-FU/capecitabine therapy. This study demonstrated that the addition of trastuzumab achieved a significant improvement in overall and progression-free survival.[66] These and other data led to the Radiation Therapy Oncology Group (RTOG) 1010 trial, which randomized patients with esophageal/GE junction tumors to receive preoperative radiation therapy concurrent with paclitaxel/carboplatin, with or without trastuzumab, followed by resection (discussed later).

GENERAL MANAGEMENT

Figure 64.5 is an algorithm for managing newly diagnosed gastric cancer.



Biopsy-confirmed gastric cancer
Workup and Staging
• History and physical
• CT scan with contrast of the chest, abdomen, and pelvis (preferably correlated with PET when PET is performed)
• Complete blood count, comprehensive chemistry profile
• Endoscopic ultrasound with or without FNA (M0 patients), notably if early stage
• HER2 testing (if metastases present)
• MSI/MMR testing

Surgical Management

Complete tumor and regional lymph node resection remains the primary curative modality for gastric adenocarcinoma and may require total or distal gastrectomy. Operative attempts are highly successful if disease is limited to the mucosa; however, the incidence of such early lesions at diagnosis is less than 5% in most US series. In Japan, the incidence of lesions initially confined to the mucosa or submucosa was only 3.8% in 1955 and 1956, although by 1966, as a result of screening procedures, this figure had increased to 34.5%, with corresponding survival rates of 90.9%.[67] For very early gastric cancer (Tis and T1a), endoscopic mucosal dissection and endoscopic submucosal dissection have been successfully used as less radical alternatives to standard surgery. Appropriateness of endoscopic resection is based on the tumor depth, tumor diameter, histologic grade, and ulcerative component. General criteria for endoscopic resection of early gastric cancers include well or moderately differentiated disease measuring 2 cm or less, without ulceration, as well as intramucosal cancer. Some authors consider expanded criteria, including intramucosal disease more than 2 cm, ulcerated disease 3 cm or less, submucosal invasion no greater than SM1 level 3 cm or less, as well as intramucosal undifferentiated disease without ulceration 2 cm or less.[68]

As in other endoscopic procedures, outcomes are operator dependent. Endoscopic laser surgery has been applied successfully to patients with very early gastric cancer whose tumors are inoperable because of complicating medical illness. Small lesions that are pedunculated, noninvasive, and well differentiated have lymph node metastasis in less than 5% of cases and can be completely removed endoscopically in 75% of cases.[67] Radiation therapy with chemotherapy may be considered as adjuvant therapy in selected situations. These approaches in early gastric cancer (uncommonly seen in

Western society) require meticulous patient selection and remain a topic of investigation.

Curative or palliative surgical resection is possible for 50% to 60% of patients at the time of initial disease presentation. However, only approximately 25% to 40% are eligible for potentially curative resection. Generally, patients with evidence of peritoneal involvement, distant metastases, or locally advanced disease (including encasement of unresectable/major blood vessels) are considered to have unresectable disease. Palliative resection is usually reserved for rare cases, including symptomatic palliation of bleeding uncontrolled by other methods, and is generally considered a last resort in patients with locally unresectable or metastatic disease. A randomized trial from Asia (the REGATTA trial) enrolled 175 patients with gastric cancer. Patients were randomized to receive either chemotherapy (oral S1 + cisplatin) or palliative D1 gastrectomy followed by the same regimen. At interim analysis, no significant difference was seen in 2-year survival rates between the arms. The authors concluded that palliative gastrectomy could not be justified even in the setting of a solitary metastasis.[69] In some instances, unresectable tumors may be debulked successfully, with sites of minimal residual disease marked judiciously with clips. This may palliate and permit accurate delivery of postoperative radiation therapy. In patients with gastric outlet obstruction, gastrojejunostomy may be performed as an alternative to endoscopic placement of a stent in patients with expected longer survival.

No prospective randomized trials have definitively established optimal surgical therapy.[70,71] Generally, it is recommended that gastric cancer surgery be performed by experienced surgeons in high-volume centers, entailing removal of the perigastric lymph nodes (D1) as well as those along the main vessels of the celiac trunk (D2), with the goal of examining 16 or more lymph nodes (discussed later). Total gastrectomy is generally necessary in most cases of proximal and midgastric carcinomas, although proximal gastrectomy may be appropriate depending on extent of disease. However, for more distal lesions, distal gastrectomy is preferred if adequate margins can be obtained. Generally, the distal margin in subtotal gastrectomy needs to be approximately 2 cm. This operation removes approximately 80% of the stomach along with the node-bearing tissue, the gastrohepatic and gastrocolic omenta, and the first portion of the

duodenum. Larger lesions may require total gastrectomy. Total gastrectomy is not recommended where 4- to 6-cm margins can be achieved with partial gastrectomy given improved safety and long-term functional outcome improvements in the latter.[72] Patients treated with total gastrectomy characteristically have 5-year survival rates of 10% to 15%, and those undergoing radical subtotal gastrectomy have 5-year survival rates of 25% to 45%.[40,71,73] The inferior survivorship of patients undergoing total gastrectomy reflects larger tumors and unfavorable proximal lesions that prompt such a procedure. The value of splenectomy has not been addressed in prospective randomized trials; however, retrospective Japanese data do not support a survival benefit.[74] Because routine splenectomy has not shown significant improved outcomes and potentially increases complication rates, complete removal of splenic nodes is not commonly performed by Western surgeons. Roux-en-Y reconstruction may be used to avoid bile reflux gastritis/esophagitis. Vitamin B supplementation is generally required following total gastrectomy because of lack of intrinsic factor production from the stomach.

Minimally invasive gastrectomy (including laparoscopic or robot-assisted resection) is being increasingly utilized, although these approaches remain a subject of investigation. These approaches carry potential advantages, including less intraoperative blood loss, faster recovery times, reduced pain, and decreased hospital length of stay. Multiple trials have indicated that minimally invasive techniques provide equivalent surgical and oncologic outcomes to open approaches.[75] The KLASS-O2 Korean randomized trial showed a lower rate of complications with laparoscopic gastrectomy with D2 lymphadenectomy, less postoperative pain, and shorter length of hospital stay compared to open surgery.[76] However, the LOGICA trial comparing laparoscopic to open gastrectomy did not find differences in complication rates or length of stay.[77] Patient selection is important. In patients who undergo adjuvant chemoradiotherapy, it may be prudent to place a feeding jejunostomy at the time of resection.

The propensity for gastric carcinoma to spread via the submucosal lymphatics suggests that a 5-cm margin of normal tissue proximally and distally may be optimal. It may be necessary to include a portion of the esophagus or duodenum to achieve adequate margins. Frozen section pathologic evaluation of surgical margins has been advocated to confirm

their adequacy.[40] The importance of careful evaluation of longitudinal margins is emphasized in multiple series with documented positive pathologic margins in approximately one-quarter of "curatively" resected specimen.[78-85] The approximate 25% positive longitudinal margin correlates almost precisely with the incidence of locoregional recurrence in the anastomosis or stump, as discussed later.

Although R0 resection with adequate lymph node sampling is a primary goal for gastric cancer surgery, many patients end up with involved margins. Even though the longitudinal margin is routinely evaluated, equally important but frequently not assessed are the radial or circumferential margins. The incidence of radial margin positivity is not well reported in the literature. The rising incidence of T3 and T4 GE tumors may result in an increasing rate of microscopically positive radial margins. Because the perigastric tissue surrounding the GE junction and distal esophagus has no serosa, lesions that extend to the pathologic radial margin likely represent a true positive margin in a large percentage of cases.

The extent of lymph node dissection remains an ongoing area of controversy. The Japanese Research Society for gastric cancer categorizes draining stomach lymph nodes into 16 stations, 6 perigastric and 10 regional along major vessels and adjacent to the pancreas (see Figure 64.3). A D1 dissection only includes perigastric nodes (stations 1-6); a D2 dissection includes those along the common hepatic, left gastric, celiac, and splenic arteries (stations 7-11); a D3 dissection includes additional nodes with any of the porta hepatis and adjacent to the aorta (stations 12-16).[72] According to the most recent AJCC staging manual, accurate nodal staging demands evaluation of at least 16 lymph nodes. This may reduce stage migration. In a D0 dissection, there is generally incomplete removal of the lymph nodes along the greater and lesser curvature. In series with rigorous pathologic evaluation of these nodes,[86] the likelihood of discovering lymph node metastasis increases markedly in both D1 and D2 procedures. There appears to be a small subset of patients who have limited metastasis in the celiac axis, superior pancreatic, or retroduodenal chains and may be cured by a D2 lymph node resection.[87,88] Data from the Surveillance Epidemiology and End Results database show that the number of nodes examined correlated with overall survival, potentially reflecting improved staging in these patients.[89] Japanese researchers advocate complete lymph

node removal to improve the rates of local control and survival. Several nonrandomized clinical trials suggested that extended lymphadenectomy may improve survival.[90-93] Others[94] reported that increasingly radical lymphadenectomies failed to improve survival or reduce the risk of locoregional failure. Multiple prospective randomized trials of lymphadenectomies have been reported[87,95-99] and show no survival advantage with more extensive lymph node dissection. A more recent update of a Dutch randomized trial showed D2 dissections to be associated with improved disease-specific survival versus D1 at a median follow-up of 15 years.[100] An Italian gastric cancer study group report similarly evaluated D1 versus D2 dissection and found that after 15 years of follow-up, there was no significant difference in overall and disease-free survival between these groups, although disease-specific survival in gastric cancer–related mortality was improved in the D2 group.[101] However, morbidity and mortality rates have been significantly higher for patients undergoing more extensive nodal dissection. Despite the mixed evidence of randomized trials, it is generally recommended that spleen-sparing D2 lymphadenectomy be performed by experienced surgeons in high-volume centers. An even more extensive lymph node dissection may entail para-aortic nodal dissection. However, a Japanese trial comparing D2 lymphadenectomy versus the same with para-aortic (D3) nodal dissection did not show any differences in overall or relapse-free survival between the groups, indicating the latter approach should not be used in patients with curable gastric cancer.[102] However, other important principles of lymph node dissection have been elucidated through these trials. The first is that as more lymph node areas are dissected and as pathologic lymph node evaluation is more rigorous, considerable stage migration occurs. This stage migration produces an apparent improvement in stage-specific survival without improvement in survival in the group overall.

Failure Patterns After Surgical Resection

Local failures in the tumor bed and/or regional lymph nodes and distant failures by hematogenous or peritoneal routes are common mechanisms of failure after “curative” resection in clinical, reoperative, and autopsy series[43,103-106] (Tables 64.4 and 64.5). For GE junction lesions, the liver and

lungs are common sites of distant metastases. With gastric lesions that do not extend to the esophagus, the initial site of distant metastasis is usually the liver, and many failures could be prevented if an effective abdominal treatment could be combined with treatment to the primary site. In the series of Landry et al,[107] 50 of 88 (57%) failing patients had disease progression within the abdomen only. Abdominal treatment also could address peritoneal seeding, which occurs in 23% to 43% of patients postgastrectomy.[103-111]

TABLE 64.4 PATTERNS OF FAILURE AFTER "CURATIVE" RESECTION OF GASTRIC CANCER

Lymph node(s)	8	42	52

Locoregional failures occur commonly in organs and structures of the gastric bed and in lymph nodes and is an established mode of failure (Table 64.5). Clinically detectable locoregional recurrence following surgical resection alone generally exceeds 25%. As an example, in long-term follow-up of the previously described Dutch Gastric Cancer Trial, even with D2 dissection, locoregional recurrence rates were 25% and 41% following D2 surgery.[100] However, reoperation and autopsy series have suggested that these rates are much higher.[43,103-106,109] Failures in the anastomoses, gastric remnant, or duodenal stump also are frequent, as suggested by the incidence of positive longitudinal resection margins (Table 64.5). As is true for most sites, clinical series underestimate the true incidence of locoregional failure when compared with reoperative or autopsy series (Table 64.4). Progressive extension of the operative procedure to include routine splenectomy, omentectomy, and radical lymph node dissection neither improved survival nor decreased the incidence of locoregional failures in the University of Minnesota series.[43] Subsequent failure in areas of initial node dissection occurred frequently, even with radical lymph node dissections[43] (see Figure 64.4). The high rate of regional node relapse (including para-aortic basins) provides a partial explanation for the lack of survival benefit with a D2 (extended lymphadenectomy) versus D1 (limited lymphadenectomy) node dissection in phase III surgical trials discussed previously. A more contemporary analysis of 382 patients with stage III (N3) disease undergoing D2 resection receiving adjuvant chemotherapy alone demonstrated that first site of recurrence (some patients had multiple) was local in 7% (most at anastomosis and few in gastric bed), regional failure as any component of first recurrence occurred in 24% of patients (isolated in 12.8% of patients), and peritoneal based in 33%. Most commonly involved lymph node groups were 16, 12, 14, 13, and 9 (primarily outside of the D2 nodal basin).[112] A further analysis of this trial of nodal CT recurrences suggested that vessel-based delineations of these volumes on CT may assist

in target design[113] (Figure 64.6A). A smaller study from Stanford investigators evaluated patients with locally advanced gastric cancer receiving preoperative chemotherapy followed by D2 resection. Three-year cumulative incidences of local regional failure and distant metastases were 8.4% and 41%, respectively. The authors concluded that patients with locally advanced gastric cancer with less-than-complete response to chemotherapy had poor outcomes due to high rates of distant metastases and that adjuvant regional therapy such as radiation is unlikely to affect survival.[114] A pattern of failure analysis of the Adjuvant Chemoradiation Therapy in Stomach Cancer (ARTIST) trial (discussed later) evaluating patterns of recurrence suggested a significant decrease in regional recurrence with the addition of radiation therapy in node-positive patients. Specifically, patients in the nonradiation arm had significantly higher likelihood of failure in the retroperitoneal lymph node basins, emphasizing the importance of covering this area in patients with gastric cancer, whereas true local recurrence rates did not differ significantly between the two arms (Figure 64.6B).[115]

Indications for Radiation Therapy

The results of the US Gastrointestinal Intergroup Gastric Adjuvant Trial changed the standard of care in the United States to the use of both

chemotherapy and radiation therapy in the postoperative setting for patients with disease extension through the gastric wall and/or with lymph nodes positive for tumor (discussed later).[116] Postoperative irradiation plus concurrent and maintenance fluoropyrimidine-based chemotherapy is recommended for patients with stage IB-IV and M0 gastric cancer.[116] Quality control of irradiation field design was conducted during the cycle of chemotherapy given before the start of concurrent chemoradiation. The up-front quality control provided the mechanism to correct most of the major or minor deviations (35% incidence) in irradiation field design before the start of treatment and resulted in only a 6.5% final major deviation rate.

Radiation therapy, usually administered with concomitant fluoropyrimidine-based chemotherapy, is also indicated for locally confined gastric cancer that either is not technically resectable or occurs in medically inoperable patients. In this setting, therapy can be administered with curative or palliative intent, depending on the clinical situation. Those who undergo gastric resection with incomplete tumor resection or have truly positive margins of resection are also managed appropriately by combined-modality postoperative therapy. A series of 409 patients from the Netherlands Cancer Registry who underwent R1 resection were analyzed, including patients who did and did not receive adjuvant chemoradiation. Median age and percentage of patients with diffuse tumors were higher in the nonradiation group, although there is no significant difference in stage. Median overall survival was significantly improved (13 vs 24 months, P = .003) in patients receiving adjuvant radiation therapy, which was an independent prognostic factor for survival on multivariable analysis.[117]

RADIATION THERAPY TECHNIQUES

Simulation

When patients with gastric cancer are simulated, the radiation oncologist should know the extent of disease based on imaging (barium swallow, CT, PET) as well as endoscopic procedures. CT simulation is appropriate for treatment planning. Some authors have recommended fasting for more than 2 hours before simulation as well as at treatment.[118] During simulation, the patient is positioned, straightened, and immobilized on the simulation table. An immobilization device is used to minimize variation in daily setup.

Arms are generally placed upward/outside of the area being irradiated. Oral contrast is generally administered to delineate the stomach and may help define the extent of mucosal irregularity (if the patient is surgically naïve). The patient is placed on the CT simulator in the treatment position, and a scan of the entire area of interest with margin is obtained. At minimum, 3- to 5-mm slices should be used, allowing accurate tumor characterization as well as improved quality of digitally reconstructed radiographs. If patients lose more than 10% of their body weight during therapy, consideration should be given to repeat CT planning. Intravenous (IV) contrast is generally used to delineate mediastinal and abdominal vascular nodal basins, including the celiac axis, and to allow the radiation oncologist to discern normal vasculature from other adjacent normal structures and potential adenopathy. The tumor (if the patient is surgically naïve) and vital structures are then outlined on each slice on the treatment planning system, enabling a three-dimensional (3-D) treatment plan to be generated. The use of respiratory gating or breath-holding techniques may help to reduce target motion with respiration and, therefore, avoidance of normal tissue irradiation associated with larger margins used in free-breathing approaches. Four-dimensional (4-D) CT scan may be appropriate to assess respiratory/ tumoral motion, facilitating appropriate margin placement on the target volumes or implementation of respiratory motion control approaches.

Treatment Planning

Target Design

For a detailed description of target and field design in proximal gastric cancer involving the GE junction, the reader is referred to Chapters 59. In the design of radiation fields for neoadjuvantly treated or locally unresectable gastric cancer (as well as in the re-creation of tumoral volumes in adjuvantly treated patients), it is important to define varying target volumes, including gross disease as well as potential areas of subclinical involvement (ie, gross tumor volume [GTV] and clinical target volume [CTV], respectively). Defining GTV (including re-creation of volumes in the adjuvant setting) is based on multiple studies, including endoscopic descriptions (from both esophagogastroduodenoscopy [EGD] and

endoscopic ultrasound) as well as cross-sectional imaging. Gastric wall thickening correlating to the GTV can frequently be visualized on diagnostic and radiation planning CT. Similarly, EUS appears to be the most reliable test in detecting lymphadenopathy related to nodal spread. The endoscopist should be encouraged to accurately define not only the primary disease extent on EGD but also the depth of penetration and potential involvement of adjacent structures on EUS, which can also be used to help guide GTV delineation. Similarly, EUS may allow detection of lymph nodes that may not be appreciated on CT or PET imaging, and the endoscopist should be encouraged to describe the size as well as location (eg, relationship to tumor or adjacent structures). Additionally, radiographic areas of lymphadenopathy should similarly be included in the GTV. In GTV design, basing potential nodal involvement (and therefore target volumes) on nodal size is problematic given that metastatic lymph nodes may frequently be below the resolution of conventional imaging. Therefore, it is not appropriate to rely exclusively on imaging modalities to define areas of subclinical spread for gastric cancer, realizing established pathologic patterns of spread data are important in determining radiation field design.

The identification of potential direct and nodal pathways for spread of subclinical disease (ie, CTV definition) in gastric cancer is of paramount importance. These areas vary significantly depending on site of origin of disease, making gastric cancer planning somewhat complex. As described previously, the stomach is characterized by a rich network of lymphatics that facilitates early lymph node spread of disease. Some authors have recommended dividing the stomach into three equal lengths (upper/proximal, middle, and distal), with tumors classified by location of the bulk of their masses in these respective sites. Therefore, practically speaking, the stomach can be divided into proximal (remembering that in the AJCC eighth edition staging system, involvement of the GE junction by very proximal third tumors would be classified as an esophageal tumor), middle, or distal segments (Figure 64.7).

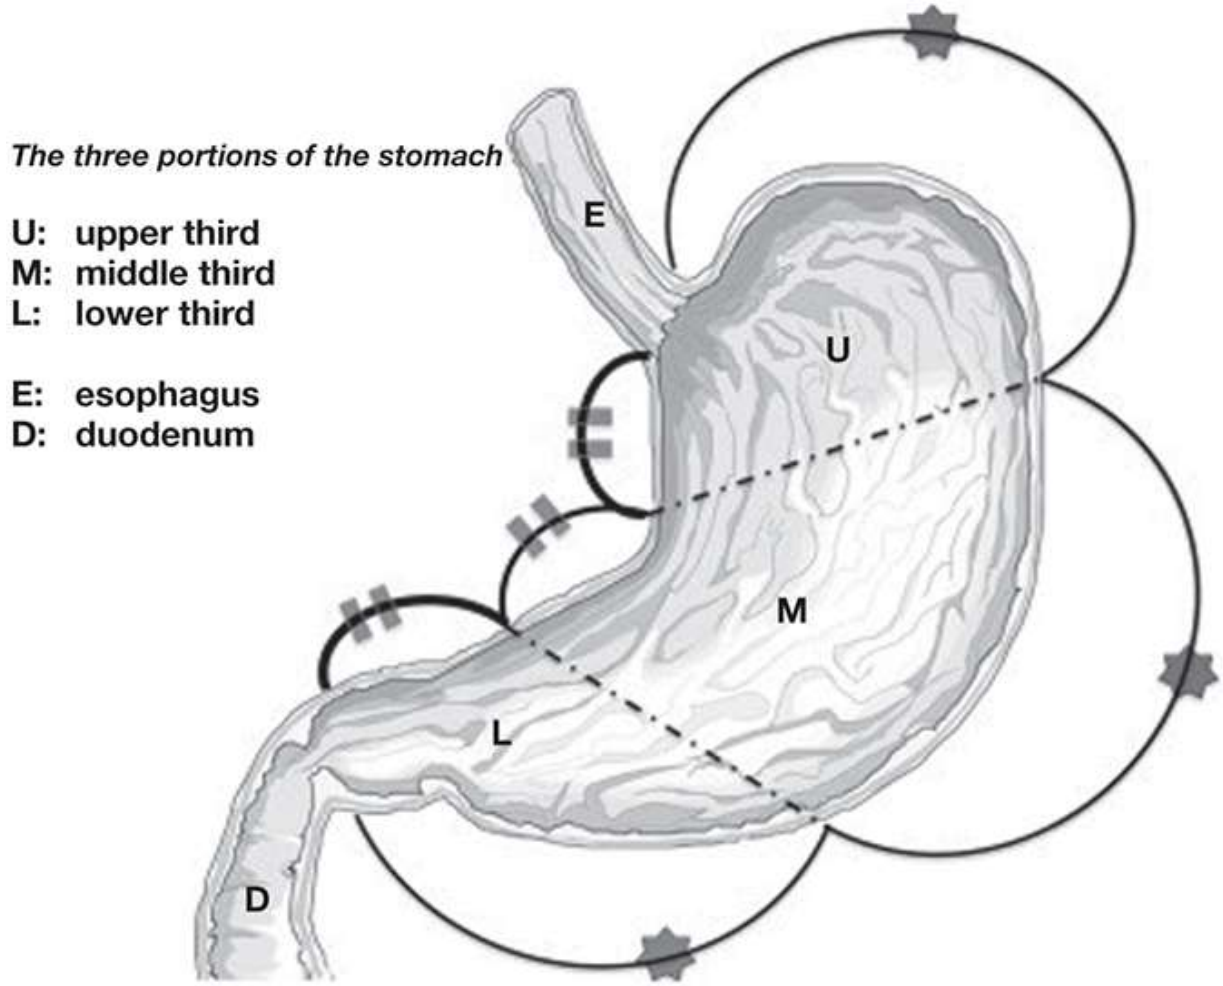

FIGURE 64.7 Subdivision of the stomach into equal lengths along greater and lesser curves. (Reprinted from Matzinger O, Gerber E, Bernstein Z, et al. EORTC-ROG expert opinion: radiotherapy volume and treatment guidelines for neoadjuvant radiation of adenocarcinomas of the gastroesophageal junction and the stomach. *Radiother Oncol*. 2009;92[2]:164-175. Copyright © 2009 Elsevier Ireland Ltd. With permission.)

Primarily based on extensive analysis of patterns of nodal spread from surgical series, Japanese investigators have developed lymph node station classifications (the Japanese classification of gastric carcinoma of the Japanese Gastric Cancer Association) that have been validated in other series (see Figure 64.3). Based on this system, general recommendations for CTV definition for tumors in varying parts of the stomach are as follows. Proximal third stomach tumors should include the contour of the stomach with exclusion of the pylorus and antrum (keeping a minimal margin of 5 cm from the GTV). Middle third tumors should include the contour of the stomach from the cardia to the pylorus. Distal third tumor CTVs should

include the stomach except for the cardia/fundus, again keeping a minimal margin of 5 cm from the GTV. However, some authors have noted that surgical series have demonstrated that less than 5% of patients have microscopic mucosal extension more than 3 cm beyond gross disease, suggesting smaller margins may be feasible.[118] If pyloric/duodenal invasion is present, the CTV would be expanded along the duodenum with a margin of 3 cm from the tumor. Nodal volumes to be included are described later, and it has been recommended that the CTV consist of a 5-mm margin around corresponding vessels. An internal target volume (ITV) may be created based on 4-D imaging, with planning target volume (PTV) expansion variable, although this typically ranges from 5 to 15 mm depending on immobilization technique and use of image guidance. If target motion is not accounted for, the minimal recommended 3-D margins to the CTV to obtain the ITV are 1.5 cm in all directions, considering physiologic organ motion, particularly respiratory motion. The PTV can then be defined as the ITV volume plus a 3-D margin of 5 mm.[119]

Field Design

Field design is based on established patterns of nodal involvement following gastrectomy and lymph node dissection as well as patterns of disease recurrence (Table 64.5). This is also dependent on tumor location within the stomach, stage of disease, as well as extent of lymph node dissection. In resected patients, the gastric/tumor bed, anastomosis and gastric remnant, and pertinent regional lymphatics should be included in most patients.[43,106,110,111,116,119] Major nodal chains at risk include the lesser and greater curvature, celiac axis, pancreaticoduodenal, splenic, suprapancreatic, porta hepatis, and, in many, para-aortic to the level of mid-L3. However, included basins are frequently modified based on margin status, type of surgery (ie, D0, D1, D2), location within the stomach, as well as stage.

The relative risk of nodal metastases at a specific nodal location depends on both the site of origin of the primary tumor[119-121] and other factors, including width and depth of invasion of the gastric wall. On the basis of previously described patterns of failure data, general guidelines in terms of field design are illustrated in Figures 64.8 to 64.10 and discussed later.

These are general guidelines, and all plans should be individualized according to available imaging and endoscopic data, and generalized portals based on patterns of failure data frequently need to be modified on the basis of the individual patient's initial extent of disease.[119-121] As seen in Figures 64.8 to 64.10, gastric tumors (ie, without GE junction involvement) that originate in the proximal portion of the stomach have a higher propensity of spread to nodes in the paracardial region but a lower likelihood of involvement of nodes in the region of the gastric antrum, periduodenal area, and porta hepatis.

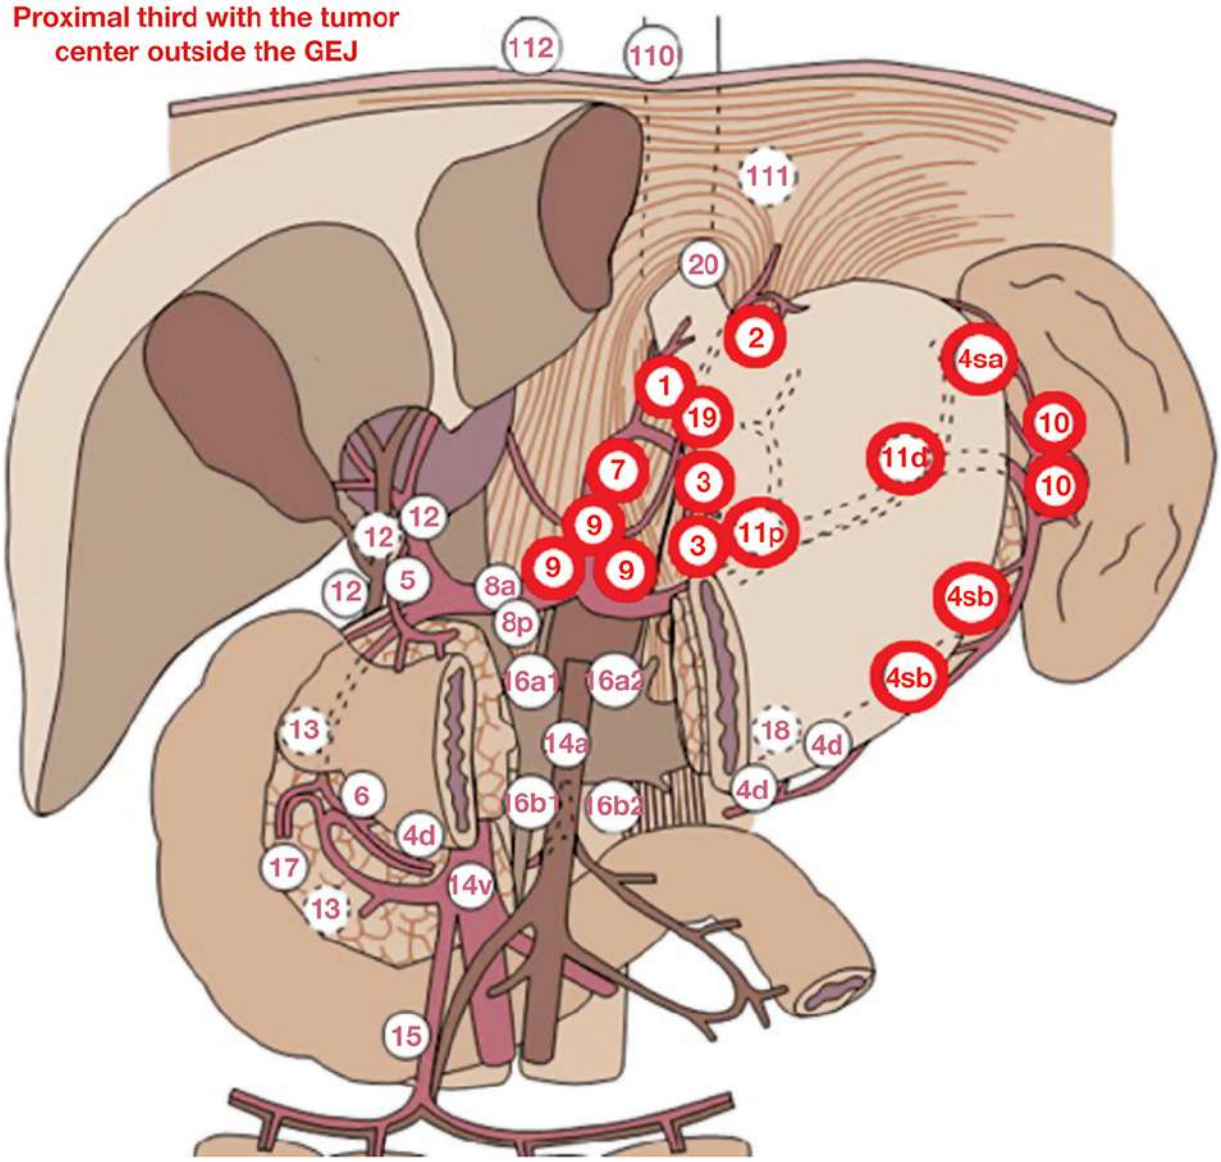

FIGURE 64.8 Suggested lymph node station coverage for tumors of the proximal third of the stomach without involvement of the GE junction (GEJ). In patients with proximal gastric cancers (gastric cardia and GE junction) undergoing esophagogastrectomy with intrathoracic anastomosis, the CTV typically includes 3 to 4 cm of the mucosa of the esophagus and distal stomach, tumor bed (typically determined by preoperative imaging and including the medial two-thirds of the left hemidiaphragm), as well as lymph node stations 1 to 4, 7, and 9 to 11, with some authors recommending inclusion of stations 12 to 13[118]; if the GE junction is involved, stations 20 and 110 to 111 are also included, and if the tumor extended to the middle stomach, stations 5, 6, and 8 frequently are

included.[118] Tumors that originate in the body of the stomach can spread to all nodal sites but have the highest likelihood of spreading to nodes along the greater and lesser curvature near the location of the primary tumor mass. Nodal basins are similar to upper third tumors with the exception of inclusion of nodal basins along the pyloric region, common hepatic artery, and additional coverage along the greater curvature. For middle third patients undergoing total gastrectomy with Roux-en-Y esophagojejunal anastomosis, the CTV typically includes 3 to 4 cm of mucosa of the esophagus and jejunum, tumor bed delineated as earlier, as well as lymph node stations 3 to 11, with some authors advocating inclusion of stations 12 to 13,[118] as well as consideration of 1 to 2 if there is proximal third stomach involvement. Tumors that originate in the distal stomach, in the region of the gastric antrum, have a high likelihood of spread to the periduodenal, peripancreatic, and porta hepatis nodes, whereas they have a lower likelihood of spread to the nodes near the cardia of the stomach, the periesophageal and mediastinal nodes, or to the splenic hilar nodes—that is, there is less emphasis placed on more proximal nodes (including coverage of the splenic artery course, including splenic hilum) and more comprehensive coverage of pancreaticoduodenal nodal basins. For distal third tumors undergoing distal gastrectomy with gastrojejunal anastomosis, the CTV typically includes 3 to 4 cm of the mucosa of the proximal stomach and jejunum as well as 3 to 4 cm of the duodenal stump, tumor bed delineated using preoperative imaging as given earlier, and lymph node stations 3 to 9 and 11 to 13.[118] Figure 64.11 shows an example of 3-D fields for a T3N1 antral tumor involving the gastric body. Figure 64.12 shows examples of varying nodal locations on axial CT images. Any tumor originating in the stomach has a high propensity of spread to nodes along the greater and lesser curvature, although they are most likely to spread to those sites in close anatomic proximity to the primary tumor mass.

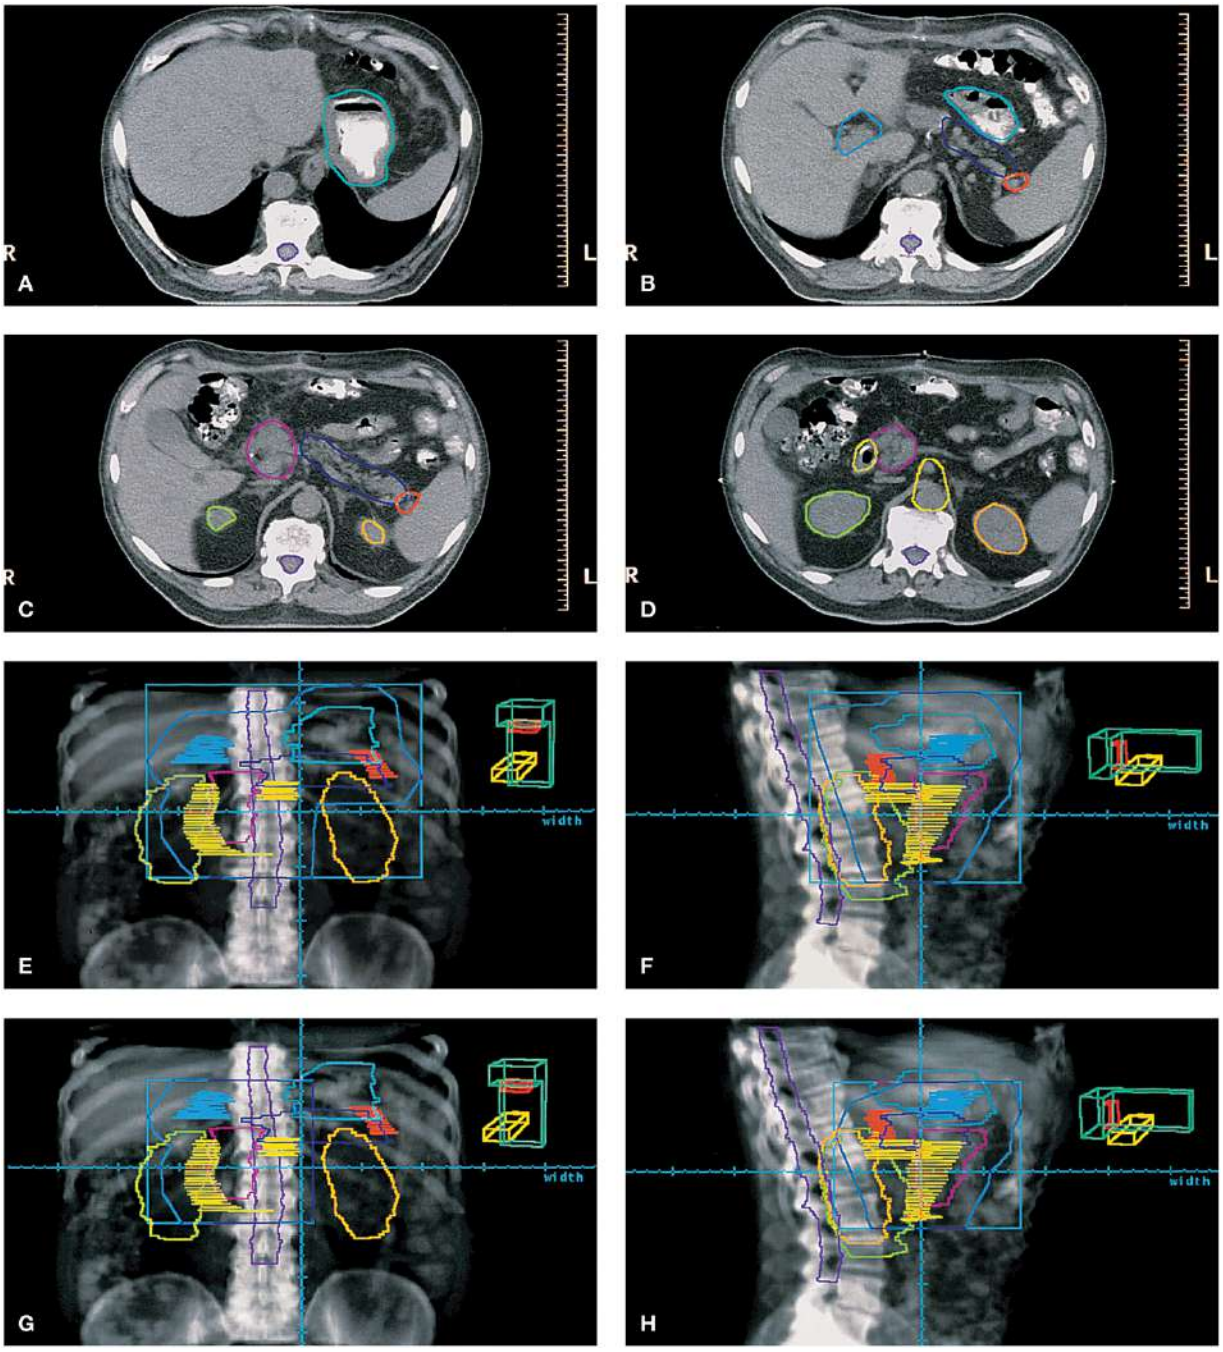

FIGURE 64.11 Optimized postoperative irradiation fields for patient with T3N1 antral primary. Structures of interest were delineated at the time of computed tomography simulation (A-D), and irradiation fields were designed with the aid of digitally reconstructed radiographs (E-H). A. Gastric remnant (teal). B. Gastric remnant plus body/tail of the pancreas (dark blue), splenic hilum (salmon), and porta hepatis (medium blue). C. Head of the pancreas (magenta) and kidneys (left, orange; right, light green) are delineated in addition to body/tail of the pancreas and splenic hilum. D. Celiac artery (yellow) and duodenum (yellow-green) are shown together with head of pancreas and kidneys. A four-field technique of AP (anteroposterior), PA (posteroanterior), and paired laterals was designed to include the gastric remnant (teal), tumor bed (head of the pancreas [magenta],

first and second part of the duodenum [yellow-green cross hatched]), pertinent nodal volumes (perigastric, pancreaticoduodenal, porta hepatic [medium blue cross hatched], celiac [yellow cross hatched], and suprapancreatic), and the optional nodal volume of splenic hilum (salmon cross hatched). E. Initial AP field (field margins as shown in medium blue exclude approximately two-thirds of the left kidney while including about 50% of the right kidney). Exclusion of the optional splenic hilar nodes would have allowed additional but minimal sparing of the left kidney in view of the adjacency of gastric antrum and splenic hilum. F. Initial right lateral field demonstrated exclusion of the spinal cord. G. Reduced AP field with exclusion of splenic hilar nodes and most of the gastric remnant. H. Reduced right lateral field.

Additional guidelines for defining the CTV for postoperative irradiation fields have been developed based on location and extent of the primary tumor (T stage) and location and extent of known nodal involvement (N stage).[120] Table 64.6 presents general guidelines on the impact of T and N stages on inclusion of the remaining stomach (gastric remnant), tumor bed, and nodal sites, whereas Tables 64.7 to 64.9 present treatment guidelines based on TN stage within each of three primary sites (proximal, mid, and distal stomach). With proximal gastric lesions or lesions at the GE junction, a 3- to 5-cm margin of distal esophagus should be included; if the lesion extends through the entire gastric wall, a major portion of the left hemidiaphragm should be included. In these circumstances, blocking can decrease the volume of irradiated heart. For unresectable lesions with moderate periesophageal extension, it may not be possible to exclude an adequate amount of the heart and adopting intensity-modulated radiation therapy (IMRT) techniques is likely indicated (Figure 64.13; discussed later). In general, for patients with node-positive disease, there should be wide coverage of tumor bed, remaining stomach, resection margins, and nodal drainage regions. For node-negative disease, if there is a good surgical resection with pathologic evaluation of at least 16 nodes, and there are wide surgical margins on the primary tumor (at least 5 cm), treatment for the nodal beds may be optional. However, it is the authors' opinion that in most cases (particularly node positive) the celiac basins/associated branches as well as periaortic nodes should be similarly covered (see earlier patterns of failure discussion). Treatment for the remaining stomach should depend on a balance of the likely normal tissue morbidity and the perceived risk of local relapse in the residual stomach.

TABLE 64.6 GENERAL GUIDELINES OF IMPACT OF T AND N STAGES ON INCLUSION OF REMAINING STOMACH, TUMOR BED, AND NODAL SITES WITHIN

IRRADIATION FIELDS

TN Stage	Remaining Stomach[a]	Tumor Bed	Nodes
T1-T2 (not into subserosa) N0	N	N	N
T2N0 (into subserosa)[b]	Variable	Y	N
T3N0	Variable	Y	N
T4N0	Variable	Y	Variable
T1-2N+	Y	N	Y
T3-4N+	Y	Y	Y

N, no; Y, yes.

[a]Inclusion of the remaining stomach is preferable in most patients if two-thirds of one kidney can be excluded. This depends on the extent of surgical resection and uninvolved margins (in centimeters).

[b]Posterior wall T2N0 lesions, or those that extend beyond the muscularis propria, especially tumors located in the proximal or distal stomach, are at risk for local relapse. In addition, patients with low-stage disease with close or positive surgical margins should be considered for treatment to the tumor bed.

TABLE 64.7 IMPACT OF SITE OF PRIMARY GASTRIC LESION AND TN STAGE ON IRRADIATION VOLUMES: CARDIA/PROXIMAL ONE-THIRD OF THE STOMACH (GENERAL GUIDELINES)

Site of Primary and TN Stage	Remaining Stomach	Tumor Bed Volumes[a]	Nodal Volumes	Tolerance Organ Structures
Cardia/proximal one-third of the stomach	Preferred, but spare two-thirds of one kidney (usually right)	T-stage dependent	N-stage dependent	Kidneys, spinal cord, liver, heart, lung
T2N0 with invasion of subserosa	Variable, dependent on surg-path findings[b]	Medial left hemidiaphragm, adjacent body of the pancreas (± tail)	None or perigastric[c]	

Site of Primary and TN Stage	Remaining Stomach	Tumor Bed Volumes[a]	Nodal Volumes	Tolerance Organ Structures
T3N0	Variable, dependent on surg-path findings[b]	Medial left hemidiaphragm, adjacent body of the pancreas (± tail)	None or perigastric; optional: periesophageal, mediastinal, celiac[c]	
T4N0	Variable, dependent on surg-path findings[b]	As for T3N0 plus site(s) of adherence with 3-5 cm margin	Nodes related to site of adherence, ± perigastric, periesophageal, mediastinal, celiac	
T1-2N+	Preferable	Not indicated for T1, as above for T2 into subserosa	Perigastric, celiac, splenic, suprapancreatic ± periesophageal, mediastinal, pancreaticoduodenal, porta hepatis[d]	
T3-4N+	Preferable	As for T3, T4N0	As for T1-2N+ and T4N0	

Surg-path, surgical-pathologic.

[a]Use preoperative imaging (computed tomography [CT], barium swallow), surgical clips, and postoperative imaging (CT, barium swallow).

[b]For tumors with wide (>5 cm) surgical margins confirmed pathologically, treatment of residual stomach may not be necessary, especially if this would result in substantial increased normal tissue morbidity.

[c]Optional node inclusion for T2-3N0 lesions if adequate surgical node dissection (D2 dissection) and at least 10 to 15 nodes are examined pathologically.

[d]Pancreaticoduodenal and porta hepatis nodes are at low risk if nodal positivity is minimal (ie, 1-2 positive nodes with 10-15 nodes examined), and this region may not need to be irradiated. Periesophageal and mediastinal nodes are at risk if there is esophageal extension.

FIGURE 64.13 A 50-year-old female with a gastric body adenocarcinoma with multiple suspicious nodes noted on CT scan (delineated in red), including lower paraesophageal, perigastric, gastrohepatic, porta, and splenic hilum. IMRT was utilized to minimize adjacent normal tissue including the heart, liver, kidneys, and spinal cord. A. Relative isodose levels, percentage. B. Superior aspect of volume, including distal esophagus with associated node in red, gastric fundus as well as very proximal spleen. C. Level of splenic hilum, gastric body (with associated adenopathy in red), as well as porta region. D. Splenic hilum region with associated adenopathy, celiac, gastric body extending into pylorus. E. More distal aspect of volume including transverse duodenum/D3 along with retroperitoneal basins. CT, computed tomography; IMRT, intensity-modulated radiation therapy.

From a historical standpoint, although parallel-opposed anteroposterior (AP)/posteroanterior (PA) fields are a practical arrangement for tumor bed and nodal irradiation, multifield techniques should be used if they can improve long-term tolerance of normal tissues. Tightly contoured AP/PA fields should be designed to spare as much normal tissue as possible (Figures 64.14 and 64.15). In institutional series, the average irradiation field measured 15 cm × 15 cm.[38,121,122] More routine use of multifield techniques should be implemented when preoperative imaging exists to allow accurate reconstruction of target volumes. Single-institution data suggest that multifield arrangements may produce less toxicity. Although AP/PA fields can be weighted anteriorly to keep the spinal cord dose at

acceptable levels, a four-field technique, if feasible, can spare spinal cord with improved dose homogeneity. Depending on the posterior extent of the gastric fundus, either oblique or more routine lateral portals can be used to deliver a 10- to 20-Gy component of irradiation to spare the spinal cord or kidney. When lateral fields are used, liver and kidney tolerance limits the use of lateral fields to 20 Gy or less. Patients should be treated with high-energy photons when possible. With the wide availability of 3-D treatment planning systems, it may be possible to more accurately target the high-risk volume and to use unconventional field arrangements to produce superior dose distributions. To accomplish this without marginal misses, it will be necessary to both carefully define and encompass the various target volumes because the use of oblique or noncoplanar beams could exclude target volumes that would be included in AP/PA fields or nonoblique four-field techniques (AP/PA and laterals). Although, historically, two-dimensional (2-D)-based radiation planning has been carried out primarily using anatomic landmarks as well as fluoroscopic barium swallow to determine field borders (Figures 64.14 and 64.15), contemporary treatment planning using CT-based planning allows improved visualization of both target and nontarget structures, along with 3-D reconstruction and creation of a “beam’s eye” view of varying fields, allowing improved conformality around target structures and improvements in normal tissue sparing. Because volumetric data can be obtained by CT scans, dose-volume histogram data can also be generated. A variety of 3-D techniques are presently used and described later. Similarly, with the implementation of IMRT, utilization of this approach should be considered where meeting dose constraints with 3-D techniques proves challenging.

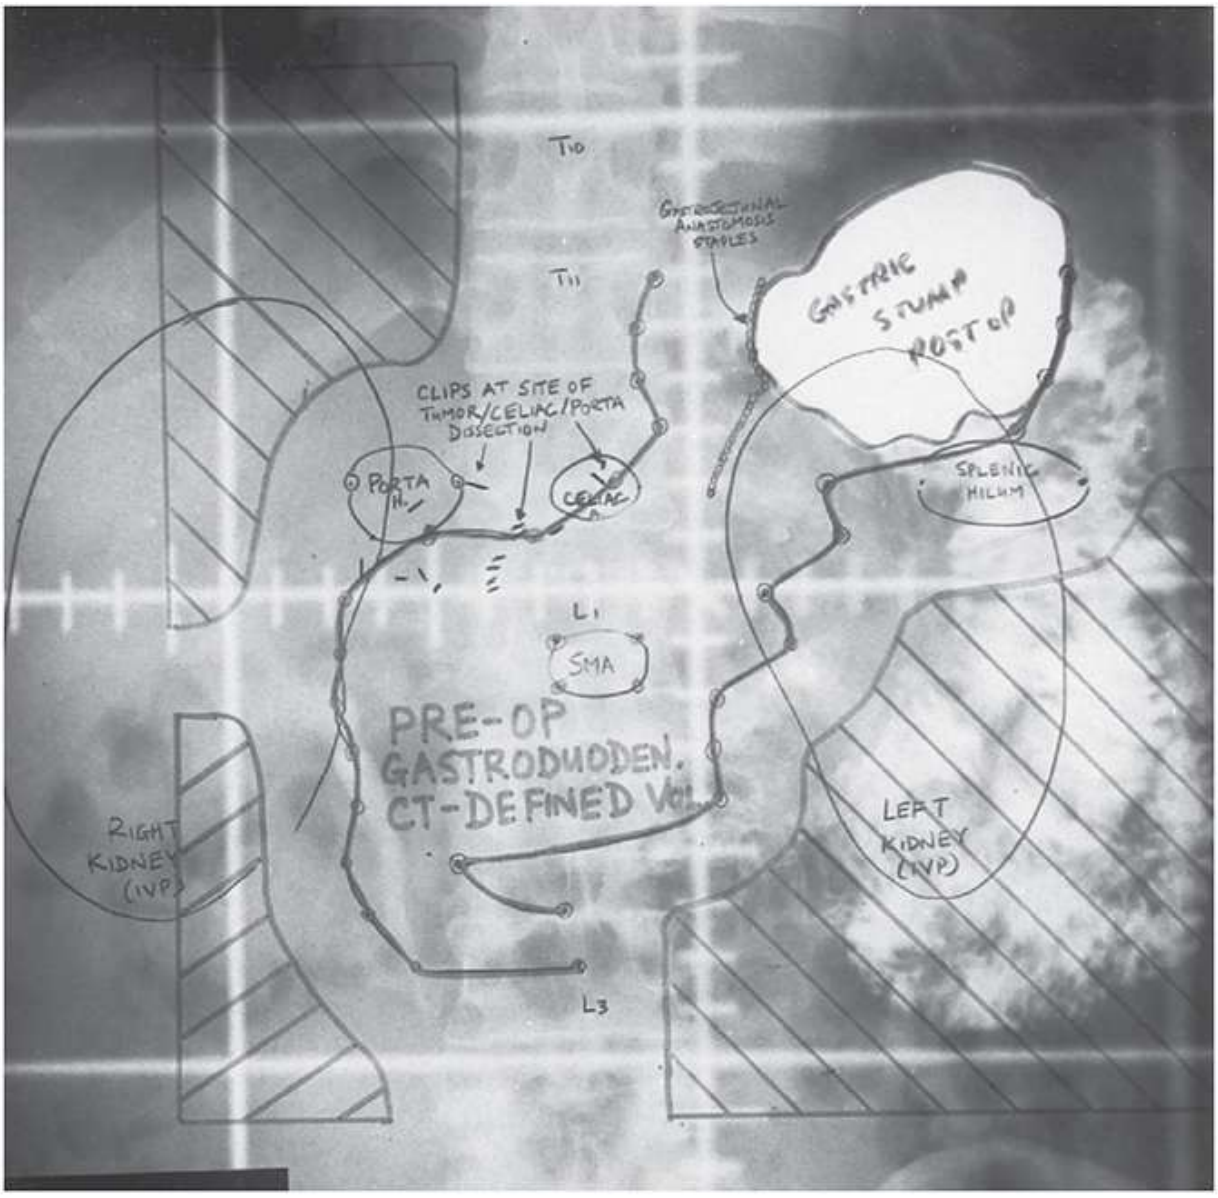

FIGURE 64.14 Simulation film for T3 antral tumor with two of five peritumoral lymph nodes metastatically involved (radical subtotal gastrectomy with D1 node dissection). Simulation film identifies areas at risk for recurrence, including preoperative gastric/tumor bed (defined by preoperative computed tomography [CT] scan), anastomotic sites and gastric stump (staple line seen on precontrast simulation films and marked on postintravenous pyelogram/postcontrast film), and regional lymphatics (celiac, porta hepatis, superior mesenteric artery, and splenic nodes identified on CT and pancreaticoduodenal nodes lying in C-loop of the duodenum identified by preoperative CT). The right kidney is spared for approximately three-fourths of its volume, whereas the left kidney has about one-third of its volume blocked. (Reprinted from Smalley SS, Gunderson L, Tepper J, et al. Because it is important to account for daily setup uncertainty as well as physiologic internal organ motion (secondary to respiration, peristalsis, cardiac motion, etc), an additional margin must be added to a CTV. Interfraction variability in stomach location occurs, often owing to variations in gastric filling. Intrafraction changes in target shape and location may be attributable to respiratory motion, which, particularly in the superior to inferior direction, may exceed 1 to 1.5 cm. In an effort to reduce this, kilovoltage radiographic matching can be used with particular emphasis on matching of surgical clips. An additional technique that may improve treatment accuracy is cone-beam CT, which allows direct target matching within a given fraction. Movement related to respiratory motion can be assessed using 4-D CT, which images the patient in all phases of respiration (similar to what is performed fluoroscopically but using CT). Similarly, respiratory gating techniques may allow reduction in the target volume/smaller margins, allowing for treatment during a more stationary phase of the respiratory cycle (example end expiration), as well as breath-holding techniques.

Another potential and likely preferred approach in the treatment for gastric cancer is the use of IMRT. IMRT also uses CT-based planning, again allowing 3-D reconstruction of varying structures. However, IMRT differs from 3-D planning through the delivery of radiation dose by partitioning a radiation field into multiple smaller fields of various shapes and sizes,

varying the dose intensity between each area. This is carried out with either dynamic IMRT (where collimating leaves move in and out of the radiation beam path during treatment) or “step-and-shoot” IMRT (where the leaves change the radiation field shape while the beam is turned off). Either method is particularly effective at conforming radiation dose to the target structures while avoiding dose to normal tissue. Radiation oncologists must determine which structures are most critical and weight their importance during the treatment planning process. Importantly, the greater the number of “avoidance” normal structures, the more difficult it is to meet all dose constraints. IMRT utilizes “inverse planning,” where an intended prescription dose is placed on target volumes and dose constraints are placed on normal tissue structures. Thereafter, computer software algorithms allow design of unconventional treatment fields that would not otherwise be possible with standard planning methods. Radiation oncologists and medical physicists critically evaluate numerous plans until dose constraints are satisfactorily met. The result should be a series of radiation doses that closely conform to the target volumes while minimizing dose to normal tissues. IMRT may be appropriate in selected cases to reduce doses to normal structures, including the heart, liver, and kidneys. A potential disadvantage of IMRT is the possibility of delivering low doses of radiation therapy to normal tissue areas that might not usually be irradiated using 2-D or 3-D techniques. Another potential disadvantage of IMRT is possible dose inhomogeneity, leading to potential “hot spots” in normal organs. Because IMRT requires precise target definition, the potential for “marginal miss” increases and careful, accurate target delineation is of paramount importance.

With setup uncertainty and physiologic organ motion, care must be taken to ensure accurate and reproducible setup, including with the use of immobilization devices as well as possible respiratory gating/breath-holding techniques. Block/volume margins may be minimized with efforts to reduce intrafractional position variability, including breath-holding techniques. Generally, high-energy photons (10-18 MV) are recommended when using 3-D conformal or IMRT therapy, potentially facilitating a reduction in the integral dose. When using more advanced radiation planning techniques, daily image guidance is generally recommended, with consideration of

frequent cone-beam CT imaging and adaptive planning pending anatomic changes.[118]

Multiple dosimetric studies comparing IMRT to two-field and 3-D conformal radiation therapy plans have shown significant reductions in kidney, liver, heart, lung, and spinal cord dose with the former. Although IMRT may result in improved normal tissue sparing, many of the acute toxicities encountered during radiation may persist given that many symptoms arise from radiation of the target, including gastric mucosa. The value of IMRT may lie primarily in normal organ sparing with potential reductions in long-term toxicity in surviving patients. A retrospective (single institution) review of 202 consecutive patients with gastric cancer analyzed patients receiving 3-D versus IMRT treatments. Grade III-IV acute toxicity was significantly lower in patients receiving IMRT (49% vs 70%, $P = .004$), along with a significant reduction in toxicity-related hospitalization, feeding tube use, hydration requirement, and breaks. The authors concluded that IMRT potentially reduced rates of high-grade acute toxicity and toxicity-related events compared to 3-D treatments.[123] There is ongoing investigation into further enhancements of this technique using volumetric modulated arc therapy, helical tomotherapy, as well as proton therapy. This may also become important with the integration of newer/novel systemic agents, in conjunction with radiation therapy, of which many act as potent tumoral (as well as normal organ) radiation sensitizers and may reduce treatment- related toxicities as well as avoidance of treatment interruptions.

Dose Constraints

In radiation therapy planning of gastric cancer, normal tissue tolerance should always be considered. The spinal cord dose is generally limited to 45 Gy using 1.8-Gy fractions (and potentially less when delivered with novel systemic agents). Accurate delineation of adjacent organs including lungs, liver, kidneys, heart, and spinal cord is important. Varying dose-volume normal organ constraints have been suggested. Historically, heart dose constraints have included maintaining one-third, two-thirds, and total heart volumes less than 45, 40, and 30 Gy, respectively. Recommended heart constraints include keeping less than 30% of the cardiac volume to a total

dose of 40 Gy and less than 50% receiving 25 Gy, minimizing dose to the left ventricle although with careful planning these constraints can be improved upon. In a secondary analysis of the NRG Oncology RTOG 0617 randomized clinical trial in which patients with lung cancer received concurrent chemotherapy of carboplatin and paclitaxel with or without cetuximab and 60- versus 74-Gy radiation doses, IMRT produced lower heart doses ($P < .05$), and the volume of heart receiving 40 Gy (V40) was significantly associated with overall survival on adjusted analysis ($P < .05$).[124] In the setting of potentially significant volumes of the heart in the radiation field, consideration of 4-D CT and/or respiratory motion management can be made. It is recommended that at least 70% of one physiologically functioning kidney receive a total dose less than 20 Gy and that collectively 50% or less of the combined functional renal volume should receive more than 20 Gy.[119] In some patients, a portion of both kidneys will fall within the treatment field; however, at least two-thirds to three-fourths of one kidney should be excluded beyond a dose of 20 Gy. For proximal gastric lesions, 50% or more of the left kidney is commonly within the irradiation portal, and the right kidney must be appropriately spared. For distal lesions with narrow or positive duodenal margins, a similar amount of right kidney often is included, and every effort must be taken to spare enough left kidney to maintain function. Late renal sequelae have not generally been encountered with these techniques.[38,82,125] One should also consider the possibility of impaired kidney function in the context of varying comorbidities, using nuclear medicine renal studies to assess individual renal function in such situations or where significant volumes of kidneys are anticipated to be within the radiation field. Generally, 70% of the liver parenchyma should be kept to a dose less than 30 Gy. Many of these constraints can be achieved through the use of 3-D planning with appropriate and careful design of shielding blocks/multileaf collimation and dose-volume histogram analysis, with the use of IMRT in appropriate cases.

Doses of Radiation

Generally, doses in the range of 45 to 50.4 Gy should be delivered at 1.8 Gy per fraction. Although primarily limited by normal tissue constraints in the

upper abdomen, several series have reported improved locoregional control with radiation dose escalation in the adjuvant setting. A report from Mayo Clinic investigators reported high locoregional control rates with radiation doses more than 54 Gy.[125] Similarly, a report from Italian investigators treating patients adjuvantly with hyperfractionated radiation therapy to a dose of 55 Gy, with concurrent 5-FU, showed an in-field recurrence rate of only 7.5% and survival rate of 52% with a median follow-up of more than 5 years.[126] With regimens using single daily fractions, the usual dose is 45 Gy delivered in 1.8- to 2-Gy fractions over 5 weeks, with a field reduction after 45 Gy in patients receiving boost-field treatments. Reduced boost fields to small areas of residual disease and a small volume of stomach or small intestine sometimes can be cautiously carried to doses of 55 to 60 Gy with multifield/IMRT techniques. In such instances, informed consent should include a discussion of an increased risk of grade 3 to 4 gastrointestinal toxicity.

RESULTS OF THERAPY

Locally Advanced Unresectable or Subtotally Resected Gastric Cancer

For patients with locally advanced unresectable or subtotally resected gastric carcinoma, radiotherapeutic approaches both with and without chemotherapy have been used because these tumors appear localized without clinically detectable metastases. Combined treatment with radiation therapy and chemotherapy appears to prolong survival but rarely results in long-term cure.[127] Although only a modest effect on survival is seen, these studies have established, importantly, the foundation of contemporary combined-modality therapy and have served as a stimulus to further clinical investigation in gastric cancer as well as other gastrointestinal disease sites. The results of these phase III studies have had a significant impact on clinical trial development in gastrointestinal malignancies (Table 64.10).

TABLE 64.10 UNRESECTABLE OR RESIDUAL GASTRIC CANCER: TREATMENT RESULTS OF RANDOMIZED TRIALS

Group or Institution	Treatment Arms	Number of Patients	EBRT Dose	Chemotherapy	Survival Results
Mayo Clinic[127]	EBRT + ChT vs EBRT	48	35-40 Gy	5-FU	Increased survival for EBRT + 5-FU with mean survival 13 vs 5.9 mo and 3/25 (12%) vs 0/23 5-y survival
GITSG[128]	EBRT + ChT vs ChT	90	50-Gy split course	5-FU + MeCCNU	Advantage in long-term survival with EBRT + ChT at 18% vs 7% ($P <$ .05)

5-FU, 5-fluorouracil; ChT, chemotherapy; EBRT, external beam radiation therapy; GITSG, Gastrointestinal Tumor Study Group; MeCCNU, 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1 nitrosourea.

In a historical trial from 1969, Moertel et al[127] reported the results of a prospective, controlled double-blind study of patients with locally advanced unresectable gastric cancer. In this study, 48 patients were randomized to 35 to 40 Gy of radiation therapy over 4 weeks with and without 5-FU. Mean survival was 13 months in patients receiving radiation therapy and 5-FU versus 5.9 months for patients receiving radiation therapy alone ($P < .01$). These results demonstrated for the first time the clinical benefit of combining concurrent 5-FU with radiation therapy and encouraged further investigation of combination therapy in gastric cancer and other gastrointestinal disease sites (esophageal, pancreatic, rectal, and anal carcinomas).

As a follow-up to this study, the Gastrointestinal Tumor Study Group (GITSG) examined the combination of 5-FU/MeCCNU, or 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1 nitrosourea, and radiotherapy (50 Gy/split course/8 weeks) versus the same chemotherapy alone in locally advanced gastric cancer.[128] Patients were eligible if the tumor involved regional lymph nodes or adjacent structures that could be completely resected en bloc. Of the 90 patients entered, 66 patients had a resection of the primary tumor. Of these, 23 patients had gross residual disease, 36 patients had microscopic residual disease, and 7 patients had no

documented residual disease. The study was closed prematurely because of an excess of early deaths in the combined chemotherapy-radiotherapy arm. The excessive early mortality of the combined-modality arm was attributed to early tumor progression and poor tolerance of the combined-modality regimen. However, further follow-up beyond 3 years indicated continuing mortality among the chemotherapy-alone arm, whereas the combined chemoradiotherapy arm exhibited a plateau with 18% of patients surviving 5 years. Thus, despite an excess of early mortality, the combined- modality arm exhibited an overall superiority in 5-year survival. It is important to note that patients who had had their primary tumor resected experienced superior survival to those without resection. All of the survival benefit in patients receiving combined modality was in patients whose primary tumor had been resected. This trial showed that combined chemoradiation therapy is capable of rendering a substantial percentage of patients with microscopic residual gastric cancer free from disease. It furthermore supported the rationale of exploring chemoradiation adjuvant trials in completely resected patients at high risk for locoregional relapse, and that chemoradiation was able to control microscopic disease and lead to long-term survival in a significant number of these patients.

A more recent multicenter phase II trial from China treated patients with medically inoperable or unresectable gastric cancer with pre- and postradiation docetaxel, cisplatin, and 5-fluorouracil, in combination with chemoradiation with concurrent cisplatin in between. Clinical complete response rate was 36%, overall response rate 83%, median survival 26 months, and 2-year survival 52%. Patients who were medically inoperable had a better prognosis than patients with frankly unresectable disease.[129]

Resectable Gastric Cancer

The recognition of the high rates of local and regional failure following surgery in patterns of failure analyses has served as the basis for clinical trials assessing the value of radiation therapy both with and without chemotherapy as an adjuvant treatment (Table 64.4). Although these studies have all addressed the important question of whether clinical outcome is enhanced by adjuvant radiation therapy, there has been marked variability in radiation dose and schedule, sequence with surgery (preoperatively,

intraoperatively, or postoperatively), and the use of concurrent and maintenance chemotherapy (Table 64.11). These differences in study design and included patients may explain in part the conflicting results observed in phase III studies.

TABLE 64.11 ADJUVANT/NEOADJUVANT IRRADIATION FOR RESECTED GASTRIC CANCER: TREATMENT RESULTS OF RANDOMIZED TRIALS

			Survival		Locoregional Relapse

[a]Long-term survival is 5-year data for Mayo Clinic, ARTIST, CRITICS, TOPGEAR, and Beijing series, and 3-year data are for British, Intergroup 0116, and ARTIST-II.

[b]In node-positive patients, 3-year disease-free survival 72% vs 76%, *P* = .04; 83% vs 94% in intestinal-type tumors.

[c]Arm 1 vs arm 2.

[d]Arm 1 vs arm 3.

[e]Local regional plus distant relapse rates 12% and 15%.

Adjuvant Radiation Therapy Alone

Two randomized phase III studies have examined the use of external beam radiation therapy (EBRT) alone with surgery.[79,130] Although both studies used similar radiation dose and schedule, sequence with surgery differed. In the British Stomach Cancer Group study, 436 patients were randomized to surgery alone, postoperative radiation therapy (45-50 Gy in 25-28

fractions), or cytotoxic chemotherapy with mitomycin, doxorubicin, and fluorouracil (FAM).[79,130] The 5-year survival for surgery alone was 20%, for surgery plus radiation therapy 12%, and for surgery plus chemotherapy 19%. In this study, no survival advantage was observed for patients who received postoperative EBRT, although there was an apparent improvement in local control, demonstrating that local disease could be affected by adjuvant radiation therapy. Locoregional failure was documented in only 15 of 153 patients (10%) in the irradiation arm versus 39 of 145 patients (27%) in the surgery-alone arm and 26 of 138 patients (19%) in the FAM group. Interpretation of the results is complicated by the inclusion of 171 patients undergoing resection with gross or microscopic residual carcinoma. These patients would not be candidates for contemporary gastric surgical adjuvant trials in the United States. In addition, approximately one-third of patients randomized to receive adjuvant treatment did not receive the assigned therapy. Of 153 patients randomized to the irradiation arm, only 104 (68%) received a dose of 40.5 Gy or more, and 36 (24%) received none.

Neoadjuvant Radiation Therapy

In contrast, the results of a phase III study from Beijing demonstrated a survival benefit for patients with gastric cardia carcinoma receiving preoperative irradiation and surgery versus surgery only.[131] In this study, 370 patients with gastric cardia carcinoma were randomized to 40 Gy in 20 fractions over 4 weeks of preoperative irradiation and surgery or surgery only. The 5-year survival rates of preoperative irradiation and surgery and the surgery-alone group were 30% and 20%, respectively (10-year rates 20% and 13%, respectively). These differences were statistically significant (P = .009). Further, local and regional nodal control was improved in patients undergoing preoperative irradiation and surgery (61% and 61%) versus surgery (48% and 45%) only. Morbidity and mortality rates were not increased in patients receiving preoperative irradiation and surgery.

Intraoperative Radiation Therapy

An alternative approach to postoperative or preoperative irradiation is intraoperative radiation therapy (IORT).[135,136] The advantage of this technique is the ability to deliver a single large fraction (10-35 Gy) of

radiation to the tumor or tumor bed while excluding or protecting surrounding normal tissue from the high-dose field. This approach permits high-dose irradiation with minimal normal tissue treatment. Two randomized trials have examined the efficacy of IORT in combination with surgery for patients with gastric carcinoma. Abe et al[135] from Kyoto University performed a randomized trial of 211 patients with gastric cancer comparing surgery alone with surgery and intraoperative radiation (28-35 Gy). Patients were randomized based on hospital day of admission for surgery. For patients with tumor confined to the gastric wall, 5-year survival rates were similar for IORT and for resection alone. However, patients with Japanese stages II to IV disease who received IORT in conjunction with resection showed improved survival over patients who underwent resection without irradiation. Among patients with stage IV disease (who usually had local residual disease after maximal resection), there were no 5-year survivors in patients who received surgery alone; however, 15% of the patients who received IORT were alive at 5 years. The experience with IORT in gastric cancer at Kyoto University suggested that IORT may be beneficial in the treatment for locally advanced malignancies of the stomach.

To further evaluate this approach, Sindelar et al[136] at the National Cancer Institute conducted a prospectively randomized controlled trial comparing surgical resection and IORT with conventional therapy in gastric carcinoma. Patients in the experimental group underwent gastrectomy, and IORT was administered to the gastric bed (20 Gy). Patients in the control group underwent resection and postoperative EBRT to the upper abdomen (50 Gy in 25 fractions) in advanced-stage lesions extending beyond the gastric wall. Of the 100 patients screened for the study, 60 patients were randomized and underwent exploratory surgery. In all, 19 patients were excluded intraoperatively because of unresectability or metastases, leaving 41 patients in the study. The median survival for patients with tumors of all stages was 25 months for the IORT group and 21 months for the control group (P = not significant [NS]). Locoregional disease relapse occurred in 7 of 16 patients with IORT (44%) and in 23 of 25 control patients (92%) ($P <$ .001). Complication rates were similar between IORT and control patients. Although IORT failed to afford a significant advantage over conventional

therapy in overall survival, it significantly improved control of locoregional disease. The use of IORT in gastric cancer remains a topic of investigation.

Adjuvant Chemoradiation Therapy

Because of the promising results in the early studies of combined-modality therapy for locally advanced unresectable or subtotally resected gastric cancer, investigators have also studied this combination in resectable gastric carcinoma. A small study from South Africa randomized 66 patients with resected gastric cancer (T1-T3, N1 or N2, M0) to low-dose postoperative irradiation (20 Gy in eight fractions over 10 days) and 5-FU or no further therapy.[99] No difference in survival was observed between the patients undergoing surgery and adjuvant therapy and those undergoing surgery alone. Given the subtherapeutic doses of radiation used in this study, it is difficult to draw any conclusions as to the efficacy of adjuvant radiation therapy and 5-FU.

In 1984, Moertel et al[111] reported the results of a prospective randomized trial conducted at the Mayo Clinic of 62 patients with poor prognosis but completely resected gastric cancers who were randomized to either surgery alone or surgery followed by irradiation (37.5 Gy in 24 fractions over 4-5 weeks) with concurrent 5-FU. A nonstratified, prerandomization scheme was used with a 2:3 ratio favoring treatment. Informed consent was requested of only the 39 patients randomized to treatment. Ten of the 39 patients refused further therapy and were observed. When analyzed by intent to treat, the adjuvant arm had statistically significant improvement in both relapse-free and overall survival (overall 5-year survival 23% vs 4%, $P < .05$). When patient outcome was compared with actual treatment received (29 adjuvant treatment, 33 surgery alone), 5-year survival still favored the adjuvant group (20% vs 12%), although the differences were not statistically significant in view of the small patient numbers. The 10 patients who refused assignment to adjuvant treatment had more favorable prognostic findings than the other two groups of patients. When the two groups with equally poor prognostic factors were compared, the 5-year overall survival was 20% versus 4%, with an advantage to those receiving adjuvant treatment. When analyzed by treatment delivered, locoregional

relapse was decreased with adjuvant treatments (54% incidence with surgery alone vs 39% with irradiation and 5-FU).

Because of these conflicting results and the fact that locoregional failure remained an established source of recurrence, an Intergroup trial (INT 0116) was initiated to evaluate postoperative combined 5-FU-based chemotherapy and irradiation to the gastric bed and regional nodes versus surgery only following resection of gastric cancer.[116] Eligibility included patients with pathologic stage group IB through IV nonmetastatic adenocarcinoma of the stomach or GE junction. After an en bloc resection (patients underwent D0-D1 dissection), 556 patients were randomized to either observation alone or postoperative 5-FU/leucovorin for one cycle followed by combined-modality therapy consisting of 45 Gy in 25 fractions plus concurrent 5-FU and leucovorin (4 days in week 1, 3 days in week 5) followed by two monthly 5-day cycles of 5-FU and leucovorin. Minor or major errors in field design were seen in 35% during preirradiation quality assurance review, allowing most deviations to be corrected prior to radiation therapy initiation, resulting in a 6.5% final major deviation rate. Nodal metastases were present in 85% of the cases. With 5 years of median follow-up, 3-year relapse-free survival was 48% for adjuvant treatment and 31% for observation (P = .001); 3-year overall survival was 50% for treatment and 41% for observation (P = .005). The median overall survival in the surgery-only group was 27 months, compared with 36 months in the chemoradiotherapy group; the hazard ratio (HR) for death was 1.35 (95% CI 1.09-1.66, P = .005). The HR for relapse in the surgery-only group as compared with the chemoradiotherapy group was 1.52 (95% CI 1.23-1.86, P < .001). The median duration of relapse-free survival was 30 months in the chemoradiotherapy group and 19 months in the surgery-only group. Patterns of failure were based on the site of first relapse only and were categorized as local, regional, or distant. Local recurrence occurred in 29% of patients who relapsed in the surgery-only group and 19% of those who relapsed in the chemoradiotherapy group. Regional relapse—typically abdominal carcinomatosis—was reported in 72% of those who relapsed in the surgery-only group and 65% of those who relapsed in the chemoradiotherapy group. Extra-abdominal distant metastases were diagnosed in 18% of those who relapsed in the surgery-only group and 33% of those who relapsed in the chemoradiotherapy group. Treatment was

tolerable, with three (1%) toxic deaths. Grades 3 and 4 toxicity occurred in 41% and 32% of cases, respectively, and 17% of patients assigned to the chemoradiotherapy group stopped treatment owing to toxicity from therapy. Long-term results at more than 10-year median follow-up continued to show significant improvement in overall and disease-free survival in the chemoradiation group, benefiting all T- and N-stage patients included in the trial.[137] The results of this large study demonstrate a clear survival advantage for the use of postoperative chemoradiation and strongly support its integration into the routine care of patients with curatively resected high-risk carcinoma of the stomach and GE junction.[137]

The follow-up Intergroup trial CALGB 80101 randomized 546 patients with resected gastric or GE junction adenocarcinoma to receive either (a) one cycle of 5-FU/leucovorin, followed by 45 Gy with concurrent continuous infusion 5-FU, followed by two additional cycles of 5-FU/leucovorin, or (b) one cycle of epirubicin, cisplatin, and 5-FU (ECF), followed by 45 Gy with concurrent, continuous infusional 5-FU, followed by two additional cycles of reduced dose ECF. With a median follow-up duration of 6.5 years, 5-year overall survival rates were 44% in the FU plus leucovorin arm and 44% in the ECF arm (P = .69, HR 0.98, 95% CI 0.78-1.24 comparing ECF with FU plus LV). Five-year disease-free survival rates were 39% in the FU plus LV arm and 37% in the ECF arm (P = .94, HR 0.96, 95% CI 0.77-1.20). The authors concluded that following curative resection of gastric or GE junction adenocarcinoma, postoperative chemoradiotherapy using ECF before and after 5-FU-based radiation does not improve survival compared to bolus 5-FU/leucovorin given in the same manner.[138]

A large retrospective study from Korea evaluated the role of adjuvant chemoradiation in patients undergoing D2 gastric cancer resection, a group that was not adequately represented in the aforementioned Intergroup trial. In the Korean study, 544 patients treated with D2 dissection and postoperative chemoradiation therapy were compared to 446 patients with similar characteristics treated with D2 dissection alone. Overall survival was significantly higher in patients treated with adjuvant chemoradiation (median survival 95 vs 63 months, P = .02) as well as significant improvement in relapse-free survival.[94] Additionally, a collective review of nine randomized trials incorporating radiation therapy approaches with

surgery alone also demonstrated a significant 5-year survival benefit with the addition of radiation therapy in patients with resectable gastric cancer.[139]

A Korean phase III trial (the ARTIST study) compared the effects of adjuvant chemoradiation (capecitabine/cisplatin [XP] + radiotherapy) to adjuvant chemotherapy alone (XP) following D2 resection of gastric cancer in 458 patients.[132] Treatment was completed as planned by 75.4% of patients (172 of 228) in the XP arm and 81.7% (188 of 230) in the XP/radiotherapy/XP arm. The addition of radiation to XP chemotherapy did not significantly prolong disease-free survival (P = .086). However, in the subgroup of patients with pathologic lymph node metastasis at the time of surgery (n = 396), patients randomly assigned to the XP/radiotherapy/XP arm experienced superior disease-free survival when compared with those who received XP alone (P = .0365), and the statistical significance was retained at multivariate analysis (estimated HR 0.69, P = .047). The authors concluded that the addition of radiotherapy to XP chemotherapy did not significantly reduce recurrence after curative resection and D2 lymph node dissection in gastric cancer. Of note is that there was a relatively high proportion of early-stage disease in both trial arms, with approximately 60% of patients exhibiting stage Ib-II gastric cancer, as well as more than 60% demonstrating diffuse-type histology (vs 39% in the Intergroup 0116 trial). A report of long-term outcomes of the ARTIST trial with 7-year follow-up showed disease-free survival remains similar between the treatment arms (HR 0.74, CI 0.52-1.05, P = .09), with similar overall survival rates. In this analysis, the effect of the addition of radiation therapy in disease-free and overall survival differed by Lauren classification and lymph node ratio. Subgroup analysis showed that chemoradiotherapy significantly improved disease-free survival in node-positive disease and intestinal-type gastric cancers with a similar trend for disease-free and overall survival by stage of disease.[133] interpretation of these trial results is challenging given the high noncompliance rates, notably in the context that only 62% of patients assigned to the radiation arm initiated radiation, with only 50% receiving the intended 5 weeks of therapy. A subsequent trial by this group (ARTIST-II) in patients with lymph node–positive/stage II-III gastric cancer undergoing D2 resection stage II-III gastric cancer randomized patients to receive (a) adjuvant S1 for 1 year versus (b) adjuvant S1/oxaliplatin for 6 months versus (c) two cycles of S1/oxaliplatin,

followed by concurrent S1/radiotherapy, followed by four additional cycles of S1/oxaliplatin with stage IB-IVA resectable gastric or gastroesophageal adenocarcinoma. A total of 546 patients were recruited. At a median follow-up of 47 months, estimated 3-year disease-free survival was 65%, 74%, and 70% in these arms, respectively, with a HR inferior in the S1 arm relative to the other two arms, which reached statistical significance with arm 2 and borderline significance with arm 3. Estimated 3-year disease-free survival rates were 64.8%, 74.3%, and 72.8%, respectively, with no significant difference between the latter two groups. The authors concluded the addition of radiation to chemotherapy did not significantly reduce the rate of recurrence after D2 gastrectomy.[134]

Chinese investigators randomized 380 patients undergoing D2 lymph node dissection to either radiation therapy using IMRT (45 Gy) with concurrent 5-FU and leucovorin or 5-FU and leucovorin alone. Five-year local recurrence rate in the radiation arm was 15.6% versus 24.2% without radiation (P = .042), although 5-year overall survival was not significantly different (48.4% vs 41.8%, P = .122). However, median relapse-free survival (50 vs 32 months, P = .029) was higher in the radiation group, and rates of all grade adverse events were similar between the two groups.[140]

Finally, a study by the Dutch Colorectal Cancer Group (the Chemoradiotherapy after Induction Chemotherapy in Cancer of the Stomach [CRITICS] trial) randomized 788 patients to receive preoperative chemotherapy (epirubicin, cisplatin, capecitabine or, alternatively, epirubicin, oxaliplatin, and capecitabine) for three cycles followed by D1+ resection, followed by a similar postoperative chemotherapy regimen, with or without radiotherapy concurrent with cisplatin/capecitabine. After preoperative chemotherapy, 372 (95%) of 393 patients in the chemotherapy group and 369 (93%) of 395 patients in the chemoradiotherapy group proceeded to surgery, with a potentially curative resection achieved in 310 (79%) of 393 patients in the chemotherapy group and 326 (83%) of 395 in the chemoradiotherapy group. Postoperatively, 233 (59%) of 393 patients started chemotherapy and 245 (62%) of 395 started chemoradiotherapy. At a median follow-up of 61.4 months, median overall survival was 43 months in the chemotherapy group and 37 months in the chemoradiotherapy group (P = .90). After preoperative chemotherapy, in the total safety population of 781 patients (assessed together), there were 368 (47%) grade 3 adverse

events, 130 (17%) grade 4 adverse events, and 13 (2%) deaths. During postoperative treatment, grade 3 and 4 adverse events occurred in 113 (48%) and 22 (9%) of 233 patients in the chemotherapy group, respectively, and in 101 (41%) and 10 (4%) of 245 patients in the chemoradiotherapy group, respectively. The authors concluded postoperative chemoradiotherapy did not improve overall survival compared with postoperative chemotherapy in patients with resectable gastric cancer treated with adequate preoperative chemotherapy and surgery, although given the poor postoperative patient compliance in both treatment groups, future studies should focus on optimizing preoperative treatment strategies.[141]

Preoperative Chemoradiation Therapy

Because preoperative radiation therapy and chemotherapy have improved the surgical and disease-related outcomes in patients with rectal, pancreatic, and esophageal cancer, this treatment is a logical approach to explore in gastric cancer as well. In the context of established limitations of perioperative and adjuvant strategies, potential advantages of preoperative therapy include improved tolerance relative to adjuvant treatments, potential downstaging with associated improvement in R0 resection rates, better target definition, better vascularization for optimal chemotherapy and radiosensitizing oxygen delivery, and allowing biologic stratification of patients for surgery, notably given that the presence of micrometastases is at initial diagnosis. Two-phase III trials for patients with esophagus cancer have included either lesions of the gastric cardia[142] or the esophagogastric junction.[143] In both trials, the trimodality arm demonstrated an improvement in survival when compared with the control arm of surgery alone. The series by Walsh et al[142] (adenocarcinoma of the esophagus or gastric cardia) demonstrated a median survival of 4.5 years versus 1.8 years (P = .002) and 5-year survival at 39% versus 16%. with the advantage to trimodality treatment. The US Gastrointestinal Intergroup phase III trial (adenocarcinoma or squamous cell of the esophagus or GE junction), which closed prematurely owing to low accrual, resulted in a median survival of 54 versus 21.6 months and 5-year survival of 39% versus 16% (P = .008), with an advantage to the trimodality arm.[143]

Preoperative chemoradiation data for patients with gastric cancer are primarily limited to phase II studies from single institutions and cooperative groups. MD Anderson Cancer Center investigators reported a study in which 33 patients completed a preoperative protocol that started with induction chemotherapy of 5-FU, leucovorin, and cisplatin, followed by 45 Gy of radiation therapy in 25 fractions over 5 weeks. Infusional 5-FU was administered concurrently with radiation therapy. In 28 patients (85%), a gastrectomy was performed and D2 lymph node dissection was attempted. Pathologic complete and partial response was found in 64% of all operated patients. These patients showed a significantly longer median survival of 64 months in comparison with 13 months in patients with tumors not pathologically responding.[144] In a study from the same institution, 41 patients with operable gastric cancer received two cycles of continuous 5-FU, paclitaxel, and cisplatin followed by 45 Gy of radiation therapy with concurrent 5-FU and paclitaxel. An R0 resection was achieved in 78% of patients, pathologic complete response in 25%, and pathologic partial response in 15%. Pathologic response, R0 resection, and postoperative T and N stages were correlated with overall and disease-free survival.[145] The RTOG reported the results of a phase II study of 49 patients undergoing induction 5-FU, leucovorin, and cisplatin followed by concurrent radiation therapy and infusional 5-FU and paclitaxel.[146] Resection was attempted 5 to 6 weeks after radiation therapy and chemotherapy. The pathologic complete response and R0 resection rates were 26% and 77%, respectively. At 1 year, more patients with tumors exhibiting a pathologic complete response (89%) were living than patients with tumors exhibiting a less favorable response (66%). Grade 4 toxicity occurred in 21% of patients. The authors indicated these data appear to support a randomized phase III study evaluating preoperative versus postoperative radiation therapy and chemotherapy.[146] Although some concerns exist regarding potential for neoadjuvant radiation to increase perioperative morbidity, a national database analysis showed no differences in overall complications or 30-day mortality relative to up-front surgery alone with this approach.[147]

Preoperative Chemoradiation Versus Preoperative Chemotherapy

A randomized trial comparing neoadjuvant chemotherapy alone versus neoadjuvant combined-modality therapy was conducted by German investigators (the Preoperative Chemotherapy or Radiochemotherapy in Esophago-gastric Adenocarcinoma Trial [POET]).[148] Patients with advanced esophagogastric adenocarcinoma were randomized to receive (a) cisplatin/5-FU-based chemotherapy alone versus (b) a similar induction chemotherapy followed by concurrent cisplatin/etoposide with 30 Gy of radiation therapy. Both groups went on to receive surgery. Although this study closed early owing to poor accrual, patients receiving preoperative chemoradiotherapy had significantly higher N0 rates (37% vs 64%, *P* = .04) and pathologic complete response rates (2% vs 16%, *P* = .03), as well as statistical trends toward improved local control (59% vs 76%, *P* = .06) and overall survival (3-year survival 28% vs 47%, *P* = .07, HR 0.67). The authors concluded that preoperative combined modality improves overall survival as compared to chemotherapy alone in patients with locally advanced esophagogastric adenocarcinoma.[148] Long-term follow-up of this study showed that local progression-free survival after tumor resection was significantly improved by chemoradiotherapy (HR 0.37, 0.16-0.85, *P* = .01, 95% CI) and 20 versus 12 patients were free of local tumor progression at 5 years (*P* = .03). Although the rate of postoperative in- hospital mortality was somewhat higher with chemoradiotherapy (10.2% vs 3.8%, *P* = .26), more patients were alive at 3 and 5 years after chemoradiotherapy (46.7% and 39.5%) compared with chemotherapy (26.1% and 24.4%). Thus, overall survival showed a trend in favor of preoperative chemoradiotherapy (HR 0.65, 95% CI 0.42-1.01, *P* = .055).[149] Along these lines, an Australian randomized phase II/III trial (the TOPGEAR study) was initiated, randomizing patients with resectable gastric and GE junction cancer to (a) preoperative chemotherapy alone (ECF) × three cycles versus (b) the same regimen (× two cycles) followed by concurrent 5-FU-based chemoradiotherapy, with both arms followed by adjuvant ECF. Interim analysis of the first 120 patients from this study demonstrated that preoperative chemoradiation could be safely delivered to the vast majority of patients without a significant increase in treatment toxicity or surgical morbidity. Specifically, 92% of patients allocated to preoperative chemoradiation received the specified treatment, which is much higher than the 50% compliance rate seen in the previously described CRITICS trial;

greater than or equal to grade III gastrointestinal toxicity occurred in 30% of combined-modality patients versus 32% in the chemotherapy-alone arm.[150] Owing to the complexity of gastric irradiation, a comprehensive radiation therapy quality assurance (RTQA) program was implemented. RTQA was undertaken in real time before treatment for the first five patients randomized to chemoradiotherapy from each center. Once acceptable quality was achieved, RTQA was completed for one-third of subsequent cases. RTQA consisted of evaluating (1) CTV and organ-at-risk contouring and (2) radiation therapy planning parameters. TOPGEAR enrolled 574 patients, of whom 286 were randomized to receive preoperative chemoradiotherapy and 203 (71%) were included for RTQA. Of these, 67 (33%) and 136 (67%) patients were from high- and low-volume centers, respectively. The initial RTQA pass rate was 72%. In total, 28% of cases required resubmission. In total, 200 of 203 cases (99%) passed RTQA before treatment. Cases from low-volume centers required resubmission more often (44/136 [33%] vs 13/67 [18%]; $P = .078$). There was no change in the proportion of cases requiring resubmission over time.[151] Recently published results showed that a higher percentage of patients in the chemoradiotherapy group achieved higher pathologic complete response rates (17% vs 8%) and greater tumor downstaging; however, at a median follow-up of 67 months, no significant differences in overall or progression-free survival were seen between the groups. Median overall survival was 46 months in the chemoradiotherapy group versus 49 months in the chemotherapy-alone group (HR 1.05, 0.83-1.31, 95% CI), with median progression-free survival of 31 versus 32 months, with similar treatment-related toxicities between groups. The authors concluded the addition of preoperative chemoradiotherapy to perioperative chemotherapy did not improve survival relative to perioperative chemotherapy alone in patients with resectable gastroesophageal junction and that at present there is little, if any, role for radiation therapy in the management of resectable gastric cancer.[152] Similarly, a follow-up Dutch phase II trial (the CRITICS-II trial) is examining the role of preoperative chemoradiotherapy using three preoperative strategies: chemotherapy (docetaxel, oxaliplatin, capecitabine) × four cycles, chemoradiotherapy (45 Gy, carboplatin, paclitaxel), and a combination of both (two cycles chemotherapy) in these patients.

Adjuvant Chemotherapy

The use of adjuvant chemotherapy has been explored in more than 30 randomized trials, many of which showed no benefit in survival compared to surgery alone. A randomized trial from Japan evaluated 579 patients undergoing resection to receive adjuvant chemotherapy alone versus observation alone. Primarily, early T-stage patients in the treatment group received a combination of mitomycin and fluorouracil twice weekly for 3 weeks following surgery, followed by delivery of uracil + tegafur (an oral 5-FU prodrug) (UFT). No survival benefit was seen with adjuvant chemotherapy.[153] However, a more recent study from Japan (the ACTS-GC trial) evaluated the efficacy of adjuvant chemotherapy in patients with stage II/III gastric cancer undergoing R0, D2 dissection (excluding T1 patients). This study randomized 1,059 patients to surgery alone versus treatment with S1, an oral fluoropyrimidine combining tegafur and oxonic acid. Three- and 5-year survival was significantly improved in patients receiving adjuvant chemotherapy (80% vs 70%; 72% vs 61%, respectively) in favor of the chemotherapy arm (HR of 0.669).[154,155] Whether the impact of S1 in the Asian population can be extrapolated to Western patients remains less clear and the subject of investigation, including potential biologic differences among populations regarding how this drug is metabolized.

A follow-up Japanese trial (the SAMIT trial) randomized patients with T4a/b gastric cancer following D2 dissection to (a) adjuvant UFT alone, (b) S1 alone, or (c) intermittent weekly paclitaxel, followed by either (a) UFT or (b) S1. The authors concluded that sequential treatment did not improve disease-free survival and UFT was not noninferior to S1 (and S1 was superior to UFT). The authors recommended S1 monotherapy should remain the standard adjuvant treatment for locally advanced gastric cancer patients in Japan.[156]

Another Asian study, the CLASSIC (capecitabine and oxaliplatin adjuvant study in stomach cancer) was conducted in South Korea, China, and Taiwan. A total of 1,035 patients with pathologic stage II-IIIB gastric cancer were randomized to a surgery-alone arm versus surgery plus adjuvant capecitabine/oxaliplatin for 6 months. Again, all patients underwent D2 gastrectomy. At a median follow-up of 62 months, the

adjuvant chemotherapy group had a significant improvement in disease-free survival compared to the surgery-alone group (68% vs 53%, $P < .0001$).[157]

Japanese investigators reported the JACCRO GC-07 trial in which 917 patients with lymph node–positive, stage IIa-IVa disease were randomized to curative gastrectomy with D2 lymphadenectomy to postoperative S-1 plus docetaxel or S-1. The docetaxel-containing group had improved 3-year relapse-free survival (66% vs 50%, $P < .001$).[158]

A meta-analysis of 17 randomized controlled trials using individual patient data comparing surgery alone to surgery with adjuvant chemotherapy in patients with resectable gastric cancer was performed. In this study, adjuvant chemotherapy was associated with a significant survival benefit in terms of overall survival (HR 0.82, CI 0.76-0.90, $P < .001$) and disease-free survival. Estimated 5-year overall survival was increased from approximately 50% to 55% with the use of chemotherapy. The authors[159] concluded that adjuvant chemotherapy with fluorouracil-containing regimens reduces the risk of death in gastric cancer compared to surgery alone. As discussed previously, how these varying studies apply to Western patients remains unclear.

Perioperative Chemotherapy

Various combinations of active drugs have been reported to improve the response rate among patients with metastatic or locally unresectable gastric carcinoma.[10] A combination of fluorouracil, doxorubicin, and methotrexate has been associated with a 30% to 40% response rate and was the most widely prescribed regimen for patients with advanced disease in the 1980s.[10] Despite an initial response rate of 64% when a combination of etoposide, doxorubicin, and cisplatin (EAP) was used by German investigators, in subsequent trials, this regimen was considerably less effective and deemed extremely toxic.[160-162] A combination of fluorouracil, doxorubicin, and high-dose methotrexate (FAMTX) was associated with a significant improvement in response rate compared with either EAP or FAM. As a result of these studies, FAMTX became standard therapy for metastatic disease.

In a British study of patients with unresectable or metastatic gastric and esophageal adenocarcinoma, 274 patients were randomized to either 5-FU,

doxorubicin, and methotrexate (FAMTX) or epirubicin, cisplatin, and continuous infusion 5-FU (ECF).[163,164] ECF was associated with a superior response rate (45% vs 21%, *P* = .0002), median survival (8.7 vs 5.7 months, *P* = .0006 vs .006), and 1-year survival (36% vs 21%). Moreover, ECF was associated with a superior quality of life and less toxicity.

The Medical Research Council (MRC) subsequently initiated a trial (the Medical Research Council Adjuvant Gastric Infusional Chemotherapy [MAGIC] trial) to address the question of perioperative chemotherapy (pre- and post-) in patients with operable gastric cancer. Patients with resectable adenocarcinoma of the stomach, GE junction, or lower esophagus were randomized to preoperative and postoperative chemotherapy with epirubicin, cisplatin, and 5-FU (ECF) versus surgery alone. Although originally designed to include patients with only tumors of the stomach, eligibility was later expanded to include tumors of the lower third of the esophagus, with approximately one-fourth of patients having adenocarcinoma involving the lower esophagus or GE junction. Of note is that there were more patients with T1/T2 disease (52% vs 37%, *P* = .002) as well as more N0/N1 patients (84% vs 71%, *P* = .01) in the chemotherapy group. Additionally, a significantly higher percentage of patients with gastric cancer receiving perioperative chemotherapy underwent surgery (79% vs 70%, *P* = .03). Nonetheless, the resected tumors were significantly smaller and less advanced in the perioperative chemotherapy group. With a median follow-up of 4 years, 149 patients in the perioperative chemotherapy group and 170 patients in the surgery group had died. As compared with the surgery group, the perioperative chemotherapy group had statistically improved progression-free and overall survival rates. No patient achieved pathologic complete response. However, patients receiving perioperative chemotherapy had an HR for death of 0.75, which was highly significant, with 5-year survival in patients receiving chemotherapy of 36% versus 23% in patients undergoing surgery alone (*P* = .009).[165] A follow-up MRC study (the ST03 trial) randomized 1,063 patients with perioperative resectable esophagogastric adenocarcinoma (36% gastric cancer, an additional 20% Siewert type III esophagogastric cancers) to epirubicin, cisplatin, and capecitabine (ECX) versus the same regimen plus bevacizumab. Three-year survival was 50.3% versus 48.1% (NS), with a higher rate of wound healing complications and anastomotic leaks in the

bevacizumab group. The authors concluded their results did not provide evidence for the use of bevacizumab in combination with ECX in patients with resectable esophagogastric cancer.[166]

French investigators reported the results of a similar randomized trial of 224 patients assigned to perioperative chemotherapy (cisplatin and 5-FU only) versus surgery alone. Although originally designed to include only patients with tumors of the lower third of the esophagus or GE junction, eligibility was later expanded to include gastric cancers, although most (75%) of the patients had disease of the lower esophagus or GE junction. Chemotherapy consisted of a planned two to three preoperative and three to four postoperative cycles. This study was prematurely terminated because of low accrual. Nonetheless, patients receiving chemotherapy had improved overall survival (5-year 38% vs 24%, $P = .02$), disease-free survival (5-year 34% vs 19%, $P = .003$), and R0 resection rates (84% vs 73%, $P = .04$). Only 50% of the patients received postoperative chemotherapy. T0 disease (complete pathologic response at the primary site) was seen in 3% of neoadjuvantly treated patients. Total locoregional recurrence rates were 24% and 26%, respectively, in the chemotherapy versus surgery group, with distant recurrence rates of 42% versus 56%, respectively.[167]

An EORTC study enrolling patients with locally advanced adenocarcinoma of the stomach or GE junction randomized patients to receive either cisplatin, leucovorin, and infusional 5-FU followed by surgery or surgery alone. Although only accruing 144 of 360 planned patients, neoadjuvantly treated patients had higher R0 resection rates (82% vs 67%, $P = .036$); however, at a median follow-up of 4.4 years, no significant difference in overall survival was seen ($P = .466$).[168]

A meta-analysis of these along with other small trials was performed, revealing that neoadjuvant chemotherapy was associated with a significant improvement in overall survival and progression-free survival and improved R0 resection rates.[169] Given these data, some authors have suggested that in terms of patient selection, a perioperative chemotherapy strategy may be most appropriate for patients with bulky primary tumors or bulky adenopathy in which there is a significant risk of micrometastatic disease as well as incomplete resection.[170]

A report from Dutch investigators described a study randomizing 716 patients with resectable gastric or GE junction cancer to 5-FU, leucovorin,

oxaliplatin, and docetaxel (FLOT) versus epirubicin, cisplatin, and 5-FU or capecitabine (ECF or ECX) given in a perioperative fashion. Disease-free and overall survival were significantly improved in patients receiving FLOT (30 vs 18 months disease-free survival, $P = .0036$; overall survival 50 vs 35 months, $P = .012$). Postoperative complications were similar in both groups. The authors concluded that in locally advanced resectable gastric or GE junction adenocarcinoma, perioperative FLOT improved overall survival compared with perioperative ECF/ECX, with these results leading to perioperative FLOT as a new standard of care in locally advanced patients with gastric cancer.[171] Ongoing[172] studies include a French study (FFCD1103) that is randomizing patients with resectable signet ring gastric cancer to receive neoadjuvant chemotherapy using perioperative ECF versus initial surgery followed by adjuvant ECF. Additionally, other ongoing randomized trials are building on a FLOT backbone, including the use of immunotherapy in patients with potentially resectable gastric cancer, the EORTC-1707 VESTIGE trial is evaluating the role of adjuvant immunotherapy with nivolumab and ipilimumab in patients with high risk for relapse following resection, and the INNOVATION study is comparing chemotherapy versus chemotherapy plus anti-HER2 therapy in operable gastric cancer. Recently results of the EORTC-1707 VESTIGE study reports reported recruitment was stopped early due to futility, with median disease-free survival for the nivolumab-ipiliumab group of 11.4 months versus 20.8 months for the chemotherapy group, with respective 12-month disease-free survival rates of 47% versus 64%, with the authors concluding that the addition of nivolumab-ipiliumab did not improve disease-free survival compared with chemotherapy in patients with ypNs+ and/or R1 gastroesophageal adenocarcinoma following neoadjuvant chemotherapy and surgery.[173]

Palliative Radiation Therapy

Radiation therapy is capable of providing substantial palliation of local gastric cancer symptoms.[174-179] It appears that 50% to 75% of patients can expect improvement of symptoms such as gastric outlet obstruction, pain from local tumor extension, bleeding, or biliary obstruction.[177] The likelihood of benefit may increase with concomitant 5-FU administration,

with less tumor bulk and if the patient's performance score is better before therapy.[125,175,180,181] The median duration of palliation varies from 4 to 18 months in reports addressing this issue.[175,180,181] A systematic review of the use of palliative radiotherapy in gastric cancer showed large variations in radiation dose and fractionation. The pooled overall response rates for bleeding, pain, and obstruction were 74%, 67%, and 68%, respectively. No difference in bleeding response rates was seen with a biologically effective dose (BED) of 39 or more versus lower doses. Grade III/IV toxicities occurred in up to 15% of patients treated with radiation alone versus up to 25% with combined-modality therapy. The authors concluded that more than two-thirds of patients receiving radiation therapy would derive clinical benefit.[182] A prospective trial from Japan evaluated the effectiveness of palliative radiation therapy. Patients requiring blood transfusion or hemoglobin <8 were entered. Response was gauged as hemoglobin more than 8, 7 consecutive days without blood transfusion between enrollment and blood sampling, and no salvage therapy or bleeding otherwise (including rebleeding). In total, 55 patients were enrolled, and per protocol response rates were 56%, 78%, and 90% at 2, 4, and 8 weeks, respectively. BED was not predictive of response.[183] Another prospective study from Singapore evaluated palliative radiotherapy in patients with symptomatic, locally advanced gastric cancer. Enrolling symptoms included bleeding, pain, or obstruction, with patients receiving a dose of 36 Gy/12 fractions. Median survival was 85 days. Eighty percent, 100%, and 100% of the patients with bleeding, obstruction, and pain responded to treatment, respectively. Improvement scores in fatigue, nausea/vomiting, and pain subscales were seen in 63%, 31%, and 50% of patients, respectively, 1 month after radiation therapy. The authors concluded that palliative gastric radiotherapy was effective and well tolerated, with significant symptomatic relief.[184]

SEQUELAE OF THERAPY

Anorexia, nausea, and fatigue are very common complaints during gastric radiation therapy; these symptoms can lead to potentially detrimental treatment breaks, with a National Cancer Database analysis evaluating overall adjuvant radiation therapy treatment time suggesting prolonged

breaks were associated with inferior survival and that efforts to minimize cumulative interruptions to less than 7 days should be considered.[185] However, the understanding of these side effects is somewhat limited.[186-189] Although visceral afferents may play some role in the acute emetogenic effects of radiation, other unknown factors, possibly chemical in nature and mediated by the chemoreceptor trigger zone, appear to be more important. Although selective serotonin (5-hydroxytryptamine 3 [5-HT_3]) antagonists effectively treat radiation-induced emesis, it is not clear whether the mechanism of action is directed at the 5-HT_3 receptor alone or has an effect on inhibition of serotonin release.[190] Additionally, the use of low-dose corticosteroids may be beneficial in patients with refractory nausea. Other compounding factors may include the altered gastric motility and prolonged gastric emptying time observed in animal experiments as a response to irradiation.[108,186,187,191] Chemotherapy-related leukopenia and thrombocytopenia may occur. If chemotherapy is used with irradiation, blood counts are generally obtained once to twice weekly. Additional acute toxicities of radiation therapy include esophagitis, epidermitis, fatigue, and weight loss in most patients. Nausea, vomiting, dehydration, and anorexia are relatively common, particularly in patients with lower esophageal and GE junction tumors. During therapy, patient tolerance, weight, and blood counts are checked at least weekly. Many symptoms resolve within 1 to 2 weeks of treatment completion. Because of potential toxicities in the treatment for patients with gastric cancer (dehydration, weight loss, anorexia, etc), aggressive supportive measurements and symptom management are indicated in efforts to avoid treatment-related interruptions, hospitalizations, or failure to complete the intended treatment course. Varying antiemetics should be used liberally, including on a prophylactic basis. Antacids including proton pump inhibitors are frequently implemented, and antidiarrheal medications may be appropriate. Additionally, nutritional supportive measurements are paramount and, when appropriate, the use of enteral methods is implemented. In selected cases, the use of feeding jejunostomy may be appropriate. Patients may require intermittent hydration both during and shortly following the treatment course. Postoperatively, vitamin B_{12}, iron, and calcium levels should be monitored and supplemented as appropriate.

Nutritional complications of treatment and myelosuppression, if concurrent chemotherapy is used during irradiation, can carry substantial morbidity and even occasional mortality from therapy. The historical GITSG reported a minimum 13% treatment-related mortality from nutritional problems or septic events on their concurrent chemoradiation arm,[127] and almost 20% of the patients of Caudry et al[192] were unable to complete therapy because of nutritional problems. However, others reported no severe or life-threatening nutritional compromise with aggressive chemoradiation.[122,125,193] Toxic gastrointestinal effects usually are managed with careful nutritional support and antiemetic therapy. It may be prudent to proactively prescribe antiemetics at the initiation of therapy in patients undergoing aggressive upper abdominal irradiation.

Myelosuppression causing serious or, rarely, lethal toxicity is also reported in many of the combined-modality trials.[122,125,193,194] If blood counts are monitored weekly during combined-modality therapy, serious problems with sepsis or bleeding should be uncommon.[193,194]

Moderate doses of 16 to 36 Gy reduce secretion of pepsin and hydrochloric acid.[1,108,195] For this reason, radiation therapy was once a common and successful therapy for peptic ulcer disease. Most of the gastric ulcers healed, although they recurred in approximately 40% of patients.[1,108,195] Gastric acid secretion decreased in almost all cases, with achlorhydria in 25% to 40%. The gastric acid decrease usually persisted from 1 to 6 months; however, 25% showed persistent decrease in acid production for 1 to 5 years or more.

Gastric late effects were categorized by the Walter Reed Group as dyspepsia, radiation gastritis, uncomplicated gastric ulcer, or gastric ulcer with perforation or obstruction.[196-198] The associations between dose and these late effects are described in Table 64.12. These data suggest a 20% to 30% incidence of ulceration with doses of 45 to 59 Gy, with complications of these ulcers in 30% to 50% of the treated patients. Some caution is necessary in interpreting this experience because the Walter Reed cohort was treated with 200 keV photons or 1 MV photons using a 70-cm target-skin distance, usually using only one field each day with daily fraction sizes of 3 Gy to midline, which sometimes produced daily given doses of 4 to 6 Gy.[197,198]

TABLE 64.12 RADIATION DOSE COMPARED WITH LATE EFFECTS IN THE WALTER REED EXPERIENCE

		Radiation Late Effects (%)[b]			
Dose (Gy)	Number of Patients[a]	Dyspepsia	Gastritis	Ulcer	Complicated Ulcer[c]
<40	111	5	2	3	0
40-44.99	23	0	22	0	0
45-49.99	27	4	19	11	11
50-54.99	34	0	24	18	12
55-59.99	14	0	50	14	7
>60	8	0	0	13	38

[a]Total number of patients treated at this dose.

[b]Results reported as number of patients with injury/total number of patients treated with this dose.

[c]Ulcers complicated by obstruction or perforation.

Most data suggest that gastric late effects are rare with doses of 40 to 52 Gy using conventional fractionation of 1.8 to 2 Gy. The relatively low risk of gastric late effects with doses less than 50 Gy is corroborated by many series using radiation therapy with or without chemotherapy for locally advanced gastric cancer.[41,48,62,74,84,142] However, doses in the range of 50 to 55 Gy may produce variable gastric late effects, which have been reported to reach 9% in some series. Doses of 60 Gy carried a 5% to 15% risk of gastric late effects.[1-3,52,62,70,93,125,142,164,175,181,188,190-193,195-200] The ability of histamine (H_2) blockers, proton pump inhibitors, and sucralfate to prevent the later development of radiation-induced gastric ulcerations is unproven. It may be reasonable to administer H_2 blockers or proton pump inhibitors prophylactically to patients receiving more than 45 Gy to any significant volume of the stomach or proximal duodenum.

Several series have described a gradual decline in renal function occurring 18 to 24 months or more following postoperative radiation therapy for gastric cancer. However, it is unclear that this is of clinical significance, and long-term renal function among gastric cancer survivors has not been reliably reported. One recent report described a dose-dependent nephrotoxicity as manifested by hypertension in patients with

gastric cancer, which may take years to manifest.[201] Similarly, another study indicated that mean creatinine clearance as well as changes in renal parenchymal volume occurred primarily within the first 4 years following radiation therapy with a clear relationship between these changes and dose volume histogram (DVH) parameters.[202] Nonetheless, advanced techniques may enhance renal sparing and also allow potential dose escalation as well as integration of novel (and potentially nephrotoxic) systemic agents.

Radiation-induced cardiac toxicity is a broad term describing potential radiation injury to a number of cardiac structures, including the pericardium (as manifested by effusion, pericarditis), coronary arteries, the heart muscle itself, and cardiac valves as well as nerve/conduction injury. Radiation injury primarily consists of fibrosis and/or small-vessel injury. The mechanism of radiation-induced cardiac injury is relatively poorly defined, particularly in the context of gastric cancer. Historical data from the treatment for patients with Hodgkin disease have suggested that dose more than 40 Gy may increase the risk of cardiac death as well as pericarditis.[203,204] Several studies of cardiac toxicity and patients with esophageal cancer have demonstrated that an increasing V_{30} predicted for a significant increase in pericardial effusion and increasing fraction size (particularly ≥3.5 Gy) also predicted for the same. Additionally, there may be a trend for decrease in ejection fraction in patients with increasing V_{20} of the left ventricle. A more detailed discussion on potential long-term cardiac sequelae of radiation therapy can be found in Chapters 59.

CONCLUSIONS AND RECOMMENDATIONS

Radiation therapy, usually administered with concomitant fluoropyrimidine-based chemotherapy, is indicated for locally confined gastric cancer that either is not technically resectable or occurs in medically inoperable patients. In this setting, therapy can be administered with curative or palliative intent, depending on the clinical situation. Those who undergo gastric resection with incomplete tumor resection or have truly positive margins of resection are also appropriately managed by combined-modality therapy. Preferably, patients that is unresectable (ie, inability to achieve R0 resection) would be identified preoperatively with endoscopic ultrasonography and CT staging. Preoperative chemoradiation then could

precede an attempt at gross total resection, alone or in combination with IORT in select situations, and maintenance chemotherapy.

With the more recent success of perioperative chemotherapy trials in gastric cancer, ongoing trials are examining the role of chemoradiation in the setting of perioperative chemotherapy and D2 lymph node dissection, including attempts to better stratify which patients might be most appropriate for (neo)adjuvant combined-modality therapy.

The irradiation field design from the phase III US Gastrointestinal Intergroup trial was based on optimized field design related to both site of the primary lesion and T and N stages of disease.[120] With the wide availability of 3-D conformal treatment planning systems, it is possible to more accurately target the high-risk volume and to use unconventional field arrangements and/or IMRT to produce superior dose distributions. To accomplish this without marginal misses, however, it will be necessary to both carefully define and encompass the various target volumes (tumor bed, nodal sites at risk), as target volumes that would be included using older approaches may be missed with more contemporary planning approaches.

CHAPTER 65

Pancreatic Cancer

Christopher G. Willett and Brian G. Czito

ANATOMY AND PATHWAYS OF SPREAD

The pancreas lies in the retroperitoneal space of the upper abdomen at about the level of the first two lumbar vertebrae. It is divided into head (including the uncinate process), neck, body, and tail (Figure 65.1). It has intimate contact with surrounding organs, including stomach, duodenum, jejunum, kidneys, spleen, and major vessels, which can be involved by direct tumor extension. Tumors in the pancreatic head often invade or compress the common bile duct, causing jaundice and dilatation of the bile and pancreatic ducts and gallbladder.

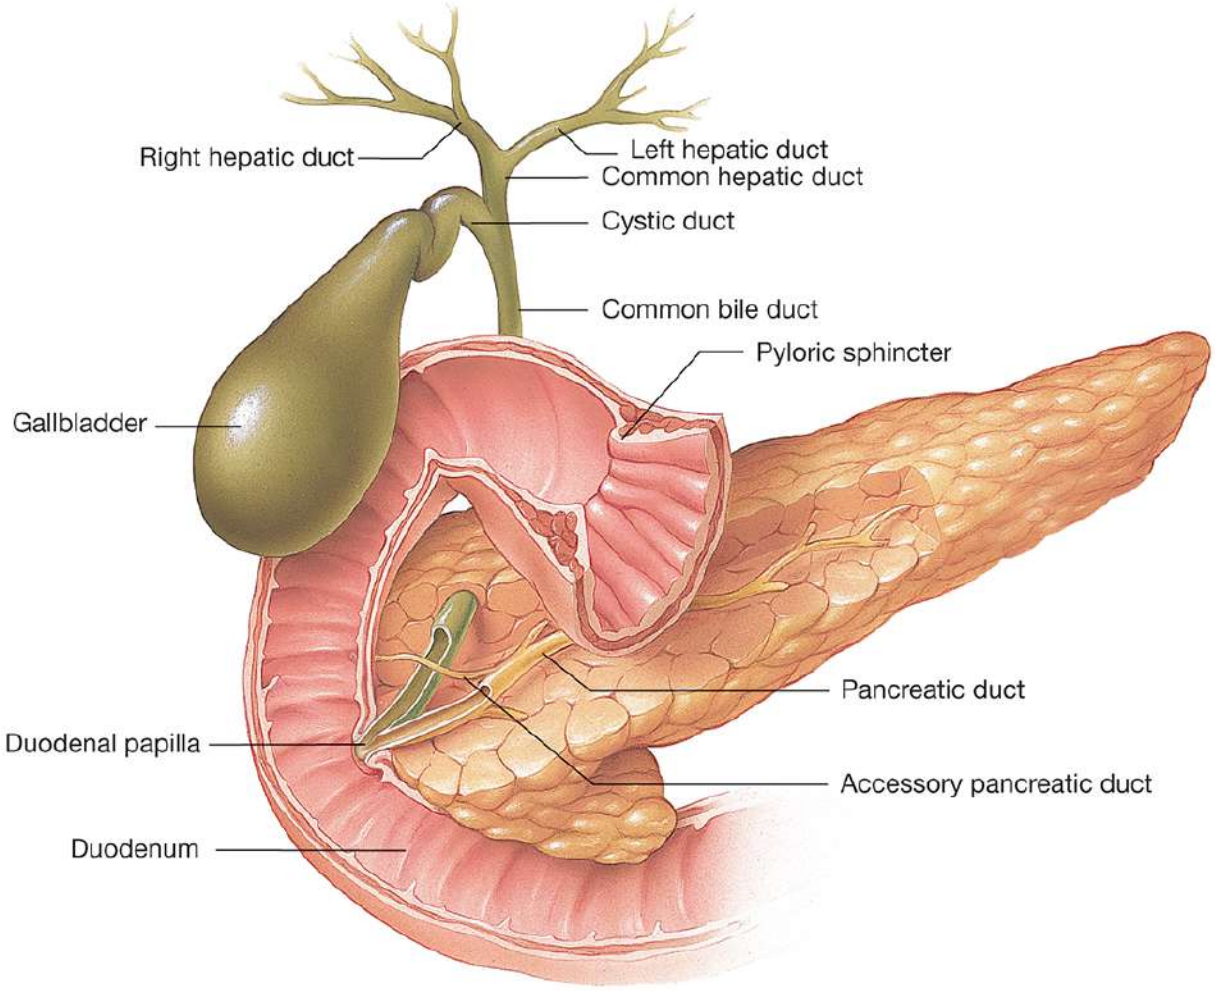

FIGURE 65.1 Pancreas and gallbladder duct anatomy. (Provided by the Anatomical Chart Company.)

The rich lymphatic drainage of the pancreas is interconnected with duodenal lymphatics. Regional drainage of the pancreatic head is to the peripancreatic, pancreaticoduodenal, porta hepatis, celiac, and superior mesenteric lymph nodes. The pancreatic body and tail drain to the splenic artery, peripancreatic, celiac, superior mesenteric, and para-aortic nodal basins.[1] With posterior, retroperitoneal tumor extension, para-aortic nodes are at risk. The main venous channels drain via the portal system to the liver. The lungs and pleura may be involved with posterior tumor extension into tissues with venous drainage by the vena cava or its tributaries. Generalized peritoneal involvement is more common with carcinoma of the body and tail than with carcinoma of the head of the pancreas.

EPIDEMIOLOGY AND RISK FACTORS

In 2023, an estimated 64,050 new cases of pancreatic cancer will be diagnosed in the United States, with 50,550 estimated deaths from the disease, making pancreatic cancer the fourth leading cause of cancer-related death in the United States.[2] At present, surgery offers the only means of cure. Unfortunately, only 10% to 20% of patients present with tumors amenable to resection. Even among patients who present with localized disease, the 5-year overall survival (OS) is approximately 20%.[3] Contemporary survival rates have reported improved results, particularly in patients with complete surgical resection (R0) and node-negative (N0) disease.[4-6] Patients who present with locally advanced, unresectable pancreatic cancer have a median survival of approximately 8 to 14 months, with rare long-term survival. Up to 60% of patients present with metastatic disease, which carries a shorter median survival of 4 to 12 months.[7]

The incidence of pancreatic cancer rises sharply after age 45, with higher rates in males than in females (1.3:1) and in Black males compared with the general population (14.8/100,000:8.8/100,000).[8] Familial aggregation of pancreatic cancer is estimated in 5% to 10% of newly diagnosed cases. It is associated with *BRCA1/2* and PALB2 mutations, familial atypical multiple mole melanoma syndrome, Peutz-Jeghers syndrome, familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, hereditary pancreatitis, ataxia telangiectasia, and Li-Fraumeni syndrome, with lifetime risk ranging from 5% to 40%.[9,10] Described risk factors for pancreatic cancer include chronic pancreatitis, smoking, alcohol consumption, *Helicobacter pylori* infection, and factors associated with metabolic syndrome, such as obesity and glucose intolerance.[11,12]

CLINICAL PRESENTATION

Most patients with pancreatic cancer experience pain, weight loss, or jaundice. Classically, pain from pancreatic cancer is characterized by radiation to the back, given the retroperitoneal location of the pancreas. Jaundice, due to biliary obstruction, is often accompanied by pruritus, acholic stools, and dark urine color. The initial presentation varies according to tumor location. Patients with tumors in the pancreatic body or tail usually present with pain and weight loss, whereas those in the head of

the gland typically present with jaundice, steatorrhea, weight loss, and pain. Recent onset of atypical or exacerbation of preexisting diabetes mellitus, unexplained thrombophlebitis, or history of pancreatitis is often noted. Patients with pancreatic cancer frequently present with unresectable or metastatic disease, in part due to these nonspecific presenting symptoms and the tendency for local and distant spread. No effective screening method to detect disease at the localized stage has been identified. Positive physical findings, if any, generally reflect incurable disease. These may include a palpable abdominal mass (ie, pancreas, liver, or gallbladder due to biliary obstruction), ascites, supraclavicular nodes, or palpable rectal shelf (ie, peritoneal seeding).

EVALUATION

Significant advances have been achieved in the imaging and staging of pancreatic cancer.[13] Currently, the principal diagnostic tools are multiphasic, helical computed tomography (CT) scan, endoscopic ultrasound (EUS), and laparoscopy. Magnetic resonance imaging (MRI) and positron emission tomography (PET) imaging techniques may be used in the initial evaluation of pancreatic malignancies. These tools have facilitated the characterization of the primary tumor (resectable or borderline resectable vs unresectable) as well as the identification of metastatic disease so patients can be appropriately and reliably triaged to operative and nonoperative therapies.

CT scan is the most commonly used staging modality. Newer generation, multidetector, high-speed helical CT coupled with a thin section imaging allows high-resolution images of the pancreas and its surrounding structures to be obtained at varying phases of enhancement. This allows for adequate imaging of the pancreas and assessment of metastatic deposits in other intra-abdominal organs, such as the liver.[14] Over 90% of patients deemed unresectable because of vascular involvement by CT are truly inoperable at the time of surgery.[15] Although CT staging is limited in detection of nodal involvement and peritoneal disease, it is useful in evaluating for metastatic disease.

Another tool for local tumor staging and diagnosis is EUS. In this procedure, an endoscope with an ultrasound transducer at its tip is passed into the stomach and duodenum, where it provides high-resolution images

of the pancreas and surrounding vessels. EUS facilitates fine-needle aspiration (FNA) without exposing the peritoneum to potential tumor seeding, as may occur with CT-guided biopsy. Sensitivity for EUS is at least comparable to CT, with tumor detection reported as high as 97%.[16] An advantage of EUS over CT is the ability to detect small or isoattenuating lesions, which might not be well visualized on cross-sectional imaging.[17] Interpretation of EUS is highly operator dependent. Frequently, EUS is performed in conjunction with endoscopic retrograde cholangiopancreatography.[18] This combined diagnostic approach allows for staging, therapeutic stenting of the common bile duct when indicated, and diagnostic FNA simultaneously.

A limitation of current imaging techniques is the inability to visualize small (1-2 mm) liver and peritoneal implants. Staging laparoscopy has been used preoperatively to assess for intraperitoneal metastases. One meta-analysis demonstrated that the adoption of staging laparoscopy and laparoscopic ultrasound will prevent up to 50% of patients from undergoing unnecessary laparotomy.[19] Patients with locally advanced disease and involved peritoneal washings or positive peritoneal biopsies have the same prognosis as do those with metastatic disease.[20]

Advances in MRI, including high-resolution imaging, faster acquisition time, three-dimensional (3D) reconstruction, functional imaging, and MR cholangiopancreatography, have led to an improved ability of MRI to diagnose and stage pancreatic cancer.[14] This modality can be used in patients with poor renal function to assess the primary tumor and determine resectability; however, studies suggest that MRI is not as sensitive as EUS or CT in tumor detection.[21] A potential advantage of MRI is identification of small foci of hepatic metastatic disease difficult to appreciate by CT or to further characterize ill-defined lesions seen on CT.[22]

Initial studies showed that PET has a higher sensitivity, specificity, and accuracy than does CT in diagnosing pancreatic carcinomas.[23-25] Integrated PET-CT had a higher sensitivity for malignancy detection than did either PET or CT alone (96% vs 84% vs 77%) but did not improve specificity (64%). PET may also be a useful adjunct in the identification of benign versus malignant lesions and the presence of metastatic disease. Although PET-CT may be useful in initial diagnosis, its role in determining resectability has been questioned as co-registration is often performed with

lesser resolution CT images and high metabolism can obscure peripancreatic planes.[26]

High-resolution pancreatic CT and EUS remain the current standard for diagnosis and staging of pancreatic malignancies. Staging laparoscopy is useful in assessing for intraperitoneal and liver disease. MRI and PET-CT are technologies that may also be useful. All imaging modalities are inadequate to stage lymph node involvement, and further advances may improve the ability to diagnose, stage, and appropriately select further therapies.

TUMOR STAGING

Staging is rarely used in published series, and tumors are instead characterized as resectable, borderline resectable, unresectable, or metastatic.

The current American Joint Committee on Cancer 2017 tumor, node, and metastasis staging system is described in Table 65.1. Common criteria of resectability are outlined in Table 65.2.

TABLE 65.1 AMERICAN JOINT COMMITTEE ON CANCER STAGING 2017 TNM CLASSIFICATION FOR PANCREATIC CANCER

Primary Tumor (T)	Regional Lymph Nodes (N)
Tis Carcinoma in situ **T1a** <2 cm, T1a ≤0.5 **T1b** >0.5 and <1 **T1c** 1-2 cm **T2** >2 and ≤4 cm **T3** >4 cm **T4** Tumor involves the celiac axis, superior mesenteric artery, and/or common hepatic artery.	**N0** No regional lymph node metastasis **N1** Metastasis in 1-3 regional lymph nodes **N2** Metastasis in ≥4 regional lymph nodes **Distant Metastasis (M)** **M0** No distant metastasis **M1** Distant metastasis

Stage Grouping

Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1-3	N1	M0
Stage III	T1-3N2M0; T4 any NM0	Any N	M0

Primary Tumor (T)		Regional Lymph Nodes (N)	
Stage IV	Any T	Any N	M1

TABLE 65.2 INTERNATIONAL CONSENSUS OF CLASSIFICATION OF BORDERLINE RESECTABLE PANCREATIC DUCTAL ADENOCARCINOMA (BR PDAC) BASED ON ANATOMICAL DEFINITION USING COMPUTED TOMOGRAPHY IMAGING THAT INCLUDES CORONAL AND SAGITTAL SECTIONS

Resectable: R	• SMV/PV: No tumor contact or unilateral narrowing • SMA, CA, CHA: No tumor contact
Borderline resectable: BR	Subclassified according to SMV/PV involvement alone or arterial invasion
BR-PV (SMV/PV involvement alone)	• SMV/PV: Tumor contact ≥180° or bilateral narrowing/occlusion, not exceeding the inferior border of the duodenum • SMA, CA, CHA: No tumor contact/invasion
BR-A (arterial involvement)	• SMA, CA: Tumor contact of <180° without showing deformity/stenosis • CHA: Tumor contact without showing tumor contact of the PHA and/or CA (The involvement of the aorta is categorized as unresectable. Presence of variant arterial anatomy is not taken into consideration.)
Unresectable: UR	Subclassified according to the status of distant metastasis
Locally advanced: LA	• SMV/PV: Bilateral narrowing/occlusion, exceeding the inferior border of the duodenum. • SMA, CA: Tumor contact/invasion of ≥180°[a] • CHA: Tumor contact/invasion showing tumor contact/invasion of the PHA and/or CA • AO: Tumor contact or invasion
Metastatic: M	Distant metastasis[b]

AO, arota; CA, celiac artery; CHA, common hepatic artery; PHA, proper hepatic artery; PV, portal vein; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

[a]In the cases with CA invasion of 180° or more without involvement of the aorta and with intact and uninvolved gastroduodenal artery thereby permitting a distal pancreatectomy with

en bloc celiac axis resection (DP-CAR), some members prefer these criteria to be in the BR-A category.

[b]Including macroscopic para-aortic and extra-abdominal lymph node metastasis.

PATHOLOGIC CLASSIFICATION

Approximately 85% to 90% of pancreatic cancers are adenocarcinomas. Other neoplasm histologic cell types include intraductal papillary mucinous neoplasm, mucinous cystic, solid pseudopapillary, acinar cell, pancreaticoblastoma, neuroendocrine, squamous cell, serous cystadenocarcinoma, and lymphoma. Management and treatment sections will focus on pancreatic adenocarcinomas, given that this is the predominate histologic subtype. The histopathology of lesions in the periampullary region of the head of the pancreas is of particular importance as different types of adenocarcinomas, originating from the pancreas, bile duct, ampullary region, or duodenum, respectively, portend different prognoses.[27]

Pancreatic adenocarcinomas evolve from noninvasive pancreatic intraepithelial neoplasias, acquiring various genetic and epigenetic mutations. Several molecular abnormalities have been implicated in contributing to the development of pancreatic cancer. The most frequent genetic alterations are activation of the oncogene *KRAS* and inactivation of tumor suppressor genes including *TP53*, p16 (*CDKN2*), *DPC4 (SMAD4*), and *BRCA2*, with reported incidences ranging from 50% to 95% in pancreatic tumors.[28] These molecular changes have the potential to identify precursor lesions with a high likelihood of progressing into carcinomas, characterizing pathologically ambiguous lesions, and are useful in the development of screening regimens.

GENERAL MANAGEMENT

Operative Considerations

Surgery, as part of a multimodality treatment approach for patients with resectable pancreatic cancer, represents the only potentially curative treatment strategy.[29] More than 80% of patients present with advanced

disease that is not amenable to curative resection, with roughly two-thirds presenting in the pancreatic head. The standard surgical treatment for pancreatic cancer of the head or uncinate is pancreaticoduodenectomy, first described by Whipple et al[30] in 1935. For pancreatic tail lesions, distal pancreatectomy is employed, frequently with splenectomy. Initially, high operative morbidity and mortality rates led to technical modifications of the operation that, combined with improvements in anesthesia and critical care, have resulted in current perioperative mortality rates of 2% or less at high-volume centers.[31-33] With reduced morbidity from the Whipple procedure, there is no age limitation, and selected patients, even at ages greater than 80 years, may undergo pancreaticoduodenectomy.[34-36]

Several studies report low postoperative mortality rates and appropriate patient selection at high-volume institutions, highlighting the importance of performing such procedures at institutions with extensive experience.[37-40] In addition, the definition of resectable lesions has broadened with the ability to perform venous reconstructions with minimal increase in morbidity or mortality.[41,42]

The prognosis, even among resectable patients, remains poor, with 5-year survival rates of 10% to 25%. The number of nodes harvested appears to impact outcomes; data suggest that 12 to 15 lymph nodes constitute an adequate assessment, although the impact on outcomes may simply reflect accurate staging.[43,44] Although appropriate lymph node dissection is desirable, trials of extended lymphadenectomy conveyed no survival benefit and compromised quality of life (QoL).[45,46] Pathologic assessment provides important prognostic information, including margin status, tumor grade, tumor size, lymphovascular invasion, and lymph node involvement. The presence of positive operative margins, poor histologic grade, larger tumor size, lymphovascular invasion, and lymph node involvement portends a poorer prognosis.[47-51] Similarly, patients with elevated preoperative and postoperative carbohydrate antigen 19-9 (CA19-9) have inferior disease-free survival (DFS) and OS rates.[51-54]

In an effort to minimize surgical morbidity, pylorus-preserving pancreaticoduodenectomy and laparoscopic resection techniques have developed. Pylorus-sparing pancreaticoduodenectomy potentially improves gastrointestinal function without compromising oncologic management.[55,56] Laparoscopic pancreatic resection was first explored in the late 1990s, and

its use has increased dramatically.[57,58] Although most experiences are small, retrospective, single-institution series, laparoscopic resection, in experienced hands, appears a reasonable option for distal pancreatic resections.[59-62] The data on laparoscopic pancreaticoduodenectomy are more limited; the difficulty with this procedure arises from more complex dissection and the need for reconstruction.[42,58] Data suggest, however, that despite prolonged operative times and potential increase in postoperative fistula formation, laparoscopic resection offers shortened hospitalization and equivalent oncologic results.[58,63-65]

Cause of Death and Patterns of Failure

For patients with locally unresectable tumors or metastatic disease, death usually results from hepatic failure secondary to biliary obstruction by local tumor extension or hepatic replacement by metastases. For the 10% to 20% of patients undergoing a potentially curative pancreaticoduodenectomy, three major sites of disease relapse dominate: locoregional, peritoneal cavity, and liver (Table 65.3). High local recurrence rates of 50% to 86% occur despite resection because of frequent lymphatic and perineural involvement and cancer invasion into the retroperitoneal soft tissues, with an inability to achieve wide retroperitoneal soft tissue margins due to anatomic constraints (superior mesenteric artery [SMA] and superior mesenteric vein [SMV], portal vein, and inferior vena cava).[50,66,67] The incidence of microscopic residual disease after careful evaluation of the posterior peripancreatic soft tissue margin is as high as 40%.[67] Therefore, tumor stage, grade, and resection margin status are the best predictors of survival after surgery.[66,67] The use of adjuvant therapy after surgery can reduce the incidence of local failure, but distant disease recurrence rates remain high.

RADIATION THERAPY TECHNIQUES

Dose-Limiting Tissues

The dose-limiting organs for irradiation of upper abdominal malignancies include the small bowel, stomach, liver, kidneys, and spinal cord. Various techniques, such as 3D conformal radiotherapy (3DCRT) and intensity-modulated radiotherapy (IMRT), can spare these organs. Given long-term survival is low, the actual number of patients at risk for late complications is small. Late small bowel and gastric effects may also be decreased through reduction of the volume of these organs within the high-dose field.

Treatment Volumes, Fields, and Doses

In patients undergoing surgery, clips should be placed to mark the extent of the lesion for postoperative irradiation. The patient should be positioned supine during simulation and treatment. 3DCRT radiotherapy allows visualization of internal organs and target delineation. CT-based treatment planning allows the construction of normal tissue dose-volume histograms and the generation of treatment plans that optimize radiation dose delivery to tumor while sparing critical normal tissues. Multiple field, fractionated, external beam techniques use high-energy photons to deliver 45 to 50 Gy in 1.8 Gy fractions to tumor bed, unresected or residual tumor, and lymph node–bearing areas at risk. After the primary fields, a boost field can be designed to include unresected or gross residual disease, as defined by CT scans and clips, while excluding most of the stomach and small bowel. Additionally, boost can also be accomplished with a simultaneous integrated technique utilizing higher doses-per-fraction, concurrent with delivery of the larger field, using more advanced planning techniques.

With lesions in the head of the pancreas, major node groups include the pancreaticoduodenal and peripancreatic (resected at the time of Whipple) and porta hepatis and para-aortic regions. If utilizing 3D techniques, approximately two-thirds of the left kidney must be excluded from the anteroposterior/posteroanterior (AP/PA) field because the right kidney is often in the field because of duodenal (bed) inclusion. The superior field extent is often at the middle or upper portion of the T11 vertebral body for adequate margins on the celiac vessels (T12, L1) and the inferior limit at the level L2 to L3 to include the superior mesenteric lymph nodes and third portion of the duodenum. The upper field extent is sometimes more superior with body lesions to obtain adequate margin on the primary lesion. With lateral fields, the anterior field margin is 1.5 to 2.0 cm beyond the initial gross disease. The posterior margin is often 1.5 cm behind the anterior portion of the vertebral body to allow adequate margins on para-aortic nodes, which are at risk of posterior tumor extension in the head or body lesions. The lateral contribution usually is limited to 15 to 18 Gy because a moderate volume of kidney or liver may be in the irradiated volume (Figure 65.2). Similarly, more advanced radiation planning techniques (including

IMRT) can be utilized to accomplish this and further spare adjacent normal organs.

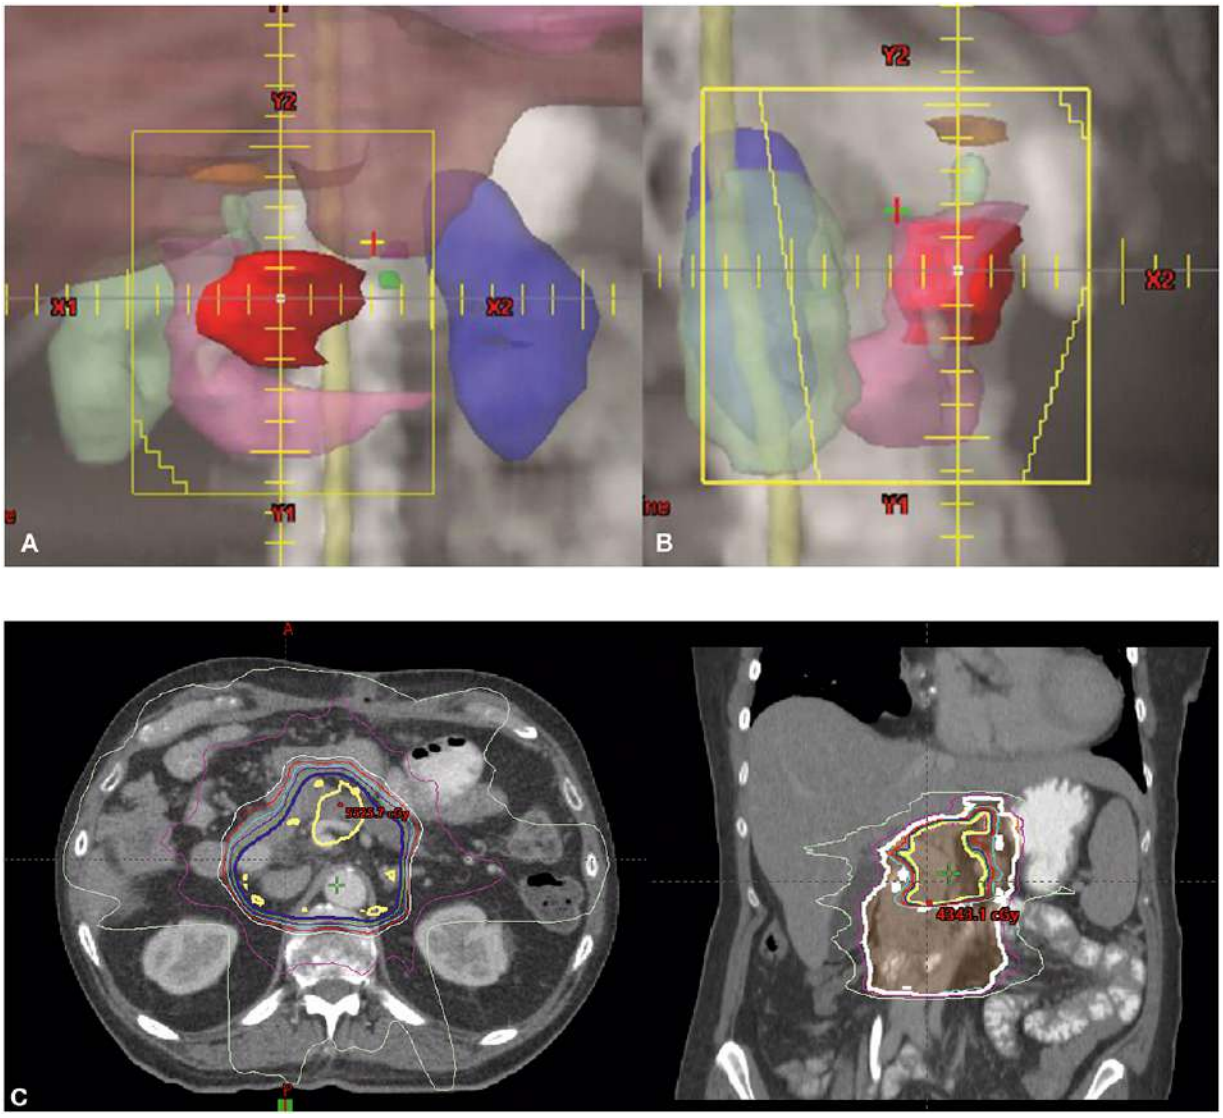

FIGURE 65.2 External beam four-field technique for pancreatic head lesion. A. The anteroposterior/posteroanterior (AP/PA) field, which includes gross tumor (red), duodenal loop (pink) (plus ~50% of the right kidney [light green]), liver (brown), and nodal areas at risk (porta hepatis: orange, superior mesenteric arteries: green, celiac: magenta). Most of the left kidney (blue) is excluded from the AP/PA field. B. The right lateral field with an anterior margin beyond gross disease and a posterior margin behind front edge of vertebral body. The liver contour (brown) has been removed from lateral field for visualization of other structures. C. IMRT-based plan for patient following R1 resection at the pancreatic neck. Note relative isodose levels, utilizing a simultaneous integrated boost technique delivered in 28 fractions.

With pancreatic body or tail lesions, at least 50% of the left kidney may be included to achieve adequate margins on node groups at risk (ie, lateral suprapancreatic, splenic artery, and splenic hilum nodes). Inclusion of the pancreaticoduodenal nodes is often not indicated with body or tail lesions, and at least two-thirds of the right kidney can be preserved (Figure 65.3).

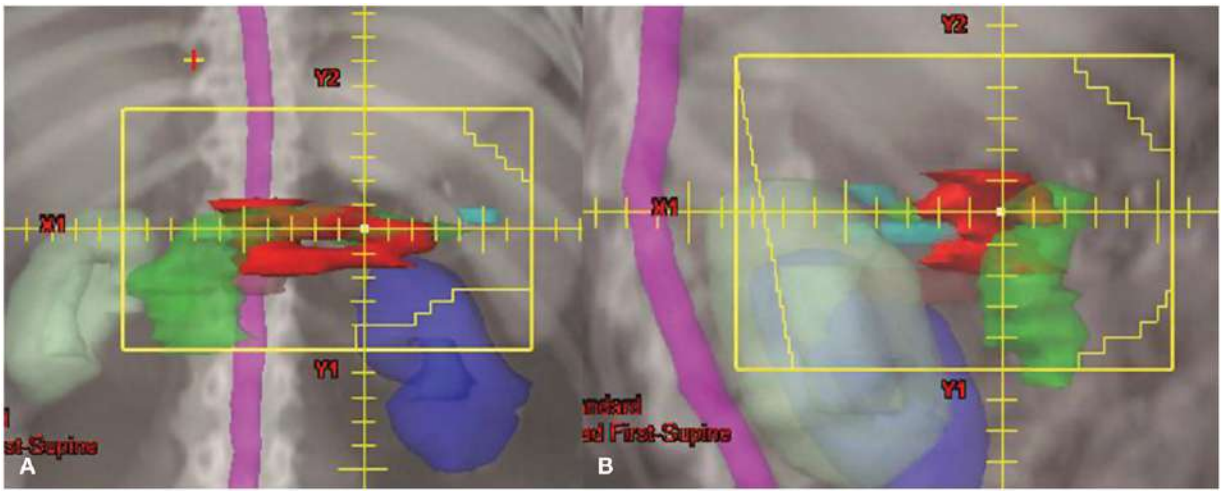

FIGURE 65.3 External beam four-field technique for unresectable tail of pancreas lesion. A. The anteroposterior/posteroanterior (AP/PA) field showing lesion (red) and head of pancreas (green). The field is extended to the patient's left to include coverage of the splenic hilum (cyan). Much of the right kidney (light green) is excluded from the field and multileaf collimators block most of the left kidney (blue). B. The right lateral field with an anterior margin beyond gross disease and a posterior margin at least 1.5 cm behind front edge of vertebral body.

After resection, AP/PA and lateral fields are often designed on the basis of preoperative CT primary tumor volumes, preoperative duodenal loop location, operative clip placement, and postoperative CT nodal volumes (Radiation Therapy Oncology Group [RTOG] contouring atlas accessible on their website). The anterior border is determined by vascular or nodal boundaries (porta hepatis, superior mesenteric, and celiac), as demonstrated on CT, as well as preoperative tumor location.[78] Again, more advanced target planning using IMRT can be utilized to further enhance normal tissue sparing.

RADIATION THERAPY RESULTS

Resectable Tumors: Adjuvant Therapy

After surgical resection of pancreatic cancer, local recurrence rates range from 50% to 86% and distant recurrence rates from 40% to 90%, most commonly to the liver or peritoneum.[50,67-69,71,72,79] This provides the rationale for adjuvant therapy, which has been employed in an effort to improve patient outcomes (Table 65.4). Despite multiple randomized trials, a definitive role for adjuvant radiotherapy for resected pancreatic cancer has not been established.

Historical Prospective Studies

The Gastrointestinal Tumor Study Group (GITSG) conducted the first multicenter prospective trial of adjuvant CRT for patients with resected pancreatic cancer and negative surgical margins, laying the foundation for the adoption of CRT in the United States. Forty-three patients were

randomized to observation or CRT to 40 Gy delivered in split-course manner with concurrent 5-fluorouracil (5-FU) (500 mg/m^2) as an intravenous bolus on the first 3 and last 3 days of radiation, followed by maintenance weekly 5-FU for 2 years or until disease progression. At interim analysis, improvements in median DFS (mDFS) and OS with CRT were observed: 11 versus 9 months and 20 versus 11 months. Two-year OS was 42% in the CRT group versus 15% in the surgery-alone arm.[80] An additional 30 patients were later enrolled to receive adjuvant CRT. These additional patients confirmed the survival outcomes seen in the original trial, with median survival of 18 months and a 2-year survival of 46%.[81]

The GITSG trial has been criticized for a number of reasons. The trial closed prematurely following enrollment of 43 of an intended 100 patients because of slow accrual over the 8-year enrollment period. The external beam radiation therapy (EBRT) approach in this trial was considered low dose and antiquated by contemporary standards because of a split-course technique and use of large treatment fields, which encompassed the entire pancreas or pancreatic bed and the celiac, pancreaticosplenic, peripancreatic, and retroperitoneal regional lymph nodes. In addition, the inclusion of both CRT and adjuvant chemotherapy after surgery evaluated two treatment variables, making it difficult to discern the true effect of either treatment alone. In the CRT arm, there were issues of compliance, with 32% of patients assigned to CRT receiving inappropriate radiation and 25% of patients failing to initiate treatment within 10 weeks postsurgery, the protocol-specified time limit. Only 9% of patients completed the planned 2-year maintenance chemotherapy course. In addition, survival in the control arm was low compared with historical studies. Despite these limitations and the failure to reach the desired patient accrual, the GITSG trial demonstrated a benefit for CRT, which became standard adjuvant therapy, particularly in the United States.

A second study sponsored by the European Organization for Research and Treatment of Cancer (EORTC) sought to confirm the findings of the original GITSG study. Two hundred eighteen patients with resected pancreas (n = 114) or periampullary cancers (n = 104) were randomly assigned to observation or CRT to 40 Gy in a split-dose manner with concurrent continuous infusional 5-FU (25 mg/kg) without further adjuvant chemotherapy. This study showed no significant improvement (P = .208) in

median survival (19 months [observation] vs 24.5 months [CRT]) or 2-year survival (41% [observation] vs 51% [CRT]).[82] Long-term follow-up of the EORTC trial demonstrated no difference in 5-year OS with CRT use: 22% (surgery alone) versus 25% (CRT). Post hoc analysis of pancreatic head lesions failed to demonstrate a benefit with CRT, with a median OS (mOS) of 1.3 years for CRT versus 1 year for surgery alone.[83]

This trial has been criticized for its heterogeneous patient population, which included patients with both pancreatic and periampullary primary tumors. Periampullary carcinomas have a significantly better prognosis compared with pancreatic cancer; the two entities thus represent truly different diseases and potentially dilute any evidence of benefit for adjuvant CRT.[97] Similar to the GITSG trial, older EBRT techniques—split course and low total dose—were used. Also, more than 20% of patients in the CRT arm did not receive the intended treatment because of postoperative complications or patient refusal. The trial did not include maintenance chemotherapy in the treatment arm. Finally, although a small subset, patients undergoing noncurative resection and patients with positive surgical margins were still eligible for enrollment. The discordant results of the EORTC and GITSG trials have led some investigators to attribute the OS benefit seen in the GITSG trial to maintenance chemotherapy administration rather than to EBRT.

An additional European trial conducted by the European Study Group for Pancreatic Cancer (ESPAC) aimed to further explore the question of appropriate adjuvant therapy for "macroscopically" resected pancreatic cancers. Treating physicians were allowed to enroll patients into one of three parallel randomized studies:

1. Chemoradiation versus no chemoradiation (n = 68), consisting of 20 Gy over 2 weeks with 5-FU (500 mg/m^2) on days 1 through 3, then repeated after a 2-week break;
2. Chemotherapy versus no chemotherapy (n = 188), consisting of bolus 5-FU (425 mg/m^2) and leucovorin (LV) (20 mg/m^2) given for 5 days every 28 days for six cycles; or
3. A 2-by-2 factorial design of 285 patients enrolled on chemoradiotherapy (n = 70), chemotherapy (n = 74), chemoradiotherapy with maintenance chemotherapy (n = 72), or observation (n = 69).

The data from the treatment groups from all three parallel trials were then pooled for analysis. There was no survival difference between the 175 patients who received adjuvant chemoradiation and the 178 patients who did not receive therapy (median survival, 15.5 vs 16.1 months; $P = .24$). In the chemotherapy arm, however, a 35% reduction in death was seen in the group who received adjuvant chemotherapy ($n = 238$) compared with those who received no chemotherapy ($n = 235$), with a difference in median survival of 19.7 versus 14 months ($P = .0005$).[84] On further follow-up of patients randomized using the 2-by-2 factorial design, the 5-year survival rate for the patients who received chemotherapy was 21% versus 8% for those who did not. In addition, adjuvant CRT was associated with a deleterious effect on survival.[85]

A number of problems are associated with the interpretation of these data. First, the complex trial design has the potential for bias, because patients or physicians could select randomization for one treatment variable. Also, as in the aforementioned trials, the EBRT technique used was, by contemporary standards, considered outdated, using split course and low total dose. No details of EBRT delivery or central quality assurance for EBRT, surgery, or pathology are available. In addition, many treatment violations occurred, as only 62% of patients received full CRT treatment and only 42% of patients in the chemotherapy arms completed the predefined regimen. Although many have attempted to draw conclusions from the updated publication, the 2-by-2 factorial cohort of the study was not powered to detect OS differences. In addition, patients receiving CRT in the ESPAC trial experienced poorer survival outcomes compared with those in other reported CRT series. Also, patients who had received prior "background" chemotherapy or radiation therapy were still eligible for enrollment. As in the EORTC trial, no maintenance chemotherapy was administered. Despite these critiques, some have speculated that the detriment seen in the CRT group may have resulted from delayed administration of systemic therapy shown to improve survival in the ESPAC trial.

A common critique of the aforementioned trials of adjuvant therapy is the lack of restaging to evaluate for the presence of persistent or metastatic disease after surgical resection and prior to the initiation of adjuvant therapy. The time between initial staging and the commencement of

adjuvant treatment can be as long as 3 to 4 months, during which a significant number of patients would be expected to develop radiographically apparent metastases. Without interval restaging, these patients may inappropriately receive CRT. Although these three trials formed the foundation for adjuvant treatment approaches to resectable pancreatic cancer, perhaps because each trial was fraught with flaws, there continues to be little consensus regarding the "most appropriate" treatment. A relative dichotomy in adjuvant treatment approaches for resectable pancreatic cancer has emerged between the United States and parts of Europe, with adjuvant CRT frequently implemented in the United States and adjuvant chemotherapy alone administered in parts of Europe.

Modern Studies

Adjuvant Systemic Therapy

Building from the data showing potential benefit to adjuvant chemotherapy, investigators in Europe conducted a randomized phase III trial of observation versus adjuvant gemcitabine in patients with resected pancreatic cancer. Three hundred sixty-eight patients were enrolled in the Charite Onkologie (CONKO) trial and randomized to observation or adjuvant gemcitabine (1,000 mg/m^2 intravenous days 1, 8, and 15 every 4 weeks for 6 months).[86] The primary end point was DFS, and patients treated with gemcitabine achieved a statistically significantly longer DFS (14.2 vs 7.5 months) than those observed after surgery. This improvement was seen in both the R0 and R1 subgroups. At initial publication, there was no difference in OS. With longer follow-up, median and 5-year OS were both improved in patients receiving gemcitabine (23 vs 20 months, and 21% vs 9%).[87] These findings were supported by a smaller randomized study from Japan, which again demonstrated a DFS benefit for gemcitabine compared with surgery alone.[98]

At the same time, the CONKO trial was enrolling patients, ESPAC-3, the largest randomized controlled trial (RCT) in pancreatic cancer to date, enrolled 1,088 patients with pancreatic adenocarcinoma who underwent R0 or R1 resection. Patients were randomly assigned to six cycles of adjuvant gemcitabine (3 weekly infusions of 1,000 mg/m^2) or six cycles of bolus 5-FU (425 mg/m^2)/LV (20 mg/m^2). Patients receiving 5-FU/LV experienced

significantly higher rates of grade 3 or 4 gastrointestinal toxicity (stomatitis and diarrhea), whereas patients receiving gemcitabine experienced significantly higher rates of grade 3 or 4 hematologic toxicity. At a median follow-up of 34.2 months, there was no difference between the two groups in the primary end point of OS.[88]

The ESPAC-4 trial randomized patients with resected pancreatic cancer to gemcitabine alone versus gemcitabine/capecitabine. Seven hundred and thirty patients with R0/R1 resection were evaluable for the primary end point of OS. The median survival for patients receiving adjuvant gemcitabine and capecitabine was 28 months compared with 25.5 months in the gemcitabine-alone arm. Estimated OS was 80.5% (95% confidence interval [CI] 76.0-84.3) at 12 months and 52.1% (46.7-57.2) at 24 months in the gemcitabine group and 84.1% (79.9-87.5) at 12 months and 53.8% (48.4-58.8) at 24 months in the gemcitabine plus capecitabine group. Although clinically significant toxicities were low in both arms, the rates of grade 3 to 4 diarrhea, infection, neutropenia, and hand-foot syndrome were statistically higher in the combined chemotherapy arm. These data suggest that adjuvant gemcitabine and capecitabine may be a reasonable alternative to single-agent gemcitabine. The focus of future European adjuvant therapies for resectable pancreatic cancer has centered on finding the ideal combination of systemic agents.[89]

Combination chemotherapy with fluorouracil, LV, irinotecan, and oxaliplatin (FOLFIRINOX) leads to longer OS than gemcitabine therapy for patients with metastatic pancreatic cancer.[92] Building on these data, the PRODIGE 24/Canadian Cancer Trials Group PA6 trial was designed to randomize 493 patients with resected pancreatic ductal adenocarcinoma to receive a modified FOLFIRINOX (m-FOLFIRINOX) regimen (oxaliplatin [85 mg/m^2 body surface area], irinotecan [180 mg/m^2, reduced to 150 mg/m^2 after a protocol-specified safety analysis], LV [400 mg/m^2], and fluorouracil [2,400 mg/m^2] every 2 weeks) or gemcitabine (1,000 mg/m^2 on days 1, 8, and 15 every 4 weeks) for 24 weeks.[93] The primary end point was DFS. At a median follow-up of 33.6 months, the mDFS was 21.6 months in the m-FOLFIRINOX group and 12.8 months in the gemcitabine group (stratified hazard ratio [HR] for cancer-related event, second cancer, or death, 0.58; 95% CI, 0.46-0.73; $P < .001$). The DFS rate at 3 years was 39.7% in the m-FOLFIRINOX group and 21.4% in the gemcitabine group.

The mOS was 54.4 months in the m-FOLFIRINOX group and 35.0 months in the gemcitabine group (stratified HR for death, 0.64; 95% CI, 0.48-0.86; $P = .003$). The OS rate at 3 years was 63.4% in the m-FOLFIRINOX group and 48.6% in the gemcitabine group. Adverse events of grade 3 or 4 occurred in 75.9% of the patients in the m-FOLFIRINOX group and 52.9% of those in the gemcitabine group. Adjuvant therapy with an m-FOLFIRINOX regimen led to significantly longer survival than gemcitabine among patients with resected pancreatic cancer, but at the expense of higher toxicity.

The long-term results of the PRODIGE 24/Canadian Cancer Trials Group PA6 confirmed the earlier results.[94] In patients receiving chemotherapy with m-FOLFIRINOX versus gemcitabine, mDFS was 21.4 months (95% CI, 17.5-26.7) vs 12.8 months (95% CI, 11.6-15.2) (HR, 0.66; 95% CI, 0.54-0.82; $P < .001$) and the 5-year DFS was 26.1% versus 19.0%. Similarly, comparison of 5-year OS was higher for patients receiving m-FOLFIRINOX (43.2%) versus gemcitabine (31.4%). As in the initial publication, the final 5-year results from the PRODIGE 24/Canadian Cancer Trials Group PA6 randomized clinical trial indicate that adjuvant treatment with m-FOLFIRINOX yields significantly longer survival than gemcitabine in patients with resected pancreatic ductal adenocarcinoma.

Other studies have explored alternative regimens to assess their efficacy and safety.[95] The APACT randomized, open-label trial compared the efficacy and safety of adjuvant *nab*-paclitaxel plus gemcitabine with those of gemcitabine for patients with resected pancreatic ductal adenocarcinoma.[96] Eight hundred and sixty-six treatment-naive patients with pancreatic ductal adenocarcinoma were randomized to *nab*-paclitaxel (125 mg/m^2) plus gemcitabine (1,000 mg/m^2) or gemcitabine alone to one 30 to 40 infusion on days 1, 8, and 15 of six 28-day cycles. The primary end point was independently assessed DFS. Additional end points included investigator- assessed DFS, OS, and safety. Two hundred eighty-seven of 432 patients and 310 of 434 patients completed *nab*-paclitaxel plus gemcitabine and gemcitabine treatment, respectively. At a median follow-up of 38.5 months, the median independently assessed DFS was 19.4 (*nab*-paclitaxel + gemcitabine) versus 18.8 months (gemcitabine; HR, 0.88; 95% CI, 0.729-1.063; $P = .18$). With a median follow-up of 63.2 months, the mOS was 41.8 versus 37.7 months (HR, 0.80; 95% CI, 0.678-0.947; $P =$

.0091). Eighty-six percent (*nab*-paclitaxel + gemcitabine) and 68% (gemcitabine) of patients experienced grade 3 or higher treatment-emergent adverse events. The primary end point (independently assessed DFS) was not met despite favorable OS seen with *nab*-paclitaxel plus gemcitabine.

Adjuvant Chemoradiation

In the United States, the GITSG trial laid the foundation for CRT as the predominant adjuvant treatment modality. The RTOG/Gastrointestinal Intergroup trial 9704 was a phase III randomized study comparing adjuvant 5-FU–based chemotherapy to gemcitabine-based chemotherapy, with both regimens followed by CRT. Four hundred fifty-one patients with resected pancreatic cancer were randomized to continuous infusion 5-FU (250 mg/m^2/day) or gemcitabine (1,000 mg/m^2 weekly) for 3 weeks prior to CRT and 12 weeks after CRT. CRT in both groups consisted of 50.4 Gy delivered with continuous infusion 5-FU (250 mg/m^2/day).[77] Prospective quality assurance of all radiation therapy plans was required. This trial was powered to demonstrate a survival benefit for the entire cohort and for the subgroup of patients with pancreatic head lesions. On initial analysis of the pancreatic head subgroup (n = 388), a nonsignificant trend toward improved median and 3-year OS was seen in the gemcitabine arm: 20.5 versus 16.9 months and 31% versus 22%. However, a higher incidence of grade 3 or higher hematologic toxicity was also seen in the gemcitabine group, with no significant differences seen in severe nonhematologic toxicities.

An update of this trial reported median and 5-year OS rates in patients with pancreatic head tumors of 20.5 months and 22% in those who received gemcitabine, compared with 17.2 months and 18% in those who received 5-FU. On multivariate analysis, in the subgroup of patients with pancreatic head lesions who received gemcitabine, there was a nonsignificant trend toward improved OS (P = .08).[90,91]

A secondary aim of RTOG-9704 was to assess the ability of postresection CA19-9 levels to predict survival. When CA19-9 levels were analyzed in a cohort of 385 patients as a dichotomized variable (<180 IU/mL vs ≥180 IU/mL, ≤90 IU/mL vs >90 IU/mL), there was a significant survival difference favoring patients with CA19-9 levels of less than 180 IU/mL. This corresponded to a 72% reduction in the risk of death.[52] Unlike

preceding randomized CRT studies, a major strength of the RTOG study was the rigorous, centralized quality control of radiation therapy techniques and delivery. A follow-up analysis demonstrated that patients treated per study guidelines had a significant survival advantage, indicating the importance of centralized review and treatment technique in this disease.[74]

The high rates of local failure and need for more efficacious systemic therapy, as well as the controversy surrounding the role of CRT in resected patients, led to the design of the current RTOG-0848/EORTC trial. Preliminary results of this trial describe 354 patients randomized, with 174 in the chemotherapy-alone arm and 180 in the chemotherapy plus combined modality therapy arm. The combined modality therapy group did not show improvement in overall survival, but did show improvement in disease-free survival. Both overall and disease-free survival were improved with combined modality therapy in patients with node-negative disease, and this treatment did not increase grade IV/V events compared to chemotherapy.[99] This trial randomly assigns patients with resected pancreatic head adenocarcinoma (stratified based on CA19-9 level, nodal involvement, and margin status) to receive treatment with gemcitabine alone for five cycles. Note initially patients were also randomized to receive erlotinib, which was ultimately discontinued due to results of the LAP07 trial discussed further, and the trial was also amended to allow oxaliplatin-based combination chemotherapy regimens. If no progression is seen on restaging following the completion of systemic therapy, patients are further randomized either to receive an additional cycle of chemotherapy (for a total of six cycles) or to receive CRT (50.4 Gy with concurrent capecitabine or 5-FU) using modern techniques and central radiation therapy quality assurance. This trial seeks to evaluate the role of CRT in the era of modern chemotherapy, particularly in patients who do not experience early disease progression (https://clinicaltrials.gov/ct2/show/NCT01013649).

Neoadjuvant Therapy

Even after undergoing curative resection for pancreatic cancer, 80% to 85% of patients will recur. In addition, positive margins or nodal disease increases this rate of recurrence to approximately 90%.[67,100] The use of

neoadjuvant therapy offers an alternative approach to improve these figures for several reasons:

1. Approximately one-third of patients experience a significant delay or do not receive adjuvant therapy following upfront resection.[49,101,102]
2. Twenty percent to 40% of patients will be spared the morbidity of resection as their metastatic disease becomes clinically apparent during the course of neoadjuvant therapy.[103-105]
3. Preoperative therapy could theoretically be less toxic and more effective as the chemotherapy and radiation would be given without the postsurgical issues of small bowel in the radiation field, decreased oxygenation, and decreased drug delivery to the remaining tumor bed.[106,107]
4. Patients with local, borderline, and unresectable lesions may be able to be downstaged to allow for surgical resection and sterilization of the operative region, which potentially facilitates R0 resection and reduces the risk of spread during surgical manipulation.

Neoadjuvant Chemoradiation

The role of neoadjuvant CRT in resectable pancreatic lesions was first explored in phase II and retrospective studies.[108] At the MD Anderson Cancer Center, multiple trials of neoadjuvant CRT with a variety of radiosensitizers have been performed.[109-113]

A review of the Surveillance, Epidemiology, and End Results (SEER) database supports the use of neoadjuvant treatment. This analysis included 3,885 patients treated for resectable pancreatic cancer: 70 (2%) patients received neoadjuvant EBRT, 1,478 (38%) received adjuvant EBRT, and 2,337 (60%) were treated with surgery alone. Given that the SEER database does not provide information on administration of chemotherapy, this variable could not be assessed. mOS was 23 months in patients receiving neoadjuvant EBRT, 17 months with adjuvant EBRT, and 12 months in the surgery-alone cohort.[114]

More recently, randomized trials comparing neoadjuvant therapy followed by surgery to initial surgery with and without adjuvant therapy have been conducted. With respect to neoadjuvant chemoradiation, the first

RCT phase II study comparing immediate surgery (arm A) with surgery after neoadjuvant chemoradiotherapy (arm B) for (potentially) resectable tumors was reported.[115] Of note, the experimental arm started with chemoradiotherapy without induction chemotherapy. Simultaneous chemotherapy was gemcitabine 300 mg/m^2 and cisplatin (CDDP) 30 mg/m^2 weekly in weeks 1, 2, 4, and 5 of radiotherapy. Conventionally fractionated, 3DCRT included a tightly restricted elective nodal volume to a dose of 50.4 and 55.8 Gy to the tumor. The trial under-recruited (73/254 planned patients) with considerable impact on statistical power. However, an important finding is that neoadjuvant therapy was well tolerated with only 7% grade 4 leukopenia and 3% grade 4 thrombocytopenia. No grade 4 gastrointestinal toxicity was observed, but grade 3 nausea and vomiting was seen in 35%, which was attributed to CDDP. Resections were R0 in 67% versus 90% in arm A versus arm B. Postoperative complications were not more frequent after chemoradiotherapy compared with immediate surgery. At intention-to-treat (ITT) analysis, OS was not different; at per-protocol analysis, mOS was 18 versus 25 months in arm A versus arm B ($P > .05$). After chemoradiotherapy, a trend for fewer local recurrences as the first site of progression was observed. Four versus eight patients (arm A vs arm B) had distant metastasis between randomization and laparotomy.[116]

The phase III PREOPANC trial randomized patients with potentially resectable or borderline resectable pancreatic cancer to neoadjuvant gemcitabine and gemcitabine-based chemoradiation followed by surgery and 4 months of adjuvant gemcitabine or to upfront surgery and adjuvant chemotherapy.[117] Two hundred and forty-six eligible patients were randomly assigned; 119 were assigned to preoperative chemoradiotherapy and 127 to immediate surgery. mOS by ITT was 16.0 months with preoperative chemoradiotherapy and 14.3 months with immediate surgery (HR, 0.78; 95% CI, 0.58-1.05; $P = .096$). The resection rate was 61% and 72% ($P = .058$). The R0 resection rate was 71% (51/72) in patients who received preoperative chemoradiotherapy and 40% (37/92) in patients assigned to immediate surgery ($P < .001$). Preoperative chemoradiotherapy was associated with significantly better DFS and locoregional failure–free interval as well as with significantly lower rates of pathologic lymph nodes, perineural invasion, and venous invasion. Survival analysis of patients who underwent tumor resection and started adjuvant chemotherapy showed

improved survival with preoperative chemoradiotherapy (35.2 vs 19.8 months; *P* = .029). Although the difference in median survival was only 1.4 months (15.7 vs 14.3 months), the 5-year OS rate was 20.5% (95% CI, 14.2-29.8) with neoadjuvant chemoradiotherapy and 6.5% (95% CI, 3.1-13.7) with upfront surgery. The proportion of patients who suffered serious adverse events was 52% versus 41% (*P* = .096). Preoperative chemoradiotherapy for resectable or borderline resectable pancreatic cancer did not show a significant OS benefit. The consistent benefits for most secondary end points and the better compliance with preoperative chemoradiotherapy compared with postoperative adjuvant chemotherapy suggest superiority of the neoadjuvant approach. Long-term results of this study, at a median follow-up of 59 months, demonstrated improved overall survival of neoadjuvant combined modality therapy versus upfront surgery groups with a median survival of 15.7 versus 14.3 months, and 5-year overall survival rates of 20.5% versus 6.5%, which was consistent across prespecified subgroups including patients with resectable and borderline resectable pancreatic cancer, with the authors concluding neoadjuvant combined modality therapy followed by surgery and adjuvant gemcitabine patients with improved overall survival compared to upfront surgery and adjuvant gemcitabine in resectable and borderline resectable pancreatic cancer.[118]

Additionally, preliminary results of the PREOPANC-2 study have been presented. In this study, 375 patients with borderline or resectable pancreatic cancer were randomized to receive neoadjuvant FOLFIRINOX for eight cycles followed by surgery versus three cycles of neoadjuvant gemcitabine with hypofractionated radiation therapy (36 Gy/15 fractions during the second cycle), followed by surgery and four cycles of adjuvant gemcitabine. At a median follow-up of 41.7 months, median overall survival was 21.9 months in the FOLFIRINOX arm and 21.3 months in the combined modality therapy arm, with resection rates of 77% and 75%, respectively, and with significant adverse effect rates of 49% and 43%, respectively. The authors concluded that neoadjuvant chemotherapy with FOLFIRINOX did not improve overall survival compared to neoadjuvant gemcitabine-based chemoradiotherapy in these patients.[119]

Additionally, preliminary results of the CONKO-007 trial reported on 525 patients randomized to receive induction chemotherapy with

gemcitabine or FOLFIRINOX, then randomized to either continue chemotherapy or receive combined chemoradiation to a dose of 50.4 Gy with concurrent gemcitabine. The majority of patients received induction FOLFIRINOX. Following subsequent exclusion of 190 patients due to progression or toxicity after initial chemotherapy, the remainder were randomized. R0 and complete pathologic response rates were significantly higher in the combined modality therapy arm, although preliminary progression-free and overall survival rates did not differ.[120]

Neoadjuvant Chemotherapy

With recent data demonstrating the efficacy of combination chemotherapy in the metastatic setting, there has been interest to assess these agents in patients with potentially resectable disease. Several randomized trials have addressed the benefit of neoadjuvant chemotherapy without CRT in potentially resectable pancreatic cancer:

A prospective, randomized phase II trial (NEONAX) was conducted with 127 patients with resectable pancreatic cancer.[121] Patients were randomized to either perioperative (two preoperative and four postoperative cycles; arm A) or adjuvant (six cycles; arm B) gemcitabine (1,000 mg/m^2) and nab-paclitaxel (125 mg/m^2) on days 1, 8, and 15 of a 28-day cycle. The primary end point was DFS at 18 months in the modified ITT population (R0/R1-resected patients who started neoadjuvant chemotherapy [A] or adjuvant chemotherapy [B]). The predefined DFS rate of 55% at 18 months was not reached in both arms (A: 33.3% [95% CI 18.5%-48.1%], B: 41.4% [95% CI 20.7%-62.0%]). Ninety percent of patients in arm A completed neoadjuvant treatment, and 42% of patients in arm B started adjuvant chemotherapy. R0 resection rate was 88% (arm A) and 67% (arm B). mOS (ITT population) as a secondary end point was 25.5 months (95% CI 19.7-29.7 months) in arm A and 16.7 months (95% CI 11.6-22.2 months) in the upfront surgery arm. This difference corresponds to an mDFS (ITT) of 11.5 months (95% CI 8.8-14.5 months) in arm A and 5.9 months (95% CI 3.6-11.5 months) in arm B. Treatment was safe and well tolerable in both arms. Patients who received perioperative therapy were also more likely to be exposed to chemotherapy; a majority of these patients completed neoadjuvant treatment (90%) and approximately 42% also completed postoperative therapy, whereas less than

half of the patients assigned to postoperative therapy alone started treatment (42%).

A randomized phase II trial assigned 93 patients (88 eligible for analysis) to receive surgery followed by 6 months of single-agent adjuvant gemcitabine (group A); surgery followed by 6 months of adjuvant cisplatin, epirubicin, gemcitabine, and capecitabine (PEGX; group B); or three cycles of PEGX before and after surgery (group C).[122] At a median follow-up of 55 months, the event-free (defined as freedom from progression, relapse, new tumor occurrence, distant metastasis, or death) survival in group A was 23% (95% CI 7%-39%); in group B, it was 50% (95% CI 32%-68%); and in group C, it was 66% (95% CI 49%-83%). The corresponding values for 3-year survival were 35%, 43%, and 55%. The R0 resection rates were 27% and 37% in both the adjuvant therapy groups, while it was 63% in group C. The trial was initially conceived as a combined phase II/III trial, but it was decided not to continue with the phase III component for two reasons: because the standard of care for adjuvant therapy had changed and because of the existence of newer chemotherapy regimens for which the evidence supporting benefit, at least in the setting of metastatic disease, was stronger than that for the PEGX regimen.

The multicenter Japanese Prep-02/JSAP-05 trial randomly assigned 364 patients with potentially resectable pancreatic cancer to two preoperative courses of gemcitabine plus S-1 versus upfront surgery; patients in both groups who were completely resected and fully recovered by 10 weeks postoperation also received 6 months of therapy with S-1 alone.[123] In a preliminary report, despite no improvement in overall and R0 resection rates, patients receiving neoadjuvant chemotherapy had significantly longer mOS (36.7 vs 26.6 months).

The Southwest Oncology Group (SWOG) phase II study compared neoadjuvant gemcitabine and nab-paclitaxel to modified 5-FU, LV, and irinotecan (m-FOLFIRNOX) for resectable pancreatic adenocarcinoma.[124] Two-year OS, the primary end point, was 47% with FOLFIRINOX and 48% with gemcitabine and nab-paclitaxel. Neither arm met the prespecified end point (58% of 2-year survival). Interpretation of these results is limited by the high rate of ineligibility after central radiologic review (44/147 enrolled patients). The ESPAC-5 trial randomized patients with borderline resectable pancreatic cancer to immediate surgery, neoadjuvant

gemcitabine/capecitabine for two cycles, neoadjuvant FOLFIRINOX for four cycles, or neoadjuvant capecitabine-based chemoradiation (50.4 Gy). Ninety patients were randomly assigned. Recruitment for this trial was described as challenging, although there was no significant difference in resection rates in patients who underwent immediate surgery versus those who underwent neoadjuvant therapy. However, there was a significant survival benefit (compared to immediate surgery) with neoadjuvant therapy, with the neoadjuvant chemotherapy-alone groups having the best survival compared to immediate surgery, supporting the use of short course neoadjuvant therapy in patients with borderline resectable pancreatic ductal adenocarcinoma.[125]

Therapy for Locally Advanced Carcinoma

Approximately 30% of patients present with locally advanced carcinoma of the pancreas, constituting a group of patients with an intermediate prognosis between resectable and metastatic disease. These patients have pancreatic tumors that are defined as surgically unresectable but have no evidence of distant metastases. A tumor is usually considered to be unresectable if it has one of the following features:

- Distant metastases
- Encasement or occlusion of the SMV or SMV/portal or vein confluence that is not amenable to reconstruction, contact with the most proximal draining jejunal branch into the SMV
- 180° or more involvement of the SMA, celiac axis, first jejunal SMA branch, or aorta or celiac axis involvement with a body or tail lesion

Recent advances in surgical technique allow for resection of selected patients with tumors involving the SMV.[41,115] Treatment with radiation and chemotherapy increases median survival for patients with locally advanced cancers to approximately 8 to 14 months but rarely results in long-term survival. The therapeutic options for patients with locally advanced pancreatic cancer include chemotherapy alone, CRT (with dose escalation), intraoperative radiotherapy (IORT), and stereotactic body radiation therapy (SBRT). In evaluating the results of these various therapies, it is useful to

remember that a median survival of 3 to 6 months has been reported for this subset of patients undergoing palliative gastric or biliary bypass only.[126]

PROSPECTIVE TRIALS

Prospective trials have evaluated the role of EBRT versus CRT, variations in CRT regimens, and CRT versus chemotherapy alone (Table 65.5). The Mayo Clinic undertook an early randomized trial in the 1960s in which 64 patients with locally unresectable, nonmetastatic stomach, large bowel, and pancreas adenocarcinoma received 35 to 40 Gy of EBRT alone or with concurrent bolus 5-FU (45 mg/kg). A significant survival advantage was seen for patients receiving EBRT with 5-FU versus EBRT only (10.4 vs 6.3 months).[127]

TABLE 65.5 PROSPECTIVE RANDOMIZED TRIALS FOR LOCALLY ADVANCED, UNRESECTABLE PANCREATIC CANCER

Series (Reference)	Number of Patients	Median Survival (Month)	Local Progression (%)	1-Y (%)	18-Mo (est %)
EBRT vs CRT

Chemotherapy, then EBRT+ capecitabine	133	15.2	32		

5-FU, 5-flurouracil; CDDP, neoadjuvant cisplatin; CRT, chemoradiation; EBRT, external beam radiation therapy; ECOG, Eastern Cooperative Oncology Group; FFCD/SFRO, Fédération Francophone de Cancérologie Digestive/Société Francophone de Radiothérapie Oncologique; GITSG, Gastrointestinal Tumor Study Group; LAP, locally advanced pancreas; MMC, mitomycin-C; NA, not available; SMF, streptozocin, mitomycin-C, and 5-flurouracil.

