PART L

Soft Tissue

CHAPTER 89

Soft Tissue Sarcoma (Excluding Retroperitoneum)

Kilian E. Salerno and Elizabeth H. Baldini

INCIDENCE

Soft tissue sarcomas (STSs) comprise a heterogeneous group of rare malignancies that vary extensively by anatomic location, histology, and biologic behavior. They can occur at any anatomic site and may arise from many soft tissues including connective tissues, fat, muscle, vascular tissue, peripheral neural tissue, or visceral tissue. Annually, there are about 13,400 expected new cases of STS in the United States, and this accounts for approximately 0.7% of all new cancer diagnoses.[1] The median age at diagnosis for all STSs is 65 years, but incidence varies by histologic subtype.[2] For example, embryonal rhabdomyosarcoma is common in children; synovial sarcoma occurs mostly in young adults; and undifferentiated pleomorphic sarcoma, liposarcoma, and leiomyosarcoma are seen mostly in older adults.

ETIOLOGY AND GENETICS

For the great majority of STS, there is no known etiology. A minority of cases can be attributed to environmental or genetic factors.[2] Associated environmental factors include radiation exposure; chemical exposures, such as vinyl chloride, dioxin, arsenical pesticides, and phenoxy herbicides; immunosuppression; lymphedema (Stewart-Treves syndrome); and viruses (human immunodeficiency virus, human herpes virus type 8). Certain

clinical syndromes are associated with a genetic predisposition for the development of sarcoma. A few examples include Li-Fraumeni syndrome and Werner syndrome, which are associated with the development of STS as well as other malignancies; neurofibromatosis type 1, which is associated with the development of malignant peripheral nerve sheath tumors (MPNSTs); and familial adenomatous polyposis (Gardner syndrome), which is associated with the development of abdominal desmoid tumors.

HISTOLOGIC CLASSIFICATION

The World Health Organization divides soft tissue tumors into four categories reflecting biologic potential: benign; intermediate, locally aggressive (eg, desmoid fibromatosis); intermediate, rarely metastasizing (eg, plexiform fibrohistiocytic tumor); and malignant. These include adipocytic, fibroblastic/myofibroblastic, so-called fibrohistiocytic, vascular, pericytic (perivascular), smooth muscle, skeletal muscle, chondro- osseous, peripheral nerve sheath tumors, and those of uncertain differentiation. There are more than 50 histologic subtypes of STS. The most common subtypes include undifferentiated pleomorphic sarcoma, liposarcoma, leiomyosarcoma, myxofibrosarcoma, synovial sarcoma, and MPNST. Together, these account for about 75% of STS cases.[2] Histologic diagnosis is determined largely by tumor cell morphology. Immunohistochemical staining, cytogenetics, and molecular genetic testing can help refine the diagnosis in many cases. Increasingly, several of the histologic subtypes have characteristic chromosome translocations and gene rearrangements. Some of these characteristic translocations include Ewing sarcoma, t(11,22); synovial sarcoma, t(X,18); myxoid liposarcoma, t(12,16); and clear cell sarcoma, t(12,22).[2]

There are several grading systems. The two most widely used are the U.S. National Cancer Institute (NCI) and the French Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) grading systems, both of which employ a three-tiered system of low, intermediate, and high grade based on mitotic activity, necrosis, and differentiation.[3,4] The College of American Pathologists prefers the FNCLCC system as it is easier to use, more reproducible, and may be a better predictor of prognosis.[5] Lastly, there are certain STS subtypes for which grading is not applicable and less

informative than histopathologic subtypes, including rhabdomyosarcoma, alveolar soft part sarcoma, clear cell sarcoma, Ewing sarcoma, and epithelioid sarcoma.[2]

Given the rarity of STS as well as the numerous histologic subtypes, it is very important to submit diagnostic slides for review by an experienced sarcoma pathologist for confirmation of diagnosis and grade prior to embarking on treatment.[6-8]

NATURAL HISTORY

STS can occur anywhere in the body. The most common site of presentation is an extremity, specifically, the thigh. The approximate distribution of STS sites at presentation is extremity, 50% to 60% (lower extremity, 40%-45%, upper extremity, 10%-15%); trunk, 15% to 20%; retroperitoneum, 10% to 15%; and head and neck, 5% to 10%.[9,10] This chapter will primarily address truncal and extremity STS. Retroperitoneal sarcoma is covered in Chapters 82. STSs arising from other anatomic sites (eg, head and neck, breast, thorax, abdomen) are less common and not directly addressed here.

Interestingly, certain histologic subtypes have predilections for specific sites. For example, angiosarcoma commonly occurs in the head and neck, desmoid tumors frequently occur in the abdomen associated with Gardner syndrome, and epithelioid carcinoma often involves the hand or forearm.[11-13]

In the classic reports by Simon and Enneking and Enneking et al, the local behavior of STS is well described.[14,15] STS tends to spread longitudinally along musculoaponeurotic planes. Depending on the location, these planes may be diagonal as in the gluteal or superficial truncal musculature, rather than craniocaudal. These tumors infrequently transgress fascial boundaries and rarely invade bone. As the sarcoma grows, it compresses surrounding normal tissue to form a pseudocapsule, which contains a compression zone and a reactive zone. The latter comprises edema, inflammatory cells, and tumor cells. Furthermore, Simon and Enneking have shown that microscopic tumor cells perforate through and extend beyond the pseudocapsule.[14]

Unlike most solid tumors, STSs rarely spread to lymph nodes. Three series, each with more than 1,000 consecutive patients with STS, cited only 1.8% to 3.7% lymph node involvement at the time of initial presentation.[16-

[18] However, there are a few histologic subtypes for which lymph node involvement is more common. Notable lymph node involvement rates have been demonstrated for *C*lear cell sarcoma (10%-18%), cutaneous *A*ngiosarcoma (10%-15%), *R*habdomyosarcoma (20%-25%), and *E*pithelioid sarcoma (20%-35%); these histologic subtypes can be remembered by the mnemonic "*CARE*."[13,17-21] Synovial sarcoma is no longer considered to have a greater propensity for lymph node involvement.[22-24]

The American College of Surgeons' Patterns of Care Study for adult STS showed that 23% of patients had metastatic disease at presentation.[9] The single most frequent site of distant metastasis (34%) was the lung; bone, liver, and brain involvement were less common. Furthermore, as was the case for lymph node spread, certain histologic subtypes exhibit distinct patterns of recurrence and distant metastatic spread. Knowledge of these unique natural histories informs the appropriate imaging that should be done for staging evaluation. For example, myxoid liposarcoma has a predilection for spread to the retroperitoneum, other extrapulmonary soft tissue sites, and bone, including the spine. Among reported recurrences, about 50% occur in the retroperitoneum, 20% in other extrapulmonary soft tissue, and 15% to 17% in bone.[25,26] For retroperitoneal STS, the most common site of recurrence is locally in the retroperitoneum.[27] These tumors also have a predilection for spreading to the liver as well as the lung.[27] Epithelioid sarcoma can present with skip metastases involving discontiguous locations in a limb as well as lymph node involvement.[2,13,19] Lastly, myxofibrosarcoma exhibits an infiltrative growth pattern and is associated with higher rates of positive resection margins and local recurrence (LR) compared to other STS histologic subtypes; conversely, the rate of distant recurrence to the lung is lower than for other STS types.[2,28-31]

INITIAL EVALUATION

Most STS cases present as a painless mass. When taking a history, one should ask how long the mass has been present, if it has changed in size and at what rate, and if there are any associated local or systemic symptoms. It is also important to ask about potential risk factors for STS, including a history of radiation exposure or a family history of malignancies including STS. On physical examination, one should assess the mass for

characteristics such as size, depth, fixation to underlying structures, the presence of overlying skin changes, and potential evidence of neurovascular compromise. On the general examination, one should also note if there are any stigmata of neurofibromatosis, such as neurofibromas or café au lait spots (as there is an association between neurofibromatosis type I and MPNST).[2]

When STS is suspected, evaluation should include imaging of the primary site prior to biopsy or surgical resection. For STS of the extremity, trunk, or head and neck, evaluation of the primary tumor with a magnetic resonance imaging (MRI) scan is generally preferred to computed tomography (CT) scanning.[32,33] The T1-weighted images of the MRI scan provide an excellent definition of the anatomic relation between the tumor and adjacent structures. T2-weighted images demonstrate the tumor and any associated edema. As peritumoral edema can contain malignant cells, it is important to identify this for both radiation and surgical planning.[34]

Figure 89.1 depicts a case of synovial sarcoma of the left gluteus medius muscle. The mass is difficult to discern on CT imaging (Figure 89.1A) but very clearly delineated on MRI (Figure 89.1B). Figure 89.2 is a second comparative example of CT and MRI and shows a leiomyosarcoma of the proximal anterior thigh. Although the differences between the imaging modalities are not as pronounced as in Figure 89.1, the MRI again provides superior information compared to the CT scan. The MRI demonstrates probable arterial wall invasion, fascial enhancement of the vastus medialis muscle, and definition of tumor spiculations into the adjacent fat and along the biopsy tract.

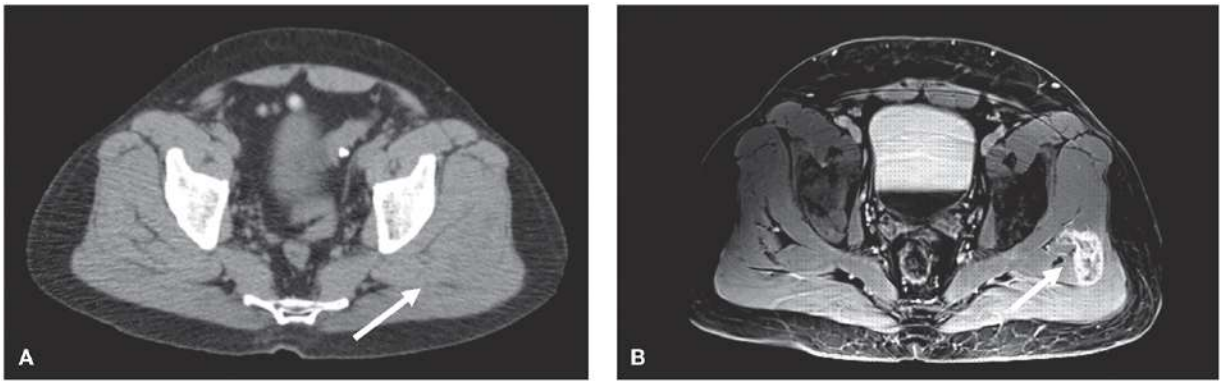

FIGURE 89.1 Comparison of computed tomography (CT) and magnetic resonance imaging (MRI) axial slices for a synovial sarcoma of the left gluteus medius muscle in a 56-year-old man. A. The CT axial slice shows a vaguely defined soft tissue mass in the left gluteus medius muscle. B. The anatomic definition of the soft tissue sarcoma is seen much more clearly on the corresponding T1 post-gadolinium axial slice of the MRI.

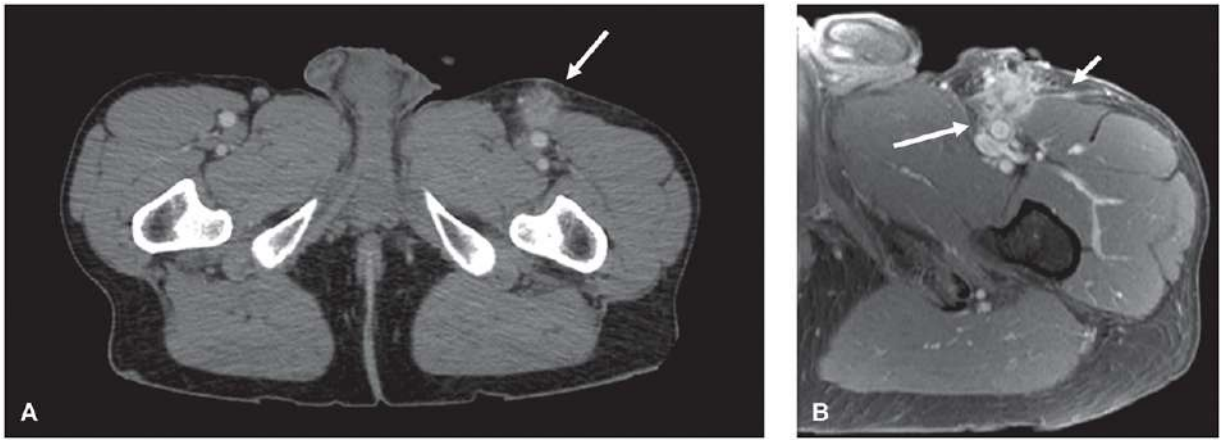

FIGURE 89.2 Comparison of computed tomography (CT) and magnetic resonance imaging (MRI) axial slices for a high-grade leiomyosarcoma of the proximal anterior thigh in a 53-year-old man. A. The CT axial slice shows a soft tissue mass in the left anterior upper thigh anterior to the superficial femoral artery and vein. B. The T1 post-gadolinium image of the MRI at the same level provides superior resolution compared to the CT. It shows a loss of fat plane between the mass and the superficial femoral artery suggestive of arterial invasion (long arrow), linear fascial enhancement overlying the vastus medialis muscle (short arrow), and tumor spiculations into adjacent subcutaneous fat and to the skin along the biopsy tract.

Diagnosis of STSs requires pathologic confirmation. Image-guided core biopsy is the preferred diagnostic approach as it is accurate, safe, and allows for directed sampling of multiple sites within the mass. Image-guided core biopsies are expeditious and do not cause a delay in time to initiation of the next therapy.[35] Incisional biopsies are accurate and

acceptable, but more invasive than core biopsy and often no longer necessary. If utilized, incisional biopsies must be appropriately oriented and should ideally be performed by the surgical or orthopedic oncologist who will be involved in the subsequent oncologic resection.[36] Tumor cells can potentially seed an incision, thereby necessitating the removal of skin incisions at the time of surgical resection. It is important that the biopsy approach does not transgress an uninvolved compartment or joint, as this would create a situation where a much more radical resection would need to be performed. Consequences of inappropriately placed incisional biopsies can be significant and include the need to perform more complex operations, with the potential for subsequent loss of function, LR, and death[36] (Figure 89.3). Excisional biopsies and marginal excisions are not recommended, as they do not provide adequate sarcoma margins and may similarly complicate subsequent oncologic resection. Fine needle aspirations can confirm malignancy for recurrent disease but typically do not yield enough tissue to establish an initial diagnosis.

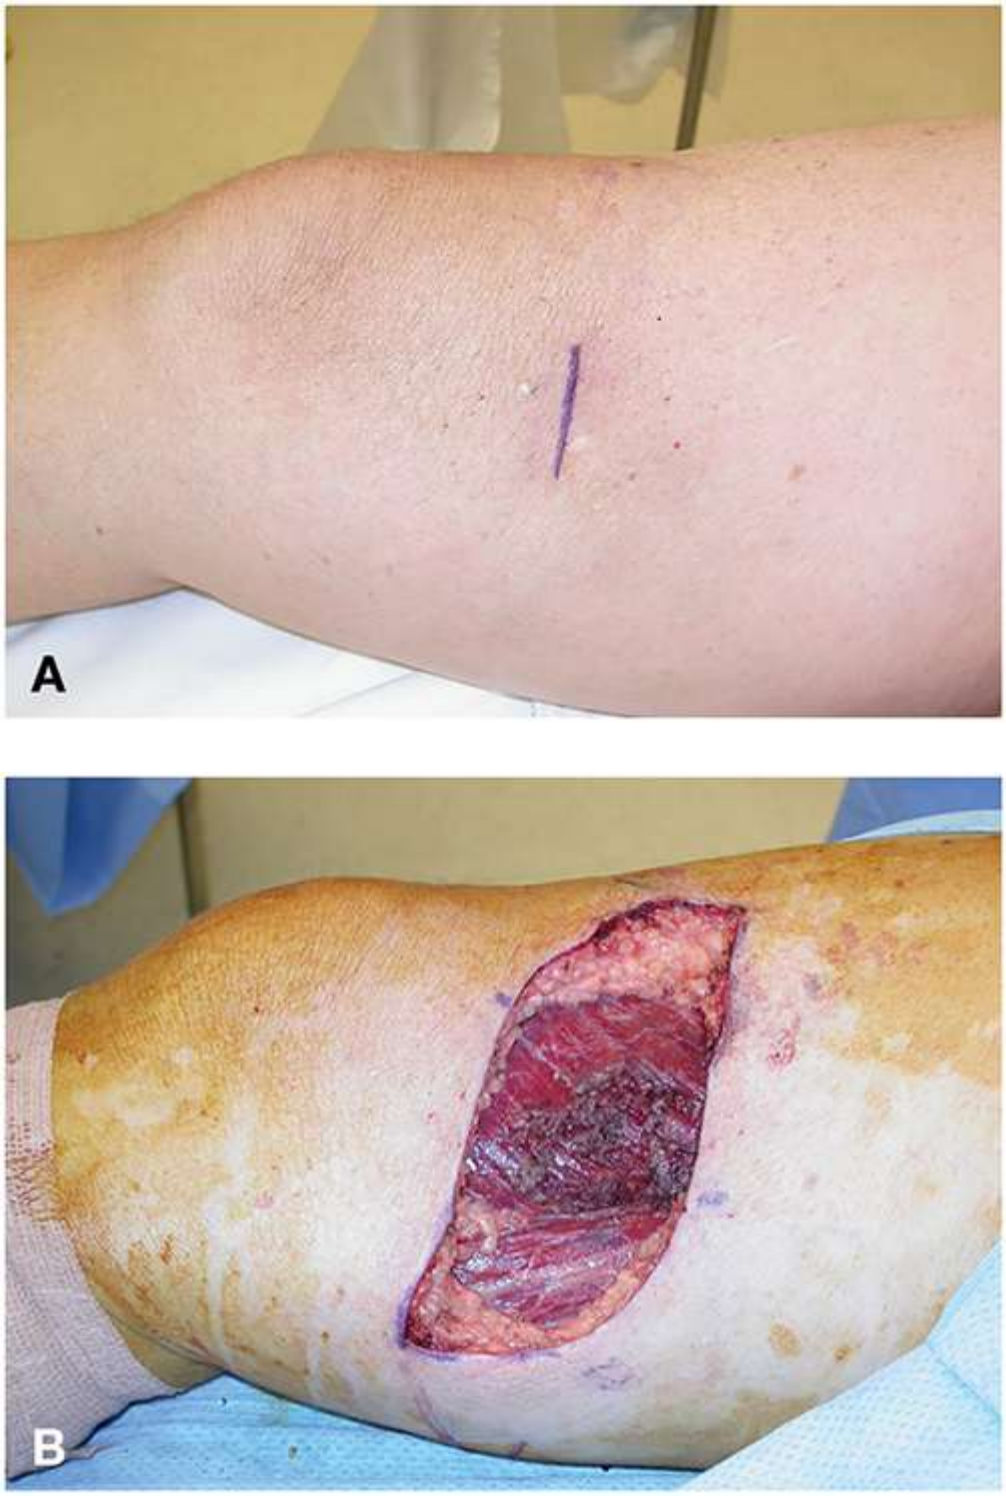

FIGURE 89.3 Images demonstrating consequences of a maloriented transverse incision from an unplanned excision. A. The purple marker overlies the prior incision. B. Extent of subsequent oncologic resection necessary to excise the prior incision. Had the initial incision been oriented longitudinally, the subsequent resection would have been smaller and less complex.

After pathologic confirmation of STS and determination of histopathologic subtype and grade, additional staging evaluation and appropriate imaging can be performed based on the risks for local, regional, and distant metastatic spread. Given the general predilection of STS for hematogenous spread to the lungs, chest imaging is most commonly performed. Chest CT scan is recommended to rule out pulmonary metastases for all cases except low-grade tumors or small (<5 cm) high-grade lesions, and even in these latter cases, it can be helpful to obtain a baseline chest CT at diagnosis. Additional site-directed staging imaging should be tailored to the unique natural history of the specific subtype. For example, given that myxoid liposarcoma has a predilection for spread to bone and soft tissue, MRI of the spine and CT of the abdomen and pelvis are recommended as part of the initial evaluation for high-risk patients with this histologic subtype.[25,26,37] Currently, there is no clearly defined role for the routine use of positron emission tomography (PET) as part of the diagnostic evaluation.[38] However, PET scanning may have potential utility to help distinguish MPNSTs from benign neurofibromas in patients with neurofibromatosis.[39,40] PET can be used to assess response to neoadjuvant chemotherapy and selectively in the evaluation of histopathologic subtypes with increased propensity for lymph node involvement (eg, epithelioid sarcoma).[41]

STAGING

In 2017, the American Joint Committee on Cancer (AJCC) published the 8th edition of the TNMG (tumor, node, metastasis, grade) staging system for STS.[37] There are several changes compared to the prior edition. Given the importance of the anatomic site, there are separate staging systems for STS involving the extremity and trunk, retroperitoneum, head and neck, and visceral sites.

In the staging system for STS of the extremity and trunk, grade, tumor size, lymph node, and distant organ involvement all remain important elements. There are now four T size categories: T1 less than or equal to 5 cm, T2 greater than 5 to 10 cm, T3 greater than 10 to 15 cm, and T4 greater than 15 cm, and tumor depth (superficial or deep to fascia) has been removed. Regional nodal involvement (N1) has moved and is now

considered stage IV. Histologic subtype is still not included as a category. The 8th edition AJCC extremity and trunk STS stage groupings are shown in Table 89.1.

TABLE 89.1 AMERICAN JOINT COMMITTEE ON CANCER TNMG STAGE GROUPINGS FOR EXTREMITY AND TRUNK SOFT TISSUE SARCOMA, 8*T*H EDITION

Stage IA	**G1,X**	**T1**	**N0**	**M0**	**Low grade, small**
Stage IB	G1,X	T2-4	N0	M0	Low grade, large
Stage II	G2,3	T1	N0	M0	Moderate/high grade, small
Stage IIIA	G2,3	T2	N0	M0	Moderate/high grade, intermediate
Stage IIIB	G2,3	T3-4	N0	M0	Moderate/high grade, large
Stage IV	Any grade	Any T	N1	M0	Nodal involvement
	Any grade	Any T	Any N	M1	Metastatic

G, grade; GX, grade cannot be assessed; M0, no distant metastasis; M1, distant metastasis; LN, lymph node; N0, no regional LN metastasis; N1, regional LN metastasis; T1, tumor ≤5 cm; T2, tumor >5-10 cm; T3, tumor >10-15 cm; T4, tumor >15 cm.

PROGNOSTIC FACTORS FOR SURVIVAL AND LOCAL RECURRENCE

Many reports have evaluated patient and tumor characteristics to determine prognostic factors for disease-free survival (DFS) or overall survival (OS) and LR. The most powerful predictor for DFS and OS is the AJCC TNMG stage of the tumor. The staging system incorporates most of the relevant prognostic variables. It is also valuable to consider predictive factors individually. The single most important individual prognostic factor for distant metastatic risk and lower survival rates is high grade.[42-47] Five-year DFS rates range from 44% to 67% for high-grade tumors compared to 90% to 100% for low-grade tumors.[42-44] Other significant predictors for DFS include tumor size and anatomic site.[37,42,44-47] For a series of 1,091 patients from MD Anderson Cancer Center, 5-year OS rates were 85% for tumors less than or equal to 5 cm, 68% for tumors greater than 5 to 15 cm, and 52% for tumors greater than 15 cm.[46] Furthermore, patients with tumors located

in the head and neck or retroperitoneum had lower survival rates than those with tumors located in the extremity or superficial trunk.[43,47,48] Histologic subtype is predictive of both OS and DFS in several reports.[42,45,46,48,49] Callegaro et al developed two robust nomograms to predict OS and DFS for extremity STS and demonstrated adverse survivals for vascular tumors, leiomyosarcoma, synovial sarcoma, and MPNST compared to all liposarcoma subtypes, myxofibrosarcoma, and undifferentiated pleomorphic sarcoma.[45] It now appears that tumor depth (superficial or deep to fascia) is not a prognostic factor, and accordingly, depth has been removed from the staging system.[37,45,47,50] Older age at presentation, positive resection margins, bone or neurovascular invasion, gender, and race all show mixed results regarding their predictive value for DFS.[42-48] Lymph node involvement for STS is rare; but if present, it is an adverse prognostic factor.[16-18]

Margin status is the most significant predictor for LR.[42,43] Other predictors for LR include presentation with locally recurrent disease, older age, tumor size, and head and neck or retroperitoneal location. Rates of LR for tumors resected with positive margins range from 28% to 56% compared to 0% to 20% for those with negative margins.[31,42,43,51-56] Patients who present with locally recurrent disease are at higher risk for subsequent LR (25%-47%) than those who present with primary disease (11%-21%).[42,52] Age has been analyzed with varying cut-off values including older than 50 years, older than 64 years, and as a continuous variable. Repeatedly, older age has been associated with higher LR rates.[42,43,57] The influence of tumor size and anatomic site on LR risk may reflect challenges in obtaining widely negative margins.[43,58]

MANAGEMENT AND OUTCOMES OF SOFT TISSUE SARCOMAS OF EXTREMITY AND TRUNK

Because of the rarity of STS and the numerous forms in which it can present with respect to tumor histology, anatomic site, and size, there are many nuances related to optimal management. Furthermore, delivery of treatment requires a multimodality team that includes experienced pathologists; radiologists; surgeons from the disciplines of surgical oncology, orthopedics, and reconstructive surgery; radiation oncologists;

medical oncologists; nurses; physical therapists; and social workers. Treatment goals include complete eradication of tumor with optimal function preservation and minimal treatment-related toxicities. Execution of these goals is complex, and, for this reason, STS is best treated by experienced multidisciplinary teams at specialized sarcoma centers.[10,59,60] Reports from Sweden, the United Kingdom, the United States, and Canada have shown superior outcomes, including higher rates of limb-sparing resections and survival, for STS treated at specialized centers and those with higher volumes of patients.[61-66]

SURGERY

In almost all cases, appropriate surgical resection is a prerequisite for curative treatment of STS. A range of surgical procedures has been employed for the treatment of STS with varying levels of success. These procedures include marginal resection or excisional biopsy, wide resection, and radical resection or amputation. A marginal resection refers to the simple removal of the tumor with its pseudocapsule. This is also often described as a "shell-out" or "whoops" procedure and is commonly performed when the diagnosis of STS is not suspected. LR rates after marginal resection range from 50% to 93%.[15,67,68] This is not surprising, as it is known that microscopic tumor cells can extend beyond the pseudocapsule and up to several centimeters beyond the palpable gross tumor.[14,34] Marginal resection is not an appropriate oncologic treatment for STS.

At the other end of the spectrum is radical resection, which involves removal of all of the muscles and neurovascular structures within the compartment where the tumor resides, or amputation. Reported LR rates after radical resection are much lower, ranging from 0% to 18%, but come at the cost of significant functional loss.[15,53,67,68] Historically, amputation was a common procedure for STS of the extremities; however, it is rarely required for local management of STS in the modern era. In approximately 5% of patients, amputation may still be indicated for appropriate oncologic management, including in those for whom no limb-sparing approach is feasible. This may be due to patient-related comorbidities or disease extent

including involvement of bone, joint, multiple compartments, or major arteries or nerves.[69]

The intermediate procedure is a wide resection. Wide resection is also described as conservative surgery, limb-sparing surgery, or function-sparing surgery. It involves *en bloc* removal of tumor with a desired rim of normal tissue varying in width from about 1 cm to several centimeters depending on anatomic constraints. Wide resection preserves good function (limb-sparing) but as a treatment by itself is usually associated with moderately high LR rates, ranging from 25% to 60%.[15,67,68,70] Radiation therapy (RT) is combined with wide resection for most patients with STS to improve local control. Surgeons should attempt to obtain oncologically appropriate negative margins at the time of definitive resection. The presence of positive margins is consistently associated with increased LR rates, even when RT is used.[42,43,51-56,71] The appropriate margin attained should be tailored to both the anatomic site and surrounding tissues and the histopathologic subtype. For example, myxofibrosarcoma and MPNST are highly infiltrative, often extending beyond the imaging-visible tumor, and associated with increased risk for LR.[29,72,73]

Although the goal of resection is to attain wide negative margins, if this would require debilitating surgery, such as resection of a nerve, vessel, or bone, a function-sparing approach with a planned positive margin is acceptable.[54] These decisions are best handled by experienced sarcoma surgeons with input from radiation oncologists regarding the addition of RT. Gerrand et al evaluated LR rates in patients who had positive margins after limb-sparing surgeries and received RT. Those with planned positive margins (abutting critical structures) had a 4% LR rate compared to a 32% to 38% rate of LR in those with unplanned (unexpected) positive margins.[54] Given the increased risk for LR in the setting of unplanned or grossly positive margins, re-resection should be considered to obtain negative margins if feasible.[74,75]

In contrast, there are some exceptions for the general indication for re-resection to obtain wide negative margins. These include following microscopic positive margin resection of atypical lipomatous tumors (formerly well-differentiated liposarcoma) involving the extremity and desmoid tumors for which observation may be appropriate in selected

patients when salvage surgical options are available for recurrence if needed.[76-82]

Because STS is rare in comparison to benign soft tissue lesions, the initial procedure performed for an unsuspected is often an unplanned excision. Close or positive margins are frequent, as these procedures do not attempt to obtain wide margins. As these unplanned excisions continue to occur frequently, it is important to have a level of suspicion for STS when evaluating soft tissue masses, particularly those that are new and growing. Following an unplanned excision, definitive oncologic re-excision is recommended, if possible, as the likelihood of finding residual disease is significant, on the order of 24% to 83%.[75,83-90] As part of the re-resection, incisions, biopsy tracts, drain sites, and any tissues contaminated by the first surgery need to be removed *en bloc* along with appropriate tumor-bed margins. Unfortunately, re-resection often results in a greater scope of surgery and increased functional deficit than would otherwise have been required had the diagnosis of STS been anticipated and the initial planned excision had been performed by an experienced oncologic surgeon.[36] When there are indications for RT, it may be delivered "preoperatively" prior to the definitive oncologic resection, and when re-resection is not feasible, "postoperatively" following the unplanned excision.[75] Although RT is typically recommended for most large and high-grade STS of the extremity, superficial trunk, and head and neck locations in the setting of unplanned excision with gross macroscopic negative margins, some centers have selectively considered observation with the use of RT and delayed resection at recurrence, particularly when there would be an increased risk for morbidity with reexcision.[91]

Conservative Surgery and Radiation Therapy

Three sentinel randomized trials have been performed and established RT combined with conservative surgery as the standard management for most (high grade) STS of the extremities and trunk (Table 89.2). The first of these trials was conducted at the NCI.[53] Patients with high-grade STS of the extremity were randomized to amputation or wide resection and postoperative external-beam RT (60-70 Gy). Patients in both treatment arms received chemotherapy. LR rates were 0% (0 of 16) and 15% (4 of 27) for

patients treated with amputation and with wide resection and RT, respectively ($P = .06$). There was no significant difference in survival rates. The NCI I trial was instrumental in establishing the new standard for limb-sparing local management of STS. Amputations are now performed sparingly and in less than 15% of cases.[69,92,93]

TABLE 89.2 RANDOMIZED CONTROLLED TRIALS INCLUDING RADIATION THERAPY FOR SOFT TISSUE SARCOMAS OF THE EXTREMITIES AND TRUNK

Study	Treatment Arms	Local Recurrence	OS or DFS
Rosenberg et al[53] NCI 1982 *N* = 43 (Extremity)	Amputation vs CS + EBRT (60-70 Gy) (both arms received doxorubicin, cyclophosphamide, and methotrexate)	0% (0/16) 15% (4/27) *P* = .06	88% 83% *P* = .99 (5-y OS)
Pisters et al[71] MSKCC 1996 *N* = 164 (Extremity + trunk)	High grade (*n* = 119) CS vs CS + BRT (42-45 Gy) Low grade (*n* = 45) CS vs CS + BRT (42-45 Gy)	30% (19/63) 9% (5/56) *P* = .0025 26% (6/23) 36% (8/22) *P* = .49	All patients 81% 84% *P* = .65 (5-y DFS)
Yang et al[70] NCI 1998 *N* = 141 (Extremity)	High grade (*n* = 91) CS vs CS + EBRT (63 Gy) (both arms received doxorubicin, and cyclophosphamide) Low grade (*n* = 50) CS vs CS + EBRT (63 Gy)	19% (9/47) 0% (0/44) *P* = .003 33% (8/24) 4% (1/26) *P* = .016	74% 75% *P* = .71 (10-y OS) 92% (22/24) 92% (24/26) (no. alive)
O'Sullivan et al[96,105] NCIC 2004 *N* = 190 (Extremity)	Preop RT (50 Gy) + CS CS + postop RT (66 Gy)	7% 8% *P* = NS (5-y LR)	73% 67% *P* = .48 (5-y OS)

BRT, brachytherapy; CS, conservative (limb-sparing) surgery; DFS, disease-free survival; EBRT, external-beam radiation therapy; MSKCC, Memorial Sloan-Kettering Cancer Center; NCI, National Cancer Institute; NCIC, National Cancer Institute Canada; OS, overall survival; postop, postoperative; preop, preoperative.

With the role of wide resection instead of amputation established, the next question posed was whether adjuvant RT is necessary following conservative surgery. The NCI II study randomized patients with low- and high-grade STS of the extremity to conservative surgery with or without postoperative external-beam RT (63 Gy).[70] Patients with high-grade STS also received adjuvant chemotherapy. LR rates for the high-grade tumors were 20% (9 of 44) for wide resection with chemotherapy compared to 0% (0 of 47) for wide resection, chemotherapy, and RT (P = .003). For the low-grade tumors, LR rates were 33% (8 of 24) for wide resection alone and 4% (1 of 26) for wide resection and RT (P = .016). There were no significant differences in survival rates between the two groups. An update of this trial confirmed the lack of survival difference with a 20-year OS of 64% for wide resection alone and 71% for wide resection and RT (P = .22).[94]

The other hallmark trial showing improved local control with the addition of RT to conservative surgery was conducted at Memorial Sloan-Kettering Cancer Center (MSKCC).[71] Similar to NCI II, this trial randomized patients between wide resection alone and wide resection plus RT; however, the RT was adjuvant brachytherapy (BRT) rather than external-beam RT. BRT was delivered using an Iridium-192 implant via catheters placed in the tumor bed in a parallel array. A dose of 42 to 45 Gy was delivered over 4 to 6 days. LR rates for high-grade tumors were 30% (19 of 63) for wide resection alone compared with 9% (5 of 56) for wide resection plus BRT (P = .0025). No difference in LR rates by treatment was seen for low-grade tumors; rates were 26% (6 of 23) and 36% (8 of 22) for patients treated with wide resection alone and wide resection plus BRT, respectively. As in the NCI trials, there were no significant differences in survival outcomes.

These randomized trials established the role of RT combined with conservative surgery for the management of high-grade (and, in select cases, low-grade) STS.[53,70,71] In modern series, local control following wide resection and RT is excellent, with most reported LR rates being less than 15%.[52,56,95-99] Current treatment recommendations for the use of RT with conservative surgery require an assessment of risk for LR.[75] For STS at increased risk for recurrence (eg, tumors that are large, high grade, or associated with expected close or positive resection margins), combined

modality therapy with wide resection and RT is recommended for local control.[75]

Conservative Surgery Alone

Although conservative surgery and RT is the standard treatment for most STS of the extremity and trunk, there are several reports that demonstrate excellent outcomes following treatment with surgery alone. It is important to acknowledge that these are single-institution or large population-based series, all but one are retrospective, and patients were highly selected for treatment. LR rates in these studies range from 0% to 20%, most are 10% or lower.[100-104] In the prospective trial of surgery alone, negative resection margins were a required criterion and LR was 10.6% at 10 years.[101] In another series of patients treated with surgery alone, the overall 10-year actuarial LR rate was 7%. No LRs were seen with resection margins greater than or equal to 1 cm compared to an LR rate of 13% for those with margins less than 1 cm ($P = .04$).[100]

Other than for low-grade tumors resected with negative margins, treatment with surgery alone should be employed cautiously. Additional characteristics of tumors considered for treatment with surgery alone often include primary presentation of disease (not locally recurrent), low-grade, small, subcutaneous, superficial to fascia, or completely intramuscular that can be resected with wide margins, tumor locations amenable to limb-sparing salvage surgery for recurrence, and patient willingness to comply with appropriate follow-up.[100,101,104] Relative indications for RT in the setting of low-grade tumors include positive margins, locally recurrent disease following prior wide excision, and tumor location that would not be amenable to subsequent salvage surgery.

In sum, for select patients with STS of the extremity or trunk at low risk for recurrence, omission of RT and management with wide resection alone is reasonable.[75] A postoperative nomogram can be used to help predict the risk for LR following wide excision without RT.[103] Risk factors for LR included in the nomogram were age, tumor size, grade, histology, and margin status.

RADIATION THERAPY

Radiation Timing: Preoperative Versus Postoperative

The foundational studies that established the role of RT in addition to conservative surgery to improve local control, RT (either external-beam or BRT) was delivered postoperatively.[53,70,71] The role of preoperative RT was investigated in the National Cancer Institute Canada (NCIC) SR2 trial.[96,105] Patients were randomized to receive either preoperative RT (50 Gy preoperative ± 16 to 20 Gy postoperative boost) or postoperative RT (50 Gy + 16 to 20 Gy boost to the tumor bed) with limb-sparing resection. Local control at 5 years was the same with either sequence of therapies, 93% and 92% for the preoperative and postoperative groups, respectively, with no difference in survival.[96] The primary endpoint of the NCIC SR2 trial was major wound complication within 120 days of resection, defined as secondary operation for wound repair or other wound management, including readmission for care, antibiotics, or deep packing. With a median follow-up time of 3.3 years, the study met early stopping rules and closed. Wound complication rates were 35% for patients treated with preoperative RT compared to 17% for those treated with postoperative RT ($P = .01$). On multivariate analysis, other predictors for increased risk of wound complications included lower-extremity site and large tumor size (>10 cm). Although wound complications adversely affected functional outcome for patients in the early postoperative period (6 weeks after surgery), this toxicity was largely reversible, as evidenced by the fact that function was equivalent between the treatment arms 1 year after resection.[106,107] The Musculoskeletal Tumor Society Rating Scale (MSTS) and the Toronto Extremity Salvage Score (TESS) were used to assess late toxicity and functional status. Rates of greater than or equal to grade 2 late toxicity were higher for the postoperative RT group than the preoperative group: subcutaneous fibrosis, 48% versus 31.5%; joint stiffness, 23% versus 18%; and edema, 23% versus 15.5%. These differences were not statistically significant, but the study was not powered to detect these differences. The presence of late toxicities predicted lower functional status ($P < .01$). Statistically significant associations were seen between field size (greater with postoperative RT) and rates of fibrosis, joint stiffness, and edema ($P = .002$, $P = .006$, and $P = .06$, respectively).[106]

Although the efficacy of these approaches seems to be similar, the toxicity profiles are clearly different. Preoperative RT is associated with a well-established increased risk of acute wound complications.[105] On the other hand, patients treated with postoperative RT have a higher rate of chronic and generally irreversible toxicities, which include subcutaneous fibrosis, joint stiffness, and edema.[106] An additional late toxicity of significant concern is the risk of radiation-associated pathologic fracture. This occurs more commonly in weight-bearing long bones of the lower extremity and can lead to nonunion and significant morbidity.[94,108,109] Many series have reported increased rates of bone fracture for patients treated postoperatively (60-66 Gy) compared to those treated preoperatively (50 Gy).[94,108-113] Other risk factors for fracture include total RT dose, circumferential bone dose and other dose-volume parameters, RT treatment technique, age, female sex, receipt of chemotherapy, tumor anatomic site and size, and extent of periosteal stripping at time of resection.[108,109,112,113]

Advantages of preoperative RT include the ability to treat with smaller RT fields and lower doses, both of which are associated with reduced permanent long-term toxicities. Lower RT doses are also associated with reduced treatment time, lower costs, and a hypothetical possibility of lower second-malignancy risks. Other potential advantages of preoperative RT include the ability to render unresectable or marginally resectable tumors operable, the potential to prevent tumor seeding of the operative bed or systemic circulation, and an increased efficacy of RT from good oxygenation of tissues due to unperturbed tumor vasculature. Furthermore, in most cases, defining the tumor volume for RT planning is relatively straightforward, given that it is in situ. The main disadvantage of preoperative RT is the higher risk of major wound complications and its concomitant increased morbidity and cost. However, most major wound complications are treatable and, therefore, this toxicity is generally considered reversible. Another disadvantage of preoperative RT is that the resected specimen is potentially less informative on pathology review due to the prior treatment.

Postoperative RT has the advantage that the complete tumor specimen is available for pathology review for determination of histology and margin status. Another important advantage is the lower risk of major wound complications. The main disadvantages of postoperative RT are the

necessity for larger treatment volumes and higher doses, which are associated with higher long-term toxicities such as subcutaneous fibrosis, joint stiffness, edema, pain, and bone fracture. For the most part, these toxicities are irreversible. In theory, the interrupted vasculature related to surgery may create a hypoxic environment, rendering RT less effective (this is a potential explanation for the need for higher doses compared to the preoperative setting). Lastly, determining an RT target definition is more complex in the postoperative setting, as it requires reconstruction of where the tumor resided as well as the definition of the entire operative field.

In conclusion, pre- and postoperative RT are associated with equivalent efficacies but different toxicity profiles, the most salient of which are increased (reversible) wound complications for preoperative RT and increased (irreversible) long-term toxicities of fibrosis, edema, joint stiffness, and fracture for postoperative RT. The sequence of RT and conservative surgery for an individual patient should be determined with multidisciplinary input and coordination, considering the risks for acute and late toxicities. In general, when RT is indicated for local control in combination with wide resection, preoperative RT is preferred over postoperative RT for STS of the extremities or trunk.[75] In select patient circumstances, the risks for major acute wound complications may supersede those of late effects and postoperative RT may be appropriate.[75] Even when a patient is at high risk of developing a wound complication, one could argue for preoperative RT, as most wound problems are highly treatable with eventual recovery of good function. In cases where there was no clear initial indication for RT and upfront surgery was performed, postoperative RT is indicated for adverse pathologic features associated with increased risk for recurrence (eg, unanticipated close or positive margins, higher grade, nodal involvement, or discontinuous spread).[75]

Radiation Therapy Dose and Fractionation

Preoperative Dose

The foundational randomized clinical trials defining the role of external-beam RT with conservative surgery for extremity and truncal STS have used conventional fractionation, which remains the standard at this time.[53,70,105] The preferred dose for preoperative external-beam RT is 50 Gy

delivered in 2 Gy fractions.[75,114] Although concurrent or interdigitated sensitizing chemotherapy combined with preoperative RT is not considered standard of care, if utilized, the RT total dose and dose per fraction may be reduced (44-50.4 Gy in 22-28 fractions).[115,116]

Postoperative Boost for Positive Margins

When positive margins occur following preoperative RT and conservative surgery, the site and type of margin (anticipated or unplanned) and options for subsequent management should be discussed in a multidisciplinary setting. If feasible without significant morbidity, re-resection to achieve negative margins should be performed. If further resection is not feasible, the potential role of a postoperative external-beam RT boost of 16 to 20 Gy (delivered in 1.8-2 Gy fractions) may be considered. However, the efficacy of such a boost dose has not been proven and, as it may be associated with increased toxicity, it is not routinely recommended.[117,118] Selective situations where a postoperative RT boost may be reasonable include those with positive margins at high risk for recurrence, where the site of the positive margin can be clearly delineated for treatment planning, and the additional dose would not confer untoward morbidity.[58,75,105,119] Other techniques to deliver an additional boost dose include BRT and intraoperative RT.

Postoperative Dose

For postoperative external-beam RT, treatment usually commences about 4 to 6 weeks following surgery and once the wound is fully healed. Recommended total doses are 60 to 66 Gy for negative margins and 66 Gy for microscopic positive margins.[43,58,75,105,119,120] Higher total doses may be considered selectively for gross residual disease. Postoperative RT is usually delivered with a dose of 50 Gy to a larger volume, and the balance of the dose is given to a reduced field. Traditionally, these doses were delivered sequentially, but they can also be given using a simultaneous integrated boost.

Alternative Dose and Fractionation Regimens

Based on the observed clinical behavior and relative radioresponsiveness of myxoid liposarcoma, the Dose Reduction of Preoperative Radiotherapy in

Myxoid Liposarcoma (DOREMY) study was designed to evaluate whether preoperative RT dose reduction to 36 Gy could result in comparable local control to conventional 50 Gy and minimize wound complications and late morbidity.[25,121,122] The primary endpoint of this prospective multicenter phase II single-arm study was extensive histologic treatment response. With a median follow-up of 25 months, local control was 100%, regardless of treatment response. Wound complications occurred in 22% of patients, with 17% requiring intervention. Grade 2 or higher late effects were less than 10% for fibrosis, edema, and joint stiffness. Although the results from this trial are appealing, further follow-up data are needed prior to incorporating dose reduction into routine clinical practice. Ongoing registry data with the use of 36 Gy in this setting are being collected to confirm the DOREMY study results (NCT04699292).

Although the current standard for preoperative external-beam RT remains conventional fractionation to 50 Gy, there is an active investigation into the use of moderate hypofractionated and ultrahypofractionated regimens. Interest in hypofractionated regimens for STS is not new, and early studies often included concurrent systemic therapy.[123-130] More recent evaluations have primarily investigated various dose regimens for preoperative RT without chemotherapy.[131-139] These studies differ significantly in the dose fractionation schema used, the timing of treatment delivery (daily or every other day), target volumes, timing to resection, length of follow-up, and toxicity assessment and reporting. Among the recently studied ultrahypofractionated regimens, 5 Gy × 5 fractions resulted in local control on the lower end of acceptable.[131-134] Regimens of 6 Gy and 7 Gy × 5 fractions appear to result in excellent local control comparable to conventional fractionation, but further study and follow-up are needed to adequately assess wound complications and late toxicity rates (fibrosis, edema, joint stiffness, fracture).[135-137] The regimen of 8 Gy × 5 fractions resulted in an unacceptable rate of amputation for complications of therapy.[138] The HYPORT-STS study used moderate hypofractionation (2.85 Gy × 15 fractions) with resulting excellent local control, but this regimen also requires further study with respect to late effects.[139] The hypofractionated regimens most radiobiologically equivalent to 2 Gy × 25 fractions are 2.85 × 15 fractions and 6 Gy × 5 fractions (using an α/β of 3-5 for STS).[140] As such, one would anticipate that the local control would be

comparable to conventional fractionation; however, given that normal connective tissues have lower α/β ratios, the question remains whether they will be comparable for toxicity. Ongoing follow-up and reporting on toxicities of wound healing, edema, fibrosis, joint stiffness, and fracture are necessary to determine the role of any of these hypofractionated regimens in routine clinical practice. No regimen can be considered an established alternative to conventional fractionation at this time; ideally, these appealing hypofractionation regimens will be tested against conventional fractionation in a randomized controlled trial.

Radiation Target Volumes

Preoperative Radiation Therapy

Historically, treatment volumes for STS of the extremities and trunk were comprised of large longitudinal margins of at least 5 cm, and sometimes greater than 10 cm, often covering the full compartment. With improved preoperative imaging modalities, treatment delivery techniques, setup reproducibility, and supportive data from studies, these margins have been reduced. Current standard target volumes for preoperative RT include the gross tumor volume (GTV), defined as the tumor delineated on T1 post-gadolinium MRI.[75,114] Fusion of the diagnostic MRI, and/or other staging imaging, with the planning CT for optimal target definition is strongly encouraged. For extremity and truncal STS, the clinical target volume (CTV) is defined as the GTV plus 3 to 4 cm margin in the longitudinal directions (along the plane of the musculature) and 1.5 cm margins radially.[75,114] These margins are anatomically constrained to not extend into bone or beyond the compartment or skin. CTV margins may also be constrained such that they only extend about 0.5 to 1 cm across intact fascial planes. For subcutaneous STS, as there are no longitudinal or radial muscle planes, the CTV is a 3- to 4-cm circumferential margin on the GTV, with an expansion of 0.5 to 1 cm into uninvolved underlying muscle. Target volumes are edited 0.5 cm beneath the skin surface in most scenarios to attain superficial dose avoidance and minimize the risk of wound complications (Figure 89.5). When this is done, the plan for resection of subcutaneous tissue and overlying skin should be confirmed with the surgeon. The biopsy tract and peritumoral edema on T2 MRI are included

within the CTV when feasible. For cases where peritumoral edema is extensive, greater clarity is needed to determine how much should be included in the CTV. One report showed the presence of sarcoma cells beyond the gross tumor in 10 of 15 patients. The location of the cells varied from 1 to 4 cm beyond the tumor but did not correlate with the location or extent of peritumoral edema on MRI.[34] It is reasonable to try to include the edema in the CTV unless doing so would require a significant increase in the treatment field. As lymph nodes are not frequently involved in STS, there is no elective inclusion of nodal basins within the CTV. The planning target volume (PTV) is defined as the CTV plus 0.5 to 1 cm or greater based on institution setup uncertainty and image guidance practices.

Figure 89.4 depicts MRI images and target volumes for a patient with STS of the right proximal medial thigh treated with preoperative intensity-modulated RT (IMRT). Figure 89.5 shows the preoperative RT treatment volumes for a patient with a subcutaneous STS involving the superficial tissues of the thigh.

FIGURE 89.5 Representative preoperative radiation treatment planning volumes for a patient with subcutaneous soft tissue sarcoma (STS) involving the superficial tissues of the thigh. A. Axial and (B) sagittal slices from the planning computed tomography (CT) showing the gross tumor volume (GTV, orange), clinical target volume (CTV, green), and planning target volume (PTV, red). The CTV is a 3- to 4-cm circumferential margin on the GTV with an expansion of 0.5 to 1 cm into the uninvolved underlying muscle. Target volumes are edited 0.5 cm beneath the skin surface in most scenarios to attain superficial dose avoidance and minimize the risk of wound complications. When this is done, the plan for resection of subcutaneous tissue and overlying skin should be confirmed with the surgeon.

Postoperative Radiation Therapy

For postoperative treatment, the nomenclature for "GTV" and CTV is variably described and is partly a matter of semantics, given that there is no actual "gross tumor." It can be helpful to recreate a "GTV" in the location where the gross tumor was preoperatively, as sometimes this volume is used for cone-down volumes. For extremity and truncal STS, the CTV1 includes the tumor bed (defined by surgical clips and preoperative imaging) plus 3 to 4 cm margin in the longitudinal directions and 1.5 cm margins radially that are anatomically constrained. For subcutaneous STS, as there are no longitudinal or radial muscle planes, the CTV1 is a 3- to 4-cm circumferential margin on the tumor bed (defined by surgical clips and preoperative imaging) with an expansion of 0.5 to 1 cm into uninvolved underlying muscle. CTV1 should encompass all the tissues within the operative field including postoperative changes, the incision, and any drain sites, when feasible.[75,114] The same principles apply as for preoperative RT target volumes in terms of using the T1 post-gadolinium images for "GTV" definition, fusing the planning CT and MRI when possible, and editing the CTV to exclude bone, intact fascial planes, skin, or extension beyond an uncontaminated compartment. As lymph nodes are not frequently involved in STS, there is no elective inclusion of nodal basins within the CTV. The PTV is typically CTV plus 0.5 to 1 cm, per institutional standard for setup uncertainty and image guidance practices. Typically, a CTV2 is used for field reduction (cone down) in the postoperative setting. For extremity and truncal STS, CTV2 includes the tumor bed with approximately 2 cm longitudinal and 1.5 cm radial margins. For subcutaneous STS, CTV2 includes the tumor bed with a 1.5- to 2-cm circumferential margin and 0.5 cm expansion into the uninvolved underlying muscle. The PTV expansion

is the same as above. CTV2 can be treated sequentially to CTV1 or delivered as a simultaneous integrated boost during the same course.

Series using treatment volumes similar to those described above have reported excellent local control rates on the order of 85% to 90%.[96-99,141] Furthermore, using these standard volumes, most LRs that occur are located within treatment fields rather than marginal to the fields, indicating that the fields are not too small.[97,98]

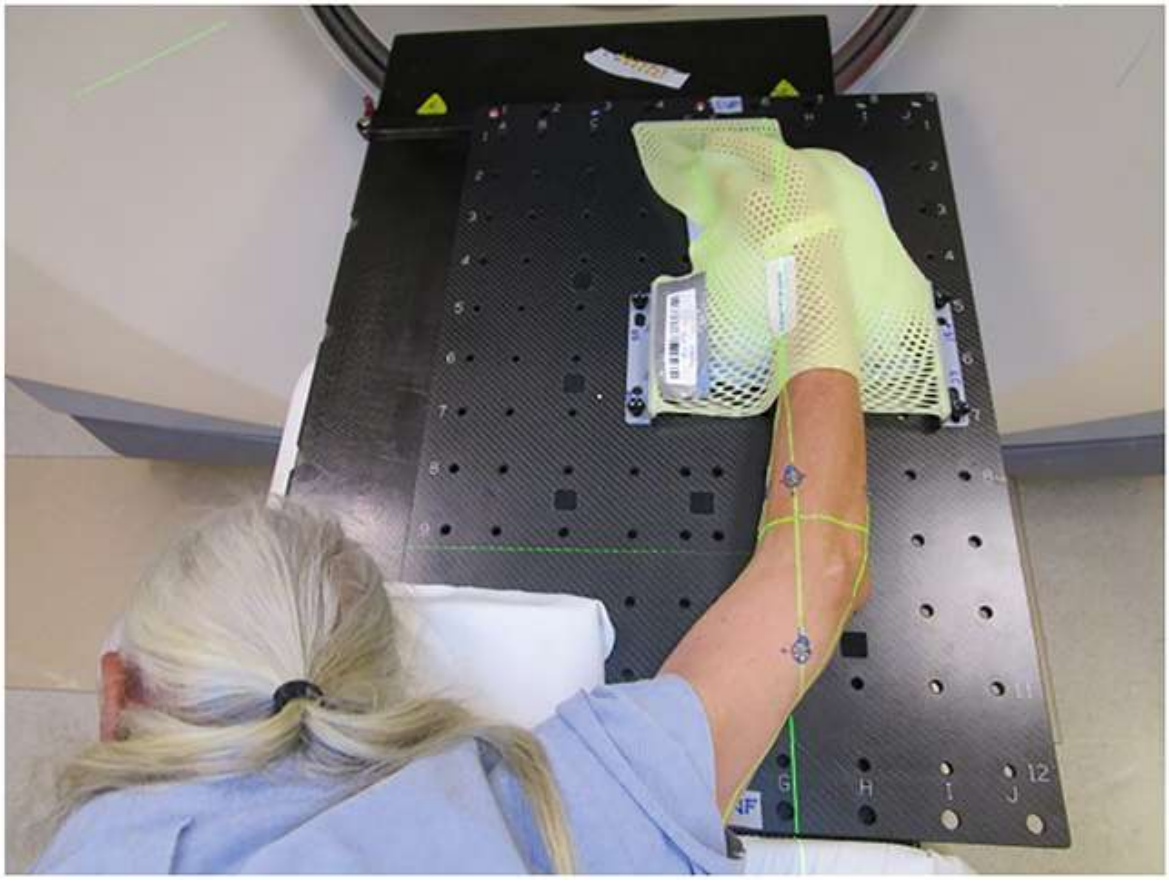
The excellent local control rates resulting from the use of standard preoperative and postoperative treatment fields establish that these fields are adequately large, but they do not address the question of whether these field sizes could be reduced. The initial design of these large fields predated the CT and MRI era, when imaging modalities to define STS were suboptimal. Moreover, the BRT experience at MSKCC produced excellent local control rates using treatment volumes that extended only 1.5 to 2 cm beyond the tumor bed.[71] Based on these observations, the RTOG 0630 and VORTEX (Randomised Trial of Volume of Post-operative Radiotherapy Given to Adult Patients with eXtremity Soft Tissue Sarcoma) trials evaluated whether treatment field sizes could be reduced.[119,142] The RTOG 0630 study was a phase II study investigating the, then novel, use of daily image-guided RT (IGRT) and (somewhat) reduced fields for preoperative RT for extremity STS. For tumors that were intermediate to high grade and greater than or equal to 8 cm, the CTV was defined as GTV plus 3 cm longitudinal and 1.5 cm radial margins; for tumors that were low-grade or less than 8 cm, the CTV was defined as GTV plus 2 cm longitudinal and 1 cm radial margins. The CTV also included suspicious edema on MRI T2 images. For a cohort of 79 patients, 2-year local control was 11%, and all five LRs occurred within the treatment fields.[119] The authors concluded that due to the absence of marginal field recurrences and reduction in reported late toxicities, the reduced volumes were appropriate. Importantly, daily image guidance is now the standard of care at most institutions. Whereas the RTOG 0630 trial evaluated margin reduction (with IGRT) in the preoperative setting, the VORTEX trial investigated CTV margin reduction for postoperative RT. Patients in this trial were randomized to standard fields with GTV plus 5 cm longitudinal and 2 cm radial margins or to tailored fields of GTV plus 2 cm in all directions. Preliminary results presented in abstract form did not show an improvement in limb function at

2 years, and there were too few events to evaluate noninferiority.[142] The study question is intriguing, but it is not appropriate to adopt reduced postoperative volumes at this time.

Radiation Therapy Planning

Positioning the Patient and Simulation

The first step of RT planning is to determine the appropriate positioning of the patient. It is important for the patient to be comfortable to ensure setup reproducibility. The multiple beam angles employed with IMRT techniques enable more positioning options than would be the case for 3D-CRT techniques.[143] As STS can occur throughout the body, there is no one typical STS simulation setup. In general, patients with extremity or truncal STS should be simulated in a comfortable, neutral, and reproducible position. This is generally in the supine position unless this places pressure on and deforms the tumor, in which case the prone position may be used. Suitable positions for upper-extremity lesions include supine with abduction of the arm away from the body with supination or pronation of the arm determined by the location of the tumor. Another good approach for upper-extremity lesions is the "swimmer position," whereby the patient is prone with the arm extended above the head (Figure 89.6A). For the treatment of a leg, the ipsilateral leg should be straight, and the contralateral leg separated to create a gap (Figure 89.6B). If the target is in the proximal thigh, the contralateral leg can be in a frog-leg position with support under the knee. For men with proximal thigh tumors, the genitalia should be displaced to the contralateral side (using mesh or other techniques). Men with treatment fields close to the genitalia should consider sperm banking if they wish to preserve fertility. Similarly, for cases with treatment fields close to the ovaries (eg, tumors of the proximal thigh, buttock, abdominal wall), women interested in fertility preservation should be referred for reproductive counseling prior to starting RT.[144]



A

B

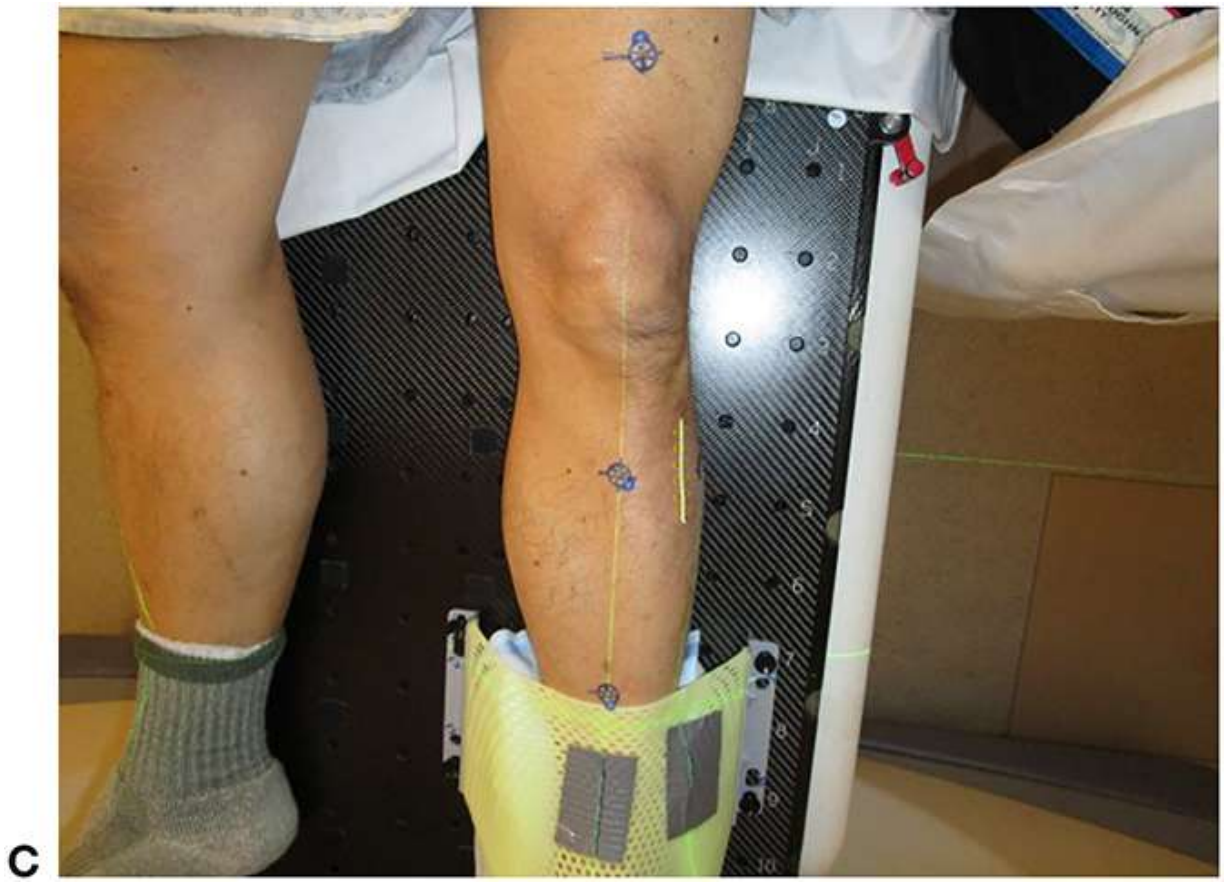


FIGURE 89.6 Examples of patient positions, immobilization, and tattoo placement for treatment of upper- and lower-extremity soft tissue sarcoma (STS). Patients are immobilized in custom casts which are indexed to the tabletop. A. The "swimmer position" is often an ideal position for treating STS of the hand, forearm, or distal upper arm. The hand is immobilized with a custom cast for all upper-extremity tumors. Anterior tattoos are placed approximately 15 to 20 cm apart along the same sagittal plane. B. For treatment of a lower leg tumor, the patient is supine with the ipsilateral leg neutral and straight, and the contralateral leg is separated to create a gap. The foot is immobilized with a custom cast for all lower-extremity tumors. Lateral tattoos are placed along the same axial plane as the anterior tattoos. C. Anterior view of the lower leg tumor showing placement of tattoos at the isocenter and approximately 15 to 20 cm apart along the same sagittal plane.

Once the position is determined, the patient must be immobilized in a reproducible fashion. A custom cast indexed to the tabletop is highly recommended for almost all scenarios; it is important to immobilize the foot with a custom mold for all lower-extremity tumors and to immobilize the hand for all upper-extremity tumors (Figure 89.6A,B). With respect to tattoo placement, a helpful protocol for extremities is to use three anterior tattoos and three lateral tattoos. The three anterior tattoos are placed

approximately 15 to 20 cm apart along the same sagittal plane (Figure 89.6A,C), and at each point, an additional lateral mark is placed in the same axial plane (Figure 89.6B). The six tattoo points are all placed in a stable anatomic location for the primary purpose of reproducing the position of the entire length of the extremity and the secondary purpose of creating a reference point for aligning the isocenter.

CT simulation with slice thickness less than or equal to 3 mm is recommended for conformal treatment planning. Biopsy sites, incisions from prior excisions, and drain sites (if present) should be marked with radioopaque wires or BBs to help define targets and sites at risk for seeding of the tumor. Relevant diagnostic imaging should be fused to the planning CT to assist with target delineation.

Radiation Treatment Planning and Delivery

As for any other malignancy, the basic principles of RT planning for STS are to achieve good coverage of the PTV with maximal sparing of adjacent normal structures. For extremity lesions, the important normal structures are the limb itself, skin and subcutaneous tissues, soft tissues, bones, and joints. For proximal thigh lesions, the perineum, external genitalia, and testes or ovaries are also relevant (Figure 89.7A). It is not always possible to preserve fertility, and patients desiring fertility preservation should be referred for consultation prior to treatment for discussion of sperm banking, oocyte cryopreservation, or other options. Every effort should be made to place the testicles as far out of the field as possible to avoid direct treatment and to minimize the contribution from internal scatter. For truncal STS, adjacent organs at risk (OARs) can include the small bowel, kidneys, spinal cord, stomach, liver, heart, and lung.

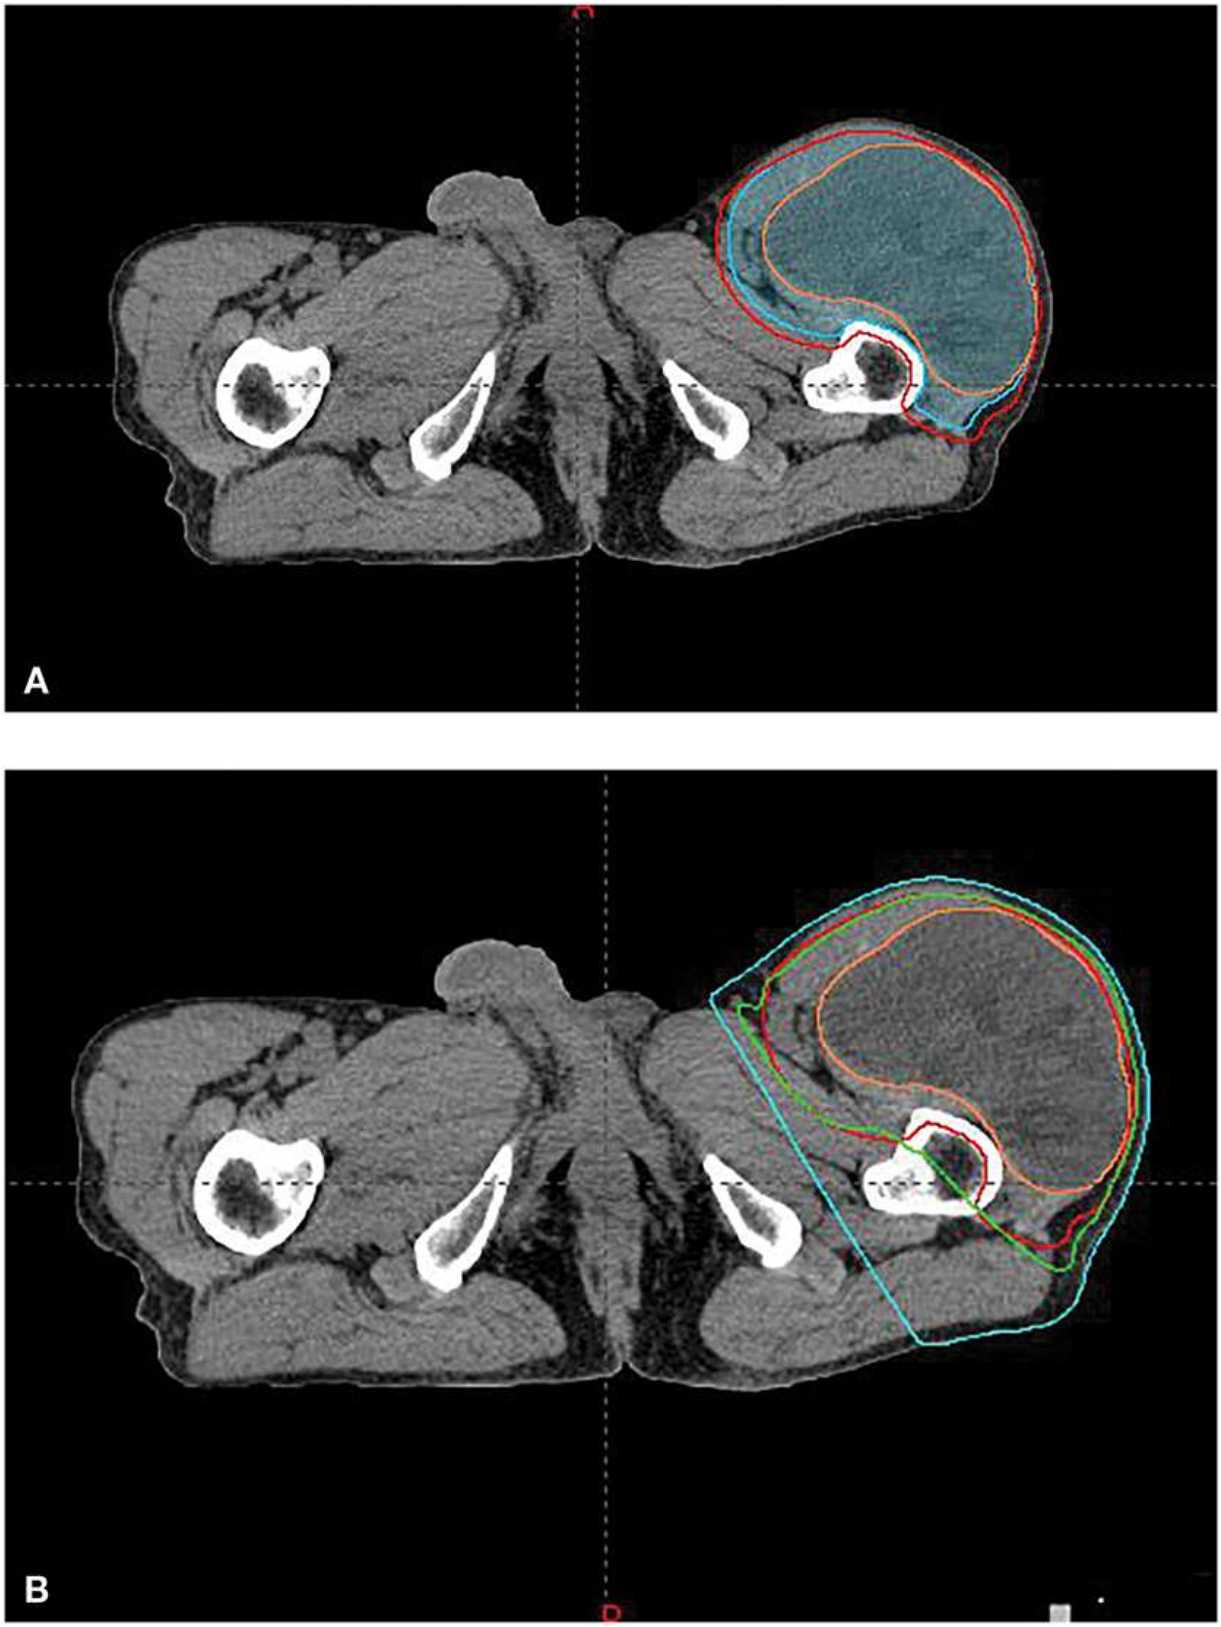

FIGURE 89.7 A myxoid liposarcoma of the proximal thigh in a 32-year-old man treated with preoperative intensity-modulated radiation therapy (IMRT) to 50 Gy. A. Axial slice of the

planning computed tomography (CT) scan showing the gross tumor volume (GTV, orange), clinical target volume (CTV, light blue), and planning target volume (PTV, red). The CTV does not extend into bone. Organs at risk (OARs) include the skin and subcutaneous tissues, soft tissues, the femur, hip, perineum, external genitalia, and testes. The external genitalia have been displaced to the contralateral side. Patients desiring fertility preservation should be referred for reproductive consultation prior to treatment. B. Axial slice from the planning CT showing the GTV (orange), PTV (red), 50 Gy isodose line (green), and the 20 Gy isodose line (cyan). The 50 Gy isodose line covers the PTV while avoiding a full circumferential dose to the femur. High dose is pulled back from the overlying skin and subcutaneous tissues. The 20 Gy isodose line shows the sparing of a strip of skin and subcutaneous tissue and avoidance of dose to the perineum, external genitalia, and contralateral limb.

Basic tenets for treating the extremity are to “spare a strip” of the limb circumference (to prevent subsequent lymphedema and pain), to avoid treating the whole thickness of bone to high doses (to diminish the risk of fracture), and to avoid treating an entire joint to high doses (to decrease joint stiffness). In the preoperative treatment setting, it is also necessary to pay attention to the dose received by skin and subcutaneous tissues comprising the future surgical resection flaps (to minimize wound complications) (Figure 89.7B).

For extremity STS, recommended OAR constraints are as follows.[75] Spare as much as possible of the limb circumference from receiving any dose, and limit the dose to a longitudinal strip of skin and subcutaneous tissue so that no more than 50% receives 20 Gy. Minimize skin dose overlying joints or sites of frequent trauma (eg, anterior leg) and hot spots within superficial tissues. For patients receiving preoperative RT, discussion with the surgeon regarding the anticipated operative plan can facilitate dose sparing of skin and subcutaneous tissue at the site of the anticipated incision and if resection of skin is planned, the PTV may be cropped 0.5 cm from the skin surface to reduce the risk for wound healing complications. Avoid entrance or exit dose through the contralateral extremity. For proximal tumors, limit the dose to the perineum, external genitalia, and testes or ovaries. Full circumferential bone irradiation should be avoided if possible, and the mean and maximum doses to the whole bone should also be kept to a minimum.[108] For planning, the weight-bearing bone OAR is defined as the extent of the long bone from 2 cm above and below the PTV.[108] The suggested dose constraints to minimize risk for fracture are volume of bone

receiving greater than or equal to 40 Gy (V40) less than 64%, mean dose to bone less than 37 Gy, maximum dose to bone less than 59 Gy and to try to limit no more than 50% of the bone within the field from receiving 50 Gy.[108,109] For select patients at high risk for fracture, when achieving these weight-bearing bone constraints is not possible and when resection will include periosteal stripping, discussion with an orthopedic oncologist regarding consideration for prophylactic fixation may be warranted.[109] Additionally, planning should minimize the dose to any joint as much as possible, avoid treating the entirety of the joint, and keep less than 50% of the joint from receiving 50 Gy.

For STS involving the trunk or other anatomic sites, dose constraints for underlying OARs should follow established tolerances. Normal-tissue complication probabilities for organs that may be affected by treatment are listed in the Quantitative Analysis of Normal Tissue Effects in the Clinic document.[145] If RT treatment of a trunk lesion may potentially significantly reduce or ablate ipsilateral kidney function, an assessment of adequate contralateral kidney function should be performed.

Use of tissue-equivalent bolus material is discouraged in the preoperative setting and infrequently necessary in the postoperative setting, with the exception of skin or subcutaneous tissue involvement.[75,119,146] In the preoperative setting, a paddle of skin is typically removed along with a superficial tumor obviating the need for bolus; furthermore, increased surface dose appears to increase wound complication risk.[99,146] In the postoperative setting, the BRT experience showed that failure to treat incision or drain sites was not associated with scar or drain site recurrences.[71]

Three-dimensional-conformal RT (3D-CRT) and IMRT, including volumetric modulated arc therapy (VMAT) are acceptable external-beam treatment techniques, but IMRT has several advantages over 3D-CRT and is generally preferred.[75] The principal dosimetric differences between these two techniques are that IMRT typically achieves comparable or improved target coverage, improved conformality of the dose distribution around the target volume, and reduced volumes of high doses to normal tissues, compared with 3D-CRT, but the volume of tissue receiving low dose is increased with IMRT.[147,148] Several studies show similarly excellent local control rates with IMRT compared to 3D-CRT, and some show superior

local control for IMRT.[96,99,119,141,146] Importantly, IMRT is associated with a more favorable late toxicity profile compared to 3D-CRT including a superior ability to spare dose to weight-bearing bone minimizing risk for fracture.[113,149] In select situations, such as STS involving the distal extremities, a carefully designed 3D-CRT approach may be helpful, as part of the limb can usually be excluded entirely from the treatment fields. However, if using 3D-CRT for preoperative RT, it is important to minimize dosimetric hotspots in the skin and subcutaneous tissues to reduce the risk of wound complications. On balance, given the dosimetric advantages and favorable toxicity profile, IMRT is the preferred technique for most STS of the extremity and trunk.

Even with custom immobilization, reproducible setup for extremity STS can be challenging. With the increased use of highly conformal techniques for treatment delivery, setup verification is necessary to ensure accurate positioning. IGRT refers to serial imaging of patient setup prior to treatment so that appropriate positional adjustments can be made before treatment delivery. Various imaging modalities, including kV orthogonal images and cone beam CT, can be used for alignment. Because the use of IGRT increases the certainty of treatment accuracy, in many cases, the added margins for “setup error” can be reduced, which allows for smaller treatment fields and potential dose escalation without undue normal tissue toxicity. Daily IGRT and reduced treatment fields were used in the phase II RTOG-0630 trial.[119] An analysis of the daily positioning variation on this trial suggested that in the absence of daily IGRT, a CTV to PTV expansion of 1.5 cm would have been required to account for all setup uncertainty.[150] The appropriate PTV margin used for planning should reflect this uncertainty, frequency of imaging, and institutional practices to address such setup errors. Another benefit of IGRT is that imaging during a course of treatment can show changes in patient anatomy (eg, due to weight loss) or changes in tumor shape. This allows for adaptive RT and the generation of an updated treatment plan. This is relevant for preoperative treatment of histologies that respond dramatically to RT, such as myxoid liposarcoma.[151,152] Daily image guidance is recommended for setup verification throughout treatment, with the inclusion of at least weekly (if not daily) volumetric imaging.[75]

Radiation Therapy Toxicities

Acute Toxicities

Acute toxicities following RT to the extremities include skin erythema, dermatitis, and possible desquamation in high-dose areas, skin folds, or when the tumor involves the skin or subcutaneous tissues, problems with wound healing, localized alopecia, and fatigue. Moist desquamation can be quite uncomfortable, but this typically heals quickly after completion of RT. Depending on tumor location, treatment of STS of the trunk can be associated with additional toxicities such as nausea, esophagitis, or bowel irritability.

The most significant of these acute sequelae is problems with wound healing. Rates of reported wound complication rates following preoperative RT were 35% on the NCIC SR2 trial and 37% on the RTOG 0630 study.[105,119] Rates following postoperative RT are lower and were 17% on the NCIC SR2 trial.[105] In addition to preoperative RT, other predictors for wound complications include lower-extremity site, tumor size greater than 10 cm, tumor proximity to skin surface less than 0.3 cm, vascularized flap closure, and diabetes mellitus.[99,105] In an attempt to decrease wound complications following preoperative RT, a phase II prospective study of image-guided IMRT was conducted for patients with lower-extremity STS.[146] Together with the surgeon, the radiation oncologist contoured the area of the subsequent surgical flaps and designated it as an avoidance structure for treatment planning. Although the resulting rate of wound complications (30.5%) was not statistically significant, rates of primary closure were higher and the need for reoperations was lower. For patients with minimal (<1%) overlap of the flap and PTV, the wound complication rate was 14.3% compared to 39.5% for those with flap and PTV overlap (P = .04). The association of higher wound complications with higher flap doses is consistent with the report showing increased complications for tumors within 0.3 cm of the skin surface.[99] Efforts continue to try to minimize postoperative wound complications, for example, the use of enhanced recovery programs employing preoperative, intraoperative, and postoperative interventions.[153]

Chronic Toxicities

The most significant chronic toxicities following RT to the extremities include edema, subcutaneous fibrosis, decreased muscle strength, decreased range of motion, pain, and, less frequently, bone fractures. Published rates of these toxicities vary, as series have different patient inclusion criteria (with respect to tumor site and treatment) and some report only moderate or severe complications, while others report any degree of complication. For series primarily comprised of patients treated with 2D or 3D-CRT, reported rates for edema are 10% to 20%, for fibrosis they are 30% to 60%, and for bone fracture, they are 0.04% to 7%.[106,108-157] Furthermore, several of these studies correlated higher complication rates with higher doses and larger field sizes. Doses greater than 60 or 63 Gy and large field sizes, as used for postoperative RT, have been associated with higher rates of fibrosis, edema, bone fracture, pain, decreased muscle strength, joint stiffness, and decreased range of motion.[106,108,110,154] There have been no randomized trials comparing chronic toxicities for patients treated with 3D-CRT versus IMRT, but series comprised primarily of patients treated with IMRT report lower chronic toxicities with rates greater than or equal to grade 2 edema of 5.3% to 11.1%, fibrosis of 5.3% to 9.3%, and joint stiffness of 3.5% to 5.6%.[146,119] The risk of bone fracture has been clearly correlated with bone doses, and IMRT enables better bone avoidance than 3D-CRT.[113]

OTHER TREATMENT MODALITIES AND TECHNIQUES

Brachytherapy

BRT can be used as monotherapy or in combination with external-beam RT depending on the clinical and pathologic features (eg, grade, size, and margins) and setting, either as primary treatment or for recurrence. A comprehensive description of BRT modalities, techniques, and indications is beyond the scope of this chapter. The American Brachytherapy Society consensus statement provides a detailed review.[158]

Particle Beams

Particle beams such as protons and heavier ions (eg, carbon ions) have favorable physical and biologic characteristics, which make them appealing for clinical use. Because of the Bragg peak dose distribution property,

treatment plans can be created with steep dose falloff at field borders.[159] This may allow for the sparing of adjacent critical normal structures, lower integral dose, smaller treatment volumes, and potential for dose escalation. Much of the data for the use of protons and heavy ions arise from the treatment of primary bone sarcomas. Most data for the use of protons specifically for STS are from the treatment of pediatric patients.[160] There have been no randomized studies comparing photons and protons for STS. Potential indications for the use of protons in the treatment of STS include young patients, clinical circumstances in which the rapid dose falloff may provide greater OAR sparing than IMRT (eg, young adults with pelvic sarcoma for sparing of reproductive organs), treatment of unresectable disease, and reirradiation.

Stereotactic Body Radiation Therapy

Stereotactic body radiation therapy (SBRT) is a technique that delivers highly focused photon radiation doses to extracranial lesions. It is also referred to as stereotactic ablative radiotherapy (SABR). The dose schedules are hypofractionated, with large ablative fractions, typically delivered in a course of one to five treatments. With respect to sarcoma, SBRT is increasingly being used in the treatment of oligometastatic disease. The lung is the most common site of metastatic spread of STS. Historically, lung metastasectomy had been the standard approach for limited pulmonary disease in selected patients. Now there are multiple options for local therapy in the setting of oligometastatic disease, including SBRT.[161] Patient and disease characteristics considered when selecting treatment intent for metastatic disease include performance status, disease-free interval, location and extent of disease, histology, response to systemic therapy, and potential morbidity.

Although most SBRT reports are in the setting of oligometas tatic lung disease, SBRT has also been reported for nonpulmonary sites, including the spine, liver, soft tissue, and lymph nodes.[162-168] Published series show that SBRT is a feasible treatment option and provides excellent 1- and 2-year local control (>90%-95%) with minimal toxicity.[162-166] Various dose fractionation regimens have been used. Figure 89.8 shows a representative SBRT plan for the treatment of pulmonary oligometastasis.

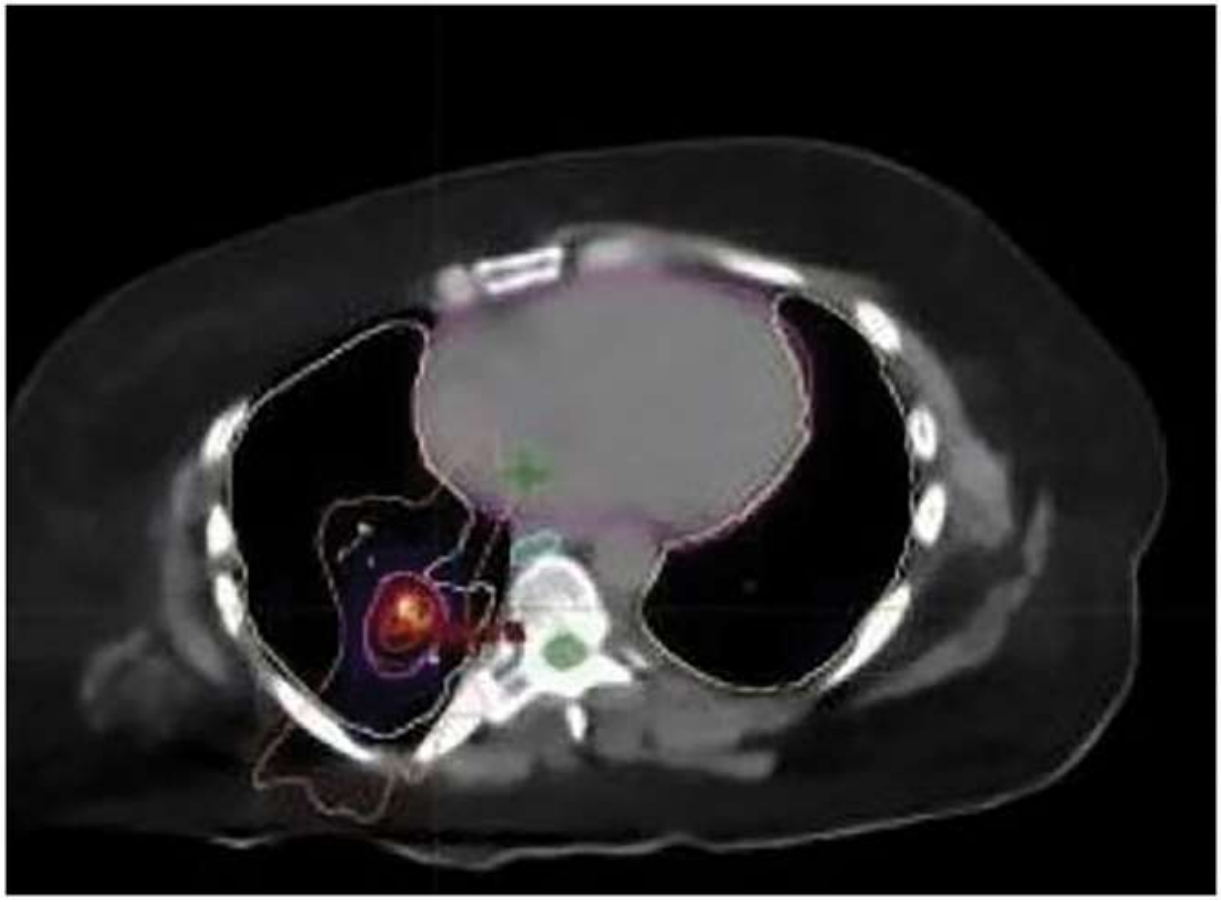

FIGURE 89.8 Axial computed tomography (CT) image showing a representative stereotactic body radiation therapy (SBRT) plan for treatment of a pulmonary oligometastasis.

There are less data regarding the role of SBRT in definitive treatment of primary sarcomas, but there may be a role in select patients with tumors located in or adjacent to sensitive normal structures. In contrast to the planning recommendations for resectable STS treated with wide resection and pre- or postoperative RT, the target volume for SBRT is a gross disease (GTV) with a PTV expansion. There is no CTV. Referral to expert centers is recommended. Figure 89.9 shows an MRI and dosimetry for an unresectable leiomyosarcoma of the inferior vena cava treated with definitive intent SBRT at Brigham and Women's Hospital.

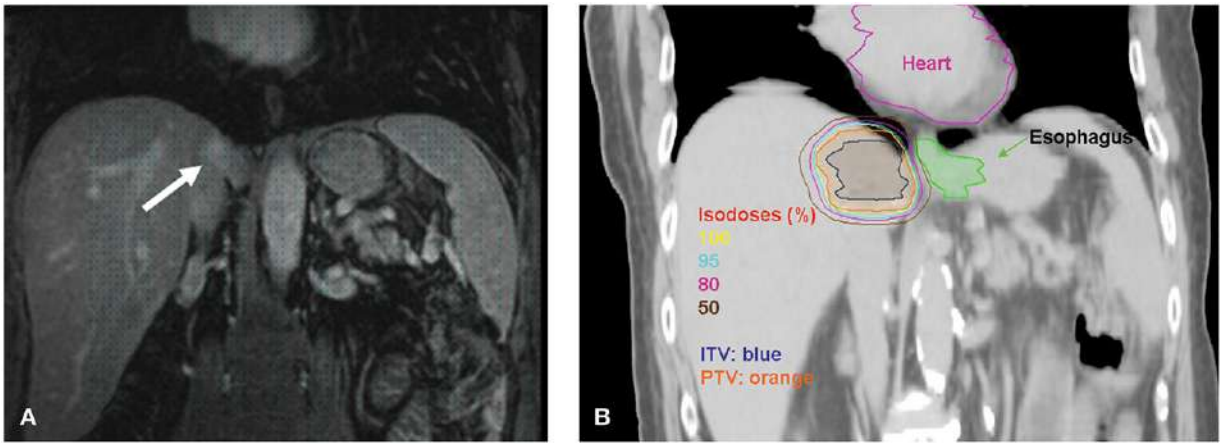

FIGURE 89.9 A 72-year-old man with a 1.8 × 1.8 cm unresectable leiomyosarcoma of the intrahepatic inferior vena cava close to the liver, esophagus, and heart treated with stereotactic body radiation therapy (SBRT) to 60 Gy in five fractions. A. Coronal T1-weighted magnetic resonance image (MRI) slice showing the tumor. B. Coronal slice of the SBRT plan showing the internal target volume (ITV, blue), planning target volume (PTV, orange), and covering isodose lines.

OTHER ROLES FOR RADIATION THERAPY

Reirradiation for Local Recurrence

When LR occurs in a previously irradiated field, management is complex. Resection with wide negative margins is the goal; however, it is not always feasible in this setting. At times, amputation may be required. The addition of reirradiation to resection may be considered in select cases, for example, when there is significant risk for subsequent recurrence and such a recurrence would be associated with significant morbidity. Additionally, reirradiation may be considered when radical resection is not feasible or declined. Multidisciplinary input and shared decision-making with the patient are necessary when reirradiation is considered, given that its use has been associated with significant wound and other complications.[169-171] BRT, particle therapy, and advanced RT planning techniques have been used for reirradiation to try to spare normal tissues and minimize toxicity.[158,172]

Radiation Therapy for Unresectable Disease

For patients with unresectable or medically inoperable disease or those who decline radical resection or amputation, the use of RT for local control may be considered, recognizing that control rates will be lower than with the use

of resection. In these circumstances, goals of care are important to define when determining the treatment intent and approach, and multidisciplinary evaluation for management is essential.

Durable control of gross disease using RT alone is best achieved for smaller tumors.[173,174] Dose escalation (>63 Gy) has been used, yet higher doses are associated with increased toxicity (particularly with doses >68 Gy).[173,174] Use of modern RT planning techniques and modalities, including SBRT and protons, has improved the therapeutic ratio, and a recent series reported less toxicity.[175,176] Hypofractionated RT can also confer durable local control and relief of symptoms.[177] The target volumes for planning in these circumstances are the gross disease (GTV), a smaller CTV expansion (~1.5 cm), and standard PTV. Systemic therapy, concurrent chemoradiation, isolated limb perfusion (ILP), isolated limb infusion (ILI), and hyperthermia are other potential approaches in the armamentarium for locally advanced and unresectable STS.

NEOADJUVANT, CONCURRENT, OR ADJUVANT CHEMOTHERAPY

Patients with STS of the extremities and trunk with high-risk features (eg, high grade, large tumors, specific histologies) have distant metastatic spread and mortality rates greater than 50%. A nomogram can be used to help predict survival and risk for distant disease in patients with extremity STS after resection.[45] The rationale for the addition of systemic therapy in patients with localized disease is to reduce distant recurrence risk and improve survival. To this end, there is an established role for chemotherapy as part of the treatment for rhabdomyosarcoma and Ewing sarcoma.[178,179] Unlike its established role in the treatment of various histologies for pediatric, adolescent, and young adults, the benefit of chemotherapy in adults with localized STS remains unproven.

Informative data are scarce regarding the use of concurrent preoperative chemotherapy and radiotherapy in adults with STS. Studies have shown that treatment with interdigitated chemotherapy and split-course RT or concurrent chemoradiotherapy is feasible but with increased rates of toxicity. Neither approach is commonly used for adults with localized

STS.[116,125,180-183] There is a selective role for use in patients with locally advanced and unresectable disease.[82]

The two most standardly used chemotherapies in the treatment of STS are doxorubicin and ifosfamide.[82,184] As STS is comprised of many heterogeneous histopathologic subtypes with unique natural histories, there are ongoing efforts to try to tailor systemic regimens to histology. Although there have been encouraging response rates noted in some trials, a phase III randomized trial did not show improved disease free or OS with histology-tailored neoadjuvant chemotherapy over anthracycline and ifosfamide-based standard therapy.[185] This remains an area of active investigation, and going forward, trials should include centralized pathology review and stratification by histology.

In totality, although there are hints of efficacy for certain subgroups, the available data do not support the routine use of chemotherapy in adults for locally advanced resectable STS (excluding Ewing sarcoma). However, for select high-risk patients with high-grade and large tumors (>8 to 10 cm), it is reasonable to address the pros and cons of neoadjuvant, concurrent or interdigitated, or adjuvant chemotherapy on an individual patient basis. Choices to proceed with chemotherapy should be a result of shared decision-making with the patient and multidisciplinary discussion.[82] Appropriate indications for the addition of systemic therapy, either neoadjuvant or adjuvant, include borderline resectable tumors, chemosensitive histologies, and patients at high risk for distant metastases with excellent performance status.[82] As toxicity can be significant, concurrent approaches are best undertaken at experienced centers.

ISOLATED LIMB PERFUSION, ISOLATED LIMB INFUSION, AND CHEMOTHERAPY WITH REGIONAL HYPERTHERMIA

ILP is a complicated technique that has been used in Europe for the treatment of locally advanced STS that would otherwise require amputation.[82,186] This procedure involves isolating the arterial and venous circulation of the limb by connecting it to an extracorporeal circulation, where it is oxygenated and instilled with systemic agents, most commonly, melphalan and tumor necrosis factor. A tourniquet is applied to the limb to prevent leakage into the systemic circulation, and the limb is often treated

with hyperthermia as well. The treatment can have significant morbidity, but reported limb salvage success rates are quite high.[186-191] ILI employs low-flow ILP without oxygenation and has been developed as a simpler alternative to ILP.[192] Available data suggest comparable efficacy and less toxicity for ILI compared to ILP.[193-196] Lastly, chemotherapy with regional hyperthermia (delivered via an external electromagnetic field) is another approach for locally advanced disease.[197] A randomized trial of doxorubicin, ifosfamide, and etoposide, with or without regional hyperthermia delivered before and after local therapy, has shown superior DFS and progression-free survival rates for the regional hyperthermia group.[198] All of these techniques are complicated to deliver and associated with significant risk for toxicity. However, they represent valuable potential alternatives to amputation in such settings as extensive LRs after prior surgery and RT, unresectable disease, or in transit metastases of epithelioid or clear cell sarcoma.

CONCLUSION AND FUTURE DIRECTIONS

STSs are rare malignancies comprised of multiple heterogeneous histopathologic subtypes with unique behaviors. The primary treatment approach for STS of extremity and trunk remains oncologic resection with RT added to improve local control in patients at increased risk for LR. The treatment plan and sequences of modalities should be determined by a multidisciplinary team with sarcoma expertise prior to the initiation of therapy. Tumor control outcomes are the same with either preoperative or postoperative RT; however, toxicities differ. Preoperative RT is associated with an increased risk of wound healing complications, which are generally temporary and reversible, whereas postoperative RT has a greater risk for late toxicities, which are permanent and can impact long-term function. In general, preoperative RT followed by resection is preferred. Advances in treatment planning and delivery, including the use of IMRT and daily IGRT, have improved outcomes for patients with STS. The role of chemotherapy for localized STS remains unproven, but it is a reasonable option for patients at very high risk for recurrence and with shared decision-making.

Future investigations and further refinements of STS treatments are needed to continue to improve cancer control and functional outcomes and to mitigate acute and late toxicities. These include innovative techniques to

reduce postoperative wound complications and late toxicities, efforts to reduce RT margins or doses, risk-adapted and histology-tailored approaches for both local and systemic therapies, and improved response assessments for neoadjuvant the rapies. Preliminary reports suggest likely similar efficacy of moderately hypofractionated and some ultrahypofractionated regimens for preoperative RT, but with concern for wound complications, including the necessity of amputation, and long-term toxicities, including fracture risk. Additional moderately hypofractionation studies are ongoing, including a single-arm phase II study of 2.85 Gy × 15 fractions (NCT04562480), and a randomized study of 3 Gy × 14 fractions versus standard 2 Gy × 25 fractions (NCT04425967), and their results are eagerly anticipated. A randomized clinical trial comparing moderate and ultra-hypofractionation to conventional fractionation for preoperative RT is greatly needed. Efforts for treatment de-escalation include better definition of patient subsets at lower risk for recurrence that can be effectively treated with surgery alone, reduced-dose preoperative RT for myxoid liposarcoma (NCT02565498 and NCT04699292), and an ongoing study of lower postoperative RT dose for patients resected with negative margins (NCT02565498). Conversely, for situations in which it is difficult to achieve local control and in the setting of recurrent or unresectable disease, more aggressive local treatment is needed; this could include the use of RT dose escalation, heavy particles, SBRT, or concurrent chemoradiation strategies. For patients with a high risk of distant relapse and death, novel systemic therapies are needed to improve outcomes.

PART M

Pediatric

CHAPTER 90

Central Nervous System Tumors in Children

Kevin X. Liu, Hesham Elhalawani, and Daphne A. Haas-Kogan

Central nervous system (CNS) tumors account for 20% to 25% of all malignancies that occur in childhood. The incidence of brain tumors in pediatric and young adult patients varies around the world from 1.12 to 5.26 cases per 100,000.[1] The incidence was highest among children younger than 4 years.[2] Since 2011, brain cancer is the leading cause of cancer-related death in pediatric patients, having surpassed leukemia.[3]

The etiology of pediatric CNS tumors remains largely unknown. Only 2% to 5% can be ascribed to a known genetic predisposition. Included in this category are those seen in patients with neurofibromatosis types 1 (NF-1) and 2 (NF-2), tuberous sclerosis, nevoid basal cell (Gorlin) syndrome, familial adenomatous polyposis, and Li-Fraumeni syndrome. An even smaller percentage can be attributed to ionizing radiation used for diagnostic or therapeutic purposes. For the majority of patients, no predisposing factors can be identified.

The management of children with CNS tumors has changed substantially over recent decades. Routine use of magnetic resonance imaging (MRI), now frequently including functional imaging, and improved neuropathologic examination and molecular diagnostics have contributed to better characterization of different tumor types. Improved neurosurgical techniques and perioperative care permit greater degrees of surgical resection even for tumors previously considered inoperable because of their location in eloquent areas of the brain. All of these, together with improved

radiotherapy (RT) techniques, newer chemotherapy agents and regimens, and national and international clinical trials, have contributed to improved outcomes for children and adolescents with CNS tumors. Five-year survival has increased from 59% for patients diagnosed in 1975 to 1979 to 75% for those diagnosed in 2003 to 2009.[2]

RADIOTHERAPY FOR PEDIATRIC CENTRAL NERVOUS SYSTEM TUMORS: GENERAL ISSUES

RT is an essential component of treatment for many children with CNS tumors. However, survivors are at significant risk for the development of long-term sequelae.[4,5] While many of the long-term toxicities post-RT are multifactorial, radiation treatment is an important contributing factor. Thus, studies in the past three decades have explored novel regimens or techniques seeking to reduce risks associated with treatment. Recent developments in RT including improved targeting, new technologies and modalities, and novel techniques for treatment offer important opportunities for therapeutic gain that are discussed later and in each section of this chapter.

Long-Term Effects of Radiotherapy

Quality of life of children with brain tumors may be compromised by long-term sequelae. Although some patients (eg, patients with NF-1) may be at particular risk and some sequelae (eg, neurologic deficits) are more often due to tumor and/or surgery, it is clear that RT is directly, either alone or modulated by other factors, responsible for many late effects. A review by Kortmann et al[6] provides an excellent account of radiation-related sequelae in children treated for low-grade glioma, including effects on brain parenchyma, neurologic deficits, neurocognitive and behavioral effects, endocrine dysfunction, vasculopathy, and second tumors.

The neurocognitive sequelae of RT have become much better characterized over recent years. It is now known that myelinization and functional maturation of the CNS continue until well into adolescence and even into young adulthood. Through its effect on the microvasculature as well as on the oligodendrocyte precursor cells that produce myelin, RT causes disrupted neurogenesis and cortical atrophy. Patients fail to acquire

new knowledge and skills at an age-appropriate rate and show a progressive decline in IQ over time.[7] The magnitude of the deficit depends most importantly on age at treatment, but many other host (eg, NF-1), tumor (eg, location, hydrocephalus), and treatment factors (eg, RT volume and dose,[8-10] use of chemotherapy[11,12]) play a role. Moreover, the development of other deficits such as behavioral difficulties related to the location of the tumor and/or surgery or hearing impairment because of cisplatin may have a modulating effect. The result for many patients is impaired school and social performance that deteriorates over time. There is increasing evidence that intervention using cognitive or behavioral therapy or pharmacotherapy and even exercise may be useful and that this should start soon after treatment for best results.[7,13,14]

Endocrine deficits are very common after RT.[15] Even though a substantial proportion of patients may have had deficits prior to RT because of the tumor or to surgery,[16,17] and even though there may be modulating factors such as chemotherapy that affect the frequency of deficits, RT is primarily responsible for the growth hormone deficiency that correlates with the dose of RT to the hypothalamic-pituitary axis[18-20] and the primary hypothyroidism seen after craniospinal irradiation (CSI). There may be direct and indirect effects on musculoskeletal development. Osteopenia is a rather common finding that may put patients, particularly those with residual neurologic deficits, at significant risk for fracture.

RT has been implicated as well in the development of cardiovascular complications, including cerebrovascular events and coronary heart disease.[16,21] Although again the etiology is likely multifactorial, it is important to be cognizant of the risks and to minimize the dose to vascular structures and the heart.

Strategies that have been used to avoid or minimize the long-term effects of treatment for pediatric brain tumors include the following:

- Avoidance of RT altogether (eg, in patients with low-grade astrocytoma [LGA] for whom surgery alone may be a good option)
- Delay of RT for young children (ie, those younger than age 3-8) using chemotherapy
- Use of daily anesthesia, improved immobilization techniques (eg, rigid casts or a stereotactic frame), and/or daily pretreatment image

verification, all of which allow the use of reduced safety margins

- Use of image-based treatment planning using computed tomography (CT)-MRI or CT-MRI–functional imaging co-registration and better treatment planning and delivery techniques that result in greater sparing of normal brain and organs at risk (OARs)
- Use of new radiation modalities (particularly proton therapy that provides even greater sparing of the surrounding normal brain and OARs). Over the past 5 to 10 years, there has been a significant increase in the proportion of children with CNS tumors treated with proton therapy.
- Use of reduced RT target volumes when it is shown safe to do so (eg, involved field boost rather than whole posterior fossa boost for standard-risk medulloblastoma [MB])
- Reduction of RT dose (eg, in young patients with standard-risk MB for whom in the North American studies dose for craniospinal irradiation [CSI] has been reduced progressively from 36 to 23.4 Gy and, in current studies, examining decreasing CSI dose for patients with WNT-driven MB)
- Use of smaller fraction sizes where appropriate (eg, 1.5 Gy/day for patients with radiosensitive tumors such as germinoma)
- Use of hyperfractionated radiotherapy (HFRT) (eg, as in the current European studies for standard-risk MB)

These are discussed later in each relevant clinical situation.

Preparation for Radiotherapy

The planning and delivery of RT for children with CNS tumors are technically challenging and labor-intensive for the entire interprofessional team. The expertise of specialist personnel such as pediatric nurses and child life specialists can be pivotal in supporting a young child through making an immobilization device, RT planning procedures, and treatment itself. For children younger than age 4 or 5 years, daily anesthesia will almost always be necessary, and this will require a skilled pediatric

anesthesiologist because anesthesia will be administered in an environment without all the support available in an operating room.

Radiotherapy Target Volumes and Treatment Techniques

Focal, Tumor, or Tumor Bed Radiotherapy

For most tumor types, target volume definition is best accomplished using CT simulation with CT-MRI co-registration. For patients who have undergone cerebrospinal fluid (CSF) diversion or surgical resection or in whom tumor shrinkage has occurred with chemotherapy, it will be important to consider any anatomic shifts that may have taken place. This will be more of an issue for tumors arising in some areas than others and often adds significantly to the time required for contouring. The clinical target volume (CTV) will be tumor type specific, whereas the planning target volume (PTV) will be technique specific, ranging from 1 to 5 mm depending on the type of immobilization device used and whether daily pretreatment image verification is to be performed.

Modern RT treatment planning and delivery techniques make it easier to achieve conformity of the treated volume to the target and sparing of uninvolved normal structures than in the past. The choice of technique in an individual patient will require careful analysis of the dosimetry in the context of available options. A review by Beltran et al[22] provides an excellent example of the issues to be considered when weighing alternatives.

Other options for focal treatment include brachytherapy and intracystic injection of radioactive colloids. These are discussed in the context of the relevant clinical situation.

Whole-Ventricular Radiotherapy

Whole-ventricular irradiation is used most frequently in patients with CNS germ cell tumors. Because subependymal spread is common, the target volume logically would include the lateral, third, and fourth ventricles with a margin of 0.5 to 1 cm. If lateral-opposed fields are used, the volume of brain spared will be small.[23] Better sparing can be achieved using intensity-modulated image-guided RT[24-26] or, more recently, the use of proton therapy is advocated.

Craniospinal Radiotherapy

The CTV for CSI has an irregular shape that consists of the whole brain and spinal cord and their overlying meninges. In standard techniques, the lower borders of lateral whole-brain fields are matched to the cephalad border of a posterior spine field, usually with a moving junction between the brain and the spine fields to minimize the risk of underdose or overdose in the cervical spinal cord. With conventional techniques, compensators may be needed to achieve dose homogeneity throughout the target volume. In recent years, when possible, intensity-modulated radiotherapy (IMRT) or proton RT, particularly pencil beam scanning, has been utilized for CSI to provide more conformal treatment and decrease dose to normal organs and toxicity.[27-30]

Patient Positioning and Immobilization

Patients have traditionally received CSI in the prone position, but modern technology allows safe treatment in the supine position that in general is more comfortable and, if anesthesia is required, allowing better control of the airway. In either case, immobilization is essential and involves the use of a head shell or full-body immobilization. Careful attention to positioning at the time of simulation is critical to minimize or even eliminate the risk of certain long-term effects. For example, using neck extension together with careful selection of the level for the junction of the brain and spine fields, it is possible to avoid including the dentition in the exit from the superior aspect of the spinal field and thus damage to developing dentition. When modern techniques are employed, it is essential to apply the relevant dose constraints to avoid excessive or unnecessary dose to OARs.

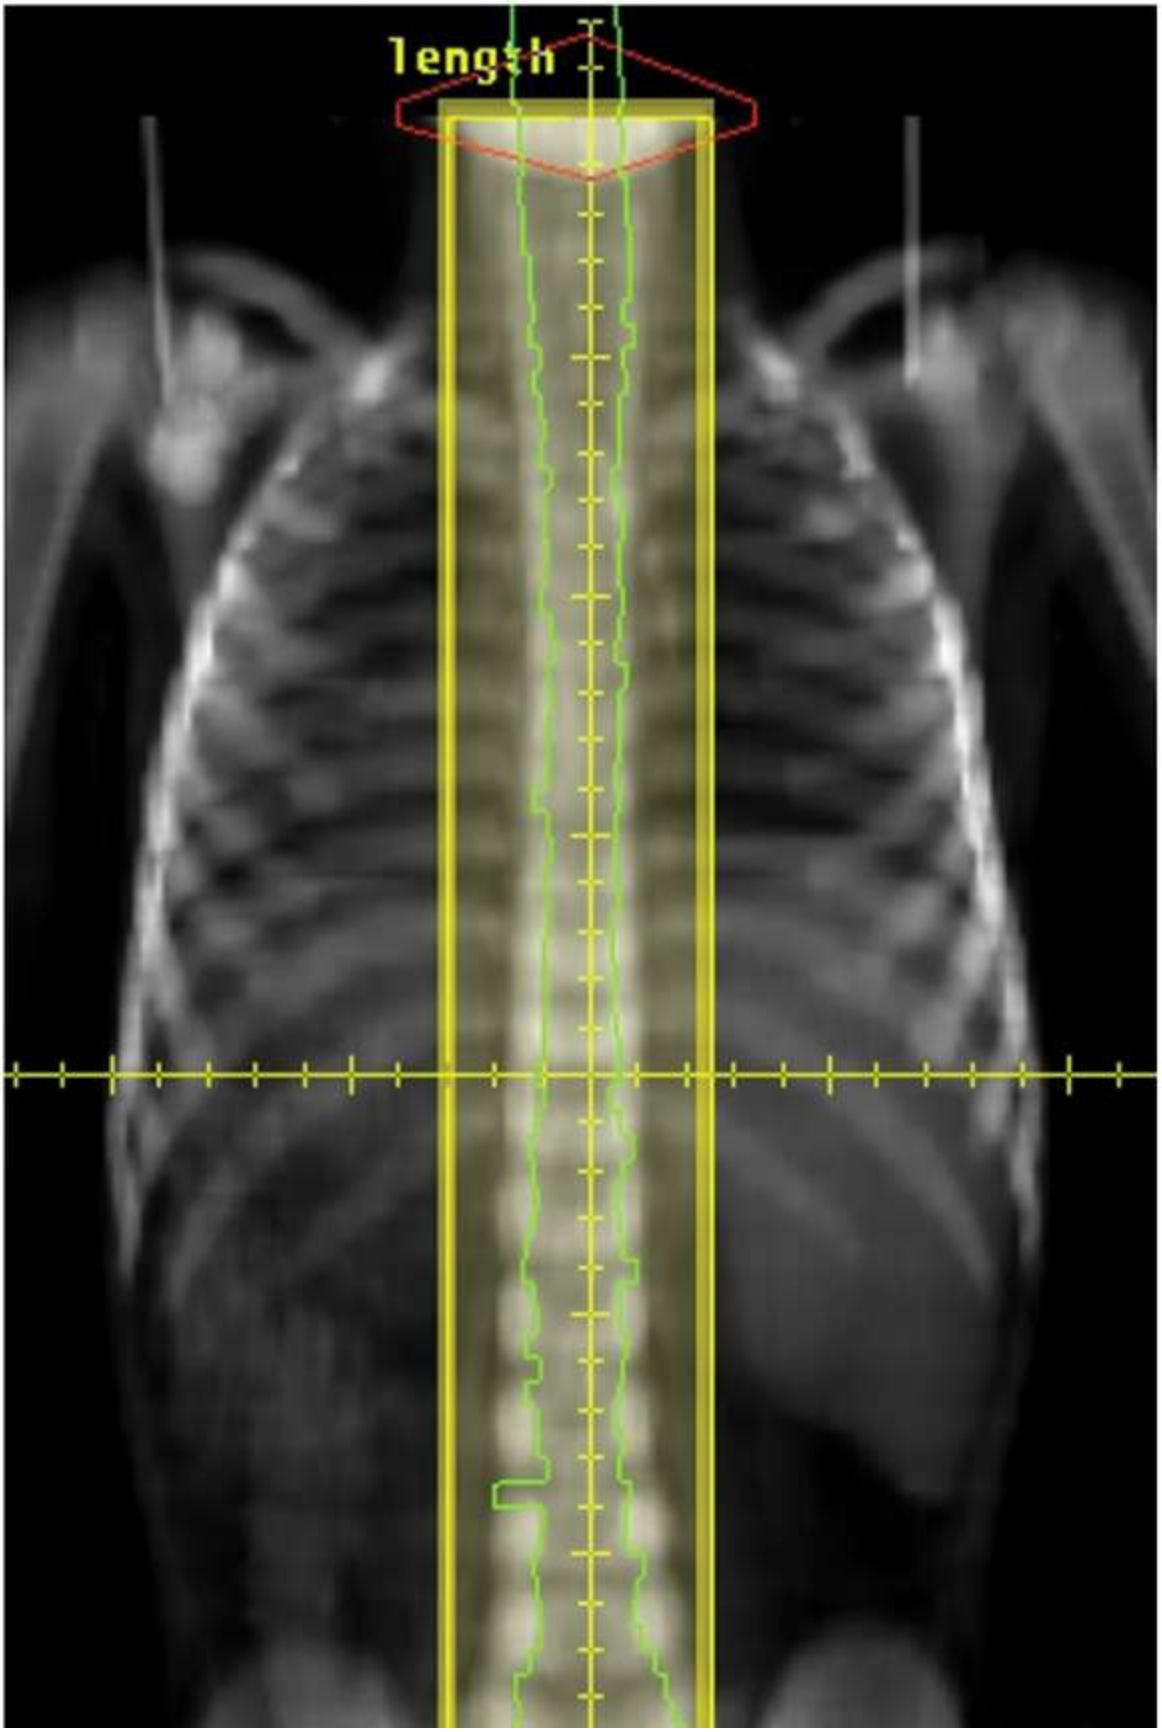
Target Volume Definition

CT simulation is necessary to ensure adequate coverage of the CTV in the subfrontal region at the cribriform plate. Traditionally, blocks have been used in the lateral fields to shield not only the facial structures but also the lenses. However, in most children, it is impossible to adequately irradiate the cribriform plate and entirely shield the lenses (Figure 90.1), and adequate PTV coverage should take precedence.

FIGURE 90.1 The use of computed tomography simulation is superior to conventional radiographs for determination of the clinical target volume for craniospinal irradiation and ensures coverage of the meninges in the subfrontal region. In most children, adequate coverage of the planning target volume precludes significant sparing of the lens.

CT simulation is also helpful in identifying the lateral aspect of CTV for the spine field that includes the extensions of the meninges along the nerve roots to the lateral aspects of the spinal ganglia (Figure 90.2). The field will be narrower in the thoracic region to avoid unnecessary irradiation of the heart and lungs and wider in the lumbar region, although here it is

important to avoid an excessively wide field that will result in unnecessary irradiation of the bone marrow and gonads. The lower limit of the CTV for the spine field should be determined using MRI. The lower border of the spinal CTV should include the lower border of the thecal sac, which can be as high as L5 or as low as S3. In the interest of both CTV coverage and normal tissue sparing, it is important that the lower border be individualized according to the MRI findings.



length

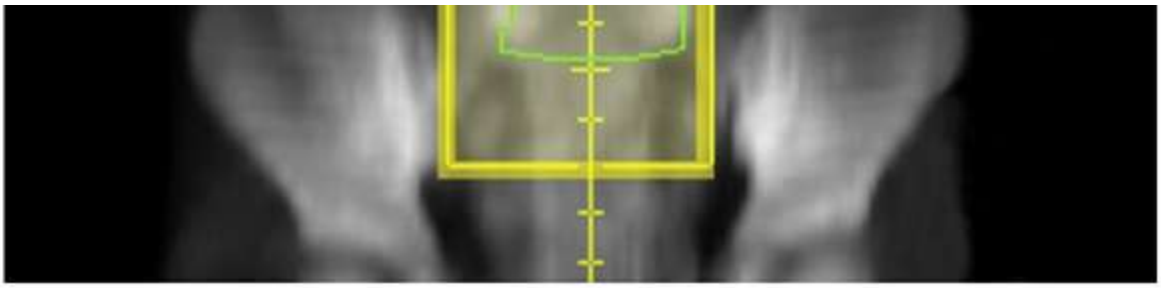


FIGURE 90.2 The use of computed tomography simulation with contouring of the cord and overlying meninges that extend laterally to the lateral aspect of the spinal ganglia results in a field width that is narrower than one based on bony anatomy. The addition of shielding further reduces the volume of normal tissues included in the treated volume.

Treatment Planning and Delivery

There are many issues that need to be addressed in designing a CSI technique. Many of the different solutions add further complexity.[31] Using modern tools for treatment planning and delivery, it is possible to greatly simplify the technique and substantially reduce planning and delivery times. One such technique is shown in Figure 90.3.[32] In general, photons in the 6- to 10-MV range provide satisfactory coverage of the PTV. A variation of dose along the spinal axis of more than 10% will require the use of dose compensation that can be achieved using multileaf collimation.

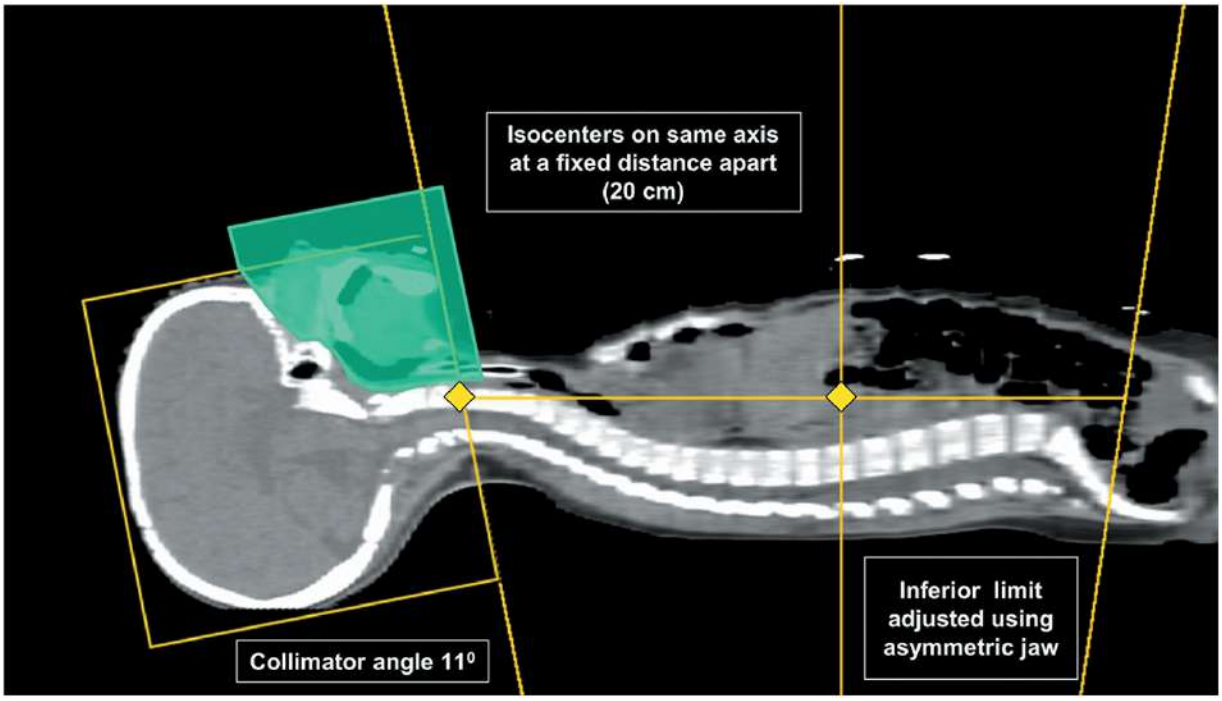

FIGURE 90.3 To cover the clinical target volume for craniospinal irradiation, lateral-opposed fields are used to treat the brain and a direct posterior field is used to cover the spinal axis. Magnetic resonance imaging is used to identify the caudal extent of the thecal sac. The field junction over the cervical cord should be at a level that avoids the inclusion of the teeth in the exit of the spinal field and is usually moved weekly ("feathered") to avoid over- or underdosage. The supine position is more comfortable for the patient and safer if sedation or anesthesia is required. In the technique shown, fixed-field parameters are used, which greatly facilitates treatment planning and delivery. (Reprinted from Parker WA, Freeman CR. A simple technique for craniospinal radiotherapy in the supine position. *Radiother Oncol*. 2006;78[2]:217-222. Copyright © 2005 Elsevier Ireland Ltd. With permission.)

Electrons are used in some centers to treat the spinal axis and in fact may be of greater interest now than in the past because of improved dose calculation algorithms and even electron dose modulation techniques.[33] However, at the same time, newer treatment planning and delivery methods such as IMRT together with daily image verification allow for improved dosimetry with photons with clinically relevant dose reductions to structures anterior to the target volume, such as the heart, gastrointestinal (GI) tract, and gonads.[34] The use of IMRT and smaller PTV margins raises new issues that are not as relevant as when lateral-opposed fields were used, such as the need to ensure adequate coverage of all CSF extensions

including those along the optic nerves and other cranial nerves (Figure 90.4).

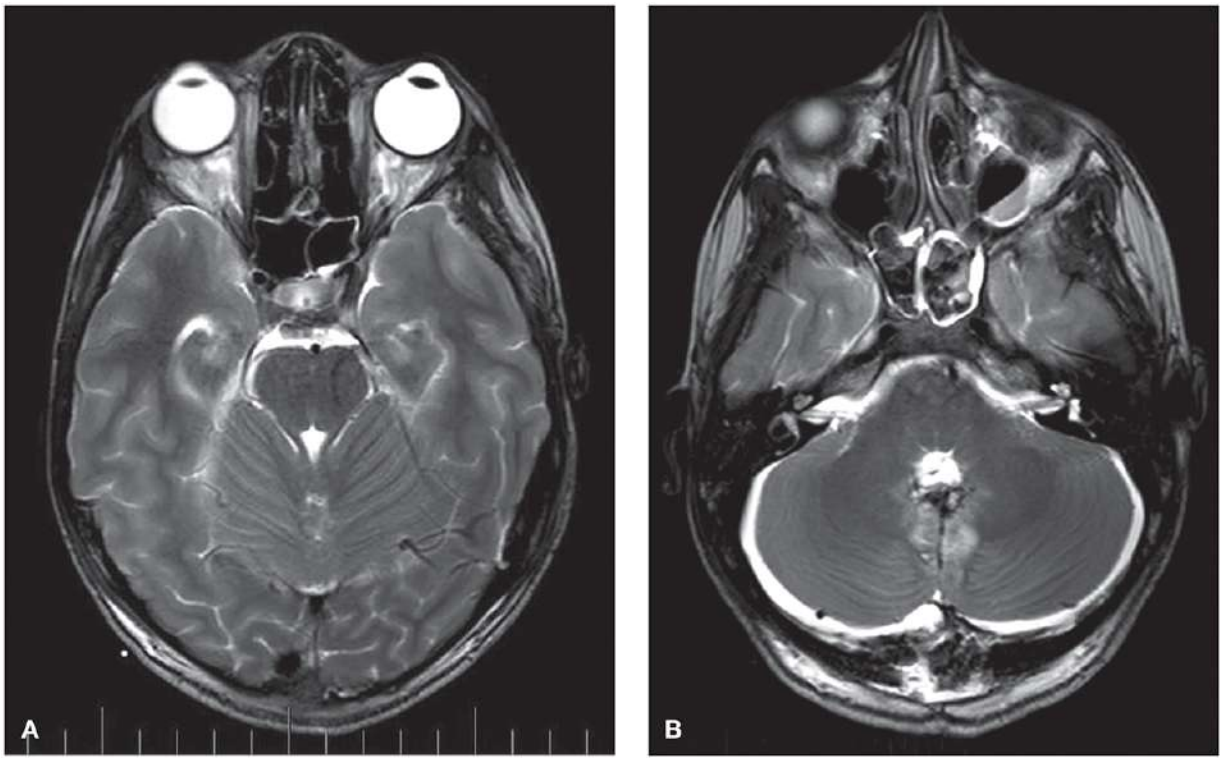

FIGURE 90.4 Postoperative axial T2-weighted magnetic resonance imaging for a patient receiving craniospinal irradiation (CSI) for medulloblastoma showing extension of cerebrospinal fluid along the optic nerves to the lamina cribrosa (A) and into the internal auditory canals (B). Care is necessary to identify all such extensions when using intensity-modulated radiation therapy for CSI, given that the margins are much tighter than when using conventional lateral-opposed fields.

New Treatment Modalities for Craniospinal Irradiation

Protons provide a dose distribution for CSI that cannot be achieved by even the most sophisticated photon beam treatment planning, with a significant reduction in low-dose exposure outside the target volume.[35] There may be significant benefits from reduced irradiation of the heart and organs anterior to the spine.[36] Currently, an increasing number of children requiring RT for CNS malignancies are treated by proton beam RT.[37]

Radiation Dose and Dose Fractionation Regimens

The conventional daily fraction size for the treatment of most pediatric CNS tumors is 1.8 Gy and the total dose typically on the order of 54 to 55.8 Gy. When treating primary tumors of the spinal cord, it is conventional to use lower total doses (eg, 50.4 Gy). Lower doses are also used for children younger than age 3 years to reduce the risk of neurocognitive deficits. When treating radiosensitive tumors such as intracranial germinoma, RT may be delivered using a lower dose per fraction (eg, 1.5 Gy) and lower total doses of 30 to 45 Gy.

Many pediatric brain tumors exhibit a dose-response relationship for tumor control, and in some cases, local progression is not prevented using a conventional "CNS tolerance" radiation dose. When the target contains only a small volume of normal brain tissue, dose escalation may be possible using newer treatment planning and delivery techniques. HFRT may be a useful strategy in situations where dose escalation cannot be achieved safely using conventional fractionation.

Follow-Up During and After Radiotherapy

An excellent review by Donahue[38] describes the acute reactions seen during treatment with RT and provides guidelines for their management. These days nausea and vomiting almost always can be prevented using the 5-hydroxytryptamine type 3 antagonists. Headache is not an expected side effect and should be investigated by physical examination for signs of raised intracranial pressure and by imaging as appropriate. Steroids, if used, usually can be tapered by the second or third week of treatment. Fatigue is a rather common symptom and is cumulative. The neurologic status of the patient, especially coordination and gait, may appear to worsen during the last weeks of treatment. Children usually recover relatively quickly and often can get back to their usual routines quite soon after completion of treatment.

Predictable effects of treatment include hormonal deficits, especially primary hypothyroidism when CSI is delivered using photons and growth hormone deficit secondary to the inclusion of the hypothalamic-pituitary axis. Patients should be monitored closely in follow-up and treatment instituted as appropriate. Many will also need regular follow-up in ophthalmology and audiology.

Extra pedagogic support may be necessary. Patients should have ready access to a neuropsychologist for evaluation of any special needs and in the longer term to vocational assessment and counseling.

RADIOTHERAPY FOR SPECIFIC TUMOR TYPES

The World Health Organization (WHO) classification of tumors of the nervous system was updated in 2021,[39] and the distribution by tumor type and location is given in Figure 90.5. The 2021 classification considers molecular characteristics of CNS tumors. There are important differences between tumors seen in childhood and those occurring in adults. In children, almost half of all tumors arise in the infratentorial compartment. Low-grade astrocytic tumors as a group account for approximately one-third to half of all CNS tumors, but MB is the most common distinct entity. High-grade gliomas, which account for most primary brain tumors seen in adults, are less common in children.

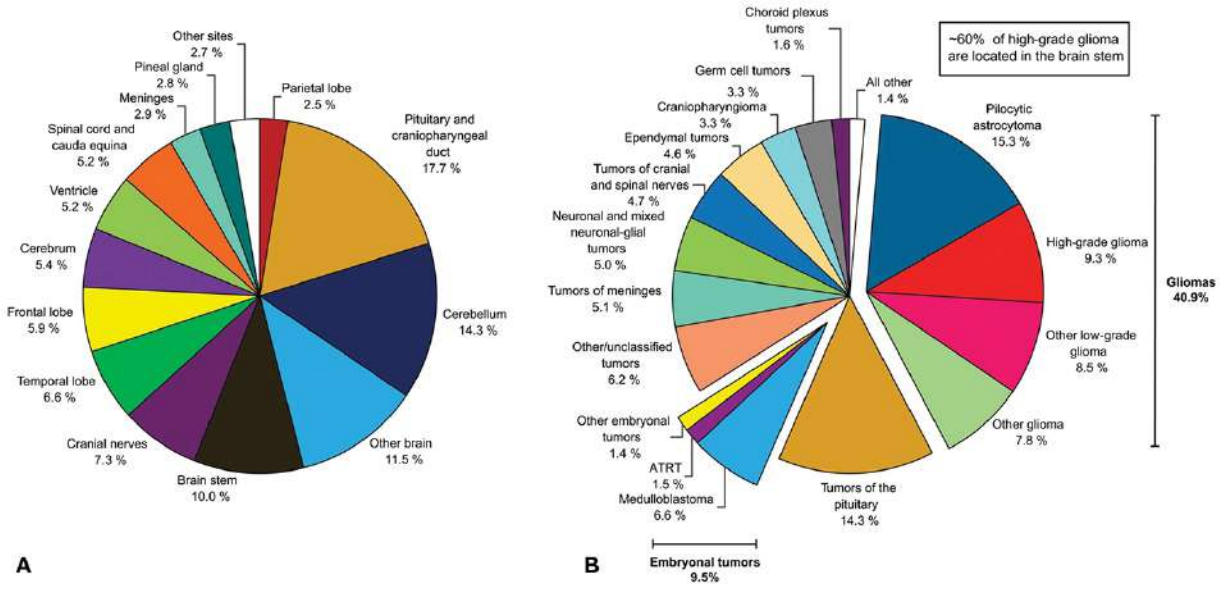

FIGURE 90.5 Distribution in children and adolescents ages 0 to 19 years of all primary malignant and nonmalignant brain and other central nervous system tumors (5-year total = 25,497; annual average cases = 5,099) by site (A) and histopathology (B). ATRT, atypical teratoid/rhabdoid tumor. CBTRUS Childhood and Adolescent Report: U.S. Cancer Statistics—NPCR and SEER, 2014-2018. (From Ostrom QT, Price M, Ryan K, et al. CBTRUS statistical report: Pediatric Brain Tumor Foundation childhood and adolescent primary brain and other central nervous system tumors diagnosed in the United States in 2014-2018. *Neuro Oncol*. 2022;24[suppl 3]:iii1-iii38. Reproduced by permission of Society for Neuro-Oncology.)

This chapter follows the order of the fifth edition of the WHO CNS tumors classification, or CNS5, published in 2021. Although tumors arising in infants and very young children were grouped together in the past and all managed similarly with chemotherapy in order to delay or if possible avoid RT, they are now managed according to the specific tumor type and so are discussed here in each relevant section.

- Pediatric-type diffuse low-grade gliomas
  - Diffuse astrocytoma, MYB or MYBL1 altered
  - Angiocentric glioma
  - Polymorphous low-grade neuroepithelial tumor of the young
  - Diffuse low-grade glioma, MAPK pathway altered
- Pediatric-type diffuse high-grade gliomas
  - Diffuse midline glioma (DMG), H3 K27 altered

    - Diffuse hemispheric glioma, H3 G34 mutant
    - Diffuse pediatric-type high-grade glioma, H3 wild type and IDH wild type
    - Infant-type hemispheric glioma
- Circumscribed astrocytic gliomas
    - Pilocytic astrocytoma (PA)
    - High-grade astrocytoma (HGA) with piloid features
    - Pleomorphic xanthoastrocytoma
    - Subependymal giant cell astrocytoma
    - Chordoid glioma

These astrocytic tumors are heterogeneous with respect to clinical presentation (age, gender, location in the CNS, imaging findings) as well as growth potential and rate of progression. Two types, pleomorphic xanthoastrocytoma and subependymal giant cell astrocytoma, are rare tumors. Their clinical presentations and imaging findings are quite characteristic, and surgery is usually curative.[39] They are not discussed further here.

Low-Grade Astrocytoma (World Health Organization Grades I and II)

So-called benign or low-grade astrocytomas (LGAs) comprise a heterogeneous group of tumors with behavior patterns in accordance with location and pathologic type. Generally, in children, they follow an indolent clinical course with overall survival (OS) rates at 10 and 15 years as high as 80% to 100%. LGAs can be grouped according to their anatomic location:

- Cerebellar astrocytomas (15%-20% of all CNS tumors)
- Hemispheric astrocytomas (10%-15% of all CNS tumors)
- Midline supratentorial tumors, including the corpus callosum, lateral and third ventricles, and hypothalamus and thalamus (10%-15% of all CNS tumors)
- Optic pathway tumors (~5% of all CNS tumors)

- Brainstem LGAs (brainstem tumors account for 10%-15% of all CNS tumors; 20%-30% of these are LGAs)
- LGAs of the spinal cord (spinal cord tumors account for 3%-6% of all CNS tumors; ~60% of these are LGAs)

PAs are the most common type in the pediatric age group, accounting for almost all LGAs at certain sites (eg, the cerebellum and the anterior optic pathway). They account for a smaller proportion of LGAs arising in the deep midline structures and in the cerebral hemispheres. Macroscopically, PAs appear well circumscribed and frequently have an associated cystic component. PAs are characterized histologically by a biphasic pattern with a varying proportion of compacted bipolar cells with Rosenthal fibers and loose-textured multipolar cells with microcysts and granular bodies. Rare mitoses, occasional hyperchromatic nuclei, microvascular proliferation, and even infiltration of the meninges are compatible with a diagnosis of PA and not a sign of malignancy. *KIAA1549-BRAF* fusions have been identified in 75% of patients with PA using a reverse transcriptase-polymerase chain reaction assay from formalin-fixed paraffin-embedded tissue.[40] A variant, pilomyxoid astrocytoma, first described in infants and young children with chiasmatic/hypothalamic tumors, appears to be associated with more aggressive behavior that may include leptomeningeal seeding.[41]

Diffuse astrocytomas account for only 10% to 15% of all LGAs in children but for a relatively higher proportion of those seen in infants and adolescents. Most intrinsic pontine tumors and a large proportion of astrocytomas arising in the cerebral hemispheres are diffuse astrocytomas. Diffuse astrocytomas grow by infiltration rather than destruction of anatomic structures and are usually not well circumscribed. Microscopically, they are composed of well-differentiated fibrillary or gemistocytic neoplastic astrocytes on a background of loosely structured, often microcystic, tumor matrix. Cellularity is moderately increased. The presence of nuclear atypia is a diagnostic criterion, but mitotic activity, necrosis, and microvascular proliferation are absent. The growth fraction as determined by Ki-67 and MIB-1 labeling indices is usually low. Diffuse astrocytomas may undergo malignant progression, although this is not common in the pediatric age group with the notable exception of tumors arising in the pons.

Patients with LGAs typically present with a long history of nonspecific and nonlocalizing symptoms. Symptoms and signs of raised intracranial pressure may be seen in patients with midline and cerebellar tumors. Patients with posterior fossa tumors may present with neck stiffness and a head tilt as a manifestation of raised intracranial pressure, causing tonsillar herniation, altitudinal diplopia, or spinal accessory nerve irritation. Seizures are present in as many as three-quarters of patients with hemispheric lesions. Other symptoms relatively less frequent and usually of more recent onset relate to the location of the tumor. These may include, for example, focal motor deficits with hemispheric tumors, visual field deficits with tumors compressing or involving the optic pathway, neuroendocrine deficits with hypothalamic tumors, and diencephalic syndrome (consisting of emaciation with loss of subcutaneous fat despite normal or increased appetite, alert appearance, increased vigor and euphoria, pallor without anemia, and nystagmoid movements of the eyes) in young children with chiasmatic/hypothalamic tumors.

Neuroimaging findings are usually quite characteristic. PAs are well circumscribed, often with a cystic component that may be large relative to the size of the solid component. There is usually little edema or mass effect. The solid component enhances brightly and uniformly with contrast material. Diffuse or fibrillary astrocytomas are usually not well seen on nonenhanced CT or MRI and usually show little enhancement with contrast material. T2-weighted or fluid-attenuated inversion recovery (FLAIR) MRI sequences usually best demonstrate the extent of disease.

Management of Low-Grade Astrocytomas: General Principles

Some children with LGAs may not require any tumor-specific treatment. These include, for example, patients with NF-1, as many as 15% of whom have optic pathway tumors.[42] Patients with NF-1 also may have astrocytic tumors in other parts of the CNS as well as hamartomatous lesions, typically in the brainstem. These lesions may be detected on routine imaging, but even tumors that are symptomatic may remain stable over long periods so that surveillance may be an appropriate initial management.[43-45] A number of clinical and imaging characteristics have been correlated with a more aggressive course, but even for these patients, active intervention

will usually be undertaken only at the time of progressive disease that is symptomatic.

Progression-free survival (PFS) without treatment may also be very good for patients with tectal plate lesions who present with hydrocephalus without localizing brainstem signs. LGA in this region may be very indolent, showing either no progression (the majority) or only very slow progression over the course of many years following CSF diversion alone. The common characteristics of these very indolent tumors are their small size (,1.5 or 2 cm) and the fact that on imaging they are hypodense/hypointense and nonenhancing. Follow-up with MRI is essential to identify patients with progressive lesions as manifested by increasing size and/or enhancement with gadolinium. Treatment at the time of progression is associated with a high probability of long-term tumor control. Treatment options can include surgery, RT, and chemotherapy.[46,47] Patients who undergo RT have an excellent prognosis with a 10-year PFS of 82%.[47] For many pediatric patients, chemotherapy may be favored in efforts to avoid brain RT and excellent prognosis.[46,47]

These special situations underscore the need for careful evaluation and individualization of the management of patients with LGAs depending on the specific clinical situation and tumor type. If in doubt, a period of surveillance generally will be an acceptable initial approach, reserving nonsurgical treatment for symptomatic progression.

Surgery is the mainstay of treatment for LGAs. Complete resection is more likely to be accomplished in patients with smaller tumors and those arising in noneloquent parts of the brain as well as in patients with the generally well-circumscribed pilocytic tumors. Modern surgical techniques that include, for example, computer-assisted resections (“neuronavigation”) aided by preoperative functional MRI, MR tractography, and intraoperative mapping of eloquent areas (Figure 90.6) together with intraoperative MRI permit greater degrees of resection in larger proportions of patients, including many who in the past would have been considered to have inoperable lesions. Complete resection is now achieved in more than 80% of cerebral, cerebellar, and spinal cord tumors and about 50% of diencephalic tumors.

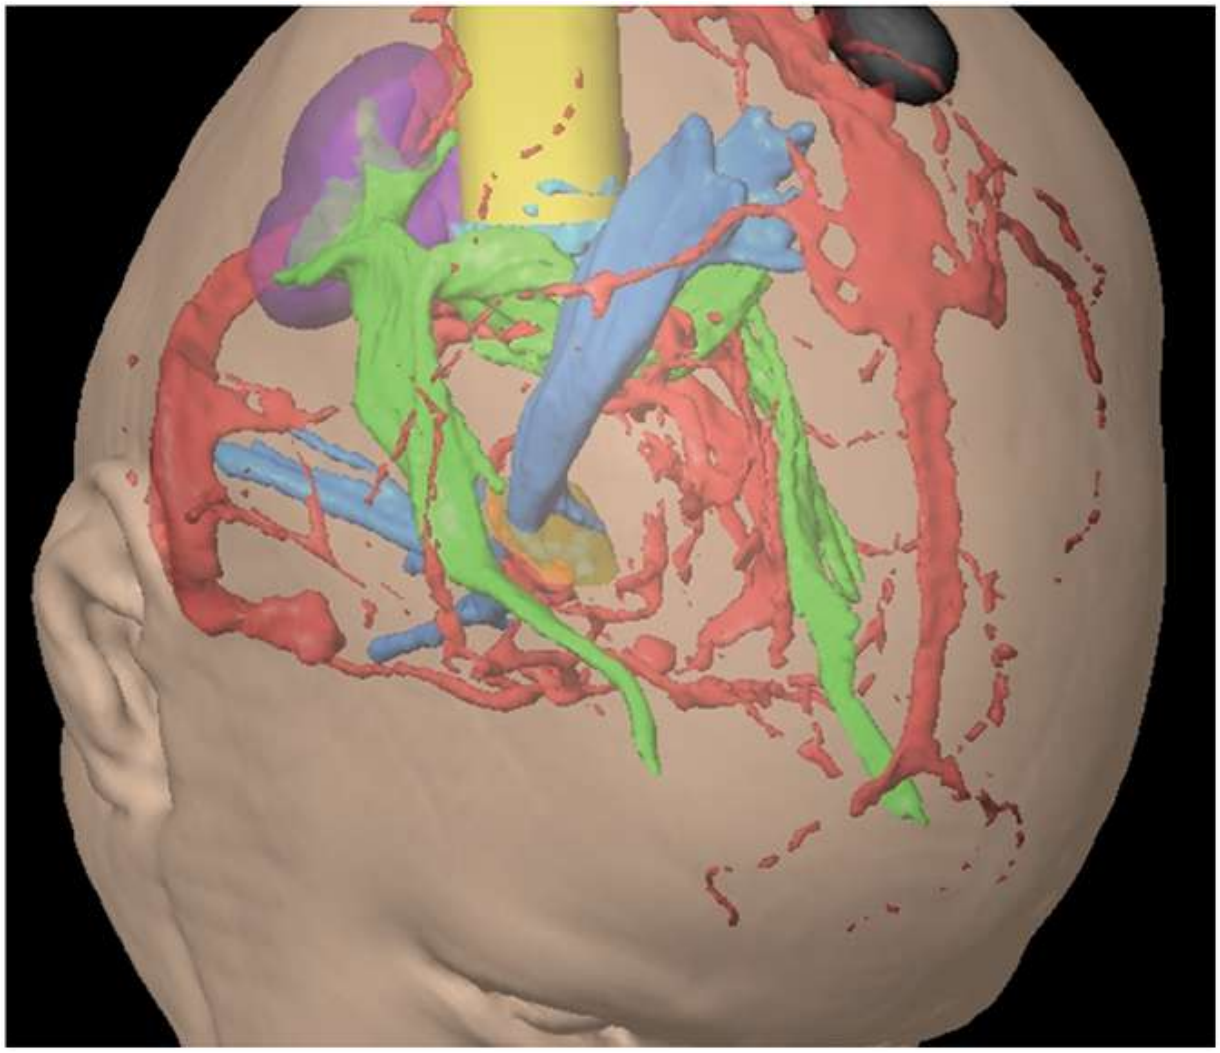

FIGURE 90.6 Surgical planning for a dysembryoplastic neuroepithelial tumor (light blue) in the right occipital lobe presenting with seizures. Functional magnetic resonance imaging data are used to identify the 1-degree visual cortex (purple). Fiber tracking identifies the optic radiations (green) and the corticospinal tract (darker blue). These data are then used to plan the trajectory (yellow). By identifying regions to be selectively avoided, similar information could be helpful in radiotherapy treatment planning.

Children with LGAs who undergo complete resection fare very well, with long-term disease-free survival and OS rates of 80% to 100%, respectively.[48-53] In most series, results are better (close to 100%) for patients with PAs than for those with diffuse or fibrillary LGAs, although some have disputed this, showing equally satisfactory results for both. In either type, postoperative adjuvant therapy is not indicated.

For children who undergo less than complete resection, the PFS rate after surgery alone is less satisfactory. In a joint Children's Cancer Group (CCG)-Pediatric Oncology Group (POG) study in which such patients were observed without adjuvant treatment, any residual tumor was associated with an inferior PFS rate: The 8-year PFS rate was 56% for patients with less than 1.5 cm^3 residual tumor and 45% for those with greater than 1.5 cm^3. However, most patients can be salvaged with a second surgical resection and/or RT. In the CCG-POG study, OS at 8 years was 95% and 90% for patients with less than 1.5 and greater than 1.5 cm^3 residual tumor, respectively.[54]

The role of postoperative RT following less than complete resection remains unclear. In most series, the use of RT in this situation results in improved disease-free survival without any benefit in terms of OS. Because only approximately half of all patients will develop PFS, the usual recommendation for a patient who is neurologically stable will be surveillance, with MRI performed at least every 6 months for the first 3 years, the period during which the risk of progression is greatest.[55] A second surgical procedure would usually be considered at the time of progression, and other treatment, either RT, chemotherapy, or targeted systemic therapies, reserved for patients with progressive, inoperable disease (Figure 90.7).

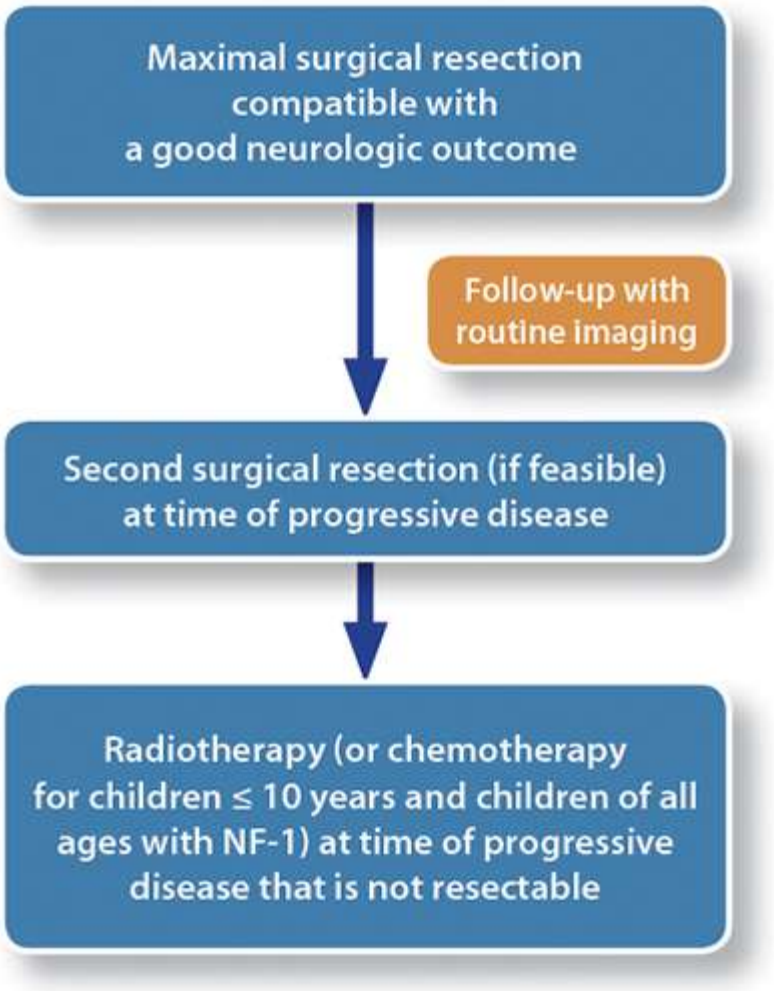

FIGURE 90.7 An algorithm for the management of patients with low-grade astrocytoma. NF-1, neurofibromatosis type 1.

In the past, patients with deep midline and other tumors considered surgically inaccessible were treated with RT, often even without histologic confirmation of diagnosis. However, using modern neurosurgical techniques, it is feasible to resect surgically about half of these lesions (Figure 90.8), and the overall strategy for these patients should now be as for patients with LGAs at other locations, albeit with the understanding that outcome is not as satisfactory. The 8-year PFS and OS rates in the CCG-POG study for patients with midline chiasmatic tumors were 25% and 84%, respectively.[55]

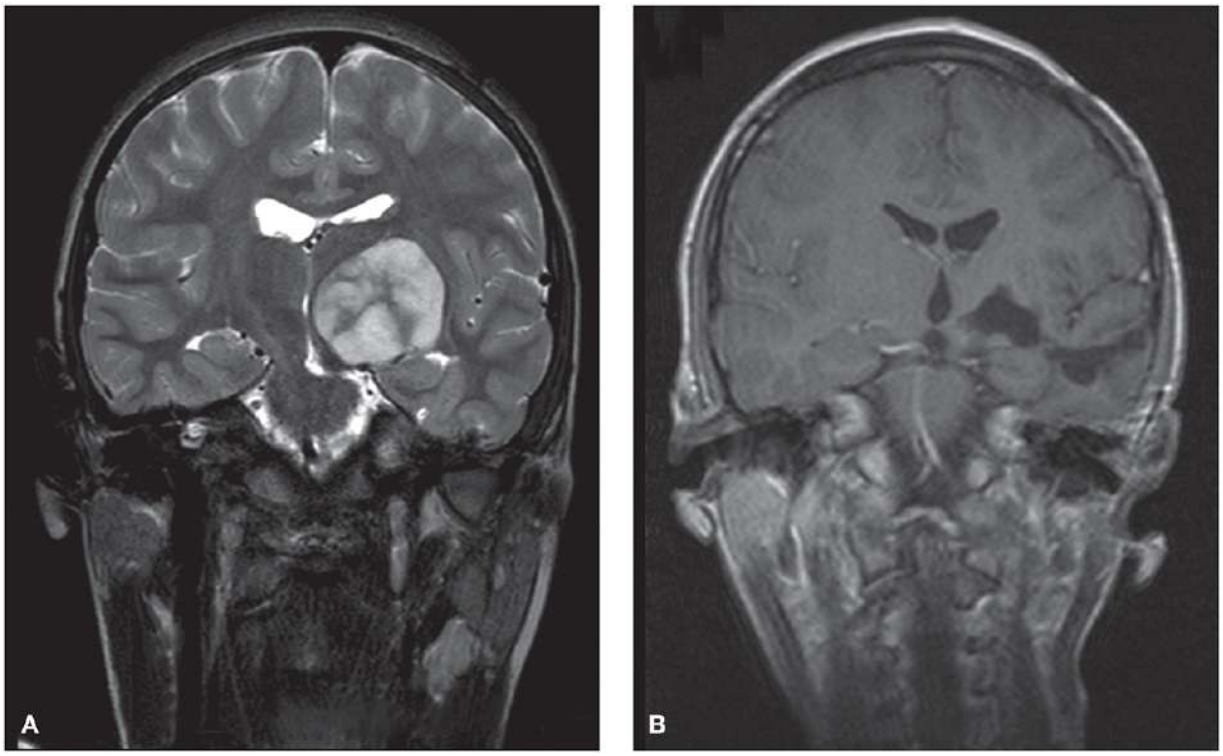

FIGURE 90.8 A 12-year-old boy referred to the radiation oncology department 3 years after diagnosis of a biopsy-proven juvenile pilocytic astrocytoma of the left thalamus at another institution. He had been deemed inoperable at diagnosis and had received chemotherapy first with vincristine and carboplatin and then with weekly vinblastine. A. At the time of referral, he was having more frequent choreoathetotic movements of his right hand, and there was evidence of progressive disease on magnetic resonance imaging (MRI). B. He underwent complete resection without complications and has no evidence of residual disease on his most recent MRI. This was a far better approach than radiotherapy, avoiding the neurocognitive, endocrine, and vascular complications associated with radiotherapy for tumors in this region, and with a greater probability of long-term tumor control.

When adjuvant therapy is indicated, the options include chemotherapy or targeted therapies, particularly for infants and young children and for patients of all ages with NF-1 who are at greatest risk of developing neurocognitive, vaso-occlusive, and neuroendocrine sequelae of treatment.[56,57] There is a trend over time for chemotherapy to be employed as the initial treatment with 5-year PFS rates at approximately 50%.[58-63] Complete responses to chemotherapy are not common, but overall response rates that include stable disease range can be up to 85% and the use of chemotherapy has been shown to allow many patients to omit RT altogether or permit the delay of RT by many years without an impact on survival.[58-62] A recent study found that pediatric patients with BRAF V600E–mutant

pediatric glioma had longer PFS compared with those receiving chemotherapy.[64] Furthermore, at the time of progression, patients often have additional systemic therapy options, including additional chemotherapy or targeted therapy.[56,65-68] It is likely that most patients will not need RT, but patients at risk of neurologic compromise from tumor progression continue to benefit from RT.[69]

Radiotherapy in Low-Grade Astrocytomas

Due largely to improvements in surgery and, to a lesser extent, to successful treatment of younger children with chemotherapy, there has been a substantial decrease in the use of RT over recent years. Currently, only approximately 10% of all children with LGAs receive RT.