The GITSG followed with a similar study comparing EBRT alone to EBRT with concurrent and maintenance 5-FU. One hundred and ninety-four eligible patients with surgically confirmed unresectable and nonmetastatic pancreatic adenocarcinoma were randomized to receive 60-Gy split-course EBRT alone, 40-Gy split-course EBRT with two to three cycles of concurrent bolus 5-FU chemotherapy (500 mg/m^2), or 60-Gy split-course EBRT using a similar chemotherapy regimen. Patients in the latter groups received 2 years' maintenance 5-FU (500 mg/m^2) after EBRT completion. The EBRT-alone arm was closed early as a result of an inferior survival rate. The 1-year survival rate in the two combined modality therapy arms was roughly 40% (with no statistical difference between CRT arms) versus 11% in the EBRT-alone arm.[128]

The Eastern Oncology Group's trial ECOG-8282 randomized 114 patients to EBRT alone (59.4 Gy) with or without continuous infusion 5-FU (1,000 mg/m^2/day) on days 2 to 5 and 28 to 31 and mitomycin-C (10 mg/m^2) on day 2. There was no difference in response rates, DFS, or OS with the addition of concurrent chemotherapy. Higher rates of toxicity, primarily hematologic, were noted in the CRT group.[129]

Further studies sought to determine a more efficacious CRT regimen. A second GITSG trial randomized 157 and analyzed results for 143 eligible patients with unresectable disease to 60-Gy split-course EBRT with concurrent and maintenance 5-FU (500 mg/m^2) (as in the prior GITSG trial) or 40-Gy continuous course radiation with weekly, concurrent doxorubicin chemotherapy (10 mg/m^2), followed by maintenance doxorubicin and 5-FU. A significant increase in treatment-related toxicity was seen in the

doxorubicin arm, with no survival difference observed between the two groups (median survival 8.5 vs 7.6 months). No clinical benefit was seen in substituting doxorubicin for 5-FU.[130]

As studies emerged demonstrating significant survival advantages with gemcitabine-based chemotherapy in the metastatic setting, it was incorporated into the locally advanced setting. A trial from Taipei randomized 34 patients to EBRT with concurrent 5-FU (500 mg/m^2) or gemcitabine (600 mg/m^2). Patients received 50.4- to 61.2-Gy EBRT and maintenance gemcitabine (1,000 mg/m^2) at the completion of CRT. mOS and time to progression were prolonged in the gemcitabine arm: 14.5 and 7.1 months (gemcitabine) versus 6.7 and 2.7 months (5-FU). There were no observed differences in grade 3 or 4 toxicity or hospitalization days between the two arms. Study criticisms include the small number of patients and relatively poor outcomes in the 5-FU arm compared with historical controls.[131]

A number of trials have compared CRT with chemotherapy alone. A subsequent GITSG trial compared combination streptozocin, mitomycin-C, and 5-FU (SMF) chemotherapy to chemoradiation with 5-FU. Forty-three patients were randomized to receive SMF chemotherapy or 54 Gy of EBRT with two cycles of concurrent bolus 5-FU chemotherapy followed by adjuvant SMF chemotherapy. The chemoradiation arm demonstrated a significant survival advantage over the chemotherapy-alone arm (1-year survival 41% vs 19%).[132]

In contrast, the ECOG reported no benefit to chemoradiation versus chemotherapy only. In this study, 191 patients with unresectable, nonmetastatic pancreatic or gastric adenocarcinoma were randomized to receive either 5-FU chemotherapy (600 mg/m^2) alone or 40-Gy EBRT with concurrent bolus 5-FU during week 1 (600 mg/m^2) followed by maintenance chemotherapy. Patients with locally recurrent disease as well as patients undergoing surgery with residual disease were eligible for this trial. In the 91 patients with pancreatic cancer eligible for analysis, no survival difference was observed between the two groups (median survival 8.2 vs 8.3 months).[134]

The FFCD/SFRO trial randomized 119 patients to CRT consisting of 60 Gy EBRT with continuous infusion 5-FU (300 mg/m^2/day) on days 1 to 5 for 6 weeks and intermittent CDDP (20 mg/m^2/day) on days 1 to 5 in weeks

1 and 5 with maintenance gemcitabine (1,000 mg/m^2) versus gemcitabine alone (1,000 mg/m^2). Survival was inferior in the CRT arm at 8.6 months compared with 13 months with gemcitabine alone. Higher grade 3 or 4 toxicity rates were observed in the CRT arm during CRT (36% vs 22%) and maintenance chemotherapy phases (32% vs 18%). This trial closed early because of poor accrual. Many criticize the inferior survival in the CRT arm, which is similar to early GITSG trials, despite use of continuous infusion chemotherapy and modern EBRT techniques.[135]

The ECOG published results from a randomized trial of CRT (50.4 Gy with concurrent gemcitabine: 600 mg/m^2/week, weeks 1-5) versus gemcitabine alone (1,000 mg/m^2/week). The trial closed early because of poor accrual. Analysis of the eligible, randomized 71 patients demonstrated no difference in progression-free survival (PFS); however, a survival benefit was seen in the CRT arm: 11.1 versus 9.2 months. This benefit came at the expense of higher grade 4 or 5 toxicity rates in the CRT arm (mainly hematologic) but with no difference in QoL.[136]

A multicenter phase II study, the SCALOP trial, evaluated the role of gemcitabine-based or capecitabine-based CRT. All patients received 12 weeks of induction gemcitabine and capecitabine chemotherapy. Seventy-four patients were randomized, and mOS in the capecitabine group was 15.2 months compared with 13.4 months in the gemcitabine arm (P = .012). More patients in the gemcitabine group than in the capecitabine group had grade 3 to 4 hematologic toxicity and grade 3 to 4 nonhematologic toxicity during CRT. These data suggest that concurrent capecitabine-based CRT may be preferable to gemcitabine-based CRT.[138]

The Locally Advanced Pancreas Cancer 07 (LAP07) trial initially randomized all patients to gemcitabine or gemcitabine and erlotinib for 4 months. A second randomization was performed in patients with no evidence of progression to continuation of chemotherapy for an additional 2 months or chemoradiation. The primary study end point was OS. A total of 442 patients underwent the first randomization and 269 patients underwent the second randomization. Interim analysis was performed after 221 patients died and early stopping rules for futility were reached. The mOS was 16.5 months for patient receiving systemic therapy and 15.2 months in the cohort receiving chemoradiation. Chemoradiation was associated with decreased local progression from 46% to 32% (P = .03)[138] and median delay

to treatment reintroduction was 6.1 months (95% CI, 4.8-7.0 months) for the chemoradiotherapy group, significantly longer than the 3.7 months (95% CI, 3.0-4.6) for the chemotherapy group ($P = .02$). Some authors have critiqued the older chemotherapy regimen of gemcitabine alone, which has now largely been replaced with combination systemic therapies such as gemcitabine/nab-paclitaxel and m-FOLFIRINOX. In addition, QoL analyses were not performed, which could have demonstrated a clinically meaningful difference between the arms.

With the publication of LAP07, many consider upfront chemotherapy with subsequent response assessment and directed radiation therapy (CRT, SBRT) to facilitate selection of patients most likely to benefit from locoregional therapy as the current standard of care.

Borderline Resectable Disease

As surgery of the primary tumor remains the only potentially curative treatment for pancreatic cancer, neoadjuvant therapy has been evaluated to assess its ability to convert locally unresectable pancreatic cancer to resectable disease. Although the definition of borderline resectable disease is contentious, there are some consensus guidelines (see Table 65.2). Approximately 30% of patients with borderline resectable disease become resectable after neoadjuvant therapy.[139,140] Similarly, there appears to be higher rates of local control, R0 resection, and N0 disease in this patient subset after neoadjuvant therapy.[141-144]

A number of single-institution retrospective studies have evaluated this patient subset. An early study from the MD Anderson Cancer Center assessed 160 patients with borderline resectable disease. Patients received 50.4 Gy in 28 fractions or 30 Gy in 10 fractions with concurrent 5-FU, paclitaxel, gemcitabine, or capecitabine at radiosensitizing doses. Forty-one percent underwent pancreatectomy with margin-negative resection in 94%. Median survival in the 66 patients who completed preoperative therapy and surgery was 44 months, comparable to patients with initially resectable disease.[142]

A review from Fox Chase Cancer Center evaluated 109 patients who underwent resection of pancreatic adenocarcinoma with varying involvement of the portal vein or SMV as determined by CT. Patients

received 5-FU or gemcitabine-based CRT. Median survival in the 74 patients who received preoperative therapy was 23 months compared with 15 months in the cohort undergoing upfront surgery. Preoperative CRT was associated with a higher rate of R0 resection and N0 disease.[143]

A smaller series from the University of Virginia reviewed the outcomes of 40 patients with borderline resectable disease. Patients received 50.4 Gy in 28 fractions or 50 Gy in 20 fractions with concurrent capecitabine. Forty-six percent of patients underwent surgery, with 75% undergoing an R0 resection. Patients undergoing surgery after neoadjuvant treatment had similar median survival rates as patients undergoing upfront surgery.[144]

The ECOG initiated a randomized phase II study of two neoadjuvant gemcitabine-containing regimens in patients with potentially resectable cancer. Patients received 50.4-Gy EBRT with weekly gemcitabine (500 mg/m^2) or induction chemotherapy with gemcitabine (175 mg/m^2), CDDP (20 mg/m^2), and 5-FU (600 mg/m^2) prior to CRT with 5-FU (225 mg/m^2). All patients received adjuvant gemcitabine (1,000 mg/m^2). This trial, the only randomized trial of borderline resectable pancreatic cancer, closed early because of poor accrual with 21 patients.[145] Although the subject of ongoing study, an approach utilizing neoadjuvant chemoradiotherapy in patients with borderline resectable disease, in efforts to facilitate R0 resection, seems appropriate.

A systematic review and meta-analysis was performed of 18 studies with neoadjuvant chemotherapy or CRT with a total of 959 patients evaluating post-treatment response rates. The following response rates were achieved: complete response, partial response, stable disease, and progressive disease were observed in 2.8%, 28.7%, 45.9%, and 16.9%, respectively. The weighted frequency of resected patients was 65.3% who achieved an mOS of 25.9 months. In contrast, patients without resection had an mOS of 11.9 months and the total group of 17.9 months.[146]

DOSE ESCALATION

Given the limited tolerance of normal tissue in the upper abdomen (liver, kidney, spinal cord, and bowel) to EBRT, total doses of only 45 to 54 Gy in 25 to 30 Gy fractions have traditionally been administered. For an unresectable tumor, this dose of radiation is inadequate, as demonstrated by

the high rates of local tumor progression and poor survival seen in both prospective and retrospective studies. Local progression as the first site of failure occurred in 58% of patients treated to 60 Gy with concurrent 5-FU in the second GITSG trial.[130] Similarly, the Mayo Clinic reported a local recurrence rate of 72% for 122 patients with unresectable pancreatic cancer treated with an EBRT dose of 40 to 60 Gy.[147] Attempts have been made to evaluate whether increasing dose of radiation may improve outcomes through 3DCRT, IORT, IMRT, and SBRT.

In a report from Thomas Jefferson University Hospital, 46 evaluable patients with unresectable disease by laparotomy were treated with 63- to 70-Gy EBRT with or without chemotherapy. Despite high-dose EBRT, the local recurrence rate was 78%.[148]

IORT is an alternative method to deliver higher radiation doses. This technique allows for administration of a single high dose of radiotherapy with the advantage of enabling healthy tissues to be displaced and shielded from radiation. IORT has been utilized postoperatively and in the treatment of locally advanced disease. Institutional reports and a randomized trial have shown that surgery followed by IORT yields lower rates of locoregional recurrence; however, no significant difference in survival has been seen.[149-152] IORT has also been evaluated in patients with unresectable disease.[153,154] A study from investigators at Massachusetts General Hospital reported the results of 150 patients with unresectable pancreatic cancer treated with IORT, EBRT, and chemotherapy. Although the study spanned nearly 25 years, it demonstrated that long-term survival is possible for patients with unresectable pancreatic cancer. Furthermore, this study shows that postoperative and late treatment-related toxicity rates were acceptable.[154,155] A lower incidence of local recurrence in most series and improved median survival in some have been reported with these techniques when compared with conventional external beam irradiation, but it is uncertain whether this is due to treatment superiority or case selection.[147]

Advances in radiation technique and delivery, such as IMRT and SBRT, also enable dose escalation and potential sparing of normal tissues. IMRT is a technique that breaks up a typical radiation treatment field into smaller beamlets. It is implemented either as dynamic IMRT (collimating leaves move in and out of the radiation beam path during treatment) or as “step-

and-shoot" IMRT (leaves change field shape while the machine is off). The cumulative effect is that the prescription dose conforms around delineated target volumes, significantly reducing doses to adjacent normal tissues. This technology has increasingly been used in a number of gastrointestinal malignancies, including pancreatic cancer. Early clinical data support both the feasibility of this technique and its potential for reducing acute gastrointestinal toxicity.[156-158]

An analysis from the University of Maryland evaluated 46 patients treated with IMRT and concurrent 5-FU–based chemotherapy. Acute toxicities in these patients were compared with those in a control group enrolled in RTOG-9704 who received conventional 3D treatment. There was a statistically significant reduction in acute grade 3 or 4 gastrointestinal toxicity in the patients who received radiotherapy via IMRT compared with those who received 3DCRT.[158] IMRT can also result in a significant reduction of dose to normal structures, including the liver, kidneys, stomach, and small bowel.[157] This may allow alternate novel systemic agents to be administered with radiotherapy.[156]

Although IMRT can reduce the dose to surrounding normal tissues, it also allows the opportunity for dose escalation. A phase I/II study by Ben-Josef et al attempted to define the maximum tolerated radiation dose via IMRT in combination with gemcitabine for unresectable pancreas cancer. Fifty patients were accrued and dose-limiting toxicity was seen at 55 Gy. Median survival was 14.8 months, and 12 patients subsequently underwent resection.[159]

Another technique for dose escalation in the treatment of pancreatic cancers is SBRT, which involves the delivery of high dose per fraction radiation treatments over a small number of fractions (generally 1-5 treatments), utilizing techniques that allow very highly conformal dose delivery of EBRT. The postulated advantage of SBRT is potentially improving local control through the delivery of ablative doses of radiation while minimizing associated side effects (Figure 65.4). Early experience and data using this technique are in the setting of locally advanced disease.[160,161] Stanford University investigators initially implemented an institutional protocol for the treatment of locally advanced pancreatic cancer using a 25-Gy single fraction with systemic therapy. This single, high dose of radiation has been estimated to result in delivery of a higher

biologically equivalent dose compared with a more standard, protracted course of radiation therapy, albeit at the potential for increased risk of normal tissue injury. A report from these investigators described 77 patients who were treated with SBRT and found that freedom from local progression was 91% at 6 months and 84% at 12 months. No patients experienced grade 3 acute toxicity, and 9% had grade 3 or higher late toxicity.[161]

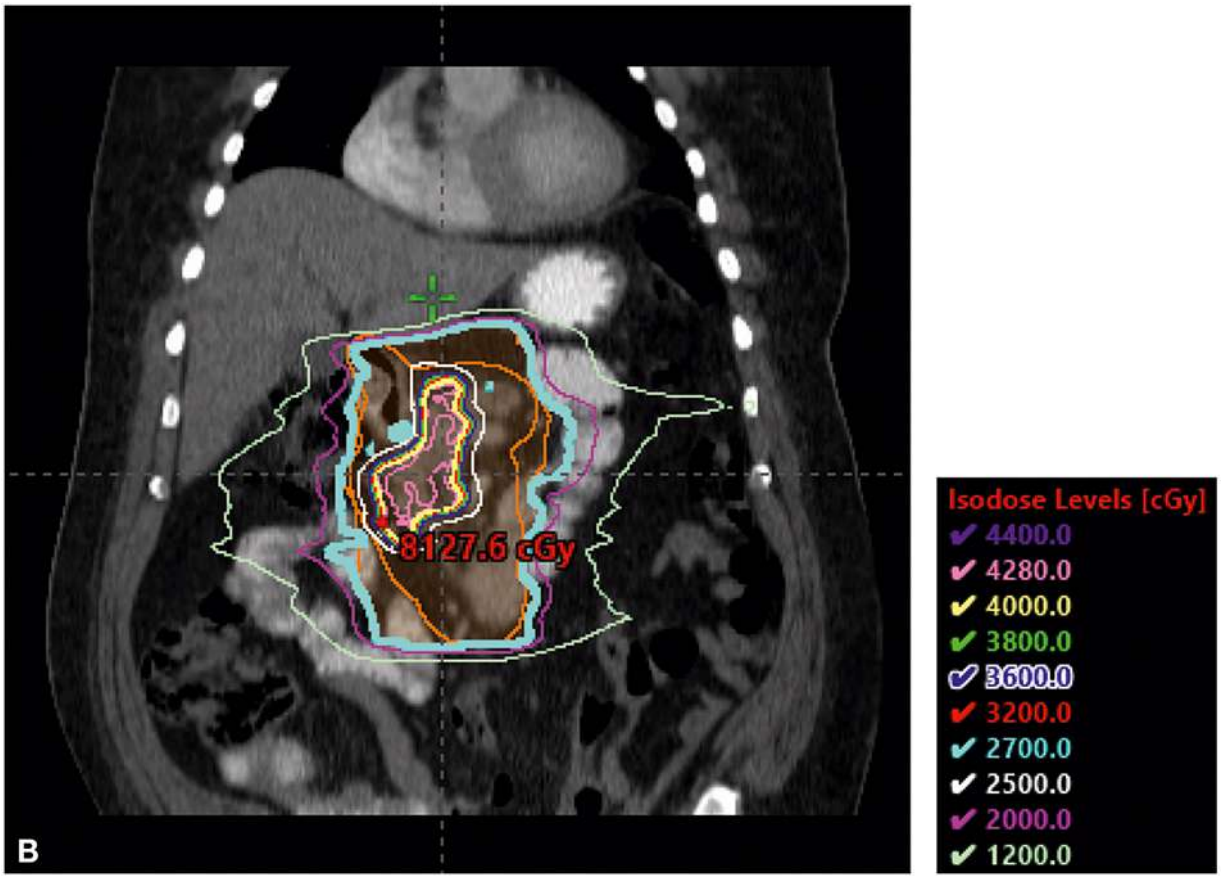

FIGURE 65.4 A. Example of SBRT in a 66-year-old female with locally advanced disease following induction chemotherapy. Note relative isodoses, utilizing a simultaneous integrated boost technique, with total prescription dose of 40 Gy in five fractions to the primary disease, delivering 25 Gy in five fractions to subclinical basins. B. Patient with medically inoperable pancreatic cancer undergoing dose escalating combined modality therapy, utilizing an SIB approach, delivering 45 Gy to subclinical volume and 75 Gy to gross disease, all in 25 fractions.

Based on these data, a prospective, multi-institutional phase II study was conducted utilizing five-fraction SBRT with primary end point to achieve a lower rate of late grade 2+ toxicity than with single-fraction SBRT. Forty-nine patients received up to three doses of gemcitabine followed by 33 Gy in five fractions. The rate of grade 2+ late toxicity was 11% and 1-year freedom from local progression was 78%. Four patients (8%) subsequently underwent a margin-negative resection.[162]

A meta-analysis of 19 studies encompassing over 1,000 patients treated with SBRT demonstrated a 1-year local control rate of 72%. The rate of acute grade 3+ toxicity ranged from 0% to 36%, and the rate of late grade

3+ toxicity did not exceed 11%.[163] Select series have demonstrated high rates of margin-negative resection in patients with borderline and unresectable pancreas cancer who ultimately underwent surgical resection.[164,165]

The ALLIANCE A021501 randomized 126 patients with borderline resectable pancreatic cancer to neoadjuvant m-FOLFIRINOX with or without hypofractionated radiation therapy with historical data and established standards for therapy.[166] Among the first 30 evaluable patients enrolled to each arm, 17 (57%) patients in arm 1 and 10 (33%) patients in arm 2 had undergone R0 resection, leading to closure of arm 2 but continuation to full enrollment in arm 1. The 18-month OS rate of evaluable patients was 66.7% (95% CI, 56.1%-79.4%) in arm 1 and 47.3% (95% CI 35.8%-62.5%) in arm 2. The mOS of evaluable patients in arm 1 and arm 2 was 29.8 (95% CI, 21.1-36.6) months and 17.1 (95% CI, 12.8-24.4) months, respectively. The authors concluded that m-FOLFIRINOX represents a reference regimen in this setting. This trial is problematic in that the study was not statistically powered to compare FOLFIRINOX with or without radiation therapy, imbalance in certain prognostic features between the two arms such as the median CA19-9 was higher in the SBRT arm versus the chemotherapy-only arm, and both arms had lower rates of pancreatectomy (35%-49%) compared with the results (84%-97%) of high-volume centers. A multicenter phase II trial evaluated SBRT in patients with borderline resectable and locally advanced cancers, utilizing an MRI-guided approach. One hundred thirty six patients were enrolled after receiving induction chemotherapy. 50 Gy was delivered in 5 fractions, with elective nodal coverage optional. At a median followup of 14 months from radiation, 2-year overall survival was 41%, with acceptable rates of toxicity. The authors concluded that trial results were encouraging with limited toxicity rates, and additional investigation warranted.[167]

Another series of 119 consecutive patients were treated with ablative radiation therapy using hypofractionated approach, using an ablative radiation dose (98 Gy biologic effective dose). Most patients were treated following induction chemotherapy for a median of 4 months. Median survival following radiation treatment was 18.4 months with 2-year survival at 38%, with 2-year local regional failure rate of 18%. The authors

concluded that this approach was associated with a durable local regional tumor control and favorable survival.[168]

Ultimately, the role of IMRT and SBRT as well as integration with systemic therapy are ongoing areas of active investigation in these patients.

CHEMORADIATION EFFECTS ON QUALITY OF LIFE

Pain, anorexia, fatigue, and cachexia are relatively common symptoms, which significantly impact a patient's QoL. When using EBRT with or without chemotherapy, approximately 35% to 65% of patients will experience pain resolution as well as some improvement in cachexia and obstructive symptoms.[130,169,170] Definite but less dramatic improvements in performance status and anorexia may be observed as well.[169,170] Patient-reported QoL with SBRT in unresectable pancreas cancer demonstrates no change in QoL at pretreatment compared with 1-month follow-up but statistical and clinical improvements in pancreatic pain and body image at 1 month.[171] Palliation from therapy can take many weeks for maximal effect, and alternative treatments, such as biliary and duodenal stents, may provide more rapid relief of obstructive symptoms. Given the high mortality rate associated with pancreatic cancer, QoL should be a study end point in trials for these patients.

TARGETED THERAPIES AND FUTURE DIRECTIONS

There is much room for improvement in the diagnosis and treatment of pancreatic cancer. Screening of high-risk individuals may allow for the detection of disease in earlier disease stages by means of novel imaging methods or assessment of serum biomarkers.[172,173] As the biologic basis of cancer is better understood, the successful use of cancer-specific targeted therapies in other cancers supports the need to identify new targets and better predictors of response to therapy in pancreatic cancer.

There is evidence of additive or synergistic effects for several targeted agents (such as antibodies against epithelial growth factor receptor [EGFR] and vascular endothelial growth factor [VEGF] receptor) with both chemotherapy and radiation therapy, making these topics of investigation. These targeted agents have been studied most extensively in the metastatic setting prior to evaluation in locally advanced and resectable disease.

Currently, the only targeted agent that has shown a modest statistically significant survival benefit in the metastatic setting compared with chemotherapy alone is erlotinib, an anti-EGFR tyrosine kinase inhibitor. However, the survival benefit with the addition of erlotinib is small, with median survival increased from 5.9 to 6.2 months and 1-year survival improvement from 17% to 24%.[174] The clinical significance of this difference has been questioned by investigators and treating physicians.

Another EGFR/*HER-1* inhibitor, cetuximab, initially showed promising phase II results in the metastatic setting. Efficacy was initially seen with the combination of cetuximab and EBRT in the treatment of locally advanced squamous cell carcinoma of the head and neck and subsequently tested in a phase III trial.[175] However, in pancreatic cancer, a phase III randomized study of gemcitabine plus cetuximab versus gemcitabine plus placebo (SWOG S0205) as first-line therapy in locally advanced, unresectable, or metastatic disease enrolled over 700 patients from the United States and Canada. No survival improvement was seen with the addition of cetuximab to gemcitabine (6.3 months gemcitabine plus cetuximab vs 5.9 months gemcitabine alone). Even among patients tested for EGFR expression (90% of specimens positive for expression), no benefit to cetuximab was seen in this patient subgroup.[176] An additional phase II study evaluated the efficacy and safety of multiagent chemotherapy in combination with cetuximab. Sixty-nine patients with locally advanced pancreatic cancer received cetuximab, gemcitabine, and oxaliplatin followed by cetuximab, capecitabine, and radiotherapy. Diagnostic cytology specimens were stained for Smad4 (Dpc4) expression. mOS was 19.2 months, and the pattern of failure for patients with Smad4 (Dpc4) expression was primarily local, rather than distant, disease failure.[177] The addition of EGFR inhibitors in localized disease is currently being evaluated in phase I and phase II trials.

VEGF inhibitors bind to receptors involved in tumor growth via vasculogenesis and angiogenesis pathways. Preclinical data have shown that inhibition of VEGF has radiosensitizing effects. Initially, promising results in the metastatic setting, however, have ultimately not shown a benefit from the addition of an anti-VEGF antibody to chemotherapy. A phase II trial of the combination of gemcitabine and bevacizumab in 52 treated patients with advanced pancreatic cancer showed a response rate of 21%, a median PFS of 5.4 months, and mOS of 8.8 months.[178] In response

to these positive results, a phase III randomized study of gemcitabine plus bevacizumab versus placebo (Cancer and Leukemia Group B CALGB-80303) was initiated. No significant difference was observed in OS or PFS.[179] Bevacizumab has also been evaluated in combination with radiotherapy. An initial phase I study of radiotherapy, capecitabine, and bevacizumab led to incorporation in the phase II setting in patients with locally advanced pancreatic cancer (RTOG-0411).[180] Eighty-two patients were treated with radiotherapy to the gross tumor, capecitabine (825 mg/m^2), and bevacizumab (5 mg/kg on days 1, 15, 29), followed by adjuvant gemcitabine (1,000 mg/m^2). The median and 1-year survival rates were 11.9 months and 47%, respectively. These results were similar to prior RTOG trials of locally advanced pancreatic cancer.[181] An additional phase II trial assessed the efficacy of full-dose gemcitabine (1,000 mg/m^2), bevacizumab (10 mg/kg), and radiotherapy to 36 Gy (in 2.4 Gy fractions) with maintenance gemcitabine and bevacizumab in patients with unresected tumors with no evidence of disease progression. Median PFS and OS were 9.9 and 11.8 months, respectively.[182] The incorporation of bevacizumab with radiotherapy has not led to profound improvements in treatment outcomes compared with 5-FU–based CRT.

Although improvements with targeted agents have been modest, other pathways are being evaluated. Pancreatic cells deficient in *BRCA* repair pathways are sensitive to poly-adenosine diphosphate-ribose polymerase (PARP) inhibitors. PARP inhibitors have been evaluated in ovarian and breast cancer, with response rates of 40%. Clinical trials of PARP inhibitors in the treatment of patients with pancreatic cancer are underway.[7,183] Other therapeutic agents under evaluation include hedgehog pathway inhibitors, multikinase inhibitors (sorafenib), and agents targeting v-src sarcoma, γ-secretase, stem cell factor receptor (c-kit), secreted protein acidic and rich in cysteine, mitogen-activated protein kinase, mesothelin, *RAS*, prostate stem cell antigen, tumor necrosis factor-α, mucin-1, mammalian target of rapamycin, tumor necrosis factor superfamily member 10, and type 1 insulin-like growth factor receptor.[7,184]

There is growing interest in immunotherapies to target the heterogeneous pancreas tumor and immunosuppressive microenvironment. A number of clinical trials in pancreas cancer alone or advanced solid tumors have been completed or ongoing evaluating the role of immune checkpoint

monotherapy, dual checkpoint blockade, immune checkpoint in combination with vaccine therapy, and in combination with cytotoxic and other systemic therapies.[185,186]

SUMMARY

Treatment of pancreatic cancer remains a challenge in oncology. Despite advances in many aspects of oncologic evaluation and management, including preoperative evaluation, surgical techniques, perioperative care, systemic therapy, and radiotherapy, the 5-year OS rate for patients with resectable pancreatic cancer remains around 20%. Local tumor control has been improved by the use of specialized radiation techniques, allowing safe dose escalation. Even with these techniques, it is not clear that a survival benefit is achieved given the proclivity of metastases in this malignancy. Similarly, even in patients with metastatic disease, morbidity and mortality associated with locoregional progression remain a major cause of morbidity and mortality. Further advances in systemic therapies, study of the optimal sequencing of therapies, earlier detection of disease, and development of new and novel therapeutic options are urgently needed in the treatment of this formidable disease. QoL should be considered a paramount end point in the care and protocol design of clinical trials for these patients. Significant improvements in long-term survival will likely be achieved through ongoing attempts at the exploitation of the malignancy's basic biologic anomalies.

CHAPTER 66

Cancer of the Liver and Hepatobiliary Tract

Jia-Shing Wu, Huei-Chuang Yeh, and Andrew T. Huang

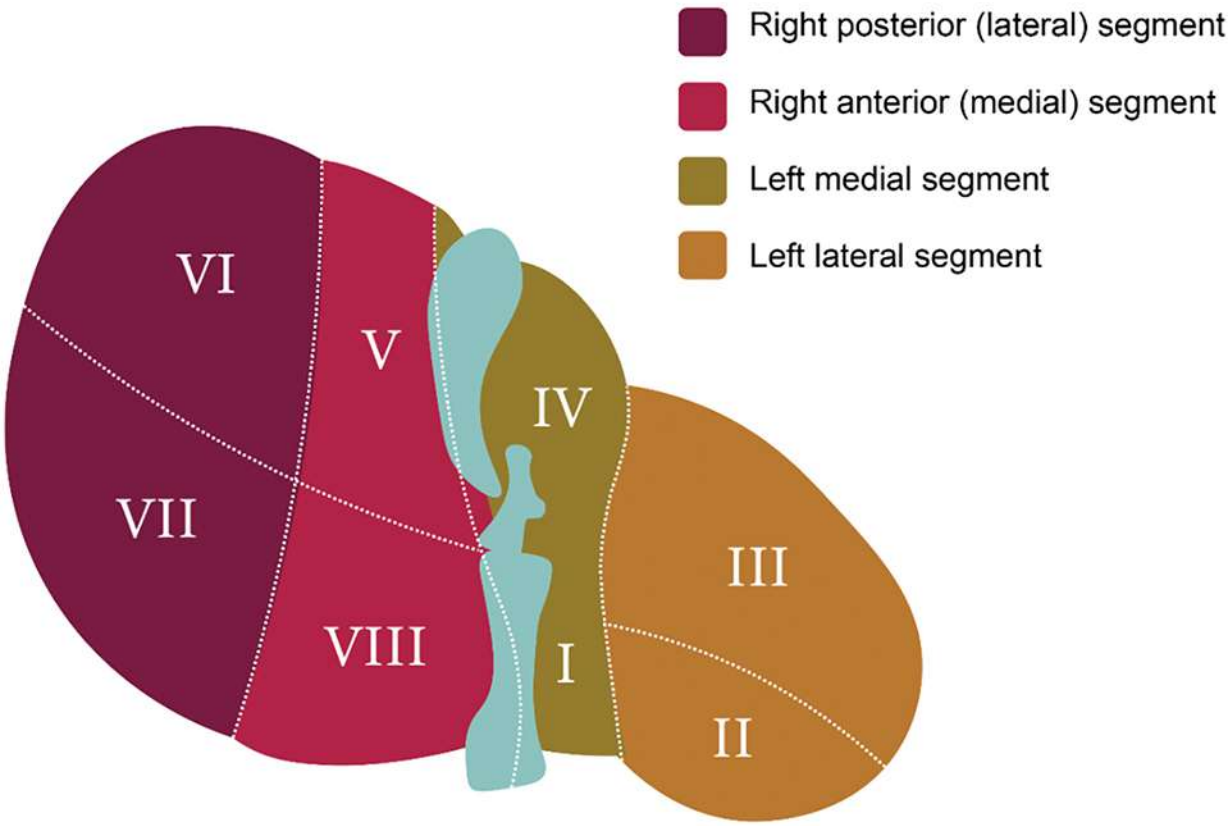
Liver and hepatobiliary malignancies are cancers that arise from the liver or extrahepatic biliary tract. Hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (ICC) are the most common primary liver cancers. Other primary liver cancers include combined hepatocellular carcinoma-cholangiocarcinoma (cHCC-ICC), along with rarer neoplasms such as sarcoma, neuroendocrine tumor, and hepatoblastoma. Gallbladder cancer and extrahepatic cholangiocarcinoma arise from outside the liver. The 2019 fifth edition of the World Health Organization (WHO) classification of digestive system tumors divides tumors of the liver and intrahepatic bile ducts into benign hepatocellular tumors (focal nodular hyperplasia and hepatocellular adenoma), malignant hepatocellular tumors and precursors (including HCC and hepatoblastoma), benign biliary tumors and precursors (bile duct adenoma, biliary adenofibroma, mucinous cystic neoplasm of the liver and biliary system, and intraductal papillary neoplasm of the bile ducts), malignant biliary tumors (ICC), combined hepatocellular-cholangiocarcinoma and undifferentiated primary liver carcinoma, and hepatic neuroendocrine neoplasms.[1] This chapter focuses on malignant tumors of the liver and hepatobiliary tract, particularly HCC and cholangiocarcinoma.

PRIMARY LIVER CANCER

Topographic Anatomy

The liver is the largest solid organ in humans. Traditionally, it is divided into left and right lobes. Surgeons need to understand the spatial relationship of a tumor to the hepatic vascular system preoperatively to determine resectability. Fortunately, progress in imaging modalities has made feasible the segmental division of the liver based on the anatomy of the portal and hepatic veins. The most used segmentation scheme, which was proposed by Couinaud, divides the liver parenchyma into right and left livers with four segments each (Figure 66.1). The anatomic landmark that separates the left and right liver is drawn between the gallbladder fossa and the inferior vena cava, to the right of the falciform ligament. The left liver consists of the caudate lobe (segment I), lateral segment (segments II and III), and medial segment (segment IV). The anatomic landmark that separates the left medial and lateral segments is the left hepatic vein. The right liver consists of the anterior segments (segments V and VIII) and posterior segments (segments VI and VII). The anatomic landmark that separates the anterior segment from the posterior segment is the right hepatic vein, while the one separating the anterior segment from the left medial segment is the middle hepatic vein. Dynamic computed tomography (CT) and magnetic resonance imaging (MRI) are useful for distinctly defining segmental anatomy as the portal vein, hepatic vein, and inferior vena cava can be demonstrated well within the same study.[2]

Liver segments



Inferior view

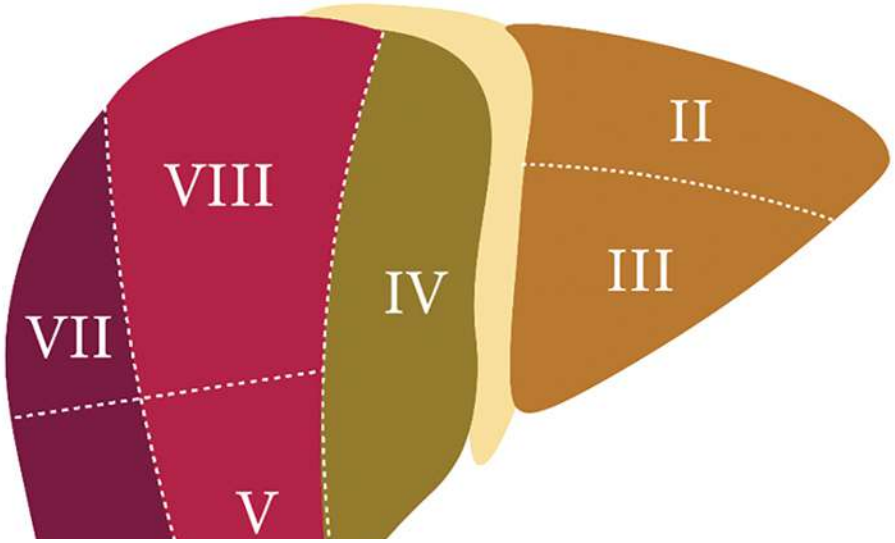


FIGURE 66.1 Segmentation scheme of the liver proposed by Couinaud.

Epidemiology

Primary liver tumor is the fifth most commonly diagnosed cancer and the second most common cause of cancer death globally.[3] It is reported to be the most frequently diagnosed cancer in six countries (Cambodia, Egypt, Laos, Mongolia, Thailand, and Vietnam) and the most common cause of cancer death in 15 countries (Burkina Faso, Cambodia, Egypt, Gabon, Gambia, Ghana, Guatemala, Laos, Mongolia, Nicaragua, Republic of Congo, the Solomon Islands, Thailand, Vanuatu, and Vietnam).[4] It is also among the top three causes of cancer death in 46 countries and among the top five causes of cancer death in 90 countries.[4]

Worldwide, there were 905,700 patients with liver cancer and 830,200 patients who died of liver cancer in 2020, according to the GLOBOCAN database.[4,5] The age-standardized incidence and mortality rates (ASRs) were 9.5 and 8.7 for new cases and deaths per 100,000 people, respectively.[4] These rates were highest in East Asia (17.8 new cases, 16.1 deaths), Northern Africa (15.2 new cases, 14.5 deaths), and Southeast Asia (13.7 new cases, 13.2 deaths)[4,5] (Figure 66.2). The male-to-female incidence ratio was about 2.5, with male-to-female ASR ratio ranging between 1.2 and 3.6.[4] Liver cancer rates are predicted to rise 55% in the next two decades, with a possible 1.4 million people diagnosed with and 1.3 million people dying from liver cancer in 2040.[4,5] A US national report showed that, although the incidence and mortality rates of cancer decreased from 2000 to 2014, the incidence and mortality rates of liver and intrahepatic bile duct cancers increased in both male and female patients.[6] However, a more recent report showed a decreasing incidence rate in the following years.[7]

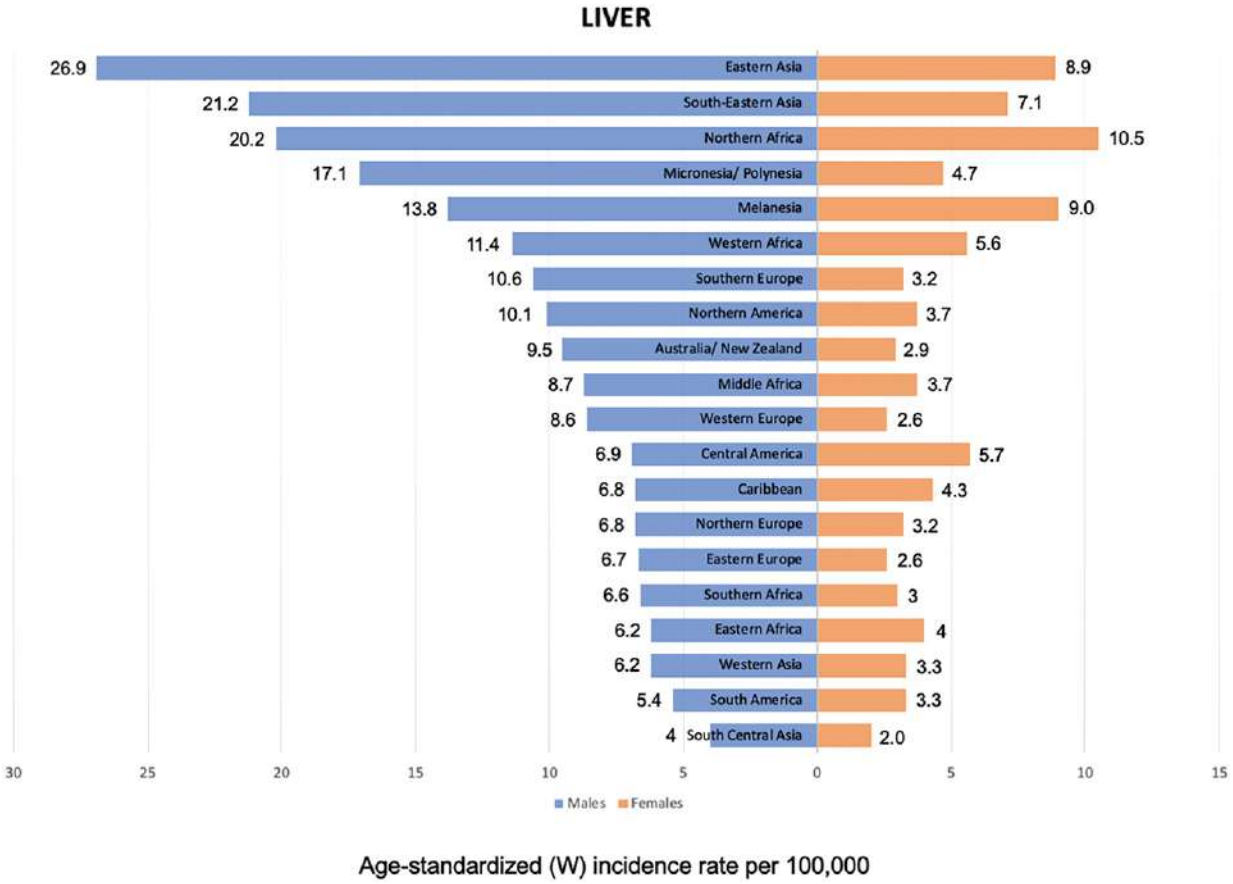

FIGURE 66.2 Incidence rates of primary liver cancer.[4,5]

Incidence rates of liver cancer are higher in East Asia, Southeast Asia, Central Africa, and West Africa compared to other parts of the world.[4] Age-standardized incidence rates per 100,000 people for liver cancer were higher in developing versus developed countries (16:7) for both genders in 2013.[8] HCC accounted for the majority of all primary liver cancers at 70% to 90%,[9] followed by intrahepatic cholangiocarcinoma at around 20%.[10] The reported incidence rate of cHCC-ICC varied from 0.4% to 14.2% between studies,[11] which may be related to changes in diagnostic criteria within the past two decades and possible misclassification as HCC or ICC if a tissue diagnosis was not obtained. According to a report from the U.S. Surveillance, Epidemiology, and End Results (SEER) database, cHCC-ICC accounted for 0.77% of primary liver cancers among over 60,000 patients.[11]

Clinical Presentation and Management of Primary Liver Cancer

Patients with liver cancer are usually asymptomatic in the early stage aside from symptoms related to chronic liver disease. However, symptoms are typically associated with advanced disease. Overall prognosis is dismal, with 5-year survival rates ranging from 0% to 10%. Only about one in five affected patients were amenable to curative resection before the implementation of screening programs for HCC, the main type of primary liver cancer, using α-fetoprotein (AFP) and ultrasonography.[12,13] Improvements in surgical techniques have raised resection rates to 30% to 50%.[14,15] The advent of liver transplantation in recent decades has further contributed to the curability of liver cancer. Surgical resection remains the primary curative treatment for hepatobiliary malignancies as many patients have inoperable or unresectable disease at diagnosis. For patients

with unresectable intrahepatic disease, treatment modalities such as transplantation, transarterial chemoembolization (TACE), local radiofrequency ablation (RFA), systemic chemotherapy, radiotherapy (RT), molecular targeted therapy, and immunotherapy are treatment options. Treatment options for different types of primary liver cancer are discussed later in this chapter (Figure 66.3).

Regional
Locally advanced or multi-focal

Systemic
Liver and distant disease

Local
Solitary tumor, technically resectable

Treatments

- Embolization
- HAI
- Transplant
- Radiation

- Cytotoxic chemotherapy
- Cytotoxic chemotherapy + Immunotherapy
- Targeted therapy
- Targeted therapy + Immunotherapy
- Clinical Trial

- Local surgery
- Local therapy
  - Ablation
  - Cryotherapy, etc.
- Radiation
- Clinical trial

FIGURE 66.3 Treatments for primary liver cancer. HAI, hepatic arterial infusion.

HEPATOCELLULAR CARCINOMA

HCC is the most common primary cancer of the liver, the fifth most common cancer worldwide, and the second highest cause of cancer mortality.[16] The male-to-female ratio ranges from 2:1 to 4:1 in most studies.[17]

High-risk regions are East Asia and Africa.[17,18] The highest incidence rates are seen among the male population of South Korea, North Korea, Thailand, China, Gambia, and Senegal (28.5-48.8/100,000 populations).[16] In low-risk areas, such as Canada, Columbia, and the United Kingdom, HCC occurs in only 1 to 3 per 100,000 people.[16] However, while the incidence rates of primary liver cancer have recently declined among the Chinese population in Hong Kong, Shanghai, Taiwan, and Singapore, the incidence rates have risen in some low-rate areas, such as the United States, the United Kingdom, and Australia.[17] This rise is most likely related to the increased prevalence of viral hepatitis infection.[19,20]

Clinical Presentation

Early-stage HCC is asymptomatic; it is generally detected by abnormalities on either or both AFP or ultrasonography screening or as an incidental finding in the evaluation of other conditions, such as chronic liver disease.[21] Some patients remain asymptomatic even in advanced stages. Symptoms experienced by patients with HCC are usually related to their chronic hepatitis and liver cirrhosis. Clinical symptoms include generalized fatigue, poor appetite, ascites, jaundice, upper gastrointestinal bleeding, splenomegaly, dilated abdominal veins, palmar erythema, gynecomastia, testicular atrophy, leg edema, and weight loss. Tumor-related symptoms include palpable masses in the upper abdomen (hepatomegaly), abdominal fullness, dull pain in the right upper quadrant of the abdomen, acute-onset abdominal pain (because of hemorrhage from a ruptured tumor), low-grade fever, obstructive jaundice, and splenomegaly.[22] Very few individuals with HCC present initially with metastatic disease affecting extrahepatic organs, such as the lungs, bones, adrenal glands, pancreas, intra-abdominal lymph nodes, and neck lymph nodes.[23] These occur mainly in patients with T4, multicentric disease, or with earlier stage disease following treatment. The most common sites of metastasis are the lungs, abdominal lymph nodes, and bones.[24]

Risk Factors

Ninety percent of patients with HCCs have at least one known underlying risk factor.[3,25] HCC is strongly associated with hepatitis B (HBV) and hepatitis C (HCV) viral infections, cirrhosis of any etiology, and other chronic liver cell injury. Chemical injury induced by ethanol, nitrites, hydrocarbons, solvents, organochlorine pesticides, primary metals, and polychlorinated biphenyls has also been implicated.[26,27] Environmental toxins, including aflatoxin, contaminated drinking water, smoking, and betel nut chewing, may also be associated with the pathogenesis of HCC.

Chronic Hepatitis B

Hepatitis B is the most important risk factor for HCC, contributing to about 50% of HCC cases globally.[3] This proportion is higher in Asia and Africa, where hepatitis B accounts for approximately 60% of HCC cases, compared to 20% in the West.[3,28] HBV is a DNA virus that can integrate into the host's genome, inducing insertional mutagenesis and leading to oncogene activation.[3] Patients with HBV can develop HCC even without cirrhosis, but the majority of patients with HBV-induced HCC cases occur in patients with cirrhosis at presentation. Those with chronic HBV infection and

cirrhosis are at the highest risk of developing HCC.[28] The relative risk (RR) of individuals with HCC with persistent HBV infection is 223 times that of uninfected individuals.[29] The presence of hepatitis B e antigen (HBeAg) suggests active HBV replication, and HBeAg-positive patients face an even higher risk of HCC than HBeAg-negative patients.[30] A synergistic effect further increases the risk of HCC in patients coinfected with both HBV and HCV.[31]

Chronic Hepatitis C

The HCV is a hepatotropic RNA virus and a major cause of chronic liver disease. Past studies showed the risk of HCC in patients with a positive HCV antibody was 17 times the risk in those with a negative result. The risk of developing HCC is about 1% to 8% per year[32] and is usually associated with cirrhosis. The RR of HCC among individuals with chronic HCV infection and cirrhosis is also approximately 100 times that of uninfected persons.[33]

Cirrhosis of Any Etiology

Cirrhosis, which is noted in about 80% of adult patients with HCC, is a strong risk factor for HCC. However, the risk varies for cirrhosis from other etiologies.[9] In general, in patients with cirrhosis, the risk of developing HCC is about 1% to 4% per year.[3,23,32]

Alcohol

Ethanol is the most common culpable chemical agent and is thought to lead to HCC through the development of liver cirrhosis or by playing the role of a co-carcinogen. Chronic alcohol use of >80 g/day for more than 10 years is associated with approximately a 5-fold risk for HCC. Alcohol use doubles the risk of HCC in patients with HCV.[34] Several pathogenic pathways for liver damage from alcohol have been proposed, including increased oxidative stress from reactive oxygen species during alcohol metabolism.

Aflatoxin

Aflatoxins, a well-known group of hepatotoxic agents produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*, are associated with HCC. Aflatoxins can contaminate corn, soybeans, and peanuts. High dietary aflatoxin intake is known to be related to the development of HCC.[35] Its combination with other risk factors may synergistically increase the risk of HCC. In Africa, the diagnosis of HCC among patients in their early 30s or 40s is likely related to aflatoxin B1 exposure acting synergistically with HBV to increase the risk of HCC.[31,36] Rates of HCC are reported to be 4-fold among persons with elevated levels of aflatoxin B1, 7-fold among chronic HBV carriers, and 60-fold among persons with both risk factors.[37]

Aflatoxin B1 is metabolized by CYP2E1, which is induced by alcohol.[37] One case-control study suggests that combining aflatoxin B1 load and alcohol intake has a synergistic and statistically significant effect on RR (= 35). The pathogenesis of aflatoxin B1 in patients with HCC may be due to a mutational hotspot of the p53 tumor suppressor gene at codon 249.[32]

Hereditary Disease

Patients with hereditary liver diseases, such as hemochromatosis, Wilson disease, hereditary tyrosinemia, and glycogen storage disease (GSD) type I, are also at risk of developing HCC.[31,38] The common mechanism in these incidences of HCC may be related to chronic injury and inflammation of the liver. Past studies have reported hereditary tyrosinemia, α-1 antitrypsin deficiency (AATD), and GSD type I to be associated with early-onset cirrhosis and HCC in childhood.

Hereditary hemochromatosis (HH), an autosomal recessive inherited disorder,[38,39] occurs in approximately 1 in 200 to 300 individuals.[39] It is caused by mutations in the *HFE* gene and leads to excess iron absorption and damage to cardiomyocytes, pancreatic islet cells, and hepatocytes.

HCC has been reported to develop in 19% to 27% of patients with HH, representing a 200-fold risk of HCC. When early dysplasia and HCC are combined, the rate is even higher, up to 43% in prior studies.[38] Patients with HCC are usually men with cirrhosis over the age of 50. A study of 18,031 hospitalizations from the National Inpatient Sample database in the United States during 2011 to 2019 revealed an HCC incidence rate of 1.2% (95% confidence interval [CI]: 0.78%-1.53%) in patients with HH and an approximately 29-fold risk of developing HCC if without cirrhosis.[39]

Hereditary tyrosinemia type 1 (HT1) is an autosomal recessive inborn disease of tyrosine metabolism that usually leads to liver failure in infancy but can also present as later onset cirrhosis, renal tubulopathy, or intermittent porphyria in childhood. Patients can currently be treated with 2-(2 nitro-4-3 trifluoro-methylbenzoyl)-1,3-cyclohexanedione, which blocks the tyrosine degradation pathway and prevents toxic product accumulation. However, the risk of primary liver cancer remains, especially when treatment is initiated after symptom onset.[41] HT1 has been reported to be associated with both HCC and hepatoblastoma.[40]

GSD is a group of inherited metabolic diseases related to glycogenolysis and gluconeogenesis. The most common type is GSD type Ia, an autosomal recessive disease where glycogen accumulates via a defect in glucose-6-phosphatase. GSD has been reported to be associated with HCC and hepatic adenoma. A case series from Korea described 32 patients who developed hepatic adenoma at a young age (7.9-26.3 years, median 14.3 years) and an additional 4 patients who later developed HCC (average interval 6.7 years between diagnosis of hepatic adenoma and development of HCC).[41]

AATD is a potentially lethal inborn disease that increases the risk of liver fibrosis or cirrhosis (odds ratio [OR] = 21.7; 8.8-53.7) and primary liver cancer (OR = 44.5; 10.8-183.6).[42] It often causes lung and liver injury as well as morbidity and mortality. Mutation of the *SERPINA1* gene, which encodes for AAT, leads to proteotoxic liver injury. In patients with AATD, inborn genotype is not the only factor associated with liver disease. Obesity, diabetes, and older age are also associated with the development of liver fibrosis or cirrhosis and primary liver cancer. Male sex is an additional factor associated with liver disease in individuals with AATD.[42-44]

Although Wilson disease is reported to be associated with primary hepatobiliary cancer, the actual incidence rate is very low. A case series of 1,186 individuals confirmed to have Wilson disease reported only 14 patients with primary liver cancer, including 8 with HCC and 6 with ICC. The prevalence of primary liver cancer in the cohort was 1.2%, and the incidence rate was 0.28 per 1,000 person-years. In addition, pathologic analysis demonstrated no abnormal concentrations of copper within the tumors.[45]

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

Nonalcoholic fatty liver disease and nonalcoholic steato hepatitis (NAFLD/NASH) are increasingly significant causes of cirrhosis. Due to the increasing prevalence of obesity, NASH has become the most common cause of cirrhosis in most regions of the world. NAFLD currently affects one-fourth of the global population.[46] Since 2010, the proportion of HCC attributed to NASH has rapidly increased, representing 15% to 20% of cases in Western countries.[9] Furthermore, the affected population may be greater than estimated due to its coexistence in patients with other liver diseases.[9] A recent study used Bayesian models to estimate that the age-standardized incidence rate of NAFLD-related liver cancer will increase from 0.92 per 100,000 inhabitants in 2018 to 1.18 per 100,000 inhabitants in 2030.[47] Other related metabolic diseases are also associated with an increased RR of HCC, including diabetes mellitus, with an estimated RR of about 2% to 2.5%, and metabolic

syndrome, with an estimated RR of about 1.81%.[32] In 2023, new nomenclature was announced that renamed NAFLD as metabolic dysfunction-associated steatotic liver disease (MASLD) and NASH as metabolic dysfunction-associated steatohepatitis (MASH), with a separate category termed *metabolic and alcohol-related/associated liver disease* for those with MASLD who consume increased weekly amounts of alcohol (140-350 and 210-420 g/week for females and males, respectively).[44]

Other Rare Causes

According to limited data, the prevalence of HCC is 17.6% in patients with Budd-Chiari syndrome and 26.5% in patients with inferior vena cava obstruction.[32] There are no statistically significant differences in sex, age, or site of obstruction between HCC and non-HCC groups.

Risk Factors and Genetic Correlation

Approximately one-quarter of HCC tumors present with actionable mutations; however, the prevalence of most mutations is <10%, thus complicating proof-of-concept studies.[9] *TP53*, *TERT* promoter, and *CTNNB21* are the most frequently found mutated genes, except in patients with HBV-related HCC. Related gene mutations are shown in Table 66.1.

TABLE 66.1 GENE-RELATED PATHOGENESIS OF HEPATOCELLULAR CARCINOMA[1,9]

Driver Gene	Pathway Involved	Related Etiologies
TP53	DNA repair and surveillance	HBV (10%-65%), HCV (24%), nonviral (16%), highest risk in areas of chronic aflatoxin B1 exposure
CTNNB1	Wnt/β-catenin signaling pathway	HBV (15%), HCV (30%), nonviral (39%)
AXIN1		HBV (12%), HCV (13%), nonviral (6%)
ARID1A	Chromatin remodeling	HBV (12%), HCV (2%), nonviral (16%)
ARID1B		HCV (4%), nonviral (2%)
ARID2		HBV (4%), HCV (4%), nonviral (7%)
ARID5A		Reported in NAFLD-related HCC
NFE2L2	Oxidative stress	HCV (9%), nonviral (6%)
KEAP1		HBV (4%), HCV (7%), nonviral (6%)
TERT promoter[a]		HBV (50%), HCV (61%), nonviral (65%)
HBV integration		HBV (65%-100%)
RPS6KA3	Oncogenic MAPK signaling	HBV (4%), HCV (9%), nonviral (6%)
CDKN2A	DNA repair and surveillance	HCV (4%), nonviral (2%)
RB1		HBV (8%), HCV (4%), nonviral (2%)
KMT2A(MLL)	Histone modification	HCV (4%), nonviral (2%)
KMT2C(MLL3)		HBV (8%), nonviral (3%)
KMT2D(MLL4)		HBV (4%), HCV (4%), nonviral (2%)
FGF19 amplification	Regulation of bile acid synthesis and hepatocyte proliferation via activation of its receptor FGFR4	HCV (5%-10%)
GSTT1		Related to toxic effect of aflatoxin B1 potentiated by HBV infection

Driver Gene	Pathway Involved	Related Etiologies
PNPLA3		NAFLD/NASH
TM6SF2		NAFLD/NASH
HSD17B13		NAFLD
MBOAT7	Regulation of hepatic lipid metabolism	NAFLD
APOB		NAFLD
TSC		
Cel	Cholesterol and lipid ester hydrolysis and absorption	NAFLD

ACVR2A, activin receptor type 2A; ARID, AT-rich interaction domain; CDKN2A, cyclin-dependent kinase inhibitor 2A; Cel, carboxyl ester lipase; CTNNB1, β-catenin; FGF19, fibroblast growth factor 19; MBOAT7, membrane-bound O-acetyltransferase domain containing 7; mTOR, mechanistic target of rapamycin; PNPLA3, patatin-like phospholipase domain containing protein 3; SNP, single-nucleotide polymorphism; TERT, telomerase reverse transcriptase; TM6SF2, transmembrane 6 superfamily member 2; TP53, tumor antigen p53; TSC, tuberous sclerosis complex.

[a]Most common mutation in HCC.

Prevention and Surveillance of At-Risk Groups

As most cases of HCC are related to viral hepatitis and chemical injuries, public health measures for the prevention of viral infection and avoidance of chemical exposure are essential for preventing HCC (Table 66.2). The HBV vaccine has been available for decades. Universal HBV vaccination in many countries, such as Taiwan, has led to a significant decrease in the incidence of HCC, from 0.70 to 0.36 per 100,000 children aged 6 to 14 years,[48] and subsequently a decrease in young adults with HCC.[49] In patients with evidence of HBV or HCV infection, oral antiviral agents should be used to effectively control the progression of infection. Antiviral therapy has also been shown to reduce recurrence and improve survival in patients with HBV-related HCC.[50]

TABLE 66.2 COMPARISON OF CURRENT GUIDELINES FOR PRIMARY PREVENTION OF HCC

	APASL 2017[32]	EASA 2018[3]	AASLD 2023[10]	Notes
HBV vaccination	Recommended	Recommended	Recommended	All newborns and high-risk adults
Antiviral therapy • HBV	Recommended	Recommended	Recommended	
Antiviral therapy • HCV	Recommended	Recommended	Recommended	HCC risk may remain higher in patients right after DAA therapy.
Lifestyle modification/bariatric surgery	Consider bariatric surgery for patients who are morbidly obese but lack data.	Not mentioned	Recommended	Healthy weight, balanced diet, avoidance of tobacco and alcohol, adequate control of comorbid conditions, including components of metabolic syndrome
Coffee consumption	Recommended	Recommended in patients with chronic liver disease	May be recommended	Suggested in patients with chronic liver disease, but unclear what preparation and quantity of coffee is most beneficial

	APASL 2017[32]	EASA 2018[3]	AASLD 2023[10]	Notes
Statins	Unclear	—	Not recommended for prevention of HCC	Can be used in other settings of chronic liver disease
Metformin	Unclear	—	Unclear; not recommended for prevention of HCC	An emerging strategy but has conflicting data

AASLD, American Association for the Study of Liver Disease; APASL, Asian Pacific Association for the Study of the Liver; DAA, direct antiviral agent; EASL, European Association for the Study of the Liver; HCC, hepatocellular carcinoma; HCV, hepatitis C virus.

Vaccination against HCV is currently not available. Strategies to prevent HCV infection include blood screening, the use of disposable needles and syringes, adoption of universal precaution for health care workers, and timely treatment of chronic HCV infection. Recent advances in interferon (IFN)-free direct antiviral agents have achieved highly effective control of HCV in infected individuals. Given good responses to antiviral therapy, major guidelines advise the use of antiviral therapy in patients with viral hepatitis B or C.[3,10,32] More recently, emerging cases of cirrhosis and HCC related to NASH/NAFLD have raised the importance of lifestyle modification to prevent HCC. Existing data suggest coffee is beneficial for preventing HCC, leading to its recommendation by current major guidelines.[3,10]

The goal of surveillance is to detect HCC in high-risk groups via serial screening tests at an early stage when curative treatment can be applied. However, cost-effectiveness of surveillance is also an important issue. A recent study has suggested a threshold of approximately 1.0% annual HCC incidence for initiating surveillance in patients with cirrhosis—lower than the traditional threshold of 1.5% per year.[51]

Patients with cirrhosis develop HCC at an approximate rate of up to 4% per year.[23] A randomized study demonstrated a 37% reduction in mortality in patients with hepatitis B undergoing surveillance.[52] A systematic review of surveillance also showed a relationship between increased detection of early-stage HCC and improved survival.[53] Abdominal sonography of the liver combined with serum AFP measurement is still the major method of HCC surveillance. Patients infected with HBV and HCV and those with autoimmune hepatitis are candidates for surveillance. Several professional organizations have proposed different surveillance guidelines. Readers may follow the updated guidelines for HCC management based on their geographic area of clinical practice. The most commonly used guidelines are the Asian Pacific Association for the Study of the Liver from 2017,[32] the European Association for the Study of the Liver from 2018,[3] and the American Association for the Study of Liver Disease (AASLD) from 2023.[7] Guidelines have evolved over time due to new evidence and treatments available, as shown in the comparison of HCC surveillance recommendations in (Table 66.3).

TABLE 66.3 COMPARISON OF HCC SURVEILLANCE SUGGESTIONS BETWEEN GUIDELINES

Population Group (Risk Factor and With/Without Cirrhosis)	Risk of HCC	Surveillance Suggestion		
		APASL 2017[32]	EASL 2018[3]	AASLD 2023[10]
Cirrhosis of any etiology; Child A-B	≥1.0% per year	≥1.0% per year	Recommended	Recommended (insufficient data for cirrhosis from NASH or etiologies that have already been treated)	Recommended

Population Group (Risk Factor and With/Without Cirrhosis)		Risk of HCC	Surveillance Suggestion		
			APASL 2017[32]	EASL 2018[3]	AASLD 2023[10]
HBV	No cirrhosis	≥0.2% per year	Recommended	Recommended for intermediate-/high-risk groups (PAGE-B ≥10)	Recommended for intermediate-/high-risk groups (PAGE-B ≥10)
HCV	No cirrhosis but severe fibrosis (METAVIR F3)		Recommended	Recommended	Not recommended routinely
	No cirrhosis		Consider	Consider	Not recommended
	No cirrhosis, post-treatment with SVR	~0.33%	Consider	Unclear	Not recommended
Alcohol	No cirrhosis	—	—		Not recommended
NASH/NAFLD	No cirrhosis	—	No conclusive recommendations	Unclear	Not recommended
Liver transplantation candidate on waiting list			—	Recommended	Recommended
Child-Pugh C cirrhosis and not candidate for transplantation)			—	Not recommended	Not recommended
Life-limiting comorbid conditions			—	Not recommended	Not recommended
Post–curative treatment of previous HCC			Recommended	Recommended	Recommended

History-Taking and Diagnosis of Hepatocellular Carcinoma

In a patient in whom HCC is suspected, a history of hepatitis, jaundice, blood transfusion, use of intravenous drugs, or exposure to aflatoxins should be noted. Asking about a family history of hepatitis and possible risk factors, such as alcohol abuse and industrial exposure to potential carcinogens, is also helpful. The physical examination should include a search for signs of underlying liver disease, such as jaundice, ascites, ankle edema, spider angiomata on the anterior chest wall, palmar erythema, splenomegaly, increasing abdominal girth, and weight loss. Evaluation of the abdomen for liver size, existence of tumor masses, tenderness, and abdominal bruits should also be included.

Laboratory testing should include liver function tests, serologies for HBV and HCV, and AFP. If HBV or HCV serologies are positive, quantitative HBV DNA or HCV RNA should be obtained.[54] Evaluation of hepatic functional reserve should include prothrombin time, activated partial thromboplastin time, and serum albumin. Platelet, red cell, and white blood cell counts should also be obtained to look for the simultaneous existence of portal hypertension and hypersplenism from liver cirrhosis. The diagnosis of HCC should be considered in the differential diagnosis for any patient with an underlying liver disease, such as cirrhosis or chronic viral hepatitis. Any dominant solid nodule that is not clearly a hemangioma should be considered HCC unless proven otherwise.[55]

Unlike other cancers that require a traditional pathologic diagnosis, HCC can also be diagnosed noninvasively via laboratory tests and clinical imaging, in accordance with current clinical guidelines worldwide. Noninvasive imaging diagnosis is an important part of the management of HCC, as HCC frequently coexists with liver cirrhosis, increasing the risk of bleeding during biopsy procedure. The identification of patterns typical of HCC on dynamic imaging has also changed diagnostic guidelines. The use of biomarkers alone as a diagnostic tool is not recommended.

Ultrasonography, CT, and MRI are the most commonly used diagnostic imaging modalities for evaluating tumors in the liver. Ultrasound examination of the liver is commonly used for screening rather than for diagnosis. Small tumors are often hypoechoic. As tumors grow, the echo pattern tends to become isoechoic or hyperechoic, and HCC can be difficult to distinguish from the surrounding liver.[56] At the author's institution, nodules <1 cm are followed with ultrasonography at intervals of 3 months. Nodules >1 cm in a cirrhotic liver should be investigated further with a four-phase dynamic CT scan. If a four-phase dynamic CT scan is not suitable for the patient or cannot confirm the diagnosis of HCC, contrast-enhanced MRI or biopsy is the next step. Contrast-enhanced sonography, which uses an intra-arterially administered microbubble agent as ultrasound contrast, can overcome the limitations of conventional B-mode and Doppler ultrasound techniques when evaluating focal lesions in the cirrhotic liver.[57] However, the technique needs to be performed by an experienced operator, and current major guidelines still focus on the use of CT or MRI dynamic studies for imaging diagnosis.

Nonpathologic diagnostic criteria for HCC have been proposed since the 2005 AASLD guidelines and consist of serum AFP level >200 ng/mL or a typical enhancement pattern (arterial enhancement and delayed portal vein washout) on dynamic imaging of hepatic masses >2 cm in a cirrhotic liver.[58] The AASLD further validated the diagnostic accuracy of a single dynamic technique in patients with chronic hepatitis B or cirrhosis of any etiology if intense arterial uptake followed by washout of contrast in the portal venous or delayed venous phases can be demonstrated.[57] A prospective validation study of 206 consecutive patients from Korea showed that the positive predictive value of typical CT findings or a serum AFP >200 ng/mL was 97.8% in patients with cirrhosis, 89.6% in high-risk patients without cirrhosis, and 82.4% in low-risk patients.[59] However, even when imaging diagnostic criteria are fulfilled, histopathologic confirmation is worthwhile in certain ambiguous situations. In the absence of cirrhosis or hepatitis B infection, histologic diagnosis is usually recommended.

For patients with risk factors for HCC, most recent clinical guidelines have established diagnostic criteria based on dynamic imaging alone that uses the Liver Reporting and Data System (LI-RADS) classification (Figure 66.4). A meta-analysis suggested a sensitivity of 82% using MRI and 66% using CT with similar specificity (MRI: 92%; CT: 91%). LI-RADS classification for CT and MRI has been widely accepted for clinical use in patients warranting HCC surveillance, including individuals with cirrhosis, noncirrhosis HBV infection with an intermediate or high risk of HCC, or a history of prior HCC.[59]

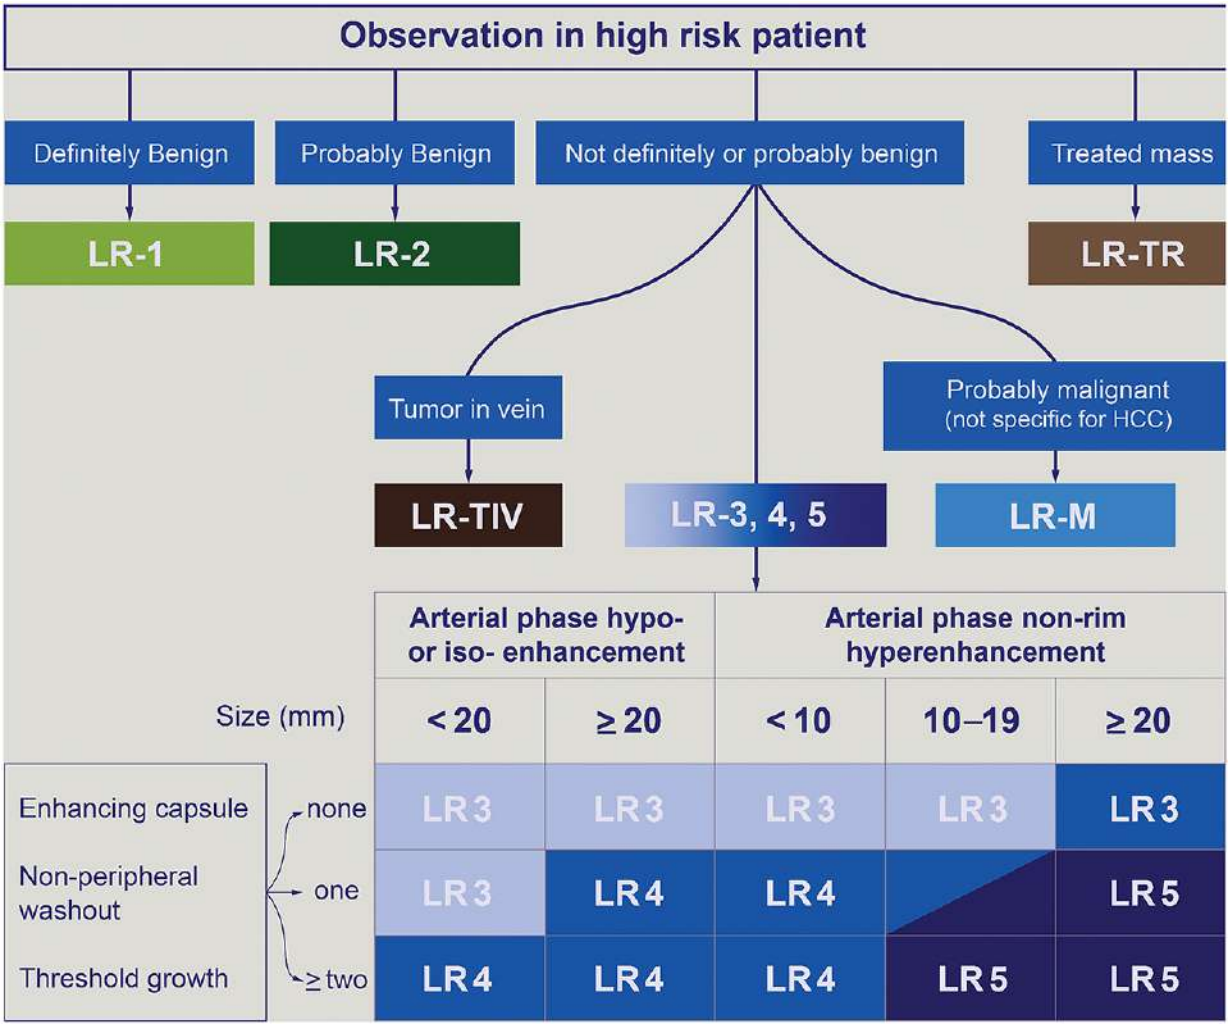

FIGURE 66.4 Liver Reporting and Data System classification.

Histologic diagnosis of HCC is also recommended for patients whose treatment plan is nonsurgical.[60] For patients for whom surgery is considered, a concern exists over the possibility of tumor seeding from biopsy or fine-needle aspiration.[60] The reported risk ranges from 1.6% to 5%.[61-63] In patients who demonstrate coagulopathy or significant ascites, biopsy or fine-needle aspiration may be contraindicated. At the author's institution, fine-needle aspiration under ultrasound guidance is frequently performed for tissue confirmation by cytology and cell block.[62] Core biopsy of the mass is generally reserved for patients in whom a definitive diagnosis by fine-needle aspiration and cell block cannot be made. A coaxial cannula is used to reduce the chance of needle-track seeding.[64] In patients with small hepatic nodules for whom diagnostic possibilities range from well-differentiated malignancy to benign disease such as nodular hyperplasia, ultrasound-guided needle, or core biopsy should be considered.[65]

Pathologic diagnosis is usually based on the International Consensus Group for Hepatocellular Neoplasia definition.[7,66] Major histologic features of HCC include stromal invasion, increased cell density, intratumoral portal tracts, unpaired arteries, pseudoglandular pattern, and diffuse fatty changes. According to the most recent fifth edition of the WHO classification of digestive system tumors, HCC can be classified into eight subtypes: fibrolamellar, scirrhous, clear cell type,

steatohepatic, macrotrabecular massive, chromophobe, neutrophil rich, and lymphocyte rich (Table 66.4).[1] Diagnosis by imaging may not be possible for these eight subtypes as they may not demonstrate typical patterns in dynamic studies. Major guidelines do not currently differentiate treatment plans by pathologic subtype.

TABLE 66.4 WHO CLASSIFICATION OF DIGESTIVE TUMORS, FIFTH EDITION: SUBTYPES OF HCC

Subtype	Relative Frequency (%)	Prognosis	Histologic Features	Molecular Features	Clinical Correlates
Steatohepatic	5-20	Similar	Cell ballooning, inflammation, pericellular fibrosis, and Mallory-Denk bodies	IL-6/JAK/STAT activation; lower frequency of CTNNB1, TERT, and TP53 mutation	Steatohepatitis background
Clear cell	3-7	Better	Cytoplasmic accumulation of glycogen with clear cell morphology (>80% of tumor)	—	—
Macrotrabecular massive	5	Poor	Macrotrabecular (>6 cells thick) architecture in >50% of tumor, with satellite nodules and macrovascular and/or microvascular invasion	TP53 mutations and FGF-19 amplifications	High serum AFP
Scirrhous	4	Variable	Dense intratumoral fibrosis in >50% of tumor	TSC1/2 mutations; TGF-β signaling activation	Mimics cholangiocarcinoma on imaging
Chromophobe	3	Similar	Light, clear cytoplasm, bland tumor nuclei, but focal areas of more striking nuclear atypia	Alternative lengthening of telomeres	—
Fibrolamellar carcinoma	1	Similar to HCC without cirrhosis	Large eosinophilic tumor cell with prominent nucleoli, dense intratumoral fibrosis	Activation of PKA via DNAJB1-PRKACA fusion gene	Young (median age 25 y/o)
Neutrophil rich	<1	Poor	Diffuse neutrophils within tumor, can have sarcomatoid loci	Tumor produces G-CSF.	Elevated white blood cell count, CRP, and IL-6
Lymphocyte rich	<1	Better	On H&E staining, lymphocytes outnumber tumor cells in most fields	Not related to EBV	—

AFP, α-fetoprotein; CRP, C-reactive protein; CTNNB1, β-catenin; EBV, Epstein-Barr virus; FGF-19, fibroblast growth factor-19; G-CSF, granulocyte colony-stimulating factor; HCC, hepatocellular carcinoma; H&E, hematoxylin and eosin; IL-6, interleukin-6; PKA, protein kinase A; TGF-β, tumor growth factor β; TERT, telomerase reverse transcriptase; TP53, tumor antigen p53; TSC, tuberous sclerosis complex; WHO, World Health Organization.

Staging

HCC generally carries a poorer prognosis compared to other cancers due to negative effects from underlying liver disease. Several factors have been identified as important determinants of survival: the severity of underlying liver disease, the size and number of tumors, vascular invasion, regional lymph node metastasis, and the presence of distant disease. Routine metastatic survey in patients with HCC is not recommended unless transplantation is being considered. There is no worldwide consensus on the use of any given HCC staging system. However, most major trials of HCC therapy have chosen the Barcelona Clinic Liver Cancer (BCLC) staging system (Table 66.5), making it the de facto reference staging system.[67,68] Other systems, such as the American Joint Committee on Cancer (AJCC) TNM staging system,[69] the Okuda staging system,[70] and the Cancer of the Liver Italian Program scoring system,[65] are also in common use.

TABLE 66.5 BCLC STAGING SYSTEM FOR HEPATOCELLULAR CARCINOMA

BCLC Stage	ECOG Performance Status	Tumor Features	Liver Function
0	ƒ0	Single nodule <2 cm	Child-Pugh A
A	0	Single or three nodules < 3 cm	Child-Pugh A-B
B	0	Multinodular	Child-Pugh A-B
C	1-2	Portal invasion, N1, M1	Child-Pugh A-B
D	3-4		Child-Pugh C

General Management

Surgical resection remains the primary treatment approach. However, a significant number of patients are ineligible for surgery due to either the extent of their tumor or underlying liver dysfunction. HCC is frequently multicentric, particularly when associated with HCV infection. The rate of multicentric disease in HCV-related HCC (53.3%) is significantly higher than in non–HCV-related HCC (7.7%).[71] The likelihood of multicentric occurrences also increases as chronic liver disease and cirrhosis progress.[72,73] While multiple tumors are less common in HBV-associated HCC, patients with persistent HBeAg positivity and high HBV DNA serum levels have a notably higher risk of intrahepatic HCC recurrence. For patients who are not eligible for surgical resection, several other treatment modalities can be considered, including liver transplantation, percutaneous ablation, TACE, RT, molecular targeted therapy, and immunotherapy. Most treatment guidelines have recommended treatments based on the BCLC staging system. In general, potentially curative treatments such as surgical resection, transplantation, and local ablation are recommended for patients with early-stage HCC. First-line treatments for intermediate- and advanced-stage HCC are TACE and systemic therapy, respectively.[9]

Surgical Resection

Surgical resection is a reliable method to achieve long-term disease control. The main limiting factors for performing resection include poor liver function, the presence of portal hypertension or vascular invasion, and the size, location, and number of tumors. The extent of hepatic tumor resection depends on the functional reserve of the residual liver after surgery. Historically, patient selection for resection was based on the Child-Pugh functional classification (Table 66.6), but this method has been found to be inconsistent in predicting outcomes. Many Japanese and other Asian physicians prefer using the 15-minute retention rate of indocyanine green (ICG) before treatment for

patient selection.[74] In Europe and the United States, the selection of optimal candidates for resection usually involves assessing portal hypertension, either clinically or via hepatic vein catheterization.[75] Clinically significant portal hypertension is suspected if the platelet count is below 100,000/μL and associated with significant splenomegaly. Other parameters proposed for liver function assessment before surgery include the model for end-stage liver stage score and the albumin-bilirubin score.[76] The goal of surgery is to remove the gross tumor with a margin of 1 to 2 cm of normal liver. Five-year survival after resection has improved through careful preoperative assessment as stated above and can reach 50% to 70%. However, the recurrence rate can still be as high as 70% within 5 years.[9]

TABLE 66.6 GRADING SYSTEM FOR CIRRHOSIS: THE CHILD-PUGH SCORE

Score	Bilirubin (mg/dL)	Albumin (g/dL)	Prothrombin Time (s)	Hepatic Encephalopathy (Grade)	Ascites
1	<2	>3.5	<4	None	None
2	2-3	2.8-3.5	4-6	1-2	Mild (detectable)
3	>3	<2.8	>6	3-4	Severe (tense)

Child class: A, 5 to 6; B, 7 to 9; C, >9.

Liver Transplantation

Many patients are not candidates for tumor resection because of underlying liver dysfunction. The increasing availability of liver transplantation has made this procedure a viable alternative to tumor resection for selected patients. Based on the Milan study and others, liver transplantation is an effective option for patients with HCC,[77,78] and the Milan criteria are still today's benchmark for patient selection. The major selection criteria are a solitary tumor less than 5 cm in size or up to three tumors less than 3 cm in size.[77] Elevated AFP concentration adds prognostic information and may be used for decision-making in combination with imaging criteria.[79] Outcomes after transplantation have been excellent, with 5- and 10-year survival rates of 70% and 50%, and recurrence rates of 10% to 15% at 5 years, respectively.[9] Risk factors for recurrence after transplantation include tumor size, number of tumors, vascular invasion, and persistence of HBV infection.[80-82] A major disadvantage of orthotopic liver transplantation is the unpredictable and potentially long waiting time for donor organs.[82] Living donor transplantation can be offered for HCC if the waiting time will likely be long.[79] The concept of downstaging with local treatment such as TACE or RFA to make more patients fit within the Milan criteria, which was first introduced by the University of California San Francisco group in 2008.[83] Downstaging could increase the opportunity for transplantation and improve survival. A US multicenter study reported excellent outcomes after liver transplantation, with a 10-year survival rate of 61.5% and recurrence rate of 13.3% for those always within the Milan criteria and a comparable 10-year post-transplant survival rate of 52.1% and recurrence rate of 20.6% for those who were downstaged.[84] In addition, local treatment could also serve as bridging therapy for patients on the transplant waiting list to prevent disease progression, thereby increasing the chance of transplantation.

Percutaneous Ablation

For patients with early-stage HCC who are not candidates for resection or transplantation, percutaneous ablation, by injecting chemical substances (ethanol or acetic acid) or modifying the

temperature (with radiofrequency, microwave, laser, or cryotherapy), could be a potentially curative option. Percutaneous ethanol injection is highly effective for small HCC. It achieves a necrosis rate of 90% to 100% for HCC <2 cm in size, but the necrosis rate is reduced to 50% if tumor size is >3 cm.[85-87]

RFA involves the local application of radiofrequency thermal energy to the lesion. RFA is a reasonable option for patients who do not meet resectability criteria for HCC due to location or patient condition and yet are still candidates for a liver-directed procedure. The best outcomes are in patients with a single tumor >2 and <4 cm in diameter. Randomized controlled trials comparing RFA and ethanol injection have shown that RFA provides superior local disease control that could result in an improved survival.[86-89] Two of three randomized controlled prospective trials comparing RFA with surgical resection for small HCCs concluded that both have similar efficacy.[90] Several guidelines have thus recommended RFA as the first-line treatment for single tumors <2 cm. For patients with early-stage single tumors 3 to 4 cm or two to three tumors <3 cm not suitable for surgical resection, RFA is an acceptable alternative.[3,91]

Intra-arterial Therapies (Transcatheter Arterial Chemoembolization and Others)

HCC is a highly vascular tumor that mainly receives its blood supply from the hepatic artery or other nearby arteries. This tumor shows significant neoangiogenic activity as it progresses, which not only forms the theoretical basis for its radiologic diagnosis but also provides the rationale for using arterial embolization as a treatment option. In contrast, normal liver parenchyma receives dual blood supply from both the portal venous and hepatic arterial system and thus is relatively protected when the hepatic arterial supply is disrupted. TACE involves selective injection of chemotherapeutic agents through arteries feeding the tumor followed by intra-arterial embolization of tumor-feeding arteries with lipiodol, an iodized oily contrast agent, Gelfoam, or plastic particles such as Ivalon. In the early 2000s, two prospective randomized controlled trials and a meta-analysis demonstrated survival benefit with TACE compared with conservative management in intermediate-stage HCC.[92-94] TACE has since been accepted as the standard treatment for unresectable disease or inoperable patients, such as those with multicentric disease or repeated relapses. It can be used selectively for tumors in different organ locations and can be repeated if necessary.[95,96] The recently reported median survival after TACE ranges from 25 to 30 months.[9] In an attempt to better standardize drug delivery and decrease postembolization syndrome, drug-eluting beads (DEB)-TACE was developed to ensure more constant and tumor-specific drug delivery. However, a phase 2 randomized study comparing DEB-TACE with TACE did not meet its primary end point of improving the objective response rate, although DEB-TACE was associated with fewer side effects.[97,98]

Transarterial radioembolization (TARE) is a procedure involving the intra-arterial delivery of glass or resin microspheres embedded with the radioactive isotope yttrium-90. Although smaller uncontrolled trials have reported encouraging outcomes in patients with portal hypertension, randomized trials have failed to confirm survival benefit compared with sorafenib in advanced disease. TARE does not cause ischemia or alteration in hepatic arterial flow; hence, postembolization syndrome may be avoided.[97]

Conventional Radiotherapy

HCC is known to be sensitive to radiation.[99] However, the radiation tolerance of surrounding normal liver tissue is poor, and precisely locating the tumor for RT can be challenging.[100,101] Advances in RT technology, such as intensity-modulated radiation therapy (IMRT), image-guided radiation therapy, respiratory gating, and stereotactic body radiation therapy (SBRT), have improved the potential and feasibility of using radiation to treat HCC. These advancements allow for more accurate targeting of

the tumor, enabling more conformal radiation dose distribution, thus sparing more normal liver tissue from high-dose radiation.[100,101] For patients with liver-confined disease treated with conformal radiotherapy (CRT) with or without TACE, local control response rates ranged from 40% to 90%, and the median survival ranged from 10 to 25 months.[102] Indications for CRT are as follows:

Early stage

1. For those unsuitable for resection or RFA
2. As a bridging therapy to transplantation

Intermediate stage

1. For patients who fail to respond or have an incomplete response to TACE
2. In combination with other local treatments to treat multiple tumors
3. To potentially downstage the disease

Advanced stage

1. For tumor-induced portal vein thrombosis
2. For palliation of symptoms
3. For a potentially additive or synergistic effect with other systemic treatments

Radiation Tolerance of the Liver

Radiation-induced liver disease (RILD) is a critical complication that can arise following liver RT and serves as an important measure of outcome in various studies. RILD is categorized into two distinct types: "classic" and "nonclassic."[103]

1. Classic RILD: This type is characterized by symptoms of anicteric hepatomegaly and ascites. It typically occurs between 2 weeks and 3 months following the completion of RT. The key laboratory finding is a significant elevation in alkaline phosphatase levels, often greater than twice the upper limit of normal or baseline level. Classic RILD can occur in patients who had relatively good liver function before undergoing RT.
2. Nonclassic RILD: This variant usually develops between 1 week and 3 months post-therapy. The liver transaminases are greater than 5 times the upper limit of normal within 3 months of completing RT. The Child-Pugh score worsens by two points or more in the absence of symptoms typical of classic RILD.

Classic estimation of whole-liver tolerance is 30 Gy in 2-Gy fractions.[104] Data from the Radiation Therapy Oncology Group (RTOG) 84-05 showed that RILD developed in 0 of 122 patients receiving 27 to 30 Gy in twice daily 1.5 Gy fractions of whole-liver RT compared to 5 (9.8%) of 51 patients receiving 33 Gy in 1.5-Gy fractions. More recently, the Quantitative Analyses of Normal Tissue Effects in the Clinic (QUANTEC) initiative recommended limiting palliative whole-liver doses to ≤30 Gy (2 Gy/fr) or 21 Gy in seven fractions for liver metastases and to ≤28 Gy (2 Gy/fr) or 21 Gy in seven fractions for primary liver cancers.[103] Preexisting liver dysfunction may render patients more susceptible to RT-induced liver injury.

Radiation Doses

Before the era of CRT, the radiation dose for liver cancer was limited to <30 to 40 Gy due to the risk of hepatotoxicity, leading to <30% of patients showing a partial response. Seong et al[105] reported a response rate of 67% in patients who did not respond to TACE and were treated with CRT with a mean dose of 51.8 ± 7.9 Gy. Dawson et al[106] found that patients with unresectable hepatobiliary cancer who received escalated radiation doses >70 Gy had better median survival (>16.4 months). This suggests that higher radiation doses can lead to better tumor responses (Table 66.7). However, caution is advised in cases of HBV-related HCC, as RT may worsen liver function due to RILD, portal hypertension, and HBV reactivation. Prophylactic treatment of HBV is recommended to prevent its reactivation during treatment.[107]

TABLE 66.7 RADIOTHERAPY WITH AND WITHOUT CHEMOTHERAPY FOR UNRESECTABLE HEPATOCELLULAR CARCINOMA

Series	Patient Number	Radiation Dose (Gy)	Chemotherapy	Response Rate (%)
Stillwagon et al[109] (RTOG)	135	21, 3 daily	Concurrent ADR, 5-FU	22
Order et al[110] (RTOG)	105	21, 3 daily + I^{131} 10-12 × 2 courses	Concurrent ADR and 5-FU	48
Seong et al[105]	27	51.8 (mean), 1.8 daily	None	67
Dawson et al[106]	25	58.5 (median), 1.5 bid	Concurrent HAI fluorodeoxyuridine	68

Treatment Volumes

While higher radiation doses can lead to better treatment responses, patients with HCC often have liver cirrhosis and dysfunction, which unfortunately limits the use of higher radiation doses. Studies of 3DCRT using photon beams indicate that tumor-affected liver areas can tolerate higher doses with acceptable side effects. Lawrence et al[108] developed a model to predict normal tissue complication probability (NTCP) from RT for intrahepatic malignancy. Based on this model, the authors designed a protocol in which each patient can receive maximum tolerated doses of radiation with no more than a 10% risk of RILD. The mean doses that can be delivered according to this protocol are 56.6 ± 2.31 Gy (range, 40.5-81 Gy). Using this dosing range, they observed a reduction of radiation complication rate to 4.8% (95% CI, 0%-23.8%). This model, however, was derived using patients with relatively normal liver function, and only 4 of 21 in their study population had HCC.[108]

The QUANTEC study analyzed the effect of fractionated partial liver irradiation using a 3D conformal technique in patients with HCC. The patient population had baseline Child-Pugh A or B liver function and was from the US and Asia- Pacific regions. This study, also using the NTCP model, found that RILD rates varied from 9.5% to 17%. The mean normal liver dose in patients with RILD ranged from 23 to 37 Gy and was lower in those without RILD, ranging from 19 to 31.3 Gy.[102] Hence, the authors suggested keeping the mean normal liver dose to <28 Gy in 2 Gy fractions for primary liver cancer and <32 Gy in 2 Gy fractions for liver metastases.[103]

Patients with hepatitis B infection and liver cirrhosis have an increased risk of developing RILD.[111] In patients with cirrhosis but classified as Child-Pugh grade A only, the liver can typically tolerate a mean dose of 23 Gy.[112] The authors suggested a dose-volume histogram for irradiation to normal liver in which volumes receiving over 10, 20, 30, and 40 Gy should be less than 68%, 49%,

28%, and 20%, respectively. Furthermore, multivariate analyses identified the severity of hepatic cirrhosis as the sole independent predictor for RILD.

The ICG retention test is useful for determining the appropriate treatment volume for HCC.[113] Based on this test, we proposed a treatment guideline for CRT in patients with impaired liver function (Table 66.8). Our guideline recommends against radiation treatment for patients with Child-Pugh class C liver cirrhosis or prolonged ICG retention, except in cases where only a very small portion of the liver is within the radiation treatment field.[99]

TABLE 66.8 RADIATION TREATMENT GUIDELINES FOR HEPATOCELLULAR CARCINOMA

	ICG (Gy)		
Nontumor Part of Liver	**≤10%**	**10.1%-20%**	**20.1%-30%**
<1/3	40 (Gy)	No RT	No RT
1/3-1/2	50 (Gy)	40 (Gy)	No RT
>1/2	60 (Gy)	50 (Gy)	40 (Gy)

Stereotactic Body Radiotherapy

SBRT has recently become a promising treatment option for intrahepatic tumors, thanks to advancements in planning systems and modern linear accelerators. This technique, leveraging advances in respiratory motion management and image guidance, allows for the delivery of higher biologic equivalent dose (BED) to liver tumors with similar or even reduced damage to normal tissue. A key benefit of SBRT is its rapid dose fall-off, which helps preserve more of the nontumor liver tissue.

There is a wide variety of dosing and fractionation schedules using SBRT to treat HCC, ranging from 24 to 60 Gy in three to six fractions. Over 400 patients have been treated in nine prospective clinical trials utilizing SBRT for HCC[114] (Table 66.9). The 1-year local control rates in these trials ranged from 65% to 100%. According to a recent meta- analysis including 1,889 patients from 17 retrospective studies reported between 2013 and 2022, the 3- and 5-year overall survival rates after SBRT were 57% and 40% and the 3- and 5-year local control rates were 84% and 82%, respectively. The analysis identified tumor size as the only prognostic factor for local control and found that tumor size and region were significantly associated with overall survival.[115]

Evaluating tumor response after SBRT can be challenging. A radiology-pathology response correlation study from the University of Michigan concluded that persistent central arterial hyperenhancement and washout within the first 12 months after SBRT may not represent residual viable tumor if there is no increase in size. There were findings of early inflammation followed by late fibrosis in liver parenchyma adjacent to the treated lesion. However, no patients in the study had significant liver function impairment.[116,117]

Simulation

It is advisable to assess the motion of the liver tumor, which is best achieved with a 4D CT. The 4D CT can generate images in 10 respiratory phases, capturing tumor motion throughout the respiratory cycle.[118] In addition, small bowel and intravenous contrast should be used to clearly demarcate the

tumor and nearby organs at risk (OARs), such as the stomach and intestines. Techniques such as abdominal compression, breath-holding, and respiratory gating can be employed during radiation treatment to reduce uncertainties caused by both inter- and intrafraction motion. This helps in minimizing the volume of tissue treated and in reducing damage to normal tissues.[119]

Tumor Contouring

Delineating the tumor target using 4D images can be challenging. For patients who have undergone TACE, the lipiodol may provide useful landmarks during the contouring process. Other helpful landmarks for contouring include fiducial markers, calcifications, and any surgical clips or stents. A contrast-enhanced MRI can provide complementary information that aids in defining the target area. Some researchers have also employed deformable image registration techniques to enhance this process.[120]

Motion Management

CRT aims to accurately target tumors while minimizing injury to surrounding normal tissue. Managing respiratory organ motion, which is the largest source of "intrafraction" movement during treatment, is especially crucial in SBRT for liver tumors. Respiratory motion management is recommended if target motion is greater than 5 mm, or when the procedure will enhance normal tissue sparing.[121] Effective motion management may allow the use of smaller margins during radiation delivery, which is important, since liver tumors may move several centimeters during respiration, and substantial rotations and deformations have also been reported.[122] Aruga et al[123] studied organ motion using CT images captured during both static exhalation and inhalation phases for upper abdomen irradiation. They observed tumor shifts between the two respiratory phases, with variation ranging from 0.4 to 5.9 mm laterally, 2.2 to 24.5 mm longitudinally, and 0.2 to 11.7 mm vertically with the patient in the supine position. Park et al[124] studied the motion of liver tumors in 20 patients using fiducial markers and reported motion ranges of 3.0 ± 2.0, 5.1 ± 3.1, and 17.9 ± 5.1 mm in the left-right, anterior-posterior, and craniocaudal directions, respectively, during planning 4D CT and similar ranges during treatment cone-beam CT.

Respiratory motion management techniques include passive approaches, such as motion-encompassing techniques (internal target volume [ITV]) and forced shallow breathing (or abdominal compression), and active approaches, such as respiratory gating in free-breathing or in breath-hold and respiratory synchronization (tracking).[121,122] These techniques may help mitigate respiratory movement during RT. In general, radiation field margins to the target can be about 6 to 9 mm laterally, 9 to 12 mm vertically, 10 mm superiorly (subphrenic), and 19 to 21 mm inferiorly.[134,135] To further preserve liver function, radiation field margins can be reduced to 5 mm if the patient receives gated radiation treatment in the expiratory or inspiratory phase. The beam-on time would be about 30% to 40% of the whole respiratory cycle, determined based on tumor motion observed on 4D CT images.

Planning and Prescription

The gross tumor volume (GTV) includes the liver tumor and any tumor thrombi. Prophylactic nodal irradiation is not necessary. The clinical target volume (CTV) is usually defined as the GTV with no expansion.[136] However, sometimes regions at high risk for harboring microscopic disease, including nontumor vascular thrombi and adjacent TACE or RFA sites, are included in the CTV. An ITV is generated from 4D CT based on the respiratory phases to be used during radiation delivery. The planning target volume (PTV) is generated by adding a margin around the CTV or ITV to

compensate for setup and internal organ motion. Depending on the methods of respiratory motion control used, the PTV margins usually range from 5 to 20 mm. Use multiple coplanar and noncoplanar beams to generate a plan with conformal dose distribution and rapid dose fall-off outside the PTV. Quality assurance is mandatory for patients at our institution treated with a daily fraction dose ≥6 Gy.

Dose and Organs at Risk

When determining doses of SBRT, it is crucial to consider the radiation tolerance of the liver and nearby organs, such as the stomach, duodenum, large bowel, kidney, and spinal cord. To ensure liver function remains adequate, a minimum volume of normal liver must be spared from receiving a critical dose of radiation. Drawing from the concept of surgical partial hepatectomy and the idea of "critical volume," the QUANTEC paper recommends that at least 700 mL of normal liver should receive ≤15 Gy in three to five fractions. Incorporating data from published prospective studies, QUANTEC, and American Association of Physicists in Medicine recommendations, the American Society for Radiation Oncology (ASTRO) published a practice guideline. The guideline provides recommended dose constraints for uninvolved liver and bowel structures across different fractionation schedules[137] (Table 66.10).

TABLE 66.10 RECOMMENDED DOSE CONSTRAINTS FOR UNINVOLVED LIVER AND BOWEL STRUCTURES

OARs	Ultrahypofx (3 fx)	Ultrahypofx (5 fx)	Moderate Hypofx (15 fx)	Standard fx (≥20 fx)	Toxicity End Point
Uninvolved liver, noncirrhotic (MLD)	Mean <1,200-1,500 cGy ≥700 cc <1,900 cGy	Mean <1,500-1,800 cGy >700 cc <2,100 cGy	Mean <2,400 cGy	Mean <3,200 cGy	RILD
Uninvolved liver, CP class A (MLD)	Mean <1,000-1,200 cGy	Mean <1,300-1,500 cGy ≥700 cc <1,500 cGy	Mean <2,000 cGy	Mean <3,000 cGy	CP increase ≥2 at 3 mo RILD
Uninvolved liver (MLD) CP class B7	Not recommended	Mean <800-1,000 cGy ≥500 cc <1,000 cGy	Mean <1,600 cGy	Mean <2,400 cGy	CP increase ≥2 at 3 mo RILD
Central bile ducts	D0.03 cc <3,570 cGy	D0.03 cc <4,050 cGy			Stenosis
Stomach	D0.03 cc <2,200 cGy D10 cc <1,650 cGy	D0.03 CC <3,200 cGy D10 cc <1,800 cGy	D0.03 cc <4,200 cGy	D0.03 cc <5,400 cGy V45 Gy <33.3% V40 Gy <66.7%	Ulcer
Duodenum	D0.03 cc <2,200 cGy D5 cc <1,650 cGy	D0.03 cc <3,200 cGy D5 cc <1,800 cGy	D0.03 cc <4,500 cGy	D0.03 cc <5,400 cGy	Ulcer
Small bowel	D0.03 cc <2,500 cGy D5 cc <1,800 cGy	D0.03 cc <3,200 cGy D5 cc <1,950 cGy	D0.03 cc <4,500 cGy	D0.03 cc <5,400 cGy V45 Gy <195 cc	Ulcer
Large bowel	D0.03 cc <2,800 cGy D20 cc <2,400 cGy	D0.03 cc <3,400 cGy	D0.03 cc <4,500 cGy	D0.03 cc <6,000 cGy V55 Gy <5 cc	Ulcer

OARs	Ultrahypofx (3 fx)	Ultrahypofx (5 fx)	Moderate Hypofx (15 fx)	Standard fx (≥20 fx)	Toxicity End Point
		D20 cc <2,500 cGy		V45 Gy <60 cc V35 Gy <150 cc V30 Gy <200 cc

Acute and Late Complications

After undergoing radiation treatment for HCC, patients may experience acute complications, such as generalized fatigue, temporary elevation of liver enzymes, nausea and vomiting (especially for tumors in the left lobe of the liver), fever, and pancytopenia.[99,105] Subacute and late complications include hepatic failure, radiation pneumonitis, and gastrointestinal bleeding. Extra caution is necessary for tumors located in the inferior portion of the right lobe of the liver where the duodenum and jejunum are in close proximity, particularly if radiation doses exceed 50 Gy.[111,138] Life-threatening complications such as hepatic failure can be avoided by adhering to the recommended radiation dose limits for the aforementioned OARs.

Stereotactic Body Radiation Therapy and Other Local Treatment Modality

Stereotactic Body Radiation Therapy and Radiofrequency Ablation

RFA is the recommended alternative curative approach for patients who are not candidates for surgical resection or transplantation. However, RFA use may be limited by tumor size or location, such as tumors that are more than 4 to 5 cm in size and those adjacent to the gallbladder, liver hilum, major vessels, bowel, stomach, or the diaphragm. SBRT may be a good alternative in such situations.[139] No randomized trials directly comparing SBRT with RFA have been published. According to three meta-analyses comparing SBRT with RFA, while the local control rate achieved by SBRT was equivalent to or higher than by RFA, the survival rate after SBRT was lower in two of those three studies. This may be explained by differences in tumor burden or baseline liver function.[140] Nevertheless, SBRT has been recommended in cooperative group guidelines from many countries as an alternative to RFA.[141]

Combined Transarterial Chemoembolization and Radiation Therapy

TACE alone rarely results in complete pathologic remission, especially for larger tumors (>3 cm).[142,143] Additional therapy is required to eradicate residual disease to achieve longer term control of HCC. The combination of TACE and CRT shows promising results in treating large HCC (Table 66.11). Guo and Yu[144] reported 107 patients with large unresectable HCC who underwent TACE followed by external beam irradiation. The tumors ranged from 5 to 18 cm in size. After a median follow-up of 24 months, the cumulative survival rates at 3 and 5 years were 28.4% and 15.8%, respectively, with a median survival time of 18 months. Cheng et al[99] treated 17 patients with unresectable HCC using TACE and CRT. The mean tumor size was 8.6 cm (range, 3.7-18 cm). The 2-year overall survival rate was 58%, with 83% local progression-free tumor control. After 24 months of follow-up, median survival had not been reached, and 4 of 17 patients remained progression free (Figure 66.2). Another study that combined TACE and local RT in 50 patients with

unresectable HCC reported a partial response rate of 66% and a 3-year survival rate of 43%.[138] Wu et al[145] treated 94 patients with HCC with 3DCRT combined with TACE. The response rate was 90.5%. The overall survival rates at 1, 2, and 3 years were 93.6%, 53.8%, and 26.0%, respectively, with a median survival of 25 months. Patients with portal vein branch thrombosis may benefit from combined treatments. Tazawa et al[146] reported 19 patients with a tumor thrombus in the first branch of the portal vein who received 3DCRT with TACE. Eleven (58%) patients had an objective response, and the 1-year survival rate was 41%. A systematic review and meta-analysis of 25 clinical trials comparing TACE plus RT with TACE alone concluded that the combination was beneficial in terms of significantly improved 1- and 5-year survival rates (OR = 1.36 and 3.98) and complete response rates (OR = 2.73). However, patients receiving TACE plus RT had a higher incidence of complications such as gastroduodenal ulcers and impaired liver function (elevated alanine transaminase [ALT] and total bilirubin levels) than patients receiving TACE alone (OR = 12.8).[147]

TABLE 66.11 INCIDENCE OF ERECTILE DYSFUNCTION AFTER RADIATION THERAPY FOR PROSTATE CANCER

Study	Treatment	Follow-Up (Months)	Pre-RT Potency (No ED)	Post-RT Potency (No ED)
Chen et al[148]	IMRT	24	100%	73%
Hoffman et al[149]	IMRT	60	78%	50%
Friedland et al[150]	SBRT	24	100%	82%
Chen et al[151]	SBRT	28	100%	79%
Obayomi-Davies et al[152]	SBRT	24	100%	54%
Nobes[153]	LDR	24	100%	62%
Solan[154]	LDR	26	100%	77%
Taira[155]	LDR	84	100%	56%

For patients with HCC with macrovascular invasion, systemic treatments like sorafenib had been the only option. A randomized trial by Yoon et al[156] compared sorafenib with TACE plus external beam RT (45 Gy, with 2.5-3 Gy per fraction). The combination significantly improved the 12-week progression-free survival (86.7% vs 34.3%), objective response rate (33.3% vs 2.2%), time to progression (31.0 vs 11.7 weeks), and overall survival (55 vs 43 weeks) compared to sorafenib alone. The rates of serious adverse events were similar in both arms. In addition, five (11.1%) patients in the TACE-RT group were able to undergo curative surgical resection due to downstaging. No patients in the TACE-RT group developed hepatic decompensation, leading to treatment withdrawal.

Particle Therapy

Charged particle therapy, which includes proton beam therapy (PBT) and carbon ion radiotherapy (CIRT), is increasingly used to treat HCC. By leveraging the physical advantage of Bragg peak, particle therapy may allow the preservation of more surrounding healthy liver tissue based on

dosimetric studies. CIRT also has higher relative biologic effectiveness, allowing for increased hypofractionation regimens. Some institutions have reported promising results, with high rates of local control of cancer and overall survival as well as low incidences of hepatotoxicity.[157] A small, randomized trial of 69 patients compared PBT (70.2 Gy equivalent in 15 fractions) with TACE and showed a trend toward improved local control and progression-free survival and fewer hospitalization days. Among 22 patients who underwent liver transplantation (12 PBTs and 10 TACEs), the pathologic complete response rate was 25% for PBT and 10% for TACE. However, overall survival rates were similar.[158] More comparative studies and randomized clinical trials are needed to confirm the clinical benefit of particle therapy compared to photon-based RT or other liver-directed therapies.

Systemic Treatment

For patients with advanced HCC not suitable for any locoregional treatment or with distant metastases, systemic therapy is recommended for palliation. There have been drastic changes in the medical treatment for HCC over the past decade. Thanks to a series of successful clinical trials, molecular targeted therapy and immunotherapy are now recommended over cytotoxic chemotherapy, and the survival rate of patients with advanced disease has gradually increased.

Chemotherapy

HCC shows only modest responses to most conventional cytotoxic chemotherapy agents, and there is no clear evidence of a survival benefit for any regimen. Hence, chemotherapy is less frequently used in clinical practice today. Some historically active drugs include gemcitabine, cisplatin, doxorubicin, oxaliplatin, and 5-fluorouracil (5-FU).

Molecular Targeted Therapy

In 2000, Hanahan and Weinberg[159] summarized the six hallmarks of cancer: self-sufficiency in growth signals, insensitivity to antigrowth signals, evasion of apoptosis, sustained angiogenesis, limitless replicative potential, and tissue invasion and metastasis. Advances in molecular biology have uncovered the structures and functions of molecules in signaling pathways associated with cancer cell growth. These have led to the development of molecular agents targeting specific molecules or pathways that drive tumor growth and survival. Molecular targeted therapy seeks to disrupt the cancer's ability to proliferate while sparing healthy cells. Molecular targeted therapy targeting the epidermal growth factor receptor and vascular endothelial growth factor (VEGF) signaling pathways has exhibited potential in inhibiting HCC tumor growth.[160] Thalidomide, a sedative with antiangiogenic activity previously associated with severe fetal malformations but highly effective for myeloma, has limited value in the treatment of HCC.[161,162] Sorafenib was the first active multitarget tyrosine kinase inhibitor for advanced HCC targeting VEGF, the platelet-derived growth factor receptor, and Raf and was approved by the U.S. Food and Drug Administration (FDA) in 2007. The SHARP phase 3 randomized trial showed that, compared with placebo, sorafenib significantly extended overall survival (10.7 vs 7.9 months) and median time to radiologic progression (5.5 vs 2.8 months).[163] The result was confirmed by a similar trial conducted in the Asia-Pacific region.[164] Sorafenib remained the only approved targeted agent for a decade, until another multi-kinase inhibitor, lenvatinib, was proven noninferior to sorafenib in the first-line setting. In the REFLECT phase 3 randomized noninferiority trial,[165] median survival times were 13.6 months for patients who received lenvatinib and 12.3 months for patients who received sorafenib (hazard ratio 0.92, 95% CI 0.79-1.06). Other approved second-line targeted agents for

patients whose disease progressed after or were intolerant to sorafenib include regorafenib,[166] cabozantinib,[167] and ramucirumab.[168] Common side effects of multi-kinase inhibitors include hypertension, hand-foot skin reaction, anorexia, and fatigue.

Some clinical studies showed benefits in local control by combining sorafenib with conventional irradiation.[169,170] However, the combination of sorafenib with radiation should be given cautiously. A single 8-Gy irradiation to the lumbar spine has been reported to be associated with the complication of bowel perforation.[171] We recommend stopping antiangiogenic agents during RT.

The NRG/RTOG 1112 trial was a randomized phase 3 trial comparing SBRT followed by sorafenib with sorafenib alone. The trial ended early. However, with 177 randomized patients, adding SBRT improved overall survival (15.8 vs 12.3 months, $P = .042$ after adjustments) and progression-free survival (9.2 vs 5.5 months, $P = .0001$), with no observed increase in adverse reactions and a strong suggestion for quality of life benefit at 6 months.[136] Therefore, adding SBRT may have the potential to further improve the treatment outcomes of targeted therapy.

Immunotherapy

Most patients with HCC have underlying cirrhosis and viral hepatitis, which cause chronic inflammatory conditions in the liver. The liver is a central immunomodulator that ensures organ and systemic protection while maintaining immune tolerance. Deregulation of this tightly controlled liver immunologic network is a hallmark of chronic liver disease and HCC, providing a rationale for the exploration of immunotherapy.[172] Inhibitors of immune checkpoints such as cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4), programmed cell death protein-1 (PD-1), and programmed cell death ligand 1 (PD-L1) were developed and tested. A phase I/II study including 262 patients demonstrated that the PD-1 inhibitor, nivolumab, was safe and effective in advanced HCC. The overall response rate was 20%, and the responses were more durable than with targeted agents (median 17 months). Common adverse effects included skin rash, pruritus, and elevation of aspartate transaminase, ALT, lipase, and amylase.[173] The trial did not observe excessive toxicity among patients with HBV or HCV infection. Another anti–PD-1 agent, pembrolizumab, also showed a response rate of 17% in the KEYNOTE-224 trial.[174]

VEGF can have immunosuppressive effects, and VEGF expression in HCC cells has been associated with expression of immune-modulating molecules on endothelial cells, including PD-L1.[175] Therefore, VEGF inhibitors may potentiate the effect of immune checkpoint inhibitors. The IMBrave150 trial was a phase 3 randomized trial comparing atezolizumab, an anti–PD-L1 inhibitor, plus bevacizumab with sorafenib for patients with advanced HCC (mostly BCLC stage C) with Child-Pugh A classification.[176] The combination significantly improved 12-month overall survival (67.2% vs 54.6%, $P < .001$) and median progression-free survival (6.8 vs 4.3 months, $P < .001$). Atezolizumab plus bevacizumab is recommended as a first-line regimen, and several other checkpoint inhibitor and VEGF inhibitor combinations are also being tested in clinical trials.

Combinations of immune checkpoint inhibitors have also been investigated. The combination of CTLA-4 and PD-L1 inhibitors has shown additive antitumor activity associated with complementary immunostimulatory effects. In the randomized 3-arm phase 3 HIMALAYA trial, the STRIDE regimen, tremelimumab (anti–CTLA-4) plus durvalumab (anti–PD-L1), was compared to durvalumab alone and sorafenib. STRIDE significantly improved median overall survival versus sorafenib (16.43 vs 13.77 months). Durvalumab monotherapy was noninferior to sorafenib (16.56 vs 13.77 months).[177]

Areas of Failure and Cause of Death

Survival with various treatments depends largely on HCC clinical stage and liver function. The 5-year survival in resectable HCC after partial hepatectomy is 50% to 73% in stage I patients, 30% to 56% in stage II patients, 10% to 29% in stage III patients, and approximately 10% in stage IV patients.[178,179] The 5-year survival rate for patients with unresectable HCC is usually <10%.[180] The major cause of failure after resection is tumor recurrence within the liver. Extrahepatic metastasis in advanced HCC has become more frequently encountered in recent years, probably due to improvements in survival from intrahepatic disease.[181,182] Patients with HCC mostly die of liver tumor progression, treatment-related complications (eg, infection), or underlying disease such as complications of chronic hepatitis with cirrhosis (eg, hepatic failure, variceal bleeding, hepatorenal syndrome).

Future Study

Currently, the prognosis for patients with HCC following various treatments remains unsatisfactory, primarily due to the high rates of intrahepatic recurrence. Future efforts should focus on preventing HBV infection by increasing vaccination and curbing HCV infection through rigorous blood product screening and adherence to universal needle precautions, particularly in endemic regions. New antiviral agents targeting HCV have been successful in managing infected individuals.

Recently, MR-guided linear accelerators (MR-Linac) combine an MRI scanner with a linear accelerator and can track and visualize tumors in real time. Compared with cone-beam CT, MR-Linac can provide better soft tissue contrast, especially in the abdominal-pelvic region. This, along with real-time tracking, improves localization of the tumor before and during the radiation treatment, allowing for minimization of treatment margins.[183] MR-Linac also provides the opportunity for daily adaptive planning and dose escalation. Treatment results from Washington University are encouraging. With a dose of 50 Gy in five fractions, the 2-year local progression rate was only 9.8%.[184]

OTHER PRIMARY LIVER TUMORS

Primary sarcomas of the liver are extremely rare in adults and represent only 1% of primary liver cancers.[185] Leiomyosarcoma is the most common histologic type, followed by malignant fibrous histiocytoma, epithelioid hemangioendothelioma, and angiosarcoma.[186] Some patients with angiosarcoma have a history of occupational exposure to vinyl chloride monomer.[187] The severity of the histologic grade determines overall patient survival. Complete resection offers a chance of long-term survival.[185]

A hemangioma is a benign lesion and is generally asymptomatic. For symptomatic hemangiomas, treatments include steroids, IFN-α, arterial embolization, and surgery.[188] If patients fail the above treatments, RT may play a role. Long symptom-free duration has been obtained with doses to the involved area as low as 13 to 30 Gy in 2.5 to 4 weeks.[188]

HEPATOBLASTOMA

Hepatoblastoma is the most common malignant liver tumor of childhood. Hepatoblastoma occurs most commonly (~48%) in young children (median age, 13-16 months) and usually presents in adults at an advanced stage with grave prognosis.[189,190] Children with familial adenomatous polyposis of the colon and rectum are at high risk for hepatoblastoma. The risk of hepatoblastoma in these children is 700 to 7,500 times that of the general population.[191,192] Chemotherapy combined with surgery has resulted in dramatic improvements in prognosis.[193] With the combination of

chemotherapy and surgery, 75% to 80% of patients may be cured.[189] Preoperative chemotherapy often converts tumors from unresectable to resectable and may reduce blood loss and technical complications.[194]

BILIARY TRACT CANCER

Biliary tract cancers consist of cancer of the gallbladder, the bile ducts, and the ampulla of Vater. They are clinically highly aggressive tumors and are usually discovered at a locally advanced stage of disease. The current edition of the WHO classification of digestive system tumors classifies these cancers into primary liver tumors and extrahepatic biliary tract tumors.[1] Biliary tract cancer can appear in small intrahepatic bile ducts as well as large intrahepatic and extrahepatic bile ducts. The term *cholangiocarcinoma* is used to describe cancers arising from the epithelial cells of the bile ducts. At present, biliary tract cancers that can be completely removed with surgical excision are associated with good long-term survival. For unresectable tumors, the treatment goal is relief of obstructive jaundice via biliary drainage and management of biliary tract infection, pain, and ascites.

CHOLANGIOCARCINOMA

Topographic Anatomy

The bile ducts originate within the liver, with the left and right hepatic ducts joining to form the common hepatic duct. At the origin of the cystic duct, it becomes the common bile duct. The cystic duct drains bile from the gallbladder into the common bile duct. The gallbladder is adjacent to the undersurface of the liver.

There is a rich lymphatic network along the submucosa of bile ducts. The primary lymphatic drainage of the biliary tract is to the pericholedochal, periportal, hepatoduodenal ligament, common hepatic artery, and pancreaticoduodenal lymph nodes.[195,196]

Epidemiology and Risk Factors

Cholangiocarcinoma is a rare tumor in developed countries; there are approximately 2,000 to 3,000 cases per year in the United States. However, it is one of the most common cancers in endemic areas of developing countries, with incidence rates as high as 87 per 100,000 people in northeast Thailand.[197] Cholangiocarcinoma accounts for about 15% of primary liver cancer worldwide. However, the proportion varies regionally: 20% in Western countries, <10% in Asian nations, and as high as 90% in northern Thailand.[197,198]

A number of risk factors have been identified as important in the development of cholangiocarcinoma; most share a history of long-standing inflammation and chronic injury of the biliary epithelium.[199] The major risk factor in Western countries is primary sclerosing cholangitis, which is closely associated with chronic inflammatory bowel disease, particularly ulcerative colitis.[200] The risk of developing cholangiocarcinoma is higher in patients with primary sclerosing cholangitis and ulcerative colitis with colonic neoplasms than in patients with primary sclerosing cholangitis and ulcerative colitis without colonic neoplasms.[200] Studies in Japan and the United States have shown that chronic hepatitis C infection elevates the incidence of ICC with an OR between 4 and 17.[201,202] In Asia, chronic infections of the biliary tract related to infestation by certain liver flukes, such as *Clonorchis sinensis* and *Opisthorchis viverrini*, are associated with cholangiocarcinoma and hepatolithiasis.[196] Hepatolithiasis itself is also a risk factor for cholangiocarcinoma. Five to 10% of patients with intrahepatic stones develop this

complication.[203,204] Moreover, the combination of liver fluke infestation and nitrosamine exposure may explain the very high incidence of cholangiocarcinoma in northeast Thailand.[205]

Other risk factors, although rare, include congenital fibropolycystic disease of the biliary system, such as choledochal cysts and Caroli disease (cystic dilatation of intrahepatic bile ducts).[206] The observed incidence and mortality of ICC have increased in the past three decades in Japan, the United States, and the United Kingdom.[21,207,208] However, the incidence of extrahepatic cholangiocarcinoma remains almost the same.[209] In the United States, the age-adjusted mortality rate has increased from 0.07 per 100,000 in 1973 to 0.69 per 100,000 in 1997. The estimated annual percent increase in mortality rate was 9.44% during this period. Between 1973 and 2012, the incidence of ICC increased from 0.44 to 1.18 cases per 100,000, representing an annual percentage increase of 2.3%; this trend has accelerated during the past decades to an annual percentage increase of 4.36%.[209] Better case ascertainment and diagnosis from improved imaging, use of image-guided biopsies, or increased use of endoscopic retrograde cholangiopancreatography (ERCP) cannot fully explain this observation.[208,210]

Diagnosis

The most common presenting symptoms of biliary tract cancer are caused by obstruction of the bile duct. These include painless jaundice, clay-colored stools, tea-colored urine, and pruritus. Other signs and symptoms include abdominal pain, fever, generalized malaise, abdominal distention, abdominal fullness, anorexia, and weight loss. The spectrum of cholangiocarcinoma can be classified into three broad groups: (a) intrahepatic, (b) perihilar, and (c) distal tumors. The age of onset is similar among these three groups and ranges from 60 to 65 years.[211] Patients with extrahepatic tumors usually present with jaundice, alcoholic stools, and tea-colored urine. Patients with intrahepatic tumors are less likely to be jaundiced and more likely to present with abdominal symptoms and more advanced disease.

There are no reliable screening methods, and early diagnosis is almost impossible even in patients with high-risk conditions, such as primary sclerosing cholangitis, parasitic infestation, and hepatolithiasis.[212] Some patients are diagnosed when blood work demonstrates elevation of alkaline phosphatase and γ-glutamyl transferase. Ultrasonography and CT are the primary tools used initially to evaluate biliary tract tumors (Table 66.12). Further tests include percutaneous transhepatic cholangiography; ERCP with brush cytology; serum carbohydrate antigen 19-9 (CA 19-9) levels; radiologic imaging with dynamic CT scan, MRI, or both; and angiography.

Arteriography

CA 19-9, carbohydrate antigen 19-9; CEA, carcinoembryonic antigen.
Modified from Gunderson LL, Willett CG. Pancreas and hepatobiliary tract. In: Perez CA, Brady LW, eds. *Principles and Practice of Radiation Oncology*. 3rd ed. Lippincott-Raven; 1997.

A serum CA 19-9 value >100 U/mL has a sensitivity of approximately 75% and a specificity of approximately 80%.[213] The optimal cutoff value for serum CA 19-9 that best discriminates between benign and malignant biliary tract diseases is influenced by the presence of cholangitis. Thus, in patients with symptoms of acute cholangitis, serum CA 19-9 concentrations should ideally be reevaluated after recovery. The sensitivity of serum carcinoembryonic antigen (CEA) is low, helpful only in one-third of patients.[214] Biliary CEA levels increase significantly in patients with cholangiocarcinoma and also in patients with intrahepatic cholelithiasis (average 50.2-57.4 ng/mL) compared to patients with benign strictures (average 10.1 ng/mL) and patients with sclerosing cholangitis and choledochal cysts (average 20.0-21.6 ng/mL).[214] Serum AFP may increase in some cases of cholangiocarcinoma, and this would suggest a diagnosis of mixed HCC and cholangiocarcinoma.[215]

Pathology

Cholangiocarcinomas arise from the epithelium of the biliary tract. There are two main histologic subtypes: bile ductular type (mixed), arising from small intrahepatic bile ducts, and bile duct type (mucinous), arising from large intrahepatic and extrahepatic bile ducts.[216] Histologic diversity in cholangiocellular carcinoma reflects the different cholangiocyte phenotypes.[217] The majority of these cancers are adenocarcinomas (>90%). Squamous cell carcinoma is the second most common histologic type. Rare histologies include mucoepidermoid carcinoma, cystadenocarcinoma, and carcinoid tumor.

Adenocarcinomas are divided into three types: sclerosing, nodular, and papillary. Sclerosing tumors are characterized by an intense desmoplastic reaction. This type of tumor tends to invade the bile duct wall early and, as a result, is associated with low resectability and cure rates. Most cholangiocarcinomas are of this type.[211] Nodular cholangiocarcinomas are also highly invasive tumors. Most patients have advanced disease at diagnosis. Resection and cure rates are both very low. In contrast, papillary-type tumors usually present as masses in the lumen of bile ducts, causing biliary obstruction early in the disease course. Therefore, these tumors have a more favorable prognosis.[218] Microscopically, cholangiocarcinoma ranges from well differentiated to undifferentiated. Cells tend to be cuboidal or low columnar and resemble biliary epithelium; mucin is always demonstrable in the cytoplasm. Readers should be aware that bile duct obstruction can be associated with reactive hyperplasia of subepithelial mucous glands in the presence or absence of cholangiocarcinoma.[219] Cholangiocarcinomas frequently invade lymphatic, perineural, and periductal spaces and portal tracts. Spread along the lumen of large bile ducts can also be seen, especially in perihilar cholangiocarcinoma.[220]

The positive association of cholangiocarcinoma with CEA, CA 19-9, and immunohistochemical staining with cytokeratin-19 can help with its differentiation from HCC.[221] Mutations in the p53 tumor suppressor gene and K-RAS proto-oncogene have been identified in cholangiocarcinoma.[222-224] p53 overexpression and K-RAS mutations are associated with a shortened survival.[222] Recent

marker analysis of cholangiocarcinoma from The Cancer Genome Atlas revealed a distinct subtype enriched for isocitrate dehydrogenase (IDH) mutants.[225] IDH mutations block normal cellular differentiation and promote tumorigenesis via the abnormal production of the oncometabolite D-2-hydroxyglutarate. Mutant IDH is a therapeutic target of tumor growth inhibitors under development.[226]

Pathways of Tumor Spread

Bile duct cancers commonly spread by direct extension through the biliary tract and the abundant lymphatic network in the submucosa. These tumors also commonly involve the surrounding structures by direct invasion. Lymph node metastases in the porta hepatis and celiac axis are common. The lymph nodes in the porta hepatis are more frequently involved with tumors in the intrahepatic duct and proximal extrahepatic bile duct, while the pancreaticoduodenal nodes are more often involved with tumors in the distal bile duct.[220,227]

The incidence of lymph node metastasis in ICC ranges from 50% to 60%.[228,229] ICCs, irrespective of their intrahepatic location, mainly spread to nodes in the hepatoduodenal ligament, then to the para-aortic, retropancreatic, or common hepatic artery nodes. In addition, the left peripheral type or hilar type of cholangiocarcinoma tends to spread along the left gastric nodes through the lesser curvature.[229] Lymph node metastasis in perihilar cholangiocarcinoma is common, occurring in about half of all patients, with a frequency of 43% in pericholedochal nodes, 31% in periportal nodes, 27% in common hepatic nodes, and 15% in posterior pancreaticoduodenal nodes. The celiac and superior mesenteric nodes are rarely involved.[220]

Lymph node metastasis in distal duct cancer is commonly observed near the pancreaticoduodenal region. Yoshida et al[227] examined 20 consecutive patients with distal bile duct cancer who underwent pancreaticoduodenectomy with extended lymph node dissection. Histologic evidence of lymph node metastasis was seen in 55% of the patients. The areas with frequent metastases were the posterior pancreaticoduodenal lymph nodes (35%), the nodes around the hepatoduodenal ligament (35%), and those around the common hepatic artery (30%). Para-aortic lymph node involvement occurred in 25% of patients and was significantly associated with pancreatic parenchymal invasion.

Staging for Cholangiocarcinoma

The AJCC TNM classifications (eighth edition) for ICC are shown as follows:

T category:

T1: solitary tumor without vascular invasion

T1a: solitary tumor ≤5 cm

T1b: solitary tumor >5 cm

T2: solitary tumor with intrahepatic vascular invasion or multiple tumors, with or without vascular invasion

T3: tumor perforating the visceral peritoneum

T4: tumor involving local extrahepatic structures by direct invasion

N category:

N0: no regional lymph node metastasis

N1: regional lymph node metastasis present

M category:

M0: no distant metastasis

M1: distant metastasis present

The complete staging groups are listed in Table 66.13. The AJCC TNM staging for both perihilar and distal cholangiocarcinoma was revised in 2017 (Table 66.13). The N category is classified based on the number of positive nodes (N1: one to three positive nodes; N2: four or more positive nodes). The T category of perihilar cholangiocarcinoma is as follows: T1 is a tumor confined to the bile duct, T2 is a tumor invading beyond the bile duct wall, T3 is a tumor invading unilateral branches of the portal vein or hepatic artery, and T4 is a tumor invading the main portal vein or its branches bilaterally. The T category in distal bile duct cancer is classified based on the depth of invasion (T1: <5 mm; T2: 5-12 mm; T3: >12 mm).

TABLE 66.13 AJCC STAGE GROUPS BY TNM CLASSIFICATION (EIGHTH EDITION)

Intrahepatic Cholangiocarcinoma
Stage IA: T1aN0M0
Stage IB: T1bN0M0
Stage II: T2N0M0
Stage IIIA: T3N0M0
Stage IIIB: T4N0M0, or any T, N1M0
Stage IV: any T, any N, M1
Perihilar Cholangiocarcinoma
Stage I: T1N0M0
Stage II: T2a-bN0M0
Stage IIIA: T3N0M0
Stage IIIB: T4N0M0
Stage IIIC: any T, N1M0
Stage IVA: any T, N2M0
Stage IVB: any T, any N, M1
Distal Cholangiocarcinoma
Stage I: T1N0M0
Stage IIA: T2N0M0, T1N1M0
Stage IIB: T2-T3N1M0
Stage IIIA: T1-T3N2M0
Stage IIIB: T4, N1-N2, M0
Stage IV: any T, any N, M1

The primary prognostic factors for cholangiocarcinoma include resectability, regional lymph node metastasis, and distant metastasis. Multivariate analysis using a Cox proportional hazards model demonstrated that multifocality, extrahepatic extension, grade, node positivity, and age >60 years (MEGNA) are independently associated with decreased overall survival. The MEGNA prognostic score was developed to improve prognostication over the AJCC seventh staging system.[230] However, one report showed that it did not perform better than the AJCC eighth staging system.[231]

General Management

Surgical resection currently is the only potentially curative treatment for cholangiocarcinoma. According to data from a large series, the resection rates for intrahepatic, perihilar, and distal lesions are 50%, 56%, and 91%, respectively.[211] The 5-year survival rates after resection range from 10% to

40%, depending on the location of the primary tumor.[211] Patients with unresectable cholangiocarcinoma generally have a very poor prognosis. Chemotherapy and RT have been the mainstay treatments, but the results are disappointing.[232]

Intrahepatic Cholangiocarcinoma

ICC accounts for 5% to 10% of all biliary tract cancers and 10% to 20% of primary liver malignancies. Only 30% to 50% of patients are eligible for surgical resection.[233,234] Postsurgical prognosis is notably poorer in patients with lymph node metastasis, regardless of the site of nodal metastasis. The 5-year survival rate for patients with lymph node metastasis is significantly lower than for those without (0% vs 51%; $P < .0001$).[229] Key factors influencing tumor recurrence include lymph node metastasis, the presence of satellite nodules, positive resection margin, tumor size, and bilobar distribution.[229,235,236] Following surgical resection of ICC, the most common sites for disease recurrence are the liver (56%), regional lymph nodes (20%), and peritoneal seeding (24%).[237]

The role of postoperative adjuvant RT, with or without chemotherapy, in the management of ICC is controversial. Limited low- to moderate-quality retrospective data suggest that adjuvant external beam RT, primarily in combination with concurrent chemotherapy, may improve locoregional control and relapse-free survival with a trend toward overall survival improvement.[137] Future phase II studies would benefit from a rational delineation of radiation fields based on patterns of failure analysis and lymph node spread.

For unresectable ICC, systemic therapy is the mainstay of treatment. However, historical median overall survival and intrahepatic progression-free survival rates after chemotherapy alone are less than 1 year. Studies suggest that consolidative RT after chemotherapy, or as salvage therapy after disease progression, may prevent liver failure caused by vascular obstruction and improve local control and overall survival.[137] The 1-year survival for patients treated with external beam radiation ranged from 39% to 70%.

Additional treatments for select patients with unresectable ICC include ablation, TACE, TARE, and RT. The efficacy of intra-arterial therapy (TACE, DEB-TACE, or TAE) was assessed in a multicenter retrospective analysis (median tumor size 8.1 cm; 47.5% of patients with a solitary lesion), which reported a median overall survival of 13.2 months with no significant difference in patient responses to different intra-arterial therapies.[238]

Emerging data suggest that liver transplantation may be an option in patients with ICC.[239] In a multinational cohort of patients with cirrhosis who underwent transplantation for presumed small HCC, incidental ICC was found on explant pathology. The 1-, 3-, and 5-year actuarial survival rates in patients with very early ICC (≤2 cm) were 93%, 84%, and 65%, respectively.[240] Lunsford et al[241] reported a 5-year survival rate of 83.3% in patients with locally advanced, unresectable ICC who underwent transplantation after neoadjuvant chemotherapy and were stable for at least 6 months, although the recurrence-free survival was only 50%.

Perihilar Cholangiocarcinoma

Perihilar cholangiocarcinoma, also known as Klatskin tumors[242] when involving the bifurcation of the hepatic duct, is the most common biliary tract carcinoma, comprising 65% to 70% of all cases (Figure 66.5).[211] These tumors are classified by Bismuth et al[243] into several types based on their location: Type I tumors are below the confluence of the left and right hepatic ducts; type II tumors reach this confluence; type IIIa and IIIb tumors obstruct the common hepatic duct and either the right or left hepatic duct; and type IV tumors are multicentric or involve the confluence as well as both the right and left hepatic ducts.

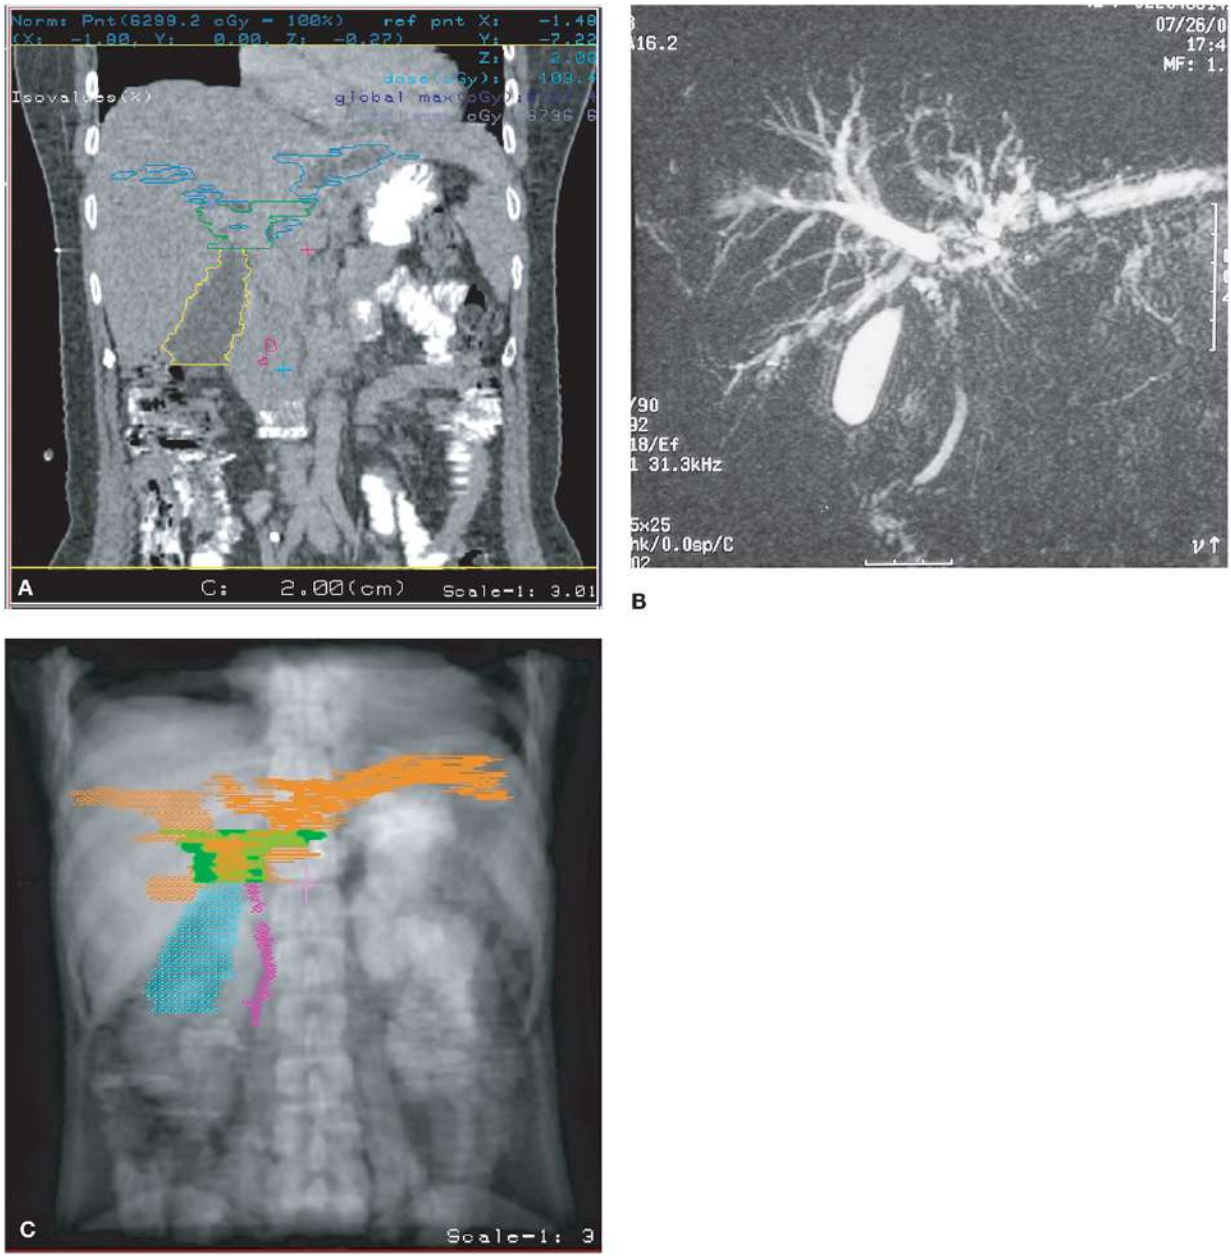

FIGURE 66.5 A. Computed tomography (CT) was performed in a 39-year-old woman who had cholangiocarcinoma of perihilar area. This image was reconstructed from a CT at 2-mm slice intervals. The tumor involved the right and left hepatic ducts (green line). B. Magnetic resonance cholangiopancreatography confirmed the extent of tumor involvement. C. Digital reconstruction radiography revealed the gross tumor volume (green) and clinical target volume (purple).

Surgical resection is only possible in 25% to 79% of patients. Definitive surgery often requires a combination of bile duct and liver resection, including caudate lobectomy.[244] The surgical approach to perihilar cholangiocarcinoma has become more aggressive over time. While more patients with locally advanced disease undergo surgery, the long-term survival rate has also increased.[239] In a series of 574 patients with perihilar cholangiocarcinoma undergoing surgical resection, the 5-year disease-specific survival rate was 32.5%. Between 2001 and 2010, 243 patients with R0 disease and no lymph node metastasis after resection had a 5-year survival rate of 67.1%, but 142 patients with

nodal metastasis had a 5-year survival rate of 22.1%.[245] Multivariate analysis revealed that lymph node metastasis was the strongest prognostic indicator.

The role of postoperative RT with or without chemotherapy in patients with completely resected cholangiocarcinoma remains unclear. A meta-analysis by Horgan et al[246] including 20 studies of adjuvant therapy for biliary tract cancers from 1960 to 2010 found a nonsignificant improvement in overall survival with adjuvant treatment compared to surgery alone (P = .06). However, patients treated with chemoradiotherapy (OR = 0.61) or chemotherapy (OR = 0.39) derived greater benefit than patients treated with RT alone (OR = 0.98, P = .02), particularly those with positive lymph nodes (OR = 0.49, P = .004) and R1 disease (OR = 0.36, P = .002). A meta-analysis of 21 clinical trials involving 1,465 patients with extrahepatic cholangiocarcinoma and gallbladder cancer showed significantly higher 5-year overall survival rates with adjuvant RT for patients with lymph node–positive disease (OR = 0.15) and margin-positive disease (OR = 0.40) and nonsignificantly higher 5-year overall survival rates for margin-negative disease (OR = 0.54).[247]

For unresectable perihilar cholangiocarcinoma, neoadjuvant chemoradiotherapy followed by liver transplantation is a viable treatment option. Data from the Mayo Clinic revealed that the 5-year survival in transplant patients of unresectable hilar cholangiocarcinoma after induction chemoradiotherapy was 80%; in resection-only patients, it was 21%.[248] Others also have reported similar promising results by treating these unresectable cholangiocarcinomas with induction chemoradiotherapy followed by liver transplant.[249,250] Data from 12 large-volume centers in the United States showed that patients with early-stage, unresectable perihilar cholangiocarcinoma who underwent neoadjuvant chemoradiation followed by liver transplantation had a 5-year post-transplant recurrence-free survival of 65% and an intent-to-treat survival of 53%.[239,251]

Patients with inoperable perihilar cholangiocarcinoma typically experience obstructive jaundice and initially require either endoscopic or percutaneous drainage or stent placement, or both. Although external beam RT alone is often insufficient for controlling advanced disease, a combination of external beam RT, chemotherapy, and intraluminal brachytherapy can be effective in alleviating pain and aiding in biliary decompression, occasionally leading to long-term survival. The most active chemotherapy agents include 5-FU, gemcitabine, docetaxel, and oxaliplatin,[252,253] with a median survival time ranging from 17 to 21 months.[254,255]

Distal Bile Duct Carcinoma

Primary distal bile duct adenocarcinoma, which includes carcinoma of the ampulla of Vater, accounts for 25% to 30% of all biliary tract carcinomas.[211] Surgical resection, the primary treatment modality for distal duct carcinoma, typically involves a pancreaticoduodenectomy (Whipple procedure). This procedure includes the removal of the gallbladder and bile duct, the head of the pancreas, and the first part of the duodenum.[239]

Patients with distal duct carcinoma have a higher likelihood of undergoing a curative resection compared to those with proximal duct carcinomas. A study of 680 patients from Korea compared surgical treatment outcomes of patients with perihilar and distal cholangiocarcinoma. The study reported a higher R0 resection rate (77.3% vs 89.9%, P = .001) and an improved 5-year survival rate (30.8% vs 47.8%, P = .001) in patients with distal cholangiocarcinoma. Patients with distal duct carcinoma confined to the bile duct without lymph node metastasis had the highest 5-year survival rate (64.3%).[256]

The role of postoperative RT is uncertain. A propensity-matched analysis of patients from the National Cancer Database undergoing pancreatoduodenectomy for nonmetastatic distal cholangiocarcinoma concluded that adjuvant RT was associated with a survival benefit. The median

survival was 29.3 months with adjuvant RT and 26.8 months without RT ($P < .001$). Multivariable interaction analysis showed this benefit, irrespective of nodal or margin status.[257]

Systemic Chemotherapy

Because of the high recurrence rate and suboptimal overall survival following surgery with curative intent in patients with cholangiocarcinoma, adjuvant chemotherapy has been explored in multiple nonrandomized and randomized clinical trials. The phase 2 Southwest Oncology Group (SWOG) S0809 trial evaluated adjuvant capecitabine plus gemcitabine followed by chemoradiotherapy with capecitabine for the treatment of resected extrahepatic cholangiocarcinoma and gallbladder carcinoma with pT2-4, N+, or positive resection margins. This trial reported a median overall survival of 35 months, with 2-year survival rates of 67% for R0 resections and 60% for R1 resections, surpassing historical rates of 55% and 38%, respectively. These results suggest a potential benefit with adjuvant therapy.[258] In addition, adjuvant chemotherapy alone has been shown to be a viable strategy. In the BILCAP trial, adjuvant capecitabine for 6 months following curative surgery demonstrated a significant survival benefit (median overall survival in the capecitabine arm was 53 vs 36 months in the observation group, $P = .028$) in a protocol-specified sensitivity analysis.[259]

For the treatment of advanced and metastatic cholangiocarcinoma, the most frequently used agents include 5-FU, gemcitabine, cisplatin, and oxaliplatin.[252,253] The phase 3 ABC-02 study enrolled 410 patients with locally advanced or metastatic cholangiocarcinoma, gallbladder cancer, or ampullary cancer. As compared with gemcitabine alone, cisplatin plus gemcitabine was associated with a significant survival advantage (11.7 vs 8.1 months) without substantially increased toxicity. Cisplatin plus gemcitabine is considered the standard first-line option for the treatment of patients with advanced biliary tract cancer.[260] Gemcitabine plus S1 is noninferior to gemcitabine plus cisplatin according to a Japanese phase 3 trial.[261] In patients whose disease has progressed on gemcitabine and cisplatin, the ABC-06 study demonstrated the benefit of folinic acid, 5-FU, and oxaliplatin in the second-line setting.[262]

Targeted Therapy

Advancements in targeted therapy for cholangiocarcinoma are increasingly driven by an in-depth understanding of its molecular biology. The advent of next-generation sequencing has identified novel molecular alterations, presenting opportunities for targeted therapy.[263] Promising therapeutic molecular targets for cholangiocarcinoma include *IDH1* and *IDH2* and fibroblast growth factor receptor 2 (*FGFR2*) gene products. The genomic landscape of ICC and extrahepatic cholangiocarcinoma notably differs. FGFR2 and IDH mutations, primarily IDH1 versus IDH2, are more prevalent in ICC. In contrast, BRCA, HER2, and BRAF mutations are more common in extrahepatic cholangiocarcinoma.[264] FGFR2 alterations, including rearrangements, amplifications, and mutations, occur in 10% to 16% of patients with ICC. In 2019, the FDA granted accelerated approval for pemigatinib, an FGFR2 inhibitor, as the first targeted therapy for locally advanced or metastatic cholangiocarcinoma with FGFR2 fusions or rearrangements. The approval was based on the phase 2 FIGHT-202 trial, which showed an objective response rate of 35.5% and median progression-free survival and overall survival of 6.9 and 21.1 months, respectively.[265] Several other FGFR inhibitors, such as infigratinib, futibatinib, and derazantinib, are currently being developed.

IDH1 gene mutations, found in approximately 13% of ICC cases, are targeted by ivosidenib, a small molecule inhibitor. The phase 3 ClarIDHy trial, a randomized, double-blind, placebo-controlled study, demonstrated that ivosidenib significantly improved progression-free survival

compared to placebo (2.7 vs 1.4 months) in patients with advanced cholangiocarcinoma and IDH1 mutations who had progressed on prior therapy.[266]

Immunotherapy

PD-L1 expression has been detected in 10% to 70% of biliary tract cancer cases. However, monotherapy with PD-1/PD-L1 checkpoint inhibitors did not achieve satisfactory results in unselected patients with cholangiocarcinoma.[267] This led to an investigation of the combination of a PD-1/PD-L1 inhibitor with chemotherapy, based on evidence of the immunomodulatory effect of chemotherapy.

Both durvalumab (anti–PD-L1) and pembrolizumab (anti–PD-1) improved overall survival when combined with the standard first-line chemotherapy: gemcitabine plus cisplatin. The phase 3 TOPAZ-1 trial showed that the 24-month overall survival rate was 24.9% for durvalumab plus chemotherapy and 10.4% for placebo plus chemotherapy (hazard ratio 0.8, $P = .021$). Objective response rates were 26.7% with durvalumab and 18.7% with placebo.[268] In the KEYNOTE-966 trial, the median overall survival was 12.7 months in the pembrolizumab plus chemotherapy group versus 10.9 months in the placebo plus chemotherapy group (hazard ratio 0.83, $P = .02$).[269] Therefore, an immune checkpoint inhibitor plus gemcitabine and cisplatin is also increasingly accepted as a first-line treatment for patients with metastatic or unresectable biliary tract cancer.

Radiation Therapy

Despite advancements in systemic therapy for unresectable or advanced biliary tract cancers, the prognosis remains poor, with a median overall survival of only 11 to 12 months using systemic therapy.[260,268] Many patients with biliary tract cancer die of hepatic failure caused by local tumor progression. Palliative RT may relieve pain and biliary obstruction, but conventional RT often results in high rates of locoregional failure (60%-75%) at 1-year post-treatment, with median survival ranging from 7 to 12 months.[270,271] Local failure remains the first site of disease progression.[271] Combining RT with 5-FU–based chemotherapy is generally recommended to enhance treatment efficacy.[272,273]

SBRT, known for its ability to deliver highly conformal ablative doses of radiation, has been studied for its potential to improve RT outcomes in cholangiocarcinoma. Many prospective and retrospective series have reported encouraging local control rates. A systematic review by Frakulli et al[274] of 10 studies involving 231 patients showed that the pooled overall survival rate was 58.3% at 1 year and 35.5% at 2 years. The pooled 1-year local control rate was 83.4%. The median prescribed dose ranged between 30 and 60 Gy in three to five fractions. The reported rate of severe toxicities, including biliary stenosis, cholangitis, gastroduodenal ulcer and perforation, and liver failure, was about 10%.

RT techniques for cholangiocarcinoma closely mirror those for HCC. A notable consideration during radiation treatment is tumor movement due to respiration. To mitigate this movement and minimize the exposure of normal adjacent organs to radiation, several techniques are recommended. During simulation, oral contrast is used to clearly define the boundaries of the duodenum, and 4D CT captures the tumor's movement over the respiratory cycle, aiding in precise treatment planning. In addition, breath-holding technique and abdominal compression may be utilized to limit organ and tumor movement during radiation delivery. The critical organs that require protection include the liver, duodenum, stomach, and spinal cord. These organs are carefully considered in the planning process to ensure they receive as little radiation as possible while still effectively targeting the tumor.

Treatment Volumes

The extent of a tumor within the bile duct can be defined by percutaneous cholangiography, ERCP, and MR cholangiopancreatography. However, identifying extraductal disease noninvasively remains challenging. Surgical clip placement is useful in delineating the extrahepatic portion of ductal lesions and helps define the primary tumor bed.

To minimize errors in radiation treatment planning, it is advisable to position patients for pretreatment CT scans as they would be during treatment. Scans should be performed with 1 to 3 mm slices and use a contrast medium to reconstruct the anatomy of bile ducts and GTV (Figure 66.3). GTV is defined as any visible tumor presence on either CT or MRI. The CTV is defined as a 1- to 1.5-cm margin beyond the GTV, especially along the bile duct and potential lymphatic drainage areas, including pericholedochal, porta hepatis, hepatic artery, pancreaticoduodenal, celiac, and superior mesenteric artery nodes.[227-229,275,276]

The PTV is defined by adding a margin of 0.5 to 2 cm to the CTV, depending on the respiratory motion control method used. For SBRT, it is recommended to irradiate only the primary tumor and metastatic lymph nodes, excluding high-risk lymph node drainage areas.[277]

In 2017, Socha et al[278] refined the delineation of lymph node regions for CTV in RT planning by analyzing the postoperative nodal involvement and recurrence data from existing research. Their findings suggested that previous RT plans might have missed some lymph nodes, such as the para-aortic and superior mesenteric lymph nodes. Conversely, certain lymph nodes, such as celiac lymph nodes in the middle or distal extrahepatic cholangiocarcinoma, were sometimes unnecessarily included in the target area. They proposed specific lymph node areas be included in the CTV depending on the primary tumor locations (right ICC; left or hilar ICC; proximal, middle, or distal extrahepatic cholangiocarcinoma; and gallbladder cancer). Marinelli et al[279] also conducted a similar analysis.

Radiation Doses

For conventional external beam 3DCRT or IMRT, ASTRO recommends conventional fractionation based on the SWOG S0809 trial.[258] This involves administering 45 Gy to nodal basins and 52.5 to 59.4 Gy to the tumor bed delivered in 25 to 33 fractions.[264] The recommended final dose is 54 Gy in 30 fractions for R0 resection and 59.4 Gy in 33 fractions for R1 resection. If using the simultaneous integrated boost technique, recommended dosages are 52.5 Gy in 25 fractions for R0 resection and 55 Gy in 25 fractions for R1 resection.

If boost-dose irradiation is feasible with brachytherapy techniques, the GTV should receive 45 to 50 Gy via external beam techniques, plus an additional 20 to 30 Gy delivered via intraluminal catheter.[280] The most common brachytherapy technique for the biliary tract involves placement of a percutaneous drainage catheter through the tumor area by an interventional diagnostic radiologist. The radiation oncologist then threads a catheter inside the drainage system catheter. When a low-dose rate system is employed, a wire with Ir-192 is positioned at the desired location inside the catheter.[280] In contrast, a high-dose rate remote afterloading system requires selection and programming of dwell time and position. It is a matter of some debate as to where the brachytherapy prescription point should be placed. Some physicians select the tumor's peripheral edge, away from the catheter, as determined by CT or MRI. Other practitioners prefer a point 0.5 or 1 cm away from the catheter. It is important to be familiar with the valves used to direct bile flow in the drainage system to prevent bile leakage onto the patient's skin and dressings during the administration of brachytherapy. Prolonged drainage system placement (ie, a month) can lead to enteric bacterial colonization and biliary tract infection. The combination of external beam irradiation and brachytherapy employed at Thomas Jefferson University resulted in 2-fold improved 2-year and

median survival rates when doses were brought up to >55 Gy.[280] However, investigators at the University of Amsterdam reported no improved survival at doses >55 Gy.[281] The role of RT and its optimal dosage remains to be determined.

More recent studies, particularly in ICC, have employed a hypofractionated regimen or SBRT. Analysis by Tao et al[282] of a hypofractionated, simultaneous integrated boost approach (ranging from 35 to 100 Gy in 3 to 30 fractions, with a median of 58.05 Gy in 15 fractions) found that the 3-year local control and overall survival rates were higher for patients treated with BED10 >80.5 Gy (78% and 73%) than those treated with BED10 ≤80.5 Gy (45% and 38%). In another retrospective cohort study of patients who received photon or proton therapy of 3,750 to 6,750 cGy (median 5,805 cGy) in 15 fractions for unresectable or locally recurrent ICC, 84% 2-year local control and 58% 2-year overall survival rates were achieved.[283] One multi-institutional retrospective series reported results using SBRT, in which 42% of patients were treated with three- and five-fraction approaches. The median prescribed BED (α/β = 10) was 67.2 Gy (range 36-115 Gy) in a median of 8 fractions (range 3-17); a median BEDmax was 91 Gy. BED >91 Gy was associated with improved local control and overall survival.[284] High-grade toxicities were uncommon in all of these series. The choice of hypofractionated external beam RT regimen should be based on tumor location, underlying liver function, the ability to meet normal tissue constraints, and the available technology, aiming to safely deliver an escalated prescription dose while meeting OAR constraints.[137]

Acute and Late Complications

The acute complications of external beam RT and brachytherapy are usually mild, including nausea, vomiting, and transient elevation of transaminases.[285]

The late and potentially dangerous complications are gastrointestinal bleeding, biliary bleeding, and duodenal stenosis.[280,286,287] The risk of gastrointestinal complications is dose dependent. It is about 5% to 10% if the dose to the duodenum or stomach is less than 55 Gy but rises to about 33% if the dose is greater than 55 Gy.[285]

Future Directions

Despite recent progress, the prognosis of most patients with cholangiocarcinoma remains poor. Due to the poor response rate or high recurrence rate of either surgery, RT, or systemic therapy alone, we should continue to explore the benefit of combined modality treatment. For example, novel combinations of SBRT and immune checkpoint inhibitors are being tested in clinical trials based on preclinical data suggesting a potential synergistic effect.[288]

ADENOCARCINOMA OF GALLBLADDER

Gallbladder carcinoma is a relatively rare malignancy of the biliary tract system with a high mortality rate. It constituted 0.9% of all cancer deaths in 2020.[6] Its incidence indicates large geographic variation.[289] In 2023, the American Cancer Society estimated approximately 12,220 new cases in the United States—5,750 in men and 6,470 in women.[290] Predisposing factors for gallbladder cancer include cholelithiasis, anomalous junction of pancreaticobiliary ducts, and porcelain gallbladder.[291] Cigarette smoking, alcohol consumption, and obesity may also contribute to cancer risk. Notably, patients with gallbladder polyps exceeding 10 mm in diameter may be at increased risk for gallbladder cancer.[292,293] Chronic infection with *Salmonella typhi* and *Helicobacter bilis* is also associated with increased risk.[289,294,295]

The most common clinical presentation is pain, followed by anorexia, nausea, and vomiting. Patients with early invasive gallbladder carcinoma are most often asymptomatic or have nonspecific

symptoms that mimic or are due to cholelithiasis or cholecystitis. Patients with gallbladder carcinoma who present with symptoms such as jaundice, anorexia, and weight loss generally have more advanced disease, which accounts for their poor prognosis.[206] A French study of 724 patients indicated that only 4% of the patients had Tis lesions, while 11% had T1 to T2 lesions and 85% had T3 to T4 lesions.[296] The 5-year survival rates reported in the SEER database were 69% for localized stage, 28% for regional stage, and 3% for distant stage.[297] However, improved outcomes have been noted since the 1990s and have continued through the past decade, likely attributable to more aggressive surgery and the use of postoperative adjuvant therapy.[298,299] Studies from Japan report 5-year survival rates of 100% for stage I, 50% to 78% for stage II, 0% to 69% for stage III, and 0% to 11% for stage IV.[300,301]

Lymphatic metastasis initially involves cystic and pericholedochal nodes, progressing to the pancreaticoduodenal system and potentially to the rest of the celiac axis or the superior mesenteric or aortic nodes.[300,301] The lymph node metastasis rate is associated with primary tumor stage: 0% to 2.5% in pT1a disease (involvement limited to the mucosa), 15% in T1b disease, 62% in pT2 disease, and 81% in pT3 or pT4 disease.[300,302,303]

Surgery remains the only curative option, but only one-quarter of patients are eligible for resection.[304] Standard surgical procedures include removal of the gallbladder, resection of various amounts of liver surrounding the gallbladder bed, resection of the extrahepatic bile duct, and dissection of the regional lymph nodes. Patients with jaundice should be considered for preoperative percutaneous transhepatic biliary drainage for relief of biliary obstruction. Overall curative resection rates for gallbladder carcinoma range from 10% to 30% in Western countries.[305] Prognosis is related to the possibility of curative resection, primary tumor extension, and regional lymph node metastasis.

GALLBLADDER CANCER TREATMENT

Patients with T1a disease are often cured after simple cholecystectomy and require no further adjuvant treatment.[303] In contrast, radical resection is recommended for more advanced stages (≥T2 disease).[298,302,306] The benefit of adjuvant RT is uncertain. After “curative” resection, locoregional relapse in the tumor bed or regional nodes is common. Patients who received radiation postoperatively had a median survival of >16 months. This was compared to <6 months for patients treated with surgery alone. Factors predicting recurrence are positive surgical margins, lymph node metastasis, and perineural invasion.[307] Several retrospective analyses demonstrated that postoperative RT improves local control and survival.[308-310] Benefits are also seen in patients who have microscopic residual tumors.[310] Combination RT and chemotherapy with 5-FU also show similar benefits.[311-313] However, there is a lack of phase 3 studies. Whether combination treatment is better than the single modality remains unknown.

Patients with stage III and IV disease are at high risk for distant metastasis. The most frequent sites of involvement are the liver, peritoneum, and lung, with less frequent spread to the ovaries, spleen, bones, and other organs.[312] In general, patients who are locally unresectable should be referred for chemoradiotherapy. Median survival is improved in several retrospective studies.[314] Systemic chemotherapy has limited success in the treatment of advanced gallbladder carcinoma. Objective response rates range from 25% to 50%. Active agents include infusion of 5-FU in combination with agents such as leucovorin modulation, capecitabine, cisplatin, oxaliplatin, gemcitabine, docetaxel, and 5-FU combined with recombinant IFN-α-2b.[315-320] Currently, the standard of care for systemic chemotherapy is cisplatin and gemcitabine, as mentioned in the section on cholangiocarcinoma.[260]

CHAPTER 67

Cancer of the Colon and Rectum

Christine E. Eyler, Manisha Palta, Brian G. Czito, and Christopher G. Willett

ANATOMY

The colorectum consists of the cecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid colon, and rectum. Variability in the peritoneal investment, bowel mobility, and lymph node drainage of the colon and rectum presents unique therapeutic issues.[1]

The posterior and lateral surfaces of the ascending and descending colon directly contact the retroperitoneum, whereas peritoneum drapes the anterior colonic surface.[1] These posterior attachments limit colonic mobility, increasing the difficulty of surgical resection. In contrast, peritoneum surrounds the more mobile transverse colon, which is supported on a long mesentery. As the sigmoid colon evolves distally into the rectum, the peritoneal coverage recedes. The rectum, approximately 12 to 15 cm in length, extends from the rectosigmoid junction to the puborectalis ring. The upper one-third of the rectum is draped with peritoneum anteriorly and laterally on both sides. Deeper in the pelvis, the middle one-third of the rectum is only covered by peritoneum anteriorly where the posterior border of the rectouterine pouch or rectovesical space dips between the anterior rectum and posterior bladder/uterus. The lowest one-third of the rectum is devoid of peritoneal covering and in proximity to adjacent structures, including the bony pelvis (Figure 67.1). Distal rectal tumors have no serosal barrier to invasion of adjacent structures and are more difficult to resect, given the close confines of the deep pelvis.

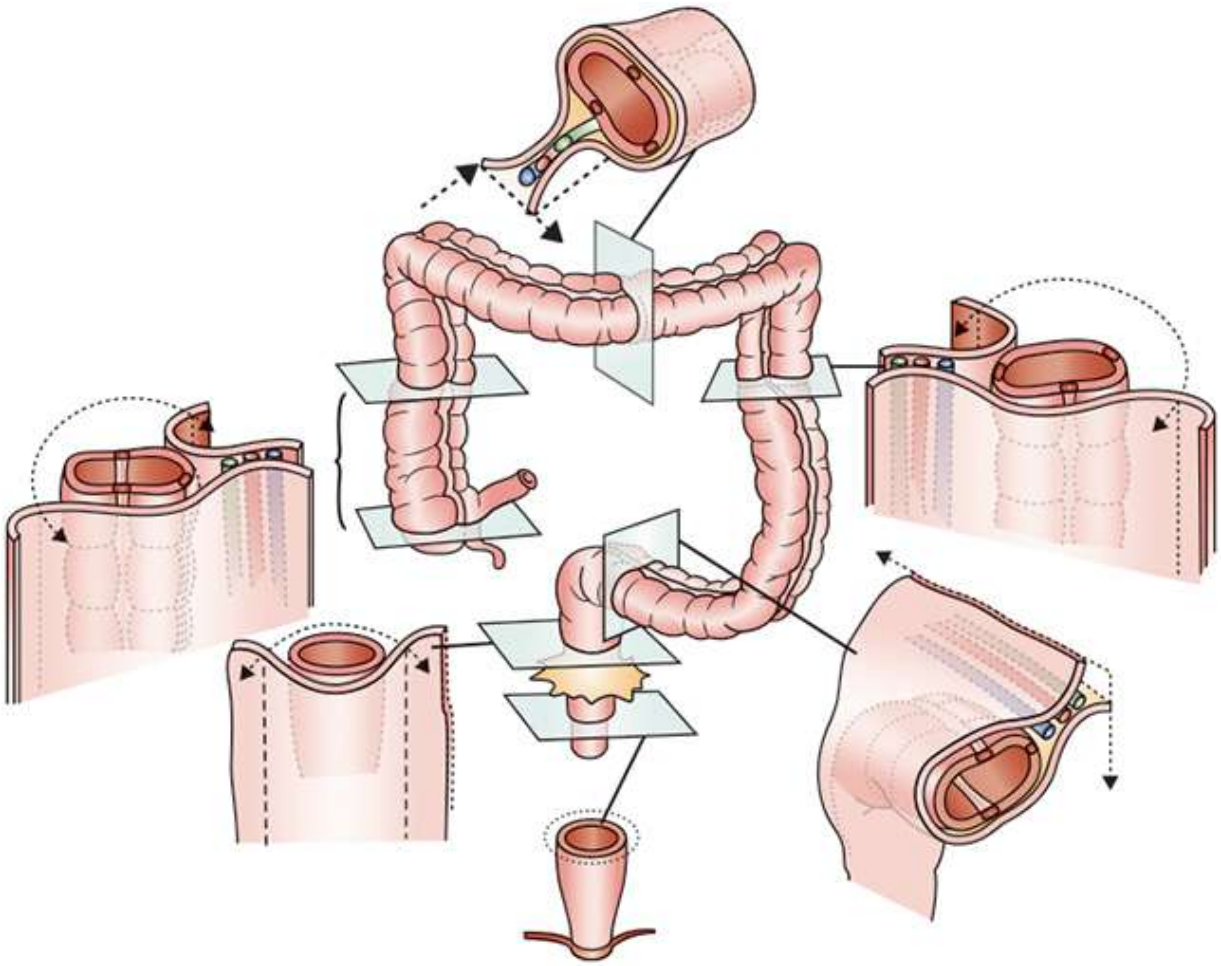

FIGURE 67.1 Idealized depiction of peritoneal relationships in the colon and rectum. The transverse and sigmoid colon are intraperitoneal, with a complete peritoneal covering (serosa) and mesentery. The ascending and descending colon are retroperitoneal, lack a true mesentery, and usually do not have a peritoneal covering posteriorly or laterally. The upper rectum begins above the peritoneal reflection and has peritoneum anteriorly and laterally. The lower one-half to two-thirds of the rectum is below the peritoneal reflection (infraperitoneal). (Used with permission of McGraw-Hill LLC from Gunderson LL, O'Connell MJ. The postoperative chemotherapy/irradiation adjuvant strategy. In: Cohen AF, Winawer SJ, eds. *Cancer of the Colon, Rectum, and Anus*. McGraw-Hill; 1995:635, Figure 67-1; permission conveyed through Copyright Clearance Center.)

Colonic nodal drainage consists of pericolic nodes and mesenteric nodes associated with the colonic vascular supply. The mobility and extent of the colonic mesentery limit the ability to strategically cover colonic regional lymph nodes using external beam radiotherapy (EBRT), but these nodal basins are usually well-treated surgically. In contrast, the major regional

groups for rectal nodal drainage can be covered within a reasonable EBRT field and include the perirectal, presacral, and internal iliac nodes.

Developmentally, the proximal or right-sided colon (cecum, appendix, ascending colon, hepatic flexure, and proximal two-thirds of the transverse colon) originates from the midgut, whereas the more distal or left-sided colon (distal one-third of transverse colon, descending colon, sigmoid, rectum) derives from the hindgut.[2] The gross appearance of colorectal tumors deriving from each location varies; right-sided colorectal cancers (CRCs) tend to have polypoid morphology, whereas left-sided CRCs classically have "apple core" annular lesions.[3] The embryologic etiology of specific CRCs has implications for underlying molecular alterations as well as potential therapeutic options, as discussed later in this chapter.

GENETICS AND CANCER BIOLOGY

A detailed discussion of the biologic and genetic pathways of development of CRC and their relevance to CRC treatment efficacy is beyond the scope of this chapter. In brief, multiple factors influence the development of colon cancer, including genomic instability, mutational inactivation of tumor suppressor genes, and activation of oncogene pathways.[3] CRC appears to arise through inactivation of the tumor suppressor genes adenomatous polyposis coli (APC), P53, and transforming growth factor beta (TGF-β), as well as activation of the RAS, BRAF, and phosphatidylinositol 3-kinase (PI3K) proto-oncogenes.[4] Though canonically presented as a stepwise accumulation of sequential mutations, modern sequencing analyses suggest CRC oncogenesis may also involve early "big bang"-like mutational expansion and subsequent neutral evolution and/or more complex concurrent subclonal evolutionary processes that contribute to pronounced intratumoral genetic mutational heterogeneity.[5-8]

Reflecting the unique developmental biology of the colon, left- and right-sided colon cancers possess some shared features (eg, APC mutation in the majority of cases) while also exhibiting differential molecular features. Microsatellite instability (MSI) and/or CpG Island Methylator Phenotype occurs more often in right-sided/proximal CRC, along with associated molecular/mutational features like mutations or hypermethylation of mismatch repair (MMR) genes and activating *BRAF* mutations.

Chromosomal instability occurs more often in left-sided/distal CRC, along with mutations in genes like *TP53*, *KRAS*, *PIK3CA*, *FBXW7*, *SMAD4*, and others.[3]

Genetic features may influence prognosis and predict treatment responsiveness. The majority of CRC occurring in patients with hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, as well as a minority of sporadic CRCs, demonstrate MSI deriving from mutations or dysregulation of genes encoding enzymes that repair DNA replication errors. These defects in MMR lead to high-frequency MSI.[9] Studies suggest that patients with tumors possessing MSI have more favorable outcomes and lower likelihood of developing metastatic disease.[10-12] Current guidelines incorporate this into treatment recommendations; for example, deintensified regimens exist for mismatch repair-deficient (dMMR)/microsatellite instable (dMMR/MSI) CRC relative to recommendations for the same stage for MMR-preserved/microsatellite stable (pMMR/MSS) CRC.[13] Promising initial data in rectal cancer, where a tiny minority of tumors exhibit MSI, hint at the potential for immunotherapy alone or in combination with surgery as a management for microsatellite unstable rectal cancer (though larger studies are needed for confirmation).[14] Some initial studies indicate other mutational characteristics that might influence treatment responsiveness but further investigations are needed to confirm.[15,16] Specific features predicting radio-responsiveness have been elusive; mutations in key tumor suppressors or oncogenes (eg, *TP53* or *KRAS*, respectively) may be associated with radiation resistance in preclinical settings, but clinical manifestations might require co-mutational combinations of multiple specific mutational alterations.[17,18] Associations between genetic features and resistance to standard chemotherapies or radiotherapy (RT) warrant further investigation.

Other recurrent CRC molecular alterations present targeted therapy options, which are increasingly incorporated into treatment algorithms for CRC. Molecules that specifically target tumors bearing *BRAF* V600E mutation, *HER2* amplification, *KRAS* G12C mutation, *NTRK* gene fusion, *POLE/POLD1* mutation, and *RET* fusion have been incorporated into first- and second-line therapies.[19-30] Even if targeted options are available, appropriate integration of molecularly targeted agents will likely require a comprehensive understanding of the active mutational profile of a given

tumor. Further elucidation of the genetic pathways in the development of CRC and their impact on treatment responsiveness remains an active area of investigation.

EPIDEMIOLOGY AND RISK FACTORS

CRC remains a major worldwide health problem. In the United States alone, in 2024 it was estimated that there would be 152,810 patients diagnosed with CRC and 53,010 deaths, with a 3.9% to 4.3% lifetime probability of developing CRC.[31] Worldwide in 2022, approximately 1.9 million new cases per year were diagnosed, with 900,000 deaths, according to the World Health Organization (WHO) International Agency for Research on Cancer.[32]

In the United States, the incidence of CRC over the last several decades declined by 2% to 3% annually, though recently the rate has diminished to a decline of 1.2% annually between 2012 and 2018.[33] Though CRC remains the second most common cause of cancer death in men and women combined, death rates from CRC have also decreased over time, declining 1.8% annually between 2012 and 2021.[31] Factors like risk factor modifications, screening implementation, and improved treatment may contribute to this trend. Age-adjusted relative CRC survival rates continue to differ by race and ethnicity in the United States, with 5-year survival rates of 64% and 59% in White and Black patients, respectively.[31] Encouragingly, recent studies have shown improvements in diminishing race-associated disparities in CRC mortality after targeted interventions to improve screening compliance, follow-up of abnormal findings, and initiation/completion of therapy.[34,35] Nevertheless, further research is needed regarding the etiologies of disparities in CRC incidence and survival by race and ethnicity, and interventions to diminish such disparities are needed.

Contrary to the trends suggesting decreased overall CRC incidence and mortality, there has been a worldwide increase in incidence of early-onset CRC in adults younger than 50 years. Since 2012, early-onset CRC has increased by approximately 1.8% annually, but this upward trend in incidence of early-onset CRC likely dates at least to the 1980s in many Western countries.[36] Associated mortality trends reflect this increased incidence of early-onset CRC; in 2021, CRC was the leading cause of

cancer-related death in US males in the age groups 20 to 39 and 40 to 49 (being the third and second most common, respectively, in females of these age groups).[31] By 2030, an estimated 1 in 10 colon cancers and 1 in 4 rectal cancers will occur in patients under the age of 50.[37] Epidemiologic data indicate this trend extends to other regions of the world, including Australia, Europe, Canada, and Asia.[38-41] Younger patients appear more likely to present with regional or distant disease than older patients, and histologically tend to display more adverse features potentially reflecting differential detection/screening or altered tumor-specific biologic factors, respectively.[42] Genetic factors may account for upward of one-third of these early-onset CRC diagnoses. Many of the epidemiologic studies have suggested birth cohort association with early-onset CRC risk, supporting hypotheses that altered environmental factors and exposures might account for the remaining increase in incidence. Factors like metabolic dysregulation/obesity, diet, alcohol consumption, vitamin D intake, microbiome features, or nonsteroidal anti-inflammatory drug (NSAID) consumption have been proposed.[36] Nevertheless, no consensus exists regarding the etiology of increasing CRC incidence in younger populations so it remains a subject of intense research interest.

Genetic and environmental factors influence CRC incidence. A number of hereditary CRC syndromes exist, including familial adenomatous polyposis (FAP), MUTYH-associated polyposis, and Lynch/HNPCC syndrome. Factors proposed as associated with elevated CRC risk include the following: increasing age; male sex; family history of CRC; inflammatory bowel disease diagnosis; increasing height; prior abdominopelvic radiation; cystic fibrosis diagnosis; metabolic dysregulation (obesity, diabetes mellitus); high consumption of processed meat, refined grains, starches, and sugars; low consumption of fiber, folic acid, vitamin B6 or vitamin D; and excessive alcohol intake and smoking. Of the non-genetic risk factors, only family history of CRC, personal history of inflammatory bowel disease, increasing age, male sex, obesity, smoking and excessive alcohol use have been associated with rectal cancer.[43-45] Discordant data exist for many of the consumption-associated risk factors, however, possibly relating to confounding factors in the studies. Other studies suggested that NSAIDs, folate, statins, or vitamin D may serve in reducing recurrent adenomas and CRC, but long-term therapy

must be weighed against potential side effects. The role of chemopreventative agents in CRC remains an area of active investigation.[43]

PATHOLOGY AND PATHWAYS OF SPREAD

Tumors of the colorectum arise in the mucosa and virtually all (>90%) are adenocarcinomas.[46] Other histologic types include squamous cell carcinoma, melanoma, small cell carcinoma, carcinoid, sarcoma, and lymphoma. Most grading systems classify adenocarcinoma as well, moderately, or poorly differentiated. Large bowel tumors invade from mucosa through the bowel wall and beyond, with involvement of lymphatic channels and lymph nodes. Hematogenous spread can occur, primarily to the lung and liver. There is little propensity for colon cancer to spread longitudinally within the bowel wall, in contrast to esophageal or gastric cancers.

SCREENING

Neoplastic polyps, including tubular adenomas, villous adenomas, tubulovillous adenomas, and serrated polyps are precursors of colon cancers.[43] Most CRCs arise from preexisting polyps during a slow transformation process occurring over an average of 10 years.[47] Though it has decreased over time, the cumulative lifetime risk of CRC in the United States remains about 4%, so screening programs for the general population continue to be implemented. Screening aims to detect preinvasive polyps or early invasive cancer. Numerous randomized studies now document that screening asymptomatic, average-risk individuals detects CRC at early, curable stages, reducing CRC mortality.[48-58]

Given the data in favor of screening, many published screening guidelines recommend screening in average-risk individuals starting at age 50 (American College of Radiology, American College of Physicians, American Association of Family Physicians), with a recent move from multiple organizations to change the age of screening to 45 (the US Multi-Society Task Force on Colorectal Cancer, the US Preventive Services Task Force, and the American Cancer Society).[52,59-61] Most of these groups recommend individualizing decisions about screening or terminating them altogether in adults aged 76 and above. Recommended screening options

and recommended intervals vary according to the guideline used, but broadly fall under headings of visual colorectal examination (colonoscopy, sigmoidoscopy, computed tomography [CT] colonography), stool-based tests (fecal occult blood test, immunochemical or DNA detection), or specific combinations of the above for detection of adenomatous polyps and cancer. As a representative set of options, the American Cancer Society recommendations are as follows:

- Flexible sigmoidoscopy every 5 years
- CT colonography every 5 years
- Colonoscopy every 10 years
- Yearly guaiac-based fecal occult blood test, fecal immunohistochemical test, and stool DNA test may be performed for CRC, but likely not polyp, detection.[62]

In high-risk patients (patients with adenomatous polyps, history of CRC, first-degree relative diagnosed with CRC or advanced adenomas below age 60, two first-degree relatives with CRC or advanced adenomas at any age, a personal history of inflammatory bowel disease, or high risk due to family history or genetic testing), more intensive surveillance is recommended. Patients with inflammatory bowel disease should initiate screening with colonoscopy 8 to 10 years after initial diagnosis. The U.S. Multi-Society Task Force on Colorectal Cancer (representing the American College of Gastroenterology, American Gastroenterological Association, and the American Society for Gastrointestinal Endoscopy) recommends the following for high-risk individuals without known genetic CRC risk syndromes based on family history:[63]

- Colonoscopy screening (vs other screening methods) is indicated for all of the indicated high-risk groups.
- If a person has a single, first-degree relative diagnosed with CRC, or advanced adenoma at age less than 60 years or two or more first-degree relatives with CRC or advanced adenoma at any age, colonoscopy screening begins at age 40 years, or 10 years before the youngest relative’s diagnosis. Screening should be performed every 5 years.

- In patients with a prior personal history of CRC or advanced adenomas, colonoscopy surveillance begins 1 year after surgical or endoscopic removal with subsequent surveillance determined by findings on that first colonoscopy (yearly if advanced adenomas found on surveillance exams, or after 3 years and then 5 years if no advanced adenomas found).[64]

Hereditary syndromes with increased CRC risk necessitate intensified screening schedules. A detailed discussion of recommendations for each genetic variant/syndrome is beyond the scope of this review but some considerations and recommendations are discussed later for context. Individuals with classical FAP have a lifetime risk of close to 100% for developing CRC without treatment. Annual sigmoidoscopy or colonoscopy beginning at age 10 to 12 years is recommended until standard (procto)colectomy treatment occurs, usually after age 18. Patients with HNPCC have a lifetime risk for CRC of 8% to 52% depending on the genetic Lynch variant, so screening recommendations vary depending on the specific molecular alteration.[65] National guidelines suggest screening every 1 to 2 years at age 20 to 25 years or 2 to 5 years prior to the earliest familial CRC diagnosis if it is diagnosed before age 25. This interval is individualized based on other risk factors; for example, some of the less pathogenic variants (eg, MSH6- or PMS2-associated Lynch syndrome) may require less stringent ages for initiation and screening intervals. Other hereditary syndromes (eg, PTEN hamartoma syndrome, juvenile polyposis syndrome, Peutz-Jeghers syndrome, MUTYH-associated polyposis) also necessitate increased screening intensity, and the timeline of initiation and testing frequency varies depending on syndrome and associated features.

Despite the successes of the screening procedures discussed earlier and the increased adoption of screening among the population, advanced CRC diagnoses still occur in many patients and may reflect persistently low rates of disease awareness, as well as the infrequency of screening in eligible candidates, as well as the perplexing increase in early-onset CRC in patients less than 50 years old. Approximately 60% to 80% of eligible adults aged 50 to 75 years underwent CRC screening in 2022.[66] Lower rates of screening are seen in younger patients, Hispanic patients, Black patients, Asian patients, individuals of lower socioeconomic status, and individuals

without health insurance.[66,67] Although all screening tests have potential drawbacks, patients should be educated regarding relative risks and benefits of screening modalities, including potential benefits in reducing the risk of CRC.

CLINICAL PRESENTATION

CRC often produces minimal or no symptoms, emphasizing the need for screening programs in the general population. Patients with symptomatic CRC most commonly experience abdominal pain, change in bowel habits, hematochezia/melena, weakness, iron deficiency anemia, and weight loss.[47,68] Less commonly, patients present with nausea, vomiting, or abdominal distention, which may be signs of tumor-related obstruction.

The clinical presentation of CRC is determined largely by site of the tumor. Cancers of the right colon are often exophytic and commonly associated with few symptoms aside from iron deficiency anemia due to occult blood loss, resulting in delayed diagnosis. Cancers of the left colon and sigmoid colon are often deeply invasive and annular ("apple core lesions") and accompanied by obstruction, rectal bleeding, and alteration in bowel habits.