Indications for Radiotherapy

- RT is not indicated after complete resection.
- RT may be indicated following incomplete resection in situations when tumor progression would compromise neurologic function (eg, "threat to vision").
- The clearest indication for RT is in patients with progressive and/or symptomatic disease (especially in settings of neurologic deficits) despite multiple lines of systemic therapy and is unresectable.

Radiotherapy Target Volume

The RT target volume (the gross tumor volume or GTV) consists of all diseases seen on MRI performed just prior to treatment (Figure 90.9). The resulting treatment volume usually will be considerably smaller than one based on preoperative imaging, which until recently would have constituted standard practice. Similarly, margins that were considered standard (and still are in adult practice) are unnecessary, particularly for the well-circumscribed pilocytic tumor for which a CTV margin of 1 cm[51] or even 0 cm (ie, CTV = GTV)[70] around the GTV as seen on T1-weighted gadolinium-enhanced images has been shown to result in excellent local control. More generous margins of 1 to 1.5 cm around the GTV as seen on T2-weighted or FLAIR images may be more appropriate for the more

infiltrative diffuse fibrillary tumors. RT planning will also consider OARs, including the hippocampus. Future protocols will specify hippocampal dose constraints.

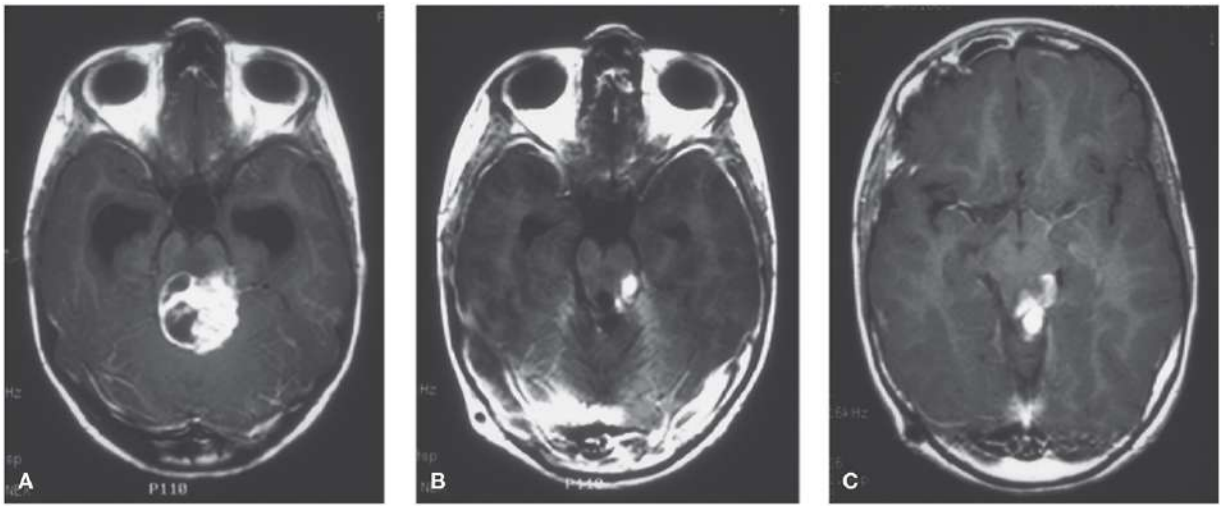

FIGURE 90.9 A patient underwent subtotal resection of a low-grade astrocytoma of the left cerebellar peduncle at age 8. A. Preoperative. B. Postoperative. C. Three years later, routine imaging showed evidence of progressive disease. The gross tumor volume for radiotherapy consists of the tumor as seen on magnetic resonance imaging at the time of treatment.

Radiotherapy Dose

Evidence for a dose-response correlation in LGAs in children is scant. Although the European and North American studies that randomized adult patients with LGAs between low-dose (45 and 50.4 Gy, respectively) and high-dose (59.4 and 64.8 Gy, respectively) RT failed to demonstrate any advantage for the higher dose,[71,72] it may be unwise to extrapolate that in children doses of 45 to 50 Gy are as effective as the higher doses of 54 to 55 Gy that until now have constituted standard practice. There are biologic differences between LGAs in children and adults. As well, children who have progressed on chemotherapy may have tumors that are less sensitive. For now, the recommendation for children with LGAs would be a "standard" dose of 50.4 to 54 Gy depending on the age of the child and the location of the tumor and its relationship to critical normal structures, such as the optic chiasm.[73,74]

Radiotherapy Technique

External beam RT using a conventional dose fractionation schedule should be considered the standard of care in LGAs and the technique to be used that provides homogeneous irradiation of the CTV and best spares surrounding normal tissues. Increasingly proton therapy is being employed for the treatment of LGAs as a means of minimizing nontarget dose and hopefully late neurocognitive effects.

Other approaches that have been used in LGAs include radiosurgery using gamma knife or linear accelerator–based techniques.[75] Although the use of a single fraction, typically of 10 to 20 Gy, to the periphery of the lesion or a small number of large fractions may not be optimal for diffuse or fibrillary LGAs with tumor cells embedded in rather than displacing normal brain, such treatment may be of interest for part or even all of the treatment for the less invasive PAs that are often small at the time of progression.

Another option for treatment is brachytherapy, which has been used with some success, particularly in European centers.[76-80] As for radiosurgery, the principal limitation with respect to the use of brachytherapy is the size of the target volume. Brachytherapy series necessarily select for smaller tumors, and there is no evidence that brachytherapy is a better treatment option than external beam RT. Radioactive solutions such as ^{33}P, ^{91}Y, ^{199}Au, and ^{187}Re may be useful in cystic LGAs, particularly for patients with recurrent disease after RT in whom symptoms not infrequently relate more to the cyst than to the solid component of tumor. Simple aspiration with or without placement of an internal shunt usually will alleviate symptoms for protracted periods, but in some cases, particularly those in which the cyst wall enhances and is felt to be biologically active, control of the cyst may be difficult, and the use of radioactive solutions could be considered. However, this is not a procedure without risks, and care must be taken to avoid leakage.

Follow-Up After Radiotherapy

Tumor regression after RT is typically slow, and patients and their families need to be warned that the tumor may remain stable or sometimes even increase in size in the first months after completion of treatment. It is important not to assume that changes seen on MRI represent progressive

disease. Close follow-up with early repeat imaging usually will be the best approach in this situation.

High-Grade Astrocytoma (World Health Organization Grades III and IV)

Anaplastic astrocytoma (AA) is a diffusely infiltrating malignant astrocytoma characterized by nuclear atypia, increased cellularity, and significant proliferative activity. Glioblastoma (GBM) is the most malignant astrocytic tumor. Histopathologic features include nuclear atypia, cellular pleomorphism, mitotic activity, vascular thrombosis, microvascular proliferation, and necrosis. Both AA and GBM may develop from WHO grade II astrocytomas. However, except for tumors that arise in the pons, they arise almost always in the pediatric age group de novo without evidence of a less malignant precursor lesion.

HGAs account for 5% of all CNS tumors in the pediatric age group. They are the most common tumor type in older adolescents. Two-thirds of HGAs are located in the cerebral hemispheres and the remainder approximately equally divided between the deep midline structures (thalamus and basal ganglia) and cerebellum. Patients with HGAs usually present with symptoms of short duration that relate to the location of the lesion.

Surgery is an important component of treatment. Because most studies show a survival advantage for patients who have undergone complete resection,[81-85] maximal surgical resection compatible with a good neurologic outcome should be the goal for all patients and a second surgical procedure should be considered if there is significant residual tumor after the first. Postoperative RT is always indicated. Although leptomeningeal seeding is seen in a substantial minority (10%-30%) of patients, the predominant failure pattern is local and the RT target volume is local, with GTV that consists of tumor bed and any residual enhancing or nonenhancing residual tumor plus any abnormality seen on T2-weighted MRI with a margin for the CTV of 1.5 cm. Because these are often large tumors and doses beyond tolerance levels for structures such as the optic chiasm are required, it is usual to consider a volume reduction at 50 to 54 Gy to a CTV that consists of the tumor bed and any residual tumor plus a reduced margin of 1 cm. The dose to the CTV should be at least 54 Gy given over 6 weeks, but a dose of

59.4 to 60 Gy is more typical when feasible. There is no evidence that higher doses delivered using radiosurgery or stereotactic boosts, boosts with brachytherapy, or HFRT result in improved outcome, but IMRT delivering accelerated treatment to a component of the target volume (such as the GTV) may be of interest, if only to decrease the overall treatment duration.

The role of chemotherapy remains to be defined. Although responses are seen to many different agents and regimens, results have often been difficult to interpret because of small patient numbers, inconsistent inclusion criteria with respect to pathology, and confounding variables such as tumor location and extent of surgical resection.[86-88] The cooperative groups in North America and Europe are investigating several approaches that include newer chemotherapeutic and biologic agents, some of which have radiosensitizing properties. Whenever possible, patients should be treated on such protocols. Off study, it may be difficult to make a recommendation with respect to adjuvant chemotherapy, although the poor prognosis, particularly for patients with macroscopic residual disease following surgery, is usually given as an argument for the use of the "current best" regimen, most often now temozolomide as in adults.[86-88]

The prognosis for children with HGAs is poor, with a median time to progression of 10 to 11 months and an OS at 5 years of only approximately 20%. Several factors correlate with outcome. Patients with lesions in the cerebral hemispheres fare better than those with tumors in other locations, apparently independent of the extent of surgical resection. The prognosis for children with thalamic lesions appears to be particularly poor.[89] Age also may be an important factor. In contrast to most other tumor types, children younger than age 3 with HGAs fare better than older children, with OS at 3 to 5 years in the 33% to 50% range in the North American and United Kingdom Children's Cancer Study Group/International Paediatric Oncology Society (SIOP) baby studies.[90-93] The prognosis may be even better for children younger than age 1.[94] Prior studies have not consistently found that histologic grade (AA vs GBM) impacts outcome, but p53 overexpression and a high MIB-1 labeling index appear to identify patients with a particularly adverse prognosis.[95]

Management of Astrocytic Tumors in Specific Locations

Optic Pathway Gliomas

Optic pathway gliomas collectively account for approximately 5% of all CNS tumors in the pediatric age group. These are tumors of young children: The peak age incidence is between 2 and 6 years, and 75% of all patients are younger than 10 years. One-third of patients have NF-1. They may be divided into three clinicopathologic entities: tumors confined to the optic nerve(s), tumors of the optic chiasm with or without optic nerve involvement (collectively "anterior" tumors), and tumors that involve the hypothalamus or adjacent structures ("chiasmatic/hypothalamic" or "posterior" tumors). Management of patients with optic pathway gliomas is often said to be controversial but is really not when differences in behavior between the different tumor types and between patients with and without NF-1 are taken into consideration.

Optic nerve gliomas may involve one or both optic nerves. Bilateral involvement is pathognomonic of NF-1. In a substantial proportion of cases, the optic nerve tumors are incidental findings on routine imaging, and patients may remain asymptomatic with nonprogressive lesions over long periods; even spontaneous regression is well documented. The frequency of progression is difficult to establish, ranging from lows of less than 10% among patients followed in NF-1 clinics to 40% to 50% in series reported by oncology centers. Even in patients with symptomatic tumors, the course can be quite variable: Only 30% to 60% of such patients will develop progressive disease that requires treatment.[44,96] Thus, management of patients with optic nerve tumors will usually consist initially of close follow-up with regular ophthalmologic examinations and MRI, with active intervention, usually chemotherapy, reserved for patients with clear evidence of progression that is symptomatic.[96-98]

Patients with unilateral optic nerve involvement may not have NF-1. They present most frequently with proptosis that may be relatively long-standing. Findings on examination may include optic atrophy and impaired visual acuity. On MRI, optic nerve tumors are usually relatively small and well circumscribed, with bright enhancement typical for PA. Biopsy is not necessary to make a diagnosis. Treatment usually, although not always, will be necessary, and the approach will depend on whether there is useful vision. If not, then surgical resection will be the treatment of choice. If

useful vision is preserved, chemotherapy would be the preferred option for infants and very young children up to age 5 years and for patients of all ages with NF-1. RT could be considered for older children. Overall, the prognosis is very good. Visual acuity remains stable or improves in most cases following chemotherapy or RT. Long-term tumor control approaches 100% with either modality.[99]

Chiasmatic gliomas are tumors that involve the optic chiasm and sometimes one or both optic nerves as well. Patients typically present with loss of visual acuity and temporal field defects. On imaging, the tumors are usually relatively small and well circumscribed and enhance uniformly and brightly with contrast material, suggestive of pilocytic histology. Biopsy is usually not necessary.

A period of surveillance is appropriate as initial management, particularly for patients with NF-1. For patients without NF-1, especially those who present before age 5 years, there is a high probability of early progression, and the majority of patients will require nonsurgical treatment within a few months following diagnosis. Surgery is rarely an option for tumors in this location. As for optic nerve tumors, chemotherapy usually will be the treatment of choice for infants and young children and for patients with NF-1. RT is reserved for salvage after chemotherapy and can be considered for definitive treatment of older children without NF-1 and visual decline despite systemic therapy, providing a reasonable expectation that vision will not deteriorate further and a probability of long-term PFS in the 60% to 90% range.[98,100-104] OS for patients with chiasmatic tumors is in the 90% to 100% range.

Posterior, or chiasmatic/hypothalamic, gliomas account for approximately 70% of all optic pathway gliomas in children. They are typically rather large lesions that probably arise in the optic chiasm and extend to involve the hypothalamus. They may extend posteriorly along the optic tracts as well. They often fill the third ventricle, eventually causing hydrocephalus. Early findings consist of nystagmus, impaired visual acuity, and visual field deficits; only later do patients present increasing head circumference and/or symptoms and signs of raised intracranial pressure.

Treatment consists of CSF diversion, if necessary, and surgical resection, particularly if tumor is growing exophytically into the basal cistern because this may provide rapid relief of symptoms. In most patients, however,

resection will be incomplete. As for LGAs at other locations, a period of surveillance following surgery is reasonable, although most patients will require adjuvant therapy.[58,99] The treatment of choice for children younger than 5 and those with NF-1 usually will be chemotherapy. PFS at 3 to 5 years is rather low at 20% to at best 60%.[58,59,61,105] However, some patients will never need further treatment, and the vast majority do not need RT with RT-free survival at 5 years of 83%.

The indications for RT are progressive disease after multiple lines of systemic therapy or growth may jeopardize important neurologic function, such as vision. RT in this situation, given to local fields to a dose of 45 to 50 Gy for younger children and of 50 to 54 Gy for those older than 5, results in local tumor control in 70% to 80% of cases.[58,99,101,106,107] Overall, however, outcomes are less satisfactory for this group of patients than for those with anterior tumors. Long-term survival is in the 50% to 80% range, and many patients will be left with significant neuroendocrine and neuropsychological sequelae. Patients with NF-1 are particularly at risk. They may have subnormal IQ even without chemotherapy and/or RT.[108] They are also at greater risk for moyamoya syndrome, a progressive vaso-occlusive process involving the circle of Willis. This may be seen without RT, but when RT is used in patients with NF-1, it is important to include MR angiography as part of the regular follow-up imaging protocol and intervene surgically if necessary to avoid a cerebrovascular accident.

Brainstem Gliomas

Tumors arising in the midbrain, pons, and medulla oblongata account for 10% to 15% of all CNS tumors in the pediatric age group. They are of several distinct types that can be broadly grouped as the more favorable low-grade focal, dorsal exophytic, and cervicomedullary tumors and the much more aggressive DMGs, formerly known as diffuse intrinsic pontine gliomas.[109-111]

Focal tumors are tumors of limited size (,2 cm) that on MRI are well circumscribed, without evidence of infiltration, and without edema. They may be cystic, and, as with cystic tumors at other sites, the cystic component may be large relative to the solid, biologically active, component. Focal tumors may occur at any level in the brainstem but most

frequently are seen in the midbrain and medulla. They usually present with a long history of localizing findings, such as an isolated cranial nerve deficit and contralateral hemiparesis. Signs and symptoms of raised intracranial pressure are uncommon, except in patients with tumors arising in the tectal region that may cause aqueduct stenosis while still small.

The management depends on the location of the tumor in the brainstem and the specific imaging characteristics of the tumor. As noted previously, patients with nonenhancing focal tumors in the tectal region who present with only hydrocephalus may do well without any treatment other than CSF diversionary procedures, usually endoscopic third ventriculostomy. Active intervention, including biopsy, is reserved for patients with clinical and radiologic evidence of progressive tumor. This is important because surgery for tumors in this location is associated with a substantial risk of morbidity, even with modern techniques.

Surgery is the treatment of choice for focal tumors at other locations that are surgically accessible (meaning that they extend either toward the surface of the brainstem laterally or at the floor of the fourth ventricle) and have imaging characteristics suggestive of low-grade histology. In this regard, uniform bright enhancement with contrast material, which correlates with pilocytic histology, and the absence of peritumoral hypodensity are of particular importance. In experienced hands, the risk of morbidity for well-selected patients is low and, as with completely or subtotally resected LGAs at other sites, results may be excellent with freedom from progression in a majority of cases.[112,113] Outcomes are less satisfactory for patients with bulky tumors and for patients with tumors in the medulla with lower cranial nerve deficits who are at risk of developing postoperative feeding and/or breathing difficulties.

There are several treatment options for patients with surgically inaccessible focal lesions. By extrapolation from series reporting results of treatment using conventional RT in brainstem tumors in which outcome correlates with location (pons vs other), imaging appearance (tumor volume, density on CT, enhancement pattern), and histology (malignant vs benign), it is reasonable to assume that 50% to 70% of focal lesions may be permanently controlled with such treatment. Similar results have been obtained in small numbers of patients treated with HFRT and with interstitial irradiation using ^{126}I.[77-79] There is also some experience with the

use of radiosurgery. However, standard treatment is as for LGAs at other locations, that is, external beam RT using a margin for the CTV of 0.5 cm, to a total dose on the order of 54 Gy given over 6 weeks. The risks of HFRT, radiosurgery, or stereotactic irradiation with large fraction sizes, or interstitial irradiation in inexperienced hands cannot be justified in the absence of any established superiority.

Dorsal exophytic tumors arise from the floor of the fourth ventricle. They are usually large, filling the fourth ventricle, but do not invade the brainstem to any significant extent. They present insidiously with failure to thrive in younger children and symptoms and signs of raised intracranial pressure in older patients. Cranial nerve deficits are seen in about half of the patients. On MRI, they are sharply delineated from surrounding structures. They are hypointense on T1-weighted images, are hyperintense on T2-weighted images, and enhance uniformly and brightly after gadolinium injection. Most are PAs.

Surgery is the treatment of choice for dorsal exophytic tumors. Intraoperative image guidance is essential to achieve a maximal degree of tumor resection. However, because there is usually no definite tumor-brainstem interface, even an optimal resection will leave a thin layer of tumor on the floor of the fourth ventricle. Nonetheless, most children do well following surgery, and routine postoperative adjuvant therapy is not indicated. RT may be considered for the rare patient who is found to have a high-grade lesion or for patients with low-grade tumors who develop progressive disease in the early (<9 months) postoperative period. For patients whose tumors recur later, further surgery should be considered, and RT reserved for those with inoperable disease. The RT volume and dose should be similar to those used for LGAs in other locations. The literature suggests that salvage is possible in most cases, and overall, the prognosis for patients with dorsal exophytic tumors is excellent.[114-116]

Cervicomedullary tumors arise in the upper cervical cord and grow rostrally beyond the foramen magnum. Most are low-grade lesions whose axial growth is limited by the pyramidal decussations located ventrally at the junction of the cervical cord and medulla. At this point, the tumor grows posteriorly, causing a bulge in the dorsal aspect of the medulla, toward the fourth ventricle.[109] These tumors typically present with lower cranial nerve

deficits, sleep apnea and feeding difficulties in younger children, long tract signs, and, sometimes, torticollis. Hydrocephalus is unusual.

Surgery is the treatment of choice. Gross total resection may be achieved in 70% to 80% of cases and subtotal removal in most of the remainder. The probability of long-term tumor control after such treatment appears to be excellent for the typical low-grade lesion. There is, therefore, no indication for routine postoperative RT for these patients.

DMGs account for 70% to 80% of all brainstem tumors. They arise in the pons and cause diffuse enlargement of the brainstem. Extension to the midbrain and medulla and/or exophytic growth are seen in at least two-thirds of cases. These tumors are defined by their H3 K27 alteration, including H3.3 K27 mutations, H3.1/H3.2 K27 mutations, and EZHIP overexpression.[117]

DMGs typically present with a short duration of symptoms consisting of multiple, bilateral, cranial nerve deficits (especially VI and VII) as well as long tract signs and ataxia. About 10% of patients have hydrocephalus at diagnosis. On CT, DMGs are isodense or hypodense, with little enhancement after contrast injection, similar to diffuse fibrillary astrocytomas at other sites. They are best seen on T2-weighted or FLAIR MRI. The presence of ring enhancement is suggestive of high-grade histology.

Surgery has no role in the management of patients with DMGs. Biopsies are now increasingly common and carry relatively low risk of morbidity, and some have advocated for biopsies as the standard of care.[118-120] Nonetheless, the MRI findings are characteristic, and for families who do not want to pursue biopsy, treatment can commence based on radiographic diagnosis alone.[121,122] Treated with conventional RT, the majority (≥70%) of patients with DMGs will improve clinically. However, the progression-free interval is short (median <6 months) and survival is poor, with a median survival of less than 1 year and survival rates at 2 years less than 20%.

Unfortunately, alternative dose or fractionation regimens have not improved outcomes for children with DMGs. HFRT was tested in a series of phase I/II studies using doses ranging from 64.8 to 78 Gy. Time to progression and OS were not improved in comparison with conventional RT.[123,124] Moreover, at the higher doses of HFRT of 75.6 and 78 Gy, morbidity was considerable. This included steroid dependency, vascular

events, and white matter changes outside the radiation field, as well as hearing loss, hormone deficiencies, and late-developing seizure disorders in the small number of long-term survivors.[123,125-127] Accelerated and hypofractionated RT regimens have also been tested in single-institution studies using, respectively, a total dose of 50.4 Gy given in 28 twice-daily fractions of 1.8 Gy over 3 weeks[128] and 39 Gy in 13 daily fractions and 45 Gy in 15 daily fractions.[129-132] PFS and OS rates were similar to those seen in the HFRT studies. However, there are potential benefits to the reduced duration of the RT course to help facilitate rehabilitation.

Alternative approaches that use chemotherapy in combination with RT also have been disappointing. Many single-agent and multiagent regimens have been tested in this patient population without providing a survival advantage compared with RT alone.[133] New agents and novel chemotherapy-RT combinations are under investigation by the pediatric cooperative groups in North America and Europe. Recent clinical studies suggest that ONC201, a novel dopamine receptor D2 antagonist,[134] and GD2-directed chimeric antigen receptor T-cell therapy[135] may be efficacious in patients with DMGs.

Currently, standard treatment for DMGs consists of RT given to the GTV as usually best demonstrated on T2-weighted or FLAIR MRI with a margin for the CTV of 1 to 1.5 cm to a dose of 54 Gy given in 30 daily fractions over 6 weeks. For tumors with supratentorial components, radiation doses up to 59.4 Gy can be considered. Because the initial progression of neurologic deficits can be rapid, treatment often needs to be started on a semi-urgent basis. Because no unexpected toxicity was seen with the hypofractionated regimens, these regimens could be considered an alternative to conventional RT in some patients if reducing the burden of treatment for the child and family is preferred.

Improvement in clinical status is usually evident as early as 2 to 3 weeks into treatment, and steroids, if used, usually can be discontinued at that point. This improvement is often impressive and well appreciated by the family, despite being of only short duration. Treatment at the time of progression may include experimental chemotherapy regimens or supportive care or even retreatment with RT in selected cases.[136-138] Of note, there is no consensus regarding the dose of reirradiation at the time of progression.[139]

Astrocytoma of the Spinal Cord

Intramedullary spinal cord tumors account for 3% to 6% of all CNS tumors in the pediatric age group. About 60% are astrocytomas, the majority of which are LGAs, 30% are ependymomas, and the remainder are gangliogliomas and developmental tumors, such as teratomas, lipomas, and dermoid and epidermoid cysts.

Patients typically present with pain and motor deficits, often of long duration. Rapid progression of symptoms and signs is suggestive of high-grade histology. On imaging, astrocytomas most often are seen to comprise a solid component and one or more cysts that may be intratumoral and/or extend rostrally and caudally beyond the solid component. Most enhance heterogeneously with the use of contrast material. Ependymomas, in contrast, only rarely harbor intratumoral cysts (although they may have an associated syrinx) and usually enhance homogeneously.

The management of spinal cord tumors has changed over recent years.[140] In the past, patients were typically treated with biopsy followed by RT, and there is evidence to suggest that this is effective treatment in more than half of children with LGAs.[141] However, improvements in surgery and the routine use of surgical adjuncts such as ultrasonic aspiration and support systems such as intraoperative ultrasonography and sensory and, more recently, motor-evoked potential monitoring improve the safety and completeness of resection so that complete or subtotal resection (STR) is now possible in approximately 80% of children with PA (the majority), especially those with a syrinx. Resection is more difficult and less likely to be complete in patients with grade II astrocytoma because of the more infiltrative nature of these tumors and the absence of a clear interface.[140] Because outcome following complete resection or STR for LGAs is very good, with long-term PFS in the 70% to 90% range,[142-144] routine postoperative adjuvant therapy is not indicated. For children in whom complete resection or STR is not possible, the options will be as for patients with LGAs in other locations, that is, early second surgery if feasible, or close follow-up with second surgery and/or RT at the time of progression. As for LGAs in other locations, chemotherapy may be an alternative to RT for young children.[145,146] The benefit of surgical resection in HGAs is less

clear, and the more usual approach is biopsy followed by postoperative RT.[147]

The RT target volume for LGAs consists of the solid portion of the tumor (including intratumoral cysts) with a margin for the CTV of 1 to 1.5 cm. The usual dose is 50.4 Gy given in 28 daily fractions over approximately 6 weeks. The CTV should be larger for patients with HGAs for whom a margin beyond the entire lesion of at least 1.5 cm (or one vertebral body) would be more appropriate. The dose usually will be as for LGA because of the substantial risk of morbidity at higher doses, but often chemotherapy will be given as well. Although older studies[141,142] and data from the Surveillance, Epidemiology, and End Results registry[148] and from the German cooperative group[149] all suggest that 20% to 35% of children with high-grade gliomas will survive following such treatment, a study from St Jude Children's Research Hospital presents an even bleaker picture with a very high rate of both local progression and leptomeningeal spread and no long-term survivors among patients with GBM.[147]

EPENDYMAL TUMORS

The following types of ependymal tumors are seen in children:

- Myxopapillary ependymoma (WHO grade II)
- Ependymoma (WHO grade II)
- Ependymoma (WHO grade III)

Myxopapillary Ependymoma

Myxopapillary ependymomas are slowly growing lesions almost always located in the conus filum terminale region of the spinal cord. They are the most common spinal cord tumor in this location. They usually present with back pain. On imaging, myxopapillary ependymomas are well circumscribed and usually enhance brightly after contrast injection. Despite their lower-grade histology, leptomeningeal spread is not uncommon even at diagnosis, and all patients should have an MRI of the whole spine and brain as part of their initial workup. In fact, myxopapillary ependymoma is now considered CNS WHO grade 2 rather than grade 1, by the 2021 WHO

CNS5 classification, in contrast to previous versions, given its relatively high likelihood of recurrence akin to conventional spinal ependymoma.[39]

Surgical resection is the treatment of choice. If the tumor is contained within the filum, complete resection may be possible after mobilization of the filum. The role of adjuvant RT remains poorly understood for pediatric myxopapillary ependymoma, but most patients may not need adjuvant RT, particularly after a complete resection.[150] A significant proportion of tumors recur locally, in multifocal locations, and/or with leptomeningeal metastases, but salvage with further surgery and/or with RT is possible in most.[151-153] If the tumor is in continuity with the conus, resection is more difficult and more likely to result in significant sequelae necessitating frequent residual tumor. If the tumor is not resected en bloc or if there is macroscopic residual tumor, the risk of recurrence is high. Postoperative RT in this setting results in improved local control.[144,154,155] Furthermore, radiation treatment provides excellent local control within the radiation field, but pediatric patients continue to be at risk of relapse outside the radiation field, including intracranial relapse.[156] The RT target volume is local (macroscopic disease plus a margin cephalad and caudad of 1.5 cm [or one vertebral body]) for the CTV, and the dose can range from 50.4 to 54 Gy depending on the location of the disease.[154-157] If focal radiation is planned to the lumbar spine and/or sacrum, the entire thecal sac inferior to the focal radiation should be considered within the field, given the propensity of myxopapillary ependymoma to relapse with drop metastases inferiorly.[156] Data also suggest that doses as low as 36 Gy may be adequate for uninvolved levels of the spinal canal.[156] The role of CSI for patients with leptomeningeal seeding at diagnosis or at relapse remains controversial, and because this disease's natural history, the long-term morbidity of treatment must also be considered when weighing treatment options.[156,158]

Ependymoma

Ependymoma is the third most common CNS tumor in children, with 5-year OS increasing from 65.4% in 1990 to 1999 to 91.4% in 2010 to 2016.[159] However, late relapses are common.[160] About half of all cases arise in children younger than 5 years.[161] Ependymoma can occur at any site in the ventricular system or in the spinal canal, but in children, approximately

two-thirds arise in the ependymal lining of the fourth ventricle. Tumors in this location typically present with symptoms and signs of raised intracranial pressure. On imaging, the tumor is usually large but relatively well circumscribed, with displacement rather than invasion of adjacent structures. Extension through the foramen magnum into the upper cervical region is not uncommon (Figure 90.10). Tumors that arise in the supratentorial compartment, some of which arise outside the ventricular system, present with focal neurologic deficits. Intramedullary ependymomas, which account for approximately 30% of all spinal cord tumors arising in childhood, usually present initially with dysesthesia and sensory deficits because of their central location in the cord and only later with pain and motor deficits.[162] Recently, the updated WHO-CNS5 classification outlined distinct groups that are defined by histopathologic, molecular, and anatomic features. These include posterior fossa A and posterior fossa B tumors in the posterior fossa; zinc finger translocation–associated (formerly RELA) fusion–positive and yes-associated protein 1 fusion–positive supratentorial tumors; and MYCN-amplified spinal ependymoma usually in the context of NF-2. Moreover, myxopapillary ependymoma is now considered CNS WHO grade 2 rather than 1, given its conventional spinal ependymoma–like odds of recurrence.[39]

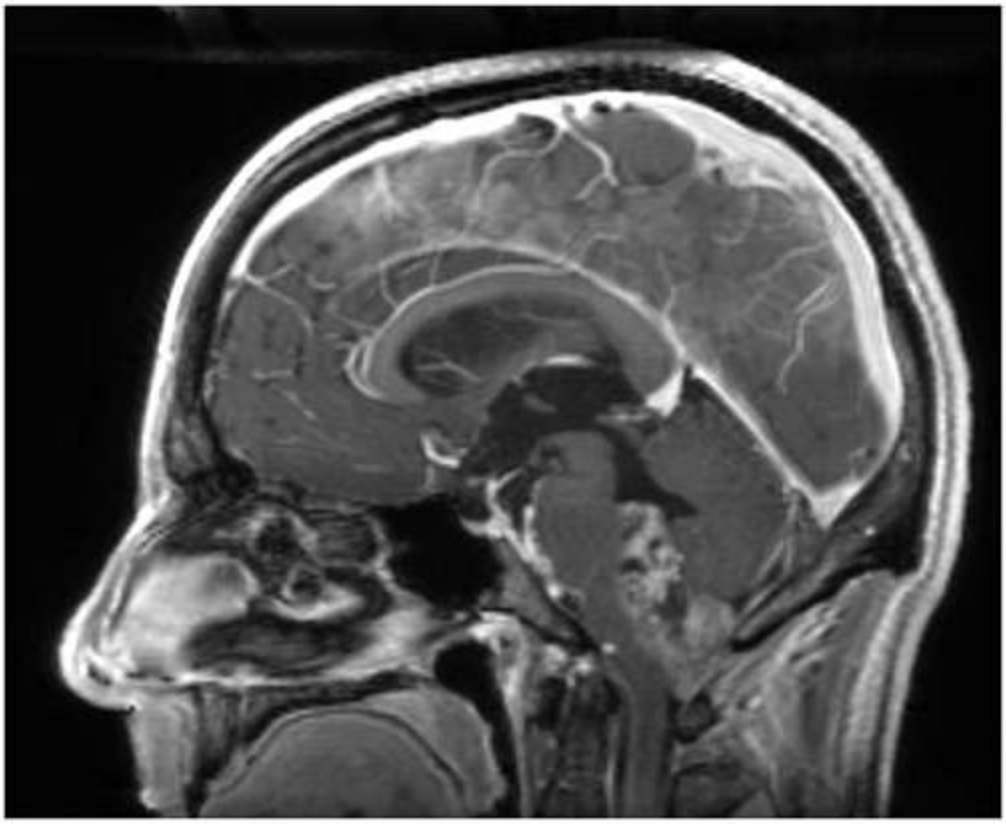

FIGURE 90.10 Typical appearance of an ependymoma that fills the fourth ventricle and extends inferiorly below the foramen magnum over the dorsal aspect of the spinal cord.

Spread of ependymoma is primarily local. However, 5% to 10% of patients have leptomeningeal seeding at diagnosis, and gadolinium-enhanced MRI of the whole CNS and CSF cytology are essential components of the workup for all patients.[163,164]

Management of Ependymoma

The completeness of the surgical resection is the factor that has the greatest impact on outcomes of patients with ependymoma.[165-171] Currently, it is estimated that complete resection is achieved in 70% to 90% of supratentorial ependymomas and in a similar percentage of spinal ependymomas. Complete resection is less frequently possible in patients with infratentorial ependymomas. Most commonly, residual tumor is left behind on the floor of the fourth ventricle or laterally at the cerebellopontine angle where tumor protruding through the foramen of Luschka encircles lower cranial nerves and vessels. “Second-look” surgery

may be considered, if feasible, either after the realignment of structures that takes place following resection of an initially bulky tumor in an often-unstable young child or after chemotherapy.[172]

Postoperative RT is the standard of care for children with ependymoma. Some have questioned the need for such treatment for patients who have undergone complete resection.[173-175] However, a number of studies including studies in young children in which the goal was to delay or avoid altogether RT suggest that such a strategy results in worse disease-free survival and OS and in the long-term greater morbidity[176-180] and, therefore, can be considered acceptable only for (a) patients with ependymoma of the spinal cord who have undergone complete resection for whom disease-free survival in contemporary series approaches 100%[181-184] and (b) select patients with supratentorial ependymoma that are solid and located in noneloquent areas and can be completely resected with a wider margin.[175] Moreover, children with grade 2 supratentorial tumors could be observed safely following complete resection as suggested by ACNS0121 (NCT01407744) phase 2 trial that reported 100% 5-year OS with the caveat of significantly lower 5-year event-free survival (EFS) of 61%.[172] A more recent phase 3 randomized trial, ACNS0831 (NCT01096368), concluded there is no survival benefit to giving maintenance chemotherapy even in patients with STR, irrespective of the extent of second-look resection after induction chemotherapy.[185] CSI was previously the standard of care for anaplastic ependymoma, but several institutional studies, a careful retrospective review, and prospective studies by the POG all suggest that there is no survival advantage for CSI.[171,186-190] Patients with leptomeningeal dissemination at diagnosis fare poorly despite intensive treatment that includes CSI and chemotherapy.

Radiotherapy Target Volume

Focal RT is the standard of care.[167,172,191] The GTV is a composite of the tumor bed, including any extension caudal to the foramen magnum and taking into account any anatomic shifts because of surgery plus any residual tumor. For several prospective studies, the margin for the CTV was 1 cm.[167,172] In patients who received immediate postoperative RT, local control was excellent (cumulative incidence of local failure 7.8%) for patients who

had undergone gross total resection, whereas patients who had undergone near-total resection or STR fared less well.[167] All failures were reported to be within the 95% isodose. The current Children's Oncology Group (COG) study uses an even smaller margin for the CTV of 0.5 cm.

Radiotherapy Dose

There is evidence for a dose-response in ependymoma, with improved tumor control using doses greater than 45 to 50 and even 54 Gy.[191] Although the lower doses may be the maximum possible for spinal ependymomas, the current standard is a dose of 54 to 59.4 Gy for children older than 18 months with infra- or supratentorial tumors.[167,172] Moreover, because failure most often occurs at the site of macroscopic residual disease, even higher doses may be desirable and most would reduce the CTV at 54 Gy to respect the tolerance of the spinal cord and/or other structures, for example, optic chiasm, and continue to a total dose of 59.4 Gy (Figure 90.11). Studies such as ACNS0831 assigned more conservative brainstem dose constraints to patients receiving proton therapy given proton's higher relative biologic effectiveness and end-of-range uncertainties, and a few unexpected brainstem-related adverse events. Goal dose constraints include brainstem D50 61 Gy or less and D10 63 Gy or less (photons) versus D50 52.4 Gy or less and D0.1 cc 56.6 Gy or less (protons); and maximum constraints of brainstem D50 62 Gy or less and D10 64 Gy or less (photons) versus D50 54 Gy or less and D0.1 cc 58 Gy or less (protons).[192]

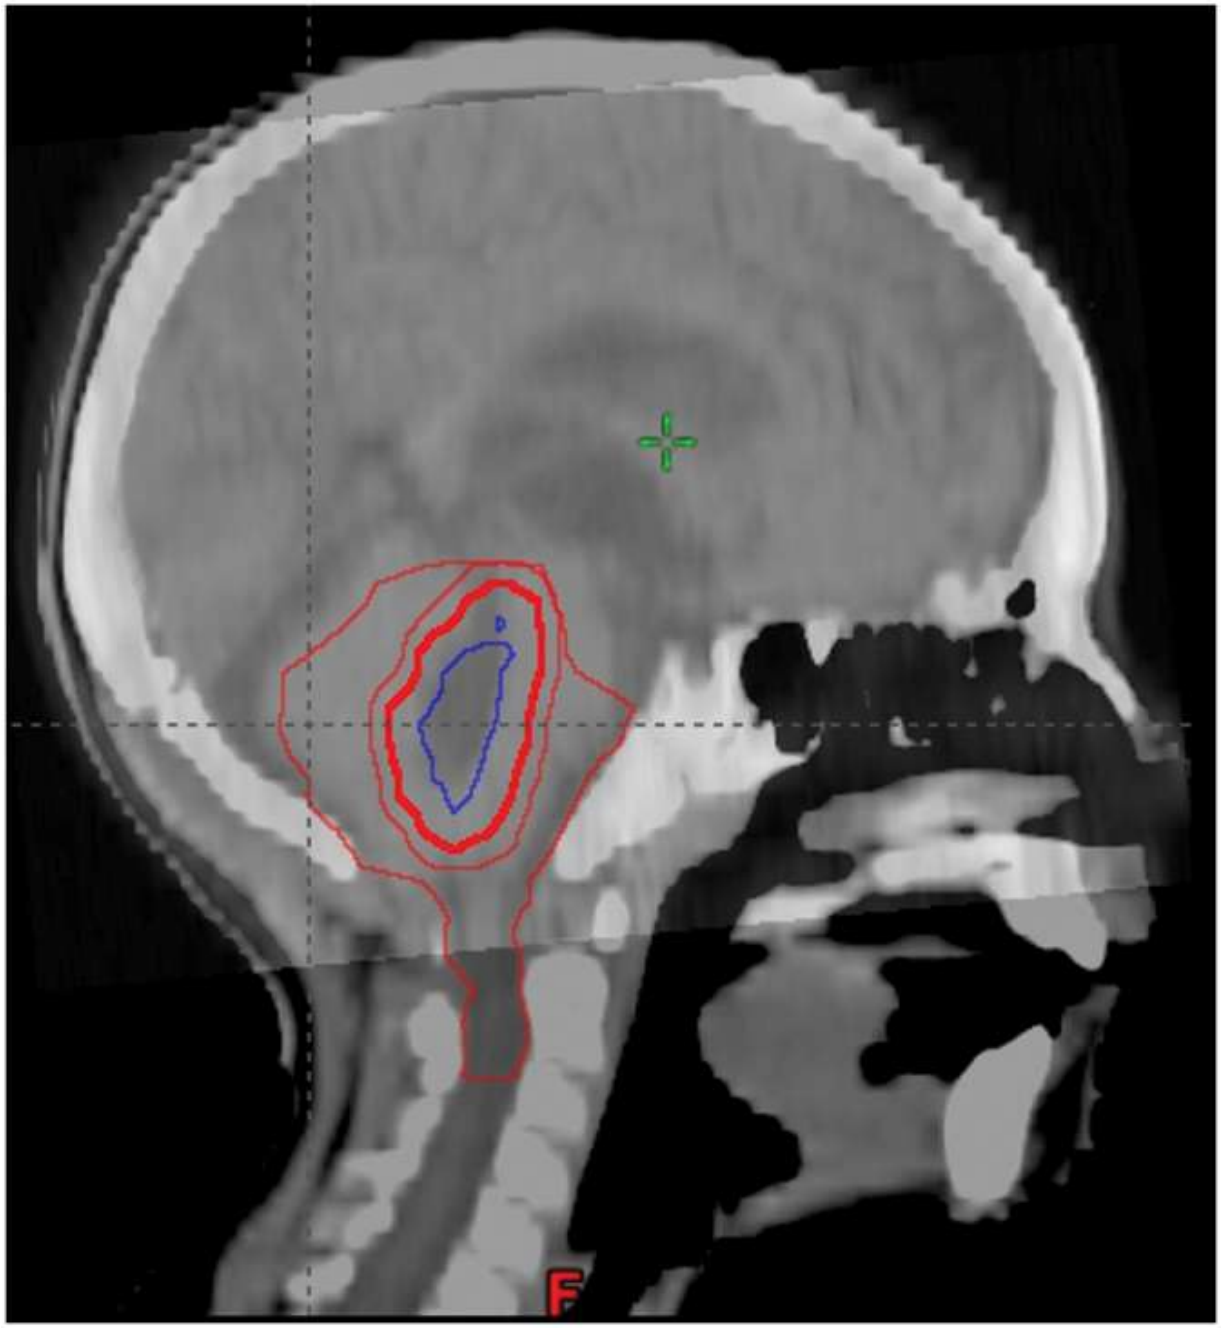

FIGURE 90.11 Care is necessary to ensure that the inferior extent of disease is included in the radiotherapy target volume. Volume reduction at 54 Gy is necessary to respect the tolerance of the spinal cord.

HFRT has been explored in ependymoma as a strategy to more safely deliver these higher RT doses. Studies from the Children's Hospital of Philadelphia in which the majority of patients received HFRT to a mean dose of 70.7 Gy,[193] from the Italian pediatric oncology group that used a

dose of 70.4 Gy,[194] and from the French pediatric oncology group that used a lower total dose of 60 Gy in 60 fractions,[195] all reported HFRT to be feasible. However, in none of these studies was there any clear evidence of benefit, particularly in the context of improved surgery and modern RT.

Reirradiation for Ependymoma

For patients who fail standard treatment with either local recurrence or, less frequently, leptomeningeal dissemination, retreatment with RT is an option that may result in durable control in a proportion of patients.[196-199] A subset of locally recurrent tumors can be managed with potentially curative intent using salvage surgery and focal RT. For children over 3 years old with local recurrence, the St Jude Phase II trial RERTEP allowed the use of photon or proton CSI to reduce the risk of metastatic tumor progression (NCT02125786). This was justified by higher risk of metastatic tumor progression in patients receiving focal reirradiation, especially those with chromosome 1q gain,[200] and backed by data from Canada and France.[198,201]

CHOROID PLEXUS TUMORS

Choroid plexus tumors arise from the epithelium of the choroid plexus of the cerebral ventricles. They include the following:

- Choroid plexus papilloma (CPP) (WHO grade I)
- Atypical CPP (WHO grade II)
- Choroid plexus carcinoma (CPC) (WHO grade III)

Choroid plexus tumors account for only 2% to 4% of all brain tumors that occur in children but as many as 10% to 20% of those seen in the first year of life. CPPs, which account for more than half of choroid plexus tumors in children, are composed of delicate fibrovascular connective tissue fronds covered by a single layer of uniform cuboidal columnar epithelial cells with round or oval basally situated monomorphic nuclei. Mitotic activity is low, and increased mitotic activity in a CPP defines an atypical CPP. In contrast to both, CPCs are solid tumors that tend to transgress the ventricular wall and invade the brain. Histologically, CPCs show frank evidence of malignancy, including frequent mitoses (>5%/10 high-power fields), increased cellular density, nuclear pleomorphism, blurring of the

papillary pattern with poorly structured sheets of tumor cells, and necrotic areas.

In children, most choroid plexus tumors arise in the lateral ventricles, causing obstruction to CSF flow. Infants commonly present with increasing head circumference and older children with symptoms and signs of raised intracranial pressure. On neuroimaging, choroid plexus tumors are usually hyperdense, contrast-enhancing masses. Even papillomas seed into the CSF space, and workup for both benign and malignant lesions should include a gadolinium-enhanced MRI of the spinal axis and CSF cytology.

Management of Choroid Plexus Tumors

Surgery is the treatment of choice for CPPs both for the primary lesion and for metastatic deposits, if feasible. Complete resection is achieved in a high percentage of cases now, and outcome in this situation is excellent. Less than 10% of tumors recur, and OS is close to 100%.[202-205] The role of RT following incomplete resection is unclear, but because not all patients will progress, follow-up without adjuvant treatment would be the usual strategy, with consideration of further surgery, if feasible, and/or RT only at the time of progression.

Results are less satisfactory for patients with CPCs. Surgery is an important component of treatment but often difficult. Blood loss may be considerable, and staged procedures may be necessary to obtain maximal resection. In most series, results are better for patients who have undergone complete resection,[205-215] and the need for adjuvant therapy in this situation is not clearly established. In one series of pooled data, survival was significantly better when RT had been given postoperatively despite a probable bias toward the use of RT in patients considered to have more unfavorable disease.[209,210] Others have reported excellent results following complete resection, in some cases with chemotherapy but without RT.[206,207,212,213] In contrast, patients who have residual disease fare very poorly. Postoperative RT appears to be useful,[215] but the desire to avoid RT in infants and very young children may mean that chemotherapy is used instead. Evidence suggests that a subset of patients can be cured without RT.[216] When both are used, RT is usually delivered early (following two cycles of chemotherapy), with the exception of infants and very young

children in whom RT is delayed until age 3 years. Genetic and genomic analyses may in the future help guide therapy. A substantial percentage of patients with CPCs have TP53 mutations, and patients without such mutations are reported to have a more favorable prognosis and be successfully treated without RT.[217,218] It is possible that radiation may have a deleterious effect in patients with Li-Fraumeni syndrome and CPCs, though selection bias with more aggressive disease undergoing RT cannot be excluded.[219]

The RT target volume is also controversial. CSI was traditionally used in patients with CPCs, and a recent literature review showed that the use of CSI was associated with improved PFS as compared with RT to the whole brain or tumor bed only.[215] Importantly, more than half of all failures occurred outside the treatment field. This is problematic given the young age of the patients, and a pragmatic approach in which local fields are used for patients with CPPs with postoperative residual (including metastatic sites) as well as for patients with atypical CPPs or CPCs without evidence of leptomeningeal seeding and only patients with atypical CPPs or CPCs with leptomeningeal seeding receive CSI would seem reasonable for now.

NEURONAL AND MIXED NEURONAL-GLIAL TUMORS

These are uncommon tumors that are characterized by the presence of both neuronal and glial elements in variable amounts. They include entities such as desmoplastic infantile astrocytoma and dysembryoplastic neuroepithelial tumor. Most will be cured by surgery, but RT may be indicated in two tumor types:

- Ganglioglioma and anaplastic ganglioglioma
- Central neurocytoma

Ganglioglioma and Anaplastic Ganglioglioma

Gangliogliomas are well-differentiated slowly growing tumors composed of mature ganglion cells in combination with neoplastic glial cells (WHO grade I or II). Tumors in which the glial component shows anaplastic features (WHO grade III) are called anaplastic gangliogliomas.

Although these tumors can arise anywhere within the CNS, most in children arise in the temporal region and typically present with seizures. Surgery is the treatment of choice. When resection is complete, the probability of long-term tumor control in patients with ganglioglioma is excellent.[220-222] Indications for adjuvant RT are WHO grade III tumors and progressive or recurrent WHO grade II tumors that are unresectable, symptomatic, and have recurred despite multiple courses of systemic therapy. The RT target volume is the postoperative cavity and residual disease with the CTV being a 1 to 1.5 cm expansion and doses can range from 54 to 59.4 Gy with standard fractionation. The significance of a high proliferation index or of the presence of anaplasia in patients with ganglioglioma is controversial. Although it seems clear that the risk of recurrence is higher in patients with these features,[220,221,223-225] the indications for postoperative RT remain undefined, except for patients with anaplastic gangliogliomas who have undergone less than complete resection in whom the use of RT has been shown to result in improved PFS.[222,226]

Central Neurocytoma

This is a neoplasm composed of uniform round cells with neuronal differentiation that arises in the lateral or third ventricles, typically the former, that is seen predominantly in adolescents and young adults. Patients usually present with symptoms and signs of raised intracranial pressure. Surgery is the treatment of choice, and when complete resection is achieved, long-term tumor control is excellent without adjuvant treatment.[227] Patients in whom complete resection cannot be achieved as well as those with tumors with atypical histology or a high mitotic rate fare less well,[227,228] and postoperative RT should be considered in these situations. Although a dose of 50 Gy appears adequate for patients with typical neurocytomas,[229] there is evidence of improved tumor control at doses of at least 54 Gy in patients with atypical neurocytoma.[230]

PINEAL PARENCHYMAL TUMORS

Pineal region tumors account for 2% to 8% of intracranial tumors in children. Approximately half are germ cell tumors, one-fourth to one-third are pineal parenchymal tumors, and most of the remainder are astrocytic

tumors. Pineal parenchymal tumors are derived from pineocytoma, which are cells with photosensory and neuroendocrine functions, or their embryonal precursors. According to the WHO classification, the following entities can be distinguished:

- Pineocytoma (WHO grade I)
- Pineal parenchymal tumor of intermediate differentiation
- Pineoblastoma (WHO grade IV)

Pineocytoma

Pineocytoma is a slow-growing tumor composed of small uniform mature cells resembling pineocytes, with occasional large pineocytomatous rosettes, that accounts for approximately half of pineal parenchymal tumors and in childhood most commonly occurs in the teenage years. Patients typically present with symptoms and signs of raised intracranial pressure. Some will have symptoms of upper mesencephalic tegmental dysfunction (Parinaud syndrome), consisting of limitation of upward gaze, lid retraction, retraction nystagmus, and pupils that react more poorly to light than to accommodation. On MRI, pineocytomas are usually spherical, well-circumscribed masses, hypointense on T1- and hyperintense on T2-weighted images, with homogeneous contrast enhancement. Leptomeningeal spread has been described in pineocytoma,[176] but it is probable that the explanation for this lies in sampling error. With better imaging and more extensive surgery with more complete histologic evaluation of the tumor, it seems that leptomeningeal spread can be considered an uncommon event.[231]

Treatment consists of surgical resection via an occipital transtentorial or an infratentorial supracerebellar approach using modern operative adjuncts such as functional MRI and MR tractography in relation to the location of the primary visual cortex and deep MR venography. If complete resection or STR is accomplished, PFS is in the 90% to 100% range.[232,233] Patients who undergo lesser degrees of resection or only biopsy fare less well, and although some have questioned its usefulness based on the results of a systematic review,[232] postoperative RT may be offered after multidisciplinary discussion.[234] The target volume is local, consisting of

macroscopic residual disease with a margin for the CTV of 1 cm, and the dose, 50 to 55 Gy over 6 weeks.

Pineal Parenchymal Tumor of Intermediate Differentiation

Pineal parenchymal tumors of intermediate differentiation are composed of diffuse sheets or large lobules of uniform cells with mild-to-moderate nuclear atypia and low-to-moderate mitotic activity. They are rare tumors, accounting for only 10% of pineal parenchymal tumors, and optimal management remains to be defined.[235,236] Some patients treated with surgery alone have survived free of disease.[233,236,237] Disseminated disease is frequent at the time of recurrence; thus, some providers recommend postoperative treatment with CSI as for pineoblastoma,[231,238] while other series have reported favorable results after focal RT.[239,240]

Pineoblastoma

Pineoblastoma is a highly malignant tumor composed of patternless sheets of densely packed small cells with round to irregular nuclei and scant cytoplasm.

Pineoblastomas most frequently affect infants and very young children, who typically present with an enlarged head circumference or symptoms and signs of short duration of raised intracranial pressure. On MRI, pineoblastomas are usually multilobulated and often enhance heterogeneously, with areas of necrosis and/or hemorrhage. Infiltration of surrounding structures is common. Leptomeningeal spread is seen in as many as 50% of patients at diagnosis.

Surgery for lesions in the pineal region is difficult, and complete resection is often not possible. Postoperatively, children older than 3 years are treated with CSI and chemotherapy as for high-risk MB (see later). Five-year survival in this age group is in the 50% to 70% range.[231,241-243] Although the standard of care remains 36 Gy CSI with a tumor bed boost to 54 Gy, there is evidence to suggest a risk-adapted approach may identify patients who may benefit from reduced dose CSI (23.4 Gy compared to 36 Gy).[244] However, infants treated with chemotherapy without RT fare extremely poorly: In prospective studies of the POG and CCG, all tumors recurred within the first 11 months (POG) and 1.2 years (CCG) and all

patients died of disease.[243,245,246] Thus, more aggressive treatment that includes chemotherapy dose intensification is necessary. Patients with familial bilateral retinoblastoma with pineoblastoma ("trilateral retinoblastoma") also have an extremely poor prognosis, most dying within a year following diagnosis.

EMBRYONAL TUMORS

Embryonal tumors as a group are the second most common type of CNS tumor in the pediatric age group. They include MB and atypical teratoid/rhabdoid tumor (ATRT):

- MB
  i. MB, WNT activated
  ii. MB, sonic hedgehog (SHH) activated, TP53 mutant versus TP53 wild type
  iii. MB, non-WNT/non-SHH, group 3
  iv. MB, non-WNT/non-SHH, group 4

These MB subgroups refer to the use of conventional histopathologic features together with molecular biologic parameters in classification. Conventional histologic varieties are also recognized and are associated with particular clinical characteristics. Desmoplastic MB is associated with a better prognosis, particularly in very young children.[247] Anaplastic/large cell MBs appear to be adverse prognostic factors.[248]

Medulloblastoma

MB accounts for 15% to 20% of all CNS tumors in children, with a median age at presentation of 6 years. It is a malignant invasive embryonal tumor of the cerebellum or posterior fossa with predominantly neuronal differentiation and an inherent tendency to metastasize via CSF pathways.

It is accepted that MBs are defined according to four subgroups based on a combination of histopathology and molecular biology.

The WNT subgroup is associated with a very good prognosis, with long-term survival greater than 90%. The majority of WNT subgroup MBs have classic histology, and a particular feature is that these tumors demonstrate

β-catenin nucleopositivity, *CTNNB1* gene mutations, and monosomy-6. Rarely, the WNT subgroup may include large cell/anaplastic cases. WNT MB can arise at all ages but is infrequent in infants. Although overall MB is more common in males, the male-to-female (M:F) ratio for the WNT subgroup is approximately 1:1. Germline mutations of the WNT pathway inhibitor APC predispose to Turcot syndrome, which includes a predisposition to MB.

The SHH MB subgroups include *TP53* mutant and *TP53* wild-type subgroups. They are named after the SHH signaling pathway, which is considered to drive tumor initiation in the majority of cases. The age incidence of SHH subgroups of MB is bimodal and is frequent in both infants aged less than 3 years and adults. The M:F ratio is approximately 1:1. The majority of nodular/desmoplastic MBs are included within the SHH subgroup. However, around 50% of SHH subgroup MB have other histologic subtypes, including classic and large cell/anaplastic varieties. The prognosis for SHH appears to be similar to group 4 (see later) and intermediate between WNT and group 3. Individuals with germline mutations of the SHH receptor PTCH have Gorlin syndrome, which, for several decades, has been recognized as carrying a predisposition to the development of MB. Preliminary clinical trials are being designed to target the SHH pathway to improve outcome for this subgroup.

Group 3 MB represents the subgroup of MB with the poorest prognosis. The majority of MBs in group 3 are classic MB and include most large cell/anaplastic tumors. They are more frequent in males than females. They arise in infants and older children, but only rarely in adults and frequently present with metastases. Group 3 MB is typically characterized by high-level amplification of the *MYC* proto-oncogene, and almost all cases exhibit aberrant *MYC* expression.

Patients with group 4 MB have an intermediate to good prognosis similar to patients with SHH tumors. They include classic and large cell/anaplastic histologies and account for approximately 30% to 40% of cases. This subgroup represents the archetypal MB, exemplified by a 7-year-old boy with a classic histology MB who has an isochromosome 17q. The M:F ratio is approximately 3:1. The molecular pathogenesis of group 4 MB is not currently clear.

Improvements in the understanding of the molecular mechanisms of MB tumorigenesis are emerging as important factors in clinical trial design, leading to a tailored approach for different histologic and molecular biologic subtypes. Collaborative clinical trial groups are developing studies that will investigate prospectively the stratification of therapy according to pathologic, biologic, as well as the more traditional clinical parameters. In particular, clinical studies are beginning to involve a cautious lowering of the treatment intensity for patients with WNT MB and maintaining intensity for those in group 3. This approach requires a timely and well-coordinated approach to tumor sample collection and analysis of biologic parameters prior to treatment decisions.[249]

In most cases of MB, the tumor arises in the cerebellar vermis and projects into the fourth ventricle. Patients typically present with symptoms and signs of raised intracranial pressure (ie, headache and morning vomiting). On MRI, MBs appear as solid masses that generally enhance homogeneously with contrast material (Figure 90.12). The frequency of leptomeningeal seeding at diagnosis is approximately 30% to 35%, and investigation at diagnosis must include a gadolinium-enhanced MRI of the spinal axis and CSF cytology. The former should be obtained whenever possible preoperatively or else at least 2 weeks postoperatively because of the artifactual changes that may be seen in the early postoperative period. CSF cytology, which should be obtained by lumbar puncture, usually cannot be obtained safely preoperatively because of the presence of raised intracranial pressure and more commonly is obtained at least 2 weeks postoperatively to avoid false positives that may be seen in the early postoperative period. MB is one of the few CNS tumors to spread outside the CNS (to lymph nodes, bone), but this is a very uncommon event at diagnosis, and other studies such as a bone scan or bone marrow aspiration or biopsy are not justified as a routine.

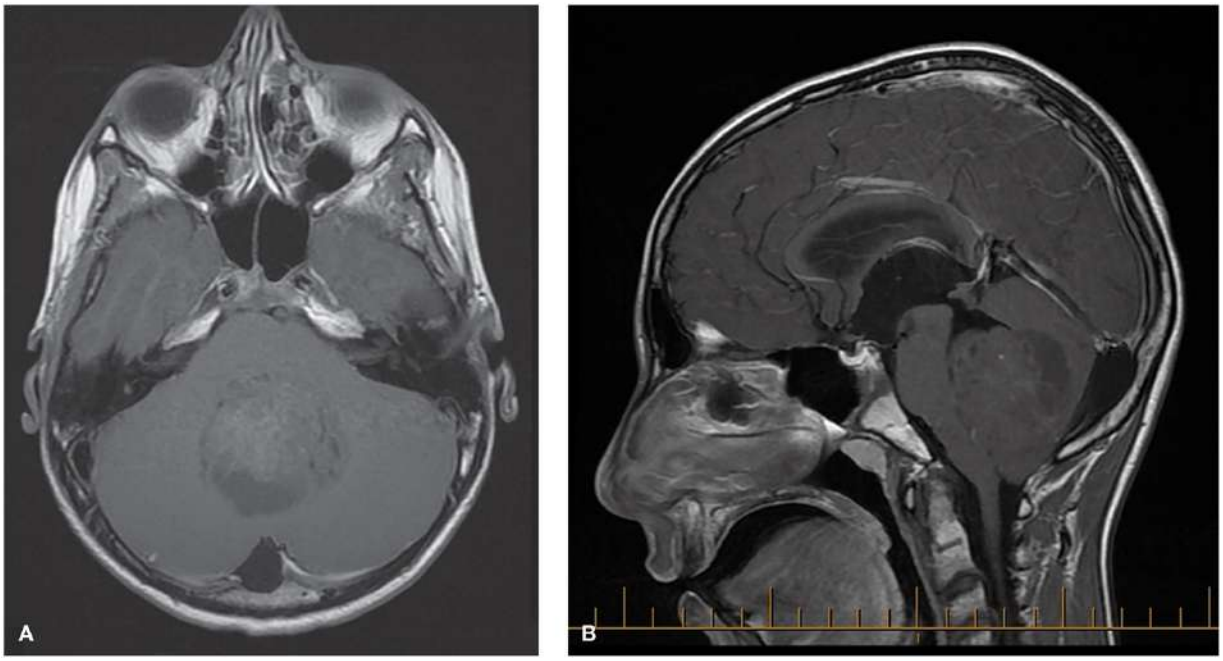

FIGURE 90.12 T1 axial (A) and T1 gadolinium-enhanced sagittal (B) magnetic resonance images of a medulloblastoma in an 11-year-old boy. Note the typical midline location of the tumor that is causing ventricular outlet obstruction with dilatation of the third and lateral ventricles.

In addition to molecular biologic parameters, conventional factors that correlate with outcome include age at diagnosis, the presence or absence of leptomeningeal spread at diagnosis, and the completeness of the surgical resection. Patients are allocated to one of two overall risk categories: standard and high risk. Those who have undergone complete resection or STR with less than 1.5 cm^2 of residual tumor on postoperative MRI performed within 48 to 72 hours of surgery, and no evidence of CSF dissemination (M0) are considered to have standard-risk disease, whereas patients who have larger volume residual tumor and those with evidence of CSF dissemination at diagnosis are characterized as high risk. With contemporary neurosurgical techniques, complete or near-total resection is accomplished in approximately 80% of cases. Overall, approximately two-thirds of patients will be standard risk and one-third will be high risk.

Management of Standard-Risk Medulloblastoma

Until the 1990s, the standard of care for patients older than 3 years with standard-risk disease consisted of postoperative RT to the craniospinal axis

to a dose of 35 to 36 Gy followed by a boost to the whole posterior fossa to a total dose of 54 to 55.8 Gy. In multi-institutional studies, such treatment results in long-term EFS in 60% to 65% of patients.[12,250,251] Sequelae of treatment include hormonal deficits, decreased bone growth, and neurocognitive deficits that correlate with the age of the child and the radiation dose.[10]

Several treatment strategies designed to reduce the morbidity associated with the use of RT have been tested. An attempt by the French Cooperative Group (SFOP) to reduce the RT target volume to avoid supratentorial radiation produced disastrous results,[252] and studies have shown that omission of RT or CSI (in favor of focal RT) leads to unacceptably poor outcomes for the WNT subgroup.[253,254] Thus, CSI remains the standard of care. The use of reduced-dose CSI (23.4 Gy) alone (without chemotherapy) in the North American intergroup study (CCG-923/POG#8631) resulted in a significantly increased risk of isolated neuroaxis failure and an EFS at 5 and 8 years of only 52%.[251] HFRT may be a more promising strategy. In an SFOP pilot study that tested HFRT to a CSI dose of 36 Gy without chemotherapy, early toxicity was reduced and PFS at 3 years was 81%.[255] The results of the European SIOP PNET-4 study in which patients were randomized to HFRT or conventional RT found no significant benefit to HFRT; thus, conventional RT remains the standard.[256]

An alternative strategy consists of reduced-dose CSI followed by a boost to the posterior fossa to a total dose of 55.8 Gy in combination with systemic chemotherapy. PFS was 79% at 5 years in a CCG pilot study that used CSI to a dose of 23.4 Gy in combination with weekly vincristine followed by adjuvant systemic chemotherapy consisting of vincristine 1.5 mg/m^2, lomustine (CCNU) 75 mg/m^2, and cisplatin 75 mg/m^2.[257] In the joint CCG/POG phase III randomized study (A9961) that followed, this regimen was compared to a regimen in which the CCNU was replaced by cyclophosphamide. EFS at 4 years was approximately 85% in both arms,[258] and such an approach is now considered the standard of care for children with standard-risk MB in North America. The recently presented COG ACNS0331 trial evaluated the safety of an even lower dose of CSI (18 Gy) in children aged 3 to 8 years and of a reduced-volume posterior fossa boost in children of all ages. There was no significant difference in EFS for patients treated with a tumor/surgical bed plus margin boost compared with

those treated with a whole posterior fossa boost.[259] However, patients treated with 18 Gy CSI had significantly inferior 5-year EFS of 71.4% compared with 82.9% for those treated with 23.4 Gy CSI.[259] Currently, the standard of care for children with standard-risk MB is with CSRT 23.4 Gy with a boost to the tumor bed to a total dose of 54.0 Gy, followed by eight cycles of chemotherapy with vincristine, CCNU, and cisplatin.

In the latest generation of trials in MB such as the open European PNET-trial, risk stratification is based on biologic parameters in addition to clinical and pathologic features.[260] Patients with anaplastic/large cell histology are no longer included in the standard-risk group, given their poorer outcome. Furthermore, evidence suggests that WNT MB with β-catenin nucleopositivity is associated with better prognosis and MYC gene amplification with worse prognosis, raising the possibility of reduced-intensity RT and chemotherapy for patients with WNT MB (NCT01878617, NCT02724579, and NCT02066220), and the evaluation of additional treatment intensity for patients with less favorable prognosis.

Management of High-Risk Medulloblastoma

Patients with residual disease greater than 1.5 cm^2 and/or those with leptomeningeal seeding are considered to have high-risk disease. This is the group of patients in which the use of chemotherapy was shown in the prospective randomized phase III studies conducted in the 1970s to result in significant improvement in disease-free survival. Research since then has largely focused on the chemotherapy regimens, including changes in scheduling in relation to RT and in doses and routes of delivery of chemotherapy. Some have used higher dose CSI or altered RT fractionation schedules. An overview of studies performed by the North American and European cooperative groups up until the early 2000s is given in Freeman et al.[261]

It is important to note that the definition of risk factors has evolved considerably over the past two decades, making comparison of published data quite problematic. Better postoperative imaging and more complete staging as well as identification of unfavorable pathologic features (eg, large cell and anaplastic histology) have led to transfer of patients from the standard-risk to the high-risk category, which may partly explain the

improving results for both standard-risk and high-risk diseases. The category of high-risk disease is heterogeneous and includes more favorable subsets such as patients with postoperative residual disease without leptomeningeal spread, and even those with M1 (cytology-positive) disease, for whom it may be appropriate to consider a treatment approach different from that for patients with M2/3 disease with nodular seeding. For example, for patients with residual disease, M0, it would be logical to consider using a boost to residual disease in the posterior fossa to a dose higher than the standard 55.8 Gy. Management of patients with M1 disease remains controversial, but the weight of evidence suggests that they should be treated similarly to those with M2/3 disease.[262] Results for patients with M2/3 disease remain quite poor, although an impressive 82% 4-year OS was reported for patients treated on a COG pilot study using carboplatin daily during RT as a radiosensitizer.[263] The most recent COG ACNS0332 study did not show a benefit to isotretinoin during maintenance chemotherapy, and only patients with group 3 MB benefited from daily carboplatin (73% vs 54%).[264] Many centers in Europe use a hyperfractionated accelerated RT regimen, given in combination with pre- and post-RT chemotherapy.[265-268]

Management of Medulloblastoma in Infants

MB accounts for 20% to 40% of all CNS tumors in infants. Although up to half of infants have more favorable histologic types (desmoplastic/nodular or MB with extensive nodularity), the prognosis overall is worse than in older children. The explanation for this is likely multifactorial. In addition to biology, the rate of complete resection is lower in this age group, and the frequency of leptomeningeal seeding at diagnosis is higher (as much as 50%), but also, many patients do not receive optimal treatment.[269] Because of the significant risks with respect to neurocognitive function associated with the use of RT in infants and very young children,[270] chemotherapy has been used in an attempt to either delay or avoid RT altogether. Infants with M0 disease who have undergone total resection may do well with chemotherapy alone, with a 5-year OS of 69% in the first POG infant study[271] and of 93% in the German study,[272] although it is noteworthy that treatment in the latter included intraventricular methotrexate for which there

are also concerns about the risk of neurocognitive sequelae. The use of high-dose chemotherapy (HDCT) followed by autologous stem cell transplant leads to similar efficacy with 5-year OS of 70% for patients who underwent a gross total resection.[273] In other studies, results were less satisfactory, in some because of the need for aggressive salvage regimens that were associated with significant long-term sequelae.[274] In fact, with the possible exception of very young children with desmoplastic/nodular MB without residual disease, evidence suggests that RT is an important component of treatment,[92] and because recurrences are generally early (6-12 months) and local,[92,270,274] the recently completed North American study used early RT to a limited treatment volume consisting of the tumor bed plus an anatomically confined margin for the CTV of 1 cm for patients without leptomeningeal seeding. Infants with M2/3 disease are generally treated with intensive chemotherapy regimens. Although patients with desmoplastic/nodular histology may do quite well, with an OS at 5 years of 52.9% to 89%,[93,275,276] the prognosis for those with other subtypes is much less satisfactory. Further studies have found that infant and very young children with SHH subtype may have better prognosis.[277] Despite this, the goal of treatment generally will still be to avoid RT (especially CSI) and the decision to use it in highly individualized based on the clinical situation and the wishes of the parents. Of note, a substantial proportion of children who relapse despite an initial CSI-sparing approach can be salvaged with RT, generally using CSI.[278]

Radiotherapy for Medulloblastoma

CSI is the standard of care, and careful attention to coverage of the entire target volume that includes the meninges overlying the brain and spine including extensions along nerve roots is critical. In the SFOP M-7 protocol, 50% of relapses could be correlated with targeting deviations. In the subsequent studies (MSFOP-93 and MSFOP-98), the relapse rate was 17% in patients who had inadequate coverage of only one part of the CTV (a typical example being the cribriform plate), 28% for patients who had inadequate coverage at two sites, and 67% for patients who had inadequate coverage at three or more sites.[279,280] In an SFOP pilot study that tested reduced-dose CSI for standard-risk disease, OS at 5 years was significantly

worse for patients with inadequate coverage at two or more sites as compared with no or only one major deviation (54.4% vs 79.3%).[281]

CSI is followed by a boost to the tumor bed or posterior fossa. For standard-risk disease, involved-field boost is appropriate. The optimal CTV for a reduced-volume posterior fossa boost remains to be defined, although an anatomically confined expansion of 1 to 1.5 cm around the GTV (any macroscopic residual tumor and the surgical bed) until recently has been regarded as reasonable. Patients with high-risk MB often receive posterior fossa boost. While no prospective study has examined the role of involved-field boost for high-risk MB, the involved field can also be considered for patients with high-risk MB. The total dose is typically 54 to 55.8 Gy. Using conformal treatment techniques, it is possible to reduce the dose to the cochlea, which is important in children who will also be receiving cisplatin-based chemotherapy. Better sparing of the cochlea,[282] pituitary, and hypothalamus, and the temporal lobes can be achieved using a reduced target volume for the boost (Figure 90.13). Fukunaga-Johnson et al[283] found a low risk of isolated failure outside the tumor bed in the posterior fossa in a cohort of 114 patients, and data from several other centers as well as an SFOP pilot study that used a conformal boost limited to the tumor bed similarly support such an approach.[255,259,284-286]

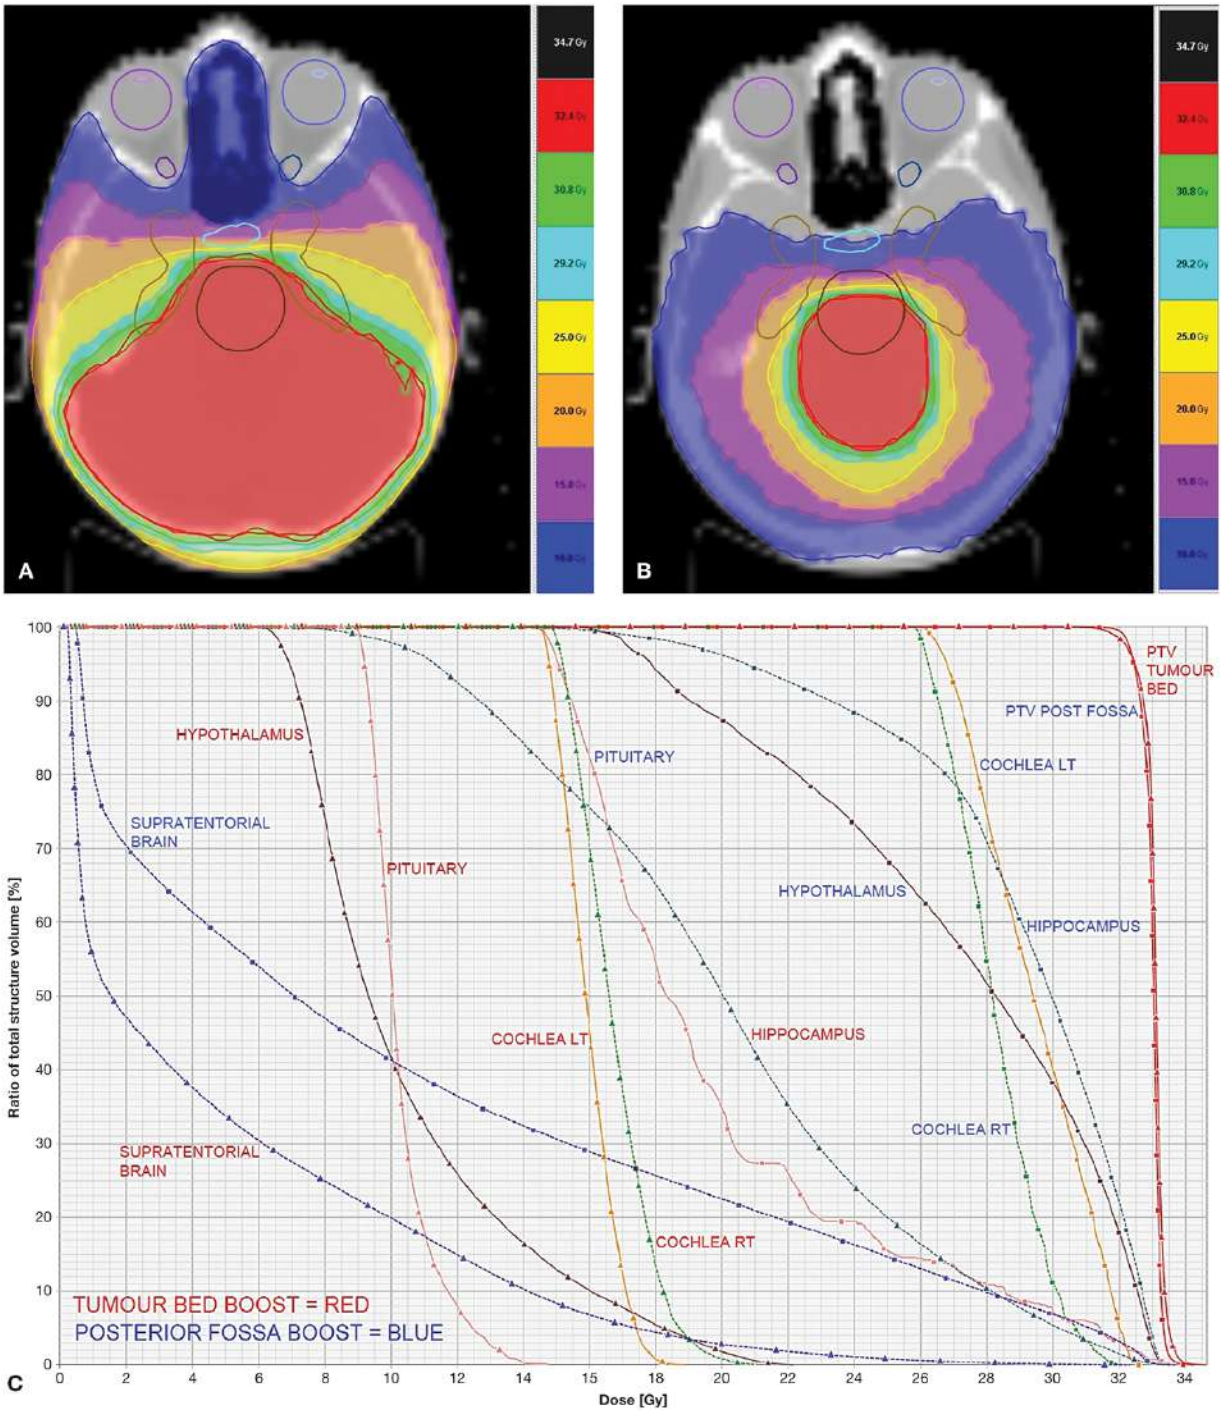

FIGURE 90.13 Axial images of an intensity-modulated radiation therapy/image-guide radiation therapy plan for a whole posterior fossa (A) and a reduced-volume posterior fossa boost (B) for a patient with medulloblastoma. C. Dose-volume histograms show significant sparing of organs at risk with the reduced-volume boost. LT, left; PTV, planning target volume; RT, right.

Further data suggest that IMRT can further spare normal OARs in the brain, and proton RT can further decrease integral low dose and acute and long-term toxicity.[36,287,288] Recent studies also suggest that the use of proton RT may improve long-term neurocognitive outcomes.[289-291]

Delay to RT may be associated with poorer outcomes, and CSI should ideally start within 28 to 40 days following surgical resection. There is also evidence that it is important to deliver RT in a timely manner, avoiding unnecessary gaps in treatment resulting from machine servicing, holidays, and the like. In the SIOP PNET-3 and PNET-4 studies, EFS and OS were significantly worse when the duration of treatment exceeded 50 days.[256,292] When CSI has to be interrupted, for example, because of hematologic toxicity, treatment should continue to the posterior fossa boost volume while waiting for the blood counts to recover. Granulocyte colony-stimulating factor may be used to hasten recovery of the counts.

Supratentorial Primitive Neuroectodermal Tumor

Recent molecular analysis of case series has established that the group of tumors previously referred to as supratentorial primitive neuroectodermal tumor (stPNET) are now more correctly allocated to various different histologic groups, including other embryonal tumors such as ATRT (see later) or sometimes those of astrocytic lineage.[293] This has led to confusion over how best to manage these patients.

Traditionally, the conventional usual approach for a child older than 3 years with an stPNET without leptomeningeal spread consisted of maximal surgical resection followed by postoperative RT (CSI followed by a boost) and chemotherapy. Experimental regimens such as HDCT with stem cell rescue (SCR) are used in infants and young children and in patients with M+ disease. In view of current knowledge, patients who would previously have been diagnosed as having stPNET require multidisciplinary discussion including detailed expert review of pathology to determine optimum management of the individual case.

Atypical Teratoid/Rhabdoid Tumor

ATRT is a highly malignant embryonal tumor seen in very young children with a peak incidence in the birth to 2-year age group, at which age in one

population-based study ATRT was as common as PNET and MB.[294] Composed of rhabdoid cells with or without fields resembling a classic PNET, ATRT is diagnosed on the basis of the characteristic molecular findings, namely, deletion and/or mutation of the INI1 locus (also known as *SMARCB1* gene) on chromosome 22 or less frequently mutations in *SMARCA4* gene on chromosome 22. ATRT can arise at any location within the CNS, including the spine. Leptomeningeal seeding is seen at diagnosis in a quarter to one-third of patients.[295] Staging workup includes renal imaging, given the high prevalence of rhabdoid tumor predisposition syndrome in 35% of patients with ATRT.[296]

Since the recognition of ATRT as a separate entity with a high frequency of early relapse and a very poor prognosis, patients have been treated with increasingly intensive chemotherapy regimens. RT appears to be an important component of treatment.[297-303] In a series of 37 patients treated at St Jude, early use of RT and the use of CSI were found to be associated with improved outcomes,[302] and it has been suggested that the worse survival reported for children younger than age 3 may be due, in part, to the less frequent use of RT and, when used, to the use of local RT rather than CSI in this age group. However, in a recent update limited to patients who received age- and risk-stratified RT, delay to RT was found to be the important factor.[304] The current treatment paradigm includes surgery, two courses of chemotherapy, followed by three courses of HDCT with peripheral blood SCR and RT: involved field with or without CSI for localized and disseminated disease, respectively. This ACNS0333 study–based treatment resulted in superior 4-year EFS and OS of 37% and 42%, respectively, compared to less than 10% in historical trials, where the protocol calls for early RT (after completion of at least two cycles of induction chemotherapy).[301] However, the use and timing of RT depend on the age of the child, the location (infratentorial or supratentorial), and the extent of disease at diagnosis (M0 or M+). Thus, children younger than 6 months at completion of chemotherapy with an infratentorial tumor and those younger than 12 months with a supratentorial tumor receive RT later, upon completion of both induction and consolidation chemotherapy with or without HDCT and autologous stem cell transplant. The RT target volume is local (tumor bed and any macroscopic residual disease plus a margin for the CTV of 1 cm) for children with localized disease and CSI followed by a

boost for those with leptomeningeal spread. Doses are age dependent for both local RT and CSI (50.4 vs 54 Gy and 23.4 vs 36 Gy for children younger and older than 3 years, respectively).[301] In Europe, patients with nonmetastatic ATRT receive doxorubicin-based chemotherapy and local RT to a dose of 54 Gy, whereas those with metastatic disease receive CSI. An ATRT registry (EURHAB) has been established to collect multi-institutional and multinational data on patient management and outcome.[305] Recently, a phase 1 study (NCT02601937) showed promising efficacy of a single-agent tazemetostat, Enhancer Of Zeste 2 Polycomb Repressive Complex 2 Subunit inhibitor, in the management of refractory or relapsed ATRT.[306]

Embryonal Tumors With Multilayer Rosettes

In 2000, Eberhart et al[307] described a variant of stPNET, the embryonal tumor with abundant neuropil and true rosettes (ETANTR) as a tumor exhibiting prominent ependymoblastic rosettes, neuronal differentiation, and a neuropil background. This tumor was predominantly recognized in young children and was associated with a very poor prognosis. More recently, in 2014, it has been recognized that there is a group of tumors that are distinct from other embryonal tumors and are referred to as embryonal tumors with multilayer rosettes (ETMRs). ETMR is now recognized as containing the three histologic variants ETANTR, ependymoblastoma, and medulloepithelioma.[220] These newly recognized tumors are yet to have a universally accepted mode of management. Given ETMR's rarity, there is no standard treatment paradigm. Current management is largely adapted from other embryonal tumor treatment strategies including surgery, age- and risk-adapted RT, HDCT with autologous SCR, and/or intrathecal therapy with relatively improved outcomes according to some case series despite an overall dismal prognosis.[308,309]

GERM CELL TUMORS

Germ cell tumors of the CNS constitute a group of rare tumors that are morphologic homologs of germinal neoplasms arising in the gonads and at other extragonadal sites. They include the following entities, although, in many cases, more than one tumor type is present:

- Germinoma
- Embryonal carcinoma
- Yolk-sac tumor (endodermal sinus tumor)
- Choriocarcinoma
- Teratoma
  - Mature
  - Immature
  - Teratoma with malignant transformation
- Mixed germ cell tumor

A teratoma is a tumor composed of an admixture of different tissue types that are representative of ectoderm, endoderm, and mesoderm. A mature teratoma is composed exclusively of fully differentiated tissues, sometimes arranged in such a manner as to resemble normal tissue relationships. Mitoses are absent or rare. An immature teratoma is composed of incompletely differentiated tissues resembling those of the fetus. Mitoses are typically present.

In the West, CNS germ cell tumors are relatively rare, accounting for 3% to 5% of all CNS tumors in the pediatric age group. They are more common in Asia, where they account for as many as 15% to 18% of all CNS tumors occurring in childhood. The peak age incidence is 10 to 12 years. Boys are affected more frequently than girls, with a ratio of approximately 3:1. CNS germ cell tumors arise from primordial germ cells in structures about the third ventricle, with the region of the pineal gland being the most common site of origin followed by the suprasellar region. Nongerminomatous germ cell tumors (NGGCTs) are the most common tumor type in the former area and germinomas in the latter.

The presenting symptoms and signs depend on the tumor type and the location of the tumor. Tumors in the pineal region cause obstruction to CSF flow at the aqueduct of Sylvius resulting in hydrocephalus, and most patients with tumors in this region present with a relatively short history with symptoms and signs of raised intracranial pressure. Another characteristic presentation of tumors in this region is Parinaud syndrome as a result of dorsal midbrain compression. In contrast, patients with tumors in

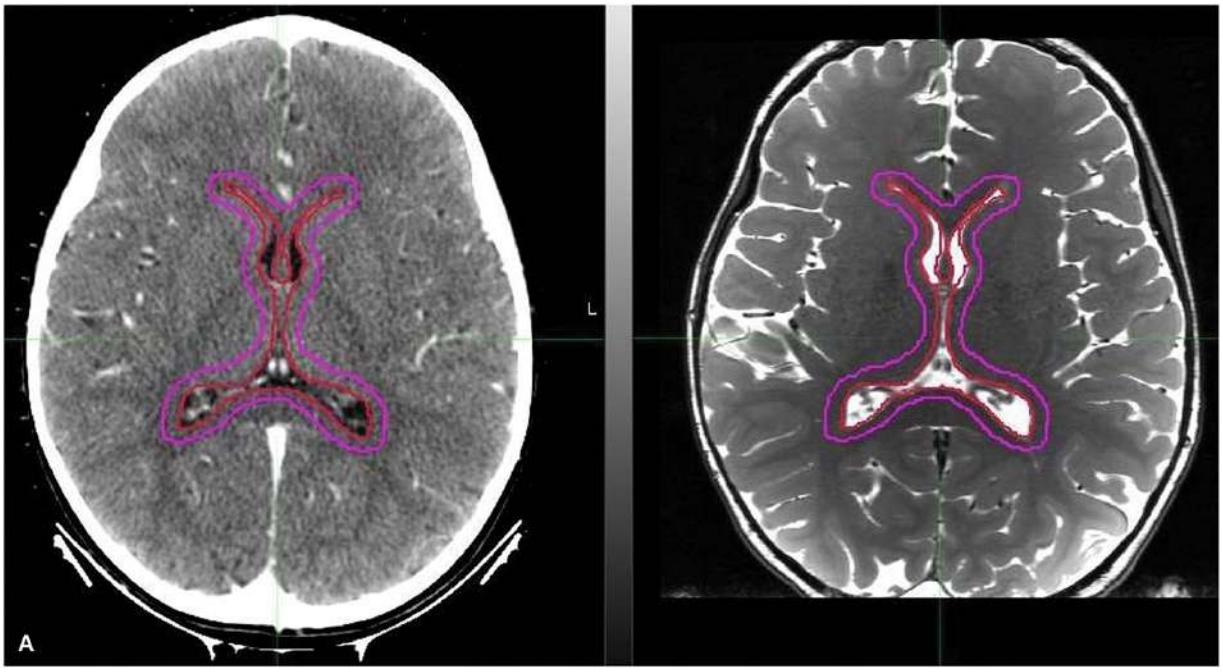
the suprasellar region usually present with a longer history initially of neuroendocrine deficits, especially diabetes insipidus, growth failure, and precocious puberty, and only later of visual field deficits and, later still, of symptoms and signs of raised intracranial pressure. On imaging, most germ cell tumors appear as solid masses. Teratomas are more heterogeneous with cysts, areas of calcification, and, sometimes, fat, whereas choriocarcinomas often contain areas of hemorrhage. Bifocal or multifocal disease around the third ventricle is seen in approximately 10% of patients with germinomas. Gadolinium-enhanced MRI of the spinal axis is an essential part of the workup to exclude leptomeningeal dissemination, which is found at diagnosis in approximately 10% of patients with germinomas and 10% to 15% of patients with NGGCTs. Measurement of serum and CSF tumor markers is another essential part of the initial workup. Modest elevation of β-human chorionic gonadotropin (β-hCG) (,100 IU/mL) may be seen with pure germinomas that may contain syncytiotrophoblastic cells. Higher levels of β-hCG are more suggestive of a choriocarcinoma. An elevated α-fetoprotein (α-FP) is diagnostic of a yolk-sac tumor.

In the past, many lesions arising in or about the third ventricle were treated without histologic confirmation of diagnosis. This is no longer considered acceptable practice because the differential diagnosis includes many disparate entities (such as Langerhans cell histiocytosis, astrocytoma, and ependymoma), and all patients should undergo biopsy unless CSF and/or serum markers confirm the presence of an NGGCT (elevated α-FP and/or β-hCG .100 IU/mL) or unless a histologic diagnosis is made by other means (eg, CSF cytology). For tumors in the pineal region with hydrocephalus, the usual surgical approach is an endoscopic third ventriculostomy, which allows access to the lesion for biopsy purposes. Intraventricular lesions have to be biopsied with care because hemorrhage, which is not infrequent, may be difficult to manage endoscopically. A stereotactic approach is also possible, but this may be quite challenging because of the proximity of deep cerebral veins and, moreover, may be suboptimal for diagnosis because of the potential for sampling error. Occasionally, complete resection will be possible; this would be a reasonable strategy for patients with NGGCTs if it can be accomplished without major morbidity because it would ensure complete characterization of the pathology and may even obviate the need for further therapy.

Germinoma

In the past, standard treatment for patients with germinoma, whether localized or disseminated, was RT alone. Results of treatment using CSI followed by a boost to the primary site are excellent, with long-term disease-free survival rates of 100% in some series.[310-313] For patients with unifocal disease without leptomeningeal spread, RT alone to limited volumes, that is, whole brain[314,315] or whole ventricle,[316] results in a high probability of local control and a low (0%-5%) risk of failure in the spinal axis. Experience with local RT (tumor plus a margin) alone generally has been less satisfactory.[317-320] To reduce the risk of morbidity associated with RT, chemotherapy has been considered another option, either alone or in combination with reduced-volume and/or reduced-dose RT. Several studies have shown clearly that the former, that is, the use of chemotherapy alone, is not acceptable: Only 40% to 50% of patients remain disease free, and although salvage using further chemotherapy together with RT is possible in most cases and OS is high, this is achieved at the cost of considerable toxicity.[321-323]

In contrast, a combined approach using platinum-based chemotherapy followed by reduced-volume, reduced-dose RT is an attractive option that results in disease-free survival rates in the 90% to 96% range.[316,324-326] Local failures were seen in 10 of 60 patients treated in the SFOP TGM-TC-90 study with chemotherapy followed by local RT and primarily located along the ventricles.[320] Local failure appears to be less frequent after whole-ventricular RT, and the recent COG ACNS1123 showed excellent outcomes (Figure 90.14).[316,317,327]



L
B

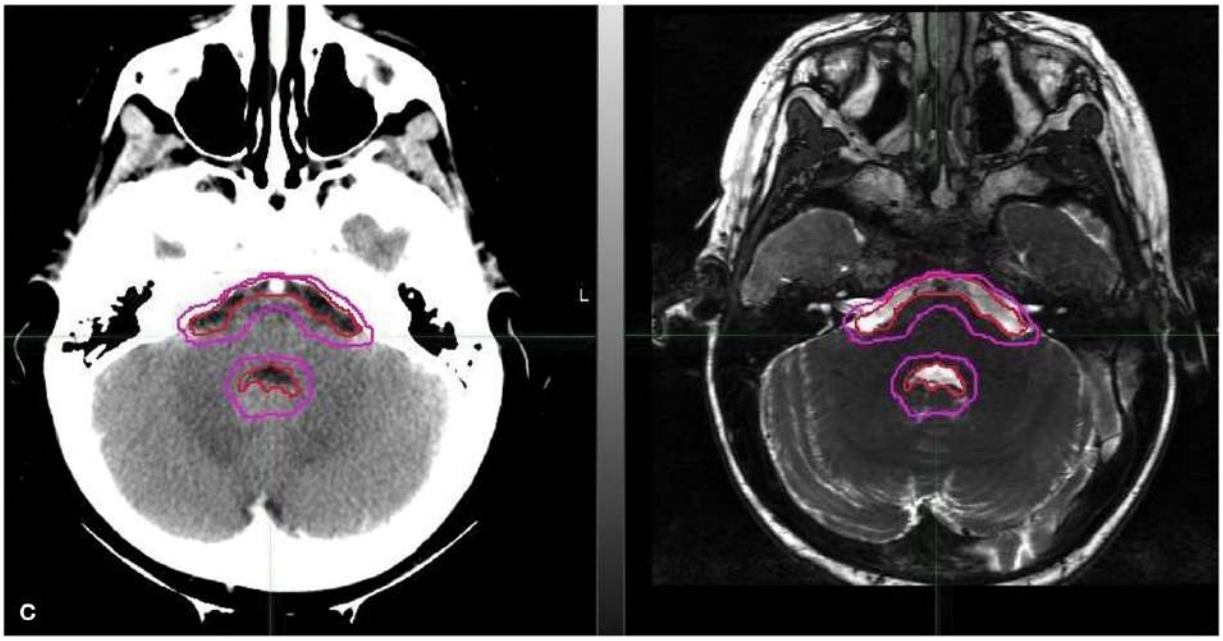

FIGURE 90.14 Target volume definition for whole-ventricular irradiation as per the guidelines for the current Children's Oncology Group study for central nervous system germ cell tumors. Planning computed tomography and T2-weighted magnetic resonance images at the level of lateral ventricles (A), hypothalamus and pineal cistern (B), and fourth ventricle and prepontine cistern (C). Note that this volume needs to be expanded to include the primary tumor and any other sites of involvement. Whether the suprasellar, basal, and prepontine cisterns need to be included is controversial for now. Better sparing of nontarget tissues will be achieved with the use of a four-field technique or intensity-modulated radiation therapy than with lateral-opposed fields. (Courtesy of Dr Shannon MacDonald.)

For patients with leptomeningeal spread at diagnosis, RT alone using CSI with boosts to macroscopic disease is certainly an option, although, in North America and Europe, chemotherapy followed by CSI followed by a boost to all sites of involvement would now be the more usual approach. Management of patients with bifocal or multifocal midline tumors is controversial. In the past, these patients were treated as having disseminated disease, but at least some, that is, those with bifocal disease by imaging or by inference (eg, in a patient with a pineal region primary who has diabetes insipidus), are now more usually treated with chemotherapy and whole-ventricular RT.

There is less controversy now with regard to the RT dose and dose fractionation schedule for germinoma. For localized (unifocal or bifocal) pure germinoma, the current standard in North America is induction chemotherapy followed by whole-ventricular RT to 18-24 Gy with an

involved-field boost to 30-36 Gy. Given recurrences can happen after biopsy through the endoscopic third ventriculostomy tract, it is important to include the tract within the radiation field. Results are excellent for those patients with metastatic disease, with a CSI dose as low as 21 Gy even in patients with leptomeningeal spread. The total dose to the primary site has typically been 40 to 45 Gy, but probably can be safely reduced to 36 Gy or even to 30 Gy[316,317] in patients treated with a combined chemotherapy-RT regimen who have had a complete response to chemotherapy. Finally, because germinoma is a very radiosensitive tumor, a fraction size of 1.5 Gy can be used, which, in theory, further reduces the risk of injury to normal structures.

Nongerminomatous Germ Cell Tumors

For NGGCTs, the diagnosis can be made in as many as one-third of all patients on the basis of imaging findings (location and appearance) plus tumor markers. NGGCTs are of several different histopathologic types that carry different prognoses. Patients with mature teratomas without any associated malignant elements can be managed with surgery alone, whereas those with mature teratoma with germinomatous elements will be treated as germinomas. All other patients with intermediate and poor prognosis tumor types[328] require more aggressive treatment. The results of treatment using RT alone are very poor, with OS in the 10% to 30% range. Results are better with chemotherapy alone, although 40% to 60% of patients relapse following chemotherapy and will be subjected to aggressive salvage regimens.[329,330] A multimodality approach that includes both chemotherapy and RT appears to be associated with the best outcome, with 5-year OS more than 80%.[331,332] The most recent COG ACNS1123 study found that omitting CSI led to increased failures in the spine, suggesting that spine irradiation is needed for patients with NGGCT.[332,333] The current standard of care, therefore, consists of platinum-based chemotherapy followed by RT.

There is controversy with respect to the RT target volume for NGGCT. Although good results have been reported by some groups using chemotherapy followed by local RT,[331] others show a high rate of failure outside the primary site.[332-335] Thus, CSI remains the standard of care for patients with NGGCT using a dose of 30 to 36 Gy, with a boost to the

primary site for a total dose of 54 Gy. There may be a subset of patients who may have favorable outcomes without CSI, but this remains to be determined. The ongoing COG ACNS2021 study will explore the role for whole ventricular and spine irradiation for patients with NGGCT.

Patients who have less than a complete response to chemotherapy fare poorly. Second-look surgery may be useful to both exclude the possibility that the residual imaging abnormality represents mature teratoma and/or resect residual viable tumor. This would be followed by CSI and more intensive chemotherapy, such as HDCT/SCR.[331]

TUMORS OF THE SELLAR REGION

Tumors arising in the sellar region in children include the following:

- Craniopharyngioma
- Adamantinomatous
- Papillary
- Pituitary adenomas

Craniopharyngioma

Craniopharyngiomas are benign partly cystic epithelial tumors that arise in the sellar region from remnants of Rathke pouch. In children, almost all are of the adamantinomatous type. They account for approximately 5% of intracranial tumors in the pediatric age group, with a peak incidence between the ages of 5 and 14 years.[336]

In most patients, craniopharyngiomas have both suprasellar and intrasellar components. Children typically present with neuroendocrine deficits, especially diabetes insipidus and growth failure. Visual field deficits often go unnoticed initially. Cognitive and behavioral changes are not uncommon. Compression of or tumor growth within the third ventricle may lead to hydrocephalus and symptoms and signs of raised intracranial pressure. On neuroimaging, the findings are very typical, with solid and cystic areas in varying proportions. Calcification is seen in the majority of cases. The solid portion(s) and the cyst capsule usually enhance with the use of contrast material.[337]

Treatment of craniopharyngiomas, although long considered a controversial issue,[338] in practice depends on the characteristics of the tumor and the availability of the surgical expertise required. Many patients have long-term tumor control after complete resection[339]; however, many patients suffer recurrence, with a prospective study finding EFS at 3 years of 64%.[340] Moreover, although visual deficits, if present, improve after surgery in the majority of cases, new neuroendocrine deficits are very common and hypothalamic damage is a major concern, particularly in patients with tumors that have grown retro-chiasmatically into the floor of the third ventricle.[341-343] Devastating sequelae that include rage, aggressivity, and hyperphagia permanently compromise the quality of life of the patient and their family. The transsphenoidal approach that has been used more frequently in recent years, even in younger children and even in patients with tumors with a supradiaphragmatic component, is associated with fewer complications. In general, therefore, tumors that are smaller and/or subdiaphragmatic in location and without hypothalamic involvement would be managed surgically. Patients who have residual tumor following surgery are at high risk for progressive disease within the first 2 to 3 years following surgery,[344-347] mandating close follow-up with MRI performed at 3-month intervals during that time period. Patients at greater risk for complications secondary to surgery would be managed with biopsy, cyst decompression, if necessary, and RT.[348-353]

RT may, therefore, be given as the sole therapy after biopsy, after incomplete surgery, or at the time of progression/recurrence after surgery. A retrospective study found that delaying radiation until recurrence can lead to worse endocrine and visual outcomes.[354] Given the heterogeneity of tumor types and situations, many treatment options have been used and explored. For example, a lesion with a small solid component and a simple cyst may be well treated with intracavitary injection of liquid radioactive material. Most contemporary experience is with β emitters such as ^{33}P and ^{91}Y delivering a high dose (ie, 200 Gy) to the cyst wall. Intracavitary injection of radioactive material is not always easy.[355] Sometimes, the cyst fluid is very thick in consistency, and there may be little or no communication between multiple cysts. It is essential to use contrast material to ensure that the catheter is well placed in the cavity and that there is no leakage of material outside the cyst before injecting radioactive

material. This could be combined with radiosurgery or fractionated stereotactic irradiation to the associated solid component, although it may be reasonable to do so only later and only if there is evidence of progressive disease. Special care is needed if, as is usually the case, the tumor is near the optic chiasm or optic nerves.[356] Tumor control rates using this approach are good for carefully selected patients.[357] However, conventionally fractionated external beam RT with photon or proton RT may be a better option for all except very small tumors, with a lower risk of morbidity.[358-362]

The target volume for external beam RT consists of the entire lesion (ie, both the solid and cystic components) as demonstrated on postcontrast T1- and T2-weighted MRI sequences for better visualization of the solid and cystic components, respectively, ideally with a 1- to 2-mm slice thickness, performed just prior to treatment. Although some have used a margin for the CTV of 1 to 2 cm,[360,361] a smaller margin of 0.5 cm or even 0 cm (ie, CTV = GTV) can be justified based on excellent tumor control using such margins.[359,363-365] However, the use of reduced margins should be paired up with close in-treatment surveillance, given the potential for cystic growth.[366] A dose of 50.4 to 55.8 Gy given in 1.8 Gy daily fractions over 6 weeks appears to be necessary to achieve a high probability of tumor control. Cyst enlargement during treatment or within the first 2 to 3 months after completion of RT is common. Early recognition and appropriate management consisting usually of cyst decompression is essential to avoid further neurologic compromise or even death.[354,367] The long-term prognosis is good, with EFS more than 80% in most series.[359-362] Patients may have long-term sequelae after RT, including vasculopathy; however, many of these toxicities are present prior to radiation.[361,368]

There is increasing interest in the use of proton therapy to reduce nontarget dose, which would be predicted to minimize late endocrine and neurocognitive effects (Figure 90.15).[359,362]

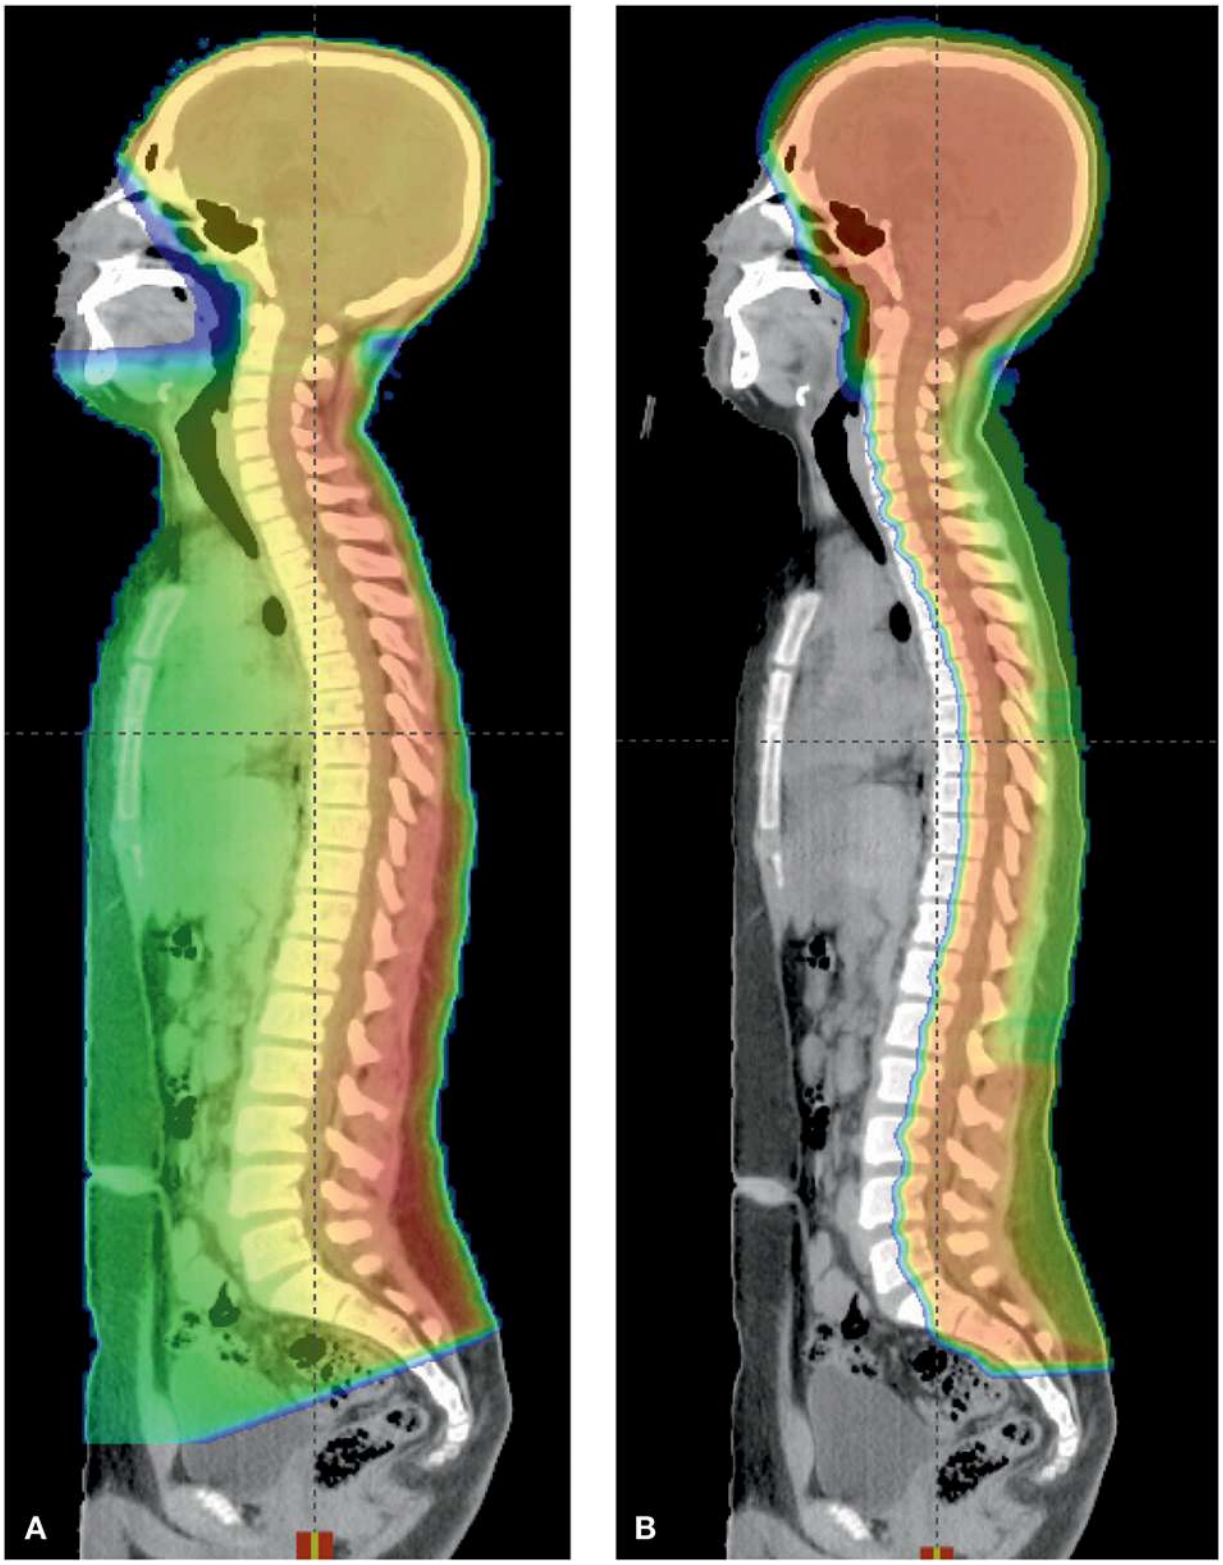

FIGURE 90.15 A. Craniospinal radiotherapy for young adult with conventional photon radiotherapy—exit from spinal field delivers low to intermediate dose to structures anterior to spine. B. Craniospinal radiotherapy for young adult with proton therapy—no exit dose

beyond Bragg peak avoiding dose to structures anterior to spine. (Figure courtesy of Dr D. Indelicato, University of Florida, Jacksonville.)

Pituitary Adenomas

Pituitary adenomas are rare in childhood. Almost all cases arise in adolescence. Most are functioning adenomas that present with endocrine dysfunction, most often menstrual irregularities and galactorrhea in girls and delayed puberty in boys. They may be quite large, with extrasellar extension, and appear to be more invasive than those seen in adults.[369-371] Visual loss, when present, may be more severe and more likely to be associated with optic atrophy.[371]

Management will, in general, parallel that for adult patients. Prolactin- and growth hormone–secreting adenomas are managed medically as in adults. When surgery is necessary, a transsphenoidal approach using neuronavigation appears to be feasible and safe in children, even in those with poor pneumatization of the sphenoid sinus.[369,370] RT is indicated if surgical resection is not possible or in cases of unresectable recurrence or intractable hormone elevation following surgery. GTV delineation should be performed using pre- and postcontrast-enhanced T1-weighted MRI, ideally with fat suppression and 1-mm slice thickness, and using preoperative imaging, if applicable.[366] Highly conformal treatment with a margin for the CTV of 0.5 cm beyond macroscopic disease is appropriate in most cases, especially in case of invasive and aggressive pituitary tumors, to encompass all potential areas of microscopic tumor infiltration while sparing adjacent critical structures, including major vessels. The usual dose, as in adults, will be 45 to 50.4 Gy and up to 54 Gy over 5 to 6 weeks for nonsecretory, secretory, and larger more aggressive pituitary tumors, respectively. Single-fraction and fractionated stereotactic radiosurgery have become increasingly adopted in clinics following comparable efficacy and safety for smaller pituitary tumors located at a safe distance from critical structures like the optic apparatus. Common dose fractionation regimens include 13 to 16 and 16 to 25 Gy in one fraction for nonfunctioning and secreting pituitary adenomas, respectively, as well as 21 Gy in three fractions and 25 Gy in five fractions for larger and/or closer tumors to the optic chiasm.[372,373] Close follow-up by an endocrinologist is essential to ensure appropriate management of hormone deficits.[374]

CHAPTER 91

Wilms Tumor

John A. Kalapurakal and Arnold C. Paulino

Wilms tumor (WT), or nephroblastoma, is a highly curable childhood neoplasm. The prognosis of children with WT has improved considerably from a very high mortality rate at the beginning of the 20th century to the current cure rate of >90%.[1] The management of WT is a paradigm for successful interdisciplinary treatment of solid tumors of childhood to maximize cure rates and minimize treatment-related complications.

EPIDEMIOLOGY

WT is the most common malignant renal tumor of childhood. The incidence of WT is 10.4 cases for every 1 million children younger than 15 years. Approximately 650 cases of WT are diagnosed in the United States each year.[2,3] The peak incidence is between 3 and 4 years of age. WT may arise as sporadic or hereditary tumors or in the setting of specific genetic disorders.[4] Most WTs are solitary lesions within a kidney, multifocal within a single kidney in 12% and bilateral in 7%.[5] The clinical syndromes associated with WT include WAGR syndrome (*WT*, *A*niridia, *G*enitourinary malformations, mental *R*etardation), Denys-Drash syndrome (pseudohermaphroditism, mesangial sclerosis, renal failure, and WT), and overgrowth syndromes like Beckwith-Wiedemann syndrome (somatic gigantism, omphalocele, macroglossia, genitourinary abnormalities, ear creases, hypoglycemia, hemihypertrophy, and a predisposition to WT and other malignancies), and Simpson-Golabi-Behmel syndrome.[4,6]

BIOLOGY

Among the various genetic changes implicated in the development of WT, the most widely studied involves *WT1*, which is a tumor suppressor gene at chromosome 11p13 that was isolated from a child with WAGR syndrome.[7]

WT1 is likely to play a specific role in glomerular and gonadal development.[8] *WT1* can also act as a dominant negative oncogene, resulting in abnormal cell growth such as in Denys-Drash syndrome.[9] Germline *WT1* mutations are observed in approximately 82% of patients with WT who have genitourinary anomalies or renal failure. The frequency of *WT1* mutations in sporadic and familial WT is much lower at 20% and 4%, respectively.[10] Beckwith-Wiedemann syndrome maps to chromosome 11p15.5; this locus is also referred to as *WT2*.[11]

Patients with loss of heterozygosity (LOH) at 16q and 1p have higher relapse and mortality rates.[12] The National Wilms Tumor Study-5 (NWTS-5) prospectively evaluated the prognostic significance of LOH on 16q and 1p. When the effects of LOH for both 1p and 16q were considered jointly, the relative risk (RR) for relapse in stage I and II familial hypercholesterolemia (FH) diseases was 2.9 ($P = .001$) and for stage III and IV FH diseases was 2.4 ($P = .01$). The RR for death for patients with stage I and II FH diseases with LOH for both regions was 4.3 ($P = .01$) and for stages III and IV was 2.7 ($P = .04$).[13]

A novel WT suppressor gene on the X chromosome, *WTX (AMER1)* is inactivated in approximately one-third of sporadic WT cases.[14] Anaplastic tumors have shown changes on 17p consistent with *TP53* deletion and specific genomic loss or underexpression on 4q and 14q and focal gain of *MYCN*.[15] Rhabdoid tumors are characterized by the genetic loss of the *SMARCB1/hSNF5/INI-1* gene located at chromosome 22q11. Global gene expression studies have shown that loss of *SMARCB1* results in repression of neural crest development and loss of cyclin-dependent kinase inhibition.[16] The rhabdoid tumor predisposition syndrome is an autosomal dominant condition observed in 30% to 35% of patients with rhabdoid tumors due to germline mutations in SMARCB1 or SMARCA4.[17] In children with very low-risk WT treated with just surgery alone, the presence of *WT1* mutation and 11p15 loss has been prospectively validated to be an important predictor of relapse.[18,19] Another Children's Oncology Group (COG) study demonstrated that gain of 1q is a promising biomarker for patients with favorable histology WT. In a report of 1,114 patients on NWTS-5, 317 (28%) patients displayed 1q gain. The 8-year event-free survival (EFS) with and without 1q gain was 77% and 90%, respectively ($P < .001$). The 8-year overall survival (OS) with and without 1q gain was

88% and 96%, respectively ($P < .001$). 1q gain was associated with a higher RR of relapse (2.4, $P < .001$).[20] In the International Society of Pediatric Oncology (SIOP) WT2001 study after preoperative chemotherapy and nephrectomy, among 586 patients, 28% had 1q gain. The 5-year EFS was 75% and 88% ($P < .001$) and OS was 88% and 94% ($P = .01$), with and without 1q gain, respectively. Other molecular aberrations associated with poorer outcomes included *MYCN* gain and *TP53* loss.[21]

PATHOLOGIC CLASSIFICATION

The first acceptable pathologic classification was reported by Beckwith and Palmer from the NWTS-1.[22] The NWTS classifies all tumors as having either FH or unfavorable histology (UH). The UH tumors include anaplastic tumors, clear cell sarcoma of the kidney (CCSK), and rhabdoid tumor of the kidney (RTK). Of 1,465 patients randomly assigned on NWTS-3, 163 (11.1%) had UH.[23] WTs are usually sharply demarcated, spherical masses with a "pushing" border and a surrounding distinct intrarenal pseudocapsule. Histologically, WT reflects the development of the normal kidney, consisting of three components, blastemal, epithelial (tubules), and stromal elements, in varying proportions.[22] The proportion of the different components has prognostic significance.[24] Nephrogenic rests consist of embryonal nephroblastic tissue and are found in 35% of kidneys with unilateral WT and in nearly 100% of kidneys with bilateral WT (BWT).[25] Nephrogenic rests may be intralobar or perilobar based on their location within the kidney.[26] Most nephrogenic rests undergo spontaneous regression, and only a small proportion (1%-5%) transform into WT.[27] The histologic feature of greatest clinical significance in WT is anaplasia.[28] Anaplasia may be focal (FA) or diffuse (DA). The definitions of FA and DA have been revised to reflect the distribution of anaplastic cells in the tumor rather than their quantitative density. These revised definitions are of prognostic significance. The 4-year survival rates for patients with stage II, III, and IV FA were 90%, 100%, and 100%, compared with 55%, 45%, and 4%, respectively, for patients with similar stage DAWT.[29]

CCSK and malignant RTK are no longer considered true WT, but they have been included in NWTS protocols.[22] CCSK has a propensity to metastasize to bone and lymph nodes (LNs), and a skeletal survey and bone

scan should be performed. RTK is commonly seen in very young children and is the most lethal renal neoplasm in children. Primitive neuroepithelial tumors of the cerebellum or pineal region may be seen in 10% to 15% of patients with RTK.[30]

CLINICAL PRESENTATION

The classic presentation for WT is that of a healthy child in whom abdominal swelling is discovered by the child's parent or by a physician during a routine physical examination. A smooth, firm, nontender mass on one side of the abdomen is felt. Gross hematuria occurs in as many as 25% of these cases.[31] The child may be hypertensive or have nonspecific symptoms, such as malaise or fever.[32] Only rarely does a patient present with symptomatic metastases.

DIAGNOSTIC WORKUP

The differential diagnosis of WT includes other malignant childhood lesions of the kidney, neuroblastoma, and benign conditions, such as hydronephrosis, polycystic disease, and splenomegaly in left-sided tumors. Plain films of the abdomen may demonstrate calcifications, which occur in 60% to 70% of neuroblastomas but in only 5% to 10% of WT. Excretory urography (intravenous pyelography) was once the mainstay of imaging in WT and now has largely been replaced by ultrasonography and computed tomography (CT) scanning. Ultrasonography is very useful because it is readily available and is cost-effective.[33] A specific advantage of ultrasonography is its ability to assess vessels for flow and tumor thrombus with duplex and color Doppler.[34] Routine use of Doppler sonography after abdominal CT scans was not found to be useful in detecting cavoatrial thrombus in a COG study.[35] Abdominal CT scans can demonstrate gross extrarenal spread, LN involvement, liver metastases, and the status of the opposite kidney (Figure 91.1).[36] Magnetic resonance imaging (MRI) has several advantages over CT scans, especially in identifying renal origin and vascular extension of the tumor.[37] CT and MRI are useful in the detection and follow-up of patients with nephrogenic rests.[38] Clinical and imaging impressions do not, however, obviate the need for inspection at laparotomy.[39] Chest CT scans are also essential because asymptomatic

pulmonary metastases are common.[40] A complete blood cell count and urinalysis should be performed. Patients with WT can be anemic from hematuria. Serum blood urea nitrogen and creatinine levels and liver function tests are routine. If neuroblastoma is not ruled out, a test for urinary catecholamines should be performed. Table 91.1 outlines the pretreatment investigations recommended by the COG.

TABLE 91.1 PRETREATMENT WORKUP

History	Record preexisting conditions, family history of cancer, or congenital defects
Physical examination	Blood pressure, weight, height, presence of abdominal masses, congenital anomalies particularly genitourinary, hemihypertrophy, and aniridia
Laboratory	Hemoglobin, white cell, differential counts, platelets, urinalysis, serum blood urea nitrogen, creatinine, protein, alanine, aspartate aminotransferases, alkaline phosphatase, bilirubin
Radiology	CT or MRI scan of the abdomen and pelvis, abdominal ultrasonography, chest CT scan Bone scan and MRI of the brain (CCSK, RTK, and renal cell carcinoma)

CCSK, clear cell sarcoma of the kidney; CT, computed tomography; MRI, magnetic resonance imaging; RTK, rhabdoid tumor of the kidney.

FIGURE 91.1 Computed tomography scan of a 4-year-old girl with a large right-sided Wilms tumor measuring 10.5 cm × 8.4 cm × 13.5 cm. The left kidney did not show any lesions. At laparotomy, the tumor was found to invade the diaphragm. She underwent a right radical nephrectomy. Surgical margins of resection were positive, and she had metastases in the para-aortic lymph nodes. The tumor was classified as stage III favorable histology and received 10.8 Gy to the right flank and chemotherapy with vincristine, dactinomycin, and doxorubicin.

NATURAL HISTORY

The disease is often localized at diagnosis, as evidenced by the fact that surgery and radiation therapy (RT) are curative in almost 50% of cases.[41] The first signs of local tumor spread beyond the pseudocapsule are invasion into the renal sinus or the intrarenal blood and lymphatic vessels. Spread throughout the peritoneal cavity may also occur, especially if there has been preoperative rupture or the disease has been spilled at surgery.[42,43] The most common sites of metastases of WT are in the lungs, LNs, and liver. Among patients with stage IV disease, lungs were the only metastatic site in

approximately 80% and 15% had liver metastases.[44] The NWTS and COG studies have clearly demonstrated the prognostic importance of LN involvement. Among children with stage III FHWT in AREN0532, those with LN-positive disease and either LOH at 1p or 16q had worse EFS compared to LN-negative disease, regardless of LOH status and node positive with no LOH at 1p or 16q.[45,46]

STAGING

Tumor staging is performed after examining the radiologic, operative, and histopathologic findings.[43,44] In NWTS-1 and NWTS-2, a tumor grouping system was used for staging and treatment stratification. After analyzing the prognostic significance of several clinical-pathologic factors in NWTS-1 and NWTS-2, a new staging system was adopted in NWTS-3. The presence of LN involvement was upstaged to stage III instead of group II, and local tumor spill was downstaged from group III to stage II.[43] In NWTS-5, the most significant change was the distinction between stages I and II. The criteria for stage I were revised to accommodate an important subset of WT that is being managed by nephrectomy alone. Before NWTS-5, the distinction between stages I and II in the renal sinus was established by the hilar plane that was difficult to apply due to tumor distortion, and thus, the hilar plane criterion has been replaced with renal sinus vascular or lymphatic invasion. This definition includes not only the involvement of vessels within the hilar soft tissue but also the vessels located in the radial extensions of the renal sinus into the renal parenchyma.[45,47] The COG staging guidelines for WT are shown in Table 91.2. The major change from NWTS-5 is that children with tumor spillage are upstaged from stage II to stage III because of the higher risk for relapse with two-drug chemotherapy alone.[48] The COG risk group classification for treatment assignment in the first generation of WT protocols is shown in Table 91.3. In addition to tumor stage, this classification will also consider the patient's age, tumor weight, presence or absence of LOH at 1p and 16q, and response to chemotherapy in children with FH tumors and lung metastases.

TABLE 91.2 CHILDREN'S ONCOLOGY GROUP STAGING OF WILMS TUMOR, RHABDOID TUMOR, AND CLEAR CELL SARCOMA OF THE KIDNEY

Stage I	Tumor limited to the kidney, completely resected. The renal capsule is intact. The tumor was not ruptured or biopsied prior to removal. The vessels of the renal sinus are not involved. There is no evidence of tumor at or beyond the margins of resection. *Note*: For a tumor to qualify for certain therapeutic protocols as stage I, regional lymph nodes must be examined microscopically.
Stage II	The tumor is completely resected, and there is no evidence of tumor at or beyond the margins of resection. The tumor extends beyond the kidney, as is evidenced by any one of the following criteria[a]: • There is regional extension of the tumor (ie, penetration of the renal capsule or extensive invasion of the soft tissue of the renal sinus). • Blood vessels within the nephrectomy specimen outside the renal parenchyma, including those of the renal sinus, contain tumor.
Stage III	Residual nonhematogenous tumor present following surgery and confined to the abdomen. Any one of the following may occur: • Lymph nodes within the abdomen or pelvis are involved by tumor (lymph node involvement in the thorax or other extra-abdominal sites is a criterion for stage IV). • The tumor has penetrated through the peritoneal surface. • Tumor implants are found on the peritoneal surface. • Gross or microscopic tumor remains postoperatively (eg, tumor cells are found at the margin of surgical resection on microscopic examination). • The tumor is not completely resectable because of local infiltration into vital structures. • Tumor spillage occurring either before or during surgery. • The tumor was biopsied (whether Tru-Cut, open, or fine-needle aspiration) before removal. • Tumor is removed in more than one piece (eg, tumor cells are found in a separately excised adrenal gland; a tumor thrombus within the renal vein is removed separately from the nephrectomy specimen).
Stage IV	Hematogenous metastases (ie, lung, liver, bone, brain) or lymph node metastases outside the abdominal-pelvic region are present (the presence of tumor within the adrenal gland is not interpreted as metastasis and staging depend on all other staging parameters present).
Stage V	Bilateral renal involvement by tumor is present at diagnosis. An attempt should be made to stage each side according to the criteria here on the basis of the extent of disease.

[a]Rupture or spillage confined to the flank, including biopsy of the tumor, is no longer included in stage II and is now included in stage III.

TABLE 91.3 CHILDREN'S ONCOLOGY GROUP RISK GROUP CLASSIFICATION FOR FAVORABLE HISTOLOGY WILMS TUMORS

Age	Tumor Weight	Stage	LOH	Rapid Response	Risk Group	COG Study	Treatment
<2 y	<550 g	I	Any	NA	Very low	AREN0532	Surgery only
Any	≥550 g	I	None	NA	Low	AREN0532	EE4A
≥2 y	Any	I	None	NA	Low	AREN0532	EE4A
Any	Any	II	None	NA	Low	AREN0532	EE4A
≥2 y	Any	I	Yes	NA	Standard	AREN0532	DD4A
Any	≥550 g	I	Yes	NA	Standard	AREN0532	DD4A
Any	Any	II	Yes	NA	Standard	AREN0532	DD4A
Any	Any	III	None	Any	Standard	AREN0532	DD4A
Any	Any	III	Yes	Any	Higher	AREN0533	M
Any	Any	IV	Yes	Any	Higher	AREN0533	M
Any	Any	IV	None	Yes	Standard	AREN0533	DD4A
Any	Any	IV	None	No	Higher	AREN0533	M

DD4A, V (vincristine), A (dactinomycin), D (doxorubicin); EE4A, VA; LOH, loss of heterozygosity at both 1p and 16q; M, VAD/Cy (cyclophosphamide), E (etoposide); NA, not applicable.

GENERAL MANAGEMENT

The diagnosis of WT is usually made before surgery and confirmed at surgery. A generous transabdominal or thoracoabdominal incision is recommended for adequate exposure. Flank or retroperitoneal approaches are strongly discouraged due to an increased rate of rupture and the inability to adequately assess the peritoneal cavity for intraperitoneal spread. Complete exploration of the abdomen should be performed. A radical nephrectomy is performed with the ureter divided as distally as possible.[49] The surgeon must excise all tumors without spillage, if possible. The presence of positive LNs is a significant prognostic factor. For the current study (AREN2231), the presence of a positive LN will affect the treatment stratum for which the patient may be eligible. Surgical sampling of LNs in the renal hilum, aortocaval window, and along the vena cava (for right-sided tumors) or aorta (for left-sided tumors) is critical for adequate staging (Figure 91.1). Even in children with stage IV disease, local staging is vital

because it will determine the need for local RT. For example, while a child with lung metastases may require pulmonary radiation, if the primary tumor is stage I or II, flank radiation could be avoided. Similarly, in cases where there is preoperative tumor rupture or intraoperative tumor spill, the local stage may be set, but the LN status will affect the protocol treatment stratum; thus, ALL cases require surgical LN sampling and pathologic confirmation.

The chemotherapy and RT regimens for WT in the first generation of COG protocols are outlined in Tables 91.4 and 91.5.

TABLE 91.4 OUTLINE OF CHILDREN'S ONCOLOGY GROUP RENAL TUMOR STUDY

Tumor Risk Classification	Multimodality Treatment
Very Low-Risk FH Wilms Tumor	
<2 y, stage I, tumor weight <550 g	Nephrectomy without adjuvant therapy, if node sampling and central pathology review have been performed
Low-Risk FH Wilms Tumor	
≥2 y, stage I, tumor weight ≥550 g, stage II without LOH	Nephrectomy, no RT, regimen EE4A
Standard-Risk FH Wilms Tumor	
Stage I and II with LOH	Nephrectomy, no RT, regimen DD4A
Stage III without LOH	Nephrectomy, RT, regimen DD4A
Stage IV FH: rapid responders of lung metastases at week 6 with regimen DD4A, without LOH	Nephrectomy, RT, regimen DD4A; no WLI
Higher-Risk FH Wilms Tumor	
Stage III with LOH	Nephrectomy, RT, regimen M
Stage IV slow responders (lung) and nonpulmonary metastases, with LOH	Nephrectomy, RT, regimen M, WLI and RT to metastases
High-Risk UH Renal Tumors	
Stage I-IV focal anaplasia	Nephrectomy, RT, regimen DD4A
Stage I diffuse anaplasia	Nephrectomy, RT, regimen DD4A
Stage I-III CCSK	Nephrectomy, RT, regimen I

Tumor Risk Classification	Multimodality Treatment
Stage II-IV diffuse anaplasia	Nephrectomy, RT, regimen UH1, RT to all metastatic sites
Stage IV CCSK	Nephrectomy, RT, regimen UH1, RT to all metastatic sites
Stage I-IV RTK	Nephrectomy, RT, regimen UH1, RT to all metastatic sites

CCSK, clear cell sarcoma of the kidney; FH, favorable histology; LOH, loss of heterozygosity at 1p and 16q; regimen DD4A, V (vincristine), A (dactinomycin), D (doxorubicin); regimen EE4A, VA; regimen I, alternating VDCy/CyE; regimen M, VAD/Cy (cyclophosphamide), E (etoposide); regimen UH1, alternating VDCy/CyC (carboplatin) E; RT, flank or abdominal irradiation; RTK, rhabdoid tumor of the kidney; UH, unfavorable histology; WLI, whole-lung irradiation.

TABLE 91.5 CHILDREN'S ONCOLOGY GROUP RENAL TUMOR PROTOCOL RADIATION THERAPY GUIDELINES

Abdominal Tumor Stage and Histology	RT Dose/RT Field[a]
Stage I and II FH Wilms tumor	None
Stage III FH, stage I-III focal anaplasia	10.8 Gy to the flank[b]
Stage I-II DA, stage I-III CCSK[c]	10.8 Gy to the flank[b]
Stage III DA, stage I-III RTK	19.8 Gy flank[b] RT, infants ≤12 mo 10.8 Gy
Recurrent abdominal Wilms tumor	12.6-18 Gy (<12 mo)[b]
	21.6 Gy (older children, previous RT ≤ 10.8 Gy)
	Boost dose of 9 Gy to gross residual tumor
Lung metastases (favorable histology)	12 Gy WLI in eight fractions[d]
Lung metastases (unfavorable histology)	12 Gy WLI in eight fractions
Brain metastases	30.6 Gy whole brain in 17 fractions
	21.6 Gy whole brain + 10.8 Gy IMRT or stereotactic boost
Liver metastases	19.8 Gy whole liver in 11 fractions
Bone metastases	25.2 Gy to the lesion plus 3-cm margin

Abdominal Tumor Stage and Histology	RT Dose/RT Field[a]
Unresected lymph node metastases	19.8 Gy

CCSK, clear cell sarcoma of the kidney; DA, diffuse anaplasia; FH, favorable histology; IMRT, intensity-modulated RT; RT, radiation therapy; RTK, rhabdoid tumor of the kidney; WLI, whole-lung irradiation.

[a]Timing of RT (RT delay): RT should begin as close to the beginning of chemotherapy as possible, preferably by day 9 (surgery is day 0), but no later than day 14, unless medically contraindicated or when there is a delay in central pathology review.

[b]Whole-abdomen irradiation (WAI) is indicated when there is diffuse tumor spillage, preoperative or intraperitoneal tumor rupture, peritoneal tumor seeding, or hemorrhagic or cytology-positive ascites. When WAI dose is >10 Gy, renal shielding is required to limit the dose to the remaining kidney to <14.4 Gy. Gross residual disease after surgery should receive a boost of 10 Gy. WAI dose is not to exceed 10 Gy in infants ≤12 months.

[c]COG protocol (AREN0321) is studying the possibility of eliminating RT in children with stage I CCSK tumors who have lymph node sampling and central pathology review.

[d]COG protocol (AREN0533) is studying the possibility of eliminating WLI in children with lung metastases who are rapid responders (complete response of lung metastasis after three-drug chemotherapy on central review of computed tomography [CT] scans at week 6). Tumor size, number of lesions, and CT or x-ray detectability are not considered indications for WLI in FH tumors.

RADIATION THERAPY TECHNIQUES

RT guidelines used for primary and recurrent WT in the COG protocols are shown in Table 91.5.

Timing of Radiation Therapy

The NWTS has shown that although RT does not need to be given immediately after surgery,[41] a delay of ≥10 days after surgery was associated with a significantly higher abdominal relapse rate, particularly among patients with UH tumors.[50-53] The influence of RT delay on abdominal tumor recurrence in patients with FH tumors treated on NWTS-3 and NWTS-4 has been reported. The mean RT delay was 10.9 days. Although univariate and multivariate analyses did not reveal RT delay of ≥10 days to adversely influence flank and abdominal recurrence, it is important to note that in 59% of children, the RT delay ranged from 8 to 12 days.[54] For the first generation of COG protocols, it was recommended that RT be given preferably by day 9 but no later than day 14 after surgery. In

the second generation of COG trials, flank/abdomen RT will be delayed until week 6 for stage IV patients with lung metastases so that both sites can be treated simultaneously if indicated, in order to avoid higher radiation doses to organs such as heart, lungs, and liver at overlapping field edges. SIOP recommends starting RT in nonmetastatic patients within 2 to 4 weeks after abdominal surgery. In non–high-risk patients with local stage III, metastatic disease, delayed RT can be considered to avoid overlapping fields.[55]

Radiation Therapy Dose

In NWTS-1 and NWTS-2, RT dosages to the operative bed were given according to the age of the patient; however, no significant dose-response association was detected.[50,51,53] In NWTS-3, there was a randomization for patients with FH tumors that resulted in elimination of RT for stage II FH and a reduction of dose from 20 to 10 Gy for stage III patients.[52] NWTS-3 and NWTS-4 data showed no RT dose response for CCSK and anaplastic tumors.[56] Therefore, it was decided to treat all abdominal disease (FH and UH) with 10 Gy in NWTS-5. In the COG protocols, the dose is 10 Gy for most indications, except for stage III DA and stage I to III RTK, where a higher dose of 19.8 Gy is recommended (Table 91.5).[57,58]

Radiation Therapy Volume

For flank and abdomen RT fields, parallel-opposed fields using 4- or 6-MV photons are preferred. The flank RT field is determined by the CT or MRI scan performed at diagnosis before any chemotherapy is administered. The planning target volume (PTV) is the tumor bed (outline of the kidney and associated tumor on the initial CT or MRI) with a 1-cm margin. The medial border must cross the midline to include the entire width of the vertebrae so as to minimize growth disturbances. An example of a flank RT portal is shown in Figure 91.2. In the UMBRELLA Renal Tumor Study Group of the International Society of Pediatric Oncology (SIOP-RTSG) protocol, for flank RT, investigators will explore the feasibility of target volume reduction to include only the posterior abdominal wall in contact with the preoperative tumor and the para-aortic nodes, while excluding noninfiltrated anterior organs, using intensity-modulated radiation therapy

(IMRT) with central quality assurance (QA) preapproval.[59] When whole-abdomen RT is administered, the femoral heads and acetabulum must be shielded (Figure 91.3). Whole-lung irradiation (WLI) anteroposterior-posteroanterior (AP-PA) portals are shown in Figure 91.4. If the lungs and either the flank or the whole abdomen have to be treated simultaneously, it is preferable to include them in one treatment portal.

FIGURE 91.3 Anteroposterior whole-abdomen irradiation portal in a patient with stage III Wilms tumor and diffuse peritoneal tumor spillage. The upper margin of the abdominal field must include the diaphragm. The acetabulum and femoral head should be excluded from the irradiated volume to decrease the probability of slipped femoral capital epiphysis. The pants zipper can be seen low on the hips. In general, it is advisable to remove the trousers completely to ensure a reproducible setup.

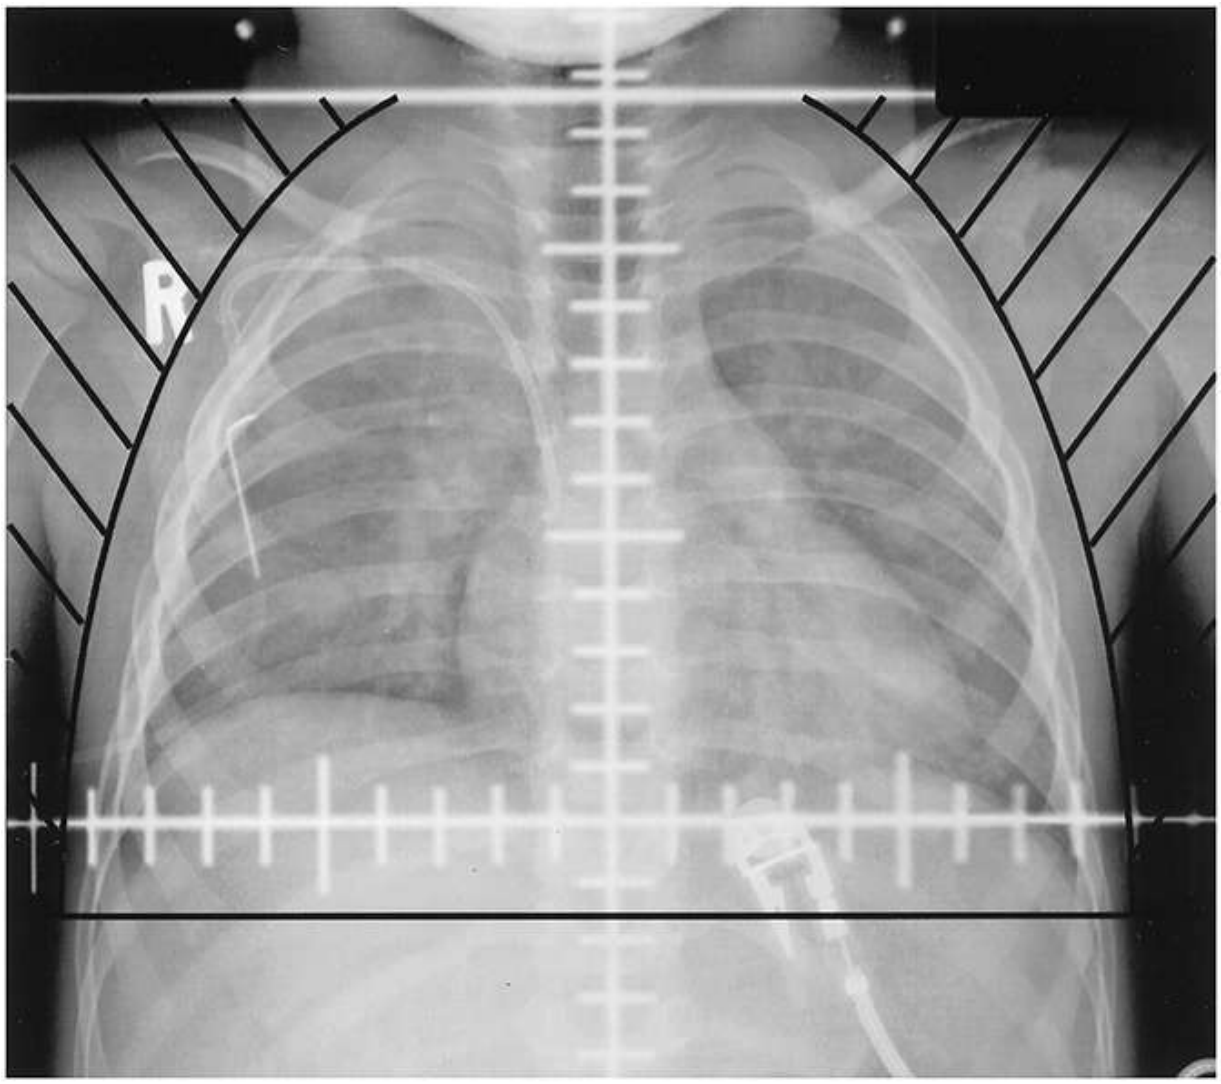

FIGURE 91.4 Anteroposterior whole-lung irradiation portal in a patient with stage IV favorable histology Wilms tumor. The axial, coronal, and sagittal chest computed tomography simulation scans should be carefully reviewed to ascertain inclusion of the anterior and posterior costophrenic angles at the inferior edge of the treatment volume with a 1-cm margin.

Intensity-Modulated Radiation Therapy for Lung and Liver Irradiation

A multi-institutional prospective clinical trial was conducted to determine the feasibility of cardiac-sparing lung IMRT. All centers were credentialed. The IMRT PTV was the four- dimensional (4D) minimum intensity projection total lung volume plus 1 cm. All target volumes, cardiac contours, and treatment plans were centrally reviewed Quality Assurance Review Center (QARC) for preapproval prior to treatment. Twenty patients were accrued. The majority had pediatric sarcomas or WTs. Lung IMRT was feasible in all patients. The median RT dose was 15 Gy (12-15 Gy). Pretreatment review resulted in target contour changes in seven, replanning in three, and minor dose deviations in two patients. There were no major deviations. The mean cardiac (whole heart, ventricles, atria, coronary arteries, myocardium) volume doses were significantly lower after IMRT compared to AP-PA techniques. The 4D lung volumes were significantly larger than 3D volumes ($P < .0001$), and thus, standard AP-PA RT would have significantly underdosed 4D lung volumes ($P = .008$). IMRT was well tolerated. No patient had radiation pneumonitis, pulmonary consolidation, or fibrosis after a minimum 2-year follow-up. The 2- and 3-year OS was 90% and 90% and lung metastasis progression-free survival was 65% and 52%, respectively. This trial demonstrated the feasibility, dosimetric advantages, safety, and efficacy of lung IMRT with chemotherapy.[60,61] The dosimetric advantages of whole-liver IMRT compared to AP-PA techniques have also been reported (Figure 91.5).[62] In all second-generation COG WT protocols (AREN1921 and AREN223), IMRT targeting 4D lung and liver volumes with Imaging and Radiation Oncology Core (IROC) central preapproval will be utilized for all stage IV patients with lung and liver metastases.

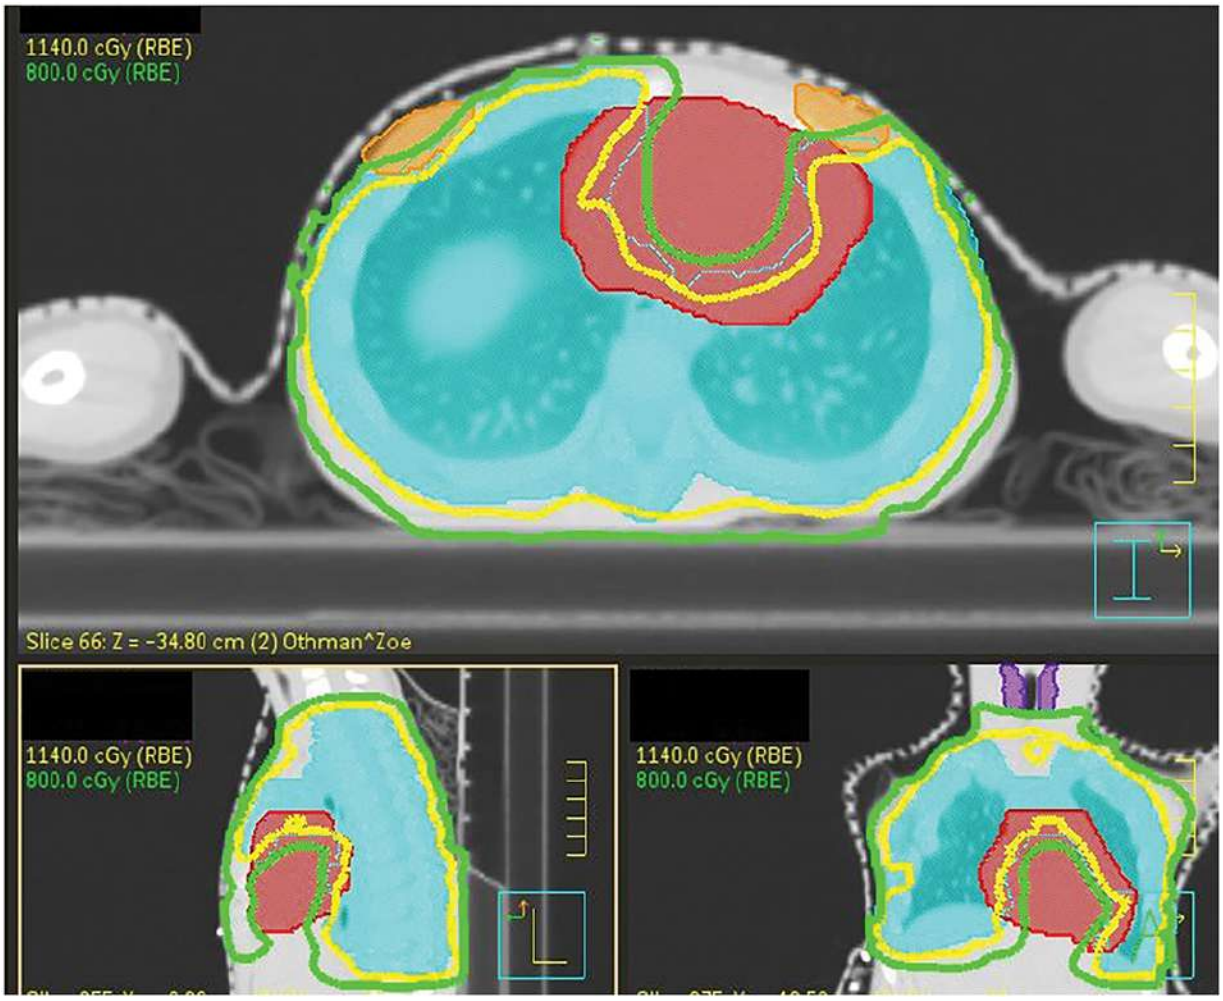

FIGURE 91.5 Cardiac-sparing whole lung intensity-modulated radiation therapy plan (12 Gy in eight fractions) showing the 11.4 Gy (yellow) and 8 Gy (green) on computed tomography images of the whole lung planning target volume (blue), heart (red), breast bud planning risk volumes (brown), and thyroid gland (purple). Axial, sagittal, and coronal images showing adequate dose coverage of planning target volume (95%, 11.4 Gy) and sparing of the heart, breast, and thyroid gland.

SUMMARY OF CLINICAL TRIALS

No tumor has been studied by clinical trials as thoroughly and effectively as WT. The NWTS conducted all WT trials in North America from 1969 to 2001. There have also been successful studies run by the SIOP. The long-term results of NWTS-3 and NWTS-4 are shown in Table 91.6.

TABLE 91.6 LONG-TERM RESULTS OF NATIONAL WILMS TUMOR STUDIES 3 AND 4

Category	Number of Patients	10-Year RFS (%)	10-Year OS (%)
Stage I FH	1,582	91.4	96.6
Stage II FH	1,006	85.5	93.4
Stage III FH	1,038	84.2	89.5
Stage IV FH	592	75.2	80.7
Stage V FH	344	65.1	77.9
All FH	4,562	84.4	90.8
Clear cell sarcoma	170	67.1	77.1
Stage II-III anaplasia	128	43.0	49.2
Stage IV anaplasia	55	18.2	18.2
Rhabdoid tumor	88	27.3	28.4

FH, favorable histology; OS, overall survival; RFS, relapse-free survival.
National Wilms Tumor Study unpublished data.

First National Wilms Tumor Study (1969-1974)

NWTS-1 showed that postoperative RT was not necessary for children younger than 2 years of age with group I tumors and that combined dactinomycin and vincristine for irradiated patients with group II and III tumors was better than therapy with either agent alone. The relapse-free survival (RFS) with and without RT among patients with group I tumors younger than 2 years of age was 90% and 88%, respectively.[50]

Second National Wilms Tumor Study (1974-1979)

NWTS-2 showed that in patients with group I tumors, there was no survival difference between 6 and 15 months of dactinomycin plus vincristine. Patients with group II to IV tumors had a superior 2-year RFS of 77% with doxorubicin, dactinomycin, and vincristine compared with 63% with dactinomycin and vincristine alone.[51]

Third National Wilms Tumor Study (1979-1985)

The overall objective of NWTS-3 was to reduce therapy for low-risk patients (stage I-III FH) and to intensify treatment by adding a fourth drug,

cyclophosphamide, for stage IV tumors with FH and all UH tumors. The results of this study demonstrated that RT and doxorubicin could be eliminated in children with stage II FH tumors. Patients with stage III FH tumors who received doxorubicin or 20 Gy had fewer abdominal relapses than those receiving 10 Gy without doxorubicin. This study provided the basis for the safe reduction of RT dose from 20 to 10 Gy in stage III FH. The addition of cyclophosphamide in high-risk patients did not improve outcomes.[52]

Fourth National Wilms Tumor Study (1986-1994)

By the conclusion of NWTS-3, it was clear that the treatment of WT had been refined for the majority of patients; 62% of patients with WT have stage I or II FH disease and, therefore, require neither flank RT nor the potentially cardiotoxic doxorubicin. NWTS-4 was designed with cost containment in mind. The results proved that the survival was similar among patients who received standard course (5 days) or single-dose, pulse-intensive (PI) dactinomycin chemotherapy. Further, PI therapy was associated with less hematologic toxicity and marked reduction of treatment costs.[63,64]

Fifth National Wilms Tumor Study (1995-2001)

One of the major goals of the NWTS-5 trial was to prospectively analyze the prognostic significance of LOH at chromosomes 1p and 16q. These results have been discussed above.[13] Patients with stage I FH and anaplastic histology and stage II FH tumors were treated with 18 weeks of dactinomycin and vincristine without RT. Stage I FH tumors in children younger than 24 months of age and with tumor weight <550 g were treated with surgery alone without chemotherapy. This treatment arm was stopped early because the number of relapses observed exceeded the predefined stopping rule. However, nearly all patients with relapse were successfully treated, leading to 5-year EFS and OS rates of 84% and 98%, respectively.[65] Stage III and IV FH and stage II to IV focal anaplastic tumors were treated with 24 weeks of dactinomycin, vincristine, doxorubicin, and irradiation. Stage II to IV diffuse anaplastic tumors and stage I to IV CCSK were treated with cyclophosphamide, vincristine, doxorubicin, and etoposide

along with irradiation.[57] Stage I to IV RTK was treated with carboplatin, etoposide, cyclophosphamide, and irradiation.[58] The RT guidelines in NWTS-5 were similar to those used in NWTS-4, except for anaplastic tumors, where a dose of 10.8 Gy to the flank and abdomen was recommended compared to an age-adjusted schedule used in NWTS-1 to NWTS-4.[57]

National Wilms Tumor Study-5 Relapsed Wilms Tumor Study

Children with relapsed FHWT have a variable prognosis depending on the site of relapse, the time from initial diagnosis to relapse, and their previous therapy. The favorable prognostic factors include no previous treatment with doxorubicin, relapse more than 12 months after diagnosis, and intra-abdominal relapse in a patient not previously treated with abdominal RT.[66] In NWTS-5 relapse protocol, patients who relapsed after initial treatment with vincristine and dactinomycin only without RT were treated on stratum "B" with regimen "I" chemotherapy, surgery, and RT. The 4-year RFS and OS were 71% and 81% for all patients, 68% and 81% for those who relapsed in the lung only, and 78% and 83% for those who relapsed in the operative bed, respectively.[67] Patients who relapsed after treatment with vincristine, dactinomycin, doxorubicin, and RT were treated on stratum "C" of NWTS-5 protocol, with alternating courses of drug pairs, cyclophosphamide/etoposide and carboplatin/etoposide, surgery, and RT. The 4-year RFS and OS were 42% and 48% for all patients and 49% and 53% for those who relapsed in the lung only, respectively.[68] The COG protocol (Table 91.5) recommends postoperative RT for all children with abdominal relapse because these tumors are generally large and infiltrative and surgical resection with negative margins is unlikely.