PATIENT EVALUATION/STAGING

CRC workup should include a complete history and physical exam, including digital rectal examination (DRE). Careful attention to family history of CRCs, colonic adenomas, and other cancers may reveal patients suspected of bearing hereditary or familial cancer syndromes, who should be referred for genetic counseling. On DRE, rectal mass size, location, distance from the verge, mobile versus fixed, and sphincter function should be noted. Pelvic exam should be performed in women diagnosed with rectal cancer to assess for vaginal involvement where appropriate. Pretreatment evaluation should include pathologic confirmation of adenocarcinoma, colonoscopy to evaluate extent of tumor and rule out synchronous primaries (occurring in 1%-5%), and baseline lab tests, including blood counts, liver function tests, and carcinoembryonic antigen (CEA) levels. Tattooing may be used at the time of colonoscopy to mark the proximal and distal disease extent; such markings take special importance in localizing the initial tumor

where patients embark upon nonoperative management (NOM) protocols with repeat posttreatment endoscopy. Biopsies should be evaluated for primary histology as well as the presence or absence of lymphovascular invasion (LVI), perineural invasion (PNI), and other pathologic features. All tumors, including rectal tumors, should be evaluated for MMR protein status and MSI on initial biopsy and potentially other actionable mutations/alterations (eg, *BRAF* V600E, *HER2* amplification), as this impacts prognosis and treatment options.

For rectal cancer, decisions regarding the utility of neoadjuvant chemotherapy and/or RT are often based largely on physical exam and the radiographic characteristics of the primary tumor. Pelvic magnetic resonance imaging (MRI) assesses T and N stage and now is recommended as the primary T and N clinical staging assessment tool.[69,70] Lymph node assessments by MRI leverage numerous features besides size alone, adding to the utility of this imaging modality in addition to CT imaging alone. MRI also evaluates features like sphincter involvement, distance of tumor from the circumferential resection margin (CRM), extranodal tumor deposits and extramural venous invasion, which are features indicative of more aggressive disease and may influence neoadjuvant treatment decisions and/or surgical planning.[71,72] Generally speaking, pelvic MRI staging is now preferred to endoscopic ultrasound (EUS) techniques in the workup of rectal cancer.[69,70] However, due to its ability to visualize the layers of the rectal wall, EUS also has quite high sensitivity and specificity for T staging when performed by experienced endoscopists and can still play an important role in staging tumors for patients in whom MRI is contraindicated or when MRI findings are equivocal.[73] In staging early depth of invasion (Tis, T1, T2) to determine suitability for transanal approaches or in posttreatment response assessment, EUS can provide helpful complementary information to MRI, where invasion depth may be difficult to assess.[74]

Contrasted abdominopelvic and chest CT scans assess for the presence or absence of distant metastases (DMs). Standard CT does not permit the visualization of the layers of the rectal wall, and therefore its utility in the assessment of primary cancer extent is limited, especially with the implementation of high-quality reproducible MRI techniques. The ability of CT scans for detecting DM, including pelvic and para-aortic lymph nodes,

is higher than for detecting perirectal nodal involvement.[75] Suspected liver metastases on initial staging CT exams could be evaluated with follow-up MRI abdomen with contrast. 18F-Fluorodeoxyglucose-positron emission tomography (FDG-PET)/CT is not routinely recommended, although it may be useful in addition to contrasted CT staging in circumstances of oligometastatic disease for which surgical and/or local metastasis-directed therapies might be available.[76,77]

All rectal cancer imaging techniques have advantages and limitations and should be considered complementary to physical examination. Radiographic assessment of response after neoadjuvant therapy has high rates of false positivity.[71,72,78]

Prognostic factors influencing survival in patients with CRC include the depth of tumor invasion into and beyond the bowel wall, the number of involved regional lymph nodes, and the presence or absence of DMs. Additional prognostic factors recommended for clinical care and staging include the presence of tumor deposits in the pericolic/perirectal fat and/or adjacent mesentery; when present, these are staged as N1c and likely have a prognostic impact similar to having positive nodes. The tumor, node, metastasis (TNM) system of the American Joint Committee on Cancer can be used as a clinical (preoperative) staging system (Tables 67.1 and 67.2).[79]

TABLE 67.1 AMERICAN JOINT COMMITTEE ON CANCER 2017, 8TH EDITION, TNM STAGING OF COLORECTAL CANCER

Primary Tumor (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intramucosal (invasion of lamina propria with no extension through muscularis mucosae)
T1	Tumor invades submucosa.
T2	Tumor invades muscularis propria.
T3	Tumor invades through the muscularis propria into the subserosa or into pericolorectal tissues.
T4	Tumor invades visceral peritoneum or invades/adheres to adjacent organs or structures.
T4a	Tumor penetrates the surface of the visceral peritoneum.[a]

T4b	Tumor directly invades or is adherent to other organs or structures.

Regional Lymph Nodes (N)

NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in one to three regional lymph nodes (0.2 mm size or greater), or any number of tumor deposits
N1a	Metastasis in one regional lymph node
N1b	Metastasis in two or three lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolorectal tissues without regional nodal metastasis
N2	Metastasis in four or more regional lymph nodes
N2a	Metastasis in four to six regional lymph nodes
N2b	Metastasis in seven or more regional lymph nodes

Distant Metastasis (M)

MX	Distant metastasis cannot be assessed.
M0	No distant metastasis by imaging
M1	Distant metastasis to one or more distant sites or organs or peritoneal metastasis
M1a	Metastasis confined to one organ or site without peritoneal metastasis
M1b	Metastasis in more than one organ/site without peritoneal metastasis
M1c	Metastasis to the peritoneal surface with or without metastasis to other sites or organs

[a]T4a tumors are characterized by involvement of the serosal surface (visceral peritoneum). Perforated tumors with tumor cells continuous with serosal surface through inflammation are also T4a. Inflammation within 1 mm of the serosa is not T4a unless careful microscopic analysis indicates serosal surface involvement. T4a designation is not applicable to those portions of the colorectum that are not peritonealized (such as the posterior aspects of ascending/descending colon and distal rectum).

COLON CANCER

Treatment of Colon Cancer

Surgery

Surgery is the primary treatment modality for patients with invasive nonrectal colonic cancers. Resection with curative intent is possible in approximately 75% of patients. Surgical approaches for primary colon cancer reflect the anatomy and mechanisms by which this disease spreads. Adenocarcinomas of the colon may grow by direct extension into the lymphatics of the submucosa and bowel wall. Resection of sufficient lengths of bowel proximal and distal to the primary cancer helps avoid transecting intramural lymphatics with microscopic tumor involvement.

Colon cancer often extends through the serosa into mesenteric lymphatics that run along the blood vessels draining into the portal watershed at the root of the mesentery. Resection involves removal of the major lymphatic drainage system in the mesentery including those lymph nodes at the origin of the feeding vessels. Consensus guidelines recommend that a minimum of 12 lymph nodes should be excised for appropriate staging.[76,79] Anatomic resections intentionally include named blood vessels and draining lymphatics; thus, the boundaries for resecting large bowel cancer are relatively uniform. Right hemicolectomy, transverse colectomy, left hemicolectomy, and sigmoid resection following surgical oncologic principles largely preserve large bowel function. Some more advanced tumors may necessitate more extensive surgical procedures; for example, curative resection for colon cancers that adhere to or invade neighboring organs requires complete en bloc resection with negative margins, and obstructive or perforated tumors may require specialized procedures or two-stage colostomy/resection procedures.[76]

Multiple large multi-institutional randomized trials established that laparoscopic resection has equivalent oncologic outcomes versus open resection for non-rectal colon cancers, with the benefits of decreased length of hospital stay and improved short-term outcomes associated with laparoscopic approaches.[80-84] Surgical guidelines now reflect a strong preference for implementing laparoscopic approaches for suitable tumors.[76] Surgeons should have experience performing laparoscopic operations and using laparoscopic methods does not remove the necessity for a thorough abdominal exploration.[85-88] Laparoscopic techniques are not appropriate for patients with perforation, complete obstruction, or particularly invasive disease (eg, extremely large size or adjacent organ invasion).

Resection results in excellent cure rates for lesions limited to the bowel wall with negative nodes (5-year overall survival [OS] 97% for T1-T2N0). Survival drops somewhat for tumors with a single high-risk feature of extension beyond the colonic wall (5-year OS 87.5% for T3N0 and 71.5% for T4N0) or involved nodes (5-year OS 67%-88% for T0-2 N+), warranting adjuvant therapy in many cases. When both high-risk features are present (T3-4 N+), 5-year survival drops to approximately 47% to 67% (T3 N+) and 27% to 50% (T4 N+), even when considering that most of these patients receive adjuvant therapy.[89] If higher T or N stage–related risk

factors are suspected on presurgical imaging, consideration for neoadjuvant treatment may be indicated to facilitate margin-negative resection (see "Neoadjuvant Treatment" section below).[76]

Surgical pathology reports should include all information to designate the T and N stage of the tumor, as well as highlight all potential pathologically prognostic information. Features to be reported include: specimen morphology and tumor site, presence or absence of macroscopic tumor perforation, tumor extension into bowel wall and adjacent organs (T stage), number of regional lymph nodes retrieved and quantification of number involved with cancer (N stage), margin status and distance (proximal, distal, radial), presence or absence of tumor deposits and tumor budding, presence or absence of LVI or PNI, and MMR protein and MSI/MSS status.[90]

Adjuvant Chemotherapy

The benefit of adjuvant chemotherapy has been clearly demonstrated in patients with stage III disease. Prospective randomized trials initially showed that adjuvant combination treatment with 5-fluorouracil (5-FU) and leucovorin (LV) improves survival for resected patients in stage III disease, and capecitabine (an oral 5-FU prodrug) in place of 5-FU/LV confers similar clinical benefit.[91-94] Subsequent trials adding oxaliplatin to 5-FU/LV (FOLFOX) demonstrated improved disease-free survival (DFS) in patients in stage III disease treated with oxaliplatin-containing regimens, with some of these studies identifying a potential OS benefit.[95-98] Addition of irinotecan to 5-FU/LV appears not to improve DFS or OS for patients with stage III colon cancer and increases toxicity.[99-103] These data helped to establish FOLFOX or capecitabine and oxaliplatin (CAPOX/XELOX) as standard chemotherapeutic regimens in the adjuvant treatment of completely resected, high-risk colon cancer. The use of monoclonal antibodies, such as bevacizumab and cetuximab, although potentially efficacious in the metastatic setting, has not yielded similar results in the setting of adjuvant treatment of non-metastatic disease.[104-109]

The utility of adjuvant treatment for patients in stage II disease varies and thus requires individualization. For the most part, these decisions are made based on pathologic risk factors (T4 disease, poorly differentiated pathology, LVI, PNI, tumor budding, bowel obstruction or perforation,

close/positive margins, inadequate nodal sampling).[110] Multigene assays and immunophenotyping analyses, while not currently incorporated into treatment decision-making algorithms, may supplement other pathologic features to help with making decisions regarding chemotherapy in difficult cases. Promising new data indicate that circulating tumor cell DNA (ctDNA) measurements may aid in determining the utility of adjuvant chemotherapy.[111] However, due to questions about the value added beyond normal risk factors and potential drawbacks, national guidelines do not currently include ctDNA in the algorithms for management but have indicated it might help with decision-making in difficult cases.

The molecular features of colon tumors contribute to whether adjuvant therapy might augment clinical outcomes. For patients with dMMR or MSI tumors, standard adjuvant treatment recommendations differ from their pMMR/MSS counterparts. Chemotherapy is not recommended for stage II high-microsatellite instability (MSI-H) or dMMR tumors. This is partially related to the improved overall prognosis of these tumors[11,112,113] and studies suggesting that these tumors may be less intrinsically prone to metastasize.[15,114] Some retrospective evidence suggests that chemotherapy for patients with stage II dMMR/MSI tumors may not improve clinical outcomes relative to surgery, or may even be detrimental, although other retrospective analyses of large trials have shown discrepant results.[10,113,115] In the setting of stage III tumors, typical chemotherapy regimens remain standard-of-care adjuvant management for dMMR/MSI-H tumors. Other molecular markers (eg, *BRAF* or *KRAS* status) do not currently factor into adjuvant therapy decision-making.

Adjuvant Irradiation With or Without Concurrent Chemotherapy

Given the documented efficacy of adjuvant chemotherapy, as well as the perception by many oncologists that colonic (as opposed to rectal) cancer is much more likely to relapse distantly than locally, there has been little evaluation of the efficacy of postoperative irradiation with chemotherapy. The potential indications for adjuvant RT in colon cancer are based on analyses of patterns of failure following resection.[66] Advanced stage predicts for local failure (LF) in both colon and rectal cancers; however, LF in colon cancer also depends on anatomic origin. The ascending and

descending colon are considered “anatomically immobile,” and their close proximity to the retroperitoneal tissues often limits wide surgical resection (Figure 67.1). Limitations in achieving satisfactory circumferential margins increase the risk of residual disease and consequently LF. In contrast, the midsigmoid and midtransverse colon are relatively “mobile,” with a wide mesentery, permitting the surgeon to obtain wide margins regardless of extent of disease invasion into the mesentery. Unless there is adjacent organ adherence/invasion by tumor, LF at these sites is uncommon. LF rates for cecal, hepatic/splenic flexure, and proximal/distal sigmoid tumors are variable, depending on the amount of mesentery present, tumor extension, and the adequacy of radial margins. When colon cancers adhere to or invade adjacent structures, LF rates exceed 30% following surgery alone. In summary, LF occurs in patients with colonic tumors where there are anatomic constraints on radial resection margins, including tumors adherent to or invading adjacent structures.

A retrospective report from the Massachusetts General Hospital (MGH) compared high-risk (T4, T3N+, and T3N0 with close margins) patients with colon cancer receiving resection and adjuvant RT (n = 171; 63 treated with concurrent 5-FU chemoradiotherapy [CRT]) with a similar cohort of patients (n = 395) treated with surgery only over the same period.[116] The tumor bed plus a 3 to 5 cm margin received 45 Gy via parallel-opposed or other 3D conformal multi-field radiotherapy techniques, followed by reduced fields to a total dose of 50.4 to 54 Gy. Draining nodes were included if they were believed to be at high risk for involvement. For patients with T4N0 and T4N+ lesions, adjuvant radiation was associated with improved local control (LC) and relapse-free survival (RFS). No significant outcome differences were observed in patients with T3 N0 and T3 N+ lesions. A trend toward improved LC in patients receiving 5-FU CRT was seen. This study concluded that postoperative radiation may benefit patients with T4 tumors, abscess/fistula formation, or margin-positive resection. In a subsequent analysis from MGH, 152 patients with T4 tumors received adjuvant irradiation and were compared to historical controls.[117] For patients with negative margins (N = 110), the 10-year actuarial LC in patients with T4 N0 and T4 N+ lesions was 78% and 48%, respectively. In patients with node-negative tumors, the 10-year actuarial LC and RFS rates were 87% and 58%, respectively, compared to 65% and

33%, respectively, in patients with node-positive tumors. In comparison with historical controls, these patients who underwent irradiation had comparably favorable LC.

Consistent institutional data in support of adjuvant RT for high-risk colon cancers were published out of the Mayo Clinic and the University of Florida. The Mayo Clinic experience described 103 patients receiving a median of 50.4 Gy RT (most with concurrent 5-FU-based chemotherapy) following surgery for locally advanced colon cancer. Most patients (>90%) had T4 disease, and many had residual disease (n = 18 with microscopic, n = 35 with gross residual).[118] Eleven patients received an intraoperative radiotherapy (IORT) boost of 10 to 20 Gy. Five-year actuarial LC was 40%; for R0 patients, LC was 90%, while it was 46% and 21% for R1 and R2 resections, respectively. Five-year OS tracked with margin status as well (66% in R0, 47% in R1, and 23% in R2 resections). In patients with residual disease, LC rates in those undergoing IORT boost were 89%, compared to 18% in those undergoing external irradiation alone, and IORT administration was associated with improved survival (76% vs 26%). The University of Florida experience described outcomes for patients with locally advanced but completely resected colon cancers receiving adjuvant radiation.[119] Their reported LC rate of 88% was similar to the 90% reported from the Mayo Clinic series for R0 patients. In addition, there appeared to be a dose-response relationship to LC. The 5-year rate of LC was 96% for patients receiving 50 to 55 Gy versus 76% for patients receiving less than 50 Gy (P = .0095).

Based on these institutional experiences, in 1992 the U.S. Intergroup designed a randomized, prospective phase III trial to assess whether the addition of RT to adjuvant chemotherapy would result in superior OS and LC rates in patients with resected, high-risk colon cancer.[120] Eligible patients had resected, high-risk colon cancer (defined as margin-negative T4 tumors, excluding peritoneal invasion; or node-positive tumors arising from the ascending or descending colon). Patients were randomized to receive (a) weekly 5-FU combined with levamisole for 12 months or (b) 5-FU and levamisole for 12 months with combined RT and chemotherapy beginning 1 month after the first 5-FU administration. The recommended total radiation dose was 45 Gy in 25 fractions over 5 weeks to the tumor with an elective nodal volume, with an optional 5.4-Gy boost. The initial

trial accrual goal was 700 patients; however, the study was closed in 1996 because of poor accrual (222 patients; 189 evaluable). Total accrual was less than one-third of the initial goal, and there was reduced statistical power to detect differences between the groups. No difference in OS or DFS was seen between the two groups. Five-year OS of patients receiving chemotherapy only was 62% versus 58% for patients randomized to chemoradiation ($P > .50$). Local recurrence rates were identical in both arms (18 patients each). Grade 3 or 4 hematologic toxicity was higher in patients receiving RT. Interpretation of study results was handicapped by decreased statistical power, high ineligibility rates, and lack of surgical clips or preoperative imaging to assist in the definition of appropriate RT fields in a high percentage of patients. Therefore, no definitive conclusions can be made regarding the efficacy of postoperative irradiation with 5-FU and levamisole based on this study.

A potential benefit for EBRT in highly selected cases might still exist, especially considering technical improvements with RT delivery and image guidance, as well as the improved systemic disease control associated with modern chemotherapy regimens. A recent study examined the role of adjuvant RT in locally advanced colon cancer in the era of modern chemotherapy.[121] The investigators reported the outcome of 62 patients with T4 colonic cancer treated with surgery only, surgery followed by adjuvant chemotherapy only, or 13 patients with adjuvant chemoradiation. A multivariate analysis demonstrated that treatment with adjuvant chemoradiation (vs adjuvant chemotherapy alone) enhanced locoregional control and DFS. The investigators concluded that adjuvant RT may be appropriate in select patients, specifically those with T4b lesions and/or residual disease following resection. Database analyses from the Surveillance, Epidemiology and End Results Program (SEER) and National Cancer DataBase (NCDB) suggest ongoing, yet very infrequent, administration of adjuvant RT for colonic tumors with very high-risk factors for local recurrence (eg, T4b tumors and/or positive margins). These studies hint at a potential association between adjuvant RT use and improved clinical outcomes, although the inherent limitations of database studies would require further data to confirm.[122-124]

As seen in some of the early institutional experiences, IORT remains an alternative means by which to administer RT to regions at high risk for

recurrence after surgery, often due to close or positive margins. Reported data on IORT for non-rectal colon cancer are rare, but extrapolation from the rectal and rectosigmoid literature supports it as a reasonable option to consider in select circumstances.[125,126]

To summarize, early institutional and some database analyses support some role for adjuvant CRT or RT (EBRT or IORT) in treating advanced non-rectal colon cancer. This approach could be considered for highly select cases with close or positive margins or T4b disease and ideally in situations where the tumor bed and/or region at risk is easily identified by surgical clips or other nonvariable anatomic markers to permit accurate localization. However, since there are no randomized data supporting this approach, decisions should be individualized and implementation of this strategy taken with care.

Neoadjuvant Treatment

Neoadjuvant therapy can be considered for locally advanced or unresectable colon cancer. The most frequently employed neoadjuvant modalities include chemotherapy or immunotherapy. Building on promising pilot results, the international FOxTROT randomized controlled study assessed the role of neoadjuvant systemic therapy administration for locally advanced colon cancer staged as T3-4, N0-2, M0.[127] A total of 1,053 patients were randomized 2:1 to a neoadjuvant/adjuvant FOLFOX group (6 weeks neoadjuvant, 18 adjuvant) versus an adjuvant-only group (24 weeks adjuvant); RAS-wildtype tumors were randomized 1:1 to additionally receive panitumumab during neoadjuvant chemotherapy. Neoadjuvant chemotherapy administration was associated with a 28% improvement in the primary outcome, 2-year residual or recurrent disease, with 16.9% in the neoadjuvant chemotherapy arm and 21.5% in the control arm ($P = .037$). Additionally, neoadjuvant chemotherapy improved R0 resection rates, augmented T and N downstaging, and was associated with fewer serious postoperative complications. This benefit was largely limited to patients with pMMR/MSS tumors. Panitumumab did not enhance the effect of neoadjuvant chemotherapy.

Neoadjuvant immunotherapy treatment regimens exist for dMMR or MSI-H colon tumors. Though very promising and likely to have very high

utilization and impact, at this point these regimens are based on nonrandomized studies with little longer-term clinical follow-up. The NICHE study demonstrated 100% pathologic response (including 57% pathologic complete response [pCR]) in 21 patients with stage I to III dMMR treated with nivolumab and ipilimumab.[128] Patients with pMMR/MSS evaluated had minimal response to this regimen. The follow-up, larger NICHE-2 study including 112 patients with stage I to III dMMR treated with nivolumab and ipilimumab remains unpublished, but meeting abstracts and presentations indicate a 99% pathologic response rate with 67% pCRs, with no recurrences after a median follow-up of 13 months.[129] Notably, the majority of enrolled patients had stage III disease. Long-term clinical outcomes for this regimen remain unreported, but clinical guidelines have now included immunotherapy as a preferred option when neoadjuvant treatment of dMMR/MSI-H tumors is planned (eg, for cT4b disease or locally unresectable). Standard neoadjuvant chemotherapy technically remains an option for dMMR/MSI-H tumors, but guidelines favor neoadjuvant immunotherapy for these patients since the FOxTROT neoadjuvant chemotherapy trial showed little benefit for dMMR/MSI-H tumors.[127]

Neoadjuvant RT (with or without concurrent chemotherapy) remains very infrequently used, for many of the same reasons as described in the previous section. Although neoadjuvant chemoradiation has been shown in randomized trials to improve LC/DFS in patients with rectal cancer, there is no high-level evidence demonstrating its effectiveness in patients with colon cancer although high rates of R0 resection and LC with low toxicity rates have been reported in retrospective studies.[130] Though its utility broadly may be limited, especially in light of improved neoadjuvant systemic options (discussed later), neoadjuvant RT may be an appropriate option for highly selected T4b tumors needing downstaging for surgical removal in fixed, reproducible anatomic locations. Addition of IORT at the time of surgery could also be considered, as described earlier.

Locally Advanced Disease and Palliation

Patients with unresectable tumors or metastatic disease at presentation often receive systemic therapy, but a complete review of systemic treatment

options for unresectable metastatic disease is outside the scope of this chapter. In many cases of metastatic colon cancer, systemic therapy can extend progression-free survival and OS. Frequently used treatments include irinotecan-based (eg, FOLFIRI: irinotecan-FU-LV) or oxaliplatin-based (eg, FOLFOX: oxaliplatin-FU-–LV or CAPEOX: oxaliplatin-capecitabine). In contrast to localized disease, the addition of bevacizumab[131] or an epidermal growth factor receptor (EGFR) inhibitor (eg, panitumumab or cetuximab)[132] prolongs progression-free survival and potentially OS. Molecular tumor features and tumor sidedness (left or right) contribute to decisions on which of these agents to include. For example, EGFR inhibition with panitumumab or cetuximab may be appropriate for patients with left-sided tumors with wild-type *KRAS/NRAS/BRAF*, and HER2-directed inhibition may be appropriate for some patients with *HER2* amplification and wild-type *RAS/BRAF*. Patients with dMMR/MSI-H or *POLE/POLD1* mutations and metastatic disease preferentially receive checkpoint inhibition immunotherapy. Patients with refractory disease may be treated with alternate regimens, depending on the initially used regimens. Treatment of refractory disease may additionally include multikinase inhibitors like regorafenib, fruquintinib or tipiracil/trifluridine, or biomarker-directed therapy for tumors bearing specific molecular alterations (eg, *BRAF* V600E, *HER2* amplification, *KRAS* G12C, *NTRK* gene fusion, or *RET* gene fusion).

Patients with near colonic obstruction may benefit from a diverting ostomy or stenting. Nonsurgical candidates may benefit from palliative radiation to shrink a painful, near- obstructing or bleeding mass.

Techniques of Irradiation

Patterns-of-failure data and the indication for treatment inform treatment field design in colon cancer. Historically, adjuvant treatment was utilized for locally advanced and/or node- positive tumors, and the larger field designs utilized reflect the goals of improving both local and regional nodal recurrence rates. However, current indications for adjuvant treatment are largely limited to treating T4 tumors, often in settings of perforation or positive margin, to prevent LF. Treatment objectives generally do not include attempts to limit regional nodal recurrences, especially considering

improved systemic therapy options. Thus, applying historical field design and doses to modern patient care should be interpreted through this refined lens. The discussion further will attempt to reconcile historical field design with modern three-dimensional (3D) CT-based planning and image-guided radiotherapy (IGRT) technologies in light of goals to reduce local recurrence.

Postoperative radiation field delineation requires great care to ensure accurate target coverage while minimizing normal tissue (especially bowel) exposure (Figures 67.2 and 67.3). If adjuvant therapy is planned, surgical clip placement in high-risk volumes (eg, positive margins) can assist with accurate field delineation as well as daily setup and alignment and should be discussed with the surgeon prior to the operation. Field arrangement will vary, depending on the site of the primary disease, as well as on areas judged to be at high risk for local recurrence. Optimal patient positioning (supine, prone, decubitus) displaces uninvolved bowel from the target volume while causing minimal target volume variability. It may be useful to compare simulation imaging in both the decubitus and supine positions to determine the actual amount of small bowel displacement. Immobilization aids and devices can be individualized to facilitate reproducibility and patient comfort. CT-based planning should be implemented to appropriately delineate target and organs at risk (OARs), and cone-beam CT image guidance utilized during treatment to ensure adequate target volume localization.

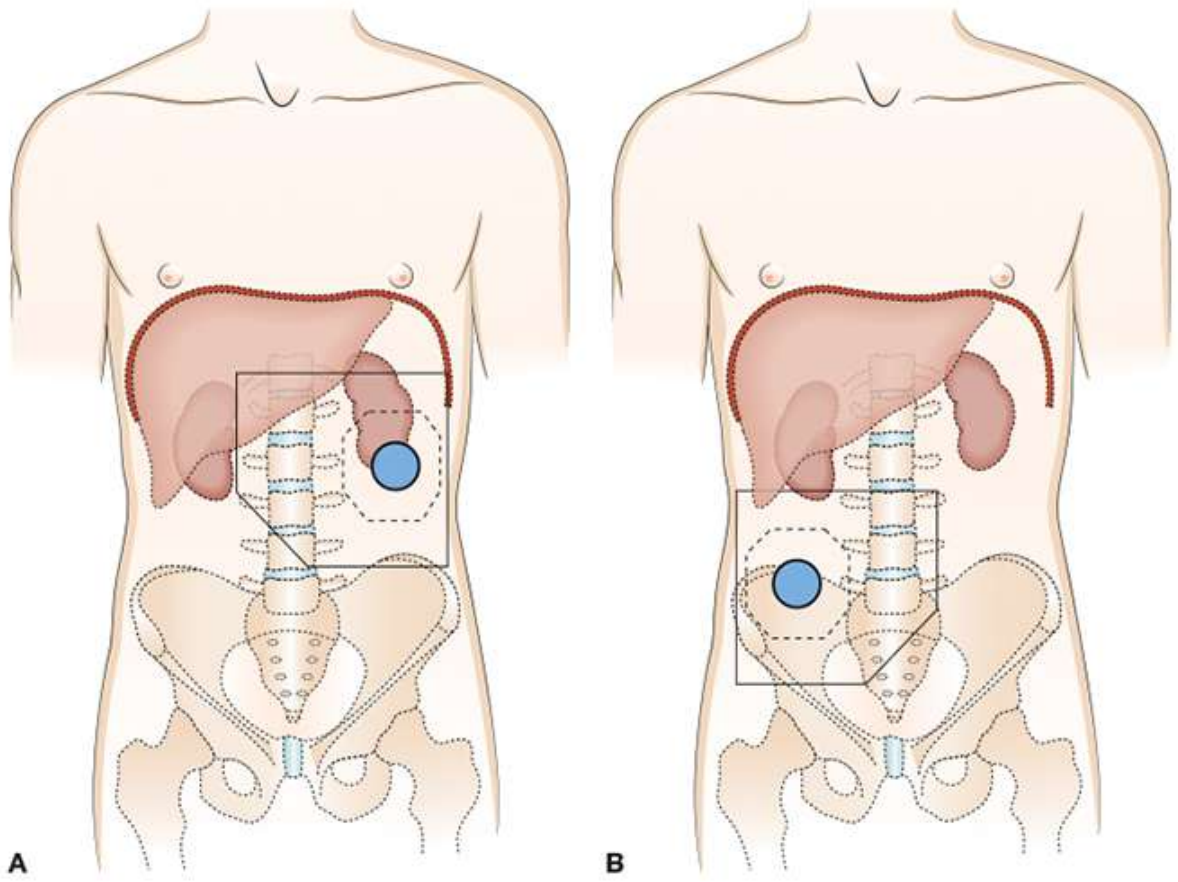

FIGURE 67.2 Historical postoperative anteroposterior/posteroanterior irradiation fields of extrapelvic colon cancer (tumor bed and nodal regions). If treated preoperatively, lateral fields could be added based on imaging with computed tomography of the abdomen and colon radiograph. A. Para-aortic nodes may be at risk, in addition to tumor bed, because of tumor adherence to posterior abdominal wall with descending colon cancer. B. External and common iliac nodes may be at risk, in addition to tumor bed, from a proximal cecal/ascending colon cancer. Note that these historical fields may be adjusted in contemporary treatments, as improved IGRT and conformal planning in light of improved systemic and surgical approaches may facilitate decreased field sizes. The total radiation dose used in the adjuvant treatment of colon carcinoma depends on the amount of suspected residual disease and tolerance constraints of surrounding normal tissue, and fields/treatment volumes depend on accurate target delineation and maintenance of safe doses to OARs like the small bowel. Much of the data regarding treatment of non-rectal colon cancers derives from studies predating the implementation of 3D conformal CT-based planning. Historically an initial dose of 45 Gy in 25 fractions at 1.8 Gy/fraction would be administered by

two-dimensional or 3D conformal multi-field radiotherapy plans to a larger at-risk region sometimes including elective nodal volumes, followed by a reduced-volume boost field to at least 50 Gy (and sometimes 54-60 Gy if a T4 tumor). Surgical clips were not always obtained and thus very large volumes were required to ensure target coverage. Historical fields covered the primary tumor site with a 4- to 5-cm margin proximally and distally and with a 3- to 4-cm margin medially and laterally. Elective nodal coverage beyond the primary volume was sometimes intentionally included in the early studies of adjuvant RT for colon cancers (as in the randomized Intergroup trial). However, the nodal basins in the mesentery beyond surgical margins rarely need treatment due to satisfactory margin clearance in these sites, and elective nodal coverage increases risk of toxicity from unnecessarily large treatment fields. For most tumors, treatment can be restricted to the tumor bed only, depending on the risk factors for recurrence and whether intensive chemotherapy is planned. Right colon tumors may represent an exception to this, depending on the circumstance, since the dual supply of the ileocolic vessels limits extent of mesenteric resection. Treatment of proximal mesenteric nodes may be appropriate if nodes adjacent to the surgical or resection margin are involved. In some instances, treatment of the para-aortic nodes may be indicated, particularly with extensive retroperitoneal involvement by tumor, but generally omission of para-aortic nodes is appropriate.

Implementing the general guidance that routine cases need not include elective nodal coverage, with modern CT-based planning and IGRT margins, can often be reduced considerably from those historically used. However, for the volume receiving 45 Gy, one should often retain a generous margin on the target of at least 1 to 2 cm (or even more if clips are not available or the site is particularly mobile) to account for target motion during either 3D conformal or IMRT planning. Ideally this at-risk volume is determined by concurrent consideration of both pre- and postoperative scans. Sequential boosting or simultaneous integrated boost IMRT strategies may permit dose escalation to 54 Gy or more to the site of highest risk while retaining appropriate OAR doses. Dosing to target is often determined by proximity to OARs and plans might require selective undercoverage in regions to maintain safety to nearby organs. Ideally, no more than 1 mL of small bowel should receive over 50 Gy and point

maximum should be limited to 54 to 55 Gy, with minimization of the volume of small bowel receiving 45 to 50 Gy. As in other abdominal malignancies, irradiation of a portion of one kidney is acceptable and results in minimal long-term clinical sequelae, assuming that baseline function in the contralateral kidney is normal.[133] At least two-thirds of one functional kidney should receive no more than 18 to 20 Gy, and at least two-thirds of the total liver volume should not receive more than 30 Gy.

Colon Cancer Summary

Advanced colon tumors may recur locally, regionally, or distantly after curative surgery, and numerous techniques have been implemented in attempts to reduce recurrence in each location. Studies investigating chemotherapy, immunotherapy, or RT as adjuncts to surgery have shown variable success rates. Depending on the tumor type and molecular features, neoadjuvant or adjuvant treatment with systemic chemotherapy or immunotherapy is often indicated for advanced colon cancers. Despite promising early data suggestive of a role for adjuvant RT in preventing local recurrences for advanced non-rectal colon cancers, the randomized Intergroup trial failed to recapitulate these findings. Although a failure to meet accrual goals, and the resultant limited statistical power, as well as several other flaws limit interpretation of that study, practice patterns have evolved since this time to reserve adjuvant RT or CRT for only very select cases where a risk of local recurrence is felt to be particularly high. Nevertheless, adjuvant (or potentially neoadjuvant) tumor bed irradiation with concurrent 5-FU-based chemotherapy should be considered for patients (a) with tumors invading adjoining structures, (b) with tumors complicated by perforation or fistula, and (c) with tumors where incomplete resection is performed. IORT with or without EBRT could also be considered for select cases, though much of the supportive literature derives from rectal cancer experiences and/or recurrent cancers.

RECTAL CANCER

Rectal cancer management paradigms differ from those for non-rectal colon cancers and generally reflect the unique features in anatomy, molecular biology, and patterns of recurrence for rectal cancers versus other CRCs.

Management of cancer of the rectum has undergone dramatic changes in the last several decades, including a rapid expansion of appropriate treatment paradigms for various clinical scenarios within the last several years. Historically, surgical resection represented the primary treatment modality. However, it became clear that in spite of radical resections, without additional treatment a significant proportion of patients developed local recurrence of disease (20%-50%), in contrast to colon cancer, which has less propensity for local recurrence (Table 67.3).[134,135] Local tumor recurrence of rectal cancer highly correlates with both the depth of penetration of the tumor and the number of regional nodes, and also likely reflects the limited space afforded for surgical interventions in the pelvis.[136] Over time, numerous cooperative group and randomized trials indicated that multimodality treatment approaches, particularly neoadjuvant treatment, result in a significantly better outcome than does surgery alone. Simultaneously, improvements in the efficacy of each treatment modality over time have revealed new opportunities to now consider de-escalation strategies that may omit one or more treatments previously considered essential for optimal management. Now, a patient with locally advanced rectal cancer may have the ability to choose between numerous excellent options for management, depending on the tumor features and anatomy, clinical comorbidities, and patient preferences.

TABLE 67.3 LOCAL AND DISTANT FAILURES: COLON AND RECTAL CANCERS TREATED WITH SURGERY ALONE

Stage	Locoregional Recurrence Rate
Colon cancer	
T1-T2 N0	3%-7%
T3/T4	13%-24%
N+	2%-19%
Rectal cancer	
T1-T2 N0	3%-14%
T3/T4	11%-31%
N+	14%-50%

Defining the True Rectum and Impact of Tumor Location

Rectal cancer comprises a spectrum of disease stages that needs careful definition to optimize multimodality treatment strategies. Moreover, as management of non-rectal colon cancers differs considerably from rectal cancer treatment paradigms, defining the true rectum remains crucial. Traditionally, the rectum extends for 12 to 15 cm from the anal verge, but this can vary considerably by sex, body habitus, and measurement technique. The inferior border of the true surgical rectum exists at the anorectal ring, just proximal to the dentate line. This represents the internal anal sphincteric muscle and is necessary for anal continence. It also represents the practical inferior limit for functional sphincter preservation surgery and defines the lymphatic watershed for rectal cancer spread. Tumors arising above the anorectal ring tend to metastasize along the distribution of the middle rectal vessels to the internal iliac lymph nodes, as compared to tumors that may extend into the anal canal, which may spread via nodes along the inferior rectal and external iliac pathways (Figure 67.4).[137] Cancers that arise in the anal canal may metastasize to the lungs (caval drainage) rather than the liver (portal drainage), as is common with most true rectal cancers. The prognosis of patients including the likelihood for LF worsens with more distal location of cancer, and these differences persist even with the addition of adjunctive therapy.[138]

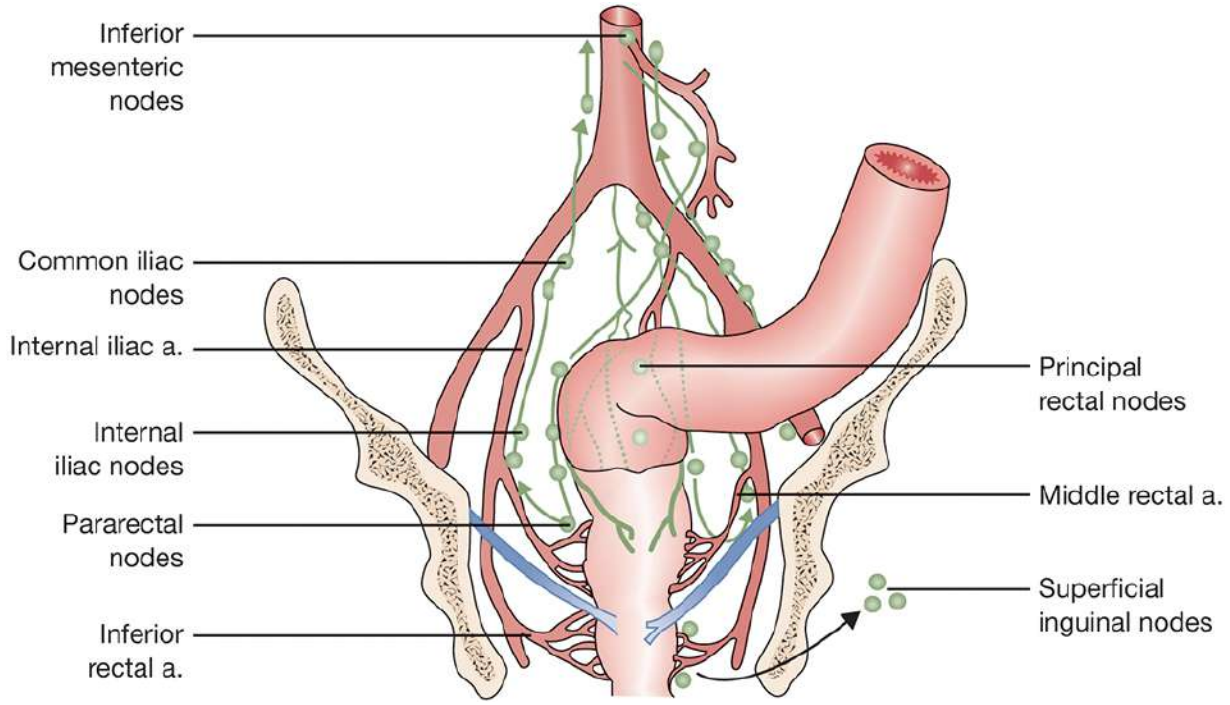

FIGURE 67.4 Lymphatics of the rectum.

During the workup of a patient with a suspected rectal cancer, information available through physical examination, radiologic studies, and endoscopy/proctoscopy examinations helps discriminate rectal cancers from more proximal sigmoid (ie, non-rectal colon) cancers or from more distal anal carcinomas.[139] Discrimination of the rectosigmoid junction can be particularly problematic.[74] A quick radiographic method to estimate the superior rectal extent from CT imaging alone involves drawing a straight line from the sacral promontory to the pubic symphysis, with the rectum generally falling below this (Figure 67.5). While a helpful tool for estimation, this technique is not foolproof in discriminating the rectosigmoid junction and may vary with patient anatomy so other tools must be utilized to determine the primary tumor site. Anatomically, the proximal rectum begins at the level at which the peritoneum is reflected along the anterior surface of the rectum (usually at the level of S3); additionally, proximally in the non-rectum colon, the teniae coli will be observed.[140] These are surgical observations and may be difficult to define in an intact patient, although MRI assists in identifying the anterior peritoneal reflection.[141] Endoscopically, the transverse folds of the rectum (also known as the valves of Houston) serve as helpful landmarks both for

rectal localization as well as distance markers from the anorectal ring. The upper valve of Houston demarcates the rectosigmoid junction endoscopically and the middle valve of Houston is a useful landmark that can often be identified endoscopically (usually about 6 cm from the anorectal ring) and can be used to differentiate proximal tumors from more distal lesions.[142] However, locations of these valves can vary from patient to patient.

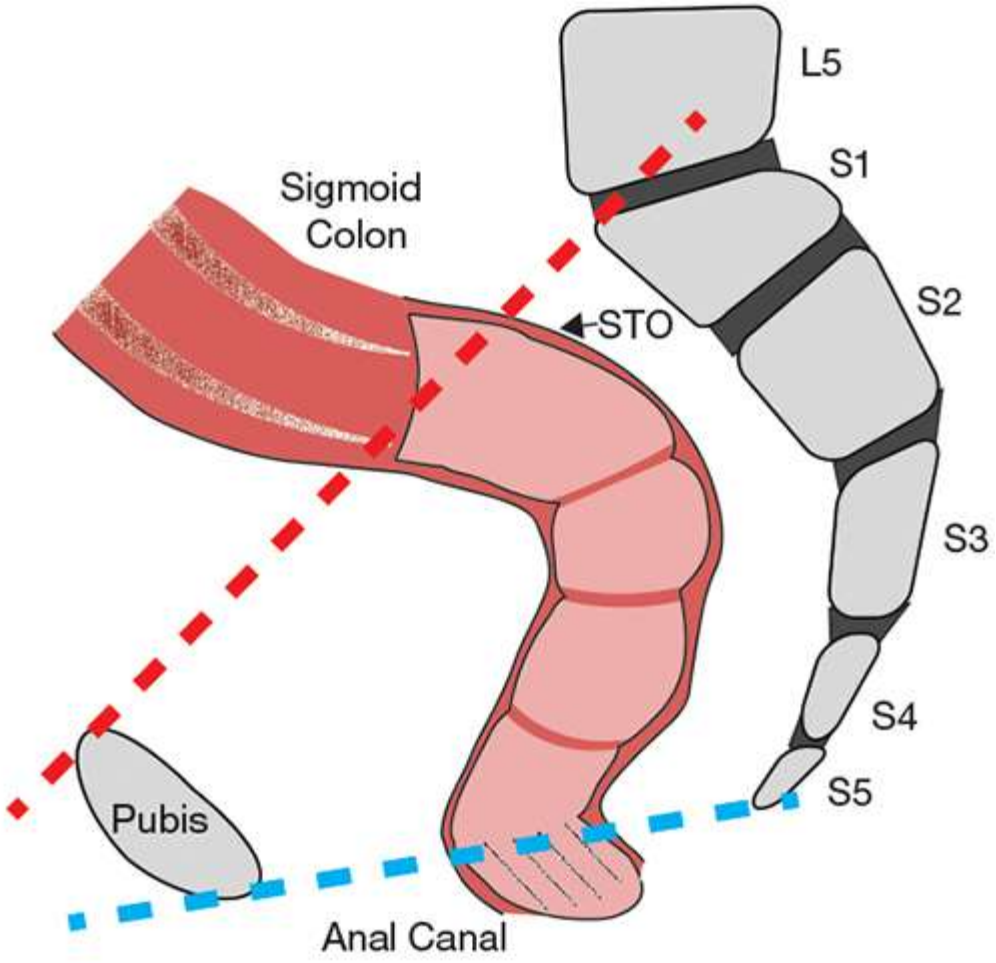

FIGURE 67.5 Schematic of rectal boundary landmarks. Sagittal view of schematized relationship between lumbar-sacral spine, rectosigmoid, anal canal, and pubis. Recent radiographic consensus indicates that the sigmoid takeoff (STO, black arrow) is the most reliable radiographic indicator of the upper rectal boundary and is the location where the rectum flexes anteriorly from the sacrum. This can vary considerably from patient to patient, so as a quick reference, the rectosigmoid boundary can be estimated as the place where a line drawn between sacral promontory and pubis intersects with the rectum (red dotted line). Though the anorectal junction is generally fairly easily distinguished at the level of the upper puborectalis sling on coronal magnetic resonance imaging, its location can be estimated on sagittal imaging as the location where a line drawn from the lower sacrum to the inferior pubis intersects with the anorectal region (blue dotted line).

Distally, the dentate line represents the transition point from columnar rectal epithelium to squamous anal epithelium, which can be observed endoscopically but is not recognizable on imaging. Radiographically, MRI can readily discriminate the anorectal junction, and this location is often

used as the landmark for rectal measurements. On CT or MRI, an estimate of the location of the anorectal junction can be made by drawing a line between the lower margin of the sacrum and the lower boundary of the pubic symphysis on sagittal sections. More accurately, on MRI the anorectal junction occurs at the level of the upper boundary of the puborectalis sling.[139] Most tumors that can be digitally palpated are generally considered distal cancers, and one can palpate the anorectal junction (the surgically defined anal/rectal boundary) at the level of the muscular anorectal ring, usually about 1 to 2 cm above the dentate line. While anal cancers tend to more often be characterized by squamous cell histology (and rectal cancers by adenocarcinoma), histology alone does not discriminate the origin of a tumor since anal adenocarcinomas and rectal squamous cell carcinomas do exist.

Prognostic Factors

Several prognostic factors, in addition to tumor location, have been shown to have a significant impact on tumor behavior. Tumor stage, as defined by the American Joint Committee on Cancer staging, clearly remains the dominant determinant of survival. Pathologic factors like LVI, PNI, mesorectal integrity on total mesorectal excision (TME), and CRM status have clinical significance and should be incorporated into treatment decision-making.[143,144] Circumferential tumors or those with total or near-total obstruction (lumen <1 cm) may respond very poorly, and tumors with deep central ulceration are associated with a high incidence of lymph node involvement.[145] Tumor mobility can be a key factor in both choice and outcome of treatment.[146,147] Mobile cancers have a much more favorable outcome as compared to tethered or fixed cancers. Surgery for fixed cancers can be ineffective, and these tumors are often classified as unresectable. Tumor fixation, although harder to assess in the proximal rectum, is less often encountered without other adverse factors such as circumferential disease with obstruction or perforation.[148] Tumor fixation is much more problematic in the distal rectum because the confines of the bony pelvis inhibit the surgeon’s ability to achieve adequate lateral/circumferential margins. Other patient factors, such as age, gender, and ethnicity, appear to have little association with outcome but may affect choice of therapy. As

neoadjuvant therapy has emerged as the standard of care, degree of tumor regression has become an important prognostic factor.[149,150] Pathologic assessment of tumors after neoadjuvant therapy receives a special designation of ypTNM in annotating pathologic staging.

Treatment

Surgical Considerations and Total Mesorectal Excision

Historically, curative treatment for rectal carcinoma required surgery. Even with the more recent proliferation of non- operative strategies for rectal cancer (discussed later), they are only possible due to the availability of high-quality oncologic surgical procedures should other modalities fail or tumors recur.

Surgical management depends on the stage and location of a tumor within the rectum. Early cancers can be managed with limited surgery (ie, local excision) in selected situations; however, the majority of tumors tend to present as more advanced disease and require either a low anterior resection (LAR) or abdominoperineal resection (APR). The general principles of a surgical approach involve the removal of all gross and microscopic disease with negative proximal, distal, and circumferential margins. In the case of radical resection, this means removal of the adjacent mesorectal tissue (TME), containing the regional lymphatics and potential tumor deposits. Several studies have shown that the surgeon's experience with resection of CRC is an independent variable in the outcome of treatment.[151] The Intergroup 0114 trial found that for stage II and III rectal cancers, not only were APR rates higher in hospitals with low procedural volume (46% vs 32%), but more patients had positive resection margins.[152]

Despite historical practices suggesting 5-cm distal margins of normal rectum were required for adequate surgical resection, distal intramural spread of tumor is rare beyond 1.5 cm, and therefore, a 2-cm distal margin is generally considered acceptable except in lesions that are poorly differentiated.[153-156] The American Society of Colon and Rectal Surgeons (ASCRS) additionally specify that for very distal tumors a margin of 1 cm or even less may be acceptable for highly selected patients who are highly motivated for sphincter preservation and demonstrate good response to neoadjuvant treatment modalities.[141] The reduced distal margin extent

requirement has led to a significant increase in the likelihood of sphincter preservation procedures in this disease.

Transanal Local Excision

Early rectal cancer (Tis or T1 disease) may be resected with local excision techniques, avoiding major surgery and a colostomy. However, patients should be carefully selected for these procedures and warned that the rate of local recurrence exceeds that seen with radical resection and that if pathologic findings indicate more advanced disease, they may still require radical resection as well as potentially treatment with other modalities. Local recurrence after local excision of T1 tumors may be as high as 7% to 21%, and historical data indicate that even T1 tumors may have occult nodal disease in 5% to 10% of patients, most often with more advanced pathologic features.[157-162] However, with proper selection T1 lesions have very good results with local excision alone, with 5-year LC ranging from 82% to 97% and OS rates of 90% or better.[163] Local excision is not oncologically appropriate for T2 lesions due to excessively high local recurrence rates (26%-47%) and the elevated risk of occult nodal disease (verging on 20%-35% for T2 disease). Given these results, efforts have been made to provide sphincter-sparing opportunities for >T1 disease by combining local excision with other modalities, like CRT, as discussed in later sections.

Transanal approaches currently dominate local excision techniques, though historical options for local excision included transsphincteric excision (York-Mason) and a posterior parasacral approach (Kraske). Transanal excision approaches are suitable for small (<3-4 cm), accessible (<8 cm from the anal verge), Tis or T1 cancers involving less than 30% of the rectal circumference that are mobile, polypoid, and not ulcerated and bear favorable histologic features like well/moderate differentiation and no tumor budding, no LVI, and no PNI.[74,164,165] An adequate resection requires full thickness resection (into the fat), with the tumor being removed in one uninterrupted specimen with at least a 1-cm radial margin and 2-mm deep margin, with orientation of the specimen so that careful pathologic assessment can be performed.[74] Multiple platforms support transanal

excisions, including transanal endoscopic microsurgery and transanal minimally invasive surgery.

Radical Surgical Approaches: Abdominoperineal Resection and Low Anterior Resection

APR has a long history of use for surgical resection of distal rectal cancer and requires removal of the primary tumor along with a complete proctectomy, leading to a permanent colostomy. As sphincter-sparing options have proliferated, the rate of APR has declined, dating back to the 1980s.[166] APR may be associated with a slightly higher morbidity and mortality than LAR and a worse quality of life (QOL) related to changes in body image and depression due to the presence of a colostomy.[166-168] There is also a higher risk of positive margins with APR because the mesorectum is thin in the distal segment of the rectum and margins are often restricted by the proximity of the prostate or vagina. The confines of the bony pelvis, particularly in males, can also restrict surgical access.[169] Perineal wound complications occur relatively commonly after APR, and neoadjuvant RT increases the risk of such complications. One meta-analysis of 7,247 patients reported a perineal wound complication rate of 15.3% without radiation, and 30.2% when APR followed neoadjuvant RT.[170] Many of the studies evaluating neoadjuvant therapy for rectal cancer have derived from a desire to avert the need for APR and its attendant side effects.

The advent of circular stapling devices expanded the role of sphincter-preserving surgical options in rectal cancers, and LAR transitioned from utilization only for upper rectal tumors to implementation for tumors in middle and even distal rectal tumors using “ultralow” anterior resections.[171] Choice of coloanal or colorectal anastomosis depends on the site of tumor and margins required. Preserving adequate anorectal function becomes increasingly difficult the more distal the level of anastomosis.[172] Patients should have good anal sphincter continence prior to considering sphincter-preserving options. Patient age, pelvic anatomy, gender, and body habitus can affect suitability for sphincter preservation. For upper tumors, routine excision of at least 5 cm of distal margin is recommended. For mid or distal tumors, guidelines recommend an ideal 2-cm distal margin, but note that 1 cm margins may be acceptable in well-selected patients and even shorter

distal margins may be acceptable in patients motivated for sphincter preservation with tumors exhibiting favorable responses to neoadjuvant therapy.[74] Creating a tension-free anastomosis may aid in preventing postoperative anastomotic leaks, so many surgeons employ splenic flexure mobilization to facilitate this reconstruction. In the irradiated pelvis, this can also ensure the availability of an unirradiated bowel segment for use in the anastomosis. Generally, contraindications for LAR include tumors involving the anal sphincter or levators, where there is loss of the intersphincteric plane, or where margin-negative resections would result in unacceptable sphincter function. For these cases, APR likely represents the best radical surgical option. Several studies comparing the results of LAR to APR generally reported similar outcomes for local and distant recurrence rates and survival as long as surgical margins are negative.[167,173] The absence of a colostomy may augment some aspects of QOL after LAR, but other toxicities including LAR syndrome (bowel urgency, frequency, or poor sphincter control) occur with some frequency and can negatively impact QOL.[74,174,175]

Total Mesorectal Excision

Historically, high rectal cancer local recurrence following standard APR or LAR (15%-30% or more) was attributed to blunt surgical dissection techniques violating the mesorectal fascia.[176] Moreover, despite limited distal intramural tumor spread beyond rectal cancers, the mesorectum facilitates more distal spread of tumors. Whereas intramural tumor is rarely found more than 1 cm beyond the edge of the tumor, deposits of mesorectal tumor or nodal spread can occur up to 4 cm distal from the tumor. Heald et al recommended en bloc removal of the tumor within the envelope of the endopelvic fascia as necessary to obtain adequate lateral clearance of disease and reduced likelihood of local recurrence.[177,178] TME, as they described, has become the established standard for all radical rectal cancer resections and requires sharp dissection along the plane that separates the visceral from the parietal pelvic fascia with complete en bloc removal of the rectum so that all of the rectal mesentery remains within the envelope of the specimen.[145] Indeed, pathologic assessment in a large randomized trial found that the plane of surgery—mesorectal, intramesorectal, or muscularis

propria plane—predicted for local recurrence. Three-year local recurrence was 4% in patients undergoing complete mesorectal excision, compared with 7% and 13% in the intramesorectal and muscularis propria groups, respectively.[100]

On gross pathology, an adequate TME specimen will have a bilobed, encapsulated appearance, with the surface looking smooth and unbroken, like a lipoma (Figure 67.6). On pathologic review, an appropriate dissection should include a minimum of 12 to 15 perirectal and pelvic lymph nodes.[74] TME, although more difficult with APR than LAR, may be associated with a somewhat higher anastomotic leak rate, especially for low rectal lesions (15%-17%).[104,145,151] Multiple series using TME surgery have reported low rates of local recurrence (ranging from 5% to 10%) and an improvement in OS approaching 80% to 85% for stage II and 65% to 70% for stage III disease.[100,139,152-154] The implementation of TME into clinical treatment paradigms drove the local recurrence rates of rectal cancer downward, and it remains an important reason for the extremely low local recurrence rates seen using modern multimodal treatments for locally advanced rectal cancer.

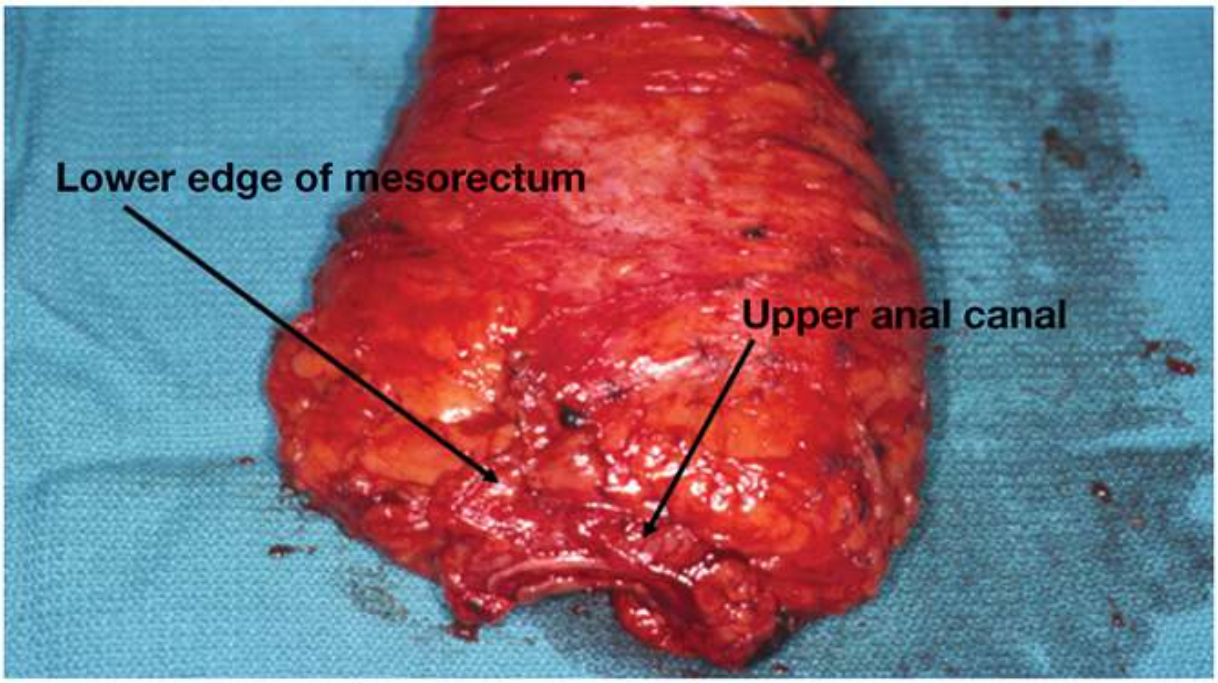

FIGURE 67.6 Total mesorectal excision specimen with designation of the lower mesorectum and upper anal canal.

Transanal TME approaches have begun to find traction in the surgical repertoire, though recommendations for routine use remain guarded. Early concerns regarding intraoperative complications and multifocal local recurrences during use of these operations led to temporary moratoria on the use of this technique in several countries.[179-181] However, two randomized trials have subsequently lent support to the safety and utility of this technique in comparison to laparoscopic TME approaches, when performed by experienced surgeons.[182,183] This has led to a conditional recommendation by the ASCRS that transanal TME may yield similar complication rates and functional outcomes, with a meta-analysis identifying no statistically significant differences in oncologic outcomes relative to open TME or laparoscopic TME.[184] More data will be required to fully characterize the efficacy of this technique in terms of oncologic outcomes, and concerns regarding the possibility for higher rates of LAR syndrome with transanal TME will be addressed in ongoing studies.[185]

Laparoscopic Approaches

As for colon cancer surgery, laparoscopic surgery for rectal cancer offers potential advantages of reduced blood loss/perioperative morbidity and shorter hospitalizations. Initial randomized studies suggested that in the hands of an experienced surgeon, outcomes from laparoscopic surgery appear no different than those from open resection in a number of randomized trials.[186-188] However, subsequent randomized controlled phase III trials prompted a reevaluation of this initial impression, as they failed to demonstrate noninferiority of laparoscopic methods versus open methods for composite pathologic outcomes or successful resection.[189,190] Meta-analyses similarly raise concerns about incomplete resection in patients treated with laparoscopic approaches.[191,192] Corroboration within survival data has lagged, as long-term results remain pending for most of these studies. Short-term oncologic outcomes did not significantly differ for local recurrence or DFS in these studies, but events were limited and thus longer term follow-up is needed.[174,193] The current ASCRS guidelines recommend laparoscopic and/or robotic TME in the hands of experienced surgeons.[74]

Radial Margin

It has long been recognized that a principal reason for local recurrence in resected rectal cancer appears to be related to the anatomic constraints in obtaining wide radial margins, despite adequate proximal and distal margins. As early as the 1980s, using whole-mount specimens, Quirke et al found that 27% (14 of 52) of patients showed spread to the lateral radial margin, even though the margins appeared negative with standard pathologic assessment. Eighty-six percent of those with positive radial margins developed local recurrence of disease, as compared to only 3% without lateral resection margin involvement.[194] A positive radial margin is a predictor not only of local recurrence but also of inferior survival.[145] In the era of widespread use of TME, a positive CRM continues to associate with increased local recurrence and decreased survival.[195,196] Fortunately, with the implementation of routine MRI local tumor staging, prediction of close or involved CRMs can yield information about recurrence risk and help guide multimodal treatment decisions.[196,197]

Adjuvant Therapy

Early Postoperative Treatment

The problem of unacceptably high local recurrence after surgery for rectal cancer prompted initial interest in selective use of adjuvant therapy. Though selective administration of adjuvant therapy based on pathologic factors (eg, T3/T4 or N+ disease) has the capacity to minimize the number of patients receiving adjunctive treatments, disadvantages exist. A potentially hypoxic postsurgical bed impacts the efficacy of radiation and chemotherapy. Postsurgical anatomy often increases the small bowel in the radiation field, increasing complications especially considering the larger treatment volumes required, particularly in patients undergoing an APR where the perineal scar may need to be covered. Though adjuvant treatment played an important role in the evolution of treatment patterns for rectal cancer and is still occasionally utilized, current paradigms strongly favor neoadjuvant treatment for locally advanced disease (see section “Neoadjuvant”).

Several early trials assessed the role of adjuvant RT compared to surgery alone. These trials showed reduced LFs with RT; however, no improvement in DFS, DM, or OS was seen. Thus, in an effort to improve outcomes, the

role of adjuvant CRT was evaluated. Summarizing the results, surgery alone resulted in a 25% LF rate and 40% to 50% OS for T3 or T4 or node-positive patients, whereas adjuvant CRT yielded a lower LF rate of 10% to 15% and higher OS of 45% to 60%. Notably, during this same era, improved surgical techniques like TME either had not been employed or were just beginning implementation. Thus, review of the results and specific outcomes numbers for each trial should consider this context.

Two early randomized studies demonstrated an OS benefit to adjuvant CRT. The Gastrointestinal Tumor Study Group (GITSG) study (1975-1980) was a four-arm trial of 227 patients with R0 resections of stage B2 and C (corresponding to T3 or N+) rectal cancer.[198] The four randomization arms were: surgery alone, postoperative bolus 5-FU/semustine, postoperative split-course radiation (40-48 Gy), and postoperative bolus 5-FU-based CRT (40-44 Gy). Early review indicated substantial benefits for CRT and the trial was terminated early, and a subsequent update reported that postoperative CRT improved 10-year OS, 45% versus 27%, compared with observation after surgery. Covariate-adjusted comparisons of survival relative to the other arms trended toward improvement with CRT, but were not statistically significant. LF rate was decreased to 10% with CRT versus 25% with surgery alone. Therefore, this trial concluded that there was a significant OS advantage (near doubling of survival) for patients who had CRT after surgical resection. The Mayo–North Central Cancer Treatment Group (NCCTG) study (1980-1986) compared postoperative RT against postoperative CRT.[199] Two hundred and four patients with T3/T4 or node-positive tumors received chemotherapy (1 cycle 5-FU/semustine) before randomization. The radiation dose was 45 to 50.4 Gy to tumor bed and adjacent lymph node regions and CRT utilized a bolus 5-FU regimen. All 5-year outcomes favored the CRT group, including locoregional failure (25% RT only vs 13% CRT) and OS (40% RT only vs 55% CRT).

In contrast to the GITSG and NCCTG trials, the NSABP R-02 study did not identify a survival benefit to CRT treatment. This study enrolled 694 patients with Dukes stage B and C (corresponding to patients with T3/T4 or N+). One of the study questions assessed the utility of 5-FU-based CRT (50.4 Gy) versus 5-FU/LV without radiation. The 5-year locoregional failure rate was 13% for the chemotherapy-only arm as compared to 8% with CRT, but survival was not impacted.[200]

Given the potential benefits seen with CRT, additional trials attempted to refine the type and delivery of chemotherapy to maximize benefit with lower toxicity. The NCCTG 86-47-51 study compared chemotherapy regimens (5-FU vs 5-FU/semustine) and methods of chemotherapy delivery (bolus or continuous infusion [CI]) when added to postoperative RT (50.4-54 Gy).[201] Semustine had no additional benefit beyond 5-FU chemotherapy, but CI 5-FU showed benefits with respect to relapse-free survival (63% CI vs 53% bolus 5-FU), DM (31% vs 40%), and 4-year OS (70% vs 60%). Toxicity type varied, but overall were temporary and manageable. Considering the absence of an LC difference, the disease outcome improvements associated with CI 5-FU likely reflected systemic rather than local disease control. The Intergroup 0114 study compared different chemotherapy in CRT regimens in 1,695 patients and found no clinical benefit, and increased toxicity, to the addition of levamisole or LV to bolus 5-FU.[164]

Adjuvant Treatment for Favorable T3 N0

Tumors that have a cT3N0 stage and other favorable features (upper rectum location, no LVI, shallow perirectal depth of invasion, and well- or moderately differentiated histology) may not warrant adjuvant treatment (chemotherapy or RT) after up-front TME. Several studies demonstrate a subset of tumors that might not need adjuvant therapy (chemotherapy or CRT or both), given the low risk of recurrence with surgery alone. Memorial Sloan Kettering Cancer Center evaluated 95 patients with T3 N0 rectal cancer treated by surgery alone.[202] Seventy-nine patients underwent LAR and 16 patients underwent APR, both with sharp mesorectal excision. With 53.3-month follow-up, 6% had local recurrence, 13% had DM, and 3% had both local recurrence and DM. LVI was the only histologic factor that was important for local recurrence. This study suggests that sharp mesorectal excision with LAR or APR for T3 N0 rectal cancers results in low local recurrences of less than 10% without the use of adjuvant therapy.

In a retrospective review of 117 patients with T3 N0 rectal cancer treated at the MGH, perirectal tumor invasion of 2 mm or more, LVI, and poorly differentiated histology were independent factors for increased risk of DM and worse RFS.[203] Only depth of invasion was significant for LC. Of the 25

patients with favorable histologic features (well differentiated/moderately differentiated, invading less than 2 mm into the perirectal fat, no LVI), the 10-year actuarial LC and RFS were 95% and 87%, respectively, as compared to 71% and 55% in the unfavorable group.

A pooled analysis of five randomized, controlled trials assessed survival and relapse rates by T and N stage in patients receiving or not receiving additional therapy after resection.[204] In patients with T3 N0 disease, 5-year survival of patients undergoing surgery and adjuvant chemotherapy alone was 84% and compared favorably to the 74% to 80% survival in patients undergoing surgery and adjuvant CRT. DFS in the T3 N0 subgroup was 69%. Notably most of these studies did not stage using EUS or MRI.

Now that neoadjuvant administration of nonsurgical treatment dominates treatment timelines, discrepancies between clinical staging and pathologic stage persist as an issue impacting treatment decision-making for the cT3N0 subset, despite the routine use of EUS- and now MRI staging. As discussed earlier, cT3N0 rectal cancers, especially those with favorable risk factors, may often be treated effectively with surgery alone or surgery plus adjuvant chemotherapy. Moreover, the German Rectal Cancer Study indicated approximately 18% of cT3/T4 or cN+ tumors were overstaged and were actually stage II disease.[205] However, a report from Memorial Sloan Kettering of 188 patients with cT3N0 rectal cancer (staged by EUS or MRI) treated with neoadjuvant CRT and radical resection indicated that 22% of patients had mesorectal nodal disease at surgery after CRT.[206] In other words, at least as many, if not more, patients are understaged than overstaged. This general perception, as well as the additional toxicity and local recurrence risk associated with adjuvant RT sequencing, had driven most oncology teams to favor neoadjuvant treatment for cT3N0 patients, even considering the likelihood that a minority are likely overstaged and thus overtreated. As discussed in section “Attempts to De-Escalate Multimodal Therapy For Rectal Cancer,” the PROSPECT trial supports providing patients an option for de-escalation of neoadjuvant multimodal therapy by omitting radiation for a subset of favorable tumors. Notably these patients still received neoadjuvant chemotherapy. Regardless, this approach lends credence to notions that some favorable T3N0 tumors may permit some de-escalation of therapy intensity, though omission of both chemotherapy and RT has not been evaluated in a randomized context.

Neoadjuvant Therapy

Neoadjuvant Radiotherapy

Though both preoperative and postoperative treatment regimens can be effective, neoadjuvant treatment has emerged as the standard of care. Neoadjuvant therapy provides tumor downstaging, improved resectability and tolerance (both acute and chronic), and potential for expanded sphincter preservation options in the distal rectum. Studies from Europe have demonstrated that appropriate neoadjuvant preoperative radiation results in improvement of LC (and OS in some studies, though this was restricted to the era predating modern surgical and chemotherapy approaches), and these results have had a significant impact on the current management of this disease.

The Swedish Rectal Cancer Trial included 1,168 patients accrued from 1987 to 1990 with resectable, Dukes A to C rectal cancer.[207] Patients were randomized to 25 Gy in five fractions in 1 week followed by surgery 1 week later versus surgery alone. At a median of 13 years, local recurrence was 9% versus 26% and OS was 38% versus 30%, both in favor of preoperative RT, with all stages benefiting.[208] One major caveat of this study is that the surgery-alone arm did not use TME, which likely contributed to the unacceptably high 13-year LF rate of 26%. Preoperative RT administration was associated with elevated rates of late effects, including increased bowel movement frequency, incontinence, urgency, and soiling in the preoperative radiation treatment arm, although overall QOL was rated good.[209] A higher rate of small bowel obstruction was also seen in the preoperative RT arm.[210] This trial set the standard of care in many European centers, but the dose of 5 Gy times five fractions may potentially contribute to late toxicity, and the short interval between radiation and surgery likely did not allow sufficient time for tumor regression (downstaging) for improved sphincter preservation. The contemporaneous Stockholm-I and -II studies had made similar comparisons, randomizing between short-course 25 Gy in five-fraction neoadjuvant RT followed by surgery versus surgery alone.[211,212] These studies corroborated the benefit of preoperative RT on LC and (for Stockholm-II) OS in the pre-TME era.

The TME experience by Heald et al[177] suggested that TME alone may be sufficient for achieving low local recurrence rates, so it was unclear what

additional benefit neoadjuvant radiation provided in the TME era. A Dutch (CKVO 95-04) multicenter, phase III study of 1,861 patients was undertaken to evaluate the role of short-course preoperative radiation with TME. Patients were randomized to TME alone versus 25 Gy in five fractions followed by TME surgery after 1 week.[213] The included patients had relatively favorable tumors—no fixed tumors were included in the study, and approximately half of the patients had T1 or T2 disease. The 2-year OS was 82% in both arms of the study; however, the 2-year local recurrence was 8.2% in the TME-only arm as compared to 2.4% in the preoperative arm. Ten-year follow-up indicates persistent benefit in local recurrence of 5% (RT) versus 11% (TME alone) ($P < .0001$) without difference in DMs or OS.[214] This highlighted the value of radiation treatment for LC, despite the use of TME and the inclusion of less advanced disease. Notably, this study also used a short interval (1 week) between RT and surgery, so the sphincter preservation rate was the same in both arms, and there was no clear evidence of any downstaging effect. The perineal complication rate was slightly higher in the preoperative radiation arm of 26% versus 18% in the TME arm.[215,216] Updated toxicity analysis indicates a higher incidence of sexual dysfunction and slower recovery of bowel function, more fecal incontinence, and generally poorer QOL with short-course preoperative radiation.[217,218] Since this trial enrolled earlier stage disease (no fixed tumors, half with T1-T2 disease), these data indicated a role for RT alongside TME, even in less advanced rectal tumors.

The UK Medical Research Council CR07 supported the Dutch TME experience, demonstrating that neoadjuvant RT administration was associated with lower locoregional recurrence rates (LRRs) in patients who largely received TME radical surgeries. This multinational study of 1,350 patients with operable non-metastatic rectal carcinoma was randomized to preoperative RT (25 Gy in five fractions) or initial surgery with selective adjuvant CRT based on CRM involvement.[219] TME was not mandated, but surgeons assessed it had been performed in 93% of operations, and pathologic specimen analysis indicated 86% were TME specimens, and those patients with appropriate TME resection planes demonstrated improved LC.[143] Neoadjuvant RT decreased local recurrence by an absolute difference of 6.8% at 5 years (4.7% in RT arm, 11.5% in up-front surgery arm; $P < .0001$), with no difference in OS.

Multiple large meta-analyses corroborate a role for preoperative radiation treatment in preventing local recurrence.[220-222] One early analysis included 14 randomized, controlled trials, albeit with wide-ranging RT and surgical techniques employed, and reported that neoadjuvant radiation treatment was associated with significantly fewer LRs, improved cancer-specific survival, and an OS benefit.[222] The Cochrane meta-analysis included four trials comparing neoadjuvant RT and surgery to surgery alone, with a total of 4,663 patients analyzed, limiting the study to trials utilizing 3D conformal multi-field RT techniques.[221] The analysis again indicated improved LC after neoadjuvant RT, regardless of whether TME was performed. OS was higher in the RT group, though this was not evident in a subgroup analysis including only those patients who received TME. In sum, these meta-analyses substantiate a role for neoadjuvant RT in decreasing local recurrence rates; any OS or cancer-specific survival benefit was quite small and likely related to premodern surgical and chemotherapy regimens.

Neoadjuvant Chemoradiation Therapy

The improvement in outcomes with CRT in the postoperative/adjuvant setting led to implementation of this approach in neoadjuvant treatment of this disease. While readily implemented in the United States, the standard European treatment paradigm remained neoadjuvant RT alone, including numerous regimens with standard fractionation (rather than the short-course RT utilized in many of the trials discussed earlier). Several studies were undertaken to compare neoadjuvant RT alone versus neoadjuvant CRT approaches using standard fractionation.

Preoperative RT was compared with combined preoperative CRT in a French study (Fédération Francophone de la Canérologie Digestive 9203; 1993-2003).[223] Seven hundred and thirty-three patients with resectable T3 and T4 tumors accessible by DRE were randomized to 45 Gy (in 1.8 Gy fractions) of radiation alone versus the same dose and radiation fractionation with concurrent bolus 5-FU plus LV and four adjuvant chemotherapy cycles. Although there was no difference in 5-year OS (primary endpoint) between the two arms, pCR rates (11.4% vs 3.6%) were higher and local recurrence rates (8.1% vs 16.5%) were lower with CRT.

Grade 3/4 acute toxicity was more frequent in patients receiving CRT, at 14.6% versus 2.7%.

A similar study undertaken by the European Organization for Research and Treatment of Cancer (EORTC 22921) randomized more than 1,000 patients to four arms (2 × 2 design): 45 Gy alone versus 45 Gy plus bolus 5-FU and LV followed by surgery, with patients further randomized to adjuvant therapy with 5-FU/LV or no adjuvant therapy.[224] Results of the study were similar to those of the French study, with increased tumor downstaging (14% vs 5.3%; $P = .0001$) and lower rates of local recurrence (9% vs 17%) but no difference in 5-year OS (65% in both arms). This information suggests that although there are lower rates of recurrence, there is no conclusive evidence that combined treatment offers a survival benefit compared to radiation alone in the neoadjuvant setting. There is, however, a higher incidence of acute toxicity associated with combined CRT.

A subsequent meta-analysis pooled four trials and compared results of preoperative RT with preoperative CRT in patients with resectable stage II or III rectal cancer.[225] The addition of chemotherapy significantly increased rates of grade 3/4 acute toxicity (odds ratio [OR], 1.68-10) and higher rates of pCR (OR, 2.52-5.27) and lowered the incidence of local recurrence (OR, 0.39-0.72). No difference was seen in 5-year DFS or OS. Although the aforementioned studies and meta-analysis do not show a DFS or OS benefit with the addition of chemotherapy to neoadjuvant RT, given higher pCR as well as improved LC, neoadjuvant CRT supplanted standardly fractionated neoadjuvant RT as a reasonable standard of care.

Long-Course Neoadjuvant Chemoradiotherapy Versus Short-Course Neoadjuvant Radiotherapy

In parts of Europe where a hypofractionated preoperative RT regimen became preferred, the Polish rectal cancer group initiated a study to determine whether outcomes of a short-course approach (5 Gy for five fractions and surgery within 1 week) surpassed a protracted approach (50.4 Gy using 1.8- to 2-Gy fractions with concomitant bolus 5-FU/LV in weeks 1 and 5).[226] TME was specified as the surgical approach. Although a higher pCR rate was seen with CRT (16% vs 1%) along with fewer positive radial margins (4% vs 13%) and considerable size reduction of the tumor (by ~1.9

cm), no difference in the rate of sphincter preservation (the primary outcome), LC, or OS was seen.

In the Australian Intergroup Trial, 326 patients with cT3NxM0 rectal cancer within 12 cm of the anal verge were randomized to short-course RT (25 Gy in five fractions) with surgery within 1 week or long-course CRT (50.4 Gy in 28 fractions with the more standardly used CI 5-FU) with surgery 4 to 6 weeks following completion of CRT.[227] Both regimens were followed by adjuvant 5-FU-based chemotherapy. Over 90% of patients were clinically staged with pelvic MRI or EUS. With a median follow-up of 5.9 years, there was no difference in 3-year local recurrence (7.5% short course vs 4.4% CRT; primary endpoint), 5-year OS (74% short course vs 70% CRT), or late toxicity. Despite tumor downstaging, there was no difference in rates of sphincter-sparing surgery. An examination of acute adverse events (AEs) and postoperative complications demonstrated more AEs in the long-course arm, and no statistically significant differences in surgical complication rates, though the authors note trends favoring long course for permanent stoma and anastomotic breakdown and favoring perineal wound complications with short course.[228]

The optimal neoadjuvant approach for resectable rectal cancer remains far from clear and approaches vary by site of treatment, with CRT more common in the United States and short course more common in Europe. Regardless, both short-course RT (25 Gy in five fractions) and long-course CRT (50.4 Gy in 28 fractions) with concurrent 5-FU-based chemotherapy represent reasonable therapeutic options. As discussed in section "Total Neoadjuvant Therapy," neoadjuvant intensification by combining preoperative local and systemic therapy has also become a frequently employed treatment option.

Preoperative Versus Postoperative Therapy

Numerous phase III trials have compared preoperative versus postoperative CRT treatment strategies. Initial smaller phase III studies provided support for the neoadjuvant administration of CRT. The NSABP R-03 study was scheduled to accrue 900 patients but closed after accruing 267 patients.[229] This study randomized individuals with operable rectal adenocarcinoma to surgery followed by one cycle of 5-FU/LV and then concurrent bolus 5-

FU/LV with radiation treatment versus 5-FU/LV for one cycle and then concurrent CRT treatment followed by surgery. Although the study was underpowered and TME was not mandated, 5-year DFS was superior in the preoperative therapy group: 64.7% versus 53.4% (P = .011), with a trend toward improved OS and a 15% pCR rate. A Korean trial randomized 240 patients with locally advanced (cT3/T4 or N+) rectal cancer to preoperative or postoperative CRT (50 Gy in 25 fractions, plus concurrent capecitabine), with TME resection and four cycles of adjuvant 5-FU- or capecitabine-based chemotherapy. The 5-year DFS, OS, and local recurrence rates were no different between the two arms. Patients with low-lying rectal tumors (<5 cm from the anal verge) had higher rates of sphincter preservation in the preoperative arm (68% vs 42%; P = .008).

The definitive phase III study in favor of preoperative RT was the CAO/ARO/AIO-94 study performed by the German Rectal Cancer Group.[205,230] Eight hundred twenty-three cT3/T4 or node-positive rectal cancers (not MRI staged) were randomized to preoperative CRT followed by TME 6 weeks later or TME followed by postoperative CRT. The radiation dose was 50.4 Gy in 28 fractions in all patients, with a 5.4-Gy small-volume boost in the postoperative arm. 5-FU (1 g/m^2/day) was administered during weeks 1 and 5 of RT as a 120-hour CI. Both arms received four additional cycles of adjuvant 5-FU (500 mg/m^2/day for 5 days every 4 weeks). All surgeons were trained in the use of TME and were asked, prior to treatment, to evaluate the possibility of sphincter preservation. There was significant tumor downstaging after preoperative CRT, with an 8% pCR. Nodal positivity was 25% in the preoperative versus 40% in the postoperative arm. The sphincter preservation rate in 188 patients with low-lying tumors (declared by the surgeon prior to randomization to require an APR) revealed that 39% versus 19% had a sphincter-preserving LAR (P = .004) in the preoperative versus the postoperative arm. Perioperative complications did not differ between the groups, but overall rates of both acute- and long-term toxicities (especially acute and chronic diarrhea, and anastomotic strictures) were lower in the pretreatment group. Consistent with the 5-year results, the 10-year LC favored neoadjuvant treatment (7.1% in pre- and 10.1% in postoperative arms, P = .048), with no difference in DFS, OS, or DMs. Thus, preoperative CRT resulted in improved LC and doubled the sphincter preservation rate

compared to postoperative therapy, while also demonstrating an improved toxicity profile.

Along with the MRC CR07 trial,[219] which demonstrated LC improvement to neoadjuvant short course RT versus selective postoperative CRT (see section "Neoadjuvant Radiotherapy"), the German rectal trial provides the basis for preoperative therapy as the current standard of care for locally advanced rectal cancers.

Surgical Timing After Neoadjuvant Radiotherapy and Chemoradiotherapy

Despite promising LC results from neoadjuvant short course and CRT regimens, in many cases the pathologic findings and improvement of sphincter sparing rates were underwhelming. The initial implementation of short-course RT included immediate (within 1 week) surgery, and even CRT was often followed by surgery in a relatively quick timeframe. Questions arose around whether increasing this interval between neoadjuvant treatment and surgery might permit improvements in downstaging, pCR, and potentially sphincter-sparing capabilities.

Justification for a longer interval after preoperative radiation treatment before surgery was demonstrated in a French trial, Lyon 90-01, which delivered 39 Gy as 3 Gy/fraction (no preoperative chemotherapy).[231,232] Two hundred and one patients were randomized to surgery within 2 weeks versus 6 to 8 weeks of RT. The LC and OS after a median follow-up of 6.3 years were the same in both arms of the study, and there was no difference in sphincter-sparing intervention or long-term anal function. However, the pCR was 7% versus 14% (P = NSS [not statistically significant]), and the pathologic downstaging was 10% versus 26% (P = .007) in favor of the longer interval before surgery.

The more recently published Stockholm III trial evaluated both fractionation and timing after RT to surgery.[233] Patients with resectable rectal cancer were randomized to: (1) 5 Gy × 5 followed by surgery within 1 week, (2) 5 Gy × 5 followed by surgery after 4 to 8 weeks, and (3) 50 Gy in 25 fractions followed by surgery after 4 to 8 weeks. The primary endpoint was time to local recurrence. Pathologic response appeared improved in the short course with delay arm, relative to the long course or

short course without delay arm. Other outcomes were similar between all three treatment arms. Although there was noted to be an increase in radiation-related acute toxicities in the short-course RT arm with delay to surgery, there was a significant decrease in postoperative complications in these patients. The authors suggest that short-course RT with delay may be an alternative to conventional short-course RT followed by immediate surgery.

Systematic comparison of longer intervals has not been attempted for neoadjuvant long-course CRT, but extrapolation from the short-course experience, and incorporation of data from studies that alter the sequencing of CRT and chemotherapy in total neoadjuvant regimens (see section "Total Neoadjuvant Therapy") support approaches that permit relatively longer intervals between short-course or CRT regimens, without being so long as to impede the surgical procedure itself.

Alternative Chemotherapy Regimens With Neoadjuvant Radiotherapy

There is considerable variability in the administration of chemotherapy in many of the trials undertaken and those that are ongoing. 5-FU has been used concurrent with radiation because of its well-established potentiating effect with radiation. However, several studies have used bolus 5-FU, whereas others have administered LV-modulated 5-FU during the first and last weeks of radiation. The results of the Intergroup study demonstrating a superiority of low-dose CI-FU were extrapolated to the neoadjuvant setting, and it appears to be a preferred approach to treatment.[201] Subsequently, newer drugs such as oral fluoropyrimidines (capecitabine), oxaliplatin, and irinotecan were shown to be effective in the treatment of metastatic CRC. Oral fluoropyrimidines, as part of a CRT regimen, now commonly replace infusional 5-FU. The incorporation of oxaliplatin and irinotecan into the neoadjuvant CRT regimen has been less promising, though in the era of watch-and-wait therapeutic options they may have a role in total neoadjuvant approaches in the chemotherapy-only component of treatment.

Capecitabine is an oral fluoropyrimidine prodrug that is readily absorbed in the gastrointestinal tract and mimics the efficacy of CI 5-FU while avoiding the risk of side effects and complications due to a central line for

CI 5-FU.[234] Capecitabine requires the presence of thymidine phosphorylase (TP) for conversion to the active form of 5-FU within the cells. TP is present in higher concentration in tumor cells, particularly CRC, than in normal tissues, and this potentially creates a therapeutic advantage for capecitabine as compared to intravenous 5-FU.[235] Capecitabine is generally given in two divided doses twice a day during the course of radiation treatment. Toxicities differ between CI 5-FU and capecitabine and may determine the best agent for an individual patient; leukopenia may occur more frequently in CI 5-FU while diarrhea, proctitis, and hand-foot syndrome may occur more often for capecitabine.

Two randomized reports supported the use of capecitabine in both neoadjuvant and adjuvant chemoradiation regimens. A German trial documented noninferiority for capecitabine versus CI 5-FU with respect to OS, with similar DFS and local recurrence noted and fewer metastases in the capecitabine group.[236] Diarrhea was the most common AE in both groups (any grade, 53% patients in the capecitabine group vs 44% in the FU group; grade 3-4, 9% vs 2%). Patients in the capecitabine group had more hand-foot skin reaction, fatigue, and proctitis than did those in the FU group, whereas leukopenia was more frequent with the FU arm. A second study, the NSABP R-04, compared the efficacy of four chemotherapy regimens. More than 1,600 patients were randomized to 5-FU (225 mg/m^2, 5 days/week) or capecitabine (825 mg/m^2, twice a day, 5 days/week) with RT with subsequent randomization to ±oxaliplatin (50 mg/m^2/week ×5).[237] For patients who received 5-FU versus capecitabine, there were comparable rates of tumor downstaging, pCR, and sphincter preservation.

The NSABP R-04 study also documented that addition of oxaliplatin failed to improve surgical outcomes, but did add significant toxicity (grade 3-4 diarrhea, $P < .001$).[237] Other randomized studies (STAR-01, ACCORD 12) also demonstrated that oxaliplatin added to standard CI 5-FU increases toxicity without improving outcomes.[238,239] In contrast, the German CAO/ARO/AIO-04 trial demonstrated a potential DFS benefit for oxaliplatin (50 mg/m^2 on days 1, 8, 22, and 29), when paired with a modified infusional 5-FU regimen (infusional FU 250 mg/m^2 on days 1-14 and 22-35) without undue toxicity.[240] Overall, the results of these randomized studies have resulted in oxaliplatin omission from most CRT regimens.

The addition of irinotecan to 5-FU-based chemotherapy has also been investigated. The Radiation Therapy Oncology Group (RTOG) conducted a randomized, phase II study of neoadjuvant CRT for distal rectal cancer. One hundred and three patients with T3 or T4 distal rectal cancer were randomized to CI 5-FU plus hyperfractionated radiation treatment of 55.2 to 60 Gy (1.2 Gy twice a day) versus CI 5-FU and irinotecan with conventional fractionation radiation of 50 to 54 Gy (1.8 Gy/fraction).[241] The response rate between the two arms was similar, with an impressive pCR of 28%, and no difference in toxicity. Other groups attempted to incorporate biologic agents into the neoadjuvant regimen. Although reports of the addition of bevacizumab and cetuximab to conventional preoperative regimens appear tolerable, the benefit remains unclear, and no phase III evaluation of these agents has been performed.[242-248] In the absence of convincing phase III data for these alternative concurrent chemotherapies, infusional 5-FU or capecitabine remains the standard choices for concurrent CRT.

Total Neoadjuvant Therapy

Total Neoadjuvant Therapy With Long-Course Chemoradiation

The role of total neoadjuvant therapy (TNT) in patients with rectal cancer was examined in the GCR-3 phase II trial from Spain. Patients with clinical stage T3/T4 tumors or node-positive disease with lesions in the distal or middle third of the rectum were randomized to neoadjuvant CRT followed by surgery and adjuvant CAPOX or a TNT regimen comprised of four cycles of induction CAPOX followed by chemoradiation and then surgery. Clinical endpoints (local recurrence, DM, DFS, and OS) were similar between the two groups at 5 years. There was improvement in compliance and lower rates of acute toxicity in patients undergoing TNT treatment.[249] A subsequent prospective multi-institutional phase II trial reported high pCR rates following a TNT regimen consisting of CRT and two to six additional cycles of mFOLFOX6 prior to surgery.[250] Increasing cycles of mFOLFOX6 improved the rate of pCR (18% in CRT alone, 25% in CRT+2 cycles, 30% in CRT+4 cycles, 38% in CRT+6 cycles).[214] It is unclear whether this improved pCR reflected increased local tumor response due to additional

chemotherapy, or simply reflected a longer interval between CRT and surgery leading to a more apparent improvement in pCR.

The PRODIGE-23 study assessed the efficacy of an intensified TNT regimen of mFOLFIRINOX followed by long-course CRT prior to TME versus CRT followed by TME.[251] Both arms received mandatory adjuvant mFOLFOX6. Improved pCR rates were seen in the TNT regimen (28% vs 12%, $P < .0001$). DFS (primary endpoint) at 3 years was improved in the TNT arm. Updated results indicate persistent 7-year DFS benefit (62.5% vs 67.6% for standard vs TNT; $P = .048$ by restricted mean survival time [RMST] test) as well as a 7-year metastasis-free survival benefit (72.3% vs 79.2%, $P = 0.021$ by RMST) and a 7-year OS benefit (76.1% vs 81.9%, $P = .033$ by RMST).[252] Locoregional failures were not significantly different, suggesting that much of this effect related to intensified chemotherapy and systemic benefits. This study confirms a utility for a TNT approach, but how and when to intensify chemotherapy to mFOLFIRINOX versus a more standard FOLFOX or CAPOX approach is unclear.

Total Neoadjuvant Therapy With Short-Course Chemoradiation

The Polish-II trial evaluated short-course RT as a component of a total neoadjuvant regimen in comparison to standard long-course CRT.[253] Patients with fixed cT3 or cT4 cancer (not staged by MRI) were randomized either to 5 × 5 Gy and three cycles of FOLFOX4 (group A) or to 50.4 Gy in 28 fractions combined with bolus and LV 20 mg/m^2/day with five weekly infusions of oxaliplatin 50 mg/m^2 (group B). The protocol was amended in 2012 to allow oxaliplatin to be then foregone in both groups; roughly two-thirds of enrolled patients received oxaliplatin-containing regimens. In the 515 patients eligible for analysis (of 547 enrolled), preoperative treatment acute toxicity was lower in group A than in group B ($P = .006$). Margin negative resection rates (primary endpoint; 77% group A vs 71% group B [$P = .07$]) and pCR rates (16% vs 12%; $P = .17$) were not significantly different. Over long-term follow-up, OS, DFS, DM, and LF showed no difference at 8 years despite an early 3-year OS benefit favoring the short-course arm.[254] The rate of late complications was similar (11% vs 9% in groups A and B, respectively; $P = .66$). There was no superiority to

the preoperative short-course TNT arm in this study, but the study was not powered for clinical endpoints.

The RAPIDO study evaluated high-risk rectal cancer (defined as T4 tumors, N2 or enlarged lateral LN, extramural venous invasion, or threatened CRM) and randomized 912 participants to receive TNT with short-course RT and CAPOX/FOLFOX versus standard neoadjuvant CRT, both followed by TME.[255] The CRT arm suggested optional chemotherapy after TME, but only 47% of these received six cycles of chemotherapy. On initial report, the short-course TNT arm had improved pCR rates (28% vs 14%), no difference in locoregional recurrence, and fewer disease-related treatment failures at 3 years (23.7% vs 30.4%, respectively), likely relating to better chemotherapy compliance in the TNT arm, with fewer chemoradiation-arm patients receiving systemic-dose chemotherapy.[256] The follow- up report indicated persistent disease-related treatment failure and DM benefit to the TNT arm, potentially related to the additional chemotherapy received by the TNT group.[257] Though overall the LRR was favorable for such a high-risk patient group, longer term follow-up revealed a significant LRR recurrence difference, with the TNT arm demonstrating more frequent LRR (10.2% in TNT arm vs 6.1% in CRT arm, $P = .027$), including more frequent LRR after R0 resection. The reason for the LRR decrement is unclear; pathologic features were similar between the two populations, R0 rates were not different, and the TNT arm had an improved pCR rate. The authors make note of a more frequent rate of mesorectal breach in the TNT arm that could have contributed to additional risk of LRR. The TNT arm more frequently received 3D CRT, which in theory should not differ in target coverage from IMRT/volumetric modulated arc therapy (VMAT), especially considering the sites of failure that were largely central in the treatment volume (anastomotic and presacral). Though this study did not compare TNT with short course versus TNT with long course, it is reasonable to extrapolate that tumors with high risk of local recurrence may benefit from the long-course TNT option (eg, ultralow tumors, threatened CRM with other concurrent risk factors, T4b). Considering the overall low rate of LRR in this study for even high-risk tumors, other lower risk tumors (eg, mid- or high rectal tumors without additional risk factors) may be suitable for a short course–based TNT regimen, albeit without this having been explicitly studied in a randomized

fashion. Ongoing studies like the ACO/ARO/AIO-18.1 trial will evaluate the efficacy of short-course TNT versus long-course TNT regimens.

Sequencing of Total Neoadjuvant Therapy

Initially, the optimal sequencing for TNT was unclear. Some rationalized that providing chemotherapy first, followed by (C)RT would provide early systemic control and would permit earlier (and thus potentially easier) operation after the RT component. Others reasoned that extension of the interval between RT and surgery may only help tumor response and pCR rates, and many patients with near-obstructive or highly symptomatic tumors may benefit from up-front RT. Several trials systematically compared these different sequencing approaches in the context of long-course CRT TNT regimens.

The CAO/ARO/AIO-12 randomized phase II study[258] from Germany allocated 300 patients to two different TNT regimens: chemo-first TNT (FOLFOX × three cycles, then CRT with the German infusional 5-FU/oxaliplatin regimen[240]) versus CRT-first TNT. Powered for a pCR comparison to historical controls, the CRT-first arm demonstrated improved pCR (25% vs 17% in the chemo-first), as well as improved overall complete response (pCR + clinical complete response [cCR] in patients who declined surgery; 21% and 28% for chemo-first vs CRT-first, respectively). Both treatments were overall well tolerated though with the CRT-first arm demonstrating lower CRT and post-op toxicities, margin-negative surgical results were not different. Importantly longer-term results documented no difference in DMs, with similar DFS, arguing that the theoretical benefits of treating micrometastatic disease with a chemo-first regimen may not drive outcomes.[259]

The Organ Preservation in Patients with Rectal Adenocarcinoma (OPRA) trial (discussed in more detail in section "Nonoperative Management" under "Attempts to De-Escalate Multimodal Therapy for Rectal Cancer") incorporated a randomization between two different TNT sequences—CRT-first versus chemo-first. Chemotherapy was FOLFOX or CAPOX for 16 to 18 weeks, and CRT included 50 to 56 Gy of standard fractionated radiation with either CI 5-FU or capecitabine.[250] Either TME radical resection or an option for NOM (for near-complete and complete clinical responders) was

employed after TNT. The study was powered to detect a difference in DFS between each arm and historical controls. The study was expanded due to favorable pCR in both arms, and ultimately accrued 324 patients. The primary outcome of DFS difference from historical controls was not significant, and DFS and OS were similar between the two arms. More importantly, the sequencing of TNT appeared to have a substantial impact on organ sparing, with a substantial difference in TME-free survival seen between the arms (at 5 years, 39% in chemo-first arm vs 54% in the CRT-first arm).[78]

In sum, these studies overall support sequencing TNT regimens with the radiation-containing component first, followed by chemotherapy. Though sequencing has not been directly compared in short course–containing regimens, it seems reasonable to cautiously extrapolate these findings to adopt an RT-first approach for those regimens when they are selected (similar to what was used in the RAPIDO trial), albeit with the caveats mentioned in the section "Total Neoadjuvant Therapy With Short-Course Chemoradiation."

Attempts to De-Escalate Multimodal Therapy for Rectal Cancer

Nonoperative Management

Despite the oncologic benefits of TME in patients with rectal cancer, there are potentially serious complications associated with this procedure including vascular injury, infection, wound complications, ureteral injury, and sexual dysfunction.[216-221] Long-term complications include chronic bowel dysfunction, urinary incontinence, and small bowel obstruction.[4,5] Despite these risks, most patients with rectal cancer undergo surgery. However, there has been increasing interest in NOM, especially in patients with distal rectal cancers requiring APR, in older patients, or those with significant medical comorbidities. Additionally, many patients experience significant impact on their QOL following either LAR or APR procedures. Another potential rationale for NOM management comes from the rate of pCR observed in patients undergoing neoadjuvant therapy, particularly those who undergo long-course CRT.

Investigators from the University of São Paulo School of Medicine evaluated NOM for patients with potentially resectable rectal cancer. The

study included patients with T2-T4 and N0-N1 disease who received neoadjuvant CRT to 50.4 Gy with concurrent 5-FU. Patients were reevaluated 8 weeks post-CRT. Response was assessed radiographically and pathologically via endoscopic biopsies. Patients with an incomplete response were sent immediately for resection. Those with cCR were followed closely with monthly physical exams, frequent proctoscopy with biopsies of any suspicious areas, serial CEA monitoring, and abdominopelvic CT scans every 6 months for the first year. Patients without evidence of disease for 1 year were considered to have a cCR.[253] Updated results have also been published with a larger cohort of patients.[260] This indicates that 31% of patients with an initial cCR went on to develop a local recurrence, the majority of which occurred in the first 12 months. Only 7% of these patients were not amenable to salvage surgery. Five-year cause-specific OS and DFS were 91% and 68%, respectively, with 14% of patients failing distantly.[261]

Maas and colleagues attempted to build upon the results of the São Paulo group by employing modern MRI staging techniques. In this study, there was a noticeably lower rate of cCR, likely the result of the strict imaging criteria that was used.[262] Memorial Sloan Kettering investigators compared the outcomes of 32 patients who had a cCR with NOM to a comparable group who had achieved a pCR with surgical resection.[263] The local recurrence rate for patients undergoing NOM was 21% versus 0% in the pCR group after 28 months; however, all patients that failed locally were successfully salvaged with surgery. The clinical outcomes were otherwise similar between the groups. This series has since been updated, with OS and DFS remaining similar between the NOM and pCR groups.

Taking a different approach, a prospective trial from Denmark evaluated patients with resectable T2-T3 primaries and N0-N1 disease who were treated with high-dose radiation to 60 Gy in 30 fractions with a 5-Gy endorectal brachytherapy boost and oral tegafur-uracil.[264] Response was assessed via endoscopy and MRI/CT. If patients achieved a cCR, they were followed closely with exams, endoscopy, and PET scans. Only 26% of patients had local recurrence failure by 2 years and all patients were surgically salvaged.[229] A subsequent randomized controlled trial allocated 148 patients with small (<5 cm) T2-T3b, N0 or N1 (<8 mm), low/mid-rectal adenocarcinoma to neoadjuvant CRT (45 Gy in 25 fractions with concurrent

capecitabine) followed by either an external beam boost of 9 Gy in five fractions or a contact x-ray brachytherapy boost (90 Gy in three fractions over 4 weeks). In the initial report, the 3-year organ preservation rate (primary outcome) was 59% in the external beam boost group versus 81% in the contact brachytherapy group (P = .0026).[265] These results are promising, and the acute and late toxicities were limited. However, the limited availability of contact x-ray endocavity brachytherapy equipment and experience, particularly for rectal treatment, may limit applicability of this approach.

As discussed earlier, the OPRA trial implemented a watch-and-wait nonoperative option into the randomized study allocating 306 patients with stage II/III distal rectal cancer to two different TNT sequencing options (chemo-first or CRT-first).[250] Though the primary outcome was DFS of each arm relative to historical controls (no difference seen), the major impact for this study has been documenting the efficacy of total "neoadjuvant" therapy in facilitating NOM. Roughly three-fourths of the enrolled patients were offered NOM after demonstrating either a near-complete or complete response (71% in the chemo-first group, and 76% in the CRT-first group). Of these, 36% developed a regrowth that prompted TME, and the vast majority of regrowths on NOM occurred within 2 years (94%). In the CRT-first arm, a 53% TME-free survival was documented at 3 years (41% in the chemo-first arm), substantiating NOM as an option for a large number of patients with locally advanced rectal cancer. Importantly, the 5-year DFS for patients receiving TME up-front and those "salvaged" after regrowth on NOM surveillance did not differ (61% vs 62%, respectively; P = .86).[78] It is worth emphasizing that the NOM surveillance on this protocol mandated very close follow-up to detect and intervene on persistent or recurrent disease early. Flexible sigmoidoscopy, and DRE and CEA measurements were taken every 4 months for 2 years, then every 6 months for 3 years; rectal MRI was performed every 6 months for 2 years, then every year for 3 years; CT chest/abdomen/pelvis performed yearly for 5 years; and colonoscopy 1 year after diagnosis and per guidelines thereafter.

The OPRA study, while not randomizing between NOM and surgical intervention, documents the feasibility, efficacy, and safety of a NOM approach with aggressive surveillance. In combination with the historical data and a systematic review[266] supporting the safety and efficacy of this

approach, these data support the judicious implementation of NOM approaches in various guidelines and widespread practice patterns.[184]

Neoadjuvant Chemotherapy with Surgery (No Radiation)

The FORWARC trial out of China investigated numerous neoadjuvant regimens, randomizing relatively advanced rectal adenocarcinomas to neoadjuvant treatment with (a) CRT with 5-FU/LV and standardly fractionated RT to 45 to 50.4 Gy, (b) CRT with mFOLFOX6 × five cycles and the same RT regimen, and (c) mFOLFOX6 × four to six cycles without CRT.[267] All groups received TME and additional matched chemotherapy after TME. TME was reported as "good" in 80%, "moderate" in 10%, and "poor" in 5%. In the initial reports and the updated data recently presented, there were no significant differences in clinical outcomes like DFS (primary outcome; 10-year DFS 55.5% in 5-FU/LV CRT arm, 63% in FOLFOX CRT arm, and 62.8% in FOLFOX-only arm) or OS.[268] Though the final treatment groups' pathologic characteristics appeared somewhat unbalanced (eg, chemo-only arm with 69.7% T2/T3 tumors vs 65.4% in the 5-FU/LV CRT and 58.3% in the FOLFOX CRT arm), and the aforementioned variable TME quality, this study suggested a potential for omitting RT for a subset of patients.

The PROSPECT trial evaluated the efficacy of neoadjuvant chemotherapy (without RT), utilizing contemporary chemotherapy regimens in hopes of permitting more selective use of RT.[269] Patients with overall lower-risk disease, with cT2N1, T3N0, or T3N1 disease located in the upper or middle thirds of the rectum, who are without evidence of mesorectal fascial involvement, were eligible. A total of 1,194 patients were enrolled. In the experimental arm, patients received six cycles of FOLFOX with subsequent assessment of treatment response. If the tumor has decreased in size by at least 20%, patients proceeded directly to TME followed by six cycles of adjuvant FOLFOX. If the tumor did not decrease by at least 20%, patients received neoadjuvant long-course CRT (with 5-FU or capecitabine), TME, and then two cycles of adjuvant FOLFOX. In the control arm, standard long-course CRT (with 5-FU or capecitabine) was followed by TME and eight cycles of adjuvant FOLFOX. Primary endpoint was changed from DFS and local recurrence to DFS alone due to overall

low rate of recurrence. The FOLFOX-alone arm was noninferior for DFS (P = .005), with a 5-year DFS of 80.8% in the chemotherapy-alone group versus 78.6% in the CRT group. There was no difference in OS or local recurrence. The local recurrence was exceedingly low in both groups for this trial of well-selected, relatively low-risk patients (1.8% in FOLFOX alone vs 1.6% in CRT group). Patient-reported outcomes (PROs) indicated more acute side effects in the FOLFOX-alone arm during neoadjuvant treatment, with 16 worse in FOLFOX-alone (anxiety, appetite loss, constipation, depression, dysphagia, dyspnea, edema, fatigue, mucositis, nausea, neuropathy, and vomiting) and one worse in CRT arm (diarrhea).[270] Late PROs indicated higher fatigue and neuropathy in the CRT arm, possibly related to closer proximity to adjuvant chemotherapy at time of survey. Sexual side effects were worse up to 24 months posttreatment, but overall health-related quality-of-life (QOL) was not significantly different.

Ultimately, the improvements in chemotherapy regimens and surgical technique have permitted consideration of omission of RT in a subset of well-selected patients, as substantiated by the PROSPECT trial. For now, omission of RT requires selection of relatively low-risk tumors for this treatment until findings are extended to more advanced disease. Moreover, a systematic method to assess neoadjuvant treatment response must be developed within institutions to permit rigorous assessment of whether or not 20% treatment response is achieved. Finally, patient guidance in decision-making is critical, as there were an assortment of toxicities that varied by treatment. Engaging in a paradigm that omits RT may eliminate options for NOM, so patient priorities should be considered in deciding upon which regimen (if either) is warranted.

Local Excision Paired With Neoadjuvant or Adjuvant Chemoradiotherapy

As mentioned previously, local excision provides a sphincter-sparing alternative to radical surgery for distal cT1 tumors. However, if pathologic findings after excision indicate T2 disease or high-risk T1 lesions, standard treatment includes radical oncologic resection, which may involve temporary or permanent colostomy depending on the tumor location. Moreover, for T2 lesions the standard treatment is radical surgery. Many

patients refuse such intervention, or may not be surgical candidates, prompting interest in administration of adjuvant or neoadjuvant treatments like radiation paired with local excision.

The RTOG 89-02 examined the efficacy of CRT after local excision in a study of 65 patients with T1-T3 distal rectal cancers not amenable to sphincter-sparing radical surgery that were node-negative by CT, with favorable pathologic features (well or moderately differentiated, negative margins, no LVI).[271] There were 13 patients with T1 tumors, 25 patients with T2 tumors, and 13 patients with T3 tumors who received postoperative CRT of 50 to 65 Gy with 5-FU (1,000 mg/m^2 on days 1-3 and 29-31); 14 patients with T1 tumors were observed without CRT. Local recurrence rates were 0% for CRT-treated T1 (vs 7% for untreated), 20% for CRT-treated T2, and 23% for CRT-treated T3 tumors. These local recurrence rates for T2 and T3 tumors exceed those seen even for more advanced tumors treated with radical surgery alone or multimodal therapy (in the case of T3), suggesting that local excision plus CRT is a potentially inferior approach for patients with T2 or more advanced tumors.

Similarly, in the CALGB 8984 study, 59 patients with T1 disease were treated with local excision alone, and 51 patients with T2 disease received adjuvant therapy with 54 Gy and 5-FU (500 mg/m^2 on days 1-3 and 29-31).[272] Outcomes were acceptable for the T1 patients (who did not receive CRT), with 10-year local recurrence, DFS, and OS rates of 8%, 75%, and 84%, respectively. However, for T2 patients (who did receive CRT), 10-year local recurrence, DFS, and OS were 18%, 64%, and 66%, respectively. Though detailed information about salvage techniques was not published in the final report, an 18% LF rate and 64% DFS for T2 cancers are both considerably inferior to the results of radical surgery with TME alone or neoadjuvant therapy followed by surgery. Like the RTOG8902 study, the CALGB8984 study supports the possibility of conservative local excision surgery for well-selected T1 lesions, but for T2 tumors, the high rate of local recurrence despite CRT warrants caution.

Interest shifted to assess whether neoadjuvant CRT combined with local excision might provide acceptable oncologic outcomes for high-risk T1 or T2 tumors. The American College of Surgeons Oncology Group (ACOSOG) conducted a multi- institutional, single-arm, open-label, nonrandomized, phase II trial of 79 patients with T2N0 distal rectal cancer

staged with EUS or MRI, treated with neoadjuvant CRT.[273] Tumors were less than 4 cm in greatest diameter, involving less than 40% of the circumference of the rectum, located within 8 cm of the anal verge, were treated with neoadjuvant CRT consisting of capecitabine, oxaliplatin, and 54 Gy radiation (primary course to 45 Gy, followed by a boost of 9 Gy) followed by local excision. AEs during CRT prompted dose reduction of capecitabine (from 825 mg/m^2 twice daily to 725 mg/m^2 twice daily) and RT (boost reduced to 5.4 Gy for a total dose of 50.4 Gy). After a median follow-up of 56 months, the estimated 3-year DFS for the intention- to-treat group was 88.2% and for the per-protocol group (n = 72 patients) was 86.9%, which was lower than anticipated for similarly staged patients treated with radical surgery. Additionally, the regimen was not without toxicity—29% had grade 3 gastrointestinal AEs, 15% grade 3 to 4 pain, and 15% grade 3 to 4 hematologic AEs during chemoradiation.

The GRECCAR2 multicenter randomized trial assessed local excision or TME for CRT-treated early-stage T2 to T3 low rectal cancers.[274,275] Eligible patients were those who responded well to CRT (50 Gy in 2 Gy fractions with concurrent 5-FU chemotherapy), as measured by a tumor size of 2 cm or less and no evidence of deep infiltration on post-CRT MRI at 6 to 8 weeks. This study did not quantify how many patients were “good responders” since that was a criterion for enrollment, and notably nodal status was not used to define eligibility. Patients were randomized to local excision or TME. In the local excision group 27/74 patients underwent TME (1 up-front, 26 as completion TME due to pathologic features), while 8 additional patients declined TME despite it being recommended per protocol. In the TME group, the majority received TME as planned (60/74; 3 excluded for various reasons, 8 underwent local excision instead as protocol deviations, and 3 elected for watch-and-wait as a protocol deviation). Five-year local recurrence, metastatic disease, OS, and DFS metrics were not statistically different between the groups, though the study was underpowered to assess for these outcomes individually (study power was calculated for a composite outcome endpoint). The earlier report identified no significant differences in acute side effects between the groups, largely due to the relatively high rate of completion TMEs required; those patients who only required local excision had less acute toxicity than the TME group, but those patients who required local excision then

completion TME appeared to have more toxicity at 2 years in many categories than the up-front TME group. In looking at the cT2 patients in particular (who are typically managed by TME without CRT, using typical management paradigms), 31% of patients in the local excision group required completion TME, suggesting that almost a third of these already-selected cT2 patients with "good" response to CRT ultimately received this additional CRT therapy without any clinical benefit and with additional toxicity beyond what would be expected with TME alone. However, this trial also demonstrated that 51% of locally excised T3 tumors were ypT0-1 after neoadjuvant CRT and did not require TME. Although they did not specifically quantify the outcomes for this T3 population, it suggests a subset of T3 patients might tolerate surgical de-escalation after neoadjuvant CRT, which many of them would receive as a typical component of management even if proceeding to TME.

The phase II CARTS study[276] out of the Netherlands assessed the feasibility of utilizing local excision by transanal endoscopic microsurgery for good responders to neoadjuvant CRT with cT1-3N0 tumors. This study documented 63.6% of patients were treated with CRT followed by local excision alone, while TME was performed in 29% of patients (half with completion after TEM, a quarter with inadequate responses necessitating TME up-front, and a quarter with salvage TME for recurrence); these numbers were consistent with the GRECCAR2 study, as were the clinical outcomes (5-year local recurrence of only 7.7% with DFS of 81.6% and OS of 82.8%). Importantly, this study quantified health care–related QOL metrics, which indicated improved emotional functioning in the local excision group. Although these metrics were quantified in the group of patients requiring TME after local excision, they were not compared to local excision-alone or TME-alone patients, which would be expected to have higher toxicity.

Short-course RT (5 Gy per fraction for five daily fractions) represents an additional potential neoadjuvant approach for downstaging tumors to permit local excision, as preliminarily examined in the TREC feasibility study for cT1-T2 tumors out of the United Kingdom.[185] Though this study had relatively few patients treated with short-course RT followed by local excision (n = 27), and the study had a fair bit of crossing over between arms, ultimately 70% of patients randomized to the local excision arm

achieved organ preservation. Patients in the organ preservation arm reported improved patient-reported bowel toxicities and QOL scores relative to the radical surgery arm. Further evaluation of this approach alongside neoadjuvant CRT as per the CARTS study in organ-sparing local excision paradigms is underway in the STAR-TREC study.[277]

In summary, local excision is a potential option for surgical de-escalation and sphincter preservation for T1 tumors. This approach can also be considered after CRT downstaging of cT1-T3N0 tumors, avoiding TME if pathologic analysis confirms sufficient treatment response (ie, ypT0-T1). However, a substantial percentage of cT2 tumors may not sufficiently respond to CRT and may require TME regardless, so this approach will likely lead to overtreatment of a proportion of patients. Moreover, toxicities in patients with local excision and then TME may be higher than with up-front TME alone, though in general the QOL assessments showed benefits for the patients who were treated with local excision alone. Many of the above trials did not implement routine posttreatment endoscopy/proctoscopy in assessing response prior to excision, and MRI can be difficult to interpret in the posttreatment setting. Real-world implementation of comprehensive response assessment including direct visualization might further refine how to identify patients appropriate for local excision after treatment. Moreover, an intensified follow-up regimen may permit some of these patients to be followed with watch-and-wait protocols similar to the locally advanced setting, although data for this in the cT1-T2 setting are limited.

Unresectable, Locally Advanced Rectal Cancer

Tumors that are fixed or adhere to adjacent structures often have a particularly high likelihood of residual gross or microscopic disease that may be unresectable. A preoperative therapy approach is recommended to potentially facilitate curative resections.

Similar to the superiority of CRT versus fractionated RT alone for locally advanced resectable rectal cancers, the superiority of preoperative CRT over RT alone was shown in a phase III, randomized controlled trial of 207 patients with unresectable T4 or locally recurrent rectal cancer. Margin-negative resections, LC, and cancer-specific survival all favored the CRT

arm, with a nonsignificant trend to improved OS with CRT. Patients receiving concurrent chemotherapy experienced higher grade 3/4 acute toxicity with no difference in late toxicity.

Despite preoperative CRT and complete surgical resection, local recurrence rates in this subgroup remain high; the LC in the randomized study mentioned earlier was only 82% even with CRT. In situations in which the margin of resection is compromised, IORT offers the possibility of improved LC. The IORT experience at MGH was reviewed by Nakfoor et al.[278] Preoperative CI 5-FU plus 50.4 to 54 Gy of radiation was given, followed by a 4- to 6-week break and surgery. No IORT was given if metastases were present at surgical exploration, if there were adequate margins more than 1 cm, or if there was less than T4 disease. Dose of IORT varied by pathologic characteristics (10-12.5 Gy for complete resection, 12.5-15 Gy for microscopic residual disease, and 17.5-20 Gy for gross residual disease). The 5-year LC was 90%, 65%, and 55%, and the disease-specific survival at 5 years was 65%, 45%, and 15%, for these three dose levels, respectively. However, the 5-year actuarial risk of complications was 15%. The risk of peripheral neuropathy was 20% for doses more than 15 Gy. IORT appeared to improve LC, especially with a gross total resection, but not OS for locally advanced rectal cancers.

A series from the Mayo Clinic evaluated outcomes in 146 patients with primary locally advanced CRC.[126] Patients received conventionally fractionated EBRT (45-50 Gy) with chemotherapy, surgery, and IORT (10-20 Gy). The rates of 5-year freedom from local recurrence and DFS were 86% and 43%, respectively. Late complications occurred in 77 patients (53%) and included peripheral neuropathy (19%), bowel obstruction (14%), and ureteral obstruction (12%). In summary, IORT is a valuable tool in an effort to improve LC in situations in which the risk of microscopic residual disease following resection remains high, albeit with potential risks for late toxicity.

Recurrent Rectal Cancer

Recurrent rectal cancer is often approached in the same way as T4 disease, often with an aggressive treatment plan of CRT, surgery (with or without IORT), and adjuvant chemotherapy. Recurrences may occur along the

pelvic sidewall or in nonpelvic sidewall areas such as the uterus, prostate, or vagina. Given the difficulty of surgical resection of pelvic sidewall recurrences, these tend to fare worse. Surgical removal often requires exenterative surgeries.

Patients with recurrent rectal cancer and no prior history of EBRT are generally treated with a course of concurrent, preoperative CRT (50-54 Gy with 5-FU-based chemotherapy) followed by surgical resection (and consideration of IORT). Patients with prior history of RT may receive reirradiation to doses of 30 to 39 Gy with or without IORT, but have the potential to experience significant late toxicity; therefore, efforts should be made to avoid small bowel within treatment fields. Hyperfractionated approaches help limit normal tissue toxicity while maintaining antitumor effect. Ultimately, the goal is to maximize the likelihood of complete surgical excision, which is a primary determinant of outcomes after treatment for locally recurrent rectal cancer.

In patients with no prior history of radiation, neoadjuvant CRT (45-60 Gy) followed by surgical resection is a reasonable treatment approach. In several series reporting outcomes for locally recurrent rectal cancer, combinations of aggressive neoadjuvant CRT, resection, IORT, and additional chemotherapy achieve 5-year LC ranging from 24% to 54%, with OS ranging from 18% to 42%.[279-281] Patients able to undergo complete resection with negative surgical margins fare better.[282] One randomized controlled trial compared outcomes of preoperative CRT or RT alone prior to surgical resection in patients with unresectable or recurrent rectal cancer without prior RT treatment; 25 of the patients included had recurrent disease.[209] Higher rates of R0 resection, LC, time to treatment failure, and cancer-specific survival were seen in the chemoradiation arm (see section “Locally Advanced Rectal Cancer”). Five-year OS rate in patients with recurrent rectal cancer was still poor, at 37%.[283]

Reirradiation for patients previously treated with radiation to the pelvis may be considered in selected situations where additional therapy might help facilitate a margin-negative operation. Modern conformal and IMRT treatment techniques provide more opportunities for these treatments, but reirradiation likely still carries additional toxicity risks. Retrospective studies examining reirradiation with 23.4 to 30.6 Gy of EBRT suggest higher disease control for patients receiving additional CRT and radical

resection, particularly R0 resected tumors; many of these patients received some combination of neoadjuvant CRT, IORT at the time of surgery, and additional adjuvant chemotherapy. Toxicities were not reported in all experiences, but one long-term study of 103 patients reported relatively tolerable acute and late toxicity though numerous patients were noted to experience severe, persistent diarrhea (18 patients), small bowel obstruction (15 patients), fistula formation (4 patients), and stricture (2 patients).[284]

Hyperfractionated RT may reduce late toxicity in reirradiated patients. A multicentric Italian phase II study of 59 patients implemented a hyperfractionated CRT regimen of CI 5-FU paired with 30 Gy given in 1.2 Gy fractions twice daily, with a reduced-field boost of 10.8 Gy (also in hyperfractionated fashion). Tumor resection was achieved in 50.8% of patients, with a total of 35% of patients having R0 resections. Five-year OS was higher in R0 resected patients (66.8%) than in patients not undergoing surgery or with subtotal tumor removal (22.3%). Toxicity during treatment was low, with 5.1% grade 3 GI toxicity and no grade 4 toxicity. Late toxicities occurred in seven patients (fibrosis, impotence, urinary complications requiring diversion, and small bowel fistula requiring diversion). A retrospective series from the MD Anderson Cancer Center evaluated reirradiation outcomes in 102 patients with prior history of pelvic RT.[285] Patients were treated in 1.5 Gy fractions twice daily to a total dose of 30 to 45 Gy (depending on the time interval between RT treatment courses). Concurrent chemotherapy was administered to the majority of patients. The 3-year freedom rate from local progression and OS rate in the entire cohort were 40% and 39%, respectively. Three-year OS rate was 62% in patients undergoing surgery (vs 20% in those without surgery), and the 3-year rate of grade 3/4 late toxicity was 34%, which was higher (54%) in those who did undergo surgery.

Radiotherapy Technique

External beam treatment fields for rectal carcinoma should encompass potential sites at greatest risk for harboring disease, including the presacral space, primary tumor site, and (for post-APR cases) the perineum. Other areas at risk include the internal iliac and distal common iliac nodes. Generally, the risk of disease involvement of the para-aortic region is

sufficiently low, and the morbidity from treatment is sufficiently high, to exclude this region from radiation fields. The external iliac nodes may be covered for lesions involving the anterior structures, including the bladder, prostate, and vagina. Notably, T4a lesions involving anterior peritoneum only do not require coverage of external iliac nodes. Inguinal node coverage may be considered for tumors invading the anal canal distal to the dentate line.

Prone positioning may help reduce the volume of small bowel within the pelvis. Maneuvers to reduce the volume of small bowel include treatment with a full bladder and the use of bowel displacement techniques such as a bellyboard (a device with a false tabletop to allow the upper abdominal contents to fall anteriorly).[286] In 3D conformal plans, the use of shaped lateral fields reduces the dose to small bowel located in the anterior and superior aspects of the pelvis. For IMRT and VMAT planning, the small bowel should be included as an avoidance structure, though it is worth mentioning that even for these plans, simulation maneuvers can greatly assist with minimizing small bowel exposure. A marker is generally placed at the anal verge. Intravenous, rectal, and small bowel contrast can be administered at the time of simulation for accurate target and normal tissue delineation if MRI fusions or other mechanisms for tumor delineation are anticipated to be difficult.

Traditional four- or three-field techniques can be used to treat rectal cancer in many cases, though depending on the patient's anatomy it may be difficult to achieve optimal OAR doses. For 3D conformal anteroposterior and posteroanterior fields, traditional borders are as follows: the superior field edge is placed at the L5/S1 interspace, the inferior field edge should be at least 4 to 5 cm below gross disease while covering the entire mesorectum, and lateral border should be shaped with multileaf collimators to cover a 1.5 cm margin around the pelvic brim. For postoperative cases, the distal field edge is about 5 cm below the best estimate of the preoperative tumor bed and (if an APR has been performed) below the perineum. Lateral fields have the same superior and inferior borders. The posterior border should encompass the entire sacrum with a 1-cm margin to ensure presacral cover, and the anterior border should extend approximately 4 cm anterior to the rectum (ensuring adequate coverage of the mesorectum) while blocking as much of the anterior abdominal contents

and bladder as possible without compromising nodal coverage. If the tumor has considerable extrarectal extension, these guidelines should be modified to make certain that all disease is encompassed with appropriate margin.

Since CT-based planning dominates modern treatment, contour delineation of elective and high-risk clinical target volumes (CTVs) helps ensure that the above blocks cover the entire treatment volume for a given patient. The elective CTV includes the entire mesorectum, and perirectal/presacral/internal iliac LN with a superior border at the bifurcation of the common iliacs and an inferior border at the pelvic floor or 2 cm beyond gross disease.[287] External iliac lymph nodal regions should be included if there is anterior pelvic organ involvement. The high-risk CTV extends for 1.5 to 2.5 cm superior/inferior beyond the primary GTV and/or 1 cm beyond involved lymph nodes and should include the elective CTV volume (including mesorectum and nodal regions) within that extent.

Modern IMRT or VMAT planning may assist in facilitating target coverage while minimizing OAR exposure, particularly for difficult patient anatomy or patients with large amount of small bowel falling into the pelvis.

The usual dose given to initial pelvic fields is 45 Gy in 25 fractions of 1.8 Gy each. An additional tumor boost may be administered, usually through opposed lateral fields, to an additional 5.4 to 9 Gy. Historically, small bowel was excluded from the boost volume after about 50 Gy in an effort to minimize acute and late toxicity, but this can largely be achieved with IMRT or subfielding of the 3D conformal plan (Figures 67.7 and 67.8).

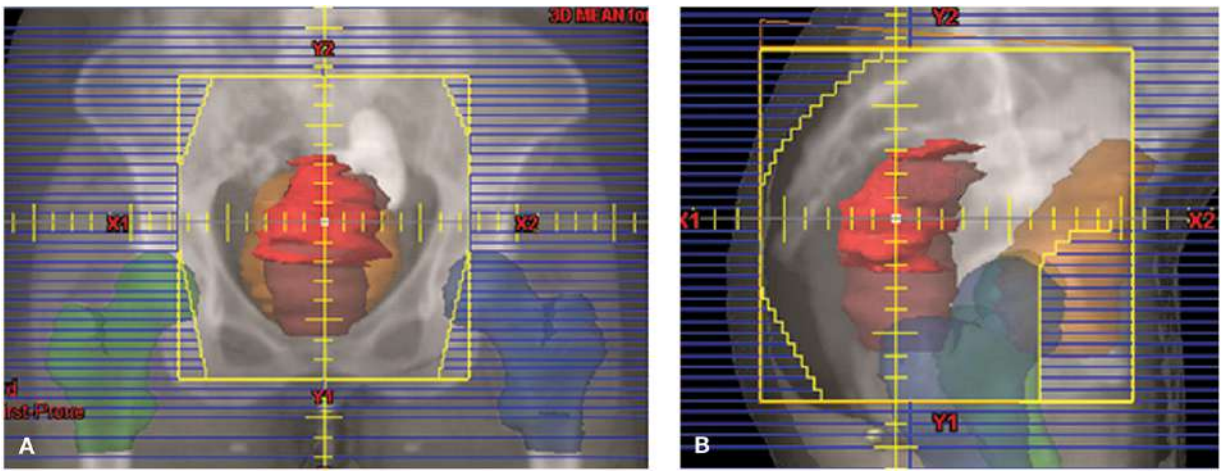

FIGURE 67.7 A. Posteroanterior treatment field of patient with T3 N1 rectal cancer. B. Lateral treatment field of a patient with T3 N1 rectal cancer. Red, gross tumor volume; brown, rectum; orange, bladder; green/blue, femoral heads.

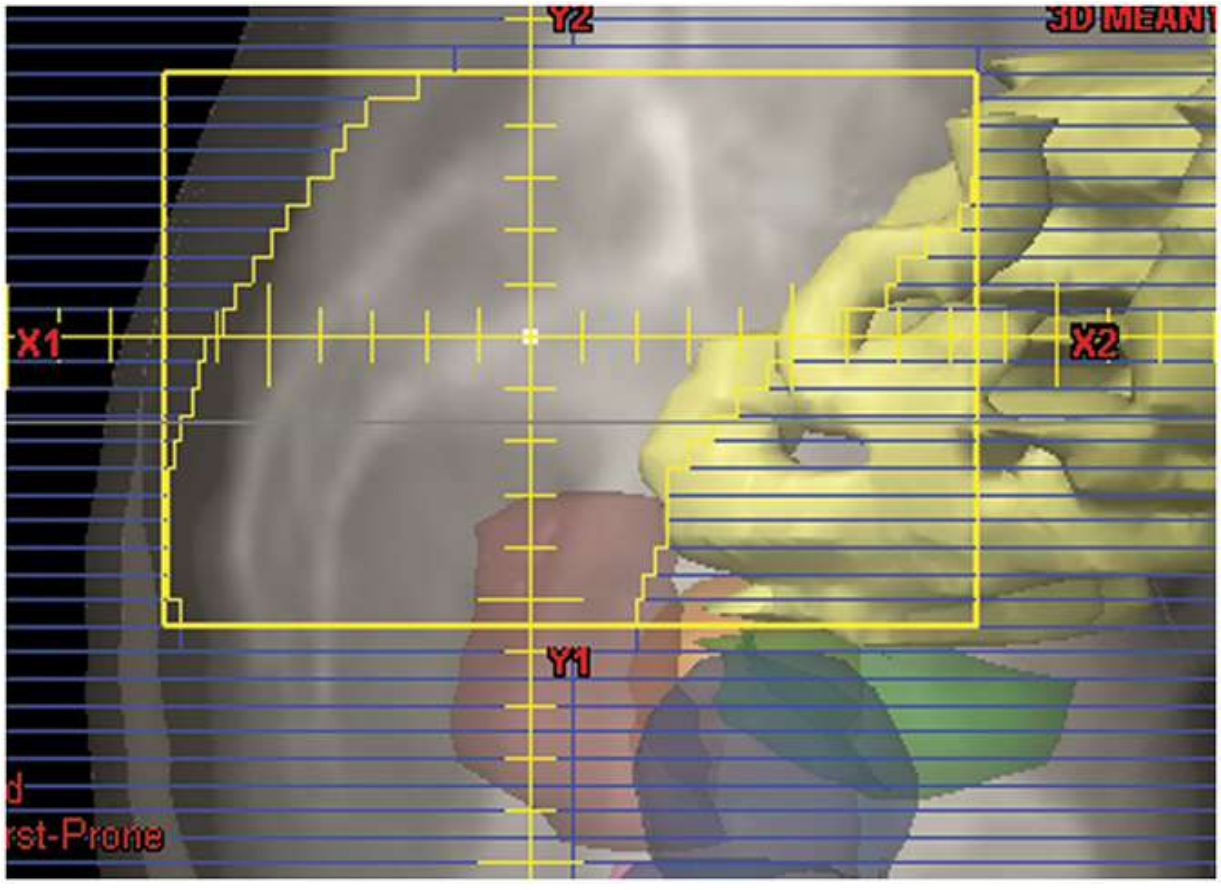

FIGURE 67.8 Lateral treatment field of patient with recurrent rectal cancer (with prior history of radiation) along presacral space. Brown, rectum; yellow, small bowel; green, bladder; orange/blue, femoral heads.

CHAPTER 68

Anal Cancer

Paul Riviere and James D. Murphy

The standard treatment for primary squamous cell cancers of the anal canal is chemoradiation, using concurrent radiation therapy (RT), 5-fluorouracil (5-FU), and mitomycin C (MMC), with surgery typically reserved for the salvage setting. This chemoradiotherapy (CRT) approach was originally developed empirically as preoperative neoadjuvant therapy in the 1970s[1] and has evolved to become on its own the standard of care without preplanned surgical resection. Trials of other chemotherapy or systemic agents in combination with radiation have thus far not improved results. About 65% of those with cancer confined to the pelvis will survive 5 years or more, and about 75% will retain anorectal function.[2]

In this chapter, the emphasis is on the management of squamous cell cancer of the anal canal. Note is also made of the role of RT in the treatment of squamous cell cancers of the perianal skin and of adenocarcinomas of the anal region.

ANATOMY

The anal canal is 3 to 4 cm in length, with the posterior wall being longer than the anterior. The canal ends superiorly at the palpable upper border of the anal sphincter and puborectalis muscle of the anorectal ring. The distal end at the anal verge is the level at which the walls of the anal canal come in contact in their normal resting state; it approximates the palpable groove between the lower edge of the internal sphincter and the subcutaneous part of the external sphincter and the junction with true skin. The American Joint Committee on Cancer (AJCC) clinical staging[2] and the International Union Against Cancer (UICC)[3] recommend this definition rather than a convention used by some centers under which carcinomas that are above or exactly astride the dentate line are classified as anal canal tumors and those lying

mainly or entirely below that line are called anal margin tumors (Figure 68.1). The terms *anal margin* and *perianal skin* are now generally used interchangeably. Perianal carcinomas are arbitrarily considered to be cancers arising from the skin within a 5-cm radius of the anal verge. Tumors arising from the anus into the perineum are treated as anal canal tumors, whereas tumors arising from the vulva into the perineal body are treated as primary vulvar cancer. For tumors of the perineum in female patients, clinical judgment may be needed to determine where the tumor likely arose from and which treatment paradigm is to be applied.[2]

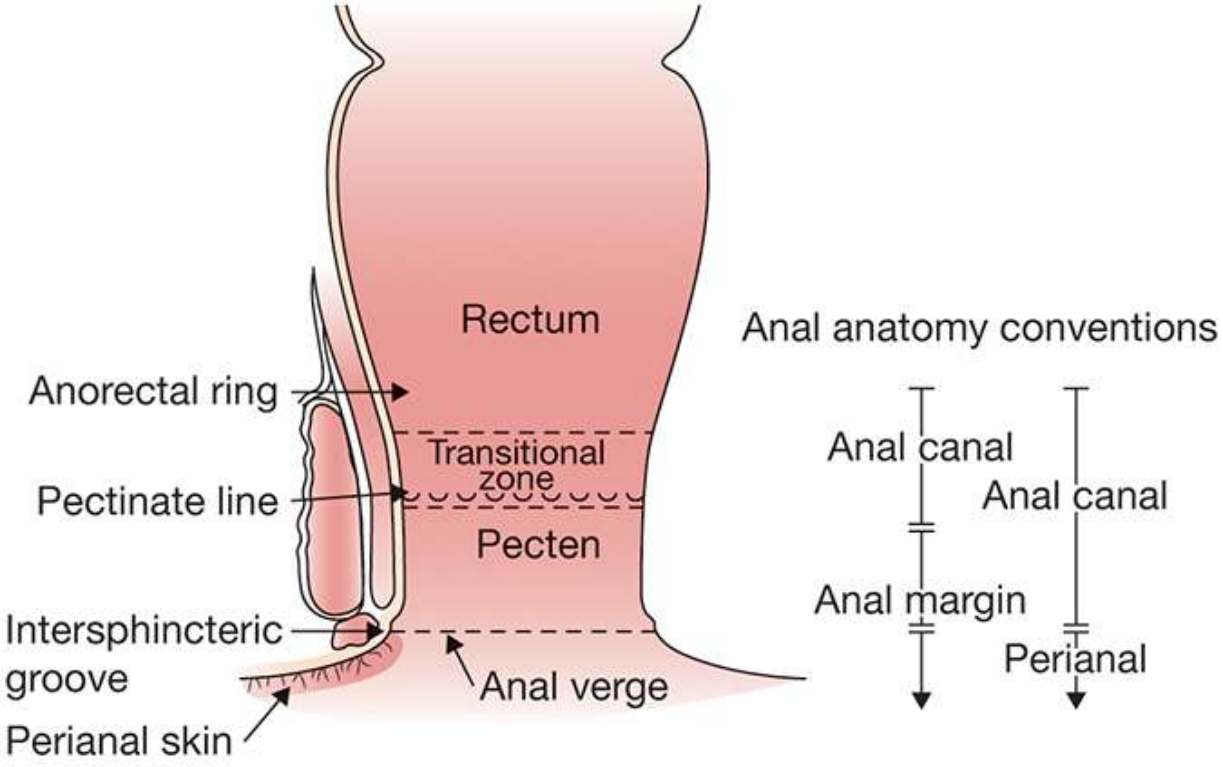

FIGURE 68.1 Anatomy of the anal region.

The anal region is composed of four different types of epithelium corresponding to its anatomic subdivisions.[4] From distal (caudal) to proximal (cranial), first, the perianal skin is similar to hair-bearing skin elsewhere. At the anal verge, the skin blends with a pale-colored zone, sometimes called the pecten, lined by modified squamous epithelium that lacks hair or glandular structures. At the level of the dentate or pectinate line (marked by the mucosal folds of the anal valves), this modified squamous

zone merges with a transitional epithelium that incorporates features of rectal, urothelial, and squamous epithelium. Most proximally, the purplish red–colored transitional zone extends proximally for about 2 cm until the pinker glandular mucosa of the rectum becomes dominant.

The major lymphatic pathways flow to three lymph node systems. The perianal skin, the anal verge, and the canal distal to the dentate line drain predominantly to the superficial inguinal nodes, with some communication to the femoral nodes and to the external iliac systems. Lymphatics from around and above the dentate line flow with those from the distal rectum to the internal pudendal, hypogastric, and obturator nodes of the internal iliac systems. The proximal canal drains to the perirectal and superior hemorrhoidal nodes of the inferior mesenteric system. There are numerous lymphatic connections between the various levels of the anal canal, and an intramural system links the lymphatics of the canal with those of the rectum.[5]

The veins of the anal canal connect with both the systemic and the portal venous systems. Venous plexuses, which lie in and surround the mucosal and muscular structures of the anal wall, anastomose around the junction of the anal verge and distal canal. The veins draining the inferior parts of these plexuses communicate with the systemic venous system via the internal pudendal and internal iliac veins, and those from the superior canal flow predominately to the inferior mesenteric vein and then to the portal system.[5]

Anorectal continence is mediated by both cerebrospinal nerves and the autonomic system. The smooth muscle of the internal sphincter is supplied by parasympathetic fibers from the second, third, and fourth sacral segments as well as sympathetic fibers from the hypogastric plexus. The upper canal has selective sensitivity for intraluminal differences in pressure, and the autonomic nerves mediate both the inhibitor and facilitator reflexes of the internal sphincter. The striated muscle of the external sphincter is under voluntary control and innervated by the internal rectal nerve, a branch of the pudendal nerve arising from the second, third, and fourth sacral nerves. The internal rectal nerve also transmits pain, touch, and other sensations from the anal lining below the dentate line and from the perianal skin.[5]

PATHOLOGIC CLASSIFICATION

The most recent revision of the World Health Organization (WHO) classification of anal tumors, published in 2010, describes intraepithelial and invasive neoplasms.[6] The term *anal intraepithelial neoplasia* (AIN) is applied to precancerous changes in the epithelium of the anal canal and perianal skin.[7]

For invasive cancers, the term *squamous cell carcinoma* is applied to all the various subtypes: squamous, large cell keratinizing and nonkeratinizing, and basaloid, cloacogenic, and transitional, all of which were considered separate entities in the previous classification.[6] Squamous cell carcinomas account for about 85% to 90% of primary anal canal cancers; the remaining 10% to 15% are predominantly adenocarcinomas, most of which arise from anal glands or within anal fistulae. Adenocarcinomas from the rectal-type mucosa in the upper canal are classified as primary rectal cancers. The WHO system retains as separate entities rare variants, such as squamous cell carcinoma with mucous microcysts, small cell, and undifferentiated cancers.

Primary cancers of the perianal skin are similar to cancers of the skin in other sites. Most are squamous cell cancers, with occasional basal cell cancers and skin adnexal adenocarcinomas.

EPIDEMIOLOGY

Anal cancers are about one-fifth as common as cancers of the rectum. Cancers arise in the canal with 3 to 4 times the frequency of perianal cancers. In North America and Europe, anal canal cancers are more common in women than in men, although this difference is decreasing[8]; perianal cancers occur with about equal frequency in both sexes. The annual age-adjusted rates per 100,000 for squamous cell cancers of the anus, anal canal, and anorectum in the U.S. Surveillance, Epidemiology, and End Results (SEER) registry for 2010 to 2014 were 1.5 for males and 2.1 for females.[8] The incidence varies widely in different parts of the world but has been increasing in North America and Europe over the past 40 years.[8] The annual incidence of invasive and intraepithelial neoplasia almost doubled in men and rose by about half in women between the periods 1973 to 1979 and 1994 to 2000.[9] The risk of anal cancer increases with age; the median age at diagnosis is 61 years.

RISK FACTORS

The most significant risk factors so far identified are sexually transmissible viruses, immunosuppression, and tobacco smoking. The role of sexual practices and sexually transmissible agents has been investigated intensively. Several mucosotropic types of human papillomavirus (HPV) are linked to cancer and precancerous lesions in the anogenital epithelium.[10-12] Subtypes of HPV with a high risk of association with cancer are type 16 in particular and, to a lesser extent, types 18, 31, 33, 35, and others.[10-12] These high-risk HPV types have been found in about 85% of anal squamous cancers in many series,[10,12] more commonly in cancer of the canal than of the perianal skin.[12,13] Some geographic variation was noted in the types of high-risk HPV identified.[12,14] Case-control studies suggest that a history of multiple sexual partners in homosexual or heterosexual relationships or of unprotected anal intercourse in males and in females is predictive of an increased risk of AIN and invasive anal cancer.[15] For instance, one study found that compared to the overall annual incidence of anal cancer in White males in the United States of approximately 0.7 per 100,000 in the early 1980s, the estimated incidence in the male homosexual population, prior to the human immunodeficiency virus (HIV) epidemic, ranged from about 12 to 37 per 100,000.[16] This rate increased to about 70 per 100,000 among HIV-positive homosexual men.[17]

Compromise of cell-mediated immunity reduces the body's ability to prevent or eliminate infection by viruses, such as HPV. An increased risk of anal cancer is associated with at least two situations in which cell-mediated immunity is significantly altered: infection with HIV and iatrogenic suppression of immunity in patients with organ transplant. Interactions between HPV and HIV are complex. Although anal cancer has not been designated an acquired immunodeficiency syndrome (AIDS)-defining condition, data from the U.S. AIDS Cancer Registry linkage study showed that the rate of HPV-associated cancers and precursors was increased in HIV-infected persons for all anogenital sites compared with the general population. The relative risk for anal cancers was 6.8 in women and 37.9 in men.[18] A national cohort study in Sweden of 5,931 patients who had undergone organ transplantation showed a 10-fold excess risk of developing anal cancer.[19] Whatever the cause of suppression of cell-mediated immunity,

those affected have increased rates of HPV infection, higher progression rates from normal epithelium to AIN and from lower to higher grade AIN, and lower rates of clearance of HPV and regression from abnormal to normal epithelium.[20,21]

The increasing effectiveness of antiretroviral therapy has led to longer survival of patients who are HIV infected and an increased number with anal cancer.[22,23] There was a 3-fold increase in incidence in the HIV-positive population from the period prior to the introduction of highly active antiretroviral therapy (HAART) in about 1996 and the later HAART era.[23] Although there was a decrease in the incidence of Kaposi sarcoma and lymphoma by a few years after HAART became available, at the time of the review, there had been no significant reduction in the incidence of less common malignancies, such as anogenital cancers.[24] Early success of prophylactic vaccines against HPV in both men and women suggests that the incidence of anal cancer can be reduced in the future.[25,26]

In addition, tobacco smoking is also associated with up to a 4-fold increase in risk of developing anal cancer in several case-control studies. Current smokers are at greater risk than are past smokers.[15,27] Benign conditions such as fistulae, fissures, and hemorrhoids do not appear to predispose to cancer.[28] Chronic anal inflammation due to inflammatory bowel disease has also been discounted as a risk factor.[29]

NATURAL HISTORY

Most squamous cell cancers of the anal region, especially the canal, are believed to be preceded by high-grade AIN.[7] However, it has been estimated that no more than 1% of cases with AIN develop invasive cancer per year,[30] a rate lower than that described for cervical intraepithelial neoplasia. Anal dysplasia recurs frequently despite excision, laser ablation, or topical therapies, presumably because of incomplete treatment or persistence of the HPV infection with which dysplasia is associated.[22] The natural history of AIN coexisting with anal cancers exposed to radiation, with or without chemotherapy, is unknown.

Squamous cancers of the anal canal spread most commonly by direct extension and lymphatic pathways. Hematogenous metastases are less common. Direct invasion from the anal mucosa into the sphincter muscles

and perianal connective tissue spaces occurs early; in a series of 137 cases, cancers were confined to the mucosa and submucosa at diagnosis in only 12%, and to the sphincter muscles, without regional lymph node involvement, in only 34%.[31] In about half the cases, anal cancers extend into the rectum or perianal skin. Invasion of the vaginal septum and vaginal mucosa is more common than invasion of the prostate gland, but anovaginal fistulas occur in fewer than 5% of women. Extensive tumors may infiltrate the pelvic walls.

Lymphatic invasion occurs relatively early. The overall risk of regional nodal involvement at diagnosis is about 25%.[32,33] Pelvic lymph node metastases were found in as many as 30% of patients treated by abdominoperineal resection.[31,34,35] In an illustrative series, metastases were present in the superior hemorrhoidal nodes in 25% (15/61); in the external iliac, obturator, or hypogastric nodes in 30% (8/27); and in the inguinal nodes in 16% (12/74) of patients.[35] Inguinal metastases were detected clinically in up to approximately 20% of patients at initial diagnosis and were present subclinically in a further 10% to 20%.[31,35-37] Nodal metastases were associated with 30% of cancers confined to the sphincter muscles, and 60% of those that had extended through the sphincters or were more poorly differentiated.[34] Lymphatic metastases increase in frequency with progressive enlargement of the primary cancer.[34,38]

Extrapelvic metastases are identified at the time of first presentation in less than 10% of patients. They are found most frequently in the liver, lungs, and para-aortic nodes. Local or regional nodal relapse is more common than in extrapelvic organs. In chemoradiation series, locoregional relapse rates as high as 30% and extrapelvic failure as high as 20% have been reported, depending on stage and chemoradiation regimen (though improvements in imaging likely have affected these rates).[31,39-41]

Perianal cancers tend to grow locally and may extend into the anal canal. When the site of origin is in doubt, it is conventional to classify the cancer as arising in the anal canal (given that involvement of the anal canal would often make a patient with perianal cancer a poor surgical candidate). The ipsilateral inguinal nodes are the most common site of metastasis and are involved in from 5% to 20% of cases (discussed later). Extrapelvic metastases are uncommon, except in locally advanced cancer or those with nodal metastases.

CLINICAL PRESENTATION

The symptoms of anal cancer are often nonspecific, contributing to delay in presentation by the patient and in diagnosis by the physician of more than 6 months in one-third of patients.[42,43] Bleeding and anal discomfort are the most common symptoms and are reported by about half of patients.[44] Less common complaints include awareness of an anal mass, pruritus, and anal discharge. Pain is uncommon but may be severe. In patients with tumors in the proximal canal, there may be an alteration in bowel habits, but this is uncommon with distal cancers.[44] Occasionally, asymptomatic tumors are found during physical examination or in the course of investigation of an enlarged inguinal node. Unsuspected microinvasive carcinoma is sometimes found in mucosa removed at hemorrhoidectomy.[45]

Small carcinomas are often nodular or plaque like, but larger tumors are more typically ulcerated and infiltrative. Coexisting benign conditions such as anogenital warts, hemorrhoids, and anal fissures may be present. Anal sphincter tone is usually preserved and may be increased by painful spasm. Gross fecal incontinence is rare but tends to be more common with more advanced T-stage as a result of sphincter destruction.[46] Similarly, vaginal fistulas are uncommon. Rarely, extrapelvic metastases may be the only symptomatic feature or finding.

DIAGNOSTIC WORKUP

The history and physical examination should stress features that delineate the extent of the primary tumor, including anal sphincter competence and possible invasion of adjacent organs including a pelvic examination and cervical cancer screening in female patients (given risk of HPV field cancerization). A biopsy of the primary tumor is necessary to establish the diagnosis and the histologic type. General anesthesia may be needed to permit detailed pelvic and anorectal examination, which should include proctoscopy. Sigmoidoscopy and colonoscopy, although often performed, infrequently disclose colonic pathology.[47] Physical examination should include detailed examination of the genital region, especially in patients who give a history of previous anogenital area dysplasia or cancer, genital warts, or anal-receptive intercourse or are HIV positive.

Only the inguinal lymph nodes are accessible to clinical examination. Because lymph node enlargement may be caused by reactive hyperplasia in as many as half of those with palpable inguinal nodes, clinically suspicious nodes should be assessed histologically by needle biopsy.[44] Metastases in the internal iliac and superior hemorrhoidal node chains, about half of which are less than 0.5 cm in diameter,[48] cannot be identified reliably by current techniques of computed tomography (CT), magnetic resonance imaging (MRI), or transanorectal ultrasonography. MRI is considered the most accurate method for assessing the primary cancer and pelvic nodes and is guideline recommended as a part of workup.[49] Both fluorodeoxyglucose (FDG) positron emission tomography (PET) with CT and inguinal sentinel lymph node (ISLN) biopsy have been used to identify inguinal node metastases and to refine RT plans.[50-52] However, a comparison of FDG-PET-CT and ISLN biopsy in 27 patients found several false-positive PET studies (4/7).[53] A meta-analysis of 12 studies found that FDG-PET resulted in a change in nodal staging in 28% of patients with anal cancer. Subsequent sections further discuss the risk of isolated inguinal recurrence in patients who are clinically/radiographically inguinal node negative.[54] Finally, in addition to MRI of the pelvis and considering a PET-CT (if available), some guidelines recommend CT of the chest and pelvis to finalize staging.[55]

Laboratory workup should include full blood count, renal and liver function tests, and, if not previously tested, assessment of HIV antibody status (see section on HIV coinfection with anal cancer).

STAGING

The staging systems for anal canal and perianal cancers most commonly used are those proposed by the UICC[3] and the AJCC[2] (Tables 68.1 and 68.2). Most authors continue to report results by T (tumor) category or N (node) category rather than by composite tumor, node, metastasis stages. Under the UICC and AJCC systems, the regional lymph nodes for anal canal cancer are the perirectal, internal iliac, and inguinal nodes. Spread to all other pelvic node groups, including the external iliac, common iliac, and sigmoid nodes, is classified as metastasis (M1). For perianal cancers, the only regional nodes are the ipsilateral inguinal nodes. The eighth edition of

the AJCC staging manual for anal cancer includes changes to nodal classification and stage groupings.

TABLE 68.1 ANAL CANAL TNM CLASSIFICATION—EIGHTH EDITION

Primary Tumor (T)			
Tis	High-grade squamous intraepithelial lesion		
T1	Tumor ≤2 cm in greatest dimension		
T2	Tumor >2 cm but not >5 cm in greatest dimension		
T3	Tumor >5 cm in greatest dimension		
T4	Tumor of any size invades adjacent organ(s) (eg, vagina, urethra, bladder) (invasion of the rectal wall, perirectal skin, subcutaneous tissue, or sphincter muscle is not included as T4).		
Regional Lymph Nodes (N)			
N0	No regional lymph node metastases		
N1a	Inguinal, mesorectal, or internal iliac lymph nodes		
N1b	External iliac nodes		
N1c	External iliac nodes *plus* any node in the N1a group		
Distant Metastases (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Stage Grouping

In a review of 19,199 patients with squamous cell carcinoma of the anal canal, diagnosed between 1985 and 2000 and recorded in the U.S. National Cancer Database (NCDB), the stage distribution per AJCC seventh edition was stage I, 25.3%; II, 51.8%; III, 17.1%; and IV, 5.7%. Tumors were greater than 5 cm in size (T3) in at least 20.6% (tumor size in T4 category not available). Nodal involvement was present in 21.8% of those for whom information on nodal status was recorded.[32]

PROGNOSTIC FACTORS

Tumor Factors

Features related to the anatomic extent of disease generally provide the most prognostic value.[56] The most adverse factor for survival is the presence of extrapelvic metastasis.[57-59] When anal cancer is confined to the pelvis, the size of the primary tumor is the most useful predictor for local control and preservation of anorectal function and survival.[40,60,61] Involvement of regional lymph nodes is an adverse factor for survival, but, in most series, not for control, of the primary tumor.[40,60]

Among the 19,199 patients recorded in the NCDB between 1985 and 2000, the overall 5-year survival was 58%.[33] Patients with distant metastases had a 5-year survival of 18.7% versus 59.4% for those without metastases. Patients with regional node metastases had a 5-year survival of 37.4% versus 62.9% in patients who were node negative. Five-year survival rates by T category were T1, 68.5%; T2, 58.9%; T3, 43.1%; and T4, 34.3%. The survival rates by AJCC stage are shown in Figure 68.2. More recent data from SEER find that in the United States from 2000 to 2019, the incidence of anal cancer has increased by 1.8% annually, possibly accompanied by an

increased mortality rate, though survival has modestly improved in that time by an annualized average absolute change in survival of 0.3%.[62]

In detailed analyses of data collected prospectively for Radiation Therapy Oncology Group trial RTOG-9811,[60,63] tumor diameter greater than 5 cm correlated with an increased likelihood of colostomy (hazard ratio [HR] 1.8; $P = .008$)[60] (Table 68.3). A tumor size greater than 5 cm and clinically positive nodes were each associated with significantly poorer 5-year disease-free and overall survival (OS).[63] These findings were combined into prognostic groups.[63] These groups are shown in Table 68.3, with additional

data drawn from the analyses by Ajani et al.[60,63] These groupings have not been verified prospectively.

TABLE 68.3 PROGNOSTIC GROUPS BASED ON DATA FROM RTOG TRIAL 9811[60,63]

End Points (3 Y)	Group 1	Group 2	Group 3	Group 4
	T ≤5 cm, N− (*n* = 365)	T >5 cm, N− (*n* = 112)	T ≤5 cm, N+ (*n* = 107)	T >5 cm, N+ (*n* = 60)
Disease-free survival (actuarial) (%)	74	65	48	30
Colostomy rate (crude) (%)	11	17	9	24
Overall survival (actuarial) (%)	86	75	75	63

N, any regional node; RTOG, Radiation Therapy Oncology Group; T, primary tumor.
Data from pooled trial groups treated by radiation therapy (RT), 5-fluorouracil, and mitomycin C or RT, 5-FU, and cisplatin (CDDP). Median follow-up 2.2 years. Most events occurred by 2 years.

Patient Factors

Patient-related factors are not consistent between series. Age, performance status, gender, baseline hemoglobin level, and race have all been considered prognostic in one or more series. Patients who continue to smoke tobacco may be at greater risk of local relapse.[64] In some series of patients who are HIV positive, high viral load, low lymphocyte CD4-positive counts, and AIDS have been prognostic of poor local tumor control and survival and, in some series, of impaired tolerance of RT and chemotherapy.[65-67]

Biochemical and Molecular Factors

A survey of nearly 50 reports on cytogenetic, flow cytometric, immunohistochemical, and other factors considered that these studies offered some insights on pathogenesis but did not help with selection of treatment or provide guidance on prognosis.[68] Studies suggest that biomarkers such as p53, Ki 67, nuclear factor κ B, 5HH, and Gli-1[69] may be associated with locoregional control or disease-free survival. High levels of MCM7 protein detected in gene expression analysis were associated with

improved cancer survival in one series.[70] None of these suggested markers has yet been validated in prospective studies.

Treatment Factors

Early response and the extent of response to chemoradiation were correlated with survival in several multivariate analyses.[56,71,72] An association with total radiation dose or with treatment duration has not been demonstrated consistently for locoregional control nor survival. A daily fraction size of 2.5 Gy appeared to be associated with increased acute and late toxicity, compared with 2-Gy fractions.[40]

TREATMENT OF ANAL CANCER

Although squamous cell cancer of the anal canal is a relatively uncommon malignancy, several practice-defining multicenter randomized trials have been completed successfully. These have established RT with concurrent 5-FU and MMC, with surgery reserved for failure, as the standard against which other treatments should be compared. These trials are outlined here and in Table 68.4.[39,73-79] The original references should be consulted for full details of patient eligibility, treatment regimens, outcomes, and statistical analyses. There have also been over 100 nonrandomized studies, many of which provided hypotheses subsequently tested in the randomized studies, or information that guided the development of technical aspects of radiation treatment.[80]

[b]In patients who received maintenance chemotherapy.

It is of note that the combination of RT and chemotherapy has long supplanted surgery as the preferred treatment for anal canal squamous cell cancer without formal comparison in a randomized trial. Nonrandomized comparisons of radical resection with this combination of RT, 5-FU, and MMC[33] or with RT alone[81] have shown the ability of radiation-based regimens to produce survival rates at least equal to those of surgical series while allowing preservation of anorectal function in the majority of patients.

Combined Radiation and Chemotherapy

Radiation, 5-Fluorouracil, and Mitomycin C Versus Radiation Alone

In both the United Kingdom and Europe in the 1970s, more so than in North America, there was already some acceptance of RT as the primary treatment for anal cancer[82]; this facilitated the development of the first multi-institutional randomized trials in which RT alone was compared with RT plus chemotherapy. The randomized trials conducted by the UK Coordination Committee for Cancer Research (UKCCCR)[39] and the European Organization for Research and Treatment of Cancer (EORTC)[74]

both demonstrated significant improvement in control of the primary cancer and regional nodes and in colostomy rate or colostomy-free survival in patients who received RT, 5-FU, and MMC. OS rates were not improved significantly in the initial reports. However, in a later report of the UKCCCR trial after a median of 13-year follow-up, locoregional control, colostomy-free survival, disease-free survival, and deaths due to anal cancer all significantly favored chemoradiation.[74] The absolute difference in risk of dying from all causes was 5.1% lower in the chemoradiation group at 5 years and 5.6% lower at 12 years from randomization. This difference approached statistical significance (HR 0.86; 95% confidence interval [CI], 0.70-1.04; $P = .12$).[74]

The UKCCCR trial included 577 patients with all stages (UICC staging system, 1987 edition) of squamous cell cancer of the anal canal (75% of patients) or anal margin (23%).[39] The radiation dose was 45 Gy in 20 to 25 fractions in 4 to 5 weeks. Those randomized to chemotherapy received 5-FU (1,000 mg/m^2/day for 4 days or 750 mg/m^2/day for 5 days) by continuous peripheral intravenous (IV) infusion in the first and final weeks of radiation treatment, plus MMC (12 mg/m^2) by bolus IV injection on day 1 of the first course of chemotherapy. If the primary tumor had not regressed by at least 50% by 6 weeks after treatment (as occurred in 10% in each group), surgery was recommended; otherwise, the patients received an additional 15 Gy in 6 fractions by a perineal field or 25 Gy over 2 to 3 days by iridium-192 implant. The locoregional recurrence rates at 3 years were 61% after RT and 39% after RT, 5-FU, and MMC ($P < .0001$). The OS rates at 3 years were 58% and 65% ($P = .25$), respectively. There were six (2%) deaths due to treatment in the combined modality arm and two (0.7%) in the irradiation-alone arm. Acute toxicity, other than hematologic, was considered comparable in each group. In the first few years after treatment, surgery that included colostomy was necessary for the management of toxicity in 10 patients (3.5%) in each group.[39] Late toxicity events (severity was not graded) after a median of 13-year follow-up were similar in each treatment group.[77]

In the EORTC study, 103 patients with advanced cancers of the anal canal were randomized in a trial of similar design.[74] The radiation dose was 45 Gy in 25 fractions over 5 weeks. Chemotherapy included 5-FU (750 mg/m^2/day for 5 days) in weeks 1 and 5 of radiation and a single dose of MMC (15

mg/m^2) by bolus IV injection on day 1 of the first course of 5-FU only. After 6 weeks, boost irradiation of 15 Gy (if complete clinical response to previous treatment had occurred) or 20 Gy (after partial response) was given by external beam or interstitial irradiation. The 5-year locoregional recurrence rate was 48% after RT and 32% after RT, 5-FU, and MMC (P = .02). The difference between OS rates (53% and 58%, respectively) was not significant. One of 51 patients who received combined modality treatment died of toxicity. Otherwise, acute and late toxicity rates did not differ markedly. These two trials established RT, 5-FU, and MMC as the standard first-line treatment.

Radiation, 5-Fluorouracil, and Mitomycin C Versus Radiation and 5-Fluorouracil

The RTOG and Eastern Cooperative Oncology Group (ECOG) established in the randomized trial RTOG 8704 that the combination of MMC with 5-FU and RT is more effective than is 5-FU alone with RT.[75] Given the hematologic toxicity of MMC, there was interest in determining if it was a necessary component of a concurrent chemotherapy regimen. Two hundred and ninety-one patients with cancers of the anal canal of any T and N category (RTOG staging system) who did not have evidence of extrapelvic metastases received 45 to 50.4 Gy in 25 to 28 fractions over 5 weeks, plus 2 courses of 5-FU (1,000 mg/m^2/day by continuous peripheral IV infusion) over 4 days, with or without MMC (10 mg/m^2 by bolus IV injection) on the first day of each course of chemotherapy. Chemotherapy was administered in weeks 1 and 5 of RT. All patients underwent biopsy of the primary tumor site 6 weeks after treatment. Biopsies were positive in 15% of those who received 5-FU only and in 8% of those who received both MMC and 5-FU (P = .14). Patients with positive biopsies had the option of receiving an additional 9 Gy in five treatments concurrently with a 4-day infusion of 5-FU (1,000 mg/m^2/day) and a single injection of cisplatin (CDDP) (100 mg/m^2) if it was thought that anal function might still be salvaged. At 4 years, the rates of local failure (16% vs 34%; P = .0008) and colostomy (9% vs 22%; P = .002) significantly favored the MMC arm. There was no significant difference in OS rates (76% with RT, 5-FU, and MMC vs 67%); however, the disease-free survival rate (73% vs 51%; P = .0003) favored the

addition of MMC. Acute hematologic toxicity was more common in the patients who received MMC, but the rates of other acute and late toxic effects were similar in each treatment group. Four of 146 (2.7%) patients who received both 5-FU and MMC suffered fatal toxicity as did 1 of 145 treated with RT and 5-FU alone. On the evidence from this trial, MMC was retained in combination with RT and 5-FU.

Radiation, 5-Fluorouracil, and Mitomycin C Versus Radiation, 5-Fluorouracil, and Cisplatin

Several pilot studies suggested high tumor response rates to concurrent, induction, or induction plus concurrent 5-FU and CDDP with RT.[83-87] CDDP was known to be effective against squamous cell cancers in several other sites and to be associated with stronger laboratory evidence as a radiosensitizer than MMC. Two large, randomized studies detailed later explored this question, ultimately resulting in MMC remaining the standard of care delivered concurrently with 5-FU and radiation. It should be noted that though MMC has unique hematologic toxicities, it does not carry the same ototoxicity nor renal toxicity risks of CDDP and is more convenient to administer (brief injection with some protocols even using a single bolus dose).

The RTOG elected to evaluate a strategy of CDDP-based induction chemotherapy intended to downsize the primary tumor and nodal metastases prior to concurrent chemoradiation. This trial included a higher total radiation dose than the earlier RTOG 87-04 randomized trial,[75] based on the analysis of nonrandomized studies that suggested a radiation dose-control relationship[80,81] and on pilot studies, which had demonstrated that a proportion of patients could tolerate uninterrupted radiation schedules of up to 59.4 Gy over 6.5 weeks with either concurrent MMC with 5-FU[88] or CDDP with 5-FU.[86]

In RTOG-9811,[73] patients received up to 59 Gy in 6.5 weeks (45 Gy in 1.8-Gy fractions, followed without interruption by 14 Gy in 2-Gy fractions boost for T3-4N+ or T2 with residual disease) with concurrent 5-FU (1,000 mg/m^2/day) by continuous infusion on days 1 to 4 and 29 to 32, and were randomized to either combination concurrent MMC (10 mg/m^2 IV bolus on days 1 and 29) versus two cycles of induction chemotherapy with 5-FU plus

CDDP (75 mg/m^2 bolus injection) and then chemoradiation with the same radiation approach substituting CDDP (75 mg/m^2 days 1 and 28) for MMC. Acute grade 3 or 4 nonhematologic toxicity rates were 75% in each arm, but hematologic toxicity was higher in the MMC group (67% vs 47%). No treatment-related deaths were reported. The rate of severe long-term toxicity was similar in each group (11% MMC vs 10% CDDP). The final report of this trial favored the MMC arm with 5-year disease-free survival of 68% versus 58% (P = .004) and OS of 78% versus 71%; (P = .021).[76] The 5-year colostomy rates and locoregional failure rates showed trends in favor of the standard of care of 5-FU/MMC chemoradiation, which did not meet significance threshold. The investigators concluded that RT, 5-FU, and MMC should remain the standard approach. It should be noted that in addition to replacing MMC with CDDP, the experimental arm of this study included two cycles of induction 5-FU/CDDP, which may have delayed time to initiation of definitive chemoradiation.

Also informing the decision of MMC versus CDDP in the concurrent setting is the second UK Anal Cancer Trial (ACT II).[78] The trial used a 2 × 2 randomization, either to 5-FU and MMC or to 5-FU and CDDP concurrently with RT and then to either no additional therapy or two cycles of adjuvant 5-FU and CDDP. Complete tumor response rates at 6 months were similar: 94% (MMC arm) and 95% (CDDP arm), and there was no significant difference in progression-free survival (PFS) between these arms at a median of 5.1 years of follow-up (HR 0.95 95% CI 0.75-1.19; P = .63). The 3-year PFS with or without maintenance chemotherapy was 74% versus 73% (P = .70). Patients who were MMC-treated had more severe hematologic toxicity (G3-4 26% vs 16%), but rates of neutropenic sepsis were similar (about 3%).

Another study exploring the use of CDDP (without comparing it to MMC) was the French study ACCORD 03, which used a four-armed factorial design to study (1) two cycles of induction 5-FU and CDDP to definitive chemoradiation with these agents (vs chemoradiation without induction) and (2) whether a higher dose of boost RT (20-25 Gy vs standard 15 Gy) would impact colostomy-free survival as the primary end point.[79] The baseline standard RT schedule was 45 Gy in 25 fractions in 5 weeks. Regarding the induction therapy question specifically, 5-year colostomy-free survival was 76.5 versus 75.0 (P = .37).[79] Local control, event-free

survival, and OS rates were similar in each arm. Taken together, both the ACCORD 03 (finding no benefit to induction chemotherapy) and the ACT II adjuvant chemotherapy arms (which did not improve PFS) suggest that the curative modality in locally advanced anal cancer is chemoradiation. Whether inferior outcomes in the CDDP arm of RTOG 9811 are due to delayed time to chemoradiation (knowing that induction outcomes in ACCORD 03 were not worse than omitting induction) or inferiority of CDDP compared to MMC remains an unanswered question, but MMC with 5-FU remains the standard chemotherapeutic regimen in combined chemoradiation. In specific circumstances such as patients with poor hematopoietic function for whom the toxicity of MMC would be a specific concern, CDDP can be considered a reasonably well-studied option.

Other Drug-Radiation Combinations

In an effort to develop a simplified schedule, the UK National Cancer Research Institute Anal Subgroup conducted a phase II trial of RT (50.4 Gy in 28 fractions in 5.5 weeks), a single IV injection of MMC (12 mg/m^2 on day 1), and oral capecitabine (825 mg/m^2 twice daily on each RT treatment day).[89] The schedule was described as well tolerated with acceptable compliance (although only 58% received the full planned doses). The overall tumor response rate after treatment was 90% (complete in 24/31 and partial in 4/31). Several guidelines list oral capecitabine as an option in lieu of IV infusions of 5-FU, though the latter remains standard.

Because epidermal growth factor receptor (EGFR) is known to be overexpressed in many epithelial cancers, including squamous cell cancer of the anal canal,[90] there was initially interest in exploring the addition of EGFR blockers to chemoradiation. This approach was found to be highly toxic, with a G3-4 acute toxicity of 88% in the UNICANCER ACCORD 16 trial resulting in early termination of that study.[91] Similarly, ECOG 3205 was a phase II study of RT, 5-FU, CDDP, and cetuximab in patients who were HIV negative, which found a 93% G3-4 toxicity rate when combined with induction chemotherapy and 82% when omitting induction therapy and a 5% treatment-associated death rate while still reporting a 23% locoregional failure rate at 3 years.[92] A similar phase II study conducted by the AIDS Malignancy Clinical Trials Consortium in patient with both anal

cancer and HIV infection reported a 72% G3-4 toxicity rate and 4% treatment-associated deaths despite a 42% locoregional recurrence rate at 3 years.[93] In light of these findings, excitement for this approach has diminished, and there are no ongoing phase III studies to explore this further.[94]

Summary

Concurrent chemoradiation is the cornerstone of curative- intent therapy for locally advanced anal cancer; the addition of neoadjuvant or adjuvant systemic therapy does not appear to offer an oncologic benefit in these patients. The standard of care for systemic agents in this setting remains 5-FU with MMC; data for replacing MMC with CDDP are mixed but do not demonstrate a conclusive equivalence to change the standard of care. Attempts at treatment intensification with adding EGFR-targeting drugs have in early studies added unacceptable toxicity without appearing to improve outcomes. There remain knowledge gaps in the optimal drug dosing (radiation dose escalation/de-escalation is discussed separately) such as more prolonged (but less daily dose-intense) infusions of 5-FU with the 96- to 120-hour infusions generally favored, nor of bolus injections with continuous infusions of 5-FU or CDDP. In addition, there is study variability in one versus two bolus injections of MMC at various doses. Finally, in most series, the timing of delivery of chemotherapy each day relative to irradiation was not tightly controlled, and the importance of this scheduling is not known.

Radiation Monotherapy

The use of RT alone, either brachytherapy or external beam, has been greatly reduced since the confirmation of improved outcome of combined modality therapy. Radiation alone is now recommended mainly to patients who are unable to undergo RT plus chemotherapy or for the treatment of smaller cancers up to about 3 to 4 cm in size where the physician does not wish to add chemotherapy. As with combined RT and chemotherapy, primary tumor control is better with small tumors. Selected results, mainly from the period prior to the adoption of chemoradiation, are shown in Tables 68.5 and 68.6.

Surgery

Surgery for Residual and Recurrent Cancer

Random biopsies from the site of the primary tumor, or abnormal nodes, shortly after chemoradiation are generally discouraged in the absence of clinical progression on serial exams. Elective biopsies at predetermined times do not lead to better results than biopsies guided by clinical evidence of residual or recurrent cancer. A negative biopsy does not exclude the possibility of cancer regrowth.[102,103] Importantly, residual masses at the site of the original anal cancer are common at the time of treatment completion and may take several months to resolve fully after chemoradiation or RT alone.[40,103] A post hoc analysis of the ACT II chemoradiation study evaluated the optimal timepoint to assess clinical complete response with assessments at 11, 18, and 26 weeks after treatment completion. The investigators found that among patients who did not have a clinical complete response by 11 weeks, 151 (72%) of 209 would ultimately achieve a clinical complete response by 26 weeks.[104] Together, these findings highlight the potentially slow primary anal tumor response to CRT and support the practice of serial

clinical examination reserving biopsy only for when persistent cancer is suspected clinically.

Suspected residual or recurrent cancer at the primary site or in regional nodes should be confirmed histologically if possible. Full restaging imaging is recommended, including with FDG-PET specifically.[105] In cases of local recurrence, abdominoperineal resection or multivisceral pelvic resection is usually required. Unfortunately, survival rates are poor when R0 resection cannot be achieved,[106,107] and even with apparent R0 resection, locoregional recurrence is common.[106,108] Five-year survival rates following salvage surgery range from 30% to 50%, reflecting the varying criteria applied when selecting patients for surgery.[106-109]

Salvage for inguinal node metastases is usually treated with radical or selective inguinofemoral lymphadenectomy. Pelvic sidewall node metastases may not be resectable because of invasion of muscle or bone or neurovascular structures.

Surgery for Primary Cancer

Surgery is the principal treatment for AIN[110] but is not a preferred option for the management of anal canal cancer. Primary definitive local excision preserving anorectal function for perianal primary lesions is discussed separately later. In the setting of a lesion of the anal canal with intact sphincter function, surgery is not the preferred intervention. There is no evidence that elective management by limited tumor excision and postoperative radiation-based protocols improves local control.[111]

In the setting of recurrent disease in the inguinal nodes, salvage groin dissection is standard, with or without adjuvant radiation, depending on prior treatment. In the upfront node-positive setting, there is no consensus on whether control of the nodal region involved is improved by limited node dissection prior to chemoradiation nor how such an approach affects morbidity, such as late limb edema.[36,38,40,41]

Extrapelvic Metastases

Deaths from extrapelvic metastases alone are relatively infrequent. Extrapelvic metastases are identified in about 10% to 20% of patients. For instance, among 585 patients randomized in the UKCCCR ACT I study, 77

patients died of anal cancer after chemoradiation, among whom 38 (49%) of 77 had cancer in the pelvis only and 21 (27%) had extrapelvic metastases only. The overall crude rate of metastasis in those who received RT and chemotherapy was 10% and in those treated by RT alone was 17%.[39] Similarly, in the EORTC trial, 17% of those treated by RT and chemotherapy developed metastases, as did 21% of those treated by RT only.[74] In RTOG-9811, the rates of distant metastases at 5 years were 13% in those who received RT, 5-FU, and MMC and 18% after RT, 5-FU, and CDDP.[76]

There is still considerable uncertainty regarding the effects on subclinical metastases outside the pelvis from the chemotherapy given concurrently with RT or as short-term induction or adjuvant treatment. Of note, in the UK ACT II trial (which omitted patients with metastatic disease at presentation), the addition of two cycles of 5-FU and CDDP did not improve 3-year disease-free survival nor OS.[78]

The median survival time after diagnosis of extrapelvic metastases ranges from 8 to about 24 months.[57,58,112] These metastases have been relatively resistant so far to all chemotherapy, RT, or combined modality protocols.[113] More recently, the preferred frontline systemic therapy regimen has become carboplatin and paclitaxel, which, in the randomized phase II InterAACT study, achieved similar efficacy as CDDP and 5-FU (the prior standard) but with a significantly lower G3-4 toxicity rate (36% vs 62%; $P = .016$). However, even in this modern series with relatively fit patients who were chemotherapy naïve, OS in the carboplatin/paclitaxel arm was only 20 months with a PFS of 5.7 months.[114] Given this, the ongoing POD1UM-303/InterAACT 2 phase III study will seek to improve these outcomes with the addition of the anti-programmed cell death protein 1 (PD-1) monoclonal antibody retifanlimab in patients with metastatic or inoperable locally recurrent anal cancer.[115] There are some preliminary clinical data supporting the use of checkpoint immune therapy in anal cancer. In the refractory metastatic setting, single-agent anti–PD-1 antibody nivolumab in a phase II study found an overall response rate of 24%.[116] Another small phase II study in patients with refractory metastatic anal cancer found that the combination of cetuximab and avelumab (a PD-L1 monoclonal antibody) results in an overall response rate of 17%.[117]

TREATMENT OF PERIANAL CANCER

The most common histologic type of invasive cancer of the perianal skin is squamous cell carcinoma, usually keratinizing. Basal cell cancers and adenocarcinomas can also occur. The principle difference between perianal cancer and anal canal cancer is the potential for definitive surgical excision in well-selected patients with T1-2N0 tumors that are well/moderately differentiated and are in an anatomic position such that wide local excision would not compromise sphincter function.[118-120] This approach is based on surgical series finding that less than 5% of well-differentiated squamous cell cancers less than 2 cm in size have nodal metastases to the pararectal or superior hemorrhoidal system.[31,34] Local excision of small cancers of the distal canal or perianal skin is generally more expedient and associated with less morbidity than radiation-based treatments. However, if resection margins are positive or considered inadequate (1 cm in perianal cancer),[113] and further local excision is not possible, the patient should receive chemoradiation or RT alone.

Either radiation alone or in combination with chemotherapy is also effective against perianal squamous cell cancers.[41,72,121-125] In patients not meeting the abovementioned surgical criteria, or who are otherwise not receiving surgery, radiation treatment protocols remain the same as for anal canal cancer. In the UKCCCR ACT I trial, one of four patients had a cancer that arose in the perianal skin (anal margin). Results by site of cancer origin were not reported, but local control and cause-specific survival rates favored combined modality therapy.[41,71] The UK investigators also included perianal cancers in their subsequent trial.[76] In institution-based series, locoregional control rates ranged from 60% to 90%, sphincter preservation rates from 65% to 85%, and 5-year OS from 55% to 80%.[41,72,121-125] Local necrosis was seen as a complication more frequently when brachytherapy was used, although, in general, the rates of serious complications were less than 5%.

The regional nodes for the perianal skin are the ipsilateral inguinal nodes. Perirectal and pelvic node metastases are uncommon unless the cancer involves the anal canal. The risk of inguinal node metastases is about 10%, principally with T3 or T4 tumors or poorly differentiated cancers. Elective bilateral inguinal nodal irradiation may be considered when these larger tumors are treated, although some advocate elective inguinal RT for all

perianal cancers.[123] The lower pelvic nodes should be included if the anal canal is invaded. The management of abnormal inguinal nodes is similar to that for anal canal cancer.

The principles of management for the uncommon basal cell and adenocarcinomas of the perianal skin are similar to those for these histologic types elsewhere on the skin.

PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS/ACQUIRED IMMUNODEFICIENCY SYNDROME

Anal cancer is a common malignancy in HIV-infected adults, but is not an AIDS-defining cancer. With the improvement in HIV-specific survival in the era of modern antiretroviral therapy, numbers of patients who are HIV infected and with anal squamous cell cancer are increasing,[126] including those previously diagnosed with AIDS.[23] Among patients with AIDS in particular, the median age at diagnosis is in the fourth decade, about 20 years earlier than in patients who are non–HIV infected.[23] Importantly, patients who were HIV infected were excluded from many of the randomized trials described earlier. The chemoradiation approach for anal cancers in patients who are HIV infected is the same as in noninfected individuals, but patients who are HIV infected are at increased risk of toxicity, particularly in the perineal skin, anorectal mucosa, and hematologic system.[127-131] The mechanisms for this increased toxicity are not known.[132] Two factors may predict for heightened acute normal tissue toxicity or poor cancer control: a CD4 count less than 200/μL at the start of treatment or the presence of AIDS.[67,133] Concurrent antiretroviral therapy does not reliably reduce the severity or incidence of toxicity of RT and chemotherapy.[30]

Locoregional control rates of about 65% or better were described in some series, similar to those in patients who were HIV negative. However, lower pretreatment CD4 count is associated with higher risk of recurrence and may increase the risk of cancer-specific mortality, suggesting a dose-response relationship between immune surveillance post-treatment.[134] Further supporting this are series reporting lower rates of local control and sphincter preservation in patients who are HIV positive, despite earlier stage disease and good initial tumor response.[66,127] A study of 40 patients who were HIV positive found that the 5-year OS rate was similar to that in 81

patients who were HIV negative, but that the major cause of death in patients who were HIV positive was anal cancer, in contrast to the patients who were HIV negative in whom causes other than cancer predominated.[66]

ADENOCARCINOMAS

Most adenocarcinomas involving the anal canal arise from rectal-type mucosa that extends below the upper muscular boundary of the canal. They are generally treated similarly to those that arise in the rectum.[50] The uncommon adenocarcinomas that develop from anal glands or in fistulae are more aggressive than squamous cancers and often metastasize early.[135] They have historically been managed with therapeutic approaches that parallel rectal cancer treatment, including neoadjuvant chemoradiation followed by abdominoperineal resection. Five-year survival rates following surgery alone are commonly below 50%, with local recurrence rates of about 25%.[33,120,135-138] Any advantage from adjuvant radiation and chemotherapy is unknown. Some small case series are reported in patients whose anal adenocarcinomas were treated with chemoradiation; in general, recurrence rates are higher than with comparable squamous tumors, though a minority of patients can achieve a cure while retaining anorectal function.[136,139,140]

RADIATION THERAPY: TECHNIQUES AND DOSES

Current radiation treatment strategies have been informed by the natural history of anal cancer, drawing from experience with sites of treatment failure after local therapy.[98,141,142] Most failures occur at the site of the primary tumor, followed by the regional and other pelvic node groups. Contemporary chemoradiation is standardly given with intensity-modulated radiation therapy (IMRT) with 1.8-Gy fractions, treating the primary tumor to 50.4 Gy (T1-2) to 54 Gy (T3-4) using simultaneous integrated boost (SIB) techniques to treat involved or elective nodal volumes. Risk-adapted radiation dose escalation and de-intensification are both areas of ongoing clinical trials.

Radiation Dose to the Primary Tumor

Older radiation trials typically treated the primary tumor in a split course, with tumor boost delivered after about a 6-week delay.[39,74,75] This practice has fallen out of favor (modern trials treat through the entire radiation schedule without interruption) but did provide information on tumor control probability and dose; RTOG 8704 was a study demonstrating superiority of concurrent chemoradiation with 5-FU and MMC over chemoradiation with 5-FU alone. The radiation schedule was 45 Gy in 1.8-Gy daily fractions to the whole pelvis (and inguinal nodes for patients with N1) with a 5.4 Gy sequential anteroposterior/posteroanterior or perineal boost for residual palpable tumor. The patients then underwent a 6-week break at which point a biopsy determined whether to treat with an additional 9 Gy to the primary tumor. In the MMC arm, 101 (69.2%) of 146 patients received between 41.76 and 47.25 Gy (ie, neither boost dose), and negative biopsy rate in this arm at 6 weeks postcompletion of induction chemoradiation was 92.2%. Importantly, this study found a 10% difference in negative biopsy rate between patients whose primary tumor was less than 5 versus 5 cm or larger. While this end point has been called into question since (see discussion earlier), the 4-year local control rate in the MMC arm was 84%, suggesting that chemoradiation with a relatively intermediate dose achieves durable local control for many patients, particularly those with smaller primary tumors.[75] In contrast, the EORTC studied chemoradiation with 5-FU and MMC in a population with much higher rates of T3-4 disease (84% of patients compared to 43% in the RTOG 8704 study) with a radiation prescription of 45 Gy in 1.8-Gy daily fractions followed by a 6-week delayed boost of 15 or 20 Gy if patients had residual disease, resulting in a 5-year local control rate of only 68% in the MMC/5-FU arm.[74] Similarly, in the 5-FU/MMC arm of ACT I (with 56% of patients having T3-4 disease), patients received 45 Gy of radiation (anus, inguinal nodes, and partial pelvis) followed by a 6-week delayed boost to either 25 Gy with iridium brachytherapy implant over 2.5 days or 15-Gy external beam boost. Of 48 patients with a more than 50% clinical response who did not complete this boost, 17% failed within 3 months; when looking at the chemoradiation arm overall, at 5 years, the local failure rate was 32.3%.[77]

This persistent issue of local failure (despite the refinement of chemoradiation), particularly in patients with bulkier primary tumors, led to the design of ACCORD 03,[79] a 2 × 2 factorial study of the addition of

induction chemotherapy (which failed as discussed in detail earlier) and boost dose escalation. Patients with primary tumors 4 cm or greater or N1-3 disease (median tumor size was 44.4 mm) received chemoradiation with CDDP 80 mg/m^2 on days 1 and 29 and infusional 5-FU 800/m^2/day on days 1 to 4 and 29 to 32 with 45 Gy in 25 fractions to the gross tumor, pelvis, and inguinal nodes (if positive or anal margin involved, or if pelvic nodes were positive); from there, randomization was between 15-Gy standard boost or high-dose boost to 20 Gy for a 80% or more response or 25 Gy otherwise. Boost could be delivered with either external beam or low-dose brachytherapy. In the radiation dose intensification arms, only 23% received a 25-Gy boost, and the median boost dose was 20 Gy compared to 15 Gy in the radiation standard-of-care arms. At 5 years, colostomy-free survival with intensified boost was 77.8 compared to 73.7 (P = .067), with an effect that was only apparent after about 2 years (albeit statistically insignificant). Given that the median dose in the standard radiation arm was already relatively high compared to other studies and that the median escalation was only 5-Gy difference, the optimal dose of radiation for bulky primary tumors remains an open question.[79] The ongoing ACT V dose escalation study may help better refine this in the future, though the highest dose arm of that study will be 61.6 Gy in 28 fractions.[143]

In contrast to bulkier, higher stage disease, patients with earlier stage disease, particularly with primary tumors less than 5 cm in size, tend to have better local control (see Table 62.3) often achieved with lower radiation doses in prior trials.[144] Two ongoing phase II studies will explore radiation de-intensification: the ACT IV study[143] will compare 41.4 Gy to the standard 50.4 in patients who were node negative with T1-2 primary tumors measuring 4 cm or less,[143] and the ECOG-ACRIN DECREASE study in similar patients will de-escalate the dose even further to 36 Gy.[94]

Management of Lymph Nodes

Similarly, older surgical data initially guided the design of clinical trials on the use of elective lymph node irradiation (ENI). One case series of 132 patients treated with surgical resection at a single institution found that almost 30% of patients without clinical inguinal node involvement subsequently had inguinal node failure and that node dissection and

radiation were effective at preventing nodal failure in patients with clinically node-positive disease.[34] In contrast, another study performed a subanalysis of 12 patients diagnosed with superficial, 2 cm or less, distal canal tumors treated with local excision resulting in only one local failure and no nodal recurrences.[31] With regard to the management of these patients with clinically negative inguinal nodes, this question of ENI was studied in a 2010 publication by a French group in a multicenter retrospective series of 181 patients.[38] Among patients receiving 40 to 50 Gy inguinal ENI, the rate of inguinal recurrence was 2% ($N = 75$) versus 16% in those who did not ($N = 106$). Specifically, among patients with T1-2 tumors who did not receive ENI, inguinal recurrence rates were 12%. Further supporting inguinal ENI in T1-2 anal cancer was the TROG 99.02 published a year later and demonstrating a 22.5% total failure rate in untreated inguinal nodes (12.5% isolated inguinal recurrence rate).[145] With regard to pelvic ENI, there is less direct evidence, but its efficacy can be inferred from the low failure rates reported radiation/chemoradiation series.[141,142] The minimum effective dose for ENI is not known. Doses as low as 24 Gy in 12 fractions in 2.5 weeks appeared effective in one series,[40] but most centers prescribe between 30.6 Gy in 17 fractions in 3.5 weeks to 50 Gy in 25 fractions in 5 weeks.[38,73,75]

Radiation Technique

Older randomized trials used radiation plans generated by two- or three-dimensional (2D or 3D) planning techniques with 1.8-Gy fractionation and sequential cone-down or boost. This has largely been supplanted by dose-painted (ie. SIB) IMRT, which is now the recommended standard of care in most consensus guidelines.[55] While IMRT has not been compared to older techniques in a randomized trial, it is hypothesized to reduce cutaneous, hematologic, and gastrointestinal (GI) toxicity without compromising oncologic outcomes and avoid many of the technical challenges of field matching for inguinal nodal coverage and oftentimes obviate the need for bolus.

The practice changing phase II nonrandomized study RTOG 0529 sought to reduce the rate of grade 2 or higher combined GI/genitourinary (GU) toxicity by 15% in patients with nonmetastatic anal canal cancer staged T2-4/N0-3 treated with concurrent 5-FU (1,000 mg/m^2/day on days 1-5 and 29-

33) and MMC (10 mg/m^2 bolus, days 1 and 29) as compared to RTOG 9811.[96] The authors initially published guidelines[146] for elective nodal coverage due to observed contouring variability, and subsequently, the Australasian Gastrointestinal Trials Group (AGITG) elaborated on these with their guidelines refining gross tumor and organ-at-risk delineation.[147] They found that among 51 analyzed patients, there were no major deviations for the primary tumor nor nodal coverage, with 14% and 6% rates of minor deviation for these, respectively. On initial reports, the combined end point of acute grade 2 or higher GI/GU toxicity overall was 77%, which was equivalent to the RTOG 9811 results, but when studying secondary end points of acute grade 3 or higher GI/GU toxicity, IMRT showed significant improvement from a historic 85% to 73% (P = .032), mostly driven by a reduction in GI toxicity. IMRT also demonstrated reduced acute grade 3 or higher dermatitis from 49% to 23% and reduced acute grade 2 or higher hematologic toxicity from 85% to 73%.[96] Importantly, at a median of 7.9 years of follow-up, oncologic outcomes were almost identical to RTOG 9811: 5-year local-regional failure 16% (95% CI, 7%-27%), OS 76% (95% CI 61%-86%), and disease-free survival 70% (95% CI 56%-81%).[97] In addition, secondary analysis of RTOG 0529 helped define small-bowel dose constraints for reducing acute grade 2 or higher GI toxicity: V25 less than 186 mL, V30 less than 155 mL, V35 less than 41 mL, and V40 less than 30.4 mL.[148] Taken together, IMRT is feasible, reproducible, and likely reduces toxicity as compared to older techniques.

With respect to patient setup during radiation, patients undergoing treatment can be treated in supine frogleg or prone position. Prone positioning may offer some bowel displacement and may help with dose to skin folds in patients with a large pannus when treating inguinal nodes. Conversely, supine positioning treatment is more easily reproducible. Both positions were permitted on RTOG 0529 and are accepted on the AGITG guidelines.[96,146,147] The intergluteal cleft does create an auto-bolusing effect for most patients, but bolus may be necessary in specific clinical circumstances, such as larger perianal tumors or fungating/superficial inguinal nodes. In patients with adequate renal function, IV contrast should be used to help with nodal delineation (in patients with a recent contrast-enhanced diagnostic CT scan that can be fused to the simulation scan it is reasonable to omit contrast); oral contrast was used on RTOG 0529 but adds

to patient appointment duration for simulation and may not reliably improve small-bowel visualization. Prior MRI and PET-CT scans should be fused to help with primary and gross nodal target delineation; given variability in pelvic tilt between imaging studies, it may be necessary to use deformable registration or separate fusions for the nodes and primary tumor. In male patients, the external genitalia is generally moved inferiorly for setup reproducibility. In female patients, some centers place a vaginal obturator at Sims and for treatment that may reduce vaginal/vulvar dose by creating additional separation; the ongoing DECREASE study has a secondary end point of female sexual function with obturator use.[94]

Regarding the volumes themselves, the gross tumor volume (GTV) and grossly involved nodes should be contoured with the assistance of fused imaging. The primary tumor clinical target volume (CTV1) should include the GTV with an isotropic margin (2 cm superior/inferior expansion, 1-2 cm radial expansion) and the entire anal canal; it is important with this to cover the perianal skin in the expansion (RTOG 0529 required a 2.5-cm expansion of perianal skin from the anal verge or gross tumor; and the RTOG atlas recommends a minimum of 2 cm). CTV may crop out of uninvolved structures such as bone or musculature. The CTV2 should include the involved nodes with a 1- to 2-cm isotropic expansion (again respecting anatomic boundaries with uninvolved structures). Finally, CTV3 is the elective nodal volume that should also include CTV1 and CTV2 as well as the following structures: (1) mesorectum (perirectal nodes), which is bound by the anorectal junction, the presacral space, the rectosigmoid junction, and anteriorly by the penile bulb/prostate in males and by the vagina, bladder, cervix, and uterus in female patients (the mesorectum is best seen on fat-saturated T2 MRI if available); (2) the presacral space, bound by the inferior edge of the coccyx, the sacral promontory, and a 1-cm volume anterior to the sacrum, including sacral hollows; (3) the internal/external iliac nodes, using a 7-mm anatomic expansion beginning at the bifurcation of the common iliac arteries and connecting to the mesorectal volume or inguinal volume; and (4) the inguinal nodes, with an anatomic volume covering at least a 7-mm expansion from the vessels and bound by the muscular structures (iliopsoas, pectineus, and adductor longus posteriorly and sartorius or iliopsoas medially) extending to about 2 cm inferiorly from the junction of the saphenous/femoral vein (guidelines differ on this inferior

extent of coverage). The RTOG and Australasian guidelines differ on whether to systematically cover the ischioanal fossa in the absence of radiographic invasion into this structure.[146,147] If image-guided RT is being used with frequent setup imaging, PTV expansions of 5 to 7 mm are reasonable, but otherwise 1 cm is standard.

Radiation Alone

If external beam irradiation is given without concurrent chemotherapy, it is usual, as in other cancers, to prescribe doses close to the tolerance of the normal tissues. There have been no studies to establish the optimum dose-time factors. A dose to the primary tumor of up to 60 to 65 Gy over 6 to 7 weeks, in 1.8- to 2-Gy fractions, is commonly prescribed, with doses to lymph nodes to be treated electively in the range of 36 Gy in 4 weeks to 50.4 Gy in 5.5 weeks. Brachytherapy may be used for part of the treatment. As with chemoradiation, interruptions in treatment should be minimized.

Perianal Cancer Considerations

If small (<4 cm) perianal cancers with low risk of regional node metastases are treated by radiation, a dose of 60 to 66 Gy in 2-Gy fractions over 6 weeks may be used. A direct perineal field is an option as this minimizes the area of skin irradiated. Orthovoltage equipment may suffice, and electrons or low-energy megavoltage photons (with bolus) are options as well. Care should be taken to flatten the perineum as much as possible to avoid areas of over- or underdosage. Larger perianal cancers, or cancers invading the anal canal, are usually treated by the techniques and schedules of radiation and chemotherapy used for anal canal cancers, based on the results of the UKCCCR ACT I trial.[39] ENI is given to the inguinal and lower external iliac nodes and to the lower perirectal and internal iliac nodes if the tumor extends into the anal canal as described earlier. If treating sequentially rather than with an SIB, the final phase of radiation may be given by direct perineal photon or electron therapy. Although brachytherapy may be used as a boost in patients undergoing sequential treatments (discussed later), full treatment of perianal cancers by brachytherapy is associated with high rates of necrosis in some series. The question of adjuvant radiation for patients undergoing resection for low-risk perianal cancers with close margins is an

ongoing study in the phase II ACT III study.[143] Data and guideline recommendations are mixed on whether resection with inadequate margins should be followed by reexcision or, possibly, radiation/chemoradiation.[149]

Other Considerations

In the era of 2D treatment planning, and later with 3D conformal planning, interruptions in external beam treatment, generally of no more than 2 weeks but of up to 4 weeks in some series, were introduced into many combined modality protocols, either as elective breaks after about 3 weeks of treatment or as required by individual patients, to reduce the severity of acute anoproctitis and perineal dermatitis. Longer intervals of 6 to 8 weeks were part of some schedules to allow time for tumor regression, particularly where further RT was to be prescribed based on the extent of the clinical or histopathologic response to the first phase of treatment.[39,74,75] The possible adverse effects of split-course irradiation on the control of anal cancer have not been studied formally, but the limited data available on the potential tumor doubling time of anal cancer suggest that it is relatively rapid and of the order of 4 days (range 1-30 days; $n = 26$).[150] Post hoc analyses suggest that the overall treatment time (OTT), including time for induction chemotherapy if given and for prolonged intervals prior to boost RT, may have more influence on outcome than the duration of radiation. Review of the UKCCCR ACT I trial did not identify an association between OTT and locoregional failure.[144] In contrast, analysis of two RTOG trials[73,75] showed a significant association with local failure. These studies are retrospective and nonrandomized with many potentially confounding factors, but the general principle recommended is to avoid or minimize the length of interruptions in the delivery of radiation.

The use of proton radiation for the treatment of anal cancer is currently under investigation in Sweden with the Proton Versus Photon Therapy in Anal Squamous Cell Carcinoma phase 2 study, with a primary end point of reduction in higher grade 2 hematologic toxicity and several other secondary toxicity and quality-of-life end points.[94] A prior pilot study of pencil beam scanning proton therapy in 25 patients found that this approach is feasible, the authors of this study noted that the reported rates of grade 2+ toxicities with proton therapy were similar to RTOG 05-29 rates of grade 2+

toxicities, and if anything, grade 3+ GI toxicity was slightly higher (36% with protons compared to 21% in RTOG 05-29). In addition, although two patients did die while on treatment, one felt to be potentially related to therapy.[151]

Brachytherapy is used more commonly in Europe than in North America, where external beam treatment is favored. Brachytherapy may have a limited role with the advent of dose painting and the equivocal data on dose escalation for local tumor control. Historically, there are a number of reports of effective brachytherapy, including low-dose rate,[72,152] pulsed-dose rate,[153-155] and high-dose rate (HDR) techniques.[156] Brachytherapy has usually been given 2 to 8 weeks after external beam therapy, although one schedule introduced HDR in the interval during split-course external beam therapy.[156] There is no agreement on whether the treatment volume should include the full extent of the initial primary cancer[72,155,156] or only the tumor remaining at the time of implant.[157] The brachytherapy dose depends on the composite dose of the total radiation prescription. Occasionally, significant toxicity has been encountered.

SEQUELAE OF THERAPY

Surveys of published studies suggest that the delivery of chemotherapy concurrently with RT is associated more with increases in acute rather than late normal tissue toxicity, beyond that expected with RT alone. Some nonrandomized series have described higher acute and late toxicity rates from combined modality therapy than those reported in the multicenter randomized trials. This probably results from the use of different criteria for recording and reporting toxicity.

In programs that combined RT, 96- to 120-hour infusions of 5-FU (750-1,000 mg/m^2/24 hour) and bolus injections of MMC (10-15 mg/m^2), moderate leukopenia, thrombocytopenia, anoproctitis, and perineal dermatitis were recorded in about 30% of patients after doses of 25 to 30 Gy in 2.5 to 3 weeks.[40,158] More profound proctitis and dermatitis occurred in up to 55% of those who received from 50 Gy in 4 to 5 weeks to 59.4 Gy in 6.5 weeks.[40,103] When CDDP has been substituted for MMC, marrow toxicity is less, but at radiation doses of 59.4 Gy in 6.5 weeks, acute soft tissue toxicity rates are similar.[73,86] Most large studies of RT, 5-FU, and MMC or CDDP

reported some mortality (<2% overall) associated with acute toxicity, usually as a result of neutropenia with sepsis. This risk can potentially be reduced with prophylactic antibiotics[39] and aggressive supportive care.

Serious late toxicity has not been reported after doses of 30 Gy in 3 weeks with 5-FU and MMC, but significant complications, often requiring surgery, were recorded in about 5% to 10% of those receiving higher radiation doses (see Table 62.5). A review of anal cancer management in Denmark from 1995 to 2003 found 5-year cumulative incidences of tumor- and treatment-related colostomy of 26% (95% CI, 21%-32%) and 8% (95% CI, 5%-12%), respectively.[159] In the randomized RTOG-9811 trial, in those who received RT, 5-FU, and MMC, only 10 of the 30 colostomy procedures performed by about 3 years were for treatment-related problems, a crude rate of about 3%.[60] It is probable that some reports, many of which were retrospective, also overlooked some treatment-related toxicity. For example, a large cohort study of 556 women aged 65 years or above who developed anal cancer showed a higher risk of pelvic fracture, principally of the hip, in those who received radiation (n = 399) compared to those not irradiated (n = 157). The cumulative 5-year fracture rate was 14% versus 7.5% ($P < .01$).[160] One of the objectives of current 3D conformal and IMRT techniques is to reduce RT dose to the proximal femurs.

There are two additional areas of possible toxicity that need further study. Pelvic RT increases the risk of secondary malignancies,[161] and some of the chemotherapy agents used to treat anal cancer also are associated with a raised risk; these risks have not been quantified in detail for patients treated for anal cancer. Second, in the only report so far of long-term follow-up of patients in a randomized trial, it was found that there were more deaths due to causes other than cancer, particularly cardiovascular related, in the first 10 years following treatment with RT, 5-FU, and MMC.[77] This difference reached +9% at 5 years, but the effect almost disappeared by 10 years. The magnitude of this difference was less than the reduction in deaths from anal cancer. Information from other randomized trials is needed to determine whether this observation was a chance phenomenon or a risk that should be addressed by further research.

Although preservation of anorectal anatomy is an advantage of treatment by chemoradiation, late anorectal function is often abnormal. Side effects of treatment are very common and may cause patients considerable discomfort

and social disability, although they are often graded as only level 1 or 2 toxicity.[162-165] These effects include changes in anorectal function, such as urgency and frequency of defecation, bleeding from anorectal telangiectasia, perineal dermatitis, pelvic fibrosis, dyspareunia, and impotence. They are usually managed medically with varying success. Systematic and prospective evaluations of the function of the anorectum and other organs potentially affected by treatment are now being reported, as are formal quality-of-life studies.[98,166] There is often dissociation between a patient's and their physician's assessment of anal and rectal function and continence and physiologic measurements of anorectal function. The few studies in this area have been inconclusive.[165,167] Prospective studies of pelvic organ function can be expected to assist the development of radiation treatment protocols by facilitating correlation of function with radiation-chemotherapy interactions, radiation techniques and dose distributions, and time-dose factors.

PART G

Urinary Tract

CHAPTER 69

Cancer of the Kidney, Renal Pelvis, and Ureter

Hiram A. Gay and Jeff M. Michalski

ANATOMY

The kidneys are retroperitoneal structures located at the level between the 11th rib and the transverse process of the 3rd lumbar vertebral body. Usually, the right kidney is inferior to the right hepatic lobe and slightly inferior to the left kidney. The renal axis runs parallel to the lateral margin of the psoas muscle. Each kidney is approximately 11 to 12 cm in length. The kidney is encased by a fibrous capsule and surrounded by perinephric fat enveloped by Gerota fascia. At the renal hilus are the pelvis, ureter, renal artery, and vein. The organs adjacent to the right kidney include the liver superiorly, the duodenum and the vertebral bodies medially, and the transverse colon and small bowel anteriorly. On the left, the kidney abuts the spleen laterally; the stomach, pancreas, and vertebral bodies medially; and the small bowel and colon anteriorly.

The kidney consists of the cortex (glomeruli, convoluted tubules) and the medulla (Henle loops, collecting ducts, and pyramids of converging tubules). Each papilla opens in the minor calyces, which unite in the major calyces and drain into the renal pelvis. The calyceal collecting systems lie on the anteromedial surface of each kidney. The ureteropelvic junction is variable in position but is the landmark to separate the renal pelvis and the ureter. The ureters course posteriorly and inferiorly, paralleling the lateral border of the psoas muscle until they curve anteriorly to join the bladder at the trigone. The mucosal surfaces of the renal collecting tubules, calyces, renal pelvis, ureter, bladder, and urethra all have the same embryologic origin. The renal pelvis and ureter have the following layers: epithelium, subepithelial connective tissue, and muscularis, which is continuous with a connective tissue adventitial layer.

The lymphatics of the kidney and renal pelvis drain along the renal vessels. The right kidney drains predominantly into the paracaval and interaortocaval lymph nodes, and the left kidney drains exclusively to the para-aortic lymph nodes.[1] The lymphatic drainage of the ureter is segmented and diffuse. It may involve any of the renal hilar, abdominal para-aortic, paracaval, common iliac, internal iliac, or external iliac lymph nodes.

EPIDEMIOLOGY AND RISK FACTORS

The lesions discussed in this chapter are limited to adult renal cell carcinoma (RCC) and urothelial carcinoma of the renal pelvis and ureter. Lymphomas, primary retroperitoneal sarcomas, and Wilms tumors are discussed in Chapters 85, 76, and 91, respectively. Approximately 88% of solid renal masses are malignant, and the probability of malignancy is proportional to the size of the lesion.[2] RCCs constitute 80% to 85% of primary kidney tumors, whereas urothelial (transitional cell) carcinomas of the renal pelvis account for 7% of kidney tumors.

Renal Cell Carcinoma

Globally in 2020, the estimated new female and male kidney cancer cases in 2020 were 431,288 (2.2%), with 179,368 (1.8%) deaths. The male kidney cancer incidence and mortality age-standardized rate per 100,000 was 7.8 and 3.0 in more developed areas and 1.8 and 1.1 in less developed areas.[3]

In the United States in 2023, the estimated number of new cases of kidney and renal pelvis cancer was 81,800, with 14,890 deaths. Men are 1.7 times as likely as women to be diagnosed with kidney cancer. Kidney cancer incidence continued to increase by about 1% annually in both men and women. Kidney cancer survival is lower in Black patients for every histologic subtype of the disease. It is only similar overall because of a higher proportion than Whites of papillary and chromophobe RCC, which have a better prognosis than other types.[4]

The median age of RCC diagnosis is 65 years. Few large epidemiologic studies have demonstrated a significant link between occupational exposure and RCC. Danish workers exposed to trichloroethylene, an industrial solvent used as a metal degreaser, had an 8-fold higher incidence of kidney cancer.[5] Occupations associated with a higher risk of RCC are employment in the blast furnace, coke oven, or the iron and steel industry and exposure to asbestos, cadmium, dry-cleaning solvents, gasoline, and other petroleum products.[6] Several other environmental (eg, exposure to thorium dioxide), hormonal (eg, diethylstilbestrol), dietary (eg, high total energy intake and fried meats increase the risk, while vegetables, fruits, and alcohol are protective), cellular, and genetic factors have been associated with the development of RCC.[7-9]

Long-term cigarette smoking is associated with an increased risk of developing RCC. Obesity, diabetes, hepatitis C, and hypertension are also associated with a higher relative risk for the development of these tumors.[10-12] Cytotoxic chemotherapy may predispose childhood cancer survivors to translocation RCC bearing *TFE3* or *TFEB* gene fusions.[13]

Acquired cystic kidney disease (ACKD), which occurs in up to 50% of patients on dialysis for more than 3 years, increases 50-fold the risk of developing RCC.[14,15] The ACKD-associated RCC is seen mainly in males, occurs approximately 20 years earlier than in the general population, and is frequently bilateral (9%) and multicentric (50%).[15]

Several inherited cancer syndromes affect the kidney: von Hippel-Lindau (VHL) disease, hereditary papillary renal cancer (HPRC), hereditary leiomyomatosis RCC

(HLRCC), Birt-Hogg-Dubé (BHD), BAP1 tumor predisposition syndrome, hereditary succinate dehydrogenase (SDH)-deficient RCC, and constitutional chromosome 3 translocation. VHL is autosomal dominant caused by germline mutations of the VHL tumor suppressor gene, located on chromosome 3p25-26. The VHL protein is involved in cell cycle regulation and angiogenesis. In patients with VHL disease, loss of the sole functioning VHL allele in somatic tissues causes a situation similar to hypoxia, with elevated levels of HIF-1α despite normal oxygen tension.[16] The renal manifestations of VHL are kidney cysts and clear cell RCC. The mean age onset for VHL-associated clear cell RCC is 37 years, and periodic screening with magnetic resonance imaging (MRI) should start after the age of 10 years.[17]

Renal cancer has low penetrance in HLRCC syndrome, with an estimated incidence from 2% to 6% to 15%, and possibly as high as 32% of germline mutation–affected families, depending upon selection bias and imaging utilized. Individuals affected with HLRCC are at risk for renal carcinoma as well as cutaneous and uterine leiomyomas. Unlike other hereditary renal carcinoma syndromes, HLRCC renal cancer usually presents as a solitary lesion, can be highly aggressive, and can metastasize early, often initially to regional and distant lymph nodes. HLRCC renal malignancies may have an early onset. The gene responsible for HLRCC was found to encode fumarate hydratase (FH), a Krebs cycle enzyme. Loss of FH shunts the cycle to overaccumulate intracellular fumarate, leading to a state of pseudohypoxia through overexpression of HIF. Overexpression of HIF and upregulation of HIF-regulated genes are postulated to be the mechanism by which a mutation in FH leads to renal malignancy.[18]

HPRC is autosomal dominant with high penetrance and is characterized by multiple, bilateral, late-onset papillary RCCs. HLRCC is autosomal dominant with a predisposition to papillary type 2 RCC. Due to the multifocal bilateral nature of these lesions, patients with HPRC are often managed by surveillance and close observation with nephron-sparing surgery when the largest tumor reaches 3 cm. The proto-oncogene mesenchymal epithelial transition (MET) factor, located on the long arm of chromosome 7, is the gene responsible for HPRC. MET encodes for a tyrosine kinase membrane receptor. The constitutively active tyrosine kinase allows for unregulated proliferation, transformation, and invasive potential.[18]

BHD is autosomal dominant with incomplete penetrance and is associated with multiple chromophobe and clear cell RCCs, papillary RCCs, and oncocytomas. Constitutional chromosome 3 translocation is associated with multiple, bilateral clear cell RCCs.[19]

SDH, formed by four subunits SDHA, SDHB, SDHC, SDHD, and an assembly factor SDHAF2, functions as a critical respiratory enzyme. Biallelic inactivation of genes encoding any of the components, mainly in the presence of a germline mutation, causes loss of function of the entire enzyme complex. Subsequent development of SDH-deficient neoplasms includes pheochromocytoma/paraganglioma, gastrointestinal stromal tumor, and RCC. SDH-deficient RCC accounts for 0.05% to 0.2% of RCCs,

frequently occurs in young adults (median age: 35 years; range: 14-80 years) and a slight male predominance (M:F ratio: 1.8:1). Up to 30% of cases present as bilateral or multifocal tumors.[20]

Autosomal dominant polycystic kidney disease does not appear to increase the incidence of RCC. However, the tumors are more often multicentric (28% vs 6%), bilateral (12% vs 1%-5%), and sarcomatoid in type (33% vs 1%-5%) than in the general population.[21]

Renal Pelvis and Ureter Carcinoma

Urothelial carcinoma of the upper urinary tract accounts for 7% of all kidney tumors and 5% of all urothelial malignancies.[22] The incidence of bilateral upper urinary tract tumors is 1.5% to 2% for synchronous and 6% to 8% for asynchronous presentations.[23] Renal pelvis tumors are found 2 to 3 times more commonly in men than in women, and the peak incidence is in the fifth and sixth decades of life. Because the mucosal surfaces of the renal pelvis, ureter, and bladder have the same embryologic origin, many of the etiologic factors in the renal pelvis and ureter tumors also apply to urinary bladder tumors. Urothelial carcinomas of the upper urinary tract tend to be multifocal due to "field cancerization," which may be caused by exposure of the urothelium to potential carcinogens. Urothelial tumors can also spread to urothelial structures that are either distal or proximal to the primary tumor and are referred to as "drop metastases." About 40% to 50% of patients with upper urinary tract tumors will have synchronous or metachronous bladder cancer.[24,25]

Cigarette smoking is the most important factor contributing to the overall incidence of urothelial cancer in Western countries. Patients with Lynch syndrome, an autosomal dominant genetic condition due to inherited mutations that impair DNA mismatch repair, have an increased risk of developing urinary tract cancer.[26]

Exposure to aristolochic acid has been associated with acute, near end-stage renal disease. Aristolochic acid is commonly found in the Aristolochiaceae family of plants, which is commonly used in Chinese herbal medicine. A high incidence of cellular atypia and urothelial carcinoma of the renal pelvis, ureter, and bladder has been associated with aristolochic acid nephropathy.[27] Arsenic-contaminated water has been associated with a high incidence of upper urinary tract urothelial carcinoma in Taiwan.[28] Prolonged heavy phenacetin-containing analgesic use can lead to urothelial carcinomas of the renal pelvis, ureter, and bladder (which may be multiple and bilateral).[29]

Balkan endemic nephropathy (BEN) is a chronic tubulointerstitial disease of unknown etiology most commonly reported in southeastern Europe. A high frequency of urothelial atypia, occasionally progressing to tumors of the renal pelvis and urethra but also involving the bladder, is associated with BEN.[29]

NATURAL HISTORY

Renal Cell Carcinoma

Primary renal cell tumors may spread by local infiltration through the renal capsule to involve the perinephric fat and Gerota fascia. The tumor may grow directly along the venous channels to the renal vein or vena cava. Lymph node metastases occur with an incidence of 9% to 27% and most often involve the renal hilar, para-aortic, and paracaval lymph nodes.[30,31] The renal vein is invaded by tumor in 21% of cases, and the inferior vena cava is invaded in as many as 4% of cases.[32]

Approximately 45% of patients with RCC have localized disease, 25% have regional disease, and about 30% have evidence of distant metastases at the time of diagnosis.[31,33] About 1% to 3% of patients with metastases have solitary lesions.[34] About half of the patients with RCC eventually develop metastatic disease.[35]

Among patients presenting with metastatic RCC, metastatic sites include lung, bone, brain, liver, adrenal gland, and distant lymph nodes. RCC can metastasize to unusual sites like nasal sinuses, skin, penis, and others. Patients with metastatic disease at diagnosis have a poor prognosis, with an expected survival of less than 5 years, regardless of the site of metastasis.[31,33]

Renal Pelvis and Ureter Carcinoma

Upper urinary tract carcinoma is frequently a multifocal process. Patients with cancer at one site in the upper urinary tract are at significant risk for the development of tumors elsewhere along the urothelium. The probability of multifocal occurrence is greatest in patients with large tumors and those with carcinoma in situ. Ureteral tumors tend to occur in the distal third of the ureter.

Urothelial carcinoma of the upper urothelial tract may spread by direct extension and hematogenous and lymphatic metastases. Implantation of tumor cells in the bladder has been demonstrated, especially in previously traumatized areas. The incidence of lymph node metastasis is highly dependent on the grade of the primary tumor. Low-grade tumors have a very low metastatic propensity. In a series of 94 patients, none of the 43 low-grade tumors had lymph node metastasis, compared with 3 of 22 grade 3 or 4 tumors.[36] Lymph node metastases were reported in 9 of 26 patients selected to receive adjuvant radiotherapy (RT).[37]

CLINICAL PRESENTATION

Renal Cell Carcinoma

Patients with RCC may present with an occult primary tumor or with signs and symptoms attributable to a local mass or systemic paraneoplastic syndromes. Gross hematuria, palpable flank mass, and pain describe a classic triad that occurs only in 5% to 10% of patients.[38,39] Indeed, a finding of the classic triad often suggests advanced disease with a poor prognosis. The most frequent symptom associated with RCC is gross or microscopic hematuria, when there is invasion of the collecting system.[40] Scrotal

varicoceles, mostly left sided, are observed in 11% of men with RCC.[41] Other symptoms include anemia, hepatic dysfunction in the absence of liver metastases (called Stauffer syndrome and due to a paraneoplastic elevation in alkaline phosphatase), secondary amyloidosis, fever, hypercalcemia, cachexia, erythrocytosis, thrombocytosis, and a syndrome resembling polymyalgia rheumatic.[41-47] RCC presenting as an incidental mass on a diagnostic imaging study ordered for other purposes accounts for 61% of all diagnoses.[48]

A wide range of paraneoplastic syndromes has been associated with RCC. Parathyroid-like hormones, erythropoietin, renin, gonadotropins, placental lactogen, prolactin, enteroglucagon, insulin-like hormones, adrenocorticotropic hormone, and prostaglandins have been identified in patients with RCC.[43,49]

Renal Pelvis and Ureter Carcinoma

Gross or microscopic hematuria occurs in 70% to 95% of patients with renal pelvis or ureter tumors.[22] The other less common symptoms include pain (8%-40%), bladder irritation (5%-10%), or other constitutional symptoms (5%). About 10% to 20% of patients may present with a flank mass secondary to tumor or hydronephrosis.

DIAGNOSTIC WORKUP

Renal Cell Carcinoma

Renal masses are not uncommon, and most of them are benign. A central renal mass may suggest the presence of urothelial carcinoma; if so, urine cytology, ureteroscopy, and biopsy should be considered. Renal masses are frequently diagnosed as incidental findings during abdominal imaging for metastatic evaluation for an unrelated malignancy or other disease. An algorithm for the workup of renal masses has been proposed.[50] Most contrast-enhancing masses tend to be malignant, and the odds ratio of malignancy increases with increasing size.[51] No further workup is necessary if computed tomography (CT) or ultrasound clearly identify the mass as a cyst. If a solid lesion is identified, then tumor removal by nephrectomy should be considered. In the case of small lesions, a follow-up CT scan to evaluate the potential growth of the mass may raise the suspicion of malignancy. The diagnostic and staging workup for RCC is given in Table 69.1. The diagnosis of RCC is established clinically and radiographically in most cases. Pathologic confirmation is often made at the time of nephrectomy.

TABLE 69.1 DIAGNOSTIC WORKUP FOR RENAL CELL CARCINOMA

General
History and physical examination
If multiple renal masses, ≤46 years,[52] or family history, consider genetic evaluation.
Avoid biopsy if resection is being considered. Consider core-needle biopsy (FNA not adequate), if clinically indicated, for small lesions to confirm the diagnosis or guide surveillance, cryosurgery, or

radiofrequency ablation strategies.
Radiographic studies
Abdominal ± pelvic CT (preferred because it shows calcification and better visualization of other body parts) or abdominal MRI with or without contrast, depending on renal function. MRI is superior to CT when evaluating the inferior vena cava and right atrium for tumor involvement.
Consider CT urography, which allows imaging of both the renal parenchyma and the collecting system.
As clinically indicated to rule out metastases:
Chest CT (preferred) or chest x-ray
Bone scan if the patient has bone pain or has an elevated alkaline phosphatase
Brain MRI with or without contrast depending on renal function, if clinical signs, presentation, and symptoms are suggestive of brain metastases
Laboratory studies
Urinalysis
Complete blood cell count (CBC)
Comprehensive metabolic panel (including LDH, serum corrected calcium, liver function tests, blood urea nitrogen, and serum creatinine)

CT, computed tomography; FNA, fine-needle aspiration; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging.

Once a radiographic diagnosis is made, a staging evaluation should be undertaken, including a complete history and physical examination, complete blood count, and liver and kidney function tests. A metastatic workup should include a chest CT and an abdominal/pelvic CT or abdominal MRI scan of the abdomen. Patients with symptoms suggestive of bone metastases and those with an elevated alkaline phosphatase level should undergo a bone scan. If metastatic lesions are detected, histologic confirmation should be made by biopsy of either the metastatic focus or the primary tumor. MRI can be valuable when evaluating the extent of involvement of the collecting system or inferior vena cava, or radiographic contrast cannot be administered. Renal arteriography is sometimes helpful in planning surgery.

Renal Pelvis and Ureter Carcinoma

The diagnostic workup for renal pelvis and ureter carcinoma is listed in Table 69.2. Staging includes a complete history and physical examination, complete blood count, and liver and kidney function tests. CT urography is now used to evaluate patients with renal pelvis carcinoma. CT or MRI of the abdomen and pelvis before and after contrast administration gives useful information regarding the possible extension of the tumor outside the collecting system. Ureteroscopic visualization of the tumor is desirable, and tissue biopsy through a ureteroscope should be performed if feasible. Cystoscopy is very important due to the high incidence of multiple tumors. Urine cytology may help determine tumor grade if tissue is not available, but false-negative rates can be high for upper tract and low-grade tumors.

TABLE 69.2 DIAGNOSTIC WORKUP FOR RENAL PELVIS AND URETER CARCINOMA

General
History and physical examination
Radiographic studies
CT of the abdomen and pelvis or MRI urogram
Multidetector CT urography (CTU)
Chest CT or chest radiograph
Bone scan if the patient has bone pain or has an elevated alkaline phosphatase
Brain MRI, if suspecting brain metastases
Special tests
Cystoscopy, the entire urinary tract has to be evaluated due to the high incidence of multiple tumors
Ureteroscopic visualization of the tumor is desirable, and tissue biopsy through a ureteroscope may be performed if feasible.
Urine cytology may help determine tumor grade if tissue is not available. The false-negative rate can be high in upper tract and low-grade tumors.
Percutaneous biopsy, if indicated
Laboratory studies
Complete blood cell count
Comprehensive metabolic panel (including liver function tests, blood urea nitrogen, and serum creatinine)
Urinalysis

CT, computed tomography; MRI, magnetic resonance imaging.

STAGING

Renal Cell Carcinoma

The American Joint Committee on Cancer (AJCC) system is currently being utilized to stage patients with RCC (Table 69.3).[51] T1 and T2 cancers are limited to the kidney. T3 tumors extend into major veins or perinephric tissues, but not into the ipsilateral adrenal gland and not beyond Gerota fascia. T4 tumors invade beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland). Regional lymph node metastases may involve spread to the renal hilar, caval, and aortic drainage sites. Metastasis in regional lymph node(s) is classified as N1.[51]

TABLE 69.3 2017 KIDNEY CANCER TNM STAGING AJCC UICC

T Category	T Criteria
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
T1	Tumor ≤7 cm in greatest dimension, limited to the kidney
T1a	Tumor ≤4 cm in greatest dimension, limited to the kidney
T1b	Tumor >4 cm but ≤7 cm in greatest dimension limited to the kidney
T2	Tumor >7 cm in greatest dimension, limited to the kidney

T Category	T Criteria
T2a	Tumor .7 cm but ≤10 cm in greatest dimension, limited to the kidney
T2b	Tumor .10 cm, limited to the kidney
T3	Tumor extends into major veins or perinephric tissues, but not into the ipsilateral adrenal gland and not beyond Gerota fascia.
T3a	Tumor extends into the renal vein or its segmental branches, or tumor invades the **pelvicalyceal system**, or invades perirenal and/or renal sinus fat but not beyond Gerota fascia.
T3b	Tumor extends into the vena cava below the diaphragm.
T3c	Tumor extends into the vena cava above the diaphragm or invades the wall of the vena cava.
T4	Tumor invades beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland).

N Category[a]	N Criteria
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)

M Category	M Criteria
M0	No distant metastasis
M1	Distant metastasis

AJCC Prognostic Stage Groups			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1 or T2	N1	M0
	T3	N0, N1	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

Histologic grade (G)	
GX	Grade cannot be assessed.
G1	Nucleoli absent or inconspicuous and basophilic at 400× magnification
G2	Nucleoli conspicuous and eosinophilic at 400× magnification, visible but not prominent at 100× magnification
G3	Nucleoli conspicuous and eosinophilic at 100× magnification
G4	Marked nuclear pleomorphism and/or multinucleate giant cells and/or rhabdoid and/or sarcomatoid differentiation

TNM, tumor-node-metastasis.

[a]The regional lymph nodes are as follows: renal hilar, caval (precaval, interaortocaval, paracaval, and retrocaval), and aortic (preaortic, para-aortic, and retroaortic).

Renal Pelvis and Ureter Carcinoma

Tumors of the renal pelvis and ureter have a natural history that is not too dissimilar from other urothelial malignancies originating in the bladder. Their prognoses are dependent on tumor invasiveness and pathologic grade. The 2017 AJCC eighth edition staging classification for renal pelvis and ureter carcinoma is shown in Table 69.4.[51]

TABLE 69.4 2017 TUMORS OF THE RENAL PELVIS AND URETER TNM STAGING AJCC UICC

T Category	T Criteria		
TX	Primary tumor cannot be assessed.		
T0	No evidence of primary tumor		
Ta	Papillary noninvasive carcinoma		
Tis	Carcinoma in situ		
T1	Tumor invades subepithelial connective tissue.		
T2	Tumor invades muscularis.		
T3	For renal pelvis only: Tumor invades beyond the muscularis into peripelvic fat or into the renal parenchyma. For ureter only: Tumor invades beyond the muscularis into the periureteric fat.		
T4	Tumor invades adjacent organs, or through the kidney into the perinephric fat.		
N Category[a]	**N Criteria**		
NX	Regional lymph nodes cannot be assessed.		
N0	No regional lymph node metastasis		
N1	Metastasis in a single lymph node, ≤2 cm in greatest dimension		
N2	Metastasis in a single lymph node, >2 cm; or multiple lymph nodes		
M Category	M Criteria		
M0	**No distant metastasis**		
M1	Distant metastasis		
AJCC Prognostic Stage Groups

PATHOLOGIC CLASSIFICATION

Renal Cell Carcinoma

RCC is a group of malignancies arising from the epithelium of the renal tubules and comprises 90% of all malignancies in the kidney. The World Health Organization (WHO) classifies renal cell tumors into six main categories: clear cell renal tumors (clear cell RCC and multilocular cystic renal neoplasm of low malignant potential), papillary renal tumors (papillary adenoma and papillary RCC), oncocytic and chromophobe renal tumors (oncocytoma, chromophobe cell renal carcinoma, and other oncocytic tumors of the kidney), collecting duct tumors (collecting duct carcinoma), other renal tumors (clear cell papillary renal cell tumor, mucinous tubular and spindle cell carcinoma, tubulocystic RCC, acquired cystic disease–associated RCC, eosinophilic solid and cystic RCC, and RCC not otherwise specified [NOS]), and molecularly defined renal carcinomas (TFE3-rearranged RCCs, TFEB-altered RCCs, ELOC [formerly TCEB1]-mutated RCC, FH–deficient RCC, HLRCC syndrome–associated

RCC, SDH-deficient RCC, anaplastic lymphoma kinase–rearranged RCCs, medullary carcinoma NOS, SMARCB1-deficient medullary-like RCC, SMARCB1-deficient undifferentiated RCC NOS, and SMARCB1-deficient dedifferentiated RCCs of other specific subtypes).[19]

Clear cell RCC is the most common (80%-90% of tumors), followed by papillary RCC (10%-15%) and chromophobe RCC (4%-5%). Renal medullary carcinoma is a very aggressive malignancy mostly associated with young Black patients with sickle cell trait, and less commonly, sickle cell disease.[53]

Renal Pelvis and Ureter Carcinoma

More than 90% of malignant tumors arising from the renal pelvis and ureter are urothelial (also called transitional cell) carcinomas. The WHO classifies urothelial tumors as invasive urothelial carcinoma, or urothelial carcinoma with the following variants: with squamous differentiation, with glandular differentiation, with trophoblastic differentiation, nested, large nested, tubular and microcystic, micropapillary, lymphoepithelioma-like, plasmacytoid, giant cell, lipid-rich, clear cell (glycogen-rich), sarcomatoid, and poorly differentiated.[19]

PROGNOSTIC FACTORS

Renal Cell Carcinoma

The 5-year relative survival rate of patients with kidney cancer has increased from 65.9% in 2000 to 78% in 2015.[54] The stage at initial presentation remains the most important prognostic factor for RCC survival. Prognostic features for RCC are tumor, patient, and laboratory related. Tumor-related prognostic factors include stage, tumor size, tumor grade, histologic type, tumor necrosis, sarcomatoid transformation, and two or more sites of organ metastases. Patient-related factors include asymptomatic versus local symptoms versus systemic symptoms, weight loss, paraneoplastic syndromes, and an interval of less than a year from original diagnosis to the start of systemic therapy. Laboratory prognostic factors include thrombocytosis and elevated erythrocyte sedimentation rate or C-reactive protein.[51,55]

For patients with metastatic RCC, the following factors were predictive of survival in a retrospective study of 670 patients: low Karnofsky performance status (KPS) (<80), high lactate dehydrogenase (>1.5 times upper limit of normal), low hemoglobin (<lower limit of normal), high “corrected” serum calcium (>10 mg/dL or 2.5 mmol/L), and absence of prior nephrectomy.[56]

Lymph node metastases are associated with increased local recurrence and distant metastasis rates.[38,57-59] Nuclear grade, sarcomatoid component, tumor size, stage, and tumor necrosis increase the likelihood of lymph node involvement.[60] The risk of lymph node metastases is 20%.[61,62] Patients with lymph node metastases in radical nephrectomy specimens have a local failure rate of 21%, compared with only 4% in patients without

lymph node metastases ($P = .0002$).[59] A select group of patients with solitary metastases may have a 5-year survival rate of 25% to 35%.[63,64]

Nuclear grade, after stage, is the most important prognostic feature of clear cell carcinoma. Fuhrman developed a four-tier grading system that is based on nuclear and nucleolar size, shape, and content.[65] Fuhrman grade is the most widely used grading system. Grade is also an independent prognostic factor for papillary RCC and chromophobe RCC, especially when using standardized criteria.[66] Worsening pathologic grade is associated with poor 5-year disease-free survival.[33,38]

Papillary RCC has a 5-year survival rate of 90% and metastasizes less frequently than clear cell RCC. The RCC's spindle cell or sarcomatoid variants are associated with statistically significant inferior 5-year survival rates, compared with pure clear, or clear and granular histologic variants.[33,38]

Nuclear morphology strongly predicts tumor stage and prognosis.[65] High nuclear grade is associated with an increased incidence of advanced tumor stage, lymph node involvement, distant metastases, renal vein involvement, tumor size, and perirenal fat involvement. In a series of 190 patients reported by Bretheau and colleagues,[67] the 5-year actuarial survival rates of patients with grade I, II, III, and IV tumors were 76%, 72%, 51%, and 35%, respectively. Sarcomatoid differentiation has a significantly poorer prognosis than the clear cell or granular cell subtypes. Almost half of patients with sarcomatoid RCC have bone metastases at presentation. The median survival time of patients with sarcomatoid renal cell cancer is only 6.6 months, compared with 19 months for other histologic types.[68]

Nomograms and algorithms have been described to facilitate the determination of cancer-free survival in patients with RCC. Based on 601 patients treated at Memorial Sloan Kettering Cancer Center with radical nephrectomy, Kattan used variables including patient symptoms (incidental, local, or systemic), histology (chromophobe, papillary, or conventional), tumor size, and pathologic stage to predict the risk of recurrence after surgery (this uses older 1997 staging and is available at the Memorial Sloan Kettering Cancer Center website https://www.mskcc.org/nomograms/renal/post-op).[69] Frank et al from the Mayo Clinic developed a predictive algorithm based on 1801 patients treated with radical nephrectomy.[70] This system combines stage, size, grade, and necrosis to predict patient survival. Finally, Zisman et al from the University of California, Los Angeles (UCLA) have developed an algorithm that utilizes AJCC tumor-node-metastasis stage, Fuhrman grade, and Eastern Cooperative Oncology Group (ECOG) performance status to divide patients into low-risk, intermediate-risk, and high-risk groups.[71] This model is also known as the UCLA-integrated staging system.

Renal Pelvis and Ureter Carcinoma

The major prognostic factors in patients with renal pelvis or ureter carcinoma are the initial stage and grade of the tumor. There is no significant difference in prognosis

between urothelial carcinomas originating in the ureter compared to those in the renal pelvis.[72]

High-grade tumors are associated with a higher incidence of metastases and worse survival. Corrado and associates[73] reported 5-year survival rates of 83%, 75%, 52%, and 0% for grades 1 through 4, respectively. These results are comparable to those described by Heney and colleagues,[74] who reported 100% survival for grade 1, 81% for grade 2, and 0% for grade 3. Local recurrence was identified in three of 24 patients with grade 3 tumors. No survival differences were seen for patients with papillary versus solid tumors. In the series of Charbit and coworkers,[25] lymph node metastases were seen exclusively in patients with high-grade tumors. Of tumor-related deaths, 90% were in patients with high-grade tumors. Hall reported a retrospective series of 252 patients treated surgically for upper urinary tract urothelial cancers.[75] Significant factors for recurrence included high tumor grade and advanced clinical stage. Older patients and patients treated with parenchymal-sparing surgical procedures had higher recurrence rates. In their series of 77 patients, Akdogan reported from a multivariate analysis that higher recurrence rates were associated with tumor location, higher grade, and advanced T-stage.[76] Tumors in the ureters were more likely to recur than tumors involving the renal pelvis. In a series of 86 patients, Park also reported a higher rate of recurrence in ureteral tumors compared to those arising in the renal pelvis.[77]

A prior history of bladder cancer has been reported to worsen the prognosis of patients with second urothelial cancers involving the upper tracts.[76,78] From the Memorial Sloan Kettering Cancer Center series of 129 patients, multivariate analysis demonstrated that patients with advanced primary tumors and a prior history of bladder cancer were associated with worse disease-free survival.[78]

Flow cytometry may aid in estimating long-term prognosis. In a multivariate analysis, Corrado and colleagues[73] demonstrated that, although stage and grade were the most important prognostic indices, DNA pattern (diploid vs nondiploid) and the number of lesions (unifocal vs multifocal) identified at initial diagnosis also determined prognosis. Patients with diploid tumors had a 79% survival rate, compared with only 46% in patients with nondiploid tumors ($P = .0003$). Recent data suggest that hypermethylation of the promoter region of patients with urothelial cancers of the urothelium is associated with a worse prognosis. Tumors of the renal pelvis and ureters demonstrate hypermethylation in 94% of cases compared to 76% of similar-appearing tumors in the bladder ($P < .0001$). Hypermethylation was also associated with higher tumor stage, tumor progression, and mortality.[79]

GENERAL MANAGEMENT

Renal Cell Carcinoma

Surgery is the therapeutic foundation for the management of kidney cancer. RT has an important and growing role in the palliative management of RCC. Although RCC is traditionally considered to be radioresistant, it has a clear dose-response to radiation.[80,81]

As long as sufficient radiation dose is delivered to the tumor while respecting normal tissue dose constraints, RCC "radioresistance" can be overcome with modern techniques. National consensus guidelines recommend the following surgical options depending on the stage:

- pT1a: partial or radical nephrectomy, active surveillance, or ablative techniques
- pT1b: partial or radical nephrectomy, active surveillance, or ablative techniques in selected patients
- Stage II: partial or radical nephrectomy
- Stage III: radical or partial nephrectomy if clinically indicated
- Stage IV: if potentially surgically resectable primary, cytoreductive nephrectomy in select patients or systemic therapy especially in clear cell histology with poor-risk features

Surgery

A radical nephrectomy includes a perifascial resection of the kidney, perirenal fat, regional lymph nodes, and ipsilateral adrenal gland. It is the preferred treatment if the tumor extends into the inferior vena cava and usually requires the assistance of a cardiovascular surgeon if there is a caval or atrial thrombus. Adrenalectomy is not indicated when imaging shows a normal adrenal gland or if the tumor is not high risk.[82] An experienced team should be involved in the context of thrombus, as treatment-related mortality can reach 10%. Open, robotic, and laparoscopic techniques may be used to perform a radical nephrectomy. Improved preoperative assessment with CT can identify patients who have no significant risk of adrenal gland involvement.[83] In 76% of cases, the adrenal gland can be spared during surgery. The European Organisation for Research and Treatment of Cancer conducted a randomized trial of radical nephrectomy with or without an elective lymph node dissection, and there was no survival advantage between the two study groups. The incidence of unsuspected lymph node metastases was low (4%).[84] Nevertheless, the lymph node dissection does provide valuable prognostic information.

Radical nephrectomies should be avoided if nephron-sparing surgery is feasible for T1a and T1b renal tumors. In this setting, nephron-sparing surgery has shown equivalent outcomes to radical nephrectomy.[85,86] Radical nephrectomy–induced chronic renal insufficiency is associated with an increased risk of cardiovascular death and death from any cause.[87] For this reason, nephron-sparing surgery is preferred in T1a and T1b tumors. Nephron-sparing surgery is also preferred in patients with hereditary RCC to preserve renal function and decrease the risk of cardiovascular events.[88] In a matched pair analysis of 164 patients undergoing nephron-sparing surgery at the Mayo Clinic, the disease-free survival was 79%, which compared favorably to 77% in patients undergoing radical nephrectomy.[89] In 117 patients with renal tumors 4 cm or less undergoing partial nephrectomy at the Memorial Sloan Kettering Cancer Center, the 5-

year freedom from recurrence was 98.6% compared to 96.4% in a similar group of 173 patients undergoing radical nephrectomy. Compared with patients undergoing partial nephrectomy, those undergoing radical nephrectomy were at a higher risk of chronic renal insufficiency.[90] There is some risk that sparing of the renal parenchyma may leave microscopic residual tumor or inadequately treat multifocal cancers.[91-93] Bilateral RCC occurs in 2% to 3% of patients. In these patients, nephron-sparing surgery is an attractive option because bilateral radical nephrectomy sentences the patient to a lifetime of renal dialysis or the need for a renal transplant.

Following surgery, 20% to 30% of patients with localized tumors relapse, with a median time to relapse of 1 to 2 years and most occurring within 3 years. Although there is no role for adjuvant therapy after surgery, a number of recent trials are exploring the role of targeted therapy.

Patients who have local symptoms, such as hematuria, pain, hypertension, or other paraneoplastic syndromes, may benefit from a palliative nephrectomy. Spontaneous regression of metastatic renal cell cancer after nephrectomy has been reported. In an extensive literature review, the incidence of regression of metastatic foci induced by nephrectomy was 0.8% (4/474 patients).[35] Cytoreductive surgery performed to prolong or increase the response of metastatic disease in response to systemic therapy may be beneficial.[94-96]

Thermal Ablation

The minimally invasive ablative technologies of cryoablation and radiofrequency ablation (RFA) have emerged as potential treatment options for clinically localized RCC, especially in the older patients or patients with a solitary kidney or comorbidities impeding surgery. Long-term oncologic efficacy for these modalities remains to be established. The most favorable lesions for this approach are less than 4 cm and in the periphery of the kidney. Relative contraindications for RFA and cryoablation include distant metastases, tumors greater than 5 cm, tumors in the hilum or central collecting system, and life expectancy less than a year. A meta-analysis comparing cryoablation and RFA suggested that cryoablation results in fewer retreatments and improved local tumor control and that cryoablation may be associated with a lower risk of metastatic progression than RFA.[97]

Systemic Therapy in the Treatment for Relapsed, Metastatic, or Unresectable Renal Cell Carcinoma

National consensus guidelines recommend the following preferred first-line systemic therapies for favorable-risk clear cell histology: axitinib plus pembrolizumab, cabozantinib plus nivolumab, lenvatinib plus pembrolizumab. First-line systemic therapies for poor-/intermediate-risk clear cell histology include axitinib plus pembrolizumab, cabozantinib plus nivolumab, lenvatinib plus pembrolizumab,

ipilimumab plus nivolumab, and cabozantinib. For non–clear cell histology, first-line systemic therapies include cabozantinib.

Axitinib is a small-molecule tyrosine kinase inhibitor targeting vascular endothelial growth factor (VEGF), c-KIT, and platelet-derived growth factor receptor (PDGFR). Pembrolizumab binds to the programmed cell death protein 1 (PD-1) receptor, blocking both immune-suppressing ligands, programmed death ligand-1 (PD-L1) and PD-L2, from interacting with PD-1 to help restore T-cell response and immune response. Cabozantinib is a small-molecule inhibitor of the tyrosine kinases c-Met and VEGFR2. Nivolumab is an antibody that selectively blocks the interaction between PD-1 and its ligands. Lenvatinib exerts its mechanism of action via inhibition of multiple receptors of tyrosine kinases: VEGFR1 (FLT1), VEGFR2 (KDR), VEGFR3 (FLT4), FGFR-1, FGFR-2, FGFR-3, FGFR-4, PDGFRa, RET, and c-KIT.

Metastasectomy

Patients with a solitary metastatic lesion have a 5-year survival rate of 24% (compared with 4% for those with more than one metastatic focus), and they may benefit from aggressive therapy.[98] The resection of one or a limited number of metastases in combination with nephrectomy or at relapse has been associated with a 13% to 50% 5-year survival in a small series of selected patients.[99-101] Selected lung, bone, brain, liver, and even pancreatic metastases, among other sites, have been treated using this approach.

Neoadjuvant (Preoperative) Radiotherapy

Neoadjuvant RT is not recommended in patients with resectable RCC. Two European studies were undertaken to test the efficacy of neoadjuvant/preoperative RT in RCC (Table 69.5). A prospective randomized study of neoadjuvant RT and nephrectomy versus nephrectomy alone was conducted in Rotterdam. No advantage was demonstrated in patients receiving 30-Gy RT in 2-Gy fractions concerning overall survival (OS) or survival free of distant metastasis. Neoadjuvant RT did appear to increase the rate of complete resectability in patients with locally advanced tumors.[102] Subsequent patients received 40 Gy in 2-Gy fractions. No benefit was demonstrated at the higher radiation dose.[103] In Sweden, a second prospective randomized clinical trial could also not demonstrate an advantage for neoadjuvant RT. In this trial, patients were randomly assigned to receive neoadjuvant RT to 33 Gy in 15 fractions administered to the flank with a betatron unit followed by nephrectomy or nephrectomy alone. Patients receiving neoadjuvant RT had a 5-year survival rate of 47%, compared with 63% for patients undergoing surgery alone.[104]

TABLE 69.5 SURVIVAL AFTER NEPHRECTOMY OR NEOADJUVANT RADIOTHERAPY AND NEPHRECTOMY FOR RENAL CELL CARCINOMA, PROSPECTIVE RANDOMIZED TRIALS

Study	Number of Patients	Radiation Dose/ Fraction Size (Gy)	Treatment	5-Y Survival Rate (%)	Comments
van der Werf-Messing et al[102,103]	85	—	N	50	No significant survival difference
	89	30-40/2	N + NART		
Juusela et al[104]	50	—	N	63	No significant survival difference
	38	33/2.2	N + NART	47	

N, nephrectomy; NART, neoadjuvant radiotherapy.

Adjuvant (Postoperative) Radiotherapy

Adjuvant RT is not recommended in RCC after complete resection. Two prospective randomized studies testing the value of adjuvant RT did not demonstrate an advantage to patients receiving RT after surgery (Table 69.6). The first study from New Castle, UK, showed an inferior survival for patients receiving adjuvant RT compared with those treated by surgery alone.[105] Local recurrence rates were not affected by adjuvant RT. Four patients died of fatal hepatotoxicity after RT to a right-sided nephrectomy bed. Patients in this study received 55 Gy in 2.04-Gy daily fractions.[7] A second randomized study conducted by the Copenhagen Renal Cancer Study Group compared patients with stage II or III renal cell cancer treated with nephrectomy alone with patients who received nephrectomy and adjuvant RT to 50 Gy in 20 fractions to the kidney bed and regional ipsilateral and contralateral lymph nodes. No difference in the relapse rate was found between the two study groups. There were significant complications involving the stomach, duodenum, and liver in 44% of patients receiving adjuvant RT. Specifically, 19% of deaths in the RT group were attributed to RT-induced complications.[106]

TABLE 69.6 SURVIVAL AFTER NEPHRECTOMY OR NEPHRECTOMY AND ADJUVANT RADIOTHERAPY FOR RENAL CELL CARCINOMA, PROSPECTIVE RANDOMIZED TRIALS

Study	Stage	Number of Patients	Radiation Dose/Fraction Size (Gy)	Treatment	5-Y Survival Rate (%)	Local Recurrence (%)	RT-Related Mortality (%)	RT Complications (%)

[a]Interpolated from graph; number at risk not known.

Aref et al analyzed the patterns of failure in 116 patients undergoing nephrectomy for RCC. They observed that local regional failure is rare following nephrectomy and that

distant metastases are the main pattern of failure. Consequently, their data did not support the role of adjuvant radiation in RCC.[107] Moreover, a retrospective study of 1,344 patients who underwent 1,390 partial nephrectomies for kidney cancer found that positive surgical margins were not associated with an increased risk of local recurrence or metastatic disease.[108] A Surveillance, Epidemiology, and End Results–based study of adjuvant RT in sarcomatoid RCC did not show an OS benefit.[109]

In contrast, a meta-analysis including the two prospective randomized trials previously mentioned and five retrospective trials with 735 patients observed a significant reduction in locoregional failure with adjuvant RT ($P < .0001$). The patient accrual for all the studies combined spanned from 1968 to 1999. There was no difference in OS or disease-free survival. The authors proposed a prospective randomized trial using modern RT techniques for high-risk patients with tumor size greater than 5 cm, positive margins or gross residual disease, perinephric fat invasion, capsule invasion, renal vein/inferior vena cava invasion, positive lymph nodes, or high-grade histology.[110]

Stereotactic Ablative Radiation Therapy for Primary Treatment

The terms *stereotactic ablative radiation therapy* (SABR/SAbR) and *stereotactic body radiation therapy* (SBRT) are often used interchangeably. Some have suggested that the term *stereotactic ablative radiation therapy* (SABR/SAbR) should be used in reference to stereotactic therapies delivered with curative intent for patients with oligometastatic disease. In contrast, the term *stereotactic body radiation therapy* (SBRT) should be used to describe RT delivered with palliative intent to sites of metastases regardless of OS burden.[111]

SABR may be considered for medically inoperable patients with stage I kidney cancer or with stage II/III kidney cancer. Figure 69.1 shows SABR to a left renal mass 14 Gy × 3.

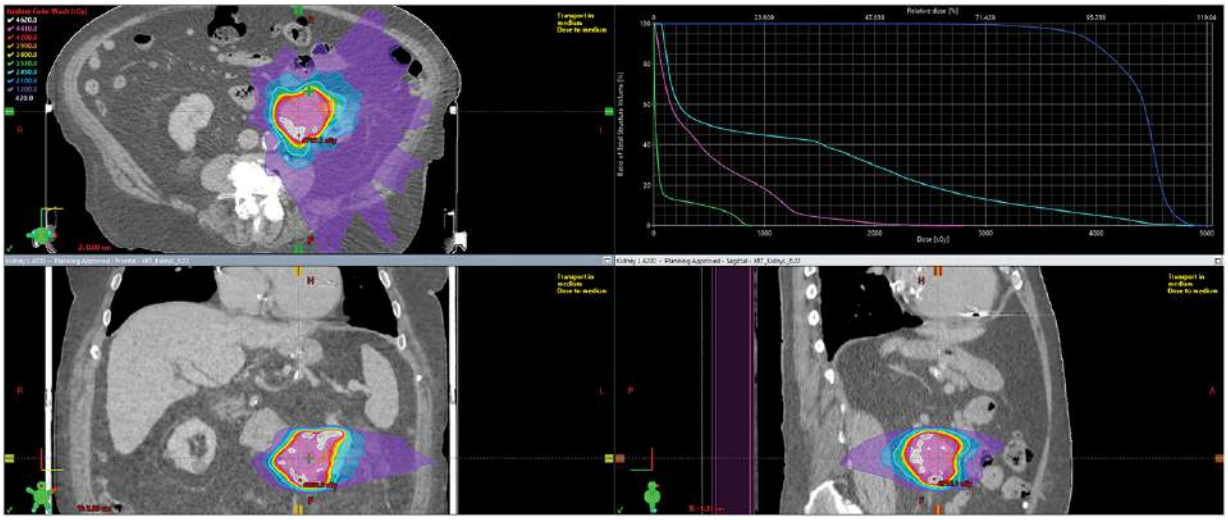

FIGURE 69.1 A 77-year-old man with a history of right renal mass status post radiofrequency ablation who now presents with a growing left renal mass. Definitive stereotactic ablative body radiation prescribed to 4,200 cGy in three fractions showing axial (left top), coronal (left bottom), dose-volume histogram (DVH) (right top), and sagittal (right bottom). Dose color wash values are 4,620 cGy (white), 4,410 Gy (magenta), 4,200 Gy (red), 3,990 (orange), 3,800 Gy (yellow), 3,570 Gy (green), 2,850 Gy (cyan), 2,100 Gy (blue), 2,000 Gy (pink), 1,260 Gy (purple), and 420 cGy (lavender). DVH structures from top to bottom (blue, planning target volume; light blue, internal target volume; purple, bowel; green, spinal cord). (Courtesy of Young Suk Kwon and Raquibul Hannan, UT Southwestern.)

Hannan et al reported the first phase 2 trial of SABR for patients with primary renal cancer. Patients with biopsy-confirmed radiographically enlarging primary RCC (≤5 cm) were enrolled. SABR was delivered in three (12 Gy) or five (8 Gy) fractions. Radiographic local control (LC) at 1 year was observed in 94% of patients, and this was accompanied by pathologic evidence of tumor response (hyalinization, necrosis, and reduced tumor cellularity) in all patients. By RECIST, 100% of the sites remained without progression at 1 year. SABR was well tolerated with no grade 2 or higher (acute or late) toxicities. The average glomerular filtration rate (GFR) declined from a baseline of 65.6 to 55.4 mL/min at 1 year ($P = .003$).[112]

An individual patient data meta-analysis from the International Radiosurgery Consortium of the Kidney included 190 patients treated with SABR for primary RCC across 12 institutions in five countries (Australia, Canada, Germany, Japan, and the United States). Single-fraction SABR was delivered in 43% of patients and multifraction SABR in 57% of patients. The median follow-up was 5 years. Median tumor diameter was 4 cm. Median baseline estimated glomerular filtration rate (eGFR) was 60 mL/min/1.73 m^2 and decreased by 14.2 mL/min/1.73 m^2 by 5 years post-SABR. Seven (4%) patients required dialysis post-SABR. The cumulative incidence of local failure at 5 years was 5.5% overall, with single-fraction SABR yielding fewer local failures than multifraction. Single fractions were as follows: 25 Gy ($n = 52$), 26 Gy ($n = 18$), and 22 Gy ($n = 6$). There were no grade 3 toxicities or treatment-related deaths. One patient developed an acute grade 4 duodenal ulcer and late grade 4 gastritis.[113]

A systematic review and meta-analysis of ablative RT for primary RCC included 383 tumors in 372 patients, most of whom were deemed inoperable. Weighted averages (ranges) of median follow-up, median age, and mean tumor size were 28.0 (5.8-79.2) months, 70.4 (62-83) years, and 4.6 (2.3-9.5) cm, respectively. RCC histology was confirmed in 78.9% of patients who underwent pretreatment biopsy. Dose fractionation varied, but 26 Gy in one fraction and 40 Gy in five fractions were the most common. The random-effect estimates for LC, grade 3 to 4 toxicity, and post-SABR eGFR change were 97.2%, 1.5%, and −7.7 mL/min, respectively. Six patients with preexisting renal dysfunction (2.9%) required dialysis. The authors concluded that renal SABR is locally effective and associated with low toxicity rates for primary RCC despite treatment of larger tumors in older, mostly medically inoperable patients.[114]

A phase II trial by the NRG (NRG-GU012), a randomized phase II SABR for metastatic unresected RCC receiving immunotherapy, will randomize patients between standard immunotherapy and SABR to the primary (42 Gy in three fractions) with standard immunotherapy.

Stereotactic Ablative Radiation Therapy for Oligometastatic Disease

A retrospective study of 47 patients with oligometastatic RCC treated with SABR to 88 metastases observed an LC rate of 91.5% at 2 years with no reported grade 3 or higher toxicity. The most common systemic therapies initiated after SABR were pazopanib (60.7%) and sunitinib (14.3%). The duration of first-line systemic therapy appeared unaffected by SABR. Improved freedom from systemic therapy was observed in patients with metachronous disease, solitary metastasis, and non–bone metastasis. One- and 2-year OS after SABR were 93.1% and 84.8%, respectively.[115]

A prospective phase II single-arm trial enrolled 23 patients who received SABR to 33 initial and 57 total sites. The median follow-up was 21.7 months. One-year progression-free survival (PFS) was 82.6%, and LC was 100%. There were no grade 3/4 toxicities, but there was one death due to immune-related colitis 3 months after SABR while on subsequent checkpoint inhibitor therapy, where an SABR contribution could not be excluded. One-year OS was 95.7%, and 1-year cancer-specific survival was 100%.[116]

A phase III trial by ECOG-ACRIN (EA8211), “Focused Radiation versus Systemic Therapy for Kidney Cancer Patients with Limited Metastasis, SOAR Trial,” will randomize patients to SABR followed by standard-of-care systemic therapy, to standard-of-care systemic therapy alone, in patients with RCC. Figure 69.2 shows SABR to a right adrenal oligometastasis 13 Gy × 3.

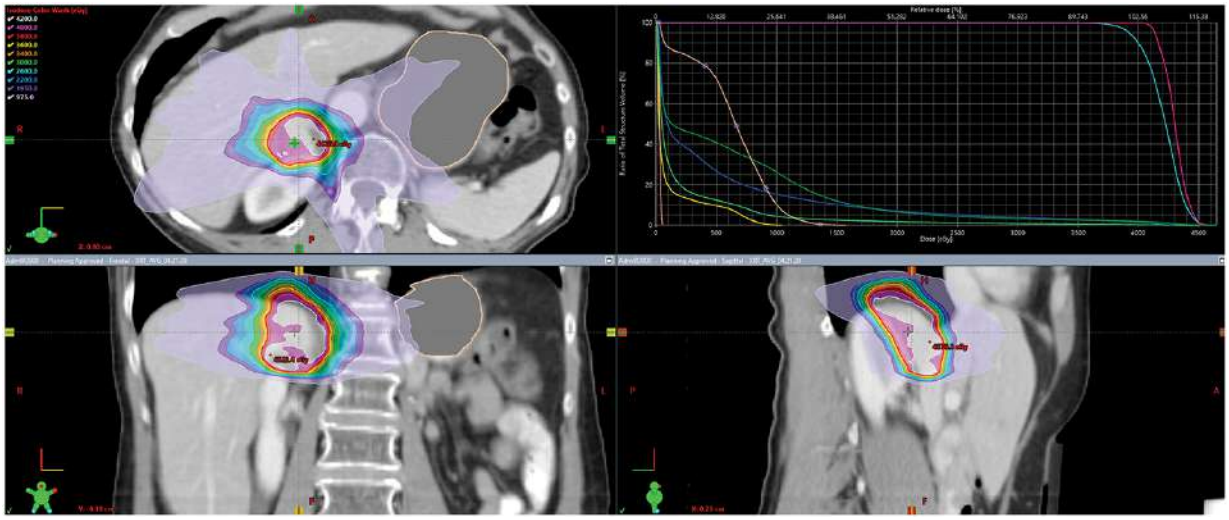

FIGURE 69.2 A 66-year-old woman with a history of left renal cell carcinoma with inferior vena cava tumor thrombus status post left radical nephrectomy with pathology revealing pT3b disease who has subsequently developed an oligometastatic lesion in the right adrenal gland. Definitive stereotactic ablative body radiation prescribed to 3,900 cGy in three fractions showing axial (top left), coronal (bottom left), dose-volume histogram (DVH) (top right), and sagittal (bottom right). Dose color wash values are 4,200 cGy (white), 4,000 Gy (magenta), 3,800 Gy (red), 3,600 Gy (yellow), 3,400 Gy (orange), 3,000 Gy (green), 2,600 Gy (cyan), 2,200 Gy (blue), 1,950 Gy (purple), and 975 cGy (lavender). DVH structures from top to bottom (magenta, internal target volume; cyan, planning target volume; orange, liver; green, R kidney; blue, R lung; yellow, esophagus). (Courtesy of Young Suk Kwon and Raquibul Hannan, UT Southwestern.)

Stereotactic Body Radiation Therapy for Oligoprogressive Disease

A retrospective study included 36 patients with extracranial metastatic RCC treated with SABR to 43 sites with a median dose of 36 Gy (range, 18-50) in three fractions (range, 1-5). The median time to SABR from the start of systemic therapy was 11.4 months. Median modified progression-free survival (mPFS) was 9.2 months. Patients receiving SABR while on immunotherapy exhibited a longer median mPFS (>28.4 months) than patients not on immunotherapy (9.2 months). The median OS from SABR administration was 43.4 months. The 1-year LC rate was 93%. Most SABR-related toxicities were grade 1 to 2 (33% of patients), with one grade 5 hemoptysis event possibly related to SABR or disease progression.[116]

A phase II trial of stereotactic ablative radiation for oligoprogressive metastatic kidney cancer enrolled 20 patients who received upfront and sequential SABR to a total of 37 sites. The LC rate was 100%. At a median follow-up of 10.4 months, SABR extended the duration of the ongoing systemic therapy by greater than 6 months in 14 patients. The median time from SABR to the onset of new systemic therapy or death was 11.1 months. One patient developed grade 3 gastrointestinal toxicity, possibly related to treatment. There was no significant decline in quality of life.[117]

Stereotactic Body Radiation Therapy for Inferior Vena Cava Thrombus

A phase 2 trial enrolled six patients who received neoadjuvant SABR for RCC inferior vena cava tumor thrombus (IVC-TT). Patients underwent neoadjuvant SABR (40 Gy in five fractions) to the IVC-TT followed by open radical nephrectomy and thrombectomy. No grade 4 to 5 adverse events (AEs) were observed.[117] Figure 69.3 shows SABR to an IVC-TT 8 Gy × 5.

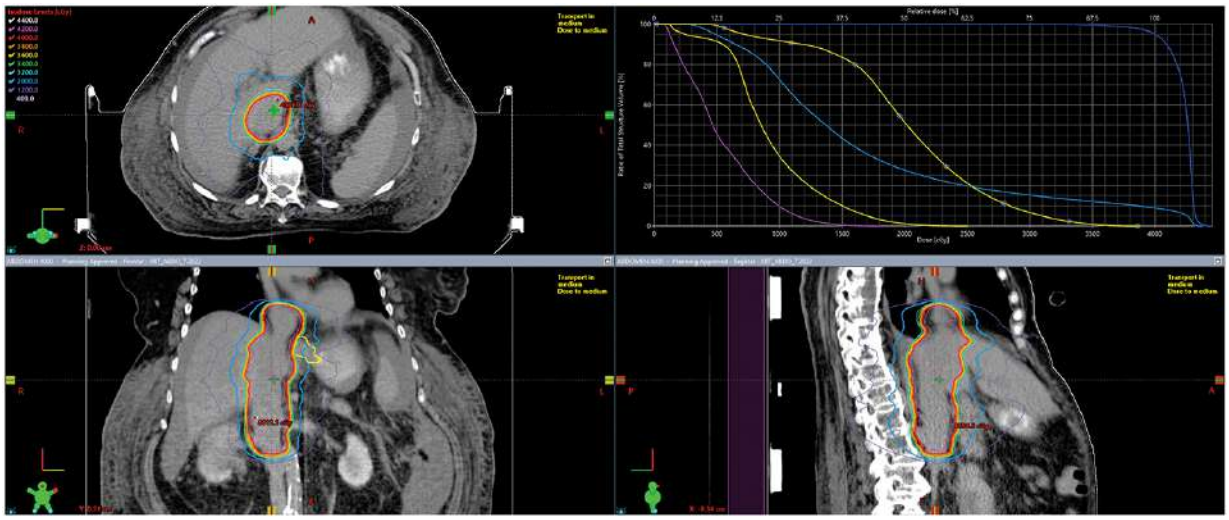

FIGURE 69.3 A 70-year-old woman with right renal mass with inferior vena cava tumor thrombus causing venous congestion. Palliative stereotactic ablative body radiation prescribed to 4,000 cGy in five fractions showing axial (top left), sagittal (bottom left), dose-volume histogram (DVH) (top right), and coronal (bottom right). Dose color wash values are 4,400 cGy (white), 4,200 Gy (magenta), 4,000 Gy (red), 3,800 Gy (orange), 3,600 Gy (yellow), 3,400 Gy (green), 3,200 Gy (cyan), 2,000 Gy (blue), 1,200 Gy (purple), and 400 cGy (lavender). DVH structures from top to bottom (blue, planning target volume; yellow [lateral], esophagus; light blue, heart; yellow [medial], duodenum; bowel, purple). (Courtesy of Young Suk Kwon and Raquibul Hannan, UT Southwestern.)

A retrospective study of IVC-TT included 15 patients. All patients received SABR to the IVC-TT. Most did not receive surgery due to high surgical risk (7/15) or recurrent thrombus (3/15). Radiographic response was observed in 58% of patients. Symptom palliation was recorded in all patients receiving SABR for this indication. Only grade 1 to 2 AEs were noted.[118]

Stereotactic Body Radiation Therapy for Oligometastatic Disease

SBRT may be considered for oligometastatic kidney cancer.

Stereotactic Body Radiation Therapy for Extracranial Metastases

A systematic review including 10 publications of extracranial RCC showed that the weighted LC was 89%, OS ranged from 11.7 to 22 months, grade 3 to 4 toxicity ranged from 0% to 4%, and the weighted rate of treatment-related mortality was 0.5%.[119]

Zelefsky et al reported 105 RCC lesions treated with either single-dose, image-guided, intensity-modulated radiotherapy (IMRT) to a prescription dose of 18 to 24 Gy

(median, 24) or hypofractionation (3 or 5 fractions) with a prescription dose of 20 to 30 Gy. The 3-year local PFS for those who received a high single-dose (24 Gy; $n = 45$), a low single-dose (<24 Gy; $n = 14$), or hypofractionation regimens ($n = 46$) was 88%, 21%, and 17%, respectively. Multivariate analysis showed significant predictors of improved local PFS: 24 Gy versus a lower dose ($P = .009$) and a single dose versus hypofractionation ($P = .008$).[81]

In a series of 50 patients with metastatic RCC, Wersall et al reported that stereotactically delivered radiation to sites including the lung, liver, and adrenal resulted in complete regression in 30% of cases and either partial regression or stabilization of the lesions in 60%.[120] Of the 162 treated tumors, only 3 recurred. Dose and fractionation ranged from 8 Gy × 4, 10 Gy × 4, and 15 Gy × 3, all delivered in 1 week.

Stereotactic Body Radiation Therapy for Spine Metastases

In a study of 48 patients (55 lesions) with metastatic RCC to the spine, patients received 24 Gy × 1, 9 Gy × 3, or 6 Gy × 5 fractions. The actuarial 1-year spine tumor PFS was 82.1%. At the pretreatment baseline, 23% of patients were pain free; at 1 and 12 months post-SBRT, 44% and 52% of patients were pain free, respectively. No grade 3 to 4 neurologic toxicity was observed.[121] A prospective study of 71 spinal segments treated with SBRT showed that the 1-year OS and LC rates were 64% and 83%, respectively. The 1-year vertebral compression fracture (VCF)-free probability rate was 82%. Multivariate analysis identified single-fraction SBRT (18-24 Gy) and baseline VCF as significant predictors of SBRT-induced VCF ($P = .028$ and $P = .012$, respectively).[122] A retrospective study of 57 patients with RCC metastases to the spine who received single-fraction SBRT to 88 treatment sites showed that the median time to radiographic failure and unadjusted pain progression were 26.5 and 26.0 months, respectively. The median time to pain relief from simulation and duration of pain relief from treatment were 0.9 months (range 0.1-4.4 months) and 5.4 months (range 0.1-37.4 months), respectively. Multivariate analyses demonstrated that multilevel disease and neural foramen involvement were correlated with radiographic failure; multilevel disease and vertebral fracture were correlated with unadjusted pain progression. Twelve treatment sites (14%) were complicated by subsequent vertebral fractures.[123]

Stereotactic Body Radiation Therapy for Bone Metastases

A study of 46 consecutive patients with RCC with 95 lesions was treated as follows: 50 SBRT and 45 conventional fractionation RT (CFRT). A biologically effective dose (BED) of 80 Gy or greater ($\alpha/\beta = 7$) predicted clinical LC. Median time to symptom control between SBRT and CFRT were 2 (range, 0-6 weeks) and 4 weeks (range, 0-7 weeks), respectively. Toxicity rates were low and equivalent in both groups, with no grade 4 or 5 toxicity reported.[124]

A potential added benefit of extracranial stereotactic RT is the abscopal effect, in which there is tumor response at a distance from the irradiated volume. Wersall and

colleagues observed an abscopal effect in 4 out of 28 patients with RCC with treated and untreated metastatic lesions. In these four patients, nonirradiated metastases regressed temporarily or seemingly permanently after treatment with SBRT of the primary tumor or other metastatic lesions. The authors' findings argued for a more active and liberal use of SBRT in metastatic RCC. They suggested that further studies were necessary to define the underlying mechanisms behind such responses or to combine SBRT with immunomodulating agents.[125]

Whole-Brain Radiotherapy for Brain Metastases

A retrospective study of 60 patients receiving whole-brain radiotherapy (WBRT) for RCC brain metastases showed that LC at 6 months was 21% after 3 Gy × 10 and 57% after higher doses of 2 Gy × 20 or 3 Gy × 15 (P = .013). The LC at 12 months was 7% and 35%, respectively. The OS at 6 months was 29% after 3 Gy × 10 and 52% after higher doses (P = .003). The OS at 12 months was 13% and 47%, respectively. The authors concluded that escalating the WBRT dose beyond 3 Gy × 10 could improve the outcomes in patients with RCC with brain metastases.[126]

Stereotactic Radiosurgery for Brain Metastases

A retrospective study of 280 consecutive patients with metastatic brain tumors (of which 80 were RCC) treated with gamma knife radiosurgery (GKS) observed that to control symptomatic peritumoral edema, a higher marginal dose of 25 Gy or more was necessary. The authors developed an algorithm for the management of RCC metastases where lesions 3 cm or greater undergo resection, lesions greater than 2 cm with symptomatic peritumoral edema undergo resection (since a 25 Gy was not considered safe for tumors >2 cm) and those without it GKS, and lesions 2 cm or less receive GKS.[127] Another retrospective study of 46 patients and 99 RCC brain lesions treated with radiosurgery observed that the good response group (as assessed by MRI) survived significantly longer than the poor response group (median survival times of 18.0 and 9.0 months, respectively; P = .025).[128]

Kano et al reported 158 consecutive patients with RCC (531 lesions) who underwent stereotactic radiosurgery (SRS). The OS after SRS was 60%, 38%, and 19% at 6, 12, and 24 months, respectively, with a median survival of 8.2 months. Median survival for patients with less than 2 brain metastases, higher KPS (>90), and no prior WBRT was 12 months after SRS. Sustained local tumor control was achieved in 92% of patients. Symptomatic adverse radiation effects occurred in 7%. Overall, 70% of patients improved or remained neurologically stable.[129]

A retrospective study of 61 patients with RCC treated with GKS, median dose 20 Gy, showed that the use of targeted agents (tyrosine kinase inhibitors, mammalian target rapamycin inhibitors, and bevacizumab) was the only factor that predicted improved survival. The median survival for patients receiving targeted agents (n = 24) was 16.6

months compared with 7.2 months (n = 37) for those not receiving targeted therapy (P = .04).[130]

A systematic review including 16 publications of cranial RCC showed that the weighted LC was 92%, OS ranged from 6.7 to 25.6 months, grade 3 to 4 toxicity ranged from 0% to 6%, and the weighted rate of treatment-related mortality was 0.6% secondary to intratumoral hemorrhage.[119]

Conventional Radiotherapy for Extracranial Metastases

Palliative RT is effective at relieving symptoms of metastatic renal cell cancer.[131-134] A patient with a solitary bone metastasis may have a long survival time, and a sufficient radiation dose should be administered to allow durable pain relief. If surgery is used to remove a metastatic lesion, postoperative RT is indicated to prevent its recurrence. In a prospective phase II study using validated quality-of-life questionnaires, Lee and colleagues from the Princess Margaret Hospital demonstrated that 83% of patients treated for pain had experienced significant pain relief with 30-Gy radiation delivered in 10 fractions.[133] DiBiase et al observed a dose-response in the palliative treatment of 107 patients with RCC. A BED greater than 50 Gy_{10} (α/β ratio of 10) was associated with a statistically significant increased rate of response: 59% versus 39% (P = .001).[80]

Figure 69.4 illustrates a painful RCC cutaneous metastasis that had a complete response after 375 cGy × 13 fractions (BED = 67 Gy_{10}) over 5 weeks. The lesion was treated with electrons, a custom bolus, and a 2-cm peripheral margin.[135]

FIGURE 69.4 This painful renal cell carcinoma cutaneous metastasis (A) had a complete response (B) after 375 cGy × 13 fractions (biologically effective dose = 67 Gy_{10}) over 5 weeks. The lesion was treated with electrons, a custom bolus, and a 2-cm peripheral margin. (From Gay HA, Cavalieri R, Allison RR, Finley J, Quan WD Jr. Complete response in a cutaneous facial metastatic nodule from renal cell carcinoma after hypofractionated radiotherapy. *Dermatol Online J*. 2007;13[4]:6. Reprinted with permission of Dr. Hiram A. Gay.)

Intraoperative Radiation Therapy for Advanced or Recurrent Renal Cell Carcinoma

A retrospective study of 98 patients who received intraoperative radiation therapy (IORT) for advanced or locally recurrent RCC at 9 institutions showed a 5-year OS of 37% for advanced disease and 55% for locally recurrent disease. The respective 5-year disease-free survival was 39% and 52%. IORT was delivered during nephrectomy for advanced disease (28%) or resection of locally recurrent RCC in the renal fossa (72%). Preoperative or postoperative external beam radiation therapy was administered to 27% and 35% of patients, respectively. Initial nodal involvement, sarcomatoid features, and higher IORT dose were statistically significantly associated with decreased survival. The outcomes for patients receiving IORT in the setting of local recurrence compared favorably to similar cohorts treated by local resection alone.[136]

Renal Pelvis and Ureter Carcinoma

Surgery is the therapeutic foundation for the management of renal pelvis and ureter carcinoma. National consensus guidelines recommend the following treatment options for renal pelvis low-grade tumors: endoscopic resection with or without postsurgical intrapelvic chemotherapy or Bacillus Calmette-Guerin, or nephroureterectomy with cuff of bladder with or without perioperative intravesical chemotherapy. High-grade renal pelvis tumors, large tumors, or tumors that invade the renal parenchyma have the following recommended treatment: nephroureterectomy with cuff of bladder plus regional lymphadenectomy with or without perioperative intravesical chemotherapy, with consideration of neoadjuvant chemotherapy in selected patients. The management of ureter tumors depends on the tumor location: upper, mid, or distal location, and disease extent.

For both the renal pelvis and ureter tumors, patients with pathologic stage pT3, pT4, or pN_+ should be considered for adjuvant platinum-based chemotherapy or adjuvant nivolumab if no platinum neoadjuvant treatment was given. Consider adjuvant nivolumab if platinum neoadjuvant chemotherapy was given and ypT2-ypT4 or ypN_+. The “y” classification is used after neoadjuvant therapy.

Surgery

Radical nephroureterectomy is the only potentially curative treatment for most patients with urothelial carcinoma of the renal pelvis or ureter. This operation includes the removal of the contents of Gerota fascia, including the ipsilateral ureter with a cuff of the bladder at its distal extent. High local or regional recurrence rates have plagued less radical surgeries, sometimes approaching 30%.[137] Hall reported an increased rate of recurrence when parenchymal-sparing procedures were performed.[75] Conservative surgical excision should be considered only in patients with low-grade, low-stage, solitary tumors in whom radical nephrectomy is not indicated because of poor kidney

function or an absent contralateral kidney. Conservative surgical options in selected cases include laparoscopic nephroureterectomy, nephrectomy and partial ureterectomy, endoscopic resection, and fulguration. The role of lymph node dissection in this disease is unclear. Patients who have the highest risk of lymph node metastases also have a high risk of systemic disease.

Adjuvant Radiotherapy

There are no randomized trials on the role of postoperative RT in patients who have had a complete resection of upper urinary tract cancer. Tumors of the renal pelvis and ureter have a significantly high local recurrence rate after nephroureterectomy, particularly in patients with high-grade tumors or deep invasion.[138] Retrospective studies suggest that adjuvant RT may diminish the likelihood of local recurrence, but it does not appear to impact OS or reduce future distant metastases.[36,139]

Cozad et al reported a retrospective study of 94 patients with urothelial carcinoma of the renal pelvis, of which 77 had resections without residual. On multivariate analysis, adjuvant RT had a significant effect on LC (P = .02). Regarding survival, the use of adjuvant RT was of borderline significance (P = .07). Of the 27 patients who were excluded from local failure and survival analysis, 19 had unresectable local disease, and of these, 11 received RT. Two long-term disease-free survivors in this group received 45 and 50.4 Gy, respectively. The authors recommended consideration of adjuvant RT in patients with high grade or stage, close surgical margins, or positive lymph nodes to improve LC.[36]

In another retrospective study of 133 patients with urothelial carcinoma of the renal pelvis, 67 patients received external beam RT following surgery (RT group), and 66 patients received intravesical chemotherapy (non-RT group). The clinical target volume included the renal fossa, the course of the ureter to the entire bladder, and the paracaval and para-aortic lymph nodes (Figure 69.5). The tumor bed or residual tumor was targeted in 14 patients. The median radiation dose administered was 50 Gy. There was a significant difference between the survival rates for these groups based on patients with T3/T4 stage cancer. A significant difference between the irradiated and nonirradiated bladder groups was observed in the bladder tumor relapse rate (P = .004). The authors concluded that RT may improve the OS of patients with T3/T4 cancer of the renal pelvis or ureter and delay bladder tumor recurrences.[140]

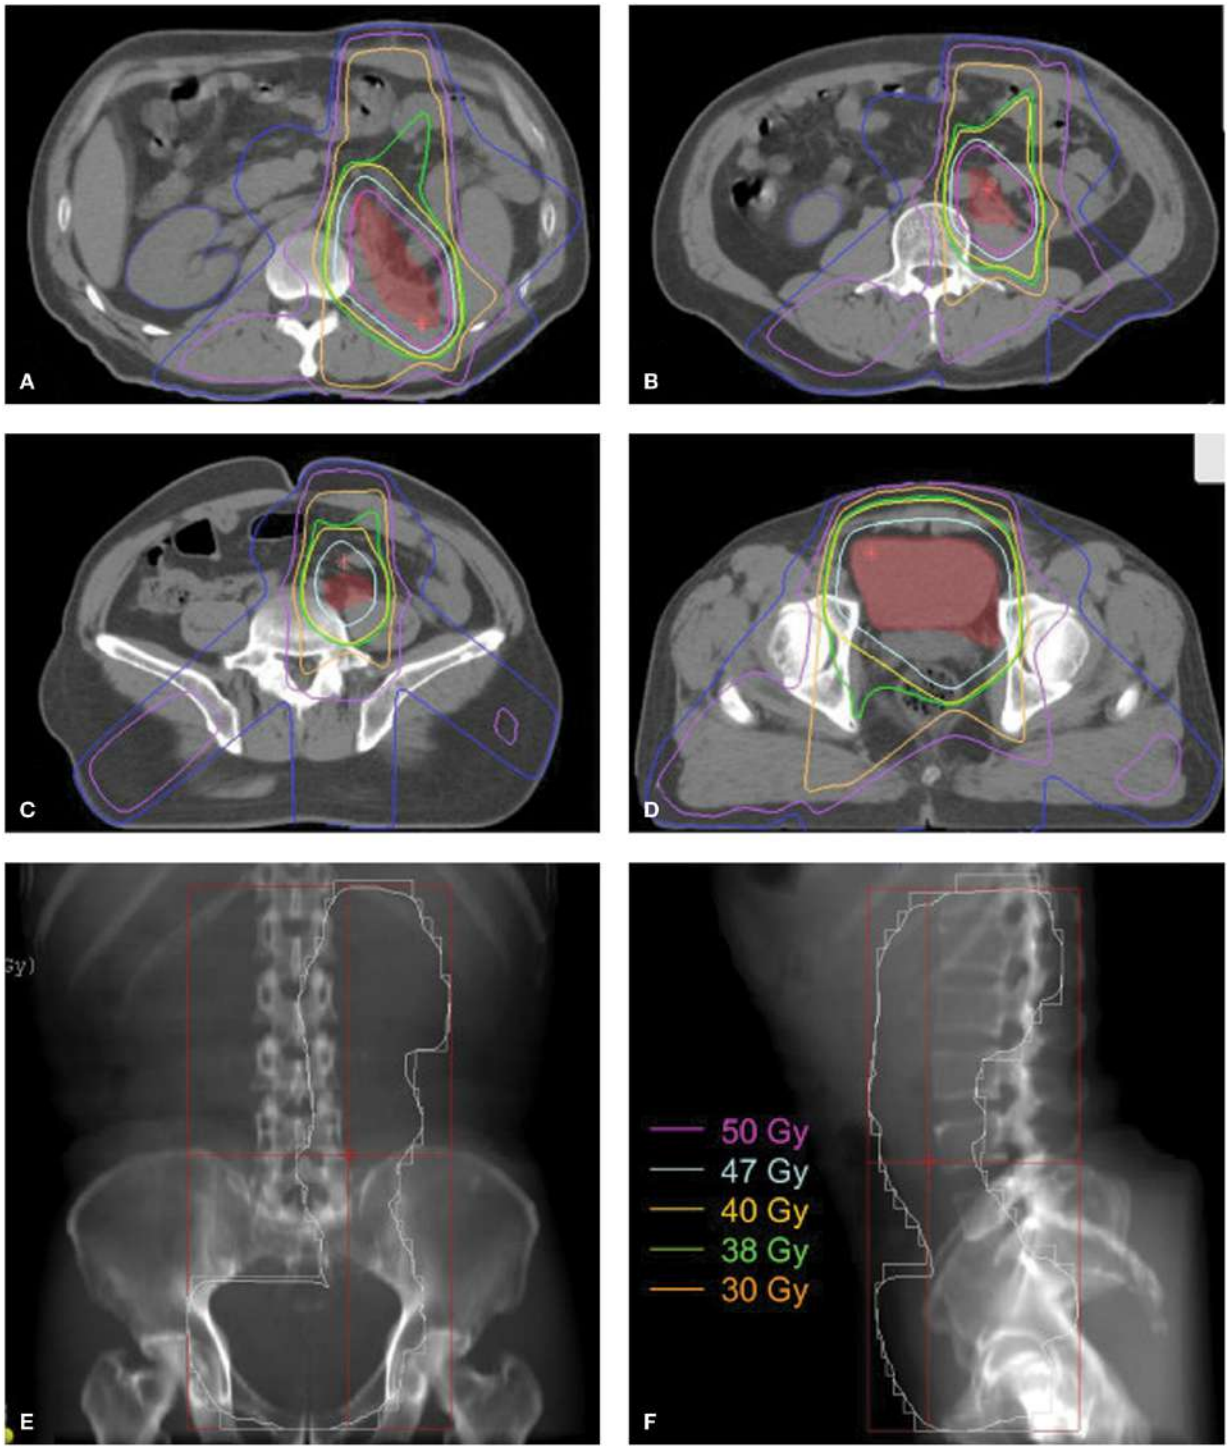

FIGURE 69.5 Dose distribution of a patient with renal pelvis cancer and beam arrangements of 0°, 129°, and 229° gantry: renal fossa (A), course of ureter (B, C), and bladder (D). Digitally reconstructed radiograph for views of 0° gantry (E) and 90° gantry (F). Internal pink and yellow lines represent the CTV50 and CTV40, respectively. CTV, clinical target volume. (Reprinted from Chen B, Zeng ZC, Wang GM, et al. Radiotherapy may improve overall survival of patients with T3/T4 transitional cell carcinoma of the renal pelvis or ureter and delay bladder tumour relapse. *BMC Cancer*. 2011;11:297. http://creativecommons.org/licenses/by/2.0.)

The patterns of failure were described in 252 patients undergoing surgery at the University of Texas Southwest Medical Center for urothelial carcinoma of the upper urinary tract.[75] Local recurrence occurred only 9% of the time, whereas new invasive urothelial tumors or distant metastases occurred in 69% and 22% of cases, respectively. Isolated local recurrences were rare. Another series from the Princess Margaret Hospital confirms the high rate of distant metastases. Although local failure occurred in 35% of patients with locally advanced disease, most patients also experienced distant metastases as well.[141]

Systemic Chemotherapy

The pathologic similarity of urothelial carcinoma of the renal pelvis and ureter to bladder cancer has encouraged medical oncologists to use similar chemotherapeutic regimens in the management of upper tract urothelial carcinomas. Dose-dense methotrexate, vinblastine, doxorubicin, and cisplatin for three to six cycles and gemcitabine and cisplatin for four cycles are considered standard neoadjuvant or adjuvant regimens. Radiosensitizing chemotherapeutic agents include cisplatin, low-dose gemcitabine, and 5-fluorouracil (5-FU) and mitomycin. Other recommended regimens include cisplatin and 5-FU, as well as cisplatin and paclitaxel.

RADIOTHERAPY TECHNIQUES

Normal Tissue Dose Constraints

Several organs at risk have to be taken into consideration when palliating an unresected kidney tumor or a kidney tumor bed recurrence. These organs include the spinal cord, liver, spleen, stomach, duodenum, small bowel, normal contralateral or ipsilateral kidney, and normal adrenal gland(s).

There are no established dose constraints for sparing the remaining kidney after nephrectomy or in the palliative setting when both kidneys are present. In the context of two normal kidneys, the QUANTEC kidney panel recommended a mean bilateral kidney dose of less than 15 to 18 Gy and a bilateral kidney dose-volume histogram with a V12 less than 55%, V20 less than 32%, V23 less than 30%, and V28 less than 20%.[142] The dose to the stomach should be kept below 45 Gy, and the small bowel V45 less than 195 mL when it is contoured as a bowel bag (Figure 69.6).[143] The male and female Radiation Therapy Oncology Group normal pelvis atlases illustrate how to contour the bowel bag and are accessible at https://www.nrgoncology.org/About-Us/Center-for-Innovation-in-Radiation-Oncology. The mean liver dose should be kept below 30 to 32 Gy, excluding patients with preexisting liver disease or hepatocellular carcinoma who have a lower tolerance. Sparing at least 700 mL of liver from radiation is another potential strategy to avoid complications.[144] There are no recognized splenic or adrenal dose constraints. Nevertheless, based on the spleen's exquisite radiosensitivity and experience with palliative RT for myeloproliferative disorders,[145] it seems prudent to

limit the spleen to 5 to 10 Gy. The spinal dose should be limited to an absolute maximum of 45 Gy.

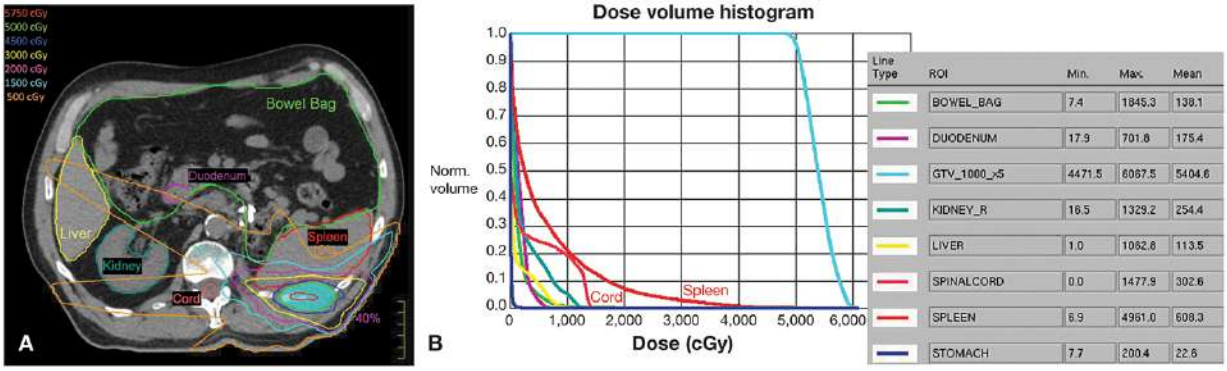

FIGURE 69.6 Treatment plan (A) and dose-volume histogram (B) showing the normalized volume versus dose (cGy) for a patient with metastatic clear cell renal cell carcinoma, with sarcomatoid and rhabdoid differentiation, after left radical nephrectomy, pT3aN1M1. The kidney tumor was Fuhrman nuclear grade IV and 15.5 cm in diameter. The patient was treated with temsirolimus, pazopanib, bevacizumab, and, finally, adriamycin plus gemcitabine with some objective response. The patient developed a painful, destructive 55-mL metastasis in the left 12th rib. The metastasis was treated with 10 Gy × 5 using a six-field (RPO 210, LAO 60, LT LAT 90, LPO 120, LPO 150, PA) 6-MV intensity-modulated radiotherapy (IMRT) technique. RPO, right posterior oblique; LAO, left anterior oblique; LT LAT, left lateral; LPO, left posterior oblique; PA, posterior-anterior. The isodose-based methodology used to evaluate the plan is explained in detail in Gay et al.[146] The skin was limited to the 40% isodose (400 cGy × 5), the spinal cord to the 30% isodose (300 cGy × 5), and the spleen to the 10% isodose (100 cGy × 5) or less as feasible. Doses to the bowel, liver, remaining kidney, and duodenum were well below tolerance. Daily imaging with 2D:2D match and cone-beam computed tomography (CT) were used prior to the delivery of the five fractions over 3 weeks.

Renal Cell Carcinoma

Neoadjuvant or adjuvant RT is not routinely recommended for patients with RCC. However, there may be special cases where the clinician may consider neoadjuvant RT to improve respectability or adjuvant RT if there are clinical tumor features suggestive of a high risk of local recurrence. Careful planning is paramount because ignoring any of the critical structures surrounding the kidney or nephrectomy bed could result in serious, even fatal, patient toxicity.

Patients receiving RT to the kidney may be simulated supine, arms up, using a wing board or alpha cradle, a wire on the surgical scar, and a planning CT scan. The kidneys are mobile organs and move vertically within the retroperitoneum an average of 0.9 to 1.3 cm and as much as 4 cm during normal respiration.[147-149] In going from the supine to upright position, the kidneys can shift inferiorly between 0.5 and 7.5 cm with an average of 3.6 cm.[150] This finding, although critical for total body irradiation treatments, further highlights the mobility of the kidneys.

The high complication rates reported in the prospective trials of postoperative RT have taught radiation oncologists an important lesson regarding RT planning, patient selection, and the tolerance of the upper abdominal viscera. IMRT may be a reasonable

consideration due to the sensitivity of adjacent surrounding structures. If IMRT is considered, a plan to manage the uncertainties in target localization, such as four-dimensional (4D) CT treatment planning, IGRT, abdominal immobilization devices, gating, or breathing control, needs to be considered. Renal function scans may assist in the treatment planning or patient selection process, but this has not been formally studied.

In unresectable lesions, 40 to 50 Gy neoadjuvant RT (1.8- 2 Gy/fraction) directed to the kidney tumor and regional lymphatics may improve resectability.[103] Multiple-field techniques, similar to those described for adjuvant RT, should be considered in patients receiving preoperative treatment.

CT-based treatment planning contributes to good LC with minimal morbidity. Careful definition of the target volume to encompass the nephrectomy bed, lymph node drainage sites, and surgical clips on the planning CT scan is important. Exclusive use of anterior- and posterior-field arrangements, particularly on the right side, is likely to result in irradiation of large volumes of bowel and liver beyond tolerance. The use of multiple beams is paramount for protecting the surrounding normal structures. Total radiation doses of 45 to 50 Gy (1.8-2 Gy/fraction) to the nephrectomy bed and regional lymph nodes with a boost to small volumes of microscopic or gross residual disease of 10 to 15 Gy (total dose 50-60 Gy) are appropriate. Stein and coworkers[151] reported two scar recurrences and recommended that the incision site be included in the target volume. If the scar cannot be covered without increasing the amount of normal tissue irradiated, an additional electron beam field to treat the scar may be considered.

Figure 69.6 illustrates a patient with metastatic clear cell RCC, with sarcomatoid and rhabdoid differentiation, status post left radical nephrectomy, pT3aN1M1. The kidney tumor was Fuhrman nuclear grade IV and 15.5 cm in diameter. The patient was treated with temsirolimus, pazopanib, bevacizumab, and, finally, adriamycin plus gemcitabine with some objective response. The patient developed a painful, destructive 55-mL metastasis in the left 12th rib. The metastasis was treated with 10 Gy × 5 using a six-field (right posterior oblique 210, left anterior oblique 60, left lateral 90, left posterior oblique [LPO] 120, LPO 150, posteroanterior) 6-MV IMRT technique. The isodose-based methodology was used to evaluate the plan and is explained in detail in the reference.[146] The skin was limited to the 40% isodose (400 cGy × 5), the spinal cord to the 30% isodose (300 cGy × 5), and the spleen to the 10% isodose (100 cGy × 5) or less as feasible. Doses to the bowel, liver, remaining kidney, and duodenum were well below tolerance (Figure 69.6A). Daily imaging with 2D:2D match and cone-beam CT was used prior to the delivery of the five fractions over 3 weeks.

Stereotactic Ablative Radiation Therapy

At UT Southwestern, for kidney SABR, 36 to 42 Gy in three fractions is preferred with 40 Gy in five fractions as an alternative.

Simulation Imaging

Contiguous CT slices of no greater than 3-mm slice thickness should be obtained starting from the level of the diaphragm and extending inferiorly through the pelvis. Contrast-enhanced diagnostic CTs and positron emission tomography/CTs should be registered and used to guide tumor and normal organ volume definition. Oral contrast to assist in visualization of the small bowel is recommended and should be given approximately 15 to 20 minutes before simulation. It is recommended that patients do not eat or drink for at least 2 hours before simulation or treatment to ensure consistent gastric filling. The reconstructed slice thickness in the target region should be 2 mm or less for SABR.[152]

Motion Management Technique

Motion management techniques include monitored voluntary or involuntary breath-hold, and gating or tracking based on implanted fiducial markers within or in the immediate vicinity of the tumor.[152]

Organs at Risk

Organs at risk may include small bowel, large bowel, duodenum, heart, kidneys, liver, skin, spinal cord, stomach, and ribs.

Renal Pelvis and Ureter Carcinoma

Adjuvant RT has been used in the management of renal pelvis and ureter cancers. For elective RT, the clinical target volume should include the renal fossa, the course of the ureter to the bladder, the entire bladder, and the paracaval and para-aortic lymph nodes (Figure 69.6).[140] As in RCC, CT-based planning may facilitate dosimetric coverage of the regions at risk while minimizing dose to normal tissues. Radiation doses of 45 to 50 Gy at 1.8 to 2 Gy per day are appropriate to treat subclinical and microscopic disease. For more extensive disease (eg, multiple positive nodes), R1 (microscopic positive margins) or R2 (macroscopic residual margins) resections, a boost of 5 to 10 Gy should be considered. For unresectable or gross residual disease, higher doses may be necessary. In this event, multiple-field arrangements, including oblique and lateral fields with field reductions, are important to minimize toxicity to surrounding normal structures (see Figure 69.5). CT-based simulation, 3D treatment planning, and contrast-enhanced radiographs are helpful in defining the RT target volume. IMRT can be considered if organ motion is managed to avoid underdosing the planning target volume. Chemotherapy may allow a lower radiation dose for gross disease.

FOLLOW-UP

Renal Cell Carcinoma

Follow-up after ablative techniques includes the following:

- History & Physical Exam annually
- Laboratory tests as indicated annually
- Abdominal CT, MRI with and without intravenous contrast at 1 to 3, 6, and 12 months after ablation, then annually after that
- Chest imaging: chest x-ray or CT annually for 5 years for patients with biopsy-proven low-risk pathologic features

The greatest risk of recurrence following surgery for RCC is in the first 1 to 2 years, with most relapses occurring within 3 years, but recurrences can occur more than a decade later.

Renal Pelvis and Ureter Carcinoma

Since patients with urothelial carcinoma of the upper urinary tract are at a high risk of urothelial tumors of the bladder, monitoring with cystoscopy at periodic intervals is necessary. For patients who have undergone a renal-sparing procedure, imaging with CT or MRI and/or ureteroscopy may be necessary. Follow-up includes the following:

- Cystoscopy every 3 months for 1 year, then at longer intervals. Consider cytology for high grade.
- Nephron-sparing surgery: imaging of upper tract collecting system or ureteroscopy at 3- to 12-month intervals ± abdominal/pelvic CT or MRI with and without contrast

SEQUELAE OF RADIOTHERAPY

The side effects and complications from RT for cancer of the kidney, renal pelvis, and ureters are similar to those expected from irradiation of the upper abdomen and pelvis. These side effects include nausea, vomiting, diarrhea, and abdominal cramping. Patients with right-sided tumors may have significant portions of the liver irradiated, and radiation-induced liver damage is possible. The Copenhagen Renal Cancer Study Group reported that 12 (44%) of 27 patients developed significant complications: 3 had biochemical changes indicating radiation hepatitis, 3 had duodenum and small-bowel stenosis, and 6 had duodenum and small-bowel bleeding.[106] Surgery was performed on four of nine patients with bowel-related RT complications, and five patients died of treatment-related complications. The total radiation dose in this study was 50 Gy given in 2.5-Gy fractions per day. Fugitt also reported four cases of "liver" failure among 52 patients who received postoperative RT.[105]

The complication rate after RT for tumors of the kidney and upper urinary tract is related to the total dose, fraction size, and technique of irradiation. CT-based simulation and 3D treatment planning may decrease the risk of complications after elective RT in patients with upper urinary tract malignancies. In a prospective clinical trial, patients received single-fraction renal SABR (26 Gy) for tumors less than 5 cm or fractionated SABR (3 × 14 Gy) for tumors 5 cm or larger. For every 10 Gy of physical dose

delivered, an exponential decline in affected kidney GFR was observed at 39% for 26 Gy in 1 fraction and 25% for 42 Gy in three fractions. When normalized to BED_{3Gy}, the dose-response relationship for each treatment prescription was similar, with a plateau beyond 100 Gy. The authors concluded that sparing the functional kidney from high-dose regions (>50% isodoses) may help reduce the risk of functional loss.[153]

CHAPTER 70

Adjuvant and Neoadjuvant Radiation Therapy for Locally Advanced Bladder Cancer

Brian C. Baumann and Mohamed S. Zaghloul

Patients with locally advanced bladder cancer who undergo radical cystectomy have an estimated 5-year overall survival (OS) of 10% to 40%.[1] While the problem of distant relapse is well recognized, locoregional recurrences are common, with approximately one-third developing a locoregional recurrence as the initial site of failure after surgery.[1-4] Adjuvant chemotherapy is frequently employed for patients with locally advanced bladder cancer who did not receive neoadjuvant chemotherapy to address the risk of distant disease. Many patients are not candidates for postoperative chemotherapy because of the morbidity of surgery, coupled with preexisting medical illnesses.

Adjuvant radiotherapy (RT) is an alternative, and potentially complementary, adjuvant treatment that has been assessed in clinical trials to reduce the risk of locoregional recurrence in patients with ≥pT3 or node-positive disease.[5] Prospective data demonstrate that the addition of adjuvant RT decreases the risk of locoregional recurrences and improves disease-free survival (DFS).[5-7] There is growing evidence to suggest that improvements in these intermediate end points translate into improvements in OS for patients with locally advanced disease. In this chapter, we review the problem of locoregional failure (LRF) after cystectomy, identify patients most likely to benefit from adjuvant RT, review the patterns of pelvic failure after cystectomy, discuss technical details of radiation treatment, and review the modern literature on this topic. We also discuss preoperative RT. We also discuss the potential role of adjuvant RT now that adjuvant immunotherapy has emerged as a new standard of care for patients treated with radical cystectomy with or without neoadjuvant chemotherapy.

EARLY CLINICAL STUDIES OF POSTOPERATIVE RADIOTHERAPY

Adjuvant RT was first studied in the 1970s and 1980s in Europe and the United States but largely fell out of favor due to the toxicity using large nonconformal radiation fields.[7,8] Zaghloul et al reported results from a clinical trial of

postoperative RT conducted at the Egyptian National Cancer Institute (NCI) in Cairo that randomized 236 cystectomy patients with pT3a-pT4a disease to receive either observation or postoperative RT given either as 37.5 Gy in 1.25 Gy fractions given 3 times per day separated by at least 3 hours over 12 days or 50 Gy in 2 Gy daily fractions over 5 weeks.[9] The study reported a 5-year DFS of 44% with conventional fractionation, 49% with hyperfractionation, and 25% with observation ($P < .01$). Local-regional control at 5 years also significantly favored the RT arms, with pelvic control rates of 93%, 87%, and 50%, respectively ($P < .01$). While 80% had squamous and 20% urothelial histology, the results were not different based on histology.[9] This trial helped to establish adjuvant RT as a standard therapy for locally advanced bladder cancer in Egypt, but the results were interpreted with some caution outside of Egypt and the Middle East, where urothelial carcinoma is the predominant histology.

INCIDENCE OF LOCOREGIONAL FAILURES

Interest in adjuvant RT was revived several years ago outside the Middle East as modern prospective cystectomy series reported that locoregional recurrences were more common for patients with locally advanced disease than was previously thought. In the SWOG 8710 trial of radical cystectomy with or without neoadjuvant methotrexate, vinblastine, Adriamycin, and cisplatin (MVAC), the 5-year cumulative incidence of LRF for patients with ≥pT3 urothelial carcinoma was 32%.[1] The 2011 update of the Medical Research Council (MRC) trial of neoadjuvant cisplatin, methotrexate, and vinblastine chemotherapy followed by cystectomy or definitive RT reported a 5-year locoregional recurrence rate of ~46% to 58% for cystectomy patients.[10] The University of Pennsylvania experience of 442 cystectomy patients who were followed with routine surveillance computed tomography (CT) or magnetic resonance imaging (MRI) every 6 months also demonstrated a high risk of locoregional recurrence for ≥pT3 patients with a 5-year cumulative incidence of 28%.[2] In PROMETRICS 2011, a cohort of prospectively followed European patients who underwent cystectomy in 2011, LRF was 15% to 39% for ≥pT3 patients.[11] Data from Korea[12] and Tata Memorial Hospital in India[4] also demonstrated high rates of local recurrence. A review of the literature demonstrates that local recurrence after radical cystectomy for locally advanced disease is relatively common, even in the modern era with chemotherapy.

RATIONALE FOR ADJUVANT RADIOTHERAPY

Adjuvant RT is a potentially attractive treatment option for patients with locally advanced disease because it can potentially prevent locoregional relapses, which can cause considerable mortality and morbidity.[13] Multiple cooperative group trials and large retrospective studies demonstrate that perioperative chemotherapy does not improve locoregional control in patients with locally advanced disease, including the SWOG 8710 study,[1,14,15] the MRC trial,[10] and the Penn experience.[1,2] Unfortunately, salvage therapy for locoregional recurrences after radical cystectomy is usually unsuccessful, with a median survival of 9 months after development of pelvic recurrence. Only 1 out of 80 patients with pelvic relapse survived at 5 years in the Penn series.[16] Salvage surgery is often precluded in these patients. Curative-intent salvage radiation is also difficult because of the radiosensitivity of the adjacent small bowel or neobladder, the absence of the native bladder to displace the bowel away from the radiation target(s), and the need for a dose >60 Gy (using standard fractionation), beyond the maximum tolerance of the small bowel (~54 Gy). A dose that would be effective and safe to eradicate microscopic residual disease in the adjuvant setting (~50 Gy in standard fractionation) is unlikely to eradicate gross disease in the salvage setting. We would argue that even if there were no measurable improvement in survival, adjuvant local therapy can potentially prevent the often substantial morbidity of pelvic recurrences,[17] which can cause obstruction of the ureters or bowel, pain, venous obstruction, and lower extremity edema. Improvements in radiation technique with the use of intensity-modulated radiation therapy (IMRT) and proton therapy offer the potential to reduce toxicity and limit radiation dose to the urinary diversion and bowel.[18,19]

There is some evidence that improving locoregional control may reduce distant disease spread and thereby improve survival.[20,21] Although there appears to be a clear rationale for adjuvant RT for locally advanced disease in combination with perioperative chemotherapy, clinical data on the utility of adjuvant RT in a majority patient population with urothelial carcinoma have been lacking, until recently.

STUDIES UTILIZING ADJUVANT RADIOTHERAPY FOR BLADDER CANCER

Several retrospective and prospective studies have been published in the past few years that demonstrate an oncologic benefit for adjuvant RT in a majority of patients with urothelial carcinoma. A 2019 study using the National Cancer Database found that adjuvant RT (n = 512) was associated with a statistically significant improvement in OS compared with no adjuvant RT in U.S. patients

with locally advanced disease, regardless of histology or receipt of chemotherapy. The results showed an improvement in OS in favor of adjuvant RT using both standard Cox multivariable analyses and propensity matching techniques.[22]

The Egyptian NCI undertook a series of randomized trials in patients with locally advanced disease who underwent radical cystectomy plus pelvic lymph node dissection with negative margins who had any of the following: pT3b/T4, pathologically node-positive, or grade 3 disease. The majority of patients had urothelial carcinoma. The initial trial was a phase III randomized trial of adjuvant RT versus sequential adjuvant chemotherapy plus RT,[6] with chemo + RT consisting of four cycles of "sandwich" chemotherapy with gemcitabine/cisplatin with adjuvant RT given after the second cycle to 45 Gy in 1.5 Gy twice-daily fractions to the cystectomy bed and pelvic nodes. Because of changes in the standard of care, a third arm of adjuvant chemotherapy alone (gemcitabine/cisplatin × 4 cycles) was added later as part of a randomized phase II clinical trial comparing adjuvant chemotherapy with or without RT.[6]

In the randomized phase II trial of 120 patients, adjuvant chemo + RT significantly improved locoregional control (the primary end point) versus adjuvant chemotherapy alone, regardless of histology, with a 2-year locoregional control of 96% versus 69% ($P < .01$).[6] OS and DFS were improved with the addition of RT, but the study was not powered for those end points, and the differences were not statistically significant (2-year DFS: 68% chemotherapy plus RT vs 56% chemotherapy alone; $P = .07$; 2-year OS: 71% chemotherapy plus RT vs 60% chemotherapy alone; $P = .11$). Adjuvant chemo + RT was reasonably well tolerated using three-dimensional (3D) conformal radiation techniques. The rate of late grade 3+ gastrointestinal (GI) toxicity was 6.7% for chemo + RT versus 2.2% for chemo alone.[6]

The results of the randomized phase II trial demonstrating a benefit for combined modality adjuvant therapy were also seen in a subgroup analysis of the original phase III trial of RT with or without chemotherapy ($N = 153$). Although there was no difference in the primary end point of DFS for the entire cohort for the RT versus chemo + RT arms, there was a statistically significant improvement in DFS and OS for chemo + RT versus RT alone in the urothelial carcinoma subgroup on the post hoc analysis (81 patients).[23] These findings showing an improvement with adjuvant chemotherapy for patients with urothelial carcinoma are notable because an improvement in OS has not been reported in the published clinical trials of adjuvant chemotherapy and suggests that there may be a role for adjuvant therapies to address the risk of both local and distant failure.[5] Several have theorized that previous trials of adjuvant chemotherapy may not have shown

a benefit in DFS or OS because those trials did not include adjuvant local therapy to address the high competing risk of locoregional relapse.

While the results of the randomized phase II trial and the post hoc analysis of the patients with urothelial carcinoma from the phase III trial both demonstrate that the combined modality adjuvant therapy appears to be the most effective approach, prospective data from the Egyptian NCI studies also support the use of adjuvant RT alone as an alternative to observation in patients with good performance status when adjuvant chemotherapy may not be appropriate or desired by either the patient or the clinical provider. In a post hoc analysis of 123 patients with locally advanced bladder cancer treated with adjuvant RT compared with adjuvant chemotherapy presented during the 2019 American Society of Clinical Oncology (ASCO) Annual Meeting, Zaghloul et al found that there was no statistically significant difference in the 2-year DFS (54% for RT vs 47% for chemotherapy).[24] Local-regional control was significantly improved with RT, while distant disease was not significantly different. OS was comparable between the two cohorts. Subgroup analysis of the urothelial cohort (n = 63) reported similar findings. Based on these data, there was a greater than 90% probability that the true difference in 2-year DFS for RT versus chemo alone was less than 10%—the prespecified noninferiority margin.[24] The study was not designed as a noninferiority trial, so we cannot confirm the noninferiority of adjuvant RT versus adjuvant chemotherapy. However, results of the post hoc noninferiority assessment suggest a role for adjuvant RT in lieu of observation for patients with good performance status who decline systemic therapy or are medically unfit for systemic therapy.

In a post hoc subset analysis of the 77 patients with squamous cell carcinoma from the Egyptian NCI trial, adjuvant RT with or without chemotherapy was associated with significantly improved OS versus chemotherapy alone (71% vs 43%, $P < .05$).[25] These results suggest that adjuvant RT should be strongly considered for patients with locally advanced squamous cell carcinoma treated with radical cystectomy, especially as systemic therapy options have proven less effective for this patient population.[25,26]

These studies set the groundwork for later studies to identify the patients most likely to benefit from radiation, the patterns of recurrence in the pelvis to design radiation targets, and radiation treatment techniques.

IDENTIFYING PATIENTS MOST LIKELY TO BENEFIT FROM ADJUVANT RADIOTHERAPY

Several investigators have examined key questions that would be needed to design modern clinical trials of adjuvant RT for urothelial carcinoma. These include (1) identifying the patients at highest risk for locoregional recurrence who may benefit from radiation, (2) identifying the patterns of pelvic failure to inform design of radiation clinical target volumes (CTVs), and (3) assessing the optimal radiation technique for adjuvant RT.

Several researchers have developed risk stratification tools to identify patients at the highest risk for LRF.[7,27,28] Baumann et al developed a risk stratification model combining data from a cohort of 442 cystectomy patients who were followed with routine pelvic CT/MRI.[2] They combined this cohort with the SWOG 8710 prospective cohort of 317 patients with cT2-T4a disease randomized to receive cystectomy with or without neoadjuvant MVAC chemotherapy.[1,14,29] LRF was defined as any failure below the aortic bifurcation detected before or within 3 months of distant metastases. From the combined cohorts, a risk stratification model was developed using pathologic T-stage, number of nodes excised (<10 vs ≥10), and margin status using cumulative incidence and competing risk analysis.[1] Three patient subgroups were identified with significantly different LRF risk: low risk (≤pT2), intermediate risk (≥pT3 with negative margins and ≥10 nodes identified), and high risk (≥pT3 with positive margins OR ≥pT3 with <10 nodes identified) with the 5-year cumulative incidence of LRF of 8%, 20%, and 41% in the SWOG cohort and 8%, 19%, and 41% in the Penn cohort, respectively.[1,30] Froehner et al validated the model using a multinational, European prospective cohort of 565 patients (PROMETRICS 2011),[11,31] and Ku et al also validated the model in a retrospective cohort of 398 Korean patients.[12] These results suggest that the risk stratification is valid in U.S., European, and Korean patients. Baumann et al performed internal validation of the model, demonstrating that trial accrual bias or changes in surgical technique over time would not affect the overall model findings.[30] The Penn/SWOG risk stratification was revisited to see if a combination of clinical/pathologic and transcriptomic data could improve the risk stratification model using The Cancer Genome Atlas. Carmona et al reported that the addition of smoking status was found to improve the model but there were no transcriptomic genetic factors that improved the risk stratification.[32]

Reddy et al proposed an alternative to the Penn/SWOG risk stratification.[3] In their single-institution series, only the pT and pN stages were significant independent predictors of pelvic failure. The Reddy study did not use competing risk analytic techniques. In the Penn/SWOG analysis, pN status was significant when doing a standard Cox regression but was no longer significant when a

competing risk model was used. More recently, Murthy et al proposed an alternative risk stratification in patients treated with cystectomy with or without adjuvant chemotherapy based on the pT stage, pN stage, and lymphovascular invasion that stratifies patients into low-, intermediate-, and high-risk groups with a cumulative incidence of LRF of 7%, 22%, and 35%, respectively.[4]

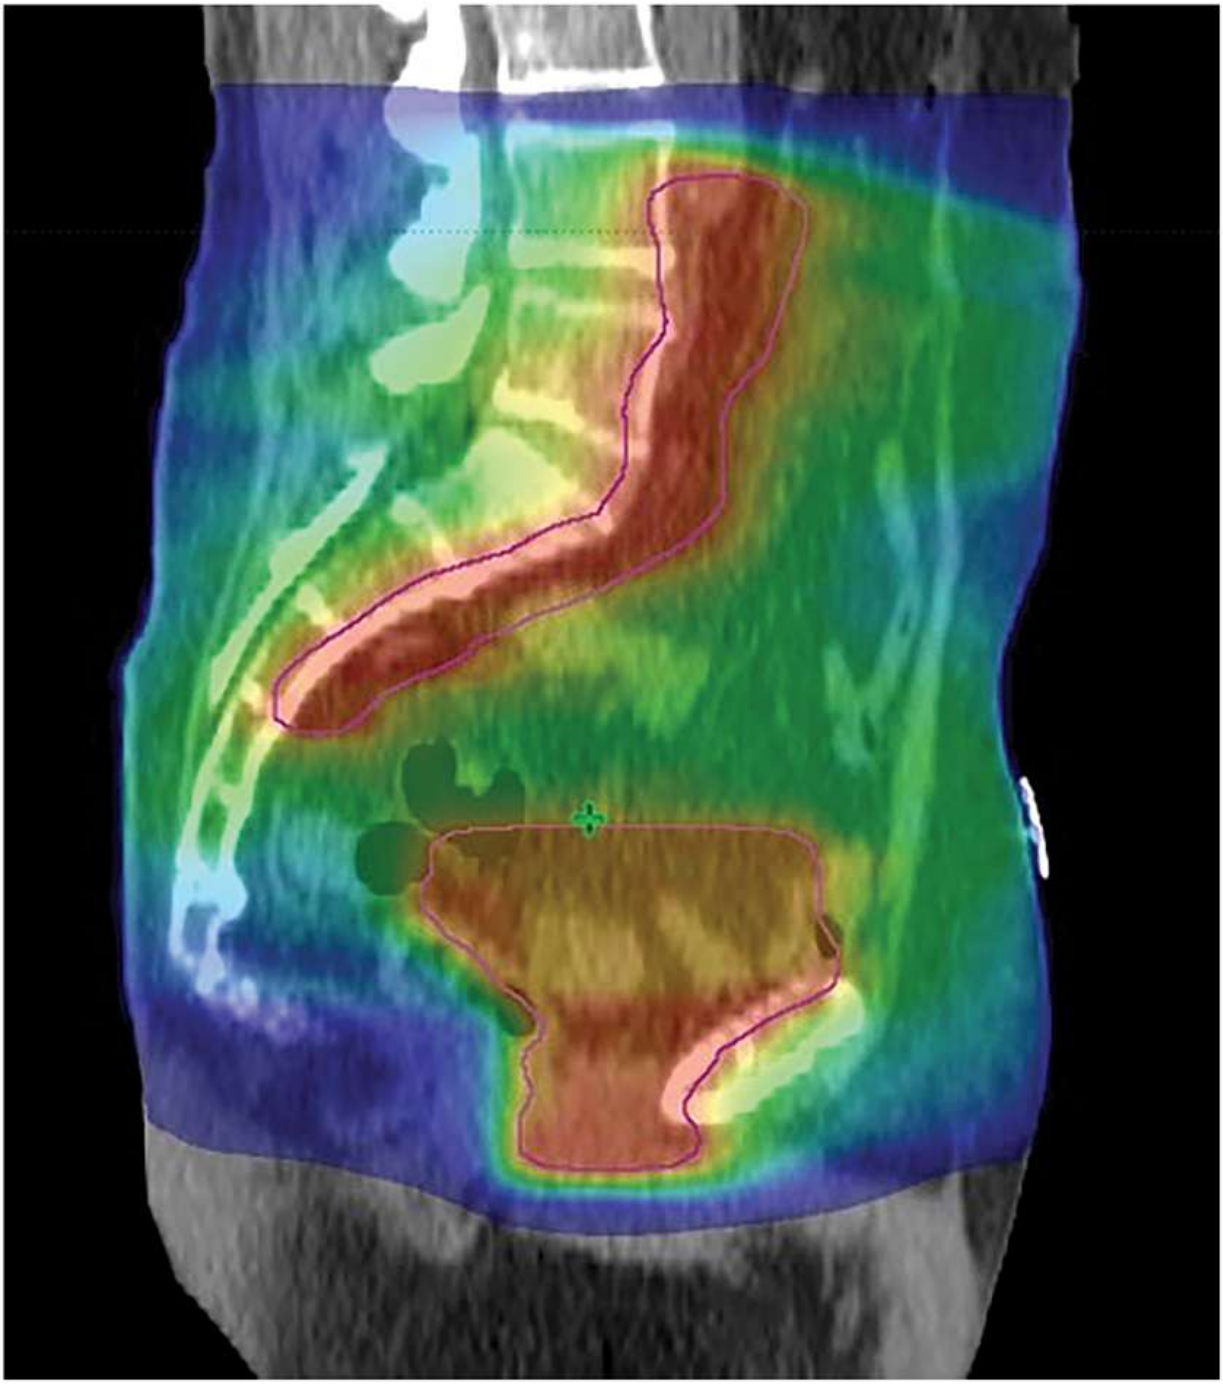
PATTERN OF RECURRENCE IN THE PELVIS

Mapping the patterns of failure in the pelvis to define appropriate RT targets is as important as identifying patients at increased risk for LRF. Baumann et al reviewed 5-year LRF rates after cystectomy for eight pelvic sites among 442 patients with urothelial carcinoma.[16] Patients with ≥pT3 disease had significantly higher LRF rates at nearly all pelvic sites compared to early-stage patients. Among stage ≥pT3 patients, margin status was the only factor that significantly altered the pattern of failure. In stage pT3 patients with negative margins, failures occurred primarily in the common iliac, obturator, and internal/external iliac nodes, with 5-year LRF rates of 9.7%, 8.8%, and 7.0%, respectively, while failure in the cystectomy bed and/or presacral nodes was uncommon (5-year LRF rates of 2% and 0.7%, respectively). For margin-negative patients, 76% of their sites of failure would have been encompassed within CTVs covering only the iliac/obturator nodes. For stage pT3 patients with positive margins, failures were most common in the pelvic sidewall nodal region, with 5-year LRF rates of 18.5%, 16.5%, and 9% for the external/internal iliac, obturator, and common iliac nodes, respectively, but the incidence of cystectomy bed and presacral nodal failures increased significantly (13.1% and 5.5%, respectively). Expanding the CTV to include the presacral and cystectomy bed regions increased the percentage of local failures encompassed to 91%. These data suggested that adjuvant RT protocols should target at least the obturator and iliac regions in stage pT3 patients with negative margins. Coverage of the presacral region and cystectomy bed was felt to be warranted for stage pT3 patients with positive surgical margins.[16] Reddy et al also showed that most failures occurred in the pelvic sidewall nodal regions with an increase in failures noted in the cystectomy bed and presacral region when the surgical margins were positive.[3]

The recent study by Murthy et al reported that the majority of failures occur in the pelvic lymph node regions, though they did report that 29% (9/31) had recurrence in the cystectomy bed despite negative surgical margins.[4] This study is important for raising awareness that cystectomy bed failures may be more common than previously reported, especially for those with particularly advanced local disease.

ADJUVANT RADIATION PLANNING AND DELIVERY TECHNIQUES

Early studies of adjuvant RT using 2D radiation treatment techniques were associated with relatively high rates of late GI toxicity.[8] A more precise identification of the organs at risk (OARs), combined with advances in radiation delivery modalities, such as 3D conformal RT, IMRT, and proton therapy, could potentially reduce GI toxicity and improve the therapeutic ratio of adjuvant RT. To date, one study has compared different radiation treatment modalities to assess the effect of each modality on bowel and rectal dose-treating CTVs that include the pelvic sidewall regions alone (for margin-negative patients) and the pelvic sidewall, presacral, and cystectomy bed regions (for margin-positive patients).[18] The study reported a dosimetric advantage for IMRT and pencil-beam scanned proton RT over 3D conformal radiation to improve rectal and bowel dose, with no significant difference between the proton and IMRT plans. Based on this dosimetric analysis, the ongoing trials at the GETUG-AFU and Tata Memorial Hospital and the prior NRG trial (NRG GU-001) require an IMRT approach.[7] A representative IMRT treatment plan is shown in Figure 70.1.



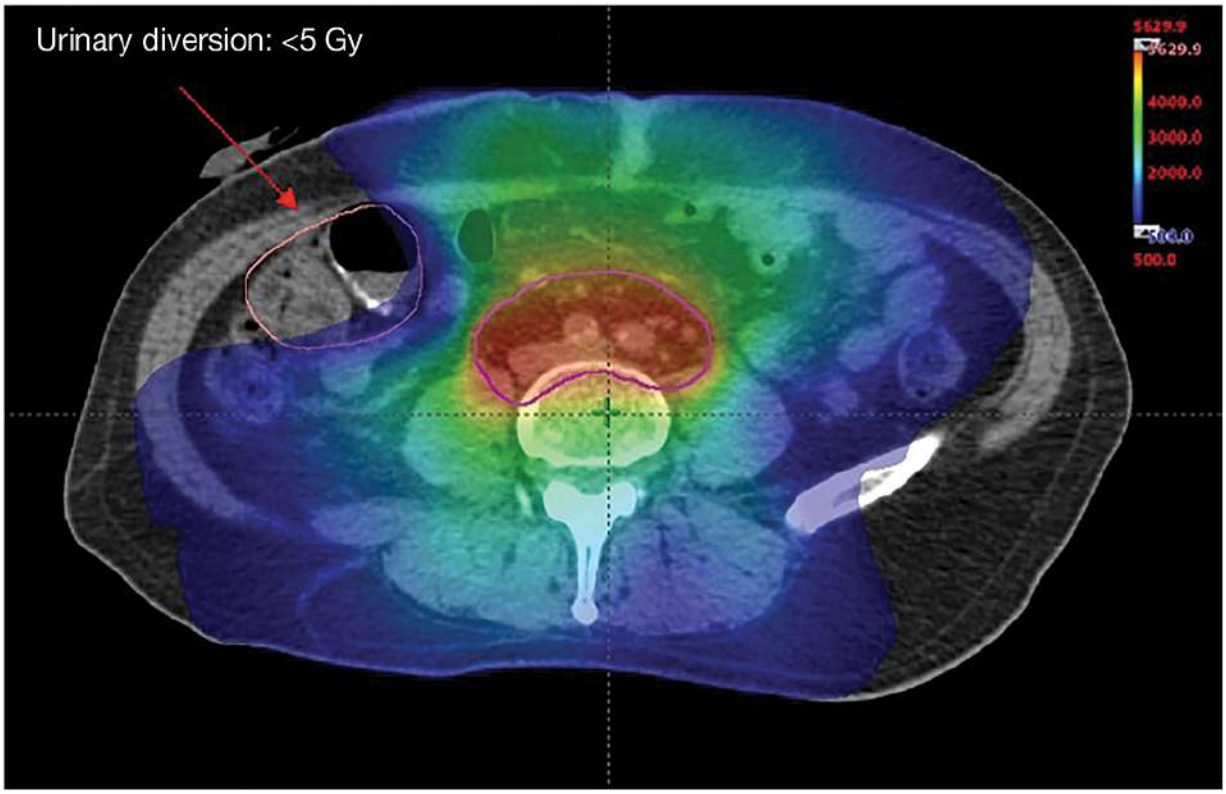


FIGURE 70.1 Pelvic nodes and cystectomy bed treated with intensity-modulated radiation therapy (IMRT). IMRT allows sparing of bowel and the urinary diversion (mean dose ≤5 Gy to the urinary diversion).

International consensus guidelines were developed for the CTVs and OARs for adjuvant RT, as these structures were not well defined in the literature.[33] Twenty-four radiation oncologists and urologists from 15 institutions and 5 countries participated in the study. The group proposed that patients at higher risk for LRF with negative margins should be treated to the pelvic nodes alone (internal/external iliac, distal common iliac, and presacral) whereas patients with positive margins should be treated to the pelvic nodes and cystectomy bed.[16,33] Proposed OARs included the rectum, bowel space, bone marrow, and urinary diversion. The area of greatest discussion in the development of the consensus contours was the cystectomy bed CTV (Table 70.1). Consensus language describing the CTVs and OARs was developed and externally validated, and the revised instructions were found to produce consistent contours.[33] The consensus contouring guidelines have been adopted for the NRG, GETUG-AFU, Tata Memorial Hospital, and the University of Ghent trials. External validation of this consensus contouring guidelines was published by researchers from the University of Chicago who recommended a slight increase in the superior border of the common iliac to cover the aortic bifurcation and a slight increase in the

medial coverage of the obturator nodal regions, based on their patterns of failure analysis.[34] Table 70.2 provides additional expert guidance on adjuvant RT treatment and planning.

TABLE 70.1 SUMMARY OF ANATOMIC BORDERS OF THE CYSTECTOMY BED CLINICAL TARGET VOLUME FROM NRG CONSENSUS CONTOURING GUIDELINES (AND CONFIRMED IN THE CONSENSUS CONTOURING GUIDELINES FROM THE IBIS GROUP)

Superior	The contour will extend 2 cm superior to the superior aspect of the pubic symphysis.
Anterior	The contour will extend to the posterior aspect of the pubic rami/symphysis. Above and below the pubic symphysis, the contour will stop anteriorly at the planes defined by extending lines superiorly and inferiorly from the posterior aspect of the symphysis.
Posterior	The contours will abut the anterior one-third of the external anorectal circumference without extending into the anorectum. Above the level of the rectum, the contour will stop posteriorly at the plane defined by extending a line superior from the anterior border of the rectum.
Lateral	The contour will extend to the medial border of the obturator internus muscles bilaterally. Inferior to the obturator internus muscles, the lateral border of the contour will extend to the vaginal wall or the prostate bed.
Inferior	The contour will stop 2-3 mm (1 axial CT slice) above the penile bulb for males and 1 cm below the lower pole of the obturator foramen for females.

CT, computed tomography.

TABLE 70.2 TIPS FOR RT PLANNING OF POSTOPERATIVE BLADDER CANCER

Topic	Commentary
Patient Selection	• Offer adjuvant RT for any of the following: pT3-4, positive margins, or pN+ disease, with strong consideration of adjuvant RT for positive margins and locally advanced squamous cell carcinoma • Presence of neobladder is not an absolute contraindication to adjuvant RT delivered with bowel-sparing IMRT technique.[35] • Postcystectomy cross-sectional imaging is recommended to rule out distant metastatic disease and to assess for gross nodal disease prior to initiation of adjuvant RT. • Gross nodes may be amenable to a boost dose depending on proximity of adjacent small bowel.
Simulation	• Intravenous contrast may be considered for ease of delineation but often not feasible due to renal insufficiency. • Oral contrast is preferable if individual bowel loops are to be delineated. • Stoma bag should be emptied prior to simulation. • Anticipate rectal distension postcystectomy and avoid aggressive use of laxatives, as distension is likely to persist through the duration of RT.

Topic	Commentary
	• Patients are typically treated 1.5-3 mo after cystectomy but can be treated up to 4 mo after cystectomy for patients treated with adjuvant chemotherapy.
Contouring	• Cystectomy bed should generally be included in target volume irrespective of margin status, especially for more advanced disease (decide on a case-by-case basis). • Cystectomy bed can be omitted for patients with neobladder who have negative surgical margins, though inclusion of the cystectomy bed in select cases is reasonable. • Cystectomy bed and nodal contour should not be carved out of the bowel loops, as variability in bowel position could lead to underdosing in this region. • While small-volume lymphoceles may be included within the pelvic nodal contour, larger ones may be partially excluded in node-negative patients. • Upper limit of nodal contour can extend to the aortic bifurcation to ensure coverage of the common iliac lymph nodes. • If the common iliac nodes are pathologically involved, upper limit of nodal contour may be extended 1-2 cm above the aortic bifurcation. • Entire bowel should be contoured as a single structure superiorly at least 3 cm above the target volume contour and inferiorly till the last visible bowel. • To identify and delineate ileal conduit, trace the ureter down from the renal pelvis. Discussion with a radiologist and intravenous contrast may help. • Delineate the stoma region as an avoidance structure to minimize RT dose.
Planning	• IMRT or proton therapy is strongly recommended. • Sparing of the stoma, ileal conduit, and neobladder should be prioritized during RT planning.
Treatment	• Stoma bag should be emptied before delivering each fraction. • Image guidance with daily CBCT is recommended for setup verification.

While the NRG consensus contouring atlas favored omission of the cystectomy bed for patients with negative margins, it is reasonable to include the cystectomy bed for patients with margin-negative resections who are felt to be at higher risk for cystectomy bed failure (eg, pT3b-T4 or close margin). This line of thinking is based on the subsequent publication of the randomized Egyptian NCI trials, which included the cystectomy bed in the target volume for all patients and achieved excellent local control (2-year local control 92%-96%) with acceptable toxicity.[36] In addition, there are recent data from Tata Memorial Hospital showing

relatively high rates of local recurrence in the cystectomy bed despite negative margins, suggesting inclusion of the cystectomy bed.[4]

Updated international consensus contouring guidelines were recently published by the International Bladder Investigator Society (IBIS) group, an organization of radiation oncologists from the United States, Europe, Asia, and the Middle East with a focus on adjuvant radiation for bladder cancer. In these guidelines, the committee recommended adopting the NRG pelvic nodal contouring guidelines to determine the nodal contouring, which recommends inclusion of the full common iliac region (extending superiorly to the aortic bifurcation) with the modification that the standard 7-mm expansion of the vessels should not be cropped out of the bowel, as NRG had recommended for pelvic nodal radiation for prostate patients. Guidance on how to contour the cystectomy bed remained unchanged, but guidelines recommend including the cystectomy bed for all pT3-T4 or pN+ patients, regardless of margin status. Inclusion of the cystectomy bed can be omitted for patients with negative margins who have a neobladder.

The modern adjuvant trials have treated patients to 50 or 50.4 Gy in standard fractionation, with the Tata Memorial Hospital trial allowing a boost to 54 Gy. 50 Gy in standard fractionation has a similar biologically effective dose (BED) to the twice-daily dose/fractionation scheme used on the Egyptian NCI trials. National guidelines currently recommend 45 to 50.4 Gy in standard fractionation.

Modern series have reported favorable toxicity results using IMRT for adjuvant RT.[37] A retrospective study of 25 patients who underwent adjuvant RT to the pelvic nodes following radical cystectomy with neobladder diversion found that no patients had acute grade ≥3 GI toxicity, with one patient having grade 3 GU toxicity. There were no grade 2 or higher late GI and genitourinary side effects.[38]

LATEST STUDIES UTILIZING ADJUVANT RADIATION

There have been several recently reported trials using adjuvant RT (Table 70.3). A single-arm trial performed at Ghent University Hospital in Belgium was reported in 2022, in which 72 patients with high-risk disease after cystectomy were treated with adjuvant RT with IMRT to a dose of 50 Gy in 25 fractions.[39] Patients had to have pT3 disease with either fewer than 10 lymph nodes removed, pathologically involved nodes, or positive surgical margins. Patients were treated to the pelvic nodes with inclusion of the cystectomy bed for patients with positive margins. Five patients had acute grade ≥3 GI toxicity (7%). With a median follow-up of 18 months, the 2-year local relapse-free rate was 83% ± 5%. This trial showed several relapses in the cystectomy bed in patients where the

cystectomy bed was omitted from the CTV. Overall, local control was very good, and the treatments were well tolerated.

TABLE 70.3 SUMMARY OF KEY PUBLISHED STUDIES EVALUATING ADJUVANT RADIATION FOR BLADDER CANCER

Study Type	Selection Criteria	# of Patients	Adjuvant Tx Arms	Local-Regional Control (2-y)	Disease-Free Survival (2-y)	Overall Survival (2 y)	Comments
Randomized phase II[6]	pT3b/T4a or pN + w/neg margins	120	Chemo + RT vs chemo (gem/cis × 4)	96% vs 69% (*P* < .01)	68% vs 56% (*P* = .07)	71% vs 60% (*P* = .11)	Positive trial: Adding RT improved local control vs chemo alone
Prospective randomized[24]	Same as above	123	RT vs chemo (gem/cis × 4)	92% vs 69% (*P* < .01)	54% vs 47% (*P* = .63)	61% vs 60% (*P* = .83)	Adj RT comparable to adj chemo for DFS
NCDB[22]	pT3-4N0-N+	512 got RT	RT vs no RT	NA	NA	HR 0.87 *P* < .01	RT associated with improved OS
Prospective single arm[39]	pT3-4N0-N+	72	RT	83%	NA	52%	6% acute grade 3 GI toxicity
Prospective randomized arm[35]	pT3-4N0-N+	122	RT vs no RT	81% vs 71% (3-y), *P* < .01	59% vs 50% (3-y), NS	47% vs 44% (3-y), NS	Adj RT improved local control in urothelial patients

DFS, disease-free survival; GI, gastrointestinal; NA, not applicable; NCDB, National Cancer Database; NS, nonsignificant; OS, overall survival; RT, radiation therapy.

A recent randomized trial from Egypt was published in 2024 in which 122 patients with locally advanced urothelial bladder cancer after radical cystectomy with or without neoadjuvant chemotherapy were randomized to receive adjuvant RT to 50 Gy in 25 fractions to the pelvic nodes and cystectomy bed versus observation. Twenty-four patients in the adjuvant RT cohort and 30 patients in the

observation cohort received neoadjuvant chemo. The 3-year adjusted locoregional recurrence-free survival rate was improved in the adjuvant RT arm, measuring 81% (95% confidence interval [CI], 69%-94%) compared with 71% (95% CI, 60%-80%; P = .0457). Adjuvant RT significantly improved the locoregional relapse-free rate in the cystectomy bed and the pelvic sidewall (P = .016 and P = .001, respectively). The trial was not powered to show a benefit in DFS or OS, but results favored the adjuvant RT cohort.

The NRG Oncology opened a trial assessing adjuvant RT versus observation (NRG GU-001), but the trial closed due to poor accrual. Large trials are ongoing assessing observation versus adjuvant radiation, including the BART trial at Tata Memorial Hospital (NCT02951325) and the GETUG-AFU-30 cooperative group trial in France. The recently published data on adverse events from the BART trial from Tata Memorial Hospital adds important data on the safety and tolerability of adjuvant radiation (REF). This trial represents the largest randomized trial comparing adjuvant RT versus observation in urothelial carcinoma patients. The preliminary toxicity results from this trial add to the existing clinical trial data from Ghent University and the Egyptian NCI and provide additional reassurance that adjuvant RT with IMRT to the pelvic nodes and cystectomy bed can be achieved with relatively low marginal risk of acute or late grade ≥3 adverse events, even in a cohort where 90% received peri-operative chemotherapy. The study reported more acute grade 2 adverse events in the radiotherapy arm; however, there was no difference in acute grade 3 adverse events (1.6% for RT vs. 4.2% for observation). Late grade 3-4 adverse events were also comparable, 10.5 % for observation vs. 8.4% for radiation.[45]

PREOPERATIVE RADIATION THERAPY

Preoperative RT for bladder cancer was explored in the 1970s and 1980s, with six clinical trials assessing preoperative RT versus cystectomy alone. Five of six trials were negative,[40-44] but the trial by Awwad et al reported improved 2-year DFS and, unlike the other trials, was limited to patients with locally advanced disease (cT3-T4 disease).[46] A meta-analysis of the preoperative RT studies showed no benefit.[47] These early studies of preoperative RT were limited by poor patient selection, with inclusion of early-stage patients unlikely to benefit from preoperative RT, and the higher toxicity of radiation in the 2D treatment era. As postoperative RT has gained traction, preoperative RT is being reconsidered by some, as improvements in preoperative imaging, radiomics, and the emergence of genomic biomarker testing allow us to better select patients who might benefit from preoperative RT.[48] Preoperative RT has several theoretical advantages over

postoperative RT, including the ability to improve the likelihood of an R0 resection, smaller radiation target volumes and less irradiated normal bowel, and enhanced tumor oxygenation in the preoperative setting that improves the effectiveness of RT. Preoperative RT is the preferred approach for other pelvic malignancies (eg, rectal cancer) where pre-op and post-op RT have been compared in a randomized trial.[49] The currently accruing RACE IT trial is a single-arm study exploring preoperative RT with immunotherapy (NCT03529890).

ADJUVANT IMMUNOTHERAPY

The role of adjuvant RT has come into question based on the results of the CHECKMATE 274 randomized trial that found a statistically significant improvement in DFS with the use of adjuvant nivolumab versus observation for patients with locally advanced disease.[50] A clinical trial of adjuvant atezolizumab was negative, though in the subgroup with detectable circulating tumor DNA levels prior to adjuvant therapy, adjuvant immunotherapy did improve DFS and OS.[51,52]

To the best of our knowledge, studies of immunotherapy have not separately reported rates of LRF, so it is unclear to what extent immunotherapy impacts on rates of LRF versus distant failure.

In small case series, adjuvant RT can be safely combined with immunotherapy, though phase I trial data are currently lacking. There is ample data on the safety of immunotherapy in combination with higher dose definitive radiation for bladder cancer. The initial toxicity results of the SWOG/NRG 1806 trial demonstrated favorable acute toxicity for patients treated with concurrent chemo + RT plus atezolizumab with intact bladders to a dose of ~64 Gy in standard fractionation.[53] Most of these patients were treated to the elective nodes. While the nodal targets are larger for adjuvant radiation than the more limited small pelvic nodal fields that many use for definitive bladder chemo + RT, the absence of concurrent chemotherapy and the overall lower radiation dose points to treatment that is likely to be reasonably well tolerated in appropriately selected patients.

In our opinion, adjuvant RT can be considered in patients who are also being treated with adjuvant immunotherapy. In the AMBASSADOR trial randomizing patients to observation vs. adjuvant pembrolizumab, adjuvant radiation therapy was allowed but had to be performed prior to initiation of pembrolizumab. In general, we would recommend treating with adjuvant radiation before initiation of immunotherapy as per the AMBASSADOR trial, since immunotherapy

continues for approximately 1 year.[54] For patients who start immunotherapy first, it may be prudent to hold immunotherapy while adjuvant RT is being delivered due to the absence of phase I trial data confirming the safety of combined modality treatment in the adjuvant setting. If the two treatments are given concurrently, tolerance to immunotherapy with respect to GI side effects should be confirmed prior to initiation of adjuvant RT, which has the potential to exacerbate immunotherapy-related side effects.

An upcoming American Society for Radiation Oncology (ASTRO) consensus project will address many of these questions.

CONCLUSIONS AND ONGOING STUDIES OF ADJUVANT RADIATION

The Egyptian NCI trials demonstrate that adjuvant RT significantly improves locoregional control and suggest that this improvement in locoregional control may translate to a benefit in survival, a benefit in OS that was seen in a larger retrospective cohort using the National Cancer Database.[22] Given the considerable morbidity and mortality of LRFs, which are rarely salvageable, reducing the risk of local recurrences is an important goal even if such a reduction does not translate to an improvement in survival outcomes, provided the treatment is well tolerated.[7] Adjuvant RT using older 3D conformal RT techniques was well tolerated in the clinical trial, with low rates of late GI complications.[6] Toxicity is expected to be even lower with the use of modern IMRT or proton therapy.[18,19,38]

Based on the existing literature, national cancer guidelines now include adjuvant RT as an option to consider along with adjuvant chemotherapy in patients with ≥pT3 disease or pN+. Adjuvant RT should strongly be considered for patients with positive surgical margins given the very high risk of LRFs[22] and those with locally advanced squamous cell carcinoma, as adjuvant RT with or without chemotherapy was associated with significantly improved OS compared with chemotherapy alone in a post hoc analysis from the Egyptian NCI trial.[25] Patients with locally advanced disease who are not eligible or refused systemic chemotherapy also warrant special consideration for adjuvant RT.[24]

Additional prospective trial data are needed to better define the role of adjuvant RT in the treatment of urothelial carcinoma. Clinical trials are ongoing, and accrual to these trials is very important. The GETUG-AFU 30 (Bladder-ART) cooperative group trial in France is actively accruing, randomizing patients to adjuvant RT versus observation. A similar randomized trial completed accrual recently but oncologic outcomes have not been published yet. at Tata Memorial Hospital (BART) (Table 70.4). These studies will contribute important data that

will help us better understand the role of RT in locally advanced bladder cancer. The IBIS group is planning a meta-analysis to pool the data from the GETUG, Egyptian, and Tata Memorial Hospital trials.

TABLE 70.4 ADJUVANT RADIOTHERAPY FOR BLADDER CANCER IN CONTEMPORARY TRIALS

Trial	Design	Patients	RT Technique and Dose	RT Volume	Status
Nonrandomized Trials					
Bladder-Aid Istituto Clinico Humanitas Rozzano, Milan, Italy NCT03718741	Phase II *n* = 80	Any of: ≥pT3/≥pN/≥R1	IMRT 50 Gy/25 fx SIB 55 Gy/25 fx to bed if R+	Cystectomy bed (+residual tumor if any) + pelvic nodes	Closed early due to poor accrual

Future efforts should examine the role of adjuvant RT in combination with immunotherapy and chemotherapy, as there may be a synergistic effect with radiation and certain immune therapies. These combinations are currently being investigated for patients undergoing definitive chemoradiation for bladder cancer (SWOG 1806 and KEYNOTE-992). While the IMvigor010 phase III trial (NCT02450331) of adjuvant atezolizumab versus observation after radical cystectomy was negative for the primary end point of DFS,[55] the phase III

Checkmate-274 trial randomizing patients to nivolumab versus observation met its primary end point of DFS in an interim analysis.[56] Evaluating the role of adjuvant RT in the setting of immunotherapy offers an exciting opportunity to improve outcomes.

CHAPTER 71

Bladder Cancer

Sophia C. Kamran, Brian C. Baumann, and Jason A. Efstathiou

Since the publication of the seventh edition of this textbook, there have been many exciting developments in the field of bladder cancer (BC) management. The treatment landscape for non–muscle-invasive bladder cancer (NMIBC), previously referred to as "superficial" BC (an imprecise term to be avoided), is rapidly changing. Although the mainstay of treatment is typically transurethral resection followed by intravesical therapy, depending on the grade of disease, novel treatment approaches are being explored, particularly for patients with bacillus Calmette-Guérin (BCG) unresponsive or refractory disease.[1,2] In addition, a randomized phase II trial (NRG/RTOG 0926) evaluating the utility of radiation therapy (RT) in this space demonstrated encouraging outcomes in patients unwilling or unfit for cystectomy (NCT00981656).[3] Targeted therapies will continue to evolve in this space as more molecular-level information is understood about NMIBC.

For muscle-invasive bladder cancer (MIBC), the traditional view of cystectomy as the only gold standard treatment option is evolving. Recent studies demonstrate comparable long-term survival rates and cancer outcomes between surgery and radiation-based approaches.[4-8] Functionally, patients do well after radiation-based therapy for MIBC[9] with low rates of significant long-term toxicity.[10,11] These, and other data, have led to the incorporation of RT for MIBC as a category 1 recommendation per national cancer guidelines. The generally widespread acceptance of RT as a reasonable treatment option for MIBC is evidenced by the recently completed accrual of the SWOG/NRG 1806 (NCT03775265) trial, the largest completed randomized, phase III trial to date of bladder-sparing chemoradiotherapy (chemoRT). With 485 patients accrued, this trial evaluates the addition of atezolizumab, an immune checkpoint inhibitor, to the standard-of-care chemoradiation treatment. Other advances in the field of radiation include the incorporation of hypofractionated regimens to shorten treatment courses[12] and adaptive RT to decrease toxicity,[13] as well as further understanding of biomarkers for improved patient selection.[14-17]

This chapter outlines the evidence base for the current therapeutic approaches to BC and highlights many exciting advances in the treatment of both NMIBC and MIBC, specifically the improved personalization of therapy as more trials are performed in this disease space.

ANATOMY

The bladder is a hollow, muscular organ situated in the pelvis when empty but able to extend up into the abdomen when full, particularly in situations where bladder emptying is impeded.

The bladder is described as having an apex, a superior surface, two inferolateral surfaces, a base or posterior surface, a trigone, and a neck. The apex reaches a short distance cephalad above the pubic bone and ends as a fibrous cord, the remnant of the fetal urachus, which connects the bladder to the allantois. The urachus lies anterior to the peritoneal cavity and is important as tumors can arise in the urachal remnant. The superior surface is covered by the peritoneum, again an important anatomic feature, as it means that there is a bowel lying superiorly to the bladder. This is a critical site to consider when planning RT. In women, it is associated with the uterus and ileum. The base of the bladder is posterior and is separated from the rectum by the vas deferens, seminal vesicles,

and ureters in the male and by the uterus and vagina in the female. The ureters typically enter into the bladder slightly superior and lateral to the seminal vesicles in men; therefore, enlarging tumors either at the base or in the prostate can involve the ureters with consequent hydronephrosis. Inferiorly and laterally to the bladder lie the various pelvic bones and muscles: pubis, the levator ani, and obturator internus muscles. Within the pelvis, the lateral parts of the bladder are surrounded by loose connective tissue. Anteriorly, the bladder is separated from the pubic bone by the retropubic space. The inferior part of the bladder is described as the neck and is in continuity with the urethra and the prostate gland in males. The superior portions distend and expand upward as the bladder fills, while the neck of the bladder is typically more closely anchored to the pelvis.

The mucosal lining of the bladder comprises a transitional epithelium that extends from the renal pelvis to the urethra. The most common tumors arising in the urinary system are urothelial carcinomas (UCs), historically known as transition cell carcinomas.[18] These tumors can arise from anywhere within the urothelium, so diagnosis, treatment, and surveillance protocols must take into account of this important biologic feature. As a distendable organ, the macroscopic appearance of the urothelium varies with distension from smooth and flat to folded when empty. A ridge called the interureteral fold lies between the ureteric orifices.

EPIDEMIOLOGY

The incidence of BC is increasing worldwide, with 613,791 cases diagnosed in 2022 based on data from GLOBOCAN.[19] BC is a major cause of cancer morbidity and leads to 220,349 deaths worldwide. The median age at diagnosis is above 70 years, and as the tumor is often smoking-related, many patients have significant comorbidity, posing risks for radical surgical approaches. Survival rates are poor, with around 45% of patients with muscle-invasive cancer surviving 5 years irrespective of treatment modality.[6,7,20] Overall, around 75% to 80% of patients with BC are male, mostly reflecting historic trends in cigarette smoking.

There are well-known associations of squamous cell carcinomas (SCC) of the bladder with bilharzia caused by *Schistosoma haematobium* infection in Africa, particularly in Egypt.[21] Aromatic amines, polycyclic aromatic and chlorinated hydrocarbons, arsenic-laced drinking water, aristolochic acid, cyclophosphamide exposure, and a range of industrial chemicals have been implicated in urothelial carcinogenesis. Importantly, as with most carcinogens, there are variations in individual susceptibility, and the basis of some of these polymorphisms regulating varied detoxification mechanisms has been identified.[22] With increasing awareness of these industrial associations, regulation of these processes means that these cases are becoming increasingly rare in the developed world. In Egypt, there have been successful public health approaches to the control of *S. haematobium* infections, leading to a substantial decline in incidence and mortality from squamous carcinomas of the bladder.[23]

Within the developed world, most bladder tumors are now UCs, and the main known causative factor is tobacco (particularly cigarette) smoking,[24-29] explaining approximately half of the cases in men and one-third of the cases in women in Europe.

NATURAL HISTORY

Non–Muscle-Invasive Bladder Cancer

Most cases (70%-80%) present with NMIBC (stage Ta, T1, and carcinoma in situ [CIS; Tis]), which is rarely lethal, but shows a high recurrence rate of 50% to 70% after treatment by transurethral resection of bladder tumor (TURBT).[30] In about 10% to 20% of patients with NMIBC,

the disease progresses to muscle invasion (≥T2 lesions), which can lead to metastasis and death.[30] However, the majority of patients with NMIBC will die of other causes, given the typically advanced age at presentation and the strong association with cigarette smoking,[24-29] although it is worth noting that up to 21% of patients with Ta tumors and 49% of patients with T1 tumors will die from BC.[31] For patients with NMIBC, it has been observed that tumor grade and stage, and also tumor number, size, presence of CIS, recurrence rate, and age at diagnosis are risk factors of progression.[32-34] The risk of both recurrence and progression necessitates lifelong follow-up for patients with bladder tumors with cystoscopies.

Muscle-Invasive Disease

MIBC has a poorer prognosis because of a very high rate of occult metastatic disease at the time of diagnosis. Evidence for this comes from the high rate of death from metastasis after apparently successful surgery.[35] Furthermore, reported 5-year cancer-specific survival (CSS) rates with RT or surgery are remarkably similar at around 80% to 85% in modern series for well-selected candidates (tumors <7 cm, no or unilateral hydronephrosis, and no extensive multifocal CIS),[8] suggesting that prognosis is driven by the presence, or otherwise, of metastases at the time of diagnosis, driven by tumor-related factors such as stage and grade.

Metastatic Disease

A minority of patients (<10%)[36] present with metastatic disease, carrying a poor prognosis. Treatment intent for patients is generally palliative, but the goal of therapy is to control tumor burden, treat cancer-related symptoms, and improve survival. Historically, for patients fit for chemotherapy, extensive randomized studies carried out in the 1980s and 1990s demonstrated the superiority of cisplatin-based combination chemotherapy over those containing other drugs or cisplatin alone. Of the platinum-based combinations, methotrexate/ vinblastine/doxorubicin (adriamycin)/cisplatin (MVAC)[37] and gemcitabine/cisplatin (GC)[38] have proven to be superior to other combinations and broadly similar in efficacy to each other[39,40] (as reviewed by Hussain and James).[41] Median survival is 12 to 18 months, depending on the extent of disease and fitness of the patient. Intriguingly, however, a small minority of patients do appear to survive long term after chemotherapy for metastatic disease, but this percentage has sadly proved very hard to increase from that originally observed in the MVAC trials.

However, newer systemic agents have proved superior to some of the traditional combination platinum-based chemotherapy. Enfortumab vedotin (EV) is an antibody targeting the cell adhesion molecule nectin-4 linked to a microtubule inhibitor conjugate. In combination with immune checkpoint inhibitor pembrolizumab, data demonstrate superiority of this regimen over standard platinum-based combination chemotherapy.[42] Thus, initial therapy is now recommended to be EV plus pembrolizumab for patients with untreated metastatic UC. This is based on the recent phase III trial, which found that overall survival (OS) was improved (median 32 vs 16 months, hazard ratio [HR] 0.47, 95% confidence interval [CI] 0.38-0.58) as well as progression-free survival (PFS) (median 13 vs 6 months, HR 0.45, 95% CI 0.38-0.54) with EV/pembrolizumab compared to standard chemotherapy. Further details on optimal systemic therapy approaches are evolving rapidly and outside the scope of this chapter.

ETIOLOGY

The link between occupational exposure and an increased risk of UC of the bladder was established more than a century ago when Rehn[43] reported on three cases of BC in a German chemical dye works in 1895. During the following 40 years, similar reports appeared from around the world. In 1938, Hueper et al[44] demonstrated that when naphthylamine, an industrial arylamine used in the synthetic dye industry, was fed to dogs, it caused BCs identical to the human disease. The link between industrial arylamines and BC was thus established and later confirmed by Case et al[45] in 1954. These authors also identified an excess of BC in the tire industry, attributable to the use of 2-naphthylamine in the manufacture of rubber.[45] Around this time, the "o-aminophenol hypothesis" of arylamine-induced human BC was proposed, suggesting that conjugation of aromatic amines by the liver and excretion in the urine with subsequent urinary reactions would liberate the carcinogen o-aminophenol.[46] Other workers later added to this hypothesis: Arylamines are hydroxylated in the liver and conjugated with glucuronic acid, followed by excretion into urine and reliberalization of the active carcinogenic metabolite into the bladder lumen by urinary glucuronidases.[44,47,48] Slow acetylation by *N*-acetyltransferase, an enzyme involved in the metabolism of arylamines, has been shown to be a contributory risk factor for bladder carcinogenesis.[25,49,50]

Because of the widespread use of arylamines in textile dyes, hair dyes, and paint pigments, a number of high-risk occupations have been identified, including chemical, dye, textile, and rubber workers and painters and hairstylists.[29,51-53] In addition, the presence of various arylamines in tobacco smoke means that a significant proportion of BC cases can be attributed to cigarette smoking.[25,26,28,29] In fact, abandonment of the manufacture of many of these arylamines in the latter half of the 20th century means that smoking is currently the single most important cause of UC.[24,54-56] Tobacco (particularly cigarette) smoking explained approximately half of BC cases in men and two-fifths of cases in women in the United States in 2014.[19,57] It has been demonstrated that an increased smoking frequency and duration and a lower age at initiation are associated with an increased risk of BC, whereas cessation seems to reduce the risk.[54] The relation between smoking and other prognostic factors is interesting, as it could give insight into biologic mechanisms of disease and, perhaps more importantly, have clinical implications by increasing the ability to identify patients at risk of more malignant disease. Cigarette smoking also appears to be a risk factor for disease recurrence following a diagnosis of bladder UC.[54,58]

Studies also demonstrate a relation between *N*-acetyltransferase-2 slow acetylators and cigarette smoking, resulting in a further increase in the risk of BC, especially in those individuals with a high smoking intensity.[59-61] A similar relation has also been demonstrated with arylamine exposure.[62,63] A number of other susceptibility loci have also been identified, although such markers do not yet have sufficient discriminatory ability to be utilized for risk prediction in the general population or for prediction or prognostication in patients diagnosed with BC.[61,64]

CHRONIC INFLAMMATION AND BLADDER CANCER

Squamous metaplasia is considered a precursor of SCC of the bladder and is a relatively common occurrence, especially on the trigone of the female bladder where a prevalence of up to 50% is reported.[65] Experimental evidence suggests that this does not occur by direct transformation of the superficial apical umbrella cells of the urothelium or by their dedifferentiation and redifferentiation; it is postulated that basal cells (probable stem cells) are selectively activated.[65] The normal urothelium is slowly proliferating, but urothelium undergoing squamous metaplasia becomes hyperplastic, and it may be that the hyperplasia component of urothelial squamous metaplasia is a major contributor to an enhanced risk of cancer formation.

SCC and adenocarcinoma of the bladder often occur in the presence of chronic inflammation. In Africa and the Middle East, where these tumors are much more prevalent, the chronic inflammation occurs as a result of infestation with the parasite *S. haematobium* (bilharziasis), with a BC incidence of 2 to 4 per 100,000 in *S. haematobium* endemic areas.[66-69] This infestation can lead to malignancy through local tissue damage, mechanical irritation, bilharzial toxins, secondary bacterial infection, and the production of nitrosamines.[70,71] With liver involvement and subsequent liver dysfunction, tryptophan metabolism may be disturbed, resulting in excretion of carcinogenic metabolites.[70] In *S. haematobium*–infected individuals, the prevalence of squamous metaplasia rises significantly during the first 10 to 15 years of life, with a plateau at roughly constant levels thereafter (30%-40% in males and 40%-50% in females) when the active infection may have subsided.[68] It is suggested that proliferative changes in the bladder urothelium may become independent of ongoing infection after long periods of chronic *S. haematobium*–induced inflammation.[70,72] Severe metaplasia of the bladder may represent a precancerous transformation in some individuals, but in others, it may only represent a marker for the prolonged inflammation that is associated with a high cancer risk.[70] This sort of proliferative growth combined with the increased excretion or local formation of mutagens in the *S. haematobium*–inflamed bladder may significantly contribute to the onset of cancer formation, possibly involving mutations of the *p53* and *CDKN2* tumor suppressor genes.[70]

In Europe and North America, the stimulus of chronic bladder inflammation is usually chronic bacterial infection, bladder calculi, or long-term indwelling catheters.[73-76] A number of metaplastic conditions (squamous metaplasia, von Brunn nests, cystitis cystica, and cystitis glandularis) may occur prior to frank malignant change, although the premalignant nature of some of these lesions is still unclear.[73-82]

Molecular Basis of Multifocality of Urothelial Carcinoma

UC is a multifocal disease, characterized by the high frequency of synchronous and metachronous primary cancers. These tumors can occur anywhere in the urinary tract, from the renal pelvis to the urethra. The multifocality can be explained by two potential theories. The first is the "field characterization effect," suggesting that the whole urothelium is exposed to the same urinary carcinogens, leading to the transformation of many independent separate urothelial cells and resulting in multiple tumors developing independently in multiple sites. These multiple tumors are thus genetically unrelated.[83] A separate theory postulates that the multifocality of UC arises because of a single carcinogenic insult to a single cell or group of cells. The progeny or clones of these cells spread throughout the urinary tract, either through intraepithelial migration or through cell shedding and reimplantation, leading to multiple synchronous and metachronous tumors.[84] These tumors are thus topographically distinct but are genetically related. Molecular studies now demonstrate that UCs present as a heterogeneous group of tumors, and these may evolve along two different pathways with distinct biologic behavior. Papillary, low-grade, noninvasive tumors are thought to arise from urothelial hyperplasia/papillomas and are often multifocal with high recurrence rate. MIBC arise through sequences of events starting from normal to dysplasia, CIS and then invasion. T1 high-grade tumors are more complex, with overlapping molecular features between the abovementioned two groups.[85] Further work into the molecular basis of UC is ongoing, particularly with the discovery of cancer stem cells (discussed in further detail later), which add a new dimension for occurrence of multifocality and recurrence of UCs.

Molecular Classification of Urothelial Carcinoma

In 2014, the Cancer Genome Atlas Research Network reported an integrated analysis of 131 UCs to provide a comprehensive landscape of UC alterations.[86] This was updated in 2017, with 412 tumors.[87] These and other studies have allowed us to further classify bladder tumor–based molecular alterations. For example, low-grade pTa tumors frequently demonstrate FGFR3 mutation and infrequent p53 mutation.[88] However, muscle-invasive tumors demonstrate complex chromosomal changes with frequent TP53 mutation and rare FGFR3 mutation. In addition, the overall mutational load observed with MIBC associates with APOBEC signature mutagenesis. Knowles et al[89] demonstrated that deletions of chromosome 9 occur in over half of bladder tumors of all grades and stages (9p, 51%; 9q, 57%). Loss of heterozygosity also occurs on 17p (32%), 11p (32%), 8p (23%), 4p (22%), and 13q (15%), and loss of heterozygosity of 5p, 8p, and 21q is significantly associated with worse grade and stage.[89] Genomic copy number alterations are also frequent in bladder UC, with the most frequent changes involving complete or partial loss of 4q (83%) and gain of 20q (78%).[88] Other frequent losses are of 18q (65%), 8p (65%), 2q (61%), 6q (61%), 3p (56%), 13q (56%), 4p (52%), 6p (52%), 10p (52%), 10q (52%), and 5p (43%).[88]

Gene expression profiling has been found to play a large role to further subclassify BC into clinically relevant subtypes. The Bladder Cancer Molecular Taxonomy Group has identified a set of six molecular classes of MIBC: luminal papillary, luminal- nonspecified, luminal-unstable, stroma-rich, basal/squamous, and neuroendocrine-like.[90] Additional work is ongoing to classify subtypes with reduced gene sets, which can potentially further inform future trials and personalized therapies.