Clear Cell Sarcoma of the Kidney

Data from NWTS-1 to NWTS-4 suggested that the addition of doxorubicin to vincristine and dactinomycin improved RFS rates of patients with CCSK.[69] NWTS-3 demonstrated no improvement in outcomes of patients with CCSK with the addition of cyclophosphamide. In NWTS-4, patients with CCSK showed no significant difference in outcome between the standard and PI chemotherapy regimens. However, there was a trend toward

improved RFS with long-duration therapy.[70] An analysis of patients enrolled on NWTS 1-5 with stage I CCSK based on the updated NWTS-5 definition of stage I disease showed that regardless of the treatment regimen, the EFS and OS rates were 100%.[71] NWTS-5 studied regimen I (vincristine, doxorubicin, cyclophosphamide, and etoposide) for patients with CCSK, yielding 5-year EFS of 100%, 88%, 73%, and 29% for stage I, II, III, and IV, respectively.[72] Based on these results, COG study AREN0321 used the same regimen as in NWTS-5 for stages I to III disease, except that RT was omitted for patients with stage I. Patients with stage IV CCSK were treated with cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide, similar to patients with diffuse anaplastic WT (AWT).

Rhabdoid Tumor of the Kidney

Patients with RTK have been treated on NWTS trials with agents such as vincristine, dactinomycin, and doxorubicin with or without cyclophosphamide. The outcomes attained with these agents have been consistently very poor.[58,73,74] To try to improve on these results, NWTS-5 adopted a different treatment strategy consisting of carboplatin and etoposide alternating with cyclophosphamide. Preliminary analysis of patients treated with this regimen revealed an OS of 26%, not an improvement compared with previous studies, and thus the treatment arm was closed.[58] The COG AREN0321 protocol evaluated whether a treatment regimen containing cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide improves the EFS and OS in these patients.

Children's Oncology Group Studies

The COG renal tumor committee is the successor of the NWTS. The COG staging and risk group classification for treatment assignment in the first generation of WT protocols are shown in Tables 91.2 and 91.3. This classification will, in addition to tumor stage, also consider the patient's age, tumor weight, presence or absence of LOH at 1p and 16q, and response to chemotherapy in children with FH tumors and lung metastases. The objectives and results of the first generation of COG protocols are described

below. The COG chemotherapy regimens and RT guidelines are outlined in Tables 91.4 and 91.5, respectively.

AREN03B2 (2006-2023)

The AREN03B2 Renal Tumor Biology and Risk Stratification Protocol opened in 2006 with a primary goal to provide real-time risk stratification to enable appropriate enrollment of patients onto COG renal tumor trials and to build a well- annotated tumor bank to enable basic and translational research.

AREN0321 (2006-2012)

In NWTS-5, the 4-year EFS and OS were 70% and 83%, respectively, for patients with stage I focal or diffuse AWT treated with vincristine and dactinomycin without flank RT.[57] In AREN0321, 18 patients with stage I AWT (8 focal and 10 diffuse) treated with doxorubicin, vincristine, dactinomycin, and RT (10.8 Gy) had a 4-year EFS and OS of 100%.[75] For stage II to IV diffuse AWT in NWTS-3 and NWTS-4, the addition of cyclophosphamide to vincristine, dactinomycin, and doxorubicin (regimen "J") improved the 4-year RFS to 55% compared to 27% for regimen DD-RT.[56] In NWTS-5, further augmentation using a regimen of vincristine, doxorubicin, cyclophosphamide alternating with cyclophosphamide, and etoposide for 24 weeks plus RT (regimen "I") resulted in additional improvement in patient outcomes.[57] However, the survival outcomes were still unsatisfactory, and 46% of the recurrences were local. AREN0321 evaluated an intensive regimen that used carboplatin in addition to the regimen "I" agents (regimen UH-1) for stages II to IV diffuse AWT and with the incorporation of vincristine/irinotecan window upfront in patients with stage IV diffuse AWT with measurable disease (regimen UH-2). The combination of vincristine and irinotecan was well tolerated and highly active, with a response rate of 79% in 14 patients. Patients with stage III DAWT received a higher flank RT dose (19.8 Gy) than NWTS-5. Compared to NWTS-5, this intensified treatment improved RFS (73% compared to 58%) for stage II to IV DAWT. The local relapse rate among patients with local stage III DAWT in AREN0321 was 6.4% compared to 14.8% on NWTS-5. However, this intensive treatment regimen in

AREN0321 was associated with increased toxicity, necessitating modification of the regimen part way through the study to reduce the doxorubicin, cyclophosphamide, and etoposide exposure. Overall, four (6%) patients died of cardiac and pulmonary toxicity.[76]

AREN0532 (2006-2013)

AREN0532 included patients with very low-risk FHWT, stage I/II FHWT with LOH at chromosomes 1p and 16q, and stage III FHWT. AREN0532 showed a 4-year EFS and OS of 89.7% and 100%, respectively, for 116 patients with very low-risk WT (stage I FH, age < 24 months, and tumor weight < 550 g, with LN sampling and no predisposition syndromes) treated with nephrectomy alone, showing excellent outcomes with a high salvage rate for relapses using DD4A and RT.[77] Molecular analysis demonstrated the association of LOH at 11p15 and loss of imprinting at 11p15, which occurs much less commonly than LOH, with an increased risk of relapse.[18] Patients with stage I or II FH tumors with LOH at 1p and 16q treated with regimen DD4A without RT had a 4-year EFS and OS of 87% and 100%, respectively. Patients with stage III FH without LOH at 1p/16q treated with regimen DD4A and RT had a 4-year EFS and OS of 88% and 97%, respectively. Positive or unknown LN status, positive LOH at 1p or 16q, and blastemal predominant histology at delayed nephrectomy were identified as adverse prognostic factors. Patients with both positive LNs and LOH at either 1p or 16q had 4-year EFS of only 73.8%.[78] A report on the prognostic impact of positive LNs and/or LOH of 1p or 16q was assessed in children with stage III FHWT enrolled on AREN0532 and AREN03B2. Lack of LN sampling, LN positivity, and LOH 1p and LOH 16q were associated with worse EFS. Patients positive for both LN and LOH had the worst EFS.[46]

AREN0533 (2007-2013)

AREN0533 included patients with stage IV FHWT and stage III FHWT with LOH at chromosomes 1p and 16q. A subanalysis of the SIOP 93-01 and SIOP-2001 populations found that lung nodule incomplete response (CR) after 6 weeks of chemotherapy was an adverse prognostic indicator.[79] Based on these observations, in AREN0533, patients with isolated lung

metastases defined by the presence of nodules on centrally reviewed CT scans, who achieved lung nodule CR after 6 weeks of DD4A continued the same chemotherapy without lung RT. Patients with lung nodule incomplete response or the presence of LOH 1p/16q received lung RT and switched to regimen M, which added 4 cycles of cyclophosphamide and etoposide in addition to DD4A. The 4-year EFS and OS for patients with isolated lung metastases was 85.4% and 95.6%, respectively, compared with 72.5% and 84.0% for patients on NWTS-5. The CR rate of lung nodule after 6 weeks of DD4A chemotherapy was 46%, and 54% had incomplete response. For patients with incomplete response, the 4-year EFS and OS were 88.5% and 95.4%, respectively, with regimen M and WLI. For those with CR, the 4-year EFS and OS were 79.5% and 96.1%, respectively, with regimen DD4A and no lung RT.[80] Patients with extrapulmonary metastases (EPMs) also received regimen M and RT to all metastatic sites, regardless of chemotherapy response. For these patients, the 4-year EFS and OS were 76% and 89.1%, respectively, compared to the 4-year EFS and OS was 64.9% and 86.5% after DD4A chemotherapy and RT in NWTS-5. Liver metastases remained the most common site of EPM. There was no difference in clinical outcomes between liver and non-liver EPM.[81] AREN0532 and AREN0533 were the first studies to describe the effect of augmentation of therapy for patients with combined LOH at chromosomes 1p and 16q. AREN0532 added doxorubicin to the standard vincristine/dactinomycin for stages I/II FHWT, and AREN0533 added cyclophosphamide and etoposide to the standard DD4A regimen for stage III/IV FHWT. The 4-year EFS and OS for patients with stage I or II FH with LOH 1p/16q were 87.3% and 100% after DD4A and no RT in AREN0532, compared to 68.8% and 91.6%, respectively, in NWTS-5. The 4-year EFS and OS for patients with stage III or IV FH with LOH 1p/16q was 90.2% and 96.1% after regimen M and RT in AREN0533, compared to 61.3% and 86% in NWTS-5.[82]

AREN0534 (2009-2015)

AREN0534 was the first prospective study for patients with bilateral, multicentric, or bilaterally predisposed unilateral WT. The primary aims for BWT were to improve 4-year EFS to 73%; to prevent complete removal of

at least one kidney in 50% of patients by using prenephrectomy chemotherapy with vincristine, dactinomycin, and doxorubicin; and to have at least 75% of children undergo definitive surgical treatment by 12 weeks after initiation of chemotherapy. Postsurgical chemotherapy was based on histology and postsurgical stage according to SIOP and COG staging systems. The 4-year EFS and OS for 189 patients with BWT were 82.1% and 94.9% respectively. A total of 39% of patients were able to undergo bilateral nephron-sparing surgery and 84% underwent definitive surgical treatment by 12 weeks after initiation of chemotherapy.[83] Among seven patients with completely necrotic tumors, the 4-year EFS rate of 100%. Among patients with intermediate-risk pathology, the 4-year EFS and OS rates were 82% and 97% respectively. Fourteen patients with blastemal-type tumors had 4-year EFS and OS rates of 79% and 93% respectively. Eighteen patients with DA had 4-year EFS and OS rates of 61% and 72%, respectively. The 4-year EFS and OS rates of seven patients who had FA were 71% and 100%, respectively.[84] In 34 children with bilaterally predisposed (syndromic features, multicentric tumors) unilateral WT, the aim of this protocol was to facilitate partial nephrectomy in lieu of nephrectomy in 25% by using prenephrectomy chemotherapy with vincristine and dactinomycin. Among the 34 patients evaluable in this stratum, 4-year EFS and OS were 94% and 100%, respectively; prenephrectomy chemotherapy facilitated renal preservation in 65% of patients.[85]

International Society of Pediatric Oncology Trials

SIOP studies have primarily used preoperative therapy with the goals of facilitating surgical removal of the tumor without rupture, allowing for early treatment of micrometastases, and stratifying patients for postoperative therapy based on pathologic tumor response at the time of surgery. The first SIOP trial found that preoperative RT reduced the incidence of tumor spillage but did not increase survival.[86] SIOP-5, reported in 1983, showed that preoperative chemotherapy with vincristine and dactinomycin was as effective as preoperative RT plus dactinomycin in preventing tumor rupture.[87] In SIOP-6, patients with stage I disease were randomly assigned to either 17 or 38 weeks of vincristine and dactinomycin

and showed no difference in survival.[88] In SIOP-9, there was a randomization of the duration of prenephrectomy therapy with vincristine and dactinomycin (4 vs 8 weeks). No advantage was noted for 8 weeks of therapy.[89] SIOP 93-01 further stratified treatment according to the pathologic response to preoperative chemotherapy. The recommended dose of RT in SIOP-9 and SIOP 93-01 was 15 Gy in patients with low- and intermediate-risk stage III disease and 30 Gy in high-risk patients.[74] SIOP 93-01 showed that the amount of postoperative chemotherapy of stage I patients with either intermediate-risk histology or anaplasia could be reduced to four doses of vincristine and one course of dactinomycin with 5-year RFS and OS rates of 87% and 95%, respectively.[90] Among 1,090 patients in SIOP 93-01, 5% had tumor progression during preoperative chemotherapy. These tumors were generally smaller at diagnosis, more often stage III after surgery, and associated with higher grade histology and had poorer outcomes.[91] A pathologic review of stage II tumors in SIOP 93-01 revealed that there was a significantly higher survival among patients who were stage II because of nonviable tumor in the renal sinus or perirenal fat compared to those with viable tumor in these sites (100% vs 91%). It was proposed that the definition of stage II be revised.[92] In a report from SIOP WT2001 trial, after preoperative chemotherapy VA (vincristine, actinomycin D) and surgery, patients with stage II to III intermediate-risk tumors were randomized to receive AVD (actinomycin D, vincristine, doxorubicin) versus AV (actinomycin D and vincristine) without doxorubicin. Stage III patients received 14.4-Gy flank RT and 10-Gy boost to positive LNs or macroscopic residual tumor. The 2-year EFS was 93% and 88%; and the 5-year OS was 97% and 96%, with no statistically significant difference between these two regimens. They concluded that doxorubicin was not required for these patients.[93] In another WT2001 report for blastemal-type WTs after VA chemotherapy and surgery, stage I patients received AVD for 26 weeks, and stage II to III patients received etoposide, carboplatin, doxorubicin, and cyclophosphamide for 26 weeks. Local RT was recommended only for stage III patients. The 5-year EFS and OS were 80% and 88%, respectively, in WT2001 compared to 67% (P = .006) and 84% (P = .4), respectively, in SIOP 93-01 trials.[94] The local control rates for intermediate-risk WT treated with SIOP multimodality regimens were excellent, with <12% overall failure and 1% to 3% local-only recurrence.[55]

LATE EFFECTS OF TREATMENT

The study of late effects is of paramount importance to prevent survivors of childhood cancer from becoming chronically sick adults. The COG long-term follow-up guidelines, version 5.0, provide extensive recommendations for the appropriate surveillance and management of childhood cancer survivors for common RT-induced toxicities observed in WT survivors (http://survivorshipguidelines.org).

Musculoskeletal Effects

Musculoskeletal toxicity may occur from RT in young children, the severity of which depends on the patient's age at treatment, RT dose, fractionation, and RT fields. Growth of normal tissues can be impaired, resulting in reduced spinal growth and sitting height after RT for WT.[95] Scoliosis and kyphosis are other possible complications of WT therapy. At a median follow-up of 12 to 13 years, WT survivors have reported scoliosis in 54% to 67% and kyphosis in 14%, with 10% to 20% experiencing symptoms or requiring intervention.[96,97] A higher scoliosis rate of 88% was observed in one report with a longer median follow-up of 19 years and more complete radiologic follow-up. However, in the vast majority of patients, the scoliosis was mild and asymptomatic.[98] In another report, the incidence of scoliosis after 10 to 12 Gy, 12.1 to 23.9 Gy, and 24 to 40 Gy was 8%, 46%, and 63%, respectively.[99] Thus, at present, with the use of megavoltage x-rays, lower doses, and coverage of the entire width of the vertebra, the incidence of scoliosis should be low.

Congestive Heart Failure

The cumulative frequency of congestive heart failure among patients on NWTS-1 through NWTS-4 was 4.4% at 20 years among patients treated initially with doxorubicin and 17.4% among patients treated with doxorubicin for their first or subsequent relapse. The factors that were significantly associated with the incidence of heart failure were female sex, cumulative doxorubicin dose, standard AP-PA WLI, and left abdominal RT.[100]

Pregnancy Outcomes

The NWTS Long-Term Follow-Up Study analyzed pregnancy outcomes among WT survivors. Malposition of the fetus and premature labor were significantly more frequent among previously irradiated women. The offspring of female patients who received flank RT were more likely to be of low birth weight (<2,500 g), premature (<36 weeks of gestation), and to have congenital malformations. A flank RT dose response was identified with higher complication rates at doses >25 Gy. A number of radiation-induced side effects involving the spine, uterus, and ovaries may all have been responsible.[101-103] The pregnancy outcomes in survivors who received abdominal RT on NWTS protocols were also analyzed. Fertility could be preserved in children with upper abdominal RT that did not include the pelvis. In rare instances, fertility could be preserved after whole-abdominal RT to 10.5 Gy. However, higher doses to the abdomen and pelvis resulted in miscarriages and fetal deaths.[104]

End-Stage Renal Disease

The 20-year cumulative incidence of end-stage renal disease among WT survivors after unilateral nephrectomy on NWTS protocols was 74% for children with Denys-Drash syndrome, 36% for children with WAGR syndrome, 7% for children with genitourinary anomalies, and 0.6% for patients with none of these conditions. Long-term follow-up guidelines emphasize the importance of long-term screening for high-risk children to facilitate early detection and treatment of impaired renal function.[105]

Second Malignant Neoplasm

Among patients with NWTS, the 15-year cumulative risk of second malignant neoplasm (SMN) was 1.6%. The risk of developing a lymphoma or leukemia was 0.4% at 8 years, after which no cases occurred. However, the risk of developing a solid tumor continued to rise sharply with time. The use of RT and doxorubicin has been clearly associated with higher risk of SMNs.[106] In the British Childhood Cancer Survivor Study, the majority of solid tumors (89.7%) of the thorax, abdomen, or pelvis developed within RT fields.[107] In the NWTS report, RT increased the risk of an SMN

(Standardized Incidence Ratio (SIR), 1.43/10 Gy) and doxorubicin potentiated the RT effect. Among 234 patients who received doxorubicin and >35 Gy of abdominal RT, the SIR was 36. The changes in RT doses in NWTS protocols from 40 Gy in the 1960s to 10 Gy in the 1990s was also associated with a decrease in time-specific incidence rates of SMNs.[106] In another NWTS report, the standardized mortality ratio was 24.3 within 5 years of diagnosis, 12.6 for the next 5 years, and >3.0 thereafter. The main cause of mortality within the first 5 years was the original disease (91%). However, beyond 5 years, the two important causes of mortality were the original disease (40%) and late effects of treatment (39%). The three common treatment- related late effects that contributed to mortality were SMNs, congestive heart failure, and end-stage renal disease. The risk of death, particularly from treatment-related late effects, remained elevated even 20 years after diagnosis.[108] Similar results have been shown recently by the Childhood Cancer Survivor Study after a follow- up of 25 years.[109] In the British Cancer Survivor Study, the cumulative incidence of a second primary neoplasm at 30, 40, and 50 years of age was 2%, 7%, and 12%, respectively.[107] In another NWTS report, female survivors who received WLI had nearly a 15% risk of developing invasive breast cancer by age 40 years.[110]

Update on 35-Year Incidence of Chronic Health Conditions Among Unilateral Wilms Tumor Survivors

An update from the Childhood Cancer Survivor Study showed that the 35-year cumulative incidence of late toxicities was as follows: 34.1% for any grade 3 to 5 chronic health condition (CHC); 6.1% for a secondary malignant neoplasm (breast, thyroid, and colorectal were most frequent); 8.1% for intestinal obstruction; 7.3% for premature ovarian insufficiency (POI); 4.0% for heart failure; and 2.4% for kidney failure. WLI was associated with an increased risk of SMN, heart failure, and intestinal obstruction. Whole Abdomen Radiation Therapy (WART) was associated with an increased risk of SMN, heart failure, intestinal obstruction, and POI, and the magnitudes of risk increased with RT dose (>20 Gy). The RR of POI after WART ≤20 Gy was 13.1, compared to 36.5 for >20 Gy. Flank RT >20 Gy was associated only with an increased risk of intestinal

obstruction compared with no RT, whereas flank RT <20 Gy was not associated with SMN or any other CHC. High-dose doxorubicin (>250 mg/m^2) was associated with a nearly 5-fold rate of the development of heart failure.[111]

Next Generation of Wilms Tumor Protocols

UMBRELLA Protocol

The SIOP-RTSG has developed a new protocol for childhood renal tumors, UMBRELLA SIOP-RTSG 2016. Histologic classification after preoperative chemotherapy defines three major subgroups of WT: low-risk (completely necrotic WT), high-risk (blastemal type and DA), and intermediate-risk tumors (all other types). The molecular biology aim is to validate the prognostic value of 1q gain and other copy number alterations (1p/16q, *MYCN*, and *TP53*). For localized WT, after preoperative AV postoperative treatment will be delivered according to tumor stage and histologic risk group as in SIOP-2001. Low-risk tumors will get no therapy (stage I), and stage II and III tumors will receive AV for 27 weeks. All intermediate-risk tumors (<500 mL) and intermediate-risk stromal or epithelial-type tumors (≥500 mL) will get AV for 4 weeks (stage I), AV for 27 weeks (stage II), and AV for 27 weeks plus flank RT (stage III). Intermediate-risk nonstromal or non–epithelial-type tumors (≥500 mL) will get AV for 4 weeks (stage I), doxorubicin added to AV (AVD) for 27 weeks (stage II), and AVD for 27 weeks plus flank RT (stage III). High-risk blastemal-type tumors will get AVD for 27 weeks (stage I); etoposide, carboplatin, cyclophosphamide, and doxorubicin (HR-1) for 34 weeks (stage II), and HR-1 plus flank RT (stage III). High-risk diffuse anaplastic tumors will receive similar chemotherapy as blastemal-type tumors, and flank RT will be given for both stage II and stage III tumors.

Stage IV low- and intermediate-risk tumors with a complete or very good partial remission and complete surgical resection of primary and metastatic tumors will receive AVD150 (150 mg/m^2 of doxorubicin) for lung nodules 3 to 5 mm and AVD250 (250 mg/m^2 of doxorubicin) for lung nodules >5 mm. Lung RT will be given only if complete resection of visible metastasis is not performed. Stage IV tumors with a partial response or stable disease will receive chemotherapy regimen AVD250 (low risk, unresectable, or resected

with viable metastasis) and CDCV regimen (cyclophosphamide, doxorubicin, carboplatin, and etoposide) for intermediate-risk tumors (unresectable, or resected with viable metastasis). Regarding RT recommendations, patients with intermediate- and high-risk stage III and stage II high risk (DA but not blastema type) will receive flank RT to 14.4 Gy for intermediate-risk and 25.2 Gy for high-risk tumors. Macroscopic residual disease in high-risk tumors will get an additional 10.8 Gy boost. Completely resected nodes are no longer irradiated with a boost since no local control or survival benefit was observed. If diffuse intraperitoneal spillage is present, whole abdominopelvic RT to 12 Gy in infants <2 years (intermediate and high risk), 15 Gy (intermediate risk), or 19.5 Gy (high risk) will be given. Intermediate-risk patients with macroscopic peritoneal deposits after surgery receive 19.5 Gy. Patients with lung metastasis will receive WLI 12 Gy in 8 fractions (intermediate-risk tumors with incomplete remission after chemotherapy or persistent viable tumor) and 15 Gy in 10 fractions (all high-risk tumors). For flank RT, this trial will explore the feasibility of target volume reduction to include only the posterior abdominal wall in contact with the preoperative tumor and the para-aortic nodes, while excluding noninfiltrated anterior organs, using IMRT with central QA preapproval.[112,113]

Children's Oncology Group Protocols

AREN2231 will be the new COG FHWT study that will open to accrual in 2024. The risk stratification will include patient age, chromosome 1q gain, LOH of 1p, LOH of 16q, LOH of 11p15, clinical response after two initial cycles of three-drug chemotherapy, postchemotherapy stage and histology of patients with delayed nephrectomy, LN metastasis, EPM, and epithelial histology. LN sampling will be required for all children in this trial. The trial will include six chemotherapy treatment regimens: EE4A (vincristine, actinomycin), DD4A (vincristine, actinomycin, doxorubicin), VIVA (vincristine, actinomycin, irinotecan), M (vincristine, actinomycin, doxorubicin, cyclophosphamide, and etoposide), MVI (vincristine, actinomycin, doxorubicin, cyclophosphamide, etoposide, and irinotecan), and UH-3 (vincristine, doxorubicin, cyclophosphamide, etoposide, carboplatin, and irinotecan). The overarching aim of the trial is to improve

outcomes within cohorts of patients with FHWT with current long-term EFS rates at or below 80% and to maintain outcomes despite therapy reduction within cohorts of patients with FHWT with current long-term EFS rates at or above 84%.

Stage I patients who will receive nephrectomy only will be expanded to include those without adverse biology and who are 2 to <4 years of age, or <2 years with tumor weight ≥550 g or those who are over 4 years of age with epithelial histology subtype. Stage I patients with adverse biology will receive regimen EE4A. Stage II patients with adverse biology will be randomized to regimen VIVA versus DD4A to determine if VIVA is noninferior to DD4A and doxorubicin can be eliminated. Stage III patients without adverse biology will receive regimen EE4A. Stage III and IV patients with adverse biology, slow incomplete lung response, or EPMs will be randomized to regimen MVI versus M, to demonstrate the noninferiority of regimen MVI to regimen M. Regimen MVI is a variation of regimen M studied on AREN0533. Regimen M includes four cycles of cyclophosphamide (cumulative dose 8.8 g/m^2) and etoposide (cumulative dose 2 g/m^2), with consequent risk of second malignancy and infertility, particularly for males. Regimen MVI will reduce alkylator exposure below the threshold for decreased fertility (cumulative dose of 4.4 g/m^2) and add known active agents (vincristine/irinotecan) to the regimen, with a goal to preserve excellent clinical outcome and potentially decrease infertility and secondary malignancy risk. Stage III and IV patients with blastemal predominance will be treated with regimen UH-3. The RT indications and doses will remain the same as in AREN0532 and AREN0533. This protocol will also determine the feasibility of IMRT with IROC preapproval required for all patients, to reduce radiation-induced toxicity to the heart, thyroid, breast, and solitary kidney for children with lung and liver metastases. This study will also encourage resection of residual pulmonary nodules for stage IV patients with standard biology and who have 1 to 3 residual pulmonary nodules on imaging after cycle 2. Lung RT will be omitted for those patients who are found to have no viable tumor in resected nodules.

AREN1921 is currently open and aims to increase the survival rates of children with stage II to IV diffuse AWT and standard-risk relapsed FHWT by the addition of vincristine and irinotecan to cyclophosphamide, carboplatin, and etoposide alternating with

vincristine/doxorubicin/cyclophosphamide (regimen UH3). Patients with high-risk and very high-risk relapsed FHWT will be treated with ifosfamide/carboplatin/etoposide alternating with cyclophosphamide/topotecan. The RT indications and doses will remain the same as in AREN0321 and NWTS-5 relapsed Wilms protocol. This protocol will also determine the feasibility of IMRT with IROC preapproval required for children with lung and liver metastases.

In AREN2231 and AREN1921 protocols, flank/abdomen RT will be delayed until week 6 for stage IV patients with lung metastases so that both sites can be treated simultaneously in case lung RT is needed to avoid higher radiation doses to organs such as the heart, liver, and lungs at overlapping field edges.

FUTURE DIRECTIONS

The cure rates of patients with WT following multimodality therapy including RT are excellent. The next generation of COG and SIOP protocols described above seeks to further refine the treatment of low-risk patients to decrease treatment-related toxicity and intensify the treatment of high-risk tumors to improve outcomes. These protocols examine the value of novel molecular biomarkers such as 1q gain, LOH of 1p and 16q, and LOH of 11p15 to further improve the WT risk stratification system and refine treatment. Novel RT techniques such as IMRT and proton therapy are also being studied to reduce normal tissue toxicity. Novel chemotherapy regimens eliminating doxorubicin and reducing the doses of alkylators and etoposide are being evaluated to safely reduce the risks of cardiotoxicity, infertility, and secondary malignancies. The biologic sample banks of COG will continue to be a valuable source of tissue for studies aimed at identifying new biologic markers that may be of prognostic significance. However, RT is an important cause of late toxicity. Currently, WT biomarkers are only utilized for defining high-risk tumors to be treated with chemotherapy. Their utilization for potentially refining indications for RT in certain risk groups remains to be studied. Detailed studies of late toxicities specifically by analyzing the effects of RT doses to target organs are critical to improve our understanding of the relationship between RT and a variety of toxicities, such as infertility, hypogonadism, congestive heart failure, and

secondary malignancies in WT survivors.[114,115] The use of novel biomarkers that could detect RT injury earlier in various organs, and genomic studies to assess individualized genetic susceptibility for late toxicities, can improve our understanding of the risks of RT and refine treatment and surveillance guidelines for high-risk survivors to mitigate late toxicity.[116-120] The National Cancer Institute is promoting the adoption of novel clinical protocols aimed at studying the mechanistic interactions and biologic consequences of RT, prioritizing a comprehensive study of patient (genomic and epigenomics), tumor, and treatment (chemotherapy, RT, dosimetry) factors, together with longitudinal multiomics (pre- and post-therapy) (RFA-CA-21-040). We hope that these innovations in radiation oncology and biology can be harnessed for the benefit of children with WT and long-term WT survivors.

CHAPTER 92

Neuroblastoma

Christine E. Hill-Kayser and Mark Gaze

HISTORY

Neuroblastoma is an embryonal cancer of the sympathetic nervous system, first described by the pioneering German physician Rudolf Virchow in 1864.[1] In 1901, William Pepper from the University of Pennsylvania reported a series of infants with a phenotype of the disease we now call stage MS neuroblastoma—extensive hepatic metastases in a young baby with a small primary adrenal tumor.[2] In 1907, Sir Robert Hutchison, a pediatrician at Great Ormond Street in London, published a series of older children with extensive osseous metastases most obviously affecting the skull—the phenotype we now refer to as stage M neuroblastoma.[3] These apparently disparate conditions were brought together as a single diagnosis by the Massachusetts General Hospital pathologist James Homer Wright, who described the characteristic rosette of cells around a central tangle of neuropil, and gave the disease the name "neuroblastoma".[4,5]

In the modern era, two exceptional individuals working together at the Children's Hospital of Philadelphia can be regarded as the parents of contemporary neuroblastoma science and practice. Giulio D'Angio,[6] a pediatric radiation oncologist, and Audrey Evans, a pediatric oncologist,[7] published in 1971 both the first staging system for neuroblastoma[8] and an analysis of stage MS neuroblastoma.[9] They established the series of *Advances in Neuroblastoma Research* meetings, initially in Philadelphia, but subsequently throughout the world, which brought together scientists and clinicians to work together to improve the understanding and treatment of this enigmatic cancer type. They worked together and published many other papers on neuroblastoma over a period of about 50 years.

DIVERSITY

Neuroblastoma is incredibly varied in its characteristics and natural history. It may be asymptomatic and discovered incidentally[10] or through screening.[11] The primary tumor is typically situated along the sympathetic chain, most commonly in the adrenal gland[12] or elsewhere in the abdominal retroperitoneum, less commonly in the thorax,[13] and occasionally in the neck[14] or pelvis.[15] Sometimes, bilateral, independent primary tumors are present.[16] Occasionally, there is widespread metastatic disease with no discernible primary tumor.[17] It may present with symptoms due to the local tumor, including spinal cord compression as a result of invasion of neural foramina,[18] metastatic disease, or the effects of hormone production or other paraneoplastic phenomena.[19-21] Pathologically, it sits on a spectrum with ganglioglioma at the benign end, then various forms of ganglioneuroblastoma through to differentiating and undifferentiated neuroblastoma, which is definitely malignant.[22] There is now a growing understanding of the molecular pathology features that govern the biologic behavior of the tumor,[23] and these are used for risk stratification[24] and, in some cases, are targets for treatment.[25] While the disease may be congenital and even diagnosed antenatally,[26] and most cases occur in the first 5 years of life, there is a tail in older children, adolescents, and even young adults.[27,28] Age at diagnosis is an important prognostic factor, with those under 18 months faring better.[29]

Once diagnosed, it is important to ensure a comprehensive assessment of the disease, including staging[30] and molecular biology.[31] These features, taken into account with age, determine the risk stratification, which guides the choice of treatment and gives an indication of the chances of survival.[32,33] Complex algorithms are used to determine the intensity of treatment based on the risk group and may involve induction chemotherapy,[34] surgery to remove the primary tumor,[35,36] one or two courses of high-dose myeloablative chemotherapy,[37,38] radiotherapy,[39,40] molecular radiotherapy,[41] and a range of biologic treatments, including differentiation therapy,[42] immunotherapy,[43,44] and anaplastic lymphoma kinase (ALK) inhibitors.[45] Different protocols are used in the main cooperative oncology groups in North America and Europe, and different questions are asked in the trials, but in general, the principles are similar.[46]

Outcomes range from spontaneous regression without treatment,[47] through babies with an excellent prognosis despite minimal treatment,

intermediate-risk patients who are likely to do well with more intensive treatment,[48] and high-risk patients who have an approximately equal chance of being cured with very aggressive treatment,[31] or having primary progressive, refractory, or relapsing disease that, despite innovative approaches, is unlikely to be cured.[49,50] For some, symptom control and palliative care are important consideration.[51] For the optimal outcome, patients are best managed in specialist centers where enrollment into cooperative pediatric oncology research group clinical trials is offered. Modified treatment protocols[52] and international tumor boards[53] are available for use in resource-challenged settings where not all components of treatment may be readily available or affordable and outcomes are recognized to be worse.[54,55]

In summary, neuroblastoma should not be considered a single entity requiring a one-size-fits-all treatment approach. Patients should be considered individually in tumor boards where all relevant specialties, including pediatric radiation oncology, are represented.[56,57] As the results of treatment are far from satisfactory, basic and clinical research should ideally be embedded into the standard of care pathway, in an attempt to improve survival rates and lessen treatment-related morbidity.[58]

ROLE OF RADIOTHERAPY

Radiation treatment has a number of distinct roles as part of the multimodality treatment for neuroblastoma, which is considered in this chapter. Arguably, the most important is the use of external beam radiotherapy to the primary site after surgery to achieve local control, or radical irradiation of the primary tumor if surgery is not considered to be safely possible.[39] Traditionally, photon techniques have been used,[59] but with increasing availability worldwide, proton beam therapy techniques are being increasingly frequently employed.[60] This is considered for almost all patients with high-risk disease and for a subgroup of harder-to-treat intermediate-risk patients. Intraoperative radiotherapy has been explored in the past but is not regarded as a universal standard of care.[61]

Metastatic site irradiation is given as the standard of care alongside primary-site radiotherapy in some, but not all, protocols—practice varies across the world.[62] Molecular radiotherapy with iodine-131 *meta*-

iodobenzylguanidine (^{131}I-mIBG), which has the advantage of biologically targeting disseminated disease, has been used for around 40 years but has yet to find an established place and remains the subject of a number of clinical trials.[63] Other forms of molecular radiotherapy including lutetium-177 DOTATATE[64] and radiolabeled monoclonal antibodies directed against the cell surface di-sialo-ganglioside GD2[65] are being evaluated in clinical trials but cannot yet be considered as standard therapy.

In patients who relapsed, radiotherapy may sometimes be used as part of potentially curative treatment, for example, following local recurrence,[66] or central nervous system (CNS) relapse,[67] but more often, this is not considered feasible, and radiotherapy is reserved for palliation of, for example, bone pain.[68]

EPIDEMIOLOGY

Incidence

Population-based cancer registry data give the most accurate idea of frequency of diseases. A report on the incidence and outcome of all malignant diseases in babies, children, teenagers, and young adults up to the age of 25 from the four nations of the United Kingdom over a 20-year period 1997 to 2016 presents interesting insights.[69] Among 42,205 registrations in total, neuroblastoma and other peripheral nervous cell tumors accounted for 1,956 (4.6%) cases; however, there was a striking difference in the various age groups. Neuroblastic tumors accounted for 11% of all malignancies in the 0- to 4-, 2.8% in the 5- to 9-, 0.75% in the 10- to 14-, 0.48% in the 15- to 19-, and 0.22% in the 20- to 24-year-old age groups. Of all neuroblastic tumors, 79% occurred in the 0- to 4-year-old cohort, 12% in the 5- to 9-year-old cohort, and just 9% in those aged 10 to 24 years. The sex ratio is broadly equal (53% male, 47% female).

Similar data have been published from the United States using the Surveillance, Epidemiology, and End Results (SEER) program database.[70] From 1975 to 2013, 3,998 (93%) cases were recorded in children aged up to 15 years and 282 (7%) cases in adolescents and adults aged 15 years or above.

A comparison of data from Southeastern European registries with U.S. SEER data shows some differences.[71] The overall age-adjusted incidence

rate was significantly lower in Southeastern Europe (10.1 per million) compared with the United States (11.7 per million); the difference was maximum during infancy (43.7 vs 53.3 per million). Incidence in babies and younger children was positively associated with the Human Development Index, whereas a lower median age at diagnosis was correlated with higher overall incidence. These findings may indicate greater case ascertainment of those young patients with disease, which might spontaneously regress if never diagnosed.

Etiology

In most cases, the cause of neuroblastoma is unknown, but as with other embryonal tumors in young children where exposure to environmental carcinogens cannot be causal, a genetic predisposition may be relevant. There are family pedigrees that display an autosomal dominance of neuroblastoma susceptibility, but these account for only approximately 1% to 2% of neuroblastoma cases.[72] Mutations in the paired-like homeobox 2B (*PHOX2B*) gene may lead to families where neuroblastoma is associated with Hirschsprung disease and congenital central hypoventilation syndrome.[73] *ALK* germline mutations have also been identified as a cause of familial neuroblastoma.[74] The identification of *ALK* mutations is important, as it may allow the use of an ALK inhibitor as a therapeutic option. In nonfamilial, or sporadic, neuroblastoma, which constitutes the majority of cases, genome-wide association studies have identified an increasing number of neuroblastoma susceptibility loci and candidate genes as independent drivers of neuroblastoma predisposition.[75]

ASSESSMENT

Presentation

Neuroblastoma may present in a variety of ways: with symptoms from the primary tumor, with symptoms from metastases, with generalized and nonspecific symptoms of advanced malignancy, or with symptoms from paraneoplastic phenomena. In addition, asymptomatic disease may be discovered as an incidental finding, for example, on a routine antenatal ultrasound scan or on a healthy baby check.

As the primary tumor is most commonly situated in the suprarenal region or elsewhere in the retroperitoneum, presentation with pain or swelling due to an abdominal mass is common. Lower limb weakness due to spinal cord compression caused by extension of the tumor through the neural foramina, referred to as a "dumbbell tumor," is not unusual.[76] It is more frequently seen in babies and younger children and may be present at birth.[77] Less commonly, the primary tumor may present as a thoracic mass, with a posterior mediastinal location.[13] Rarely, the primary tumor may be in the neck, perhaps associated with Horner syndrome and anisocoria if it arises from the stellate ganglion.[78] Sometimes, bilateral or multiple primary tumors may be found.[79] Examples of various primary tumors are shown in Figure 92.1.

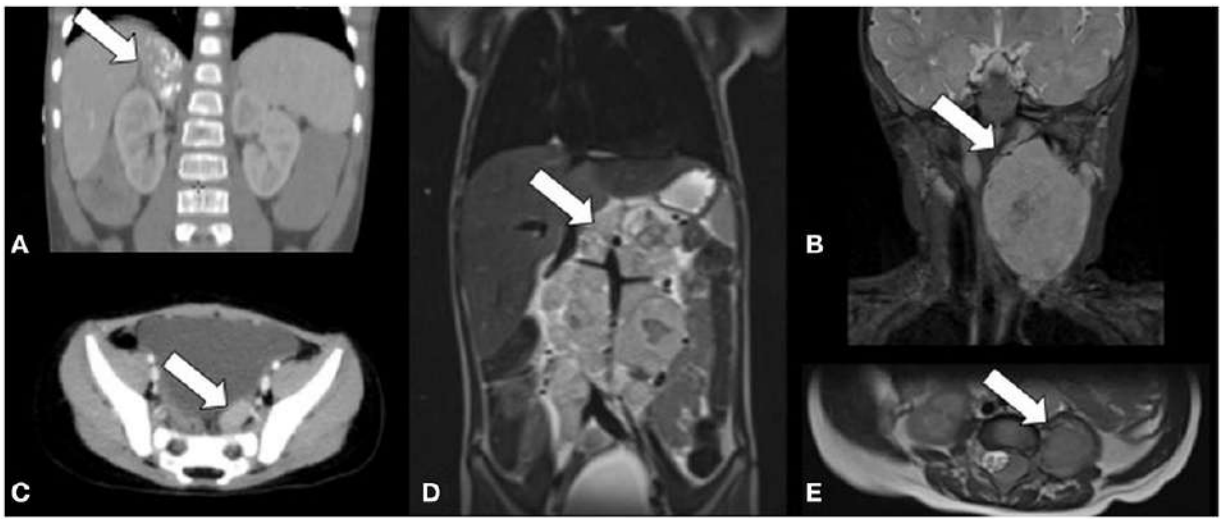

FIGURE 92.1 Examples of different primary neuroblastoma tumors. A. Coronal computed tomography (CT) scan of the upper abdomen showing a relatively small right suprarenal tumor (*arrow*) with extensive calcification. B. Coronal magnetic resonance imaging (MRI) scan showing a large localized left cervical tumor (*arrow*) stage L2 displacing the carotid vessels and airway. C. Axial CT scan through the pelvis showing a small, localized stage L1 left presacral tumor (*arrow*) behind the bladder, which presented with opsoclonus-myoclonus. D. Coronal MRI scan showing a large central abdominal mass encasing the abdominal aorta, renal arteries bilaterally and other branches, and extending below the aortic bifurcation. E. MRI scan demonstrating left-sided paravertebral mass entering the spinal canal through the neural foramen and displacing the thecal sac.

In very young children, rapidly progressive hepatomegaly due to metastatic disease in the liver, which may cause respiratory distress, may be

the presenting feature.[80] This can be associated with the “blueberry muffin” appearance of multiple cutaneous metastases. These are features of stage MS disease.

In older children, symptoms of metastatic disease may dev elop more slowly. Bone metastases are common, and so pain in the back or limbs, sometimes associated with limping, and occasionally resulting in a pathologic fracture, is nonspecific, and diagnosis of the underlying cancer may be delayed. Swelling arising from the bones of the skull may lead to proptosis and orbital ecchymoses. These are classic characteristics of stage M disease. Rarely, base of skull disease may cause visual compromise.[81] Sometimes, metastatic lymphadenopathy may be palpable, most often in the left supraclavicular fossa.[82] Lung and parenchymal cerebral metastases are unusual at diagnosis. Examples of metastatic spread are shown in Figure 92.2.

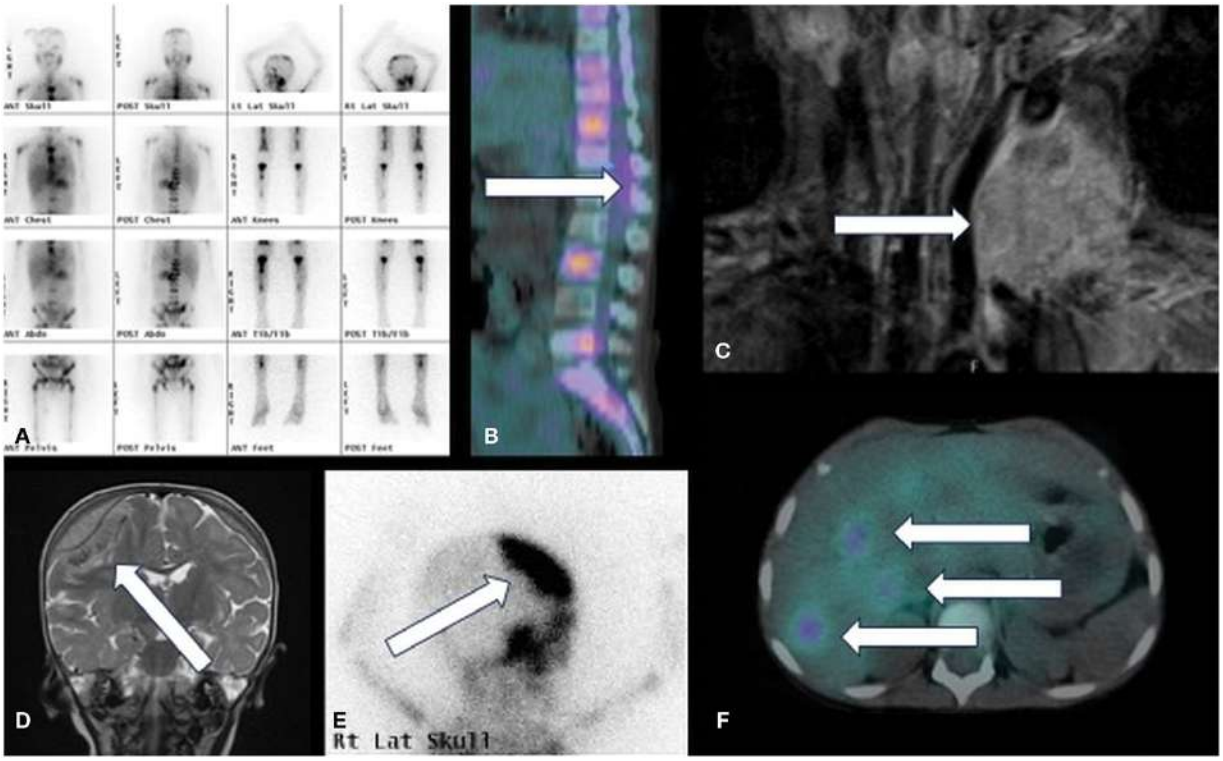

FIGURE 92.2 Examples of metastatic spread of neuroblastoma. A. Planar spot view ^{123}I-mIBG scans of a patient with extensive avid pathologic uptake throughout the skeleton. B. Sagittal ^{123}I-mIBG single-photon emission computed tomography (SPECT) computed tomography (CT) scan through the lower thoracic and lumbar spine of the same patient showing multiple vertebral metastases and disease within the spinal canal at T12/L1 (*arrow*). C. Coronal magnetic resonance imaging (MRI) scan of the neck showing a left supraclavicular lymph node metastasis (*arrow*). D. Coronal MRI scan of the brain showing a large right parietal bone metastasis with soft tissue extension internal and external to the skull (*arrow*). E. Right lateral skull ^{123}I-mIBG spot view planar scan of the same patient showing avid uptake in the large right parietal bone metastasis (*arrow*). F. Axial ^{123}I-mIBG SPECT/CT scan through the liver showing several hepatic metastases (*arrow*). ^{123}I-mIBG, iodine-123 *meta*-iodobenzylguanidine.

Other general and nonspecific symptoms, which may be present alongside the symptoms of the primary tumor and metastases, are lethargy, tiredness, weight loss, anorexia, fever, anemia, and petechiae due to thrombocytopenia.

Sometimes, an autoimmune (paraneoplastic) phenomenon can result in the opsoclonus-myoclonus-ataxia, or "dancing eyes," syndrome.[21] This is not always caused by neuroblastoma, but if it is, the tumor is often low risk.

The neurologic symptoms may persist after successful treatment of the cancer.

The wide variety of symptoms means that there is a broad differential diagnosis. If neuroblastoma is not borne in mind as a possibility, it is likely that there may be a delay in diagnosis. There is evidence that diagnostic delay leads to worse clinical outcomes.[83] Increased symptom duration before diagnosis is also associated with an increased risk of early death.[84] Public awareness of cancer in children and young people and its presenting symptoms is low.[85] Even knowledge of childhood cancers among junior doctors is suboptimal.[86] It is impor tant, therefore, for these reasons, that there is at least an awareness of cancer, including neuroblastoma, in children and young people among primary care doctors and general pediatricians, even if it is highly unlikely that the patient in front of them has this disease. National guidelines aimed at reducing diagnostic delay indicate symptoms that merit urgent referral for further investigation.[87]

Previously, cases of neuroblastoma without symptoms were diagnosed on screening by the testing of babies' urine for catecholamine metabolites. This approach resulted in an increased incidence, but the mortality rate remained stubbornly unchanged. Many of the additional cases diagnosed by screening were good prognosis tumors destined to regress spontaneously had they not been identified. As a number of studies failed to show a population benefit for this approach, population-based screening is no longer a standard practice.[88-90]

Imaging

There are several roles for imaging in a newly presenting pati ent suspected to have neuroblastoma: to provide supportive evidence for that disease or another alternative diagnosis, to guide a biopsy, and to define precisely the anatomic location of the tumor, the presence or absence of imaging-defined risk factors, and metastatic staging to indicate and quantify the presence of nodal and distant metastatic disease.

Following a definitive diagnosis of neuroblastoma, repeat imaging is required to assess the response to systemic therapy in terms of both distant disease and the suitability of the primary tumor for surgical removal. Postoperatively, completeness of excision can be determined. Repeat

imaging may be required for surveillance and to investigate symptoms of possible relapse.

Ultrasound is the initial imaging modality for the investigation of a child with a suspected abdominal mass. It will confirm whether a mass is present and indicate its location in relation to organs such as the kidneys, the presence of nodal or hepatic metastases, and displacement and encasement of great vessels, which is typical for neuroblastoma. Endovascular extension is more likely to be seen with primary renal tumors than neuroblastoma. Ultrasound may also be useful in evaluating abnormalities at other sites, such as supraclavicular fossa nodes.

Following the demonstration of an abdominal abnormality, a computed tomography (CT) scan and/or magnetic resonance imaging (MRI) are required. Both modalities have advantages and disadvantages. CT is often more widely available and faster to perform, with, therefore, less need for anesthesia in younger children. It is better at showing calcification, which is often a feature of neuroblastoma. MRI shows greater soft tissue detail, particularly invasion into the spinal canal and bone marrow involvement, and does not utilize ionizing radiation.[91] The accurate identification of imaging-defined risk factors is key to the accurate local staging of neuroblastoma.[30] In essence, these risk factors include encasement of critical structures, such as major blood vessels and nerves, and invasion of the spinal canal (Figure 92.3).

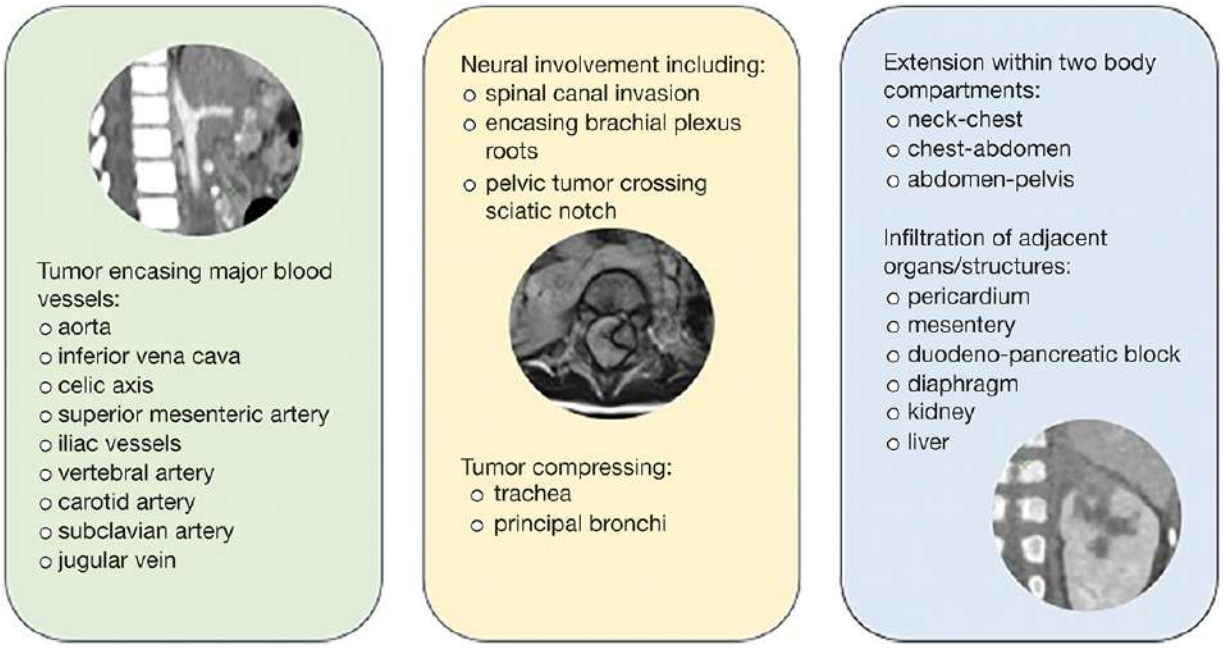

FIGURE 92.3 Infographic to indicate some of the imaging-defined risk factors used in the staging of neuroblastoma in the International Neuroblastoma Risk Group Staging System.

Biopsy is essential for the diagnosis of neuroblastoma, as well as characterization of its molecular biology. Interventional radiology core needle biopsies have largely replaced open surgical biopsies.[92] These may be performed at the same time as bone marrow aspirates and trephines, and insertion of a central venous catheter, thereby reducing the number of general anesthetics the child requires.

The standard of care for the assessment of distant metastatic disease, in addition to bone marrow examination, is ^{123}I-mIBG planar scintigraphy and single-photon emission computed tomography CT (SPECT/CT). In some countries, ^{123}I-mIBG is not available, and ^{131}I-mIBG is used, although the radiation exposure is greater and the image quality is infe rior.[93] Semiquantitative scoring of ^{123}I-mIBG scans allows for estimation of the disease burden, which correlates with prognosis, and a more objective assessment of response. Two systems are in current use, both divide the planar scan into a number of segments, and a numerical score is assigned to each segment. In the United States, the Children's Oncology Group (COG)[94] protocols use the Curie score, where 10 body segments are given a score of 0 to 3, making a maximum possible score of 30.[95] In Europe, the International Society of Paediatric Oncology European Neuroblastoma

group (SIOPEN)[96] system is used, where 12 body segments are given a score of 0 to 6, making a maximum possible score of 72.[97] Both systems appear equally useful, with the SIOPEN score having been cross-validated in COG trial patients, and the Curie score similarly assessed in SIOPEN patients.[98,99]

While over 90% of neuroblastoma tumors take up ^{123}I-mIBG, and so are amenable to this form of scoring, a small number do not. In this patient group, ^{18}F-fluorodeoxyglucose positron emission tomography (FDG PET) scanning is preferred to demonstrate the presence or absence of distant metastatic disease.[100] FDG PET may also be used in countries where ^{123}I-mIBG is not readily available.

A variety of other positron-emitting radiotracers may also be used for PET scanning in neuroblastoma, including somatostatin receptor imaging with ^{68}Ga-DOTA-peptide PET radiopharmaceuticals (^{68}Ga-DOTATOC, ^{68}Ga-DOTATATE, and ^{68}Ga-DOTANOC) and catecholaminergic PET tracers (^{11}C-meta-mydroxyephedrine, ^{18}F-dihydroxyphenylalanine ^{124}I-mIBG, and ^{18}F-meta-fluorobenzylguanidine).[101,102] However, while there is considerable interest in the evaluation of these alternative forms of imaging, none has yet become the standard of care in neuroblastoma management.

There is a strong research interest in radiomic evaluation of imaging data in neuroblastoma, and while this may be demonstrated to be of clinical value in the future, at present, it has no clearly established place in neuroblastoma care.[103]

Pathology

Primary surgery is not often undertaken for neuroblastoma, and so most often the tissue diagnosis is based on core bio psies. Neuroblastoma is one of the embryonal malignancies collectively referred to as “small, round, blue cell tumors of childhood.” Conventional light microscopy may show such cells forming rosettes around neuropil, and Schwannian stroma and larger ganglion cells may also be apparent in varying proportions. Immunohistochemical staining adds infor mation and allows the differential diagnosis between neuroblastic tumors and “small round blue cell tumors” of other types to be reliably distinguished.[104,105]

Depending on the level of differentiation and the balance bet ween stroma, mature cells, and neuroblasts, peripheral neuroblastic tumors are grouped into (1) ganglioneuroma, which is benign and is mostly mature Schwannian stroma and ganglion cells with no neuroblastoma; (2) ganglioneuroblastoma where stroma predominates, but with a neuroblastic component where immature cells may be scattered widely (ganglioneuroblastoma intermixed) or focally concentrated (nodular ganglioneuroblastoma); and (3) neuroblastoma, which has a limited stromal component and may be subcategorized as undifferentiated, poorly differentiated, or differentiating.[106] The International Neuroblastoma Pathology Classification (INPC) separates neuroblastic tumors into two categories: favorable histology and unfavorable histology.[22] This is based on a number of factors including grade, mitosis-karyorrhexis index, and age—which, although important, is not a histopathologic feature and may lead to confounding.

Molecular Biology

Molecular biology is a fast-moving area of scientific endeavor and is increasingly valuable in the management of neuroblastoma. It is a complex field, and a detailed review is beyond the scope of this chapter; however, the importance of sending tumor tissue, bone marrow, and blood for detailed analysis in a specialist laboratory at the time of diagnosis and in the case of subsequent relapse cannot be overstated.

One of the earliest findings of prognostic importance was that amplification of the oncogene *MYCN* was associated with advanced disease stage[107] and rapid disease progression.[108] Following these discoveries, *MYCN* has been an important factor in risk stratification.[24]

The presence or absence of numerical (eg, hyperdiploidy) and segmental (eg, 1p deletion, 11p deletion, and 17q gain) chromosomal abnormalities is another fundamental finding of significance.[109,110]

Disruptions in telomere maintenance caused by *ATRX* mutation and *TERT* rearrangement resulting in alternative lengthening of telomeres are indicators of poor prognosis, especially in older children.[111]

ALK mutations are important to identify, as they are of therapeutic value as well as prognostic significance.[112,113]

In addition to assessing tumor tissue for these abnormalities, repeated bone marrow and blood tests assaying messenger RNA and cell-free DNA, sometimes called "liquid biopsies," are becoming increasingly important to identify complete response, minimal residual disease, and early rela pse, especially in high-risk disease.[114,115]

Staging and Risk Group Assignment

The three factors most important for risk group assignment, which guide the treatment schedule used and prognosis, are stage, age, and molecular biology characteristics.

Over the years, the staging classifications used for neuroblastoma have evolved from the original Evans system[8] through the International Neuroblastoma Staging System (INSS)[116] to the International Neuroblastoma Risk Group Staging System (INRG SS).[30] The INRG SS is the most commonly used classification currently, which will likely be subject to revision in keeping with future data. In essence, patients are divided into two groups, depending on whether tumors are localized or metastatic. Localized tumors are further subdivided into two categories depending on the absence (stage L1) or presence (stage L2) of imaging-defined risk factors. Metastatic tumors are classed as stage M, except when metastases are confined to the liver, skin, and/or bone marrow in babies and children less than 18 months of age, and stage MS—broadly equivalent to Evans stage IVS.[9] The fundamental difference between the INRG SS and the earlier INSS is that the previous classification was a postsurgical system, where the stage is depended on the completeness of excision of the primary tumor, whereas currently, surgery is rarely the first treatment for neuroblastoma of any stage, and the classification relies predominantly on anatomic relations as demonstrated by radiologists. Imaging-defined risk factors indicate a higher probability of complications when surgery is performed.

Age has long been recognized as an important prognostic factor in neuroblastoma, with babies faring much better than older children. Previously, patients were separated into those aged less than or more than 1 year at diagnosis; however, analyses performed in very large numbers of patients have shifted the cutoff point to 18 months.[29,117] A large retrospective

study has demonstrated no detriment to children between 12 and 18 months of age as a result of deintensification of therapy as a result of this change.[118]

The key biologic factors used in risk stratification are amplification of *MYCN* and, in the absence of that, the presence of segmental chromosomal abnormalities. Ploidy and the INPC category add further value.

Broadly speaking, risk classification schemes divide cases into low-, intermediate-, and high-risk cases, where there is a strong association with prognosis. However, this field is complex and evolving as new data emerge, for example, from the INRG Data Commons.[119,120] Examples of the complexity include the addition of a very low-risk category in the INRG classification.[24] Different cooperative clinical trial groups use similar, but slightly different, risk classification systems.

The European group SIOPEN defines high risk in its High-risk 2 Trial (clinicaltrials.gov ID NCT04221035) as stage M disease in children over the age of 12 months, with any *MYCN* status or stage L2, M, or MS neuroblastoma with *MYCN* amplification, at any age. SIOPEN had one trial for low- and intermediate-risk patients (clinicaltrials.gov ID NCT01728155). The low-risk group included patients without *MYCN* amplification and either aged less than 18 months with stage L2 or aged less than 12 months with stage MS. The intermediate-risk group included patients with stage L2 aged less than 18 months without MYCN amplification; those aged less than 12 months with stage M, without MYCN amplification; and those with stage L1 disease and MYCN amplification.

The COG has used a similar, but slightly more complex classification with age, *MYCN* status, INSS stage, ploidy, and INPC histology criteria. While this has been functionally valuable, the use of age, when age is already a criterion in the INPC system, may lead to a degree of bias.[121] The relative contributions of the different elements to risk have been teased out, and a refined classification system has been developed.[31]

Even within established risk groups, subgroups of patients can be identified who have a greater risk; for example, att empts have been made to define an ultra-high-risk subgroup of patients,[122] and a nomogram has been devised to subdivide high-risk patients into groups with better (about 58% 3-year overall survival) and worse (about 30% 3-year overall survival) prognosis.[123]

TREATMENT STRATEGIES

Low Risk

Patients with low-risk neuroblastoma—babies with localized or stage MS disease with no adverse biologic features (*MYCN* nonamplified tumors without segmental chromosomal abnormalities)—have an excellent prognosis, with reported 5-year event-free survival of 90.7% and overall survival of 97.9%.[31] In the absence of life-threatening symptoms, a watch-and-wait policy may be justified, as a proportion of patients may experience spontaneous regression of their tumors. Otherwise, relatively simple chemotherapy schedules may be used, sometimes, but not always, in association with surgery. Primary-site radiotherapy is not indicated.

Intermediate Risk

Intermediate-risk neuroblastoma characterizes disease with a range of different characteristics. Overall, the prognosis is good: A 5-year event-free survival of 85.1% and overall survival of 95.8% has been reported.[31] However, more intensive chemotherapy is required for this to be achieved, compared with low-risk patients. Primary-site radiotherapy is indicated for those older than 18 months at diagnosis with poorly differentiated or undifferentiated MYCN nonamplified tumors. Of note, this latter category of patients is considered intermediate risk on European protocols but is included on high risk in U.S. protocols.

High Risk

High-risk disease requires intensive multimodality therapy. Outcomes have improved significantly over the years as a result of sequential clinical trials refining our understanding of biology, evaluating innovative treatment strategies, and better supportive care. For example, patients with metastatic high-risk neuroblastoma treated between 1990 and 1999 in the ENSG5 trial had a 5-year overall survival of 21.2% or 31.5% depending on which treatment arm they were allocated to, or about 26% overall.[124] In contrast, high-risk patients enrolled from 2007 to 2017 in ANBL00B1 had 5-year event-free survival of 51.2% and a 5-year overall survival of 62.5%.[31]

Current high-risk neuroblastoma treatment protocols vary in detail, but in general have the same concept, which includes a series of systemic therapies designed to treat metastatic disease as well as to shrink the primary tumor, interlaced by local treatments aimed at removing the primary tumor and reducing the chance of local recurrence. Typically, induction schedules are based on chemotherapy,[34] although molecular radiotherapy in addition has been explored.[125] Following several cycles of systemic therapy, maximal safe resection of the primary tumor is undertaken if feasible.[35,36] This is normally followed by intensification with one (or two) high-dose chemotherapy administrations, supported by peripheral blood stem cell reinfusion.[37,38] Historically, total body irradiation (TBI) was used as part of intensification but is no longer used because of the associated long-term toxicity.[126] Radiotherapy is then given to the primary tumor bed as described later,[39] and sometimes to sites of residual metastatic disease.[62] Following this, minimal residual disease-directed therapy follows, with the differentiating agent 13 *cis*-retinoic acid[42] and immu notherapy.[43,44] Each of these steps has evidence-based support; however, as there is still substantial mortality and treatment-related morbidity in high-risk neuroblastoma, further research is needed in order to determine which patients may require escalated therapies versus those who may need less intensive therapy. The paradigm in well-resourced countries is for children to be offered treatment within clinical trials wherever possible. The main cooperative groups running front-line trials are COG and SIOPEN. Early-phase clinical trials are also run by cooperative groups including the New Approaches to Neuroblastoma Therapy (NANT) consortium[127] and the Innovative Therapies for Children with Cancer in Europe (ITCC) consortium,[128] as well as individual institutions, for children with refractory or relapsed high-risk neuroblastoma. It is beyond the scope of this chapter to provide a very detailed review of the nonradiotherapeutic aspects of treatment, but some key references have been given.

EXTERNAL BEAM RADIOTHERAPY

Primary Tumor Treatment

Photon Techniques

Radiotherapy for children should only be given in departments that have appropriately trained staff for this highly specialist area of practice.[57] A broadly based multiprofessional team including pediatric anesthesiologists is required.[129]

Following a multidisciplinary discussion in a pediatric oncology tumor board and agreement that radiotherapy is appropriate, the pediatric radiation oncologist, possibly accompanied by other team members, should meet with the patient and family to explain what is proposed, and why. An assessment is to whether general anesthesia is required. Support and preparation for radiotherapy from a child life and health specialist (hospital play specialist) with experience in radiotherapy may help children to receive radiotherapy without the need for anesthesia. The principles and practicalities of the planning and treatment procedures should be explained, along with the likely short-term and possible longer term side effects. This discussion should be supplemented by the provision of written information. There should be an opportunity for reflection and time to ask questions. Informed consent will then be received from the parent or guardian, or the patient in the exceptional case of adult neuroblastoma.

Specific immobilization is not normally required for the treatment of abdominal neuroblastoma, but a vacuum bag may help with reliable repositioning. The patient will be positioned supine, with the arms either over the chest or above the head. In the rare case of a cervical primary tumor, a head and neck shell with five-point fixation may be required. A planning CT scan with contrast will be performed, under general anesthesia if necessary. Typically, the region scanned will encompass the thorax, abdomen, and pelvis, to enable dosimetry of organs at risk, as well as the tumor to be outlined. Consideration may be given to performing four-dimensional (4D) CT to assess diaphragmatic and upper abdominal movement with respiration. However, this can be difficult to achieve in very young children under general anesthesia, and probably not necessary as respiratory excursions are small and regular.[130] Most radiotherapy centers utilize tattoos to allow accurate and reproducible positioning for treatment.

Fusion of the planning CT scan to prior diagnostic imaging is required. As a minimum, this will be the postinduction chemotherapy, presurgery CT scan, and/or MRI scan used for surgical planning, but other imaging including other time points or types such as mIBG SPECT/CT scans may be

of value. As the extent of tumor found at surgery is sometimes more exten sive than was indicated by the imaging, the operation note from definitive surgery is required, and it can be helpful if this includes the International Neuroblastoma Surgical Report Form.[131] The histopathology report should also be available.

The preoperative gross tumor volume (GTV) should be carefully delineated on the presurgical scan(s). This should be extended, if necessary, in light of information from the surgical and histopathology reports. Care should be taken to include extension retrocrurally, and inferiorly along the vasculature, if necessary. The GTV can then be cut back on the planning CT scan where previously displaced organs, for example, the liver and kidneys, have returned to a more normal position following resection of the tumor mass.

The clinical target volume is then formed by an isotropic expansion, typically 5 to 10 mm, and cut back to normal barriers of spread such as the vertebrae, unless there was evidence of extension into spinal foramina at the time of surgery. A narrower margin may be used over uninvolved organs such as the liver or kidneys to spare function. However, care should be taken to include all surfaces that were in contact with the tumor before surgery. It is important to ensure that coverage in areas where tumor abutted or encompassed vascular structures such as the aorta and its branches, including the celiac axis and superior and inferior mesenteric arteries, the renal vessels, the inferior vena cava, and the hepatic portal vein, are not compromised.

The planning target volume (PTV) is formed by an isotropic expansion of typically 5 mm, or slightly greater or smaller than this depending on institutional standards and the results of departmental audits of motion, to ensure robust coverage (Figure 92.4).

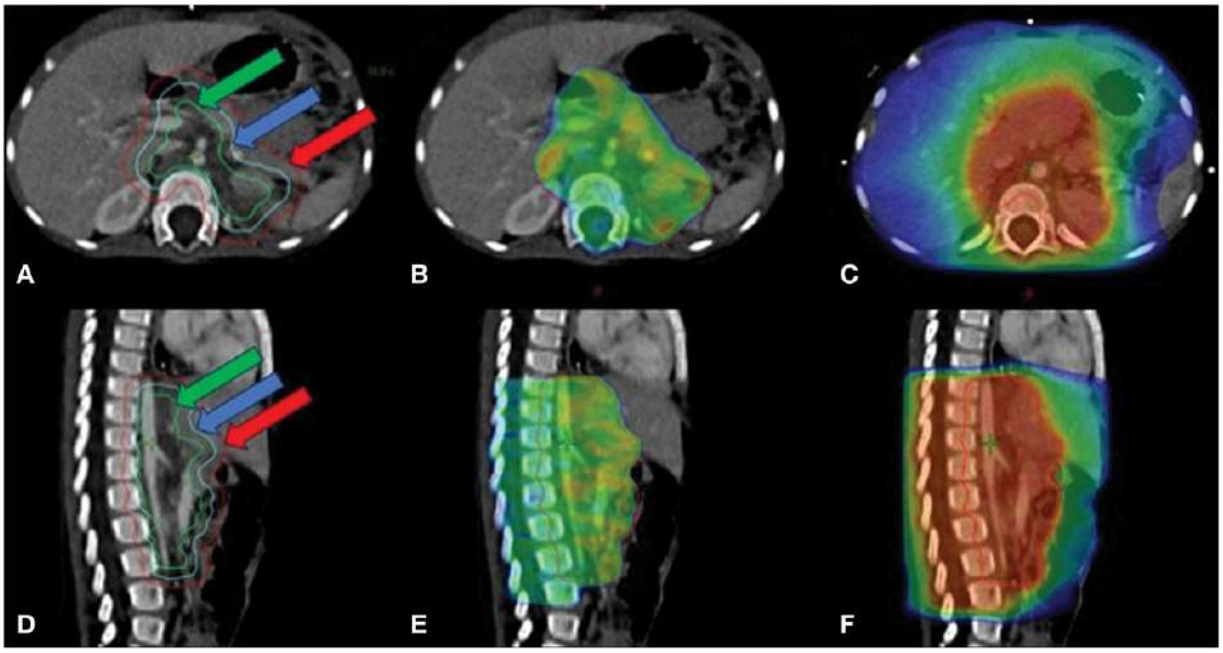

FIGURE 92.4 Intensity-modulated arc photon radiotherapy of a left suprarenal neuroblastoma with extensive nodal disease around the great vessels. A. Axial contrast-enhanced computed tomography scan to show target volumes: gross tumor volume (GTV) (*green arrow*), clinical target volume (CTV) (*blue arrow*), and planning target volume (PTV) (*red arrow*). B. Axial scan showing volume receiving 95% or more of the prescribed dose (21.6 Gy). C. Axial scan showing volume receiving a dose of 5 Gy or more, indicating the "low-dose bath" with photon treatment. D. Sagittal scan of the same patient showing GTV (*green arrow*), CTV (*blue arrow*), and PTV (*red arrow*). E. Sagittal scan showing volume receiving 95% or more. F. Sagittal scan showing volume receiving 5 Gy or more, demonstrating low dose outside the target volume.

All relevant organs at risk should be delineated to allow the dosimetrist to keep doses outside the target volume as low as reasonably achievable and within generally accepted tolerance doses.[132] International Consensus guidelines to support consistent practice are available.[133] Some organs deserve special mention.

The kidneys are radiosensitive organs[134] and are often intimately related to the location of neuroblastoma tumors. As renal function may be impaired by chemotherapy and surgical trauma, it is sensible to have an up-to-date assessment (including glomerular filtration rate measurement and a technetium-99m dimercaptosuccinic acid scan to show the contribution of each kidney separately) to guide preservation of kidney function during radiotherapy planning.

Splenic function is also affected by radiation, and the spleen is often incidentally irradiated to some extent during upper abdominal radiotherapy, especially if the tumor is lateralized to the left. High-quality volumetric evidence on splenic tolerance is limited, but it has been suggested that, if possible without compromising target volume coverage, the mean spleen dose should be kept below 10 Gy.[135]

Radiotherapy affects vertebral growth in young children, and a significant radiation dose gradient, especially laterally, across the vertebral column may lead to scoliosis. Care must, therefore, be taken to outline vertebrae adjacent to or overlapped by the PTV and to ensure symmetrical coverage.[136] The spinal cord, of course, runs through the vertebrae in the spinal canal. While the standard neuroblastoma dose of 21.6 Gy is well tolerated without adverse effects, a higher dose may result in myelopathy, especially following high-dose chemotherapy containing busulfan. It may be necessary to constrain the maximum cord dose to a lower level, such as 30 Gy, than the standardly recognized tolerance.[137]

It is considered good practice for volumes to be peer- reviewed internally by colleagues before they are accepted, as even experienced radiation oncologists may make errors that can be detected and corrected.[138] For some patients in clinical trials, external prospective peer review by radiation oncologists from the trial team is also required.[139]

The dosimetrists will then produce a plan for review. While previously parallel-opposed techniques were usually used, organ at risk tolerance frequently limited delivery of the prescribed dose to the PTV.[140] The widespread introduction of rotational intensity-modulated radiotherapy, or intensity-modulated arc therapy, has allowed better delivery of the prescribed dose to the PTV and also permits safe dose escalation if required.[141]

The standard-dose fractionation schedule prescribed in both North America and Europe is 21.6 Gy in 12 fractions, 5 days per week over 16 days. Some controversy still remains surrounding radiation dose for patients with significant residual disease following induction chemotherapy, surgical resection, and consolidation with high-dose chemotherapy. On the COG protocol ANBL0532, patients with incompletely resected primary neuroblastoma received an additional 14.4 Gy boost to areas of gross residual disease, for a total dose of 36 Gy; however, analysis of local

control rates compared to historical controls suggested no benefit of this escalated dose, resulting in removal of the "boost" from current COG protocols.[142] Arguments for both higher and lower doses exist for the cone-down/boost phase of therapy when residual disease is present,[143,144] but randomized data are not yet available. A randomized SIOPEN trial will provide evidence. Photons with an energy of 6 MV are most commonly used.

Image guidance with kilovoltage (kV) imaging and cone-beam CT (CBCT) will be used to ensure accuracy of treatment delivery. Typically, kV imaging will be used daily, and CBCT for the first 3 days, then weekly.[145]

Care of the patient on treatment will include regular review of the complete blood count as anemia should be avoided and irradiation of a significant number of vertebrae, especially after intensive chemotherapy, may lead to myelosuppression. Antiemetics should be provided. Acute side effects may include anorexia, nausea and vomiting, and tiredness. Supplementary feeding may be needed. Diarrhea can occur, but is not frequent. Patients are at risk of general complications, not specifically related to radiotherapy, such as central venous catheter infections, while receiving radiotherapy, and access to urgent pediatric care may be needed. Families may require social support, especially if treatment requires staying at a long distance away from home to receive the treatment, or help with psychological issues such as anxiety.

Following completion of treatment, a discharge summary detailing the radiotherapy delivered, including doses to organs at risk, should be sent to the referring pediatric oncologist and other relevant health care professionals involved in the child's care, to guide follow-up, especially with regard to late effects and the possible requirement for organ function monitoring or prophylactic care against overwhelming infections.