Pathways to Muscle-Invasive and Non–Muscle-Invasive Bladder Cancer

Several different approaches can be taken to describe the molecular alterations involved in bladder urothelial tumorigenesis. Prior descriptions[91,92] exist in detail based on the six original "hallmarks of cancer" described by Hanahan and Weinberg[93] in 2000. In 2011, Hanahan and Weinberg[94] updated their original landmark review, describing genome instability and inflammation as underlying these hallmark changes and proposed "reprogramming of energy metabolism" and "evading immune destruction" as two emerging hallmarks with potential for generality. In addition, they reported that tumors exhibit another dimension of complexity by containing a repertoire of recruited, ostensibly normal cells that contribute to the acquisition of hallmark traits by creating the "tumor microenvironment." The timing and sequence of hallmark events can vary widely between tumors of the same type and within the same tumor, but ultimately, these hallmark capabilities of cancer will be reached. In their 2011 update, Hanahan and Weinberg[94] also introduce the concept of "cancer stem cells," a concept that has existed for quite some time for hematopoietic malignancies.[95] Cancer stem cells are a subset of tumor cells that have the ability to self-renew and to generate all of the heterogeneous cells that comprise a tumor (properties that are analogous to a stem cell, the original cell of an organ, and responsible for organogenesis and organ maintenance).[96] It is proposed that these cells are responsible for tumorigenesis, tumor differentiation, tumor maintenance, tumor spread, and tumor relapse.[97] In the setting of BC, cancer stem cells appear to play a role in a subset of tumors, but their true significance has yet to be clarified.[98,99]

Several other authors have also reviewed this field in detail,[100-107] and there is general consensus on a divergent pathway for the development of Ta/T1 disease and Tcis/T2+ disease (Figure 71.1)[107-112] (Leeds, UK). In their 2010 review, Goebell and Knowles[100] propose a third hypothetical pathway for the development of high-grade papillary tumors. Significant contributions to work in this field have been made by Knowles and colleagues.[101-107]

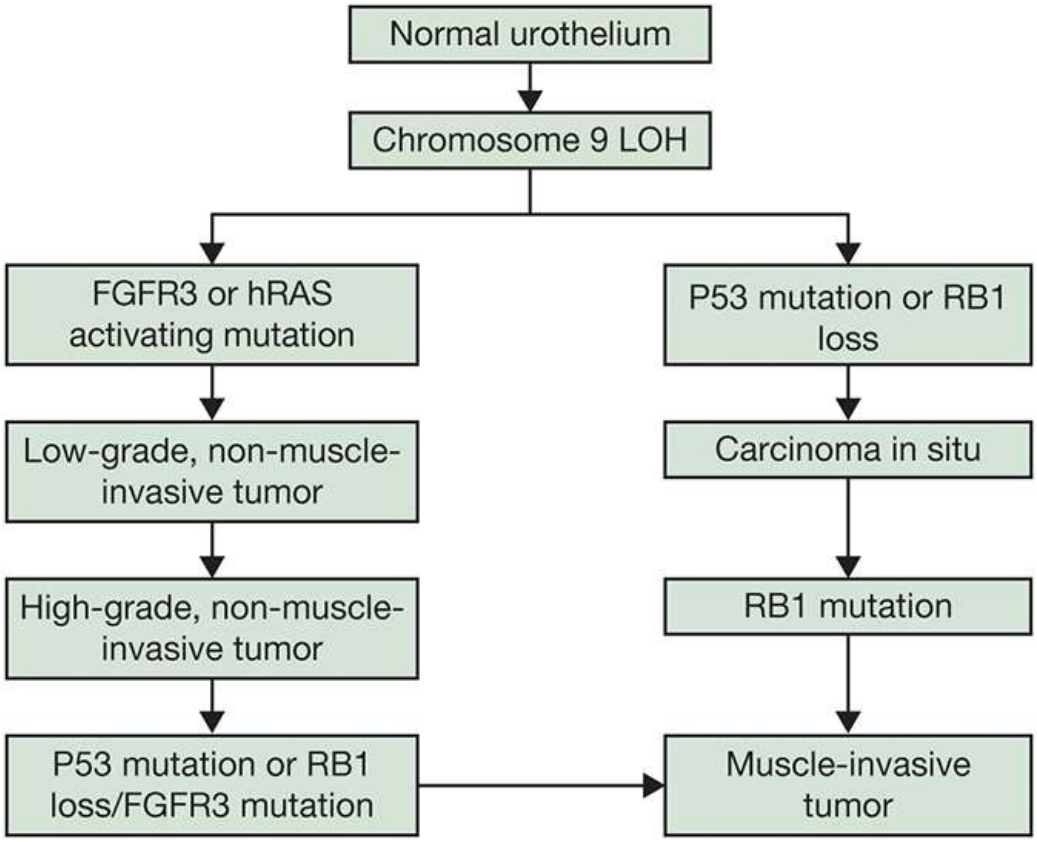

FIGURE 71.1 Pathways to the development of bladder cancer. LOH, loss of heterozygosity. (Adapted from Pollard C, Smith SC, Theodorescu D. Molecular genesis of non-muscle-invasive urothelial carcinoma (NMIUC). *Expert Rev Mol Med*. 2010;12:e10. Copyright © 2010 Cambridge University Press. Reproduced with permission.)

A detailed examination of these pathways and related biomarkers is beyond the scope of this chapter. In addition, this is a rapidly changing field, and new developments appear frequently with the advent of high-throughput experimental platforms, including "deep sequencing,"[87,113,114] proteomics,[115] and metabolomics,[116] so readers are directed to the reviews cited earlier or to the latest work in this field.

SIGNS AND SYMPTOMS

The classic presentation for BC includes painless, visible hematuria; however, irritative voiding symptoms (dysuria, lower urinary tract symptoms) can also be the presenting symptom. As hematuria is typically transient and urinary tract symptoms can often be attributed to the prostate (in men), or urinary tract infections (in women), patients often go undiagnosed for considerable periods, and it is known that delays in diagnosis lead to worsened prognosis.[117] Evidence suggests that poorer survival in women with BC is associated with delayed diagnosis compared to men.[118] Hematuria from BC is more likely to be misinterpreted in women of child-bearing age, given the association of blood in urine when women are menstruating. However, given the intermittent nature of the hematuria associated with BC, patients presenting with a convincing episode of hematuria require urgent assessment.

DIAGNOSIS

In developed countries, most patients will be referred for evaluation because of hematuria or suspected BC. A minority may present via other routes (eg, with metastatic symptoms). Workup for suspicion of BC generally includes a clinical assessment, urinalysis, complete blood count and metabolic profile, prostate-specific antigen (if indicated), urine cytologic examination, flexible cystoscopy, and imaging of the urothelial tract (eg, computed tomography [CT] urogram or magnetic resonance [MR] urogram). Patients identified as having a bladder tumor on flexible cystoscopy will then require further investigations to stage the disease.

STAGING

As part of the workup for suspected BC, an examination under anesthesia coupled with TURBT is needed. The presence or absence of a residual mass after TURBT is an important prognostic factor, as it potentially indicates either unsuccessful clearance of tumor, extravesical extension, or both. This serves as both definitive staging of the bladder lesion and a substantial proportion of the initial treatment. Pathologic review of the resected specimen will ascertain whether muscle invasion is present and whether there is CIS. These are the key determinants of further investigation and treatment. Patients with NMIBC, including CIS, do not usually require detailed further imaging, and treatment and surveillance are primarily by intravesical means. The main exception to this is patients with either extensive CIS or grade 3 lesions for whom additional cross-sectional imaging may be warranted. Patients with MIBC will require detailed cross-sectional staging with CT or magnetic resonance imaging (MRI) of the chest, abdomen, and pelvis. If there are any features suggestive of bone metastasis (eg, raised alkaline phosphatase, bone pain), a bone scan is additionally indicated.

A major confounding factor with imaging in BC is the effect of TURBT on the interpretation of the extent of the primary bladder tumor. Recent TURBT will cause perivesical changes that may be interpreted as extravesical spread. For similar reasons, enlarged pelvic nodes may be related to reactive rather than metastatic effects. On the other hand, changes such as infiltration of adjacent organs or hydronephrosis are likely to be reliable indicators of tumor stage and poor prognosis. However, MRI is a promising modality to better assess the extent of disease and improve local staging, particularly prior to TURBT.[119] Due to the improved resolution with MRI, a standardized approach to imaging and reporting for bladder MRI was developed, called the Vesical Imaging-Reporting And Data System.[120] This system is useful given the increasing use of pelvic MRI for BC staging and can allow for improved communication between physicians and better staging accuracy for patient care.

STAGING SYSTEMS

The American Joint Committee on Cancer (AJCC) TNM staging system (eighth edition, 2017) and the Union for International Cancer Control (UICC) TNM staging system (eighth edition, 2016) are the currently used staging systems.[121] Both use the same TNM definitions, albeit with minor terminology variations. Staging is based on the size and extent of the primary tumor (T), presence or absence of nodal (N), and metastatic spread (M) (Table 71.1). The TNM stage must be used in conjunction with the pathologic assessment of tumor removed at TURBT to decide on optimal therapy.

TABLE 71.1 AJCC TNM STAGING SYSTEM FOR BLADDER CANCER, EIGHTH EDITION

T	*Primary Tumor*

Tx	Primary tumor cannot be assessed.		
T0	No evidence of primary tumor		
Ta	No invasive papillary carcinoma		
Tis	Carcinoma in situ: “flat tumor”		
T1	Tumor invades lamina propria (subepithelial connective tissue).		
T2	Tumor invades muscularis propria. T2a invades superficial muscularis propria (inner half). T2b invades deep muscularis propria (outer half).		
T3	Tumor invades perivesical tissue: T3a microscopically T3b macroscopically (extravesical mass)		
T4	Tumor invades any of the following: prostate stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall. T4a tumor invades prostate, stroma, seminal vesicles, uterus, or vagina. T4b tumor invades pelvis or abdominal wall.		
N	*Regional Lymph Nodes*		
Nx	Nodes cannot be assessed.		
N0	No lymph node metastasis		
N1	Metastasis in a single lymph node in the true pelvis (perivesical, obturator, internal and external iliac, or sacral)		
N2	Metastasis in multiple lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)		
N3	Metastasis in a common iliac lymph node(s)		
M	*Distant Metastasis*		
M0	No distant metastasis		
M1	Distant metastasis M1a distant metastasis limited to lymph nodes beyond the common iliacs M1b non–lymph node distant metastases		
Stage grouping			
Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2a,b	N0	M0
Stage IIIA	T3a,b	N0	M0
	T4a	N0	M0
	T1-T4a	N1	M0
Stage IIIB	T1-T4a	N2, N3	M0
Stage IVA	T4b	Any N	M0
	Any T	Any N	M1a
Stage IVA	Any T	Any N	M1b

PATHOLOGY

Over 90% of BCs are UCs. Nonurothelial BC accounts for less than 5% of all bladder tumors. Approximately 90% of nonurothelial BCs are epithelial in origin, including SCC (associated with infestation with *S. haematobium)*, adenocarcinoma (which are associated with urachal remnants), and small cell carcinoma. Small cell carcinoma is generally very chemosensitive, and treatment tends to follow paradigms of small cell lung cancer. Nonepithelial tumors include sarcoma, melanoma, lymphoma, paraganglioma, and carcinosarcoma. These are extremely rare.

Bladder UCs are typically graded using Gx (cannot be assessed) and then G1 through to G3 (well differentiated through poorly differentiated).[122] CIS will frequently be found in addition to a tumor mass and can affect treatment choices.

MANAGEMENT OF BLADDER CANCER

Non–Muscle-Invasive Bladder Cancer

Around 70% to 75% of patients with BC present with NMIBC.[123] These are classified as Tis, Ta, and T1 by the TNM classification system, and histology for NMIBC should be classified using the 2004 World Health Organization/International Society of Urological Pathology grading system.[124] The gold standard for diagnosis is the resection of the lesion with adequate sampling of the detrusor muscle deep to the lesion (TURBT). This will give tissue for accurate staging of the bladder lesion as well as definitive treatment for the lesion.

Prognostication and management strategies are based on accurate initial staging and grading of the disease. If the initial TURBT results in a macroscopically incomplete resection, there is a high volume of tumor, there is not muscle available in the specimen, or there is high-grade T1 disease, repeat TURBT should be performed approximately 4 to 6 weeks after initial resection. At the time of diagnosis, the upper urinary tract also needs assessment. This is typically done with CT urography.

Between 40% and 80% of NMIBC recurs within 6 to 12 months after complete TURBT without any additional therapy, and approximately 10% to 25% will progress to muscle-invasive, regional, or metastatic disease.[125] Therefore, the recommendation for additional therapy to reduce the risk of recurrence is based on multiple tools to risk stratify and prognosticate BC recurrence.

Multiple prognostication tools are available to guide potential adjuvant therapies and surveillance, including the European Organisation for Research and Treatment of Cancer (EORTC) BC recurrence risk calculator,[34] the Club Urologico Espanol de Tratamiento Oncologico risk stratification system,[126] and the American Urological Association/Society of Urological Oncology (AUA/SUO) risk stratification system.[127,128] All of these generally incorporate the following clinical and pathologic factors: number of tumors, tumor size, prior recurrence rate, T category, presence of concurrent CIS, and tumor grade. In the United States, the AUA/SUO system is primarily used and described as follows:

- *Low-risk* tumors include following: (1) solitary, low grade, 3 cm or less, and Ta; and (2) papillary urothelial neoplasms of low malignant potential.
- *Intermediate-risk* tumors include the following: (1) recurrent tumors within 1 year that are low-grade Ta; (2) solitary low-grade Ta, greater than 3 cm; (3) multifocal low-grade Ta; (4) high-grade Ta, 3 cm or less; and (5) low-grade T1.
- *High-risk* tumors include the following: (1) high-grade T1; (2) any recurrent high-grade Ta; (3) high-grade Ta, greater than 3 cm or multifocal; (4) any CIS; (5) any patient with high-grade

NMIBC and BCG failure; (6) any variant histology; (7) any lymphovascular invasion; and (8) any high-grade prostatic urethral involvement.

A comprehensive discussion regarding risk-adapted adjuvant therapy in NMIBC is outside the scope of this chapter. In general, low-risk tumors have a 15% probability of recurrence and a 0.2% risk of progression at 1 year.[34] These patients should undergo cystoscopic surveillance, but immediate intravesical chemotherapy can be considered. For surveillance, the use of flexible cystoscopy with urine cytology is the standard. Based on a systematic review and individual patient data meta-analysis of randomized trials, immediate intravesical instillation of chemotherapy reduced the 5-year recurrence rate from 59% to 45%.[129] Gemcitabine and mitomycin-C (MMC) are the two chemotherapy agents used most frequently and with the strongest data supporting their use.[130,131] Gemcitabine is typically preferred to MMC due to lower toxicity and cost.

Intermediate- and high-risk tumors have up to a 38% to 61% probability of recurrence and a 5% to 17% risk of progression at 1 year, respectively.[32] The mere presence of CIS in the bladder carries a 50% risk of disease progression to muscle-invasive disease within 5 years without any treatment post-TURBT, and a 30% to 40% risk of progression within 10 years despite treatment.[132] Therefore, adjuvant treatments are more strongly recommended for these tumors. In patients with intermediate-risk tumors, either intravesical chemotherapy or intravesical immunotherapy using BCG can be offered.[127,128] Patients with high-risk tumors should be offered BCG therapy (European Association of Urology [EAU] and AUA guidelines).[127,128,133] Patients with high-risk tumors with aggressive features (CIS, lymphovascular invasion, or variant histologies) should be recommended for radical cystectomy (RC).[128]

For BCG therapy, there are a variety of treatment schedules in the literature, but per AUA/SUO guidelines, generally an intravesical treatment once a week for 6 weeks for induction followed by a rest period of 4 to 6 weeks, with a full cystoscopic evaluation 12 weeks after initial BCG therapy.[134] If there is no cystoscopic evidence of recurrence, the patient should then be offered ongoing maintenance BCG with a 3-week BCG regimen. In a meta-analysis of trials with BCG maintenance, a 32% reduction in the risk of recurrence was seen for BCG compared with MMC ($P < .0001$), whereas there was a 28% increase in the risk of recurrence ($P = .006$) for patients treated with BCG in the trials without BCG maintenance.[135] There are multiple schedules that have been evaluated; however the strongest data support a 3-week regimen used in the SWOG trial, demonstrating reduced disease progression and metastasis.[136] Patients can receive maintenance BCG for 1 to 3 years. A randomized study of 1,355 patients with a median follow-up of 7.1 years found that there was no benefit to continuing maintenance BCG for 3 years compared to 1 year for intermediate-risk patients. However, 3-year maintenance BCG reduced recurrence but did not impact progression or survival in high-risk patients.[137] Thus, 1 year of maintenance BCG is offered for patients with intermediate-risk disease, while 3 years is offered for patients with high-risk disease.

In treatment-refractory disease within 12 months of completion of adequate BCG therapy (defined as persistent or recurrent high-grade NMIBC after two courses of BCG [eg, two induction 6-week courses or a 6-week induction course and maintenance 3-week course]), the patient should be offered RC treatment for the bladder.[127] Yet many patients decline to undergo RC, given the associated negative impact on quality of life (QoL),[138,139] or they may not be eligible due to age or comorbidities. Management for such situations has yet to be fully defined. Pembrolizumab is a programmed cell death protein-1 immune checkpoint inhibitor that was approved in patients with BCG-unresponsive NMIBC with CIS based on the single-arm KEYNOTE-057 trial.[1] Of 96 patients enrolled, 39 (41%) achieved a complete response (CR) at 3-months. The CR rate was 31% at 6

months and 19% at 12 months. A similar trial with atezolizumab reported a CR rate of 27% at 6 months and 25% at 12 months.[2,140] A recent single-arm, prospective phase II cooperative group clinical trial, NRG/RTOG 0926, evaluated patients with high-grade recurrent T1 BC using bladder-sparing chemoradiation. Patients received 61.2 Gy concurrently with either cisplatin or MMC/5-fluorouracil (5-FU) after maximal TURBT. This trial was recently presented in 2021,[3] and of 34 evaluable patients with a median follow-up of 4.2 years (>5 years in surviving patients), the 3-year freedom from cystectomy rate was 88%. The 3- and 5-year OS rates were 69% and 53%, respectively. The cumulative incidence of distant metastasis at 3 and 5 years was 12% and 20%, respectively. Twenty patients had grade 3 adverse events, including anemia, gastrointestinal events, urinary tract infections, lymphopenia, metabolism and nutrition disorders, as well as hematuria. These results need further validation; however, they may represent a well-tolerated option for select patients with high-grade T1 disease who have recurred despite intravesical therapy. A follow-up trial, NRG-014, will begin enrollment soon and will randomize 160 patients with cystectomy-eligible high-risk T1 BC to chemoradiation to the bladder only (BO) versus radiation to the BO plus 1 year of pembrolizumab (PIs: Baumann & Delacroix). Patients will be stratified based on recurrent versus de novo disease and on the basis of urothelial/mixed histology versus nonurothelial histology. Focal CIS is allowed. The trial hypothesizes that RT plus pembrolizumab will result in an improvement in 3-year bladder-intact event-free survival versus chemoRT.

Muscle-Invasive, Nonmetastatic Disease

For a review of recent guidelines and recommendations for broad therapeutic options in the multidisciplinary integrated management of invasive non–metastatic MIBC by the AUA, American Society of Clinical Oncology, the American Society for Radiation Oncology, SUO, and the EAU, the reader is referred to the original publications in the *Journal of Clinical Oncology* and the *Journal of Oncology Practice*.[141,142]

Radical Cystectomy Versus Bladder Preservation Therapy

RT has been offered as a primary treatment for MIBC for many years, but utilization rates vary around the world from around 12% to 18% in the United States[143,144] to over 50% in the United Kingdom.[145] In addition, there is significant underutilization of bladder preservation therapy in noncystectomy candidates, particularly the older and racial minorities.[146,147] Bladder-sparing approaches are reasonable (and preferred) in patients who are medically unfit for surgery. However, between 23% to 50% of patients aged 65 years and above receive no treatment or nonaggressive therapy, despite prospective, phase II data demonstrating good outcomes and acceptable toxicity in this cohort of patients, with 2-year OS of 94.4% and 2-year disease-free survival (DFS) of 72.6%.[148]

For patients who are surgical candidates, RC was traditionally the gold standard treatment for MIBC. Bladder preservation trials, particularly in the United States, are largely phase II studies because of historical lack of acceptance of bladder preservation.[149] The two largest phase III, randomized controlled trials published to date of bladder preservation for MIBC were both performed in the United Kingdom. These demonstrated benefit for locoregional DFS (BC2001)[150] and OS (BCON),[151] using either chemotherapy (BC2001) or hypoxia-modifying therapy (BCON)[151] along with RT, compared to RT alone. The BC2001 trial[150] allowed either 55 Gy in 20 fractions or 64 Gy in 32 fractions for RT. Patients were then randomly assigned to receive synchronous chemotherapy (5-FUl and MMC) or no chemotherapy. The BCON trial[151] allowed for the same RT fractionations, and patients were randomly assigned to receive synchronous treatment with

carbogen and nicotinamide or no synchronous treatment. Despite these data demonstrating good efficacy with the use of bladder preservation for MIBC, there are no completed direct head-to-head randomized comparisons comparing surgery with RT, so the data on comparative efficacy can only be inferred indirectly. The only randomized controlled trial evaluating RC versus bladder-sparing RT (+/− concurrent chemotherapy) that was performed is the UK SPARE trial (randomized trial of Selective Bladder Preservation against Radical Excision [cystectomy] in muscle-invasive T2/T3 transitional cell carcinoma of the bladder), which was closed due to poor accrual.[152] Yet, data from RTOG/NRG prospective protocols as well as other modern series comparisons demonstrate similar long-term clinical outcomes between RC and bladder-sparing therapy, helping to solidify bladder preservation with RT as an appropriate, alternative option for well-selected patients.[4,5,8] It is listed as a category 1 recommendation in national consensus guidelines, as well as multiple international organizations and evidence-based consensus guidelines.[141,153] Several highlights of the data demonstrating comparable outcomes between surgery and radiation for MIBC are discussed later.

Large population-based studies suggest that the main determinants of survival after diagnosis of BC are stage, grade, age, and, to some extent, social class. For example, Hayter et al[154] studied patterns of care and outcomes in over 20,000 patients with BC in Ontario. There were significant variations in the use of cystectomy and RT between different districts, but there was no evidence that these variations led to any differences in long-term outcomes. It was thus concluded that bladder-sparing approaches were equivalent to surgery for invasive BC.[155]

In the United Kingdom, both surgery and RT approaches are routinely employed for MIBC; therefore, it is possible to compare their outcomes in Cancer Registry data. A paper from Munro et al[145] examined outcomes in 458 patients with invasive BC treated in Yorkshire between 1993 and 1996. The ratio of cystectomy to RT was 1 to 3, reflecting UK practice at the time. Overall 10-year survival was similar between those who underwent RT (22%) and RC (24%). Prognostic factors for inferior outcome at 10 years included female versus male, poor performance status, hydronephrosis, and increasing T-stage; treatment modality was not a factor in the prognosis.

Giacalone et al[4] conducted a contemporary analysis of 465 patients with cT2-T4a BC treated at a single institution with maximal TURBT followed by concurrent cisplatin-based chemotherapy and RT. A subset of patients also received neoadjuvant chemotherapy. Repeat cystoscopy with biopsies was performed after 40 Gy. Patients with a CR received consolidation chemoradiation to 64 to 65 Gy, and those with less than a CR or invasive recurrence were recommended to undergo salvage RC. Median follow-up was 4.5 years for all patients and 7.2 years for surviving patients. Seventy-five percent of patients had a CR to induction chemoradiation, 84% after a visibly complete TURBT achieved a CR versus 58% with an incomplete TURBT ($P < .001$). When divided into three treatment eras, the CR rate has improved from 66% in years 1986 to 1995 to 88% in years 2005 to 2013. One hundred twenty-nine patients (28%) underwent salvage RC, 65 for less than CR and 64 for superficial or invasive recurrences. The 10-year actuarial rates for noninvasive, invasive, regional nodal, and distant failures were 26%, 18%, 14%, and 35%, respectively. The 5-, 10-, and 15-year disease-specific survival (DSS) rates were 66%, 59%, and 56% (cT2 74%, 66%, 60%; cT3-T4a 50%, 45%, 45%), respectively. The 5-, 10-, and 15-year OS rates were 57%, 39%, and 25% (cT2 65%, 46%, 29%; cT3-T4a 42%, 26%, 17%), respectively. Neither neoadjuvant nor adjuvant chemotherapy improved DSS or OS. The authors noted this series represented one of the largest cohorts of MIBC treated with combined modality treatment (CMT) and the data supported the high rates of CR and bladder preservation in patients receiving CMT and demonstrated long-term DSS similar to modern cystectomy series.

Using the National Cancer Database (NCDB), patients with AJCC clinical T2-T3, N0, and M0 UC (MIBC) diagnosed between 2004 and 2013, Zhong et al[156] carried out an analysis of patients treated with definitive intent with either RC (with or without chemotherapy) or concurrent chemotherapy and radiation (bladder preservation) (BPCRT). Only patients documented to undergo a transurethral tumor resection followed by a definitive course of radiation with chemotherapy were included in this BPCRT cohort. Among 8,454 patients with MIBC, 7,276 (86%) underwent RC with or without chemotherapy, and 1,178 (14%) underwent BPCRT. Patients undergoing BPCRT were significantly older (median age 77 vs 68 years, $P < .001$) and had higher comorbidity scores ($P = .002$). The median follow-up time was 4.5 years. Using matched propensity score analysis, there were 1,002 patients remaining in each cohort, and there was no significant difference in 4-year OS between the two groups (39.1% surgery vs 42.6% BPCRT, $P = .15$). BPCRT demonstrated similar survival outcomes compared to those treated with RC with or without chemotherapy. In the absence of prospective randomized studies, these results may help guide decision-making for patients with MIBC considering nonsurgical management options.

Vashistha et al[157] searched seven databases (PubMed, Scopus, EMBASE, Proquest, CINAHL, and ClinicalTrials.gov) for randomized controlled trials and prospective and retrospective studies directly comparing RC with CMT from database inception to March 2016. They conducted a meta-analysis evaluating OS, DSS, and PFS with HRs. Nineteen studies evaluating 12,380 subjects were selected. For the eight studies encompassing 9,554 subjects eligible for meta-analyses, there was no difference in OS at 5 years (HR 0.96, favoring CMT) or 10 years (HR 1.02, favoring cystectomy). No difference was observed in DSS at 5 years (HR 0.83, favoring radiation) or 10 years (HR 1.17, favoring cystectomy), or PFS at 10 years (HR 0.85, favoring CMT). The cystectomy arms had higher rates of early major complications, whereas rates of minor complications were similar between the two treatments. In summary, this meta-analysis showed no differences in OS, DSS, or PFS between RC and CMT.

The Surveillance, Epidemiology, and End Results (SEER) program was used by Wilhite et al[158] to identify patients diagnosed from 1992 to 2013 with localized, muscle-invasive bladder (stages II-III) UC, SCC, or adenocarcinoma histology. Cystectomy was defined as partial or radical. Those who did not receive either cystectomy or RT were excluded. Treatment utilization patterns over time were assessed using Cochran-Armitage tests. Among 16,175 patients eligible for analysis, 11,917 (74%) and 4,258 (26%) received cystectomy and RT, respectively. Patients who received RT were older (median age 79 vs 68, $P < .01$), Over time, there was a statistically significant increase in the proportion of patients receiving RT relative to cystectomy (24% 1992-2002 vs 28% 2003-2013, $P < .01$), despite median patient age throughout the study period remaining unchanged (71 for both 1992-2002 and 2003-2013). For RT, compared with patients diagnosed from 1992 to 2009, those diagnosed from 2010 to 2013 showed improved CSS (71% vs 67% at 1 year, $P = .01$; 51% vs 40% at 3 years, $P < .01$) and OS (64% vs 60% at 1 year, $P < .01$; 38% vs 29% at 3 years, $P < .01$). The significant improvement in CSS and OS for patients receiving RT who were diagnosed in more recent years compared with earlier years support continued use of bladder preservation strategies utilizing RT.

A multi-institutional study using propensity score matching (PSM) and inverse probability treatment weighting (IPTW) along with 3:1 matching with replacement provides the best evidence to date demonstrating similar oncologic outcomes between RC and bladder preservation with TURBT followed by chemoradiation (trimodality therapy, TMT). Zlotta et al[8] included 722 patients with clinical stage T2-T4N0M0 MIBC (440 underwent RC, 282 received TMT) who would have been eligible for both approaches (eligibility criteria: solitary tumors <7 cm, unilateral

hydronephrosis allowed, no extensive or multifocal CIS, adequate bladder function). In the PSM analysis, the 3:1 matched cohort comprised 1,119 patients (837 RC, 282 TMT). Median follow-up was 4.38 years versus 4.88 years for surgery versus TMT. The 5-year metastasis-free survival was 74% (95% CI 70-78) for RC and 75% (95% CI 70-80) for TMT with IPTW and 74% (95% CI 70-77) and 75% (95% CI 68-79) with PSM. There were no differences in metastasis-free survival with either IPTW or PSM between the two groups (P = .40 and P = .64, respectively). Adjusted 5-year regional failure-free survival was 95% (95% CI 93-97) for RC and 91% (95% CI 89-93) for TMT using IPTW, and 95% (95% CI 93-96) and 92% (95% CI 87-95) using PSM. There were no differences between the two groups with respect to CSS using IPTW or PSM (P = .071 and P = .057, respectively) and DFS (P = .35 and P = .37, respectively). OS favored TMT (IPTW HR, 0.70, 95% CI 0.53-0.90, P = .010; PSM HR 0.75, 95% CI 0.58-0.97, P = .0078, Figure 71.2). These data further emphasize that TMT should be offered to eligible patients in the setting of multidisciplinary shared decision-making.

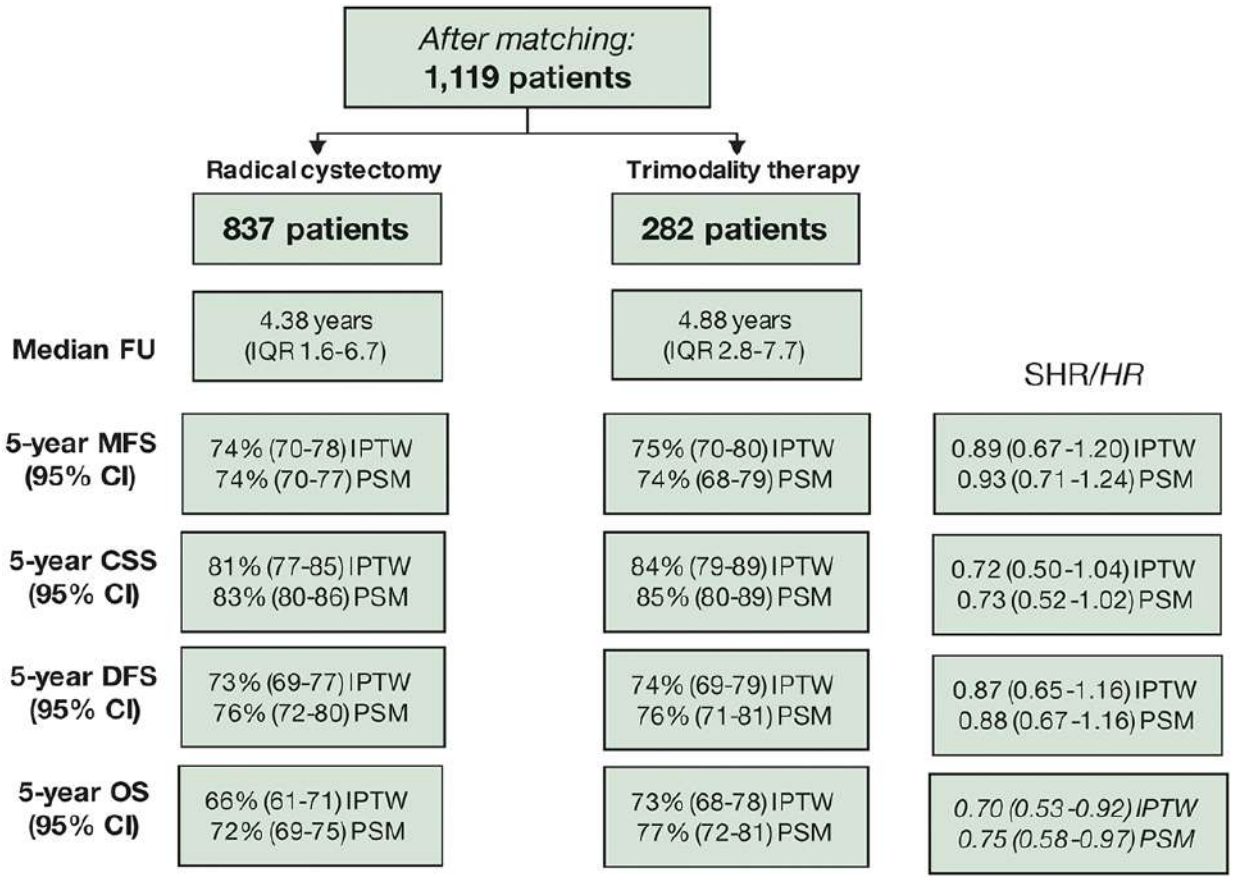

FIGURE 71.2 Outcomes in the matched analysis between radical cystectomy and trimodality therapy.[8] CSS, Cancer-specific survival; CI, confidence interval; DFS, disease-free survival; FU, follow-up; HR, hazard ratio; IPTW, inverse probability treatment weighting; MFS, Metastasis-free survival; OS, overall survival; PSM, propensity score matching; SHR, subdistribution hazard ratio.

A proportion of patients, approximately 10% to 15% in contemporary series, undergoing RT will relapse within the bladder and go on to salvage cystectomy. An important consideration, therefore, is whether cystectomy after RT can be carried out safely and whether the delay compromises survival. However, modern series generally do not suggest significant differences in terms of DSS

and OS or acute toxicities between those who undergo primary cystectomy versus salvage cystectomy.[159] An analysis by Pieretti et al[160] evaluated 265 patients who underwent RC at Massachusetts General Hospital between 2003 and 2013. Patients were grouped by primary cystectomy (n = 216), primary cystectomy in patients with a history of any abdominal/pelvic RT (n = 28), versus salvage cystectomy (after chemoradiation for bladder preservation, n = 23). Early (≤90 days) and late (>90 days) complications were compared, as well as DSS and OS. With a median follow-up time of 65.5 months, there was no difference in intraoperative and early complications between the groups. Late complications were higher in the salvage cystectomy group compared to both the primary cystectomy and the primary cystectomy in patients with a history of RT groups (P = .03). This was also found on multivariable Cox regression analysis that salvage cystectomy was associated with a higher incidence of any late (HR 2.3, P = .02) and major late complications (HR 2.1, P < .05). However, there was no difference in DSS (P = .8) or OS (P = .9). These data suggest that salvage cystectomy following chemoradiation for bladder preservation is feasible with acceptable complication rates and good clinical outcomes and can be offered at an experienced institution.

In summary, surgery and RT should not compete and should be complementary approaches of treatment of invasive BC. There are particular groups of patients who appear to do poorly with primary RT, for example, those with poorly functioning bladders or extensive CIS in addition to their invasive disease. In the former case, RT is unlikely to improve bladder function; in the latter, the lack of effect of RT on CIS means that the patient remains at risk of further bladder intervention and ultimately cystectomy.[161] Older studies also cited features such as hydronephrosis as a contraindication to RT.[162] However, hydronephrosis is also a poor prognostic factor for surgery and does not help in selecting patients one way or another.[163] On the other hand, there are many patients who may benefit from radical therapy but are poor surgical candidates, such as older patients, those who are obese, patients with diabetes, poor anesthetic-risk patients, or those who may struggle with their urinary diversion; thus, a radiation-based approach would be beneficial. In general, although there are no absolute criteria for selecting patients for one treatment option versus another (Table 71.2), the following factors are important considerations when considering a radiation-based versus surgical approach:

TABLE 71.2 FACTORS INFLUENCING SURGERY VERSUS BLADDER PRESERVATION THERAPY

Favor radical cystectomy
Poor bladder function
Inflammatory bowel disease
Prior abdominal or pelvic radiation
Diffuse CIS
Tumor-associated hydronephrosis
Favor bladder preservation therapy
High surgical risk
Strong desire to preserve bladder
Favor both
Good performance status
T2 disease
Unifocal tumor
Unfavorable for either treatment[a]
Poor performance status
Poor renal function (cisplatin ineligible)

T3-4 disease Multifocal tumor

CIS, carcinoma in situ; TURBT, transurethral resection of bladder tumor.

[a]In patients with poor performance status, a nonsurgical approach would favor.

- Maximal TURBT achieved
- Clinical T2-T4a disease
- Absence of tumor-associated hydronephrosis or only unilateral hydronephrosis
- Kidney function (for receipt of concurrent chemotherapy, namely, if cisplatin)
- Absence of extensive CIS
- Unifocal tumors less than 6 cm
- Good bladder function/capacity
- No history of prior abdominal/pelvic RT

Clinicopathologic factors as earlier may be insufficient to fully provide guidance in selection of one treatment over another, particularly if patients are good candidates for either approach. Advances in the molecular understanding of UC have identified new predictive biomarkers that may guide the tailored selection of therapy as discussed later.

Predictive and Prognostic Molecular Biomarkers

Extensive work has been performed to understand the molecular and genomic characteristics of BC. This work has led to the identification of potential molecular biomarkers that can be either prognostic or predictive factors, with the latter that may help with selection of appropriate therapy for a patient presenting with MIBC (Table 71.3).[164-166] BCs frequently display mutations in DNA repair pathways. MRE11 demonstrates promise as a biomarker of radiation response. In a study using immunohistochemical (IHC) staining of MRE11 in a cohort of patients treated with RT alone found that patients with the lowest amounts of MRE11 staining had worse 3-year CSS.[167] A validation study using tissues from patients enrolled in six NRG/RTOG bladder-sparing radiation trials found that low levels of MRE11 nuclear/cytoplasmic expression scores were associated with significantly higher disease-specific mortality.[168] Laurberg et al[169] similarly found that low MRE11 staining was associated with worse DSS in a cohort of 148 patients treated with bladder preservation and did not find any association with MRE11 staining and outcomes among patients who received cystectomy.

TABLE 71.3 PROMISING MOLECULAR BIOMARKERS FOR IMPROVED TREATMENT SELECTION FOR MIBC

Biomarker	Evidence
MRE11	• MRE11 measured by immunohistochemistry in a radiation-alone cohort found low MRE11 levels were associated with worse 3-y cancer-specific survival.[166] • Separate study confirmed low levels of MRE11 nuclear/cytoplasmic expression scores were associated with higher disease-specific mortality in tissues from six NRG/RTOG bladder-sparing trials.[167]
ERCC2	• In a homogenously treated TMT cohort of 76 patients with MIBC, those with *ERCC2* mutations had significantly improved bladder-intact event-free survival as well as improved bladder-intact event-free survival.[15] • Having any DNA repair pathway alteration was associated with improved locoregional control and modified bladder-intact event-free survival.

Biomarker	Evidence
EGFR	• EGFR expression assessed by immunohistochemistry was associated with improved outcomes in a study using tissue from patients enrolled on RTOG 8802, RTOG 8903, RTOG 9506, and RTOG 9706.[173]
HER2	• HER2 expression via immunohistochemistry was associated with poorer outcomes using tissue from patients enrolled on RTOG 8802, RTOG 8903, RTOG 9506, and RTOG 9706.[173] • HER2 overexpression was associated with pathologic incomplete response and worse cancer-specific survival in a cohort of 119 patients treated with bladder preservation therapy.[174] • RTOG 0524 evaluated the use of trastuzumab in patients with HER2/neu overexpression with concurrent chemoradiation, demonstrating that the addition of trastuzumab mitigated previously known worse prognosis in patients with HER2 overexpression.[175]
T-cell activation and interferon-γ signaling signatures	• In a large bladder preservation cohort, immune signature evaluation found that signatures associated with T-cell activation and interferon-γ signaling were associated with improved disease-specific survival.[14] • In a validation study using tissues from patients on prospective trials of MIBC, gene expression profiles with clusters of high immune cell content were associated with longer DFS and OS compared to the cluster with low immune cell content.[16] • In addition, higher expression of T-cell infiltration genes was also associated with longer DFS and OS.[16]
24-Gene hypoxia signature	• In the BCON trial, patients with “high hypoxia” signatures had better overall outcomes compared to those with “low hypoxia” signatures.[179]
Circulating tumor DNA (ctDNA)	• In a study of 68 patients undergoing neoadjuvant chemotherapy followed by radical cystectomy, the presence of ctDNA at various time points throughout the care pathway was prognostic for worse outcomes.[182]

DFS, disease-free survival; MIBC, muscle-invasive bladder cancer; OS, overall survival; TMT, trimodality therapy.

Additional investigations into DNA repair pathway alterations have been performed. A small study of 48 patients treated with bladder preservation found that deleterious mutations in DNA repair pathways, specifically ERCC2, were associated with improved outcomes after chemoradiation. In a homogenously treated TMT cohort of 76 patients with MIBC with a median follow-up of 74.6 months,[15] patients with ERCC2 mutations had significantly improved modified bladder-intact event-free survival (a composite end point that reflects long-term cancer control with bladder preservation, HR 0.15, 95% CI 0.06-0.37, P = .030) as well as improved bladder-intact event-free survival (an end point that includes all-cause mortality, HR 0.33, 95% CI 0.15-0.68, P = .044). In addition, having any DNA repair pathway alteration was associated with both improved locoregional control (HR 0.31, 95% CI 0.12-0.80, P = .0088) and modified bladder-intact event-free survival (HR 0.51, 95% CI 0.27-0.97, P = .004). A separate study evaluated ataxia telangiectasia mutated (ATM) deficiency in the same aforementioned cohort of 76 patients, finding that, among 11 patients with ATM alterations and tumor tissue available for study, among those with loss of ATM expression by IHC, clinical outcomes were improved, with significantly longer modified bladder-intact event-free survival among those with ATM expression loss (P = .015).[170]

Alterations in signal transduction pathways have been implicated in bladder preservation. A study of patients enrolled in four prospective bladder preservation studies (RTOG 8802,[171] RTOG 8903,[162] RTOG 9506,[172] and RTOG 9706[173]) found that EGFR expression assessed by IHC was associated with improved outcomes; however, HER2 expression was associated with poorer

outcomes.[174] This finding was confirmed by work by Ionue et al in a cohort of 119 patients treated with bladder preservation therapy. HER2 overexpression was associated with pathologic incomplete response and worse CSS.[175] The RTOG 0524 phase I/II trial evaluated the use of trastuzumab along concurrent chemoradiation (paclitaxel for chemotherapy) among patients who were HER2/neu 2+ or 3+.[176] Patients who were HER2/neu negative or 1+ by IHC were treated with chemoradiation alone. Both groups had similar CR rates, suggesting that in patients with HER2/neu 2+ or 3+ expressing tumors, the addition of trastuzumab mitigated the associated worse prognosis, demonstrating the ability of biomarker-driven trials to improve outcomes in challenging diseases.

Gene expression profile work has led to definitions of various molecular subtypes within UC.[86,87,177-179] These subtypes have been broadly characterized based on luminal and basal gene expression patterns and correlated with response to cystectomy and neoadjuvant chemotherapy. Using patients from the BCON trial[151] to evaluate outcome by molecular subtype, it was found that the basal subtype patients had a greater benefit with hypoxia modification than those with a luminal subtype.[180] A 24-gene hypoxia signature was developed and validated in the BCON cohort of patients. Patients with a "high hypoxia" signature had improved outcomes than those with a "low hypoxia" signature.[181] In one of the largest studies of molecular subtypes within a cohort of patients receiving TMT, four subtypes were described: luminal, luminal-infiltrated, basal, and claudin-low.[14] There was no association between subtype and CR, DSS, or OS. However, upon further defining immune signatures based on gene expression, signatures associated with T-cell activation and interferon-γ signaling were associated with improved DSS in the TMT cohort. In a comparison cohort of patients treated with neoadjuvant chemotherapy and RC, this association did not hold. In a separate analysis validating prognostic immune biomarkers from prospective trials of MIBC (RTOG 0524[176] and 0712[182]), genes correlating with immune cell activation and gene expression profiles with clusters with high immune cell content associated with longer DFS and OS compared to the cluster with low immune cell content. Higher expression of T-cell infiltration genes was also associated with longer DFS and OS.[16] These findings will need to be further examined in the ongoing trials evaluating TMT plus immune checkpoint inhibitors, including the INTACT: SWOG/NRG 1806 study, evaluating chemoRT with or without atezolizumab in MIBC (NCT03775265); the KEYNOTE-992 study, evaluating chemoRT with or without pembrolizumab in MIBC (NCT04241185); and the CCTG BL13 trial, evaluating chemoRT followed by with or without adjuvant durvalumab.

Finally, there is a growing interest in the use of liquid biopsy tools including circulating tumor cells and circulating tumor DNA (ctDNA) to help personalize treatment recommendations for patients with MIBC. However, at this time, completed studies of ctDNA to predict responses after chemoradiation are lacking. In a study of 68 patients undergoing neoadjuvant chemotherapy followed by cystectomy, the presence of ctDNA was prognostic for worse outcomes. This was found to be highly specific and significant at diagnosis before chemotherapy, after chemotherapy and before cystectomy, and during disease surveillance after cystectomy. It will be important to assess the utility of ctDNA presence and the association with outcomes at various time points throughout the care of patients with MIBC undergoing TMT.[183]

As ongoing trials with correlative translational studies close, findings will help inform improved treatment selection for patients with MIBC.

TREATMENT OPTIONS

Surgery

Management of Invasive Bladder Cancer

Although the majority of patients present with NMIBC, 20% to 40% will either present with or ultimately develop muscle-invasive disease.[123] Invasive BC is potentially lethal; if untreated, over 85% of patients will die of the disease within 2 years of diagnosis.[184] Furthermore, a certain percentage of patients with high-grade bladder tumors without involvement of the lamina propria will recur or progress or fail intravesical management, and they may be best treated with an earlier cystectomy when survival outcomes are optimal.[127]

The rationale for an aggressive treatment approach employing RC for high-grade, invasive BC is based on several important observations. First, the good long-term survival rates, coupled with the lowest local recurrences, are seen following a definitive surgical approach to removing the primary bladder tumor and regional lymph nodes.[7,185] Second, the morbidity and mortality of RC have substantially improved over the past several decades.[185,186] Third, advocates say that RC provides accurate pathologic staging of the primary bladder tumor and regional lymph nodes, thus selectively determining the need for adjuvant therapy based on precise pathologic evaluation. However, it should be noted that the evidence base for adjuvant (as opposed to neoadjuvant) therapy is rather weak. For the abovementioned reasons, RC has become a standard form of therapy for high-grade, invasive BC.

The evolution and improvements in lower urinary tract reconstruction, particularly orthotopic diversion, have been major components in enhancing the QoL for patients requiring cystectomy. Currently, most men and women can safely undergo orthotopic lower urinary tract reconstruction to the native, intact urethra following cystectomy,[187,188] although availability varies worldwide. Orthotopic reconstruction aims to mimic the native bladder in location and function, provides a continent means to store urine, and allows volitional voiding per urethra, although patients need to do this by coordinating opening the sphincter with a Valsalva maneuver, which does require training. The orthotopic neobladder eliminates the need for a cutaneous stoma, urostomy appliance, and the need for intermittent catheterization in most cases. These efforts have improved the QoL of patients who require removal of their bladders and have also stimulated patients and physicians to consider RC at an earlier more curable stage for high-grade, invasive BC.[189,190] A dedicated effort has been made to improve the surgical technique of RC and to provide an acceptable form of urinary diversion, without compromising a sound cancer operation.

Timing of cystectomy after the TURBT is important, and it has been demonstrated that a delay of more than 3 months undermines patient survival. This evidence forms the basis to negotiating resource needs with health care providers.[191] Certain technical issues regarding RC and an appropriate lymph node dissection are critical to minimize local recurrence and positive surgical margins and to maximize CSS.[192] Attention to surgical detail is important in optimizing the successful functional outcomes of orthotopic diversion by preserving the urinary sphincter mechanism and, therefore, continence. Finally, the observed associations between hospital volume and operative mortality are largely mediated by surgeon volume. Patients can often improve their chances of survival substantially, even at high-volume hospitals, by selecting surgeons who perform the operations frequently, as those centers that have adopted this strategy have demonstrated declining mortality in the past decade.[193,194]

RC by definition implies the en bloc removal of the pelvic-iliac lymph nodes along with the pelvic organs anterior to the rectum: the bladder, urachus, prostate, seminal vesicles, and visceral peritoneum in men and the bladder, urachus, ovaries, fallopian tubes, uterus, cervix, vaginal cuff, and the anterior pelvic peritoneum in women. An appropriate lymphadenectomy is an important component of RC and is related to the clinical outcomes of patients with high-grade, invasive BC. Evidence suggests that a more extended lymphadenectomy is beneficial in both lymph node–

positive and lymph node–negative patients with BC,[195-197] although this could be a surrogate for either case selection or surgical skill. Although the exact limits of the lymphadenectomy for patients with BC undergoing cystectomy are currently debated, the boundaries include initiation at the level of the inferior mesenteric artery (superior limits of dissection), extending laterally over the inferior vena cava or aorta to the genitofemoral nerve (lateral limits of dissection), and distally to the lymph node of Cloquet medially (on Cooper ligament) and the circumflex iliac vein laterally. This dissection includes bilaterally all obturator, hypogastric, presciatic, and presacral lymph nodes.[198,199] Removal of more than 15 lymph nodes has been postulated to be both sufficient for the evaluation of the lymph node status and beneficial for OS in retrospective studies.[199,200] However, potential interindividual differences in the number of pelvic and retroperitoneal lymph nodes and difficulties in processing the removed tissue by pathologists are issues. Furthermore, the reality is that even in today's practice, the number of lymph nodes retrieved is low (<10) in a majority of patients (75%) and the chances are even lower if the patients are older, Hispanic (in the United States), and managed at low-volume, nonurban centers.[199] The true curative value of lymph node dissection and the optimal extent of dissection are both still unknown.

Technical variations from the standard cystectomy have been performed to improve patients' QoL, including prostate-sparing cystectomy, to preserve continence and potency. However, this carries a higher risk of missing unsuspected adenocarcinoma of the prostate. Coexistent prostate cancer and prostatic UC are reported in 23% to 54% of cases, respectively, of which 29% were clinically significant, leading to local recurrence and even metastasis.[201]

Both laparoscopic and robot-assisted cystectomy have been shown to be feasible and safe, but with a relatively shorter follow-up.[202,203] Despite an increased materials cost for a robotic-assisted cystectomy, it has been demonstrated to be cost-effective in a subgroup of patients undergoing ileal conduit when the impact of complications is considered in a single-institution series.[202,203]

Morbidity and Mortality of Radical Cystectomy and Lymphadenectomy

The early clinical results and outcomes regarding the morbidity and mortality of RC were disappointing. The lack of universal acceptance of this procedure was attributed to the considerable complication rate and the need for improvements in urinary diversion. Prior to 1970, perioperative complication rates of RC were approximately 35%, with a mortality rate of nearly 20%.[204] However, with contemporary medical, surgical, and anesthetic techniques, along with better patient selection, the mortality and morbidity from RC have dramatically decreased. Frequency of complications and mortality appears to be related to surgeon experience and hospital volume,[193,194] as well as age/comorbidities of the patient.[205] The issue of the need to select patients for surgery complicates the comparison of bladder-sparing techniques, because frequently those not suitable for surgery will be the ones who appear in the RT-based series.

The early complication rate following RC should not be underestimated. Of the 1,054 patients undergoing cystectomy in a University of Southern California series,[7] 28% developed an early complication within the first 3 months of surgery. Early complications included all events related to the cystectomy, perioperative care, and urinary diversion. The administration of preoperative therapy (radiation or chemotherapy) and the form of urinary diversion did not significantly increase the early complication rate in these cystectomy patients. Most early complications following RC are unrelated to the urinary diversion (85% diversion unrelated) and can be managed conservatively without the need for reoperation in approximately 90% of cases.[206] The most common early diversion-unrelated complication is dehydration, whereas the most common early diversion-related complication following RC is prolonged urinary leakage. Overall, most surgical

complications after cystectomy are associated with urinary diversion in relation to the intestinal segments.[185,207]

RC may appropriately be performed in carefully selected older patients; however, this emphasis in the surgical literature on "careful selection" highlights as much the deficiencies as the efficacy of cystectomy as it emphasizes that the published results are not applicable to the entire population. It is emphasized that physiologic age may be more important than chronologic age when determining appropriate candidacy for RC. Proper patient selection, strict attention to perioperative details, as well as a dedicated and meticulous team-oriented surgical approach are critical components to minimize the morbidity and mortality of surgery and to ensure the best clinical outcomes in all patients following RC.[206,208] A recommended approach is the adoption of an enhanced recovery pathway protocol (Figure 71.3).[209]

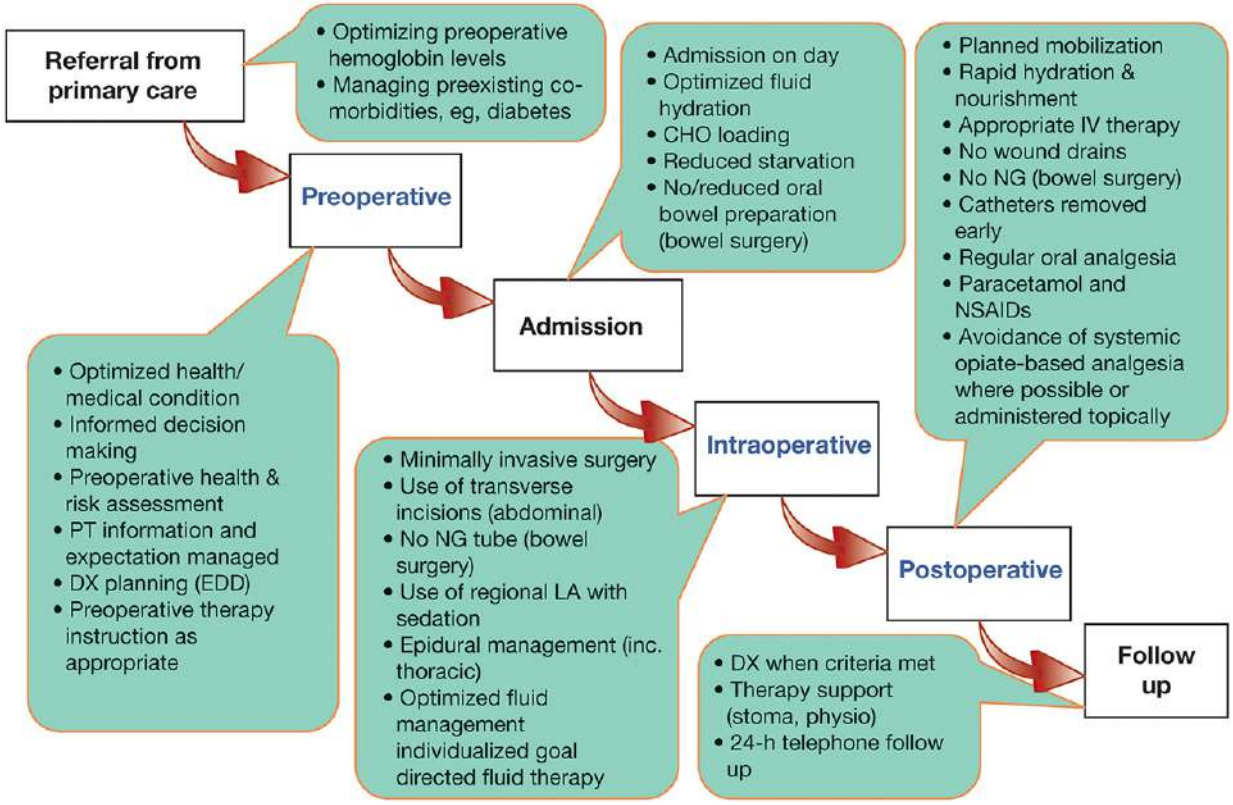

FIGURE 71.3 Schematic representation of the enhanced recovery program in patients undergoing a radical cystectomy. CHO, carbohydrate; IV, intravenous; LA, local anesthesia; NG, nasogastric; NSAIDs, nonsteroidal anti-inflammatory drugs; PT, physical therapy.

Prognostic Factors for Survival Outcomes

The 5-year recurrence-free survival and OS rates for the entire group of 1,054 patients in the University of Southern California series were 68% and 66%, respectively, and it was 60% and 43%, respectively, at 10 years. Most deaths occurred within the first 3 years following RC and were attributed to cancer recurrence. However, with longer follow-up (>3 years), most deaths in this older group of patients were primarily related to comorbid diseases unrelated to BC. This underscores the effective and durable outcomes of RC.

Tumor stage is among the most important factors to predict both relapse and survival following RC.[7,185,210,211] In patients with organ-confined disease without lymph node involvement, long-term survival is reported to be about 75% to 85%. In patients with extension to the perivesical fat and/or adjacent pelvic viscera, long-term survival is reported to be around 45% to 55%. In patients with regional nodal metastasis, patients generally have a poorer prognosis.

The receipt of neoadjuvant chemotherapy is also associated with lower risk of recurrence and improvement in OS (see "Role of Neoadjuvant/Adjuvant Systemic Therapy").

Negative surgical margins and removing sufficient lymph nodes have been associated with improved survival and local recurrence. A 2017 meta-analysis of 36 studies associated a positive surgical margin with poorer survival after RC for BC.[212] Removal of >10 lymph nodes has also been found to be associated with increased OS (HR 0.52, 95% CI 0.43-0.64).[213] Surgeon experience and institutional volume strongly predict favorable outcomes as well.[193,194] Lymphovascular invasion is an independent predictor of progression in T1 and MIBC in several cohorts.[214-216] Finally, molecular markers, including p53, p21, p27kip1, pRB, and p16, have been found to be independent predictors of postcystectomy survival in several series,[217-220] but these are not routinely evaluated and require further validation before widespread adoption into clinical practice.

Organ-Confined, Lymph Node–Negative Tumors

In the University of Southern California series, 56% of patients demonstrated pathologically organ-confined, lymph node–negative tumor.[7] The outcomes in this pathologic subgroup were excellent, with a 5- and 10-year recurrence-free survival of 85% and 82%, respectively, while 5- and 10-year OS was 78% and 56%, respectively. No significant survival differences were observed when comparing superficially noninvasive (Tis, Ta), lamina propria invasive (T1), and muscle-invasive (T2a, T2b) tumors as long as the tumor was confined to the bladder without evidence of lymph node involvement. Similar outcomes for patients with pathologic non–muscle-invasive bladder tumors following cystectomy have been previously reported.[221] Collectively, these data support the treatment of patients with surgery when a tumor is confined to the bladder, without evidence of extravesical extension or lymph node metastasis. Treatment delays in patients with invasive BC should be avoided. Evidence suggests that prolonged delays may lead to more advanced pathologic stage and decreased survival in patients with MIBC.[191] Furthermore, caution should be taken in delaying definitive therapy in patients with high-risk, non–muscle-invasive bladder tumors or those with non–muscle-invasive tumors that have not appropriately responded to conservative forms of therapy.

Extravesical, Lymph Node–Negative Tumors

Non–organ-confined (extravesical), lymph node–negative tumors were found in 20% of the University of Southern California series patients undergoing cystectomy. No obvious survival differences between extravesical T3 and T4 (node-negative) tumors were observed. The 5- and 10-year recurrence-free survival and OS rates for this pathologic subgroup were 58% and 55%, and 47% and 27%, respectively.[7] Similar outcomes were reported by Madersbacher et al,[185] demonstrating a 56% 5-year recurrence-free survival for the same pathologic subgroup. A more contemporary analysis of 2,287 patients treated with RC[221] demonstrated a 5-year OS and DSS for non–organ-confined node-negative disease (>pT2N0) of 53% and 62%, respectively.

Lymph Node–Positive Disease

Approximately one-fourth of patients in a large cystectomy series were found to have positive lymph nodes at the time of surgery. Although patients with lymph node tumor involvement are a high-risk group of patients, the AJCC eighth edition[121] was modified and reclassified node-positive disease (defined as N1-N3 disease) as stage III (previously identified as stage IV disease). This is because node-positive disease behaves differently than patients with metastatic (M1) disease. One prospective observational study of patients treated with RC found that 5-year CSS was 81% for patients with node-negative versus 40% for patients with node-positive BC.[222] The 5-year CSS is reported as 20% for M1 disease, which is lower than node-positive disease.[223]

The prognosis in patients with lymph node–positive disease can be stratified by the number of lymph nodes involved (tumor burden), the stage of the primary tumor, and the presence of extracapsular extension[224] of lymph node metastases. Patients with fewer than five positive lymph nodes among those with lymph node–positive organ-confined bladder tumors had a significantly improved recurrence-free survival rate.[197]

The number of lymph nodes involved with tumor and the extent of the lymph node dissection are both important variables for patients undergoing cystectomy for BC. Stein et al[197] examined 244 patients with lymph node tumor involvement following RC to evaluate other prognostic factors in this high-risk group. They used lymph node density to account for the extent of the lymph node dissection (number of lymph nodes removed) and the tumor burden (number of positive lymph nodes) following cystectomy for patients with lymph node–positive disease. Lymph node density as defined in this study was a significant and independent prognostic variable in patients with lymph node metastases.

Future staging systems and the application of adjuvant therapy in clinical trials may consider applying these concepts to better stratify pathologic node-positive patients.

Role of Neoadjuvant/Adjuvant Systemic Therapy

The addition of neoadjuvant therapy to RC is a widely accepted standard of care based on several trials demonstrating an OS and DFS benefit.[20,32,225] The meta-analysis (Advanced Bladder Cancer Collaboration) of 11 randomized trials,[32,225] which included 3,005 patients with localized MIBC, evaluated neoadjuvant platinum-based combination chemotherapy to local therapy. Compared with local therapy alone, neoadjuvant platinum-based chemotherapy improved 5-year OS (HR 0.86, 95% CI 0.77-0.95) and DFS (HR 0.78, 95% CI 0.71-0.86). There are multiple systemic regimens that can be used; however, for cisplatin-eligible patients, dose-dense MVAC (ddMVAC) and GC are good options. There are ongoing investigations into neoadjuvant immunotherapy as part of therapy; however, these are not recommended as part of routine clinical practice as of yet.

Conversely, the role of adjuvant therapy for patients found to be at high risk for recurrence based on findings at the time of surgery is more complex. Given the morbidity associated with cystectomy, it may be difficult to get patients to adjuvant therapy and to receive all intended cycles of therapy. Nevertheless, for patients with high-risk characteristics (which include pathologic T3 or T4 disease and/or pathologic node involvement), adjuvant therapy is recommended. Most studies suggest that adjuvant cisplatin-based chemotherapy delays recurrences and improves OS.[226-229] A meta-analysis included 10 randomized trials with 1,183 patients who did not receive neoadjuvant chemotherapy.[230] At a median follow-up of 6 years, the addition of adjuvant cisplatin-based chemotherapy postcystectomy improved OS (HR 0.82, 95% CI 0.70-0.96). Adjuvant cisplatin-based chemotherapy also improved recurrence-free survival (HR 0.71, 95% CI 0.60-0.83).

In patients who previously received neoadjuvant cisplatin-based chemotherapy and have high-risk features at the time of surgery (namely, persistent muscle-invasive [ypT2-T4a] or node-positive

disease), 1 year of immunotherapy with either nivolumab or pembrolizumab is recommended. Separate randomized trials found that adjuvant nivolumab confers both a DFS and OS advantage,[231] while adjuvant pembrolizumab confers a DFS advantage.[232]

In patients who are ineligible for adjuvant cisplatin-based chemotherapy, 1 year of adjuvant immunotherapy using either nivolumab or pembrolizumab. The aforementioned immunotherapy randomized phase III trials[231],[232] included this cohort of patients as part of their patient population and found that both of these therapies improved DFS. However, these studies were not powered to evaluate this specific subgroup of patients separately.

Summary of Surgical Therapy

Surgery is an important mode of therapy for invasive BC and undoubtedly can provide durable disease control for many patients with the disease. In addition, an integrated approach with other treatment modalities such as neoadjuvant chemotherapy is essential if the best results are to be achieved in the entire patient population. RC provides an accurate evaluation of the primary bladder tumor along with the regional lymph nodes, yielding important prognostic information. This, coupled with the evolution and successful application of orthotopic lower urinary tract reconstruction in both men and women, has provided patients with a more physiologic and acceptable means to store and eliminate urine. However, most deaths from BC still occur due to distant metastases, presumably present at the time of original surgery, so further improvements in outcome will depend on the development of both better systemic therapies and predictive (as opposed to prognostic) markers that will allow better selection of therapies.

Radiation Therapy

External Beam Radiation Therapy

Although RC is the most common treatment used for MIBC, RT use is increasing, in part due to the recently accrued SWOG/NRG 1,806 study (NCT03775265) trial, the largest randomized, phase III trial to date of bladder-sparing chemoRT. However, treatment patterns vary worldwide. In the United States, RT is administered as part of a package of multidisciplinary care comprising maximal TURBT, chemotherapy, and RT, also known as trimodality therapy (TMT) (Figure 71.4).[149] There are options in the treatment schedules used, in terms of dose and treatment frequency. In addition, treatment volumes are varied, with multiple acceptable choices.

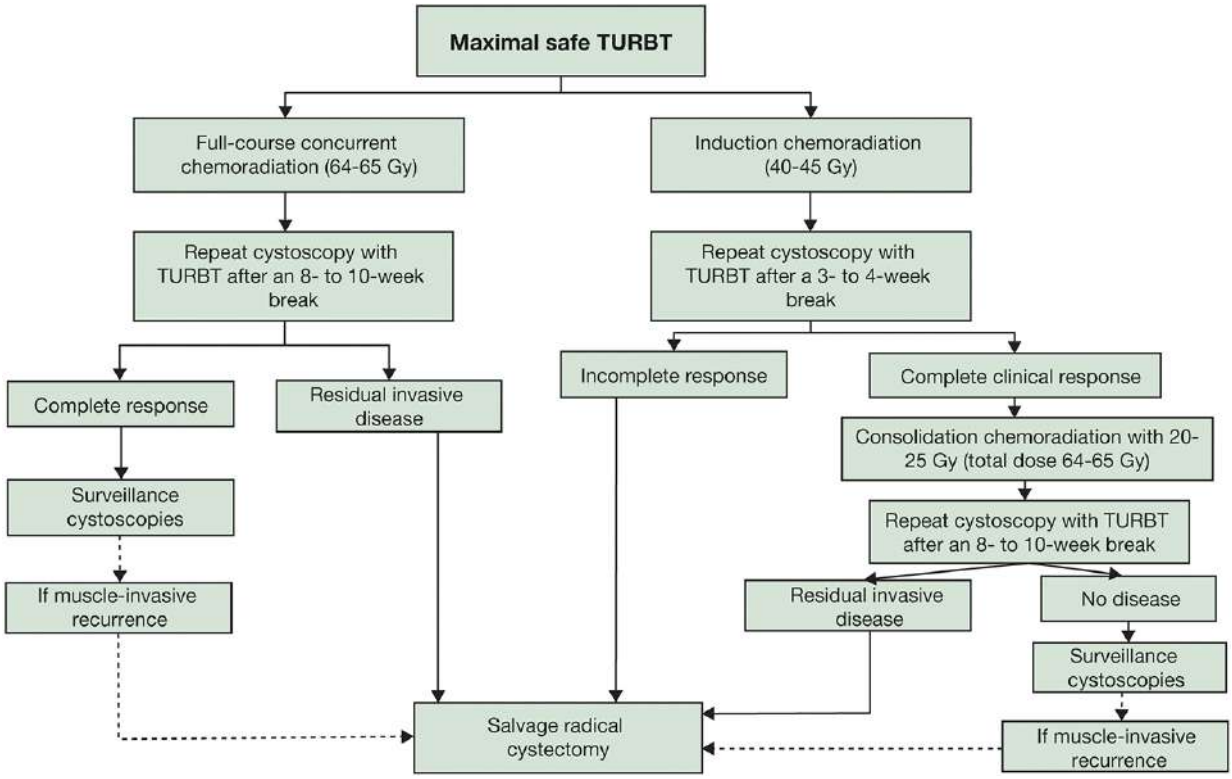

FIGURE 71.4 Trimodality therapy schema in the United States. TURBT, transurethral resection of bladder tumor.

Dose and Fractionation

Radiation dose has been fairly standardized through multiple trials, typically in the 60 to 66 Gy range using a standard fractionation of 1.8 to 2 Gy/fraction. However, moderate hypofractionation, in the form of 2.75 Gy/fraction to a total dose of 55 Gy, like what was used in the BC2001 trial,[150] is also an acceptable standard of care.

Korpics et al[233] conducted a retrospective cohort study of 843 patients with cT2-4 N0-3 M0 transitional cell MIBC treated with RT using the NCDB. Patients were divided into dose groups: less than 50, 50 to 59, 60 to 66, and greater than 66 Gy, using conventional fractionation. A subgroup analysis was performed for patients treated with 60 to 66 Gy by dividing them into three groups (60-62, 63-64, and 65-66 Gy). Median follow-up was 16.3 months; 267 (32%) patients received less than 50 Gy, 169 (20%) received 50 to 59 Gy, 376 (45%) patients received 60 to 66 Gy, and 31 (4%) patients received greater than 66 Gy. Patients receiving concurrent chemoRT were more likely to receive an RT dose of 60 Gy ($P < .001$), and patients with higher T-stage were more likely to receive a lower RT dose ($P = .003$). Two-year OS rates, when divided by RT dose, were 26%, 31%, 56%, and 55%, respectively, for less than 50, 50 to 59, 60 to 66, and greater than 66 Gy. Univariate analysis demonstrating increasing RT dose ($P < .001$) was associated with improved OS. On multivariate analysis (MVA), when compared to a dose of 60 to 66 Gy, less than 50 Gy (HR 2.36, $P < .001$) and 50 to 59 Gy (HR 1.72, $P < .001$) were associated with worse OS. Escalation of dose to higher than 66 Gy was not associated with OS (HR 1.01, $P = .977$). In the subgroup of patients treated with 60 to 66 Gy, MVA revealed that compared to 65 to 66 Gy, there was worse OS with a dose of 60 to 62 Gy (HR 1.66, $P = .020$), but no difference in OS with a dose of 63 to 64 Gy (HR 1.12, $P = .549$). The authors concluded that RT doses of less than 60 Gy are

associated with worse OS in patients undergoing bladder RT and thus should be avoided in definitive treatment. In addition, there is no survival advantage to increasing dose beyond 66 Gy.

Separately, Huddart et al[234] evaluated whether reducing radiation dose to the uninvolved bladder while maintaining dose to the tumor would reduce side effects without impairing local control (LC) in the treatment of MIBC. In the phase III multicenter trial BC2001, there was a component of comparing radiation treatment volumes in its 2 × 2 design. Two hundred nineteen patients were randomized to standard whole-bladder radiation therapy (WBRT) (sRT) or reduced high-dose volume radiation therapy (RHDVRT) that aimed to deliver a full radiation dose to the tumor and 80% of the maximum dose to the uninvolved bladder. Overall incidence of late toxicity was less than predicted, with a cumulative 2-year RTOG grade 3/4 toxicity rate of 13% and no statistically significant differences between groups. The difference in 2-year locoregional recurrence-free rate (RHDVRT vs sRT) was 6.4% under an intention-to-treat analysis and 2.6% in the "per protocol." The authors concluded that RHDVRT did not result in a statistically significant reduction in late side effects compared with sRT and that noninferiority of locoregional control could not be concluded formally.

A meta-analysis of BC2001 and BCON trials[12] to evaluate the hypofractionated treatment schedule compared to the conventional fractionation schedule found that a hypofractionated schedule of 55 Gy in 20 fractions is noninferior to 64 Gy in 32 fractions with respect to toxicity and is superior with regard to invasive locoregional control. Specifically, 782 patients with known fractionation schedules were evaluated and included in the meta-analysis. With a median follow-up of 120 months, patients who received hypofractionation had a lower risk of invasive locoregional recurrence (adjusted HR 0.71, 95% CI 0.52-0.96) compared to conventional fractionation.

A small phase II trial of 65 patients with MIBC deemed unfit for radical therapy (surgery or standard chemoradiation) was planned to receive 36 Gy in 6 weekly fractions, randomized to either adaptive plan of the day (POD) or standard planning.[235] It was found that toxicity rates were low overall (6%, 2/33, 95% CI 0.7%-20.2% for the POD group and 13%, 4/30, 95% CI 3.8%-30.7% for the standard group). In 48 patients assessed at 3 months post-treatment, disease was present in nine, giving an LC rate of 81.3% (95% CI, 67.4%-91.1%). Thus, it was concluded that this treatment schedule is safe and provides good LC for older patients unfit for radical therapy.

Radiation Treatment Frequency

Radiation can be delivered either daily or twice daily (BID). Some earlier studies had a built-in treatment break after approximately 40 to 45 Gy (induction) for restaging cystoscopy (also known as split-course therapy). If a patient had a CR or Ta/Tis residual disease on restaging cystoscopy, the patient could proceed with consolidation chemoradiation (to a total dose of 64-68 Gy). If not, prompt salvage cystectomy was recommended.[149] However, an interim check cystoscopy is no longer necessary, and many centers/institutions are now simply continuing treatment to completion (single definitive course RT).

To understand how the split-course approach arose, it must be understood that TMT was offered as an alternative to cystectomy in countries where the prevailing opinion is that surgery is the treatment of choice. Patients undergoing this treatment are offered what is termed *selective bladder preservation*, with the multiple checkpoints allowing early exit to surgery aimed at providing reassurance to surgeons in particular that the opportunity for cure is not being lost. The median ages (mid-60s) reported in studies using this approach reflect this patient selection and are similar to large surgical series.[7,156] Yet, this approach was not used in the United Kingdom, as there is a long tradition of using radical RT after TURBT, and the much older patient groups compared with

surgical series reflect a different decision-making process in which younger, more fit patients are more likely to get surgery and older or less fit patients RT.[145,151,157,158] Overall, the treatment break in the split-course schedule is debated. It allows for early identification of patients who are responding poorly so that early salvage cystectomy can be performed and allows surgery to occur after only approximately 40 to 45 Gy of dose rather than the full-dose RT. However, radiobiologic concerns exist with such a treatment break,[236,237] and there are a subset of patients who may not have yet responded to just 40 to 45 Gy of dose and need a higher dose before seeing response; thus, these patients may be recommended for surgery prematurely and potentially unnecessarily. Overall, given the complexity of coordinating a treatment break with a cystoscopy followed by consolidative chemoradiation, most centers have moved away from this split-course treatment toward a daily radiation regimen, as what was allowed on the SWOG/NRG 1806 trial.

Historically, RTOG trials[162,171-173,176,182,238-240] have evaluated radiation regimens that are either delivered once daily or BID (Table 71.4). Most RTOG protocols utilized BID treatment,[149] but, as mentioned previously, this presents a logistical burden to patients and treating centers. NRG/RTOG 0712[182] compared once-a-day radiation with gemcitabine to BID radiation using a cisplatin-based chemotherapy regimen, finding a rate of freedom from distant metastasis of more than 75% with either treatment schema, suggesting that the two are comparable.

TABLE 71.4 RADIATION THERAPY ONCOLOGY GROUP/NRG ONCOLOGY BLADDER PRESERVATION TRIALS

Study	Phase	N	Neoadjuvant Chemotherapy	RT	Arms	Adjuvant Chemotherapy	OS
RTOG 8512[237]	II	42	None	40 Gy + 24 Gy	Cisplatin + RT	None	3 y: 64%
RTOG 8802[170]	II	91	MCV	39.6 Gy + 25.2 Gy	Cisplatin + RT	None	4 y: 62%

		Arm 2: 46	None		Paclitaxel + RT	None	NR
NRG/RTOG 0712[181]	II	Arm 1: 33	None	64.3 Gy daily RT	Cisplatin/5FU + BID RT	Cisplatin/gemcitabine	BI-DMFS 3 y: 67%
		Arm 2: 33	None	64 Gy BID	Low-dose gemcitabine + daily RT		BI-DMFS 3 y: 72%
RTOG/NRG 0926[3]	II	37	None	61.2 Gy daily RT	Cisplatin + RT or MMC/5-FU + RT	None	3 y: 69% 5 y: 53%

BI-DMFS, bladder-intact, distant metastasis-free survival; BID, twice daily; CR, complete response; FU, fluorouracil; fx, fractions; MCV, methotrexate, cisplatin, vinblastine; MMC, mitomycin-C; NR, not reported; OS, overall survival; RT, radiotherapy.

Treatment Volumes

There are few data on the optimal RT volume. There are multiple reasonable options based on trials/experiences to use certain doses and fields for radiation.[241] The SWOG/NRG 1806 trial (ClinicalTrials.gov NCT03775265) is very inclusive, and radiation fields are as per physician discretion. Patients can be treated with a small pelvic radiation field, followed by (1) whole-bladder boost followed by bladder tumor boost, (2) whole-bladder boost alone, or (3) bladder tumor boost alone. Alternatively, patients can be treated without a small pelvic field and receive only (1) whole-bladder radiation followed by a bladder tumor boost, (2) whole-bladder radiation alone, or (3) bladder tumor radiation alone.

Inclusion of the pelvic lymph nodes in the initial course of RT is an area of debate. The rationale for treatment of the lymph nodes is due to the potential for occult lymph node metastases in these regions.[242] Extensive lymphadenectomy at the time of surgery was also shown to improve survival in an NCDB analysis.[243] This is being formally evaluated in a randomized trial (SWOG S1011, ClinicalTrials.gov NCT01224665). However, the nodal relapse rate in the BC2001 trial[150] was only 4.9% in the chemoRT arm and 6.7% with RT only. A single-institution study of patients treated with chemoradiation with weekly cisplatin randomized patients to either whole-pelvic RT (WP-RT)

versus BO-RT. There was no difference in 5-year DFS, bladder preservation rates, nodal failures, nor OS observed.[244] This study had an editorial comment of concern,[245] due to questions about the validity of the data, the analyses, and other irregularities noted; therefore, there is a low likelihood of full confidence in the data as presented. Patel et al investigated the impact of treatment volumes using the NCDB.[246] Among 2104 patients with BC treated with chemoradiation with a median follow-up of 6.2 years, there was no difference in survival between the two groups of BO versus bladder plus pelvic lymph node (BPN) irradiation (5- and 10-year OS 27.4% [95% CI 23.4%-31.4%] in the BO group vs 31.9% [95% CI 29.3%-34.6%] in the BPN group, and 13.1% [95% CI 9.7%-17.1%] in the BO group vs 13.2% [95% CI 10.6%-16.0%] in the BPN group [log-rank $P = .10$]). A recently presented study of 599 patients with MIBC[247] who underwent curative RT at 10 academic centers across Canada evaluated the utility of RT volume on outcomes: WP-RT versus BO-RT. IPTW was used to evaluate the two groups. In MVA, WP-RT did not impact CR post-RT (OR 1.13, $P = .526$), but was associated with improved CSS (HR 0.66, $P = .016$) and OS (HR 0.68, $P = .002$). We must await the final publication of these data, but it may suggest that there could be a benefit to pelvic nodal treatment.

Follow-Up Post-Radiation Therapy

After completion of treatment, patients remain on long-term cystoscopic surveillance, along with imaging to assess for distant disease. Noninvasive recurrence can be managed by further TURBT and intravesical therapy. Those with isolated muscle-invasive recurrence or failure to respond (but with no systemic relapse) can undergo salvage cystectomy with or without further chemotherapy.

Radiation Therapy Practice Patterns

At this time, practice patterns to implement TMT, particularly in the United States, vary widely among radiation oncologists. Solanki et al[248] conducted an electronic survey of U.S. radiation oncologists regarding the management of patients with cT2-3N0M0 transitional cell MIBC; 277 physicians completed the survey. Most respondents (58%) stated that they only treated one to three patients with BC in the prior year. Seventy- four percent of respondents primarily treated patients deemed unfit for cystectomy, whereas only 28% saw patients prior to cystectomy for consultation to discuss bladder preservation therapy. Most radiation oncologists (91%) used conventional fractionation instead of hypofractionation (7.6%), but more variability existed for RT targets. Sixty percent used a small pelvic field, 29% used a whole-pelvic field, and 12% treated the BO. There was increased use of hypofractionation (29%) and BO-RT (34%) in patients who were not candidates for cystectomy or chemotherapy ($P < .001$). Cisplatin-based concurrent chemotherapy was most preferred (89%). In noncisplatin candidates, most respondents preferred 5-FU plus MMC (32%) or carboplatin (32%), although the latter is a nonpreferred option. IMRT use and midtreatment cystoscopic reevaluation were variable, whereas hyperfractionation use was low. Although there are areas of consistency, variability exists in many technical and practical aspects of treatment delivery. It is important to note, however, that this study was published in 2017, and since then, BO-RT has increased, along with hypofractionation, and noncisplatin regimens such as gemcitabine are in greater use and preferred to carboplatin. Further research and education are needed to determine the optimal RT target, dose/fractionation, and concurrent chemotherapy regimen.

Practical *External Beam Radiation Therapy* Planning/Treatment Techniques

Patient Position and Immobilization

- The patient should be planned and treated in the same position; supine with arms on their chest.[241] Knee and ankle immobilization should be used to ensure patient positioning is reproducible.
- Patients may be simulated prone using a belly board to minimize small bowel in the field; however, this is not standard and is dependent on institutional experience.
- The rectum should be empty of flatus and feces. The use of daily microenemas may be considered.
- Patients should be asked to empty the bladder 10 to 15 minutes prior to scanning. This allows for more reproducibility and helps to minimize field size.
- All planning and treatment should be carried out with the bladder empty to minimize the risk of geographic miss and to keep the treated volumes as small as possible. Patients with significant residual volumes postvoiding should be considered for planning and treatment with a catheter in situ, although this is likely to increase urinary toxicity.
- However, it is reasonable to simulate the patient with a fuller bladder for tumor boost planning.
- While breathing normally, the patient should have a CT scan performed with 3- to 5-mm slices. Patients are scanned from the bottom of ischial tuberosities to 3 cm above the dome of the bladder or bottom of L5 (whichever is higher). If including a small pelvic field, the scan should go higher, to at least the top of L1.
- Intravenous contrast may be used to further delineate the pelvic vessels.
- Reference tattoos should be made at the base of the abdomen and over each hip. The location of the tattoos should be marked on the planning scan by the use of radio-opaque markers to allow cross-referencing of the planning scan and setup instructions.

Delineating Target Volumes

- The gross tumor volume can be difficult to define and should integrate information from the staging CT or MRI as well as the cystoscopy report and TURBT. MRI-CT fusion may be helpful, where available.
- If treating a small pelvic field, this typically includes the entire bladder, the prostatic urethra (in males) or proximal urethra (in females), as well as the lymph node basins in the pelvis (external iliac, internal iliac, and obturator lymph nodes). The top border is around the midsacroiliac joint (~S1/S2 or S2/S3). The inferior border is typically at the bottom of the obturator foramen. The lateral field extends 1.5 cm laterally from the pelvic brim. When using CT simulation, these borders are determined by contouring the target organs and vessels.
- The whole-bladder target volume contains the entire bladder, including the outer wall. For three-dimensional conformal RT, an expansion of 1.0 to 1.5 cm is needed. A 0.5 to 1.0 cm expansion for intensity-modulated RT constitutes the planning target volume (PTV) for this structure.
- The bladder tumor target volume is defined as including any original bladder tumor per imaging, cystoscopy, and TURBT. This volume can be difficult to define, especially if the tumor has been fully resected. The use of fiducial markers at the time of TURBT is being explored and may help identify the tumor target for image-guided adaptive RT (ClinicalTrials.gov NCT04442724).

Novel Techniques

Inter- and intrafraction anatomy changes in patients undergoing RT for BC are common and have been studied with implanted fiducial markers, CT, MRI, as well as online adaptive RT.

Fischer-Valuck et al[249] assessed the soft tissue imaging capabilities of an integrated magnetic resonance image-guided RT (MR-IGRT) system to analyze daily positioning in a preliminary study of 14 patients with BC treated on an MR-IGRT system (ViewRay Corp). Patient setup was performed via volumetric MRI with a resolution of 0.15 × 0.15 cm^2. Alignment was performed according to skin marks and shifts assessed by comparing the treatment volume from the planning CT to the daily MRI. Two hundred forty pretreatment MRIs were analyzed, and three shifts were recorded for each image. The daily volumetric MRI allowed for accurate alignment and daily monitoring of bladder volume and normal tissue anatomy. Recorded shifts of the treated volume were 0.9 × 0.5 cm^2 in the right/left direction, 0.7 × 0.3 cm^2 in the anterior/posterior direction, and 0.7 × 0.4 cm^2 in the craniocaudal direction. In 66 (28%) cases, the vector shift was initially greater than the PTV margin. For two patients, pretreatment MRI showed the tumor reduced in size and dose to the bowel would have exceeded constraints, and treatment adaptation was performed to reduce the normal tissue toxicity. Using CTCAE criteria, no grade 3 or higher toxicities were reported.

Daily image guidance, particularly with cone-beam CT, can improve the accuracy of radiation targets, particularly when boosting small volumes to a higher dose. Identifying where the pre-TURBT tumor was located within the bladder can be tricky. Some institutions implant fiducial markers into the area where bladder tumor was resected. This is being formally studied in a trial (ClinicalTrials.gov NCT04442724) to determine whether implanted fiducials help reduce collateral dose to uninvolved areas.

Online adaptive RT is being explored for its utility for MIBC treatment, given its increasing adoption in RT centers. Foroudi et al[250] described a multicenter feasibility study at 12 departments of online adaptive RT, using a choice of three “POF” for patients with MIBC (which used a uniform 7-mm margin to create PTVs from each of the three adaptive clinical target volumes [CTVs]). Departments were activated if they were part of the pilot study or after a site-credentialing visit and real-time review of the first two cases from each department. Fifty-four patients (mean age 78 years, 43 males and 7 females) were recruited, with 50 proceeding to RT. The tumor stages included T1 (one patient), T2 (35 patients), T3 (10 patients), and T4 (four patients). One patient died of an unrelated cause during RT. The three adaptive plans were created before the 10th fraction in all cases. In eight (16%) of the patients, a conventional plan using a “standard” CTV-to-PTV margin of 1.5 cm was used for one or more fractions where the pretreatment bladder CTV was larger than any of the three adaptive plans. The bladder CTV extended beyond the PTV on post-treatment imaging in 9 (18%) of the 49 patients. In general, it was concluded that an online adaptive RT technique is feasible and can be instituted in a multicenter setting. Without further bladder filling control or imaging, a CTV-to-PTV margin of 7 mm was determined to be insufficient.

Ongoing trials are evaluating the utility of adaptive planning for the treatment of advanced BC. One such trial is the RAIDER study (ClinicalTrials.gov NCT02447549), which is a randomized phase II trial of either standard planning and radiation delivery, adaptive image-guided tumor-focused radiation, or adaptive image-guided dose-escalated tumor boost radiation. The primary end point is the proportion of patients meeting radiation dose constraints to the bladder, bowel, and rectum in the dose-escalated group, as well as the proportion of patients experiencing severe late side effects following treatment. Late toxicity outcomes of 345 randomized patients from the study were recently presented.[13] Patients were randomized to standard WBRT, standard dose adaptive

tumor-focused RT (SART), or dose-escalated adaptive tumor boost RT (DART). Two fractionation schemes were utilized, either 64 Gy in 32 fractions or 55 Gy in 20 fractions for WBRT and SART or 70 Gy in 32 fractions or 60 Gy in 20 fractions for DART. In terms of RT-related grade 3 or higher toxicities, in 20-fraction DART, it was 1 of 58 (90% CI 0.1-7.9) and in 32-fraction DART, it was 0 of 57. It was concluded that 20- and 32-fraction DART was safe and feasible to deliver with toxicity rates below predefined thresholds.

Synchronous Chemotherapy and Other Systemic Therapies

There are several data sources that support the use of concurrent chemotherapy with radiation as part of TMT for MIBC. A pooled analysis of six NRG/RTOG trials studied the efficacy of chemoRT and included 468 patients with a median follow-up of over 4.3 years.[5] The CR to chemoRT was 69%. The 5- and 10-year DSS rates were 71% and 65%, respectively. The 5- and 10-year rates of muscle-invasive local failure were 13% and 14%, respectively, while the 5- and 10-year rates of non–muscle-invasive recurrence were 31% and 36%, respectively, and the 5- and 10-year rates of distant metastases were 31% and 35%, respectively. Of the 205 patients alive at 5 years, 80% had an intact bladder.

Single-institution retrospective series also support the use of concurrent chemotherapy with radiation for bladder preservation. The aforementioned study by Giacalone et al[4] found that, in a cohort of 475 patients with cT2-T4a MIBC treated at the Massachusetts General Hospital between 1986 and 2013, with a median follow-up of 7.2 years in surviving patients, 75% of patients had a CR to induction chemoradiation. The 5- and 10-year OS were 57% and 39%, respectively. The risk of salvage cystectomy was 29% at 5 years and was performed in 129 patients. In the more contemporary era (2005-2013), the rate of salvage cystectomy decreased to 16%.

A separate observational study of 415 patients with high-risk cT1 or cT2 to T4 BC were treated at the University of Erlangen between 1982 and 2000 with radiation (n = 126) or chemoradiation (n = 302).[6] Patients received either cisplatin or carboplatin-based chemotherapy. With a median follow-up of 5 years, the CR rate following RT or chemoRT was 72% for all patients. For patients receiving RT alone, the CR rate was 61%, and for those receiving chemotherapy, the rates were 66% (carboplatin), 82% (cisplatin), and 81% (5-FU/cisplatin). The 5- and 10-year OS rates were 51 and 31%, respectively, while the 5- and 10-year DSS rates were 56 and 42%, respectively. In MVA, chemoRT was associated with improved OS and CR rates compared with RT alone.

The aforementioned randomized trials of radiosensitization, the BC2001[150] and BCON[151] studies, used UK treatment schedules. These trials used radiosensitization with either concurrent chemotherapy (BC2001) or carbogen and nicotinamide (BCON). BC2001 has shown a significant improvement in locoregional DFS with concurrent 5-FU and MMC (HR 0.68; 95% CI, 0.48-0.96, P = .03).[150] Figure 71.5 shows the Kaplan-Meier curves for invasive locoregional DFS. Survival data show a trend toward an improvement in OS (HR 0.82; P = .16), although not statistically significant. The BCON trial[12] with synchronous carbogen and nicotinamide found that 3-year OS improved with carbogen and nicotinamide (59% vs 46%, P = .04), with a trend toward improvement for local relapse-free survival (54% vs 43%, P = .06). In multivariate comparison, RT plus carbogen and nicotinamide reduced the risk of relapse (P = .05) and death (P = .03).

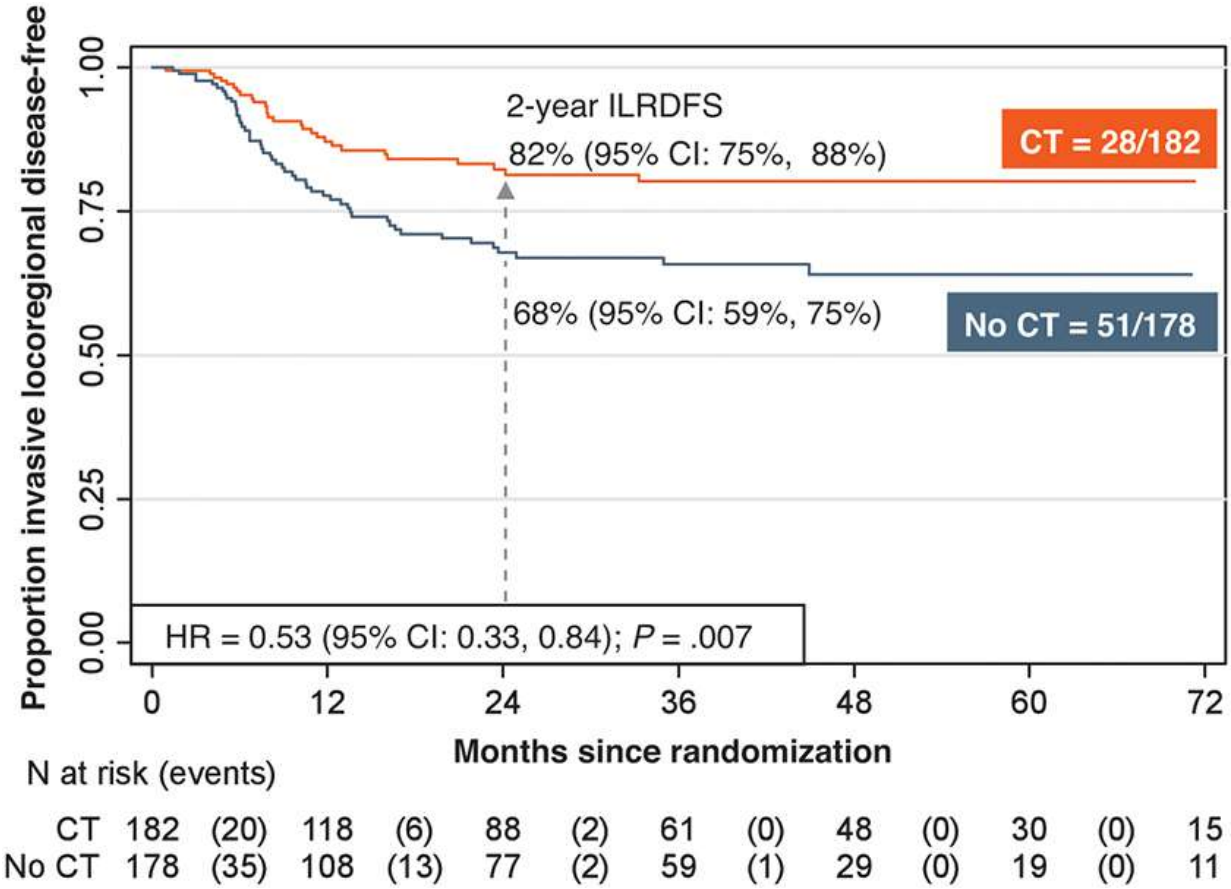

FIGURE 71.5 Invasive locoregional disease-free survival with or without chemotherapy. CI, confidence interval.

A small trial conducted by the NCIC randomly assigned patients to concurrent cisplatin with RT or RT alone.[251] There was a significant decrease in the incidence of first recurrence in the pelvis (15/51 vs 25/48) with the addition of cisplatin; however, the study failed to demonstrate an improvement in OS (although it was not powered for this end point).

Taken together, the trial data with chemoRT suggest good tolerability even in relatively older patients with excellent late toxicity profiles in the majority of patients whether treated with the North American TMT approach or the UK approach. Benefit observed in multiple studies suggests that range of chemotherapy approaches can probably be used with the selection based on toxicity. This is also evidenced by the multiple chemotherapy schedules evaluated in the NRG/RTOG studies in North America. The ongoing SWOG/NRG 1806 trial allows for one of three concurrent chemotherapy options (cisplatin, 5-FU/MMC, gemcitabine).

Immunotherapy has been shown to have efficacy in metastatic BC (see section on role of systemic therapy). Other data suggest that the combination of immunotherapy and radiation may improve outcomes in localized MIBC.[252,253] This is actively being studied in ongoing INTACT: SWOG/NRG 1806 trial, which evaluates chemoRT with or without atezolizumab in the localized MIBC disease space. The 1806 trial recently completed accrual and is the largest U.S.-based trial of bladder preservation to date (accrued 485 patients). The permissive radiation design was highly pragmatic to aid in accrual, allowing a range of radiation fields to be treated. This contemporary design will allow the results to be interpreted within the context of modern use of RT for MIBC.

Toxicity

The toxicity of definitive RT varies with the dose and schedule used. Within BC2001 and BCON, there were two schedules: 55 Gy in 20 fractions and 64 Gy in 32 fractions. Acute and late toxicities are shown in Figures 71.6 and 71.7, respectively, for both schedules, with and without chemotherapy with 5-FU/MMC. In BC2001, synchronous chemotherapy increased toxicity but was predominantly grade 1 or 2, with a nonstatistically significant effect on grade 3 or 4 events (27.5% vs 36%; $P = .07$; boundary for significance set at 0.01 to reflect multiplicity of testing).[150] As discussed earlier, the component of comparing radiation treatment volumes in its 2 × 2 design, evaluating WBRT compared to RHDVRT (or partial bladder) did not find that the RHDVRT resulted in lower rates of toxicity compared to standard WBRT.[234] Treatment completion rates in both trials were very high, with an excess of 95% of patients receiving the prescribed dose. The majority of patients failing to complete did so for tumor-related reasons rather than toxicity. Late toxicity was of great interest in both trials and was analyzed somewhat differently. In BCON, the cumulative rates of grade 3 or 4 events were reported, which gives the worst-case scenario but does not reflect the overall toxicity at any given time point post-treatment. BC2001 reports the toxicity rates at prespecified times.

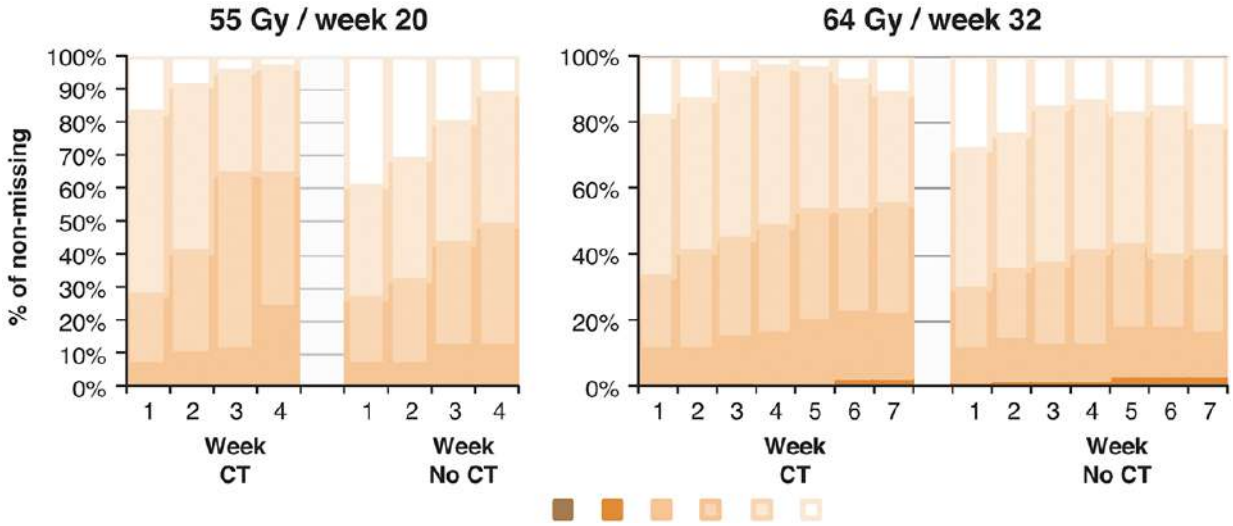

FIGURE 71.6 Acute toxicity of radiotherapy with and without synchronous chemotherapy. Graphs show a worst grade of on-treatment toxicity by radiotherapy dose and week. Darkest bars indicate National Cancer Institute common terminology class grade 4; white indicates grade 0. Proportions with a grade 3 or 4 at any time on treatment: 64/178 (36.0%) chemotherapy (CT) versus 50/182 (27.5%). No CT-stratified chi-square test ($P = .07$).

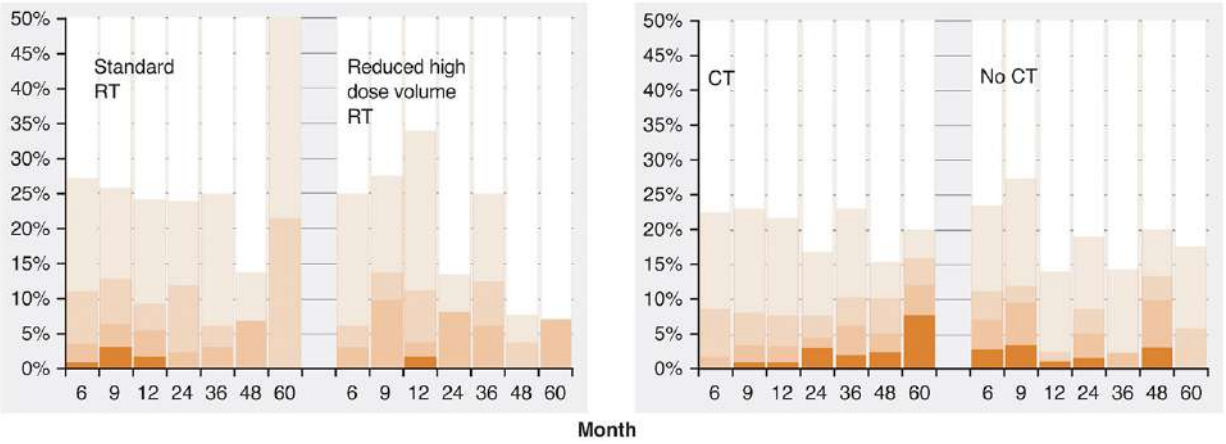

FIGURE 71.7 Late toxicity in the BC2001 trial. Darkest bars indicate Radiation Therapy Oncology Group (RTOG) grade 4; white indicates grade 0. Proportion of patients with grade 3 or 4 RTOG toxicity at any month during follow-up (6 months onward), up to 3 months before a recurrence: RT, 12.9% sRT versus 17.9% RHDV; odds ratio (95% confidence interval) 1.34 (0.55, 3.24); *P* = .52; CT, 8.3% CT versus 15.7% no CT; odds ratio 0.48 (0.21, 1.10); *P* = .07. Patients with no available assessment were excluded from analysis. CT, chemotherapy with radiotherapy; RHDV, reduced high-dose volume radiotherapy; RT, radiotherapy; sRT, standard volume radiotherapy.

There are a number of points of note here. First, late toxicity was the same with both randomizations in BC2001 (ie, reduced-volume RT did not impact late toxicity). More significantly, the addition of synchronous chemotherapy also had no effect on reported late side effects. In addition, at any given point, 75% to 80% of patients report no late toxicity at all. This is supported by bladder capacity measurements in BC2001, which show a mean change in bladder volume at 1 year of less than 5 mL. Of those reported grade 3 or 4 RTOG adverse events, fewer than 10% reported events in the chemoRT group and fewer than 20% reported events in the RT group at some point during follow-up. Very similar findings pertain to the BCON trial.[151]

Other data support the good acute tolerance of bladder RT. A large, retrospective study of 487 patients treated with radiation to a mean total dose of radiation dose of 65.5 Gy, the incidence of RTOG grade 3 or higher acute bladder and bowel toxicity was 5% and 3%, respectively.[254]

In terms of late toxicity, in the same retrospective analysis of 487 patients, the incidence of RTOG grade 3 or higher late bowel/bladder toxicities, defined as toxicities that occurred or persisted after the third month from the end of RT, was 12% and 3%, respectively.[254] In 2009, Efstathiou et al[10] reported late toxicity results in 285 patients who had participated in four RTOG TMT trials. Median follow-up was 5.4 years. Overall 5.7% reported persistent late genitourinary and 1.9% gastrointestinal toxicity of grade 3 or higher, consistent with the BCON and BC2001 results.

The good toxicity and functional results associated with RT are borne out by surveys of QoL and symptoms in cystectomy and RT patients carried out by multiple groups.[9,255-257] Furthermore, RT and cystectomy patients report different patterns of symptoms, with sexual dysfunction being more prominent in surgical patients and bowel symptoms more prominent in RT patients.

In a study evaluating long-term health-related QoL in MIBC survivors who either received TMT or RC[9] found that, after a median follow-up of 5.6 years, patients who received TMT had improved general QoL compared to those who received surgery (9.7 points, *P* = .001) and higher physical, social, emotional, role, and cognitive function by 6.6 to 9.9 points, *P* = .04. Bowel function was improved, as well as sexual function and body image.

One study compared effectiveness of TMT and RC using decision-analytic modeling with the end point of quality- adjusted life years (QALYs).[257] It was found that TMT resulted in an incremental gain of 0.59 QALYs over surgery. When limiting the model to favorable, contemporary cohorts, TMT remained more effective with an incremental gain of 1.61 QALYs. These data support the need for prospective validation of QoL end points in future studies evaluating surgery as well as bladder preservation for patients with MIBC. This is particularly important as less is known about toxicity/QoL in female patients treated with TMT. In a small study of TMT patients completing health-related QoL questionnaires (64/74 TMT patients with completed questionnaires, 86%), 14 (22%) were women.[258] Fewer women reported no diarrhea compared to men (50% vs 86%, $P = .02$), and a greater percentage of women reported some degree of sexual activity in the 4 weeks prior to questionnaire completion ($P = .04$) as well as less decline in sexual interest with age compared to men. However, given the small numbers in the study, it is important to gather further information surrounding QoL by age and gender for patients undergoing surgery and TMT.

When using immunotherapy in conjunction with RT for localized MIBC, the safety and tolerability must be adequately assessed. Two early phase I studies evaluated immunotherapy in combination with hypofractionated RT to the bladder.[259,260] The PLUMMB trial (ClinicalTrials.gov NCT02560636) was a phase I study of five patients with locally advanced/metastatic BC, treated with 36 Gy in 6 weekly fractions along with pembrolizumab starting 2 weeks prior to radiation and concurrently with radiation.[260] This trial was stopped early as two patients experienced severe bladder irritation (cystitis or pain). These were determined to be protocol-defined dose-limiting toxicities judged to be related to treatment. A separate phase I trial evaluated atezolizumab along with weekly gemcitabine for 4 weeks concurrent with hypofractionated radiation (50 Gy in 20 fractions) for localized MIBC.[259] The protocol included radiation to the pelvic lymph nodes. There were a total of eight patients enrolled. The first give patients received atezolizumab at 1,200 mg intravenously every 3 weeks for 16 cycles. Three patients developed grade 3 side effects (gastrointestinal), two of which qualified as dose-limiting toxicity. Thus, the dose of atezolizumab was decreased to 840 mg for the remaining three patients. However, the study was ultimately terminated due to the development of additional grade 3 toxicity in two patients treated with the reduced dose. The toxicities were mostly gastrointestinal. Four patients developed grade 3 colitis. Due to these findings, the SWOG/NRG 1806 trial did not allow for hypofractionation. An early analysis of safety data of 73 patients enrolled onto the trial (36 receiving standard TMT, 37 receiving TMT + atezolizumab) found reasonable toxicity rates, with 11 grade 3 or higher toxicities on the standard arm versus 23 on the experimental arm.[261] An updated analysis presented in 2022 of 213 patients (100 receiving standard TMT, 113 receiving TMT + atezolizumab) found 44 patients with grade 3 or higher toxicity events on the standard arm versus 65 on the experimental arm.[262] The most common toxicity was hematologic and considered nonimmune related, with overall reasonable rates of toxicity in these early safety analyses. Thus, the combination of conventionally fractionated radiation and immunotherapy appears to be safe with acceptable early toxicity. The combination of hypofractionated RT and immunotherapy may be a good use case for online adaptive RT—the ability to adapt the treatment daily to avoid high-dose RT near-critical organs at risk, such as the small bladder, may circumvent the observed toxicities observed in the aforementioned phase I trials.

Pattern of Failure

The BC2001 study gives a good indication of patterns of failure in response to bladder preservation therapy.[150] A summary of relapse patterns in the chemoRT arm of the trial is shown in Figure 71.8.

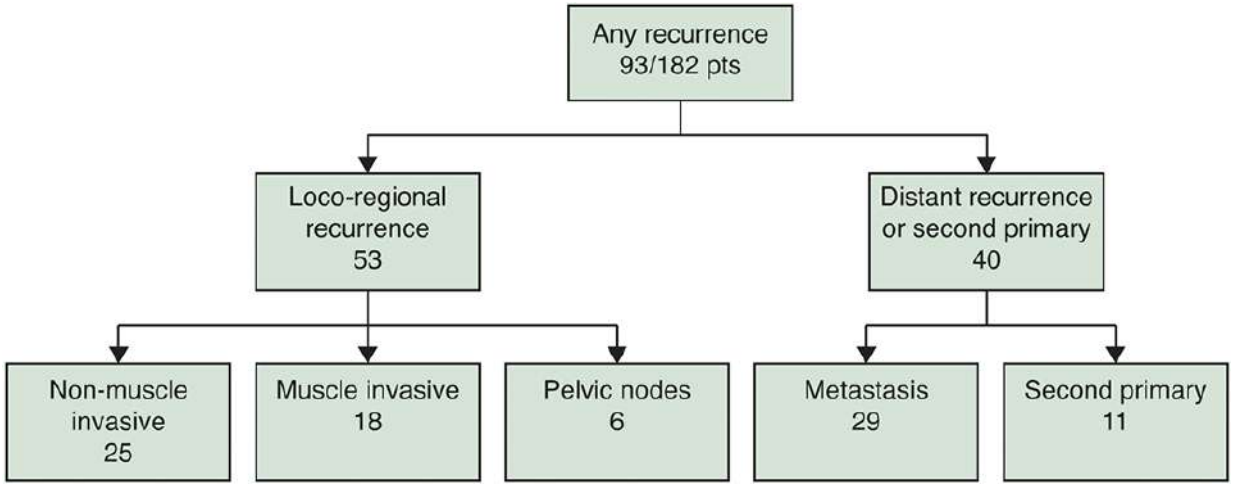

FIGURE 71.8 Patterns of failure after chemoradiotherapy in BC2001.

There are a number of features of note here. First, the majority of locoregional failures are in the bladder, and there are more noninvasive than invasive recurrences. This underlines the need for regular surveillance post-RT and the requirement for multidisciplinary care if patients are to be managed by bladder conservation. Many noninvasive recurrences can be successfully managed conservatively without the need for cystectomy. For those with invasive recurrence, cystectomy remains an option if the patients are sufficiently fit. The low rate of nodal relapse in BC2001 is also of interest, as no attempt was made to include pelvic nodes in the field, although lower pelvic nodes would have been included in the treated volume. For improvement in the metastatic relapse rate, better systemic therapies must be found.

Role of Systemic Neoadjuvant/Adjuvant Therapy

Contrary to management with RC, the role of neoadjuvant or adjuvant chemotherapy in conjunction with concurrent chemoradiation is not firmly established, given the limited high-quality data for either approach, as reviewed later.

The RTOG 89-03 trial[162] assigned 123 patients to two cycles of neoadjuvant cisplatin/methotrexate/vinblastine (MCV) chemotherapy prior to concurrent chemoradiation or to concurrent chemoradiation without neoadjuvant chemotherapy. The addition of neoadjuvant chemotherapy did not improve OS or decrease the rate of distant metastases. There were four treatment-related deaths in the arm that received neoadjuvant chemotherapy versus one in the control arm. Three of the four deaths in the neoadjuvant chemotherapy arm were due to neutropenic sepsis. Given the risks observed with no improvement in oncologic outcomes, it was concluded that neoadjuvant MCV chemotherapy was not beneficial when combined with TMT. However, there are some limitations worth mentioning, including that the study did not fully accrue (planned accrual $n = 174$) as it was closed early due to the unexpectedly high rate of severe neutropenia and sepsis, patients were planned for two cycles of MCV instead of three, and there was not good supportive care in that era for chemotherapy treatments, likely contributing to high rates of complications and deaths in the neoadjuvant chemotherapy arm.

The BA06 30894 trial[35] randomized 976 patients (treated with either cystectomy or curative-intent RT) to either three cycles of MCV neoadjuvant chemotherapy or no neoadjuvant chemotherapy. There was a 16% reduction in the risk of death with neoadjuvant chemotherapy compared to no neoadjuvant chemotherapy (HR 0.84, 95% CI 0.72-0.99). Five-year OS rate in the

no neoadjuvant chemotherapy group was 43% versus 49% in the neoadjuvant chemotherapy group, while 10-year OS rate in the no neoadjuvant chemotherapy group was 30% versus 36% in the neoadjuvant chemotherapy group. The patients in the RT group did not receive concurrent chemotherapy along with the RT; thus, it is unclear whether this benefit would be maintained in a cohort of patients treatment with modern techniques and concurrent chemoRT.

A retrospective analysis of 2,566 patients in the NCDB with cT2-4N0M0 urothelial cell carcinoma of the bladder treated with definitive concurrent chemoradiation between 2004 and 2015 evaluated the receipt of neoadjuvant chemotherapy versus those without neoadjuvant chemotherapy.[263] With a median follow-up of 6.2 ears, there was no difference in survival between groups (neoadjuvant chemotherapy, 462 patients vs chemoradiation alone, 2,104 patients): 5-year OS 30.6% (95% CI 28.4%-32.9%) in neoadjuvant group versus 31.8% (95% CI 27.0%-36.8%) in the standard chemoradiation group; 10-year OS 13.3% (95% CI 11.2%-15.5%) in the neoadjuvant group versus 13.0% (95% CI 8.4%-18.7%) in the standard chemoradiation group (log-rank P = .19). There was no association between receipt of neoadjuvant chemotherapy and OS on MVA (P = .921). These results suggest that that there is no benefit to the routine addition of neoadjuvant chemotherapy to standard chemoradiation for BC.

Finally, the BC2001 study[150] allowed neoadjuvant chemotherapy prior to RT or chemoRT. Thirty-three percent of patients received neoadjuvant chemotherapy. The benefit observed from concurrent chemoRT compared to RT alone was similar in those who received neoadjuvant chemotherapy (HR 0.62, 95% CI 0.35-1.13) and in those who did not receive neoadjuvant chemotherapy (HR 0.71, 95% CI 0.46-1.10). The effectiveness of neoadjuvant chemotherapy was unable to be fully assessed, given the small numbers of patients who received it.

Given the limited data available, we certainly feel that neoadjuvant chemotherapy is an option with TMT depending on the clinical situation. Importantly, we do not feel that the receipt of neoadjuvant chemotherapy should preclude the option of proceeding with a bladder-sparing approach.

Role of External Beam Radiation Therapy for Node-Positive Disease

As reviewed in the Surgical section, the AJCC eighth edition[121] was modified and reclassified node-positive disease (defined as N1-N3 disease) as stage III (previously identified as stage IV disease), because node-positive disease has more favorable outcomes compared to M1 disease.

However, there is a paucity of data on optimal treatment approach for patients with clinically node-positive disease, particularly with respect to bladder preservation strategies. The phase II ECOG-ACRIN/NRG EA8185 trial (INSPIRE) evaluated the role of chemoRT with or without durvalumab in node-positive BC to identify an appropriate treatment approach for these patients (ClinicalTrials.gov NCT04216290). This trial was also novel given the nodal treatment design, which could help answer the question of whether regional nodal involvement may be considered curable with the use of chemoRT. Unfortunately, this study was recently closed due to poor accrual; hence, we must await additional studies/data to further understand the optimal treatment approach for these patients.

Palliative Radiation Therapy

In patients in whom palliative radiation is warranted, the Medical Research Council prospective randomized trial BA09 established that 21 Gy in 3 fractions on alternate weekdays is as effective as 35 Gy in 10 fractions.[264] Five hundred patients were recruited, but data on symptomatic improvement at 3 months were only available on 272 patients. Of these, 68% achieved

symptomatic improvement (71% for 35 Gy, 64% for 21 Gy), with no evidence of a difference in efficacy or toxicity between the two arms. On the basis of these results, 21 Gy in three fractions is widely used in the United Kingdom as a palliative schedule. The data are congruent with other data on hypofractionation for palliation as well as the growing trend for hypofractionation in other pelvic sites, in particular the prostate.

Electron and Proton Beam Therapy

Electron beams are only of interest in the context of intraoperative RT. The role of this modality for carcinoma of the bladder needs to be assessed in a prospective trial and cannot at present be recommended outside a suitable study.

There is scanty published information on the use of protons in the treatment of patients with MIBC. Takaoka et al[265] retrospectively reviewed patients with MIBC who received TMT using proton beam therapy at a single institution. Between 1990 and 2015, 70 patients with cT2-3N0M0 MIBC were treated. Median follow-up was 3.4 years. The 5-year cumulative OS rate, PFS rate, and time to progression rate were 82%, 77%, and 82%, respectively. Twenty-six (18%) patients had grade 3 to 4 acute hematologic toxicities, and two (3%) patients had late grade 3 genitourinary toxicity. Overall, treatment was well tolerated, and patients had favorable clinical outcomes. A separate study by Araya et al[266] reviewed the outcomes of 36 patients with MIBC enrolled in the Proton-Net prospective registry study and received proton beam therapy with concurrent chemotherapy between May 2016 and June 2018. OS, PFS, and LC rates were 90.8%, 71.4% and 84.6%, respectively, after 3 years. Only one case (2.8%) experienced a treatment-related late adverse event of grade 3 urinary tract obstruction, and no severe gastrointestinal adverse events occurred. More data from long-term follow-up are needed to further guide the use of proton beam therapy for MIBC.

Brachytherapy

There is considerable historic literature on the use of brachytherapy (BT), particularly from the Netherlands. The main advantage for this technique is the conservation of bladder function. Reported results seem to be very good; for example, van der Werf-Messing et al[267] report the outcomes in 328 patients treated with 3 × 3.5 Gy external irradiation followed by a radium implant. Overall 5- and 10-year survival rates were 56% for T2 tumors and 39% and 13%, respectively, for T3 disease. Similar results have been obtained in more recent series with iridium-192 implants and manual afterloading.[268,269] There are also descriptions in the literature of the use of high-dose rate (HDR) afterloading, although one paper suggests that this may be less effective and more toxic than low-dose rate treatment.[270] The striking feature of most of these series is the very low patient numbers and long time spans reported, suggesting that these techniques are only rarely used, even in centers with relevant expertise.

van der Steen-Banasik[271] reported on 57 patients with a T2 solitary bladder tumor treated with transurethral bladder resection followed by external beam irradiation to the bladder and regional iliac lymph nodes (40 Gy in 20 fractions, 5 fractions per week), and within 1 week interstitial HDR BT, in selected cases combined with partial cystectomy and lymph node dissection. The BT catheters were placed via a transabdominal approach with robotic assistance from a Da Vinci robot. The fraction schedule for HDR was 10 fractions of 2.5 Gy, 3 fractions per day, which was calculated to be equivalent to a reference low-dose rate schedule of 30 Gy in 60 hours. Average postoperative hospitalization was 6 days, with minimal blood loss and no wound healing problems. Two patients had severe acute toxicity: one pulmonary embolism grade 4 and one cardiac death.

Late toxicity was mild (two urogenital grade 3 toxicity). The median follow-up was 2 years; the 2-year OS, DFS, DSS, and local tumor control rates were 59%, 71%, 87%, and 82%, respectively.

The GEC-ESTRO/ACROP (Groupe Européen de Curiethérapie- European Society for Radiotherapy and Oncology/Advisory Committee on Radiation Oncology Practice) published recommendations to perform bladder implants and BT as a treatment option for MIBC and techniques were described.[272]

Summary of Radiation Therapy

RT for BC has evolved tremendously with many exciting technological advances and opportunities for further enhancement. Radiation treatment has emerged as a viable alternative to RC for selected patients with MIBC. The largest trial to date of bladder preservation therapy in North America recently completed accrual (n = 485 patients, SWOG/NRG 1806), and it is a highly pragmatic and contemporary trial with or without the inclusion of immunotherapy to potentially improve upon clinical outcomes. We eagerly await the results of this and other studies, as well as await corresponding correlative analyses, which may identify biomarkers of response and treatment selection.

ROLE OF SYSTEMIC THERAPY

Up to 50% of patients will develop metastatic disease. BC is a chemosensitive disease, with responses reported to a range of agents. Systemic combination chemotherapy can be effective and result in tumor responses and symptom control. Overall response rates may be as high as 70%, with a median survival of approximately 12 to 14 months.[41,204]

Separately, the development of immune checkpoint inhibitors as well as antibody-drug conjugates has changed the treatment landscape for metastatic UC.[273] These agents have been evaluated as first-line therapy for metastatic UC, with improvement in median OS to as high as 30 months, such as in the case of combination EV plus pembrolizumab,[42] redefining the treatment paradigm for this disease. Their role in localized disease is not fully established, although there are ongoing studies evaluating safety and efficacy in this clinical space.

Systemic Regimens in Metastatic Disease

Initial therapy for patients with metastatic UC is actively evolving. Based on recent data, patients with advanced or metastatic UC should undergo initial therapy with EV plus pembrolizumab rather than platinum-based chemotherapy with maintenance immunotherapy (Figure 71.9). This is pasted on a phase III study (EV-302)[42] where EV conferred a large OS benefit with an acceptable toxicity profile. Patients who were eligible for platinum-based chemotherapy were randomized to EV plus pembrolizumab versus chemotherapy (gemcitabine plus either cisplatin or carboplatin). EV plus pembrolizumab improved OS (median 32 vs 16 months, HR 0.47, 95% CI 0.38-0.58) and PFS (median 13 vs 6 months, HR 0.45, 95% CI 0.38-0.54) in the entire study population. Among cisplatin-eligible patients, both OS (median 32 vs 18 months, HR 0.53, 95% CI 0.39-0.72) and PFS (median 15 vs 7 months, HR 0.48, 95% CI 0.38-0.62) were improved. Among cisplatin-ineligible patients, EV plus pembrolizumab improved both OS (median not reached vs 13 months, HR 0.43, 95% CI 0.31-0.59) and PFS (median 11 vs 7 months, HR 0.43, 95% CI 0.33-0.55) compared to chemotherapy.

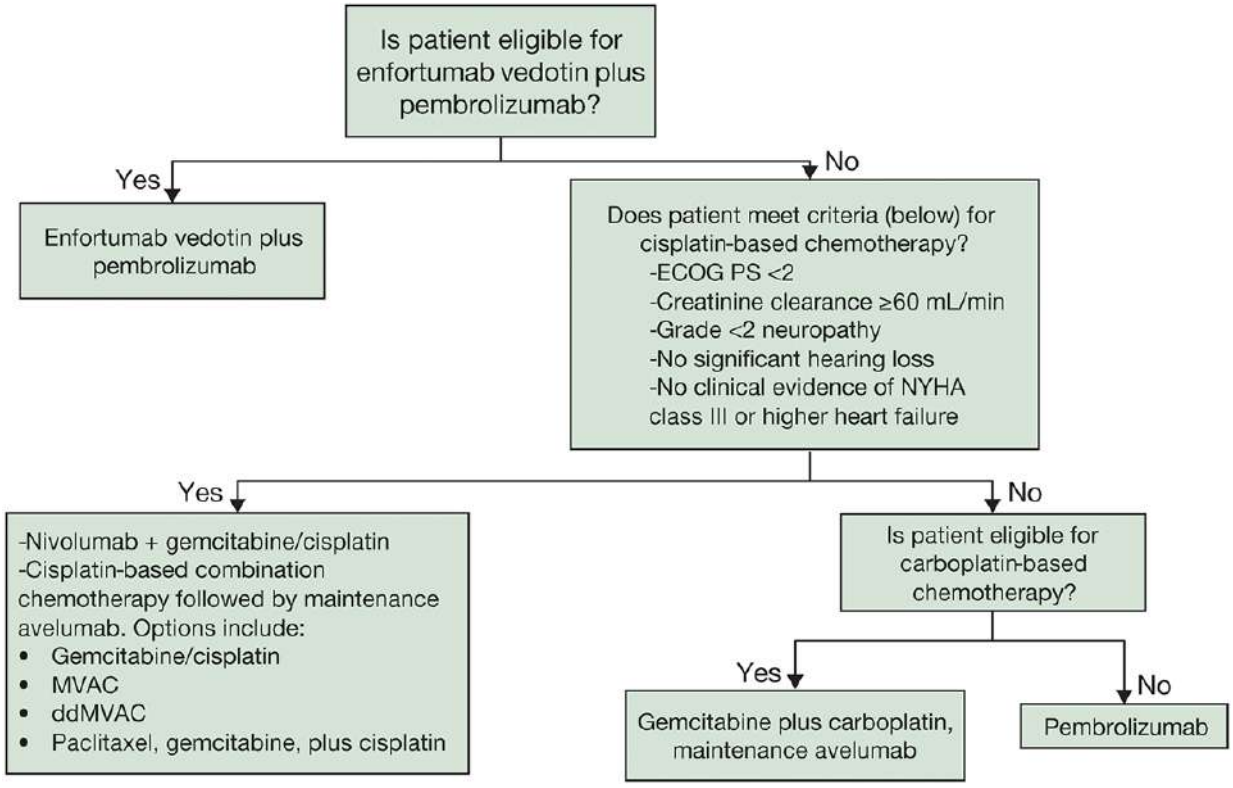

FIGURE 71.9 First-line systemic therapy for metastatic urothelial carcinoma. MVAC, methotrexate/vinblastine/doxorubicin (adriamycin)/cisplatin; NYHA, New York Heart Association.

For those who are not eligible for EV plus pembrolizumab (eg, patients with preexisting or poorly controlled neuropathy or have preexisting cutaneous disorders), first-line therapy depends on cisplatin eligibility.

Cisplatin Eligible

There are several cisplatin-based regimens available to patients, and the choice is based on provider and patient preferences.

Nivolumab plus GC is an option for cisplatin-eligible patients. An open-label phase III trial (CheckMate-901)[274] with 608 cisplatin-eligible patients were randomly assigned to either nivolumab plus GC followed by maintenance nivolumab, or GC. At a median follow-up of 33.6 months, the addition of nivolumab to GC improved OS (median 21.7 vs 18.9 months, HR for death 0.78, 95% CI 0.63-0.96, $P = .02$). PFS was also longer (HR for progression or death, 0.72, 95% CI 0.59-0.88, $P = .001$). Median duration of CR was 37.1 months with the nivolumab/gemcitabine/cisplatin regimen compared to 13.2 months with GC alone. Grade 3 or higher toxicity rates were higher with the combination therapy; however, health-related QoL after 4 months of treatment was similar between the two groups.

The four-drug combination MVAC is one such treatment option for the initial therapy of patients with locally advanced or metastatic UC. A multicenter trial of 269 patients were randomly assigned to treatment with either MVAC or single-agent cisplatin.[275] The use of MVAC significantly improved the response rate (39% vs 12%, $P < .0001$), a significant increase in median PFS (10 vs 4 months) and a significant improvement in median OS (13 vs 8 months). However, it is associated with more toxicity compared to single-agent cisplatin.

ddMVAC, which increases the dose intensity of MVAC by administering treatment every 2 weeks with granulocyte colony-stimulating factor support, has been evaluated with the hope of improving long-term survival. A phase III study (EORTC 30924)[276] randomized 263 patients to either classic MVAC or ddMVAC found that ddMVAC improved median PFS (9.1 vs 8.2 months) as well as 2-year PFS (25% vs 12%, HR 0.75, 95% CI 0.58-0.98) and was associated with higher CR rates (21% vs 9%). However, ddMVAC failed to improve OS over classic MVAC (median 15.5 vs 14.1 months, 2-year OS 35% vs 25%, HR 0.80, 95% CI 0.60-1.06). The 7-year update of the trial demonstrated improved 5-year survival with ddMVAC (21.8%) over classic MVAC (13.5%), but this difference was not statistically significant.[277] ddMVAC was also associated with an improved toxicity profile over classic MVAC.

GC is another option for initial therapy. It has been found to have similar efficacy and less toxicity compared with MVAC. A phase III trial of 405 patients randomized to either GC or MVAC[39],[278] found that, after a median follow-up of 19 months, OS was similar between both arms (HR 1.04, 95% CI 0.82-1.32, $P = .75$) as was time to progression (HR 1.05, 95% CI 0.85-1.30), time to treatment failure (HR 0.89, 95% CI 0.72-1.10), and response rate (GC 49%, MVAC 46%). There was less grade 3 or higher toxicity with GC.

The addition of paclitaxel to gemcitabine and cisplatin (PCG) was evaluated in a phase III clinical trial by EORTC (study 30987), which enrolled 627 patients with advanced UC. The regimens were well tolerated. Results showed that the PCG arm resulted in a higher rate of overall response rate (55.5% vs 43.6%, $P = .0031$) and median OS (15.8 vs 12.7 months, HR 0.85, $P = .075$) compared with GC arm. Both treatments were well tolerated.

Cisplatin Ineligible

In patients who are not eligible for either EV plus pembrolizumab or cisplatin, gemcitabine plus carboplatin is a reasonable alternative for these patients. In a randomized phase II/III trial (EORTC 30986),[279] 238 patients were randomized to either gemcitabine plus carboplatin versus a more complex carboplatin regimen (methotrexate, carboplatin, and vinblastine—M-CAVI). With a median follow-up of 4.5 years, gemcitabine plus carboplatin resulted in similar OS (median 9.3 vs 8.1 months, $P = .64$) compared to the M-CAVI regimen. There was no difference in PFS between the two arms ($P = .78$). There were lower grade 3-4 toxicity rates in the gemcitabine and carboplatin arm (9% vs 21%).

Maintenance Therapy

In patients who have not progressed on platinum-based chemotherapy alone and are eligible to receive immune checkpoint inhibitors, it is recommended to proceed with maintenance avelumab based on results from the randomized phase III JAVELIN Bladder 100 trial.[280,281] In this study, 700 patients who experienced either an objective response or stable disease after four to six cycles of gemcitabine plus platinum-based chemotherapy were randomly assigned to maintenance avelumab or best support care. After a median follow-up of 39 months, in the entire study population, the addition of avelumab improved OS and PFS (3-year OS 36% vs 30%, median 24 vs 15 months, HR 0.76, 95% CI 0.63-0.91; 3-year PFS 16% vs 5%, median 6 vs 2 months, HR 0.54, 95% CI 0.46-0.64). This was demonstrated regardless of type of platinum-based chemotherapy regimen received. Although this study evaluated maintenance avelumab in patients who received gemcitabine plus platinum-based chemotherapy, it is suggested to offer this approach who have not progressed on other platinum-based chemotherapy regimens, extrapolating from this study.

Second-Line Therapy and Beyond

For patients who progress post-initial therapy, the choice of second-line therapy is largely dependent on what the patient received as part of initial therapy and is beyond the scope of this chapter. Similarly, later-line therapies are dependent on multiple clinical factors, including prior therapies received, molecular alterations present, and patient comorbidities, as well as treatment goals. We encourage clinical trial enrollment where possible.

TREATMENT OF PATIENTS WITH UNCOMMON BLADDER TUMORS

Squamous Cell Carcinoma

SCC is uncommon in the developed world, and many reported cases may in fact reflect sampling of squamous elements within UC. As these tumors are often excluded from systemic therapy trials, there are few data on outcomes with treatment as most papers are retrospective collections of unconnected observations.[282,283] It appears that local failure may be more prevalent than distant relapse, but even that observation is based on very few cases.

Although SCC is represented in many of the studies on bladder preservation, some physicians may be reluctant to offer this approach to patients with MIBC with this rare histology because of its perceived poor response to therapy and adverse outcomes in comparison to more common histologies of MIBC. Stokes et al[284] queried the NCDB for patients with T2-T4 or TX, N0M0 SCC of the urinary bladder diagnosed from 2004 to 2012 receiving both chemotherapy and high-dose RT (>55 Gy) without upfront cystectomy. Patients with UC were queried separately to serve as a comparison group. Fifty-four patients with SCC and 2,054 those with UC were identified. Patients with SCC were more likely to be younger, female, or non-White and were more likely to have more advanced disease at presentation. Age greater than 70, comorbidity score greater than 0, and stage T3 or higher were associated with worse OS, whereas gender, race, insurance status, household income, facility type, chemotherapy (single vs multiagent), and histology showed no association with OS. OS estimates were not significantly worse for SCC compared to UC (5-year OS 25.4% vs 33.3%; adjusted HR, 1.34, $P = .12$). Overall, it was concluded that OS did not significantly differ between patients with SCC and those with UC undergoing organ preservation for MIBC, whereas other prognostic factors were relevant in both groups.

Using the SEER database queried from 1998 to 2007, Li et al[285] evaluated patients with muscle-invasive (stage II-IV) SCC of the urinary bladder who underwent complete cystectomy. A total of 331 patients were included in the analysis. The majority had cystectomy alone ($n = 297$), whereas 10% ($n = 34$) received postoperative RT. Factors associated with postoperative RT were younger age ($P = .03$) and more advanced stage at diagnosis ($P < .001$). The addition of RT was not associated with an OS benefit ($P = .55$). Median survival was 21 months for patients treated with cystectomy alone and 18 months for postoperative RT. Cox regression analysis confirmed the lack of improvement in OS among patients who received postoperative RT ($P = .47$).

A prospective randomized trial conducted in patients with locally advanced BC after RC sought to evaluate whether adjuvant sequential RT plus chemotherapy could improve locoregional recurrence-free survival compared with adjuvant chemotherapy alone.[286] As this study was conducted in Egypt, of the 120 patients enrolled, almost 47% had SCC or other histology. The chemotherapy plus RT arm had 75 patients, while the chemotherapy alone arm had 45 patients. Adjuvant chemotherapy plus RT was significantly associated with improved locoregional recurrence-free survival (2-year outcome of 96% vs 69%, adjusted HR 0.08, 95% CI 0.02-0.39, $P < .001$) and marginal improvements in DFS (2-year outcome of 68% vs 56%, adjusted HR 0.53, 95%

CI 0.27-1.06, P = .07) and OS (2-year outcome of 71% vs 60%, adjusted HR 0.61, 95% CI 0.33-1.11, P = .11). In addition, adjuvant RT was reasonably well tolerated.

Urachal Adenocarcinomas

Urachal adenocarcinomas are extremely rare. Surgical resection with a partial cystectomy and en bloc resection of the urachal ligament with umbilicus are the treatment choices in the setting of localized disease. A retrospective analysis of 66 cases at a single institution between 1951 and 2004 evaluated the efficacy of different treatments.[287] Most patients received partial cystectomy (70%), followed by complete cystectomy in 21% and RT in 9%. Five-year OS was 49%. MVA found that low tumor grade and negative surgical margins were associated with better survival, while higher pathologic stage and surgical margin involvement were associated with a poor prognosis. There is currently no definitive role for neoadjuvant or adjuvant chemotherapy in this tumor. Unfortunately, there are many patients who present with metastatic disease, which currently is not likely to be curable. There is no standard chemotherapy regimen for these patients.

Small Cell Carcinoma

Small cell carcinoma of the bladder is rare; however, it is associated with aggressive clinical behavior and has high metastatic potential.[288] These patients generally get treated along the same lines as small cell lung carcinoma, but the benefit of prophylactic cranial irradiation is unclear.[289-292]

Pasquier et al[293] reported on a retrospective study at 15 Rare Cancer Network medical centers that contributed 107 cases of pure or mixed small cell carcinoma of the bladder. Patients could have local, locoregional, or metastatic disease. Mean follow-up time was 4.4 years, with 66% of these patients having pure small cell carcinoma of the bladder. Seventy-two percent and 12% of the patients presented with T2-4N0M0 and T2-4N1-3M0 stages, respectively, and 16% presented with synchronous metastases. When employed, the most frequent curative treatments were radical surgery and chemotherapy, sequential chemotherapy and RT, and radical surgery alone. The median (interquartile range, IQR) OS and DFS times were 12.9 months (IQR, 7-32 months) and 9 months (IQR, 5-23 months), respectively, for the entire cohort. The metastatic, T2-4N0M0, and T2-4N1-3M0 groups differed significantly (P = .001) in terms of median OS and DFS. In the patients with nonmetastatic disease, the type of treatment (ie, radical surgery with or without adjuvant chemotherapy vs a bladder-sparing approach) did not significantly influence OS or DFS (P = .7), suggesting that a bladder-sparing treatment is appropriate in these patients.

A retrospective analysis of patients presenting with pure or predominant histology small cell carcinoma of the bladder in the United Kingdom between 2006 and 2016 was conducted.[288] A total of 409 patients were included, and 189 (46.2%) patients had pure histology small cell carcinoma of the bladder. The median OS of the entire cohort was 15.9 months (95% CI 13.2-18.7 months). A total of 247 patients received primary chemotherapy, with a median OS of 21.6 months (95% CI 15.5-27.6 months) versus a median OS of 9.1 months (95% CI 5.4-12.8 months) among those who did not receive primary chemotherapy (HR 0.46, 95% CI 0.37-0.59, P < .001). Chemotherapy choice did not impact outcomes. Among those with bladder-confined disease, 61 underwent cystectomy and 104 underwent RT. Survival outcomes were similar between both treatments. Only six patients (1.5%) were identified as having brain metastases at any time during their clinical course, confirming their relative rarity. Survival is improved in those who are able to receive chemotherapy.

Histologic Variants of Urothelial Carcinoma Treated With Trimodality Therapy

Outcomes of patients with histologic variants of UC, specifically with respect to treatment with TMT, are emerging. Given that TMT is associated with excellent and comparable outcomes to RC for those with pure UC histology, Krasnow and authors sought to evaluate the outcomes of patients with histologic variants following TMT.[294] Of 303 patients treated with TMT, 66 (22%) were found to have variant urothelial carcinoma (VUC). These patients were compared to 237 with pure urothelial carcinoma (PUC). CR rate after induction TMT was not different between the two groups (83% in PUC vs 82% in VUC, $P = .9$). The 5- and 10-year DSS was 75% and 67% in PUC versus 64% and 64% in VUC. The 5- and 10-year OS was 61% and 42% in PUC versus 52% and 42% in VUC. Salvage cystectomy rates were similar in the two groups ($P = .3$). This analysis suggests that the presence of VUC should not necessarily exclude the option of TMT for the treatment of MIBC.

PART H

Male Genitourinary

CHAPTER 72

Low-Risk Prostate Cancer

Hiram A. Gay and Bridget F. Koontz

ANATOMY

Gross Anatomy and External Architecture

The prostate gland is an ovoid-shaped structure that is part of the male reproductive system. The prostate is made up of several types of tissue, including glandular and stromal tissue. Glandular tissue is responsible for producing prostate fluid, one of the components of semen. This fluid is rich in enzymes, proteins, and minerals that are vital for the viability and motility of sperm cells. The stromal tissue, which includes muscle and elastic fibers, helps in the expulsion of semen during ejaculation.

The prostate is located in the pelvis, adjacent to dorsal and periprostatic venous complexes, pelvic sidewall musculature, the pelvic plexus, and cavernous nerves, inferior to the bladder, anteroinferior to the seminal vesicles (SVs), and anterior to the rectum. The prostate surrounds segments of the urethra before it passes through the genitourinary diaphragm (GUD; Figure 72.1). Two of the five segments of the male urethra are the preprostatic urethra adjacent to the preprostatic sphincter and the prostatic urethra, which is placed from the verumontanum to the GUD. The paired SVs are situated posterosuperiorly to the prostate gland and secrete seminal fluid into the bilateral ductus deferens as they become the ejaculatory ducts. These ducts transverse the prostate to join the urethra at the verumontanum (Figure 72.1, right). At this point, the urethra changes its angulation by bending 30° to 40° anteriorly.

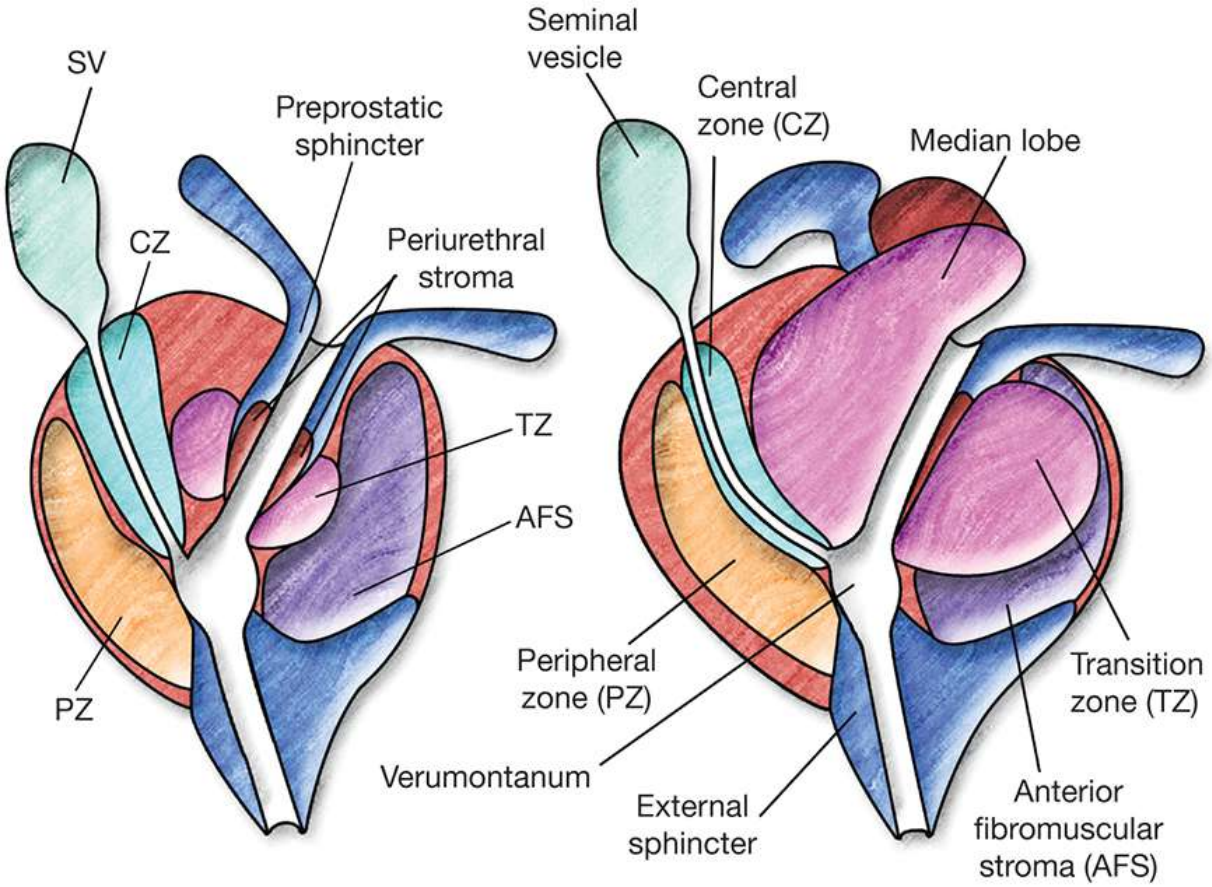

FIGURE 72.1 Zonal anatomy of the prostate. On the left, a young man with minimal transition zone (TZ) hypertrophy. Note that the preprostatic sphincter and periejaculatory duct zone (central zone of McLean) are clearly defined. On the right is an older man with TZ hypertrophy, which effaces the preprostatic sphincter and compresses the periejaculatory duct zone. AFS, anterior fibromuscular stroma; CZ, central zone; PZ, peripheral zone; SV, seminal vesicle. (Reprinted from McLaughlin PW, Troyer S, Berri S, et al. Functional anatomy of the prostate: implications for treatment planning. *Int J Radiat Oncol Biol Phys.* 2005;63[2]:479-491. Copyright © 2005 Elsevier. With permission.)

The prostate is contained within a thin, fibrous, adherent capsule that is structurally continuous with the stroma of the gland. The apex of the gland rests above the GUD. The GUD surrounds the membranous sphincter and may vary in length and thickness. The puboprostatic ligaments extend anteriorly from the gland's surface to the pubic symphysis. The prostate is separated from the rectum posteriorly by Denonvillier fascia (rectovesical septum), which attaches above to the peritoneum and below to the GUD. This portion of the prostatic fascia restricts posterior extension of prostatic carcinoma into the rectum. The lateral margins of the prostate are usually delineated against the levator ani muscles, forming the lateral prostatic sulci.

The anterior aspect of the prostate and the lateral pelvic floor are covered with the periprostatic fascia (Figure 72.2). The endopelvic fascia lateral to the prostate gland contains neurovascular structures, including the venous plexus of Santorini, which is the primary drainage for the prostate and penis. This venous network, also called the *dorsal vein complex*, covers the anterolateral surfaces of the prostate. The primary arterial blood supply to the prostate is via branches of the internal pudendal, inferior vesical, and middle rectal arteries. The internal pudendal arteries also provide the blood flow to the penis. The nerves originate from the pelvic plexus, containing both sympathetic and parasympathetic fibers, and are distributed to the prostate, SVs, and the corpora cavernosa of the penis and urethra.

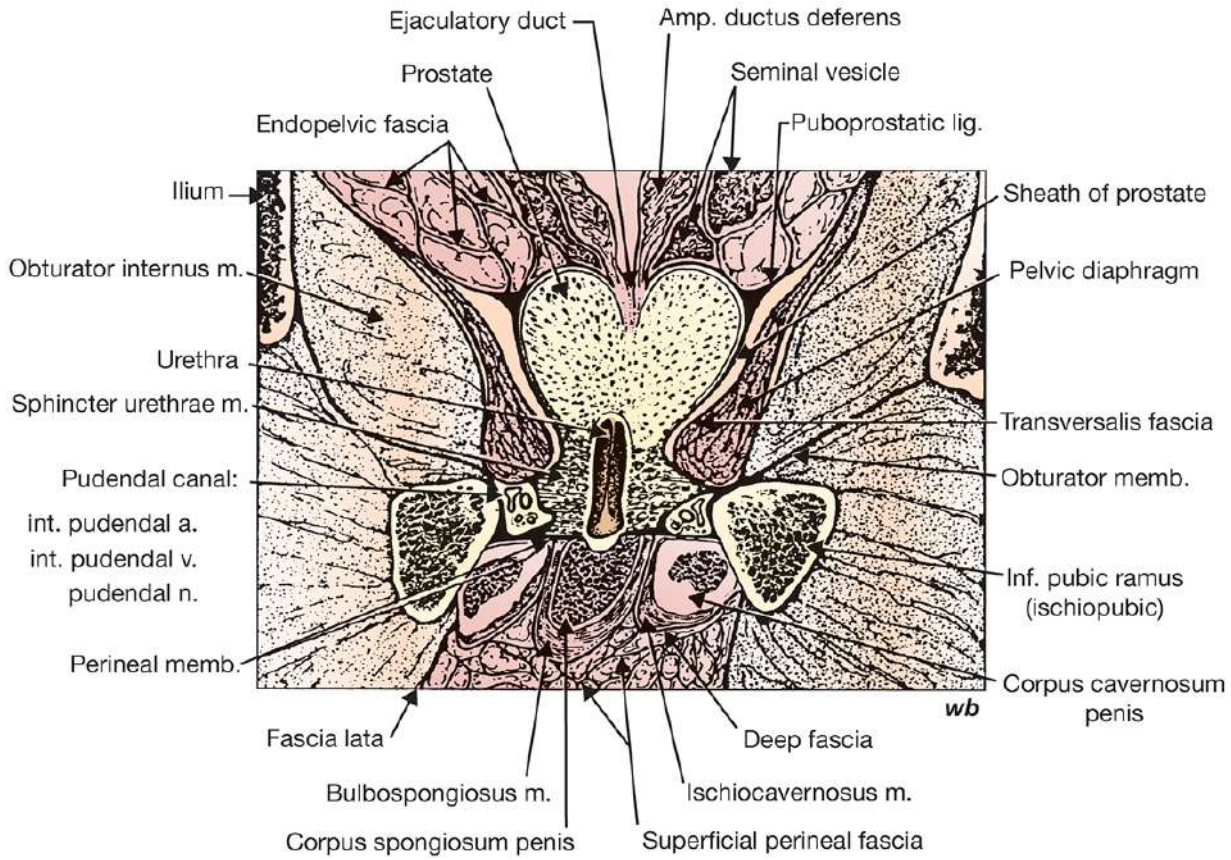

FIGURE 72.2 Frontal section of the male pelvis at right angles to perineal membrane. (From Oelrich TM. The urethral sphincter muscle in the male. *Am J Anat*. 1980;158[2]:229-246. Copyright © 1980 Wiley-Liss, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

The prostatic apex is definable on diagnostic imaging and is very important anatomically for radiation therapy (RT) treatment planning.

Although the apex and the GUD, which surrounds the membranous sphincter, are easily visualized on coronal magnetic resonance imaging (MRI), it is important to recognize that the level of the GUD from the apex to the penile bulb may vary because the absence of an apical capsule contributes to the difficulty in discrimination of the gland from the GUD during computed tomography (CT)-based treatment planning. Delineation of the neurovascular bundle is also limited on CT imaging.

Prostatic Zonal Anatomy

There are four zones of the prostate (Figure 72.1): the peripheral zone (PZ), transition zone (TZ), central zone (AZ), and anterior fibromuscular stroma (AFS) zone. The PZ is the posterior region of the prostate and constitutes the largest portion of the gland, comprising about 70% of the gland's volume in a young man. It is the most common site for prostate cancer (PCa), accounting for approximately 70% to 80% of cases, and is the region palpated during rectal examination. The CZ accounts for approximately 25% of the prostate's volume and surrounds the ejaculatory ducts. The TZ surrounds the urethra and constitutes about 5% to 10% of the prostate's total volume in a young man but becomes with age due to benign prostate hypertrophy (BPH). The TZ is the primary area where BPH occurs. The AFS is a nonglandular area that constitutes about 5% of the prostate's total volume. It consists of muscle and fibrous tissue and is located anterior to the prostate and contiguous with the bladder muscle and external sphincter.

It is important to note that there is no "median lobe" zone in this nomenclature, although such a "lobe" may be present in some patients with PCa and may have important implications for treatment planning and treatment selection. Histologically, the median lobe arises from the TZ or periurethral stroma, with varying proportions of fibrous, glandular, and muscle tissue.

Prostate Physiology

Histologically, the prostate consists of compound tubuloalveolar glands lined by two layers of cells. The glands are embedded in connective tissue comprising collagen and abundant smooth muscle that make up the prostatic stroma. This fibromuscular stroma functions both to control micturition by

acting as a sphincter of the urethra and to express acidic prostatic secretions into the urethra by contracting during ejaculation.

The primary function of the prostate is the production of seminal fluid that protects and nourishes the sperm after ejaculation. The prostate contributes approximately 30% to the seminal fluid, and the SVs, testicles, and bulbourethral glands provide the remaining 70%. Enzymes, including acid phosphatase and prostate-specific antigen (PSA), are secreted into the seminal fluid. PSA is a serine protease involved in the liquefaction of the seminal coagulum. Because PSA is produced primarily by benign and malignant prostatic epithelial cells and normally found at low concentrations in the serum, it is useful for PCa screening and post-treatment monitoring of disease status.

Androgens regulate the synthetic activity and growth of the prostate gland. The primary circulating androgen is testosterone. In the prostatic stroma, testosterone is converted to its active and more potent form, α-dihydrotestosterone, by 5-α-reductase. Secretory epithelial cells and stromal cells have intracellular androgen receptors (ARs). Dihydrotestosterone forms a complex with the dihydrotestosterone-binding domain of the AR, altering the structure of the DNA-binding domain such that it can reversibly bind DNA sequences known as *androgen response elements* in promoter or enhancer regions of androgen-regulated genes. The response includes cell division stimulation, apoptosis inhibition (programmed cell death), or cellular differentiation. In secretory epithelial cells, testosterone stimulation may result in the production and secretion of prostatic fluid. These mechanisms are tightly regulated at many levels, from the hypothalamus secreting luteinizing hormone–releasing hormone (LHRH) to maintain testosterone levels in the blood, to the local regulation of 5-α-reductase in the prostate stroma.

EPIDEMIOLOGY AND RISK FACTORS

Clinical Incidence

Adenocarcinoma of the prostate is the most frequently diagnosed visceral cancer of men in the United States, accounting for 29% of non–skin cancers in 2023.[1] The lifetime risk for American men is one in eight. It was estimated

that 288,300 new cases of PCa would be diagnosed in 2023, but only 34,700 patients would die of the disease.

The incidence rate for PCa dropped approximately 40% from 2007 to 2014 because of declines in the diagnosis of localized tumors through PSA testing, the prevalence of which decreased after the United States Preventive Services Task Force (USPSTF) recommended against screening for men aged 75 years and above in 2008[2] and for all men in 2012.[3] However, the PCa incidence rate has risen by 3% per year from 2014 through 2019, and about half of these cases were advanced. This is driven by increases of about 4.5% annually for regional- and distant-stage diagnoses that began as early as 2011.[1] These patterns are consistent with continued reports of a shift toward higher grade and stage at diagnosis since 2010.[4] Efforts to regain the benefit of early PCa detection while lessening overdiagnosis and overtreatment include a USPSTF upgrade to informed decision-making in men aged 55 to 69 years in 2018.[5]

Black men benefit more from screening in general[6,7] and from the integration of personalized biomarkers because they are more likely to harbor genomically aggressive cancer, even with clinically low-risk disease.[8] High overall cancer incidence in Black men is mainly because of PCa, which is 70% higher than in White men, 2 times higher than in American Indian/Alaska Native (AIAN) and Hispanic men, and 3 times higher than in Asian American/Pacific Islander (AAPI) men.

PCa mortality has declined by 53% since the peak in 1993 because of earlier detection through widespread screening with the PSA test and advances in treatment.[9] PCa remains the second greatest cause of male cancer mortality, behind cancer of the lung and bronchus. PCa mortality rates in Black men are approximately 2 times higher than White men, AIAN, and Hispanic men, and 4 times higher than AAPI men.[1]

Of the known or suspected risk factors for PCa, the most important is age (Table 72.1). The Göteborg-1 Prostate Cancer Screening Trial showed that for men with screen-detected PCa, age was associated with the risk of clinically significant PCa above and beyond the screening round and year of testing ($P < .001$). For each 1-year increase in age, the risk of being diagnosed with a Gleason score (GS) 3 + 4 cancer or higher (vs <7) increased by 11%, whereas the risk of being diagnosed with a GS 4 + 3 cancer or higher (vs <7) increased by 8.5%.[10]

TABLE 72.1 KNOWN OR SUSPECTED RISK FACTORS FOR PROSTATE CANCER

Factor	Effect on Prostate Cancer Risk
Age	Increase
African American race	Increase
Geography	**High**: Guadeloupe, Martinique, Ireland, Barbados, Saint Lucia, Estonia, Puerto Rico, Sweden, France, Bahamas, Norway, New Caledonia; **Low:** India, China
Family history	Increase
Agent Orange	Increase
Tobacco	Decrease in incidence, but current smokers have an increased prostate cancer mortality risk
Chlordecone	Increase
NSAID	Decrease

NSAID, nonsteroidal anti-inflammatory drug.

The median age at diagnosis is 66 years, and the disease incidence escalates sharply with increasing age. The incidence among men aged 50 to 59 years is 1 in 55, increasing to 1 in 19 among men aged 60 to 69 years, and 1 in 11 among those aged 70 years and above.[1] According to autopsy data, 70% of men older than 80 years and 40% of men older than 50 years have pathologic evidence of cancer in the prostate.[11]

Risk Factors

Hormonal Influences

Khera et al reviewed the relationship between serum testosterone and PCa.[12] The authors concluded that high endogenous serum testosterone does not increase the risk of developing PCa and that low serum testosterone does not protect against PCa. Although limited in size and duration, current studies similarly fail to indicate any increased risk of PCa in men receiving testosterone therapy. These results indicate a finite ability of androgens to stimulate PCa growth (the saturation model). The saturation model explains the paradoxical observations that prostate tissue is exquisitely sensitive to changes in serum testosterone at low concentrations but becomes indifferent

at higher testosterone concentrations. A threshold effect occurs in which increasing androgen concentrations reach a limit (the saturation point) beyond which there is no further ability to induce androgen-driven changes in prostate tissue growth. Most studies demonstrate an association between low serum testosterone and poor prognostic features of PCa, including high-grade disease, advanced pathologic stage, and increased risk of biochemical recurrence (BCR) following radical prostatectomy (RP). Current evidence indicates that maximal androgen-stimulated PCa growth is achieved at relatively low serum testosterone concentrations.

Muller et al reported on 3,255 men in the placebo arm of the reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial who underwent planned prostate biopsies at 2 and 4 years and found no association between PCa risk and baseline serum testosterone or dihydrotestosterone.[12,13]

Dietary Influences

A systematic review and meta-analysis of the associations between body mass index (BMI), PCa, advanced PCa, and PSA noted that there is little or no evidence of an association between BMI and the risk of PCa or advanced PCa. However, there was strong evidence of an inverse and nonlinear association between BMI and PSA. In the meta-analyses with continuous BMI, a 5 kg/m^2 increase in BMI was associated with a percentage change in PSA of −5.88%. Using BMI categories, compared to normal weight men, the PSA levels of men who are overweight were 3.43% lower, and men who are obese were 12.9% lower. The association between BMI and PCa is likely biased if missed diagnoses are not considered.[14]

The results of a long, prospective, cohort study (The National Institutes of Health [NIH]-AARP Diet and Health Study) in a cohort of 175,343 U.S. men aged 50 to 71 years, red meat (hazard ratio [HR] = 1.31), processed meat (HR = 1.32), heme iron (HR = 1.28), nitrite (HR = 1.24)/nitrate (HR = 1.31) from meat, grilled/barbecued meat (HR = 1.36), and benzo[a]pyrene (HR = 1.28) were associated with elevated risks of advanced PCa.[15]

In the Danish “Diet, Cancer and Health” cohort of 27,178 men aged 50 to 65 years, neither toenail selenium nor plasma selenoprotein P (SELENOP) was associated with advanced, high-grade, or advanced-stage PCa.[16] The Selenium and Vitamin E Cancer Prevention Trial (SELECT) with a total of 35,533 men showed that dietary supplementation with vitamin E (400 IU/d)

significantly increased the risk of PCa among healthy men. This study also observed an increased PCa risk among men with high blood concentrations of long-chain Ω-3 polyunsaturated fatty acids (LCΩ-3PUFA). Compared with men in the lowest quartiles of LCΩ-3PUFA, men in the highest quartile had increased risks for low-grade (HR = 1.44), high-grade (HR = 1.71), and total PCa (HR = 1.43).[17]

The screening arm of the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial evaluated the association between PCa risk and intake of fruits and vegetables in 1,338 patients with PCa among 29,361 men. Although vegetable and fruit consumption was not related to PCa risk overall, the risk of stage III or IV PCa decreased with increasing vegetable intake (relative risk [RR] = 0.41).[18]

Lycopene is abundant in tomatoes and a potent antioxidant. A systematic review and meta-analysis of 26 studies with 17,517 cases of PCa reported from 563,299 participants showed that higher lycopene consumption/circulating concentration is associated with a lower risk of PCa.[19] A study among 49,898 male health professionals observed that dietary intake of lycopene was associated with a reduced risk of lethal PCa and a lesser degree of tumor angiogenesis.[20]

A systematic review and meta-analysis of 266,699 study participants with 21,612 PCas reported observed that total soy food ($P < .001$), unfermented soy food ($P < .001$), and soy isoflavones genistein ($P = .008$) and daidzein ($P = .018$) intakes were significantly associated with a reduced risk of PCa.[21]

A 30-year prospective cohort study of 11,372 Finnish twins observed that compared to light drinkers (≤3 drinks/week; nonabstainers), heavy drinkers (.14 drinks/week) were at a 1.46-fold higher risk (HR = 1.46) of PCa, adjusting for important confounders.[22] Among current drinkers, binge drinkers were at a significantly increased risk of PCa (HR = 1.28) compared to nonbinge drinkers. Abstainers were at a higher risk (HR = 1.90) of PCa-specific mortality compared to light drinkers, but no other significant associations for mortality were found. Co-twin analyses suggested that alcohol consumption may be associated with PCa risk, independent of early environmental and genetic factors.[22]

A systematic review and meta-analysis with 57,732 cases of PCa and 1,081,586 total cohort members showed that higher coffee consumption was significantly associated with a lower risk of PCa. Compared with the lowest

category of coffee consumption, the pooled RR was 0.91 for the highest category of coffee consumption. There was a significant linear trend for the association (P = .006 for linear trend), with a pooled RR of 0.988 for each increment of one cup of coffee per day. For localized, advanced, and fatal PCa, the pooled RRs were 0.93, 0.88, and 0.84, respectively.[23]

A meta-analysis of dairy product and calcium intakes and PCa risk observed that men with the highest intake of dairy products (RR = 1.11) and calcium (RR = 1) were more likely to develop PCa than men with the lowest intake. The authors concluded that a high intake of dairy products and calcium may be associated with an increased risk of PCa, although the increase appears to be small.[24]

A summary of associations of various dietary factors with PCa development is shown in Table 72.2.

TABLE 72.2 NUTRITIONAL RISK FACTORS FOR PROSTATE CANCER

Food or Nutrient	Direction of Association With Prostate Cancer Risk
Selenium	Null
Tomato and lycopenes	Inverse
Vitamin E	Positive
Vegetable and fruits	Null
Calcium and dairy	Positive
Red meat, processed meat	Positive
Soy/isoflavones	Inverse
Alcohol	Positive
Coffee	Inverse
LCΩ-3PUFA	Positive

LCΩ-3PUFA, long-chain Ω-3 polyunsaturated fatty acids.

Familial Associations

Men with a family history of PCa are at a significantly greater risk of developing the disease compared to those with no such history. The risk is even higher for individuals with relatives diagnosed at a young age (before age 60) or with more than one relative affected. RRs to sons of cases appeared to be lower than in brothers.[25] The Swedish Family-Cancer

Database supports family history as an important factor in PCa, especially in cases of fatal PCa. Familial risks were somewhat higher for fatal than for incident PCa, suggesting that fatal PCas may be a genetic subgroup. If the father had PCa, the HR for sons was 2, and it increased to 17.7 when three brothers were affected. The highest HR (23) was observed for men before age 60 years with three affected brothers.[26]

Genetic and Molecular Influences

The proportion of PCa attributable to hereditary factors has been estimated in the range of 5% to 15%. The genes more consistently associated to hereditary PCa susceptibility include mismatch repair (MMR) genes 0.7% to 1.74% (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) and homologous recombination genes *BRCA1* (0.9%-1.25%), BRCA 2 (1.2%-5.3%), *ATM* (1.6%-2.7%), *PALB2* (0.4%-0.5%), and *CHEK2* (1.8%-2.8%). Additional genes are also recommended to be integrated into specific research, including *HOXB13* (0.6%-6.5%), *BRIP1* (0.1%-0.2%), and *NBS1* (0.1%-0.2%).[27] The previous PCa susceptibility genes are summarized in Table 72.3.[27,28]

TABLE 72.3 PARTIAL LIST OF PROSTATE CANCER SUSCEPTIBILITY GENES[26]

Gene	Location	Molecular Mechanism	Prostate Cancer Risk Increase
MLH1	3p22.2	DNA mismatch repair	2.0-3.7 fold RR
MSH2	2p21-p16.3	DNA mismatch repair	2.0-3.7 fold RR
MSH6	2p16.3	DNA mismatch repair	2.0-3.7 fold RR
PMS2	7p22.1	DNA mismatch repair	2.0-3.7 fold RR
BRCA1	17q21.31	DNA damage repair	1.8-3.8 fold RR
BRCA2	13q13.1	DNA damage repair	2.5-4.6 fold RR. In < 55 y old, 8-23 fold RR
ATM	11q22.3	DNA damage response	6.3-fold RR
PALB2	16p12.2	DNA damage repair, essential component of the BRCA complex formation	8.05 odds ratio for developing high-risk prostate cancer
CHEK2	22q12.1	DNA repair through phosphorylation of BRCA2	1.9-3.3 fold overall risk. In Sweden, CHEK2 was the

Gene	Location	Molecular Mechanism	Prostate Cancer Risk Increase
			most frequently mutated DNA repair gene (3.8%).
HOXB13	17q21.32	Androgen receptor repressor	3.4-8.6 fold RR
BRIP1	17q23.2	DNA damage repair, binds directly to the BRCA1 C-terminal repeats	2.4 odds ratio
NBN	8q21.3	Nibrin carries the MRE11A and RAD50 proteins into the cell's nucleus and guides them to sites of DNA damage.	4.6 odds ratio

RR, relative risk.

HOXB13 is a homeobox transcription factor localized on chromosome 17. HOXB13 remains the most widely replicated and specific PCa susceptibility gene. BRIP1 is localized on chromosome 17 and encodes a DNA helicase that binds directly to the BRCT repeats of BRCA1 and that is involved in double-strand break (DSB) repair. Another gene of interest is *NBN*, located on chromosome 8 and encodes another protein involved in DSB repair since it is responsible for the localization of the complex and for the interactions with other proteins belonging to repair signaling complexes.[27]

Research delving into the molecular physiology of the prostate gland has also uncovered specific DNA sequences that may be related to the occurrence and progression of PCa. It is well known that PCa cells, like their normal counterparts, are usually sensitive to androgens, and their growth depends on androgen-stimulated cell division. Two main polymorphisms include CAG and GGN repeats in the AR gene. Moreover, CAG is associated with the transcriptional activity of the AR in response to ligand binding. A meta-analysis of AR gene polymorphisms and the risk of PCa showed that short CAG repeats (,22 repeats) carriers presented an elevated risk of PCa than long CAG repeats (≥22) carriers (odds ratio [OR] = 1.31). Short GGN repeats (≤16) carriers presented an increased risk of PCa than long GGN repeats (.16) carriers (OR = 1.38). In subgroup analyses, the abovementioned

significant association was predominantly observed in Caucasian populations.[29]

In addition to these genetic alterations identified in PCa, epigenetic changes such as abnormal DNA methylation have also been observed. They may play a role in upregulation or loss of expression of genes. Peripheral blood DNA methylation was measured for 133 of the 469 members of 25 multiple-case PCa families. After correcting for multiple testing, 41 heritable methylation marks were associated with PCa risk. Separate analyses, based on 869 incident cases and 869 controls from a prospective cohort study, showed that nine of these marks near the metastable epiallele VTRNA2-1 were also nominally associated with aggressive PCa risk in the population.[30]

Other Risk Factors

A cigarette smoking and PCa systematic review and meta-analysis of 17 prospective cohort studies included a total of 2,537,664 participants and 47,536 incident cases. Fifteen studies showed that cigarette smoking has an inverse association with PCa incidence, with an RR of 0.84. However, the five studies that examined the association between current smokers and the risk of death from PCa showed that current smokers had a 42% higher risk of death from PCa when compared to nonsmokers with an RR of 1.42.[31]

A cohort of all Vietnam-era veterans registered within the Northern California VA Health System was stratified as either exposed (56,214) or unexposed (56,930) to Agent Orange. Agent Orange–exposed men were diagnosed at a younger age (59.7 years) compared with unexposed men (62.2 years), had a 2-fold increase in the proportion of GSs 8 through 10 (21.8%) compared with unexposed men (10.5%), and were more likely to have metastatic disease at presentation than men who were not exposed (13.4%) than unexposed men (4%).[32]

Chlordecone, an organochlorine insecticide with well-defined estrogenic properties, was extensively used from 1973 to 1993 in the French West Indies to control the banana root borer. A study with 623 men with PCa and 671 controls found a significant increase in the risk of PCa with increasing plasma chlordecone concentration (OR = 1.77) and cumulative exposure index (OR = 1.73).[33]

The American Cancer Society's Cancer Prevention Study II Nutrition Cohort examined the association between nonsteroidal anti-inflammatory

drug (NSAID) and aspirin use and PCa incidence among 70,144 men. Long-duration regular use (≥30 pills per month for ≥5 years) of NSAIDs was associated with reduced risk of PCa (RR = 0.82). Long-duration regular use of aspirin was also associated with a reduced risk of PCa (RR = 0.85).[34]

NATURAL HISTORY

Local Growth Patterns

The studies of prostate morphology conducted by McNeal[35] showed that almost all prostatic carcinomas (.70%) develop in the PZ of the prostate, whereas benign prostatic hyperplasia (.90%) arises from the TZ. In addition, examination of prostatectomy specimens revealed that small tumors tend to occur in the anteromedial gland, adjacent to the fibromuscular stroma, whereas larger, more advanced T-stage tumors are often located in the posterior gland near the prostatic capsule.[36,37]

Multifocality is characteristic of PCa. On digital rectal examination (DRE), the disease may be nonpalpable or there may be one or many nodules, located unilaterally or bilaterally. Histologic and molecular studies of prostatectomy specimens of patients with PCa have revealed that most contain a dominant or index tumor and one or more spatially separate, often heterogeneous, tumors.[38-41] Jewett[42] reported that multiple foci of disease were found throughout the prostate in 77% of prostatectomy specimens. Wise et al[43] noted that only 17% of 486 patients treated by radical retropubic prostatectomy had one carcinoma detected by 3-mm step-section histologic examination. Of the 83% with multifocal disease, secondary cancers were mostly small; 58% were less than 0.5 cm^3 in volume. Qian et al,[44] using fluorescence in situ hybridization to detect chromosomal abnormalities, found that an increasing incidence of chromosomal anomalies among specimens was positively correlated with progression from high-grade prostatic intraepithelial neoplasia to prostatic carcinoma. When lymph node (LN) involvement was present, there was usually evidence of one or more foci of the primary tumor sharing chromosomal anomalies with associated LN metastases, suggesting that just a single focus of carcinoma may give rise to metastases. This heterogeneity and multicentricity may account for the discrepancy between needle biopsy GS and the grade determined from the dominant tumor in the prostatectomy specimen.

Tumors arising from the TZ tend to demonstrate a lower frequency of extracapsular extension (ECE) and may harbor large volumes of disease with relatively high PSA levels but remain confined to the prostate. Despite a high PSA value (≥10 ng/mL), these tumors should be considered to have a favorable prognosis and be managed accordingly. Noguchi et al[45] described the histologic characteristics of 148 cases of TZ PCa from RP specimens. Seventy percent were clinical stage T1c, with a preoperative serum PSA of 10 ng/mL or greater in almost two-thirds of cases. Only 63% had a positive initial prostatic biopsy. On pathologic review, 80% had organ-confined disease, and more than one-third of cases had a cancer volume greater than 6 mL. When compared with 79 PZ cancers matched by volume, there were no differences in percentage Gleason grade 4/5, serum PSA, or prostate weight, although differences in clinical stage T1c to T2c and organ-confined cancer were highly significant. The actuarial 5-year PSA relapse-free survival (RFS) rate was 71.5% among men with TZ cancer, compared with 49.2% for those with PZ cancer.

PZ cancers tend to spread along the capsular surface of the gland and may extend through the capsule of the gland, invade SVs and periprostatic tissues, and involve the bladder neck or the rectum. Clinical stage closely correlated with risk of ECE and disease progression.[46-48] The incidence of microscopic tumor extension beyond the capsule of the gland (at the time of RP) in patients with clinically organ-confined disease ranges from 8% to 57%.[48,49] Catalona et al,[50] in an analysis of patients with stage T1c disease treated with RP, noted that 53% had pathologically organ-confined tumors, 35% had ECE, and 9% had SV invasion. Of the last group, 66% had positive surgical margins, an incidence comparable with that for clinical stage T2 tumors. In a similar group of patients with T1c tumors, Epstein et al[51] found that 34% had established ECE, 6% had SV invasion, and 17% had positive surgical margins.

Pretreatment serum PSA is also predictive of extraprostatic extension and SV invasion. The rate of organ-confined PCa ranges from 53% to 67% for men with a PSA level between 4 and 10 ng/mL and from 31% to 56% for men with a PSA level between 10 and 20 ng/mL.[52-54] D'Amico et al,[55] in a pathologic evaluation of 347 RP specimens, reported that none of 38 patients with PSA of 4 ng/mL or less had SV involvement, in contrast to 6% of 144 patients with PSA of 4 to 10 ng/mL, 11% of 101 with PSA of 10 to 20

ng/mL, 36% of 45 with PSA of 20 to 40 ng/mL, and 42% of 19 with PSA of greater than 40 ng/mL. The incidence of positive surgical margins for these PSA subgroups was 11%, 20%, 33%, 56%, and 63%, respectively. The incidence of SV involvement also is associated with the level of PSA, the GS, and the clinical stage.[56,57] SV involvement has been observed in from 10% of patients with A2 tumors to 30% of the patients with B2 lesions.[58,59]

Roach[60] proposed formulas based on analysis of RP specimens to estimate the probability of ECE+ and SV+ involvement here provided in Table 72.4.

TABLE 72.4 ROACH FORMULAE CALCULATING THE LIKELIHOOD OF PATHOLOGIC STAGE BASED ON CLINICAL FACTORS

Predicted Stage	Formula
Extraprostatic extension	(PSA × 3/2) + ([Gleason score − 3] × 10)
Seminal vesicle involvement	PSA + ([Gleason score − 6] × 10)
Lymph node involvement	(PSA × 2/3) + ([Gleason score − 6] × 10)

PSA, prostate-specific antigen.

Regional Lymph Node Involvement

Tumor size and degree of differentiation affect the tendency of prostatic carcinoma to metastasize to regional lymphatics. With an increasing number of patients being diagnosed in earlier stages (as a result of screening PSA), there has been a decreased incidence of LN metastases in patients with clinical stage T1c and T2 tumors.[61] In the patients with low-risk PCa, the risk of LN involvement is generally considered less than 10%.

Several groups[52,62-67] have developed models based on clinical or pathologic data that predict the risk of LN metastases. This information is important to decide whether a patient with PCa should be subjected to a staging lymphadenectomy (including laparoscopic technique) or considered for irradiation of the pelvic LNs. Partin et al[68] analyzed data from 703 patients and generated a nomogram for predicting nodal metastases based on three factors: clinical stage, preoperative PSA, and tumor biopsy grade. This model was validated in a larger multicenter study of 7,014 men and

accurately predicted nodal metastases in 78% of patients.[69] The negative predictive value (NPV) was 99%. Bluestein et al[64] tested a model based on multivariate logistic regression analysis on 1,632 patients who underwent pelvic lymphadenectomy at the Mayo Clinic for staging of PCa. Using this method, they determined that 29% of the patients with clinical stage T1a to T2c disease would have been spared pelvic lymphadenectomy, with only a 3% rate of missed nodal metastases. Bishoff et al[63] reported similar results demonstrating that 20% to 63% of patients with PCa could be spared pelvic lymphadenectomy when accepting a 2% to 10% risk for missed nodal metastasis. Machine-learning algorithms can outperform traditional tools in the ability to predict LN metastases.[70] These results suggest that many patients can be spared pelvic lymphadenectomy solely by analyzing preoperative PSA, Gleason grade, and clinical stage, without incurring an unacceptable risk for failing to identify regional metastasis.[71]

Stock et al,[57] in a study of 99 patients who underwent laparoscopic LN dissection, correlated incidence of positive nodes with PSA, GS, stage, and involvement of SVs. None of the patients with a GS of 4 or lower, even those with PSA of greater than 20 ng/mL, had positive pelvic LNs, and 8% in the group with GSs of 5 or 6 and PSA levels of 4 to 10 ng/mL had positive nodes. However, the incidence of positive LNs increased significantly (to 24%) in patients with PSA greater than 20 ng/mL. These results are similar to those reported in patients treated with RP.[64,68]

In an analysis of 2,144 patients treated at two institutions, Rees et al[72] noted that only 30 (2.2%) of 1,390 patients with a negative DRE and either PSA of 5 ng/mL or less, GS of 5 or less, or a combination of PSA of less than 25 ng/mL and GS of 7 or less had pelvic LN metastases.

It has been suggested that the Roach formula cutoff of 15% does not identify up to one-third of patients with LN involvement. A study of 3,115 patients treated by RP and extended pelvic lymph node dissection (PLND) validated the Roach formula and found that Roach accuracy was 80%. With a cutoff of 33% of the patients with nodal involvement would not have been recommended for nodal irradiation. Using the 15% benchmark, 33% of patients with nodal involvement would not have been recommended for nodal irradiation.[73]

Prognosis is closely related to the presence of regional LN metastases; patients with positive pelvic LNs have a significantly greater probability

(.85% at 10 years) for the development of distant metastasis (DM) than those with negative nodes (,20%).[74] However, a single nodal metastasis is not an unfavorable prognostic sign. In a study by Cheng et al,[75] 322 patients with positive LNs after RP and bilateral pelvic lymphadenectomy were followed up for a median of 6 years. Patients with prostate carcinoma who had multiple regional LN metastases had an increased risk of death from disease, whereas patients with a single positive LN appeared to have a more favorable prognosis after RP and immediate adjuvant hormonal therapy. Prout et al,[76] in 92 patients with various stages of prostatic carcinoma, noted solitary LN metastasis in 11 (34%) of 32 patients with positive nodes. Bilateral pelvic LN involvement was present in 14 (58%) of 24 patients who had more than one metastatic LN. Only 2 (18%) of 11 patients with a single metastasis showed tumor progression, compared with 15 (76%) of 21 with multiple LN involvement. Golimbu et al[77] reported a 10-year survival rate of 50% in patients with a single positive LN, compared with 20% for those with multiple LN involvement.

The prognostic significance of multiple involved LNs should be considered with the extent of lymphadenectomy. Several studies have evaluated the anatomic extent of PLND on outcome.[78,79] At Johns Hopkins University Hospital, two surgeons performed 4,000 RP with or without an extended LN dissection. The extended dissection removed more LNs (mean 12 vs 9; $P < .0001$) and detected more LN-positive PCa (3.2% vs 1.1%; $P < .0001$) than more limited procedure. If disease was found involving less than 15% of the extracted LNs, extended LN dissection resulted in a more favorable 5-year PSA progression-free survival (PFS). Thus, in certain subgroups, an extended dissection may be beneficial. In another study, the number and percentage of involved LNs correlated with recurrence-free and overall survival (OS).[79] These results need additional validation in prospectively controlled studies.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

Screening Methods and Markers

Although DRE is still an essential element in screening and assigning clinical stage, only 25% to 50% of men with an abnormal DRE have PCa on biopsy. Moreover, because carcinoma of the prostate can be asymptomatic until

attaining a significant size, if a patient presents with a palpable tumor, there is a significant risk that there already may be locally advanced or metastatic disease. With the advent of PSA screening, the diagnosis of PCa may precede palpable disease on DRE and the symptoms of urinary obstruction or metastatic disease by many years. DRE is associated with 70% sensitivity and 50% specificity.[80] In fact, 70% of cancers detected by PSA screening are confined to the prostate, and 40% of cancers detected by PSA are not palpable.[50]

The first widely available clinical biomarker was prostatic acid phosphatase (PAP), used to diagnose and monitor treatment response for PCa in the 1940s and 1950s. However, PAP has a sensitivity of approximately 10% and a specificity of about 90% for malignant tumors[80] and, to a large extent, has been superseded by PSA testing. Stamey et al[81] reported PSA and PAP measurements by radioimmunoassay in 2,200 serum samples from 699 patients, 378 of whom were known to have prostatic carcinoma. PSA was elevated in 122 of 127 patients with newly diagnosed prostatic carcinoma, whereas PAP was elevated in only 57 patients with cancer and correlated less closely with tumor volume than did PSA.

Initially identified and purified from prostatic tissue by Wang et al[82] in 1979, PSA is a protein with a molecular weight of 33,000. It is localized in the cytoplasm of ductal epithelial cells and in secretory materials in ductal lamina.[83] PSA is detected not only in prostatic tissue (normal tissue, benign hyperplasia, and malignant tumors) and seminal fluid but also in the sera of patients with prostatic cancer. PSA has been detected with immunohistochemical techniques in pancreas and salivary glands and in women; therefore, it is not absolutely specific for prostatic epithelium.[84] After RP for cancer, PSA routinely declines to undetectable levels, with an associated half-life of 2.2 days.

The incidence of PCa rose dramatically with the onset of PSA screening in the early 1990s.[85] However, concern of possible overscreening and two landmark screening trials led to the USPSTF recommending in 2008 against PSA screening in men aged 75 years or above and concluding that current evidence was inadequate to make a PSA screening recommendation for men younger than the age of 75 years.[86] These decisions were partly based on two large screening trials. The European Randomized Study of Screening for Prostate Cancer (ERSPC) randomized 162,387 men aged 50 to 74 years to

PSA screening an average of once every 4 years or to no such screening.[87] At a median follow-up of 9 years, PSA screening showed a modest reduction in death from PCa that would require screening of 1,410 men and treatment of 48 men to prevent one death from PCa. The reduction in death from PCa was apparent only in men aged 55 to 69 years. The contemporaneous US-based Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer screening trial randomized 76,693 men aged 55 to 74 years to annual PSA testing for 6 years and annual DRE for 4 years versus no such screening.[88] At a median follow-up of 7 years, no difference in mortality was noted between the arms.

As a result of the USPSTF 2008 recommendation, PCa incidence decreased from 534.9 men per 100,000 in 2005 to 416.2 men per 100,000 in 2012.[89] The incidence of metastatic PCa began to rise by 0.58% per year after 2008, for the first time since 2004, and continued to increase to a rate of 2.74% per year in 2012.[90] In 2017, the USPSTF updated their recommendation to support PSA screening in men aged 55 to 69 years (grade C) but continues to recommend against PSA screening in men aged 70 years or higher.[5] This partial reversal in approach toward PSA screening was in part due to longer follow-up of the ERSPC trial, which at 13 years of follow-up found significantly reduced PCa mortality in the screening cohort, with one cancer death averted for every 781 men screened.[91]

Several investigators[92-94] reported no significant impact of DRE on the plasma levels of PSA in patients with various prostatic abnormalities in whom blood samples were collected before, immediately after, and 30 minutes after rectal examination of the prostate. Others[95-97] detected a significant increase in PSA after DRE. Ornstein et al[97] noted an increase in both total and free PSA in 31% and 48% of men, respectively, at 1 hour after DRE. Matzkin et al[98] found no significant change in PSA levels after inserting a urethral catheter and maintaining it for several days. Yet, significant PSA elevation has been demonstrated after prostatic massage, transrectal ultrasonography (TRUS), prostate biopsy, and transurethral resection of prostate (TURP).[94,95,99,100] The kinetics of serum PSA elevation after DRE and needle biopsy were investigated in a Dutch study with few participants.[101] Blood samples were taken at 1 and 30 minutes and 1, 3, 6, and 12 hours and then every 24 hours until 5 days had elapsed. The peak levels were between 30 and 60 minutes after DRE and returned to baseline 24 to 72 hours after the examination. There was a 3-fold increase in PSA after needle

biopsy, and only two of seven patients had returned to their baseline PSA at 5 days. Studies reporting the effect of ejaculation on PSA also have contradictory results. Some authors found no effect at all,[102,103] whereas others demonstrated that ejaculation increased PSA levels in 87% of 64 men evaluated with serial determinations (at 1, 6, 24, and 48 hours).[104] A return to baseline was observed in 92% of subjects by 24 hours and in 97% by 48 hours.

Nadler et al[105] quantified the causes of elevated PSA in 148 men with PSA of greater than 4 ng/mL (a finding suspect for cancer) and multiple negative biopsies. They were compared with 64 men who had a suspect DRE, multiple negative biopsies, and PSA of 4 ng/mL or less. Acute or chronic inflammation of the prostate was more prevalent in the high PSA group (63% vs 27%; $P = .0001$). Patients with elevated PSA had significantly larger prostate volumes (median, 68 cm^3) than those without PSA elevation (median, 32.5 cm^3). Simultaneous regression analysis demonstrated that prostatic size accounted for 23%, inflammation for 7%, prostatic calculi for 3%, and nonisoechoic ultrasonographic lesions for 1% of the PSA serum variances.

The positive predictive value for PSA of greater than 4 ng/mL ranges from 31% to 54%. A greater yield is observed when elevated PSA is coupled with positive ultrasonographic and rectal examinations[106] (Tables 72.5 and 72.6). The estimated rate of cancer detection by PSA screening ranges from 1.8% to 3.3%. The percentage of clinically localized tumors detected by PSA ranges from 81% to 97%. The percentage of pathologically localized tumors ranges from 36% to 91% and is significantly higher when serial PSA screening is done.

TABLE 72.5 LIKELIHOOD OF DETECTING PROSTATE CANCER ON TRANSRECTAL BIOPSY FOR 2,054 MEN AGED 40 TO 80 YEARS AS A FUNCTION OF SERUM PSA LEVEL, INDEPENDENT OF DRE RESULT

	Likelihood at Given Age[a]			
PSA (ng/mL)	<50 Y	51-60 Y	61-70 Y	>71 Y
<2.5	10	14	17	23

An important issue is the clinical significance of small tumors detected by PSA testing. Epstein et al[51,107] identified a subset of patients with potentially biologically insignificant tumors among men with clinical stage T1c disease who underwent RP. On multivariate analysis, the best model predicting

insignificant tumor was a PSA density of less than 0.1 ng/mL/g and no adverse pathologic findings on needle biopsy, or a PSA density of 0.1 to 0.15 ng/mL/g, with a low- to intermediate-grade cancer less than 3 mm found in only one needle biopsy core specimen. The positive predictive value of the model was 95%, with a NPV of 66%.[51] Dugan et al[108] offered a definition of clinically insignificant cancer as a tumor that gives rise to no more than 20 cm^3 of cancerous tissue in the prostate by the time of expected death and a GS of less than 4 in 40-year-old patients, 5 in 50- to 59-year-old patients, 6 in 60- to 69-year-old patients, and 7 in 70- to 79-year-old patients. Using these definitions, a review of 337 prostatectomy specimens showed that, for cancer volume doubling times of 2, 3, 4, and 6 years, clinically insignificant cancer was identified in 1 (0.3%), 13 (3.9%), 25 (7.4%), and 49 (14.5%) of specimens, respectively. Humphrey et al[109] determined that in 11% to 30% of PSA-detected PCas, the tumor volumes were less than 0.5 mL. Therefore, by these definitions, most men treated with RP or RT have clinically significant cancer.

The incidence of clinically unimportant cancers has been reported to be between 4% and 16%.[51,61,110,111] Researchers at the Fred Hutchinson Cancer Research Center developed a computer model to estimate the rates of PCa overdiagnosis because of PSA testing. Using the National Cancer Institute's (NCI) Surveillance, Epidemiology, and End Results (SEER) registry data as a comparison for their computer-generated incidence rates, they calculated overdiagnosis rates of 15% in Whites and 37% in Blacks. These men were predicted to have PCa that would be detected only at autopsy.[112] Conversely, an epidemiologic study randomizing men from Göteborg, Sweden, to PSA screening or a control group demonstrated that screening did not lead to overdiagnosis of PCa; rather, most cancers detected at PSA-guided screening would eventually develop into clinical, frequently fatal, disease.[113]

Although PSA screening–detected cancers may be smaller, they may harbor aggressive disease. Investigators from the Netherlands studied 121 RP specimens from screened patients and found that screening-detected specimens were more likely to be pathologically organ-confined tumors and to have GSs of less than 8.[114] However, 60% of screening-detected tumors contained areas with high-grade cancer (Gleason pattern 4 or 5) and 50% had a GS of 7, suggesting that most of these tumors are clinically important. Updated results from a study of expectant management of patients with

nonpalpable PCa believed to have small-volume disease showed a 6.5-year median survival free of intervention and a 33% intervention rate at a median of 2.2 years, with a median follow-up among the entire cohort of 2.7 years.[115] Increased PSA density and decreased percentage free PSA correlated with progression of disease. Ninety-two percent of patients had curable disease at the time of their diagnosis of progression. These investigators concluded that observation with close follow-up may be a reasonable alternative for older men with a high likelihood of harboring small-volume PCa.

Refinements of the PSA screening test have been introduced to increase the sensitivity and specificity of the test. It was anticipated that such approaches would be able to more readily find curable cancers in younger men and to avoid unnecessary biopsies of benign hypertrophic disease in older men. Unfortunately, none of these modifications listed in the following sections has proven reliable enough alone on which to base a treatment decision for the individual patient.

Prostate-Specific Antigen Density

PSA density relies on the fact that cancers produce less PSA per cell than nonmalignant prostatic tissues. It is calculated by dividing the serum PSA concentration by the volume of the prostate gland measured by TRUS. A higher PSA density is associated with malignancy.

Prostate-Specific Antigen Velocity

Another method is to obtain serial PSA measurements and calculate the rate of rise in PSA, or PSA velocity. A rate of rise of greater than 0.75 ng/mL/year has been associated with a higher frequency of cancer. Two large retrospective analyses suggested that an increase greater than 2.0 ng/mL in PSA in the year prior to diagnosis is correlated with greater PCa-specific mortality following RT[116] and RP[117] for localized PCa, respectively.

Free Prostate-Specific Antigen

Serum tests for the molecular forms of PSA (free vs complexed vs total) have been developed to discriminate between elevated PSA levels from benign prostatic hyperplasia versus cancer. This is based on the concept that PSA exists in serum in a complex form bound to either α_1-antichymotrypsin or α_2-

macroglobulin, two extracellular protease inhibitors. Bound to α_1-antichymotrypsin or α_2-macroglobulin, the enzyme is inactive but still detectable using conventional immunoassays. In a study of free PSA, complexed PSA, and total PSA (free + complexed), the complexed-to-total ratio was higher and free PSA lower in patients with PCa relative to those with benign prostatic hyperplasia.[118] Catalona et al[119] reported on 113 patients with PSA levels between 4.1 and 10 ng/mL (63 with histologically confirmed benign prostatic hyperplasia, 30 with PCa and enlarged gland, and 20 with cancer and a normal-sized gland). The median percentage of free PSA was 9.2% for men with cancer and a normal-sized gland, 15.9% for those with cancer and an enlarged gland, and 18.8% for those with benign prostatic hyperplasia ($P < .001$). Men with PCa and either a normal or an enlarged gland had a significantly lower percentage of free PSA than men with benign prostatic hyperplasia only. At Washington University, a ratio of free to total PSA of 0.2 or less was most likely associated with PCa and with higher percentages with BPH. A ratio of 0.15 or less was associated with a higher GS and poorer prognosis.[120]

Oesterling et al[121] analyzed free, complexed, and total PSA in 422 healthy men aged 40 to 79 years. The respective recommended age-specific reference ranges (95th percentile) for the three forms were 0.5, 1, and 1 ng/mL for men aged 40 to 49 years; 0.7, 1.5, and 3 ng/mL for men aged 50 to 59 years; 1, 2, and 4 ng/mL for men aged 60 to 69 years; and 1.2, 3, and 5.5 ng/mL for men aged 70 to 79 years. Similar observations were made by investigators at Johns Hopkins.[122]

Reverse Transcriptase Polymerase Chain Reaction Assay

Molecular biologic methods, particularly reverse transcriptase polymerase chain reaction (RT-PCR), can be used to measure markers by detecting low levels of messenger RNA (mRNA) for PSA and prostate-specific membrane antigen (PSMA) expressed by circulating metastatic PCa cells. The assay is highly specific because the only cells expressing PSA in the peripheral blood are circulating PCa cells. However, there is a wide range of sensitivities of detection of PSA-expressing cells in the peripheral blood reported in the literature.[122]

Katz et al,[123] in 94 patients on whom RT-PCR assay for PSA mRNA was performed, reported an enhanced reaction in 26 (72%) of 36 patients who had extraprostatic tumors at the time of surgery. The test was negative in 51 (88%) of 58 patients with organ-confined disease. Six months after surgery, an increased PSA level was noted in 19% and 2% of the two groups, respectively. This bioassay may have significant staging value in patients who are candidates for RP. Cama et al[124] noted that, in contrast to the RT-PCR assay for PSA, the assay for PSMA did not correlate with pathologic stage of PCa.

Oefelein et al,[125] using RT-PCR for PSA, identified positive cells in 20 (91%) of 22 operative field samples, and 4 (25%) of 16 had evidence of intraoperative hematogenous dissemination ($P = .046$). Their results suggest that tumor cell spillage and, less frequently, hematogenous dissemination may be associated with operative manipulation of the prostate during RP and may potentially represent the mechanism of failure after this treatment.

Israeli et al,[126] using the PCR assay, also reported circulating prostatic tumor cells in 2 (6.7%) of 30 men. However, prostate-specific membrane primer assay demonstrated tumor cells in 19 (63%) of 30 patients. All 16 negative control subjects had negative PSA and PSMA PCR results. Using PSA mRNA as a marker for prostatic epithelial cells, Seiden et al[127] noted that 5 of 65 patients with clinically localized carcinoma of the prostate had PSA mRNA-detectable cells by transcription and PCR. On the other hand, 10 of 20 patients with hormone-refractory and progressive PCa also demonstrated the same increased frequency of PSA mRNA-detectable cells.

Overall, most studies report a 0% PSA rate by RT-PCR in negative control cases, whereas the positive rate in the metastatic group ranges between 31% and 88%.[125] However, 25% of men with localized PCa who underwent RP and had specimen-confined disease had a positive PCR PSA assay.[123] These men would be denied surgery if it was concluded that circulating PCa cells are synonymous with incurable disease. A new approach is to use a combination of primers to improve the overall staging accuracy of RT-PCR. Preliminary work from the Cleveland Clinic suggests that combining RT-PCR for PSA and PSMA may improve the staging accuracy.[128] Until the significance of a positive PCR assay is determined with long-term follow-up, RT-PCR remains experimental and should not change treatment recommendations.

Evaluation and Diagnosis

Patients with localized prostatic carcinoma are frequently asymptomatic; the diagnosis is often made with a screening PSA test. In the pre-PSA era, asymptomatic patients were diagnosed on the basis of palpating a firm prostate nodule on DRE. Patients with locally advanced tumors have presented with bladder outlet obstructive symptoms such as urinary hesitancy, decreased force of the urinary stream, and postvoid dribbling as the tumor impinges on the membranous urethra. Chronic obstruction and bladder distension can lead to decreased compliance of the detrusor muscle that is manifested by symptoms of urinary frequency, urgency, and nocturia. Very early-stage disease (T1a or T1b) may occasionally be diagnosed at TURP for symptoms of bladder outlet obstruction caused by benign prostatic hyperplasia. With local invasion into the urethra or ejaculatory ducts, patients may experience hematuria or hematospermia. As the disease penetrates the capsule of the prostate, there may be invasion into the neurovascular bundles that course along the lateral aspects of the prostate, leading to erectile dysfunction. Disseminated disease frequently manifests as bone pain from distant osseous metastases.

A complete clinical history and a general physical examination including DRE are mandatory. The DRE is best performed with a well-lubricated glove; the patient may be standing and bent over at the waist with their elbows resting comfortably on a firm surface or in the lateral decubitus position on the examining table. The examiner should note the size of the prostate gland, its overall consistency, the presence of any firm areas, and, currently, rarely, extraprostatic tumor extension. A typical neoplastic nodule of prostatic carcinoma is extremely firm, often not elevated above the surface of the gland, but surrounded by compressible prostatic tissue. The examiner should determine whether the lateral sulci are involved by tumor and also the degree of spread superiorly. In most patients, the SVs cannot be palpated as discrete structures, and the finding of a firm area extending above the prostate suggests that the SVs are involved by malignancy. Only approximately 50% of prostatic nodules found on DRE are confirmed to be malignant on biopsy.[42]

An abnormal DRE result, a consistently elevated PSA, or a combination of the two warrants a biopsy to establish a pathologic diagnosis. A TRUS-guided needle biopsy is the most common method for obtaining

representative samples of the prostatic tissue. Ten to 18 cores are taken, including cores from the base, mid, and apex bilaterally and additional cores from the midline and lateral PZ. If clinically indicated by obstructive symptoms, a separate biopsy of the TZ is taken. The pathology report frequently includes the length of each core and the length of each core that contains tumor.

Once the tissue diagnosis of PCa is ascertained, the patient should undergo a staging workup including laboratory data such as a baseline PSA, complete blood count, and testosterone level. The standard tests required in the evaluation of patients with prostatic carcinoma (Table 72.7) have significantly changed with the advent of molecular imaging.

TABLE 72.7 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE PROSTATE

Clinical
Perform physical examination.
Perform digital rectal examination (DRE) to confirm clinical stage.
Estimate life expectancy.
Inquire about known high-risk germline mutations.
Obtain family history.
Assess quality-of-life measures.
Laboratory
Perform and/or collect prostate-specific antigen (PSA) and calculate PSA density.
Total serum testosterone if ADT indicated
Pathology
Obtain and review diagnostic prostate biopsies (transrectal, transperineal, and/or MRI guided).
Radiographic imaging
Multiparametric magnetic resonance imaging of the abdomen and pelvis
Transrectal ultrasonography (for biopsy guidance)
PSMA PET (for intermediate and high risk)

ADT, androgen deprivation therapy; PET, positron emission tomography; PSMA, prostate-specific membrane antigen.

Imaging Studies

Some diagnostic imaging studies have become an essential aspect of pretreatment evaluation and treatment selection. New techniques have allowed for more precise assessments of tumor location, volume, and extent, as well as biologic activity. As a result, clinical staging can be used more accurately as a prognostic factor for defining treatment options.

Transrectal Ultrasonography

The normal adult prostate imaged by TRUS appears as a symmetric, triangular, relatively homogeneous structure with an echogenic capsule. TRUS is used routinely for guidance during the transrectal biopsy and during prostate brachytherapy (BT). However, only PCas located in the PZ can be reliably detected by ultrasonography. Attempts to characterize adenocarcinoma by pattern on TRUS have indicated that PCas can have variable echogenicities. Rifkin et al,[129] in 443 men undergoing TRUS of the prostate, found 130 pathologically proven cancers and 313 cases of benign prostatic disease. Cancers were hyperechoic in 69% of the cases and had poorly defined margins, whereas benign lesions were hyperechoic in only 46% of the cases.

Chodak et al,[130] in a prospective, randomized study of TRUS in 216 men, reported a sensitivity of 86% but a specificity of only 41%; tumors less than 1 cm were the most difficult to detect. For staging purposes, Rifkin et al[129] found a sensitivity of only 60% using TRUS to distinguish between T2 and T3 lesions.

Positron Emission Tomography

Molecular imaging has transformed PCa staging. Staging at diagnosis has relied on PSMA, a transmembrane protein that is overexpressed in PCa, particularly high-grade PCa.[131,132] In one study of PSMA positron emission imaging (PET) in high-risk PCa, PSMA PET detected nodal disease in 32% of men.[133] Most nodal metastases were pelvic versus extrapelvic (64% vs 36%).

Multiple diagnostic tracers targeting PSMA have been U.S. Food and Drug Administration (FDA) approved. The first was Ga-68-PSMA-11, based on the proPSMA trial performed in Australia. This study compared Ga-68-PSMA-11 to conventional bone scan and CT and found that Ga-68-PSMA-11 had greater accuracy (92% vs 65%), sensitivity (85% vs 38%), and specificity (98% vs 91%).[134]

F-18-DCFPyl is also FDA approved, based on the OSPREY[135] and CONDOR[136] studies. These studies evaluated F-18-DCFPyl in newly diagnosed and biochemically recurrent PCa, respectively. In newly diagnosed high-risk PCa, the OSPREY found a sensitivity of 38% for any positive LN, which increased to 60% for diagnosing nodes larger than 5 mm.

F-18-rhPSMA-7.3 is a third FDA-approved molecular tracer that was engineered to have strong diagnostic characteristics with a specificity of 94% to 97% and somewhat delayed renal excretion, which may improve the detection of recurrence within the prostate bed.[137] PET imaging is essential for higher risk disease but is not indicated in low-risk disease.

Computed Tomography

The primary role of CT in PCa is for size determination of the prostate gland, RT treatment planning, and assessment of pelvic nodal metastases. CT lacks the soft tissue resolution needed to detect intraprostatic disease, capsular extension, or SV involvement. Moreover, for most patients with newly diagnosed PCa, the incidence of positive LNs is less than 5%; thus, there is little role for CT as a routine staging procedure.[138] CT identification of pelvic adenopathy depends on LN enlargement, and the correlation between nodal size and metastatic involvement is poor.[138-140]

Albertsen et al[141] performed a population-based analysis to determine the positive yield of imaging studies performed on men with newly diagnosed PCa. The positive yield of a CT scan was less than 12% for men with PSA of 4 to 20 ng/mL. More than 10% of men with PSA of greater than 20 ng/mL and GS of 6 or greater were likely to have CT scans positive for extracapsular or metastatic disease. For combinations of high GS and PSA of greater than 50 ng/mL, the positive yield on CT scan was as high as 62%. Flanigan et al[138] retrospectively studied 173 men who underwent preoperative CT scanning and found that none of the patients with a PSA of less than 25 ng/mL had an abnormality by CT scan. Of 33 patients with PSA levels of greater than 25 ng/mL, 9 had nodal metastases, but only 3 (9%) of these 33 patients were correctly diagnosed by CT scanning. These authors concluded that routine preoperative CT scanning could not be justified in patients with a PSA of less than 25 ng/mL. Although the histologic incidence of positive pelvic LNs is substantial when PSA levels exceed 25 ng/mL, the sensitivity of CT for detecting positive nodes is only approximately 30% to 35% even at these levels.[142]

Bone Scan

A close correlation exists between pretreatment PSA level and incidence of abnormal bone scan results.[143,144] Given the low risk of osseous metastasis in

patients with early-stage PCa, the yield of a bone scan is low unless the PSA is greater than 20 ng/mL or the patient complains of bone pain. In a retrospective analysis of 589 patients with untreated carcinoma of the prostate and PSA levels of 20 ng/mL or less, Rees et al[142] reported that only 3 (1%) of 274 patients evaluated by bone scan and 3 (1%) of 262 patients evaluated by CT scan had evidence of metastatic disease. Only 1 of 108 patients with a PSA of 10 ng/mL or less had metastatic disease, and no patient with a GS of 5 or less had an abnormal bone scan or CT scan result or positive LNs.

Huncharek and Muscat,[145] in an analysis of 265 patients with localized carcinoma of the prostate, noted that no patients with PSA of less than 4 ng/mL had a positive bone scan. In patients with PSA of 4.1 to 10 ng/mL and PSA of 10.1 to 20 ng/mL, 2.2% and 3.6%, respectively, had positive bone scans. In patients with PSA of greater than 20 ng/mL, 6.7% had a positive bone scan. The guidelines established by the American College of Radiology appropriateness criteria for pretreatment staging of clinically localized PCa recommend that a radionuclide bone scan be considered only for patients with PSA of 20 ng/mL or more, T3-T4 disease, or GS of 8 or higher or for patients with skeletal symptoms.[146]

From a clinical standpoint, a baseline bone scan may be helpful before treatment with RT, especially in older patients or those with a history of arthritis, to document degenerative changes that may later be interpreted as metastatic osseous disease. Bone scintigraphy in routine follow-up has no value because PSA is more sensitive in detecting recurrence, and treatment of asymptomatic bone metastases (except in cases of impending pathologic fracture) cannot be justified. Periodic PSA assessment is adequate for follow-up of these patients, and bone scan should be limited to patients with rising PSA levels when clinically warranted.[147]

Magnetic Resonance Imaging

MRI can be very useful in delineating intraprostatic tumor and local extension beyond the capsule. Kagawa et al,[148] using CT-MRI fusion software for planning three-dimensional conformal radiation therapy (3DCRT), demonstrated that MRI was clearly superior to CT in defining the prostate apex, neurovascular bundles, and anterior rectal wall. The

discrepancy in prostate location between the two imaging studies was also greatest at the apex and base of the gland.

There have been significant improvements in MR technique and performance for imaging the prostate, such as the use of multiparametric MRI (MP-MRI) that improves spatial resolution, analytic image correction software to eliminate artifacts, fast spin-echo imaging to reduce image acquisition time and provide higher signal-to-noise ratio, and magnetic resonance spectroscopy imaging (MRSI) to detect metabolic activity in the prostate.[149] Moreover, increasing reader experience has greatly improved the accuracy of MRI staging for PCa. Strict MRI criteria for the diagnosis of ECE have been elucidated. Nevertheless, there is still interobserver variability, depending on the experience of the radiologist. One study demonstrated that the specificity for diagnosis of ECE was 93% for senior readers and 94% for junior readers, whereas sensitivity was 50% for senior readers and only 14% for junior readers.[150]

The appearance of the prostate and the information that can be gleaned for staging purposes depend on the MR technique used. On axial T1-weighted images, the prostate gland appears homogeneous and the zonal anatomy is not well appreciated.[151] However, there is a larger field of view, allowing for the detection of locoregional adenopathy and suspected bony lesions (Figure 72.3A). Postbiopsy hemorrhage is evident on T1-weighted images as high T1 signal intensity (Figure 72.3B), which may be in the prostate, SVs, or both. This is an important observation because hemorrhage may mimic tumor on T2-weighted images and because hemorrhage greatly limits the accuracy in the assessment of ECE.[152]

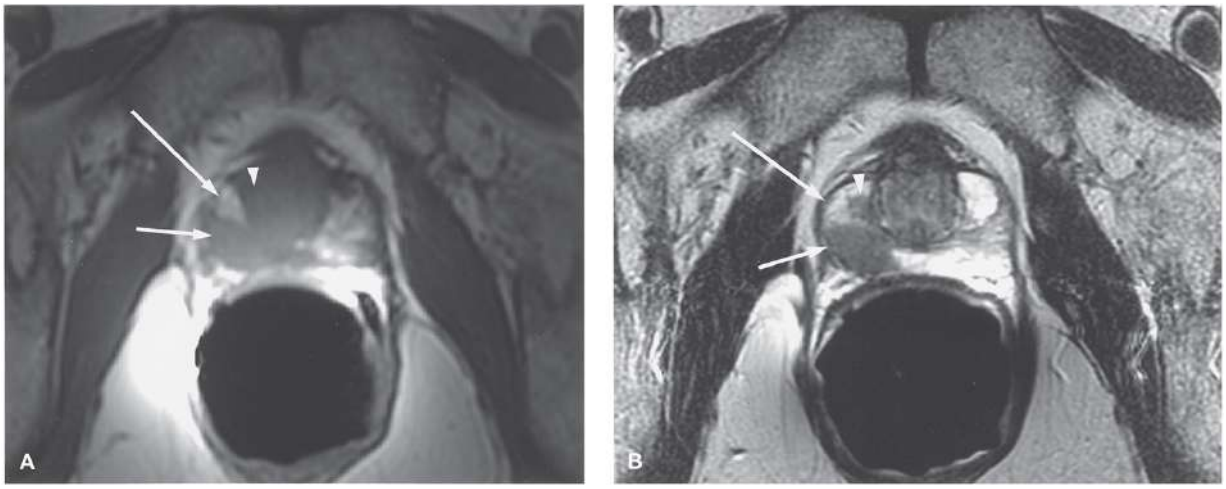

FIGURE 72.3 A. Normal T1-weighted axial magnetic resonance image. Age-related benign prostatic hyperplasia in the transition zone is evident (long arrow). The neurovascular bundles lie adjacent to the peripheral zone (short arrow). B. The T2-weighted axial image of the same level of the gland demonstrates areas of low signal intensity adjacent to the postbiopsy hemorrhage that are suspect for tumor (short arrow and arrowhead). This is an example of the hemorrhagic exclusion sign. (Courtesy of Steven Eberhardt, MD.)

The zonal anatomy of the prostate is clearly depicted on axial and coronal T2-weighted images. The vas deferens and SVs are also discernible on T2-weighted axial and coronal images, whereas the neurovascular bundles can be seen best on axial images[151] (Figure 72.4). The penile bulb is better imaged on T2-weighted coronal sections and is seen much more accurately than with CT. The PZ is normally of high signal intensity, whereas tumor appears as low signal intensity. There are many other causes of low T2 signal intensity, including hemorrhage, prostatitis, hormone treatment, and RT. An area of low signal intensity can be attributed to hemorrhage if it causes high T1 signal intensity in the corresponding region. Low T2 signal intensity due to treatment (RT or hormonal therapy) may be suspected when the signal change is diffuse and associated with a small, featureless prostate gland. Signs of ECE are a focal, irregular capsular bulge, asymmetry or invasion of the neurovascular bundles, and obliteration of the rectoprostatic angle.[150]

FIGURE 72.4 Normal T1-weighted axial magnetic resonance image. Age-related benign prostatic hyperplasia in the transition zone is evident (long arrow). The neurovascular bundles lie adjacent to the peripheral zone (short arrow). (Courtesy of Steven Eberhardt, MD.)

MP-MRI can visualize prostate tumor characteristics (extraprostatic extension [ECE], tumor volume, etc) that can be predictive of final pathologic findings such as LN involvement, pathologic ECE (pECE), and BCR, all pivotal factors in the decision-making process regarding treatment. Tumor contact length (TCL) is defined as the length of cancer in contact with the prostatic capsule. Kongnuyun et al[153] evaluated the ability of 3T MP-

MRI–determined TCL in predicting pECE, BCR, and LN in patients undergoing RP. All 1,260 patients who underwent a 3T MP-MRI at the NCI from 2007 to 2015 were retrospectively classed into no ECE, suspicious ECE (sECE), and frank ECE (fECE) based on MP-MRI findings. sECE was defined as tumor with capsular bulge on MRI, whereas fECE was clear capsular obliteration and tumor extension beyond the prostatic capsule. Demographic data were obtained on patients with fECE and sECE on MP-MRI with the presence of pECE, LN, and BCR status following RP from a single surgeon (PP) experience. The authors focused on 146 patients who had sECE[68] or fECE[78] on MP-MRI. Median PSA was 11.7 ng/mL. Logistic regression analysis showed that MP-MRI–determined TCL was predictive of ECE (P = .01), LN status (P = .0001) on final pathology, and BCR (P = .05) during follow-up. Patients with pECE had a longer median MP-MRI TCL (2.8 cm) compared to those without pECE (2.4 cm), P = .04. When analyzed individually, fECE correlated with pECE (P = .05), whereas s ECE did not correlate with pECE (P = .11). Although not statistically significant, the median MP-MRI TCL for sECE with pECE was still longer than in sECE with no pECE in the subgroup analysis.

Magnetic Resonance Spectroscopy Imaging

Spectroscopy is based on the principle that the electron cloud surrounding different chemical compounds shields the resonant atoms of interest to varying degrees, depending on the specific atomic structure of the compound.[154] Because MRSI uses the same clinical MRI scanner, gradients, and radiofrequency coils as MRI, it can be added to an MRI examination, and the metabolic data can be overlaid directly on the corresponding anatomic images.[149] This modality is particularly useful in the prostate because there are metabolic compounds that localize to regions of the prostate and can be used to distinguish between normal prostate cells and malignant cells. Human prostatic glandular cells produce large amounts of citrate during cellular metabolism that are secreted into the prostatic fluid, yielding concentrations 240 to 1,300 times greater than blood plasma concentrations. High levels of citrate are found in the glandular regions of the prostate such as the PZ and lower levels in the TZ and CZ. Choline is another metabolite found at intermediate levels in the normal prostate and SVs. On MRSI, regions of PCa can be identified by differences in these two

metabolite levels. A significant reduction in prostate citrate and a significant increase in prostate choline levels relative to the normal PZ have been observed.[149] The elevated levels of choline in PCa may be attributed to the increased rate of cell proliferation, an increase in cell density in regions of cancer, and a change in the composition of the cell membrane leading to higher concentrations of choline-containing phospholipids.[149] The result of MRSI is a metabolic map of the prostate corresponding to normal and abnormal metabolic activity that can be used to pinpoint the location of prostatic tumors. This is exceptionally useful for accurate localization of prostate tumors and, in particular, when distinguishing between tumor and postbiopsy hemorrhage, which obscures MRI interpretations of PCa. Moreover, there is great potential for the use of this technique for follow-up after treatment and in the development of more focused therapy.

The contribution of metabolic information gleaned from MRSI to MR anatomic imaging has improved the diagnostic accuracy of MRI both in localizing and staging PCa.[154] Investigators at the University of California, San Francisco,[155] assessed the accuracy of combined MRSI and MRI for tumor detection and localization in 62 patients by comparing preoperative imaging results with histopathologic step-section examination after prostatectomy. MRI tended to have a higher sensitivity and MRSI a higher specificity for detecting definite sites of cancer. The addition of MRSI significantly improved specificity over MRI alone. Compared with step-section pathology results, the specificity for tumor location with combined MRI and MRSI reached 91%. Combined MRI/MRSI allowed localization of cancer to a sextant of the prostate with a sensitivity of up to 95% compared with MRI alone when either MRI or MRSI was positive. Moreover, a study from the University of California, San Francisco,[156] found MRI and MRSI are comparable with biopsy in accurately localizing intraprostatic cancer and are more accurate than biopsy in the prostate apex.

In addition to improving PCa localization, MRSI is complementary to MRI in staging and risk-stratifying patients with PCa. Combined MRI/MRSI enhances the assessment of both ECE and SV invasion.[150] Furthermore, the addition of MRSI to MRI improves the accuracy of less experienced MRI readers and reduces interobserver variability in the diagnosis of ECE.[154] Metabolic information from MRSI may also be predictive of tumor aggressiveness. Preliminary MRI/MRSI studies have shown that citrate

levels are lower in poorly differentiated PCas and that choline levels may be elevated in more aggressive tumors with greater membrane phospholipid synthesis.[157]

RISK STRATIFICATION SYSTEMS AND STAGING CLASSIFICATION

Based on tumor stage, pretreatment PSA, and biopsy GS, PCa is generally grouped according to one of several risk stratification models. These systems are useful to stratify disease-free survival (DFS), compare treatment results, and provide a means to recommend treatment options appropriately. A nomogram developed by Partin et al[53] first combined PSA at diagnosis, clinical stage, and biopsy pathology to predict pathologic stage, which assisted in guiding treatment decision-making. The original "D'Amico stratification" criteria were published in 1998, finding that these three tumor characteristics determined at diagnosis were predictors of response after surgery or RT.[56] Over time, multiple iterations have updated a widely used stratification model predicting low, intermediate, or high risk of PSA failure and risk of metastasis after primary treatment.

The 2017 American Joint Committee on Cancer/Union for International Cancer Control staging system is less used for treatment decision-making, but its TNM components are used in summarizing disease extent. All information that is available before first definitive treatment (DT) may be used for clinical staging, including imaging studies. For example, pelvic MRI findings of ECE are frequently used to determine cT3a status.

Genomic Testing and Molecular Biomarkers

Molecular biomarkers have extended the potential for risk stratification beyond traditional TNM, PSA, and GS. Three tissue-based tests for PCa risk stratification/prognosis for very low- and low-risk PCa: Decipher, Oncotype DX prostate, and Prolaris. These are further described in Table 72.8.

TABLE 72.8 TISSUE-BASED TESTS FOR LOW- AND VERY LOW-RISK PROSTATE CANCER RISK STRATIFICATION/PROGNOSIS

Test	Platform	Populations Studied	Outcome(s) Reported (Test Independently Predicts)	Molecular Diagnostic Services Program (MolDX) Recommendations
Decipher	Whole-transcriptome 1.4M RNA expression (46,050 genes and noncoding RNA) oligonucleotide microarray optimized for FFPE tissue	Biopsy, localized prostate cancer post-RP or EBRT	• Non–organ confined (pT3) or grade group 3 disease at RP • Lymph node metastasis • Biochemical failure/recurrence • Metastasis • Prostate cancer–specific mortality • Grade group ≥4 disease at RP	Cover postbiopsy for very low-, low-, favorable intermediate-, and unfavorable intermediate-risk prostate cancer in patients with at least 10 years life expectancy who have not received treatment for prostate cancer and are candidates for active surveillance or definitive therapy
Oncotype DX Prostate	Quantitative RT-PCR for 12 prostate cancer–related genes and 5 housekeeping controls	Biopsy, very low- to high-risk treated with RP	• Non–organ-confined pT3 or grade group 4 disease on RP • Biochemical recurrence • Metastases • Prostate cancer–specific mortality	Cover postbiopsy for very low-, low-, and favorable intermediate-risk prostate cancer in patients with at least 10 y life expectancy who have not received treatment for prostate cancer and are candidates for active surveillance or definitive therapy
Prolaris	Quantitative RT-PCR for 31 cell cycle–related genes and 15	• Biopsy, conservatively managed (active surveillance)	• Prostate cancer–specific mortality	

Test	Platform	Populations Studied	Outcome(s) Reported (Test Independently Predicts)	Molecular Diagnostic Services Program (MolDX) Recommendations
	housekeeping controls			
		• Biopsy, localized prostate cancer	• Biochemical recurrence • Metastasis	
		• Biopsy, intermediate-risk treated with EBRT	• Biochemical recurrence	
		• Biopsy, Gleason grade 3 + 3 or 3 + 4	• Non–organ-confined pT3 or grade group ≥3 on RP	

EBRT, external beam radiation therapy; FFPE, fresh frozen paraffin embedded; RP, radical prostatectomy; RT-PCR, reverse transcriptase polymerase chain reaction.

The Genomic Prostate Score (GPS), based on the Oncotype DX Prostate Cancer assay, ranges from 0 to 100, with increasing scores indicating more biologically aggressive disease. Previous studies have validated it as a predictor of adverse pathology and BCR after RP. Van Den Eeden and colleagues[158] retrospectively assessed how the GPS predicted DMs and PCa-specific death in 259 men with localized PCa treated with RP between 1995 and 2010. During a median follow-up of 9.8 years, 64 PCa-specific deaths, 79 metastatic events, and 117 BCRs occurred, according to a 2017 European Urology online report. Each 20-point increase in GPS was associated with a 2.34-fold increased risk of DMs, a 2.69-fold increased risk of PCa-specific death, and a 2.11-fold increased risk of BCR, after adjustment for other variables. Among the four biologic pathways represented in the GPS, downregulation of androgen signaling and upregulation of stromal response gene groups were most strongly associated with each outcome, although all four gene groups contributed to the prediction. The score predicted all three outcomes within clinically relevant subsets of patients by, age, race, and

central biopsy GS. One of the authors noted that “it was unclear which subset of patients might benefit most from this test, because men with low-risk PCa have very high 10-year survival, and those with high-risk cancer are usually recommended for treatment. Furthermore, our study was limited to patients who had undergone RP, and it is unknown how the test may perform for those treated with radiation therapy or who undergo active surveillance.” The authors commented that “several other genomic assays exist and have been validated to predict the risk of death from PCa. In addition, other refined risk prediction tools include advanced imaging, such as MP-MRI, that allows for more accurate clinical staging. Comparative studies are currently lacking, and may be increasingly important as we seek to understand how best to evaluate patients with newly diagnosed prostate cancer.”

Prolaris is a panel of RNA cell cycle progression (CCP) genes measuring cancer proliferation. The primary end point of this test is the 10-year risk of PCa death with conservative management. Cuzick et al[159] examined the biopsy specimens from 761 men diagnosed with PCa who were managed conservatively. After adjusting with PSA and GS, CCP score was a significant predictor of PCa death (HR = 1.65).

The Prolaris test measured on biopsy has also been shown to predict outcomes after radical treatment. Freedland et al[160] reported on 141 men diagnosed with PCa who received external beam radiation. CCP score was a significant predictor of BCR (HR = 2.11, P = .034) after adjusting for PSA, GS, positive cores, and use of hormonal therapy. There was also a statistically significant relationship with PCa death on univariate analysis, but the number of events was small. Similarly, Bishoff et al[161] showed that biopsy CCP scores were a significant predictor of BCR after RP (HR = 1.47) in a multi-institutional cohort. It was also a significant predictor of metastatic disease on univariate analysis. Another recent study by Oderda et al[162] in 52 Italian men treated by RP showed that mean Prolaris scores were −1.2, −0.444, and 0.208 in low-, intermediate-, and high-risk patients, respectively. Prolaris was a significant predictor of high-risk disease (OR, = 5.73). Prolaris was also significantly associated with BCR on univariate, but not multivariate, analysis, although there were only 15 events.

Clinical utility studies have been performed using surveys, such as shown by Shore et al[163] who surveyed 15 urologists about the influence of Prolaris results in 294 different cases, and they reported that approximately one-third

of the results would potentially lead to changes in practice. Another study by Crawford et al[164] reported changes from interventional to noninterventional management, and vice versa due to Prolaris results. Less is known about the long-term impact of changing initial management decisions on the basis of genomic test results or how these tests fit in a context with widespread MP-MRI use.

The Ontario (Canada) Technology Assessment[165] conducted a systematic review of the clinical and economic evidence of the CCP test in low- and intermediate-risk, localized PCa in a medical and health economic databases search from 2010 to June or July 2016. For the review of clinical effectiveness, 3,021 citations were screened, and two before-after studies met their inclusion criteria. In one study, the results of the CCP test appeared to change the treatment plan (from initial to final plan) in 64.9% of cases overall (GRADE rating of the quality of evidence: very low). In the other study, the CCP test changed the treatment received in nearly half of cases overall, compared with the initial plan (GRADE: very low). No evidence was available on clinical outcomes of patients whose treatment was informed by CCP results. For the review of cost-effectiveness, 100 citations were identified and screened, and no studies met the inclusion criteria. Patients viewed the test as potentially helpful but, because of the complexity of treatment decision-making, were unsure the test would ultimately change their treatment choices. The study found no evidence to demonstrate the impact of the Prolaris CCP test on patient-important clinical outcomes. The limited evidence available showed that the test appeared to provide information that, when considered in addition to clinical risk stratification, may change the treatment plan or actual treatment for some patients with low- and intermediate-risk PCa, but there are insufficient data to assess the cost-effectiveness of the CCP test.

The Oncotype Dx prostate biopsy test calculates a GPS based on genes from four different pathways involved in PCa: stromal response, androgen signaling, proliferation, and cellular organization. The primary end point of this test is to predict the risk of adverse disease at RP. Unlike Prolaris and Decipher (in postprostatectomy patients), Oncotype Dx was designed for use with biopsy tissue and does not have a commercially available test for postprostatectomy risk stratification.

Klein et al[166] defined the 17-gene panel for use in the Oncotype Dx GPS and tested it in the biopsies of 395 men with low- to intermediate-risk PCa. A 20-unit increase in GPS was associated with a significantly increased risk of high-grade and/or high-stage disease (OR = 2.1; 95% confidence interval [CI] = 1.4-3.2), after adjusting for the CAPRA score. Adding in a GPS measurement improved the discrimination of adverse disease compared with that of the CAPRA risk classification alone (area under the receiver operating characteristic curve [AUC] 0.67 vs 0.63). Cullen et al[167] subsequently validated the Oncotype Dx biopsy test in independent populations of men from military hospitals. On multivariable analysis, a 20-unit increase in Oncotype DX GPS associated with 3.3 times increased risk of adverse disease at RP and 2.7 times increased risk of BCR. Badani et al[168] reported that the GPS was discordant to the risk category, as defined by national consensus guidelines, in 39% of patients and that 18% of recommendations between active surveillance (AS) and treatment changed as a result of Oncotype Dx. Clinicians also reported that the results increased their confidence in decisions.

Ehro et al[169] using a transcriptome-wide assay developed a biomarker signature for patients assessed as low risk at diagnosis who are upgraded or upstaged following RP. Gene expression data of 56 RP samples from the Memorial Sloan Kettering Oncogenome Project (GSE21034) that met the low-risk criteria (ie, biopsy GS $\leq$ 6, clinical stage T1 or T2A, and pre-op PSA $\leq$10 ng/mL) were used. Of these tumors, 31 underwent upgrading or upstaging (defined by pathologic GS $\geq$7 or a pathologic tumor stage > T3A). In the training set (n = 29), a median fold difference filter (MFD > 1.4) was applied to select features. The top 16 t-test ranked features were modeled with a K-nearest neighbor (KNN) classifier (k = 3), which predicted upgrading/upstaging events. The KNN was applied to the test set (n = 27) and achieved an AUC of 0.93, significantly better discrimination than pre-op PSA (AUC = 0.52) or tumor stage (AUC = 0.63). Compared to the null model's accuracy of 56%, the KNN correctly predicted 81% (P < .005) of the upgrading/upstaging events. In multivariable analysis with pre-op PSA, tumor stage, and age at diagnosis, the KNN remained the only significant (P < .05) factor with an OR of 2.7. Validation studies of this signature in prospectively designed cohorts of AS candidates have been underway to

determine if the molecular signature can improve treatment and management decisions for patients with low-risk PCa.

PATHOLOGY

Adenocarcinoma, arising from peripheral acinar glands, is the most common tumor in the prostate. It is graded as well, moderately, or poorly differentiated according to cellular characteristics, such as nuclear content, number of nuclei, pleomorphism, gland formation, and invasion of the stroma.[56]

In the 1960s, Gleason[170,171] and Gleason and Mellinger[172] initially proposed a prognostic classification system based on the clinical stage and the degree of differentiation of primary and secondary morphologic patterns of the tumor, each graded from 1 to 5. Subsequently, only pathologic features were scored, resulting in a GS that sums grades to yield nine discrete scores ranging from 2 to 10. The GS is one of the strongest predictors of biologic behavior in PCa, including invasiveness and metastatic potential; however, it is limited by its subjectivity. There is significant interobserver and intraobserver variability reported using the Gleason grading system.[173] In addition, the treatment with hormonal therapy agents can affect the pathologist's ability to accurately identify a GS.[173]

In 2016, a new grading system was accepted by the World Health Organization simplified the groups based on pathologic features and clinical outcomes. This system was validated in a landmark paper by Epstein et al, evaluating 20,000 men with long-term outcomes after prostatectomy.[174] Grade groups 1, 2, 3, 4, and 5 correlated with 5-year biochemical PFS of 98%, 93%, 78%, 64%, and 49%, respectively. The grade groups combine previous GSs (Table 72.9).

TABLE 72.9 DEFINITION OF HISTOLOGIC GRADE GROUP (G)

Grade Group	Gleason Score	Gleason Pattern
1	≤6	≤3 + 3
2	7	3 + 4
3	7	4 + 3
4	8	4 + 4

Grade Group	Gleason Score	Gleason Pattern
5	9 or 10	4 + 5, 5 + 4, or 5 + 5

Recently, the Gleason system has been compressed into the so-called grade groups.
Used with permission of the American College of Surgeons, Chicago, Illinois. The original source for this information is the AJCC Cancer Staging Manual, Eighth Edition (2017) published by Springer International Publishing.

Grading errors may reflect sampling error because the needle biopsy samples a small fraction of the prostate gland, and the grade of cancer obtained on needle biopsy may not always be representative of the actual histologic subtype or degree of differentiation of the tumor. Most studies demonstrate a tendency of pathologists to undergrade biopsy specimens. Johnstone et al[175] noted that, compared with subsequent RP specimens, the incidence of correct grading of prostatic carcinoma from needle biopsies was 71%, with 23% undergrading and 6% overgrading. In a study from Memorial Sloan Kettering Cancer Center (MSKCC), GSs from 18-gauge needle biopsies were compared with radical retropubic prostatectomy specimens in 226 consecutive patients. The biopsy score was identical to the specimen score in 31% of cases, whereas 26% were discrepant by 2 or higher GSs. Overall, 54% of biopsies were undergraded and 15% were overgraded.[176] A large, retrospective analysis[177] of the correlation between GSs from biopsy and prostatectomy specimens and prediction of DFS was carried out among 1,031 patients. Overall accuracy was 58.3%. When categorized by GSs of less than 7, 7, and greater than 7, patients with tumors of GSs of less than 7 on prostatectomy specimens had a significant survival advantage over those with GSs of less than 7 by biopsy, whereas DFS was superior for patients with GSs of greater than 7 by biopsy than those with GSs of greater than 7 on prostatectomy specimens. The overall DFS was similar among all patients with GS of 7. These data should be kept in mind when the results of RP and irradiation are compared.

Predicting tumor extent and location using biopsy results was investigated by Humphrey et al[109] in a correlative study of multiple parameters with pathologic features in 50 RP specimens. They noted that it was very difficult to predict tumor extent in the gland quadrants based on the extent of tumor in the needle biopsy. There were 53 negative quadrant biopsies with carcinoma present in that quadrant in the RP specimen. Gregori et al[178] evaluated the

accuracy of sextant biopsies in predicting tumor location among 289 patients with clinically localized PCa who underwent radical perineal prostatectomy. These investigators found that 33% of patients with a unilateral positive biopsy had cancer confined to one side of the gland, whereas 66% showed bilateral disease in the prostatectomy specimen.

Stamey et al[179],[180] emphasized that, with regard to the natural history of PCa and prognosis, it is not just the GS that is important but also how much of the tumor is present. In a study of histologic prognostic variables for PSA relapse among 372 men with PCa followed for 3 years after retropubic prostatectomy, the most important variables predicting biochemical disease-free status for PZ cancers were percentage Gleason grade 4/5, cancer volume, serum PSA, and prostate weight.[180] Percentage Gleason grade 4/5, cancer location in the PZ, cancer volume, and LN involvement had prognostic value in large-volume PCa. These investigators also noted that TZ cancers have a better prognosis than PZ tumors because they are separated from the neurovascular bundles and the ejaculatory ducts by the compressed surgical capsule caused by expanding benign hyperplastic nodules.[36] From the Stanford experience,[181] cancer location in the PZ and percentage Gleason grade 4/5 were the most powerful predictors of biochemical failure in men whose cancer was 6 cm^3 or higher and contained in the prostatic capsule. Preoperative serum PSA was not helpful in distinguishing biochemical failure rates in large-volume cancers, regardless of whether they were organ confined.

D'Amico et al[182],[183] showed that the percentage of positive prostate biopsies added clinically significant information regarding time to PSA failure among 960 men with PSA-detected or clinically palpable PCa treated with RP. Investigators at the University of Michigan,[184] in an analysis of preoperative factors, including clinical stage, PSA, biopsy GS, greatest percentage of a biopsy core involved by cancer, number of biopsy cores containing cancer, and perineural invasion, found that only PSA, GS, and greatest percentage of a biopsy core involved by cancer were highly predictive of PSA RFS on multivariate analysis. This additional prognostic information may identify patients who are candidates for adjuvant therapy after RP. In addition, with the use of RT, histologic features from prostatectomy specimens are not available to incorporate into prognostic

models, and pretreatment risk stratification is important owing to the increasing use of nonsurgical treatment options.

Prostate core biopsy histologic features have been investigated for predicting extraprostatic extension and LN involvement. Researchers at the Mayo Clinic[185] compared biopsy specimen GSs, percentage positive cores, and percentage surface area involved in all cores with pathologic stage determined from RP specimens. Multivariate analysis using these pathologic variables, in addition to patient age, clinical disease stage, and PSA, showed that the percentage of positive cores, initial serum PSA, and GS of cancer in the needle biopsy were the only parameters that jointly predicted pathologic stage (T2 vs T3 disease). Narayan et al[66] used the combination of preoperative PSA plus biopsy GS in 932 patients who had undergone pelvic lymphadenectomy to predict the risk of positive pelvic LNs. Patients with biopsy GSs of 6 or less and preoperative PSA concentrations of 10 ng/mL or less had a less than 1% false-negative rate for pelvic LN metastases, suggesting that a staging pelvic lymphadenectomy is unnecessary.

Finally, the tumor histologic characteristics change with time and progression of disease. Cheng et al[186] reported a trend toward histologic dedifferentiation when prostate carcinoma metastasized to regional LNs. Among 242 patients treated with RP and pelvic lymphadenectomy at the Mayo Clinic, GS in the LN metastases was higher than in the primary tumor in 45% of patients, lower in 12% of patients, and matched exactly in 43% of patients. The 5-year PFS rate was significantly different between patients with histologic dedifferentiation and those without dedifferentiation.

Other Histologic Subtypes

Periurethral duct carcinoma is a separate clinicopathologic entity, usually consisting of a transitional cell type of carcinoma, although a mixture of glandular and transitional cells is also observed. Large anaplastic tumor cells cluster in the periurethral ducts and spread into the stroma. Mitoses are frequently seen. This tumor does not invade the perineural spaces as commonly as does adenocarcinoma of the prostate.

Reese et al[187] reviewed 49 patients with *transitional cell carcinoma* of the prostate; 29 patients had stromal invasion and 20 had transitional cell carcinoma in the prostatic ducts only. LN metastases were found in 14 (54%) of 26 patients with stromal invasion, compared with 4 (24%) of 17 with

duct/acinar involvement. The 5-year survival rates were 80% for stromal node–negative, 45% for ductal node–negative, 55% for ductal node–positive, and 30% for stromal node–positive patients.

Ductal adenocarcinoma arises rarely from the major ducts. These tumors are usually papillary and on microscopic sections are composed of tall columnar cells with eosinophilic cytoplasm that may resemble endometrial carcinoma.[188] Originally, this lesion was believed to originate in the prostatic utricle, a Müllerian remnant; however, most ductal adenocarcinomas are not derived from Müllerian remnants and behave as acinar adenocarcinomas.[40]

Most reports point to aggressive behavior, with invasion of the prostatic stroma and the bladder neck and metastases to the LNs, bone, and lung. In most series, the majority of patients die of the tumors within 4 years.[189,190] This tumor is moderately hormonally responsive and is sensitive to RT.[189] The treatment of choice is RP.[189,191] Kopelson et al[192] reported a good prognosis in early stages; however, in stage C, the 5-year survival rate was only 34.5%. They noted a 76% local tumor control rate and a 58% 5-year survival rate in patients treated with irradiation, in contrast to 14% local tumor control and 24% 5-year survival rates in patients not receiving this treatment. Brinker et al[193] also observed a shortened average time to progression relative to a previous study group of men with acinar carcinoma among 58 patients treated with RP at Johns Hopkins.

Neuroendocrine tumors are a rare variant of a malignant tumor composed of small or carcinoid-like cells. Neuroendocrine cell substances found in these tumors include serotonin, neuron-specific enolase, chromogranin, calcitonin, and others. PAP and PSA are valuable to determine the prostatic origin of the tumor. Of 22 patients with stage T2 lesions, 4 died of the disease and 3 of them had positive neuroendocrine cell findings.[194] Of the 20 patients with stage T3, 5 died of the disease and all 5 had positive neuroendocrine cell features.

Mucinous carcinoma, not arising in major ducts or the urethra, with positive histochemical stains for PAP, has been reported.[195]

Sarcomatoid carcinoma is a rare tumor and is difficult to distinguish from a true sarcoma. There is coexistence of prostatic adenocarcinoma with sarcomatoid components that have spindle cells with large pleomorphic hyperchromatic nuclei. The pattern is that of a high-grade sarcoma in most patients, similar to the malignant fibrous histiocytoma of soft tissues. Mitotic

figures range from 6 to 36 per 10 high-power fields. In 12 patients reported by Shannon et al,[196] tumor presentation was stage A or B in 4, C or D in 5, and unknown in 3 patients. Metastases data were available for 10 patients; the most common metastatic sites were the bone (seven patients), LNs (two patients), lung (two patients), liver (one patient), and skin (one patient). Immunostaining or electron microscopy demonstrated epithelial differentiation in the sarcomatoid areas in 6 of 11 patients on whom these studies were performed. All nine patients for whom follow-up data were available died of disease within 3 to 48 months after diagnosis. In three patients, sarcomatoid elements were part of the tumor at initial diagnosis; in the other nine, the sarcomatoid component was confirmed in subsequent evaluations after initial diagnosis (2-89 months). Four patients were treated with RT without beneficial result. These tumors are considered a very aggressive variant of prostatic adenocarcinoma.

Endometrioid tumors occasionally arise from the verumontanum. Endometrial glands and cells with numerous mitotic figures may be seen. These tumors may have an exophytic configuration in the prostatic urethra or infiltrate the adjacent tissues.

Adenoid cystic carcinoma is a rare tumor in the prostate (representing <0.1% of all tumors of this gland). The histologic appearance is similar to that of its salivary gland counterpart.

Other epithelial tumors, such as carcinoid or small cell carcinoma, have been reported in the prostate.[197,198] The experience with these lesions is very limited and, in most patients' behavior, is highly aggressive and fatal.[199] A review of the literature showed that in 130 patients reported with small cell carcinoma of the prostate, the 2-year survival rate was 3.6%, the 3-year rate was 1.8%, and the 5-year rate was less than 1%.[200] A subsequent SEER database analysis of 241 cases of small cell carcinoma of the prostate identified 1- and 5-year OS of 47.9% and 14.3%, respectively.[201] Squamous cell carcinoma originating primarily in the prostate is rare.[202] Metastatic malignant tumors from other locations to the prostate are occasionally reported.[202,203]

Sarcomas (leiomyosarcoma, rhabdomyosarcoma, or fibrosarcoma) constitute approximately 0.1% of all primary neoplasms of the prostate. Leiomyosarcoma is more common in middle-aged or older men, whereas rhabdomyosarcoma is found more frequently in younger patients. These

tumors tend to invade lymphatics and blood vessels, causing widespread regional lymphatic and DMs.

Carcinosarcoma of the prostate constitutes 0.1% of prostatic neoplasms. A mixture of adenocarcinoma invading the stroma and sarcomatous elements is seen histologically; smooth or striated muscle, fibroblasts, or other mesenchymal malignant cells may be identified.

Primary lymphoma of the prostate is rare, with less than 100 cases having been reported. It accounted for only 0.1% of newly diagnosed lymphomas and only 0.09% of all prostatic neoplasias at MD Anderson Cancer Center.[204]

GENERAL MANAGEMENT IN THE UNITED STATES

The optimal management of clinically localized PCa remains controversial and is often a source of confusion, frustration, and anxiety for many patients who are compelled to make a decision regarding a treatment intervention for their disease. The practitioner must be aware that the natural history of this tumor is variable and influenced by multiple prognostic factors. All of the various forms of therapy for PCa can affect quality of life (QoL) and sexual function in varying degrees. In the process of counseling and discussing therapeutic options, it is important for the radiation oncologist to present all available data regarding the natural history of this disease, prognostic significance of the diagnosis, potential therapeutic benefit of the various modalities, and immediate as well as late treatment-related sequelae. Life expectancy and QoL considerations should be carefully discussed with the patient and spouse or significant other.

Based on the available data, when comparing patients with similar prognostic features, there are no significant differences in the biochemical and DFS outcomes for patients with early-stage PCa treated with AS, RP, high-dose external beam or stereotactic body radiation therapy (EBRT or SBRT), or interstitial BT.[205-209] The United Kingdom landmark Prostate Testing for Cancer and Treatment (ProtecT) trial provides randomized evidence in support of similar cancer control outcomes between RP and EBRT. ProtecT was a British trial randomizing 1,643 men to AS, RP, or EBRT. Most men had low-risk disease (66%), although a significant minority were intermediate risk (24%). With 15-year follow-up, death from PCa was similar for all three groups (3.1%, 2.2%, and 2.9%, respectively). However,

clinical progression was significantly greater in men treated with AS compared to either treatment group (25.9%, 10.5%, and 11.0%).[210]

However, there has been long-standing wide geographic variation in the preferred therapeutic intervention for early-stage PCa practiced by urologists and radiation oncologists prior to the publication of the ProtecT trial. Observations from the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) database—a registry of 11,000 men accrued from 36 community-based urologic practices across the United States—shed light on practice patterns. Cooperberg et al[211] reported that, in this cohort of patients, 50% elected to be treated with RP, 12% were treated with EBRT, 13% received BT, 4% received cryotherapy, and 14% were treated with primary androgen deprivation therapy (ADT). In these patients, it was noted that among those with higher prognostic risk features, there was an increased use of primary ADT. Younger patients and especially those with low-risk disease were more often selected for prostatectomy. In addition to age playing a role in treatment selection, the presence of medical comorbidities, the socioeconomic status of the patient, and the personal practice trends of individual clinic treatment sites (irrespective of the patient's stage of disease) played important roles in treatment selection as well.

A report based on the SEER-Medicare linked database included 85,088 men with the diagnosis of PCa at age 65 years and above.[212] In this cohort of patients, 42% were treated with RT, 21% were treated with RP, 17% were treated with primary ADT, and 20% were followed expectantly. The authors also noted a strong association between the type of specialist seen (urologist vs radiation oncologist vs medical oncologist) and the primary therapy the patient had received. For patients who were 65 to 69 years old and evaluated by a urologist, 70% underwent a prostatectomy, whereas among patients who were 70 to 74 years old, surgery was selected in 45% of patients. In addition, among men who were seen by both a urologist and a radiation oncologist, RT was the most commonly used treatment modality (83% of this cohort). These data are consistent with prior studies showing that specialists more often made treatment recommendations favoring their particular specialty.

Within the practice of radiation oncology, there have been trends in management and treatment delivery. Higher radiation doses, shorter courses, and the use of adjunctive ADT with RT for various prognostic risk groups are more common than in the past. Intensity-modulated radiation therapy

(IMRT) and image-guided radiation therapy (IGRT) have become standard with a shift toward moderate and ultra-hypofractionation (also known as stereotactic body radiotherapy, or SBRT). Daily target localization (cone-beam imaging) has progressed to application of adaptive treatment technology.

In 2013, Zelefsky et al[213] reported the results of the Quality of Research Radiation Oncology group, which surveyed 414 patients with clinically localized PCa treated with EBRT or BT that were selected from 45 institutions in the United States. Among favorable-risk patients, 72% were treated to 75 Gy or higher. For high-risk EBRT patients, 60 (87%) were treated with ADT in conjunction with EBRT and 13% (n = 9) with RT alone. Among low- and intermediate-risk patients, 10% and 42%, respectively, were treated with ADT plus EBRT. For patients treated with EBRT, weekly electronic portal imaging was obtained as verification films without daily target localization in 35%, and the remaining 64% were treated with daily localization of the target, such as fiducial markers, cone-beam imaging, TomoTherapy, or intrafraction localization with a ferromagnetic marker device. In 2023, Qureshy et al reported on the increasing use of moderate hypofractionation and SBRT for PCa, reaching 31% and 12.2% of EBRT courses in 2020, respectively, compared to only 10% and 0.2% in 2004.[214]

Active Surveillance

For selected patients with low-risk PCa, expectant management (AS) is an increasingly acceptable approach to avoid overtreatment and the potential morbidity associated with any therapy. Candidates for expectant management include those patients with low PSA values with relatively slow doubling times who have low-volume disease (5% core involvement) and GS 6 disease based on biopsy findings.

Three large trials compared AS with treatment in the low-risk population: the Scandinavian Prostate Cancer Group Trial Number 4 (SPCG-4),[215] the Prostate Cancer Intervention versus Observation Trial (PIVOT) trial,[216] and the ProtecT study.[210] All three studies suggest that AS and active treatment both have roles in the management of low-risk PCa.

The long-term results of a phase III, randomized trial from SPCG-4 demonstrated a reduction in the cause-specific mortality with local therapy compared to an expectant management approach.[215] In this study, 695 men

were included with early-stage T1 or T2 PCa. The median follow-up was 12.8 years, the primary end point was death attributed to PCa, and the secondary end point was OS. In the watchful-waiting group, 58% died, compared with 48% in the RP group ($P = .007$). The cumulative incidence of death directly related to PCa was 14.6% in the surgery group versus 20.7% for the expectant management cohort. The survival benefit was noted among low-risk patients, and this benefit was limited to patients who were younger than 65 years of age.

The PIVOT[216] enrolled 761 U.S. patients diagnosed by PSA screening. At 12-year follow-up, prostatectomy did not significantly reduce all-cause or PCa-specific mortality compared with observation for localized PCa in selected patients (T1-T2NxM0 with PSA <50 ng/mL, life expectancy of at least 10 years, negative bone scan for metastatic disease, and age no .75 years). Unlike the SPCG study, the PIVOT study stratified OS and PCa-specific survival by patient race; nearly one-third of study patients (233/761) were African American. The generalizability of PIVOT conclusions to the contemporary U.S. population has been questioned by a recent National Cancer Database (NCDB) analysis of PIVOT-eligible patients, which found that U.S. men were younger, healthier, and more likely to have RP for higher risk disease than men in the PIVOT study.

The ProtecT study[210] provides insight into the expectant management of PCa. The median age was 62 years (range, 50-69 years), the median PSA level was 4.6 mg/L (range, 3-19.9 mg/L), 77% of patients had a GS of 6, and 76% of patients had T1c disease. The AS protocol was based on PSA levels alone with no routine imaging or repeat biopsies. A more than 50% increase in PSA level triggered review. EBRT was delivered as 74 Gy in 37 fractions using 3DCRT with ADT for 3 to 6 months. Failure was defined according to nadir plus 2 mg/L.

As noted earlier, the trial showed no difference in PCa mortality or all-cause mortality among all three groups. However, disease progression as defined by metastatic disease, clinical T3 or T4 disease, or initiation of lifelong ADT was higher in the AS group ($P < .001$).

While ProtecT is often used to support patient choice between RP and EBRT techniques, it also highlights the natural history of low- and intermediate-risk men initially managed with AS. While noting that these patients form a younger age group than those men often seen in the clinic,

not only are the death rates from PCa very low at 10 years, with only 17 deaths overall (~1%), but all-cause mortality is also very low across all three groups (~10%).

In addition, more than half of the men assigned to AS have undergone active treatment by 10 years, but 44% of men had undergone no treatment (NT) at all and had thus been spared any overtreatment.[217] This is despite the fact that AS protocols have evolved since the conception of this trial with the regular use of MP-MRI and repeat, often targeted biopsies.

A companion article to the original ProtecT publication after 10-year follow-up describing patient-reported outcomes is of particular interest as a comparison of toxicity across the three groups.[218] Sexual and urinary outcomes are significantly worse with surgery, whereas the rate of bowel side effects is higher with EBRT. However, the long-term side effects after surgery are far from inconsequential, with approximately one in five men using urinary incontinence pads and a similar number unable to maintain an erection at 6 years. This does beg the question: If men are to be treated for their low-risk PCa, is EBRT the treatment of choice? Surgeons will say that there has been an evolution in prostatectomy with robotic laparoscopic surgery and nerve-sparing techniques; however, there is little evidence that in the multicenter setting, late effects are significantly different in the modern era.[219]

Conversely, there is significant evidence that with the advent of image-guided IMRT and BT, RT toxicity has decreased further since the conception of ProtecT. The results of two moderate hypofractionation studies—the Conventional or Hypofractionated High-Dose IMRT for Prostate cancer trial[220] and RTOG 0415[221]—have confirmed that hypofractionated RT is as effective as conventional RT, leading to a change of practice, with EBRT being delivered in 4 to 5 weeks with minimal side effects and favorable long-term QoL compared with prostatectomy; advocates of surgery for low-risk PCa should be wary.

Unfortunately, subsequent SEER-based work has indicated that the encouragement of deferring definitive intervention (RP or definitive RT) in favor of AS may be deleterious for African American patients with low-risk PCa. One study involving more than 51,000 men with low-risk PCa (T1-T2a, GS = 6, and PSA = 10 ng/mL) found African American race to be an independently predictive risk factor for PCa-specific mortality (43,792

Caucasian vs 7,523 African American patients). Another analysis found that definitive intervention for screening-detected, low-risk PCa (T1c, GS = 6, PSA = 10 ng/mL) was more likely to occur in men who were Caucasian, married, and/or with high socioeconomic status.

As noted by McClelland et al,[222] the absence of race-based results from two of these randomized controlled trials (RCTs) and questions about generalizability of PIVOT results to the general population (even more so to African American men), combined with findings from SEER, which examined more than 7,500 African Americans with low-risk PCa, indicate that the results of AS versus definitive intervention for clinically localized PCa may not be as robust for African Americans as the RCTs indicate.

This situation sheds light on the dangers of interpreting RCT results independent of patient race or sociodemographic factors such as insurance status, when these factors have clearly influenced access to optimal care for cancers of the prostate and other organ systems. Work using genomic sequencing samples from within The Cancer Genome Atlas has found Caucasians overrepresented in comparison with the U.S. population, with samples from racial minorities being comparatively insufficient to detect moderately common mutational frequencies. The relatively low enrollment of racial minorities in cancer sequencing studies hinders the ability to detect race-specific targetable mutations, which could prove particularly pertinent for African Americans with PCa.

The authors concluded that the findings from a low-risk PCa population more than 30 times larger than the ProtecT study and 75 times larger than the SPCG and PIVOT studies should at minimum raise questions toward endorsing a blanket recommendation of delaying intervention for the sake of AS for African Americans or other underrepresented ethnic groups (Hispanics, Native Americans) with low-risk PCa.

Musunuru et al[223] reported on 522 patients with low-risk PCa (T1-T2a, GS = 6, and PSA = 10 ng/mL) between 2006 and 2008 who were recruited to AS, low-dose rate brachytherapy (LDR-BT), stereotactic ablative radiotherapy (SABR), or standard EBRT. Out of the 522 patients, 178 opted for AS program, 76 for standard EBRT (76 Gy/38 fractions), and 83 for SABR (35 Gy/5 fractions) as part of a phase 2 trial, and 185 patients had LDR-BT (I-125 implant-median dose of 145 Gy). Median follow-up was 51 months for the entire cohort; 10.1%, 16.85%, 6.02%, and 21.05% of the

patients in AS, LDR, SABR, and EBRT groups had clinical T2 disease, respectively; median pretreatment PSAs for the four groups were 4.65, 5.66, 5.90, and 6.57 ng/mL, respectively ($P < .0001$). In the AS cohort, 38 (21.3%) patients underwent active treatment. Median time to treatment was 18.25 months (8-72 months). Among the 522 patients, 17 had biochemical failure. The 6-year biochemical DFS (bDFS) was 96.1%. There was no difference in bDFS when stratified by clinical stage or pretreatment PSA. The results for 6-year bDFS were 97.7%, 93.2%, 97.4%, and 96.8% for the AS, LDR, SABR, and EBRT groups, respectively ($P = .28$). Hematochezia was observed in 2.24%, 3.13%, 7.14%, and 9.88% of the AS, LDR, SABR, and EBRT groups, respectively. Higher incidence of hematuria was noticed in the LDR-BT cohort (11.98%), when compared to the other groups. Thus, AS, LDR, EBRT, and SABR were effective management options for patients with low-risk PCa.

Lester-Coll et al[224] investigated trends and predictors of AS in a large national cohort of men with low-risk PCa (nonmetastatic cT1eT2a, GS 6, and PSA < 10), in the NCDB from 2010 to 2012. Management strategy and facility type (academic vs nonacademic) were compared using univariable logistic regression. Additional covariates tested against management strategy included T-stage (T1c vs T2a), age (age <65 vs 65 or older) Charlson/Deyo comorbidity score, location, insurance, rurality, race, education, and income.

Eighty-one thousand six hundred ninety men were identified, among whom 34,612 (42%) were evaluated at an academic center and 47,078 (58%) at a nonacademic center. Median age was 63. Initial management was AS in 8,228 (10%), DT in 70,064 (86%), and NT in 3,398 (4%). Patients evaluated at academic centers were significantly more likely than those at nonacademic centers to receive AS than DT or NT (15% vs 7% AS, 81% vs 89% DT, 4% vs 4% NT, $P < .001$). After adjusting for age, T-stage, insurance, and location, evaluation at an academic versus nonacademic facility was independently associated with increased odds of AS utilization (adjusted OR = 1.91; 95% CI = 1.83-1.99, $P < .001$).

Even now, there is still controversy as to AS protocols. Both ASCO[225] and a European coalition[226] have published guidelines as to surveillance testing and frequency. DT is recommended for men with localized PCa at high risk of tumor progression. RP, EBRT with hormone therapy in selected patients,

and BT are all acceptable options. High-intensity ultrasound or cryotherapy was not recommended unless the patient is part of a clinical trial.

Thankapannair et al evaluated the UK National Institute for Health and Care Excellence tiered prognostic groupings for men undergoing AS.[227] All patients were initially screened by MP-MRI for low-risk status. Based on PSA density and initial Likert lesions from the MRI at diagnosis, men underwent follow-up MRIs either every 12, 18, or 36 months. PSAs were monitored every 3 months for all participants. Biopsy was only performed for a change in PSA or MRI for the lowest risk group and mandated only for higher risk groups at 36 months. Overall, only 8.9% of the 156 men enrolled in the prospective study had pathologic progression, although median follow-up was short at 1.5 years. There was excellent compliance for the protocol, with 86.5% of men remaining on AS.

National consensus guidelines recommend AS for men with low-risk PCa and life expectancy of 10 years. Keeping men well informed of their options and considering individual preferences are key tenets of these guidelines. It is clear that patient information and careful selection are key. There are a number of studies seeking to address the role of genomic markers of both RT responses to tumor and normal tissues. Recent suggestions that molecular subgroups outside the traditional prognostic factors can stratify patients more accurately need to be explored further. No definitive data on genetic or molecular markers in primary PCa are available.[228]

Treatment Techniques

Radical Prostatectomy

RP is a treatment option for patients with very low-risk PCa with a life expectancy of longer than 20 years or low-risk PCa with a life expectancy of at least 10 years.

RP has had a limited role in the management of gross extracapsular disease or SV involvement or the presence of LN metastases; however, more recently, there has been an increased use of surgery for locally advanced disease. Two approaches for the classic RP are used: retropubic and perineal. The procedure consists of the complete removal of the prostate and its surrounding capsule, together with the SVs, the ampulla, and the vas deferens. The prostate is entirely removed by excision of the urethra at the prostatomembranous junction, leaving no residual prostatic tissue at the

apex. Many urologic surgeons prefer the retropubic approach as this procedure also facilitates access for performing a bilateral PLND.

There has been an increasing interest and practice of laparoscopic and robotic RP approaches in the United States and Europe. Advantages cited for using the laparoscopic procedure versus the open approach include improved visualization of the anatomy optical magnification, less blood loss, less postoperative pain, and more rapid resumption of everyday activities. Preliminary functional and oncologic outcomes with this approach compare favorably to those achieved with open RP approaches. The da Vinci robotic surgical system (Intuitive Surgical) uses three multijoint robotic arms, with one arm controlling the binocular endoscope and the other arms controlling small-wristed instruments. This system is controlled by the surgeon, who can be in a remote location from the patient, seated at an operative console. The stereoscopic view of the operative field provides the surgeon with 3D visualization with a 10-fold magnification.

A prospective randomized single-center study of 145 consecutive men referred to RP in a tertiary referral center in Finland randomized 1:1 to robot-assisted laparoscopic prostatectomy (RALP) (n = 75) and 3D laparoscopic radical prostatectomy (3D-LRP) (n = 70). Postoperative continence at 12 months after surgery, according to the EPIC-26 incontinence domain, was 79.25 in both groups (P = .4). At 12 months, there was no statistically significant difference in the rates of positive surgical margin or BCR between the two surgical modality groups.[229]

An evidence-based meta-analysis of comparative outcomes between robot-assisted radical prostatectomy (RARP) versus standard LRP included 16 “high-quality” (RCTs and Newcastle-Ottawa scale 8-9) studies were included. Among the 13,752 patients included, 6,135 (44.6%) and 7,617 (55.4%) were RARP and LRP, respectively. Overall and major complication (Clavien-Dindo ≥ III) rates were similar in the LRP than in the RARP group. The BCR rate at 12 months was significantly lower for RARP (OR 0.52; P < .00001). RARP reported a lower urinary incontinence rate at 12 months (OR 0.38; P = .01). The erectile function recovery rate at 12 months was higher for RARP (OR 2.16; P = .007). Current evidence shows that RARP offers favorable outcomes compared with LRP, including higher potency and continence rates and less likelihood of BCR. An assessment of longer term

outcomes is lacking, and higher cost remains a concern of robotic versus laparoscopic PCa surgery.[230]

Radiation Therapy Techniques

In the late 1980s, 3D (also known as conformal) treatment techniques became increasingly available. CT-based images referenced to a reproducible patient position are used to localize the prostate and normal organs and to generate high-resolution 3D reconstructions of the patient anatomy. Treatment field directions are selected using beam's-eye view techniques, and the fields are shaped to conform to the patient's CT-defined target volume, thereby minimizing the volume of normal tissue irradiated. CRT simulation, treatment planning, and delivery incorporate various additional maneuvers to reduce treatment uncertainties and enhance setup reproducibility required during a protracted course of therapy.

IMRT is a refinement of 3D conformal techniques that uses treatment fields with highly irregular radiation intensity patterns to deliver exquisitely conformal radiation dose distributions.[231] IMRT delivery is significantly more complex than 3D conformal delivery, requiring a computer-controlled beam-shaping multileaf collimator.

There has been increasing use of SBRT for the treatment of low- and intermediate-risk PCa. The main advantage is that the highly conformal treatment, based on image-guided approaches with narrow margins, is delivered in five fractions (750-800 cGy per fraction), with lower doses to adjacent organs at risk, more convenient for the patient. Biochemical control has been comparable to standard IMRT, and treatment morbidity has been low.

Katz and Kang[232] reported on 515 patients with organ-confined PCa (471 T1c and 44 T2a, all N0M0) who received robotic radiosurgery SBRT. The mean PSA was 6.48 ng/mL; 343 were low risk, 134 intermediate risk, and 38 high risk. ADT was administered to 70 patients. One hundred fifty-eight patients received 3,500 cGy delivered in five daily fractions. The remaining patients, from all risk groups, received a total dose of 3,625 cGy in five daily fractions. At a median follow-up of 54 months (range, 9-79 months), 40 patients died of other unrelated causes and 33 were lost to follow-up. The median PSA at 60 months was 0.11 ng/mL. Biochemical failures occurred for eight low-risk patients (none locally), nine intermediate-risk patients (one

locally), and nine high-risk patients (two proven local failures). The actuarial 6-year freedom from biochemical failure was 97.4%, 92%, and 70.4%, for the low-, intermediate-, and high-risk groups, respectively ($P < .001$). Late RTOG toxicity was mild with 4% grade 2 rectal, 7.8% grade 2 urinary, and 1.4% grade 3 urinary (all with 36.25 Gy). Late grade 2 urinary toxicity for 35 Gy was 5.1% versus 9.9% for 36.25 Gy. Sexual QoL declined by 23% at 6 to 12 months where it remains. Seventy-four percent and, at 8 years, 62% of the patients potent at baseline remain potent.

Meier et al[233] described results in 309 patients with biopsy-proven adenocarcinoma of the prostate 172 low-risk (CS T1-T2a, GS 6, PSA < 10 ng/mL) and 137 intermediate-risk (CS T1c-T2b with either GS 7 and PSA < 10 ng/mL or GS 6 and PSA between 10 and 20 ng/mL) treated with a nonisocentric robotic SBRT using real-time tracking of implanted fiducials, at 21 community, regional, and academic hospitals. The prostate dose was 40 Gy in five fractions of 8 Gy and SVs received 36.25 Gy. Normal tissues were rigidly constrained (rectal V_{36Gy} <1 mL; bladder V_{37Gy} <5 to 10 mL). No patient had concomitant or adjuvant androgen ablation therapy. The median follow-up was 61 months. Five grade 3+ toxicities (1.6%) were reported, far below the 10% rate deemed excessive. There were no grade 4 or 5 toxicities. All reported grade 3 genitourinary (GU) toxicities occurred between 11 and 51 months after treatment. Five patients (1.6%) developed urinary retention, which required a temporary catheter placement. Seven patients were diagnosed with bladder cancers between 21 and 50 months after treatment. For the entire population, actuarial 5-year OS was 95.6%. Actuarial 5-year nadir +2 RFS was 97.1% for all patients and was 97.3% and 97.1% for the low- and intermediate-risk groups, respectively. Actuarial 5-year ASTRO RFS was 92.3% and 91.3% for these respective risk groups.

Blacksburg et al[234] reported on 773 patients with PCa treated with robotic SBRT (35 Gy in five daily fractions) without the use of ADT. Mean age was 67 years; 43.2%, 47.7%, and 9.1% of patients had low-, intermediate-, and high-risk disease, respectively. The GS was 6 in 50.5%, 7 in 42.0%, and 8 to 10 in 7.5%. The median pretreatment PSA was 5.73 ng/mL (range 1.2-68.18): At 30 months, the median PSA was 0.36, 0.41, and 0.40 ng/mL in low-, intermediate-, and high-risk patients, respectively. Despite a convergence in absolute PSA values at this time point, the shape of post-treatment PSA curves prior differs considerably based on GS and initial PSA.

At 12 months, 42.2%, 50.0%, and 70.8% of patients with low-, intermediate-, and high-risk disease, respectively, have a PSA that has declined by at least 80% ($P < .0001$). 44.3%, 50.3%, and 66.7% of patients with GS 6, 7, and 8 to 10, respectively, experience this decline at the same time point ($P = .007$). 44.5% of patients with an initial PSA less than 10 ng/mL experience this decline as compared to 70.9% of those with an initial PSA greater than 10 ng/mL ($P < .0001$).

More recently, a multiarm randomized trial comparing SBRT with other treatment modalities, including RP and conventional IMRT, is maturing. The Prostate Advances in Comparative Evidence (PACE) trials performed by the UK Institute of Cancer Research include three foci: PACE-A enrolled low- or intermediate-risk patients into a randomized trial comparing RP or SBRT. PACE-B enrolled the same population to a noninferiority trial randomizing to either SBRT or conventional fractionation (62 Gy or 78 Gy). PACE-B reported 5-year outcomes at ASTRO 2023 noting that SBRT was noninferior to conventional EBRT with an unadjusted HR of 0.73 (90% CI, 0.47-1.12).[235] There was a slight but not statistically significant increase in 2+ GU toxicity in the SBRT arm (8.5% vs 5.9%, $P = .19$).

Another important trial evaluated an emerging technology in RT delivery —MRI guidance. The MRI-Guided Stereotactic Body Radiotherapy for Prostate Cancer trial enrolled 178 patients and randomized them to 40 Gy in five fractions delivered by traditional CT-guided therapy versus MRI guidance. The study was written with different expansion margins for CT (4 mm) versus MRI (2 mm) because of the ability for MRI-LINAC (linear accelerator) to provide intrafractional real-time imaging. Similar numbers of patients had perirectal spacers. The study found that MRI guidance significantly reduced the incidence of acute (up to 90 days) grade 2+ GU toxicity by CTCAE (24.4% vs 43.4%, $P = .01$). Grade 2+ gastrointestinal (GI) toxicity was also reduced with MRI guidance (29.5% vs 44.7%, $P = .001$). While most patients were intermediate or high risk, the results have been extrapolated to low-risk PCa.[236]

Simulation, Treatment Planning, Target, and Normal Tissue Contouring

The techniques for simulation and treatment planning have been described in detail in earlier chapters. Anatomic details and target volumes are defined in

CT scan sections of 1 to 3 mm thickness. Although in the past patients with PCa were treated in the prone position at MSKCC based on comparative studies[237] that demonstrated improved geometry of the normal anatomy juxtaposed to the prostate target, currently patients are routinely treated in the supine position. These changes were made based on the observation of less prostate motion observed in the supine compared to the prone position.[238]

Image guidance is the standard of care to allow for small setup uncertainty margins and reduced normal tissue radiation. Fiducial marker placement via transrectal ultrasound guidance is widely utilized, but other methods exist. Fiducials are implanted prior to simulation. With the advent of image guidance, immobilization technique varies, from the use of a thermoplastic mold to just a toe-ring. At simulation, the patient is scanned through an approximately 20- to 30-cm region around the prostate with a slice spacing and thickness of 3 mm (thinner slices can be used for SBRT). Before the start of the CT planning study, several transverse images through the prostate and bladder are obtained to ensure that the rectal lumen is clearly visible, the bladder and rectum are not excessively filled, and the patient is properly positioned within the scan circle. With the use of the CT data set, a "virtual simulation" is performed, using digitally reconstructed radiographs to localize the treatment area rather than conventional simulation films. The treatment isocenter is placed according to anatomic landmarks near the center of the prostate gland: midline, at the caudad aspect, and approximately 5 cm posterior to the symphysis pubis. The triangulation points for the isocenter are then tattooed or temporarily marked, along with an additional alignment tattoo, along the sagittal line, approximately 10 cm superior to the isocenter.

Perirectal hydrogel spacers within Denonvillier fascia have been used as a method of increasing the distance between the posterior prostate and the anterior rectum. Several prospective studies have shown that the use of hydrogel spacers decreases rectal dose. In the first large trial, Mariados et al[239] noted a significant reduction in mean rectal V_{70} (12% in control vs 3% in spacer, $P < .0001$) and a reduction in rectal toxicity at 15 months (7% vs 2%, $P = .04$). Later follow-up at 3 years noted grade 2 or higher rectal toxicity (5.7% vs 0%; $P = .012$), with no difference in grade 2 or higher urinary toxicity.[240] A separate report noted that men with good sexual function at baseline had maintained sexual QoL better when treated with a spacer versus

the control. A more recent study using a different spacer also noted similar reduction in rectal toxicity associated with the use of a hydrogel spacer: 14% versus 3% (P = .01).[241] Main risk of the spacer is rectal infiltration, which may delay treatment but at least in one retrospective series was not associated with late rectal toxicity.[242]

MRI-supported planning is key to accurate delineation of the prostate, prostatic apex, and adjacent organs at risk. T2-weighted MRIs are merged with the planning CT to aid in delineation of these structures. Roach et al[243] evaluated 10 patients with both MRI and CT images of the prostate and noted that the prostate volume was 32% larger when defined by noncontrast CT than when determined by MRI. Areas of disagreement tended to occur in the posterior and posteroinferior-apical portions of the prostate, the apex (because of disagreement between urethrography and MRI), and the regions corresponding to the neurovascular bundle. Rasch et al[244] also observed differences in CT- and MR-defined volumes. On average, the prostate and SV volume defined on CT was 40% larger than that defined on MR. The CT-defined prostate was 8 mm larger at the base of the SVs and 6 mm larger at the prostatic apex. This difference was found to be significantly larger than interobserver variation.

For low-risk PCa, the clinical target volume (CTV) is defined as the prostate and proximal 1.5 cm of SVs. The planning target volume (PTV) is defined as the CTV with a margin to account for physical uncertainties, including setup reproducibility and interfractional and intrafractional organ motion.

Without image guidance, a 0.8- to 1-cm margin is added to the CTV to form the PTV in all directions, except posteriorly at the interface with the rectum, where the margin is reduced to 0.5 cm. Clinically, these margins were found to provide adequate target coverage based on a serial CT scan study evaluating organ motion during a course of 3DCRT.[237] When using image-guided approaches with daily target localization, margins are reduced to 5 to 6 mm circumferentially around the CTV. For SBRT, when increased imaging is used to ensure more precise targeting, these PTV expansions can be reduced to 0.3 to 0.5 cm. Normal tissues identified on each CT slice include the inner and outer walls of the rectum and bladder, the femoral heads, and the outer skin surface. Portions of the small bowel or sigmoid colon within 1 cm of the PTV are also contoured and taken into

consideration, if necessary, during planning. In addition, the central 1-cm-diameter portion of the prostate encompassing the prostatic urethra is defined for dosimetric consideration and evaluation during IMRT planning.

Accurate anatomic delineation of the prostate and, in particular, the prostatic apex has been a topic of some controversy. Prior to routine use of MRI, some used urethrography at the time of simulation as a method to accurately localize the apex.[238] Mah et al[245] performed sagittal MR scans immediately before and after urethrogram in 13 patients. No significant systematic motion of the prostate itself or the apex was observed, leading the authors to conclude that urethrography during simulation does not introduce localization error.

Contouring Techniques

There have been several reports documenting the variability of prostate-contouring techniques among practitioners. McLaughlin et al[246] provided an excellent demonstration of common contouring errors, such as overestimation of the prostatic apex and underestimation of the prostatic base. The apex and the base in particular represent regions of the target volume that can be challenging to identify on CT images and better defined with MRI. Two methods recommended include the inspection of lateral view projections of the contours to detect regions of the irregularities of the target geometry and improved recognition of the GUD elements. These elements are shown in the MRI representation of the GUD in Figure 72.5 and in the CT representation in Figure 72.6.

The beam weights are adjusted to obtain a uniform dose within the PTV and to place the hot spots away from the rectum. The plan was normalized so that the prescription isodose (95%-100%) covers the PTV with a hot spot of 6% to 9% within the PTV. Although a small volume of the rectal wall close to the PTV is expected to receive the prescription dose, the rectal wall volume receiving greater than prescription should be minimal. For 60 Gy in

20 fractions, for example, the volume of rectum receiving more than 60 Gy should be less than 10 mL. Other normal tissue dose limits for these 3DCRT plans included limiting the maximum dose to the femurs to 48 Gy or less in 2 Gy equivalent (90%), the maximum dose to large bowel to 60 Gy or less in 2 Gy equivalent, and the maximum dose to small bowel to 50 Gy or less in 2 Gy equivalent.

A variety of beam arrangements have been proposed for prostate IMRT treatment, including multifield axial or noncoplanar arrangements, in addition to intensity-modulated arc therapy. Primarily because of concern about an increased risk of secondary cancers from higher neutron doses associated with IMRT treatment at high energies,[247,248] 6-MV IMRT techniques are preferred for the treatment of PCa. As shown by Pirzkall et al,[249] however, a larger number of treatment fields may be necessary to achieve a dose distribution similar to that observed with 15-MV x-rays.

Dosimetric guidelines defining acceptable target coverage, dose uniformity, and normal tissue doses have grown out of the 3DCRT and IMRT planning experience during the past 20 years and include several refinements resulting from the retrospective outcome and toxicity analyses. Most notably, studies by Skwarchuk et al[250] and Jackson et al[251] retrospectively evaluating the rectal wall dose-volume histograms (DVHs) for patients treated to 70.2 and 75.6 Gy, respectively, using 3DCRT techniques found that, on average, patients with late rectal bleeding had significantly higher rectal DVHs than patients who did not bleed. Both high- and intermediate-dose levels were found to be independently correlated with rectal bleeding.

The physician should carefully review the treatment plan and DVHs of the target and normal tissue structures to select the optimal treatment plan for the patient. Target coverage should be carefully assessed, as well as the dose inhomogeneity and location of hot spots. In addition, careful attention should be given to determining whether the treatment plan adequately meets acceptable dose constraints for the rectum, bladder, and bowel.

Prescription Doses for Intensity-Modulated Radiation Therapy and Stereotactic Body Radiation Therapy

Historically since the understanding of the benefit of fractionation on normal tissue dose recovery, with conventional fractionation, that is, daily fractions of 1.8 to 2 Gy, five fractions per week, was the standard for PCa. The current

standard dose for conventional fractionation based on clinical trials has been 78 Gy, although dose escalation up to 86 Gy has been delivered to favorable-risk patients using IMRT. At doses above 80 Gy, PTV coverage may be sacrificed as needed to respect the target and normal tissue goals. Typically, at least 90% to 95% of the PTV receives the prescription dose. However, with the publication of multiple moderate hypofractionation trials, doses of 60 Gy in 20 fractions or 70 Gy in 28 fractions have become routine.[252,253] In addition, ultra-hypofractionation with SBRT (36.25 Gy in five fractions) has become more common, providing excellent control with acceptable toxicity burden.

Treatment Delivery and Organ Motion Control

Movement of the prostate during treatment or between treatment fractions has long been a concern for prostate RT. Many studies investigating interfractional and intrafractional motion of the prostate and SVs have been reported.[254-257] Most groups have measured prostate motion relative to bony landmarks through repeated imaging of implanted radiopaque markers or serial CT studies. Although the reported magnitude of motion has varied, relatively little motion in the lateral direction and potentially significant movement in the anterior-posterior and superior-inferior directions has been consistently reported. Many studies have also observed a correlation between prostate and SV motion and rectal or bladder filling.

Interfractional prostate motion was studied in approximately 50 patients by Crook et al.[256] Gold seeds implanted in the prostate were visualized on kilovolt radiographs taken at the simulation and approximately midway through treatment. Minimal prostate motion was observed in the lateral directions (0.1-0.5 cm), but inferior displacements of 0.5 and 1.0 cm or more were observed in 43% and 11% of their patients, respectively. Average displacement in the posterior direction was 0.72, 0.62, and 0.46 cm for seeds placed at the SVs, posterior aspect of the prostate, or apex of the gland, respectively; 60% of patients showed greater than 0.5 cm posterior displacement of the prostate base, and 30% showed greater than 1 cm.

Zelefsky et al[257] obtained four serial CT studies for 50 patients (planning scan and three additional scans during the course of therapy). Prostate displacements in the anteroposterior and superior-inferior directions were most frequently observed. The mean prostate motion in the anteroposterior,

superoinferior, and left-right directions was 1.2, 0.5, and 0.6 mm, respectively. Anterior-posterior movements were correlated with changes in rectal volume. Patients with large rectal volumes (.60 cm^3) and large bladder volumes (.40 cm^3) on the planning scan experienced a higher likelihood of having greater than 3-mm systematic displacement of the prostate and SVs, leading the authors to conclude that these patients may require more generous PTV margins to ensure adequate CTV coverage. However, among patients without larger bladder and rectal volumes, a 1-cm margin around the CTV with a 6-mm margin at the prostate-rectal interface enclosed the posterior, anterior, superoinferior, and left-right aspects of the CTV within the prescription dose level with a probability of 90%, 100%, 99%, and 100%, respectively, indicating that the MSKCC margins provided adequate CTV coverage for most patients.

Intrafractional prostate motion was studied in 20 patients by Huang et al[258] using pretreatment and post-treatment B-mode rectal ultrasound evaluations. Although the intrafractional motion was relatively insignificant in all directions, the predominant directions of motion were in the anterior and superior directions. Standard deviations of 0.4, 1.3, and 1.0 mm were observed in the lateral, anterior, and superior directions, respectively. Several methods have been developed to reduce uncertainty because of interfractional organ motion and thereby improve treatment delivery using computer-assisted transabdominal ultrasonography, radiopaque marker tracking, or CT/cone-beam image guidance. Recent technological advances have opened up the possibility of acquiring pretreatment or post-treatment megavoltage or kilovoltage CT images directly on the LINAC with the patient in the treatment position, such as TomoTherapy. Langen et al[259] compared three methods of registering megavoltage CT images from a TomoTherapy unit with the kilovoltage planning CT images and found that manual registration performed using implanted fiducial markers exhibited the least interobserver variability and agreed best with automatic registration computed from the center of mass of the three implanted fiducial markers. LINAC-based kilovoltage image guidance systems are routinely used now for image-guided therapy approaches. They possess capabilities for kilovoltage 2D projection imaging (radiographs), fluoroscopy, and 3D cone-beam CT and are ideally suited for monitoring of interfractional and intrafractional motion.

Using IMRT (volumetric modulated arc therapy), 10-year biochemical control has been in the range of 85% to 88%, and 15-year biochemical control 76% with acceptable morbidity.[260] These recent technological advances have allowed dose escalation, with improvement in the results of treatment. A study from MD Anderson Cancer Center[261] showed that patients with favorable (low-risk) PCa treated with 78 Gy had a 10-year biochemical control of 88% compared to 63% in patients treated with 70 Gy. Grade 3 toxicity was 7% versus 1%. A French multicenter trial compared 8,000 to 7,000 cGy in patients with various risk prognostic groupings.[262] The 5-year biochemical freedom-from-failure rate (BCFFR) was 76.5% versus 67.9%. There was a trend toward more toxicity in the 8,000-cGy group (grade 3 rectal toxicity 6.5% and 1.5%, respectively).

In a study comparing 8-year outcomes of RP or EBRT, Kupelian et al[263] (Cleveland Clinic) reported on 1,054 patients who were treated with surgery and 628 with EBRT. With a median follow-up of 51 months, the PSA RFS was 72% and 70%, respectively.

Brachytherapy for Early-Stage Disease: Treatment Techniques

Low-Dose Rate Brachytherapy

Preplanned Transperineal Implantation Techniques. The preplanning technique essentially attempts to map the seed-loading patterns before the implantation procedure. During the procedure, the brachytherapist will simulate the preplanned needle positions with the operative conditions and settings. The technique can be summarized as follows: TRUS imaging is obtained before the planned procedure to assess the prostate volume. A computerized plan is generated from the transverse ultrasound images, producing isodose distributions and the ideal location of seeds within the gland to deliver the prescription dose to the prostate. Several days to weeks later, the implantation procedure is performed. Needles are then placed under ultrasonographic guidance through a perineal template according to the coordinates determined by the preplan. Radioactive seeds are individually deposited in the needle with an applicator's aid or preloaded seeds on a semirigid strand containing the preplanned number of seeds. In the latter case, this is accomplished by stabilizing the needle obturator that holds the seed column in a fixed position while the needle is withdrawn slowly, depositing a row or series of seeds within the gland. One of the inherent

advantages of a stranded seed approach is the reduction of seed migration and lung embolization compared with the use of free seeds. Among patients implanted with loose seeds, usually less than 2% of the implanted seeds are likely to migrate. There is no evidence of any adverse effect caused by seed embolization.[264]

Careful evaluation of the preplan with attention to DVH analyses of both the target and normal tissues is essential to ensure that the dose to the urethra and rectum is within tolerance ranges and the prescription dose is being delivered to the prostate target. In a multi-institutional analysis, there remains a great deal of variability within preplans regarding acceptable target volume, seed strength, dose homogeneity, treatment margins, and extracapsular seed placement, although prostate BT prescription doses are uniform.[265]

Intraoperative Planning Techniques for Prostate Brachytherapy. With the current availability of sophisticated treatment planning programs that can rapidly generate highly conformal dose distributions in the operating room, intraoperative planning for prostate BT is an attractive method. Intraoperative planning takes advantage of the opportunity of using real-time measurements of the prostate during the procedure. In contrast, preplanning is often performed several weeks before implantation, frequently under different conditions than the actual operative procedure. Subtle changes in the position of the ultrasound probe, as well as the distortion of the prostate associated with needle placement and subsequent edema, may result in profound changes in the shape of the gland compared with the preplanned prostatic contour. Consequently, intraoperative adjustments of seed and needle placements are frequently required using a preplanned technique, and the postplan CT-based dosimetry only sometimes corresponds to the idealized preplan.

At MSKCC, intraoperative conformal optimization and planning for ultrasound-based transperineal implantation have been routinely used for over the two decades.[266] This technique involves a sophisticated optimization system that incorporates acceptable dose ranges allowed within the target, and dose constraints for the rectal wall and urethra. An ultrasound probe is positioned in the rectum, and the prostate and normal anatomies are identified. Needles are inserted through the perineal template at the periphery

of the prostate. The prostate is subsequently scanned from apex to base, and these 0.5-cm images are transferred to the treatment planning system using a computer-based video capture system. On the computer monitor, the prostate contours and the urethra are digitized on each axial image. Needle positions are identified on each image, and their coordinates are incorporated into a genetic algorithm optimization program. After the optimization program identifies the optimal seed-loading pattern and the dose calculations are completed, isodose displays are superimposed on each transverse ultrasound image and carefully evaluated. DVHs for the target volume, rectum, and urethra are also carefully assessed. For the intraoperative plan, the V_{100} for the prostate is set at 95% or higher, and the maximum urethral and rectal dose thresholds are set at less than 130% and 1 cm^3 less than 100% of the prescription doses, respectively. The entire planning process, from the contouring of images to the generation of the seed-loading pattern, requires approximately 10 minutes. Seeds are then loaded with a standard applicator. A cone-beam CT scan from a mobile unit is routinely used to obtain postimplantation dosimetric analysis while the patient is under anesthesia before the conclusion of the procedure to ensure optimal coverage of the target volume with the prescription dose. Figure 72.7 shows a postimplantation CT image used for dosimetric evaluation.

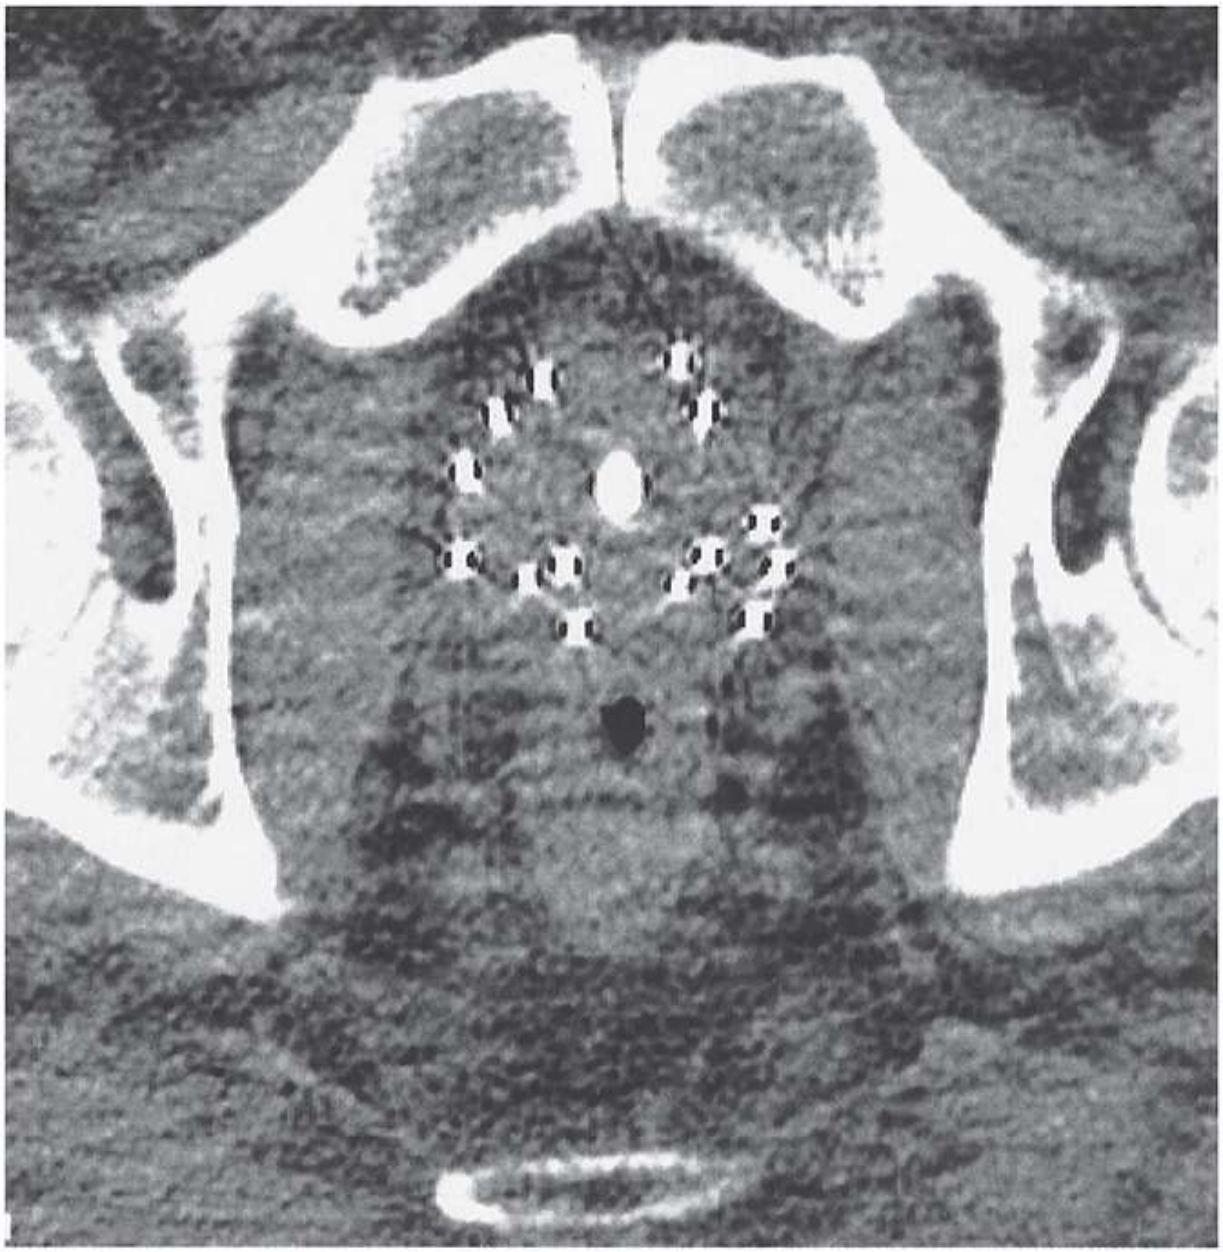

FIGURE 72.7 Postimplantation computed tomography scan after permanent transperineal ultrasound-guided seed implantation with urethral sparing.

Dose, Isotope, and Activity Considerations for Prostate Low-Dose Rate Brachytherapy. At present, the commonly used dose for LDR interstitial implantation when using ^{125}I is 144 to 145 Gy, prescribed to the isodose surface that completely encompasses the prostate as contoured from imaging studies. For ^{103}Pd, 125 Gy is the recommended prescription dose when the isotope is used as monotherapy.[267] There are clear physical

differences between these two isotopes. The half-life of ^{125}I is 59.4 days, with a mean photon energy of 28.4 keV and an initial dose rate of 7 cGy/hour. In contrast, the half-life of ^{103}Pd is 17 days, with a mean photon energy of 20.7 keV and an initial dose rate of 19 cGy/hour. Dosimetric analyses of treatment plans performed with either isotope have not revealed significant differences.[268]

A prospective trial randomized 125 patients between ^{125}I (144 Gy) and ^{103}Pd (125 Gy) for low-risk disease. The actuarial BCFFR at 3 years was 89% for ^{125}I patients versus 91% for Pd-103 patients (P = .76). The 3-year BCFFR for patients with a D_{90} less than 100% of the prescription dose was 82% versus 97% for patients with a D_{90} 100% or more of the prescription dose (P = .01). Similarly, the 3-year BCFFR for patients with a V_{100} less than 90% of the prescription dose was 87% versus 97% for patients with a V_{100} 90% or more of the prescription dose (P = .01). The effect of the dosimetric parameters on biochemical control was most pronounced for ^{125}I but also apparent for ^{103}Pd.[269] Patients treated with ^{103}Pd had more intense radiation prostatitis in the first month after implantation, but they recovered from their radiation-related symptoms sooner than ^{125}I patients, consistent with palladium's shorter half-life.[270]

A prospective randomized trial randomized patients between ^{125}I and ^{131}Cs. The prescription dose was 144 Gy for ^{125}I and 115 Gy for ^{131}Cs. ADT or supplemental EBRT was not allowed. One hundred forty men were enrolled; 81.4% were low risk, and 18.6% were intermediate risk. The median follow-up was 97 months. The 9-year biochemical RFS was 87.2% and 84.0% for the ^{125}I and ^{131}Cs group, respectively (P = .897). Short- and long-term urinary, sexual and bowel QoL, and long-term biochemical control were comparable between ^{125}I and ^{131}Cs.[271]

Postimplantation Dosimetric Evaluation. Postimplantation dosimetric evaluation after prostate BT is recommended as the standard assessment of the quality of permanent interstitial implantation used for the treatment of PCa. Recommended preimplant dosimetry PTV parameters are as follows for ^{125}I: V_{100} 95% or more, V_{150} 65% or less, and V_{200} 30% or less; for ^{103}Pd: V_{100} 95% or more, V_{150} 75% or less, and V_{200} 45% or less; and for ^{131}Cs V_{100} 95% or more, V_{150} 55% or less, and V_{200} 20% or less.[267]

Commercial software is routinely available to determine prostate coverage and dose to critical normal tissue structures. Isodose curves and DVHs produce a detailed analysis of the radiation dose distribution relative to the prostate and surrounding normal tissues. Postimplantation evaluation is performed on the day of the procedure or 30 days after. Although the latter time point takes advantage of assessments when prostate edema is less significant after the implant, with a potential decreased underestimate of the prostate coverage with the prescription dose, assessments made on the day of the procedure provide more rapid feedback regarding the adequacy of the dose delivered to the prostate.

Postimplantation evaluation is a critical quality assurance procedure for prostate BT. It provides important feedback to the brachytherapist concerning the quality of the implant, the dose delivered to the prostate, and what corrections need to be made to optimize target coverage to reduce normal tissue dosing. Postimplant dosimetry parameters include D_{90}, V_{100}, and V_{150}. Acceptable postimplant dosimetry parameters are D_{90} 80% or more and V_{100} 85% or more.[267]

A study analyzed patients with N0, M0, and nonsurgical PCa diagnosed between 2004 and 2015 from the NCDB. Patients were grouped into six categories based on RT modality: IMRT with BT boost, IMRT with/without IMRT boost, proton therapy, SBRT, LDR-BT, and high-dose rate (HDR)-BT. For low-risk patients, both LDR-BT and HDR-BT have been declining. During 2004-2007, 2008-2011, and 2012-2015, the LDR-BT monotherapy utilization percentages were 40.5%, 34.6%, and 33.5%, respectively. During 2004-2007, 2008-2011, and 2012-2015, the HDR-BT monotherapy utilization percentages were 22.4%, 17.3%, and 13%, respectively.[272]

High-Dose Rate Brachytherapy

HDR-BT (iridium-192 sources) is used for prostate HDR monotherapy of 13.5 Gy × two implants and 9.5 Gy BID × two implants. Recommended PTV planning goals are V_{100} 95% or more and D_{90} greater than 100%.[273]

The reader is referred to Chapters 23 and 24 for techniques' description and dose schedules.

Results of Standard Treatment Interventions for Clinically Localized Prostate Cancer

Outcome With Radical Prostatectomy

The National Institute for Health Research-supported ProtecT trial recruited men aged 50 to 69 years in the United Kingdom. Approximately 66% of patients were low risk.[274] A total of 1,643 agreed to undergo randomization to active monitoring (545 men), surgery (553), or RT (545). There were 17 prostate cancer–specific deaths overall: 8 in the active-monitoring group, 5 in the surgery group, and 4 in the RT; the difference among the groups was not significant. In addition, no significant difference was seen among the groups in the number of deaths from any cause. Metastases developed in more men in the active-monitoring group (33) than in the surgery group (13) or the RT group (16) (P = .004 for the overall comparison). Higher rates of disease progression were seen in the active-monitoring group (112 men) than in the surgery group (46) or the RT group (46). At a median of 10 years, prostate cancer–specific mortality was low irrespective of the treatment assigned, with no significant difference among treatments.[274]

Of the three treatments, prostatectomy had the greatest negative effect on sexual function and urinary continence, and these outcomes remained worse in the prostatectomy group than in the other groups throughout the trial. The negative effect of RT on sexual function was greatest at 6 months, but sexual function then recovered somewhat and was stable thereafter. RT had little effect on urinary continence. Sexual and urinary function declined gradually in the active-monitoring group. Bowel function was worse in the RT group at 6 months than in the other groups but then recovered somewhat, except for the increasing frequency of bloody stools. Bowel function was unchanged in the other groups. Urinary voiding and nocturia were worse in the RT group at 6 months but then mostly recovered and were similar to the other groups after 12 months.[218]

Outcome With External Beam Radiation Therapy for Low-Risk Disease

Kuban et al[275] reported the results of a large multi-institutional analysis of 4,839 patients with T1-T2 PCa treated with EBRT between 1986 and 1995; no patient received neoadjuvant hormone therapy. The median follow-up was 6.3 years. Most of the patients included (70%) were treated with

conventional EBRT, and 30% were treated with 3DCRT planning techniques. Prescription doses ranged from 60 to 78 Gy. For the cohort of patients treated to dose levels of less than 70 Gy, the median dose was 67 Gy; among those patients who received 70 Gy or more, the median dose in this cohort was 72 Gy. PSA failure as defined according to ASTRO definition was three consecutive rising PSA values above the nadir value. The overall 8-year PSA control rates for patients with pretreatment PSA values of 0 to 4, 4 to 9.9, 10 to 20, and greater than 20 to 30 ng/mL were 80%, 60%, 46%, and 34%, respectively. The overall 8-year PSA control rates for patients with post-treatment nadir PSA values of 0 to 0.49, 0.5 to 0.99, 1 to 1.99, and 2.0 ng/mL or more were 93%, 88%, 86%, and 72%, respectively. Higher prescription dose levels of 72 Gy or more were associated with a significant decrease in PSA relapse rates, and these differences were most noted among patients with intermediate- and higher risk disease. Although there was no apparent dose response for low-risk patients, the number of patients who received higher doses in this study was small.

The randomized phase III PACE-B compared prostate SBRT to conventional or moderate hypofractionation.[235] The study randomized 884 low- or favorable intermediate-risk patients to 36.25 Gy in 5 fractions versus either 78 Gy in 29 fractions or 60 Gy in 20 fractions. Five-year follow-up reported BCR-free survival (BRFS) at 95.8% for the SBRT arm and 94.6% with conventional/moderate hypofractionation.

Reported separately, urinary and bowel toxicity were not statistically different between SBRT and conventional/moderate hypofractionated regimens.[276] RTOG 2+ urinary toxicity at 2 years was 3% versus 2% (P = .39). Bowel toxicity was 2% versus 3% (P = .32).

Dess et al[277] evaluated sexual potency preservation in 830 men treated with SBRT in a prospective trial at a single institution. Prospective health-related QoL data were collected via the EPIC-26, including five major domains of urinary irritative, urinary incontinence, bowel, sexual, and hormonal. The median age was 69 years old, 25% were low risk, 57% were intermediate risk, and 18% were high risk. Twenty percent received ADT and 16% received supplemental standard fractionation radiation in addition to SBRT for higher risk features. With a best possible score of 100, the mean baseline urinary irritative, urinary incontinence, bowel, sexual, and hormonal scores were 91, 87, 95, 53, and 92, respectively. Depending on the time point post-

SBRT, between 10% and 15% of patients had 1× MID multidomain decline, and 1% to 5% of patients had 2× MID multidomain declines. On multivariable analysis, early toxicity in urinary incontinence, bowel, and hormonal domains predicted 3- and 12-month multidomain declines, with no consistent predictors at 2-, 3-, and 5-year time points.

Johnson et al[278] evaluated bowel, urinary, and sexual patient-reported QoL following treatment for PCa with either moderately hypofractionated RT (,5 Gy/fraction) or SBRT (5-10 Gy/fraction). Three hundred seventy-eight men who underwent moderate hypofractionation were compared to 534 men treated with SBRT. After 1 year, patients receiving moderate hypofractionation were more likely to experience worsening in bowel symptoms (39.5%) when compared to SBRT (32.5%; $P = .06$), with a more substantive difference at 2 years (37.4% vs 25.3%, $P = .002$).

Similarly, patients receiving moderate fractionation had worsening urinary symptom score compared to patients who underwent SBRT at 1 and 2 years (34.7% vs 23.1%, $P < .001$; and 32.8% vs 14.0%, $P < .001$). Patients receiving moderate hypofractionation had more frequent worsening in sexual symptom score, although the difference was nonsignificant at either 1 or 2 years (32.7% vs 29.1%, $P = .30$; and 38.5% vs 33%, $P = .18$). After adjusting for age and cancer characteristics, patients receiving moderate hypofractionation were more likely to experience worse urinary symptoms scores than patients receiving SBRT at 2 years (OR = 0.24; 95% CI = 0.07-0.79); there was no difference in likelihood of worsening bowel or sexual symptoms scores between groups at 1 or 2 years in the adjusted analysis.

Dose Escalation for Low-Risk Prostate Cancer

Five randomized clinical trials in men with nonmetastatic PCa showed that dose-escalated EBRT resulted in lower rates of biochemical failure and local progression but did not affect OS.[261,279-283] Two of these trials yield further insights into the impact of dose escalation in low-risk PCa.[261,282]

The phase III trial from MD Anderson Hospital[261] accrued 301 patients with T1b-T3 PCa, of whom 150 were treated to 70 Gy (conventional EBRT) and 151 were treated to 78 Gy (conventional EBRT followed by a 3D boost). A significant improvement in 8-year biochemical control was noted among low-risk patients who received 78 Gy compared to 70 Gy (88% vs 63%; $P = .042$; Figure 72.8). GI toxicity of grade 2 or greater occurred twice as often

in the high-dose patients (26% vs 13%), although GU toxicity of grade 2 or greater was less (13% vs 8%) and not statistically significantly different.

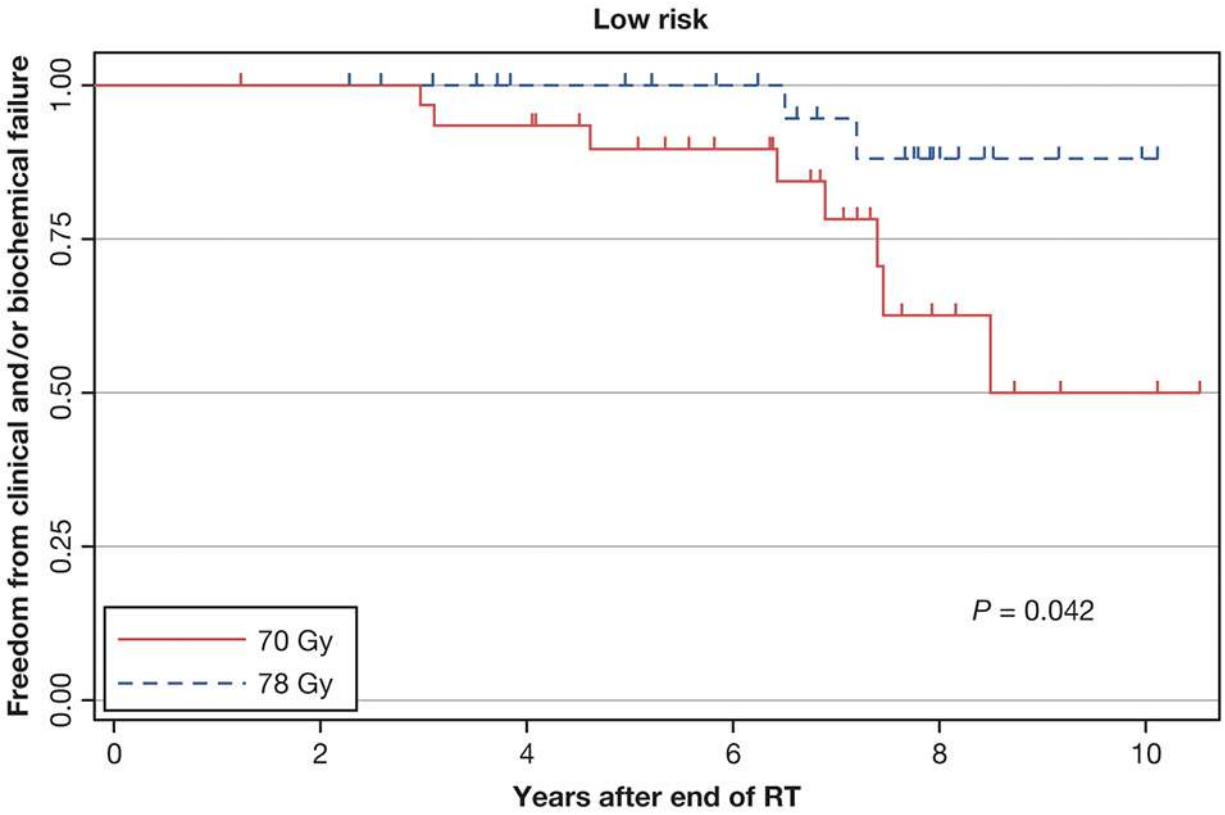

FIGURE 72.8 Freedom from biochemical failure for the subset of low-risk patients treated in the MD Anderson randomized trial with 78 versus 70 Gy. RT, radiation therapy. (Reprinted from Kuban DA, Tucker SL, Dong L, et al. Long-term results of the M.D. Anderson randomized dose-escalation trial for prostate cancer. *Int J Radiat Oncol Biol Phys.* 2008;70[1]:67-74. Copyright © 2008 Elsevier. With permission.)

Zietman et al[282] reported the result of a randomized trial of 393 patients with T1b-T2b PCa with pretreatment PSA levels of 15 ng/mL or less. Patients were randomized to receive conventional EBRT to a dose level of 70.2 or 79.2 Gy equivalents. In both treatment arms, RT was delivered using a combination of photon and proton beams. The median follow-up in this study was 8.9 years. The 10-year ASTRO biochemical failure rates were 32.4% for conventional dose and 16.7% for high-dose RT ($P < .0001$). This difference was held when only those with low-risk disease ($n = 227$; 58% of total) were examined: 28.2% for conventional and 7.1% for high dose ($P < .0001$).

The experience from MSKCC was reported by Zelefsky et al in 2,551 patients with T1-T3 PCa treated with follow-up that extended beyond 20 years. The radiation dose was systematically increased from 64.8 to 86.4 Gy by increments of 5.4 Gy in consecutive groups of patients. This study also demonstrated an advantage for dose escalation in low-risk patients. The 10-year PSA RFS among patients with low-risk disease who received dose levels of 75.6 Gy and higher was 84%, compared to 70% for patients who received lower dose levels (P = .04; Figure 72.9). This report showed no apparent differences in long-term outcomes among patients who received 81 versus 75.5 Gy for low-risk disease.[279-283]

Michalski et al reported the outcome of RTOG 94-06, which evaluated dose escalation using 3DCRT for patients with localized PCa. Patients were accrued on five sequential dose levels: 68.4, 73.8, 79.2, 74, and 78 Gy. For patients with low-risk disease (n = 403), the 5-year PSA RFS outcomes for these respective dose levels were 68%, 73%, 67%, 84%, and 80%.[284]

A retrospective, nonrandomized comparative effectiveness study of dose-escalated versus standard-dose EBRT for PCa diagnosed from 2004 to 2006 using the NCDB evaluated three cohorts: men with low-risk (n = 1,229), intermediate-risk (n = 16,714), or high-risk (n = 13,538) PCa. Patients were categorized patients in each risk cohort into two treatment groups: standard-dose (from 68.4 to <75.6 Gy) or dose-escalated (≥75.6-90 Gy) EBRT. Dose-escalated EBRT is associated with improved OS in men with intermediate- and high-risk PCa, but not with low-risk PCa.[285]

Comparison of External Beam Radiation Therapy Outcomes With Surgery for Early-Stage Prostate Cancer

Kupelian et al[263] compared the 8-year outcomes of surgery and EBRT from the Cleveland Clinic. In this report, 1,054 patients were treated with surgery and 628 were treated with EBRT. Treatments (surgery or RT) were given between 1990 and 1998, and the median follow-up was 51 months. There were significant differences in the patient groups because, in general, those treated with surgery were younger and had lower clinical stages, pretreatment PSA levels, and GSs. The 8-year PSA RFS outcome for patients who underwent RP and EBRT was 72% and 70%, respectively (P = .01). Multivariate analysis demonstrated that the clinical stage, pretreatment PSA, biopsy GS, use of neoadjuvant therapy, and year of treatment were all independent predictors of disease relapse, whereas the treatment modality (RT vs surgery) did not influence likelihood of failure. These authors also noted a benefit for higher radiation doses in the favorable-risk subset of patients. Among favorable-risk patients who received 72 Gy or more, the 8-year PSA RFS outcome was similar (P = .08) to that of patients treated with RP and significantly better, in turn, than that of patients treated with RT to dose levels of less than 72 Gy (P < .001). Similarly, Zelefsky et al[208] found similar DM-free survival outcomes between high-dose IMRT and surgery for low-risk patients.

The PACE-A study compared SBRT for low- and intermediate- risk PCa to RP.[286] The trial halted accrual early secondary to the COVID-19 pandemic but enrolled 123 patients. Cancer outcomes have not yet been reported, but early- to intermediate-term toxicity results show excellent outcomes for SBRT. Most of the patients assigned to RP underwent RARP (84%), and 76% of SBRT patients used Cyberknife technology. The primary end point of

urinary incontinence, defined as any use of pads, was reported at 2 years: 47% for RP and 4.5% for SBRT ($P < .001$). However, SBRT did result in worse patient-reported bowel symptoms per the EPIC bowel subdomain: 88.7 for SBRT versus 97.3 for RP ($P < .001$), although patient reports of bowel symptoms being a significant detractor on QoL was very low (2.2%). Sexual outcomes favored SBRT: The EPIC sexual bother subdomain mean scores were 57.7 for SBRT versus 29.3 for RP ($P < .001$).

Proponents of RP have argued that, whereas the results of radiation and radical surgery are comparable up to 10 years, there is a rapid decrement in the probabilities of both DFS and OS after that time point among irradiated patients. However, such conclusions are likely erroneous owing to selection bias factors favoring a younger cohort with more favorable prognostic features who are more often chosen for surgery compared with RT. In addition, because of the lack of information in most RT series of the pathologic status of the LNs, patients with microscopic nodal disease will likely be included in RT reports yet routinely excluded from surgical series. An additional argument posed for surgery is that if such an approach fails, salvage RT remains a viable option, whereas for those who fail RT, salvage surgery can be associated with an increased risk of postoperative complications. Nevertheless, patients need to be informed that there are risks associated with salvage RT after a failed prostatectomy and that the likelihood of a successful outcome after well-delivered primary RT is high and comparable to surgery outcomes.

Outcome With Brachytherapy

Low-Dose Rate Brachytherapy

The single-arm phase II prospective RTOG 9805 study enrolled 101 patients with low-risk disease treated with I-125 monotherapy (145 Gy). No patients received ADT. At a median follow-up of 8.1 years among 94 eligible patients, the 8-year cumulative incidences of biochemical failure and metastasis were 8% and 1.1%, respectively.[287]

Appropriate candidates for BT monotherapy include low-risk disease for patients declining AS and favorable intermediate-risk disease. Recommended radionuclides for permanent prostate BT include iodine-125, palladium-103, and cesium-131. The suggested monotherapy doses are 144 to 145 Gy for iodine-125, 125 Gy for palladium-103, and 115 Gy for cesium-131.[267]

Crook et al analyzed data from seven institutions for 14,220 patients with localized PCa treated with LDR-BT, either alone (8,552) or with EBRT (n = 1,175), ADT (n = 3,165), or both (n = 1,328). Since 98.7% of patients with PSA 0.2 ng/mL or less at 4 years after LDR prostate BT were disease free beyond 10 years, the authors suggested adopting this biochemical definition of cure for patients with 4 years or more follow-up after LDR-BT.[288]

Similar to the predictors of biochemical outcome after EBRT for PCa, PSA RFS after permanent seed implantation depends on several prognostic variables, including the pretreatment PSA, biopsy GS, clinical stage, and the implant dose delivered to the target volume. In general, among patients with pretreatment PSA of 10 ng/mL or less, permanent seed implantation alone is associated with excellent biochemical outcomes and appears comparable with other local interventions.[289] Fifteen-year outcomes were reported by Sylvester et al from 215 patients treated between 1988 and 1992. The PSA RFS outcomes were 86%, 80%, and 62% for favorable-, intermediate-, and high-risk patients, respectively. Similarly, Taira et al reported on 1,656 patients.[290] For low-risk patients, the 7-year biochemical tumor control, cause-specific survival, and OS outcomes were noted to be 98.6%, 99.8%, and 77.5%, respectively.

Eleven institutions combined data on 2,693 patients treated with permanent interstitial BT monotherapy for T1-T2 PCa.[291] Of these patients, 1,831 (68%) were treated with ^{125}I (median dose, 144 Gy) and 862 (32%) were treated with ^{103}Pd (median dose, 108 Gy). The median follow-up was 63 months. The 8-year PSA RFS outcomes for low-, intermediate-, and high-risk patients were 82%, 70%, and 48%, respectively ($P < .001$) according to the ASTRO consensus definition.

Stone et al reported on 2,111 patients who underwent BT followed for a median of 6 years. In this group, 55.5% of the patients were treated with ^{125}I, 10.4% were treated with ^{103}Pd, and 34.1% were treated with combined EBRT and ^{103}Pd implant.[292] Among low-risk patients, the PSA RFS outcome at 12 years was 88.1%.

Table 72.10 summarizes the published biochemical outcomes after LDR interstitial seed implantation according to prognostic risk groups.

TABLE 72.10 BIOCHEMICAL CONTROL AFTER BRACHYTHERAPY ALONE FOR CLINICALLY LOCALIZED PROSTATE CANCER ACCORDING TO PROGNOSTIC RISK GROUP CLASSIFICATIONS

Study	Patients	Years	Low Risk (%)
Taira et al[290]	1,656	12	98.6
Sylvester et al[289]	215	15	86
Multi-institutional[291]	2,693	8	82
Stone et al[292]	2,111	12	88
Potters et al[352]	1,449	12	89
Zelefsky et al[353]	1,466	5	98

High-Dose Rate Brachytherapy

Morton et al reported the efficacy results from a randomized phase II clinical trial of one fraction of 19 Gy or two fractions of 13.5 Gy. The median follow-up was 60 months. The 5-year bDFS and cumulative incidence of local failure were 73.5% and 29% in the single fraction arm and 95% (P = .001) and 3% (P < .001) in the 2-fraction arm. The authors concluded HDR monotherapy delivered as two fractions of 13.5 Gy is well tolerated with a high cancer control rate at 5 years, and 19-Gy single fraction monotherapy is inferior and should not be used.[293]

A systematic review of HDR-fractionated BT monotherapy for localized PCa identified 7 studies and 2,123 patients. Low-, intermediate-, and high-risk patients comprised 40%, 40%, and 20% of patients, respectively. The 5-year BRFS rate was 95%.[294]

ACUTE AND LATE TREATMENT-RELATED SEQUELAE OF STANDARD TREATMENT INTERVENTIONS

Sequelae of Radical Prostatectomy

Complication rates after prostatectomy vary in the literature and recently have been shown to depend on the experience of the surgeon. Begg et al[295] used the Medicare claim records from 11,522 patients who underwent prostatectomy between 1992 and 1996. Postoperative morbidity was found to be significantly reduced in hospitals that were considered to have high volume compared with lower volume ones (27% vs 32%; P = .03) and among surgeons with a high-volume practice compared to those with lower volumes (26% vs 32%; P < .001).

Immediate intraoperative/postoperative complications include pelvic pain and transient incontinence. Although intraoperative blood loss can range from 300 to 4,000 mL, meticulous surgical technique should reduce blood loss. The operative mortality rate has been reported to be 1% to 2%, but in experienced hands, the incidence is a fraction of 1%. The incidence of postoperative stress incontinence ranges from 5% to 57%.

Catalona et al[296] reported on the complication rates in 1,870 patients who underwent RP. They reported a 2% incidence of a thromboembolic event and a 4% incidence of an anastomotic stricture. Recovery of urinary continence depended on the age of the patient. Among patients in their 50s, 60s, and 70s, the likelihood of persistent urinary incontinence was 3%, 8%, and 13%, respectively. The incidence of impotence after bilateral and unilateral nerve-sparing surgery procedures was 53% and 32%, respectively. Bilateral nerve-sparing procedure was associated with improved potency preservation among patients who were younger than 70 years of age (71% vs 48%; $P <$ .001), whereas these differences were not significant in the older age group.

Bianco et al[297] reported continence and potency outcomes in 1,472 patients who underwent surgery since 1991 and were operated on by a single surgeon. Among 1,288 patients who were continent prior to surgery, the actuarial likelihood of maintained continence was 91% at 12 months and 95% at 24 months. Of 785 patients with potency information available, the median time to erectile function recovery was 12 months, and the 2-year likelihood of potency preservation was 70%.

A large review from the Nationwide Inpatient Sample extracted from this data set 11,889 patients who underwent RARP and compared the perioperative complication rates to 7,389 patients who underwent an open RP.[298] This analysis found that, among patients undergoing an RARP, significantly lower likelihoods for blood transfusions and intraoperative and postoperative complications were observed compared to the open prostatectomy procedure. In addition, a shorter duration of hospital stay was noted for the patients who underwent an RARP. However, one of the limitations of this retrospective study was the fact that these findings were not adjusted by the clinical stage of the patients and the surgeon's experience or volume, which play important roles in the frequency of surgical-related complications.

A large meta-analysis of 910 studies reporting outcomes for either open or RARP found that the annual volume of surgeries performed correlated with complication rate.[299] For open RP, the expected annual volume to achieve a complication rate of 12% or less was 95.3 surgeries per year. For RARP, the annual volume to achieve the same complication rate was at least 30.2 surgeries per year.

Sequelae of Conventional External Beam Radiation Therapy

EBRT delivered with conventional techniques is fairly well tolerated, although grade 2 or higher acute rectal morbidity (discomfort, tenesmus, diarrhea) or urinary symptoms (frequency, nocturia, urgency, dysuria) requiring medication occur in approximately 60% of patients. Symptoms usually appear during the third week of treatment and resolve within days to weeks after treatment is completed. The incidence of late complications that develop 6 months or more after completion of treatment is significantly lower, whereas serious complications that require corrective surgical intervention are rare. In general, the incidence of chronic urinary sequelae (ie, cystitis, hematuria, urethral stricture, or bladder contracture) using conformal treatment delivery techniques is less than 5%, and the incidence of grade 3 and 4 urinary-related complications requiring major surgical interventions or hospitalization is less than 1%. The incidence of chronic intestinal or rectal sequelae (chronic diarrhea, proctitis, or rectal bleeding) that requires medical management ranges from 3% to 10%, and less than 1% of grade 3 to 4 complications are observed after more targeted treatment delivery techniques, such as IMRT and IGRT. Fecal urgency and incontinence are documented side effects after treatment and have been reported to occur in less than 2% of patients, occur less than once per week, and are often associated with incontinence for flatulence.[300] Most complications attributed to RT are observed within the first 3 to 4 years after treatment, and the likelihood of complications developing after 5 years is low. Even patients with a prior history of inflammatory bowel disease currently in remission may have significant increases in rectal toxicity, and alternative treatments should be considered for these patients. Among patients who undergo RT and experience acute rectal side effects, a higher incidence of late rectal toxicity has been observed.[301,302]

The NRG Oncology/RTOG 0126 randomized clinical trial randomized 1,532 patients from 104 North American RTOG institutions. Men with stage cT1b to T2b, GS 2 to 6, and PSA level of 10 or greater and less than 20 or GS of 7 and PSA less than 15 received 3DCRT or IMRT to 79.2 Gy in 44 fractions or 70.2 Gy in 39 fractions. The 5-year rates of late grade 2 or greater GI and/or GU toxic effects were 21% and 12% with 79.2 Gy and 15% and 7% with 70.2 Gy (P = .006 and P = .003, respectively).[303] Erectile dysfunction at 12 months based on the single question was not significantly different between the 70.2 Gy arm (38.1%) versus the 79.2 Gy arm (49.7%). The treatment arm (70.2 vs 79.2) had no significant impact on any patient-reported outcome metrics measured across all collected domains.[304]

Michalski et al published a report on the toxicity outcomes of various risk groups enrolled in RTOG 9406, a phase I/II dose escalation study. The dose for level I was 68.4 Gy, 73.8 Gy for level II, 79.2 Gy for level III, 74 Gy for level IV, and 78 Gy for level V. Disease group I patients were treated to the prostate only; group 2 patients were treated to the prostate and the SVs with a prostate boost, and group 3 patients were treated to the prostate and SVs. The median follow-up period for surviving patients was 6.1 years for 68.4 Gy to 12.1 years for 78 Gy. The incidence rates of RTOG grade 3 or less GI or GU toxicity were 3%, 4%, 6%, 7%, and 9% in group 1 and 6%, 2%, 6%, 9%, and 12% in group 2 at dose levels of I, II, III, IV, and V, respectively. There was significantly more grade 2 or greater toxicity with a dose of 78 Gy at 2 Gy/fraction than with 68.4 to 79.2 Gy at 1.8 Gy/fraction and 74 Gy at 2 Gy/fraction.[305]

Storey et al reported late rectal toxicity among patients treated in the phase III trial from the MD Anderson Hospital. The 5-year Kaplan-Meier risks of late grade 2 or higher rectal and bladder toxicity for the 70- and 78-Gy dose level arms were 14% and 21%, and 20% and 9%, respectively. The 5-year risks of grade 2 or higher late bladder toxicity were 20% and 9% for the 70 and 78-Gy groups, respectively.[306]

Zelefsky et al[307] reported the long-term tolerance of high-dose CRT at MSKCC. The 10-year actuarial rate of grade 2 or higher rectal toxicity was 9%. The use of IMRT significantly lowered the risk of grade 2 and higher toxicities from 13% to 5% (P < .001). This decline in rectal toxicity was observed despite the application of higher doses of 81 Gy with IMRT compared to generally lower doses used with 3DCRT of 75.6 Gy (Figure

72.10). In addition, patients who experienced acute GI (AGI) side effects during treatment were 6 times more likely to experience late GI (LGI) toxicities than patients who did not experience such acute side effects (42% vs 9%; $P < .001$). The 10-year incidence of grade 2 or higher late urinary toxicities was 15%, and the predictors for late toxicity included higher radiation doses and the presence of acute urinary symptoms during EBRT. The 10-year actuarial incidence of grade 2 and 3 GI toxicities was 2% and 1%, respectively. The 10-year actuarial incidence of grade 2 and higher urinary-related toxicities was 17%.[308]

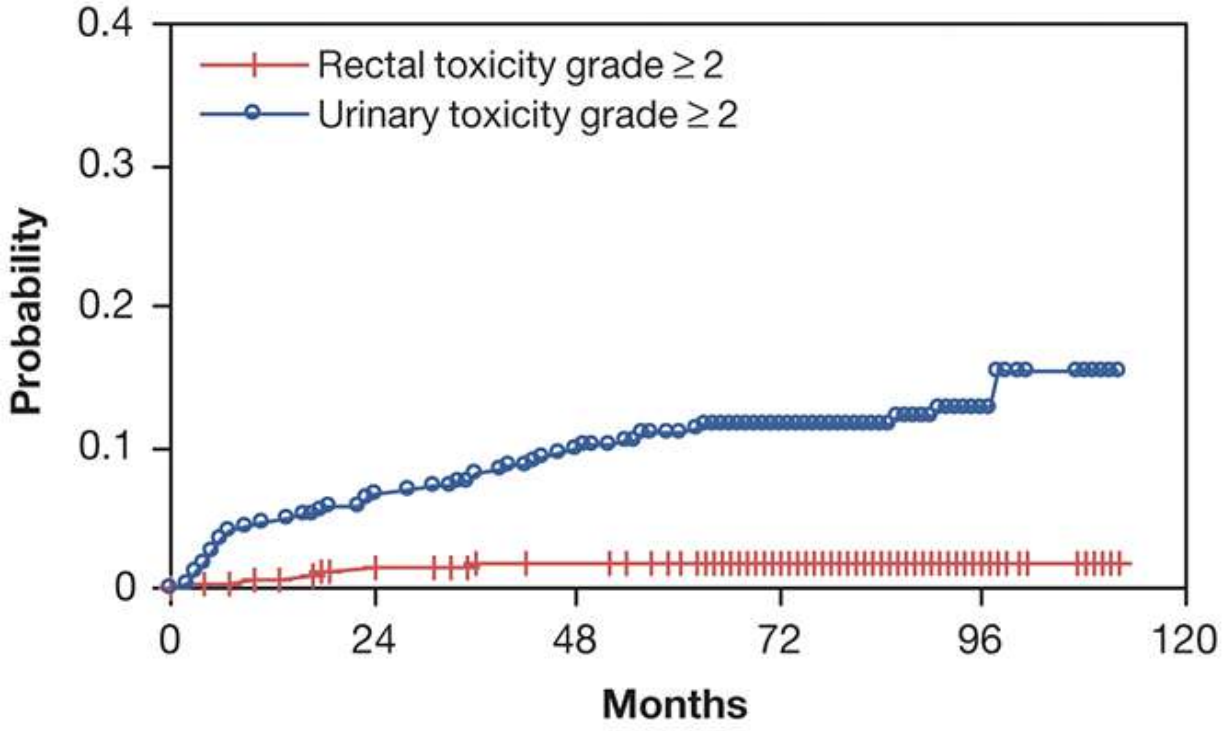

FIGURE 72.10 Actuarial likelihood of late grade 2 or greater rectal toxicities or late grade 2 or greater rectal toxicities. Long-term outcome of high dose intensity modulated radiation therapy for patients with clinically localized prostate cancer. *J Urol*. 2006;176[4 Pt 1]:1415-1419. Copyright © 2006 by American Urological Association.)

Peeters et al described the incidence of acute and late complications in a multicenter randomized trial comparing 68- to 78-Gy 3DCRT.[309] The median follow-up was 31 months. The 3-year incidence of grade 2 and higher GI and GU toxicities for the 68-Gy dose arm was 23.2% and 28.5%, respectively. The 3-year incidence of grade 2 and higher GI and GU toxicities for the 78-

Gy dose arm was 26.5% and 30.2%, respectively. The differences were not statistically significant. However, the authors did note a significant increase in grade 3 rectal toxicity requiring laser treatment or transfusion for the higher dose arm.

Quantitative Analyses of Normal Tissue Effects in the Clinic (QUANTEC) recommended the following rectal dose-volume constraints as a conservative starting point for 3D treatment planning: V_{50} less than 50%, V_{60} less than 35%, V_{65} less than 25%, V_{70} less than 20%, and V_{75} less than 15%. Contemporary protocols like NRG GU010 have stricter dose constraints for V_{75} less than 10% and add V_{80} less than 5%.[310] For typical DVHs, the normal tissue complication probability models predict that following these constraints should limit grade 2 or higher late rectal toxicity to less than 15% and the probability of grade 3 or higher late rectal toxicity to less than 10% for prescriptions up to 79.2 Gy in standard 1.8 to 2 Gy fractions.[311] The QUANTEC recommended bladder dose constraints are V_{65} less than 50%, V_{70} less than 35%, V_{75} less than 25%, and V_{80} less than 5%.[312] Contemporary protocols like NRG GU010 have stricter bladder dose constraints: V_{50} less than 0%, V_{65} less than 40%, V_{70} less than 35%, V_{75} less than 20%, and V_{80} less than 10%.[310]

Potency Preservation With External Beam Radiation Therapy

The rates of erectile dysfunction after EBRT ranged from 6% to 84%.[313] The wide range of outcomes reflects the varying assessment tools used and disparity in the patient population, with heterogeneity of comorbidities, ages, and baseline functional status. Most studies show a progressive decline in erectile function with longer follow-ups, consistent with what is observed in an aging population with coexisting comorbidities such as hypertension, atherosclerotic heart disease, and diabetes. In one report comparing erectile function between patients who received 68 versus 78 Gy,[314] no differences were observed between the different dose levels. Overall, in the studied cohort, the incidence of erectile dysfunction at 1 and 2 years after therapy was 27% and 36%, respectively. Aside from erectile dysfunction, other aspects of sexual dysfunction after RT include decreased volume of ejaculate, absence of ejaculate, decreased intensity of orgasm, and decreased

libido. A summary of reported potency rates after treatment is shown in Table 72.11.

TABLE 72.11 INCIDENCE OF ERECTILE DYSFUNCTION AFTER RADIATION THERAPY FOR PROSTATE CANCER

Study	Treatment	Follow-Up (Months)	Pre-RT Potency (No ED)	Post-RT Potency (No ED)
Chen et al[315]	IMRT	24	100%	73%
Hoffman et al[316]	IMRT	60	78%	50%
Friedland et al[317]	SBRT	24	100%	82%
Chen et al[318]	SBRT	28	100%	79%
Obayomi-Davies et al[319]	SBRT	24	100%	54%
Nobes et al[320]	LDR	24	100%	62%
Solan et al[321]	LDR	26	100%	77%
Taira et al[322]	LDR	84	100%	56%

ED, erectile dysfunction; IMRT, intensity-modulated radiotherapy; LDR, low dose rate brachytherapy; SBRT, stereotactic body radiotherapy.

Significant limitations exist with the aforementioned reported potency preservation rates because the data are derived from retrospective analyses and information was often obtained without the use of validated questionnaires. Prospective studies suggest that when patients are assessed with validated tools, erectile dysfunction—defined as the inability to achieve adequate erection sufficient for sexual intercourse—reaches 60% to 70%. What also complicates the interpretation of published incidence rates is the multifactorial nature of erectile dysfunction. The factors that impact erectile function include age, presence of medical comorbidities such as cardiac disease and diabetes, antihypertensive medications, baseline erectile function, and the use of neoadjuvant and concurrent hormonal therapy. Pinkawa et al observed that the presence of spontaneous erection in the

evening or morning before treatment was a strong predictor for maintaining erectile function after RT.[323] The QUANTEC recommended penile bulb dose constraints are a mean dose to 95% of the penile bulb volume to less than 50 Gy, D_{70} less than 70 Gy, and D_{90} less than 50 Gy. It is acknowledged that the penile bulb may not be the critical component of the erectile apparatus, but it seems to be a surrogate for yet to be determined structure(s) essential for erectile function for at least some techniques.[324]

Brachytherapy: Acute and Late Toxicity

Urinary Toxicity

Low-Dose Rate Brachytherapy

The most common urinary toxicities after LDR-BT within the first 3 years include the following grade 1 to 2 toxicities: dysuria (7%-13%), weak stream (8%-49%), frequency (7%-62%), urgency (7%-20%), hematuria (0%-14%), incontinence (,0.5%-8.9%), and acute urinary retention (2%-34%). Rare urinary complications following LDR-BT include urinary infection 3%, late urinary retention (0.6%-6%), urethral stricture grade 3+ (1%-9%), and vesicourethral fistula less than 0.2%.[325] BT monotherapy is associated with transient urinary irritative symptoms that peak within the first 3 months of treatment and tend to resolve toward baseline at 1 year for I-125 and 6 months for Pd-103.[267]

Management of irritative/obstructive symptoms may consist of α-1 adrenoceptor antagonists and anticholinergics, NSAIDs, and dietary modification to reduce the consumption of bladder irritants such as caffeine and alcohol. The best evidence is for α-adrenergic medications. Two RCTs compared an α-adrenergic blocker to no further therapy. In one trial of 118 patients, 2 months of tamsulosin 0.8 mg daily resulted in a significant improvement in the American Urological Association score at 5 weeks compared to placebo.[326] Another randomized trial involving 105 patients showed that adding silodosin 8 mg daily for 6 months improved International Prostate Symptom Score at 1, 3, and 6, but not at 12 months.[327] Acute urinary retention may require a temporary Foley catheter. Urethral strictures may require endoscopic urethral dilation. A fistula could be managed with conservative treatment with urinary diversion or surgical treatment.

Recommended metrics for preimplant and postimplant I-125 dosimetry (day 0-60) for the urethra are D_5 less than 150%.[267]

High-Dose Rate Brachytherapy

A systematic review of HDR-fractionated BT monotherapy for localized PCa identified 7 studies and 2,123 patients. Low-, intermediate-, and high-risk patients constituted 40%, 40%, and 20% of patients, respectively. The estimated adjusted late grade 3 or higher GU was 2%.[294] Grade 2 or higher CTCAE GU toxicity ranges from 0 to 25%.[328]

For a 13.5 Gy × 2 monotherapy HDR implant, Washington University in Saint Louis uses the following dose constraints: urethra: V_{125} less than 1 mL, D_{max} less than 150%; and bladder: V_{75} less than 1 mL, D_{max} less than 150%. The American Brachytherapy Society consensus guidelines for HDR-BT list additional dose constraints used at other institutions.[329]

Rectal Tolerance

Low-Dose Rate Brachytherapy

Acute LDR-BT bowel toxicity includes urgency/frequency (3%-11%), incontinence (1%-4%), grade 1 rectal bleeding (1%-30%), radiation proctitis grade 2+ (0.5%-6%), and rectal pain (1%-5%). Late rectal toxicity grade 3+ includes rectal ulcer (0.1%-0.3%) and rectal fistula, with rectourethral the most reported (,0.5%).[325]

Rectal ulcers may require conservative medical management, colostomy, and/or hyperbaric oxygen. Biopsies should be avoided to prevent progression into a fistula. Rectal fistulas may require conservative treatment with urine diversion, colostomy, hyperbaric oxygen, and/or surgical management.

Recommended metrics for preimplant I-125, Pd-103, and Cs-131 dosimetry (days 0-60) for the rectum are RV_{100} less than 1 mL, RV_{100} less than 1 mL, and RV_{100} less than 0.5 mL. Acceptable postimplant dosimetry is as follows: RV_{100} less than 1 mL for I-125/Pd-103, and RV_{100} less than 0.5 mL for Cs-131.[267]

High-Dose Rate Brachytherapy

The same systematic review of 2,123 patients treated with HDR-fractionated BT monotherapy for localized PCa and estimated adjusted late grade 3 or higher GI toxicity rate at 0.3%.[294] Grade 2 or higher CTCAE GI toxicity ranges from 0% to 6%.[328]

For a 13.5 Gy × 2 monotherapy HDR implant, Washington University in Saint Louis uses the following rectal dose constraints: V_{75} less than 1 mL, D_{max} less than 150%. The American Brachytherapy Society consensus guidelines for HDR-BT list additional dose constraints used at other institutions.[321]

Erectile Function

Low-Dose Rate Brachytherapy

Erectile dysfunction after LDR-BT can range between 19% and 50%.[325] Erectile dysfunction is often managed with phosphodiesterase type 5 inhibitors. Dutasteride and bicalutamide, when used for cytoreduction, allow for improved sexual function preservation compared with LHRH agonists.[267] Even though no prospective randomized trials compare LDR and HDR monotherapy, nonrandomized evaluations have suggested that potency impairment is less frequent after HDR than LDR treatment. Martinez et al carried out a comprehensive toxicity comparison between 248 HDR and 206 LDR monotherapy patients, documenting a 5-year potency preservation rate of 80% for HDR and 70% for LDR.[330]

High-Dose Rate Brachytherapy

Potency preservation rates of 60% to 90% have been documented.[328] Although no prospective randomized trials compare LDR and HDR monotherapy, nonrandomized evaluations have suggested that potency impairment is less frequent after HDR than LDR treatment. Martinez et al carried out a comprehensive toxicity comparison between 248 HDR and 206 LDR monotherapy patients, documenting a 5-year potency preservation rate of 80% for HDR and 70% for LDR.[330]

POSTIRRADIATION PROSTATE-SPECIFIC ANTIGEN

A transient increase in PSA during RT, even as soon as the first fraction, has been reported in some patients.[331,332] Because there is no prognostic

significance to the PSA response during a course of RT, obtaining PSA levels during treatment is not necessary or recommended. PSA fluctuations are common in the follow-up period and have been termed *PSA bounce*. In one report,[333] 35% of patients after combined permanent interstitial implantation and EBRT experienced a transient rise in their PSA value after treatment. The median time from treatment to this bounce effect was 18 months, and 92% of the fluctuating levels were observed during the first 26 months after RT. These investigators reported fluctuations ranging from 0.11 to 15.8 ng/mL. Similar results have been reported by Cavanagh et al[334] for patients treated with implantation alone or when combined with EBRT. Hanlon et al[335] observed a PSA bounce effect in approximately one-third of patients treated with EBRT alone. In that series, the 5-year biochemical control rate for patients who experienced a PSA fluctuation was inferior to that in those patients who did not have a PSA bounce in their follow-up period (69% vs 52%; $P = .02$). On the other hand, investigators from the MD Anderson Hospital[336] noted that, of 964 patients treated with EBRT, only 12% experienced a PSA bounce, and the 5-year PSA outcome was superior for those patients who experienced this PSA fluctuation compared with those who did not (82% vs 58%; $P = .0001$).

Ciezki et al[337] defined PSA bounce as an increased PSA level of at least 0.2 ng/mL greater than the nadir PSA with a subsequent PSA value declining back to the nadir level or lower. One hundred sixty-two patients were treated with a permanent ^{125}I implantation and followed for a minimum of 5 years. With this as the definition of a PSA bounce, almost half of the patients (46%) experienced this phenomenon. The authors observed that the patients who experienced this fluctuation were more likely to be younger and less likely to develop a biochemical relapse. The authors also noted that PSA bounces generally occurred much sooner after treatment than did a true PSA relapse. The median time to the first rise in PSA from the nadir was 15 months, compared with 30 months for an ASTRO-defined biochemical relapse or 22 months for a nadir +2-defined relapse. Other reports define PSA bounce in various ways, and for this reason, the literature needs to be interpreted with caution.[338]

Although a low absolute PSA level or nadir value after RT has prognostic significance for improved DFS, it is difficult to assign a specific PSA cut-point or nadir level as a definition of biochemical relapse. Currently, the

nadir +2 definition (a rise by ≥2 ng/mL above the nadir PSA) is considered the standard definition for biochemical failure after EBRT with or without hormonal therapy. A consensus panel[339] also recommended that the date of failure be determined "at call" (not backdated). Several studies examined the significance of post-treatment PSA doubling time (PSADT). Following prostatectomy, in a single-institution experience, Pound et al[340] noted that, for patients treated with RP, PSADT of less than 10 months predicted the development of metastatic disease. Zelefsky et al[341] reported on the impact of PSADT in a cohort of patients who developed biochemical relapse after EBRT. The PSADT for favorable-, intermediate-, and unfavorable-risk patients who developed a biochemical failure was 20.0, 13.2, and 8.2 months, respectively ($P < .001$). The 3-year incidence of DM for patients with PSADT of 0 to 3, 3 to 6, 6 to 12, and greater than 12 months was 49%, 41%, 20%, and 7%, respectively ($P < .001$). Patients with PSADT of 0 to 3 and 3 to 6 months demonstrated a 7.0 and 6.6 increased hazard of developing DMs or death, respectively, compared with patients with a doubling time of greater than 12 months. Freedland et al[342] noted that PSADT of less than 9 months correlated with PCa-specific mortality but did not evaluate postprostatectomy PSADT as a surrogate for cause-specific survival. Using larger, multi-institutional databases, Albertsen et al[141] and D'Amico et al[343] noted that short PSADT correlated with an adverse effect on survival in patients treated with either prostatectomy or RT for PCa.

To date, data strongly correlate a rising PSA level with positive postirradiation prostate biopsies. Crook et al[344] reported on 226 patients treated with conventional EBRT who underwent serial biopsies after treatment. At 13 months after RT, the incidence of a positive biopsy was 51%, but it decreased to 30% for biopsies obtained at 30 months. Post-treatment biopsies require an experienced pathologist to interpret because of the significant radiation effect that takes place in the prostate, which can easily be mistaken at times for residual disease. Immunohistochemical staining for high-molecular-weight keratin can often distinguish radiation atypia in benign glands from residual tumor.

Proton/Heavy Ion Particle Therapy

Proton beam therapy (PBT) and carbon ion radiotherapy (CIRT) offer unique biologic and physical advantages over conventional RT with x-rays. Carbon

ion beams have an estimated 3-fold higher relative biologic effectiveness (RBE) than x-rays.[345] CIRT and PBT can create a better dose distribution based on the ability of accelerated ions to release a maximum amount of energy at the end of their track, resulting in a Bragg peak.[346] These features permit dose escalation for tumors with less toxicity in normal tissues. In the absence of randomized trials comparing efficacy and toxicity to high-dose photon therapy, no cogent evidence supports its superiority over other forms of EBRT.

Five-year outcomes from three prospective trials of image- guided proton therapy for PCa included a total of 211 patients with PCa (89 low risk, 82 intermediate risk, and 40 high risk). Treatment consisted of 88 cobalt gray equivalent (CGE) in 39 fractions for low-risk disease, 78 to 82 CGE for intermediate- risk disease, and 78 CGE with concomitant docetaxel therapy, followed by ADT for high-risk disease. Five-year rates of biochemical and clinical freedom from disease progression were 99%, 99%, and 76% in low-, intermediate-, and high-risk patients, respectively. Actuarial 5-year rates of late CTCAE, version 3.0 (or version 4.0) grade 3 GI and urologic toxicity were 1.0% (0.5%) and 5.4% (1.0%), respectively.[347]

Five-year outcomes from a prospective trial of image-guided accelerated hypofractionated proton therapy for PCa included 215 patients with PCa receiving 70 Gy (RBE) in 28 fractions for low-risk disease (n = 120) and 72.5 Gy (RBE) in 29 fractions for intermediate-risk disease (n = 95). Five-year rates of freedom from biochemical and clinical disease progression were 95.9%, 98.3%, and 92.7% in the overall group and the low- and intermediate-risk subsets, respectively. Actuarial 5-year rates of late radiation-related CTCAE v3.0 grade 3 or higher GI and urologic toxicities were 0.5% and 1.7%, respectively.[348]

Five-year outcomes from 284 patients treated with an ultrahypofractionated intensity-modulated proton therapy (IMPT) schedule (36.25 GyE in five fractions) included 121 low-risk, 125 favorable, and 33 unfavorable intermediate-risk patients with PCa. The 5-year bDFS was 96.9%, 91.7%, and 83.5% for the low-, favorable, and unfavorable intermediate-risk groups, respectively. Late toxicity CTCAE v.4 was as follows: GI: grade 1, 62 (22%) patients, grade 2, 20 (7.2%) patients, and grade 3, 1 (0.36%) patient; GU: grade 1, 80 (28.7%) patients, grade 2, 14 (5%) patients, and grade 3, 0 patients.[349]

The Prostate Advanced Radiation Technologies Investigating Quality of Life study is a multi-institutional phase III randomized clinical trial of proton therapy versus IMRT for low- or intermediate-risk PCa. The hypothesis is that proton therapy will improve patient-reported outcomes for a given radiation dose. The trial has enrolled 454 patients. Results are pending.

A Prospective Comparative Study of Outcomes with Proton and Photon Radiation in Prostate Cancer is a large, prospective, pragmatic, controlled comparison of patient-centric outcomes (QoL, toxicity, and disease control) between parallel cohorts of men with PCa treated simultaneously at proton therapy facilities and at geographically similar conventional (photon-based) radiation facilities using IMRT techniques. The study completed enrollment on October 31, 2022, after enrolling 2,524 patients over 4 years. Results are pending.

The evidence suggests that proton therapy is a safe and effective treatment option for low-risk PCa, offering comparable efficacy to traditional therapies with potentially fewer side effects. However, cost-effectiveness remains a consideration. The ongoing clinical trials and future research are expected to provide more definitive data on the role of proton therapy in PCa treatment.

Carbon ion therapy is currently offered in five countries: Japan, Germany, China, Italy, and Austria. A systematic review and meta-analysis comparing the clinical efficacy and safety of PBT and CIRT for PCa included 13 CIRT- and 20 PBT-related publications involving 54,101 participants. The quality of the studies was either low or moderate. Random model single-arm meta-analysis showed that both the CIRT and PBT have favorable efficacy and safety, with similar 5-year OS (94% vs 92%), the incidence of grade 2 or greater acute genitourinary (AGU) toxicity (5% vs 13%), late genitourinary (LGU) toxicity (4% vs 5%), AGI toxicity (1% vs 1%), and LGI toxicity (2% vs 4%). However, compared with CIRT and PBT, photon RT was associated with lower 5-year OS (72%-73%) and a higher incidence of grade 2 or greater AGU (28%-29%), LGU (13%-14%), AGI (14%-19%), and LGI toxicity (8%-10%). The meta-analysis showed the 3-, 4-, and 5-year local control rate of CIRT for PCa was 98%, 97%, and 99%, respectively; the 3-, 4-, 5-, and 8-year biochemical relapse-free rate was 92%, 91%, 89%, and 79%, respectively. Given that the quantity and quality of the available evidence are insufficient, more high-quality controlled studies are needed in

the future. The need for more CIRT high-quality controlled studies is evident to strengthen the evidence base, especially in the context of low-risk PCa.

Focal Ablative Therapies

As the trend for low-risk PCa has been to minimize the toxicity of treatment through AS, there has also been an increased interest in focal therapies, those which are targeted to PCa but do not treat the whole prostate gland. The rationale for such focal therapies is to provide therapeutic effect on the known cancer while limiting injury to normal tissues, such as bladder, rectum, and peripheral nerves.

The two approaches to focal therapy are cryoablation and high-intensity focal ultrasound (HIFU). Cryotherapy was initially developed in the 1960s and for many years has been used as a salvage treatment for post-RT local recurrence.

HIFU was developed in the 1990s first as a partial gland tumor–targeted therapy, and more recently as a "whole gland" therapy, although care is taken to avoid the urethra, bladder neck, and neurovascular bundles.

A systematic review and meta-analysis was performed in 2023, including both retrospective and prospective studies of at least 50 patients and follow-up of at least 5 years.[350] The meta-analysis pooled 29 studies, with 52% of patients having a GS of 6 or less and 32% with a GS of 7. Pooled BRFS rate (most using the Phoenix definition of BCR) for both cryoablation and HIFU was 69% at 5 years and 58% at 10 years. HIFU had somewhat better oncologic outcomes, with a 5-year BRFS of 73% compared to 64% for cryotherapy. When the cohort was evaluated by risk classification, 5-year BRFS ranged from 66% to 89%.

The review noted that complications were not always reported. However, in studies that reported urinary toxicity, rates of stricture, urinary retention, and rectourethral fistulae were 11%, 10%, and 0.7%, respectively. Erectile function was preserved in 37% of patients potent prior to ablation. HIFU studies overall reported better erectile preservation (46% vs 23% with cryoablation).

MRI guidance has also been applied to focal therapy. Ghai et al[351] reported the 6-month follow-up of a phase 1 trial of four patients treated with focal transrectal MRI-guided focused ultrasound in North America. The patients had PSA level of 10 ng/mL or less, tumor stage cT2a or less, and a GS of 6

(3 + 3). Under MRI guidance and real-time monitoring with MR thermography, focused high-frequency ultrasound energy was delivered to ablate the target tissue. MRI and repeat transrectal ultrasound-guided biopsy were performed 6 months after treatment. All four patients had normal MRI findings in the treated regions (100%); biopsy showed that three patients (75%) were clear of disease in the treated regions, representing complete ablation of five target lesions (83%). It was concluded that MRI-guided focused ultrasound is a feasible method of noninvasively ablating low-risk PCas with low morbidity.

Overall, focal therapy data have not yet matured, and there are minimal randomized comparisons to definitive curative intent options such as RP, EBRT, or BT. While these therapies continue to improve with better targeting technology, the excellent treatment options that already exist for low-risk PCa and which provide very high recurrence-free survival rates with low toxicity burden create a high bar for focal therapy to achieve.

CHAPTER 73

Management of Intermediate- and High-Risk Prostate Cancer

Quaovi H. Sodji and Mack Roach III

The management of clinically localized prostate cancer has changed considerably over the past 10 years. Fewer men are being treated for low-risk disease (eg, prostate-specific antigen [PSA] ,10 ng/mL, Gleason score [GS] ,7, and T-stage ,T2b), as more frequently, such men are being managed by active surveillance (AS).[1] Consequently, a higher percentage of men diagnosed with prostate cancer are now being treated with what is categorized as "intermediate-" (IR) to "high"-risk (HR) disease.[2] Concurrent with these developments, there has been a resurgence in enthusiasm among urologists for recommending radical prostatectomy (RP) as the treatment of choice for men with HR and locally advanced disease.[3,4] This trend appears to be in part fueled by the plethora of post hoc retrospective studies.[5-7] This practice is not supported, however, by other recent studies that attempt to account for the "quality of care delivered," defined as treatment delivered in compliance with national consensus guidelines nor is it supported by the findings from contemporary phase III randomized trials.[2,8-13] This chapter was written in an attempt to bring clarity to the controversies surrounding the management of patients currently considered to have IR and HR disease. We focus on the radiation-based therapeutic options and the evidence behind our recommendations. Since the last edition, a number of advances have been made in the technical delivery of radiation for prostate cancer, and some have now been established as "standard of care." Details on the management of low-risk prostate cancer can be found elsewhere in the textbook.

CLINICAL PRESENTATION

Patients with IR or HR prostate cancer *may* present with locoregional symptoms, but this is not common (although it appears to have increased after PSA screening declined). Lower urinary tract symptoms, when seen, may include nocturia, urinary frequency, urgency, decreased flow, incomplete voiding, intermittent flow, hesitancy, and, occasionally, erectile dysfunction (ED) and/or bloody ejaculations. Rarely, patients with bulky primary disease may present with urinary tract obstruction or difficulty in passing stool or even bloody stool. When patients do present with obstruction, aggressive local regional radiation including stereotactic body radiotherapy (SBRT) may be very effective at relieving this obstruction.[14] With increasing PSA and GS, the risk of metastases increases. Metastatic spread is generally sequential, proceeding from the prostate to the periprostatic pelvic lymph nodes, but some metastases appear to spread directly to the common iliac nodes and then to bone. Rarely, patients may present with renal failure, lymphedema of the lower extremities, and bone pain.

DEFINITIONS OF INTERMEDIATE- AND HIGH-RISK DISEASE

Risk Stratification Groups

Three prognostic factors have traditionally been used to define IR and HR patients: (a) clinical T-stage (generally based on palpation [although imaging when compelling is frequently included]), (b) the pretreatment PSA, and (c) the biopsy GS. To simplify treatment recommendations and prognostication, several risk classification schemes have been proposed by grouping patients who are thought to have similar biochemical and/or clinical outcomes.[15-18] Low risk is defined as meeting all the criteria: T1c to T2a, PSA less than 10 ng/mL, and GS 6 or less. Intermediate risk (IR) is defined as T2b to T2c, PSA 10 to 20 ng/mL, or GS = 7. HR prostate cancer is any of the following: T3a or higher, PSA greater than 20 ng/mL, or GS 8 to 10.[19] This system represents a modification of the system proposed by D'Amico et al,[20] and given the widespread acceptance of this system, for practical purposes, the readers should assume that we are referring to this classification system throughout this chapter.

Limitations of Risk Group Classifications, Age, and Biomarkers

Perhaps the greatest misunderstanding in using the risk groups based on PSA, GS, and T-stage is the implied assumption that each of these factors is roughly equally important. For example, a patient can be considered IR if either the clinical stage is T2b, PSA 10 to 20, *or* GS of 7. However, the clinical T-stage is relatively subjective with a high degree of interobserver variability. Pretreatment PSA appears to be a strong predictor of biochemical (PSA) recurrence, but a relatively weak predictor of cause-specific survival (CSS) and GS is the most powerful predictor of CSS, followed in importance by T-stage.[21] This has major implications for post hoc comparisons of the results of treatment wherein the distribution of these factors cannot be adequately controlled for. Of note, somewhat paradoxically, very high PSAs are not as important as most people think and very low PSAs can be associated with a worse prognosis.[22,23] Despite the clear importance of GS, it is important to understand the exceptions to the rule. At one extreme, patients whose GS = 3 + 4 but only 5% grade 4 behave more like a 3 + 3.[24] At the other end of the spectrum are patients with focal high grade (eg, GS = 4 + 4) who behave more like a GS = 7.[25-27]

Another major limitation of the risk groups most used is their dependence on biochemical failure (BF) or PSA relapse after radiation therapy (RT). In 2005, the Radiation Therapy Oncology Group (RTOG) and American Society for Radiation Oncology (ASTRO) co-sponsored a conference in 2005 in Phoenix, Arizona, and developed a revised definition for BF, now known as the "Phoenix definition" (to distinguish it from an earlier definition).[28] PSA relapse was defined as a rise of 2 ng/mL or more above the absolute PSA nadir. This definition was considered applicable only to patients treated with external beam radiation therapy (EBRT) with or without short-term androgen deprivation therapy (ADT). The date of failure is taken at the time of meeting the definition (ie, not backdated). Any salvage therapy initiated prior to meeting the criteria should also be declared as a failure. With the Phoenix definition, sensitivity and specificity are 64% and 78%, respectively. This definition to date continues to be considered the standard definition for BF but should *not* be used to determine cure rates (eg, compared to RP) nor should PSAs that are consistently rising be ignored in men who could potentially benefit from salvage therapies.[28-30]

In addition to the T-stage, GS, and PSA, other factors are known to impact outcomes. More than 20 years ago, a number of studies showed that the number and/or percentage of biopsy cores positive for prostate cancer (PPC) impacted the outcomes of patients treated definitively by RP or EBRT.[31,32] For example, status post-RP, those patients with less than 34% PPC had similar outcomes as low-risk patients (5-year PSA control 85% vs 91%), whereas patients with more than 50% PPC had similar outcomes as HR patients (5-year PSA control 30% vs 43%). The prognostic significance of PPC has also been reported to extend to prostate cancer–specific mortality (PCSM) in IR patients such that when stratified by 50% or less and more than 50% PPC, 7-year prostate cancer–specific survival was 100% versus 57% ($P = .004$).

In addition to the percentage of positive biopsies, an analysis of RTOG data demonstrated that older age (.70) was associated with a reduced risk of PCSM and metastases, after adjusting for the expected increased risk of non-PCSM in this subgroup.[33] This observation was recently extended and supported by a systematic review.[34] In this systematic review, Shaheen et al showed that for men older than 70 ± 5 years treated for prostate cancer with RT with or without ADT, age is a favorable prognostic factor, but for patients treated with RP, age is an adverse factor. For example, in patients undergoing RP when adjusted for other factors, older age is associated with a more advanced pathologic stage. Thus, older men treated with RT should also be expected to do worse, due to the more advanced stage. The more favorable outcome seen in association with RT suggests that the radiobiology of prostate cancer may be different in older men.

In this era of personalized medicine, biomarkers have become increasingly important. However, confusion exists surrounding the distinction between predictive and prognostic biomarkers. A predictive biomarker offers insights into improving outcomes, by enabling the determination of treatment responses between biomarker-positive and biomarker-negative patients.[35] Whereas a prognostic biomarker provides information about disease outcomes in patients, irrespective of any therapeutic interventions.[35] There have been a number of unsuccessful attempts to incorporate biomarkers as prognostic and/or predictors of response to RT with or without ADT-based treatments.[36-42] More recently,

however, a number of studies have demonstrated that some biomarkers can offer prognostic insight.

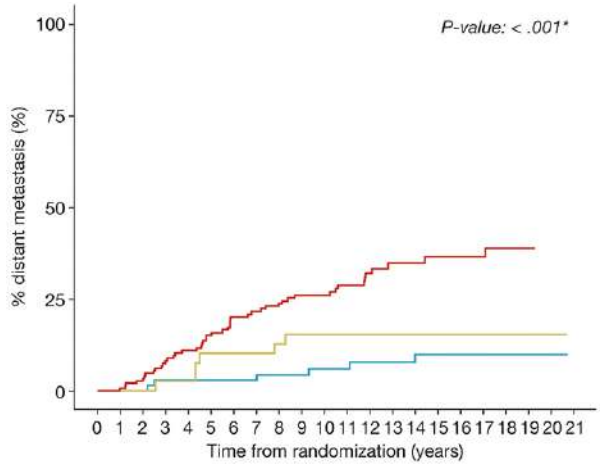
Tissue-Based Molecular Biomarkers

Among the rigorously validated risk stratification assays, at least three rely on multigene analysis (Decipher, Oncotype Dx Prostate, and Prolaris), whereas ProMark is founded on protein analysis.[43]

Prolaris uses reverse transcriptase polymerase chain reaction (RT-PCR) to determine the expression of 31 genes associated with cell cycle progression (CCP) and 15 housekeeping genes in tumor samples obtained from RP, biopsy, and transurethral resection of the prostate (TURP). The ensuing analysis generates the CCP score aimed at evaluating disease aggressiveness, which has the potential to predict clinical outcomes. Retrospective analyses have demonstrated that the CCP score can predict biochemical recurrence (BCR) following RP, and with patients whose disease was diagnosed after a TURP, it was useful in predicting the time to death from prostate cancer.[44] In a cohort with localized prostate cancer managed conservatively, the CCP score obtained on biopsy specimens was predictive of the 10-year risk of prostate cancer death.[45] Furthermore, in a pooled analysis of 1,062 patients with localized prostate cancer treated with either RP or RT, the CCP score showed a correlation with the 10-year risk of metastasis, indicating its utility as a risk stratification tool.[46]

Decipher generates a score ranging from 0 to 1.0 by analyzing the expression of 22 genes in samples collected from either a prostate biopsy or RP. These 22 genes are involved in diverse cellular processes, including cell proliferation, differentiation, adhesion, motility, CCP, and immune response.[47] When analyzing a biopsy specimen, the Decipher score can classify a patient into either HR, IR, or low-risk group, informing decisions about treatment or surveillance.[48] In the postprostatectomy setting, this score, which correlates with adverse pathology, has been proposed as a guide to the selection of therapeutic interventions, including adjuvant versus salvage therapy or no treatment.[48] Genomic classifier groups were initially selected and validated using retrospective cohorts composed of RP specimens and pretreatment biopsy samples, and further validated using prospective patient cohorts.[48] Analysis of a retrospective cohort of patients

who underwent RP revealed relatively small differences in the cumulative incidence of metastasis and PCSM between the low-risk group and the favorable IR group, or between the unfavorable IR and HR/very HR groups. However, using the clinical genomic risk system, statistically significant differences in outcomes, including the cumulative incidence of metastasis and PCSM, were observed between the low, intermediate, and high tiers.[48] The use of the Decipher-based clinical genomic classification appears to improve our ability to accurately identify prognostic subgroups and potentially improve our ability to make more logical therapeutic recommendations for patients. For instance, data by Spratt et al demonstrated that 15% of patients initially said to have a low-risk disease, for whom AS could have been considered, would be reclassified as IR based on the clinical genomic risk system and, as such, may not have been suitable for AS. Conversely, up to 56% of those patients classified as favorable IR group could be reclassified into the low-risk group based on the clinical genomic risk grouping system, potentially qualifying them for AS.[48] While early efforts to validate biomarkers were relatively unfruitful, genomic classifiers have been shown to be highly prognostic in patients treated with definitive EBRT, based on patients treated on multiple phase III randomized trials conducted by the NRG (Figure 73.1).[37,49] Even more recently, this genomic classifier has been shown to be predictive of the benefits of dose escalation in patients with IR prostate cancer (Figure 73.2).[50]



High	150	103	47	13

The Oncotype Dx Prostate Cancer Assay employs RT-PCR to assess the expression of 5 reference genes and 12 cancer-related genes on biopsy samples. These cancer-related genes are implicated in various pathways, such as androgen pathway, stroma response, cell proliferation, and organization. From these gene analyses, the Genomic Prostate Score (GPS), ranging from 0 to 100, is derived.[51] The Oncotype Dx Prostate Cancer Assay has been validated in biopsy specimens and demonstrated its ability to predict the likelihood of high-grade disease and adverse pathologic features, including extracapsular extension (ECE) and seminal vesicle invasion (SVI) after RP.[51,52] A primary objective of the GPS is to aid therapeutic decisions in patients diagnosed with low-risk or low-IR prostate cancer.[53] Indeed, analysis of oncologic practices has shown that the use of the GPS led to an increase in recommendation for AS in cohorts with very low- and low-risk prostate cancer.[54] While the GPS has been validated for predicting adverse pathologic features after RP, emerging evidence suggests

that it may also independently prognosticate clinical outcomes, including time to BF, distant metastasis (DM), and prostate cancer–related mortality after EBRT.[55] However, further validation through prospective studies is still warranted.

ProMark is a proteomic assay based on the expression of eight proteins detected using immunofluorescence in tumor specimens. These proteins are involved in various cellular processes, including proliferation, differentiation, survival, and metabolism.[56,57] Through the analysis of these proteins, a risk score from 0 to 1 is generated, aiming to categorize patients into favorable or nonfavorable disease pathology groups. Validation studies have shown that for a risk score of 0.33 or less, the ProMark assay can identify individuals with favorable pathology among a cohort of very low-risk, low-risk, and favorable IR disease, with positive predictive values (PPV) of 95% and 81.2%, respectively, who may be suitable for AS. Conversely, a risk score greater than 0.8 has a PPV of 76.9% for nonfavorable pathology, and such PPV is nearly 100% for a score greater than 0.9.[57]

Although initial validation studies mainly involved American men of European ancestry, comprising 94%, 76%, and 86% of patients for Prolaris, Oncotype Dx Prostate, and Decipher, respectively, it is important to extend their application to African American (AA) men as well.[58] Howard et al evaluated the performance of the Decipher genomic classifier in the post-RP setting to predict outcome (5-year metastasis and PCSM) in a cohort of 548 patients, 55% of whom were AA men. It followed that Decipher was a strong predictor of these outcomes and race was not found to impact the performance of Decipher.[59]

Artificial Intelligence–Based Biomarker

Tissue-based biomarkers have the potential to transform the risk stratification of patients with prostate cancer. Among the limitations that have hindered the widespread use of tissue-based biomarkers have been the absence of validation through prospective randomized trials, the financial burden incurred due to limited insurance coverage, and the lack of direct comparison among these tissue-based biomarkers.[60] The Multimodal Artificial intelligence (MMAI) has emerged as a promising solution to

address some of these challenges, given its capacity to analyze large data sets, including digitized images, at a lower cost than other tissue-based biomarkers. Esteva et al utilized digital histopathology and clinical data, including age, PSA, and GSs (combined, primary, and secondary), from five NRG Oncology phase III randomized clinical trials (RTOG-9202, RTOG-9408, RTOG-9413, RTOG-9910, RTOG-9910, and RTOG-0126), to develop an MMAI as a digital biomarker (Figure 73.3). The resulting prognostic model performed better than currently used risk stratification tool across all selected end points, including 5- and 10-year BF, 5- and 10-year DM, 10-year prostate cancer–specific survival, and 10-year overall survival (OS).[61] More recently, this MMAI approach has been shown to also be predictive of the need for ADT in patients with IR disease (Figure 73.4).[62]

#1 Beware of Randomized Trials that Are Too Small and Heterogeneous Patient Selection!