Proton Techniques

Proton therapy is a radiation modality that has been used to treat malignancies for over 40 years[146] and has become more widely available in the United States, Europe, and Asia over the past decade. Proton therapy may allow improved normal tissue sparing compared to x-ray therapy due to the abrupt dose falloff of the proton beam, an appealing quality

considering the vulnerability of growing tissues to radiation damage.[147,148] Local control is an important part of treatment for high-risk neuroblastoma, but, as described earlier, neuroblastoma tumors are often in close proximity to vital structures and organs at risk, including kidneys, liver, spleen, spinal cord, and lungs. Patients with high-risk neuroblastoma are also subjected to myriad lifesaving systemic therapies, requiring intact organ function; it is essential to avoid toxicity that could compromise delivery of other essential components of therapy required to cure the disease. In addition, as the number of long-term survivors of neuroblastoma grows, survivors who have received abdominopelvic radiation are increasingly recognized to be at risk for a wide range of late toxicities, including bowel obstruction, hepatotoxicity, diabetes, infertility, cardiac toxicity, kidney hypoplasia, and second malignancy.[149-154] Proton therapy is an appealing method for radiation delivery while potentially decreasing the risk to normal tissues (Figure 92.5). Concerns regarding increased relapse risk related to the precise nature of proton therapy have not been validated, with excellent outcomes in patients with neuroblastoma treated with proton therapy having been documented at the institutional and cooperative group levels.[60,155,156]

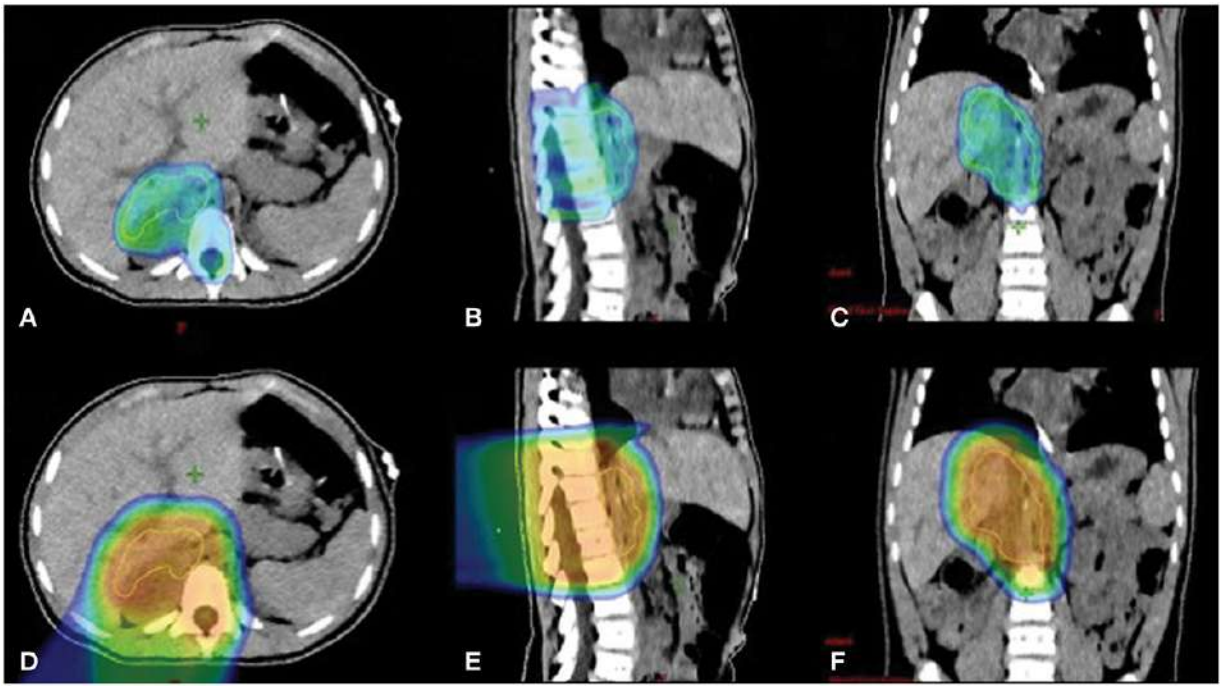

FIGURE 92.5 Pencil-beam scanning proton therapy for a small localized right suprarenal neuroblastoma. Axial (A), sagittal (B), and coronal (C) computed tomography (CT) scans through the upper abdomen showing volume treated with 95% or more of the prescribed dose of 21.6 Gy. Axial (D), sagittal (E), and coronal (F) CT scans showing volume receiving 5 Gy or greater, indicating the lack of an extensive "low-dose bath," in contrast to photon treatment (see Figure 92.4).

As is true with any treatment modality, nuances in delivery of proton therapy are numerous. A major distinction must be made with regard to delivery of the proton beam—namely, the use of a double scattered versus a pencil beam. Double-scattered technology has been available for clinical use for more years than has been pencil beam; it involves the use of a scattering foil to broaden a narrow proton team. This broad beam is directed through custom-milled compensators to sculpt its distal edge, and through apertures or a multileaf collimator to modify its lateral edges in accordance with the target. Collimators and apertures must be custom milled for each beam used to treat a patient, which is expensive and labo rious, and may also increase the risk of quality concerns.[157] Radiation planning with double-scattered beams is analogous to 3D planning with x-rays, including limited conformality. Because neuroblastoma target volumes are complex and in proximity to other normal structures, they may not be suitable for all patients with neuroblastoma. In some circumstances, in particular large and

centrally located tumors, rotational arc x-ray therapy may prove to provide optimal dosimetry compared to double-scattered proton beams.[158]

In contrast, pencil beam scanning beams utilize a single narrow beam to "paint" across a target, reducing dose to adjacent tissues and allowing sculpting to accommodate concave targets. It requires less planning time and has many fewer mechanical parts compared to double-scattered proton therapy[60] and is rapidly becoming a standard of care for delivery of proton therapy.

Target volumes for the treatment of neuroblastoma with proton therapy versus photon therapy are identical (as described earlier), with the exception of the PTV, which may be different for each beam as compared to an isotropic expansion used for photon planning; planning expansions include beam-specific planning targets based on range to target and width of the spread-out Bragg peak. Even so, a classic PTV should be created to allow plan comparison to other modalities. 4D planning may have increased utility in proton planning because understanding normal organ motion can improve robustness of proton planning.[130] The longer nature of daily treatments and the sensitivity of proton beams to motion may result in more patients requiring anesthesia compared to those being treated with photons, and this should be taken into account during decision regarding treatment modality. In general, posterior beams (posterior and posterior-oblique) should be used to avoid traversing bowel, minimizing positional uncertainty from varied bowel filling and breathing. Daily image guidance for delivery of proton beam radiotherapy is usually performed using kilovoltage x-ray image pairs or CBCT; image guidance should be performed with the lowest radiation dose possible during the treatment of pediatric patients.[159]

Metastatic Site Treatment

Radiotherapy to metastatic sites remains a topic of uncertainty, with practices varying widely. The presence of continued mIBG-avid metastatic disease on end-induction scans is associated with poorer prognosis[98,160,161]; the potential benefit of radiotherapy to address these disease sites is not definitively known.[62] COG protocols include radiotherapy (21.6 Gy) to sites of disease that persist at end-induction; however, when the number of sites is five or greater, radiation is not mandated and may be adjusted to be

directed only at sites still avid after high-dose chemotherapy. This stands in contrast to the SIOPEN approach, which does not include radiotherapy to metastatic sites due to the lack of evidence of benefit.

The role of metastatic site irradiation has been evaluated in several retrospective studies, with several institutional and multi-institutional author groups finding decreased risk of relapse at irradiated metastatic sites,[162-164] and retrospective data from Memorial Sloan Kettering Cancer Center finding improved overall survival after metastatic site radiation.[161] These data are intriguing, but the question of utility of metastatic site irradiation remains unanswered in a randomized manner.

A retrospective review of three COG high-risk neuroblastoma trials suggested that patients who had undergone TBI during consolidation had fewer metastatic relapses in sites with prior mIBG avidity.[165] As noted earlier, TBI is no longer utilized due to its very high toxicity profile in very young children, but the authors suggest that systemic radiotherapy in the form of ^{131}I-mIBG might have utility in the management of metastatic sites. This concept remains under investigation.

Low-dose radiotherapy can be effective for extensive metastatic disease in the liver in stage 4S disease,[166] but is less commonly used now, as other treatments are often effective.[167]

Palliation

For patients, especially when relapse has occurred after high-dose chemotherapy, where cure seems a very unlikely outcome, external beam radiotherapy can be used for palliation of symptoms. While often effective and widely used, there is a significant diversity of practice.[68] The most common indication is bone pain from skeletal metastases.[168] Short courses of treatment result in high rates of pain control with limited toxicity.[169] Craniospinal radiotherapy may be effective for CNS metastatic relapse, particularly when no extra-CNS disease is identified.[170]

MOLECULAR RADIOTHERAPY

Meta-iodobenzylguanidine Therapy

The catecholamine analog, mIBG, is taken up by the majority of neuroblastoma cells, and some normal tissues, though an active transport process. This has enabled the use of ^{123}I-mIBG to become the standard of care for imaging and staging of neuroblastoma, as discussed earlier. The use of higher activities of ^{131}I-mIBG can be cytotoxic when localized in neuroblastoma cells. First used as a palliative treatment in the 1980s, ^{131}I-mIBG therapy has gradually moved to an earlier stage in the management of metastatic neuroblastoma.[171] Reported response rates vary widely, depending on the schedule used, the position of the patient in the disease trajectory, and the definition of response.[172] The majority of reports of ^{131}I-mIBG therapy are case series in patients with relapsed or refractory disease, and despite evidence of effectiveness, it is difficult to ensure which schedules are best. To date, only one phase II randomized trial has been published, comparing either ^{131}I-mIBG therapy alone or in combination with irinotecan, vincristine, or vorinostat.[173] The response rate reported in the vorinostat arm was higher than that in the other two. The results of the COG ANBL1531 trial, which incorporated mIBG therapy into front-line therapy, are awaited.

Other Therapy Radiopharmaceuticals

Several other radiopharmaceuticals are being investigated in metastatic neuroblastoma, but all must be considered experimental rather than established therapy of proven benefit. ^{177}Lu-DOTATATE, which targets the somatostatin receptor and is an established form of peptide receptor radionuclide therapy for gastro-entero-pancreatic neuroendocrine tumors, has been assessed for the treatment of metastatic neuroblastoma. One study showed some transient responses, but no patient achieved the end point of a partial response after completion of therapy.[64] A further study with increased dose intensity is in progress.[174]

An alternative approach is the compartmental use of radiolabeled monoclonal antibodies to treat meningeal dissemination of neuroblastoma. Rather than intravenously, the radiopharmaceutical is delivered directly into the cerebrospinal fluid.[175]

RADIOTHERAPY SIDE EFFECTS

Acute Toxicity

Primary-site radiotherapy is generally well tolerated. Children having abdominopelvic treatment may experience gastrointestinal side effects, which should be managed with antiemetic and antidiarrheal medications, and stool softeners, as needed. Persistent nausea and/or vomiting can often be addressed with antiemetics given approximately an hour prior to radiotherapy. Symptoms of gastrointestinal reflux are rare due to low radiation dose but can be managed with H_2-blockers or proton pump inhibitors.

Children receiving radiation to the chest or neck may experience odynophagia from esophagitis; this is generally not severe, again due to low dose. Radiation to the head may cause fatigue, corneal irritation, or mucositis, which should be managed supportively. Skin toxicity is rarely more than grade 1 and can be managed with emollients.

Long-Term Effects

Long-term radiation toxicities are unfortunately common in young children and are based on the location of the radiation delivered. Toxicities from primary-site radiotherapy can include bowel obstruction, hepatotoxicity, diabetes, acute ovarian insufficiency/premature ovarian failure, cardiac toxicity, kidney hypoplasia, and second malignancy.[149-153] Short stature and/or scoliosis from vertebral body irradiation are also risks.[176] Patients who have undergone such radiotherapy should undergo screening tests for liver/kidney function annually, as well as hemoglobin A1c to screen for endocrine pancreatic insufficiency. Survivors should also consider screening for colorectal cancers and breast cancers in adulthood, as breast tissue may be part of an abdominal radiation field in small children.[177] Survivors may benefit from consultation with a reproductive endocrinologist if parenting is desired.

When radiotherapy is delivered to the thorax, cardiopulmonary toxicity is a long-term risk, and patients should undergo regular screening with pulmonary function testing and echocardiogram. Patients who have undergone head/neck radiation may develop dental anomalies, including missing teeth, caries, and/or malformed teeth, as well as cataract deve

lopment and orbital hypoplasia.[178,179] Those treated with skeletal metastases may be at risk for limb-length discrepancy and/or arthritis.[176]

Survivor education including abstaining from tobacco use, use of sun protection, recommended screening tests, healthy diet, and symptoms of bowel obstruction is essential to healthy survivorship, particularly as children develop and transition away from parental management of their medical care.[180]

OUTCOMES

The overwhelming majority of patients with low- and intermediate-risk neuroblastoma are survivors. Although for high-risk disease, prognosis has improved in recent decades as a result of better understanding of biology, improved supportive care, and additional therapeutic options, the mortality rate is still substantial, with only about half of those treated becoming long-term survivors. There is also a significant treatment-related long-term morbidity among those who do not die from disease. Therefore, for high-risk disease, although the landscape is gradually changing, efforts must continue to refine present treatments and find new treatments, with the twin aims of improving the probability of cure and diminishing late treatment-related complications.

FUTURE PRIORITIES

In the relatively resource-rich developed world, large cooperative clinical research groups such as COG and SIOPEN are running trials to refine and optimize care, and early-phase consortia such as NANT and ITCC are piloting new approaches. However, it must be remembered that most of the world's children live in less privileged environments, where access to cutting-edge treatment may not be available, and even the more standard approaches of chemotherapy, surgery, and radiotherapy may be hard to access.

Therefore, the priority for the future must not be restricted to basic science and clinical research aimed at improving outcomes and diminishing morbidity, but we must work toward making the best quality of evidence-based established treatment as widely available as possible.

CHAPTER 93

Rhabdomyosarcoma

Michael D. Young and Dana L. Casey

ANATOMY

Rhabdomyosarcoma (RMS) is a highly malignant soft tissue sarcoma that arises from unsegmented, undifferentiated mesoderm or myotome-derived skeletal muscle. It may occur at any site in the body, but the most frequently involved sites are the orbit (9%), head and neck (excluding parameningeal tumors) (7%), parameningeal (25%), genitourinary (31%), extremity (13%), trunk (5%), retroperitoneum (7%), and other sites (3%).[1]

EPIDEMIOLOGY AND RISK FACTORS

RMS is the most common of the childhood soft tissue sarcomas, with an annual incidence of 4.4 per 1 million White people and 1.3 per 1 million Black people. The male-to-female ratio is approximately 1.5 to 1.0.[2]

The great majority of patients are less than 10 years of age at the time of diagnosis, and approximately 5% are less than 1 year of age. There are two peak age frequencies, at ages 2 to 6 and in adolescence. Tumors in the younger age group are likely to be of embryonal histology. About 25% of patients are 10 years or above at diagnosis, and their tumors are often of alveolar histology. Age has been identified as an independent predictor of prognosis, with children below 1 and above 10 years having inferior survival.[3] Adults with RMS have been reported to have poor outcomes, although there is evidence that when they are treated aggressively using pediatric-type protocols, the prognosis may be similar to that of younger patients.[4-6]

Although 5% to 10% of cases are associated with cancer predisposition syndromes, most cases of RMS are sporadic and the cause is unknown; however, it is associated with disorders in development, including central nervous system, genitourinary, gastrointestinal, and cardiovascular

anomalies, and with congenital disorders including congenital pulmonary cysts, Gorlin basal cell nevus syndrome, and neurofibromatosis. In addition, RMS is the most frequently occurring childhood cancer in families with Li-Fraumeni syndrome, and its incidence is increased in children with neurofibromatosis type 1, Beckwith-Wiedemann syndrome, and Costello syndrome.

Recent developments in cytogenetics and molecular genetics now provide a more comprehensive understanding of the origin and biologic behavior of RMS. The classic distinction of embryonal versus alveolar histology has been largely replaced by the PAX/FOXO1 fusion status (fusion negative vs fusion positive) for both prognostic and therapeutic decision-making. These details are discussed in more detail later.

NATURAL HISTORY AND PATTERNS OF SPREAD

There are unexplained associations of site of primary tumor with age at diagnosis and tumor histology. For example, tumors arising in the urinary bladder and vagina occur primarily in infants and are often of the embryonal or botryoid histologic type. Tumors arising in the trunk and extremity occur in adolescents and are often alveolar. Tumors of the head and neck area occur throughout childhood and are commonly of the embryonal type.

RMS, a locally invasive tumor often with a pseudocapsule, has the potential for local spread along fascial or muscle planes, lymphatic extension, and hematogenous dissemination. The overall risk of regional lymphatic spread is approximately 15% but varies with the site of the primary lesion. Lymph node metastases are rare in orbital tumors, but they occur in approximately 15% of tumors at other head and neck sites, most commonly the nasopharynx. Accounting for staging inaccuracies, regional lymph node extension occurs in approximately 25% of children with paratesticular, extremity, and truncal tumors and in approximately 50% of children with perineal and perianal tumors.[7,8] The risk for lymph node involvement also correlates with primary tumor invasiveness and large tumor size.

Hematogenous metastases are detected at the time of presentation in approximately 15% of patients, particularly those with truncal and

extremity primary tumors. The most common sites of hematogenous dissemination are lungs, bone marrow, and bone. Malignant pleural and peritoneal effusions may also accompany tumors primarily to the chest and abdomen or pelvis, respectively.[9]

CLINICAL PRESENTATION

Because RMS occurs in multiple primary sites, there are many site-specific clinical signs and symptoms. It usually presents, however, as an asymptomatic mass. When symptoms are present, they relate to the mass effect on associated organs and tissues. Tumors in the orbital area may cause proptosis and ophthalmoplegia. Patients with parameningeal tumors often present with nasal, aural, or sinus obstruction; cranial nerve palsy; and headache. Genitourinary tumors may cause hematuria, urinary obstruction, or constipation.

DIAGNOSTIC WORKUP

Determination of tumor extent is best done with a multidisciplinary approach by a radiation oncologist, pediatric oncologist, and appropriate subspecialty surgeon. An expeditious local and systemic workup is essential because these tumors have the potential to grow rapidly. The initial assessment by all members of the team permits accurate staging and the formation of a uniform treatment plan. Table 93.1 provides recommendation for diagnostic workup at various sites. Experience with combined positron emission tomography (PET) and computed tomography (CT) scanning indicates this modality may be a valuable component of staging[10] and may in fact provide more accurate staging than conventional imaging.[11] PET-CT may be especially valuable in assessing response to therapy and in predicting outcomes, as conventional imaging has not shown a good correlation of tumor response to long-term clinical outcome.[12-14] Some children whose tumors exhibit characteristic fusion transcripts can be shown to have micrometastatic disease using reverse transcriptase polymerase chain reaction techniques, even when there is no evidence of metastases from routine diagnostic procedures. The clinical significance of this is, however, unknown.[15] For imaging of the primary tumor, magnetic resonance imaging (MRI) is often indicated and provides superior soft

tissue contrast when compared with CT imaging. For radiation planning, preferred sequences include morphologic sequences (T1-, T2-weighted sequences with fat-suppressed T2 sequences) and postcontrast T1 sequences (Figure 93.1). In addition, diffusion-weighted sequences can help distinguish reactive edema from residual tumor and aid in tumor response and radiation planning.

TABLE 93.1 RECOMMENDED WORKUP FOR TUMORS AT VARIOUS SITES

All Patients	Optional
All sites	
History	
Physical examination by several observers (including a pediatric oncologist, surgical oncologist, and radiation oncologist)	Examination under anesthesia for infants and youngsters
Laboratory studies Complete blood count Liver function tests Renal function tests Urinalysis	Plain films of bones abnormal on scans Abdomen/pelvis CT, MRI, or ultrasound
Imaging studies	
PET-CT (this study can likely replace chest/abdomen/pelvis CT and bone scan studies)	
MRI or CT of primary tumor	
Bone marrow biopsy and aspirate	
Head and neck	
MRI or CT of primary tumor (with contrast)	Plain films of area
Lumbar puncture with cytologic examination of fluid (in parameningeal primary tumors)	Dental evaluation and x-rays Paranasal sinus and skull films MRI of the spine if cerebrospinal fluid is positive or patient is symptomatic
Genitourinary	
CT of MRI of the abdomen/pelvis (with contrast)	Ultrasound of the pelvis
Pelvic examination under anesthesia	Cystoscopy
Extremity and truncal lesions	

All Patients	Optional
MRI or CT of primary lesion (with contrast)	Plain films of primary site
	Ultrasound
	Barium gastrointestinal contrast studies

CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

B

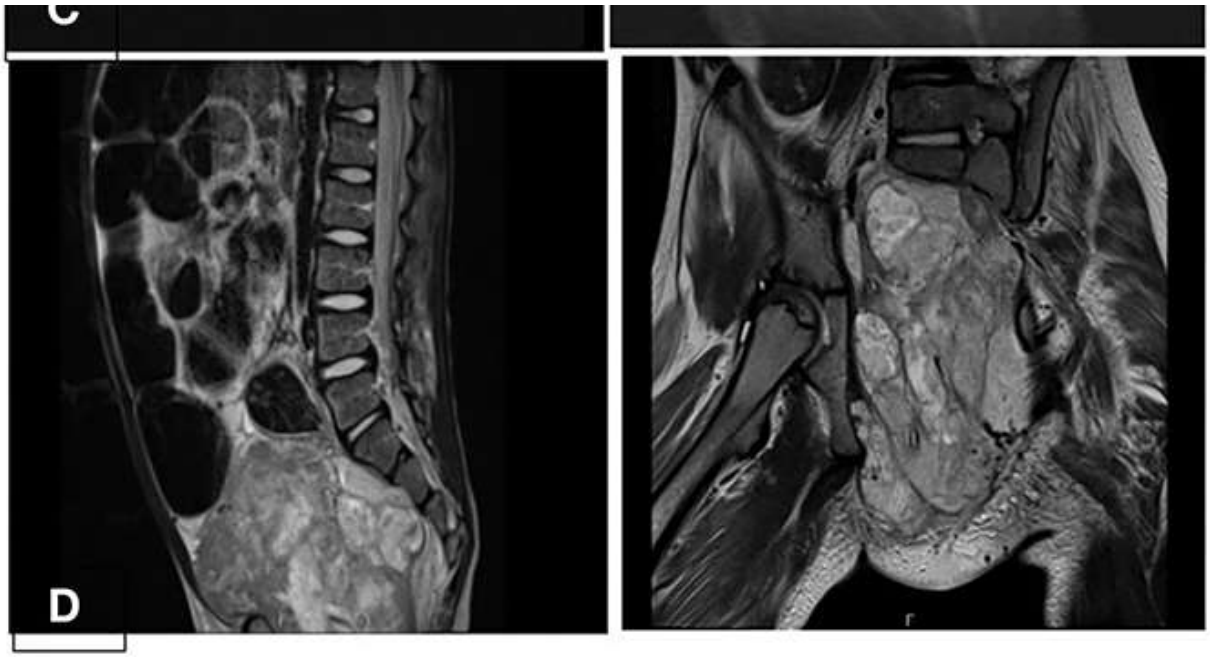

FIGURE 93.1 Magnetic resonance images with T1 postcontrast and T2 sequences with and without fat suppression depicting orbital rhabdomyosarcoma (A), parameningeal rhabdomyosarcoma with intracranial extension appreciated on coronal views (B), extremity rhabdomyosarcoma (C), and pelvic rhabdomyosarcoma (D).

STAGING SYSTEMS

The clinical grouping classification used extensively by the Intergroup Rhabdomyosarcoma Study (IRS) Group (now known as the Children's Oncology Group Soft Tissue Sarcoma [COG STS] committee) investigators is somewhat of a misnomer because it actually requires surgical pathologic evaluation (Table 93.2). It is not a staging system and does not accurately reflect the biology of the disease; rather, it reflects the surgical procedure selected for an individual patient. It is, however, useful for guiding decisions for radiotherapy, based on the amount of residual tumor after the initial surgical procedure. A more valid pretreatment staging system uses a tumor, node, metastasis (TNM) approach, which emphasizes characteristics of the primary tumor, size and invasiveness, nodal status, and systemic spread. Noninvasiveness, small size, and an absence of metastases have been shown to influence prognosis.[16] The site of primary tumor also has a significant impact on local control and survival.[17,18] The Intergroup Rhabdomyosarcoma Study-IV (IRS-IV) prospectively demonstrated the validity of a staging system incorporating TNM classification along with

primary tumor site (Table 93.3). Three-year failure-free survival was 86% for stage 1 tumors, 80% for stage 2, 68% for stage 3, and 25% for stage 4.[1,9] Of note, the clinical grouping did not correlate as well with survival. In fact, failure-free survival for clinical group II patients in the IRS-IV study was superior to that for clinical group I patients (86% vs 83%), probably reflecting the routine use of radiotherapy for group II patients.

TABLE 93.2 INTERGROUP RHABDOMYOSARCOMA STUDY CLINICAL GROUPING CLASSIFICATION

Group I	Localized disease, completely resected
A	Confined to organ or muscle of origin
B	Infiltration outside organ or muscle of origin; regional nodes not involved
Group II	Compromised or regional resection
A	Grossly resected tumor with microscopic residual disease
B	Regional disease, completely resected, in which nodes may be involved or extension of tumor into adjacent organ may exist
C	Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual disease
Group III	Incomplete resection or biopsy with gross residual disease
Group IV	Distant metastases at diagnosis

TABLE 93.3 INTERGROUP RHABDOMYOSARCOMA STUDY PRETREATMENT STAGING SYSTEM

Stage	Site[a]	Invasiveness	Size	Nodal Status	Metastases
I	Favorable	T1 or T2	a or b	N0 or N1	M0
II	Unfavorable	T1 or T2	A	N0	M0
III	Unfavorable	T1 or T2	B	N0	M0
			a or b	N1	M0
IV	Any site		T1 or T2	N0 or N1	M1

a, ≤5 cm; b, >5 cm; M0, no distant metastasis; M1, evidence of distant metastasis; N0, no evidence of regional node involvement; N1, evidence of regional node involvement (enlargement of nodes on radiographic imaging is considered evidence of involvement, although histologic confirmation is recommended when possible); T1, tumor confined to site or organ of origin; T2, regional extension beyond the site or organ of origin.

[a]Favorable sites: orbit, head and neck (nonparameningeal), and genitourinary (non–bladder-prostate); unfavorable sites: genitourinary (bladder-prostate), extremity, and parameningeal, other.

PATHOLOGIC CLASSIFICATION

The histogenesis of RMS can be traced from mesoderm to mesenchyme and ultimately to striated muscle tissue. The classification of RMS initially used by the IRS investigators consisted of four histologic subtypes: embryonal, botryoid subtype of embryonal, alveolar, and pleomorphic. Embryonal histologies constitute approximately two-thirds of all cases, with most of the rest having alveolar histology.[19] Other variants including a "solid" alveolar pattern, considered a subtype of alveolar RMS, a spindle cell subtype of embryonal RMS, and a diffuse anaplastic variant have also been described.[20]

To improve reproducibility of pathologic subtyping and prognostic utility, pediatric pathologists developed an updated classification system: the International Classification of Rhabdomyosarcoma. This system is based on a review of the second IRS (IRS-II) data, and it groups pathologic subtypes into distinct prognostic groups. The International Classification of Rhabdomyosarcoma system appears to be predictive of outcome and has been reproduced by several reference pediatric pathologists.[20,21] The superior prognosis group, consisting of two subsets (botryoid and spindle cell), carries a projected 5-year survival rate of 88% to 95%.[21] The botryoid subtype, a polypoid variant of embryonal RMS, has a grapelike appearance. The stroma consists of loose cellular tissue with a myxoid appearance. Under the superficial stroma is a hypercellular zone of tumor cells called the cambium layer of Nicholson. Botryoid tumors are usually noninvasive and localized and occur in mucosal-lined organs, such as the vagina, urinary bladder, middle ear, biliary tree, and nasopharynx. The spindle cell subtype of embryonal RMS has a spindled appearance, often with a storiform pattern. It is frequently found in paratesticular sites.

Patients with embryonal RMS have an intermediate prognosis, with an 83% failure-free survival at 3 years.[17] The embryonal type consists of blastemal mesenchymal cells that tend to differentiate into cross-striated muscle cells. There is often a considerable variation in the degree of cytoplasmic development, ranging from primitive mesenchymal to highly differentiated muscle tumor cells. Most of the tumor cells have eosinophilic cytoplasm, which is positive by periodic acid-Schiff staining. Immunohistochemistry may demonstrate actin- or desmin-positive reactions. Ultrastructural studies exhibit evidence of myogenesis with the presence of thick and thin cytoplasmic intermediate filaments or Z-band material. Ribbon or strap-shaped cells and tadpole cells are characteristic. The presence of cross-striations confirms the diagnosis. The embryonal form may be distinguished from the other subtypes by specific structural abnormalities. A consistent loss of heterozygosity at the chromosome 11p15.5 locus suggests that this site is specific for the embryonal subtype,[22] although, unlike alveolar histology, no characteristic translocation has been identified. Immunohistochemical presence of epidermal growth factor receptor and fibrillin-2 appears to be highly specific for embryonal histology and is predictive of a favorable outcome.[23,24] Dysregulation of the renin-angiotensin system (RAS) pathway has also been found in some patients and may be involved in the pathogenesis of this subtype.[25] The embryonal histology is found most commonly in the orbit, head and neck, and genitourinary sites.

The group with poor prognosis includes alveolar, diffuse anaplastic, and undifferentiated sarcomas. With routine use of immunohistochemistry and molecular genetic analysis, about one-third of RMSs are classified as alveolar; it is most commonly found in adolescents with truncal, retroperitoneal, and extremity tumors. The alveolar subtype is characterized by a pseudoalveolar pattern of connective tissue trabeculae, lined by large rhabdomyoblasts and multinucleated giant cells. The “solid” variant of alveolar RMS grows as solid nests of closely aggregated tumor cells with less alveolar pattern. Alveolar histology is strongly associated with hyperdiploid content.[26] Approximately 75% of children with alveolar RMS exhibit a characteristic translocation involving chromosomes 2 and 13, t(2;13)(q35;q14), and, occasionally, a 1;13 translocation.[22,27] These translocations correspond to abnormal fusion genes involving *PAX3-FKHR*

and *PAX7-FKHR*, respectively, and are probably the initial oncogenic events in these tumors.[28,29] Immunohistochemical presence of AP2-β and P-cadherin is also highly specific for alveolar histology.[23,24] The projected 3-year failure-free survival for children with the alveolar subtype is 66%.[1]

Undifferentiated sarcoma is largely a diagnosis of exclusion; it consists of a diffuse cell population of primitive, noncommitted mesenchymal cells. The 3-year failure-free survival rate of patients with undifferentiated sarcoma is 55%.[1] Today, sarcomas that lack characteristics of differentiation are most appropriately managed as non-RMS soft tissue sarcomas, though their outcomes have been similar to alveolar RMS.

The pleomorphic type is extremely rare; many cases formerly classified as pleomorphic RMS are currently considered to be malignant fibrous histiocytoma. Previously, tumors classified as extraosseous Ewing sarcoma were treated using guidelines for RMS. These are more appropriately considered in the Ewing family of tumors and are managed as such.

As more is learned about the molecular biology of RMS, fusion status rather than histology seems to be the more important driver of clinical outcomes. Recent data suggest that fusion-negative alveolar RMS is more similar to embryonal histology both clinically and molecularly.[30] On COG D9803, there was a trend toward improved event-free survival (EFS) among patients with fusion-negative alveolar RMS when compared to those with embryonal RMS (EFS 90% vs 77%).[31] Other studies have confirmed that fusion status may be more important prognostically than histology.[30,32] As such, modern COG clinical trials account for fusion status in addition to histology for risk stratification.

PROGNOSTIC FACTORS AND THERAPEUTIC CONSIDERATIONS

Because RMS is protean in presentation, factors such as age, site, stage, extent of disease, and pathologic characteristics of the tumor influence therapeutic decisions. These prognostic factors are interrelated and are best discussed as a function of the specific site (Figure 93.2). Although most treatment failures occur within 3 years of diagnosis, about 10% of children who are free of disease at 5 years will subsequently experience disease recurrence.[33]

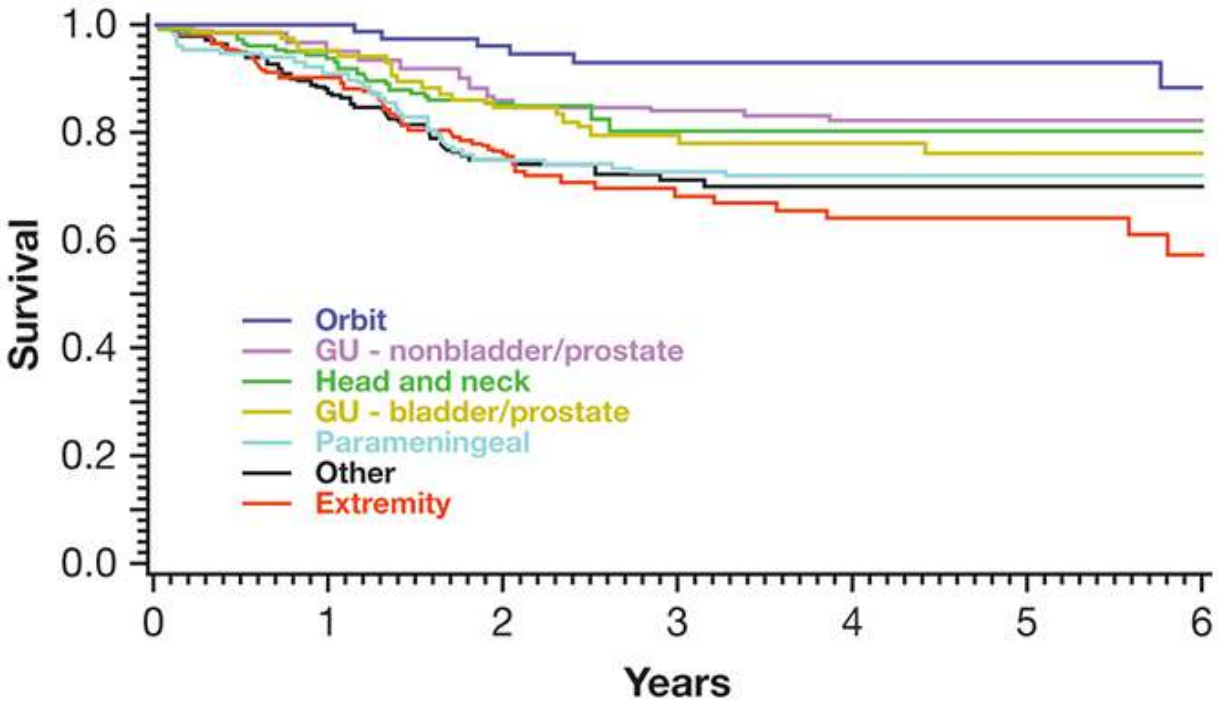

FIGURE 93.2 Survival curves for 883 children with nonmetastatic disease entered into the fourth Intergroup Rhabdomyosarcoma Study are shown by anatomic site of the primary tumor. GU, genitourinary. (Adapted with permission from Crist WM, Anderson JR, Meza JL, et al. Intergroup rhabdomyosarcoma study-IV: results for patients with nonmetastatic disease. *J Clin Oncol*. 2001;19[12]:3091-3102. Copyright © 2001 by American Society of Clinical Oncology.)

Orbit

The orbit has long been recognized as a favorable prognostic site (see Figure 93.1A). In addition to prompt recognition of the tumor, the paucity of lymphatics in this area means that lymphatic extension is rare. Most tumors in this site have embryonal histology and are fusion negative, and hematogenous metastasis at the time of diagnosis is uncommon. Approximately 10% are alveolar histology, however, and the prognosis for these children is more guarded.[34]

When treatment for orbital tumors is individualized, it is generally agreed that no surgical procedure should be used that may compromise vision or loss of function. In most patients, this means that biopsy only should be performed to provide the diagnosis. Primary treatment typically consists of vincristine, actinomycin-D, and cyclophosphamide (VAC) or vincristine and actinomycin-D (VA) chemotherapy with local radiotherapy beginning

after the 12th week of treatment. Radiation doses of approximately 50 Gy are often used. Dose reduction to 45 Gy was tested on D9602, resulting in a local failure rate of 14% (compared to 5% seen on IRS-IV).[35,36] A dose of 45 Gy was shown to result in unacceptable rates of local control for orbital RMS again on ARST0331 in those without a complete response to chemotherapy. As discussed later, orbital tumors should be treated with similar doses as other primary sites.

Chemotherapy without irradiation has resulted in local relapse and inferior EFS.[37] Although salvage radiotherapy for these patients can still be curative, functional vision in this setting is often poor.[38] Orbital exenteration should be reserved for salvage treatment and enucleation for the management of post-treatment ocular complications.

With a combined modality approach, radiotherapy can be directed to the tumor plus a margin without necessarily irradiating the entire orbit. Technique is very important for minimizing corneal and lacrimal gland dose and for preserving useful vision, ocular function, and appearance. Photon irradiation with the eyelid open can minimize the corneal dose when an anterior field is used and may be associated with improved long-term functional outcome.[39] Intensity-modulated radiotherapy techniques or proton therapy when available are optimal for treating the target volume and sparing normal structures.[40]

Head and Neck: Parameningeal Sites

Nonorbital RMS of the head and neck is grouped into parameningeal sites (nasopharynx, nasal cavity, paranasal sinuses, middle ear, pterygopalatine fossa, and infratemporal fossa; see Figure 93.1B) and nonparameningeal sites based on differences in natural history, treatment, and prognosis. Parameningeal RMS represents the majority of nonorbital head and neck RMS, and radiotherapy is essential for maximizing the probability of cure.[17,41] These tumors have a propensity for invading the base of the skull, creating a potential for cranial nerve palsy and direct extension into the central nervous system, a pattern of spread that is seen in as many as 41% of these patients.[42] Historically, as many as 35% of children with tumor arising in a parameningeal site would later have meningeal extension, and previous irradiation regimens called for whole-brain irradiation as part of

central nervous system prophylaxis.[43] However, the prognosis of these patients is markedly improved with appropriate imaging, multiagent chemotherapy, and adequate irradiation of the primary tumor and adjacent meninges, and studies demonstrate that whole-brain irradiation is not necessary, even in the presence of direct intracranial tumor extension.[44] However, patients with known meningeal dissemination (as determined via cerebrospinal fluid analysis and/or imaging) may receive craniospinal irradiation. A radiation dose of 50.4 Gy in 28 fractions to the primary site is commonly used. Data from the IRS studies show improved local control in patients with intracranial tumor extension when radiotherapy is started within 2 weeks of diagnosis,[42] although other reports show no disadvantage with delayed radiotherapy.[45]

Aggressive surgery is rarely indicated because complete resection is usually not possible, does not obviate the need for high-dose radiation therapy, and often results in a delay of systemic chemotherapy because of postoperative complications. Surgical approaches to these tumors have been described by proponents of multispecialty skull base surgery, but the efficacy of these approaches has not been firmly established.[46] Delayed surgical resection has been proposed as beneficial for children with residual tumor after completing chemotherapy and radiotherapy but is not considered standard of care and has not been shown to improve oncologic outcomes.[47-49]

Five-year survival for patients with parameningeal RMS is approximately 75% with adequate radiotherapy.[50] For the subset of parameningeal tumors arising in the nasopharynx or nasal cavity, middle ear, and parapharyngeal locations, survival may be even higher,[44] and functional and cosmetic outcomes can be good with conformal radiation techniques in spite of an aggressive treatment regimen (Figures 93.3 and 93.4).

FIGURE 93.3 A 12-year-old girl treated at age 3 years for an embryonal rhabdomyosarcoma of the nasal cavity. Her treatment consisted of excisional biopsy, followed by vincristine, actinomycin-D, and cyclophosphamide chemotherapy and 41.4-Gy radiotherapy. Slight hypoplasia of the midface is evident, but overall cosmesis is excellent.

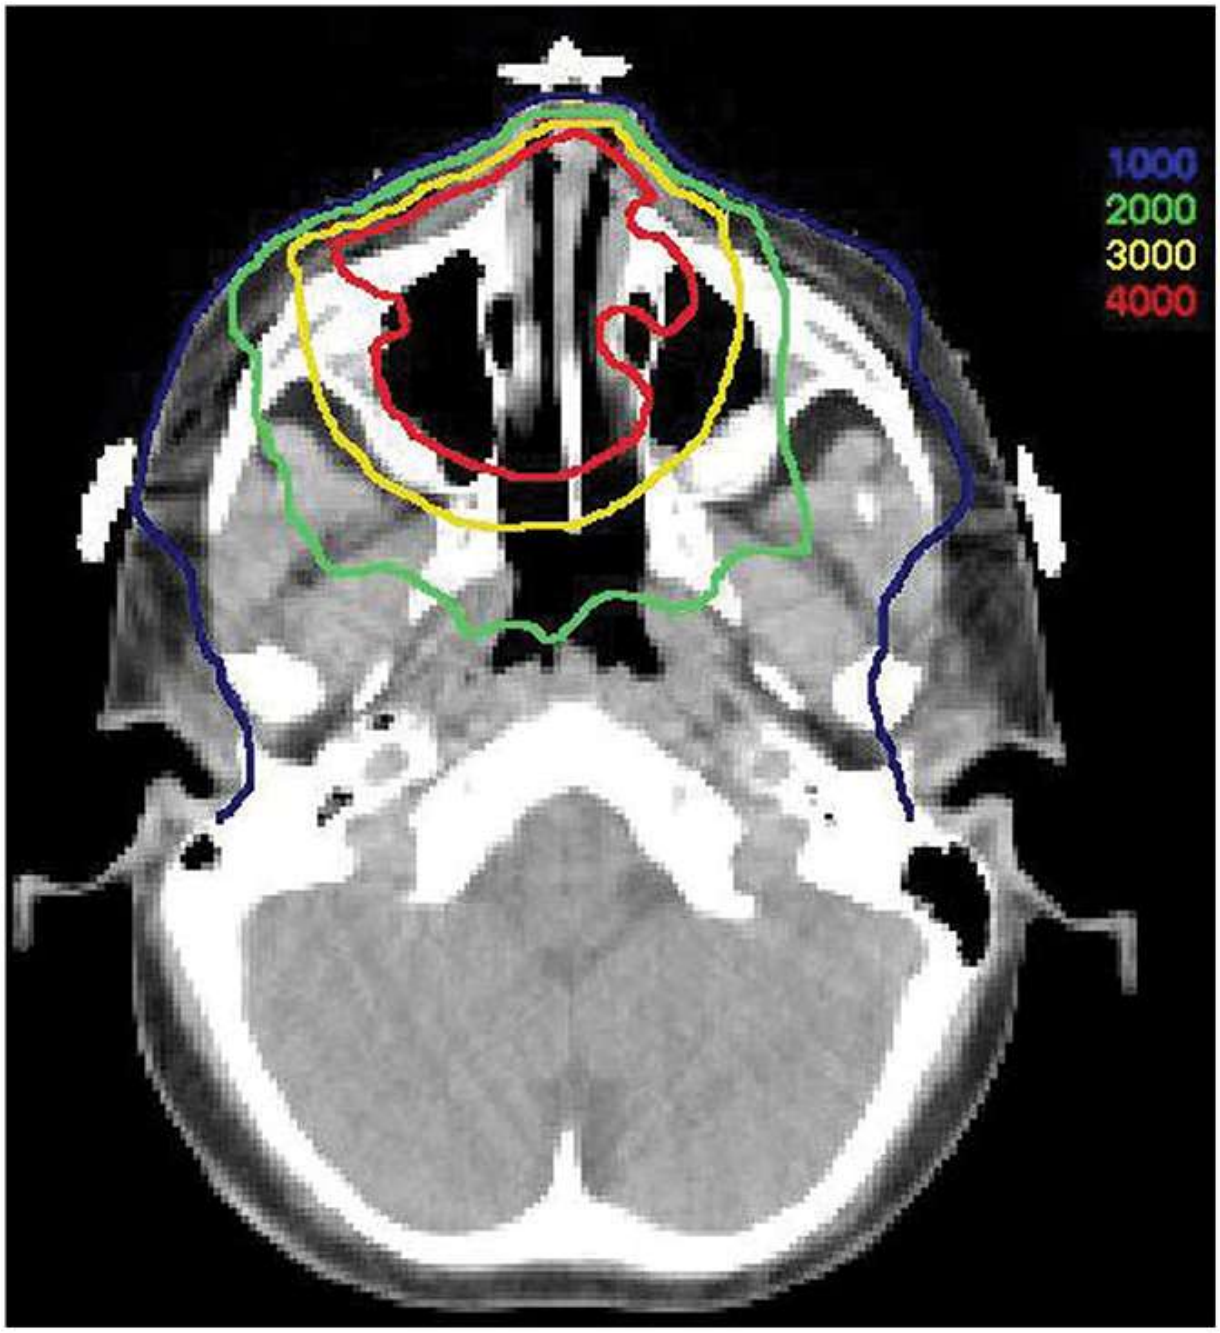

FIGURE 93.4 Isodose distribution from the treatment of the child in Figure 93.3 (doses in cGy).

Head and Neck: Nonparameningeal Sites

Children with tumors in nonparameningeal head and neck sites tend to have a better outcome than their parameningeal counterparts (80% 5-year failure-free survival in IRS-IV) and may require less intensive chemotherapy.[1,17]

These sites include the scalp, parotid, oral cavity, larynx, oropharynx, and cheek (see Figure 93.1C). These tumors may be more amenable to complete gross surgical excision compared with their parameningeal counterparts. Approximately 15% of these patients present with regional lymph node metastases. Radiotherapeutic management is based on the extent of resection, if performed. Draining regional lymph nodes are not routinely irradiated unless they are considered to be involved with tumor by clinical or pathologic assessment.

Pelvis

Pelvic tumors are usually divided into anatomic subgroups because the natural history, treatment, and prognosis are different for each site (see Figure 93.1D). Some children present with locally advanced pelvic tumors for which an exact site of origin cannot be determined. These large tumors are associated with an unfavorable prognosis.

Bladder and Prostate Tumors

Bladder and prostate primary tumors account for about half of all pelvic RMS[41]; 75% of patients are aged less than 5 years at presentation, and more than 90% of these tumors are of the embryonal histologic subtype, with approximately one-third having a botryoid morphology. In boys, it is often difficult to differentiate a tumor of prostatic origin from one of bladder origin because the disease usually involves both structures. However, patients with tumors arising in the prostate have significantly inferior survival compared with those with tumors confined to the bladder.[51]

Historically, anterior pelvic exenteration (or partial cystectomy for small tumors arising from the dome of the bladder) combined with chemotherapy and irradiation for microscopic or gross residual disease has been associated with a survival rate of approximately 70%.[18] This strategy evolved to one with limited surgery to preserve bladder function. The IRS-II study treated these patients primarily with chemotherapy followed by delayed surgery or radiation therapy when there was residual or recurrent disease. This approach resulted in an inferior 3-year disease-free survival rate of 52%, compared with 80% for a primary radical surgical approach, and only 22% of patients survived with intact bladders.[52] Subsequently, IRS-III intensified

the therapy with systematic use of planned irradiation 6 weeks after the start of treatment and added cisplatin and doxorubicin (Adriamycin) chemotherapy.[53] The 5-year survival rate for patients with locoregional disease was 82%, with 64% of surviving patients retaining functional bladders, demonstrating the necessity of routine radiation therapy early in treatment.[54] Survival of patients with locoregional bladder or prostate tumors treated on IRS-IV was similar, with 40% of all enrolled patients reporting normal bladder function at follow-up.[55] A more recent analysis showed maintenance of continence in 69% treated with conservative surgery in a multimodality treatment program.[56]

The German Cooperative Weichteilsarkom Studiengruppe CWS-96 protocol treated children with bladder or prostate RMS using multiagent chemotherapy followed by response-adapted radiotherapy and surgery. Children with complete resection did not have radiotherapy, whereas others received 32 to 44.8 Gy using 1.6 Gy twice a day, depending on the tumor's IRS group and response to chemotherapy. Five-year EFS was 70%.[57]

A pooled analysis of patients treated prospectively on several cooperative group trials from North America and Europe showed improved local control for those who received radiotherapy as part of their initial treatment, but this did not translate into improvement in overall survival.[58]

Paratesticular Tumors

Paratesticular tumors represent approximately 7% of all RMS and may arise anywhere along the spermatic cord, from the intrascrotal area through the inguinal canal.[59] At presentation, the tumor is usually a painless scrotal or inguinal mass that does not transilluminate. Most boys with paratesticular RMS present with early-stage disease that is amenable to complete resection and is associated with cure rates approaching 90%. As with prostatic primary tumors, the lymphatic network is rich, draining directly to the retroperitoneal nodes along the external iliac and spermatic vessels, the aorta, and the vena cava. The incidence of retroperitoneal lymph node involvement varies with the age of the patient and the method of staging (surgical vs nonsurgical). In the IRS-III study, retroperitoneal lymph node sampling was done in most patients, showing a 14% incidence of node involvement for children less than 10 years of age and a 47% incidence for

those 10 years or above. In IRS-IV, thin-cut CT without surgical sampling was used for staging, and the incidence of detected nodes dropped to 4% and 13% for the two age groups, respectively.[59]

The recommended surgical procedure for the primary tumor is inguinal orchiectomy. If there is no evidence of invasion into the scrotum and the proximal spermatic cord is free of tumor, this procedure is considered equivalent to an amputation, and no further local therapy is necessary. In the IRS, the high risk of nodal involvement in certain subsets of these patients has led to the recommendation for ipsilateral retroperitoneal nerve–sparing node dissection for staging of all children 10 years of age or above.[59] In the absence of histologic documentation, enlargement of retroperitoneal lymph nodes on thin-section CT imaging is considered evidence of tumor involvement.

Patients with nodal disease have a 5-year survival rate of 69%, compared with 96% for those without regional nodal disease ($P < .001$). Regional lymph node irradiation to the periaortic and ipsilateral iliac nodes is recommended when there is nodal involvement.[60] Surgical violation of the scrotum or tumor extension to the structure is an indication for hemiscrotectomy or, less commonly, scrotal irradiation. If scrotal irradiation is used, orchiopexy should be considered prior to treatment to protect the remaining testes. Treatment programs must be planned to reduce morbidity, particularly among this group with a high likelihood of cure.

Gynecologic Tumors

Tumors arising in the vulva, vagina, cervix, and uterus are about one-third as common as bladder and prostate primary tumors and account for 4% of all RMS.[61] Within this group, the vagina is the most common site of origin.

Patients with vaginal tumors are often much younger than those with other pelvic RMS, with most girls diagnosed before the age of 3 years. Most present with a vaginal mass or discharge; botryoid morphology is common. Initial surgery is used primarily for diagnosis, although gross tumor resection is occasionally possible without cosmetic or functional deformity. These tumors are often quite sensitive to chemotherapy, and treatment regimens had previously used a strategy of chemotherapy only, reserving surgery and radiotherapy for persistent or recurrent tumor.[61-63]

However, analysis of data from the IRS-IV and IRS-V studies has revealed high rates of local failure for vaginal tumors when local control with surgery or radiotherapy is omitted.[36,64] Current guidelines from the COG STS committee call for radiotherapy, often with intravaginal brachytherapy to limit dose to surrounding normal tissues such as ovaries, in all patients with postsurgical microscopic or macroscopic tumor.

Uterine, cervical, and vulvar tumors receive chemotherapy and radiotherapy based on the amount of tumor present after initial surgery. Intracavitary and interstitial brachytherapy are useful irradiation techniques in some of these patients.[65] Data are limited, but with proper patient selection, disease control is excellent and late normal tissue effects may be significantly less with brachytherapy than is seen with external beam techniques.[66] Permanent implants with iodine-125 and temporary low-dose rate and high-dose rate brachytherapy have all been used, and there are no clear differences among these techniques in terms of disease control or late effects. When temporary implants are used, high-dose rate brachytherapy has the practical advantage of minimizing radiation exposure to the family and medical personnel caring for the child.

Survival after treatment is excellent. Children aged 1 to 9 years have a 98% 5-year survival. Survival for infants and adolescents approaches 90%, although these patients may require more intensive systemic therapy for cure.[61]

Other Pelvic Sites

These tumors include perianal, perirectal, and perineal primary sites. The location of these primary tumors creates surgical and irradiation challenges. Combined chemotherapy and radiation therapy programs are favored over primary surgical procedures if excision requires exenteration with urinary and fecal diversion procedures or is associated with organ or sphincter dysfunction. In general, tumors in these locations are associated with poor prognostic features, high rates of regional nodal involvement, and dismal outcomes, especially in children above 10 years of age.[8]

Extremity

Tumors arising in the extremity are often of the alveolar or undifferentiated subtypes, large, deeply invasive, and associated with a high probability of lymphatic and hematogenous metastasis (Figure 93.1).[67] Complete surgical resection is difficult to achieve, usually requires extensive dissection, and is associated with a high risk of residual disease. Because radiation therapy and multiagent chemotherapy have been shown to provide excellent local control, it is advisable to avoid disfiguring and mutilating surgical procedures, with their attendant functional disabilities, and to recommend limb-salvage procedures, including irradiation and chemotherapy.

Regional lymph node involvement is present in approximately 24% of patients and confers a more guarded prognosis.[67] Aggressive surgical staging of draining lymph node basins is important to define the extent of involvement, although if lymph node dissection is performed, it is for the purpose of staging, not for treatment. Sentinel lymph node mapping and biopsy provide diagnostic and prognostic value for extremity tumors.[68,69] Radiotherapy of involved regional lymphatics is mandatory, and aggressive treatment of involved in-transit nodal sites may improve overall local control.[7]

Radiation therapy for extremity primary tumors requires careful immobilization techniques, sparing of nonirradiated skin for lymphatic drainage, and use of shrinking fields. Routine physical therapy during and after radiation therapy is important for obtaining an optimal functional result. Overall survival at 3 years for these patients is about 70%, although failure-free survival is only 55%.[70]

Other Sites

Patients with tumors arising in sites such as a paraspinal, retroperitoneal, or intrathoracic location have a poor outcome compared with other patients.[17] Most patients with tumors in these locations are unable to undergo complete resection of the tumor. Both local and distant relapse are common. These patients should be treated aggressively with high-dose radiation therapy and multiagent chemotherapy.

Metastatic Disease

Hematogenous or distant lymph node metastasis at the time of diagnosis is an ominous finding, although not all these children do poorly. The subset of patients who are less than 10 years of age, fusion negative, and have only one or two sites of metastatic disease may have long-term survival chances of more than 50%.[9] Intensive multiagent chemotherapy plays a major role in the treatment of these patients, although marrow ablative techniques have not improved efficacy compared with conventional chemotherapy approaches.[71,72] Local control of the primary tumor is site specific, as previously described. Metastatic sites should be treated with comprehensive radiotherapy whenever feasible for optimal oncologic outcomes, and control rates after radiation are similar to local control rates at the primary site.[73] The role of stereotactic body radiotherapy (SBRT) for bony sites of metastatic disease is currently being explored. Whole-lung irradiation for lung metastases is currently the standard of care, although SBRT for residual lung metastases is also an area of active investigation.[74,75]

RESULTS OF THERAPY: SUMMARY OF CLINICAL TRIALS

Because of the low incidence of RMS, much of what has been learned about its treatment has come from cooperative group trials performed in North America and Europe. Various cooperative groups have used different philosophies of treatment. In general, the North American IRS and COG studies have emphasized the role of local control measures, and European studies have focused more on chemotherapeutic approaches.

Intergroup Rhabdomyosarcoma Studies

The IRS began intergroup clinical trials for RMS in 1972 and has enrolled several thousand children with this disease since then. A primary goal has been to test the efficacy of chemotherapy and radiation therapy as a function of surgical stage. In the IRS-I study, radiation therapy was given initially for patients with group I and II disease and was delayed until week 6 for those with group III and IV disease. All patients received multiagent chemotherapy for 2 years. This study made several important observations[76]:

1. For localized tumors amenable to complete resection (IRS group I), postoperative radiation therapy is unnecessary if the patient is given 2 years of VAC. For these patients, the relapse-free survival rate in IRS-I at 5 years was 80%, and the 5-year survival rate was 81% to 93%. Subsequent analysis has shown a benefit to postoperative radiation therapy for patients with group I tumors of alveolar or undifferentiated histology.[119]
2. VAC failed to improve results obtained with intensive VA for patients with group II disease if postoperative radiation therapy was given. For these patients, the relapse-free survival rate at 5 years was 65% to 72%, and the overall 5-year survival rate was 72%.
3. VAC + Adriamycin provided no advantage over VAC for patients with group III disease (gross residual) or group IV disease (metastasis) if routine radiation therapy was used in addition. The complete remission rate for group III patients was 69%, and for group IV patients, it was 50%. Those who achieved complete remission had a 60% chance of staying in remission for 5 years in group III and a 30% chance in group IV. The survival rate at 5 years was 52% for group III and 20% for group IV patients.
4. The 5-year survival rate for the entire group was 55%.
5. Survival after relapse was poor—32% at 1 year and 17% at 2 years.
6. The risk of distant metastasis was much greater than the risk of local recurrence.
7. Primary tumors of the orbit and genitourinary tract carried the best prognoses, and tumors of the retroperitoneum had the worst.
8. The alveolar histologic subset had a poor prognosis, especially in extremity lesions.

IRS-II was built on the findings of IRS-I.[41] The results from this study include the following:

1. The 5-year survival rate for the IRS-II group was 62%, with a 7% improvement over the IRS-I rate.
2. Patients in group I (excluding patients with alveolar extremity) had better disease-free status with VAC (82%) than those who received only

VA (68%), but they had similar survival rates (82% and 88%) at 5 years. Cyclophosphamide could not be withdrawn safely from the standard VAC regimen if irradiation was omitted from patients with group I disease.

3. Intensive (cyclic-sequential) VA therapy was as effective as repetitive pulse VAC therapy for patients with group II disease, if all patients received postoperative irradiation. At 5 years, 68% to 75% remained disease free and 77% to 90% were alive, with no differences between the two therapy groups.
4. Repetitive pulse chemotherapy for 2 years increased survival in children with group III disease, but not in those with group IV disease; doxorubicin and dactinomycin had comparable efficacy in the pulse regimens used. The complete remission rates were 72%. At 5 years, 70% remained in complete remission and 64% were surviving.
5. In IRS-I, patients having tumors in parameningeal sites with high-risk factors (cranial nerve palsy, erosion of the base of the skull, or intracranial extension) had a high incidence of central nervous system relapse. In IRS-II, whole-brain radiotherapy irradiation, with or without intrathecal chemotherapy, was introduced. This prevented meningeal recurrence and increased survival in these patients with high-risk parameningeal primary tumors.
6. Primary repetitive pulse VAC for patients with special pelvic primary tumors (ie, bladder, prostate, uterus, vagina) did not reduce the frequency of total cystectomy or produce durable bladder salvage, although survival was not compromised.
7. Survival after relapse was only 17% at 5 years.

The IRS-III study covered the period 1984 to 1991. This study revealed the following[17]:

1. The 5-year survival rate for the IRS-III group was 71%, with an 8% improvement over the IRS-II rate. The 5-year progression-free survival rate was 65%, with a 10% improvement over IRS-II.
2. Patients with group I favorable-histology tumors fared as well on a 1-year regimen of VA as did a comparable group treated with VA plus

cyclophosphamide. The 5-year progression-free survival rates were 83% and 76%, respectively ($P = .18$).

3. Results for patients with group II favorable-histology tumors, excluding orbit, head, and paratesticular sites, were not improved with the addition of doxorubicin over VA chemotherapy × 1 year and radiation therapy.
4. Patients with group III tumors, excluding those in special pelvic, orbit, and other selected head sites (scalp, parotid, oral cavity, larynx, oropharynx, and cheek), fared better on the more intensive regimens of IRS-III than on pulsed VAC or VAC vincristine and doxorubicin (VADR) in IRS-II; the 5-year progression-free survival rates were 62% and 52%, respectively. The intensive regimen from IRS-III included multiple agents (VAC + doxorubicin + cisplatin + etoposide) plus radiation therapy plus second-look surgery. There were no differences in outcome among the three chemotherapy programs on IRS-III.
5. Patients with group IV tumors did not benefit from the aggressive therapy of IRS-III.
6. Patients with tumors in the bladder, vagina, and central pelvis in clinical group III had significantly improved outcome as compared with those with IRS-II, primarily because of the routine administration of early radiation therapy, which improved the bladder salvage rate from 25% in IRS-II to 60% in IRS-III.
7. Patients with unfavorable histology, in clinical groups I and II, who received VADR-VAC + cisplatin and radiation therapy had improved outcome over patients in IRS-II receiving VA or VAC and irradiation.
8. Patients with favorable-histology group II paratesticular tumors and those with favorable-histology orbit and head tumors in groups II and III do not require cyclophosphamide when VA × 1 year plus radiation therapy is used.
9. Whole-brain radiotherapy was omitted for patients with parameningeal primary tumors and cranial nerve palsy or base of skull erosion (although patients with intracranial extension of tumor still received this treatment). Risk of central nervous system relapse and survival was not compromised by this change if adequate local fields were used.

The IRS-IV study was conducted from 1991 to 1997 (Figure 93.5).[1] The results from this study are as follows:

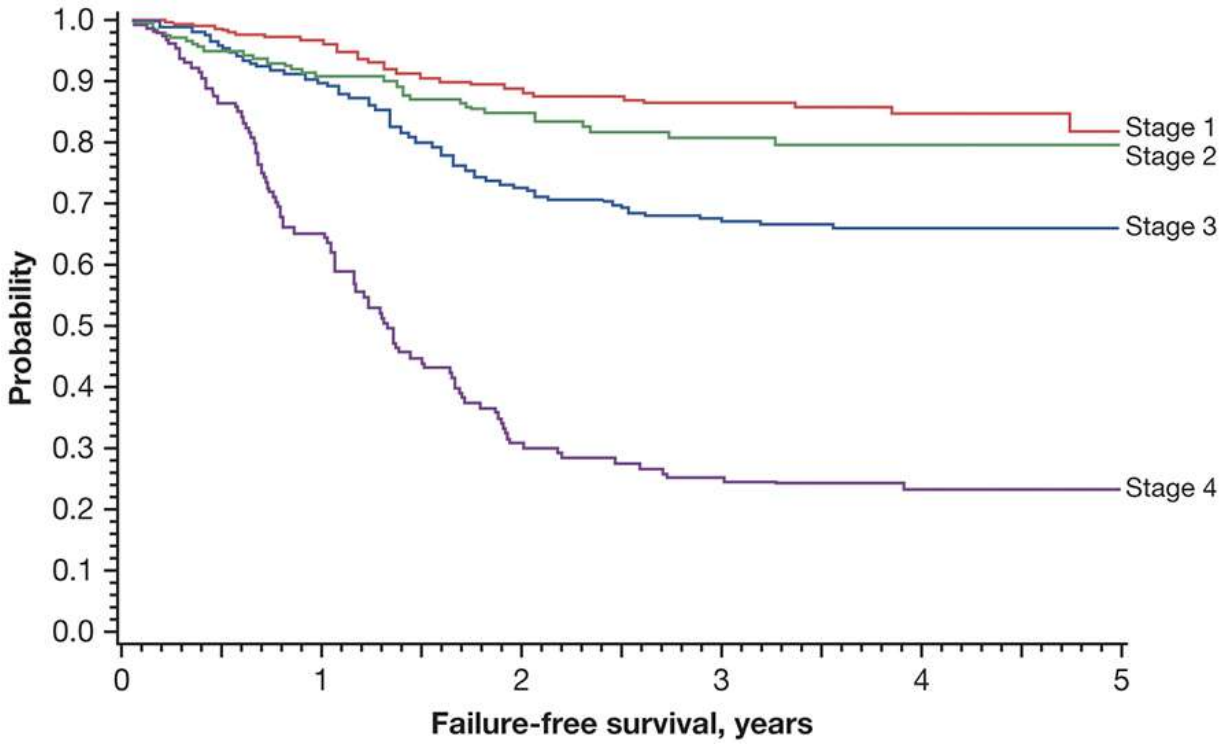

FIGURE 93.5 Survival curves of 1,010 children with rhabdomyosarcoma entered into the fourth Intergroup Rhabdomyosarcoma Study are shown by stage. (From Crist WM, Anderson JR, Meza JL, et al. The Intergroup Rhabdomyosarcoma Study-IV: results for patients with non-metastatic disease. *J Clin Oncol*. 2001;19[12]:3091-3102; Breneman JC, Lyden E, Pappo AS, et al. Prognostic factors and clinical outcomes in children and adolescents with metastatic rhabdomyosarcoma—a report from the Intergroup Rhabdomyosarcoma Study IV. J Clin Oncol. 2003;21:78-84.)

1. For patients with group III tumors, hyperfractionated radiotherapy was no more effective than conventional radiotherapy for tumor control and survival. Local control at 5 years was 87% for all patients with group III tumors (98% orbit, 88% head/neck, 84% parameningeal, 81% bladder/prostate, 93% extremity, 86% other).[115]
2. There was no difference in survival between VAC and vincristine/actinomycin/ifosfamide and vincristine/ifosfamide/etoposide in children with nonmetastatic disease.

3. Failure-free survival at 3 years for patients with embryonal histology was superior to results seen in IRS-III (83% vs 74%), but no difference was seen for alveolar or undifferentiated subtypes.
4. Survival for patients with group I or II orbit or eyelid tumors was excellent when treated with VA and radiotherapy for group II disease.
5. Prognostic subsets of patients based on histologic subtype, stage, and group could be identified as follows: Low-risk patients had embryonal histology and were stage 1 (all groups), or stage 2 or 3 and group I or II. All other patients with locoregional disease were at intermediate risk.
6. Survival for patients with metastatic disease was superior with the drug pair ifosfamide/etoposide when compared with vincristine/melphalan.[100]
7. Whole-brain radiotherapy was omitted for all patients with parameningeal primary tumors, except when there was cytologic evidence of cerebrospinal fluid involvement. Survival was not compromised by this approach.

The fifth IRS (IRS-V) studies consisting of COG D9602, COG D9803, and COG D9802 were conducted from 1997 to 2005. The results from these studies are as follows:

1. Failure-free survival for low-risk patients (treated without cyclophosphamide and given decreased radiation doses with 36 Gy for microscopic disease) was similar to results seen in IRS-III, which also did not use cyclophosphamide, but was inferior to results from IRS-IV where cyclophosphamide or ifosfamide was given. The conclusion of this study was that reduced radiotherapy doses with 36 Gy for microscopic disease did not appear to compromise local control, but the inclusion of an alkylating chemotherapy agent in the treatment regimen may be important for maximizing outcomes in these patients.
2. For group III orbital tumors specifically, dose reduction to 45 Gy resulted in an unacceptably high rate of local failure rate at 14% (compared to 5% seen on IRS-IV). As such, 50.4 Gy remains the standard of care for orbital tumors without a complete response to induction chemotherapy.[35,36]

3. For vaginal tumors treated without radiation, local failure rates were also unacceptably high (26% on D9602 and 43% on the subsequent trial ARST0031).[64] Omission of radiation therapy for these children is not advisable, and intravaginal brachytherapy may be the preferred modality of treatment, given the high-dose gradient and subsequent sparing of surrounding normal tissue.
4. For patients who undergo second-look surgery or delayed primary excision (DPE) after induction chemotherapy, radiation dose can be successfully reduced to 36 Gy for negative margins and 41.4 Gy for microscopically positive margins without compromising local control.[77] However, an oncologic benefit to DPE (compared to radiotherapy alone) was not observed.
5. For patients with intermediate-risk disease treated on D9803, the addition of topotecan to the standard VAC regimen did not improve failure-free survival.[78]

Following IRS-V, the COG conducted separate protocols by risk group from 2004 to 2013: ARST0331 for low-risk patients,[79] ARST0531 for intermediate-risk patients,[80] and ARST0431 for high-risk patients.[81] The results from these studies are as follows:

1. On ARST0331, unacceptable local control rates were again seen for orbital tumors treated to 45 Gy with reduced-dose cyclophosphamide and incomplete response to chemotherapy, as well as for vaginal tumors not treated with radiotherapy, confirming results from D9602.[82]
2. A reduction in cyclophosphamide dose from prior trials appeared to result in inferior survival outcomes for subset 2 low-risk patients treated on ARST0331[83] and intermediate-risk patients treated on ARST0531.[97]
3. For patients with intermediate-risk disease treated on ARST0531, the addition of irinotecan to the standard VAC regimen did not improve survival outcomes.[80]
4. On both D9803 and ARST0531, tumor size 5 cm or more at diagnosis was associated with significantly increased local failure after radiotherapy.[84,97]

5. For patients with high-risk disease treated on ARST0431, those with embryonal histology 10 years of age or less had a superior prognosis compared to other high-risk patients, leading to reclassification of this subset of patients as intermediate risk for subsequent trials. [81] In distinction, those with metastatic fusion-positive disease experienced long-term survival outcomes of less than 20%.

GENERAL MANAGEMENT

A multidisciplinary approach using surgery, irradiation, and chemotherapy is important in the management of RMS; however, the optimal sequence and specific application of each modality continue to be investigated. Although the primary goal remains long-term cure, improvement in therapeutic results necessitates considerations of quality of life, with particular attention to maximization of functional and cosmetic results.

Surgery

Before the era of multidisciplinary therapy, surgical ablation resulted in a long-term survival rate of approximately 20% of those patients able to undergo resection.[85] Certain primary sites represented exceptions to these data; for example, approximately 50% of those with localized disease of the orbit survived after orbital exenteration.[86] However, with the introduction of effective adjunctive treatment, preservation of function and appearance became major goals. The concept of reasonable surgery has evolved. It involves maximal conservation of anatomic structures, including preservation of bladder, bowel, and sexual function in patients with tumors of genitourinary origin; limb function in patients with extremity tumors; and vision, voice, deglutition, and appearance in patients with head and neck tumors.

Resection of RMS from normal surrounding tissues is often technically challenging. Only 20% of tumors are located in sites where complete excision can readily be accomplished without an undesirable loss of function or cosmesis.[17] An additional 20% of patients have compromised surgical procedures, leaving microscopic residual disease. Sixty percent of patients have tumors amenable to biopsy only or present with metastatic disease and are not candidates for primary resection. When the IRS surgical

grouping system is used, patients with tumor amenable to complete excision fare better than those who have subtotal resection or biopsy alone. However, the tumors that are most accessible to surgical excision are small and noninvasive and are confined to the organ or structure of origin. Assessment using a TNM system demonstrates that prognosis is dictated by tumor size and invasiveness rather than by the initial surgical approach.[87] Furthermore, combined modality therapy provides good local control of the primary tumor, even after subtotal excision.[88] For these reasons, local control most often consists of less aggressive surgical resection, with more reliance on radiation therapy and chemotherapy to provide control of local-regional disease.[17]

In cases of suspected RMS, the initial surgical procedure should be an incisional biopsy. Surgical excision is indicated if it can be done without compromise of function or cosmesis. Normal tissue margins of at least 5 mm around the tumor are usually required to consider the resection complete (IRS group I), although this is sometimes not feasible in some anatomic sites and smaller margins may suffice. If microscopic disease remains after initial resection, a primary reexcision can be considered prior to begin chemotherapy. Those children who can be rendered microscopically free of disease by this procedure have an improved outcome, compared with children who remain in clinical group II following initial surgery.[89,90] Amputation of an extremity, orbital exenteration, mutilating surgery of the head and neck area, therapeutic lymphadenectomy, and radical neck dissection are not routinely performed upfront and are instead reserved in case initial therapy fails.

Second-look operations (also termed *delayed primary excisions* [DPEs]) may be useful for converting partial responses after chemotherapy into complete responses, and there is conflicting evidence regarding whether these procedures affect oncologic outcomes.[12,48,85,91] The IRS-V study evaluated whether DPE might allow a reduction in the amount of radiotherapy that is necessary to provide local tumor control; local control following DPE and reduced-dose radiation for bladder dome, extremity, and trunk tumors was similar to historic results after higher doses of definitive radiation. Some investigators have used second-look operations in an attempt to eliminate radiotherapy, although this approach of radiation omission has resulted in inferior local control and survival and has not been

recommended on previous COG trials.[92] Second-look operations may be used to evaluate therapeutic response after chemotherapy or radiation therapy. In the IRS-III study, 28% of patients categorized as having clinical partial response and 43% of those scored as having no response to induction chemotherapy were reclassified as having pathologic complete response after second-look operation.[93] These children enjoyed a survival rate similar to that of children who were able to undergo complete surgical excision at the time of initial diagnosis. Therefore, a clinical or radiographic evaluation indicating residual tumor after initial therapy may be misleading and is not associated with worse outcomes. Further investigation of the role of DPE and potential oncologic benefit (or lack thereof) on ARST1431 is being evaluated.

Chemotherapy

Chemotherapy is necessary in all cases. Several drugs have demonstrated single-agent activity measured as a percentage response rate, including vincristine (59%), dactinomycin (24%), cyclophosphamide (54%), cisplatin (15%-21%), dacarbazine (11%), mitomycin-C (36%), etoposide (15%-21%), ifosfamide (86%), irinotecan (23%), and topotecan (46%).[94-96] Agents with known activity against central nervous system tumors, such as nitrosoureas and methotrexate, have not shown activity against RMS.

The most extensive experience in combination chemotherapy is with VAC. Some studies have suggested that patients with embryonal histology tumors in favorable sites who have no gross residual disease or lymph node involvement after the initial surgical resection may be adequately treated with VA for 1 year, provided that irradiation is given for microscopic residual disease.[17] However, data from the IRS-V study and ARST0531 suggest that local control for low- and intermediate-risk RMS may be compromised when alkylating agents are omitted or reduced in dose.[35,36,97] Patients with unresectable pelvic tumors may benefit from the addition of doxorubicin and cisplatin to VAC, but tumors in other sites do not seem to benefit from the addition of these drugs compared with an intensive regimen of VAC alone.

Some subsets of patients, such as those with tumors of unfavorable histology or unfavorable site and those with extensive tumor burden,

continue to fare poorly. Some of these patients with embryonal histology may benefit from intensification of the cyclophosphamide or ifosfamide component of their chemotherapy, although there are conflicting data regarding this.[98,99] Patients with metastatic RMS may benefit from the addition of ifosfamide and etoposide to the standard VAC regimen,[100] and the role of upfront vinorelbine for the treatment of metastatic RMS is currently being explored on ARST2031. High-dose chemotherapy with total-body irradiation and autologous bone marrow transplantation has not improved the outcome in these high-risk patients.[71,72]

Initial intensive chemotherapy has been used as a means of pharmacologic debulking, potentially allowing for a more conservative surgical approach or less aggressive radiation therapy.[52,101,102] However, data consistently fail to show that response to induction chemotherapy predicts the ultimate outcome.[14,103] When chemotherapy alone is used for tumors in sites such as the head and neck or pelvis, most children require radiation therapy.[18,37,104,105] Omission of radiotherapy in these patients may result in inferior survival.[92,106] Even patients with only microscopic disease after initial resection (group II) require radiotherapy to achieve optimal local control.[107] In patients with group II disease who routinely receive radiotherapy, local control is 92%.[108] The approach of initial chemotherapy followed by limited irradiation or less radical surgery may be appropriate in the management of infants and very young children, in whom late effects of aggressive surgery or high-dose, large-volume irradiation are particularly severe, although this may lead to inferior local control and survival.

Radiation Therapy

Adequate irradiation implies careful attention to volume and dose. It is essential to evaluate the soft tissue extent of the primary lesion with cross-sectional imaging by CT scan and often MRI. Because RMS tends to infiltrate tissue planes widely, tumors often extend beyond a fascial compartment and beyond the obvious visible margins. Careful examination by a radiation oncologist at the time of initial diagnosis, even if the treatment plan calls for neoadjuvant chemotherapy, is essential to establish the appropriate tumor volume.