Roach et al assessed the performance of a novel MMAI tool across racial groups (AA and non-AA men) treated for localized prostate cancer during phase III randomized clinical trials (NRG/RTOG-9202, RTOG-9408, RTOG-9910, RTOG-0126) using an "algorithmic fairness" framework. The MMAI algorithms demonstrated strong prognostic signals for DM and PCSM in both AA and non-AA patient subgroups. Despite biases associated with general artificial intelligence (AI) use, no issues related to "algorithm

fairness" were observed with these cohorts of patients using MMAI models.[63] These findings suggest that AI biomarkers may be used across racial groups (AA and non-AA) for treatment selection.

Altogether, molecular- and AI-based biomarkers have substantially changed our understanding of how to select patients who need dose escalation and ADT.[50,62]

Cautionary Notes on Selected Phase III Randomized Prostate Cancer Trials

Much of the confusion concerning the optimum management of men with IR to HR prostate cancer comes from the misinterpretation of high-profile phase III randomized controlled trials (RCTs). There are what can be called the "three classic sins" in trial design that are common to a number of these trials: (1) selection criteria, "you can't prove something does not work by treating people who don't need it"; (2) statistical power, "you can't prove something does not work with an underpowered study"; and (3) nonoptimized interventions, "you can't prove something does not work if it is not done properly."

The first "sin" arises in part because when eligibility criteria for a trial are defined, they are usually heterogeneous in terms of their impact on prognosis, and prior to enrollment, there is no simple way to guarantee what the distribution of prognostic factors will be. The design of underpowered studies tends to arise in part because for most studies, the data necessary to accurately estimate the required sample size do not exist; thus, assumptions and guesses must be made. In addition, investigators tend to be overly optimistic about their ability to accrue patients, do not adequately account for stage migration, changes in practice patterns, and relevant new information about treatment. Another sin arises from the use of nonoptimized interventions, it tends to arise from the fact that it can take several years to design and launch a trial. Unfortunately, prior to completion of the trial, the standard of care could change, making the intervention being studied no longer relevant.

An example of a high-profile trial committing these "three sins" is the GETUG-01 (Groupe d'Etude des Tumeurs Uro-Génitales) trial. This French multicenter phase III reported by Pommier et al concluded that there was no

value to the use of prophylactic lymph nodal irradiation.[64] The majority of the patients did not have HR disease (ie, risk of positive nodes ,15%) (sin #1), not only was this trial grossly underpowered with only 203 men with a risk of lymph node involvement (LNI) more than 15% (sin #2), but *none* of the patients actually received "whole-pelvic" EBRT but instead were treated using a "mini-pelvic" technique (sin #3).[65] The limitations of trials are discussed in more detail elsewhere.[66]

Another example of a trial committing these three sins is the trial reported by Nabid et al[67] This RCT has been purported to support the notion that 18 months of long-term ADT is as effective as 36 months in 630 men with HR prostate cancer receiving EBRT.[67] Based on these data, some physicians have concluded that it has established a "new standard of care" for HR patients.[68] However, there were several methodological issues that we and others have pointed out.[66] First, the patients in general were probably not as HR as the earlier study conducted by the European Organization for Research and Treatment of Cancer (EORTC) that required clinical evidence of locally advanced disease (ie, "palpable T3-4") and allowed some node-positive patients (~9%).[69] Furthermore, pretreatment PSA greater than 20 ng/mL (a less powerful predictor of survival) alone was not included for the eligibility criteria for the earlier HR study (PSAs up to 160 ng/mL were allowed). The earlier EORTC trial verified that 6 months of ADT was *inferior* to 36 months, based on an assessment of 970 patients (~50% more patients than the Nabid trial). To prove that lengthening ADT by 12 months (ie, 18 months) was *noninferior* should be expected to require at least as many patients, particularly if they were lower risk (eg, fewer T3 patients). However, they chose to perform a *superiority* trial, which could be done with fewer patients. At 5 years, they noted a trend for a better OS favoring 36 months over 18 months (91% vs 86%; *P*-value of .07). Also of note, the 10-year BF at 10 years (25% vs 31%) and disease-free survival (DFS) (45% vs 39%; $P = .08$), favoring 36 months over 18 months. Had the trial been much larger it is likely that these differences in outcome would have been clearer. Further evidence that this study Nabid et al[67] was underpowered is supported by the observation that known prognostic factors such as GS and T-stage were also not significant predictors of outcome. The desire to shorten the duration of ADT is admirable, and many

patients would love to be spared the unnecessary use of ADT, but for most, a loss of life may be deemed an excessive price.

The three trials evaluating the role of salvage radiotherapy (SRT) versus adjuvant radiotherapy (ART) in the postoperative setting are perhaps the best examples of the concept of violating the "three sins" and discussed in detail in the section on postoperative RT. In addition to the "three sins" of clinical trial design and implementation (described earlier), there is a hazard of biased large post hoc retrospective studies comparing surgery versus RT and/or assessing post-treatment toxicity.

#2 Beware of Large Post Hoc Population-Based and Biased Retrospective Studies!

Unfortunately, urologists have continued to publish a plethora of fundamentally flawed large and small retrospective studies attempting to prove that RP is more effective than RT at curing prostate cancer.[5,6] The systematic review and meta-analysis published by Wallis et al garnered the most attention when first published. A review of some of the biases and some of the numerous methodological flaws have been touched on previously.[9,10,70] Most noteworthy was the decision to use an unreliable method to assess bias, the incorporation of studies with biases previously shown to have incorporated unreliable data, and the failure to include RT series with contemporary management techniques.[10,71,72] Also of concern is the dependence on data extracted from national registries and databases such as the Surveillance, Epidemiology, and End Results (SEER), the National Cancer Database (NCDB), or the Cancer of the Prostate Strategic Urologic Research Endeavor.[10,73-75] There are numerous limitations using these population-based registries and databases that require comment.[6,76] First, after adjusting for all available factors (many excluding PSA data), SEER data continue to show evidence of a selection bias, in favor of the results of patients treated by RP, even when compared to patients who do not have prostate cancer.[77] This observation is strongly supported by a study from Johns Hopkins demonstrating that men undergoing RP had an all-cause mortality standardized mortality ratio (SMR) less than half of men in the general population (SMR = 0.47, 95% confidence interval [CI] 0.44-0.49).[76] Of note, their risk of death from second cancers was also less than

half of men in the general population (SMR = 0.45, 95% CI 0.40-0.49), highlighting the fact that post-RP patients *should not* be considered an appropriate control group for estimating the risk of second cancer in patients treated with RT.

Additional limitation arises from attribution bias. For instance, in a study examining the survival of men with high-grade prostate cancer, death was attributed to prostate cancer if it was listed as the primary or contributing cause of death, meaning that prostate cancer appeared on the first three lines of the death certificate.[78] Thus, potentially leading to a misattribution in the cause of death, in part because men undergoing RT tend to older, have more comorbidity. If a man is more likely to die from these things, even a small absolute error rate can result in highly statistically significant differences being asserted when large data sets such as SEER are used. Hoffman et al evaluated the concordance between prostate cancer–related deaths recorded on death certificates by the New Mexico Bureau of Vital Statistics and evaluations by board-certified physicians, experts in cancer epidemiology, who independently reviewed the clinical data, in 1985 and 1995. This assessment revealed a net misattribution rate of 16.8% in 1995 compared to 1.9% in 1985. Over this period, crude prostate cancer mortality increased by 33.5%; however, after adjusting for misattribution, the increase in prostate cancer mortality was only 15.9%, indicating that approximately half of the observed rise in prostate cancer deaths could be attributed to misattribution.[79]

Most studies indicating a potential benefit of RP over RT in localized prostate cancer have relied on data from registries, thus subjected to the biases and limitations mentioned earlier.[5,73-75] However, a Swedish RCT that compared RP to high-dose rate (HDR brachytherapy plus EBRT) in localized/locally advanced prostate cancer found no significant difference in treatment outcome and health-related quality of life (QoL) and complications, including urinary incontinence, bowel, and sexual functions after a 10-year follow-up between the two groups.[11] It is worth noting that this study was underpowered. The ProtecT trial is a randomized study that accrued over 1,500 men that evaluated the efficacy of three interventions: RT, RP, and active monitoring in patients with localized prostate cancer.[80] Subsequent stratification of study patients revealed that 34% had IR or HR prostate cancer.[81] After a median follow-up of 15 years, death from any

causes was similar across all three interventions groups. Specifically, prostate cancer survival rates were 96.6%, 97.2%, and 97.7% for active monitoring, RP, and RT, respectively; more importantly for freedom from progressive disease was similar with RP and RT.[82] Furthermore, no new treatment-induced side effects were observed beyond those reported during the 10-year analysis.[12] This suggests that based on randomized studies available thus far, there seems to be no difference in outcomes between RP and RT.

While we await the results from SPCG-15, a prospective phase III trial that randomized patients with locally advanced prostate cancer to RT with ADT or RP, a reliability score (RS) has been proposed to assist in assessing the trustworthiness of conclusions drawn from studies comparing the effectiveness of RP to RT with or without ADT.[83,84] This scoring system evaluated various aspects of a study, including the data source, the appropriate use and duration of ADT, the provision of the Charlson comorbidity index, additional comorbidity adjustments, sample size, adjustment of survival curves for prognostic factors, and the provision of cancer-related prognostic factors, such as GS, T-stage, and PSA levels. Using this framework, studies with high RS, indicating greater reliability, typically demonstrate minimal differences, often less than 1%, in 10-year CSS between men treated with RP and those undergoing RT.[84] Table 73.1 summarizes the key points highlighted earlier regarding the misconception that RP is more effective than RT.

TABLE 73.1 SELECTED MYTHS REGARDING INTERMEDIATE- AND HIGH-RISK PROSTATE CANCER

Myth and Example of Arguments	Arguments Against the Myth	Comments
"RP is associated with better OS than RT ± ADT." *Sources of data: Observational databases and registries (SEER, NCDB, CaPSURE, etc)*[73-75]	Existing RCTs: No difference in OS	Swedish randomized trial[a]: No difference in OS, HRQoL, and complications at 10 y[11] ProtecT trial[b]: Similar PCS with RP, RT, and AM at 15 y[82]
	Biases with observational databases and registries:	Selection bias: Lower all-cause mortality in RP pts

Myth and Example of Arguments	Arguments Against the Myth	Comments
	• Selection bias • Attribution bias	compared to noncancer control group[77] Attribution bias: Misattribution in the cause of death[78,79]
	Older age (.70 ± 5 y): Risk factor for RP but not for RT	30-d mortality after RP: 3-fold increase with each decade increase in age[104] Outcome of RT and RP in older patients (70 ± 5 y)[34]: • 74% of RT studies: Age associated with better outcome or trend toward better outcome; age not linked to worse outcome • 50% of RP studies: Age associated with worse outcome; older age not linked to favorable outcome
"Sexual function not worse after RP compared to RT± ADT with long-term follow-up" *Based on similar sexual function scores*[73,91,92]	Sexual function of RP patients better at baseline RT patients older with more comorbidities	Larger decrease in sexual functions in RP pts than RT patients in long term Older age and comorbidities associated with sexual dysfunctions[93,94]
"RT is available as a 'salvage' option for recurrences after RP, but there are no good 'salvage' options (such as RP) for recurrences after RT." *Challenges with salvage RP after RT: Poor wound healing, RT-induced fibrosis, intra-op injuries, stricture,*	There are multiple published surgical and nonsurgical series documenting "salvage" options for patients recurring after RT with .160 studies including .10,000 patients documenting the effectiveness of "salvage" results.	Meta-analysis data-modality 5-y RFS[97]: RP 54%, SBRT 60%, HDR 60%, LDR 56%, cryotherapy 50%, HIFU 53% Phase II trial salvage LDR after EBRT 10-y outcomes[98]: OS 70%; DSS 70%; LF 5%; DF 19%

Androgen Deprivation Therapy and/or Other Drugs and Survival From Prostate Cancer

Short-term ADT for unfavorable IR and long-term ADT for HR prostate cancer has become the mantra for managing these subsets of patients.[8] In addition, there is a growing body of data that suggest that for men with locally advanced disease being managed with definitive RT, there may be benefits associated with adding chemotherapy and/or "next-generation" drugs as well.[85-87] While the addition of chemotherapy yielded negative (RTOG 9902) or relatively unconvincing results (RTOG 0521), the addition of "next—generation" agents seems more promising. For example, STAMPEDE (Systemic Therapy in Advancing or Metastatic Prostate Cancer: Evaluation of Drug Efficacy) was a large, RCT (*n* = 1,917), complicated by its very heterogeneous design. STAMPEDE included patients with metastatic and nonmetastatic disease (the latter including node-positive patients with HR localized prostate cancer), making it difficult to parse out who benefited the most. Per protocol, EBRT was mandated for patients with node-negative, nonmetastatic disease and

"encouraged" for those with positive nodes. The primary outcome measure was OS, with failure-free survival (treatment failure was defined as radiologic, clinical, or PSA progression or death from prostate cancer) as an "intermediate primary outcome." The authors concluded that "among men with locally advanced … prostate cancer, ADT *plus* abiraterone … was associated with significantly higher rates of overall and failure-free survival than ADT alone …." However, they reported no OS advantage for "nonmetastatic" patients and no trend for benefits for men older than 70 years of age (the median age for men treated on previous phase III RTOG trials involving RT and ADT). Thus, although encouraging, it remains unclear of the role of abiraterone in the setting of typical HR prostate cancer managed with ADT and EBRT, particularly in those older than 70 years of age (who may have more favorable biology as mentioned earlier).

#3 Beware of Confusion Concerning the Importance of Radiation Dose and Volume!

We (radiation oncologist) have been a bit illogical, concerning our interpretation of the data from trials involving the three most commonly "tweakable" interventions—radiation dose, radiation volume, and the use of ADT. Despite a plethora of trials involving dose-escalated radiation, all failing to prove that higher doses improve OS, high doses have become standard of care (see JNCI and other consensus guidelines). These studies have generally demonstrated improved biochemical control based on PSA but at increased cost and in some cases with increased toxicity. Despite the improvements in PSA control associated with whole-pelvic radiation therapy (WPRT) in at least three well-powered phase III trials, nearly half of radiation oncologists have not adopted WPRT as standard for HR patients (personal communication, based on an informal audience surveys).[88-90] Also of concern is the willingness of radiation oncologists to completely abandon ADT or shorten or lengthen the duration or based on post hoc retrospective data, despite their lack of reliability. Omitting ADT because "maybe, it would not be needed if higher doses of radiation were used" is potentially dangerous and should require a randomized trial to justify.

Selected Myths Regarding Intermediate- and High-Risk Prostate Cancer

In addition to the misconception that RP is associated with a better OS than RT, we highlight existing myths associated with IR and HR prostate cancer (Table 73.1). Another common myth is that after a long-term follow-up, RP does not lead to a worse sexual function compared to RT with or without ADT. A commonly used argument to support this myth is that the sexual function scores are similar after long-term follow-up.[73,91,92] While sexual function at long follow-up may be similar as reported, it is important to remember that in these studies, patients undergoing RP had significantly better sexual functions before treatment initiation than those treated with RT, highlighting the fact that RP patients experience a larger decline in sexual functions than RT patients. Furthermore, RT patients tend to be much older with more comorbidities than patients undergoing RP, two factors (older ager and comorbidities) that are known to be associated with sexual dysfunctions.[93,94]

Another myth that is commonly mentioned by urologists is that RT is available as a salvage option for recurrences after RP, but there are no good "salvage" options for recurrences after RT. While it is true that there are reports of poor wound healing, intraoperative injuries, strictures, and anastomotic leaks after salvage RP, not all series report such negative results.[95,96] Furthermore, in addition to surgical salvage, there are numerous nonsurgical salvage options after RT including SBRT, brachytherapy (HDR and low-dose rate [LDR]), cryotherapy, and high-intensity focused ultrasound with documented effectiveness.[97,98]

There is also a myth that prostate cancer is more aggressive in AA men than other races. An argument used in support of this myth includes genetic mutations in AA men favoring aggressive disease.[99] However, numerous other cancers including breast, colorectal, esophageal, lung, and cervix are associated with lower survival in AA, suggesting the existence of other etiologies.[100] It is highly likely that such etiologies comprise racial disparities, including in screening, early detection, and quality of care.[101-103] Moreover, when such quality of care is the same across all treated patients, Black race is not an adverse prognostic factor and, in some instances, AA men tend to have better outcomes (Table 73.2).

Novel Imaging Techniques: Implications of Nodal Imaging for Radiation Therapy

Until very recently, imaging contributed relatively little to the management of patients with clinically localized prostate cancer, such that the patient eligibility for early RTOG trials has initially been based primarily on palpation T-stage.[118] This philosophy was by necessity largely based on the fact that neither CT nor magnetic resonance imaging (MRI) has been shown to be sensitive or specific enough to be routinely used to rule out LNI.[119] In the absence of definitive evidence of the presence and location of LNI, a class solution is used to design radiation fields when WPRT is intended.[120,121] However, there are at least three imaging approaches that may compliment the use of class solutions—positron emission tomography (PET) imaging, the use of lymphotropic nanoparticles, and sentinel lymph node imaging, with the first of these options becoming the standard of care.

The use of prostate—specific membrane antigen (PSMA)-based PET imaging for staging and managing unfavorable IR and HR prostate cancer has been rapidly adopted in the United States over the past 5 years. This practice evolved after a compelling body of evidence primarily from Europe and Australia demonstrated the utility of PSMA-PET imaging. Subsequently, the hard work of investigators in the United States resulted in U.S. Food and Drug Administration (FDA) approval.[122-128] The underlying principle for approval was based on studies showing superiority to conventional imaging such as CT scans and better than other available imaging agents.[129-131] For example, higher detection rates have been observed with ^{68}Ga-PSMA-PET/CT compared to ^{11}C-choline PET/CT, and fewer false positives have been noted.[132]

Currently, there are multiple compounds available for targeting PSMA in prostate cancer. However, clinically, two of the most commonly used radioactive isotopes utilized for PSMA imaging are fluorine-18 (^{18}F) and gallium-68 (^{68}Ga).[133] The FDA-approved PSMA imaging agents include ^{68}Ga-gozetotide (^{68}Ga-PSMA-11), ^{18}F-piflufolastat (^{18}F-DCFPyL), and ^{18}F-flotufolastat (^{18}F-rhPSMA-7.3).[134] The choice of PSMA imaging agent can be guided by factors such as regulatory institutions' approvals, the capacity to produce the needed radioisotope (^{18}F vs ^{68}Ga), and their physical properties, including half-life.[135] A comprehensive meta-analysis conducted

by Jeet et al assessed the accuracy of PSMA-PET/CT across various settings in prostate cancer, including localized disease, lymph node metastasis (LMN) in IR and HR prostate cancer, and BCR.[136] The sensitivity and specificity of PSMA-PET/CT varied across these settings, with primary staging demonstrating a sensitivity of up to 71.0% and a specificity of 92.0%. In patients with LMN, sensitivity and specificity were 57% and 96%, respectively, while in patients with BCR, sensitivity was 84% and specificity was 97%.[136]

While the use of PSMA-PET/CT in the staging in prostate cancer has resulted in change in the clinical management in upward of 28% of patients with primary prostate cancer and 54% of patients with BCR, there are some pitfalls associated with PSMA-PET/CT.[136] In addition to known physiologic uptake of these PSMA tracers in the lacrimal and salivary glands, there are various PSMA—avid benign lesions that can confound the interpretation of PSMA-PET/CT.[134,137] Thus, it is crucial for the PSMA-PET/CT scan interpreter to understand and be aware of the appearance of cancerous lesions and the metastasis pattern of prostate cancer.[134] These benign lesions have been observed in multiple anatomic locations, including the lung (eg, sarcoidosis, infectious diseases: histoplasmosis and SARS-CoV-2), adrenal gland (eg, adenoma), soft tissues (eg, desmoid tumors, nodular fasciitis), and bone (eg, trauma, Paget disease, hemangioma).[138-146] The presence of these PSMA—avid osseous benign lesions can complicate clinical management decisions, as highlighted by findings indicating that PSMA-avid solitary rib lesion on pretreatment 68Ga-PSMA-PET/CT may be benign, suggesting caution in interpreting PSMA-PET/CT results.[147] For example, in a study involving patients with prostate cancer presenting with solitary rib lesions, 98.4% met their criteria for having benign lesions. Also, of particular concern when using RT for the treatment of patients with more advanced disease is the recognition that ureters, neural ganglia, and, rarely, schwannomas can be easily misinterpreted as nodes and irradiated in error.[148-151]

Sentinel lymph node dissections are standard in a variety of cancer sites (eg, breast cancer), but its application in prostate cancer has been very limited. Intraoperative gamma probe and dynamic lymphoscintigraphy appear to be a very sensitive approach for defining disease intraoperatively. For example, Wawroschek et al reported that about one-third of sentinel

lymph nodes were in areas outside of a limited node dissection, such as the presacral, hypogastric, and pararectal regions.[152] Holl et al also demonstrated that sentinel lymph node dissections guided by using radiolabeled nanocolloid were reliable in detecting positive nodes in over 2,000 patients.[153] Using a 2-day protocol, involving injection of a radioisotope injected into the prostate, combined with intraoperative scanning, they concluded that the detection rate was 97.6% and false-negative rate only 6%. Krengli et al reported on the application of sentinel lymph node imaging (single-photon emission computed tomography [SPECT]-CT) to pelvic RT for prostate cancer and reported that at least 25% of patients had nodes outside the standard nodal pelvic clinical target volume (CTV).[154]

Chen et al reported on a feasibility study performed at University of California San Francisco (UCSF) using sentinel lymph node image–guided intensity-modulated radiation therapy (IMRT) for prostate cancer and compared it to RTOG-based IMRT plans.[155] Patients were injected with 99^{m}Tc-sulfur colloid into six prostate locations and then imaged with SPECT-CT to generate a lymphatic drainage map. Although all patients had sentinel nodes identified in the internal or external iliac nodal basins, 50% had sentinel nodes in the para-aortic area. We concluded that RTOG consensus guidelines on pelvic lymph coverage would have included all relevant lymph nodes in only 30% of cases. Guided by this sentinel nodal study, we reported that in comparative RT plans, there would have been no significant increase in the doses received by organs at risk, in part because volume reductions in areas not including a sentinel node.

Perhaps the most sensitive (but least available) diagnostic imaging test involves the use of lymphotropic superparamagnetic nanoparticles, which, combined with MRI, has been reported to be a very sensitive and specific test for detecting LNI.[156,157] It not only appears to be more specific than the “Roach equation” in assessing nodal involvement, but it can also identify the location of disease. These nanoparticles are transported by lymphatic vessels and filtered by lymph nodes. Lymph nodes that have been infiltrated by metastases will have distorted lymphatic flow and accumulate the nanoparticles. Of particular note, documented by histologic confirmation, 71% would not have met the MRI size criteria for malignancy. This imaging approach was associated with sensitivity in excess of 90% versus

35% with MRI alone (*P* , .001). When only nodes that were between 5 and 10 mm in diameter on the short axis were considered, the sensitivity increased from 28.5% to 96.4% (*P* , .001). Shih et al proposed margins around major vessels as an alternative based on their studies because of the lack of availability of this imaging agent.[158] Dinniwell et al proposed a pelvic nodal model based on nanoparticles and recommended CTV margins to the distal para-aortic (12 mm), common iliac (10 mm), external iliac (9 mm), and internal iliac (10 mm), drawn in continuity with a 12-mm expansion anterior to the sacrum and 22-mm expansion medial to the pelvic sidewall.[159] Unfortunately, despite great promise, at last, we checked this agent is currently only available in the Netherlands.[160]

MANAGEMENT OF PELVIC LYMPH NODES: THE RATIONALE AND EVIDENCE

The Rationale

Despite the improvements in the detection rate of LNI provided by PET imaging agents, the ability of current imaging techniques to detect involved nodes is hampered by their sole reliance on size criteria.[161] The true incidence of clinically occult disease is generally much higher when sophisticated assays, imaging agents that have increased affinity to lymph nodes, and more extensive node dissections are performed. For example, Shariat et al used RT-PCR assay to detect human glandular kallikrein 2 (hK2) messenger RNA expression in *histopathologically* normal pelvic nodes in patients with pT3N0 prostate cancer.[162] Of the 199 evaluable men, 20% and 40% had positive and equivocal results, respectively. In multivariate analysis, a positive RT-PCR/hK2 result was associated with PSA progression, development of DMs, and PCSM.

When an extended pelvic lymph node dissection (including the nodes surrounding obturator vessels and internal iliac veins) is performed rather than the traditional limited dissection (or sampling), wherein the posterior extent is carried to the obturator nerve, more disease is found. For example, Bader et al conducted a prospective study of the anatomic extent of pelvic nodal involvement in a cohort of 365 men who underwent an extended lymph node dissection and RP.[163] The median number of nodes retrieved was 21. They used hematoxylin and eosin (H&E) stains to evaluate the

extracted nodes, 24% of patients had node-positive disease. The internal iliac nodes (which are not usually dissected in a limited dissection) were involved in 58% of men with node-positive disease. Of note, 19% of node-positive men had involved nodes that were exclusively found in the internal iliac region, suggesting that the lymphatic drainage of prostate cancer is variable. The rate of problematic lymphocele was 2%.

Another important consideration, when reviewing surgical studies, is whether H&E staining was performed or whether more sensitive analyses were included, such as immunohistochemistry (IHC) or RT-PCR. Heidenreich et al reported on the incidence of LNI between standard and extended pelvic lymphadenectomies in 203 patients.[164] IHC staining was performed if the H&E findings were negative. There were more dissected nodes in the extended dissection group (28 vs 11; *P* , .01), at the expense of longer operative time (179 vs 125 minutes; *P* , .03). There were more than twice the number of patients with positive nodes (26% and 12%; *P* , .03) in the extended dissection group, with 42% of all metastases lying outside the planes of a limited dissection. In patients deemed as HR (GS 7-10 and PSA ≥10.6 ng/mL) for LMN, 60.9% of patients had histologically positive nodes. There was no difference in pelvic lymphocele or postoperative complications between the two groups. Data reported by Briganti et al also attempted to address the question concerning the optimal number of lymph nodes to be removed during a nodal dissection.[165] In a cohort of 858 men who were treated predominantly with an extended lymph node dissection and who had a median PSA of 5.8 ng/mL, 62% with GS 6 or less and approximately 25% had GS of 7, based on a receiver operator curve analysis, they concluded that the removal of 28 nodes yielded a 90% ability to detect LNI, while the assessment of 10 or fewer nodes was associated with a very high false-negative rate. These data highlight the shortcomings of studies postulating much lower rates of LNI involvement than suggested by the so-called Roach equation.[166-169]

Relevant to the rationale of recognizing the true incidence of LNI are circumstantial data to suggest that there may be a benefit of removing more involved lymph nodes even if they are occult. For example, in a retrospective study from Johns Hopkins, the pathologic findings and biochemical outcomes were compared between two high-volume surgeons, each of whom exclusively performed either limited (*n* = 1,865) or extended

(*n* = 2,135) node dissections during RP.[170] As expected, the extended dissection group had more lymph nodes retrieved than the limited group (11.6 vs 8.9 nodes; *P* , .0001). Yet, the proportion of patients with involved nodes was also significantly higher in the extended dissection group (3.3% vs 1.2%; *P* , .0001). When only patients with GS of 7 or 8 to 10 were considered, the difference was even more striking (8.2% vs 2.4% and 23.2% vs 8.9%). The relative risks of detecting a patient with involved nodes were remarkably similar, varying between 2.5 and 3 when adjusted by GS, organ-confined status, SVI, and surgical margin status. There was a trend in favor of the extended dissection group for 5-year BCR-free survival (34.4% vs 16.5%; *P* = .07). Among patients with less than 15% positive lymph nodes, the difference was more remarkable (42.9% vs 10%; *P* = .01), suggesting a therapeutic benefit of an extended dissection in low-volume disease. Clinically significant lymphoceles occurred in only 0.3% in the extended dissection group. However, more recent studies have questioned the therapeutic value of more extensive dissection.[171]

On the basis of these studies, national consensus guidelines recommend an extended lymph node dissection for all patients who have a predicted probability of lymph node metastases of more than 2% for both diagnostic and potentially therapeutic reasons. Although there have been numerous nomograms to predict nodal involvement, most are derived from surgical data where only limited node dissections were performed.[172,173] Nomograms also have been developed using surgical data from patients who had an extended lymph node dissection to predict pelvic nodal involvement.[174] Despite these advances from a practical standpoint, because of its simplicity, it appears that the so-called Roach equation is still held relevant and has been validated with a cohort of over 3,000 patients treated with RP and *extended* lymph node dissections.[169,175] Overall, the accuracy of this equation was found to be 80% in this cohort; however, Abdollah et al found that applying the recommended cutoff of 15% or more (to decide on whether to treat the pelvic nodes) might lead to missing about one-third of patients with LNI, and thus, they recommended that the threshold be lowered to 6%.[169]

Collectively, these studies argue that an extended node dissection may or may not yield a therapeutic benefit in the subgroup of patients with minimal nodal disease.[171] In the application of radiation with curative intent, this

issue may have great relevance to prophylactic WPRT. Unfortunately, only one relevant large phase III trial has been completed to date, and although most retrospective studies have been supportive, some post hoc population-based studies have yielded conflicting results.[176-178] Much of this confusion concerning this issue stems from a misunderstanding of the data available from RTOG-9413.[179] Table 73.3 summarizes a body of selected literature addressing WPRT in patients with IR to HR disease managed in the definitive and postoperative setting.

TABLE 73.3 MAJOR TRIALS ASSESSING WPRT IN DEFINITIVE AND POSTOPERATIVE SETTINGS

Reference	Source	Patients	Study Design	Key Findings
Roach et al[176,180]	RTOG 9413	1,323	RCT compared sequence of ADT, and WPRT vs PORT Primary end point: PFS	WPRT improved PFS when preceded by ADT but not when administered before ADT.
Pommier et al[64,181]	GETUG-01	444	RCT PORT vs partial pelvic RT (superior border at S1-S2); 55% had risk + nodes ,15%	Patients did not receive WPRT (defined as top L5-S1); most were low risk for lymph nodes.
Mason et al,[182] Warde et al[183]	UK, Canada, USA	1,205	Prespecified final analysis of an RCT ADT vs ADT + RT	Patients planned for WPRT showed a trend for improved OS vs PORT (HR = 0.70; *P* = .12); DSS (HR = 0.53; *P* = .098).

			setting post-RP	WPRT vs PBRT

ADT, androgen-deprivation therapy; FFS, failure-free survival; HR, high risk; OS, overall survival; PBRT, prostate bed radiation therapy; PFS, progression-free survival; PORT, prostate-only radiotherapy; pts, patients; RCT, randomized controlled trial; RP, radical prostatectomy; RT, radiation therapy; WPRT, whole-pelvic radiation therapy.

RTOG-9413 was a landmark trial that featured a two-by-two factorial randomization scheme to either prostate-only radiation therapy (PORT) or WPRT followed by a prostate boost and either 4 months of neoadjuvant and concurrent hormones or 4 months of adjuvant ADT (AHT) at the completion of EBRT.[176] Patients with an estimated nodal risk of more than 15% or T2c to T4 with a GS of 6 or higher were eligible for the study. The 4-year progression-free survival (PFS) was 54.2% and 47% in the combined WPRT arms and PORT arms (P = .02), respectively. When the four arms were analyzed separately, the neoadjuvant hormone and WPRT arm (59.6%) had a significantly better 4-year PFS than the other three arms (44.3%-49.8%; P = .008). Although there was no difference in acute (3% vs 4%; P = .39) and late (2% vs 2%; P = .85) grade 3 to 5 genitourinary (GU) morbidities, a trend toward increased acute (2% vs 1%; P = .06) and late (1.7% vs 0.6%; P = .09) grade 3 to 5 gastrointestinal (GI) morbidities was seen in the combined WPRT and prostate-only arms, respectively.

Although RTOG-9413 affirmed the role of WPRT and neoadjuvant hormonal therapy (NHT) in HR prostate cancer, there has been some lingering reluctance among some radiation oncologists, with many instead opting for “mini-pelvic” fields or omitting the pelvic field entirely.[185] To reinforce this notion of the volume dependence on control of microscopic nodal disease, we conducted a secondary post hoc secondary subset analysis of patients treated on RTOG-9413.[65] Because of the disparity in the time point at which the neoadjuvant and AHT arms became susceptible to relapse (ie, end of both RT and ADT), only patients (n = 649) who received NHT were included in this analysis. After stratifying by volume irradiated, the 7-year PFS was 40%, 31%, and 27% in the groups that received WPRT, mini-pelvic RT, and PORT, respectively (P = .02; Figure 73.5). There was no difference in acute grade 3 or higher GU or GI toxicities among the three volumes. No difference was seen in the incidence of late grade 3 or higher

GU toxicities between the WPRT, mini-pelvic RT, and PORT groups at 48 months (3.0%, 2.4%, and 0%, respectively; $P = .24$). There was a small but significant increase in the incidence of late grade 3 or higher GI toxicities with larger fields at 48 months (4.3%, 1.2%, and 0%, respectively; $P = .006$). Of note, three-dimensional conformal radiation therapy (3DCRT), let alone IMRT, was not routinely performed in this study. It is conceivable that with either modality, late toxicities may be further decreased (Figure 73.6).

Although the results of GETUG-01 seem to contradict that of RTOG-9413, there are significant differences in the methodology of the two studies that warrant mention. First, more than half of the patients (~54%) had an estimated nodal risk of less than 15% ("Roach formula"), meaning that these patients had more favorable disease than those in RTOG-9413 and, therefore, would likely not benefit from WPRT. Thus, this study was vastly underpowered, as is made a bit clearer, by considering this example. Suppose you designed a trial wherein the minimum eligibility was a risk of LNI more than 15%, such that the average risk for this cohort was one-third. If you enrolled 1,200 patients, then 400 would really be the basis for the study outcome because only this number could potentially benefit. If the

local recurrence rate was 50% (eg, as might be expected after 66 Gy), then only 200 patients would be left to assess the merits of WPRT. This means that only 100 patients would remain on the WPRT arm that could potentially benefit. If competing causes of death eliminated 50% of the patients, the remaining assessable patients would then be down to 50 per arm. Thus, even starting off with 1,200 patients, it would be challenging to assess the potential impact of WPRT. Clearly, GETUG-01, which only started out with 200 patients with a risk of more than 15%, was not adequately powered to either disprove or prove the value of WPRT.

Equally important, the protocol-defined pelvic fields on GETUG-01were much smaller than those used in RTOG-9413. Specifically, the superior border was taken at the level of S1-S2 interspace, rather than L5-S1 interspace, which meant that a significant portion of the presacral and common iliac nodes were not treated. Thus, *none* of the patients included in this trial received WPRT in accordance with RTOG-9413, and *all* of the patients assigned to the "pelvic nodal" radiation arm would have been included in the PORT arm of RTOG-9413.

NRG/RTOG-0924, opened in 2011 and completed accrual in June 2019, was designed using a subset of patients from RTOG-9413 that appeared to have benefited the most from WPRT.[176,177] In addition, it incorporated the percentage of positive biopsy cores into the eligibility criteria. For NRG/RTOG-0924, the WPRT superior border was placed slightly higher and the PORT fields slightly smaller, with the phase I dose of 45 Gy in both arms and can be delivered with 3DCRT or IMRT. The phase II prostate boost (a stratification variable) could be delivered by IMRT (34.2 Gy; total dose 79.2 Gy), LDR brachytherapy (110 Gy for iodine-125 [^{125}I] and 100 Gy for palladium-103 [^{103}Pd]), or HDR brachytherapy (15 Gy in one fraction with iridium-192 [^{192}Ir]). Patients were also stratified by duration of ADT into 4 to 6 or 32 months.

The bottom line concerning WPRT as summarized in Table 73.3 is as follows:

1. Most retrospective studies involving EBRT support the value of WPRT. Thus, there is no strong evidence to withhold WPRT based on retrospective data.

2. Every major RTOG and EORTC trial including HR patients with ADT included WPRT. In fact, even the largest trials populated by IR patients were treated with WPRT. For example, nearly 75% of the patients treated on RTOG-9408 received WPRT.[186,187] Thus, there is no evidence that the results of these trials would be the same if WPRT was withheld.
3. The three largest contemporary phase III randomized trials completed to date (RTOG-9413, RTOG-0534, and POP-RT) support an improved PSA control when NHT is added to WPRT compared to PORT.[88-90]
4. A larger confirmatory study with a survival end point is pending with greater than 2,500 patients already enrolled (RTOG/NRG-0924) and is expected to be reported out by early 2025.

RADIATION THERAPY TECHNIQUES: REGIONAL AND LOCAL

Boost Techniques: Options and Considerations

Over the past two decades, the therapeutic options for definitive radiation in men with clinically localized disease have evolved immensely. At UCSF, favorable IR patients are usually managed with monotherapy, a permanent prostate implant (PPI), an HDR implant, or SBRT directed only at the prostate and/or the proximal seminal vesicles (SVs) with or without ADT. For patients with more unfavorable IR disease, image-guided EBRT (IGRT) directed at periprostatic tissues (± the pelvic lymph nodes) is generally combined with a PPI, HDR, or an SBRT boost and/or short-term ADT (eg, 4 months), whereas for HR patients, long-term ADT (eg, 2-3 years) with WPRT is usually recommended.

Off study, the authors continue to recommend prophylactic WPRT using IMRT to patients with an estimated risk of nodal involvement of more than 15% for unfavorable IR and HR prostate cancer. The authors recommend either adherence to the RTOG Genitourinary Radiation Oncology consensus statement on pelvic nodal volumes or use of a higher superior border.[120,188,189] If positive pelvic nodes are suggested by imaging (eg, CT or PET), prophylactic para-aortic nodal treatment is usually added to WPRT. The prostate boost is delivered with either an IMRT, a PPI, HDR brachytherapy, or an SBRT boost. Brachytherapy or SBRT is generally preferred by the authors because of their ability to deliver a higher biologic

dose to the prostate. Brachytherapy or SBRT can be performed either before or 1 to 3 weeks following pelvic RT. For T3 disease, the authors use an SBRT, HDR, or IMRT boost, which allows better coverage of extracapsular disease than PPI boost. Table 73.4 summarizes some of the consideration when selecting the type of boost preferred for a given patient. Figures 73.7 and 73.8 provide a summary of some of the data supporting SBRT with or without ADT.[2] Based on the results of patients treated on RTOG-0232 comparing PPI to PPI plus EBRT, the former is preferred in favorable IR patients.[190]

TABLE 73.4 RADIATION THERAPY "PREFERRED" OPTIONS AND RELATIVE CONTRAINDICATIONS FOR PROSTATE CANCER AT UCSF (CIRCA 2024)

Type of Radiation Therapy	Primary Indications	Relative Contraindications
IGRT (intensity-modulated image-guided external beam radiation)[a]	1. Combination therapy pre-/postboost treatment 2. Post-op adjuvant treatment 3. Post-op salvage treatment 4. Large transurethral resection of the prostate (TURP) defects 5. Other options not covered by insurance 6. Patient preference	1. Previous full-dose radiation 2. Patient preference (eg, logistically problematic) 3. Focal recurrence (favor focal treatments) 4. Technical issues (eg, too large for CT scan but BT suitable) 5. Inflammatory bowel disease or connective tissue disorder 6. Noncompliant for many visits
PPI (permanent prostate implant) BT (brachytherapy)	1. Monotherapy for low- or favorable intermediate-risk pts 2. Boost in clinically T1-T2 with IMRT 3. Focal salvage postrecurrence after IMRT 4. Focal salvage postrecurrence after PPI 5. Patient preference	1. Not a candidate for anesthesia 2. Discontinuation of anticoagulation is unadvisable 3. Excessive pubic arch interference (PAI) 4. Excessively large TURP defect 5. Severe baseline urinary symptoms (eg, urinary retention)

Type of Radiation Therapy	Primary Indications	Relative Contraindications
HDR (high-dose rate) BT	1. Monotherapy for low- or favorable intermediate-risk pts 2. Boost in clinically T1-T3 with IMRT 3. Focal salvage postrecurrence after IMRT 4. Pubic arch interference prohibiting PPI 5. Median lobe too large for SBRT 6. Insurance prohibits SBRT 7. Patient preference	1. Not a candidate for anesthesia 2. Discontinuation of anticoagulation is unadvisable 3. Excessive pubic arch interference 4. Excessively large TURP defect 5. Severe baseline urinary symptoms (eg, urinary retention)
SBRT (stereotactic body radiation therapy)	1. Monotherapy for low- or favorable-risk pts 2. Boost for clinically T1-T4 with IMRT 3. Focal salvage in selected pts postrecurrence after IMRT when not a candidate for BT salvage 4. Patients presenting with obstruction because of locally advanced disease (eg, “reverse” boost) 5. Patient preference (eg, convenience)	1. Very large median lobe 2. Unable to lie still and flat for 45 min (eg, tremor) 3. Poor localization because of metal artifacts (eg, hip replacement, presence of PPI seeds) 4. Poor seed positioning (“too close”) 5. Not covered by insurance 6. Protocol requires other treatments

IMRT, intensity-modulated radiation therapy; pts, patients; UCSF, University of California San Francisco.

[a]Delivered with either conventional fractionation or hypofractionation. “Primary”: This term reflects the clinical nuances that go into the decisions concerning the use of various radiation options considered while practicing the “Art” of radiation therapy. There may be exceptions to what physicians decide to recommend to specific patients, but these “Primary” options as listed in this table reflect our typical considerations and our practice habits. It is recognized that for purposes of continuity of care and presumed clinical equivalence, patients who could be managed appropriately by more than one boost modality are more likely to be managed via the modality favored by the “clinical lead” radiation oncologist as listed earlier.

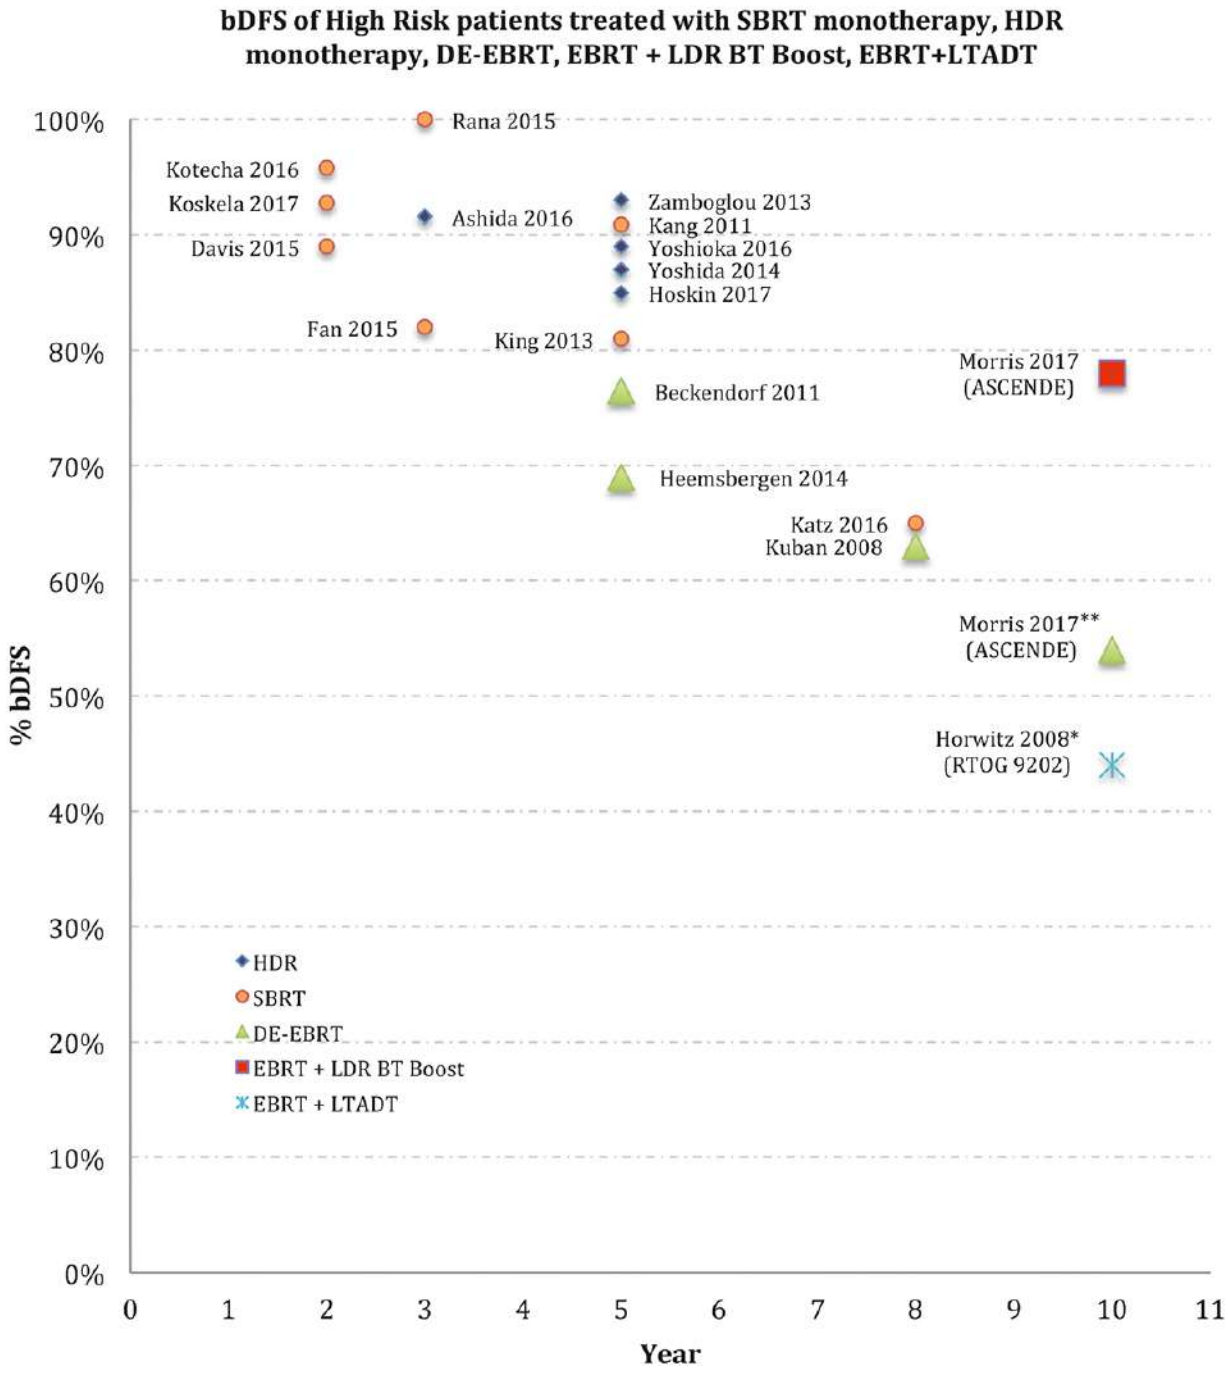

FIGURE 73.7 Biochemical disease-free survival (bDFS) (Phoenix) of high-risk (HR) patients treated with stereotactic body radiation therapy (SBRT) boost, high-dose rate (HDR) boost, external beam radiation therapy plus long-term androgen deprivation therapy (EBRT + LTADT), dose-escalated external beam radiation therapy (DE-EBRT), and low-dose rate brachytherapy (LDR-BT) arm of the ASCENDE-RT trial. Data from the ASCENDE-RT trial were estimated from the Kaplan-Meier curve of bDFS for HR patients. Data for RTOG-9202 (EBRT + LTADT) were estimated from biochemical rate reported. *RTOG-9202 used the ASTRO definition for biochemical failure. **DE-EBRT arm of the ASCENDE-RT trial received 8 months of neoadjuvant androgen deprivation therapy. Brachytherapy and Stereotactic Body Radiation Therapy Boost

Brachytherapy Boost

Notwithstanding the downsides that brachytherapy is an invasive procedure that requires anesthesia, additional resources, and clinical expertise, the advantages of incorporating prostate brachytherapy to boost the dose to the prostate are compelling. First, the achievable biologically effective dose to the prostate exceeds what can be achieved by IMRT, which appears to translate into a higher rate of local control and possibly cure. In addition to

the ASCENDE-RT trial involving PPI boost, there are several other comparative studies supportive of HDR brachytherapy boost as well.[191] For example, Hoskin et al reported the results of their phase III trial comparing EBRT alone (55 Gy in 20 fractions) with combined EBRT (35.75 Gy in 13 fractions) followed by HDR prostate brachytherapy (17 Gy in two fractions over 24 hours) among 218 patients with clinically localized prostate cancer.[192] Biochemical control was significantly higher in patients treated with EBRT plus HDR ($P = .04$). In multivariate analysis, risk category and ADT were significant covariates for risk of relapse. The improvement noted in the biochemical control still held after 12-year follow-up.[193] Of note perhaps because of the study size, there were no differences in OS. Fortunately, the incidence of severe late urinary and bowel morbidity was similar. In addition to apparently rendering improved PSA results, with a brachytherapy boost, the overall treatment time is usually less than the usual 8 weeks of conventionally fractionated x-ray therapy and, therefore, more convenient for patients.

As compared to LDR brachytherapy, HDR brachytherapy yields the following advantages: greater flexibility in source positioning, adaption of dose to target and healthy organs, target volume-dose optimization, high-quality planning and dose distribution, lower risk of radiation exposition to health care personnel or public, and reduced cost. The potential disadvantage of HDR is that it is often fractionated and takes more time and, therefore, may require more workload and careful coordination from the health care personnel. The indications of combined EBRT and brachytherapy boost include those with IR or HR prostate cancer, particularly in patients who are relatively young and have high-volume disease. Relative contraindications to the use of a brachytherapy boost include those with a large prostate (.60 mL), prior TURP with a large residual urethral defect, anticoagulation use, and significant urinary symptoms (ie, International Prostate Symptom Score >20).

As noted previously, HDR brachytherapy may be performed before, during, or after the EBRT. The optimal HDR dose fractionation is currently unknown, and there is significant variability across centers. Nonetheless, there is a shift toward fewer implants, fewer fractions, and higher dose per fraction because of the radiobiologic advantage of high dose per fraction in prostate cancer. Reflecting this lack of consensus, RTOG-0815 and RTOG-

0924 stipulate different HDR prescription doses. In RTOG-0815, the HDR brachytherapy boost may be performed during EBRT or within 1 week prior to its initiation or following its completion. The prescription is 21 Gy delivered in two equal fractions of 10.5 Gy, separated by at least 6 hours, and given within 24 hours. In RTOG-0924, the implant may be done during EBRT or within 2 weeks prior to its initiation or following its completion. The prescription is 15 Gy in a single fraction. In both protocols, the dose constraints to the bladder are V_{75} less than 1 mL, rectum is V_{75} less than 1 mL, and urethra is V_{125} less than 1 mL and V_{150} is 0%. An example of HDR brachytherapy with ultrasound planning and dose-volume histogram for various organs at risk is shown in Figure 73.6.

Stereotactic Body Radiotherapy Boost

Over the past 10 years, there has been an increased interest in the use of SBRT as an alternative to brachytherapy.[2] The review by Gonzalez-Motta and Roach, the systematic review and meta-analysis including more than 6,000 patients by Jackson et al, and the propensity matched retrospective study by investigators at UCSF provide a supportive body of work for using SBRT as a boost following EBRT or as monotherapy for selected patients with HR disease.[2,194,195] These systematic literature reviews and matched comparisons cited document high rates of biochemical disease-free survival (bDFS) and reasonable toxicity associated with the use of SBRT in HR prostate cancer either as monotherapy or as a boost. In addition, they compared their outcomes to selected series including patients treated with HDR, PPI, and EBRT (Figure 73.7). Cited 5-year bDFS were 81% to 91% or higher with monotherapy and 90% to 98% in boost studies comparable to studies reporting bDFS of 85% to 93% and 72% to 93%, respectively, with HDR monotherapy or boost in selected HR patients. They also reported that the incidence of late grade 3 GU toxicity was 0% to 4.4% and 0% to 2.3% in SBRT monotherapy and SBRT boost studies, respectively, not dissimilar to those seen with other forms of radiation (Figure 73.8). Table 73.4 summarizes the generally preferred options and the associated indications for how various types of boost techniques are chosen in patients undergoing definitive RT for clinically localized prostate cancer at UCSF.

TECHNICAL CONSIDERATIONS FOR EXTERNAL BEAM RADIATION

External Beam Radiation Therapy

IMRT (as opposed to 3DCRT) is recommended for optimal target coverage and avoidance of rectum and bladder.[196] At a minimum, the prostate, proximal SVs, and periprostatic tissue should be irradiated. Inclusion of the first echelon lymph nodes (ie, mini-pelvis) or the entire pelvic nodal contents (ie, whole pelvis) may be considered, based on the estimated risk of involvement. The recommended EBRT dose is 45 to 50.4 Gy in 1.8 to 2.0 Gy per fraction. Several investigators have conducted relatively small studies evaluating the merits of ultra-hypofractionated pelvic nodal RT.[197] In a systematic review and meta-analysis reported by Mohamad et al,[197] they identified 16 studies, with 7 meeting their criteria for a meta-analysis (n = 417, patients). The median dose to the pelvic nodes was 25 Gy (range, 25-28.5 Gy), with a median of five fractions. All patients received ADT, for a median of 18 months. They reported that the rates of acute grade 2 or higher GI and GU toxicity were 8% and 29%, respectively. For late grade 2 or higher GI and GU toxicity, the rates were 13% and 29%, respectively. They concluded that "ultra-hypofractionated pelvic nodal irradiation appears to be a safe approach in terms of acute and late genitourinary and gastrointestinal toxicity." We believe these rates are a bit high, considering that patients tend to report higher rates than physicians, and we suspect that the fields used are likely to be substantially smaller than the superior border used on RTOG-0924 (L4-L5). Thus, although promising, generally speaking, the role of hypofractionated regimens has not been well defined in patients with unfavorable to higher risk disease.[198-200]

Prostate Motion and the Use of Image-Guided Intensity-Modulated Radiation Therapy

While the use of fiducial gold seed markers and daily electronic portal imaging (EPI) with online correction and/or the use of cone-beam computed tomography (CBCT) are favored at UCSF, the use endorectal balloons or rectal spacers may be considered standard elsewhere.[201,202] Well-placed marker migration was found to be minimal, with 79% within 1 mm and 96% within 1.5 mm. The latter results have been corroborated by

Kupelian et al, who demonstrated that the average absolute variation in intermarker distance was 1.01 ± 1.03 mm.[203-205] Only 1% of the markers exhibited frequent movement, and it was found to be due to prostate deformation secondary to rectal filling. CBCT for online correction is gaining popularity as it allows for soft tissue matching and does not require an invasive procedure to implant fiducial markers. Moseley et al compared kilovoltage CBCT with fiducial markers and EPI and found no significant difference as a means for image guidance.[202] Langen et al described broadly two different types of intrafraction motions.[206,207] One type of motion is a slow, small drift, usually posteriorly and inferiorly, that is thought to be associated with pelvic muscle relaxation or the gradual movement of rectal contents away from the prostate. Second is a sudden and transient motion, usually anteriorly and superiorly, that can be significant in extent and is thought to be due to peristalsis. In the cohort of 17 patients (550 fractions), the average proportion of the total treatment time that the prostate was displaced by greater than 3 and greater than 5 mm was 13.6% and 3.3%, respectively. However, when analyzed by patient-to-patient basis, the prostate was displaced by 36.2% and 10.9%, respectively.

In an analysis of patients treated at UCSF, Chen et al demonstrated that an isocenter shift of 5 or 10 mm in the superior direction could reduce nodal target coverage by 11% and 26%, respectively, with whole-pelvic IMRT. Xia et al compared multiple adaptive plans, iso-shifting, and multileaf collimator (MLC) shifting and concluded that MLC shifting was the most effective in addressing the independent movement of the prostate and pelvic nodes during RT.[208-210] In a study by Chung et al, patients treated with image-guided IMRT to pelvic nodes had significantly lower dose to the rectum and bladder and fewer toxicities than those who received IMRT only.[211]

Rectal spacers are not generally recommended for unfavorable IR and HR patients because of the potential concern for areas of ECE and the observed marginal impact on grade 1 toxicity.[212,213] Serious concerns have been raised by several investigators about the use of this technology.[214] These concerns are supported by a recent review of “Real-World” complications following the placement of rectal spacers, suggesting there should great caution for all patients receiving definitive RT.[215]

Volumes and Setup Variation

We routinely have three fiducial gold seed markers placed into the prostate under transrectal ultrasound guidance—one in the base, one in the mid-gland, and one in the apex. Each marker is approximately 1.1 mm in diameter and 3 mm in length. We use an amorphous silicon flat panel detector to make any necessary adjustments prior to each treatment. As such, the authors typically apply a 3-mm margin around the prostate gland and SVs in defining the planning target volume (PTV). For patients with hip replacements, the authors use CBCT for image guidance. At institutions without daily EPI to control for intra- and interfraction prostate motion, larger margins such as 0.5 to 1 cm should be considered. Patients are instructed to empty their rectum with an enema prior to simulation. Patients are told to maintain a full bladder during simulation and treatment. A retrograde urethrogram is no longer performed at UCSF to assist in identifying the apex of the gland, except in patients undergoing SBRT for whom an MRI is not possible or contraindicated. Three-millimeter slice thickness is used for the CT simulation. The critical organs that are contoured include the penile bulb, small bowel, rectum, bladder, and femoral heads. The entire rectum is contoured from the anus to the rectosigmoid junction. Rectal spacers are not recommended for patients with IR and/or HR disease.

Intensity-Modulated Radiation Therapy Treatment Planning

For patients opting for definitive IMRT to the pelvis and prostate, the authors use a two- or three-phase plan. The first phase delivers 25 to 30 fractions of 1.8 Gy (total 45-60 Gy [the latter PET-positive sites], superior border L4-L5 with node negative by imaging). Concurrently, 2 Gy per fraction (total 54-56 Gy) to the SVs and prostate PTV. PET-positive nodes are boosted to 60 Gy and para-aortic nodes added if pelvic nodes are positive. The second phase is a cone-down boost to the prostate PTV alone with 12 fractions of 2.0 Gy per fraction. Therefore, the minimum total dose to the prostate (prescribed to the PTV) is 78 Gy. In postoperative patients opting for pelvic RT, the authors prescribe 25 fractions of 1.8 Gy to the nodes (total dose 45 Gy) and 2 Gy per fraction to the tumor bed PTV (total

dose 50 Gy) and then 9 or 10 fractions of 2.0 Gy per fraction to the prostate bed (total minimal PTV dose 68-70 Gy).

Bounders and Considerations for Pelvic Intensity-Modulated Radiation Therapy

Over the past 15 years, IMRT has been adopted as standard of care for pelvic nodal irradiation. For historical purposes, with conventional technique, pelvic irradiation is usually treated with a four-field box. The target volume usually includes the prostate, SVs, obturator, and proximal internal and external iliac nodal regions. Occasionally, common iliac, para-aortic, and even perirectal nodes are included in the initial target. The traditional field borders of the anteroposterior portals previously were as follows: superior at the L5-S1 interspace, inferior at 2 cm distal to the membranous urethra (defined by the apex of the urethrogram peak), and 1.5 to 2 cm lateral of the pelvic brim. Based on work involving sentinel lymph nodal imaging, we now recommend extending the superior border to L3-L4 or L4-L5 instead of L5-S1.[155] In the lateral portals, the superior and inferior borders are placed at the same point as the anteroposterior portals; the anterior border is placed at the anterior most aspect of the pubic symphysis, and the posterior border is placed at the S2-S3 interspace. With CT planning, the prostate, SVs, rectum, small bowel, bladder, pelvic vessels, and penile bulb may be contoured to facilitate shielding of the rectum and small bowel.

Compared to conventional technique, IMRT allows unprecedented sparing of nearby critical structures like the rectum, small bowel, bladder, and femoral heads. In a study from UCSF, Wang-Chesebro et al compared the nodal target coverage by conventional field borders with IMRT (Figure 73.9).[216] The nodes that were contoured included the obturator, internal or external iliac, common iliac, and presacral regions. In the conventional four-field plan, only 70.3% of the nodal target volume received the prescription dose of 45 Gy, whereas 96.2% was covered in the IMRT plan (P = .002). Even worse, conventional field placement led to 20.2% of the nodal target volume to receive less than 80% of the prescription dose. The rectal and bladder volume receiving 95% of the prescribed dose was

significantly reduced with IMRT, with an absolute reduction of 23% and 80%, respectively.

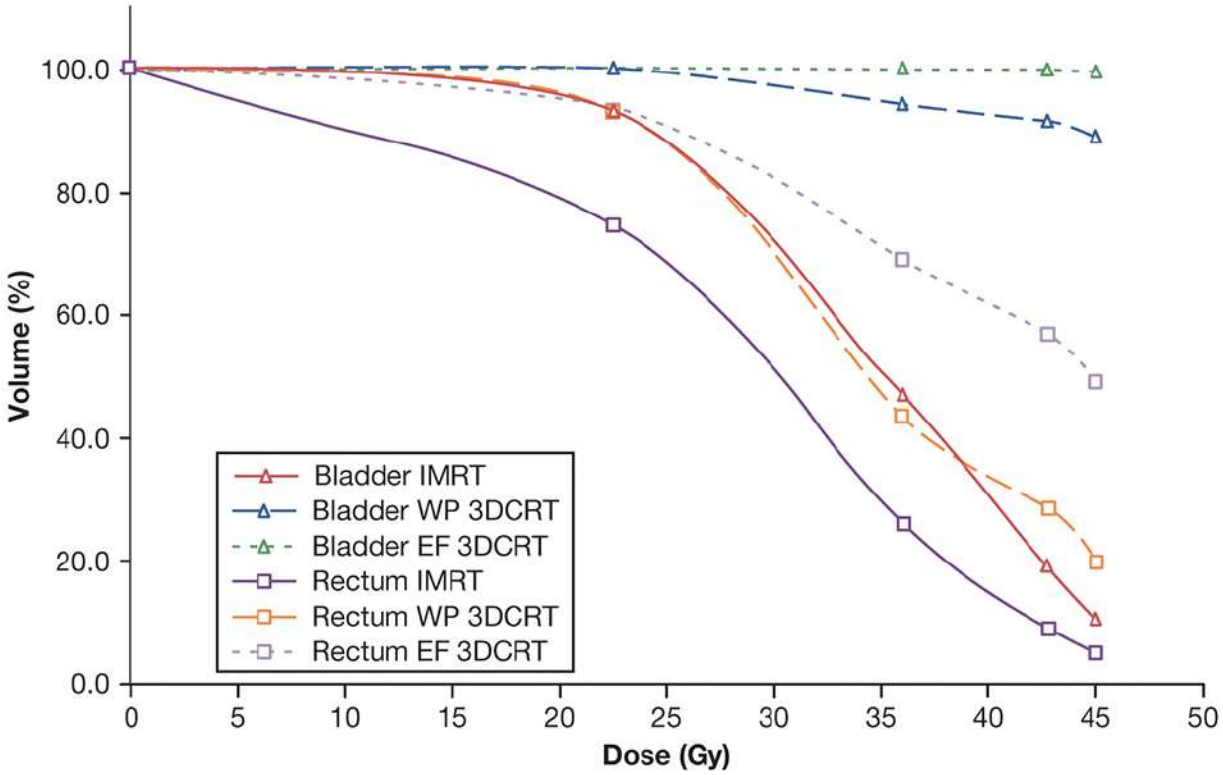

FIGURE 73.9 Comparison of dose-volume histograms for the rectum and bladder for whole-pelvic only phase using intensity-modulated radiotherapy (IMRT), whole-pelvic (WP) three-dimensional conformal radiotherapy (3DCRT), and extended-field (EF) 3DCRT plans. For both the bladder and rectum, IMRT significantly reduced V_{45}, $V_{42.75}$, V_{36}, and $V_{22.5}$ (P , .01 for all comparisons) compared to both WP and EF 3DCRT plans. Whereas conventional technique involved simply placing field borders based on bony anatomy, IMRT requires the delineation of a nodal target volume based on vasculature. Investigators have used lymphotropic nanoparticle-enhanced MRI and ultra-small superparamagnetic iron oxide lymph node contrast agent, ferumoxtran-10, to develop nodal CTV models.[119] These MRI studies have formed the foundation for the RTOG Genitourinary Radiation Oncology consensus on pelvic nodal CTV delineation, as shown in Figure 73.10.[120,189] However, the RTOG guidelines

did not use sentinel lymph node imaging, which in a study by Chen et al demonstrated that the RTOG pelvic nodal CTV included all identified sentinel lymph nodes in only 30% of patients.[155] In the same consensus, Lawton et al recommended dose constraints to the rectum (V_{50} Gy ≤50%, V_{70} Gy ≤20%), bladder (V_{55} Gy ≤50%, V_{70} Gy ≤30%), femoral heads (V_{50} Gy ,5%), and small bowel (maximum dose ,52 Gy). Based on an extensive literature search, Chan et al proposed guidelines on rectal dose constraints for patients receiving pelvic RT.[196]

DOSE ESCALATION AND ANDROGEN DEPRIVATION THERAPY: EVIDENCE AND INDICATIONS

EBRT Alone Versus EBRT Plus ADT and ADT Alone Versus ADT Plus EBRT

The optimal dose of radiation required to obtain a high level of local control while maintaining an acceptably low level of complications is not known. Several phase III randomized trials have compared conventional dose with high-dose (76-82 Gy) EBRT, and although essentially all have demonstrated an improvement in PSA control, no survival advantage attributable to radiation dose were observed.[8,217,218] The largest and most recent of dose escalation trials is RTOG-0126, which compared 70.2 Gy in 39 fractions versus 79.2 Gy in 44 fractions.[219,220] In the initial report, at 8 years while there was no improvement in OS, the rate of DM was 4% for the 79.2 Gy arm versus to 6% on the 70.2 Gy arm (P = .05), and BF was 20% versus 35% (P , .001). Although the 5-year rates of late grade 2 or higher GI and GU toxicities were 21 and 12% for 79.2 Gy versus 15 and 7% for 70.2 Gy (P = .006 and P = .003), the overall impact on QoL was modest at best, with no significant impact on any patient-reported outcome (PRO) metrics measured across all collected domains. Of note, however, at 12 months, 49.7% versus 38.1% developed ED on the 79.2 versus 70.2 Gy arms (P = .051) a finding not inconsistent with earlier work.[221]

Recently, the RTOG (now NRG [NSAB, RTOG, and GoG]) reported the first analysis of RTOG-0815.[222,223] This phase III multicenter trial compared dose-escalated RT alone (arm 1), achieved by either 3DCRT or IMRT (79.2 Gy), combined LDR (110 Gy with ^{125}I or 100 Gy with ^{103}Pd) brachytherapy boost with 3DCRT or IMRT (45 Gy to the prostate and SVs), or combined HDR (two fractions of 10.5 Gy per fractions) to dose-escalated RT with the addition of 6 months ADT (arm 2).[222,223] This trial was specifically designed to address the question of the need for ADT when dose-escalated radiation

is used. Eligible patients had either clinical stage T2b-T2c, or a GS of 7, or pretreatment PSA greater than 10 and 20 ng/mL or less. Patients harboring all three or more than 50% of cores positive were ineligible (but eligible for RTOG-0924). While this trial with a median follow-up of 6.3 years failed to demonstrate an OS advantage (the primary end point), there was an improvement in the risk of metastasis (*P* , .001), prostate cancer–specific survival (*P* = .007), and PSA failure (*P* , .001). Only 219 deaths occurred triggering the interim analysis, with only 10 in arm 1 (RT alone) and 1 in arm 2 (RT + ADT) attributed to prostate cancer. Thus, we believe that with longer follow-up, an OS end point may be met.

At UCSF, we have long favored brachytherapy boost (or SBRT) for suitable patients treated with curative intent, based on the lower PSA nadir, degree of metabolic atrophy noted, and PSA control rates compared to any form of dose-escalated EBRT (including proton beam RT).[224-226] This philosophy seems to have been vindicated by the findings from the ASCENDE-RT trial, which confirmed a substantially higher PSA control rate with an LDR brachytherapy boost after ADT and EBRT compared to ADT and dose-escalated EBRT alone (see the discussion of brachytherapy).[191,227]

Multiple phase III RCTs and several meta-analyses have been published in the peer-review literature that compared RT alone with RT and ADT.[8] At UCSF, the authors' practices regarding integrating pelvic RT and hormonal therapy are summarized in Table 73.5. Previously, RTOG-9408 was designed to evaluate whether similar duration and timing of ADT (2 months neoadjuvant [NHT] and 2 months concurrent) could improve outcomes in patients with primarily IR disease.[186] Among the 1,979 eligible patients, 54% had IR disease and 11% had HR disease. With a median follow-up of 9.1 years, 10-year OS (57% vs 62%; *P* = .03), PCSM (8% vs 4%; *P* = .001), PSA failure (41% vs 26%; *P* , .001), and DMs (8% vs 6%; *P* = .04) were significantly in favor of the ADT arm. In a post hoc analysis, the benefit in OS and PCSM appeared to be primarily among IR patients. Two-year positive prostate biopsy rates (39% vs 20%; *P* , .001) were significantly improved with ADT. The authors give 2 months of NHT using a luteinizing hormone–releasing hormone (LHRH) agonist and an antiandrogen. An updated post hoc subset analysis of RTOG-9408 concluded that ADT was only beneficial in patients with unfavorable IR prostate cancer.[228] An even

more recent analysis using an MMAI system demonstrated that this same study could be used identify patients who are most likely benefit from the addition of ADT.[229]

TABLE 73.5 GENERAL RECOMMENDATIONS FOR RADIATION THERAPY AND ADT

Therapy	Low Risk	Favorable Intermediate Risk	Unfavorable Intermediate Risk	High/Very High Risk
Active surveillance	Preferred	In highly selected patients	Only appropriate in those with a short life expectancy	Only appropriate in those with a very short life expectancy
Radiation therapy	PORT	PORT ± ADT (4 mo)[a]	WPRT + NHT (4 mo)	WPRT
ADT	Not indicated	None or neoadjuvant and concurrent with (4 mo) or adjuvant ADT if prostate-only EBRT (4 mo)	Neoadjuvant and concurrent with (4 mo) ADT with	Neoadjuvant, concurrent and adjuvant (18-36 mo)
Other				± Second-generation ADT or chemotherapy in selected patients[b]

ADT, androgen deprivation therapy; EBRT, external beam radiation therapy; NHT, neoadjuvant hormonal therapy; PORT, prostate-only radiation therapy; WPRT: whole-pelvic radiation therapy.

[a]Omit ADT if low risk by Artera assay.

[b]STAMPEDE trial.

In addition to NHT, 2 to 3 years of AHT (eg, LHRH agonist) is recommended for HR disease, but on occasion, lifelong androgen deprivation is used in patients with very HR disease (Table 73.5). Early trials demonstrated that for men with locally advanced disease, initial management with hormonal therapy resulted in a survival advantage when compared to deferred ADT.[8,230] Subsequently, numerous trials showed that the addition of ADT to EBRT improved survival for men with IR and HR

disease.[8] There is also clear level I evidence that EBRT plus ADT renders a better survival than ADT alone for men with locally advanced disease.[183,231,232]

SEQUENCING, TIMING, AND DURATION OF ANDROGEN DEPRIVATION THERAPY AND RADIOTHERAPY

Sequence-Dependent Interactions Between Androgen Deprivation Therapy and External Beam Radiation Therapy

NHT implies delivery of the hormone prior to definitive radiation, whereas AHT implies the initiation of hormonal therapy after the completion of radiation. Few studies have assessed the optimal sequence or precise duration of ADT. RTOG-9413 randomized 1,323 men to either receive 4 months of NHT (commenced 2 months prior to starting EBRT) compared to 4 months of AHT.[176] The authors noted sequence-dependent beneficial interactions, such that when NHT is used, PSA control favored the use of WPRT over PORT. However, NHT plus WPRT was also associated with higher rates of late grade 3 GI toxicity at 10 years occurring in 5.1%, compared to 1.6% and 0.6% in both AHT groups and patients treated with NHT plus PORT (P = .0009). Of note, when PORT is used, AHT appears to be at least as effective as NHT. The mechanism by which these sequence-dependent interactions occur is unknown.

Optimal Duration of Short-Term Androgen Deprivation Therapy (Indicated for Intermediate-Risk Patients)

To date, there are at least eight randomized trials (two Canadian, one Irish, one Australian, two conducted in the United States [RTOG-9202, RTOG-9910], and two conducted by the EORTC) evaluating the optimal duration of ADT with a survival end point and an additional three randomized trials (two Canadian and one EORTC) with a PSA control end point.[8] The Canadian Urologic Oncology Group study randomized 378 patients to either 3 or 8 months of NHT plus EBRT, whereas the Irish Clinical Oncology Research Group designed a randomized study comparing 4 and 8 months of NHT with EBRT.[233,234] TROG compared 0 versus 3 versus 6 months ADT with EBRT, whereas RTOG-9910 compared 8 versus 28

weeks of NHT (total 4 vs 9 months).[235,236] Taken together, these studies suggest that for patients with IR disease, there is no reason to extend short-term ADT beyond 4 months when combined with EBRT.[8,118]

Optimal Duration of Long-Term Androgen Deprivation Therapy (High-Risk Patients)

A meta-analysis of RTOG trials conducted more than 20 years ago suggested that long-term ADT was superior to short-term ADT for patients with HR disease.[118] This assertion was subsequently confirmed by EORTC-22961 that compared 6 months with 36 months of AHT in 1,113 patients with locally advanced prostate cancer and demonstrated the superiority of the latter.[69] RTOG-9202, another phase III trial, also demonstrated that the addition of 24 months of AHT could improve the outcome in HR patients, compared to short term (4 months).[237] Aside from OS, all other end points were significantly in favor of the long-term ADT arm: PCSM (83.9% vs 88.7%; $P < .0001$), DFS (13.2% vs 22.5%; $P < .0001$), and biochemical control (31.9% vs 48.1%; $P < .0001$). In subgroup analysis, again, patients with a GS of 8 to 10 had a significant improvement in OS with long-term ADT, but not with a GS of 2 to 7. The authors speculate that the absence of OS difference may be due to insufficient follow-up among patients with a GS of 2 to 7. These data, as previously noted, are completely consistent with the meta-analysis of five consecutive RTOG randomized controlled prostate cancer trials (including RTOG-8531 and RTOG-8610), where 2,742 men were stratified into four previously identified risk groups based on GS, clinical T-stage, and pelvic nodal involvement.[118] More recently, Nabid et al compared 18 versus 36 months of ADT in patients with HR disease (discussed earlier).[67] This was a *superiority* trial (should have been a noninferiority trial) that was 35% smaller ($n = 630$) than the earlier EORTC trial that showed that 6 months was inferior to 36 months.[69] The EORTC trial also included more patients with T3-4 disease and node-positive patients.[67] Despite this suboptimal study size, at 5 years, the trial led by Nabid et al[67] demonstrated a trend in favor of 36 months in terms of OS (91% vs 86% [$P = .07$]), as well as biochemical control ($P = .02$) and DFS (45% vs 39%; $P = .08$) at 10 years. Thus, for patients who are primarily at HR because of a PSA greater than 20 ng/mL and node-negative disease, 18

months may be adequate, but for patients with bulkier or node-positive disease, we favor longer term ADT.

Toxicities Associated With Androgen Deprivation Therapy

Having established that ADT improves survival when combined with RT, enthusiasm has been somewhat tempered by the increasing recognition of the potentially serious complications of ADT.[238] Some of these complications have been exaggerated.[239] What is clear is that the risks of fractures, fatigue, weight gain, osteoporosis, depression, decreased cognitive function, ED, loss of libido, gynecomastia, anemia, decreased high-density lipoprotein, insulin resistance, and hot flashes are increased with ADT. For example, in a study of 50,613 men with prostate cancer compiled from a linked database of SEER and Medicare, the addition of ADT significantly increased the risk of any fracture from 12.6% to 19.4%; fractures requiring hospitalization similarly increased from 2.37% to 5.19%.[240]

More controversial is the issue of the impact of ADT on cardiovascular disease.[241-245] Some studies have raised the question of whether ADT, by way of increasing body fat and cholesterol levels, increases the risk of cardiovascular disease.[239] In an observational study of a population-based cohort of 73,196 patients with clinically localized prostate cancer, ADT was associated with an increased risk of incident diabetes (hazard ratio 1.44; P , .001), cardiovascular disease (hazard ratio 1.16; P , .001), myocardial infarction (hazard ratio 1.11; P = .03), and sudden cardiac death (hazard ratio 1.16; P = .004). However, data from RCTs of RT with or without ADT have generally not shown any increased cardiovascular disease, although these studies were not powered adequately.[246] The bottom line is that *if* ADT increases the risk of cardiovascular disease, the risk is quite low and the subset of patients who are at risk are those with severe underlying cardiovascular disease.[242]

Many investigators adopted the belief that LHRH agonist might be more cardiotoxic than the gonadotropin-releasing hormone (GnRH) antagonist. Despite encouraging findings from the HERO trial involving the oral antagonist relugolix, the subsequent randomized trial evaluating major adverse cardiovascular events in patients with prostate cancer with

concurrent cardiovascular disease treated with the GnRH antagonist degarelix or antagonist leuprolide was closed early due to a small number of events and no difference in major cardiovascular side effects at 1 year between the treatment groups.[247,248] Thus, this question remains unanswered.

In addition to cardiovascular risk, another area to which much attention has been paid is the risk of the potential impact of ADT on the brain. For example, Nead et al published a series of methodologically flawed studies that essentially ignore the tendency for men with declining mental status to be at greater risk for receiving ADT.[249,250] The best data suggest that the risk of damage to both the central nervous system and cardiovascular systems is low, such that with rare exceptions the benefits justify the risk.[246,251]

POSTOPERATIVE (POSTPROSTATECTOMY) RADIATION THERAPY

Local Versus Distant Recurrence

A significant number of men undergoing an RP for IR and HR prostate cancer will experience a recurrence, with the only curative treatment afterward being postoperative radiation.[252] Such patients tend to have adverse characteristics, such as a high percentage of positive biopsies (eg, ≥50%), higher GSs (eg, ≥7), SVI, positive surgical margins (PSMs).[31,253] For example, D'Amico et al reported 5-year recurrence rates exceeding 75% in IR patients with more than 50% of their biopsies positive who underwent RP at the University of Penn or Harvard University.[31] Another frequently overlooked fact is that patients with high-grade tumors tend to recur after RP, even if they have *pathologically* confined disease. For example, from a series of 904 patients undergoing post-RP at the Mayo Clinic in the subset of patients with high-grade tumors (eg, ≥8-10), the recurrence rates at 5 years exceeded 50%, even if they have pathologically confined disease (most do not have organ-confined disease).[254] In an analysis of patterns of treatment failure in the study by the South West Oncology Group, SWOG-8794, the first randomized trial evaluating ART in patients with adverse pathologic features (pT3a-b or PSM), the predominant site of failure was believed at that time to be local rather than metastatic.[255] However, these historical data must now be considered unreliable, given the fact that PSMA-PET imaging was not available and that conventional imaging (eg,

CT, MRI, and bone scans) has a very poor sensitivity in this setting. More recent data incorporating PSMA imaging tends to support the notion that regional recurrences may be as common or more common than local recurrences.[256]

Based on three early trials, the American Urological Association (AUA) and ASTRO produced guidelines in 2013, which encouraged the consideration of ART in patients with adverse pathologic feature following RP.[257-260] However, subsequently, three more contemporary trials, and an associated meta-analysis, specifically comparing adjuvant versus early salvage, provided support for a contrary opinion.

The largest of three earlier studies was EORTC-22911 (n = 1,005) in men with pT2-3N0 and at least one of the following risk factors: ECE, PSM, or SVI.[261] In the ART arm, radiation was commenced at a median of 90 days postoperative. ART consisted of 50 Gy in 25 fractions to a large volume that encompassed the surgical limits and subclinical disease, followed by 10-Gy boost given over five fractions to a reduced margin around the prostatic bed. The protocol SRT was a bit more aggressive delivering 70 Gy in 35 fractions. Five-year biochemical PFS was significantly improved from 52.6% to 74.0% (P , .0001) with ART, representing a 52% reduction in PSA relapse. The treatment benefit was significant for all postoperative prognostic factors, including negative surgical margins or absence of SVI and ECE. Long-term results, with a median follow-up of 10.6 years, were recently published and continued to support the use of ART.[258] The ART arm continued to have significantly improved biochemical PFS (60.6% vs 41.1%; hazard ratio 0.49, $P < .0001$). Similarly, 10-year cumulative rate of locoregional relapse was lower in the ART arm (7.3% vs 16.6%; hazard ratio 0.45, $P < .001$). No difference in metastases-free survival or OS was observed, though it was not powered to detect a difference. However, the 10-year cumulative incidence of severe (grade 3) late toxicities (5.3% vs 2.5%, $P = .052$) and late grade 2 or higher GU toxicities (21.3% vs 13.5%; $P = .003$) were higher in the ART arm. There was no significant difference in cumulative incidence of DMs ($P = .94$), prostate cancer mortality ($P = .34$), or OS ($P = .20$). In the wait-and-see arm, 275 patients had clinical or biochemical progression, of which 231 (84%) went on to receive active treatment and 155 (56%) received SRT at a median PSA of 1.7 ng/mL.

The first of the early trials, SWOG-8794, randomly assigned 425 node-negative patients initially treated with RP but found to have either PSM or pT3 (ECE and/or SVI) disease to ART or observation.[262] Central pathology review was performed in 73% of patients, and there was a 95% concordance with the community pathologist. Ninety percent of patients had ECE or PSM. Two-thirds of patients had a postoperative PSA less than 0.2 ng/mL. ART consisted of 60 to 64 Gy. Median PSA relapse-free survival was significantly longer with ART (10.3 vs 3.1 years; hazard ratio 0.43; *P* , .001). Updated results have been published with a median follow-up of 12.6 years.[257] The 10-year DM-free survival (71% vs 61%; hazard ratio 0.71; *P* = .016) and OS (74% vs 66%; hazard ratio 0.72; *P* , .023) were significantly improved with ART. The median DM-free survival was prolonged from 12.9 to 14.7 years with ART, and OS from 13.3 to 15.2 years. On subgroup analyses, there was no interaction between the adverse pathologic features and treatment effect, and therefore, the benefit in DM-free survival was seen in all subsets. Among patients in the ART arm, those with an undetectable postoperative PSA had a significantly better 10-year DM-free survival (73% vs 65%; *P* = .03) than those with a PSA greater than 0.2 ng/mL. In the observation arm, only one-third of patients eventually received SRT, of which the median pre-RT PSA was 1.0 ng/mL. Hormonal therapy was initiated later (median 12.4 vs 9.9 years) and less frequently (39% vs 50%) in the ART arm. Complications observed in the ART arm included proctitis (3.3% vs 0%), urethral stricture (17.8% vs 9.5%), and total urinary incontinence (6.5% vs 2.8%).

From the German Cancer Society, ARO-96-02/AUO-09/95 accrued 388 patients from 22 centers with pT3 or PSM to either ART (60 Gy in 2 Gy fractions) or observation.[263] In contrast to SWOG-8794 and EORTC-22911, only patients who achieved an undetectable post-op PSA were included, 3DCRT planning was mandated, and central pathology review was required. In the initial report with a median follow-up of 54 months, using intention-to-treat analysis of only patients who achieved an undetectable postoperative PSA, ART significantly improved PFS (*P* , .0001). When analyzed according to the received treatment, 5-year PFS was 72% versus 54% in favor of ART (*P* = .0015; hazard ratio 0.53). ART was very well tolerated, with only 3% reporting acute grade 3 bladder toxicity and none with grade 3 rectal toxicity (12% had grade 2 rectal toxicity). Of note, the

compliance in the ART arm was surprisingly poor—19% did not proceed with RT. Updated results with 10-year follow-up have since been published.[259] The 10-year PFS was significantly better in the ART arm (56% vs 35%; hazard ratio 0.51, *P* , .0001). However, despite longer follow-up, no difference in the development of DMs (*P* = .53) or OS (*P* = .59) was seen. The cumulative incidence of late grade 3 toxicities was 5.3% with ART and 2.5% with observation (*P* = .052). There was only one event of late grade 3 toxicity, which involved the bladder, and no late grade 4 GI or GU toxicities were observed.

A significant limitation of these three clinical early trials was that they were conducted prior to the current era of ultrasensitive PSA assays, which can detect PSA levels as low as 0.01 ng/mL. For instance, the ARO trial defined undetectable PSA as those less than 0.1 ng/mL, of which 59% had a PSA of greater than 0.03 to 0.1 ng/mL. In the EORTC-22911 and SWOG-8794 studies, 11% and 34% of patients, respectively, had a postoperative PSA greater than 0.2 ng/mL. In effect, a significant proportion of patients enrolled in these trials had "measurable disease" and thus received SRT.[264] Although there was an initial surge in enthusiasm in embracing ART, it has given way to increasing skepticism. In an observational study of post-op patients identified by the NCDB, which tracks outcomes on 71% of newly diagnosed cancer cases in the United State, 130,681 patients with at least one HR pathologic factor and diagnosed between 2004 and 2011 were analyzed.[265] The overall rate of ART was surprisingly low (9.9%) and did not change during the study period despite three RCTs demonstrating improved outcomes with ART. Similarly, SEER data of 35,361 post-op patients diagnosed between 2004 and 2011 revealed that ART utilization remained low, 15.8% after March 2009 versus 13.5% before.[266]

Given the prevalence of ultrasensitive PSA assays, it is unclear whether a strategy of AS with PSA tests and the early initiation of RT only when PSA has shown an upward trend can yield equivalent or better results. The advantage of such an approach is that perhaps the 50% of patients who do not relapse after surgery will be spared from RT. The disadvantage is that biochemical control and DM-free survival (SWOG-8794) may be compromised by waiting too long to intervene with definitive treatment, which could serve as a nidus for metastatic spread. In an editorial, King showed that for every 0.1 ng/mL increment in postoperative PSA, there is

an estimated 4% reduction in biochemical control.[264] Nonetheless, the EORTC-22911, SWOG-8794, and ARO-96-02 provide consistent level I evidence that ART is better than expectant management in terms of biochemical control, at an acceptable toxicity. It remains to be seen whether with longer follow-up this translates into an improvement in survival. Accordingly, in 2013, the ASTRO/AUA published guidelines based on a systematic review on ART and SRT.[260] The panel recommended that those with adverse pathologic features (SVI, EPE, and PSM) should be counseled and that there is level I evidence that ART reduces the risk of BCR, local recurrence, and clinical cancer progression.

Three Newer Trials and the ARTISTIC Meta-analysis

The three key more recent randomized phase III trials, RADICALS, RAVES, GETUG-17, and their associated meta-analysis also investigated ART versus early SRT.[267-270] As a group, these trials tended to suggest that SRT should be preferred to ART, primarily due to reduced toxicity (because of sparing RT is a significant subset of patients). RADICALS was a MRC-led phase III trial that randomized postoperative patients to immediate postoperative RT or early SRT. RADICALS also has a hormone duration randomization substudy in which patients were randomized to RT alone or 6 months or 2 years of adjuvant hormones. RAVES was a phase III multicenter study ran in Australia and New Zealand, while GETUG-17 was a French study that randomized patients to ART and ADT versus early SRT with ADT. The major shortcoming of these three trials is that the committed the "three sins" of trial design described earlier. First, the patient eligibility included patients for whom we would never recommend ART, including those with GS of 7 or pre-op PSA greater than 10 ng/mL (sin #1). As a result, only 15% to 20% of the recruited patients had HR disease. Second, the studies were grossly underpowered due to discontinuation by the monitoring committees because of their low event rates (sin #2). In addition, ADT was not used nor was elective nodal irradiation (ENI) applied (sin #3). Thus, although it is likely to be safe to defer RT pending a detectable PSA for many patients, for those with truly HR disease, ART should still be considered.

Salvage Radiation Therapy

An update of the often-cited Stephenson predictive nomogram to estimate BCR following SRT was published.[3,271] This was based on multi-institutional data of 2,460 patients. Unlike the initial nomogram, patients with pre-SRT PSA less than 0.2 ng/mL were included in the updated nomogram. The median pre-SRT PSA was 0.5 ng/mL, with 18% of patients having less than 0.2 ng/mL. Higher pre-SRT PSA was associated with worse outcomes. The 5-year freedom from BF was 71%, 63%, 54%, 43%, and 37% for those with a pre-SRT PSA of 0.01 to 0.2, 0.21 to 0.50, 0.51 to 1.0, 1.01 to 2.0, and greater than 2.0 ng/mL, respectively (P , .001). Similarly, the 10-year cumulative incidence of DM was 9%, 15%, 19%, 20%, and 37%, respectively (P , .001). Independent predictors of BCR included higher pre-SRT PSA, higher GS, presence of ECE, SVI, negative surgical margins, lack of ADT, and SRT dose less than 66 Gy.

Genomic classifiers are being used to identify post-op patients with adverse pathologic features who would benefit from ART. In a study by Dalela et al, they evaluated a risk stratification tool that included the Decipher multigene expression array score (GenomeDx Biosciences, Vancouver, British Columbia, Canada) with routine clinicopathologic features.[272] Their cohort included 512 post-op patients with at least one pathologic adverse feature (≥pT3a disease, PSM, or pathologic LNI) and received either ART or initial observation (with 42% subsequently receiving SRT). In multivariate analysis, in addition to GS, pathologic pT3b-4 disease, and LNI, a high Decipher score was an independent predictor of higher risk of clinical recurrence. Based on these factors, a novel nomogram was created to identify those at higher risk of clinical recurrence and thus would benefit from ART, with a predictive accuracy of 85%. In another study of Decipher, Freedland et al investigated whether it could predict for the subsequent development of metastatic disease in 170 post-op patients treated with SRT for recurrence.[273] On multivariate analysis, the Decipher score was significantly predictive of metastases (hazard ratio 1.56, P = .003). By identifying patients at HR of developing metastases, treatment intensification with hormonal therapy and/or systemic therapy can be explored. Likewise, patients with low risk of developing clinical recurrence

or metastases could be observed. While encouraging, external validation in larger prospective cohorts is needed.

As it stands, we have only retrospective data, though very large patient cohorts, that suggest that early SRT is more effective than later SRT, and this is likely due to reduced tumor burden.[3,271] Whether *early* SRT is as good as ART is unknown. Although RADICALS, RAVES, and GETUG-17 tend to suggest that SRT should be preferred to ART, there are some major limitations with these studies, as discussed earlier.

Androgen Suppression Therapy and Postoperative Radiation Therapy

Extrapolating from the benefits of shown in multiple phase III trials in the definitive setting, it is not surprising that ADT would be investigated in the postoperative setting. Recently, the results of RTOG-9601, a placebo-controlled phase III study to evaluate the addition of 2 years of antiandrogen therapy with SRT, were published.[274] Eligible patients included those with pathologic stage T2 with a PSM or T3 without nodal involvement. Patients were also required to have a detectable PSA of 0.2 to 4.0 ng/mL and were considered eligible. Bicalutamide 150 mg daily for 24 months was used in the antiandrogen arm. The median follow-up among surviving patients was 13 years. The addition of antiandrogen significantly improved 12-year OS (76.3% vs 71.3%; hazard ratio 0.77, P = .04), incidence of death from prostate cancer (5.8% vs 13.4%, P , .001), cumulative incidence of metastatic prostate cancer (14.5% vs 23.0%, P = .005), and BCR (44.0% vs 67.9%, P , .001). Post hoc subgroup analyses suggested that those with a PSA greater than 1.5 ng/mL or a GS of 7 had the greatest OS benefit. There was no difference in radiation-related acute or late toxicities. As expected, gynecomastia was more common in the antiandrogen arm and occurred in 69.7% of patients. Of note, antiandrogens alone are rarely used currently, replaced by gonadotropin-releasing hormone agonist and antagonist, and are no longer approved by the FDA.

GETUG-AFU16 was a phase III trial that randomized 743 postoperative patients undergoing SRT for BCR with or without 6 months of goserelin.[275] All patients had to have an undetectable post-op PSA before BCR. The PSA at the time of randomization was less than 0.5 ng/mL in 80% of patients,

with the upper limit of acceptance being 2 ng/mL. After a median follow-up of 63 months, the 5-year PFS was significantly better in the hormone arm (80% vs 62%, *P* , .0001). Independent predictors of disease progression were pre-SRT PSA greater than 0.5 ng/mL, SVI, negative surgical margins, and pre-SRT PSA doubling time less than 6 months. There was no significant difference in acute or late GU and GI adverse events between the two arms.

In post-op patients with *very HR* clinicopathologic features, investigators are evaluating the addition of docetaxel to RT and ADT based on docetaxel and found improved survival in men with metastatic prostate cancer.[276] RTOG-0621 is a phase II study of 74 patients who had either a post-op PSA nadir greater than 0.2 ng/mL and a GS 7 or higher or a PSA nadir 0.2 ng/mL or less, GS 8 or higher, and pT3 or higher. Patients received 6 months of ADT, RT, and six cycles of docetaxel after RT. The 3-year freedom from progression was 73%. Although grade 3 to 4 hematologic toxicities were common, only 4.1% of patients developed febrile neutropenia. Currently accruing, the follow-up phase II/III trial is NRG-GU002, which is randomizing patients with a GS 7 or higher and post-op PSA nadir 0.2 ng/mL or greater to ART and ADT with or without adjuvant docetaxel.

Postoperative Radiation Therapy Dose

Currently, ART doses of 60 to 64 Gy and SRT doses of 66 to 70 Gy appear to be the most used. The ASTRO/AUA guidelines recommend at least 64 to 65 Gy in the post-op setting, with no distinction between adjuvant and salvage doses.[277] In a retrospective study by Cozzarini et al, 334 patients with adverse pathologic features and an undetectable postoperative PSA who received ART were analyzed for a dose response.[278] From 1993 to 2003, the RT dose gradually increased from 55.8 to 72 Gy. When stratified by dose (,70.2 Gy [median 66.6 Gy] vs ≥ 70.2 Gy [median 70.2 Gy]), the high-dose group had significantly better 5-year biochemical relapse-free survival (83% vs 71%; *P* = .001) and DFS (94% vs 88%; *P* = .005). In a systematic review, 71 studies (10,034 patients) of patients treated with SRT were identified.[189] The median radiation dose prescribed was 65.8 (range 60-76 Gy). A sigmoidal dose-response relationship was identified between SRT dose and relapse-free survival, with a TCD_{50} of 65.8 Gy and a 2.0%

improvement with each additional Gy within a dose range of 60 to 70 Gy. Based on the sigmoidal dose-response curve, the relapse-free survival was 58.4% and 38.5% for 70 and 60 Gy, respectively. The clinical outcomes of the SAKK-09/10 trial, which randomized patients to conventional dose (64 Gy) or dose-intensified SRT of 70 Gy to the prostate bed without ADT, showed no differences in outcomes, including PFS, time to ADT, or radiation dose OS, but a significant increase in late grade 2 or higher GI toxicity.[279]

NRG-GU003 is a randomized phase III trial of hypofractionated (62.5 Gy in 25 fractions) versus conventionally fractionated (66.6 Gy in 37 fractions) RT in postprostatectomy patients. After a median follow-up of 2 years, no difference in the BF rate was noted between the two arms. Although patient-reported GI toxicity was higher with the hypofractionated RT regimen when the radiation was completed, after 2 years, the hypofractionated regimen was noninferior to the conventionally fractionated regimen with respect to patient-reported GI or GU toxicities.[280]

Postoperative Radiation Therapy Volume

Several consensus guidelines on delineation of the CTV in post-op patients have been published.[281-285] We refer to readers to these details but acknowledge that PSMA-PET imaging and clinical features in individual patients should result in personalized refinement of these fields. Another area of controversy has involved the utility of prophylactic ENI in the post-op setting, especially for those with higher risk disease.[286-289] As a historical note, retrospective data assessing ENI with SRT have been supportive, with a significantly better 5-year freedom from BF of 62% versus 49% (*P* , .001), but more importantly, RTOG-0534 confirmed the value of evaluated ENI and ADT.[1,90]

Postoperative Radiation Therapy: Conclusions

We continue to endorse the original ASTRO/AUA guidelines whereby patients with adverse pathologic features should be jointly counseled by their urologist and radiation oncologist on the pros and cons of ART.[66,277] In those devoid of very unfavorable features (eg, SVI, nodes positive) and undetectable post-op PSA of less than 0.02 ng/mL, we recommend

observation with a PSA every 3 to 6 months. We recommend offering early SRT in those with a consisting rising PSA, even if below 0.2 ng/mL. The authors recommend adherence to the 2021 NRG updated consensus guidelines on the definitions of CTV in the postoperative setting.[285] For adjuvant patients, the authors usually prescribe 66 Gy, whereas for salvage patients, the authors use 70 Gy, both of which are in 1.8 Gy per fraction to the pelvis and 2.0 Gy to the bed. WPRT, as defined by the RTOG contouring guidelines, to a dose of 45 Gy, is considered depending on the extent of pelvic lymph node dissection, presence of SVI, and the estimated nodal involvement.[285] For both the prostate bed and ENI, we recommend IMRT technique with image guidance.

There are now at least three phase III trials that support the addition of ADT with post-op RT.[91,274,275] We recommend that those at higher risk of developing metastatic disease, including a detectable post-op PSA, pre-SRT PSA greater than 0.5 ng/mL, SVI, PSA doubling time less than 6 months, or node-positive disease, be considered for 4 to 6 months of LHRH, or longer for those at particularly HR (eg, GS = 9-10). In addition, we favor IGRT in the postoperative setting guided by the place of gold marker seeds at the anastomosis.[290]

CONCLUSIONS AND RECOMMENDATIONS

In summary, compared to patient convenience, cost, and PSA control, we favor PPI, HDR, or SBRT monotherapy for patients with favorable IR disease. For unfavorable IR disease, we favor short-term ADT (4 months) combined with IMRT and a boost with either PPI, HDR, or SBRT, with WPRT. In selected patients with biomarkers indicative of nonbenefit from ADT, low-volume disease omitting ADT seems appropriate. For truly HR patients, we favor long-term ADT (eg, ≥28 months) combined with WPRT and an HDR, an SBRT, or a PPI boost. For patients who are HR by PSA (eg, PSA . 20 ng/mL) but no other factors, 18 months of ADT may be adequate. Image-guided techniques *without* rectal spacer are preferred at UCSF. In selected patients (especially those age ,70 years with node positive), additional systemic agents (eg, abiraterone) are strongly considered. Based on recent data, leveraging novel biomarkers and/or molecular assays as well as advances in imaging will help us refine what we

mean by the categories that range from favorable IR to very HR disease. In the postoperative setting, we favor adjuvant over early salvage IMRT guided by ultrasensitive PSA monitoring combined with ADT, in the very highest risk patients but salvage in the more favorable patients.

CHAPTER 74

Testicular Cancer

Gerard C. Morton

EPIDEMIOLOGY

Testicular cancer is the most common malignancy among young men in North America and most Western European countries, although it accounts for only 1% of all male tumors.[1] More than 95% of testicular cancers are germ cell tumors, with almost equal division between seminomas and nonseminomas. Seminomas are most commonly diagnosed between the ages of 30 and 34 years, whereas nonseminomas are usually diagnosed 5 to 10 years earlier. Other histologies such as sex cord-stromal tumors and lymphomas are less frequent, although the latter is the most common testicular malignancy in men older than 60 years.[2] It is estimated that just over 9,000 new cases of testicular cancer are diagnosed annually in the United States, with approximately 470 deaths.[1]

There is a marked variation in incidence worldwide. The highest incidence occurs in Northern and Western European countries (up to 9 per 100,000) and the lowest in Asian and African populations (<1 per 100,000).[3] In North America, the incidence of testicular cancer in White males is around 4 to 5 times that in African American or Asian American males, with an overall increase in age-adjusted incidence rate in the United States of 72% between 1975 and 2004.[4,5] A continued increasing incidence is seen worldwide, with a particularly rapid increase in the past decade in Asian countries, which previously had a low incidence. Despite the increased incidence of both seminoma and nonseminoma, there has been a significant reduction of mortality and improvement in survival. The most dramatic reduction in mortality occurred in the 1970s with the introduction of cisplatin-based chemotherapy.[6,7] The 10-year survival for seminoma increased from 81% in the 1970s to 95% in 2000 to 2002 and that for nonseminoma increased from 54% to 92%.[8] Survival continues to improve in most countries.[9]

A history of undescended testicle has long been recognized as a risk factor for the development of testicular cancer. There is also an increased risk of malignancy in the normally descended contralateral testicle. The relative risk (RR) is estimated to be 6 in the undescended testicle and 2 in the contralateral testicle.[10] The mechanism of the increased risk is unclear. It is hypothesized that a common etiologic agent predisposes to both testicular maldescent and subsequent malignancy (uterine theory). Nevertheless, it is also possible that the maldescended testicle is subject to a hostile and malignancy-inducing environment (position theory). If that were the case, orchidopexy during the prepubertal phase would be expected to reduce the risk of testicular cancer. However, the RR of developing testicular cancer remains higher than in the general population, even after early orchidopexy.

The temporal and geographic variation in incidence rates strongly suggests environmental etiologic factors. Global epidemiologic studies demonstrate an association between gross domestic product, alcohol consumption, inactivity, obesity and high cholesterol, and testicular cancer incidence.[3] Male infertility is associated with an increased risk of testicular cancer, and infertile men with abnormal semen analyses have a 20-fold greater risk of testicular cancer than the general population.[11,12] The increasing incidence has paralleled a decline in semen quality over the past several decades.[13] This has led to the hypothesis that poor semen quality, testicular cancer, cryptorchidism, and hypospadias represent a testicular dysgenesis syndrome as a result of disruption of gonadal development during embryonal development.[14] Various exogenous hormonal disruptors (eg, exogenous estrogens, herbicides) have been proposed, although with no conclusive evidence implicating one particular agent.[15]

A few modifiable environmental exposures have been identified as possible risk factors for testicular cancer. Men who have used muscle-building supplements were found to have an increased incidence of testicular cancer. The association was greatest in men who started supplement use at a younger age and were exposed to different supplement types or used supplements for a longer duration.[16] Likewise, cannabis exposure was found to be associated with the risk of testicular germ cell tumors in some, but not all, reports.[17,18] These associations need further validation, but the magnitude of the association and the positive correlation between dose and incidence support a causal relationship.

Approximately 2% of patients report a positive family history. Sons of cases have a 4- to 6-fold increase in risk and brothers a 6- to 10-fold increase.[19,20] Migration studies in the Nordic countries have strengthened the hypothesis of shared genes rather than shared environmental exposure, and several candidate genes have been proposed to explain familial testicular cancer; however, it is likely that no single genetic change explains most familial cases.

In summary, germ cell tumors are thought to arise in testes predisposed to the development of malignancy owing to a combination of familial predisposition and intrauterine hormonal imbalance, later compounded by environmental factors and manifested by impaired spermatogenesis.

PATHOLOGY

More than 95% of testicular neoplasms are germ cell tumors. The most recent World Health Organization (WHO) classification of testicular tumors[21] divides germ cell tumors into two groups: those derived from germ cell neoplasia in situ (GCNIS) and those unrelated to GCNIS. The former group includes seminomas and nonseminomas that share recognizable morphologic and genetic similarities, such as impaired spermatogenesis, microlithiasis, and amplification of chromosome 12. Nonseminomas include embryonal carcinoma, yolk sac (postpubertal type), choriocarcinoma, trophoblastic tumors, and postpubertal teratomas. The group not derived from GCNIS is heterogeneous and includes spermatocytic tumors, prepubertal teratoma, dermoid cysts, and prepubertal yolk sac tumors. Sex cord-stromal

tumors make up the remaining 3% to 4% of testicular neoplasms, and most are benign (Table 74.1).

CLASSIFICATION OF TESTICULAR TUMORS

Germ Cell Tumors

Tumors Derived From Germ Cell Neoplasia In Situ

Germ Cell Neoplasia In Situ

GCNIS, previously called intratubular germ cell neoplasia or testicular carcinoma in situ, is currently the WHO recommended term for this precursor lesion.[22] This entity is found

adjacent to invasive germ cell tumors in >95% of cases and also in all clinical groups known to be at high risk for testicular cancer development: cryptorchidism (2%-4%), infertility (1%), ambiguous genitalia (25%), and contralateral testes of patients with testicular cancer (5%).[23] GCNIS is characterized by seminiferous tubules showing decreased spermatogenesis in which the normal constituents of the tubules are replaced by abnormal germ cells with the appearance of seminoma cells. These cells stain strongly for placental-like alkaline phosphatase (PLAP), whereas normal germ cells are negative. GCNIS is a precursor to testicular germ cell cancer and has a 50% risk of developing into an invasive tumor within 5 years. It is hypothesized that the cells originate from primordial germ cells early during embryogenesis, possibly owing to an excess of estrogens. They likely remain within the seminiferous tubules in a dormant stage until puberty when replication begins, possibly as a consequence of raised sex hormone levels. Transition to an invasive germ cell tumor then occurs.

SEMINOMA

Seminoma accounts for >50% of all germ cell neoplasms. Serum level of human chorionic gonadotropin (hCG) is elevated in 15% to 30% of men at presentation, related to the presence of syncytiotrophoblastic cells. These may be identified in 7% of tumors on routine hematoxylin and eosin sections or by immunoperoxidase stains in 24%. The presence of syncytiotrophoblastic cells does not alter prognosis. Serum α-fetoprotein (AFP) is not elevated in pure seminoma. Grossly, seminoma is a soft tan-colored diffuse multinodular mass. Focal necrosis is sometimes present. A prominent lymphocytic infiltrate is commonly seen within the fibrous stroma. More than 90% of seminomas will stain positive for PLAP.

NONSEMINOMATOUS GERM CELL TUMORS

Nonseminomatous germ cell tumors (NSGCTs) usually contain a mixture of germ cell types (embryonal, yolk sac, teratoma, and choriocarcinoma), although tumors composed of just one component may also be found. Commonly, NSGCTs are heterogeneous and present with a considerable amount of necrosis and hemorrhage on gross examination.

Embryonal carcinoma is the most common component in mixed tumors, and AFP- and hCG-positive cells are present in 33% and 20%, respectively. Postpubertal yolk sac tumors rarely occur in a pure form and have a complex histology. High levels of AFP are usually present. Postpubertal teratoma has marked morphologic differences from the prepubertal type with a predominantly solid appearance, disordered tissue arrangement, and frequent mitotic figures.[24] This tumor is not associated with elevated AFP or hCG and presents with distant metastasis in approximately 20% of the cases. Trophoblastic tumors have choriocarcinoma as the main component. This is the least common type of pure NSGCT and is present in about 4% of mixed tumors. It is particularly aggressive, almost always metastatic at diagnosis, often to brain, and is associated with high levels of hCG. Seminomatous components are also common in mixed tumors, and serum markers (AFP and hCG) are elevated depending on the relative germ cell elements present.

Tumors Unrelated to Germ Cell Neoplasia In Situ

This heterogeneous group of tumors lacks association with GCNIS and abnormalities on chromosome 12. These include spermatocytic tumor, prepubertal-type yolk sac tumor, and prepubertal-type teratoma.

Spermatocytic Tumor

Previously known as spermatocytic seminoma, the spermatocytic tumor accounts for 2% of testicular tumors. It tends to occur in an older age group at a mean age of 57 years and is more common in African Americans.[25] The new nomenclature better differentiates this from seminoma, which reflects its different origin and natural history. Spermatocytic tumor is confined to the testes, is not associated with elevated hCG levels, and is almost always cured by orchiectomy alone.[26] Bilaterality occurs in 10%, and metastasis is rare. Metastases are more common in those with aggressive histology (sarcomatous differentiation) and respond poorly to chemotherapy.[27] The cell of origin of the spermatocytic tumor is probably the postpubertal mature spermatogonia that acquire abnormal proliferative capacity. Spermatocytic tumor does not contain glycogen, stains negative for PLAP, and is not associated with GCNIS. It has a unique amplification on chromosome 9 and is not associated with other germ cell tumors.[28,29]

Yolk Sac Tumor and Teratoma, Prepubertal Type

Prepubertal-type yolk sac tumor is the commonest type of germ cell testicular cancer in infants and children and is associated with high levels of AFP. This malignancy arises from a distinct pathway to the postpubertal-type yolk sac tumors, although it has no significant morphologic difference. The prepubertal teratoma is composed of somatic elements from ectoderm, mesoderm, and endoderm. These tumors lack cytologic atypia and arise from a germ cell line that has not undergone malignant transformation. Both prepubertal yolk sac tumor and teratoma are less aggressive and have a better prognosis than the postpubertal versions.

ANATOMY AND NATURAL HISTORY

In the developing embryo, the testes originate from the genital ridge located near the second lumbar vertebra. Accompanied by their blood supply and lymphatics, they descend into the scrotum via the inguinal canal. As a result, the primary lymphatic drainage from the testis is to the retroperitoneal lymph nodes. The lymphatic vessels first drain into the collecting trunks at the hilum of the testicle. These lymphatic trunks accompany the testicular artery, vein, and spermatic cord through the internal inguinal ring and then continue proximally to the retroperitoneal lymph nodes. The retroperitoneal lymph nodes are situated anterior to the T11 to L4 vertebral bodies, concentrated at the L1-3 level. On the left, the lymphatics drain primarily into the preaortic and para-aortic lymph nodes around the left renal hilum and from there to the interaortocaval nodes (Figure 74.1A). On the right, the first nodes involved are usually in the precaval or interaortocaval region,

followed by the preaortic lymph nodes (Figure 74.1B). Contralateral spread is mainly seen with right-sided tumors and rarely with left-sided tumors. Exclusive metastasis in the contralateral nodes (without ipsilateral involvement) is rare.

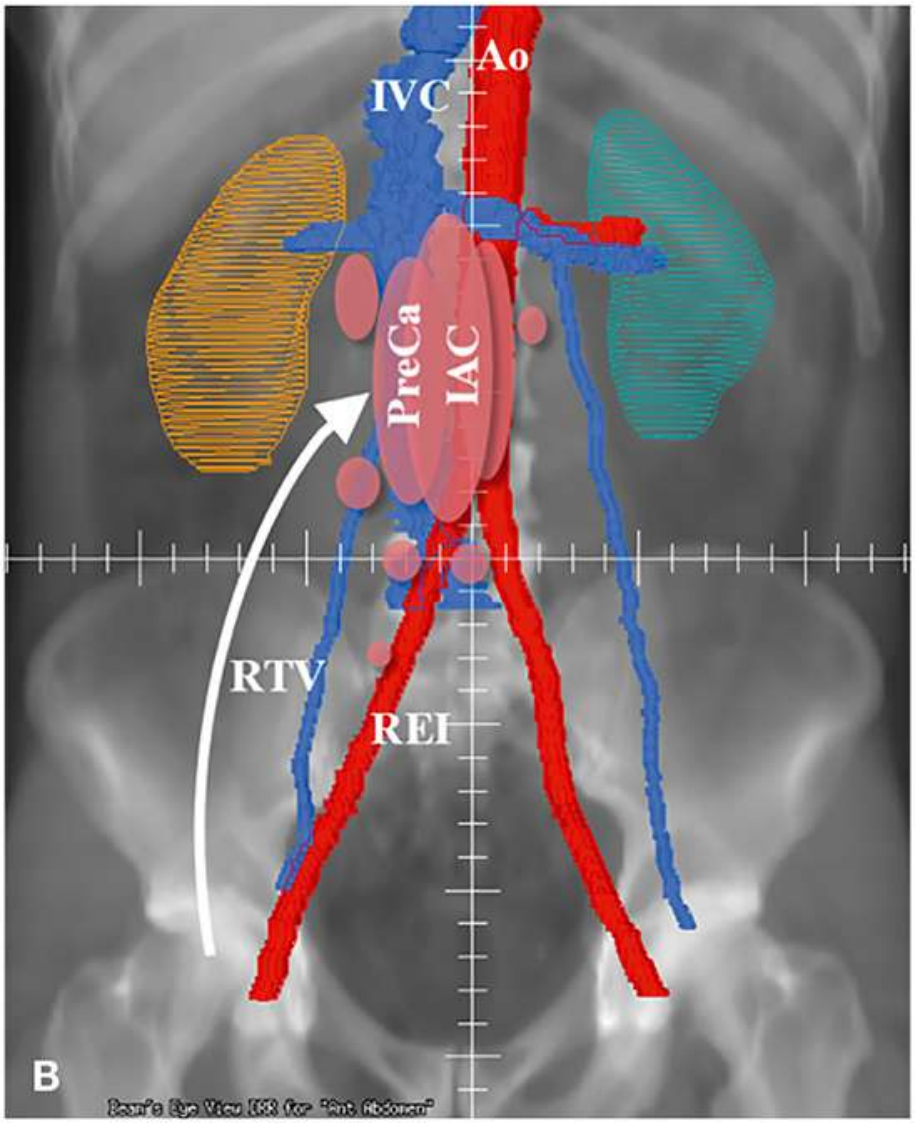

FIGURE 74.1 A. The left testis drains primarily by lymphatics along the left testicular vein (LTV) to lymph nodes inferior to the left renal vessels (LRV). Left para-aortic (PaA), preaortic (PreA), and interaortocaval (IAC) nodes are most commonly involved. Less commonly, nodal involvement may be found inferior to bifurcation of the aorta (Ao) or inferior vena cava (IVC), or superior to the renal vessels. B. Primary lymphatic drainage from the right testis (arrow) is along the right testicular vein (RTV) to precaval (PreCa) and then to IAC and PreA nodes. Less commonly, PreA, right common iliac, or right external iliac (REI) nodes are involved.

From the retroperitoneal nodes, the lymph drains into the cisterna chyli, thoracic duct, posterior mediastinum, and left supraclavicular fossa. The thoracic duct drains into the left subclavian vein in the left supraclavicular region. In 5% to 10% of patients, drainage into the right supraclavicular area can occur.

Aberrant lymphatic drainage may occur in the event of previous scrotal or inguinal surgery. Hernia repair alters the drainage of the testicle. The testicular lymphatic vessels anastomose with the regional lymph vessels, resulting in drainage into the ipsilateral inguinal and iliac lymph nodes. In addition, the testicular trunks may abandon the spermatic vessels at the internal inguinal ring and pass posteriorly and superiorly into the

external iliac lymph nodes. The scrotum drains directly into the inguinal and external iliac lymph nodes. Therefore, direct invasion of the tunica vaginalis or scrotum could result in spread to pelvic and inguinal nodes.

Seminoma has an orderly and predictable pattern of spread. Locoregional lymphatics are the first site of metastatic disease. From the retroperitoneal lymph nodes, seminoma spreads proximally to involve the next echelon—the mediastinal lymph nodes—and then the supraclavicular lymph nodes. Very occasionally, metastases from retroperitoneal lymph nodes can drain directly via the thoracic duct to the supraclavicular fossa, resulting in supraclavicular metastases in the absence of mediastinal disease. Hematogenous metastases are rare in pure seminoma, being much more common with NSGCT. Lung is the most common site of distant disease, although bone, liver, and brain may also be involved.

CLINICAL PRESENTATION

A testicular tumor usually presents as a painless swelling in the scrotum; however, pain, heaviness, and tenderness at presentation are not uncommon. Disease in the lymph nodes of the retroperitoneum may produce back pain or abdominal swelling. Widely disseminated parenchymal disease in the lungs, liver, bone, or brain is rare but, if present, may produce systemic symptoms. Gynecomastia is a rare presentation of embryonal carcinoma that may be seen in association with the very uncommon sex cord-stromal tumors. Gynecomastia and hyperthyroidism may rarely result from high levels of hCG produced by the tumor. Occasionally, patients present with metastatic germ cell malignancies diagnosed by biopsy or elevated levels of serum tumor markers without evidence of a palpable mass in the testis. Occult primary disease in the testis is often detected by testicular ultrasound. If there is no evidence of a primary tumor in the testis, a diagnosis of an extratesticular germ cell tumor —usually mediastinal, retroperitoneal, or pineal—may be made.

DIAGNOSTIC WORKUP (TABLE 74.2)

Diagnostic Radiology
Chest x-ray films, posterior/anterior and lateral views
Computed tomography (CT) scan of the abdomen and pelvis
CT scan of the chest for nonseminomas and stage II seminomas
Bilateral testicular ultrasound
Special Study
Semen analysis

A complete history should be taken, including information about previous inguinal or scrotal surgery, cryptorchidism, retractile testes, and orchidopexy. The physical examination should pay special attention to possible sites of lymph node metastases. The presence or absence of gynecomastia is an important observation. If testicular tumor is suspected, testicular ultrasound should be performed. This helps define the origin of the scrotal mass as the vast majority of extratesticular lesions are benign.[30] Testicular tumor usually appears as a solid mass within the testis, often with associated testicular microlithiasis. The contralateral testis should be examined clinically and by ultrasound. Inguinal biopsy of the contralateral testis may sometimes be considered during surgery if atrophy, cryptorchidism, or suspicious abnormalities on ultrasound are found. Radical orchiectomy through an inguinal incision is diagnostic and removes the primary tumor.

Laboratory Studies

A routine complete blood count and chemistry screen, including renal function tests, should be performed. Pulmonary or renal function tests should be performed for patients who may receive bleomycin or combination chemotherapy. NSGCTs of the testes are uniquely associated with reliable serum tumor markers: the β-subunit of human chorionic gonadotropin (β-hCG) and AFP. One or both of these serum markers are elevated in 80% to 85% of patients with disseminated nonseminomatous disease. These markers are important prognostic factors and contribute to cancer staging.

The metabolic half-life of AFP is approximately 5 days and for β-hCG is approximately 18 to 24 hours. Although β-hCG may be modestly elevated in 15% to 30% of patients with pure seminomas, usually, any elevation of AFP connotes nonseminomatous disease. In the setting of elevated AFP with pure seminoma seen in the pathology specimen, an undetected nonseminomatous focus may be assumed, and the clinical management should follow accordingly. Serum tumor markers may be elevated in other circumstances or conditions, such as laboratory error, cross-reactivity with luteinizing hormone, marijuana use, hepatitis, or the development of antibodies to the glycoproteins. Serum lactate dehydrogenase (LDH), although nonspecific, is elevated in 80% of patients with advanced testicular cancer and has prognostic value.

If a testicular cancer is suspected, serum tumor markers should be assayed before and after orchiectomy, and interpretation of the levels of markers should take into account their metabolic half-lives. Serum tumor markers can document persistent or recurrent cancer after surgery or chemotherapy and may predict the responsiveness of nonseminomas to

treatment. The level of β-hCG should decrease by ≥90% every 21 days with each successful treatment cycle of chemotherapy. A slow decline in β-hCG after treatment may imply suboptimal response to chemotherapy, permitting early implementation of salvage therapy before the development of overt resistance to chemotherapy. The decline in AFP is less predictable.

Semen analysis and banking of sperm should be considered for patients in whom treatment is likely to compromise fertility. With newer technologies, it is possible to retrieve and bank sperm even with poorer quality sperm.

Radiographic Studies

Investigations should routinely include chest x-ray films for all patients and computed tomography (CT) of the thorax for any patient with NSGCTs of the testis. CT scans of the abdomen and pelvis should be performed to evaluate the retroperitoneal nodal areas and assess the liver. A thoracic CT scan should also be performed in patients with seminoma with an abnormal abdominal CT scan or chest x-ray. Magnetic resonance imaging (MRI) of the brain and bone scan are indicated if symptoms are present. Brain MRI is also indicated for choriocarcinoma.

CT of the abdomen and pelvis relies on nodal size to assess the retroperitoneal nodes, with lymph nodes >1 cm in the short axis highly suspicious for metastatic disease. Reported overall sensitivity ranges from 65% to 96% and specificity from 81% to 100%, depending on the threshold size used[31] CT, therefore, has limited ability to exclude the presence of disease, although enlarged lymph nodes in the appropriate clinical context (location, laterality, disease parameters) are very likely to be truly positive. Likewise, lymph nodes with certain morphologic features, such as central necrosis and rounded shape, are considered more suspicious.[32] MRI appears equivalent to CT in determining the size and location of retroperitoneal adenopathy and is considered an equally appropriate staging investigation.[31,33] Fluorodeoxyglucose-positron emission tomography (FDG-PET) scan is not recommended for initial staging.[34,35] While it has a high negative predictive value, its positive predictive value varies across studies. It is unable to detect lesions <5 mm in size or teratomas of any size owing to their very low metabolic activity. It has an important role in evaluating residual retroperitoneal disease following chemotherapy.

In ultrasound imaging, a solid intratesticular mass associated with internal vasculature suggests tumor. Testicular Doppler ultrasonography has a high accuracy in detecting malignancy, with both sensitivity and specificity over 90%.[36] Ultrasonography is not reliable in predicting tumor histology, but in general, seminomas are commonly hypoechoic and homogeneous, whereas calcifications and heterogeneity in echotexture are more often seen in NSGCTs. Baseline ultrasonography of the remaining testis should also be performed. If the contralateral testis is atrophic and the patient is <30 years of age, then there is a 30% risk of GCNIS. Biopsy of the contralateral testis is suggested by some authorities in this setting.

STAGING AND PROGNOSTIC FACTORS

Patients are staged according to the American Joint Committee on Cancer (AJCC) criteria as indicated in Table 74.3, which incorporates features of the primary tumor (T), node (N), metastasis (M), and level of serum tumor markers (S).[37] Approximately 80% of patients with seminoma and 50% to 60% of patients with nonseminoma have stage I disease at presentation. For stage I seminoma, tumor size (>4 cm) and rete testis invasion (RTI) are the most commonly reported predictors of recurrence. For nonseminomas, T stage, extensive embryonal component, and lymphovascular invasion (LVI) are prognostic. Increased age has also been identified as an adverse risk factor and is associated with lower cause-specific survival.[38]

TABLE 74.3 AMERICAN JOINT COMMITTEE ON CANCER 2017 STAGING FOR TESTICULAR CANCER

Primary Tumor (T) (Pathologic Classification)	
*p*Tx	Primary tumor cannot be assessed.
*p*T0	No evidence of primary tumor (scar, etc)
*p*Tis	Intratubular, noninvasive
*p*T1	Tumor limited to testis and rete testis, no vascular/lymphatic invasion pT1a <3 cm pT1b ≥3 cm
*p*T2	Tumor limited to testis with vascular/lymphatic invasion *or* tumor invading hilar soft tissues or epididymis *or* tumor penetrating through tunica albuginea
*p*T3	Tumor invades spermatic cord.
*p*T4	Tumor invades scrotum.
Lymph Node (N)	
N0	No regional node metastasis
N1	Metastasis in single or multiple nodes ≤2 cm in greatest dimension
N2	Metastasis in single or multiple nodes 2-5 cm greatest dimension
N3	Metastasis in lymph nodes >5 cm in maximum diameter
Distant Metastasis (M)	
M0	No distant metastasis
M1a	Nonregional lymph node or pulmonary metastasis
M1b	Nonpulmonary visceral metastasis
Serum Tumor Markers (S)	
Sx	Serum tumor markers not performed
S0	Serum tumor markers within normal limits
S1	LDH <1.5 × N and hCG <5,000 and AFP <1,000
S2	LDH 1.5-10 × N or hCG 5,000-50,000 or AFP 1,000-10,000
S3	LDH >10 × N or hCG >50,000 or AFP >10,000

The International Germ Cell Cancer Collaborative Group (IGCCCG) developed a widely accepted classification system for patients with metastatic germ cell malignancies,[39] which has been incorporated into the TNM system (Table 74.4). The prognostic classification is based on data collected on approximately 6,000 patients with metastatic germ cell tumor from 10 countries during the platinum era. The classification was internally and prospectively validated on subsequent cohorts of patients. The factors most strongly associated with a poor prognosis were mediastinal primary, nonpulmonary visceral metastases, or grossly elevated tumor markers (AFP >10,000 ng/mL, hCG >50,000 IU/L, or LDH >10 times normal). Patients with NSGCT were divided into three prognostic groups (good, intermediate, and poor prognosis) and seminomas into either good or intermediate prognostic groups (Table 74.4). The good prognosis group comprised >50% of all patients with metastatic NSGCTs and 90% of seminomas and was associated with a 5-year survival of >90%. The intermediate prognosis group comprised 25% to 30% of patients and had a 5-year survival of 80%. The poor prognosis group comprised 15% to 20% of patients with NSGCT and had a 5-year survival of approximately 50%. Contemporary series continue to validate the prognostic value of this classification system, now with reported 5-year overall survivals as high as 98%, 96%, and 66% for those in the good, intermediate, and poor prognostic groups, respectively.[40]

TABLE 74.4 INTERNATIONAL GERM CELL CANCER COLLABORATIVE GROUP CONSENSUS CLASSIFICATION OF METASTATIC GERM CELL CANCER[A]

Nonseminoma	Seminoma
Good Prognosis Group With All of the Following:	
Testis/retroperitoneal primary	Any primary site
No nonpulmonary visceral metastases	No nonpulmonary visceral metastases
AFP <1,000 ng/mL	Normal AFP
hCG <5,000 IU/L	Any hCG
LDH <1.5 × normal	Any LDH
Intermediate Prognosis Group With All of the Following:	
Testis/retroperitoneal primary	Any primary site
No nonpulmonary visceral metastases	Nonpulmonary visceral metastases
Intermediate markers:	
AFP > 1,000 and <10,000 ng/mL *or*	Normal AFP
hCG > 5,000 and <50,000 IU/L *or*	Any hCG
LDH > 1.5× and <10× normal	Any LDH
Poor Prognosis Group With Any of the Following:	
Mediastinal primary *or*	

Nonseminoma	Seminoma
Nonpulmonary visceral metastases *or*	
AFP > 10,000 ng/mL	
hCG > 50,000 IU/L *or*	
LDH > 10× normal	

AFP, α-fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

[a]Survival at 5 years is approximately 91%, 80%, and 50% for good, intermediate, and poor prognostic groups, respectively.

GENERAL MANAGEMENT (FIGURE 74.2)

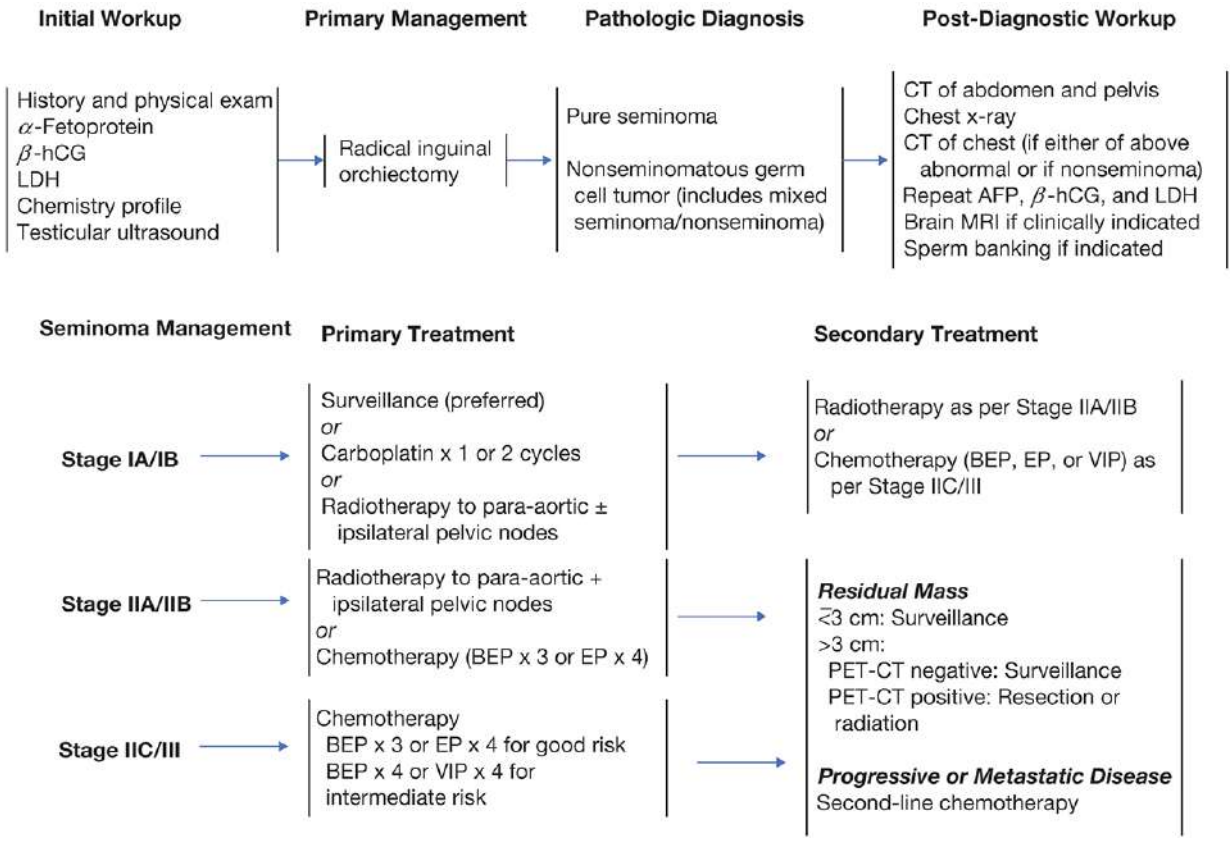

FIGURE 74.2 Diagnosis and management of testicular cancer. BEP, bleomycin, etoposide, and cisplatin; CT, computed tomography; EP, etoposide and cisplatin; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET, positron emission tomography; VIP, cisplatin, etoposide, and ifosfamide.

The initial management of a suspected malignant germ cell tumor of the testis consists of obtaining serum AFP, β-hCG, and LDH measurements and then performing a radical (inguinal) orchiectomy with division of the spermatic cord at the internal inguinal ring. In

this procedure, the involved testis is removed en bloc with the spermatic cord, enclosed by the tunica layers through an inguinal incision, minimizing the chance of tumor spillage. Historically, it had been thought that scrotal violation (transscrotal orchiectomy, open testicular biopsy, or fine-needle aspiration) compromised prognosis. Scrotal violation is associated with a slight increase in local recurrence rate compared with inguinal orchiectomy (2.9% vs 0.4%) but is not associated with any difference in distant recurrence rates or overall survival.[41] Orchiectomy is both diagnostic and therapeutic. Further management depends on pathologic diagnosis and the stage and extent of disease. Radiation treatment plays a significant role in the management of seminomas. Nonseminomatous tumors are generally managed by cisplatin-based combination chemotherapy and/or surgical resection.[42] A detailed discussion of the management of nonseminomatous tumors is beyond the scope of this chapter.

Seminoma

Stage I

Most patients with stage I seminoma are cured by orchiectomy alone, and 15% to 20% will relapse if no adjuvant therapy is offered. Either adjuvant radiation therapy or adjuvant chemotherapy with single-agent carboplatin is associated with a disease-free survival of >95% and disease-specific survival approaching 100%.[43] Surveillance, with treatment at the time of relapse, is associated with a similar survival outcome and allows over 80% of patients to avoid the morbidity of treatment.

Surveillance

There has been a major change in the standard management of stage I seminoma over the past several decades, as adjuvant radiotherapy has been replaced with surveillance. Kollmannsberger et al document the increasing use of surveillance for managing patients with stage I seminoma in a population-based cohort from British Columbia, Canada, and Oregon.[44] Between 1999 and 2008, the proportion of patients receiving adjuvant radiation therapy decreased from 50% to 9%, and the proportion being managed by surveillance increased from 47% to 87%. A similar trend was seen in the United States by Matulewicz et al through analysis of the National Cancer Database.[45] The authors reported that the use of surveillance for stage I seminoma increased from 25% in patients diagnosed between 1998 and 2000 to 61% in those diagnosed between 2010 and 2012. Jia et al reported similar trends using the Surveillance, Epidemiology, and End Results (SEER) database.[46] Over a 40-year period, the rate of adjuvant radiotherapy use decreased from 100% in 1975 to 47% in 2008 and 5% in 2015. Over that same time period, the use of surveillance increased from about 20% before 2000 to 77% in 2015, with the steepest increase noted around the turn of the century. Of 411 patients with stage I seminoma diagnosed between 2000 and 2022 in the Australian and New Zealand iTestis database, only a single patient received adjuvant radiotherapy.[47] Adjuvant carboplatin (almost always single dose) was administered to 26%, and 74% were managed by surveillance.

The early surveillance series (Table 74.5) all reported similar rates, timing, and patterns of recurrence.[44,48-56] When managed by surveillance, up to 20% of patients were found to relapse at a median time of around 14 months. Over 90% of relapses occur in the first 3 years. An early pooled analysis of 638 patients with stage I seminoma from four series (Princes Margaret, Royal Marsden Hospital, Royal London Hospital, and the Danish Testicular Cancer Study Group) reported 5- and 10-year relapse-free rates of 82.3% and 78.7%, respectively.[57] Most relapses (69%) occurred within the first 2 years of surgery, whereas 7% relapsed beyond 6 years. The 5-year cause-specific survival was 99.3%. A further pooled analysis of databases from Sweden and Norway, the Princess Margaret Cancer Centre, British Columbia and Oregon, Bart's Cancer Institute, and the University of Oxford reported similar findings.[58] With a median follow-up time of 52 months, relapse occurred in 13% of 1,344 patients with stage 1 seminoma at a median of 14 months. No patient died from seminoma, although one patient died from complications of treatment.

TABLE 74.5 PATTERNS OF RECURRENCE FOR STAGE I SEMINOMA MANAGED BY SURVEILLANCE IN SELECTED SERIES

Author (Reference)	Number	Median Follow-Up (Months)	Relapse-Free Survival (%)	Proportion Relapsing in Retroperitoneum (%)	Disease-Specific Survival (%)	Median Time to Relapse (Months)
Kollmannsberger et al[44]	313	34	81	—	100	14
von der Maase et al[48]	261	48	80	94	99	14

Kamba et al[55]	186	45	79	79	100	21
Tandstad et al[56]	512	60	86	94	99.8	17

Almost all patients (99%) who relapse after surveillance are classified by IGCCCG in the good risk category, and the predominant site of relapse is in the retroperitoneum (76%-94%). Approximately 5% to 15% of patients relapse in the mediastinum or lungs, with inguinal relapse described in 3% to 11%, usually only after previous scrotal interference. Some variability is reported in management at the time of relapse. Traditionally, most (74%-82% of patients in the older series) were initially managed by radiation therapy, with a second relapse occurring in about 10% (6%-16%). Second relapse almost always occurred at distant sites, with a 90% to 95% rate of successfull salvage with chemotherapy. More recent series describe a greater use of chemotherapy as initial salvage

treatment. In the population-based study from the Swedish Norwegian Testicular Cancer Study Group (SWENOTECA), cisplatin-based combination chemotherapy as salvage treatment was given to 89% of relapsing patients, with further relapse in only 1 of 58 patients.[56] Kollmannsberger et al report the use of salvage chemotherapy in 68% of relapsing patients in the British Columbia and Oregon Testis Cancer Program database.[44] No further relapse occurred in the 32 patients managed by chemotherapy, whereas relapse occurred in 3 of 15 patients who received salvage radiotherapy. Although salvage chemotherapy is effective, it is associated with greater toxicity than salvage radiotherapy.

The outcome of patients relapsing on surveillance is likely no worse and possibly better than that of those presenting with de novo metastatic seminoma. In a retrospective bi-institutional review of 73 patients treated with radiation therapy, Rosen et al reported higher progression-free survival in relapsed (92%) compared with de novo metastatic (73%) patients, although with 100% cause-specific survival in both groups.[60] Lauritsen et al reported outcome data of 1,014 patients with metastatic seminoma from the ICGCCG database—298 who had relapsed on surveillance for stage I disease and 716 with de novo metastatic disease.[61] There was no significant difference in 5-year progression-free survival (84.6% vs 80.0%) or overall survival (93.3% vs 88.7%) between the two groups.

Risk factors for relapse on surveillance were identified early on. In the pooled analysis, tumor size, RTI, and LVI were predictive of relapse on univariate analysis.[57] On multivariate analysis, tumor size (hazard ratio [HR] 2.0) and RTI (HR 1.7) remained significant. The relapse-free rate decreased from 87.8% for tumors <4 cm without RTI to 68.5% for tumors >4 cm with RTI. Tyldesley et al also noted the importance of size >4 cm and RTI, reporting a 5-year relapse-free rate of 86%, 71%, and 50% in patients with no risk factor, one risk factor, or both risk factors, respectively.[62] These risk factors were validated by the SWENOTECAVII study.[63] In this prospective and population-based protocol, a significant difference in relapse was seen between patients with no risk factor (4%) and patients with these one to two factors (15.5%) managed by surveillance. Wagner et al investigated risk factors for recurrence in 924 patients on surveillance for stage I seminoma diagnosed between 2013 and 2018 from the prospective Danish Testicular Cancer database.[64] Relapse occurred in 16% at a median follow-up of 6.3 years. Invasion of the testicular hilum, LVI, and elevated preorchiectomy levels of β-hCG and LDH were independent predictors of recurrence and could be used to define groups with risk of relapse ranging from 6% (no risk factors) to 62% (all risk factors).

The European Association of Urology Testicular Guidelines Panel performed an individual patient data analysis of 1,016 patients with stage I seminoma managed by surveillance from nine institutions.[65] After a median follow-up of 7.7 years, 14.7% had relapsed. Ninety-seven percent of relapses were in the retroperitoneal lymph nodes, and 54% were then treated with radiotherapy and 46% with chemotherapy. Tumor size, presence of RTI, and LVI were independently associated with the risk of recurrence and were used to define risk groups with a low, intermediate, and high risk of recurrence. Low-risk patients comprised 56% of the cohort and were defined as having tumor size ≤5 cm without RTI or LVI, *or* ≤2 cm with either RTI or LVI. Their risk of recurrence at 5 year was 8%. Intermediate-risk patients comprised 41% of the cohort and had tumor size ≤2 cm with

both RTI and LVI, *or* >2 to 5 cm with either RTI or LVI, *or* >5 cm, but not with both RTI and LVI. Relapse risk was 20%. Less than 3% of patients belonged to a high-risk group having tumor size >5 cm with both RTI and LVI and having a risk of relapse of 44%. Results were validated in a further cohort of 285 patients.

Surveillance involves regular axial imaging of the abdomen and pelvis, with the frequency based on the risk and time course of recurrence. Although chest x-ray was routinely used in most surveillance series, no relapse was detected on chest x-ray alone and can be omitted.[66] Similarly, there is no role for routine measurement of serum tumor markers.[67] The use of low-dose CT, less intensive imaging protocol, and MRI have been investigated to further reduce long-term radiation exposure.

Based on the pattern and timing of relapse, surveillance policies have been proposed by various organizations, including the European Association of Urology, the European Society of Medical Oncology, the American Urologic Association, and the Australian and New Zealand Urogenital and Prostate Cancer Trials Group. Either CT or MRI can be used for cross-sectional imaging of the retroperitoneum, the primary site of recurrence. MRI has the advantage of avoiding ionizing radiation but does take longer and has been shown to be noninferior to CT in the Trial of Imaging and Surveillance in Seminoma Testis study.[68] This phase III noninferiority trial randomized 669 patients with stage I seminoma to a surveillance policy of either seven or three CTs or MRIs. The primary outcome was bulky relapse (>5 cm) at 6 years. Although more events occurred with three scans (2.8% vs 0.3%), this was statistically noninferior and MRI was found to be noninferior to CT. Five-year survival was 99% with no tumor-related deaths. Chavarriaga and colleagues comprehensively reviewed these clinical practice guidelines to propose a unifying schedule based on current best evidence.[69] They suggest CT or MRI scans of the abdomen and pelvis every 6 months for the first 2 years, then annually until year 5. Consideration could also be given to further imaging at year 7 and year 9. They do not recommend routine chest x-ray or serum tumor markers.

Surveillance has become the preferred approach for most men with clinical stage I seminoma, particularly those at low or intermediate risk of recurrence. Although more costly than upfront adjuvant treatment due to the increased number of radiologic investigations, it leads to less overall treatment burden to patients.[70,71] Given the high efficacy of salvage treatment, cause-specific survival approaches 100%, and population-based data from Denmark show no excess of deaths or second malignancy compared to a population-based control group out to 20 years.[72] Surveillance is an option even for patients at higher risk of relapse. Mortensen et al identified 473 patients with stage I seminoma and tumor size ≥6 cm from the Danish Testicular Cancer database, managed with adjuvant radiotherapy (n = 254) or surveillance (n = 219).[73] The 10-year estimate of disease recurrence was 3% with radiotherapy and 32% with surveillance, but with no difference in overall survival.

Adjuvant Radiation Therapy

In the past, the standard postoperative management of patients with stage I seminoma had been adjuvant radiation therapy to the para-aortic and ipsilateral pelvic lymph nodes (the

"dog-leg" or "hockey stick" radiation field). This is a highly effective treatment, with a reported relapse rate between 1% and 5% and a disease-specific survival of 100% in many mature series[56,74-84] (Table 74.6) without the need for ongoing abdominal imaging.[85] Adjuvant treatment evolved to commonly only include the para-aortic region. Series that treat just the para-aortic report a higher rate of failure in the pelvic nodes; however, the disease-free survival is minimally compromised. A multicenter single-arm trial of para-aortic radiotherapy was reported by the German Testicular Cancer Study Group, which included 721 patients with stage I seminoma.[80] Disease-free survival at 8 years was 95%. Of 26 recurrences, 21 were within infradiaphragmatic lymph nodes beyond the treatment volume (mostly ipsilateral pelvic), with no in-field recurrences. The Medical Research Council (MRC) performed a randomized controlled trial comparing classic dog-leg irradiation to para-aortic irradiation in stage I seminoma.[84] Those with previous ipsilateral inguinal or scrotal surgery were excluded. Radiation therapy was better tolerated in the para-aortic alone arm with a reduction in the severity and frequency of acute gastrointestinal and hematologic toxicity. At a median follow-up of 4.5 years, there was no difference in the 3-year relapse-free survival or overall survival. For those in the para-aortic radiation therapy arm, the pelvis was the most frequent site of recurrence, whereas the pelvis was a rare site of recurrence in those in the para-aortic and ipsilateral pelvic radiotherapy arm. A retrospective review showed that the median size of pelvic nodal recurrence was 7.3 cm (range, 2.8-13 cm) if CT scans were not included in the follow-up schedule of patients treated with para-aortic radiation therapy.[86]

DL, dog leg; PA, para-aortic.

Given that nearly all recurrences following para-aortic radiation therapy are in the lower common iliac or upper external iliac nodes, another approach was to use a modified dog leg wherein the inferior border is placed at the midpelvic level. This encompasses the nodal areas at risk while further reducing the volume of normal tissue irradiated.[87]

Adjuvant Chemotherapy

Adjuvant chemotherapy using single-agent carboplatin has emerged as an alternative to radiotherapy for stage I seminoma. For men with advanced seminoma, carboplatin has long been known to have significant efficacy with relatively low toxicity.[88] It was logical to investigate the use of one or two cycles of carboplatin as adjuvant treatment following orchiectomy.[89-91] With a median follow-up of 75 months, Steiner et al reported a 5-year relapse-free survival of 98% in a population of 276 men with stage I seminoma treated with two cycles of carboplatin.[92] Aparicio et al described a risk-adaptive strategy wherein patients with stage I seminoma deemed at low risk of recurrence were managed with surveillance, and those considered at higher risk based on RTI or tumor size >4 cm received two cycles of carboplatin.[93] With a median follow-up of 67 months, relapse occurred in 56 (12%) of 467 on surveillance and in 13 (3%) of 412 following carboplatin.[94] The predominant site of recurrence was in the retroperitoneum (88% vs 85%), and 90% were subsequently treated with cisplatin-based chemotherapy. No seminoma-related deaths occurred.

Recurrence following adjuvant carboplatin tends to be in the retroperitoneum and can be salvaged with cisplatin-based chemotherapy, in approximately 85% of the cases resulting in an overall disease-specific survival approaching 100%.[95] Between 2001 and 2006, the use of single-course carboplatin following orchiectomy for stage I seminoma increased from 0% to 70% in Sweden and Norway.[56] Over the same time period, the use of adjuvant radiotherapy decreased from 40% to 5%. The relapse risk with chemotherapy was higher than that following radiotherapy (3.9% vs 0.8%); however, overall survival was the same.

In the British Columbia/Oregon database, 73 of 545 patients received either one or two cycles of carboplatin, with only one relapse, yielding a relapse-free survival probability of 98% and a cause-specific survival of 100%.[44]

The MRC performed a randomized comparison of single-agent carboplatin and nodal irradiation in stage I seminoma.[83] Almost 1,500 patients from 14 European countries were randomized to receive either adjuvant radiation therapy or one injection of carboplatin. Radiation was limited to para-aortic fields in 87%, and the remainder also had inclusion of the ipsilateral pelvic nodes. Information on tumor size and RTI was not detailed. With a median follow-up time of 6.5 years, the 5-year relapse-free survival rates were similar at 96.0% and 94.7% in the radiation therapy and carboplatin arms, respectively. In the adjuvant radiation therapy arm, the most common site of recurrence was either distant (57%) or in the pelvic nodes (31%). In the carboplatin arm, most of the relapses (74%) were in para-aortic nodes. Only one death from testicular cancer occurred in the radiation therapy group, with no cancer-related deaths in the chemotherapy group. An 80% reduction in the rate of contralateral testicular cancer was seen in the carboplatin arm (2 vs 15 cases). Long-term toxicity (eg, risk of leukemia) is unknown; however, the regimen is well tolerated acutely with only mild myelotoxicity. Powles et al found no increased risk of death from circulatory disease or risk of second malignancy in a cohort of 199 patients who received adjuvant carboplatin and were followed for a median of 9 years.[96] Ruf et al reported a higher than expected rate of second malignancy (2.4-fold) in a cohort of 451 patients with stage I seminoma who had received carboplatin rather than surveillance, but the number of events was small and the results need further validation.[97]

Mead et al[98] analyzed mature results of three randomized noninferiority MRC clinical trials for stage I seminoma, which included nearly 2,500 patients. They concluded that either radiation therapy or carboplatin was a reasonable adjuvant therapy. It is clear that the survival of patients with stage I seminoma approaches 100%, no matter what treatment strategy is employed.[99] The goal of management is to limit treatment morbidity without compromising the chance of cure. For the compliant patient, surveillance is the option of choice. For patients not suitable for surveillance, adjuvant radiation therapy or adjuvant chemotherapy significantly reduces the risk of relapse.

Stage II

For patients with stage II seminoma, the recommended treatment depends on the bulk of retroperitoneal nodal disease. Radiotherapy and chemotherapy are standard options, with retroperitoneal lymph node dissection (RPLND) being offered on some protocols.[42],[100] Radiation therapy (25-35 Gy) remains the treatment of choice for patients with nonbulky stage II seminoma, generally considered to be <3 cm. Irradiation of the para-aortic and ipsilateral pelvic nodes is a highly effective treatment strategy with a recurrence rate of <10% (Table 74.7) and a disease-specific survival rate of 97% to 100%.[75,101-109] The most common site of relapse following infradiaphragmatic radiation therapy is in the supraclavicular fossa or mediastinum. In the past, some authors recommended prophylactic supraclavicular irradiation.[103] However, the proportion of patients destined to relapse

exclusively in the supraclavicular fossa is <5%, and the results with infradiaphragmatic irradiation alone with chemotherapy as salvage are excellent.[110]

Chemotherapy with bleomycin, etoposide, and cisplatin (BEP) for three cycles, or etoposide and cisplatin (EP) for four cycles, is an alternative to radiotherapy for patients with stage II disease. It is often recommended as the treatment of choice for disease >3 cm.[100] Although it is clear that most patients with stage IIA/B seminoma can be cured with cisplatin-based chemotherapy, greater levels of toxicity are expected with this treatment than that associated with radiotherapy alone.[111] Chemotherapy toxicity includes pulmonary toxicity (including death), ototoxicity, peripheral neuropathy, and nephrotoxicity. Given the high cancer control and disease-specific survival associated with radiotherapy, it is considered preferable to BEP for nonbulky stage II seminoma.

Less toxic alternatives to standard cisplatin-based chemotherapy have been investigated. Single-agent carboplatin has less toxicity than BEP or EP, but early clinical trials suggested inferior cancer control and survival.[112] A phase II study by the German Testicular Cancer Study Group delivered three or four cycles of carboplatin to patients with stage IIA or stage IIB seminoma, respectively.[113] The overall failure rate was 18%, with all relapses occurring in the retroperitoneum, which seemed higher than that expected with cisplatin combinations or radiotherapy. The problem, however, may have been dose. A multicenter UK study treated 216 men with good prognosis metastatic seminoma with three or four cycles of carboplatin AUC10 every 21 days.[114] Two-thirds had stage IIA or IIB disease. The progression-free survival was 96.5%, with a 5-year disease-specific survival of 98.3%. The main toxicity was hematologic with grade III neutropenia in 37% and neutropenic sepsis in

5%. Results were an improvement on historical experience with single-agent carboplatin and similar to what might be reported with BEP with the potential less late toxicity.

Another way to de-intensify treatment with carboplatin was explored in the GETUG SEMITEP trial.[115] The trial enrolled 102 patients with metastatic seminoma, mostly stage IIB, and all were treated with two cycles of EP chemotherapy. Those with a negative FDG-PET at that point (73%) received one further cycle of carboplatin, while those with a positive FDG-PET went on to receive a further two cycles of EP. One patient died from chemotoxicity after the second cycle of EP. The cumulative incidence of peripheral neuropathy and ototoxicity was less in the carboplatin arm. Over 90% of patients in both arms were free of recurrence at 3 years.

A few authors have retrospectively assessed the benefit of a combined approach using neoadjuvant carboplatin followed by radiation therapy in patients with stage IIA/B seminomas.[104,116] SAKK 01/10 was a single-arm, multicenter trial of carboplatin followed by involved field radiotherapy, which enrolled 120 patients with stage IIA and IIB seminoma.[117] Patients received a single dose of carboplatin 7AUC, followed by involved field radiotherapy to a dose of 30 Gy in 15 fractions for stage IIA or 36 Gy in 18 fractions for stage IIB. Grade 3 hematologic toxicity occurred in 7%. The 3-year progression-free survival was 95.2% in those with stage IIA disease and 92.6% in those with stage IIB disease. Disease-specific survival was 100%. Although these results are not definitive, this strategy appears to reduce the rate of relapse compared to carboplatin alone and may be a promising approach, especially for patients with bulkier disease.

Several authors have investigated RPLND as a treatment option for patients with stage IIA and IIB seminoma in order to avoid potential toxicities of radiation or chemotherapy. The PRIMETEST trial enrolled patients with retroperitoneal metastases <5 cm, either de novo or on relapse after surveillance or carboplatin for stage I disease.[118] Patients underwent either an open or robot-assisted unilateral RPLND. After a median follow-up of 32 months, progression-free survival was 64%, with almost all of the recurrences in the retroperitoneum. These were further successfully treated with cisplatin-based chemotherapy. The SEMS trial was a single-arm prospective trial of RPLND in men with one or two ipsilateral retroperitoneal nodal metastases <3 cm in maximal size.[119] With a median follow-up of 33 months, recurrence occurred in 12 of 55 patients, with a 2-year recurrence-free survival of 81%. Again, most of the recurrences were in the retroperitoneum. While enabling a significant proportion of men to avoid chemotherapy or radiotherapy, RPLND is not considered the standard of care and is being investigated in ongoing clinical trials.

Factors other than stage may be considered in the selection of treatment strategy after orchiectomy in stage II seminoma. A greater number of retroperitoneal nodal metastases may suggest an overall greater bulk of disease, indicating a higher likelihood for distant metastasis. Furthermore, Domont et al[120] have reported that nodal diameter ≥3 cm on CT is associated with a higher risk of distant failure following local therapy and suggested that these patients would be better managed with systemic treatment. The risk of distant metastasis is likely proportional to the extent of disease seen in the retroperitoneal nodes, and this should be taken into account when deciding which strategy to follow.

Patients with stage IIC retroperitoneal disease (nodes >5 cm) are usually managed with systemic chemotherapy. Radiation therapy remains a treatment option; however, the relapse rate of >30% is considered by many to be excessive. Chung et al[101] reported recurrence in 10 of 16 patients with stage IIC disease managed with radiation therapy compared to only one relapse in a similar group of 23 patients managed by chemotherapy. The choice of modality is also influenced by the size and location of the retroperitoneal nodal mass. If the mass is centrally located and does not overlie most of one kidney or significantly overlap the liver, primary radiation therapy remains an option. If the location of the mass is such that the irradiation volume covers most of one kidney or significant volumes of the liver, then the potential morbidity of radiation therapy can be avoided by the use of primary cisplatin- containing combination chemotherapy (usually EP or BEP). For nodal disease >10 cm in diameter, the relapse rate is >40% with radiotherapy, and such patients should be managed with systemic chemotherapy.

For the rare patient with stage III disease (ie, supradiaphragmatic nodal disease or dissemination to parenchymal organs), or those with relapse following radiation therapy, the current standard therapy is three courses of BEP or four courses of EP chemotherapy. These patients are classified into either a good prognosis or intermediate prognosis group by the International Germ Cell Cancer Collaborative Group Consensus Classification, depending on the absence or presence of nonpulmonary visceral metastases, respectively. The 5-year survival is expected to be over 95%.[40]

Residual Mass

For patients with stage II or III disease treated with primary chemotherapy, residual masses are present at 1 month in up to 80% of patients. Most of these then gradually regress over a period of several months. Fléchon et al[121] reported that 50% of residual masses disappeared on follow-up and that viable cancer cells were found only in masses >3 cm in size. Management strategies involve the use of consolidative radiotherapy, surgical resection, or observation. In an effort to define the role of postchemotherapy radiation therapy, the MRC Testicular Tumour Working Party conducted a retrospective review of patients with advanced seminoma managed by chemotherapy from 10 European centers.[122] Of 302 patients identified, 174 (58%) had residual masses on completion of chemotherapy, with a subsequent 3-year progression-free survival of 85%. Approximately half of these patients underwent postchemotherapy radiation therapy, with selection based predominantly on institutional preference. Radiation therapy did not significantly influence the risk of progression, contributing to an absolute increase in progression-free survival of only 2.3%. Instead, the most important prognostic factors for progression were the presence of prechemotherapy visceral metastases or raised LDH, or persistent visceral metastases postchemotherapy. At St Bartholomew's Hospital, 43 (40%) of 107 patients with advanced seminoma had a residual mass postchemotherapy.[123] Positive histology was found in 3 (15%) of 19 patients who underwent surgical exploration, whereas relapse at the site of the mass occurred in 3 other patients observed. Residual disease was only found in masses >3 cm in size. Of the 107 patients, 98 (92%) patients remained alive and free from recurrence. The largest report of surgical resection following chemotherapy comes from the Memorial

Sloan- Kettering Cancer Center.[124] A total of 55 patients with advanced seminoma underwent resection or biopsy of residual mass within 4 weeks of chemotherapy. Of 27 patients with a mass >3 cm, eight (30%) patients had residual tumor. No viable tumor was found in any of the 28 patients with a residual mass <3 cm in maximal diameter.

From the reports discussed, it is clear that observation alone is adequate for a residual mass <3 cm in size. Two patterns of response to chemotherapy are evident on CT: The residual mass may be well defined with discrete borders or the mass may have indistinct borders merging into surrounding structures and resembling a fibrous plaque. The former is more amenable to surgical resection. Furthermore, if the tumor is well defined on CT and measures >3 cm in greatest dimension, positive histology can be found in 50%. It is reasonable to resect these masses. If the mass is poorly defined, even if >3 cm, the chance of finding positive histology is <10%. Resecting such a mass is hazardous, with the risk of great vessel, ureteric, and small bowel injury. These should be observed.

FDG-PET scans have been shown to reliably predict the presence of viable disease in retroperitoneal masses postchemotherapy in seminomas. This diagnostic examination has a higher accuracy in identifying persistent disease than CT.[125] De Santis et al[126] evaluated the efficacy of FDG-PET by analyzing 51 patients with 56 postchemotherapy lesions. The FDG-PET correctly identified 54 lesions with two false-negative results, both in nodes <3 cm. For the whole cohort, this test sensitivity was 80%, but FDG-PET accuracy for residual masses >3 cm was 100%. Based on this result, authors estimated that 45% to 73% of patients with >3 cm residual mass would be overtreated with surgery if FDG-PET information is not taken into account, as a negative scan may be reliably used as a tool for avoiding surgical resection. Radiotherapy may also be considered for FDG-positive residual masses following chemotherapy. Murthy and colleagues reported a nonrandomized trial of radiotherapy and observation in patients with FDG-PET–positive residual masses postchemotherapy.[127] Patients treated with radiotherapy, to a median dose of 36 Gy in 18 fractions, had a lower rate of local failure (1/27) compared to those observed (8/27). This improvement in locoregional control did not translate into an improvement in overall survival. FDG-PET should be performed 6 weeks after day 21 of the last chemotherapy cycle, as earlier imaging has a higher risk of false-positive results.

Bilateral Testicular Cancer

Testicular cancer is bilateral in up to 5% of cases, with one-third being synchronous and two-thirds being metachronous.[128] Although bilateral orchiectomy is an effective management strategy in synchronous disease, the option of testis-sparing surgery and postoperative radiation therapy has emerged as an alternative.[129] Partial orchiectomy may be considered for selected patients with bilateral disease or a solitary testicle. Ideally, tumors should be <2 cm in size and have negative surgical margins for invasive disease. Postoperative radiotherapy to a dose of 18 to 20 Gy is usually administered to the residual testicle to eradicate GCNIS, which is found in >80% of cases.[130,131] Observation alone has also been reported.[132] In either case, some degree of hormonal dysfunction is common, and many patients may still require lifelong testosterone replacement. Patients with testicular cancer are at a higher risk of developing contralateral malignant disease. In consequence,

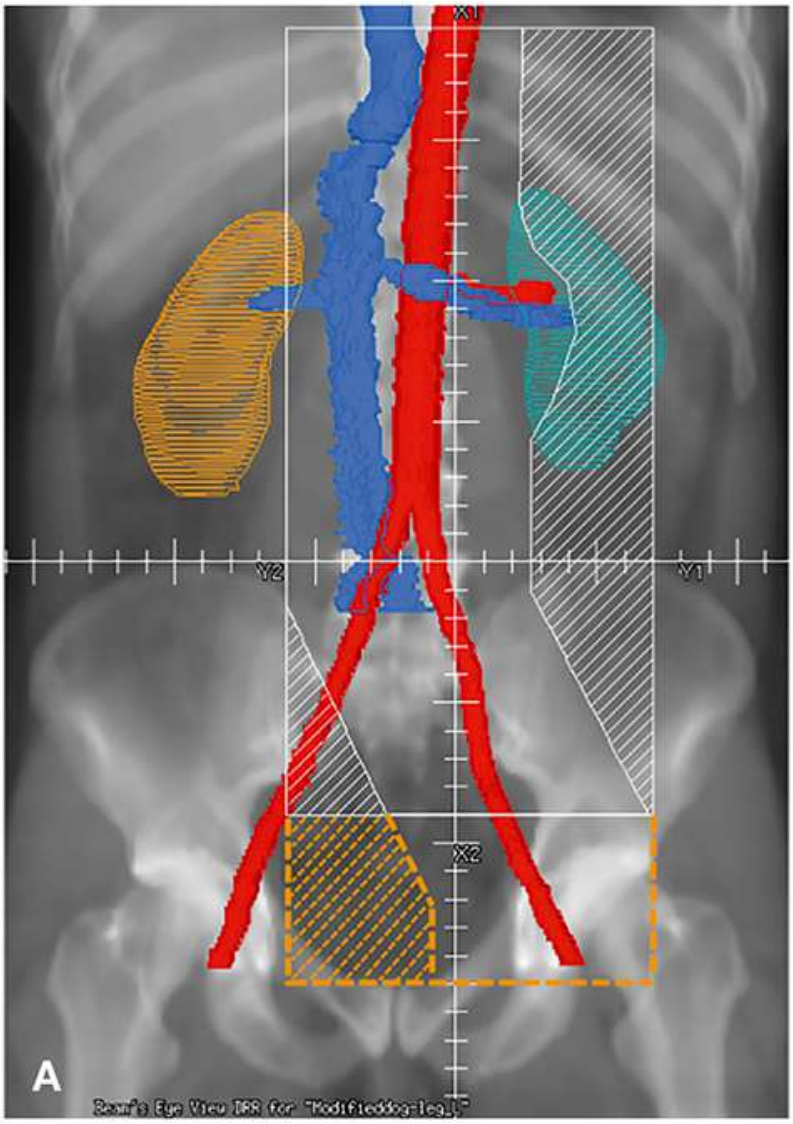
some authors advocate performing a biopsy of the contralateral testis during the radical orchiectomy procedure for early diagnosis of GCNIS or invasive disease. However, routine biopsy of the contralateral testicle has not been shown to significantly reduce the incidence of metachronous germ cell malignancy.[133] In the setting of GCNIS identified by the biopsy, a course of radiation therapy may be considered to the contralateral testis for the treatment of the in situ component of the neoplasia, as patients with GCNIS almost invariably progress to invasive cancer. In this setting, a low dose of radiation is able to preserve some function of the Leydig cells and avoid progression of disease.

RADIATION THERAPY TECHNIQUE

Target Volume and Field Borders

For stage I disease, the clinical target volume (CTV) encompasses the interaortocaval, preaortic, and para-aortic nodes (see Figure 74.1). The left renal hilar nodes are included for left-sided tumors. The ipsilateral external iliac and common iliac nodes may also be included, particularly if there is concern about aberrant drainage. Inclusion of the inguinal scar, inguinal lymph nodes, or hemiscrotum is not routinely warranted. For stage II disease, a gross tumor volume is identified from diagnostic imaging, and the CTV also usually includes the ipsilateral pelvic nodes.

The planning target volume (PTV) includes the CTV plus a margin to account for positional and setup uncertainties. To cover the known location of the retroperitoneal and iliac lymph nodes with an appropriate margin, standard anatomic field borders have been used. This is commonly referred to as the dog-leg or hockey stick field. Classically, the superior border is placed between the T9 and T10 vertebral bodies, with the inferior border at the top of the obturator foramen. A modified approach is now commonly used wherein the superior border is placed between T10 and T11 and the inferior border is placed at the superior aspect of the acetabulum (Figure 74.3). The field is approximately 9 cm wide in the para-aortic region and usually covers the transverse processes. On the left, the lateral border is extended to include the left renal hilum, and customized shielding is positioned to reduce the amount of kidney irradiated. Field width here is typically 11 to 12 cm. At the mid-L4 level, the field is extended laterally to cover the ipsilateral external iliac nodes. Multileaf collimators are used to define the field shape. If retroperitoneal nodes alone are to be treated, the superior and lateral borders are as described previously, and the inferior border is placed at the L5/S1 disc space. Some report using a lower superior border, T11-12, and a higher inferior border, the bottom of L4.[81]



X1
Y2
Y1
X2
A
Beam's Eye View DRR for "Modifieddog-leg_1"

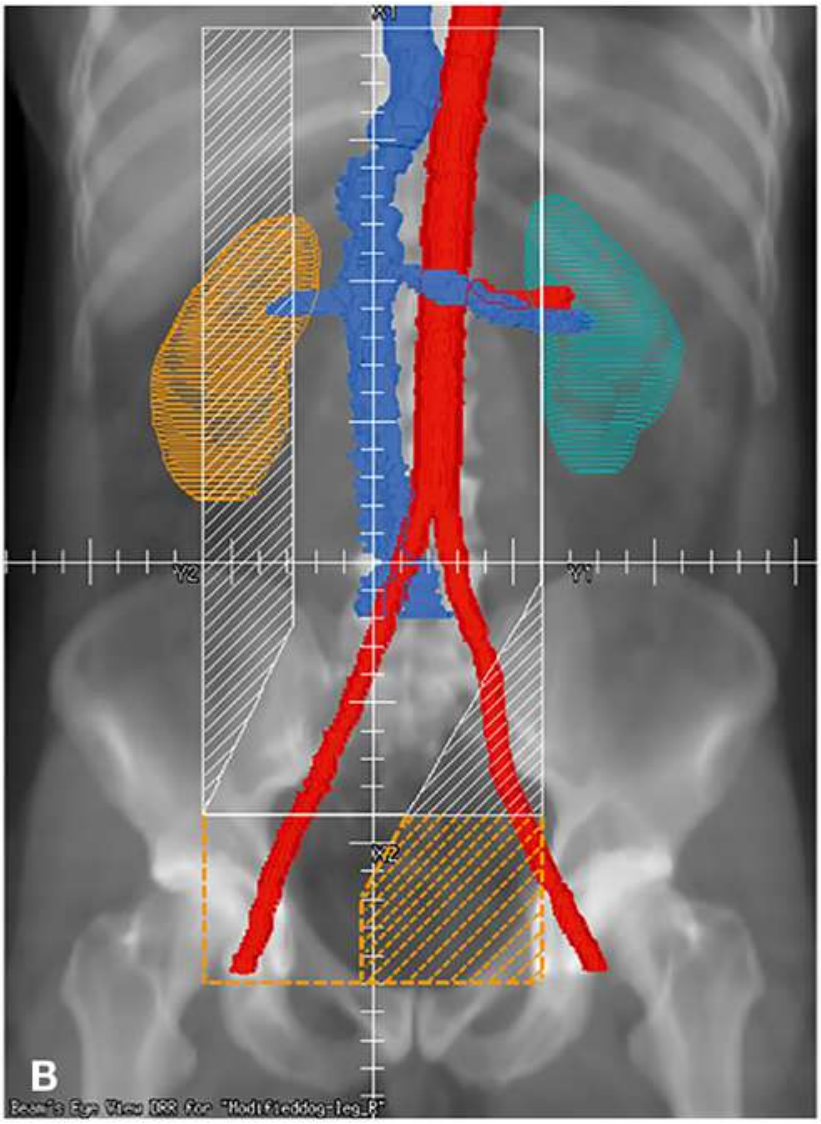


FIGURE 74.3 For stage I seminoma, a modified "dog-leg" field is used to encompass nodal regions at risk. The superior border is placed at the upper border of T10 or T11 and the inferior border at the superior aspect of the acetabulum. Traditionally, the inferior border was placed at the superior obturator foramen (indicated in orange) to include all external iliac nodes. These nodes are rarely involved, and using a higher border as indicated will reduce toxicity. If para-aortic fields are to be used, the inferior border is placed at the bottom of L5. The left renal hilum is included for left-sided tumors (A), but not for tumors on the right (B).

Once these borders are placed, the planning CT can be used to ensure adequate coverage of the target volume. Distance from the PTV to the field border is 8 to 15 mm depending on field size, energy, separation, and shielding. It should be noted that there is often a distance of several centimeters between the cranial and caudal field edges and the 95% isodose, which is related to the large field size and variability in separation.

In stage II disease, the PTV includes the same CTV as for stage I disease with an appropriate margin. Care must be taken to include the gross nodal disease in the CTV (Figure 74.4). If the lymphadenopathy is >2 cm in size, a boost to gross disease is commonly used. This may be delivered either concurrently or sequentially. The advantage

of a sequential approach is that it allows for reduction in disease volume and less irradiation of normal tissues. This is particularly appropriate where the initial disease is large and overlies the kidney.

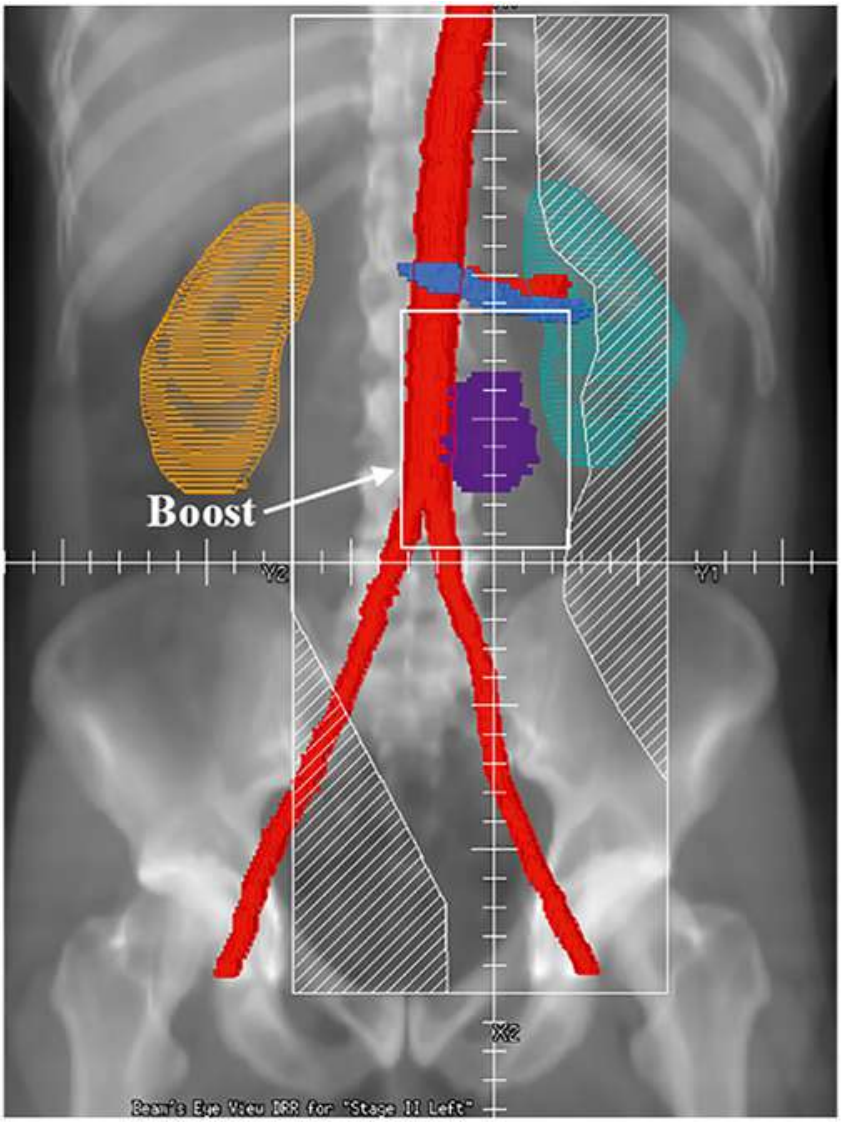

FIGURE 74.4 Stage IIA and stage IIB seminomas may be treated with a traditional or modified dog leg to a dose of 25 Gy in 20 fractions, with a boost of 10 Gy in 5 fractions to nodes >3 cm in diameter.

Paly et al analyzed the location of metastatic lymph nodes relative to vascular structures in stage II or stage I patients presenting with nodal relapse after surveillance.[87] They found, after analyzing 90 patients, that almost all detected nodes were contained within a 2.5-cm posterior and lateral margin and a 2.1-cm anterior margin from the arterial vasculature. No positive nodes were identified above the L1 level. Although requiring further validation, this suggests that the classic field borders based on bony anatomy treat a larger volume than

required, and modification, for example, by lowering the superior border, may be considered.

Simulation and Treatment Planning

A volumetric planning CT scan is acquired with the patient supine and arms at the sides. Testicular shielding (often in the form of a clamshell device) is used. Utilization of a CT-based planning technique enables visualization of the location of the lymph node regions, adjacent tissues, and critical normal structures, including the kidneys and liver. In addition, the beam's-eye view allows evaluation of the coverage of the PTV, and shielding can be appropriately placed. Treatment is delivered with a linear accelerator using anterior and posterior parallel- opposed fields. Depending on the separation, 6- to 18-MV photons are utilized. More elegant treatment techniques using intensity-modulated radiotherapy (IMRT) to cover the target volume with greater sparing of organs at risk are described.[134] Although IMRT enables reduction of dose to organs at risk (stomach, bowel, bone marrow), it increases integral doses to surrounding normal tissues, and it is not clear how this is reflected in the reduction of early or late side effects of treatment, including the risk of second malignancy. Proton radiation therapy has also been described. It allows conformality of dose to the CTV similar to that with IMRT but with less integral dose and potential risk of second malignancy.[135-137]

Dose and Fractionation

Stage I Seminoma

Radiation doses between 20 and 40 Gy at 1.25 to 2 Gy per fraction have been reported. A dose of 25 Gy in 20 fractions has been the most commonly used dose/fractionation at North American institutions,[138] with close to 100% control of retroperitoneal disease. The UK MRC (MRC TE18) completed a randomized controlled trial of 30 Gy in 15 fractions over 3 weeks or 20 Gy in 10 fractions over 2 weeks.[82] Relapse-free survival was similar in both groups. Acutely, there was significantly more moderate or severe lethargy and inability to carry out normal work in the group that received 30 Gy. However, by 12 weeks, there were no differences between the two groups.

Stage II Seminoma

In general, patients with stage II seminoma should have the ipsilateral pelvic nodes treated. The optimal radiation dose is yet to be determined, and several regimens are used. One regimen of 25 Gy in 20 fractions is frequently used with a boost (10 Gy in 5 fractions) to the residual mass for lymphadenopathy >2 to 3 cm.[101] Alternatively, 30 Gy in 15 fractions for stage IIA and 36 Gy in 18 fractions for stage IIB seminoma have been shown to provide excellent local control.[139]

Testicular Shielding

During a fractionated course of radiotherapy to the retroperitoneal and ipsilateral iliac lymph nodes, the dose to the remaining testis ranges between 0.3 and 1.5 Gy. Dose received strongly depends on the distance from the testicle to field edge. Several effective shielding devices have been described to reduce dose received by the testicle to <1% of the midplane dose.[140-142] Most departments use simple forms of gonadal shielding, such as the clamshell device, which consists of a cup that is 1 cm thick. This shields the testicle from low-energy scattered photons and effectively reduces the testicular dose by a factor of 4.

RESULTS OF THERAPY

Seminoma

The outcome of treatment depends on the stage and extent of disease at presentation. Age >40 years at diagnosis is also an adverse prognostic factor in most series.[38,143,144] For stage I disease, routine irradiation of the para-aortic and ipsilateral pelvic nodes results in 10-year relapse-free survival rates of 96% to 98%. Approximately 1% to 4% of patients relapse after infradiaphragmatic irradiation, usually within the first 3 years. The sites of relapse are usually evenly distributed between the mediastinum and distant sites. Occasional relapses occur as nonseminomatous germ cell malignancies, even after careful review of the initial tumor has shown a pure seminoma. Deaths from stage I seminoma are extremely rare. Most relapsing patients are salvaged with subsequent treatment, usually chemotherapy. Cause-specific survival rates in the large series are 99% to 100%.

The outcome for patients with stage II disease treated with infradiaphragmatic irradiation is shown in Table 74.7. Disease- free survival is approximately 92% and 86% for patients with stage IIA and IIB disease, respectively. Relapse most commonly occurs in the mediastinum, supraclavicular nodes, and lungs. Cisplatin-based chemotherapy is able to salvage in excess of 80% of the relapses, leading to a 5-year cause-specific survival of 96% to 100%. The relapse rate for patients with stage IIC disease managed by primary radiotherapy is >30%, and these patients are best managed with initial chemotherapy. Because of the ability to salvage patients who relapse following radiotherapy with cisplatin-based combination chemotherapy, the survival results following primary radiotherapy or chemotherapy as initial therapy even in patients with bulkier nodal disease are comparable. The potential toxicities of each approach must be evaluated for each patient, along with other factors influencing the choice of therapy.

Cisplatin-based chemotherapy (BEP × 3 fractions or EP × 4 fractions) is the standard treatment for patients with stage III seminoma, as well as for those with retroperitoneal masses >3 to 5 cm. Even those with advanced metastatic seminoma can expect a favorable response rate of over 95%, with a 5-year survival of over 90%.[40]

SEQUELAE OF TREATMENT

Radiation Therapy

The long-term sequelae of standard infradiaphragmatic irradiation for stages I and IIA disease are related to the dose of radiation used. There appears to be no curative advantage

for doses >25 Gy; however, there is an increase in toxicity. In the MRC randomized trial comparing 30 Gy in 15 fractions delivered to either dog-leg or para-aortic fields, 33 (7%) of 478 patients were diagnosed with a peptic ulcer during follow-up. The occurrence rate was similar in both treatment arms. Very few patients report diarrhea as a long-term consequence, and most patients report a satisfactory quality of life, with a maintained body image and few side effects.[82]

Approximately 50% of patients with testicular seminoma have some degree of impairment in spermatogenesis at the time of diagnosis, with rates of reported abnormal sperm morphology as high as 90%.[145] Exposure of the remaining testis to therapeutic irradiation may further impair fertility, and the degree of impairment is dose dependent. Available data suggest that hormonal function and spermatogenesis may be compromised at dose levels as low as 0.5 Gy and those cumulative doses >2 Gy probably lead to permanent injury.[146] Hahn et al[147] reported the induction of aspermia in 10 of 14 patients who received >65 cGy to the remaining testis. Aspermia was not detected at doses <50 cGy. Recovery of sperm in the semen occurred in most within 30 to 80 weeks of radiation therapy. A detailed assessment of fertility and sexual function was performed in the Southwest Oncology Group Study 8711 in a series of men following orchidectomy and radiation therapy for seminoma.[148] Fourteen of 26 (54%) patients were subfertile at baseline, with a sperm count <20,000/mL. The average prescribed dose was 26 Gy in 1.6-Gy fractions, delivering a median dose of 79 cGy to the remaining testis. With a testicular dose below the median, the sperm count tended to drop to a nadir value around 6 months, with recovery of fertility by 12 months. With a higher testicular dose, recovery of sperm count was further delayed. Jacobsen et al[149] reported a 50% reduction in sperm count at 1 year in 21 men following dog-leg radiation therapy (median testis dose, 32 cGy). No change in sperm count was noted in 24 men treated with para-aortic fields (median testis dose 9 cGy). Baliga et al[150] reported similar findings from the PENTEC task force—a testicular dose <1 Gy results in a 50% to 80% risk of oligospermia, but this recovers by 12 months in 75% to 100% of men. A dose of >1 Gy is associated with oligospermia in 90% of men at 12 months. There also is a dose-related effect on hormone production. Doses of 0.2 to 12 Gy result in low testosterone in 25% of men, with a steep dose-response above 20 Gy where 68% of men can be hypogonadal. Subclinical hypogonadism, with elevation of follicle-stimulating hormone and luteinizing hormone, is noted with doses over 0.5 Gy. So most men treated with radiotherapy can expect at most a temporary effect on sperm count, and rarely any long-term effect on hormonal function.

Patients are at an increased risk of developing a second primary malignancy following treatment for testicular cancer.[151-153] Travis et al[154] investigated the occurrence of second malignancies among >40,000 men who had undergone treatment for a testicular cancer between 1943 and 2001 from 14 population-based cancer registries in North America and Europe. The risk of developing a second solid tumor among 10-year survivors was almost twice that of the general population, with an RR of 1.9. The risk remained elevated for 35 years, with the highest risk for cancers of the stomach (RR 4.0), pancreas (RR 3.6), and bladder (RR 2.7). There was also an increased risk of developing cancers of the lung, esophagus, colon, and pleura. An increased risk was found for both seminomas and

nonseminomas and in patients treated with radiation therapy alone (RR 2.0), chemotherapy alone (RR 1.8), and both modalities (RR 2.9). Milano et al[155] investigated the incidence of second malignancy in a U.S. SEER population diagnosed with testicular cancer between 1973 and 2014. The 30-year cumulative incidence of second solid malignancy was 8.8%, 10.1%, and 16.9% in men treated with surgery alone, chemotherapy, and radiotherapy, respectively. Radiotherapy was associated with a significantly increased risk of pancreatic cancer in every decade beyond 10 years, with standardized incidence ratios increasing to 4.8 beyond 30 years. A significant increased risk of late hematologic malignancy was seen with chemotherapy, with a 7-fold increased risk of acute myeloid leukemia, but not with radiotherapy. A case-control study of leukemia risk in a cohort of 18,567 patients treated for testicular cancer between 1970 and 1993 has also been reported.[156] Radiation therapy (mean dose 12.6 Gy to bone marrow) without chemotherapy was associated with a 3-fold elevated risk of leukemia. Risk increased with increasing dose of radiation to the bone marrow largely associated with the use of mediastinal irradiation. The cumulative dose of cisplatin was also predictive of excess leukemia risk, being 3.2 with the commonly administered dose. In absolute terms, it is estimated that 25 Gy to the retroperitoneum would result in nine excess cases of leukemia in 10,000 patients followed for 15 years. Commonly used doses of cisplatin might result in 16 excess cases. Although treatment factors are strongly implicated in the development of second primary malignancies following treatment, an excess risk of second cancers is seen even among patients with testicular cancer who have just been observed. An increased rate of spontaneous chromosomal translocations is seen in lymphocytes of patients with early-stage seminoma compared to healthy controls.[157] Following radiation therapy, the translocation rate increases before returning to preradiotherapy levels at around 30 months.[158] It is hypothesized that this genomic instability may be a predisposing factor toward malignancy development.

Long-term survivors following radiation therapy for seminoma are also at increased risk of death related to cardiac disease, even without mediastinal irradiation,[159] with a cardiac standardized mortality ratio of 1.85 in patients followed out beyond 15 years. Survivors are also at an increased risk of hypertension, diabetes, and atherosclerosis,[160] with an increased standardized mortality ratio even beyond 25 years.[161]

Chemotherapy

Cisplatin-based chemotherapy is associated with alopecia and the potential for substantial nausea and vomiting. Modern antiemetics have improved gastrointestinal reactions. Serious short-term problems are myelosuppression, bleomycin- induced pulmonary fibrosis, and nephrotoxicity. Myelosuppression and pulmonary fibrosis are fatal in 0.5% to 4% of treated patients. There is also an increased risk of secondary malignancy. As discussed previously, the cumulative dose of cisplatin strongly correlates with the risk of subsequent malignancy.[156] Etoposide exposure also increases the risk of leukemia. Morphologically, these leukemias are usually monocytic or myelomonocytic. Characteristic chromosomal translocations are frequently, but not invariably, present. The onset of leukemia is ordinarily closer to chemotherapy exposure than is the typical leukemia induced by alkylating agents.

Other late toxicities reported include high-tone hearing loss, neurotoxicity, Raynaud phenomenon, ischemic heart disease, hypertension, renal dysfunction, and pulmonary toxicity.[162] In an observational study of 1,800 men treated with cisplatin-based chemotherapy for testicular cancer, Brydøy et al[163] noted long-term Raynaud-like phenomena in 39%, paresthesia in 29%, hearing impairment in 22%, and troubling tinnitus in 22%. Long-term fertility seems a little impaired following chemotherapy.[164] BEP causes immediate azoospermia; however, with time, more than half of patients may recover normal or near-normal spermatogenesis. The paternity rate following two to four cycles of BEP is 70% to 85%.[165] Symptomatic hormone dysfunction only occurs with high cumulative doses of cisplatin,[166] although subclinical endocrine abnormalities are more common.[167]

CHAPTER 75

Cancer of the Penis and Male Urethra

Vivek Verma and Hiram A. Gay

ANATOMY

The basic structural components of the penis include two corpora cavernosa and the corpus spongiosum. These are encased in a dense fascia (Buck fascia), separated from the skin by a layer of loose connective tissue. Distally, the corpus spongiosum expands into the glans penis, which is covered by a skin fold known as the prepuce. The skin extends over and is firmly attached to the glans.

The male urethra is composed of a mucous membrane and the submucosa. It extends from the bladder neck to the external urethral meatus. The posterior urethra is subdivided into the membranous urethra (the portion passing through the urogenital diaphragm) and the prostatic urethra, which passes through the prostate. The anterior urethra passes through the corpus spongiosum. It is subdivided into fossa navicularis (a widening within the glans); the penile urethra, which passes through the pendulous part of the penis; and the bulbous urethra, the dilated proximal portion of the anterior urethra. The prostatic urethra is covered by transitional epithelium only. The distal portion of the anterior urethra is covered by stratified squamous epithelium, which changes proximally to pseudostratified columnar epithelium. The columnar epithelium gradually changes into transitional epithelium in the membranous urethra.

The lymphatic channels of the prepuce and the skin of the shaft drain into the superficial inguinal nodes located above the fascia lata. The rich anastomotic network of the lymphatics within the penis and at the base of the penis means that, for practical purposes, lymphatic drainage may be considered bilateral. There is some disagreement about whether the glans and the deep penile structures drain into the superficial or deep inguinal lymph nodes (those under the fascia lata). The so-called sentinel nodes located above and medial to the junction of the epigastric and saphenous

veins have been identified as the primary drainage sites in carcinoma of the penis.[1] Selective biopsy of this group of nodes is of obvious importance in the assessment of tumor extent because, if they are not involved by tumor, a complete nodal dissection may not be necessary. Some have not supported the reliability of this procedure.[2,3] Catalona[4] found that biopsy of the sentinel nodes showed false-negative results in 10% of Cabanas's[5] cases who died of carcinoma.

The lymphatics of the fossa navicularis and the penile urethra follow the lymphatics of the penis to the superficial and deep inguinal lymph nodes. The lymphatics of the bulbomembranous and prostatic urethra may follow three routes. Some pass under the pubic symphysis to the external iliac nodes, some go to the obturator and internal iliac nodes, and others end in the presacral lymph nodes. The pelvic (iliac) lymph nodes are rarely involved without inguinal lymph node involvement.[6]

EPIDEMIOLOGY AND RISK FACTORS

Penile Cancer

In the United States in 2023, the estimated number of new cases of penis and other genital cancers cancer was 2,050, with 470 deaths. This accounts for less than 1% of cancer in males in the United States.[7] In the European Union, the annual number of males who develop penile cancer is estimated at 3,100, which is equivalent to an age-standardized rate (ASR) of 12 per million males. Squamous cell carcinoma is the predominant morphologic entity.[8]

A systematic review and meta-analysis showed that men circumcised in childhood/adolescence are at substantially reduced risk of invasive penile cancer, and this effect could be mediated partly through an effect on phimosis. In contrast, there was some evidence that circumcision in adulthood was associated with an increased risk of invasive penile cancer.[9] A trade-off analysis of routine newborn circumcision was performed on the Comprehensive Hospital Abstract Reporting System for Washington State. Routine newborn circumcisions performed over 9 years (1987-1996) were retrospectively examined. Of 354,297 male infants born during the study period, 37% were circumcised during their newborn stay. Overall, 0.2% of circumcised children and 0.01% of uncircumcised children had

complications potentially associated with circumcision. The authors estimated that almost two complications can be expected for every case of penile cancer prevented.[10]

A study of 1,010 penile invasive cancers diagnosed between 1983 and 2011 from 25 countries showed that between one-quarter to one-third of penile cancers were related to human papillomavirus (HPV), with HPV-16 being the most frequent HPV subtype in HPV-positive cancers.[11] A more recent meta-analysis of 1,836 patients showed that the rate of HPV positivity was considerably higher (51%).[12] A Brazilian study of 110 asymptomatic men and 30 patients who underwent circumcision due to phimosis showed that HPV was present in 46% of patients with phimosis, of whom 50% were high-risk phenotypes. They detected a significantly high rate of HPV genital infection in patients presenting with phimosis compared with asymptomatic men. The prevalence of high-risk HPV genotypes in patients with phimosis was also statistically significant.[13]

The quadrivalent vaccine against HPV serotypes 6, 11, 16, and 18 has been approved for females aged 9 to 26 years to prevent cervical cancer. Based on the demonstrated ability to significantly decrease the incidence of penile lesions (primarily HPV-6 and HPV-11 associated genital warts) in young men, the U.S. Food and Drug Administration also approved the use of the vaccine in males aged 9 to 26 years. Because the incidence of penile cancer in the United States is much lower than that of genital warts, the reduction in penile cancer incidence is expected to be low cancer rates. Perhaps the greatest benefit of vaccination of young men in the United States would be the reduced HPV infection rate in the overall population and subsequent reduced transmission to females at risk for cervical cancer.[14] Other potential strategies for the prevention of penile cancer could include smoking cessation and hygienic measures.[15]

Urethral Cancer

Carcinoma of the male urethra is also rare. Each year, around 650 individuals in the European Union develop cancer of the urethra. The ASR for cancer of the urethra is 1.1 (males 1.6; females 0.6) per million inhabitants. The 5-year relative survival rate for cancer of the urethra is

54%. Transitional cell carcinoma (TCC) is the predominant morphologic entity of cancer of the urethra.[8]

There are no recognized racial or geographic predisposing factors. Although the etiology remains unknown, there seems to be some correlation between the incidence of carcinoma of the urethra and chronic irritation (infection, venereal diseases, strictures). Some evidence suggests that some cases of female urethral carcinoma may originate from Skene glands.[16] Significant past medical history of patients with male urethra cancer includes venereal disease (24%-37%), urethral stricture (35%-54%), urethral trauma (7%), and urethral polyps (2%).[17,18] The part of the urethra covered by the transitional epithelium (prostatic and membranous urethra) may be susceptible to the same carcinogenic factors that affect the bladder and the upper urinary tract. The average age at presentation of these tumors is 58 to 60 years, although 10% occur in men younger than 40 years.[5,18]

NATURAL HISTORY

Penile Cancer

Most carcinomas of the penis start within the preputial area, arising in the glans, coronal sulcus, or the prepuce itself. Lesions arising in the skin of the shaft are rare. In most patients, carcinoma of the penis is characterized by slow locoregional progression. The penis is handled and observed daily, yet there is often significant debate as to when patient recognition and medical diagnosis should have occurred. The patient often experiences fear and embarrassment, leading to delayed diagnosis. Therefore, expeditious diagnosis of all penile lesions should be the rule. Extensive primary lesions may involve the corpora cavernosa or even the abdominal wall. The inguinal lymph nodes are the most common site of metastatic spread. Pathologic evidence of nodal metastases is reported in about 35% of all patients and approximately 50% of those with palpable lymph nodes.[5,19-21]

Distant metastases are uncommon (about 10%), even in patients with advanced locoregional disease, and usually occur in patients with inguinal lymph node involvement. These patients often die of septic complications, erosion of large vessels in the groin, or a combination thereof.

Tumors can also metastasize to the penis. The most common primary sites are the genitourinary tract (mostly bladder urothelial carcinoma and

prostatic adenocarcinoma) and the lower gastrointestinal tract (rectal and sigmoid colon adenocarcinomas). Secondary tumors tend to be localized in the penile shaft and invade the vascular spaces of erectile tissues, with corpora cavernosa involved in most cases. For patients with penile metastasis, the cancer-related death rate is high, and the prognosis is dismal.[22]

Urethral Cancer

The natural history of carcinoma of the anterior urethra in the male is similar to that of penile carcinoma. Approximately 40% of tumors originate in the anterior urethra.[17] Many tumors are low grade and progress slowly at primary and regional sites rather than spread to distal areas. Tumors of the penile urethra spread to the inguinal lymph nodes first, whereas those of the bulbomembranous and prostatic urethra metastasize first to the pelvic lymph nodes. Approximately one-third of men will present with either clinically or pathologically involved lymph nodes.[17]

Urethral cancers tend to spread by direct extension to adjacent structures. Invasion into the vascular space of the corpus spongiosum in the periurethral tissues is common. Malignancies beginning in the bulbomembranous urethra often invade the deep structures of the perineum, including the urogenital diaphragm, prostate, and adjacent skin. In the majority of prostatic urethral tumors, the bulk of the prostate gland is invaded at the time of diagnosis. Hematogenous spread is uncommon, except in advanced regional disease. Kaplan et al[18] reported distant metastases in about 15% of patients, and most had corpora cavernosa invasion at diagnosis.

CLINICAL PRESENTATION

Penile Cancer

Carcinoma of the penis may present as either an infiltrative ulcerative or an exophytic papillary lesion. Figure 75.1 demonstrates the localization of penile tumors in 259 patients from 14 cancer institutes in France. The glans and the prepuce were the predominant sites of the primary lesion, whereas tumors of the shaft were rare.[23] The presence of phimosis may obscure the assessment of the primary lesion. Secondary infection and associated foul

smell are quite common. Urethral obstruction is an unusual symptom of carcinoma of the penis. The most common presenting symptom is a mass, which occurs in over two-thirds of patients. Ulceration is also common, occurring in approximately half of patients.[21,24] In a collective series of 552 patients with penile carcinoma, the presenting symptoms were mass lesions (78%), pain or itching (12%), bleeding (7%), groin mass (7%), and urinary symptoms (4%).[25-27] Inguinal lymph nodes are palpable on presentation in 30% to 45% of patients[5,19,20,26,28,29]; however, only half contain tumor.[20,21] Enlargement of the lymph nodes is often related to inflammatory (infectious) processes. Administration of antibiotics over several weeks results in regression of inguinal lymph nodes in a substantial proportion of cases, and many have advocated this practice before the status of the regional lymph nodes is definitively assessed. Conversely, between 20% and 40% of patients with clinically negative inguinal lymph nodes have occult metastases.[3,30-33]

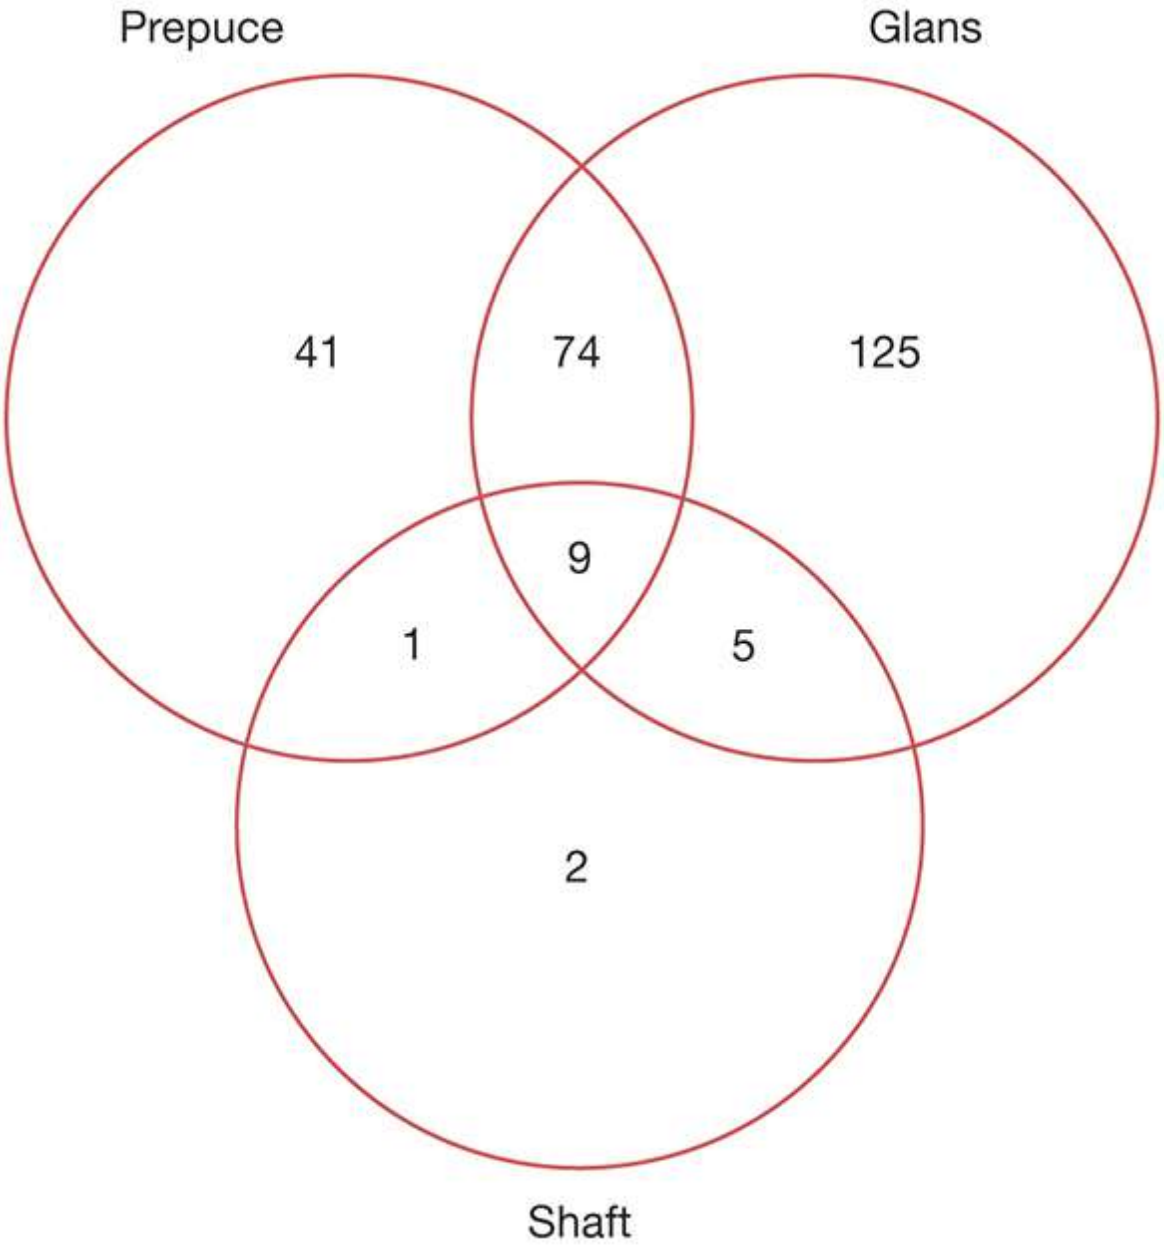

FIGURE 75.1 Localization of the primary tumor in 259 patients; each circle represents one anatomic compartment. Intersections indicate the involvement of two or three compartments. Unknown: two. (Reprinted from Rozan R, Albuisson E, Giraud B, et al. Interstitial brachytherapy for penile carcinoma: a multicentric survey (259 patients). *Radiother Oncol*. 1995;36[2]:83-93. Urethral Cancer

Patients with urethral carcinoma most commonly present with obstructive symptoms (43%). Other presenting signs and symptoms include mass (28%), bleeding (20%), abscess (20%), and irritative symptoms (20%).[17]

These symptoms are often attributed to urethritis or urethral stricture, which may precede the development of urethral carcinoma and may also result in a delay in diagnosis. The majority of urethral carcinomas occur in the bulbomembranous (posterior) region (61%), and tumors in this location have a worse prognosis compared with those arising in the anterior urethra.[17]

DIAGNOSTIC WORKUP

In penile and urethral cancers, imaging plays a crucial role in enhancing the precision of clinical staging and facilitating optimal surgical planning. High-resolution magnetic resonance imaging (MRI) now represents the gold standard for evaluating the primary tumor and its local extension. Lymphotropic nanoparticle-enhanced MRI and dynamic sentinel lymph node biopsy combined with fine-needle aspiration seem to be superior for imaging regional lymph nodes. Positron emission tomography/computed tomography (PET/CT) has shown great promise for the detection of distant metastases.[34]

Penile Cancer

See Table 75.1 for the diagnostic workup of penile cancer.

TABLE 75.1 DIAGNOSTIC WORKUP FOR PENILE CANCER

History and physical examination

- Risk factors: Balanitis, chronic inflammation, penile trauma, lack of neonatal circumcision, tobacco use, lichen sclerosus, poor hygiene, sexually transmitted
- Lesion characteristics: Diameter, location, number of lesions, morphology (papillary, nodular, ulcerous, or flat), relationship to other structures (submucosal, corpora spongiosa, cavernosa, and/or urethra)
- Lymph node characteristics: Diameter, unilateral or bilateral, number, relationship to other structures, mobility or fixation, skin involvement

Histologic diagnosis

- Punch, excisional or incisional biopsy
- Assess human papillomavirus (HPV) status

Cross-sectional imaging of chest/abdomen/pelvis may include:

- Abdomen/pelvis CT or MRI with contrast
- Chest x-ray or CT with contrast
- PET/CT
- CT/MRI of the pelvis with contrast for nodal evaluation if difficult to clinically assess

CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

On MRI, penile tumors are best evaluated on T2-weighted images owing to the superior contrast resolution between the hypointense fascial layers and the adjacent hyperintense corporal bodies. Squamous cell carcinomas typically appear as hypointense lesions when compared to the adjacent corpora. On MRI, nonsquamous variants of penile cancer can appear different from squamous carcinomas. Although penile cancers enhance with gadolinium, the normal corporal bodies enhance even more, which makes contrast enhancement less useful.[34]

The presence of central nodal necrosis and/or an irregular nodal border of the regional lymph nodes on preoperative CT images are accurate and reproducible (sensitivity of 95% and a specificity of 82%) criteria to identify high-risk pathologic node-positive penile cancer.[35]

Sentinel lymph node biopsy with a radiotracer (Tc-99m nanocolloid) is a reliable method with low morbidity associated with a low radiation burden for clinical staff. The false-negative rate and morbidity are less than 5%.[36]

Limited prospective data regarding the use of PET with CT are available, but preliminary results show encouraging sensitivity (88%) and specificity (98%) in evaluating inguinal lymph nodes[37] and diagnostic accuracy of 96% in evaluating pelvic lymph nodes in patients with known inguinal metastases.[38]

Urethral Cancer

See Table 75.2 for the diagnostic workup of urethral cancer.

TABLE 75.2 DIAGNOSTIC WORKUP FOR URETHRAL CANCER

General

- History and physical examination
- Cystourethroscopy, examination under anesthesia, transurethral resection, or transvaginal biopsy

Radiographic studies

- MRI of the pelvis with and without contrast
- Chest x-ray or CT

- Palpable lymph nodes: chest, abdominal, and pelvic CT with contrast. Lymph node biopsy

CT, computed tomography; MRI, magnetic resonance imaging.

A cystourethroscopy is essential for urethral primaries. Inguinal lymph nodes should be thoroughly evaluated. CT is useful in identifying enlarged pelvic and periaortic lymph nodes in patients with involved inguinal lymph nodes.[34]

On MRI, urethral tumors tend to show a decreased signal intensity relative to the surrounding normal corporal tissue on T1- and T2-weighted images. Malignant lesions usually enhance with gadolinium.[34]

STAGING

Penile Cancer

Urethral Cancer

The American Joint Committee on Cancer (AJCC) staging systems for carcinoma of the penis and urethra are shown in Tables 75.3 and 75.4, respectively.[39]

TABLE 75.3 2017 PENIS CANCER TNM STAGING AJCC UICC

T Category	T Criteria
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma in situ (penile intraepithelial neoplasia [PeIN])
Ta	Noninvasive localized squamous cell carcinoma
T1	Glans: Tumor invades the lamina propria. Foreskin: Tumor invades dermis, lamina propria, or dartos fascia. Shaft: Tumor invades connective tissue between epidermis and corpora regardless of location. All sites with or without lymphovascular invasion or perineural invasion and is or is not high grade
T1a	Tumor is without lymphovascular invasion or perineural invasion and is not high grade (ie, grade 3 or sarcomatoid).
T1b	Tumor exhibits lymphovascular invasion and/or perineural invasion or is high grade (ie, grade 3 or sarcomatoid).

T Category	T Criteria		
T2	Tumor invades into corpus spongiosum (either glans or ventral shaft) with or without urethral invasion.		
T3	Tumor invades into corpus cavernosum (including tunica albuginea) with or without urethral invasion.		
T4	Tumor invades other adjacent structures (ie, scrotum, prostate, pubic bone).		
Regional Lymph Nodes (N)[a]			
Clinical N (cN)			
cN Category	**cN Criteria**		
cNX	Regional lymph nodes cannot be assessed.		
cN0	No palpable or visibly enlarged inguinal lymph nodes		
cN1	Palpable mobile unilateral inguinal lymph node		
cN2	Palpable mobile ≥2 unilateral inguinal nodes or bilateral inguinal lymph nodes		
cN3	Palpable fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral		
Clinical N (pN)			
pN Category	**pN Criteria**		
pNX	Lymph node metastases cannot be established.		
pN0	No lymph node metastasis		
pN1	≤2 unilateral inguinal metastases, no ENE		
pN2	≥3 unilateral inguinal metastases or bilateral inguinal metastases		
pN3	ENE of lymph node metastases or pelvic lymph node metastases		
M Category	**M Criteria**		
M0	No distant metastasis		
M1	Distant metastasis present		
AJCC Prognostic Stage Groups			
0is	Tis	N0	M0
0a	Ta	N0	M0
I	T1a	N0	M0
IIA	T1b or T2	N0	M0

T Category	T Criteria		
IIB	T3	N0	M0
IIIA	T1-3	N1	M0
IIIB	T1-3	N2	M0
IV	T4	Any N	M0
	Any T	N3	M0
	Any T	Any N	M1
Histologic Grade (G)			
GX	Grade cannot be assessed.		
G1	Well differentiated		
G2	Moderately differentiated		
G3	Poorly differentiated/high grade		

AJCC, American Joint Committee on Cancer; ENE, extranodal extension; NOS, not otherwise specified; UICC, International Union Against Cancer.

[a]The regional lymph nodes are as follows: superficial and deep inguinal lymph nodes, pelvic nodes (NOS), and pelvic nodes (specified): external iliac, internal iliac (also called hypogastric), and obturator.

TABLE 75.4 2017 URETHRA CANCER TNM STAGING AJCC UICC

Male Penile Urethra and Female Urethra	
T Category	**T Criteria**
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue.
T2	Tumor invades any of the following: corpus spongiosum, periurethral muscle.
T3	Tumor invades any of the following: corpus cavernosum, anterior vagina.
T4	Tumor invades other adjacent organs (eg, invasion of the bladder wall).
Prostatic Urethra	

T Category	T Criteria
Tis	Carcinoma in situ involving the prostatic urethra or periurethral or prostatic ducts without stromal invasion
T1	Tumor invades urethral subepithelial connective tissue immediately underlying the urothelium.
T2	Tumor invades the prostatic stroma surrounding ducts either by direct extension from the urothelial surface or by invasion from prostatic ducts.
T3	Tumor invades the periprostatic fat.
T4	Tumor invades other adjacent organs (eg, extraprostatic invasion of the bladder wall, rectal wall).
N Category	**N Criteria**
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Single regional node metastasis in the inguinal region or true pelvis (perivesical, obturator, internal [hypogastric] and external iliac), or presacral lymph node
N2	Multiple regional lymph node metastases in the inguinal region or true pelvis (perivesical, obturator, internal [hypogastric] and external iliac), or presacral lymph node
M Category	**M Criteria**
M0	No distant metastasis
M1	Distant metastasis

PATHOLOGIC CLASSIFICATION

Penile Cancer

The World Health Organization (WHO) classifies malignant epithelial tumors of the penis as squamous cell carcinoma (Basaloid, warty [condylomatous], verrucous, papillary not otherwise specified, sarcomatous, mixed, and adenosquamous carcinoma), Merkel cell carcinoma, small cell carcinoma of neuroendocrine type, sebaceous carcinoma, clear cell carcinoma, and basal cell carcinoma.[40] Basaloid carcinoma has a poor prognosis and frequently early inguinal nodal metastases. Warty carcinoma has a good prognosis with rare metastases. Verrucous carcinoma has a good prognosis with no metastases. Papillary carcinoma has a good prognosis with rare metastases. Sarcomatous carcinoma has a very poor prognosis with early vascular metastases. Mixed carcinoma has a heterogeneous prognosis. Adenosquamous carcinoma occurs in the central and perimeatal glans and is high grade with high metastatic potential but low mortality.[41]

Most malignant penile tumors are well-differentiated squamous cell carcinomas.[42] Although an apparent adverse prognostic effect of anaplasia

has been reported in some series,[19] others found no significant correlation between histologic grade and survival.[26,43]

Bowen disease is squamous cell carcinoma in situ that may involve the shaft of the penis as well as the hairy skin of the inguinal and suprapubic area. Clinically, the lesion is a solitary, dull red plaque with areas of crusting and oozing. Approximately 25% to 50% of patients with this disease have a concomitant visceral malignancy.[6]

Erythroplasia of Queyrat is an epidermoid carcinoma in situ involving the prepuce or glans' mucosal or mucocutaneous areas.[42] It appears as a reddened, elevated, or ulcerated lesion. Graham and Helwig[44] reported that 10 of 100 patients presenting with erythroplasia of Queyrat had invasive squamous cell carcinoma at diagnosis. Mikhail[45] reported on 5 of 15 patients with the same presentation.

Basal cell carcinoma of the penis is an extremely rare entity, accounting for less than 0.03% of all basal cell carcinomas.[46]

Extramammary Paget disease is a rare intraepithelial apocrine carcinoma. The most common sites are the scrotum, inguinal folds, and perineal region.[45] The lesion tends to metastasize, necessitating frequent assessment of regional nodes. Radiation therapy (RT) can be recommended as palliative treatment.[45]

Soft tissue tumors are uncommon. Approximately half of the tumors are benign and may include angiomatous, neurogenous, myogenous, fibrous, and lymphoreticular tumors.[47,48] Most soft tissue tumors occur on the shaft and are malignant.

Primary lymphoma of the penis was reported in one patient with Peyronie disease without other evidence of lymphomatous involvement. Five cases of secondary involvement of the penis by lymphoma were reported in the literature.[49]

Cancers metastatic to the penis are rare and usually represent late, advanced carcinomatosis. The most common neoplasms metastasizing to the penis are from the genitourinary organs, followed by the gastrointestinal and respiratory systems (Table 75.5). The predominant cell type is carcinoma, occurring in 202 of 219 cases.[50] Sarcomas and tumors of unknown histologic type are rare. A palpable mass, swelling, nodule, or skin change frequently occurs. Priapism as an initial presenting feature or subsequent development occurs in 40% of patients.[50]

TABLE 75.5 PRIMARY MALIGNANCIES ASSOCIATED WITH SECONDARY CANCERS OF THE PENIS IN 219 PATIENTS

Site of Primary Malignancy	Number of Patients

Urethral Cancer

The histologic subtypes in the Memorial Sloan-Kettering Cancer Center series of urethral cancers included squamous cell carcinoma (52%), TCC (33%), epidermoid carcinoma (11%), adenocarcinoma (2%), and anaplastic carcinoma (2%).[17] Primary malignant melanoma arising from the urethra has

been reported.[51,52] The frequency of histologic type varies with site. Over 90% of carcinomas of the prostatic urethra are of transitional cell type. Adenocarcinomas occur only in the bulbomembranous urethra.

PROGNOSTIC FACTORS

Penile Cancer

The principal prognostic factors in carcinoma of the penis are the extent of the primary lesion and the status of the lymph nodes.[24,53] The incidence of nodal involvement is related to the size, location, and grade of the primary lesion. Invasion of deep-seated structures (corpora cavernosa) carries a high risk of deep inguinal node involvement.

Several studies have corroborated that HPV-associated cases have improved prognosis as compared to HPV-negative disease.[54,55] In addition, p16 positivity, a surrogate for HPV infection, confers an improved prognosis and has excellent interobserver reproducibility.[56]

Tumor-free regional nodes imply an excellent (80%-90%) long-term survival or cure.[20,29,53] Patients with involvement of the inguinal nodes fare considerably worse, and only 40% to 50% survive long term.[20,29,53,57] Pelvic lymph node involvement implies a worse prognosis; less than 20% of these patients survive.[5,20,26] Gerbaulet and Lambin[58] reported the results of 109 patients with penile carcinoma at the Institut Gustave-Roussy. The actuarial survival rates of patients with negative nodes were 82% at 5 years and 59% at 10 years. The survival rates for patients with positive nodes survival rates were 36% and 18%, respectively. The number of positive lymph nodes has also been reported to have prognostic significance. Brkovic et al[59] reported a 5-year survival rate of 71% in patients with solitary inguinal lymph node metastasis compared with 33% in patients with multiple positive inguinal nodes. Extranodal extension in dissected nodes is another poor prognostic factor, with median survival around 10 to 12 months.[60]

Fraley et al showed tumor differentiation as an important prognostic factor.[61] None of nine patients with carcinoma in situ, 1 of 20 with well-differentiated, 5 of 13 with moderately differentiated, and 3 of 4 with poorly differentiated lesions died of their tumors. Other investigators have confirmed the prognostic significance of tumor grade.[24,53,62,63]

Carcinoma of the penis has been reported to have a greater propensity to metastasize and poorer prognosis in patients younger than 50 years[61] and patients older than 65 years.[62] Soria et al[24] and O'Kelly et al[64] reported younger age at presentation adversely affected disease-free survival and cancer-specific survival (CSS), respectively, but neither discerned differences in overall survival. Marcial et al[65] observed no difference in survival in relation to age.

An epithelial-mesenchymal transition (EMT) phenotype at the invasion front of squamous cell carcinoma of the penis confers a worse prognosis. EMT is a process that allows polarized epithelial cells to undergo biochemical, molecular, and morphologic changes that affect the acquisition of a mesenchymal cell phenotype with increased migration, tissue invasion, and resistance to apoptosis. A retrospective study of 149 penile cancers showed that the 10-year overall survival and CSS rates in patients with the presence or absence of complete EMT status were 38.0% and 55.6% and 48.0% and 91.9%, respectively.[66] Activation of mTOR signaling may contribute to penile squamous cell carcinoma progression and aggressive behavior.[67] CD44 levels and expression patterns can be considered markers for penile squamous cell carcinoma aggressiveness and may serve as predictive markers for lymph node metastases.[68]

Predictors of cancer-specific mortality after disease recurrence in patients with squamous cell carcinoma of the penis include shorter time to disease recurrence, lymph node metastasis at the time of initial treatment, and regional recurrence.[69] Nomograms have been developed to predict outcomes based on several of the aforementioned prognostic factors.[70]

Urethral Cancer

A Surveillance, Epidemiology, and End Results (SEER) database study of 2,065 men from 1988 to 2006 showed that predictors of death and death from disease included advanced age, higher grade, higher T stage, systemic metastases, other histology versus TCC, and no surgery versus radical resection. Adenocarcinoma was associated with a lower likelihood of death and death from disease as compared with TCC. Nodal metastasis was a predictor of death. Surgery had a better outcome than radiation for stage T2-T4 nonmetastatic disease.[71]

Another SEER database study of 722 women from 1983 to 2008 showed that advanced age, T stage, node-positive disease, nonsquamous histologic features, and Black race were associated with reduced CSS. Surgical resection was associated with a longer CSS.[72]

Overall prognosis in males with carcinoma of the urethra varies considerably with the location of the primary lesion.[17,73-78] Distal lesions generally have a prognosis similar to that of carcinoma of the penis. Lesions of the bulbomembranous urethra are usually quite extensive and are associated with a dismal prognosis. Dalbagni et al[17] reported a 5-year overall survival of 69% in patients with anterior tumors compared with 26% in patients with posterior tumors. Other prognostic factors included lymph node status and histology (superficial vs invasive). A study of an international cohort of 154 patients with primary urethral cancer showed that clinical nodal stage is a critical parameter impacting outcomes.[79] Tumors of the prostatic urethra show prognostic features similar to those in bladder carcinoma. Superficial lesions have a good prognosis and may be managed with transurethral resection.[76] Deeply invasive tumors have a greater tendency to develop inguinal or pelvic lymph node and distant metastases.

GENERAL MANAGEMENT

Penile Cancer

General Treatment Approach

According to U.S. cancer guidelines for penile cancer, as well as guidelines from the European Association of Urology and American Society of Clinical Oncology,[80] clinical Tis, Ta, and T1 penile cancer lesions may be amenable to organ-sparing approaches, such as topical therapy (5-fluorouracil [5-FU] or imiquimod), laser therapy, glansectomy, wide local excision, and Mohs micrographic surgery. For T1 G1-2 tumors, interstitial brachytherapy (preferred) or external beam radiation therapy (EBRT) can be considered (category 2B). Circumcision should always precede RT to prevent radiation-related complications. For T1 G3-4 or T2 tumors smaller than 4 cm with negative nodes, interstitial brachytherapy or EBRT with or without inguinal lymph node RT are options after circumcision. Tumors 4 cm or larger, or unresectable node-positive disease, circumcision followed by

chemoradiotherapy, and carefully selected patients may be amenable to brachytherapy. Postsurgical RT to the primary tumor site may be considered for positive margins.

If the patient is unable or unwilling to undergo surgical management, prophylactic EBRT to the lymph nodes should be considered. For patients with pN2-N3 disease, a pelvic lymph node dissection with or without adjuvant chemotherapy or chemoradiotherapy should be considered. Definitive chemoradiotherapy is also an option. Postoperative RT or chemoradiotherapy may be considered after pelvic lymph node dissection, particularly in the setting of a positive surgical margin, viable cancer in multiple inguinal or pelvic lymph nodes, and/or extranodal extension on pathology.

The InPACT, International Penile Advanced Trial (NCT02305654), sponsored by the Institute of Cancer Research (United Kingdom), will consist of two randomizations. The first randomization relates to inguinal management and has three arms: therapeutic inguinal node dissection (arm A), neoadjuvant chemotherapy followed by therapeutic inguinal node dissection (arm B), and neoadjuvant chemoradiotherapy followed by therapeutic inguinal node dissection (arm C). Pathologically high-risk patients (defined as ≥3 nodes or extranodal spread) undergo a second randomization: Arm A and arm B are randomized between adjuvant chemoradiotherapy or prophylactic pelvic lymph node dissection followed by adjuvant chemoradiotherapy, and arm C is randomized between surveillance or prophylactic pelvic lymph node dissection. Neoadjuvant chemotherapy consists of up to four cycles of paclitaxel, ifosfamide, and cisplatin (TIP), and concurrent chemoradiotherapy uses cisplatin.[81]

Conservative Therapies

Treatment for carcinoma in situ and very small penile carcinomas includes topical imiquimod and 5-FU.[82] Conservative laser surgery[83] or Mohs micrographic surgery is used for larger lesions.[84]

Surgery

Treatment of patients with carcinoma of the penis is generally performed at two separate levels: (1) management of the primary tumor and (2) treatment

of the regional lymphatics. According to national cancer guidelines, organ-sparing surgical interventions at the primary site include laser therapy, wide local excision, glansectomy, and Mohs micrographic surgery. Partial or total penectomy should be considered for high-grade primary penile tumors or tumors invading the corpus cavernosum.

In very advanced proximal tumors, more aggressive resections such as total emasculation (penectomy, scrotectomy, orchiectomy) or cystoprostatectomy may be indicated. Although surgical resection is a highly effective and expedient treatment modality in most cases, it may not be acceptable to sexually active patients. Radical surgery, especially total penectomy, may be psychologically devastating to the patient. The ideal surgical procedure removes the disease with adequate margins while preserving sexual and urinary function, although this is not always possible because of the extent of the disease. The high local recurrence rates described in some reports with limited surgery[85,86] illustrate the need for careful patient selection in choosing a surgical approach.

Lesions confined to the prepuce may be treated with wide circumcision. Microsurgical techniques have shown local excision to be an acceptable and desirable option with small superficial lesions. A local control rate of 92% was achieved in 29 patients, with a 5-year survival rate of 81% for stage I and 57% for stage II lesions.[87] A study of 129 patients at MD Anderson Cancer Center undergoing various organ-sparing surgical procedures demonstrated a local control of 84% at a median follow-up of 28 months, with local failures salvageable with further penile-sparing procedures.[88] A large multicenter study of 1,188 patients undergoing organ-preserving surgery demonstrated a 5-year local recurrence-free survival of 74%, which was roughly comparable between Ta/Tis, T1, and T2 cases; the secondary penectomy rate was 19%.[89]

Some patients can remain sexually active after partial penectomy. Jensen[90] reported that 45% of patients with 4 to 6 cm and 25% of patients with 2 to 4 cm of penile stump could perform sexual intercourse. D'Ancona et al[91] evaluated the quality of life in 14 patients treated with partial penectomy. Sexual function was reported to be normal or only slightly decreased in 64% of patients. Complete loss of sexual function was reported in 14% of patients.

Surgical Treatment of Inguinal Lymph Nodes

According to national cancer guidelines, standard or modified inguinal lymph node dissection (ILND) or dynamic sentinel lymph node biopsy (DSNB) is indicated in patients with high-risk features for nodal metastases: lymphovascular invasion, pT1G3 or higher or T2 or higher, or more than 50% poorly differentiated. The sensitivity of DSNB is roughly 87% for clinically N0 disease (95% confidence interval, 82%-91%).[92]

For clinically node-positive disease, ILND is the standard of care. For clinically node-negative disease, either DSNB or ILND can be performed per physician judgment. The goal of DSNB is to potentially avoid ILND and its associated sequelae; however, if DSNB turns out positive, then ILND remains the standard approach because the degree/extent of nodal involvement is the most powerful predictor of additional inguinal lymph node metastases.[93-95]

ILND can occur either at the same time as penile resection or separately in a staged manner.[96] Open surgical approaches have been traditionally utilized, but endoscopic approaches offer fewer complications and side effects.[97] Although bilateral ILND remains the standard of care, emerging data have suggested that unilateral ILND with contralateral DSNB may not compromise outcomes.[98] There is no optimal cutoff regarding how many nodes should be removed, but some data have suggested a threshold of 15.[99]

Pelvic lymph node dissection (PLND) should be considered at the time or following ILND in patients with two or more positive inguinal nodes on the ipsilateral ILND site or any evidence of extranodal extension on pathology. A bilateral PLND should be considered at the time or following ILND in patients with four or more total positive inguinal nodes. It has been suggested that an adequate PLND comprises removing at least nine nodes, but there remains no consensus to date.[99]

The clinical evaluation of inguinal lymph nodes in men with penile cancer is unreliable. Several series have shown the sensitivity of clinical staging of the nodes to be 40% to 60% and false-negative rates of 10% to 20%.[3,4] McDougal et al[100] reported the correlation between clinical findings and pathologic positivity of inguinal nodes in patients with penile carcinoma. For tumors with no invasion or superficial invasion, moderately or well differentiated, only 12% of clinically enlarged inguinal nodes were pathologically positive. However, 78% to 88% of invasive or poorly

differentiated tumors metastasized to inguinal nodes, regardless of clinical findings. In a prospective study involving 37 patients with clinically negative groins, Solsona et al[33] have demonstrated the predictive value of histologic grade and T stage in predicting the likelihood of occult positive lymph nodes. Three groups were identified: low, intermediate, and high risk, with an incidence of occult positive nodes of 0%, 33%, and 83%, respectively (Table 75.6).

TABLE 75.6 T STAGE AND GRADE PREDICT THE RISK OF OCCULT POSITIVE LYMPH NODES

Risk Group		Occult Positive Lymph Nodes (%)
Low	Tis, T1 grade 1	0/13 (0)
Intermediate	T1 grade 2-3 T2 grade 1	4/12 (33.3)
High	T2 grade 2 T2-3 grade 3	10/12 (83.3)

Data from Solsona E, Iborra I, Rubio J, Casanova JL, Ricós JV, Calabuig C. Prospective validation of the association of local tumor stage and grade as a predictive factor for occult lymph node micrometastasis in patients with penile carcinoma and clinically negative inguinal lymph nodes. *J Urol*. 2001;165(5):1506-1509.

Radiation Therapy

The primary advantage of RT is organ preservation. According to national cancer guidelines for penile cancer, T1-T2 tumors less than 4 cm can be managed with circumcision followed by brachytherapy alone (category 2B), EBRT (category 2B), or EBRT with concurrent chemotherapy (category 3) to a total dose of 65 to 70 Gy with conventional fractionation. Prophylactic EBRT to the inguinal lymph nodes may be considered for nonsurgical candidates or those who decline surgery.

T1-T2 tumors 4 cm or larger can be managed with circumcision followed by EBRT with concurrent chemotherapy (category 3) to 45 to 50.4 Gy to a portion of or the whole penile shaft depending on the extent of the lesion plus pelvic lymph nodes, followed by a boost to the primary lesion to 60 to 70 Gy with conventional fractionation. Brachytherapy alone may be considered in select cases.

T3-T4 or N positive tumors (surgically unresectable) can be managed with circumcision followed by 45 to 50.4 Gy to the whole penile shaft, pelvic lymph nodes, and bilateral inguinal lymph nodes followed by a boost to the primary lesion to 60 to 70 Gy with conventional fractionation.

If the margins are positive following penectomy, postsurgical EBRT to 60 to 70 Gy to the primary tumor site and surgical scar is recommended. Brachytherapy may be considered in select cases. Bilateral inguinal lymph nodes and pelvic lymph nodes may be irradiated for inadequate (or lack of) lymph node dissection, but adjuvant RT to the dissected inguinal basin(s) is currently not routinely performed.[101]

Palliative courses of 20 to 25 Gy in 5 fractions or 30 to 35 Gy in 10 fractions are acceptable for painful metastases. These regimens are unlikely to palliate advanced locoregional disease effectively. If the patient's general condition permits, a more prolonged fractionation, especially with the addition of chemotherapy, such as low-dose weekly cisplatin, may produce longer lasting benefits.[102]

Chemotherapy

The use of systemic chemotherapy, either adjuvant to or concomitantly with RT, has not been fully investigated in patients with penile cancer. Modern multiagent chemotherapy regimens have overall response rates ranging from 15% to 55% in patients with advanced disease (Table 75.7). Additional clinical trials are needed to adequately define the role of chemotherapy in the management of cancer of the penis.

TABLE 75.7 MULTIAGENT CHEMOTHERAPY IN ADVANCED PENILE CARCINOMA

Reference	Agents	*n*	PR (%)	CR (%)	Median Survival (Month)	Fatal Toxicity (%)
Corral et al[103]	Bleomycin Cisplatin Methotrexate	29	41	14	11.5	3.4
Di Lorenzo et al[104]	Cisplatin 5-FU	78	32	0	8	0
Di Lorenzo et al[105]	Paclitaxel	25	20	0	5.25	0

Reference	Agents	*n*	PR (%)	CR (%)	Median Survival (Month)	Fatal Toxicity (%)
Hass et al[106]	Bleomycin Cisplatin Methotrexate	40	20	12.5	7	12.5
Kattan et al[107]	Varied (platinum based)	13	8	8	7.6	—
Pagliaro et al[108]	Paclitaxel Ifosfamide Cisplatin	30	40	10	17.1	0

CR, complete response; PR, partial response; 5-FU, 5-fluorouracil.

Preoperative TIP can yield clinically significant responses among patients with regionally advanced penile cancer. About 50% of such patients with an objective response to chemotherapy who undergo consolidative lymphadenectomy will remain alive at 5 years.[109] Cetuximab has antitumor activity in metastatic penile cancer and may enhance the effect of cisplatin-based chemotherapy.[110]

According to national cancer guidelines, the preferred chemotherapy regimens are TIP and 5-FU plus cisplatin (not recommended neoadjuvantly).[111] Cisplatin with or without 5-FU is preferred for chemoradiotherapy with mitomycin-C plus 5-FU or capecitabine (palliation) as alternatives.[112]

Targeted Therapy

Presently, there are limited data regarding the efficacy of targeted therapies for penile carcinoma. A retrospective study of 17 metastatic cases that underwent chemotherapy and dual pharmacologic inhibition of the epidermal growth factor receptor, as well as programmed cell death-1, revealed that 13 patients had partial responses; of the 12 who subsequently received resection, half achieved a pathologic complete response. The 2-year progression-free and overall survival were 68% and 63%, respectively.[113]

In contrast to the above, the prospective data have not been as encouraging. A single-arm phase II trial examined the pan-HER tyrosine kinase inhibitor dacomitinib for advanced or nonmetastatic disease, noting a

response rate of 32% and 1-year progression-free and overall survival of 26% and 55%, respectively.[114] In addition, the nonrandomized phase II PERICLES trial of atezolizumab for 32 patients with advanced disease showed a response rate of 17%, along with a 1-year progression-free survival of 12.5%, which did not meet the primary end point.[115]

Urethral Cancer

The primary mode of therapy for carcinoma of the male urethra is surgical excision. According to U.S. national cancer guidelines and European Association of Urology guidelines, patients with clinical Tis, Ta, or T1 tumors should be managed with a transurethral resection followed by intraurethral chemotherapy or Bacillus Calmette-Guérin in selected cases.[116]

Clinical T2 tumors of the male pendulous urethra can be managed with a distal urethrectomy or partial penectomy. Positive margins are managed with further surgery, RT, or chemoradiotherapy (preferred). Clinical T2 tumors of the male bulbar urethra are managed with urethrectomy with or without cystoprostatectomy. Subsequently, pathologic T3-T4 or N1-N2 tumors can be considered for adjuvant chemoradiotherapy or chemotherapy.

Clinical T3 and T4 tumors that are cN0 can receive neoadjuvant chemotherapy and consolidation with surgery or RT, chemoradiotherapy, or RT. (Of note, the European Association of Urology guidelines also extend this recommendation to clinical T2 disease.)[116] Clinical T3 and T4 tumors that are cN1 or cN2 can be treated with RT, preferably with chemotherapy (especially for squamous cell carcinoma), chemotherapy, or chemoradiotherapy, followed by consideration of consolidative surgery. Combined modality therapy has become more common in recent years and may offer improved outcomes in select patients.[117]

Owing to the rarity of this disease, comparison of the cure rates with RT or surgery is difficult. The principal advantage of RT is organ preservation. Noninvasive carcinoma of the proximal urethra can be treated with transurethral resection. In lesions of the distal urethra, results with either penectomy or RT are similar to those for carcinoma of the penis, and the 5-year survival rates are comparable (50%-60%).[118] Involved regional lymph nodes are treated with lymphadenectomy. A study of 2,614 patients from a large national database showed similar survival with surgery or RT, but

information on other end points was not available; however, for locally advanced disease, adding adjuvant radiation improved survival over surgery alone, particularly for nonsquamous histologies.[119]

Most patients, however, present with advanced invasive lesions, which are difficult to manage with either radical surgery or RT. The major problem remains the high rate of local recurrence. In an attempt to improve the locoregional control rate, extended resections encompassing the inferior pubic rami, prostate, bladder, and perineum have been performed after preoperative RT.

Chemotherapy

Gheiler et al[51] reported their experience with multimodality treatment of 21 patients (10 women, 11 men) with urethral carcinoma. Treatment consisted of cisplatin- and 5-FU–based chemotherapy for squamous cell carcinoma and concurrent external beam irradiation. Patients with TCC were treated with concomitant methotrexate, vinblastine, Adriamycin (doxorubicin), and cisplatin. Some patients underwent surgical resection following chemoradiation. With a median follow-up of 42 months, the overall disease-free survival rate was 62%. Of significance is the pathologic complete response rate of 87.5% in eight women undergoing resection following chemoradiation.

Another retrospective study of 29 males with urethral cancer treated with two cycles of 5-FU and mitomycin-C with concurrent EBRT to the genitalia, perineum, and inguinal and external iliac lymph nodes showed that 79% had a complete response to treatment, while the rest did not respond and died of their disease. Of the complete responders, 42% had disease recurrence at a median of 12.5 months. The 5-year overall, disease-specific, and disease-free survival rates were 52%, 68%, and 43%, respectively.[120]

A series of 124 patients with primary urethral cancer treated between 1993 and 2012 from 10 referral centers showed that those who received neoadjuvant chemotherapy or neoadjuvant chemoradiotherapy with adjuvant chemotherapy for cT3 and/or cN+ tumors appeared to demonstrate improved survival compared with those who underwent upfront surgery

with or without adjuvant chemotherapy. Proximal tumor location correlated with an inferior 3-year relapse-free survival and overall survival.[121]

Another large study of a national database of 191 patients (2004-2016) demonstrated that chemotherapy reduced the rate of all-cause mortality. Although the database did not capture response rates or disease recurrence rates, overall survival was higher with neoadjuvant chemotherapy than adjuvant chemotherapy. The median survival figures were 66 versus 33 months (5-year values not reported).[122]

RADIATION THERAPY TECHNIQUES

Penile Cancer

If indicated, circumcision must be performed before RT is initiated. The purpose of this procedure is to minimize RT-associated morbidity: swelling, irritation of the skin, moist desquamation, and secondary infection.

Although external beam therapy has become prevalent in the treatment of the primary lesion in carcinoma of the penis, plastic molds or interstitial implants are still used.

External Beam Radiation Therapy

External beam therapy requires specially designed accessories (including bolus) necessary to achieve homogeneous dose distribution to the entire penis. Frequently, a plastic box with a central circular opening that can be fitted over the penis is used. The space between the skin and the box must be filled with tissue-equivalent material (Figure 75.2). This box can then be treated with parallel-opposed megavoltage beams. An alternative to the box technique is the use of a water-filled container to envelop the penis while the patient is in a prone position.[123]

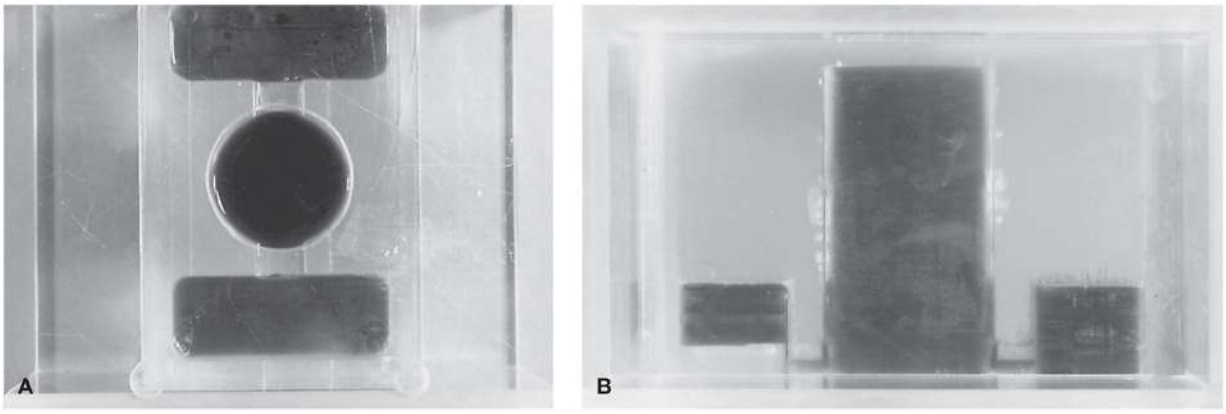

FIGURE 75.2 A. View from above of plastic box with a central cylinder for external irradiation of the penis. Patient is treated in the prone position. The penis is placed in the central cylinder, and water is used to fill the surrounding volume in the box. The depth dose is calculated at the central point of the box. B. Lateral view.

Another more complex device is a Perspex tube attached to a baseplate resting on the skin.[124] This is placed as close as possible to the base of the penis, and a flexible tube is connected to a vacuum pump. The suction effect keeps the penis in a fixed position during treatment. Appropriate bolus is placed outside the tube. The patient can also be treated in the prone position, with the penis hanging through a small hole placed in the Perspex cylinder.

Regional lymphatics may be treated with EBRT, with bilateral groins irradiated most frequently. The fields should include inguinal *and* pelvic (external iliac and hypogastric) lymph nodes (Figure 75.3). The posterior pelvis may be partially spared by anterior loading of the beams. Depending on the extent of the nodal disease and the proximity of the detectable tumor to the skin surface or the presence of skin invasion, the application of a bolus to the inguinal area should be considered. Techniques such as intensity-modulated RT are preferred, as they better allow for the treatment of the inguinal lymph nodes and/or pelvic lymph nodes while sparing the bladder, small and large bowel, and rectum. Primary lesions should be boosted with 2 cm margins. Treatment doses are discussed in the previous section “Radiation Therapy.”

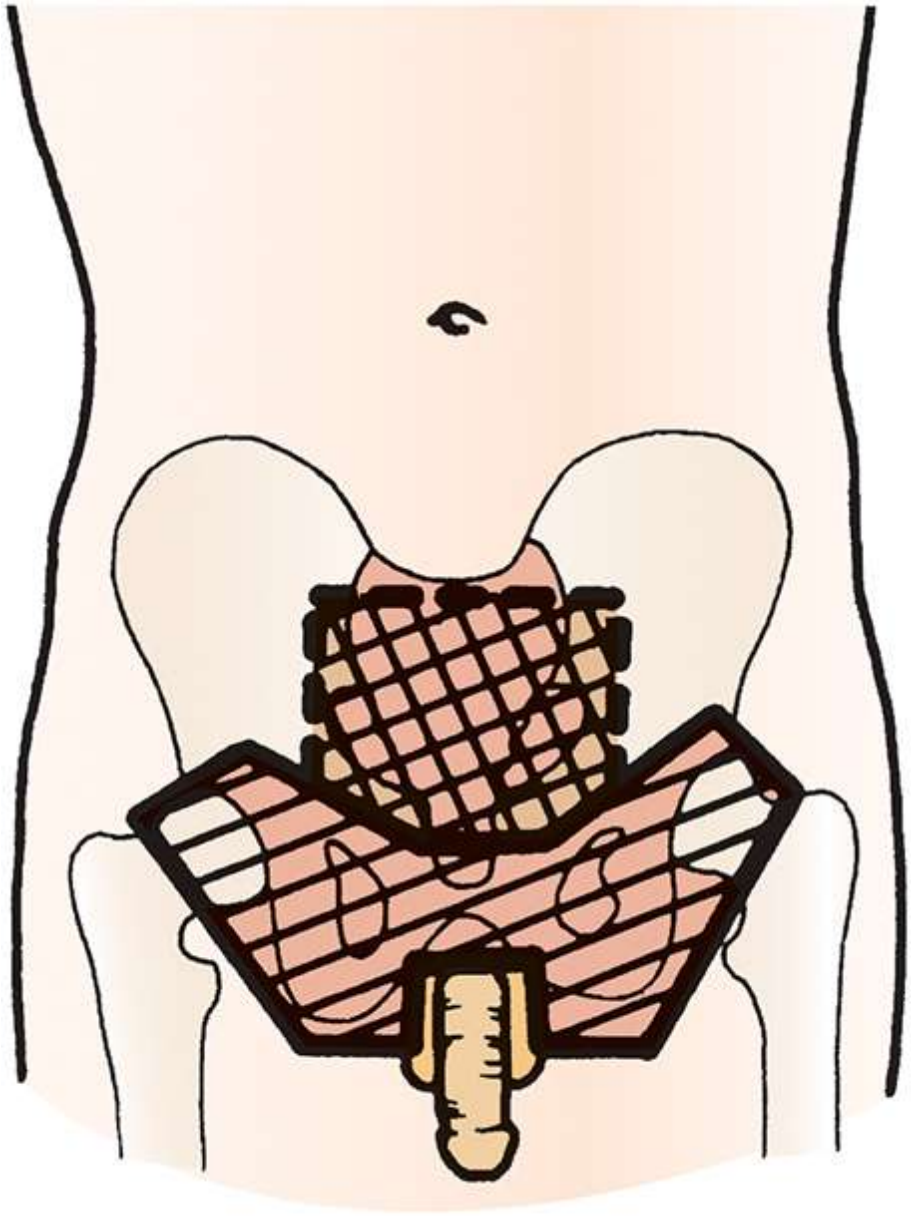

FIGURE 75.3 Portals encompassing inguinal and pelvic lymph nodes.

Brachytherapy

For detailed coverage of this topic, we refer the reader to the American Brachytherapy Society–Groupe Européen de Curiethérapie–European Society of Therapeutic Radiation Oncology (ABS-GEC-ESTRO) consensus statement for penile brachytherapy. Tumors of clinical stage T1b or T2 and less than 4 cm in maximum diameter are most suitable for primary brachytherapy. Lesions confined to the glans are ideal, but those with minor

extension across the coronal sulcus are also suitable, provided the extension can be covered with no more than one additional plane of needles.[125]

The low-dose rate (LDR) prescribed dose is generally 60 Gy at 0.5 to 0.6 Gy/hour, with the treatment completed in about 5 days. For pulsed-dose rate (PDR) treatments, pulses equivalent to the hourly dose rate of an LDR implant are delivered every hour. According to the Paris system, the prescription for LDR and PDR is to 85% of the dose rate minima between the planes (Figure 75.4).[125]

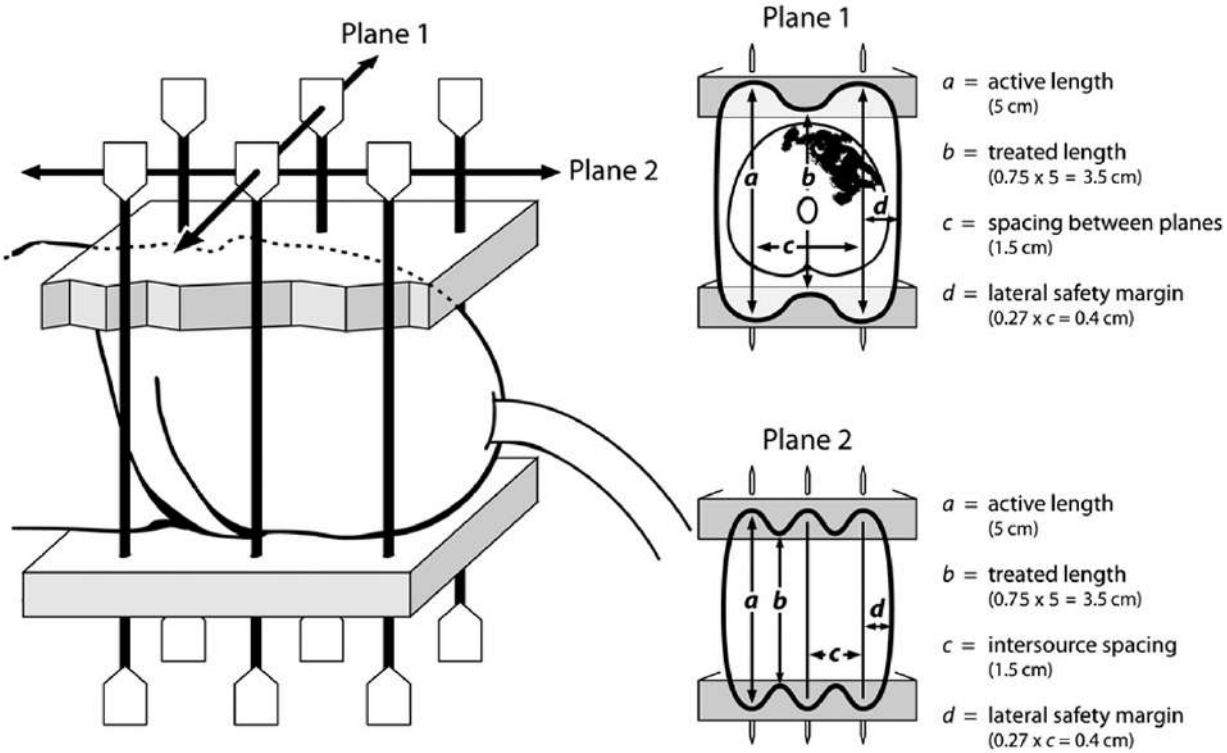

FIGURE 75.4 Schematic of a two-plane, six-needle implant showing the prescription isodose coverage according to the Paris System rules. (Reprinted from Crook JM, Haie-Meder C, Demanes DJ, Mazeron JJ, Martinez AA, Rivard MJ. American Brachytherapy Society-Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (ABS-GEC-ESTRO) consensus statement for penile brachytherapy. *Brachytherapy*. 2013;12[3]:191-198. Copyright © 2013 American Brachytherapy Society. With permission.)

ABS-GEC-ESTRO experts concluded that high-dose rate (HDR) fractionation volume implants of 3.2 Gy twice daily for 38.4 Gy in 6 days is well tolerated (Figures 75.5 and 75.6). The interval between fractions should be at least 6 hours. Penile necrosis has been observed after doses of 3.5 to

3.75 Gy × 12 Gy in 6 days, but this risk may be reduced if attention is paid to dose homogeneity and the V125 (percentage of the planning target volume receiving 125% of the prescribed dose) is less than 40% and the V150 is less than 20%. To decrease the incidence of urethral strictures, the urethra V115 should be less than 10% and the V90 less than 95% of the volume. Confluent areas of the skin receiving more than 125% of the prescription will reduce the risk of skin necrosis. CT-based planning is mandatory for HDR ^{192}Ir penile brachytherapy, with three-dimensional delineation of the gross tumor volume, clinical target volume, skin, and urethra.[125]

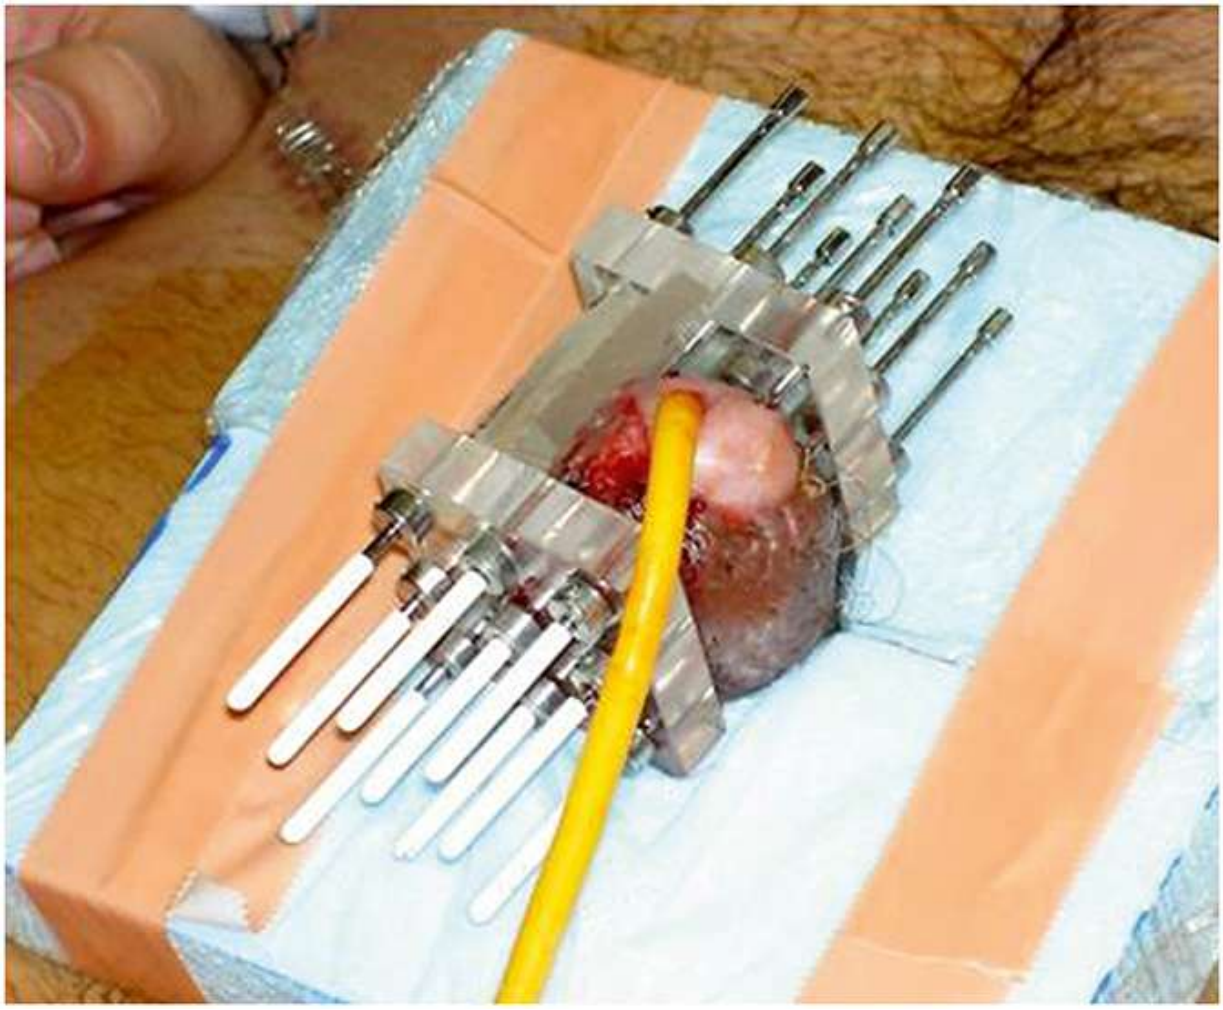

FIGURE 75.5 Interstitial implant showing the templates and needles in place. A layer of tissue-equivalent bolus material is seen on the left side of the photograph (patient's right) with an overlying plane of needles to ensure that full dose is delivered to the skin surface. FIGURE 75.6 Three-dimensional printing can be used to make a custom mold fitted with catheters to deliver the high-dose rate (HDR) source. This device would be applied twice daily for 5 days and is used to treat superficial cancers where no more than 5-mm depth of treatment is required. (Courtesy of Dr. Gerard Morton, Department of Radiation Oncology, Odette Cancer Center, University of Toronto. Reprinted from Crook J. The role of radiotherapy in the management of penile cancer. *Curr Probl Cancer*. 2015;39[3]:158-165.)

Urethral Cancer

RT for carcinoma of the anterior (distal) urethra is quite similar to that for carcinoma of the penis; lesions of the bulbomembranous urethra can be treated with a set of parallel-opposed fields covering the groins and the pelvis, followed by perineal and inguinal boost. Lesions of the prostatic urethra can be treated with techniques and doses similar to those used for carcinoma of the prostate.

RESULTS

Penile Cancer

At many institutions, patients with carcinoma of the penis are treated surgically. A summary of selected modern surgical series is presented in Table 75.8. Ornellas et al[32] reported the results of 350 patients treated with surgery alone. Five-year disease-free survival was 62% for patients treated with immediate lymphadenectomy versus 8% for those treated with delayed lymphadenectomy. For all patients who are node-negative, 5-year disease-free survival was 87% compared with 29% for patients who are node-positive. Boon et al[126] reported tumor control in 13 (81%) of 16 patients with carcinoma in situ or T1 and T2 tumors treated with wide local excision and lasers.

The 20-year experience of the Institut Gustave-Roussy was reported by Soria et al.[24] In all, 102 patients with tumors less than 4 cm in diameter with less than 1 cm corpora cavernosa invasion were treated with a conservative approach consisting of limited surgery (biopsy, local excision, or therapeutic circumcision) and interstitial brachytherapy (65-70 Gy delivered over 5-7 days). Regional lymph nodes were not treated electively but were dissected in patients with clinically enlarged nodes. With a median follow-up of 111 months, the local tumor recurrence rate was 25%. A regional nodal recurrence developed in 21% of patients. Disease-free survival at 5 and 10 years was 56% and 42%, respectively. Overall survival at 5 and 10 years was 63% and 50%, respectively.

Irradiation of the involved regional lymph nodes in patients with carcinoma of the penis results in durable control for a substantial proportion of patients. In the classic series of Staubitz et al,[43] 13 patients with proven involvement of regional lymph nodes received RT to these nodes. Five of 13 (38%) survived 5 years. Mazeron et al[130] observed tumor control in 8 of 9 patients with stage T1, 21 of 27 with T2, and 10 of 14 with T3 tumors treated with ^{192}Ir, using the Paris dosimetry system, to deliver doses of 60 to 70 Gy to the 85% minimal tumor isodose. The tumor-free 5-year actuarial survival rate was 63%. The penis was preserved in 75% of patients with a follow-up of 8 years. Thirty-seven patients received no prophylactic treatment to the inguinal nodes, and only two (one with a T2 and another with a T3 lesion) later developed inguinal lymph node metastases treated by

inguinal node dissection and postoperative irradiation. One patient was alive with no evidence of disease at 10 years. Five patients with metastases to the lymph nodes at the time of diagnosis were treated with therapeutic nodal dissection and postoperative irradiation. Four patients had uncontrolled lymph node metastases, and all five died with distant disease.

Urethral Cancer

Historically, men with urethral carcinoma have been treated surgically. Dalbagni et al[17] have reported the outcome of 46 patients with carcinoma of the anterior and bulbar urethra treated at the Memorial Sloan-Kettering Cancer Center. The majority of patients were treated with definitive surgery. With a median follow-up of 125 months, the local control rate was 51%. The 5-year overall survival was 42%. Improved survival was seen in patients with anterior lesions (69%) compared with those with posterior lesions (26%).

Bracken et al[141] described results in 11 patients with tumors at or anterior to the penoscrotal junction, 8 of which were epidermoid carcinoma, 2 TCC, and 1 melanoma. Three of four patients treated with total penectomy and perineal urethrostomy had tumor control. Partial penectomy controlled the local tumor in two patients. The patient with melanoma had a local recurrence after the operation. Two patients were treated with RT, and one-third with a combination of preoperative irradiation (45 Gy) and total penectomy. In all of these patients, the tumor recurred locally. In four patients with inguinal lymph node metastases, the regional disease was controlled by bilateral lymphadenectomy. All six patients in whom local and regional tumor was controlled remained alive and disease free at 1 to 20 years. In 16 patients, the urethral tumors arose posterior to the penoscrotal junction: 13 lesions were squamous cell carcinoma, 2 TCC, and 1 adenocarcinoma. Penectomy was performed in five patients, all of whom had tumor control and no evidence of recurrence 5 to 29 months after therapy. Two patients treated with local excision died of disease 14 and 18 months after surgery. Irradiation was used in three patients unsuccessfully, and all died of cancer 13 to 31 months after therapy.

Kaplan et al[18] reported on 29 patients treated at Northwestern University and reviewed the literature. In their analysis, lesions of the distal urethra

carried the best prognosis and those in the bulbomembranous urethra the worst. Five-year survival rates were 22% (16/71 patients) with tumors in the distal urethra, 10% (10/99 patients) with bulbomembranous urethra lesions, and 25% (4/16 patients) with prostatic urethra tumors. RT was infrequently used for these patients. Table 75.12 demonstrates equivalent local tumor control with either definitive RT or en bloc resection.

The combination of RT and chemotherapy using 5-FU and mitomycin-C has been reported for urethral carcinoma for organ preservation in locally advanced tumors. Reports by Baskin and Turzan,[144] Johnson et al,[145] Licht et al,[146] and Shah et al[147] support the efficacy of this combination for squamous cell carcinoma of the male and female urethra. The Cleveland Clinic[146] reported results of patients with locally advanced squamous cell carcinoma of the urethra treated with concomitant chemoirradiation, including 5-FU (1 g/m^2 intravenous infusion on days 1-4 and days 29-32) and mitomycin-C (50 mg/m^2 bolus intravenous injection on day 1). External beam irradiation (30 Gy in 15 fractions) to the pelvis and inguinal lymph nodes began on day 1. An additional 20 Gy tumor boost was given. Complete response was obtained in three patients, who remained disease free after 43 months of follow-up. One grade 3 acute toxicity (skin reaction) occurred that did not compromise the therapeutic plan, and one patient developed urethral stricture that was managed successfully with urethral dilatation.

The Wayne State experience[51] involved concomitant 5-FU and cisplatin for squamous cell carcinoma and concomitant methotrexate, vinblastine, doxorubicin, and cisplatin for TCC. A pathologic complete response was reported in 87.5% of women undergoing resection following chemoradiation. With a median follow-up of 42 months, the overall disease-free survival rate was 62%.

SEQUELAE OF TREATMENT

Irradiation of the penis produces brisk erythema, dry or moist desquamation, and swelling of the subcutaneous tissue of the shaft in virtually all patients. Although quite uncomfortable, these reversible reactions subside with conservative treatment within a few weeks. Telangiectasia is a common late consequence of RT and is usually asymptomatic (Figures 75.7 and 75.8).

FIGURE 75.7 Telangiectasia and area of hypopigmentation 6 years after pulsed-dose rate brachytherapy. (Reprinted from Crook JM, Haie-Meder C, Demanes DJ, Mazeron JJ, Martinez AA, Rivard MJ. American Brachytherapy Society-Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (ABS-GEC- ESTRO) consensus statement for penile brachytherapy. *Brachytherapy*. 2013;12(3):191-198. A

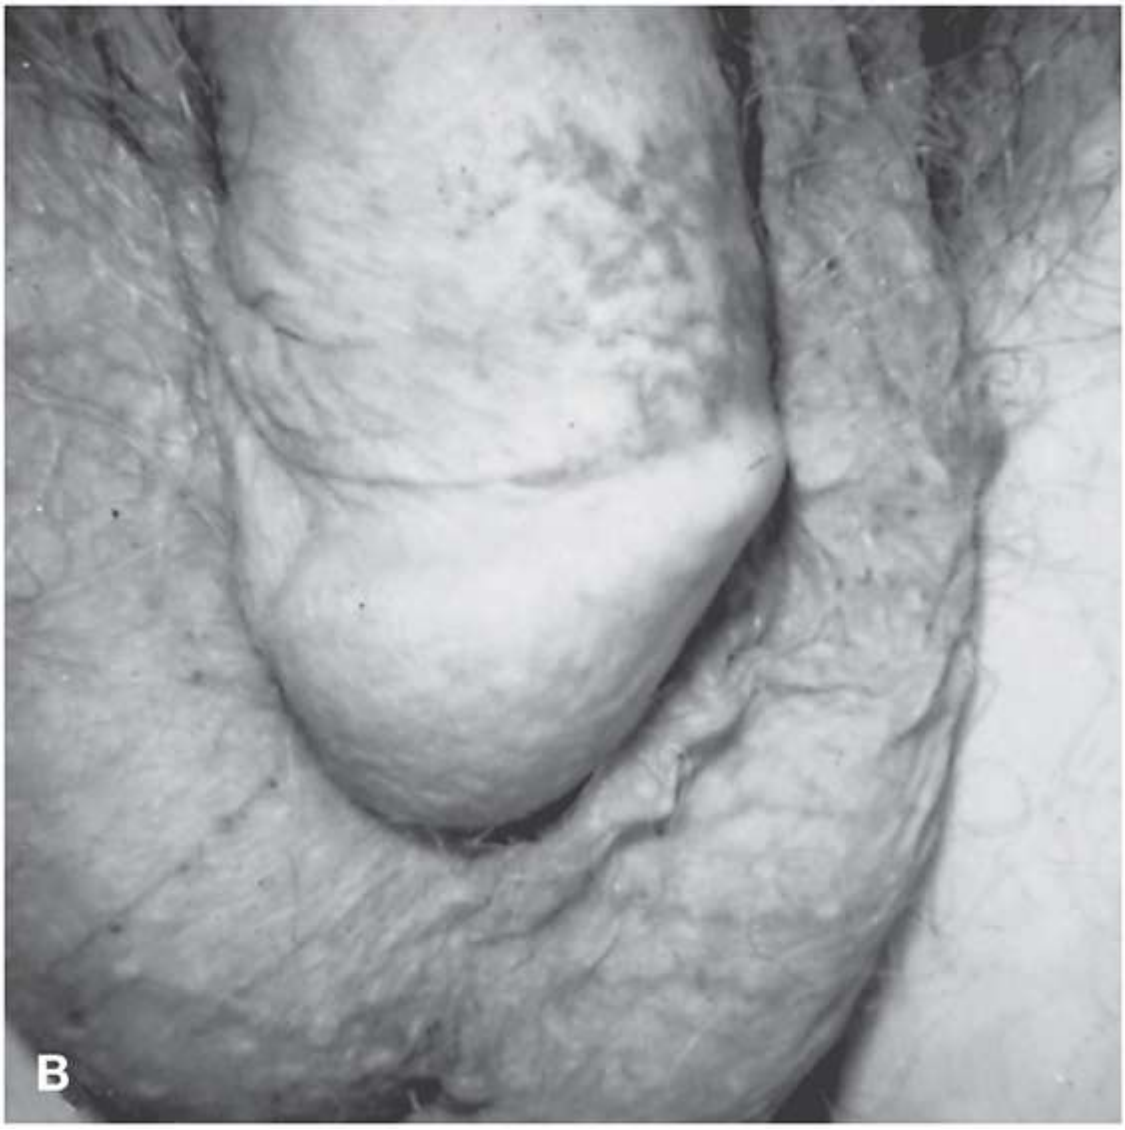

FIGURE 75.8 A. Squamous cell carcinoma of the balanopreputial region with extension into the glands (stage I). The patient was treated with 120-kVp x-rays, 0.3-mm Cu half-value layer, receiving a 60-Gy skin dose in 5 weeks. B. Same patient 4 years later with no evidence of disease. Telangiectasia is present.

In the reported LDR and PDR brachytherapy series, stenosis occurs in 9% to 45% of patients and necrosis in 0% to 26% (see Table 75.10).[23,24,130,133-137] This incidence compares favorably with the incidence of urethral stricture following penectomy.[21] Most strictures following RT are at the meatus.

Lymphedema of the legs has been reported following inguinal and pelvic RT, but the role of irradiation in the development of this complication

remains controversial. Many patients with this symptom have active lymphatic disease that may be responsible for lymphatic blockage.

Routine use of a meatal dilator in the healing phase and for a few months beyond can decrease the rate of meatal stenosis. Soft tissue ulceration is more frequent in larger and more deeply invasive cancers but will usually heal with conservative measures, such as attention to hygiene, topical antibiotics, or steroid creams.[102] More severe cases may respond to a course of hyperbaric oxygen.[148]

Of all male genitourinary cancers, penile cancer poses the greatest threat to sexual function and carries the most devastating psychological impact of penectomy. Despite recent advances in treatment, sexual function is not likely to be adequately preserved in some patients. These patients and their partners need information about the physical impairments after surgical intervention and should be taught adjustment skills before undertaking treatment. Referral to a trained sexual consultant or therapist for help is indicated.

CHAPTER 76

Cancer of the Uterine Cervix

Yosef Landman-Gigi, Darien Colson-Fearon, Akila N. Viswanathan

ANATOMY

The uterus is a hollow, thick-walled, pear-shaped, muscular organ located in the pelvis above the vagina, behind the bladder, and in front of the rectum (Figure 76.1A). On average, it is approximately 7 to 8 cm long, 5 to 7 cm wide, and 2 to 3 cm thick. The uterus is divided into the uterine corpus superiorly and the uterine cervix inferiorly, with the most superior part of the corpus also known as the fundus and the middle portion of the corpus known as the body. The fundus is located superiorly to the line joining the entrance of the fallopian tubes. The body of the uterus is enclosed between layers of the broad ligament and is freely mobile. The regions of the body where the fallopian tubes enter are called the cornua. The most inferior, slightly constricted, portion of the uterus is called the isthmus or lower uterine segment (LUS). The cervix rests inferior to the LUS.

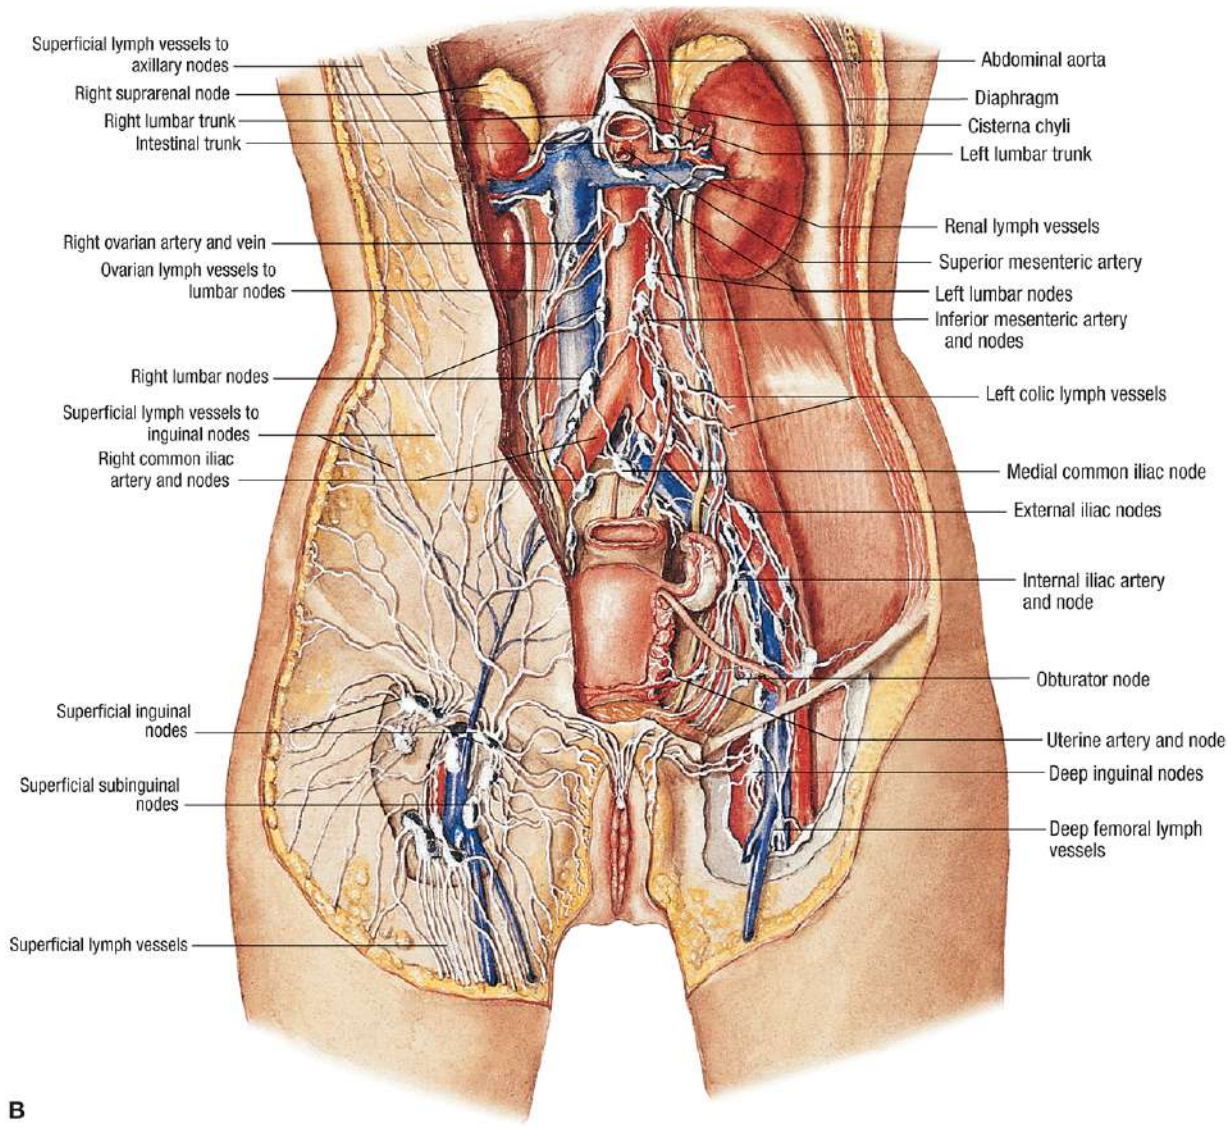

FIGURE 76.1 A. Anatomy of the pelvis. B. Lymph vessels and lymph nodes of the cervix and the body of the uterus. (Anatomical Chart Company, Lexington, SC.)

The uterus is usually bent anteriorly (anteflexed) between the cervix and the uterine body. The entire uterine cervix structure is normally bent anteriorly (anteverted) in the pelvis. The uterus may be posteriorly retroverted, especially in older women who have a small uterus. The wall of the uterus has three layers: the outer serosal layer; the middle myometrium, which is approximately 12 to 15 mm of muscle through which the main blood vessels and nerves flow; and the inner coat called the endometrium.

The cervix measures approximately 3 by 3 cm and is predominantly a fibrous organ. The cervix is divided into an upper or supravaginal portion,

above the ring containing the endocervical canal, and the vaginal portion, projecting in the vaginal vault. Central in the rounded vaginal region is the external os, bounded by the anterior and posterior lips of the cervix, extending inward to the internal os, the endocervical canal, and endometrial canal.

The uterus is partially covered by peritoneum in its fundal and posterior portions; its anterior and lateral surfaces are related to the bladder and the broad ligaments, respectively. It is attached to the surrounding structures in the pelvis by two pairs of ligaments—the broad and round ligaments. The broad ligament is a double layer of peritoneum extending from the lateral margin of the uterus to the lateral wall of the pelvis. It contains the fallopian tubes. The two layers of peritoneum forming the broad ligament enclose the parametrium as it reaches the uterus. Inferiorly, the broad ligament follows the plane of the pelvic floor and ends medially in the upper portion of the vagina.[1]

The round ligament, a band of smooth muscle and connective tissue that contains small vessels and nerves, extends forward horizontally from its attachment in the anterolateral portion of the uterus to the lateral pelvic wall. The cord ascending from the lateral wall of the true pelvis crosses the pelvic brim and extends laterally to reach the abdomino-inguinal ring, through which it leaves the abdomen to traverse the inguinal canal and terminates in the superficial fascia.

The uterosacral ligaments are paired supports for the lower uterus, extending from the uterus to the sacrum and running along the rectouterine peritoneal fields. The cardinal ligaments, also called transverse cervical ligaments (Mackenrodt), are thickened connective tissue and fascia arising at the upper lateral margins of the cervix and inserting into the fascial covering of the pelvic diaphragm.

The uterus, including the uterine cervix, has a rich lymphatic network (Figure 76.1B) that drains principally into the paracervical lymph nodes; from there, it goes to the external iliac (of which the obturator nodes are the innermost component) and the hypogastric lymph nodes. The major lymphatic drainage of the cervix runs in the cardinal ligament superior to the ureter and in the uterosacral ligaments to the rectal area. No lymphatic vessels run in the vesicouterine space, rather those from the upper vagina fuse with those from the bladder and extend laterally into the parametrium. The pelvic lymphatics drain into the common iliac and the para-aortic lymph nodes (PANs).

Lymphatics from the fundus pass laterally across the broad ligament and are continuous with those of the ovary, ascending along the ovarian vessels into the PANs. Some of the fundal lymphatics also drain into the common iliac lymph nodes. The main artery supplying the uterus is the uterine artery, which originates from the anterior division of the hypogastric artery.

EPIDEMIOLOGY

Over the past century, the relative morbidity and mortality of locally advanced invasive cervical cancer has declined in the United States and Europe because of effective screening and treatment of preinvasive lesions. In the United States, 50% of women who develop cervical cancer have never been screened.[1] However, in the past decade, incidence rates of invasive carcinoma have remained relatively constant due to population growth and aging. The American Cancer Society estimates in 2023 that approximately 13,960 new cases of invasive carcinoma of the cervix arise in the United States and about 4,310 deaths will occur per year (Figure 76.2).[2] Worldwide, cervical cancer remains the eighth most common cancer by incidence and the ninth most common cause of cancer mortality, with over 662,301 women globally developing this tumor as reported in 2022 and 348,874 dying of the disease every year.[3] Adjusting for population growth and aging, the global incidence rate for cervical cancer declined by 1.2% from 2005 to 2015.[4] The majority of cases are in Africa, because of the paucity of screening measures and the prevalence of immunodeficiency because of human immunodeficiency virus (HIV). Unfortunately, it often affects young women, with therapies that commonly result in loss of the ability to bear future children and other chronic toxicities.

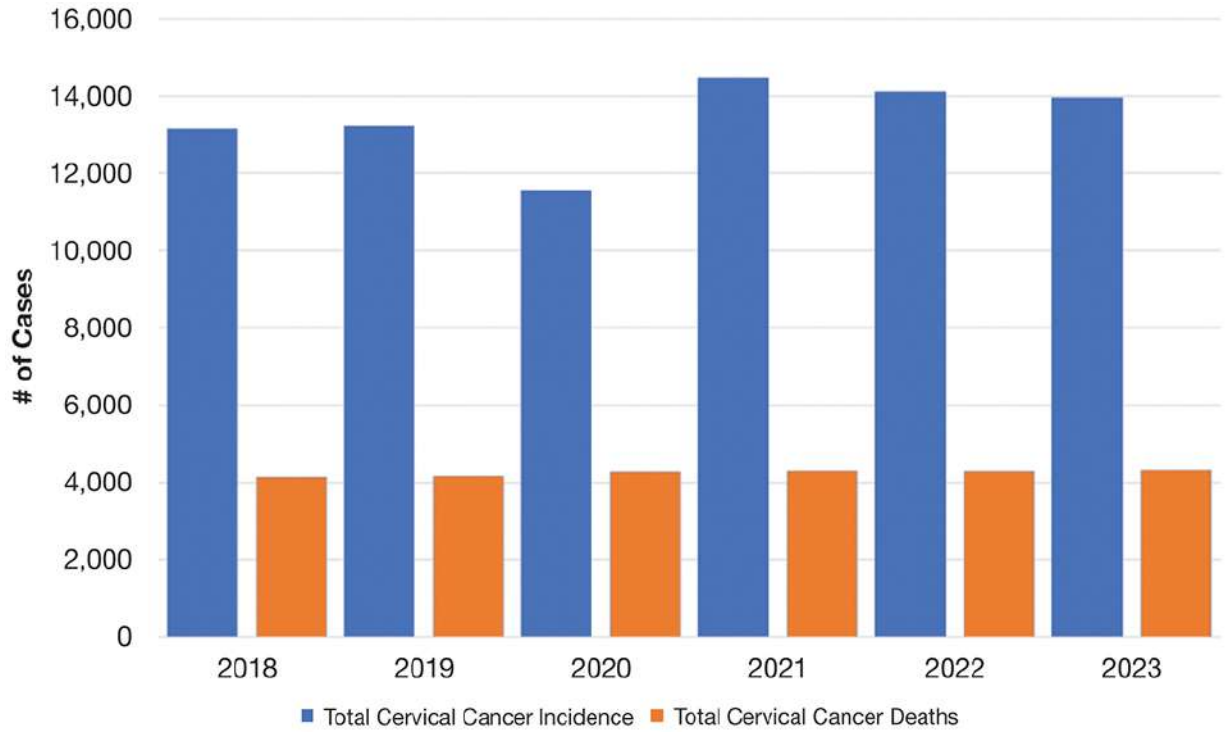

FIGURE 76.2 The incidence of cervical cancer increased slightly in the United States from 2018 to 2023.

Cervical cancer is more common in areas where women have less access to screening, including parts of Asia, Africa, and Central and South America. Whether regional differences in predisposition to developing cervical cancer exist is debated because it is impossible to adequately correct for unknown and known confounders, such as socioeconomic status, access to health care, parity, smoking, presence of other infections, immune status, and other factors affecting host immunity such as nutritional status.

Human Papillomavirus

Estimates indicate that more than 90% of cervical cancers are related to the presence of human papillomavirus (HPV) and are contracted via sexual intercourse.[5] HPV is a small, double-stranded deoxyribonucleic acid (DNA) virus; HPV-16 and HPV-18, as well as a long list of other, less frequent subtypes, including, but not limited to, HPV types 31, 33, 35, 39, 45, 51, 52, 56, and 58, have been well characterized as causative agents for cervical cancer, with some geographic variation. The HPV genome integrates into the host cell chromosomes in cervical epithelial cells and codes for six early and

two late open reading frame proteins, of which three (E5, E6, and E7) alter cellular proliferation. Two viral genes, E6 and E7, are typically expressed in HPV-positive cervical cancer cells. The E6 protein inactivates the major tumor suppressor p53; this causes chromosomal instability, inhibits apoptosis, and activates telomerase. The E7 protein affects the retinoblastoma protein, resulting in a loss of regulation of the cell's proliferation and immortalization. The Cancer Genome Atlas identified three main subtypes: keratin-low, keratin-high, and adenoma-rich. HPV integration was observed in all HPV-18 and 76% of HPV-16–related cases. Endometrial-like cervical cancer was HPV negative, occurred in 5% of cases, and had high frequencies of *KRAS*, *ARID1A*, and *PTEN* mutations.[6]

Although a high prevalence of HPV exists worldwide, peaking at ages 25 to 35 years, less than 15% of exposed women develop persistent infection that results in dysplasia, whereas the majority of women clear the infection within 2 years.[7] Cervical cancer may develop 10 to 20 years after initial exposure to HPV. Social factors related to cervical cancer include those associated with HPV transmission, such as early age of first intercourse, a history of multiple sexual partners, a male partner with a history of multiple sexual partners, a large number of pregnancies, and a history of sexually transmitted disease, including gonorrhea, chlamydia, herpes simplex virus II, and/or HIV. A higher incidence of cervical cancer exists among women whose spouses are known or suspected to have had higher exposure to HPV or whose partners have a history of penile carcinoma. Whether circumcision may be protective to women is controversial because circumcision may be a surrogate for unknown factors related to HPV transmission. The integration pattern of HPV as episomal (best), single-copy or multiple-copy tandem repetition, or undetectable (worst) is a strong prognostic factor for disease-free survival (DFS) after radiation therapy (RT) in cervical cancer.[8]

Chemical, hormonal, or other carcinogens may be implicated in cervical cancer. An association between cervical carcinoma and oral contraceptive use has been reported but is considered controversial. Prenatal exposure to diethylstilbestrol (DES) is linked to the development of clear cell adenocarcinoma (AC), although the overall incidence is small (0.14-1.4 per 1,000 DES-exposed women). Cigarette smoking may increase the risk of cervical cancer, HPV infection, and carcinogenesis.[9] However, passive smoking may not be an independent factor in the absence of active smoking.[10]

Current smoking (relative risk [RR] = 1.55) and younger age at HPV exposure (RR = 1.75) are considered risk factors among HIV-positive women.[11] Intrauterine device use may decrease cervical cancer risk, potentially through an increase in cellular immunity triggered by the device.[12] Immunocompromised individuals, including those with HIV or autoimmune conditions on immunosuppressants, have also been observed to higher risk of persistent HPV infection and cervical cancer.[13] Specifically, for HIV, an up to 22-fold increased risk for the development of cervical cancer has been observed.

Human Papillomavirus Vaccination

The nine-valent HPV recombinant vaccine for HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58, more commonly known as Gardasil-9, was first approved in the United States in 2014 for all individuals aged 9 to 26 years. This was done after a randomized study involving over 14,000 girls and women showed noninferiority to the previous quadrivalent HPV vaccine in reducing any high-grade cervical disease and increased efficacy in reducing disease related to the five additional HPV types.[14] In 2018, approval was expanded to include those aged 27 to 45 years. There are two previous vaccines that have been approved, including the quadrivalent covering HPV types 6, 11, 16, and 18 and bivalent covering types 16 and 18.[15,16]

Equitable distribution of the vaccine around the world has historically been hindered due to cost and access; however, efforts continue to be made to mitigate these disparities.[17] To date, 117 nations have added the HPV vaccine to their routine national immunization schedules.[18] Globally, an estimated 15% of girls and 4% of boys within the target age have been fully vaccinated, as of 2019.[19] With an increase in understanding and availability, the hope is that all children will be given a vaccine covering all subtypes in the future.

NATURAL HISTORY AND PATTERNS OF SPREAD

Squamous cell carcinoma (SCC) of the uterine cervix usually originates at the squamous columnar junction (transformation zone) of the endocervical canal and portion of the cervix.

Cellular transformation follows a stepwise progression from normal to higher levels of dysplasia. Of patients diagnosed with cervical intraepithelial neoplasia (CIN) type 1, 60% have regression of the lesion, and of those with

CIN2, 40% regress. Higher levels of dysplasia are more likely to progress to cancer, particularly in the presence of cofactors such as smoking or impaired immunity. Although progression typically takes 10 to 20 years, in some instances, a rapid development of carcinoma may be associated with aggressive disease.

The development of a malignant phenotype results from cells that break through the basement membrane of the epithelium and invade the cervical stroma. Invasion may result in spread to pelvic lymph nodes or other, more distant sites. If the cells are detected at this stage by a Papanicolaou (Pap) or thin preparation test, appropriate minimally invasive therapy may suffice. However, if the lesion progresses, it may present as a superficial ulceration or exophytic tumor in the ectocervix or with extensive infiltration of the endocervix. If untreated, the tumor may spread to the adjacent vaginal fornixes, paracervical or parametrial tissues, or adjacent organs, including the bladder, the rectum, or both. Paracervical extension was related to the depth of stromal invasion, tumor size, lymphatic invasion, and presence of lymph node metastasis.

Approximately 10% to 30% of patients with carcinoma of the uterine cervix have extension into the LUS and the endometrial cavity. Decreased survival rates and a greater incidence of distant metastases were reported in patients with stromal endometrial invasion (EI) or replacement of normal endometrium by cervical carcinoma. Regional lymphatic or hematogenous spread may occur and increases with stage, although dissemination does not always follow an orderly sequence, and occasionally, a small primary tumor may spread to the pelvic lymph nodes, invading the bladder or rectum, or metastasizing distantly.

Both adjacent parametrial and pelvic lymph nodes may be involved. Girardi et al[20] analyzed 359 radical hysterectomy (RH) specimens and found positive parametrial nodes in 280 (78%) patients; the incidence of positive nodes was 11.4% in stage IB and 21.5% in stage IIB disease. With negative parametrial nodes, only 26% of patients had positive iliac lymph nodes, whereas 81% of patients with positive parametrial lymph nodes also had pelvic node metastases. These data underscore the need to irradiate the parametrial tissues or carry out a complete bilateral pelvic lymphadenectomy with an RH in patients with invasive cervical carcinoma.

Spread of carcinoma of the cervix may progress to the obturator lymph nodes, considered a medial group of the external iliac chain, to other external iliac nodes, and to the hypogastric lymph nodes. From these, there may be tumor metastases to the common iliac or PANs. In one study, pelvic lymph nodes were dissected in 225 patients with cervical carcinoma treated with RH[21]; positive pelvic nodes were identified in 13 (14.2%) of 91 women with stage IB and IIA, 16 (19.8%) of 81 with stage IIB, and 11 (28%) of 40 with stage IIIB diseases. The most commonly involved groups were the parametrial, obturator, external iliac, and common iliac nodes (Figure 76.3). PANs were involved in 3 (3.3%) of 91 patients with stage IB or IIA tumors 4 cm or less and in 5 (13.1%) of 38 patients with stage IIB or III disease.

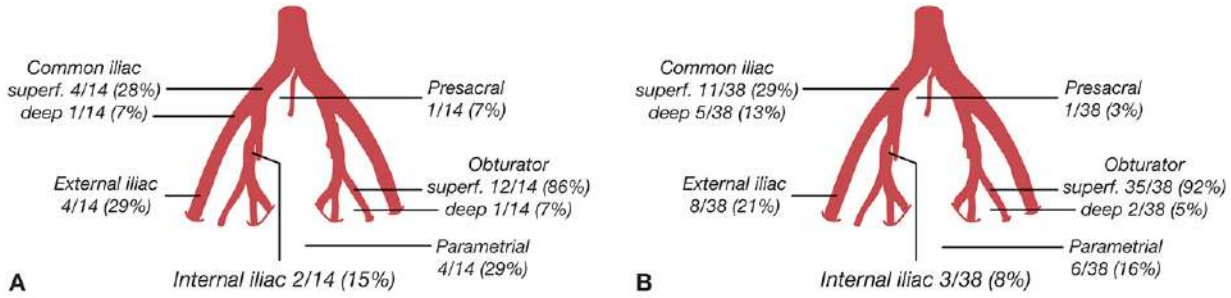

FIGURE 76.3 Distribution of pelvic node metastases in 14 patients with stage IB to IIA cervical cancers, tumor size <4 cm (A), and 38 patients with locally advanced cervical cancer treated with neoadjuvant chemotherapy (B). (Reprinted from Benedetti-Panici P, Maneschi F, Scambia G, et al. Lymphatic spread of cervical cancer: an anatomical and pathological study based on 225 radical hysterectomies with systematic pelvic and aortic lymphadenectomy. *Gynecol Oncol*. 1996;62[1]:19-24. Copyright © 1996 Elsevier. With permission.)

Spread through the venous plexus and the paracervical veins resulting in hematogenous dissemination, though infrequent, is relatively common with more advanced stages. In an analysis of 322 patients in whom distant metastases developed, the most frequently observed metastatic sites were the lung (21%), PANs (11%), abdominal cavity (8%), and supraclavicular lymph nodes (7%). Bone metastases occurred in 16% of patients, most commonly to the lumbar and thoracic spine.[22] Spinal epidural compression from metastatic tumor, often involving lumbar segments, can occur rarely, and metastases to the brain and the heart have been reported, although it is unusual to have spread to the brain without evidence of pulmonary metastases already present, even for small cell carcinoma of the cervix.

PAPANICOLAOU SMEAR SCREENING

The U.S. Preventive Services Task Force and the American College of Obstetrics and Gynecology published updated guidelines in 2021, which have been reaffirmed in 2023, recommending that cervical cytology screening should begin at age 21 years regardless of sexual activity status and continue every 3 years until age 29 years. Starting at age 30 to 65, screening can include cytology alone every 3 years, Food and Drug Administration-approved primary high-risk human papillomavirus (hrHPV) testing alone every 5 years, or co-testing with cytology and hrHPV every 5 years.[23,24] HPV testing is not recommended for women younger than age 30. After age 30, women have the option of having Pap smears every 3 years or having Pap with HPV testing every 5 years. At age 65, women can stop having Pap smears as long as their routine screening was within the past 10 years, with normal results. Women who have had a hysterectomy for benign reasons and have no history of high-grade squamous intraepithelial lesion (SIL) may discontinue testing. Women who have been treated for CIN2 or CIN3 need annual screening for at least 20 years. Those who have had a hysterectomy and a history of CIN2/CIN3 should continue to undergo screening with annual pelvic examinations.

When obtaining the Pap smear, special attention should be directed to not using a lubricating agent (warm water on the speculum will suffice), to obtaining good "scrapings" from the cervix and vaginal posterior fornix (without blood), and to using a small brush to obtain an endocervical sample. The patient should be instructed not to cleanse with a douche before the examination, and if indicated, specimens should be obtained to check for trichomonas. If the cytologic smear shows atypia or mild dysplasia (class II), it should be repeated no sooner than 2 weeks after the initial test to allow representative cellular exfoliation to occur. Guidelines for reporting results of cervical and vaginal cytology were promulgated in 1988. The Bethesda system eliminated the classes of Pap cytology. The correlation between the cytologic diagnosis and subsequent histologic examination is more than 90%. This system was updated in 2014.[25]

CLINICAL PRESENTATION

Cervical cancer in the United States is most frequently identified during routine gynecologic examination. Intraepithelial or early invasive carcinoma

of the cervix may be detected by cytologic smears before symptoms appear; Pap smear, colposcopy and biopsies, and HPV testing have high specificity and sensitivity. Visible lesions present with an exophytic mass or a barrel-shaped cervix because of an endocervical lesion. Patients may present complaining of metrorrhagia (intermenstrual bleeding), menorrhagia (heavier menstrual flow), or postcoital bleeding. If chronic bleeding occurs, the patient may complain of fatigue or other symptoms related to anemia.

In cases with more advanced disease, bowel obstruction, renal failure, foul-smelling serosanguinous or yellowish vaginal discharge, pelvic pain, flank and/or leg pain, rectal bleeding, obstipation, dysuria, hematuria, or persistent edema of lower extremities because of lymphatic/venous blockade by pelvic sidewall disease may occur. Pain in the pelvis or hypogastrium may be caused by tumor necrosis or associated pelvic inflammatory disease. In patients with pain in the lumbosacral area, the possibility of PAN involvement with extension into the lumbosacral roots or hydronephrosis should be considered.

DIAGNOSTIC WORKUP

Diagnostic workup for abnormal smear results is based on a patient risk, factoring in smear results, current HPV status, and prior findings.[26,27] When a patient presents with abnormal squamous cells of undetermined significance (ASCUS) but HPV status is negative and prior results are unknown or negative, follow-up testing in 3 years is recommended. When both ASCUS and HPV are present or AC in situ or an SIL is identified, directed biopsies at the time of colposcopy should be carried out. Endocervical curettage may be performed, except in pregnant women. If the biopsy results are negative, the procedure should be repeated in 6 months, and if they are positive, a conization should be performed.

Patients presenting with low-grade squamous intraepithelial lesions (LSILs) on cytology are further triaged based on age and HPV status. Women aged 25 years and above with LSIL and positive HPV are evaluated with colposcopy. For women aged 21 to 24 years, ASCUS or LSIL on cervical cytology is managed with repeat cytology at 12 months.

Results from a large-scale cervical cancer screening trial, conducted over a span of 15 years from Mumbai, India, were reported. Over 75,000 women were screened every 2 years using visual inspection and acetic acid vinegar. There was a significant 31% reduction in cervical cancer mortality in the

screening group, compared with the control group. The 7% reduction in all-cause mortality in the screening group did not reach significance. These results suggest acetic acid screening can be utilized in places that lack standard Pap smear screening and treatment resources.[28]

Patients who present with a clinically visible lesion should be jointly evaluated by the radiation and gynecologic oncologists. After obtaining a careful clinical history and performing a general physical examination, with attention to the inguinal and supraclavicular (nodal) areas, abdomen, and liver, a careful pelvic examination should be carried out with as little discomfort to the patient as possible without compromising the thoroughness of the evaluation. Pelvic examination should include inspection of the external genitalia, vagina, and uterine cervix; a rectal examination; and bimanual palpation of the pelvis. Pelvic examination under anesthesia (EUA) is a universally accepted component in the evaluation and clinical staging of patients in order to provide a pain-free examination that allows a clearer estimation of parametrial or sidewall tumor extension. In countries in which magnetic resonance imaging (MRI) is available, this may be used to assist with assessing tumor extension beyond the lower cervix, and in many institutions, it has replaced the EUA. Cystoscopy or rectosigmoidoscopy should be performed in all patients with symptoms consistent with the presence of a fistula of the urinary or lower gastrointestinal (GI) tract, patients with clinical stage IIB, III, or IVA disease who cannot undergo an MRI, or patients with an MRI suspicious for bladder or bowel invasion. The diagnostic procedures for carcinoma of the cervix are presented in Table 76.1.

TABLE 76.1 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE UTERINE CERVIX

General
History, with special emphasis on possible interventions:
Fertility preservation
Comorbidity management
Smoking cessation
Nutritional and mental support
Physical examination, including bimanual pelvic and rectal examinations
Diagnostic Procedures
Cytologic smears (Papanicolaou) if not bleeding
Colposcopy
Conization (subclinical tumor)
Punch biopsies (edge of gross tumor, four quadrants)
Endocervical curettage

Cystoscopy, rectosigmoidoscopy (stages IIB, III, and IVA)

Radiographic Studies
Computed tomography
Magnetic resonance imaging
Positron emission tomography scan

Laboratory Studies
Complete blood count
Blood chemistry
Urinalysis
Squamous cell antigen levels
HPV circulating tumor DNA
Immunohistochemistry for programmed death ligand 1 (PD-L1) expression

Conization/Loop Excision

Conization involves a conical removal of a large portion of the ectocervix and endocervix. Cold knife cone biopsy specimens should always be obtained with a scalpel or other appropriate instrument. At least 50% of the endocervical canal should be removed without compromising the internal sphincter. Curettage of the remaining endocervical canal should be carried out.

Conization must be performed in the following situations: No gross lesion of the cervix is noted and an endocervical tumor is suspected; the entire lesion cannot be seen with the colposcope; diagnosis of microinvasive carcinoma is made on biopsy; discrepancies are found between the cytologic and histologic appearances of the lesion; or the patient is not reliable for all necessary follow-up. With careful selection of patients who have a negative positron emission tomography (PET) scan and an MRI with a central lesion less than 2 cm in width, knife conization with lymphadenectomy may be considered for fertility preservation. Laser conization and loop diathermy excision are frequently done in an office setting as an alternative to conization; loop excision is less expensive and more reliable than laser conization.

Biopsy

Multiple punch biopsies of a grossly visible lesion should be adequate to confirm the diagnosis of invasive carcinoma. Specimens should be obtained from any suspect area and from all four quadrants of the cervix and any suspect areas in the vagina. It is important to obtain tissue from the periphery of the lesion with some adjoining normal tissue; biopsy specimens from

central ulcerated or necrotic areas may not be adequate for diagnosis. Dilation and curettage are not required if other biopsies confirm the diagnosis of invasive disease.

Laboratory Studies

For invasive carcinoma, patients should have the following laboratory studies: complete peripheral blood evaluation, including hemogram, white blood cell count, and differential and platelet count; blood chemistry profile, with particular attention to blood urea nitrogen and creatinine; liver function values; and urinalysis.

Imaging Studies

In countries where three-dimensional (3D) imaging is not routinely available, International Federation of Gynecology and Obstetrics (FIGO) recommended evaluation for patients with cervical cancer includes a chest radiograph to assess for lung metastases and an intravenous pyelogram (IVP) to determine whether hydronephrosis is present. The IVP in many countries has been replaced by computed tomography (CT) scan of the pelvis and abdomen with intravenous (IV) contrast material or by PET-CT scan. In places where CT is not available, patients with stage IIB, III, and IVA diseases who have symptoms in the colon and rectum may benefit from a barium enema. A skeletal survey may be performed to determine whether bone metastases are present. Historically, pedal lymphangiography was used to assess lymph node involvement in the pelvic or PAN with mixed results. The number of physicians trained to perform lymphangiography has declined in the United States, and instead, PET scan is preferred.

Since the 1990s, the use of CT scanning has rapidly increased worldwide. A CT provides diagnostic information about the presence of metastases, enlarged lymph nodes, and the primary tumor. On a CT scan, the cervical tumor may be seen as an enlarged, irregular, hypoechoic cervix or as a mass with ill-defined margins. Parametrial regions appear dense when involved, and uterosacral involvement may be seen. Lymph nodes appear enlarged, with most greater than 1 cm on axial dimension considered pathologic. The overall accuracy of CT scanning in staging cervical cancer ranges from 63% to 88%.[29,30] In the detection of lymph node abnormalities, the overall accuracy of

conventional CT scanning is 77% to 85%, with sensitivity of 44% and specificity of 93%.[31]

In order to correlate radiographic and surgical findings, Camilien et al[32] reported on 61 patients with carcinoma of the cervix who had both preoperative CT scans and exploratory laparotomy; results showed that 75% of the enlarged pelvic lymph nodes on CT contained metastases, and 97% of patients with negative nodes on CT scan had pathologically negative findings (specificity of 97%). However, histologically positive pelvic nodes were often missed on CT scan (sensitivity of 25%). The CT scan is more valuable in the evaluation of the PANs (specificity of 100% and sensitivity of 67%).

Several studies explored the role of CT or PET-CT with regard to PAN evaluation (Table 76.2). The ACRIN6671/GOG0233 trial enrolled 109 patients with PET and pathology available; sensitivity of PET was 0.5 and for diagnostic CT was 0.42 (P = .052).[33] Heller et al[34] conducted a prospective evaluation of 320 patients with stage IIB to IVA carcinomas of the cervix entered into a Gynecologic Oncology Group (GOG) protocol in which preoperative CT scan, lymphangiography, and ultrasonography of the aortic area were performed. PAN dissection was done in patients with negative staging studies. Lymphangiography, CT scan, and ultrasonography had false-negative frequencies for pelvic lymph node evaluation of 14.2%, 25%, and 30%, respectively. The sensitivity was 79% for lymphangiography, 34% for CT scan, and 19% for ultrasonography, and the specificity ratings were 73%, 96%, and 99%, respectively. Ultrasonography, therefore, is not reliable in preoperative detection of lymph node metastases, but it has limited value in evaluating extrauterine tumor involvement. Ultrasound (US) has a primary role in assisting with intracavitary brachytherapy (BT) applicator insertion and may detect uterine perforation, allowing for proper positioning, which is critical for adequate dosing and affects survival.[35] PET has a higher sensitivity than CT and higher specificity than MR in detecting bone metastases.[36]

Magnetic Resonance Imaging

MRI is frequently used for the initial assessment of the cervical tumor and of extracervical tumor extension, often in lieu of a EUA. MRI is contraindicated in patients with pacemakers/implantable cardioverter-defibrillators, cochlear implants, metallic prostheses, metallic fragments from prior accidents, or large vascular clips. On T2-weighted images, a cervical cancer may be seen as a mass of intermediate to high signal intensity, usually of greater intensity than the fibrocervical stroma. On T1-weighted images, tumors are usually isointense with the normal cervix and may not be seen but can increase in intensity with the administration of IV contrast. Abnormal, irregular cervical margins; prominent parametrial strands; exocentric parametrial enlargement; and loss of parametrial fat planes on T1-weighted images or high signal in the parametria or cardinal/uterosacral ligaments on T2-weighted images are indicative of more extensive tumors. Parametrial tumor may be identified as brighter regions on T2-weighted images when compared to the low signal intensity of the cervix and uterine ligaments.

Pretreatment tumor staging and volume were assessed by EUA, transrectal ultrasonography (TRUS), and MRI in 60 patients with invasive carcinoma of the cervix.[37] TRUS and MRI assigned the same tumor stage in only 30% of patients, and EUA and MRI agreed on tumor stage in an additional 27%. In

cases of disagreement, the MRI staging correlated better with outcome than TRUS or EUA. Sixty-two percent of patients with enlarged lymph nodes on pretreatment MRI either died or had tumor recurrence or metastases. MRI was superior to both TRUS and EUA in assessing the full extent of bulky tumors and lymph node enlargement.

Postema et al[38] compared MRI with pelvic examination (including under general anesthesia in selected patients) and surgico-pathologic findings in 103 patients with invasive cervical carcinoma. MRI was better at identifying extracervical tumor spread, but it had more false-positive results. The pelvic examination led to correct treatment decisions in 89% of patients. In a study by Hansen et al,[39] clinical assessment (done according to FIGO recommendations) was superior to low-field MRI with contrast enhancement in staging cervical cancer in 95 women who had both within 2 weeks after clinical diagnosis; the clinical staging correctly classified 57 patients (accuracy, 92%) compared with 52 for MRI (accuracy, 84%).

A prospective study by the American College of Radiology Imaging Network compared clinical examination, CT, and MRI.[40] MRI was significantly better than clinical examination or CT for detecting uterine body involvement or measuring tumor size, but no method was accurate at evaluating the cervical stroma. MRI was significantly better at detecting the tumor and parametrial involvement. MRI also somewhat increased detection of involved lymph nodes.[31]

The tumor is less likely to be as visible on MRI for AC cases, compared to squamous cell cancer. Haider et al[41] evaluated 56 patients with AC involving the cervix using MRI and noted that only 42 (75%) had a visible mass.

Radiation-induced changes detected over the course of radiation may predict local recurrence (LR) and survival. Mayr et al[42] studied 34 patients with cervical cancer of various FIGO stages who underwent 1.5-T MRI before and after RT. Tumor volumetry (3D measurements) based on T2-weighted images quantified the tumor regression rate. Sequential tumor volumetry using MRI may be a very effective measure of the responsiveness of cervical cancer to irradiation. MRI dynamic contrast enhancement during the first 2 weeks of RT may provide early prediction of tumor regression rate. In seven patients, tumor regression rates ranged from 2% to 15.2% per day and correlated positively with changes in both peak and mean tumor enhancement ($P < .01$). Hatano et al[43] evaluated MRI in 42 patients with

advanced cervical cancer treated with external beam irradiation and high-dose rate (HDR) BT. In biopsies performed immediately after RT, no residual cancer was found in 36 (86%) patients. The simultaneous MRI study demonstrated no high signal intensity on T2-weighted images in 28 (75%) patients. A high signal intensity area was observed in 14 patients, and this disappeared 3 months after RT in 8 patients with a negative biopsy. The sensitivity, specificity, and accuracy of MRI tumor response studies at 3 months after RT were 100%. MRI studies performed after 30 Gy of external beam irradiation and 3 months after all RT predicted local tumor control. Furthermore, MRI is useful in providing accurate target volume definition in BT treatment planning (Figure 76.4).[44]

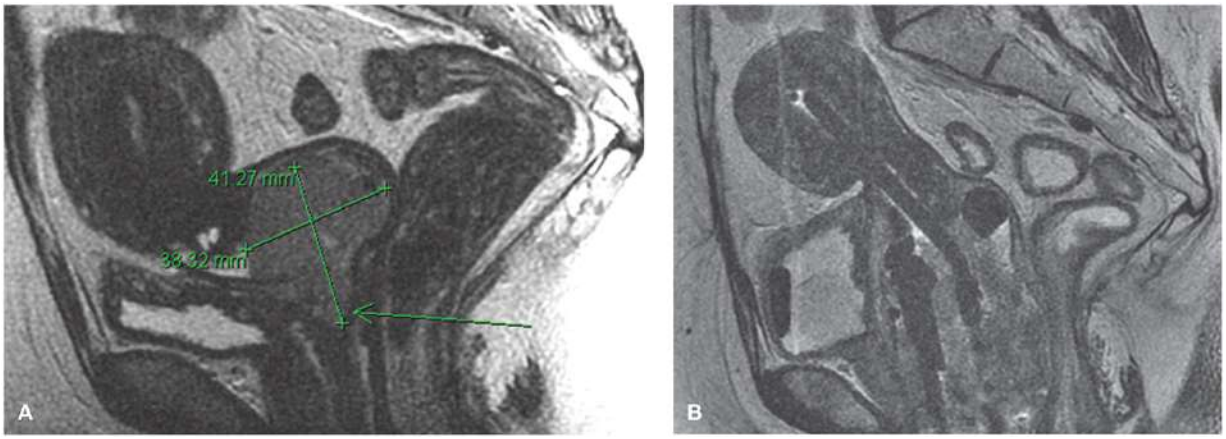

FIGURE 76.4 A. Magnetic resonance imaging (MRI) at diagnosis showing an enlarged cervical tumor. B. MRI with tandem and ring brachytherapy applicator in place showing dramatic shrinkage of the tumor after concurrent chemotherapy with external beam radiation.

Positron Emission Tomography

PET scanning is increasingly used in the evaluation of patients with malignant neoplasia, including invasive cervical cancer, using 2-[^{18}F]-fluoro-2-deoxy-D-glucose (FDG). Rose et al[45] observed uptake in 91% of the primary tumors in 32 patients with locally advanced carcinoma of the cervix. SCC is more often FDG avid than is AC. Compared with surgical staging, PET scanning had a sensitivity of 75% and a specificity of 92% in detecting para-aortic metastasis.[46] PET-CT provides highly accurate localization of focal radiotracer uptake, which significantly improves the diagnostic accuracy compared with PET or CT alone. Diagnostic PET images may be fused with simulation CT images to ensure accurate radiation dose coverage of the target and any PET-

avid lymph nodes. Proton therapy may provide a favorable distribution of dose allowing dose escalation while maximally sparing normal tissues (Figure 76.5). Care must be taken in interpretation because physiologic FDG excretion into the urinary bladder may result in false-positive assessment of the primary tumor, and ureters may be contoured as lymph nodes; therefore, tracing the ureters and complete bladder voiding prior to imaging are recommended.

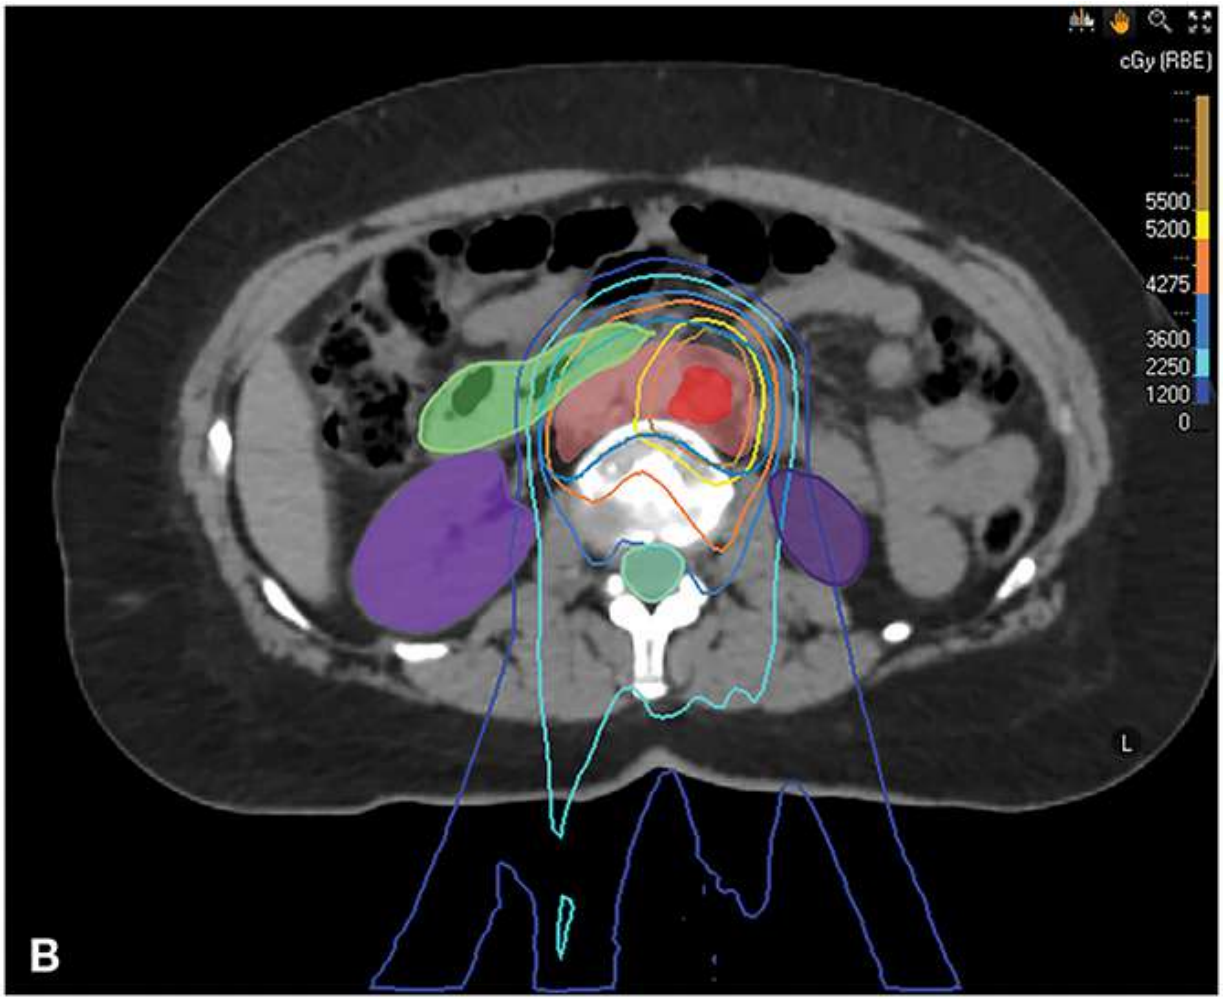

FIGURE 76.5 Target coverage of positron emission tomography–positive para-aortic lymph nodes on a computed tomography. Comparison between a photon intensity-modulated radiation therapy plan (A) and a proton plan (B) for the treatment of the para-aortic lymph node region, with a required boost to a gross pathologic node in two different patients. The duodenum (green) and the kidneys (purple) may cause a challenge to safely escalate dose to the involved node(s). Proton therapy has less scatter allowing a better dose distribution that in some cases is crucial to meet normal tissue constraints and may be especially beneficial in patients requiring reirradiation.

Grigsby et al[46] compared CT and FDG-PET scanning for lymph node staging in 101 patients with carcinoma of the cervix. CT demonstrated abnormally enlarged pelvic lymph nodes in 20 patients and PANs in 7, whereas PET demonstrated abnormal FDG uptake in pelvic lymph nodes in 67, in PANs in 21, and in supraclavicular lymph nodes in 8. The 2-year progression-free survival (PFS) rate, based solely on PAN status, was 64% in CT-negative and PET-negative patients, 18% in CT-negative and PET-positive

patients, and 14% in CT-positive and PET-positive patients ($P < .0001$). The most significant prognostic factor for PFS was the presence of positive PANs on PET imaging ($P = .025$). Among 76 patients with no abnormal FDG uptake, the 2-year survival rate was 86%, with persistent abnormal uptake in 40%; there were no survivors among patients who developed new sites of abnormal uptake.[47] In a follow-up study of 152 patients, the authors reported a 5-year cause-specific survival (CSS) rate of 80% in 114 patients without abnormalities on post-therapy FDG-PET versus 32% in 20 patients with persistent uptake and no survivors among 18 patients with new sites of abnormal uptake.[48] In another study, Grigsby et al[49] noted in 208 patients a close correlation between radiation doses, the number and size of positive lymph nodes, and outcome (treatment failures and survival; Figure 76.6). Hope et al[50] performed FDG-PET scans in 58 patients with cervical carcinoma who had an endometrial biopsy or dilation and curettage; 36 (64%) had pathologic EI. Pelvic lymph node metastasis was more commonly detected in this group than in patients without EI (70% vs 23%; $P < .001$), as were para-aortic and supraclavicular nodal metastasis (30% vs 0%; $P = .006$). Furthermore, 2-year survival rates were 78% versus 58%, and overall survival (OS) rates were 92% versus 65% ($P = .047$).

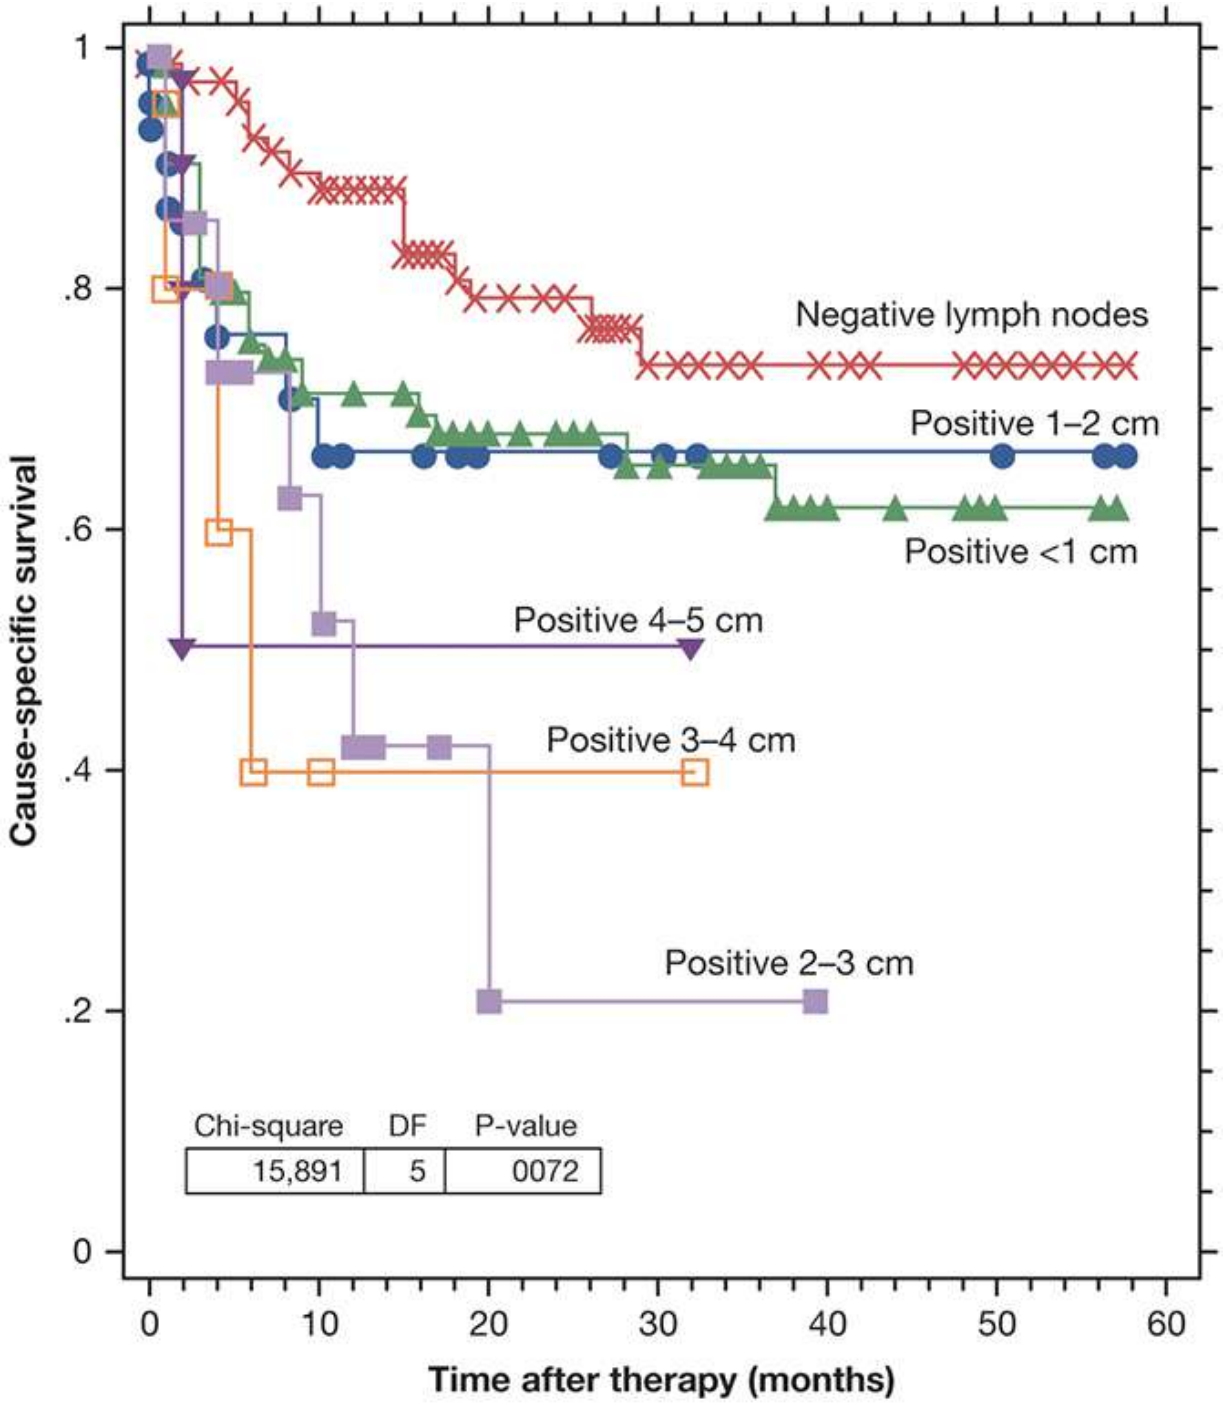

FIGURE 76.6 Cause-specific survival in patients with carcinoma of the cervix correlated with pelvic lymph node status on post-treatment 2-[^{924}F]fluoro-2-deoxy-D-glucose/positron emission tomography. (Reprinted from Grigsby PW, Singh AK, Siegel BA, Dehdashti F, Rader J, Zoberi I. Lymph node control in cervical cancer. *Int J Radiat Oncol Biol Phys*. 2004;59[3]:706-712. Copyright © 2004 Elsevier. With permission.)

Kidd et al[51-53] demonstrated that maximum standardized uptake value (SUVmax) is an independent predictor of death from cervical cancer and is associated with persistent disease. Similarly, the SUV of the pelvic node predicts pelvic disease recurrence. Survival rates are worse with supraclavicular nodal PET positivity; PAN metastases portend a survival rate between those of pelvic node and supraclavicular positivity. The detection of supraclavicular metastases on FDG-PET at diagnosis and its relationship to clinical outcome for 186 patients with cervical cancer was reported by Tran et al.[54] Fourteen patients (8%) had abnormal FDG uptake in the left supraclavicular lymph nodes without palpable disease, confirmed on biopsy; six were treated with palliative intent, and seven received definitive irradiation and concurrent chemotherapy. The median OS was 7.5 months; all patients developed distant metastases. After external beam radiation is finished, an FDG-PET scan provides important information about post-treatment uptake and is prognostic with regard to outcome.[55]

STAGING

The FIGO staging system was historically based on clinical evaluation (inspection, palpation, colposcopy); roentgenographic examination of the chest, kidneys, and skeleton; and endocervical curettage and biopsies. The updated 2018 FIGO staging system allows for the use of imaging to determine the size of cervical tumor in stage I and stage II disease and for the identification of retroperitoneal lymph nodes in stage I to III. In addition, the 2018 FIGO staging system for cervical cancer has several other modifications from the previous version: Stage IA1 is characterized by stromal invasion of less than or equal to 3 mm with IA2 correlating to stromal invasion of greater than 3 mm but less than 5 mm. Stage IB disease has now been divided into IB1, IB2, and IB3 based on the depth of stromal of greater than 5 mm to 2 cm or less, greater than 2 cm to 4 cm or less, and greater than 4 cm, respectively. The updated staging system also introduces the category stage IIIC. This has been further subdivided into stage IIIC1 to include all tumors with pelvic lymph node metastases only and stage IIIC2 to include tumors with PAN metastases. Both of these subcategories exist, irrespective of the tumor size and extent.

Patients with hydronephrosis or a nonfunctioning kidney ascribed to extension of the tumor are classified as stage IIIB, regardless of the pelvic

findings. Other prognostic factors, such as endometrial extension of cervical carcinoma, stromal invasion, lymphatic/vascular permeation, and involvement of the lateral parametrium (as opposed to the medial parametrium) in stage IIB, are not included in the staging system. Suspected invasion of the bladder or rectum should be confirmed by biopsy. Bullous edema of the bladder and swelling of the mucosa of the rectum are not accepted as definitive criteria for staging. For a lesion to be classified as stage IIIB based on tumor extension without hydronephrosis, the tumor should extend to the lateral pelvic wall, although fixation is not required.

A parallel tumor-node-metastasis staging system is published by the American Joint Committee on Cancer; however, this system requires nodal staging, which is not feasible in many settings, and radiologic nodal information is not available to most patients with cervical cancer worldwide. The FIGO system remains the standard staging system, given the lack of 3D imaging to determine nodal status in countries with the highest incidence of cervical cancer. All histologic types should be included. When there is a disagreement regarding the staging, the earlier stage should be recorded (Table 76.3; Figure 76.7).

TABLE 76.3 FIGO STAGING OF CARCINOMA OF THE UTERINE CERVIX

I	Cervical carcinoma confined to the cervix (extension to the corpus should be disregarded)
IA	Invasive carcinoma, diagnosed by microscopy only, maximum depth of invasion ≤5 mm
IA1	Stromal invasion ≤3 mm
IA2	Stromal invasion .3 mm and ≤5 mm
IB	Invasive carcinoma, .5 mm depth, confined to the cervix
1B1	>5 mm depth of stromal invasion and ≤2 cm
IB2	>2 cm and ≤4 cm in greatest dimension
IB3	>4 cm in greatest dimension
II	Invasion beyond uterus, limited to upper two-thirds of vagina, no pelvic wall invasion
IIA	Limited to upper two-thirds of vagina, no parametrial involvement
IIA1	≤4 cm in greatest dimension
IIA2	>4 cm in greatest dimension
IIB	Parametrial involvement, but not pelvic wall

III	Cervical carcinoma extends to the pelvic wall and/or involves lower one-third of the vagina and/or causes hydronephrosis or nonfunctioning kidney.
IIIA	Involves lower one-third, no pelvic wall extension
IIIB	Tumor extends to the pelvic wall and/or causes hydronephrosis or nonfunctioning kidney.
IIIC	Involvement of pelvic and/or para-aortic lymph nodes, irrespective of tumor size
IIIC1	Pelvic lymph node metastasis only
IIIC2	Para-aortic lymph node metastasis
IVA	Tumor invades mucosa of the bladder or rectum and/or extends beyond the true pelvis.[a]
IVB	Distant metastasis

FIGO, International Federation of Gynecology and Obstetrics.

[a]Presence of bullous edema is not sufficient evidence to classify a tumor as T4.

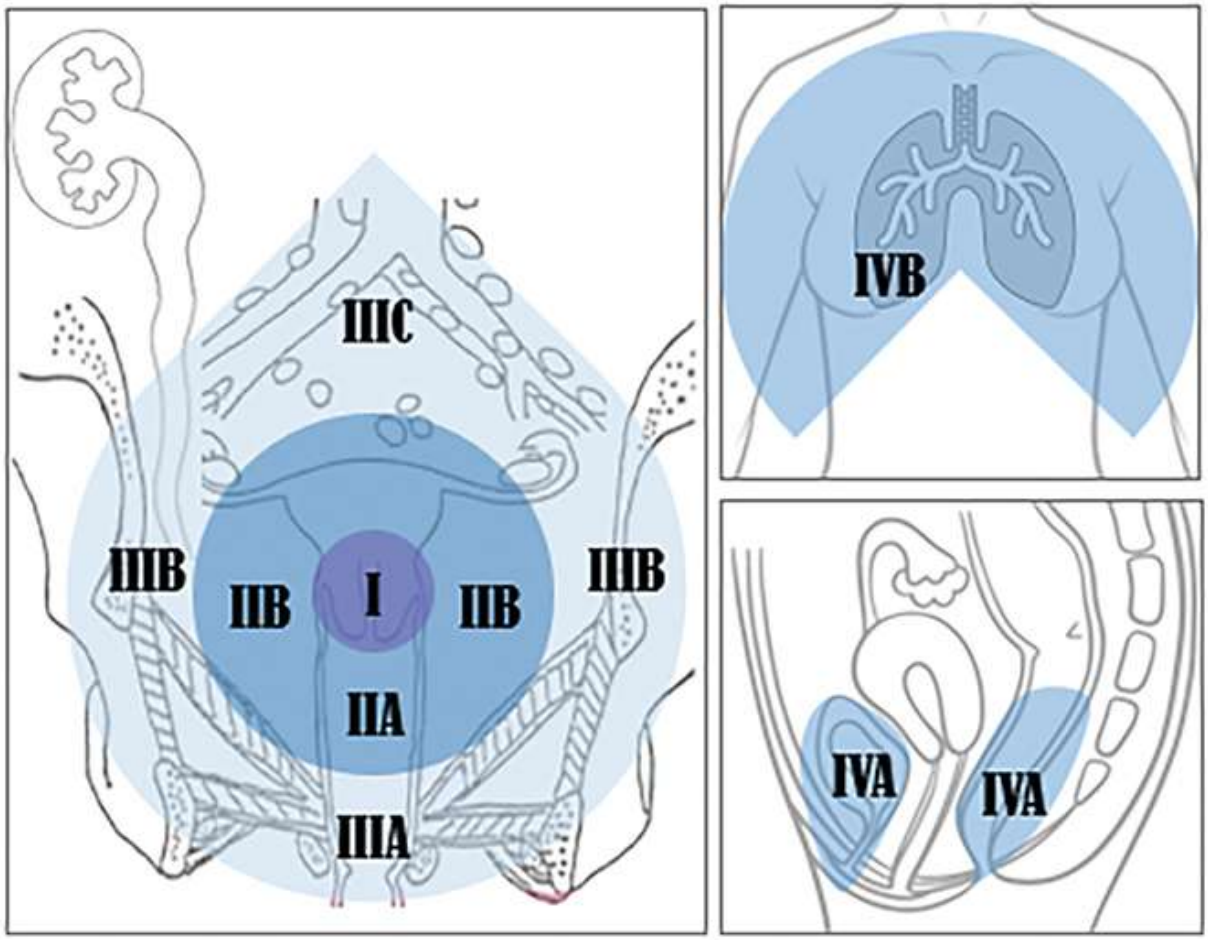

FIGURE 76.7 Diagrammatic representation the anatomic stages of carcinoma of the uterine cervix, according to the 2018 International Federation of Gynecology and Obstetrics classification. Stage I is further divided by depth of invasion and size. Stage IIA has been divided by size up to and over 4 cm to stage IIA1 and IIA2, respectively. Stage III is divided by area of invasion—IIIA in lower vagina, IIIB in pelvic sidewall or obstruction of ureter, and IIIC to lymph nodes (IIIC1 pelvic and IIIC2 in para-aortic nodes). Stage IVA invades pelvic organs and IVB is distant metastases.

PATHOLOGIC CLASSIFICATION

More than 90% of tumors are SCC. Approximately 7% to 10% are classified as AC, and 1% to 2% are the clear cell mesonephric type. Squamous cell (or epidermoid) carcinoma is composed of cores and nests of epithelial cells arranged randomly; cells show central keratinization with pearls and sometimes necrosis. Nonkeratinizing tumors may be seen. Electron microscopy may show desmosomes and tonofilaments. SCCs are divided into three types: large cell keratinizing, nonkeratinizing, and small cell

carcinomas. They are subdivided according to the degree of differentiation into well, moderately, or poorly differentiated.

Verrucous carcinoma is a variant of a very well- differentiated SCC that characteristically has a tendency to recur locally, but not to metastasize. Mitotic activity is very low. It may be difficult to discriminate verrucous carcinoma from a giant condyloma with cytologic atypia or from a well-differentiated invasive squamous carcinoma. Microscopically, verrucous carcinoma is exophytic, with an undulating, hyperkeratotic surface; the deep margin is composed of large, bulbous masses that invade along a wide front in a “pushing” manner.

AC arises from the cylindrical mucosa of the endocervix or the mucus-secreting endocervical glands. Mucinous is the most common subtype of AC. This endocervical AC may form mucosal glands lined by high columnar cells and produce tubular folds oriented in many directions. In another subtype, cells resemble those of the intestines; the epithelium tends to be pseudostratified and may contain goblet cells. The third variant is the signet-ring cell AC, which is rare and usually mixed with the endocervical or intestinal patterns.

Endometrioid carcinoma is the most common cell type of endocervical AC; the cells resemble those of the endometrium, and the presence of intracytoplasmic mucin in some cells may be seen in a substantial proportion of tumors. The World Health Organization recommends that endometrioid or endocervical types of ACs be graded according to their architecture, based on the degree of gland formation. Sometimes, it is difficult to differentiate a primary endocervical AC from an endometrial tumor. HPV is greatly associated with cervical ACs, with an overall prevalence of 90%, and has been identified in most subtypes with varying rates.[56]

Adenoma malignum is a rare form of cervical cancer that is difficult to diagnose and often highly malignant and refractory to treatment. Adenoma malignum is associated with Peutz-Jeghers syndrome and has an ominous natural history, with few reported cures. Adenosquamous carcinoma is also relatively rare (2%-5%) and consists of intermingled epithelial cell cores with squamous features and glandular structures. The squamous component is frequently nonkeratinizing. If the squamous component is benign metaplasia, the tumor is called adenoacanthoma.

Glassy cell carcinoma (1%-2%) is considered a poorly differentiated adenosquamous tumor; it is rare and highly malignant. Survival is poor after surgery or irradiation. Light and electron microscopy demonstrate both glandular and squamous differentiation.

Adenoid cystic carcinoma is a rare variant of AC of the cervix (<1%), with an appearance similar to its counterparts in the salivary gland or the bronchial tree. The tumor is composed of nests and nodules of small carcinoma cells with a few characteristic cribriform patterns. Immunohistochemical findings for type IV collagen and laminin reveal intercellular cylinders composed of basement membrane material in the solid area without a cribriform pattern. They are locally aggressive and prone to metastasize.[57]

Clear cell carcinoma (mesonephric), not related to DES exposure, comprises approximately 2% primary cervical ACs and is believed to arise in mesonephric remnants. These tumors are submucosal, composed of clear and "hobnail" cells, and may grow in a tubular, glandular, papillary, or solid pattern. They appear at any age, with one-third occurring in women younger than 30 years of age. The clear cell is characterized by a voluminous cytoplasm filled with glycogen and the hobnail cell by single-cell apical projections into the neoplastic lumina. These tumors tend to be deeply positioned, with the bulk of the lesion on the stroma forming tubular structures, diffusely infiltrating the cervical stroma.

Cervical malignant mixed Müllerian tumors, compared with their counterparts in the corpus, are more commonly confined at presentation and may have a better prognosis. Clement et al[58] described the clinicopathologic features with mixed Müllerian tumors of the cervix in nine patients. Gross examination revealed polypoid or pedunculated masses that invaded the cervical wall in 50% of the hysterectomy specimens. On microscopic examination, five tumors contained basaloid carcinoma or SCC and four contained AC. In seven tumors, the sarcomatous component was homologous, usually resembling fibrosarcoma or endometrial stromal sarcoma, and two tumors contained heterologous sarcomatous elements.

Small cell carcinoma of the cervix, according to some authors, arises from endocervical argyrophilic cells or their precursors, multipotential neuroendocrine cells; however, some small cell tumors do not contain morphologic evidence of neuroendocrine origin. Nuclear molding, absence of nucleoli, cell necrosis, and high mitotic activity are common. One-third to

one-half stain positively for neuroendocrine markers, such as chromogranin, serotonin, synaptophysin, or somatostatin. In the majority of patients, the cervical stroma is extensively infiltrated by single small, round cells. Lymphatic and vascular invasion are significantly more common in small cell carcinomas (noted in 58% of patients with stage IB disease; 40% of these patients had lymph node metastases at the time of radical surgery). HPV-18 has been detected in the majority of these tumors.[59,60] Survival rate is considered poorer to matched large cell SCCs. Viswanathan et al[61] studied 21 patients. All were confirmed after central pathology review to stain positively for chromogranin, synaptophysin, or CD56. The median time to first relapse from the initiation of treatment was 8.4 months. No patient had brain metastases as the sole site of first recurrence. However, two patients developed brain metastases concurrently with lung metastases. The OS rate was 29% at 5 years; none of the patients who had disease more extensive than stage IB1 or clinical evidence of lymph node metastases survived their disease. A 5-year OS of 29% was also reported in 487 patients in the Surveillance, Epidemiology, and End Results (SEER) registry.[62]

Basaloid carcinoma or adenoid basal carcinoma, an extremely uncommon tumor, is characterized by nests or cords of small basaloid cells, prominent peripheral palisading of cells in the tumor nests, no significant stromal reaction or capillary space invasion, and an infiltrating growth pattern. Some authors have suggested a slow growth pattern with limited local invasiveness and low probability of lymph node metastases. Prognosis is excellent.

Primary sarcomas of the cervix have been occasionally described (eg, leiomyosarcoma, rhabdomyosarcoma, stromal sarcoma, carcinosarcoma). Malignant lymphomas, primary or secondary in the cervix, have been sporadically reported. They should be treated like other lymphomas. Melanoma of the cervix is similarly extremely rare and difficult to cure despite attempts at radical surgery and immunotherapy. Metastasis of distant tumors to the uterine cervix is rare (about 4% of all tumors) and should be considered in the differential diagnosis. Metastases to the cervix from the breast, ovary, and kidney have been reported.

PROGNOSTIC AND PREDICTIVE FACTORS

The NRG/GOG combined data from randomized trials of chemoradiotherapy (CRT) and created nomograms predicting PFS, OS, and pelvic recurrence in

locally advanced cervical cancer. Multivariable analysis of 2,042 patients identified histology, race/ethnicity, performance status, tumor size, stage, grade, pelvic node status, and treatment with cisplatin-based chemotherapy concurrently as significant measures for outcomes.[63]

Patient-Related Factors

Age

According to some reports, age is not a prognostic factor in carcinoma of the cervix. Other authors noted decreased survival in women younger than 35 or 40 years, who have a greater frequency of poorly differentiated tumors. In contrast, two European studies showed improved outcome for younger patients. This apparent contradiction may be explained by an analysis by Rutledge et al,[64] who showed an interaction between age and stage in the relative hazard plots for 250 patients younger than 35 years of age and matched control subjects, with a detriment to the younger group. Mitchell et al[65] evaluated 398 patients with stage I to III cervical carcinomas treated with RT. Patients were divided into non-older (35-69 years of age; n = 338) and older (≥70 years of age; n = 60) groups. Comorbid conditions in the older patients resulted in diminished ability to undergo intracavitary BT. Although the 5-year actuarial DFS and CSS rates were comparable in the two groups, tumor recurrence and death from cervical cancer were more common beyond 5 years in the older group.

Race/Ethnicity

Several authors noted a correlation between racial characteristics of patients and outcome of therapy. Mundt et al[66] examined factors affecting outcome in 316 African American and 94 White patients undergoing RT for cervical cancer. With a median follow-up of 72.4 months, African Americans had a trend toward poorer 8-year CSS rates (47.9% vs 60.6%; P = .10) compared with White patients. Factors correlating with poor outcome, including lower hemoglobin (Hb) levels during RT (P = .001), lower median income (P = .001), and less frequent intracavitary BT (P = .09), were more likely to be present in the African American group. Multivariate analysis demonstrated that race was not an independent prognostic factor after controlling for differences in patient, tumor, and treatment factors. In a report on 452 White and 124 African American women with stage II or III cancer of the cervix

treated with RT alone, Grigsby et al[67] observed 5-year CSS rates of 66% and 61% (P = .56) for those with stage II and of 38% and 47% (P = 0.34) for those with stage III disease. OS rates for stage II for the two racial groups were different (60% and 51%, respectively; P = .02) and may be related to non–cancer-related comorbidity factors.

More recently, differential rates of BT underutilization across racial and ethnic strata have been redemonstrated. Colson-Fearon et al utilized the National Cancer Database (NCDB) to evaluate factors related to BT use and survival differences between patients receiving and those not receiving BT for the treatment of cervical cancer.[68] African Americans (P < .001) and Hispanic (P < .001) patients were observed to have significantly lower rates of BT receipt. In addition, patients not receiving BT were noted to have significantly worse OS (P < .01).

Social Determinants of Health

A number of social determinants of health have been studied for their impact on outcomes among patients with cervical cancer. Tjioe et al performed a meta-analysis utilizing 24 studies performed from 2001 to 2022 to identify potential social determinants as predictors of differential prognosis. It was observed that not being married at the time of diagnosis, lack of insurance, being insured under Medicaid/Medicare, and receiving treatment in a low-volume facility may be associated with worse OS.[69]

Moreover, in an analysis of the 1994 Patterns of Care study of 471 cases of SCC treated in the United States and a randomly selected 215 additional cases from 17 institutions that admitted more than 40% minority patients, women who lived in low-income neighborhoods, who had only Medicaid coverage, or who were treated at large academic or minority-rich institutions tended to have a poorer initial performance status, higher stage or bulky central tumor, and a lower pretreatment Hb level.[70]

Social factors may also play a role in a patient's decision to pursue treatment. Samuel et al evaluated the impact of social determinants on rates of refusal of surgery for the treatment of gynecologic malignancies, including cervical cancer.[71] Utilizing the NCDB, 788,164 patients were identified of which 5,875 refused surgical treatment. Factors significantly associated with refusal included lack of insurance, coverage under Medicaid, and lower regional rates of high school completion. Similarly, Colson-Fearon et al[72]

analyzed rates of refusal of radiation treatment among patients with gynecologic cancer in the NCDB. Of 12,081 of 209,976 patients who refused radiation, predictive factors included lower annual income and lack of insurance.

General Medical Factors

Anemia

Although stage, tumor volume, histologic type of the lesion, and vascular or lymphatic invasion are known to affect the prognosis of patients with cervical carcinoma, whether Hb levels contribute to patient prognosis is controversial. Many radiation oncologists routinely administer red blood cell transfusions to correct anemia before treatment with RT. This may have a generally favorable effect on the patient's sense of well-being and energy level and an impact on tumor radiosensitivity. Typically, patients receive transfusion to maintain Hb levels greater than 10 to 12.5 g/dL. However, in practice, the effect on outcome is less evident.

A randomized trial reported by Bush[73] on 132 patients with stage IIB to III cervical cancers required the control arm to receive transfusions only if the Hb level dropped to less than 10 g/dL, whereas the experimental arm had to maintain the Hb level 12.5 g/dL or more. The results suggested an improved outcome for patients in the experimental arm who received transfusion; however, there was not a statistically significant difference in outcome between treatment arms when compared using an intent-to-treat analysis.[74] Second, the randomization was not stratified according to the potentially confounding influence of tumor size. Finally, the thresholds for transfusion were based on anemia during therapy, not the initial Hb.

Retrospective reports, mainly prior to the CRT era, on targeting anemia with transfusion have failed to show clear benefit that was not related to other patient and tumor factors. The largest one was a large retrospective review of 2,454 patients with cervical cancer showed on multivariate analysis, an Hb level of less than 10 g/dL during RT was found to be significant for lower disease-specific survival (DSS) (hazard ratio [HR] 1.28) and freedom from distant metastases (HR 1.33), but not freedom from central recurrence. In a subset analysis of patients receiving CRT, transfusion did not provide a benefit.[75]

Koulis et al[76] conducted a retrospective single-institutional study, identified 257 patients with cervical cancer, and observed that anemia identified prior to the start of primary CRT and on-treatment anemia were associated with significantly worse 5-year PFS and OS. Those who underwent correction of anemia diagnosed prior to treatment had improved survival when compared to those who did not.

Recombinant human erythropoietin is not routinely recommended as an alternative means of sustaining or raising Hb levels during RT. Thrombotic complications[77] and the lack of any survival benefit[78] mitigate the utility of this as a therapeutic intervention.

Thus, a prudent recommendation is to treat anemia prior to and during therapy in any symptomatic patient and to maintain Hb levels above 9 to 10 g/dL.

Other Medical Factors

Older reports observed a higher incidence of pelvic recurrences and complications in patients with arterial hypertension (diastolic pressure of .110 mm Hg) and a higher incidence of distant metastases and a lower survival rate in patients with temperatures of greater than 101 °F during BT procedures. In patients with cervical cancer screened for HIV and treated with RT, Campbell et al[79] observed a 4.2% positive HIV rate. These patients had more advanced tumors. The duration of remission was shorter than in the HIV-negative group. RT had no effect on the HIV titers. Women who are HIV positive or have acquired immunodeficiency syndrome associated with in situ or invasive carcinoma of the cervix are at a higher risk for tumor recurrence after treatment and death as a consequence of the malignant process.

Evidence suggests that increasing levels of plasma micronutrients are associated with a decreasing risk of cervical cancer. Increasing serum lycopene and α- and γ-tocopherol levels and higher intake of dark green and deep yellow vegetables and fruit were significantly inversely associated with cancer.[80] Women should be counseled to eat a well-balanced diet, particularly those at high risk for developing cervical cancer.

The neutrophil-to-lymphocyte ratio (NLR) has been shown to be prognostic, with an NLR greater than 2.95 associated with a worse OS (HR 1.65, $P < .001$) and event-free survival (HR 1.57, $P < .001$).[81]

Tumor Factors

Human Papillomavirus Subtype

HPV-16 and HPV-18 are the most frequent HPV subtypes worldwide. Studies have reported a higher risk of lymph node and other distant metastases with HPV-18 compared to HPV-16.[82] Wang et al[83] studied 1,010 patients with cervical cancer after RT between 1993 and 2000. The HPV genotypes were determined by a gene chip that can detect 38 types of HPV. A total of 25 genotypes of HPV were detected in 992 specimens, of which 8 types that predominated were HPV types 16, 58, 18, 33, 52, 39, 31, and 45. Two high-risk HPV species were identified: α-7 (HPV types 18, 39, and 45) and α-9 (HPV types 16, 31, 33, 52, and 58). Risk groups determined included the high-risk group, which consisted of patients without HPV infection or those infected with the α-7 species only. The medium-risk group included patients coinfected with the α-7 and α-9 species. Demarco et al[84] evaluated rates of clearance, persistence without progression, and progression to CIN3+ among 11,573 HPV-positive patients. They observed that the viral subtype with the highest risk of progression to CIN3+ within 7 years was HPV-16 (22%). Given the significant differences of disease progression observed in their study, the categorized subtypes into four groups. Rates of infection clearance in the absence of progression and persistence with progression were similar across subtypes.

Tumor Volume

There is a close correlation between depth of stromal invasion, tumor size and local extent, and incidence of parametrial and pelvic node metastases and survival in patients with cervical cancer. This is true, regardless of treatment modality. In a study of women treated with RH, the 5-year DFS rate was 90% in 181 patients with stage IB1 ($\leq$4 cm) and 72.8% in 48 patients with stage IB2 disease (P = .02).[85] Perez et al[86] reviewed 1,499 patients (stages IA-IVA) treated with definitive irradiation (combination of external beam irradiation plus two intracavitary insertions to deliver doses of 70-90 Gy to point A). There was a close negative correlation between increasing tumor size and extent and pelvic tumor control, freedom from distant metastasis, and DFS in all stages. Local extent of the tumor into the uterine corpus, parametria, and other pelvic organs is also well known to impact prognosis, and thus, it is incorporated in the staging system. In a SEER database validation study for

the 2018 FIGO staging system, it was shown that increasing tumor size negatively affects survival also in node-positive patients (stage IIIC).[87]

Impact of Histology on Outcomes

Several series have questioned whether AC has a worse prognosis than SCC. A SEER analysis of women with stage IB to IVB cervical cancers treated between 1988 and 2005 stratified 24,562 women by SCC (77%), AC, or adenosquamous histology. Patients with AC were younger and presented with early-stage disease ($P < .0001$). For both early- and advanced-stage diseases, women with AC had an increased likelihood of dying from disease compared to those with squamous neoplasms (HR 1.39 and HR 1.21, respectively).[88]

In a retrospective analysis of 1,671 patients accrued on prior prospective GOG trials with locally advanced cervical carcinoma treated with either radiation alone or CRT, a total of 70 patients with AC treated with radiation alone had a borderline poorer survival difference ($P = .0499$) compared to 647 patients with SCC. In patients treated with concurrent CRT, 112 patients with AC had no difference in OS ($P = .47$) compared to 842 patients with SCC. The authors conclude that in the era of CRT, no difference in outcome exists between squamous cell and AC in this large retrospective analysis.[89]

Alvarado et al[90] retrospectively evaluated survival differences between those with SCC against those with AC among patients with locally advance cervical cancer receiving concurrent CRT. Of 1,291 patients, 134 patients with AC had significantly worse DFS ($P = .043$) and OS ($P = .002$) when compared to 1,154 patients with SCC.

Histologic Grade

Most reports have shown no significant correlation of survival or tumor behavior with the degree of differentiation of SCC or AC of the cervix. Alfsen et al[91] analyzed 417 ACs and 88 other non-SCC of the cervix; on multivariate analysis, small cell histology, corpus infiltration, vascular invasion, and positive lymph nodes were significant prognostic variables. In the era of CRT, Monk et al[92] showed no significant impact of histology or grade on survival in postoperative patients with cervical cancer with other high-risk features.

Margin Status After Radical Hysterectomy

In addition to the known high-risk factors of positive margins, positive parametrial spread, and/or positive lymph nodes and the intermediate-risk factors of depth of stromal invasion, lymphovascular invasion, and tumor size, a small series have indicated the significance of close margin status. Viswanathan et al[93] studied 284 patients after RH and central pathology review. The crude rates for any recurrence were 11%, 20%, and 38% for patients with negative (≥1 cm), close (.0 and <1 cm), and positive margins, respectively. Postoperative RT decreased the rate of LR from 10% to 0% for negative, 17% to 0% for close, and 50% to 25% for positive margins. The significant predictors of decreased relapse-free survival on univariate analysis were the depth of tumor invasion (HR = 2.14/cm increase, $P = .007$), positive margins (HR = 3.92, $P = .02$), tumor size (HR = 1.3/cm increase, $P = .02$), lymphovascular invasion (HR = 2.19, $P = .03$), and margin status (HR = 0.002/increasing millimeter from cancer for those with close margins, $P = .03$).

Treatment Duration

In patients treated with RT, overall treatment time (OTT) should be as short as possible, and any planned or unplanned interruptions or delays should be avoided. Attempts to mitigate their harmful effect should be made by adding an additional fraction per week. Timely integration of external beam and BT in patients with carcinoma of the uterine cervix is an important factor in improving pelvic tumor control (Figure 76.8). Perez et al[94] in 1,330 patients treated with definitive irradiation noted a strong correlation between OTT and CSS. Regression analysis confirmed previous reports that prolongation of OTT resulted in an increased failure rate of 0.59% per day in stage IB and IIA and 0.86% per day in stage IIB disease. Performance of all intracavitary insertions within 4.5 weeks from initiation of irradiation yielded lower pelvic failure rates (8.8% vs 18% in stage IIB tumors; $P \leq .01$)

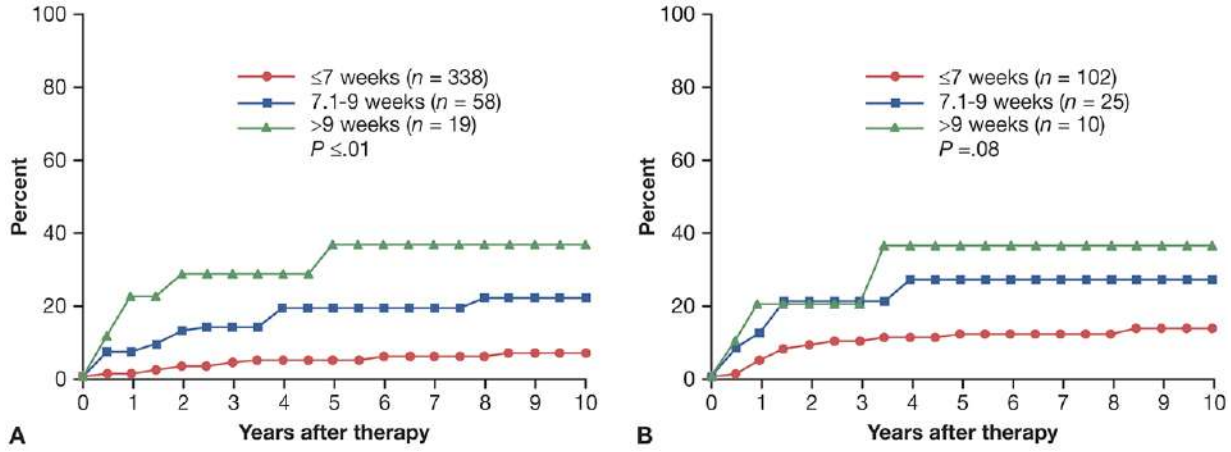

FIGURE 76.8 Pelvic failure rate correlated with length of treatment in stage IB (A) and IIA (B) carcinomas of the uterine cervix. (Reprinted from Perez CA, Grigsby PW, Castro-Vita H, Lockett MA. Carcinoma of the uterine cervix. I. Impact of prolongation of overall treatment time and timing of brachytherapy on outcome of radiation therapy. *Int J Radiat Oncol Biol Phys*. 1995;32[5]:1275-1288. Copyright © 1995 Elsevier. With permission.)

Whether treatment duration has an impact in the era of CRT has also been demonstrated. In a retrospective review of 488 patients all treated with CT or MRI-based BT in the retroEmbrace study, the high-risk clinical target volume (HR-CTV) volume, D90 dose, and longer OTT were associated with local control (LC).[95] The authors calculated that 1 week of delay was equivalent to 5 Gy decrease in the HR-CTV D90, which caused a 1% reduction in the rate of 3-year LC. This was further validated in the prospective EMBRACE cohort, which included 1,318 patients with a median of 46-month follow-up, and the OTT was significantly associated with LC in a multivariate analysis. Each additional day of OTT above the median 46 days had an HR for local failure of 1.03 (95% confidence interval [CI] 1.01-1.06, $P = .024$).

Clinical Biomarkers

Cytokeratin Markers and the Epidermal Growth Factor Receptor Pathway

Altered expression of c-ercB-2 (HER2) protein was shown to have prognostic significance in AC, but not in SCC, of the cervix. HER1, as well as coexpression of epidermal growth factor receptor and HER2, has been associated with poor DFS.[249] PTEN mutations have also been associated with poor prognosis.[96] A meta-analysis of studies examining the prevalence of HER2 overexpression in cervical cancer reported a pooled rate of 5.7%

(1.5%-11.7%).[97] Trastuzumab deruxtecan is an HER2-directed antibody-drug conjugate that after showing activity in breast and gastric cancers was also examined in other HER2-expressing solid tumors (determined with immunohistochemistry as either +3 or +2) in the DestinyPanTumor02 phase 2 trial.[98] It was found that in 40 patients with metastatic cervical cancer previously treated with at least one standard-of-care systemic treatment, the response rate was 50%, with a median PFS of 7 months, and better results with increased Her2 expression. In 80 patients with carcinoma of the cervix, expression of cytokeratin 10, cytokeratin 13, and involucrin was found in 24%, 64%, and 53%, respectively.[251] There was no difference in the expression of cytokeratin or involucrin between patients with positive or negative lymph nodes, although, in the lymph node–positive group, survival was higher in patients lacking cytokeratin 13 expression ($P = .02$).

Squamous Cell Carcinoma Antigen and Carcinoembryonic Antigen

Tsai et al,[99] in 117 patients with AC of the cervix, 28 of whom had preoperative carcinoembryonic antigen (CEA) levels of greater than 5 ng/mL, noted a correlation with larger tumor size, deeper cervical invasion, and lymphovascular invasion ($P < .001$). A Spanish study of 96 patients with invasive carcinoma of the cervix and 7 with intraepithelial neoplasia showed elevated CEA levels in 33%, carbohydrate antigen 19-9 (CA 19.9) in 32%, and CA 125 in 21.5% of patients.[100] Specificity for each tumor marker was 98%. Increased CEA and CA 19.9 levels were found with more advanced stages of the disease and in patients with AC compared with SCC. At follow-up, all cases of progressive tumor or recurrence were detected by elevation of one of the three antigens. Specificity during follow-up was 92% for CEA and CA 125 and 92.6% for CA 19.9.

In a study of 272 patients with invasive carcinoma of the cervix with 1,053 samples, Bolli et al[101] noted an elevation of squamous cell carcinoma antigen (SCC-Ag) before treatment in 53% of 103 patients, increasing with advancing tumor stage at diagnosis. In 70 patients with recurrent tumor, 81% had elevated SCC-Ag.

Hong et al,[102] in 401 patients with stage I to IV SCC of the cervix treated with RT, noted that the preirradiation SCC-Ag level strongly correlated with disease stage. A persistently elevated SCC-Ag level 3 months after RT was a

stronger predictor for treatment failure than residual induration by pelvic examination, and it was associated with a higher incidence of distant metastasis. A later report including 1,031 patients with SCC cancer treated with RT with or without chemotherapy noted that independent risk factors for local relapse were advanced stage, age less than 45 years, and lower SCC-Ag levels; 5-year local relapse–free survival was higher (90%) if SCC-Ag was less than 2.[103] Markovina et al have shown that SCC-Ag is a significant independent predictor of positive post-therapy FDG-PET/CT, recurrence, and death.[104]

A meta-analysis by Charakorn et al,[105] which included 61 different trials assessing either pretreatment or post-treatment SCC-Ag levels in relation the disease outcomes, found that both were associated with poorer outcomes, but the persistently elevated levels conveyed higher risk for recurrence—HR 3.14: 95% CI 1.29, 7.65 from post-treatment SCC-Ag versus HR 2.23: 95% CI 2.03, 2.45 from pretreatment SCC-Ag. The cutoff variability between high and low SCC-Ag levels was also lower for the post-treatment levels, residing between 0.9 and 3.5 and 1.5 and 2.0 ng/mL for predicting recurrence and survival, respectively, making it a useful tool to predict prognosis in clinical practice and research.

Human Papillomavirus Circulating Tumor DNA

Tumors release fragments of DNA into circulation, allowing accessible testing. It was shown that circulating HPV DNA is associated with increased FIGO stage while not being useful for detecting premalignant lesions and primary diagnosis of cervical cancer.[106,107]

However, its use in monitoring disease response and identification of patients most at risk for recurrence was shown by Han et al.[108] A prospective validation study in 70 patients with HPV+ cervical cancer showed that detectable HPV circulating tumor DNA at the end of CRT, 4 to 6 weeks post-CRT, and 3 months was associated with worse 2-year PFS (77% vs 51%, $P = .03$; 82% vs 15%, $P < .001$; and 82% vs 24%, $P < .001$). This could allow better selection of patients for treatment escalation trials.

Programmed Death Ligand 1 Expression

Immune checkpoint inhibitors such as anti-programmed cell death protein 1 antibodies have shown clinical benefit in patients with metastatic cervical

cancer, both in the first-line setting and in subsequent lines.[109-111] The combined positive score (CPS) of programmed death ligand 1 (PD-L1) is determined with immunohistochemistry as the number of positively stained cells (either tumor cells, lymphocytes, or macrophages) divided by the number of viable tumor cells multiplied by 100. It has emerged as a useful and reproducible method to predict response to checkpoint inhibition.[112] In the KEYNOTE-826 trial, a CPS 1 or greater conveyed a significant reduction in the risk of progression or death with the addition of pembrolizumab to chemotherapy with or without bevacizumab (HR 0.62 and HR 0.64, respectively, in both $P < .001$), while no benefit was seen in the CPS less than 1 group.[110]

TECHNIQUES USED FOR TREATMENT

Preinvasive Disease

Patients with CIN may be candidates for observation or treatment. CIN1-2 has a spontaneous regression rate in 1 to 3 years of more than 50%; therefore, observation may be an appropriate course. For patients with persistent dysplasia, cryotherapy has a very low complication rate and is highly successful but may be less effective than laser ablation for high-grade dysplasia. Patients with no visible lesion undergo frequent serial examinations. Cold knife conization (CKC) may be used for diagnostic and therapeutic intent, with side effects of bleeding, cellulitis, cervical stenosis, or loss of cervical competence. Loop electrosurgical excision procedure (LEEP) has become popular, although bleeding and stenosis may occur; pregnancy outcomes may be better with LEEP than with CKC.[113]

Invasive Disease

Surgical Techniques

Simple Conization

In patients with minimal invasion, no parametrial involvement, and small tumor size, simple conization with lymphadenectomy has been reported.[114] Although only 36 patients were studied, after a median follow-up of 66 months, only one pelvic nodal relapse was observed.

In more advanced disease with patients pursuing fertility preservation, neoadjuvant chemotherapy (NACT) followed by CKC can be attempted. A

prospective study by De Vincenzo et al[115] showed that of the 13 patients with initially stage IB2 to IIA1 larger than 2 cm, 11 (85%) were able to undergo CKC, 1 had stable disease and underwent radical surgery, and 1 had progressive disease and eventually died of disease. Of those undergoing CKC, four needed LEEP and one had an RH due to involved margins with SIL and invasive disease, whereas one developed distant recurrence on follow-up. Only three patients eventually tried to conceive with two succeeding spontaneously.

Radical Trachelectomy