Treatment portals are designed to encompass the involved region at the time of presentation (before chemotherapy) with margins that encompass surgical sites and biopsy tracts. A biopsy should be performed of clinically suspicious lymph nodes, or they should be included in the radiation therapy portal. Prophylactic lymph node irradiation is not necessary for children with clinically negative findings who will be receiving combination chemotherapy. The gross tumor volume is defined as the tumor as seen at the time of initial diagnosis. A clinical target volume of 1 cm is added and can be modified to account for anatomic barriers to tumor spread (such as the bony orbit in primary orbital tumors) or to account for regression of "pushing" the tumor border after chemotherapy, such as may occur in large pelvic tumors that initially displace contents of the peritoneal cavity. The planning target volume adds a patient-specific margin, which is typically about 5 mm, although varies by setup and radiation technique (protons vs photons). Many current treatment protocols use a cone-down boost or simultaneous integrated boost to any gross post-treatment tumor volume after a microscopic tumor dose has been delivered. Patients with tumors at parameningeal sites (middle ear, paranasal sinuses, nasopharynx, nasal cavity, infratemporal fossa, and parapharyngeal area) have developed meningeal extension of tumor when inadequate irradiation portals were used.[44] With improved imaging modalities, intracranial extension may be more accurately delineated, and radiation therapy volumes that cover any involved adjacent meninges are necessary.[17,42]

Intensity-modulated radiotherapy treatment planning techniques are valuable for ensuring adequate treatment of the tumor volume and minimizing acute and chronic toxicity from the irradiation of uninvolved, adjacent structures.[42,109-111] Proton-beam radiotherapy is being increasingly utilized as access to this form of therapy increases,[40] and dosimetric studies consistently demonstrate decreases of integral dose to normal structures compared to photon-based techniques for many children with RMS (Figures 93.6 and 93.7).[112,113] Local control and survival outcomes appear similar after proton radiation compared to historical cohorts treated with photon radiation. In addition, acute and early late toxicity rates with protons appear quite promising, especially for tumors in the head and neck region.[114] Follow-up is limited, though, and long-term toxicity data are necessary to follow up for adverse events that may take many years to develop.

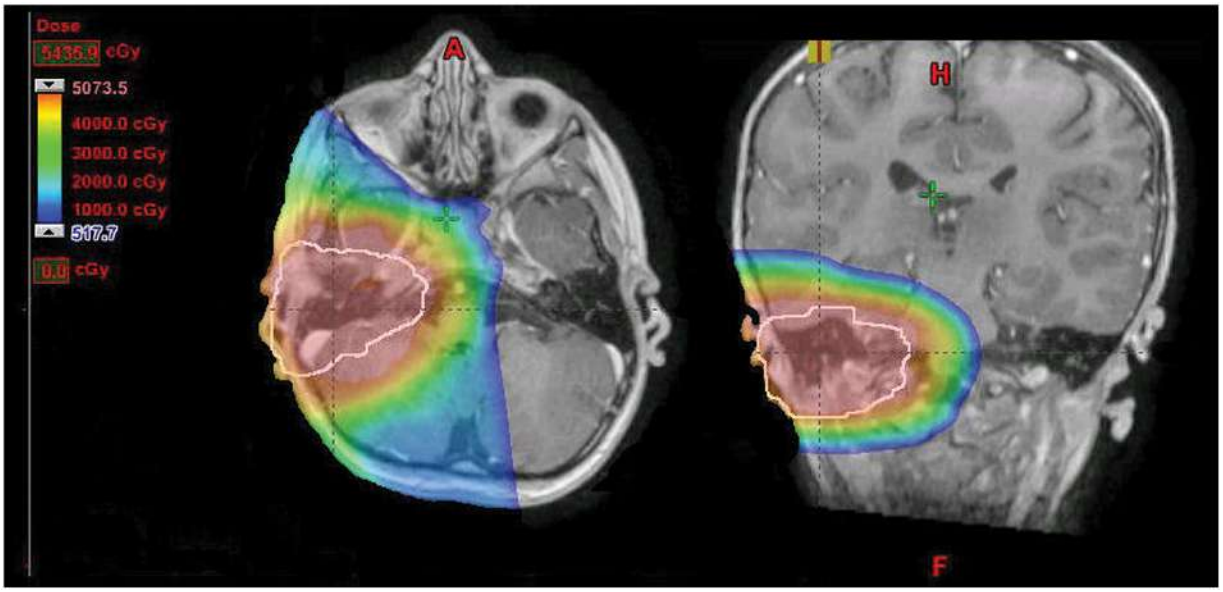

FIGURE 93.6 Isodose distribution in the axial and coronal planes for treatment of a middle ear rhabdomyosarcoma using protons. The physical properties of protons permit complete sparing of the contralateral structures and ipsilateral eye. 3D-CRT, three-dimensional conformal radiation therapy; VMAT, volumetric arc–based therapy. (Courtesy of Danny Indelicato, MD.)

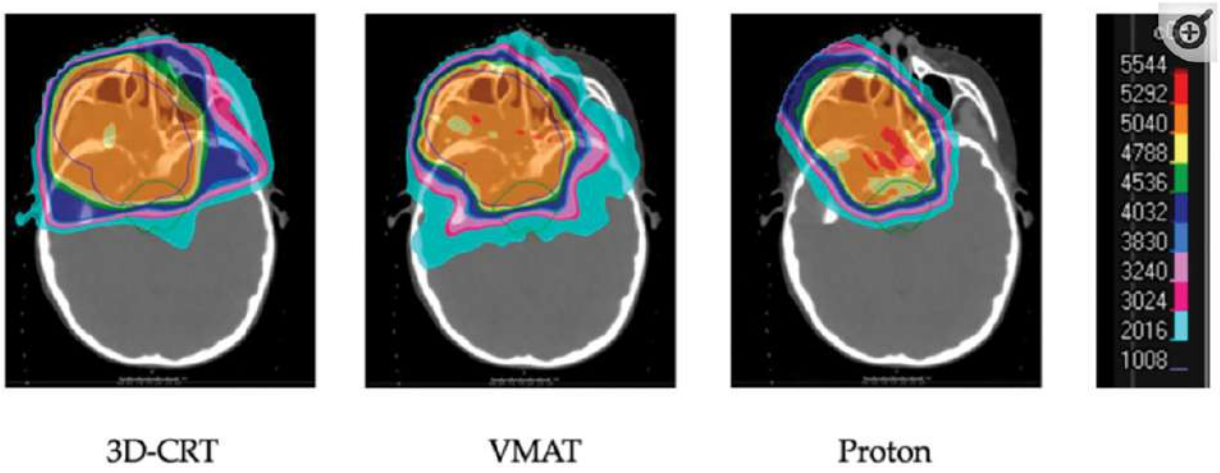

FIGURE 93.7 Comparison of isodose distribution in the axial planes for treatment of parameningeal rhabdomyosarcoma using three-dimensional conformal radiation therapy, volumetric arc–based therapy, and proton therapy, highlighting the reduction in dose to normal tissue with proton therapy. (Courtesy of Andrew Frankart, MD.)

Immobilization techniques that ensure reproducibility are essential. Sedation or anesthesia may be necessary to ensure adequate implementation of the treatment plan in young children. These complex programs are best

conducted in regional centers by an experienced team of physicians, including a pediatric surgeon, pediatric anesthesiologist, pediatric oncologist, and radiation oncologist.

Local control of gross disease in most anatomic sites requires doses of 50 to 55 Gy. In the IRS-IV study, investigators studied the efficacy of a higher radiation dose (59.4 Gy), given in 1.1-Gy fractions twice daily at 6-hour intervals for children with gross residual disease.[115] This hyperfractionated regimen was compared in a prospective, randomized manner to a standard radiotherapy regimen consisting of 50.4 Gy given as 1.8 Gy once daily. There was no difference in locoregional disease control, failure-free survival, or overall survival between the two groups. Therefore, the standard of care for group III RMS continues to be conventionally fractionated radiation (50.4 Gy) with chemotherapy. The value of a boost to 59.4 Gy delivered with daily fractionation for group III tumors measuring 5 cm or more in size at diagnosis is being investigated in the recently closed ARST1431 trial for intermediate-risk patients.

Ninety percent of patients with microscopic residual tumor achieve local control with 41.4 Gy, and the D9602 study results suggest that 36 Gy may be adequate for microscopically positive margins that are not associated with lymph node involvement as described in more detail later. Investigators have been unable to generate a strict dose-response curve but have observed an association with age that suggests that lower doses, often given to infants and youngsters, are associated with higher relapse rates.[116] They also suggest that local tumor control is greater for tumors less than 5 cm in diameter than for larger lesions, supporting the adult experience with soft tissue sarcomas and the investigation of a radiation boost for these larger tumors.[84,117,118]

The results of the IRS-I study had indicated that radiotherapy was not needed for patients whose tumors were completely resected at diagnosis (group I). Subsequently, a reanalysis of data from the IRS-I to IRS-III studies suggested that the subset of group I patients with alveolar or undifferentiated histology had improved overall and failure-free survival when radiotherapy was given to the primary tumor site.[119] A more recent analysis using data from IRS-IV did not, however, show a significant advantage for radiotherapy in group I alveolar tumors. This practice is

currently under review for the next generation of RMS protocols, with fusion status playing a critical role in risk stratification.[120]

Interstitial radiation therapy may play a role as primary treatment or as a boost after external beam therapy for selected sites at specialized centers.[46,66] The advantages of precise shaping of the dose distribution, sharp falloff of radiation dose, and shortening of overall treatment time are especially attractive in dealing with infants and young children. Some investigators report a decrease in late normal tissue effects when compared with external beam techniques.[121] There are no data regarding comparative efficacy or toxicity between high-dose rate and low-dose rate techniques. However, high-dose rate remote brachytherapy may be particularly attractive in this patient population for logistical reasons. These children often require extensive care from family members and medical personnel during their treatment, and high-dose rate techniques can eliminate radiation exposure to these caregivers.

The timing of radiation therapy must be carefully coordinated with planned surgical intervention and combination chemotherapy scheduling to optimize local control and ensure optimization of drug doses and unimpaired postoperative healing. Although radiation therapy is often delayed for several weeks (approximately weeks 12-13) to allow administration of neoadjuvant chemotherapy, some data suggest that earlier irradiation, particularly in high-risk parameningeal patients with intracranial extension, may provide better local tumor control.[42,122,123] Interaction between radiation and some of the commonly used chemotherapeutic drugs can produce undesirable early and late effects. This is particularly true of dactinomycin and doxorubicin. Radiation therapy given concurrently with these agents is usually avoided. In contrast, systemic treatment with drugs such as vincristine and cyclophosphamide can usually be continued concurrently with the administration of irradiation.

Retrieval Therapy

Salvage after recurrence of RMS is difficult, which probably accounts for the inferior survival seen with treatment approaches that do not maximize therapy at the time of initial diagnosis.[106,124] Because local recurrence is the most common pattern of failure, surgery, and radiotherapy play especially

important roles in the treatment of these children. Aggressive treatment programs utilizing radical resection and brachytherapy have had success in selected patients with head and neck RMS.[46] Care must be taken when evaluating patients for local recurrence. Residual masses can be seen in as many as 40% of children who are shown to be pathologically free of tumor.[125]

SEQUELAE OF TREATMENT

Acute Effects

Acute side effects from surgery are primarily postoperative complications that are usually reversible and not serious. The acute toxicity from chemotherapy includes nausea, vomiting, mucositis, alopecia, and hematopoietic suppression. Drug-induced granulocytopenia significantly increases the risk of fever and infection, although the routine use of granulocyte colony–stimulating factor has lessened these risks. Protocols using more aggressive therapy, including topoisomerase inhibitors, ifosfamide, etoposide, and other agents, have other acute side effects, including renal and electrolyte imbalance, which demand close monitoring.

Acute radiation toxicity is related to the regions irradiated and the dose administered. It can be especially pronounced for tumors of the head and neck, abdomen, and pelvis. The synergistic effect of chemotherapeutic drugs such as dactinomycin and doxorubicin can be severe and may require modification of the treatment plan. Both dactinomycin and doxorubicin are known to accentuate a “recall” of radiation injury if given during or immediately after the course of radiation therapy.

Prompt attention to skin care is important. Moisturizers and steroid creams are effective symptomatic treatments for erythema and dry desquamation. Moist desquamation may be treated with aluminum acetate soaks or hydrocolloid dressings. Occasionally, a delay in radiation therapy is necessary to permit healing.

After orbital irradiation, an acute inflammatory reaction of the cornea and conjunctiva may be seen within weeks of completion of treatment. This can result in pain and photophobia. Topical steroids should be administered under the direction of an ophthalmologist for these symptoms.

Acute otitis externa or media with hyperemia and swelling of the membranes of the eustachian tube is common during or soon after treatment of head and neck areas. Decongestants are helpful in reducing the swelling. Erythematous mucositis, leading to a patchy, fibrinous exudate, is seen after head and neck irradiation, after drug therapy, and almost universally if the two are used simultaneously. Mouthwashes such as baking soda, 1% hydrogen peroxide, or combinations of diphenhydramine elixir, hydrocortisone, and antibiotics partially alleviate the reaction. Bacterial or fungal superinfection requires specific drug management. Pretreatment evaluation by a dentist is important to correct preexisting problems and help guide preventive therapy, such as dental hygiene and fluoride applications.

Acute gastrointestinal sequelae, such as vomiting and diarrhea, are usually managed by supportive care. Parenteral nutritional support may be necessary to prevent protein or calorie malnutrition.

Late Effects

Life-threatening late events occur in approximately 9% of survivors after treatment.[33] A higher percentage experience lesser degrees of late morbidity, with the risks dependent on factors such as primary tumor site, disease stage, and the treatment modalities employed.

Long-term sequelae related to specific chemotherapy drugs are usually organ specific, and the morbidity may be accentuated by radiation therapy. Cyclophosphamide may induce hemorrhagic cystitis, and doxorubicin is implicated in late myocardiopathies.[126] Cisplatin carries a high incidence of hearing impairment. Alkylating agents and topoisomerase inhibitors are associated with the development of secondary neoplasms, particularly acute myeloid leukemia.[127,128]

Late radiation effects are related to the irradiated site, the dose of radiation, and the age of the child at the time of treatment. Effects include bone and soft tissue growth disturbances, dental abnormalities, cataract, hypopituitarism, gonadal dysfunction, induction of second malignant tumors (particularly bone sarcomas), and chronic organ dysfunction.[56,127,129-131] Long-term follow-up and treatment are important to minimize the impact of these, particularly for endocrine and dental complications.[132] Combined modality treatment programs are significantly implicated in many of these

complications. Long-term follow-up and data are needed to determine whether proton therapy can reduce the incidence of the abovementioned late radiation effects compared to photon-based techniques.

Late surgical complications depend mainly on the choice of surgical procedure for the primary treatment of the tumor. They include disfigurement and loss of function. Serious late effects of surgical treatment include the consequences of fecal and urinary diversion as well as ejaculatory impotence after retroperitoneal lymph node dissection. Long-term complications from initial surgical resections or DPE have not been reported.

FUTURE DIRECTIONS AND RESEARCH

Advances in molecular biology are providing a more comprehensive understanding of the biologic behavior of RMS and directing new research initiatives. Although the PAX3-FOXO1 fusion gene plays a key role in the oncogenesis of fusion-positive RMS, its targeting for therapeutic purposes has thus far been unsuccessful due to its nuclear localization, lack of catalytic activity, and disordered state. Attempts to target its co-regulators and other chromatin-remodeling proteins are currently underway, as well as investigation of histone deacetylase inhibitors, drugs that target the RAS pathway, and drugs that can take advantage of the dysregulated DNA damage response that is sometimes observed.[133] The utility of circulating tumor DNA to inform management is also under current investigation.

With advances in molecular characterization of RMS, fusion-negative RMS has been found to have recurrent point mutations in genes, such as *TP53*, *NRAS*, *KRAS*, *HRAS*, *MYOD1*, *FGFR4*, and *PIK3CA*. Among these, *TP53* and *MYOD1* have been associated with significantly worse survival outcomes.[134,135] As a result, these alterations are now incorporated into risk classification in the ongoing COG trials, and patients who harbor these mutations are treated with more intensive systemic therapy.

The recently closed ARST1431 trial did not show a clear benefit of adding temsirolimus for intermediate-risk patients in initial results, although final publication is pending. The current generation of COG STS studies tests a number of clinical hypotheses, including testing the ability to reduce the duration of chemotherapy for molecularly favorable low-risk tumors,

boosting tumors initially measuring more than 5 cm to 59.4 Gy total, evaluating the prognostic value of early treatment response as assessed by PET imaging, exploring the utility of circulating tumor DNA, investigating the ideal dose of cyclophosphamide for optimal local control and survival outcomes, and testing the value of SBRT and comprehensive radiation to metastatic sites for those with high-risk disease. Future directions and research in RMS are being driven by many exciting molecular biologic and technological advances.

CHAPTER 94

Nonrhabdomyosarcoma Soft Tissue Sarcoma in Children

Leslie Chang, Erin McCammack, Dana L. Casey, Susan Hiniker, Colette J. Shen, and Stephanie A. Terezakis

EPIDEMIOLOGY

Soft tissue sarcomas (STS) are a group of rare tumors that arise primarily from mesenchymal cells in connective tissues. Approximately 900 pediatric patients a year are diagnosed with STS, amounting to about 7% of all pediatric malignancies.[1] STS in pediatric patients is classified into two groups: rhabdomyosarcoma (RMS) and nonrhabdomyosarcoma soft tissue sarcoma (NRSTS). NRSTS accounts for approximately 60% of pediatric STS diagnoses annually,[2] with incidence highest in adolescence from 10 to 19 years of age.[1] The incidence of STS subtypes varies with age; in infancy, infantile fibrosarcoma, malignant rhabdoid tumor, and RMS are the most common histologies, whereas synovial sarcoma and malignant peripheral nerve sheath tumor (MPNST) are observed more frequently in the adolescent population.[1] Although the etiology of NRSTS is unclear in the majority of patients, there are several genetic predisposing conditions associated with the development of NRSTS: Neurofibromatosis 1 (NF1) is associated with MPNST, Li-Fraumeni germline P53 mutation leads to increased risk of NRSTS and retinoblastoma, DICER1 and APC mutations can lead to desmoid fibromatosis, and IN1 deficiency can lead to malignant rhabdoid tumor. In addition, the risk of secondary sarcoma is increased after exposure to radiation and anthracyclines.[1]

PATHOLOGY

The classification of soft tissue tumors is based on the World Health Organization (WHO) Classification of Tumors of Soft Tissue and Bone, with the fifth edition published in 2020,[3] as well as within the WHO Classification of Paediatric Tumors, published in 2022. Histologic classification is determined by cellular differentiation and molecular drivers. Each tumor entity is then grouped according to biologic behavior: benign, intermediate locally recurrent or rarely metastasizing, and malignant locally aggressive with a risk of distant metastasis. Table 94.1 includes the most common intermediate and malignant NRSTS histologies in pediatric patients, which require more aggressive treatment based on their pathologic and clinical risk factors. Although benign neoplasms are not discussed in this chapter, they comprise a large proportion of histologic entities and may still have rapid growth or local recurrence, despite not being locally destructive or metastatic.

TABLE 94.1 WHO CLASSIFICATION OF TUMORS OF SOFT TISSUE

Classification	Intermediate Entities: Locally aggressive or Rarely Metastasizing	Variants	Malignant Entities	Variants
Adipocytic	Atypical lipomatous tumor		Liposarcoma, well differentiated, NOS	Lipoma-like liposarcoma Inflammatory liposarcoma Sclerosing liposarcoma
			Dedifferentiated liposarcoma	
			Myxoid liposarcoma	
			Pleomorphic liposarcoma	Epithelioid liposarcoma

Classification	Intermediate Entities: Locally aggressive or Rarely Metastasizing	Variants	Malignant Entities	Variants
			Myxoid pleomorphic liposarcoma	
Fibroblastic and myofibroblastic	Solitary fibrous tumor, benign		Solitary fibrous tumor, malignant	
	Palmar/plantar-type fibromatosis		Fibrosarcoma, NOS	
	Desmoid-type fibromatosis	Extra-abdominal desmoid Abdominal fibromatosis	Myxofibrosarcoma	Epithelioid myxofibrosarcoma
			Low-grade fibromyxoid sarcoma	
	Lipofibromatosis		Sclerosing epithelioid fibrosarcoma	
	Giant cell fibroblastoma			
	Dermatofibrosarcoma protuberans, NOS	Pigmented dermatofibrosarcoma protuberans Dermatofibrosarcoma protuberans, fibrosarcomatous Myxoid dermatofibrosarcoma protuberans Plaque-like dermatofibrosarcoma protuberans		
	Solitary fibrous tumor, NOS	Fat-forming solitary fibrous tumor Giant cell–rich solitary fibrous tumor		
	Inflammatory myofibroblastic tumor	Epithelioid inflammatory myofibroblastic sarcoma		
	Myofibroblastic sarcoma			
	Superficial CD34-positive fibroblastic tumor			
	Myxoinflammatory fibroblastic sarcoma			
	Infantile fibrosarcoma			
Fibrohistiocytic tumors	Plexiform fibrohistiocytic tumor		Malignant tenosynovial giant cell tumor	
	Giant cell tumor of soft parts, NOS			
Vascular	Kaposiform hemangioendothelioma		Epithelioid hemangioendothelioma, NOS	Epithelioid hemangioendothelioma with WWTR1-CAMTA1 fusion Epithelioid hemangioendothelioma with YAP1-TFE3 fusion
	Retiform hemangioendothelioma			
	Papillary intralymphatic angioendothelioma		Angiosarcoma	
	Composite hemangioendothelioma	Neuroendocrine composite		

Classification	Intermediate Entities: Locally aggressive or Rarely Metastasizing	Variants	Malignant Entities	Variants
		hemangioendothelioma		
	Kaposi sarcoma	Classic indolent Kaposi sarcoma Endemic African Kaposi sarcoma AIDS-associated Kaposi sarcoma Iatrogenic Kaposi sarcoma		
	Pseudomyogenic (epithelioid sarcoma–like) hemangioendothelioma			
Perivascular	Glomus tumor, NOS	Glomangioma Glomangiomyoma Glomangiomatosis Glomus tumor of uncertain malignant potential	Glomus tumor, malignant	
	Myopericytoma	Myofibromatosis Myofibroma Infantile myofibromatosis		
	Angioleiomyoma			
Smooth muscle	Leiomyoma, NOS		Leiomyosarcoma, NOS	
	EBV-associated smooth muscle tumor/smooth muscle tumor of uncertain malignant potential		Inflammatory leiomyosarcoma	
Gastrointestinal stromal tumors			Gastrointestinal stromal tumor	
Peripheral nerve sheath tumor			Malignant peripheral nerve sheath tumor, NOS	Malignant peripheral nerve sheath tumor, epithelioid
			Melanotic malignant peripheral nerve sheath tumor	
			Granular cell tumor, malignant	
			Perineurioma, malignant	
Tumors of uncertain differentiation	Hemosiderotic fibrolipomatous tumor		Phosphaturic mesenchymal tumor, malignant	NTRK-rearranged spindle cell neoplasm (emerging)
	Angiomyolipoma, epithelioid		Synovial sarcoma	Synovial sarcoma, spindle cell Synovial sarcoma, biphasic Synovial sarcoma, poorly differentiated
	Atypical fibroxanthoma			
	Angiomatoid fibrous histiocytoma			
	Ossifying fibromyxoid tumor, NOS		Epithelioid sarcoma	Proximal or large cell epithelioid sarcoma Classic epithelioid sarcoma
	Mixed tumor, NOS			

Classification	Intermediate Entities: Locally aggressive or Rarely Metastasizing	Variants	Malignant Entities	Variants
	Mixed tumor, malignant, NOS		Alveolar soft-part sarcoma	
	Myoepithelioma, NOS		Clear cell sarcoma, NOS	
			Extraskeletal myxoid chondrosarcoma	
			Desmoplastic small round cell tumor	
			Rhabdoid tumor, NOS	
			Perivascular epithelioid tumor, malignant	
			Intimal sarcoma	
			Myoepithelial carcinoma	
			Undifferentiated sarcoma	Spindle cell sarcoma, undifferentiated Pleomorphic sarcoma, undifferentiated Round cell sarcoma, undifferentiated

AIDS, acquired immunodeficiency syndrome; EBV, Epstein-Barr virus; NOS, not otherwise specified; NTRK, neurotrophic tyrosine receptor kinase; WHO, World Health Organization.
Data from Sbaraglia M, Bellan E, Dei Tos AP. The 2020 WHO classification of soft tissue tumours: news and perspectives. *Pathologica*. 2021;113(2):70-84.

There are significant differences in the prevalence, biology, prognostic factors, response to therapy, and outcomes of STS histologic subtypes in pediatric versus adult patients.[4] This chapter first discusses the pathophysiology and management considerations according to specific tumor subtypes and then describes the overall approach to treatment for NRSTS.

Adipocytic

Of the adipocytic class of tumors, there are few that occur in pediatric patients. Myxoid liposarcoma and myxoid pleomorphic liposarcoma are the most common adipocytic subtypes in young patients; myxoid pleomorphic liposarcoma frequently occurs in the mediastinum.[5] The most common adipocytic tumor in all patients is the atypical lipomatous tumor or well-differentiated liposarcoma, which is very rare in children, but can be associated with Li-Fraumeni syndrome.[6]

Fibroblastic and Myofibroblastic

There are several locally aggressive entities within the fibroblastic and myofibroblastic classification that occur in pediatric patients. Desmoid fibromatosis is a locally aggressive tumor that can be associated with familial adenomatous polyposis and is usually located in the abdomen but can occur in the head and neck.[7] The majority of desmoid tumors result from a gain-of-function mutation in beta-catenin (CTNNB1) with constitutive activation of the Wnt pathway.[8] Notably the primary approach to treatment is active surveillance, with surgery reserved for patients who fail observation.[9] Lipofibromatosis, or infantile fibromatosis, is a locally aggressive entity that can be congenital with a median age of presentation of 1 year, occurring most commonly on the extremities, hands, or feet.[10] Giant cell fibroblastoma is another locally aggressive entity in childhood that can evolve into dermatofibrosarcoma protuberans (DFSP); both entities can bear a (17;22)(q22;q13) translocation, resulting in a *COL1A1::PDGFB* gene fusion.[11] DFSP is typically well localized and most frequently identified in

childhood or early adulthood. It has been described as slow growing before a more rapid period of growth.[12]

The fibroblastic and myofibroblastic entities with metastatic potential are few. DFSP can transform into a fibrosarcomatous variant with an increased risk of recurrence and metastasis.[13] Inflammatory myofibroblastic tumor has a predilection for children and can present with elevated inflammatory markers and systemic symptoms thought to be related to cytokine release.[14] Infantile fibrosarcoma presents before age 2 with rapid growth, with most cases harboring a (12;15)(p13;q26) translocation, in contrast to adult-type fibrosarcoma, which occurs after age 10 and is not associated with translocation.[15] Low-grade fibromyxoid sarcoma is occurring with increasing frequency in pediatric patients, is located most commonly in the thigh and trunk, and has the potential to metastasize.[16]

Fibrohistiocytic

The fibrohistiocytic class of tumors includes only a few entities. Within this group, the most common entity in the pediatric population is plexiform fibrohistiocytic tumor. Plexiform fibrohistiocytic tumor presents on average at age 14, with female predominance; it typically occurs on the extremities, with a tendency to recur locally rather than metastasize.[17]

Vascular

Within the vascular classification of STS, there are a number of entities that are locally aggressive and occur in pediatric populations. Kaposiform hemangioendothelioma (KHE) is a solitary tumor that presents at birth or during infancy.[18] Tufted angioma, a precursor to KHE, is superficial and likely to regress, while KHE is locally aggressive, presenting as a violaceous plaque within the trunk or extremities, often associated with a thrombocytopenic coagulopathy known as Kasabach-Merritt phenomenon.[18] Retiform hemangioendothelioma typically pres ents after age 10 as a violaceous plaque on the skin of the extremities and is locally aggressive.[19] The papillary intralymphatic angioendothelioma, Dabska tumor, occurs on the skin of children and rarely metastasizes to nodes.[20] The composite hemangioendothelioma occurs across the pediatric age spectrum, is located on the hands and feet, and is locally aggressive with low metastatic potential.[21] Kaposi sarcoma related to human herpesvirus 8 can be found in children; the variant that is endemic to Sub-Saharan Africa can present in the viscera or lymph nodes, while Kaposi sarcoma associated with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome occurs on mucosa, skin, and viscera.[22] Lastly, pseudomyogenic hemangioendothelioma occurs typically as a nodule of the lower limbs of young male patients and is locally aggressive, but rarely metastatic.[23]

Of the malignant entities within the vascular class of tumors, epithelioid hemangioendothelioma and angiosarcoma occur rarely in pediatric patients. Epithelioid hemangioendothelioma occurs mostly in females on any body location and is often multifocal and infiltrative.[24] Angiosarcoma in the first two decades of life is exceedingly rare; when it occurs, it is aggressive, typically occurring in the head, neck, or mediastinum.[25]

Perivascular

There are two main types of perivascular tumors that can be found in pediatric patients: glomus tumor and myopericytoma. The glomus tumor occurs primarily in the extremities.[26] Myopericytoma is also most common in the extremities and has a male predominance.[27] Both tumors are typically benign but can be locally aggressive or malignant depending upon the level of nuclear atypia, infiltrative growth, and mitotic figures.

Smooth Muscle

Several tumors that arise from smooth muscle can occur in young patients. The Epstein-Barr virus–associated smooth muscle tumor occurs in the setting of immunodeficiency. In adults, it is found in association with HIV or post-transplant. In pediatric patients, it is seen in association with primary immunodeficiency disorders like GATA2 and CARMIL2 deficiency.[28] These tumors occur anywhere in the body, are unlikely to metastasize, and often require stem cell transplant as part of the treatment regimen.[28] Leiomyosarcoma is rare in pediatric patients. When it occurs, it is typically low grade and can be associated with hereditary retinoblastoma, Li-Fraumeni syndrome, and radiation exposure.[29] It can occur in any body location, but in children, it is more common in the gastrointestinal tract.[30] Childhood leiomyosarcoma is similar to gastrointestinal stromal tumor but can be distinguished on the basis of CD117 (KIT) staining patterns, which helps guide treatment options.[31]

Peripheral Nerve Sheath Tumors

As previously mentioned, the peripheral nerve sheath tumors are seen in children and young adults. MPNST commonly occurs in the trunk and extremities; the risk of MPNST in the setting of NF1 is around 10%.[32] MPNST has a high propensity for local relapse without complete surgical resection; however, large tumor size and extensive nerve involvement often impede negative margin resection.[33] Distant metastatic progression is also common, with up to 40% of patients developing metastases during their disease course. Malignant melanotic nerve sheath tumor or melanotic schwannoma is a very rare type of nerve sheath tumor that commonly involves the paravertebral nerve roots and can be associated with the multiple neoplasia syndrome Carney complex.[34] Granular cell tumors are typically solitary slow-growing lesions that occur sporadically in all body sites; they have been observed in the setting of NF, Noonan syndrome, and LEOPARD syndrome.[35,36] Finally, intraneural and soft tissue perineurioma occur in the arms and legs, while intraneural perineurioma can present with weakness, muscle atrophy, and sensory disturbances, soft tissue perineurioma typically presents with a painless mass.[37]

Tumors of Uncertain Differentiation

The last class of tumors to be discussed encompasses all NRSTS of uncertain differentiation. Angiomatoid fibrous histiocytoma is locally aggressive, occurring on the superficial extremities of children and young adults, and has a small risk of metastasis; it is associated with fusion of EWSR1/ATF1 as well as EWSR1/CREB1.[38] Ossifying fibromyxoid tumor can be seen in young adults, most commonly in the lower extremities, and presents as a slow-growing, painless mass.[39] Mixed tumor, myoepithelioma, and, the more aggressive entity, myoepithelial carcinoma arise as a nodule with progressive growth on the trunk and extremities and can be seen in newborns throughout teenage years.[40]

There are numerous malignant tumors of uncertain differentiation that occur in pediatric patients. In all, 17% of synovial sarcoma occurs in pediatric patients.[41] Synovial sarcoma can occur anywhere in the body but is most common in the extremities; it has characteristic fusion (X;18)(p11;q11), resulting in impaired tumor suppressor function.[42] Clear cell sarcoma infrequently occurs in teens and young adults, is most common in the lower extremities, and, like angiomatoid fibrous histiocytoma, can result from fusion of EWSR1/ATF1 or EWSR1/CREB1.[38] Malignant epithelioid tumor comprises 4% to 8% of NRSTS in pediatric populations, can be associated with trauma at the site of tumor development, and occurs in the extremities or trunk.[43] Alveolar soft-part sarcoma has a tendency to metastasize and occurs first in the deep soft tissues of extremities of young adults or in the head and neck of children; it is associated with (X;17)(p11;q25) translocation.[44] Desmoplastic small round cell tumor primarily occurs in the abdomen of children and young adults with male predominance; the (11;22)(p13;q12) translocation has been observed in these tumors.[45] Rhabdoid tumor occurs in infants and young children and arises primarily in the brain and kidney, but has been described in other body sites; it can develop sporadically or in association with SMARCB1 mutation.[46] The perivascular epithelial cell tumor is rare in pediatric patients, with reports of occurrence starting after age 5, and can be associated with tuberous sclerosis.[47]

Last of all, undifferentiated sarcoma, a diagnosis of exclusion, includes spindle cell, pleomorphic (UPS), and round cell types; it is typically high grade and occurs in the extremities.[48] It is common in older adults, with a median age of 52, but can also occur in young adults.[49]

CLINICAL PRESENTATION

Clinical presentation varies depending upon the particular entity of NRSTS. Most commonly, NRSTS presents as a painless mass located in the trunk or extremities. Displacement of local structures can lead to symptoms, including numbness, weakness, pain, and swelling; systemic symptoms are uncommon with nonmetastatic disease.[50] Approximately 15% of patients present with distant metastatic disease at diagnosis. The most common site of metastatic disease involves the lung, and other less frequent sites of metastasis include bone, liver, and peritoneum. Involvement of the regional lymphatics is also rare, with the exception of clear cell sarcoma, angiosarcoma, and epithelioid sarcoma histologic subtypes.[51]

DIAGNOSTIC WORKUP

Ultrasound can be utilized for an initial evaluation to identify size, extent, homogeneity, and solid versus cystic components and to justify subsequent imaging. Following the ARST0332 protocol,[52] computed tomography (CT) and magnetic resonance imaging are then utilized in further evaluation of NRSTS primary lesions to provide soft tissue definition and define the extent of disease or invasion into the nearby structures. Biopsy, either core needle or incisional, is needed for diagnosis and should be carefully planned to be surgically excised or included within the radiation field during definitive management. For staging of high-grade/unresectable tumors, CT of the chest is required and CT of the abdomen and pelvis is often obtained. Fluorodeoxyglucose-positron emission tomography imaging is optional but encouraged particularly if patients undergo neoadjuvant chemoradiation for assessment of tumor response.

STAGING

Grade can be determined by two methods: Pediatric Oncology Group (POG) and French Federation of Cancer Centers Sarcoma Group (FNCLCC) grading systems. The POG system, a prospectively validated variation of the National Cancer Institute grading, defines tumor grade using the propensity for malignancy based on histologic subtype, percent necrosis, and mitotic count (Table 94.2).[53] In comparison, FNCLCC assigns a score for each of three categories: tumor differentiation, mitotic index, and tumor necrosis.[54] A sum equaling 2 or 3 is grade 1, 4 or 5 is grade 2, and 6 to 8 is grade 3 (Table 94.3).[55] Both the FNCLCC and POG systems provide adequate prognostic measures in NRSTS, with the mitotic index being a key parameter in grading pediatric NRSTS.[53] Comparing the POG and FNCLCC grading systems, the FNCLCC system was found to be a better predictor of tumor mortality and distant metastasis; this system may be favored in determining the aggressiveness of STS but may also lead to overtreatment.[56] Currently, the FNCLCC system is more widespread due to its use in adult STS. Prognosis including the risk of metastasis may be better evaluated by genetic signatures using tools such as CINSARC, which quantifies chromosomal complexity[54]; Genomic Grade Index[57]; and Immunologic Constant of Rejection gene signature[58]; importantly, the majority of this type of analysis has been based on adult tumor samples.

TABLE 94.2 PEDIATRIC ONCOLOGY GROUP GRADING SYSTEM

Grade	Description
1	Liposarcoma: myxoid and well differentiated Deep-seated dermatofibrosarcoma protuberans Fibrosarcoma: well differentiated or infantile (<5 y) Hemangiopericytoma: well differentiated or infantile (<5 y) Well-differentiated malignant peripheral nerve sheath tumor

Grade	Description
	Angiomatoid malignant fibrous histiocytoma
2	All NRSTS not in grades 1 or 3; <15% of tumors with geographic necrosis, or mitotic index <5 mitoses/10 HPFs
3	Fibrosarcoma with >15% of tumor with geographic necrosis or mitotic index >5 mitoses/10 HPFs Liposarcoma: pleomorphic, round cell Mesenchymal chondrosarcoma Extraskeletal osteosarcoma Malignant triton tumor

Prognostication requires stratification of several key factors, including the presence of distant and nodal metastases, histologic grade, size of the primary tumor (≤5 cm vs >5 cm), and extent of surgical resection.[52,59]

Per the North American Children's Oncology Group (COG) ARST0332, tumors are divided into three tiers of risk: low, intermediate, and high. Any nonmetastatic tumor is either low or intermediate risk. Low-risk tumors are resectable and low grade of any size or high grade with a maximal diameter of 5 cm or less. Intermediate-risk tumors are resectable, high grade, and larger than 5 cm or nonmetastatic, but unresectable. Finally, high-risk tumors are metastatic to lymph nodes and/or distant sites.[52] This risk group system was highly predictive of survival when tested in this prospective trial.

GENERAL TREATMENT PARADIGMS

Treatment decision-making is often complex, and patients should be treated using a multidisciplinary approach and enrolled in prospective clinical trials whenever possible. Two large multinational

prospective studies (ARST0332 and EpSSG NRSTS 2005) currently define the management for NRSTS.[52,59] Patients undergo a risk-stratified treatment paradigm based on initial clinicopathologic factors that include histologic grade, size of primary tumor, extent of surgery, and involvement of nodal or metastatic sites (Table 94.4).

TABLE 94.4 RISK STRATIFICATION AND TREATMENT

Staging	Treatment
Grade 1, R0-1 resection	Initial resection only, no adjuvant treatment
Grade 2-3, R0 resection, tumor size ≤5 cm	
Grade 2-3, R1 resection, tumor size ≤5 cm	Adjuvant radiation
Grade 2-3, R0-1 resection, tumor size >5 cm	Adjuvant chemotherapy +/− radiation
Grade 2-3, delayed surgery planned or unresectable, tumor size >5 cm	Neoadjuvant chemotherapy and radiation
Grade 2-3, metastatic NRSTS	

NRSTS, nonrhabdomyosarcoma soft tissue sarcoma.

Low Risk

Low-risk patients encompass those with low histologic grade (POG grade 1-2 or FNCLCC grade 1) with an R0 or R1 resection or a high-grade tumor (POG grade 3 or FNCLCC grade 2-3) 5 cm or smaller with R0 resection. These patients are treated with surgery alone as the risk of metastatic recurrence is extremely low. For patients who have a high-grade tumor with an R1 resection, they should receive adjuvant radiation to 54 to 55.8 Gy. Five-year event-free survival (EFS) was 89% to 91% and 5-year overall survival (OS) was greater than 90% in both ARST0332 and EpSSG NRSTS 2005.[52,59] There was a statistical difference in 5-year OS between low-grade histologies (>99%) and high-grade histologies (93%-96%) in both studies.

Intermediate Risk

Intermediate-risk patients require adjuvant therapy due to concern for local control or distant metastatic progression. These patients include high-grade tumors greater than 5 cm who receive neoadjuvant or adjuvant chemotherapy and radiation based on planned surgical resection. Chemotherapy is delivered using ifosfamide and doxorubicin, with timing dependent on the sequence of surgery and radiation. Preoperative radiation is delivered using 45 Gy in 1.8 Gy fractions. An additional boost of 9.0 to 10.8 Gy in 1.8 Gy fractions is delivered for R1 resection and 14.4 to 19.8 Gy for gross residual disease following surgical resection. In this cohort, the estimated 5-year OS was 79.2% in ARST0332 and 5-year EFS was 65.0%, with the majority of progressions being metastatic recurrence.[52] Comparatively, in the EpSSG NRSTS 2005 study, estimated 5-year EFS and OS for patients receiving chemotherapy were 66% and 76% for the adjuvant arm and 56% and 70% for the neoadjuvant arm, respectively.[59]

High-Risk/Metastatic Disease

The high-risk cohort is composed of patients with disease involving the lymph nodes or metastatic sites. If the tumor is low grade, surgical resection of the primary and all metastatic sites is recommended if feasible and no further adjuvant therapy is necessary. If the tumor is high grade, neoadjuvant chemotherapy with doxorubicin and ifosfamide is initiated, and patients with resectable disease may receive adjuvant chemotherapy and radiation. Unresectable metastatic sites should be evaluated for focal radiation treatment. Whole-lung or liver radiation is generally not recommended for diffuse metastases,

except in the setting of synovial sarcoma where whole-lung radiation is considered.[60] Estimated 5-year EFS for the high-risk cohort was 21% and OS was 36% in ARST0332.[52]

GENERAL MANAGEMENT

Surgery

En bloc surgical resection with R0 margins remains the mainstay of treatment for NRSTS. If there is concern for residual microscopic disease after initial resection, a primary reexcision should be performed to achieve a negative surgical margin. Extent of surgical resection is significantly associated with survival outcomes. Pediatric patients who received a gross total resection or microscopic residual disease had an estimated 5-year OS of 90%, which was significantly higher than patients who had macroscopic residual disease with an estimated 5-year survival of 63%.[52] Estimated 5-year OS was also significantly improved in patients who had negative margins as compared to those with microscopic residual disease (93% vs 80%). Although margin adequacy is still an ongoing question, particularly as wide margins are not feasible in a small child or in various anatomic locations, ARST0332 defined negative microscopic margins as 5 mm or larger[52]; however, more recent international consensus guidelines define a negative margin as greater than 1 mm.[61] For high-risk patients, neoadjuvant therapy and delayed resection were very successful in achieving local control, with up to 94% of patients achieving an R0/R1 resection.[62] Systematic lymph node sampling should be considered in certain histologic subtypes as the overall incidence of regional nodal dissemination is less than 10%. Lymph node sampling should be considered in pediatric patients with histologic subtypes with the highest incidence of lymph node metastases, which include epithelioid sarcoma (18%), angiosarcoma (17%), and clear cell sarcoma (14%),[51] with the caveat that many of these patients will have radiographic evidence of lymph node involvement.

Chemotherapy

The role of systemic therapy is largely derived from data on adult STS. In the two large prospective clinical trials on pediatric NRSTS, both the ARST0332 and EpSSG NRSTS 2005 trials utilized ifosfamide/doxorubicin-based chemotherapy, although the regimens were not identical. ARST0332 assigned (ifosfamide 9 g/m^2/cycle × 6 cycles and doxorubicin 75 mg/m^2/cycle × 5 cycles) to all patients treated with adjuvant or neoadjuvant chemotherapy.[62] EpSSG NRSTS 2005 utilized (ifosfamide 9 g/m^2/cycle × 3-7 cycles, doxorubicin 75 mg/m^2/cycle × 3-5 cycles), with cycles of chemotherapy dependent on histology (synovial sarcoma vs other histologies), tumor size, lymph node involvement, extent of resection, and margin status.[59] ARST1321 investigated the efficacy of neoadjuvant chemotherapy with the addition of a targeted tyrosine kinase inhibitor, pazopanib, which acts on the vascular endothelial growth factor receptor (VEGF-R), PDGF-R, and cKit pathways in STS.[63] Although the addition of pazopanib improved the rate of pathologic near-complete response (≥90% nonviable tumor) from 22% to 58%,[63] long-term outcomes did not find a difference in 3-year EFS (76% vs 65%, P = .19),[64] indicating pathologic near-complete response may not be a good surrogate marker for survival outcomes.

RADIATION THERAPY

Indications for radiation are based on the risk for disease progression and potential side effects. Postoperative radiation is recommended for high-grade tumors 5 cm or smaller with positive surgical margins and high-grade tumors greater than 5 cm, regardless of margin status due to the risk of local recurrence. Low-grade tumors do not need adjuvant radiation when gross total resection is completed unless there is a particular individual concern. Omission of radiation can also be considered in low-grade tumors with a positive microscopic surgical margin, as ARST0332 demonstrated 18% local recurrence without adjuvant radiation in low-grade tumors,[52] although further surgical resection for negative margins is often pursued. When the patient has unresectable primary disease or delayed resection is planned,

patients should receive preoperative chemoradiation to improve the extent of resection. This is recommended as compared to postoperative adjuvant radiation, as much of the irradiated tissue is resected and there is a higher likelihood of negative margins[65] as well as a less than 15% rate of wound complication.[52] Relative to historical neoadjuvant chemoradiation with wound complication rates near 35%,[66] the use of modern techniques has significantly decreased this rate; these data mirror wound complication rates in modern adult STS neoadjuvant paradigms.[67] In addition, volumes for preoperative radiation are often smaller than those utilized for postoperative radiation, which can, in turn, lead to less late morbidity such as fibrosis.

Radiation Dose and Volumes

Radiation volumes in the pediatric population are smaller than in adults in effort to decrease long-term toxicity. With this approach, prospective studies have demonstrated low rates of local failure. For unresected tumors, preoperative radiation (45-50.4 Gy) is delivered to the initial target volume (gross tumor volume [GTV]) as defined by preoperative imaging (Figure 94.1). The full list of dose fractionation schema for preoperative and postoperative volumes is given in Table 94.5. Clinical target volume (CTV) should include at least a 1.5-cm expansion, with consideration of areas with potential occult tumor involvement, adjacent lymph nodes for sites with clinical or pathologic involvement, and modified to account for anatomic barriers. CTV expansion for extremity tumors is defined by skeletal maturity with different margins for patients older than 18 years (skeletally mature). CTV expansion for patients older than 18 years with intermediate- to high-grade tumors 5 cm or larger includes a 3-cm longitudinal margin and 1.5-cm radial margin. For patients older than 18 years with all other tumors, CTV should include a 2-cm longitudinal margin and 1-cm radial margin. The planning target volume (PTV) includes a setup margin, typically 5 mm, although it can vary depending on the institution and immobilization methods. Proton PTV varies with each individual field and should account for range and setup uncertainty. The postoperative radiation field (PTV1) is defined by the initial tumor location on preoperative imaging excluding the volume that extends into cavities that have returned to normal anatomic position (Figure 94.2). A boost (PTV2) should be delivered to gross residual disease and the operative tumor bed determined by the operative note, pathology report, and surgical clips. Dose is prescribed where at least 95% of the specified dose encompasses 100% of the PTV. No more than 10% of the PTV should receive greater than 110% of the prescription dose. Organs at risk dose guidelines are shown in Table 94.6.

TABLE 94.5 PRESCRIBED DOSE AND FRACTIONATION

	Total Dose (Gy)	CTV1 (Gy)	CTV2 (Gy)
Postoperative Radiation			
Negative margins (R0)	54.0-55.8	45.0	9.0-10.8
Microscopic margins (R1)	54.0-55.8	45.0	9.0-10.8
Macroscopic margins (R2)	59.4-64.8	45.0	14.4-19.8
Preoperative Radiation			
Negative margins (R0)	45.0-50.4[a]	45.0-50.4	0
Microscopic margin (R1)	54.0-55.8	45.0	9.0-10.8
Macroscopic margins (R2)	59.4-64.8	45.0	14.4-19.8

All treatment given in 1.8 Gy per fraction.
CTV, clinical target volume.
[a]45 Gy recommended for concurrent preoperative chemoradiation.

TABLE 94.6 ORGANS AT RISK DOSE GUIDELINES

Organ	Volume (%)	Dose (Gy)
Single Organ		
Bladder	100	45.0
Esophagus	50	40.0
Heart	100	30.0
Liver	100	23.4
Liver	50	30.0
Rectum	100	45.0
Optic chiasm	100	54.0
Small bowel	75	45.0
Spinal cord	Any volume	50.4
Paired Organs[a]		
Kidney (bilateral)	50	24.0
Kidney (bilateral)	100	14.4
Lung (bilateral)	20	20.0
Lung (bilateral)	35	20.0
Optic nerve	100	54.0
Eye	100	45.0
Lens	100	6.0
Cochlea	100	40.0

[a]Paired organs volume refers to one of the paired organs unless specified as bilateral (kidney, lung) in which both of the paired organs are included in the percentage.

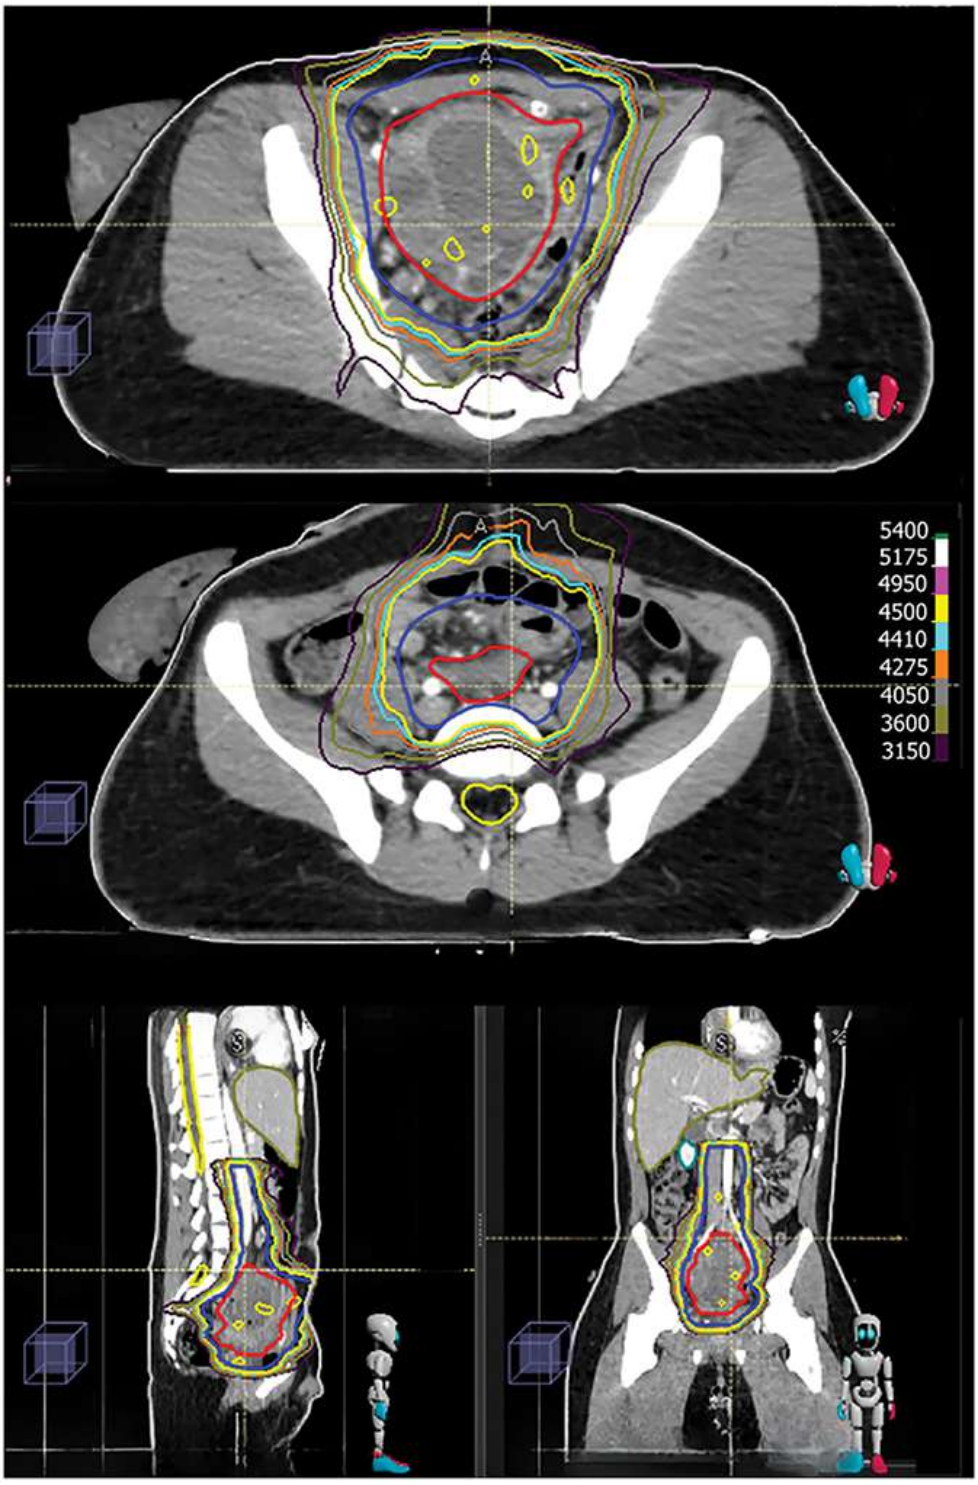

FIGURE 94.1 Preoperative radiation plan for abdominal nonrhabdomyosarcoma soft tissue sarcoma. Contouring the gross tumor volume (red) and regional involved retroperitoneal and pelvic lymph nodes in the clinical target volume (blue).

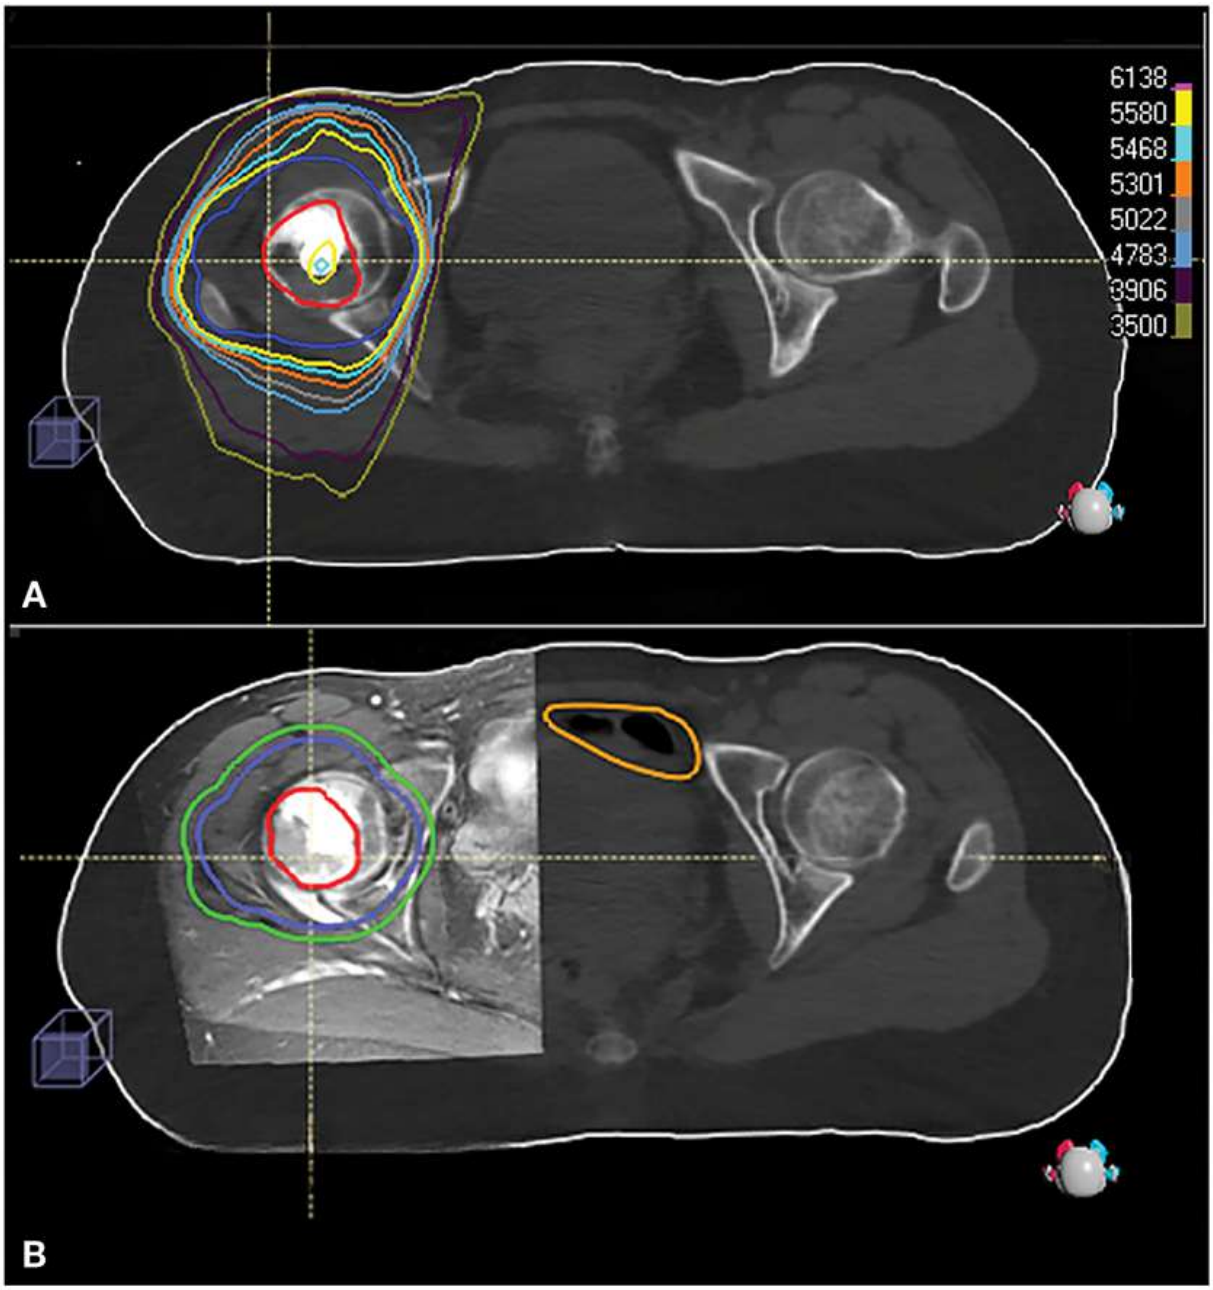

FIGURE 94.2 Postoperative radiation plan for a femoral head nonrhabdomyosarcoma soft tissue sarcoma. A. postoperative plan with the preoperative gross tumor volume (red) and postoperative hardware covered in the clinical target volume (blue). B. preoperative and magnetic resonance imaging with superimposed volumes.

Radiation Technique

Treatment planning techniques to treat the target volume and spare normal structures include three-dimensional conformal radiation therapy (3DCRT), intensity-modulated radiation therapy (IMRT), and proton radiation. Secondary analysis of ARST0332 preoperative radiation planning found that IMRT plans significantly improved CTV coverage and reduced the volume of skin and adjacent joint coverage receiving 45 Gy (V45 Gy) as compared to 3DCRT, which may reduce clinical and toxicity outcomes.[68] Proton beam radiotherapy (RT) is also being increasingly used as dosimetric studies demonstrate a decrease in integral dose to normal structures and, therefore, reduce the risk for radiation-related adverse

events as compared to photon-based techniques.[69] However, the potential benefit of proton therapy over IMRT is dependent on site; for many extremity tumors, photon-based techniques achieve comparable plans.

Site-Specific Considerations

Extremity Tumors

Whenever possible, the CTV should be modified to avoid circumferential irradiation of extremity lymphatics by sparing at least a 1- to 2-cm strip of tissue to prevent lymphedema. If there is no extension across the joint space, a smaller margin may be considered so the adjacent epiphysis can be excluded. The most active epiphyses for growth include the knee, shoulder, and wrist.

Head and Neck Tumors

Many of these tumors may be considered unresectable due to proximity to critical structures. Dose limitations to the brain, cochlea, optic chiasm, orbit including the eye, lacrimal gland, and optic nerve should be attempted. Conformal techniques such as IMRT or proton therapy should be utilized.

Chest Wall/Intrathoracic Tumors

GTV will be defined as the pretreatment tumor volume, excluding the component that has decreased in size or has been removed in tumors where lung parenchyma has returned to normal anatomic position after surgery or chemotherapy. All areas of pleural involvement will be included in the GTV.

Intra-Abdominal/Retroperitoneal Tumors

GTV will be defined as pretreatment tumor volume, excluding the component that has decreased in size or has been removed in tumors where bowel parenchyma has returned to normal anatomic position after surgery or chemotherapy. All areas of peritoneal or mesenteric involvement will be included in the GTV. Whole-abdomen radiation is typically not indicated in patients with diffuse peritoneal involvement or malignant ascites, with the exception of desmoplastic small round cell tumor.

Radiation Boost for Postoperative Margin Status

Postoperative radiation boost included 10.8 Gy in six fractions for R0 with less than 5-mm margins/R1 resection and 19.8 Gy in 11 fractions for R2 or unresected tumors in ARST0332.[52] However, in patients who received a boost after R1 resection, many were found to recur locally within the 100% isodose distribution,[62] providing little evidence to support a postoperative radiation boost for close margins. In ARST1321, boost was only delivered to gross disease using 19.8 Gy in high-grade extremity and trunk primary sites. Similarly, in adults with STS, postoperative boost after preoperative radiation and a margin-positive excision did not provide an advantage in preventing local recurrence.[70]

Radiation Therapy for Metastases

Consideration of radiation for metastatic disease depends on resectability, symptomatic metastases, and feasibility of radiation due to the number and location of metastatic sites. Patients with oligometastatic disease may benefit from dose-escalated radiation using conformal techniques like stereotactic ablative radiation to provide durable local control and provide a potential progression-free survival benefit.[71,72] Whole-lung or liver radiation is generally not recommended for diffuse metastases, although whole-lung irradiation has been evaluated in a single-institution series from Memorial Sloan Kettering Cancer Center for patients with synovial sarcoma and lung metastases.[60] Most of the patients (13/14) had gross residual disease in the lungs for which whole-lung irradiation was delivered via IMRT 15 Gy in 10 fractions. Although this was well tolerated with limited toxicity, durable pulmonary control was not achieved, as

pulmonary failure-free survival was 14% at 18 months. However, two of three patients who received a stereotactic body radiotherapy (SBRT) boost (25-30 Gy in five fractions) to gross disease experienced improved local control, which suggests that boost should be considered for gross disease. Treatment of malignant pleural or peritoneal effusions or intracavitary tumor spill with radiation is generally not recommended. Palliative radiation for symptomatic metastases should be considered for quality-of-life improvement.

Long-Term Toxicity

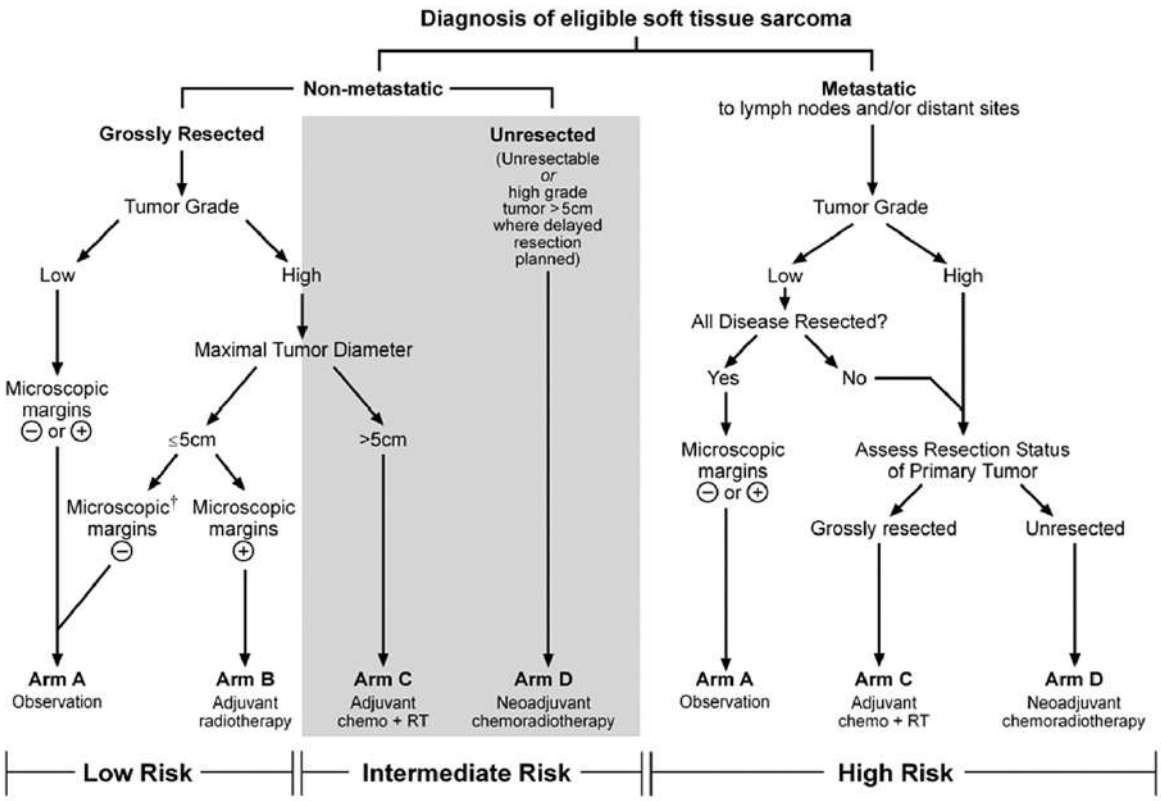
Late effects of therapy depend on the site of disease treated and the treatment modalities used. Late adverse effects can include psychosocial changes and decrements in quality of life. Importantly, patients should continue to be followed by supportive services, including physical and occupational therapies and nutrition and psychosocial services. These measures aim to mitigate long-term risk of lower education achievement, disability due to chronic pain, financial hardship, and development of mental health disorders and anxiety. Radiation to the extremity may lead to fibrosis, impaired bone growth, edema, nerve injury, and bone fracture. Progressive organ dysfunction can also occur due to radiation treatment, including pulmonary fibrosis, radiation nephropathy, and gonadal hormonal failure.[73,74] In addition, secondary malignancies may emerge several years after the completion of radiation and chemotherapy treatments.[75]

Chemotherapy can also cause long-term organ dysfunction. Specific agents including doxorubicin and other anthracyclines may result in a dose-dependent cardiomyopathy. Both ARST0332 and EpSSG NRSTS 2005 restricted cumulative dose of doxorubicin to 375 mg/m^2 as incidence of cardiotoxicity is significantly higher with a cumulative dose of doxorubicin above 500 mg/m^2.[76] Alkylating agents can contribute to oligospermia/azoospermia,[77] loss of oocytes, and gonadal hormonal insufficiency, potentially causing delayed or arrested puberty, premature menopause, infertility, and other complications.[78,79] Although advancements in supportive care have reduced the risk of hemorrhagic cystitis, alkylating agents still pose the possibility of chronic or recurrent cystitis, leading to bladder fibrosis and dysfunctional voiding.[80] Ifosfamide may cause glomerular and tubular nephrotoxicity, coupled with associated metabolic bone disease, though permanent and clinically significant renal impairment is relatively rare. Regular monitoring and ongoing support services are essential components of comprehensive care to address and mitigate these late effects.

SUMMARY OF CLINICAL TRIALS

ARST0332

ARST0332 is the first large-scale clinical trial for pediatric NRSTS in the United States, which enrolled patients less than 30 years of age with NRSTS of all stages. The primary objective was to use a risk-stratified treatment strategy and assess clinical outcomes and patterns of failure in treated patients (Figure 94.3). Patients were stratified based on metastatic status, extent of primary tumor resection, tumor size (≤5 cm vs >5 cm), and POG histologic grade (see Table 94.2). All patients had a gross total resection of their tumor prior to enrollment, unless they had a high-grade tumor greater than 5 cm and there was anticipated residual disease after resection, unresectable disease, or high-grade metastatic disease. Low-risk patients received surgery alone. Patients received adjuvant or neoadjuvant chemotherapy and radiation based on their risk group and the extent of resection of the primary tumor at study entry. All patients received the same ifosfamide/doxorubicin chemotherapy regimen (ifosfamide 9 g/m^2/cycle × 6 cycles and doxorubicin 75 mg/m^2/cycle × 5 cycles), with the timing of each cycle dependent on the sequence of surgery and RT. A radiation dose of 45 Gy was given neoadjuvantly with a boost of 10.8 Gy for R1 resection and 19.8 Gy for R2 or unresectable disease. Despite the lower radiation dose with neoadjuvant therapy, there was a high rate of local control, with 94% of eligible patients with high-grade tumors greater than 5 cm achieving an R0/R1 resection.



† Negative microscopic margins defined as the presence of a cuff of non-malignant tissue measuring at least 5mm in all directions surrounding the tumor in the operative specimen. When the tumor abuts fascia or periosteum and the fascia or periosteum is removed in continuity with the tumor specimen, this margin will also be considered negative.

FIGURE 94.3 ARST0332 treatment schema. RT, radiation therapy. (Reprinted from Spunt SL, Million L, Chi YY, et al. A risk-based treatment strategy for non-rhabdomyosarcoma soft-tissue sarcomas in patients younger than 30 years (ARST0332): a Children's Oncology Group prospective study. *Lancet Oncol*. 2020;21[1]:145-161. Copyright © 2019 Elsevier. With permission.)

The study outcomes demonstrate that risk stratification was able to separate patients into prognostic subgroups with significantly different 5-year EFS and OS (Figure 94.4). Clinical factors prognostic for OS include patient age, tumor size, tumor depth, tumor invasiveness, POG and FNCLCC grade, presence of metastases, extent of resection, and risk group. In patients who received neoadjuvant chemoradiation, response at week 13 was also prognostic for 5-year OS and EFS. Histologic subtype was found as a predictor for local control, with synovial sarcoma having a low rate of local recurrence (2.7%), whereas MPNST had a higher rate of recurrence (27.9%) likely also related to their propensity to involve the brachial/lumbosacral plexus, which is a challenging location for surgical resection. Secondary analysis of patients with lymph node involvement found that overall lymph node metastases are rare in this population, approximately 4% of the entire cohort, and limited to specific subtypes, including epithelioid sarcoma, undifferentiated sarcoma, clear cell sarcoma, and angiosarcoma. Pediatric patients with isolated lymph node metastases have a high 5-year OS of 86% and should be treated with curative intent. This risk stratification system was able to successfully separate patients into low-risk, intermediate-risk, and high-risk prognostic subgroups and risk-adapted treatment paradigms.[52]

EpSSG NRSTS 2005

In Europe, the EpSSG cooperative group enrolled patients with nonmetastatic NRSTS under 21 years of age in EpSSG NRSTS 2005.[59] These patients were assigned to different treatment groups depending on the extent of primary tumor resection, tumor size (≤5 cm vs >5 cm), nodal involvement, and FNCLCC histologic grade ("adult-type" NRSTS only) (see Table 94.3). Patients with synovial sarcoma were

further stratified by tumor site. Treatment groups included surgery alone, adjuvant radiation, adjuvant chemotherapy (with or without radiation), and neoadjuvant chemotherapy (with or without radiation) (Table 94.7). All patients with synovial sarcoma received chemotherapy, except those with a 5 cm or less tumor that had undergone R0 resection. Chemotherapy administration was limited to "adult-type NRSTS" histologies with unresectable disease, greater than 5 cm FNCLCC grade 3 with R0 or R1 margins, or involved lymph nodes. Chemotherapy regimen utilized ifosfamide 9 g/m^2/cycle × 3 to 7 cycles and doxorubicin 75 mg/m^2/cycle × 3 to 5 cycles, with the number of cycles dependent on the stage of disease. RT dose ranged from 50.4 to 59.4 Gy depending on the extent of primary resection and could be given preoperatively or postoperatively.

TABLE 94.7 TREATMENT GROUPS FOR NONRHABDOMYOSARCOMA SOFT TISSUE SARCOMAS IN THE 2005 EUROPEAN PEDIATRIC SOFT TISSUE SARCOMA STUDY GROUP

Treatment	Stage	Radiation Dose (Gy)
Surgery alone		
Synovial sarcoma	R1 resection, tumor size ≤5 cm	
Adult-type NRSTS	R0 resection, tumor size ≤5 cm, any grade	
Adjuvant radiation		
Adult-type NRSTS	R0 resection, tumor size >5 cm, grade 2	Dose 50.4
Adult-type NRSTS	R1 resection, tumor size ≤5 cm, grade 2-3	Dose 54
Adjuvant chemotherapy +/− Radiation		
Synovial sarcoma	R0 resection, tumor size >5 cm	
Synovial sarcoma	R1 resection, tumor size ≤5 cm	Dose 50.4
	R1 resection, tumor size >5 cm	Dose 54
No Adjuvant Radiation		
Adult-type NRSTS	R0-1 resection, tumor size >5 cm, grade 3 or N1	Dose 54
Neoadjuvant chemotherapy		
Synovial sarcoma and adult-type NRSTS	Unresected primary or unresected N1	Dose 50.4-59.4

NRSTS, nonrhabdomyosarcoma soft tissue sarcoma.

Reprinted from Ferrari A, van Noesel MM, Brennan B, et al. Paediatric non-rhabdomyosarcoma soft tissue sarcomas: the prospective NRSTS 2005 study by the European Pediatric Soft Tissue Sarcoma Study Group (EpSSG). *Lancet Child Adolesc Health*. 2021;5(8):546-558. Copyright © 2021 Elsevier. With permission.

The primary end points were EFS and OS, which were evaluated per treatment group. The highest estimated 5-year EFS was 91% and OS was 98% in the surgery-alone group. In the adjuvant RT group, 5-year EFS was 76% and 5-year OS was 88%. For patients receiving chemotherapy, 5-year EFS and OS were 66% and 76% for the adjuvant arm and 56% and 70% for the neoadjuvant arm, respectively. On multivariable analysis, the variables prognostic for OS included histology, tumor grade, extent of surgical resection, and tumor site, with intra-abdominal primary having the worst prognosis. In patients who received neoadjuvant chemotherapy, receipt of RT and delayed surgery was shown to significantly improve 5-year OS; however, pathologic response to chemotherapy was not found to be prognostic.

Secondary analysis of 60 patients enrolled in ARST0332 and EpSSG NRSTS 2005 with low-risk synovial sarcoma found that adequately resected synovial sarcoma 5 cm or less could be safely treated with surgery alone, with 3-year EFS of 90%. In addition, EpSSG NRSTS 2005 found differences in both 5-year OS and EFS outcomes based on histology. MPNST had the worst outcomes (5-year OS 58% and 5-year EFS 43%), whereas patients with "adult-type" NRSTS (5-year OS 86% and 5-year EFS 80%) and synovial sarcoma (5-year OS 89% and 5-year EFS 76%) had improved outcomes. Similar to ARST0332, this study demonstrated the ability to use risk-adapted multimodal treatment, with results suggesting low-

risk patients can be successfully treated with surgery alone. In patients with locally advanced or unresectable disease treated with neoadjuvant chemoradiation, this study illustrated improved outcomes in comparison to historical cohorts, with 5-year EFS increasing from 48.2% to 56.4%.[81]

BERNIE Study

EpSSG patients with metastatic NRSTS and RMS were enrolled in BERNIE, a phase II randomized study to evaluate the addition of bevacizumab, a monoclonal antibody inhibitor of VEGF, to the standard RMS induction chemotherapy with ifosfamide, vincristine, actinomycin D, doxorubicin, and maintenance low-dose cyclophosphamide and vinorelbine for 1 year. The addition of bevacizumab did not improve EFS as compared to historical controls, with an estimated 2-year EFS of 41% in both arms.[82]

ARST1321

Following ARST0332, ARST1321 was the first jointly conducted pediatric/adult sarcoma trial developed by COG and NRG oncology. This is a randomized phase II study for patients with intermediate- or high-grade NRSTS greater than 5 cm in the trunk/extremity. This study was conducted to evaluate the benefit of adding pazopanib, an oral tyrosine kinase inhibitor, to neoadjuvant radiation alone or chemoradiation with concurrent ifosfamide and doxorubicin with the primary end point of improvement of pathologic response, a known predictor for outcomes in adult STS. This study enrolled patients in a concurrent chemotherapy cohort for chemosensitive WHO intermediate or malignant tumors, including liposarcoma, undifferentiated STS, synovial sarcoma, angiosarcoma of soft tissue, adult fibrosarcoma, mesenchymal chondrosarcoma, leiomyosarcoma, liposarcoma (excluding myxoid liposarcoma), UPS, and embryonal sarcoma of the liver. Patients were enrolled in nonchemotherapy cohort and treated with radiation and pazopanib alone for the following histologies: fibrohistiocytic tumors, fibroblastic/myofibroblastic tumors, tumors of uncertain differentiation, chondro-osseous tumors, perivascular tumors, nerve sheath tumors, and undifferentiated sarcomas. Interim analysis determined that the pathologic near-complete response (≥90%) was significantly improved with the addition of pazopanib (58.3% as compared to 22.2%), and the study was terminated early. Despite the high pathologic response rate, there was not an associated improvement in the estimated 3-year EFS or OS, though these data need to be interpreted within the context of the primary study design to assess pathologic response. Secondary analysis also found significantly increased rates of wound complications among patients randomized to receive pazopanib as compared to induction chemoradiation alone (50% vs 22%).[63]

FUTURE DIRECTIONS

Future multi-institutional collaborative trials play a crucial role in advancing the care for pediatric patients diagnosed with NRSTS. The INSTRuCT consortium was created by three large cooperative groups (EpSSG, CWS, and COG) to collaborate and pool resources and expertise of major pediatric STS groups.[83] This subgroup of experts defined a common approach concerning the treatment of pediatric NRSTS with recommendations for a multidisciplinary approach at experienced centers where patients can enroll in prospective clinical trials in national and international sarcoma networks. Future integration between the histologic diagnosis and molecular characterization is being studied to improve diagnosis and genetic drivers of NRSTS as well as molecular targets for novel therapies.[58] Larger collaborative efforts for this translational research include the European MYKIDS project (Molecular Identification and Characterization of non-Rhabdomyosarcoma Soft Tissue Sarcoma in Kids, Adolescent and Young Adults),[84] HEROES-AYA (Heterogeneity, evolution and resistance of sarcomas driven by fusion genes in adolescents and young adults) project, and the COG's 2023 blueprint for research[85] to better study the epidemiology and molecular characterization of childhood cancers. Within the COG blueprint for STS, future trials will explore immune checkpoint inhibitors and genomic alteration-specific novel agents, including multi–tyrosine kinase inhibitors. For example, COG is currently investigating the potential to

develop a trial investigating novel agents in combination with SBRT for relapsed/refractory pediatric NRSTS. In addition, continued collaboration with adult cooperative groups in the National Clinical Trials Network is planned, with an umbrella trial utilizing comprehensive genomic screening and circulating tumor DNA for prognostic and response assessment.

CHAPTER 95

Osteosarcoma and Other Primary Tumors of Bone

Safia K. Ahmed and Nadia N. I. Laack

Primary bone tumors are rare, accounting for approximately 0.2% of all malignancies. Osteosarcoma, Ewing sarcoma, and chondrosarcoma account for the majority of primary bone tumors. Other rarer histologies include chordoma, fibrosarcoma, and fibrous histiocytoma. This chapter discusses osteo sarcoma for the younger age group, chondrosarcoma, and chordoma in detail. Ewing sarcoma is discussed separately in Chapters 96. Chordoma and chondrosarcoma in skull-base loca tion in adults are discussed in Chapters 42.

OSTEOSARCOMA

Epidemiology

Approximately 1,000 new osteosarcoma cases are diagnosed annually in the United States. Osteosarcoma has a bimodal age distribution. Most cases occur in children and adolescents, with a smaller peak seen in adults over 65 years of age. Most childhood and adolescent cases occur sporadically, whereas cases in adulthood are more commonly associated with sarcomatous degeneration of Paget disease or other benign bone lesions. Osteosarcoma is also associated with retinoblastoma gene mutations and a history of radiation therapy (RT), especially in patients with genetic abnormalities such as retinoblastoma.

Pathogenesis and Risk Factors

Osteosarcoma is derived from bone-forming mesenchyme and is described as a malignant sarcomatous stroma associated with the production of osteoid bone.[1] The peak incidence coincides with a period of rapid bone growth. The most common osteosarcoma type in pediatric patients is conventional osteosarcoma, including osteoblastic, chondroblastic, and fibroblastic types. Each subgroup has varied amounts of osteoid formation and a different predominant component. Conventional osteosarcoma accounts for 90% of cases and are mostly high-grade tumors. There is no difference in outcome or treatment recommendations based on osteosarcoma subtypes. Other less common subtypes include telangiectatic, small cell, juxtacortical, periosteal, paraosteal, and high-grade surface osteosarcomas.

Approximately one-third of osteosarcoma cases are associated with inactivation of the retinoblastoma tumor suppressor gene (13q14).[2] Other genetic abnormalities include abnormal TP53 function, gene amplification, and translocations.[3,4] Prior history of RT is associated with the risk of secondary osteosarcoma. Overall, the rate of secondary osteosarcoma has dec reased in patients with retinoblastoma, given the declining use of RT in this population. Some data suggest limiting dose to less than 60 Gy in patients with Ewing sarcoma treated with RT can reduce the risk of secondary osteosarcoma.[5] Benign bone lesions, such as Paget disease, chronic osteomyelitis, fibrous dysplasia, and multiple hereditary exostoses, have also been associated with osteosarcoma. Malignant transformation is generally observed in long-standing Paget disease and occurs in 0.7% to 1.0% of cases.[6]

Clinical Manifestations, Diagnostic Evaluation, and Staging

In general, patients with osteosarcoma present with localized pain, swelling, and a palpable mass. The most common primary tumor sites are femur (49%), tibia (26%), and humerus (10%). Approximately 90% of patients present with localized disease. Lung is the most common site of metastases followed by bone.

A complete history and physical examination are performed, with particular attention to the duration of symptoms, the presence of pain, difficulty of function, and the location and size of the mass. Studies commonly obtained to evaluate the extent of disease include routine blood work, plain radiographs, a computed tomography (CT) scan to assess bone involvement and integrity, and magnetic resonance imaging (MRI) to assess soft tissue extent. CT and MRI are both required (Figure 95.1) of the primary region and should encompass the entire bone to evaluate for skip metastases (<5% incidence). Plain radiographs typically show sclerotic or lytic lesions of the metaphysis. A bony sunburst pattern is often seen as a result of the periosteal new bone formation. The elevated periosteal reaction may generate a Codman triangle. ^{18} fluorodeoxyglucose-positron emission tomography (^{18}FDG- PET) is obtained to evaluate for metastatic disease. PET is also helpful in assessing response to neoadjuvant chemotherapy. Tumors that are not particularly ^{18}FDG avid should undergo a bone scan. In addition, if high-resolution CT is not performed with PET, a diagnostic chest CT scan should be obtained to rule out lung metastases. In general, lung nodules are considered to be metastatic if the lesion size is 5 mm or larger or there is calcification. Nodules 3 mm or larger are highly suspicious for metastatic disease if they have at least two of the following features: occurrence in the context of two or more nodules, nonsubpleural location, documented growth, or solid density.

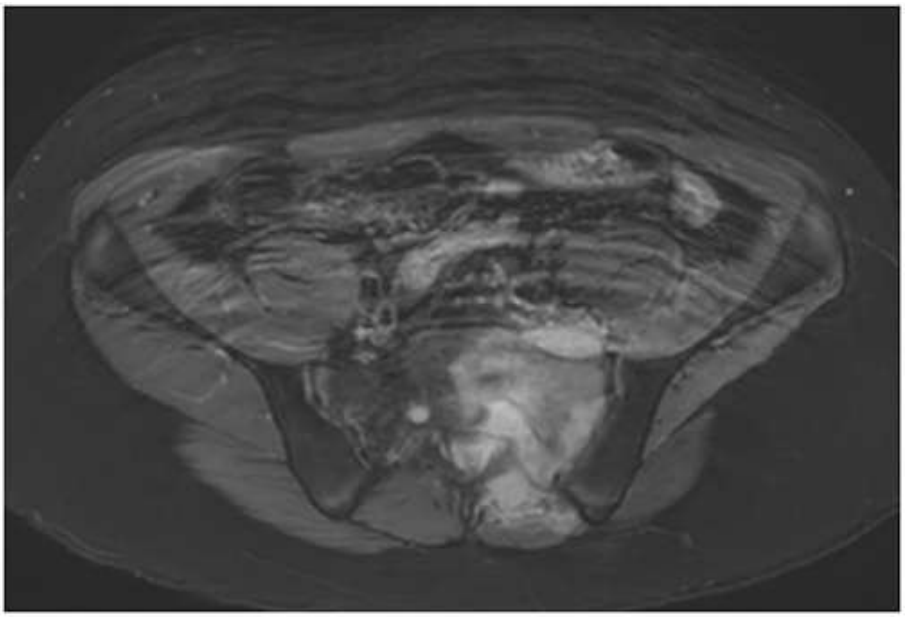

FIGURE 95.1 Magnetic resonance imaging demonstrating a primary pelvic osteosarcoma involving the left sacrum, adjacent soft tissue/muscles, left sacroiliac joint, left iliac bone, left L5-S1 and S1-S2 neuroforamen, and spinal canal.

A biopsy of the primary tumor should be obtained after complete evaluation, ideally by the surgeon who will perform the definitive resection. The biopsy should be placed carefully to avoid contamination of uninvolved areas, vital structures, and hematoma development. It must not increase the extent of surgery, especially jeopardize the possibility of a limb-preserving procedure. Staging systems include those from the Musculoskeletal Tumor Society (MSTS) and the American Joint Committee on Cancer (AJCC).[7,8] The MSTS staging system is a surgical staging system stratifying tumors by grade and subdividing by local extent (Table 95.1).[8] The AJCC system is less routinely used (Table 95.1). Prognostic features include the presence or absence of metastatic disease, tumor location, and size, whether complete resection of the primary tumor is possible, and response to chemotherapy.[9] Retrospective analysis suggests circulating tumor DNA levels correlate with the risk of recurrence and death.[10]

Treatment

Treatment involves multiagent chemotherapy and local therapy. If only the primary tumor site is treated, about 90% of patients will experience metastatic disease.[1] Surgical resection is the preferred local treatment and consists of amputation or a limb-sparing procedure. RT has a limited role in osteosarcoma because of the radioresistant nature of the tumor. Currently, between 60% and 70% of patients with localized osteosarcoma are cured. Survival is superior in cases of less common low-grade tumors, such as parosteal osteosarcoma. Oftentimes, surgery alone is sufficient for these cases and is associated with survival rates of 80% to 90%.[11]

Chemotherapy

Chemotherapy is given prior to and after surgical resection. The concept of neoadjuvant chemotherapy arose in combination with evolving surgical techniques striving for limb-preserving surgeries and improved functional outcomes. The Pediatric Oncology Group (POG) study randomized 8,651 patients with nonmetastatic, high-grade osteosarcoma to neoadjuvant chemotherapy followed by surgery versus surgery followed by chemotherapy.[12] The rate of limb salvage was not statistically significant between the two groups (55% vs 50%).[12] There was also no difference in 5-year relapse-free survival between both groups (65% vs 61%).[12] This trial demonstrated equivalence for both approaches and established a benchmark for

comparison with future studies. Most centers favor neoadjuvant chemotherapy with the notion that the likelihood of limb-salvage surgery can be higher with improved functional outcomes. Prospective randomized studies have also demonstrated an improvement in overall survival outcomes for patients treated with adjuvant chemotherapy.[1,13-16] Currently, the initial chemotherapeutic agents used include methotrexate, doxorubicin, and cisplatin (MAP). Pathologic response (tumor necrosis >90%) is associated with improved survival in osteosarcoma.[13,17] Patients with minimal response to neoadjuvant chemotherapy can be considered for alternative adjuvant therapy regimens, but this approach has not been proven.[18] Recent prospective studies have evaluated the efficacy of additional systemic therapy agents to the MAP regimen. The international collaborative study EURAMOS-1 evaluated the addition of pegylated interferon α-2b following completion of MAP chemotherapy in good (>90% histologic response to preoperative chemotherapy) responders. High-dose ifosfamide and etoposide were added to MAP chemotherapy in poor (≤90% histologic response to preoperative chemotherapy) responders. The results did not demonstrate an improvement in outcomes with either approach.[18,19]

The ongoing Children's Oncology Group (COG) study AOST2032 is evaluating the feasibility and efficacy of adding the VEGFR2/MET inhibitor, cabozantinib, in a randomized manner to the MAP regimen. The rationale for this approach is to target signaling pathways known to be altered in osteosarcoma. There is clinical evidence of activity with cabozantinib in prospective studies for pediatric and adult patients with advanced osteosarcoma. Neoadjuvant MAP with or without cabozantinib is given for two cycles prior to primary tumor surgery and for four cycles following primary tumor surgery in the study. Patients randomized to the cabozantinib arm will receive six additional cycles of maintenance cabozantinib.

Local Therapy

Surgery is the mainstay of local treatment of osteosarcoma. Surgical resection is performed by either amputation or a limb-sparing approach and is associated with a less than 10% local failure rate. For extremity tumors, limb preservation is preferred and can be accomplished in most cases. Retrospective series have demonstrated equivalent outcomes between amputation and limb-sparing approaches as long as adequate margins are achieved.[20-22] Contraindications to limb-preserving surgery are pathologic fracture, nerve or vascular encasement, or large biopsy-related hematoma. Reconstructive options include endoprostheses, allografts, and rotationplasty. Axial tumors pose a greater challenge with surgical resection, though these primary tumor sites are less common. Pelvic tumors typically require a hemipelvectomy in order to obtain an en bloc resection. An internal hemipelvectomy (resection of hemipelvis

with preservation of the extremity) is associated with better functional outcomes compared to an external hemipelvectomy, which involves a hindquarter amputation in addition to resection of the hemipelvis. Spine tumors are often resected with vertebrectomy for an en bloc resection combined with mechanical stabilization.

Osteosarcoma is usually considered to be a radioresistant tumor. However, in vitro studies demonstrate osteosarcoma has a radiosensitivity similar to that of other human tumor cell lines.[23] In addition, case reports document that patients with inoperable or residual tumor treated with RT doses ranging between 50 and 70 Gy have remained in continuous remission.[24] As such, RT can be used for unresectable and metastatic cases as well as for cases with residual disease postresection. For example, postoperative RT can also be added for axial tumors when negative margins cannot be obtained, such as microscopic dural involvement with a spine tumor.

Research studies suggest RT is most effective with de novo cases, when the tumor burden is small, when patients have had a good response to chemotherapy, and/or with cases that have undergone a gross total or subtotal resection. Machak et al reported a 5-year progression-free survival rate of 56% in a series of patients with osteosarcoma who refused surgery but received systemic therapy and local RT.[25] Moreover, the survival rate was approximately 90% at 5 years in the subgroup of patients who responded to chemotherapy and received RT. Schwarz et al reported local control was higher for primary tumors at 40% versus 17% for recurrent tumors in a series of 100 patients with osteosarcoma treated with RT.[26] DeLaney et al[27] reported outcomes in a series of 41 patients with osteosarcoma treated with definitive RT or adjuvant RT for surgical cases with close or positive margins at the time of resection. The 5-year local control rate was 40% for patients treated with definitive RT, 78% for postoperative RT with a close surgical margin, and 78% for postoperative RT with positive surgical margins.[27] The median dose was 66 Gy, with doses as high as 80 Gy for gross disease. Over half of patients received some or all of their treatment with proton RT, given the unfavorable tumor locations often seen with definitive or postoperative RT cases as well as the high treatment doses needed. Carbon therapy may be beneficial for unresectable osteosarcoma. A retrospective review of 78 patients with unresectable axial osteosarcoma treated with carbon ion RT demonstrated local control was 62% at 5 years for all patients and 88% for tumors less than 500 mL. Patients received a median of 70.4 CGE (cobalt gray equivalent) in 16 fractions over 4 weeks.[28] Other series have also reported acceptable local control outcomes with particle therapy.[29,30]

To summarize, although surgery is the local treatment of choice, RT is an acceptable treatment option in inoperable tumors or patients refusing surgery. RT should also be administered in R1 and R2 resections. The current recommended doses per AOST2032 are 73.8 Gy for gross disease and 66.6 Gy for resected tumors

with microscopic residual disease, both in 1.8 Gy per fraction. RT is given after completion of consolidation chemotherapy.

Radiation Therapy Volumes and Techniques

Current COG recommendations are outlined in this section. The prechemotherapy/presurgery gross tumor volume (GTV) includes all T1 gadolinium-enhancing tumor, all T2 signal abnormalities, and all CT and MRI bone abnormalities. This volume is then expanded by 1.5 to 2 cm (up to 3 cm craniocaudally for extremities) to create the prechemotherapy/presurgery clinical target volume (CTV). The prechemotherapy GTV and CTV can be modified for pushing, noninfiltrative borders. These volumes are treated to 50.4 Gy in 28 fractions. The postchemotherapy GTV includes the residual soft tissue mass after induction chemotherapy and all bone abnormalities evident prior to chemotherapy. For tumors with microscopic residual disease following surgery, the postchemotherapy GTV is the postinduction chemotherapy target volumes determined on preoperative imaging. For partially resected tumors, the volume also includes the tumor bed. The postchemotherapy CTV is generated with a 1-cm expansion of the GTV, anatomically modified to barriers of tumor spread. These volumes are treated to 66.6 Gy in 37 fractions. The final boost volume is treated to 73.8 Gy for definitive RT cases or for gross residual disease postsurgery. This volume encompasses the residual tumor following induction chemotherapy without margin (ie, GTV = CTV). Planning target volumes are a 0.5 to 1-cm expansion on the CTVs, depending on tumor location and daily image-guidance available.

Circumferential irradiation of the extremities should be avoided to reduce the risk of lymphedema. In growing children, growth plates must be factored into RT planning. Growth plates should either be fully included in the high-dose RT field or not included at all (no portion of the growth plate receiving >30 Gy). A dose gradient through the epiphysis can result in asymmetric growth and lead to functional deficits. Similarly, vertebral bodies should be either fully included or spared (no portion of the vertebral body receives >20 Gy). Given the high dose needed for RT, advanced planning techniques, such as intensity-modulated RT or proton therapy, are recommended.

Metastatic Disease

The overall approach to metastatic disease with osteosarcoma is surgical resection and multiagent chemotherapy. The overall prognosis depends on the location and number of metastases, response to chemotherapy, and whether complete surgical resection of all tumors is possible.[31,32] Patients with metastasis only in the lung or a limited number of metastases who can undergo complete surgical resection are

associated with slightly improved outcomes. The 3-year survival rate in this population is approximately 50%, compared with 20% to 30% for more advanced disease. The currently open COG study AOST2031 is a randomized trial comparing open versus thoracoscopic management of pulmonary metastases. The primary aim of the trial is to determine if open surgical resection is superior to thoracoscopic resection for thoracic event-free survival in patients with resectable oligometastatic pulmonary osteosarcoma.

The use of whole-lung RT in the setting of metastatic disease or as prophylaxis for metastatic disease is controversial. Randomized trials from the European Organization for Research and Treatment of Cancer demonstrated prophylactic whole-lung RT with or without chemotherapy did not result in a statistically significant difference in outcomes.[33] As such, whole-lung RT is currently not recommended for patients with osteosarcoma.[34] The currently open COG study AOST2032 recommends definitive local therapy (surgery, conventionally fractionated RT, hypofractionated RT, or stereotactic body radiation therapy [SBRT]) to all metastatic sites documented at diagnosis. The study will evaluate the feasibility and efficacy of metastatic site–directed local therapy for osteosarcoma. The recommended RT dose for pulmonary metastatic sites is 50 Gy in 5 fractions for unresected pulmonary metastases measuring less than <5 cm, 60 Gy in 8 fractions for unresected pulmonary metastases measuring 5 cm or more but 8 cm or less, and 70 Gy in 10 fractions for unresected pulmonary metastases measuring greater than 8 cm.

RT may be utilized to treat osseous metastatic sites not amenable to surgical resection. The Cooperative Osteosarcoma Study Group demonstrated improved outcomes when metastases were surgically excised in a cohort that analyzed prognosis of relapsing patients. In addition, RT of inoperable sites was associated with improved survival compared to patients who received no local therapy.[35] AOST2032 recommends SBRT 50 Gy in 5 fractions for bone metastatic sites amenable to SBRT and 73.8 Gy in 41 fractions for metastatic sites not amenable to SBRT.

CHONDROSARCOMA

Epidemiology

Chondrosarcomas are a group of primary bone malignancies that produce chondroid (cartilaginous) matrix. They are completely devoid of osteoid, which is characteristic of osteosarcoma. Chondrosarcomas account for approximately 30% of primary bone tumors.[36] Chondrosarcomas can occur at any age but most commonly occur in middle-aged and older adults.[37]

Pathogenesis and Risk Factors

Chondrosarcomas can occur sporadically or with malignant transformation of benign cartilaginous lesions, including enchondromas or osteochondromas. Enchondromas develop in the bone marrow cavity. Enchondromatosis, or Ollier disease, is a condition characterized by the presence of multiple enchondromas causing a deformity. Malignant transformation of solitary enchondromas is extremely rare, but the risk is as high as 30% with enchondromatosis.[38,39] Osteochondromas are cartilage-capped bony projections arising on the external surface of bone. They contain marrow cavities that are continuous with the underlying bone. Most osteochondromas are located on long bones, especially around the knee. Multiple osteochondromas are associated with hereditary multiple exostoses. Malignant transformation occurs in 5% of patients with either solitary or multiple osteochondromas.[38,40]

Conventional chondrosarcomas account for about 90% of cases.[41] Conventional chondrosarcoma is further subdivided into central, peripheral, and periosteal. Central chondrosarcoma is the most common type, accounting for 75% of all chondrosarcoma cases. Forty percent of cases may arise from underlying enchondromas. The proximal femur, proximal humerus, and pelvis are commonly involved. Peripheral chondrosarcomas arise from a preexisting osteochondroma. The long bones, pelvis, and shoulder girdle are most commonly affected. Periosteal chondrosarcomas arise from the surface of bone, are rare, and usually affect young adults in their 20s and 30s. These malignancies tend to have a better prognosis.[36] High-grade chondrosarcomas account for the remaining 10% of cases and include dedifferentiated, mesenchymal, myxoid, and clear cell chondrosarcoma.[41] Clinical behavior of chondrosarcoma is highly dependent on histologic grade.[42,43]

Clinical Presentation, Diagnostic Evaluation, and Staging

Patients often present with localized pain involving the affected bone. There may or may not be a palpable mass and associated soft tissue swelling. Plain radiographs, CT, and MRI are obtained to characterize the lesion and evaluate the full extent of disease. Pathologic confirmation of chondrosarcoma is obtained via biopsy aimed at the most aggressive portion seen on imaging. This approach avoids potential biopsy of an associated benign precursor lesion and also guides the optimal surgical approach if a high-grade component is present. CT of the chest should also be obtained to evaluate for metastatic disease. The risk of lung metastases is less than 10% for low-grade lesions and 30% to 70% for intermediate- and high-grade lesions.[44,45] Similar to osteosarcoma, both the MSTS and AJCC staging systems can be used to stage chondrosarcoma.

Treatment

The primary treatment for chondrosarcomas is surgical resection. Histologic grade and tumor location are key factors in determining surgical extent, associated morbidity, and need for adjuvant treatments. For low-grade tumors, surgical resection alone is sufficient to achieve a high rate of disease control. For low-grade central tumors, intralesional excision or curettage is the preferred method of resection. This can be combined with local adjuvant chemical treatment or cryotherapy. These approaches result in good local control rates and minimize the morbidity of more extensive surgical resection.[46-49] Larger tumors, tumors with intra-articular or soft tissue involvement, and axial or pelvic tumors have higher local recurrence rates with these more conservative treatments. As such, these tumors are best treated with wide excision.[50] For the less common intermediate- and high-grade tumors, wide en bloc excision is the optimal surgical approach.[43,51] RT is indicated for incompletely resected high-grade or locally recurrent tumors, as well as for tumors that are unresectable. Chondrosarcomas are believed to be more radiosensitive than chordomas and can be treated with high-dose RT only in the setting of a highly morbid surgery. If a tumor is incompletely resected, reresection is generally only recommended if a separation surgery between residual disease and critical organs at risk is needed to safely deliver high-dose RT. Chemotherapy is not very effective for chondrosarcoma, especially for conventional chondrosarcoma. There is no established adjuvant chemotherapy regimen. There is some suggestion that dedifferentiated and mesenchymal chondrosarcomas may potentially benefit from chemotherapy, but phase III randomized data are lacking in these rare tumors.[52-54]

Radiation Therapy

RT principles for chondrosarcoma are similar to that for osteosarcoma. Definitive RT is recommended for inoperable tumors or for patients refusing surgery. Adjuvant RT is indicated after incomplete resection of tumors at high risk for local recurrence. Goda et al reported outcomes in 60 patients with high-risk extracranial chondrosarcoma treated with surgery and RT. With a median follow-up of 75 months, the local control rates were 100%, 94%, and 42% for R0, R1, and R2 resected patients, respectively. Overall survival at 10 years was 86%.[55] Definitive RT has also been used for chondrosarcomas of the spine and skull base, where an R0 resection is difficult to achieve.[56,57] Similar to osteosarcoma, particle therapy is often advantageous in terms of permitting dose escalation while sparing adjacent critical normal tissues. Rosenberg et al reported on a series of 200 patients with skull-base tumors treated to a median dose of 72 Gy CGE with a combination of photon and proton RT. They reported a 10-year local control rate of 98%.[58] Similar local control

rates have been reported by other institutions with particle therapy.[59-61] Table 95.2 summarizes the results of select particle therapy studies for bone sarcomas involving the pelvis. RT doses, volumes, and planning approaches are similar to that of osteosarcoma.

TABLE 95.2 SELECT PARTICLE THERAPY STUDIES FOR PELVIC BONE SARCOMAS

Series	Histology	Pelvic Patients/Total Patients	Modality	Median Dose (GyRBE)	Local Control	Survival	Toxicities
Aibe et al[84]	Chondrosarcoma	33/33	Proton	70.4	89.6% @ 3 y	92.7% @ 3 y	Grade 3: dermatitis (1), ileus (1), sacral fracture (2)

CHORDOMA

Epidemiology

Chordomas are slow-growing, locally aggressive neoplasms that arise from embryonic remnants of the notochord. They account for 1% to 4% of primary bone tumors. The median age at presentation is 60 years, but skull-base tumors typically present in the third or fourth decade of life.

Pathogenesis and Risk Factors

During normal embryologic development, the notochord regresses. Notochord remnants, however, can be found along the tract anywhere from the skull base to the sacrum, with the largest foci of remnants located at the cranial and caudal ends. This pattern corresponds with the anatomic distribution of chordomas. Approximately half of chordoma cases arise in the sacrococcygeal region and one-third of cases at the skull base, usually the clivus. The remainder of cases involve the cervical, thoracic, and lumbar spine.[62]

Chordomas are histologically classified as conventional/classic, chondroid, and dedifferentiated. Most cases are conventional chordomas. Chondroid chordoma accounts for 5% to 15% of cases and is typically associated with a superior prognosis. Dedifferentiated chordoma accounts for less than 5% of cases and is more aggressive, faster growing, and more likely to metastasize.[63] Brachyury, a transcription factor required for notochord development during embryogenesis, is often used as a diagnostic marker for chordoma.[64] Molecular characterization of chordomas is evolving. Zenonos et al demonstrated homozygous 9p21 deletions and 1p36 deletions are independent prognostic factors in clival chordoma and likely correlated with progression-free survival after local therapy.[65] This suggests that a continued molecular characterization of these tumors may help guide management.

Clinical Presentation, Diagnostic Evaluation, and Staging

Patients with chordoma often present with pain of the affected area that may be long-standing in nature. Associated neurologic symptoms are frequent. Skull-base tumors can present with cranial nerve deficits, especially cranial nerve 3 or 6 palsies. Sacral tumors can present with bowel or bladder dysfunction secondary to sacral nerve root involvement. Sensory motor deficits are also seen.

Diagnostic evaluation includes CT and MRI to characterize the extent of the primary tumor and involvement of adjacent neurological structures (Figure 95.2). Biopsy is needed to confirm the pathologic diagnosis. Metastases can occur in 10% to 40% of patients.[66-69] Metastatic spread typically occurs late in the disease course and can involve lung, bone, liver, lymph nodes, or soft tissues. Similar to the primary site, metastatic sites tend to be slow growing.

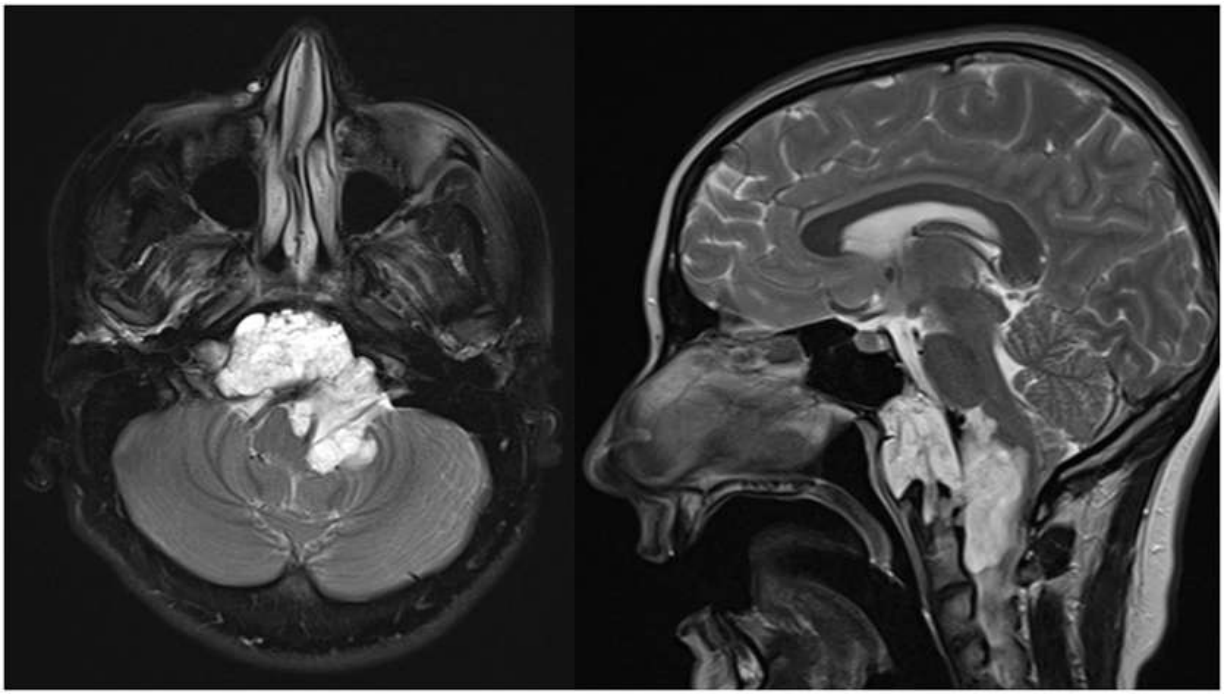

FIGURE 95.2 Magnetic resonance imaging demonstrating a skull-base chordoma. Given the compression of the brainstem and spinal cord, the patient underwent a maximum safe resection followed by postoperative radiation therapy.

Treatment

Given the locally aggressive nature of chordoma, aggressive upfront local therapy is needed for cure. The standard of care is surgery with an en bloc resection if possible. This approach is associated with local control in 70% to 80% of patients.[70] En bloc resection, however, is challenging for most tumors, given the proximity to critical adjacent tissues. Less than half of sacral tumors and even fewer skull-base tumors are amenable to complete resection. In addition, aggressive surgery can result in

significant morbidity. This includes cranial nerve deficits for skull-base tumors and bowel and bladder dysfunction when S2 or S3 nerves are injured or sacrificed for sacral tumors.[71-73] As such, surgery in combination with RT is often used.[74] An analysis of the Surveillance, Epidemiology, and End Results program of the National Cancer Institute consisting of 345 patients treated from 1974 to 2011 showed that 5-year overall survival of 78% to 80% was achieved with treatment using surgery with or without RT.[75] Chordomas, however, are considered to be quite "radioresistant," with studies demonstrating the volume of disease as well as proximity to critical structures associated with suboptimal oncologic outcomes.[76-78] As such, repeat surgery is often considered in the event of an incomplete resection prior to administering RT in order to optimize oncologic outcomes. Chemotherapy does not play a role in the definitive management of patients with chordoma, given the absence of active and effective agents.

Radiation Therapy

RT principles for chordoma are similar to that for osteosarcoma and chondrosarcoma. Definitive RT is recommended for inoperable tumors or for patients refusing surgery. Adjuvant RT is indicated after incomplete resection of tumors at high risk for local recurrence. Chordomas are considered "radioresistant" tumors, and as such, doses greater than 70 Gy are required. Given the high RT doses and adjacent critical normal tissues, advanced planning techniques, such as particle therapy, are favored. Local control rates ranging from 54% to 90% have been reported with definitive RT.[57,59,79,80] Figure 95.3 illustrates treatment volumes and proton treatment plan for a sacral chordoma treated with definitive RT. When treating pelvic bone tumors to high doses, it is essential to be mindful of dose constraints for the cauda equina, sacral plexus, bowel, and rectum. DeLaney et al provide guidance on dose constraints for these organs at risk based on treatment-associated toxicities with their phase II study of high-dose radiation for bone sarcomas.[80] Skull-base tumors also require particular attention to organs at risk during treatment planning, including brainstem, optic structures, spinal cord, cochlea, and temporal lobes.[81-83] In general, we accept higher dose constraints (and consequently higher risk of toxicities) when treating bone sarcomas compared to nonradioresistant tumors to enhance local control. Careful review of dose distribution to the treatment volumes and organs at risk during treatment plan review is essential to ensure the optimal therapeutic ratio has been achieved. Oftentimes, target volumes are undercovered near critical organs at risk. In addition, it is important to consent patients appropriately to the higher risk of toxicities.

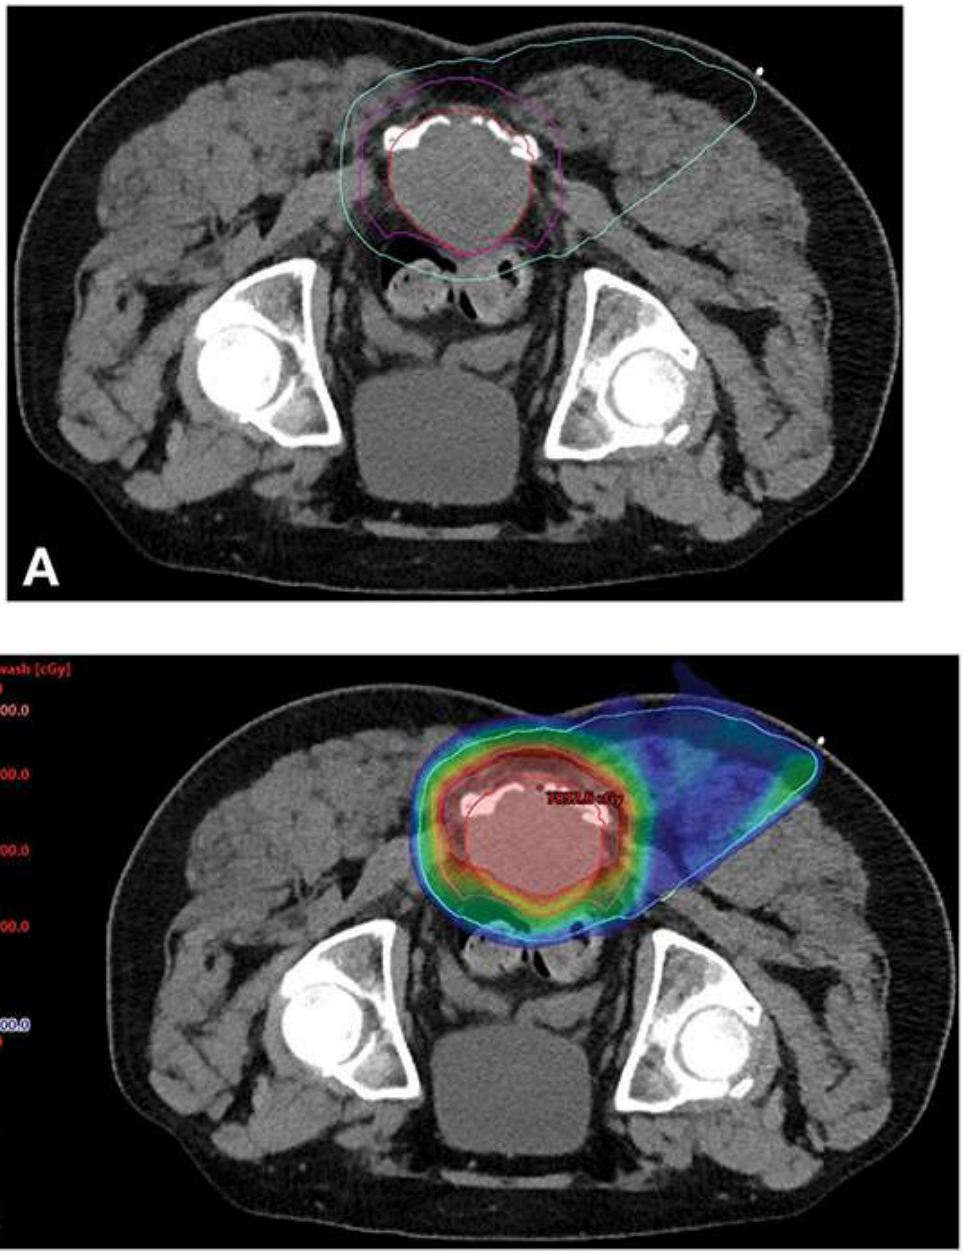

FIGURE 95.3 A. Treatment volumes for a patient with sacral chordoma. The patient was simulated and treated in the prone position. Gross tumor volume (GTV) is represented in red. The high-dose clinical target volume (CTV) is represented in magenta. The low-dose CTV includes the biopsy tract and is represented in cyan. B. Proton treatment plan. The GTV was treated to 73.5 Gy in 30 fractions (equivalent to 83 Gy in 1.8 Gy per fraction), the high-dose CTV was treated to 69 Gy in 30 fractions (equivalent to 77.4 in 1.8 Gy per fraction), and the low-dose CTV was treated to 54 Gy in 30 fractions.

TREATMENT-ASSOCIATED TOXICITIES

Given the aggressive approaches needed for the treatment of bone sarcomas, it is important to be mindful of the treatment-associated toxicities. For tumors treated with surgery, late complications are largely related to surgical interventions. Limb

functional outcomes are associated with the location of the primary tumor along with the type of resection and reconstruction performed. Radiation-associated complications depend on tumor location as well. For pelvic tumors, treatment-associated toxicities can include joint fibrosis, decreased range of motion, bone fracture, limb-length discrepancy, weakness, neuropathy, fertility issues, sexual dysfunction, bowel toxicity, rectal bleeding, lymphedema, osteonecrosis, and risk of secondary malignancy. For extremity tumors, radiation can be associated with joint fibrosis, decreased range of motion, bone fracture, limb-length discrepancy, weakness, gait changes, lymphedema, osteonecrosis, and risk of secondary malignancy. For spine tumors, key treatment-associated toxicities include spinal cord damage, bone fracture, osteonecrosis, and risk of secondary malignancy. For skull-base tumors, there is a risk of blindness, cranial nerve dysfunction, pituitary dysfunction, stroke, brain necrosis, osteonecrosis, hearing loss, and secondary malignancy. Physical rehabilitative therapy should be considered for all cases to help minimize late functional impairment.

CHAPTER 96

Ewing Sarcoma

Line Claude, Akmal Safwat, Raquel Davila Fajardo, Marija Kacar, Matthew Krasin, and Daniel Indelicato

EPIDEMIOLOGY

Ewing sarcoma family of tumor (EWS) accounts for about 2% of cancers in children and is the second most common primary tumor of the bone in childhood. EWS primarily affects adolescents/young adults, with a median age of 15 years and rarely occurring in children younger than 8 years or adults older than 25 years.[1] The incidence is estimated to be 3 in 1,000,000 per year in White population[2] but is rarer in African and Asian people.[3]

Overall survival (OS) has improved mainly in localized disease since a few decades, thanks to a multimodal treatment approach. Five-year OS in localized EWS increased from approximately 45% to 70% after the 1990s.[4] Five-year OS in metastatic disease has also increased but remains quite poor (30%-40%),[3] especially for patients with metastasis beyond isolated lung lesions.

PATHOLOGY AND CYTOGENETICS

Light microscopy shows a tumor of small, round blue cells that lack markers for lymphoma, neuroblastoma, or rhabdomyosarcoma. Cytogenetics has shown that EWSs of the bone and soft tissue are undifferentiated members of a tumor family that shares a common neuroectodermal precursor cell, arrested at different stages of differentiation.[5] Cells are periodic acid-Schiff positive, vimentin positive, and often cytokeratin positive. Approximately 95% of EWSs have a translocation between the *EWS* gene on chromosome 22 and the *FLI1* gene on chromosome 11 (t[11;22][q24;q12]) or the *ERG* gene on chromosome 21 (t[21;22][q22;q12]).[6] The translocations are present only in tumor cells and occur in bone and soft tissue EWS, primitive neuroectodermal tumors of the

bone and soft tissue, peripheral primitive neuroectodermal tumors, Askin tumors, some esthesioneuroblastomas in children, and some central nervous system (CNS) tumors.[7]

The t(11;22) juxtaposes the *EWS* gene with the *FLI* gene (*EWS/FLI* gene), which seems to act as an aberrant transcription factor, resulting in tumorigenesis.[8] The t(11;22) breakpoint location has been reported as prognostic factor in some publications,[9] but both recent reports from EURO-EWING 99 (EE99) study and Children's Oncology Group (COG) study have not confirmed this impact.[10,11]

Since 2020, the World Health Organization (WHO) has recognized three other small round cell tumors previously classified as EWS but now distinctly recognized as separate, both pathologically and molecularly. This includes translocations involving the *EWS* gene and non-ETS genes (*NFATc2*, *SMARCA5*, *PATZ1*, *SP3*), CIC-rearranged sarcomas (eg, CIC-DUX4 fusion), and BCOR-rearranged sarcomas (eg, BCOR-CCNB3 fusion). These translocations are associated with different mechanisms of oncogenesis and have different clinical impacts and, therefore, are now classified as undifferentiated small round cell sarcomas of bone and soft tissues along with EWS by WHO.[12-14]

CLINICAL PRESENTATION

Locoregional pain is the most common presenting symptom in patients with EWS, reported in about 90% of cases. Pain can be intermittent and variable in intensity, often not completely disappearing during the night.[15] As the majority of patients with EWS are in their second decades of life and physically active, pain is often mistaken for "bone growth" or injuries. Tumor growth eventually leads to a visible or palpable swelling of the affected site. The tumor bulk, however, may be indiscernible for a long time in patients with pelvic, chest wall, or femoral tumors. Significant limitation of movement has been described in 25% of presentations, and a pathologic fracture is reported in 10% to 15% of cases.[15]

As EWS may arise in virtually any bone and in soft tissue, additional symptoms, depending on the affected site, may vary considerably. Patients with chest wall or pelvic primaries may experience significant complaints only at a very late stage. Neurologic symptoms or signs occur in 15% of

children, either as spinal cord compression or as peripheral nerve compression.

Unlike other bone sarcomas, constitutional symptoms such as fever, weight loss, and fatigue can be noted at presentation, mostly in advanced and/or metastatic stages, affecting about one-third of patients.[16] The duration of symptoms prior to the definitive diagnosis can be weeks to months, with a median of 3 to 9 months.[17]

DIAGNOSTIC WORKUP: LOCAL AND SYSTEMIC

Local Workup

The initial imaging investigation when an osseous lesion is suspected is usually a simple radiograph. EWSs are defined as a destructive lesion of the bone. Tumor-related osteolysis, detachments of the periosteum from the bone (Codman triangle), and spiculae of calcification in soft tissue tumor masses suggest the diagnosis of a malignant bone tumor. Diaphyseal location suggests an EWS, as compared with the metaphyseal location more common in osteosarcoma.[18]

Local computed tomography (CT) and magnetic resonance imaging (MRI) are needed, and complementary CT outlines better the bone extent of central EWS. The most precise definition of the local extent of disease, including tissue extension, the intramedullary portion, and the relation of the lesion to adjacent blood vessels and nerves, is provided by MRI[19] (Figure 96.1).

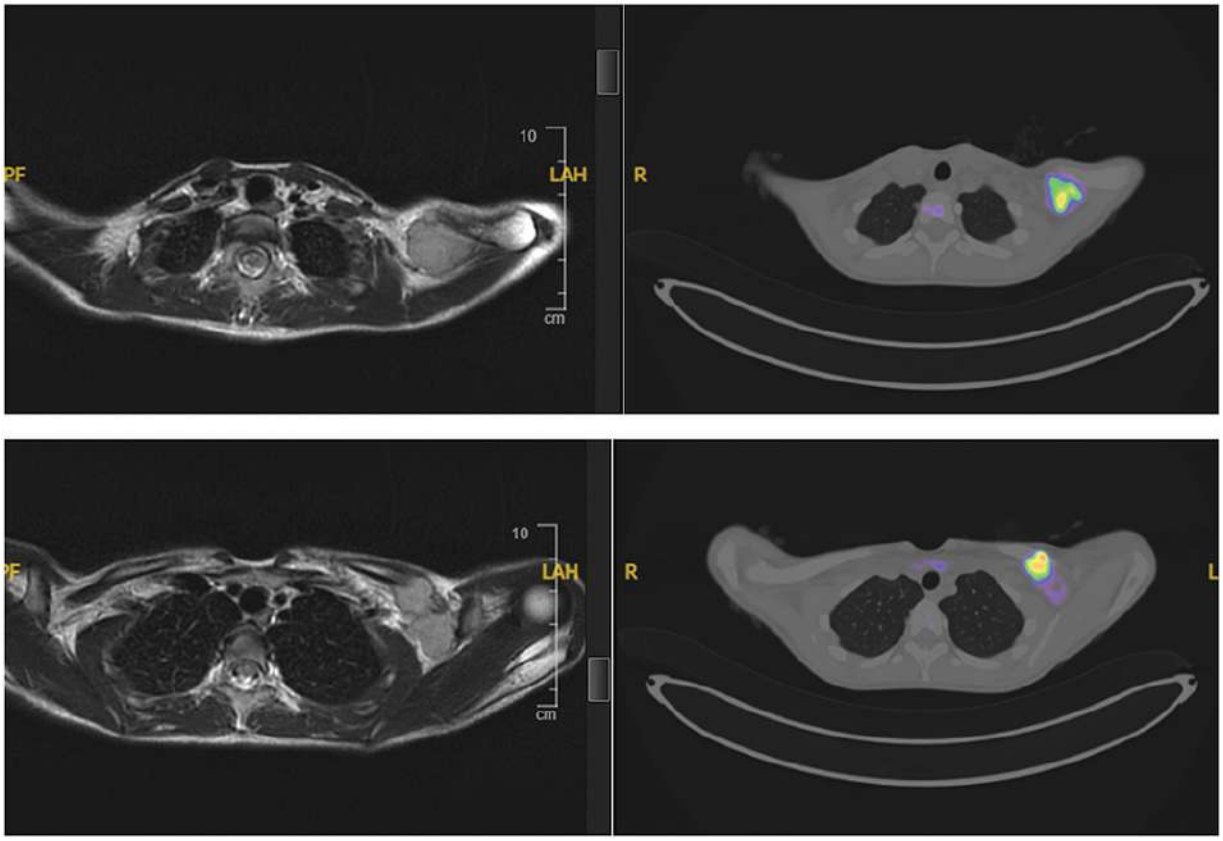

FIGURE 96.1 Example of a localized Ewing sarcoma from the left clavicle in a 14-year-old girl. Magnetic resonance images are shown on the left and fluorodeoxyglucose positron emission tomography/computed tomography on the right.

Systemic Workup

Nonspecific signs of tumor or inflammation may be noted, such as an elevated erythrocyte sedimentation rate, moderate anemia, or leukocytosis. The pretreatment serum lactate dehydrogenase rate may be a prognostic factor.[20]

Currently, fluorodeoxyglucose positron emission tomography (FDG-PET/CT) is recommended in the systemic staging; it is sensitive and accurate in staging EWS compared with non-PET imaging.[21] FDG-PET/CT has been shown to detect more bone metastases than traditional bone scans do, both at diagnosis and at recurrence.[22]

The gold standard diagnosis for bone marrow (BM) involvement has long been made by cytologic and pathologic analysis through BM aspiration and biopsy. Several recent studies suggest that invasive BM biopsy should no longer be systematically performed for the staging at the

diagnosis of EWS if FDG-PET/CT shows no sign of distant BM involvement.[23,24]

CT remains a superior diagnostic method for detecting lung metastasis as lesions less than 8 mm are not always detectable using plain film or FDG-PET/CT imaging.[21,22] Whole-body MRI has also been reported to be superior to bone scan in detecting bone metastases in patients with EWS, particularly diffusion-weighted images or short-time inversion recovery images.[19] It also involves substantially less radiation than at FDG-PET/CT. The whole-body MRI availability is still a limiting point, and the question whether whole-body MRI or FDG-PET/CT has a better diagnosis ability still has to be confirmed on large studies.[25]

The potential utility of integrated PET/MRI for the primary diagnostic workup in patients with EWS has also to be confirmed in the future, but preliminary results are positive.[26]

Results of Workup

EWS can occur in any part of the body but most commonly involves the pelvis and proximal long bones. EWS can be extraosseous (20%) and can arise in numerous organs (kidney, liver, brain, etc) and are more frequent in adults.[27,28]

Approximately 53% of EWS have a primary site in an extremity, and 47% have central primaries.[2,29] EWS can be localized everywhere, but the most frequent sites are the pelvis (23%-25%), femur (16%-18%), below the knee (10%-16%), ribs (12%-13%), spine (8%), and humerus (5%).[30] On the whole, the proportion of metastatic patients at diagnosis is about 25% in large prospective studies. Metastasis is more frequent in pelvic primaries as compared with tumors of the extremities or ribs.[2,31,32]

Metastatic extent can vary from solitary lesion in a lung or a bone to systemic disease with extensive affection of multiple organs, including BM. Most frequent metastatic sites are the lungs (40%) and bones (40%), with less common disease involving the BM, lymph nodes, soft tissue, and visceral sites. Rarely, the CNS is involved.[2,20]

PROGNOSTIC FEATURES

Metastatic status at diagnosis is the strongest prognostic factor across different treatment strategies, whereas the 5-year progression-free survival (PFS) remains less than 30% for metastatic patients.[31] However, patients with only lung metastasis have a better clinical outcome than those with metastases in other sites. Three-year PFS is about 50% to 55% in recent studies.[4]

The most important risk factors in both localized disease and metastatic disease are reported in Table 96.1.

TABLE 96.1 POOR-RISK FACTORS IN EWING SARCOMAS AT DIAGNOSIS

Poor-Risk Factors in Localized Disease	Poor-Risk Factors in Metastatic Disease
Axial tumor (pelvis ++, spine) vs extremities[2,29,33,99,125-131]	Metastasis other than in lung[4,31,132]
Large volume > 200 mL or size > 8 cm	Large volume > 200 mL or size > 8 cm[31]
Poor histologic response[133-136]	
Age > 14 y[2,29,33,127-130,133,137]	Age > 14 y[2,29,31,33,127-130,133,137]
Inflammatory disease at diagnosis (fever, LDH, CRP, anemia)[138,139]	Inflammatory disease at diagnosis (fever, LDH, CRP, anemia)[138-140]
	>5 extralung metastases and/or bone marrow involvement and/or uncommon sites[31,61]

CRP, C-reactive protein; LDH, lactate dehydrogenase.

RESULTS OF THERAPY

Results of Clinical Trials for Patients With Localized Disease at Diagnosis

Local controls (LCs) and survival rates are shown in Table 96.2 for patients treated with different local treatment strategies in recent cooperative group trials that reported appropriate data. LC after surgery (or surgery and radiotherapy [RT]) is over 90% in recent trials. Historically, LC after definitive RT was reported close to 75%, but nonoperated tumors were usually much bigger, in poorer sites (pelvis especially) than tumors treated by surgery. In recent international studies using "modern" RT and local strategy optimized to the situation (site, tumor volume, and expected local

treatment sequelae), the LC after surgery, definitive radiation, and combined modality local therapy is the same (over 90%), regardless of approach.[33,34]

Results After Definitive Radiotherapy

The question whether RT dose escalation in nonoperated patients can increase the LC as well as the survival is pending and was suggested in four studies.[34-37] Ongoing studies, such as the International Clinical Research Programme to Improve Outcomes in Newly Diagnosed Ewing Sarcoma–Trial 1 (INTER-EWING-1, EudraCT number: 2021-005061-41) and the iEuroEwing trial (EudraCT number 2019-004153-93), investigate the role of a boost delivered on the postinduction chemotherapy residual volume, in a randomized manner. The COG is likewise investigating the indications for, and benefits of, dose escalation for large tumors. This will be paired with necessary data collection on toxicity and functional consequence.

EWS of the pelvis is historically associated with a worse prognosis when compared to nonpelvic tumors. Patients with pelvic tumors often present with larger tumor volumes compared with extremity sites and more often have metastatic disease at diagnosis. The 5-year-PFS is between 41% and 66%[38] as compared with 5-year PFS over 75% in patients with nonpelvic localized tumors using recent strategies.[39] However, in the last COG AEWS1031 trial using optimized local and systemic strategies, results were better with a 5-year event-free survival (EFS) of 75%.[33] In this study, the pelvis location was not a risk factor for inferior LC or EFS. Encouraging results with 3-year PFS of 83% have also been obtained after high-dose proton therapy (+/− surgery) in a retrospective study on selected patients with pelvic localized EWS.[37] These results support the question of dose-escalation strategies addressed in current trials in patients with pelvic EWS to optimize the outcome.

Impact of Postoperative Radiotherapy

Different factors have traditionally served as indicators for postoperative RT, that is, histopathology, response to induction chemotherapy, site of primary tumor, quality and size of the resection margins, and whether the

prechemotherapy tumor volume extension and/or the originally contaminated tissue were completely removed. In general, tumors located in the pelvis and paraspinal tumors are very likely to benefit from RT.[40-42] The indication for RT and its benefits should be carefully balanced in very young children, as well as in the situations where radiosensitivity genetic predisposition is present.

Jereb et al[43] found that the local recurrence rate after conservative surgery was high without RT. Ozaki et al[44] also reported a slight advantage for adding postoperative RT for patients with inadequate margins. Dunst and Schuck[45] reported that patients with a wide resection alone but a poor histologic response had a local failure rate of 12%, in comparison with 6% for similar patients who received postoperative RT.

In addition, taking into account competing events, a recent analysis of the EE99 trial showed that adjuvant RT improves LC for all the patients, even after good response to induction chemotherapy.[40] With a median follow-up of 6 years, 8-year local relapse incidence was 12%. A statistically significant reduction of local relapse was shown in patients treated with surgery and RT compared to surgery alone ($P = .02$). The benefit of RT was particularly marked for tumors larger than 200 mL at diagnosis and less than 100% necrosis. A nonsignificant trend for benefit associated with postoperative RT for PFS, EFS, and OS was reported.

As a consequence, in the EE2012 protocol, postoperative RT was discussed for all patients, except for those who have had a wide local excision, defined as negative resection margins of at least 1 mm, and a good histologic response (>90% necrosis) to preoperative chemotherapy and with removal of all tissues originally involved by the prechemotherapy tumor volume. Results are pending.

Prospective studies with quality control on radiation are, however, highly required to assess the balance between adjuvant RT benefit and risks, especially in patients with complete R0 resection and good histologic response.

Within the INTER-EWING-1 trial, as well as in the iEuroEwing trial, randomizations are proposed in order to attain evidence as to the optimal dose in postoperative setting. A dose escalation of 9 Gy with prescriptions ranging between 45 versus 54 Gy (or 50.4 vs 59.4 Gy, depending on the anticipated risk for local recurrence) is used in the iEuroEwing trial.

The INTER-EWING-1 trial will randomize 45 versus 54 Gy in postoperative situations. In the trial, a prospective quality control is mandatory for all the randomized patients to ensure the homogeneity of the treatment (delineation and planning treatment).

In the COG trials, a dose of 50.4 Gy (1.8 Gy once a day) is given if postoperative RT is indicated, mainly in case of microscopic positive margins. The most recent COG study (AEWS1031) did not consider histologic response as an indication for radiation, but it did inform the size of the RT treatment margins.[33]

Doses in the range of 30 to 44.8 Gy at 1.8 Gy a day have also been reported to be effective for subclinical disease.[44,46]

In a review of 153 patients treated with surgery followed by postoperative RT from Cooperative Ewing Sarcoma Study (CESS) 86 and EICESS 92, Schuck et al showed that the interval between surgery and RT did not influence survival, although there was a slight trend for improved LC in patients receiving RT less than 90 days postoperatively.[47]

Systemic therapy does also influence the rate of local relapse and ultimately survival. The first Intergroup Ewing's Sarcoma Study reported that the addition of doxorubicin improved LC.[48] The first Children's Cancer Group/Pediatric Oncology Group (CCG/POG) intergroup study showed an improvement in survival in the intensified arm for patients with localized disease and large primary or pelvic tumors. The improvement with the more intensive regimen resulted from a decrease in the rate of local relapse; the rate of distant metastases was similar in both arms.[30]

Impact of the Systemic Treatment

The dose intensity of the induction chemotherapy is also important. In a randomized trial for patients younger than 50 years with localized EWS (*n* = 568), Womer et al. reported that vincristine, actinomycin D, cyclophosphamide, and doxorubicin and ifosfamide-etoposide (VAC-IE) given on an every-2-week schedule was found to be more effective (median 5-year EFS 73%) than VAC-IE given on an every-3-week schedule (median 5-year EFS 65%), with no increase in toxicity.[39]

The compressed vincristine, doxorubicin, cyclophosphamide, ifosfamide, and etoposide (VDC-IE) scheme was confirmed as the best induction

treatment (as compared with the vincristine, ifosfamide, doxorubicin, and etoposide [VIDE] induction) in the international randomized European trial for both patients with localized disease and metastatic patients. The 3-year PFS was over 80% in patients treated with surgery with or without RT compared with patients with good histologic response.[49]

The time interval between initiation of chemotherapy and start of RT has also been reported to influence survival (LC was not evaluated), with early RT preferable to late RT.[45]

In addition, few institutions have used a single transplant to treat high-risk patients with localized disease (large primary tumors or tumors of the pelvis/trunk), while both LC and survival are poorer in these patients. Two cooperative groups used high-dose chemotherapy busulfan-melphalan (HDCT-BuMel) as consolidation treatment for high-risk localized EWS, defined by poor histologic response to induction chemotherapy.[50,51] They have reported encouraging results (5-year EFS between 49% and 72% in high-risk patients), which were the basis of EE99-R2 trial for high-risk localized disease. Between 2000 and 2013, from 477 patients classified as "high-risk patients," 216 were randomized to vincristine, actinomycin D, and ifosfamide (VAI) or HDCT-BuMel. Some patients requiring RT to the primary site were excluded to avoid excess organ toxicity from interaction between axial RT (high dose to digestive tract, spinal cord, or lung) and busulfan. In an intention-to-treat analysis, the risk of an event was significantly decreased by HDCT-BuMel compared to VAI: 3-year EFS was 67% using BuMel versus 53% after VAI (P = .023). OS was also significantly better after HDCT-BuMel.[52]

As a consequence, HDCT-BuMel can be considered an option for adjuvant therapy in poor responder patients with high-risk localized disease, instead of conventional adjuvant chemotherapy.

Results of Clinical Trials for Patients With Metastatic Disease at Diagnosis

Patients With Lung Metastasis Only

The 5-year EFS for patients with lung metastases ranges is about 50% to 55% in the most recent studies.[53-55]

The phase III EURO-EWING 2012 (EE2012) trial established the VDC-IE chemotherapy to be the new standard induction therapy for EWS, including patients with lung metastasis at diagnosis.[49]

Whole-lung irradiation (WLI) has been shown to improve survival in the CESS 81, CESS 86, and EICESS 92 trials for patients with lung metastases as the only site of metastatic disease at diagnosis.[55],[56] The CESS 81 and CESS 86 studies also showed increasing survival rates with an increasing RT dose to the lung fields, particularly with a dose of greater than 18 Gy (corrected for lung transmission) at either 1.5 Gy once a day or 1.25 Gy twice a day.

The Italian Sarcoma Group and the Scandinavian Sarcoma Group designed a joint prospective study for 102 patients with metastatic EWS (lungs, pleura, or single bone).[53] Intensive combination chemotherapy, surgery, and/or RT and consolidation treatment with HCDT-BuMel and WLI were planned. Only 71 patients of 102 received the whole therapeutic program, mostly because of disease progression. With a median follow-up of 62 months, 5-year OS and PFS for the whole group were 52% and 43%, respectively. However, for the patients with only lung metastases who completed the therapeutic program, 5-year OS and PFS were 66% and 53%, respectively.[53]

The EE99-R2Pulm and subsequent EWING 2008 trials thus evaluated in a randomized way the question of the best consolidation treatment after initial chemotherapy with VIDE, comparing WLI with conventional VAI chemotherapy versus HDCT-BuMel in patient with lung metastasis. Two hundred and eighty seven patients were randomized: 143 received VAI-RT and 144 received HDCT. The 3 and 8-year EFS of the randomly assigned patients was 56.6% and 52.9%, respectively, after HDCT versus 50.3% and 43.1% for the conventional arm patients (P = .16). No benefit of BuMel compared with VAI plus WLI in terms of OS was observed. Significantly, more patients in HDCT experienced severe acute toxicities than in the standard arm. The authors concluded that in EWS with lung metastases, there is no clear benefit associated with HDCT-BuMel compared to conventional chemotherapy combined with WLI.[54]

The question whether local treatment (surgery or stereotactic body radiotherapy [SBRT]) in addition to WLI should be done on residual lung metastasis after induction chemotherapy remains under debate, but several

nonrandomized studies encourage to develop and test this strategy.[57,58] As an example, in a study from MD Anderson, pulmonary metastasectomy with or without WLI significantly improved survival, compared to those not having metastasectomy (80% vs 0% at 5 years). Despite a clear selection bias in this study, it shows potential for improved survival among patients who undergo metastasectomy.[58]

Results in Patients With Metastasis Other Than Lung

Patients with de novo bone metastasis fare poorly compared to patients presenting with pulmonary-only metastasis.[59,60] Moreover, solitary bone metastasis has superior outcomes compared to those with more than one bony metastasis.[31]

In patients with disseminated disease, results are better with adequate treatment of the primary as well as all the metastases whenever feasible. EE99 showed that the 3-year EFS was better (47%) for patients receiving both surgery and radiation to the primary lesion versus either surgery alone (25%) or RT alone (23%). Without local therapy, the EFS was 13%.[59]

Paulino et al showed similar results with local therapy to all sites of metastatic disease in a pediatric series, with disease control rate at 3 years of 94% versus 32% when no local treatment was performed on mets.[61] Similarly, an American retrospective study on adults showed a survival benefit after local treatment of all the extrapulmonary metastasis when feasible.[62]

These analyses are subject to selection bias and need to be confirmed with addition data. If pursued, it is acceptable to delay the RT to metastatic sites until close to the end of chemotherapy if a significant amount of BM would be treated.

Further intensification of this strategy through adding ganitumab (a monoclonal antibody against the insulin-like growth factor-1 receptor) was tested in a phase III trial of pediatric patients with newly diagnosed metastatic EWS (AEWS1221 COG protocol). In the experimental arm, ganitumab was added to the standard VDC-IE treatment. No difference in EFS or OS between the two arms was shown.[63] Despite the increased toxicities in the ganitumab arm, the study has shown the feasibility of using targeted therapy in addition to intensive chemotherapy in this clinical

situation. Other targeted therapy may prove more effective in the future. For example, a phase Ib study using the combination of regorafenib with conventional chemotherapy for the treatment of newly diagnosed patients with multimetastatic EWS was recently opened to assess the feasibility of the combination (NCT05830084). If the safety is established, regorafenib will be randomized in addition to VDC-IE in the INTER-EWING-1 trial for patients with other than lung metastatic EWS.

Many institutions have investigated end intensification with HDCT and stem cell rescue with and without total-body irradiation (TBI), for patients with metastatic disease. TBI has been largely abandoned as part of the conditioning regimen. Many different regimens have been used, mostly a combination of melphalan with etoposide, busulfan, carboplatin, and thiotepa.[64]

Table 96.3 presents results of the most recent studies with HDCT in metastatic situations.

TABLE 96.3 SURVIVAL IN METASTATIC EWING SARCOMA: MOST RECENT STUDIES

BuMel, busulfan/melphalan; HDCT, high-dose chemotherapy; IE, ifosfamide-etoposide; N, number of patients; OS, overall survival; PFS, progression-free survival; TBI, total-body irradiation; VAC, vincristine, dactinomycin, and cyclophosphamide; VACA, vincristine, actinomycin D, cyclophosphamide, doxorubicin; VAI, vincristine, dactinomycin, ifosfamide; VAIA, vincristine, dactinomycin, ifosfamide, and doxorubicin; VDC-IE, vincristine, doxorubicin, cyclophosphamide, ifosfamide-etoposide; VIDE, vincristine, ifosfamide, doxorubicin, etoposide; WLI, whole-lung irradiation.

Patients with metastatic disease treated on EICESS studies between 1990 and 1995 had a superior 4-year EFS when HDCT was added to the end of therapy, but CCG-7951 showed no improvement with this approach over a matched cohort from other Ewing tumor studies for patients with bone or BM metastases.[60,65] Some institutional pilot studies without strict selection criteria show promising, but not conclusive results.[66-71] The EURO-EWING 99-R3 study evaluated the efficacy of induction chemotherapy (six courses of VIDE), local treatment (surgery and/or RT), and HDCT in 281 patients with EWS with primary disseminated disease. After a median follow-up of 3.8 years, the 3-year EFS for the entire study cohort was disappointing (27%), but the EFS rates were 57% and 25% for patients with complete and partial response after HDCT, respectively. The comparison of the outcome of patients with and without HDCT was not possible because of the bias introduced in the nontransplant group: 82% of patients without HDCT died after a median time of 1 year.[31]

More recently, 109 patients with metastasis other than lung were randomized in the Ewing 2008 trial, between adjuvant HDCT (treosulfan/melphalan) versus conventional adjuvant chemotherapy. No

difference in survival was shown, and results were still disappointing with 3-year EFS about 20%.[72]

The benefit of HDCT in patients with nonpulmonary metastatic disease remains under debate in Europe. It is generally avoided in North America. The question whether patients with highly chemosensitive disease benefit from HDCT will be hopefully answered by the French trial CombinaiR3 (NCT03011528). These results are forthcoming.

GENERAL MANAGEMENT

Biopsy

The biopsy should be performed at the same institution where the treatment will be performed, ideally by a sarcoma specialist. Tissue has to be collected for microscopy as well as cytogenetics. Image-guided core-needle biopsy has been reported as safe and efficient and is now the first-line method for establishing a definitive diagnosis in EWS.[73] As often as possible, extraosseous soft tissue alone is sampled.

Induction Chemotherapy

Effective local *and* systemic therapy is necessary for the cure of EWS. Induction chemotherapy is preferred to starting the systemic therapy and local therapy concomitantly, in both localized and metastatic EWS. There are several advantages to this approach: Administering the chemotherapy first allows an evaluation of the effectiveness of the regimen. Response rates to induction chemotherapy are high, with radiologic complete response and partial response rates of up to 90% reported.[66,74,75] Good histologic response (>90% have been reported in >60% in recent studies).[49] Dose-intensive chemotherapy with VDC-IE has been reported as the most effective, less toxic, and shorter in duration and is now the standard of induction chemotherapy in all stages of newly diagnosed EWS.[49] Induction chemotherapy also allows local treatment to adapt to the postchemotherapy tumor volume. For example, shrinkage of the soft tissue mass may help the surgeon or radiation oncologist decrease the volume of the local therapy. Shrinkage of the soft tissue mass may also allow the surgeon to achieve better margins.

Primary Tumor Local Treatment

Retrospective studies demonstrate better LC and EFS after complete surgery (+/− followed by RT) as compared with RT alone.[61,76,77] However, patients treated with exclusive RT often come from older protocols and generally have a lower prognosis: larger tumors, more pejorative sites, and poor response to chemotherapy.[77-79] Modern prospective cooperative group studies tend to demonstrate that LC, EFS, and OS are similar following definitive surgery, definitive radiation, or surgery plus radiation.[33,80] Thus, the decision regarding local therapy is based on a multidisciplinary discussion of expected side effects and toxicity of each approach.

North American Versus European Strategies

In North America, the use of surgery (vs RT or surgery + RT) as part of local therapy is guided by the results of COG study AEWS1031, which had a cumulative incidence of local failure of 6%, the lowest reported to date in prospective trials of EWS.[33,80] There were no statistically significant difference in outcomes by LC modality, tumor site, or patient age. Thus, determination of RT versus surgery versus surgery and RT is based on a multidisciplinary discussion of side effects and toxicity of local therapy for each given situation. Generally speaking, surgery alone is often the choice for extremity tumors while definitive radiation is utilized for axial tumors. If surgical margins are unexpectedly positive following an attempt at definitive surgery, postoperative radiation is indicated. The role of preoperative radiation remains undefined in North America but may have a role in selected cases of borderline resectability because the preoperative radiation dose is less than the definitive or postoperative radiation dose.

In Europe, the strategy has gradually moved from exclusive RT to surgery with or without RT. Surgery of the primary tumor is nowadays considered as the standard of treatment, providing a complete resection is expected. In case of either incomplete surgical resection or inacceptable surgical toxicity is expected, definitive RT is the alternative, representing 23% to 30% of the EWS local treatment in the recent trials.[49,66,81] Intralesional resection or debulking procedures followed by RT do not offer increased LC or PFS compared with definitive RT and should be avoided.[77]

After surgery, different factors have traditionally served as indicators for postoperative RT, that is, histopathology, response to induction chemotherapy, site of primary tumor, quality and size of the resection margins, and whether the prechemotherapy tumor volume extension and/or the originally contaminated tissue were completely removed. In general, tumors located in the pelvis and paraspinal tumors are very likely to benefit from RT.[40-42] The indication for RT and its benefits should be carefully balanced in very young children, as well as in the situations where radiosensitivity genetic predisposition is present.

The indications, technical details, and value of preoperative RT for EWS are still being defined. Good results have been reported with preoperative RT for patients with a poor response (<50% reduction of the evaluable soft tissue mass) after two cycles of chemotherapy.[44,82,83] Situations where preoperative radiation can be considered include the following:

- RT is thought to be definitely required.
- Technical advantages to delivering RT prior to surgery (eg, dosimetry, limiting dose to organs at risk)
- Higher risk of microscopic positive margins for resectable tumors in selected sites (eg, pelvis, chest wall)
- The information on the histologic response after induction chemotherapy is not relevant for the further management of the patient.

Consolidation Chemotherapy

Consolidation chemotherapy is indicated in all patients. Consolidation using vincristine, cyclophosphamide, etoposide, and ifosfamide is the standard of care.

For poor-risk localized disease (histologic response >10% viable tumor in resected tumors, or tumor volume >200 mL for nonoperated tumors), EE99 and Ewing 2008 trials conducted randomized studies comparing high-dose therapy using BuMel against standard chemotherapy (VAI, seven courses), demonstrating that BuMel significantly reduces events and deaths compared to standard chemotherapy arm. A 10% difference in both EFS and OS (60% and 64%, respectively) in the BuMel arm was reported. The

BuMel strategy can thus be discussed in poor responding patients with localized disease.[52]

Local Therapy for Metastases

Patients with only lung metastasis have a better outcome than patients with metastasis in other sites.[56] The standard of treatment for patients with only lung metastasis is conventional chemotherapy followed by WLI, while no clear benefit from HDCT (BuMel) was reported. Three-year EFS is around 55% and 50% to 53% at 8 years.[54] Surgical resection or radiation boost using SBRT before WLI can be discussed in case of postchemotherapy-limited residual lung metastasis, as suggested in the current European trials INTER-EWING-1 (EudraCT number: 2021-005061-41) and iEuroEwing trial (EudraCT number: 2019-004153-93).

Local therapy to nonlung metastatic sites is believed to improve survival outcome and is, therefore, recommended whenever feasible.[60,61] Three-year EFS after local therapy of both primary and metastatic sites was reported to be 39% compared to 17% when local therapy is only given to either the primary or the metastatic sites.[60] Local therapy of metastatic sites can be given together with the local therapy of primary site or delayed until the end of the adjuvant chemotherapy, particularly if it involves irradiation of a large volume of the patient's BM.

The option of locally treating all metastatic sites is not feasible in all cases, and the criteria with which to choose patients for this approach (eg, number, site, size) are not clearly defined.

RADIOTHERAPY TECHNIQUES

All patients should be discussed in a multidisciplinary team meeting to decide on the indication for RT of the primary and metastatic sites.

Radiation of the Primary Tumor

Table 96.4 shows the RT dose for primary tumor.

TABLE 96.4 RECOMMENDATIONS FOR RADIATION THERAPY ON PRIMARY TUMOR VOLUMES AND DOSES

Clinical Situation	Total Dose (Gy)	Dose Per Fraction (Gy)[a]	Volume
Definitive radiotherapy	45-50.4	1.8-2	Original bone and soft tissue mass + margin
	5.4-14.4[b] (total dose 54-59.4 to GTV)	1.8-2	Original bone and *residual* soft tissue mass + margin
Postoperative radiotherapy (especially after marginal resection and/or poor histologic response at surgery)	45-54	1.8-2	Original bone and soft tissue mass plus surgical scars and drains (if no increased toxicity deemed) + margins
Preoperative radiotherapy	45-50.4	1.8-2	Original bone and soft tissue mass + margins

CTV, clinical target volume; GTV, gross target volume.

[a]Equivalent doses in the context of the use of simultaneous integrated boost are allowed.

[b]Depending on initial dose.

Exclusive Radiotherapy

Patients not undergoing surgery for the primary tumor or those in whom macroscopic disease is present after resection (R2) will receive definitive RT.

For gross disease, standard treatment is a total dose of 55.8 at 1.8 Gy/day. Prospective studies suggest that doses ranging from 59.4 to 70.2 Gy may enhance LC for large tumors.[34-36]

A dose of 45 to 54 Gy is usually recommended to the initial prechemotherapy target for the initial tumor site (PTVp_Pre), including the initial bone and soft tissue involvement. A boost to a total dose greater than 54 Gy should be directed to the initial bone and the postchemotherapy soft tissue residue (PTVp_Post). Unresectable EWS of the spine and paraspinal region may be treated to 50.4 Gy without compromising LC. LC at doses less than 40 Gy is significantly worse, even for small lesions[84] (Figures 96.2 and 96.3).

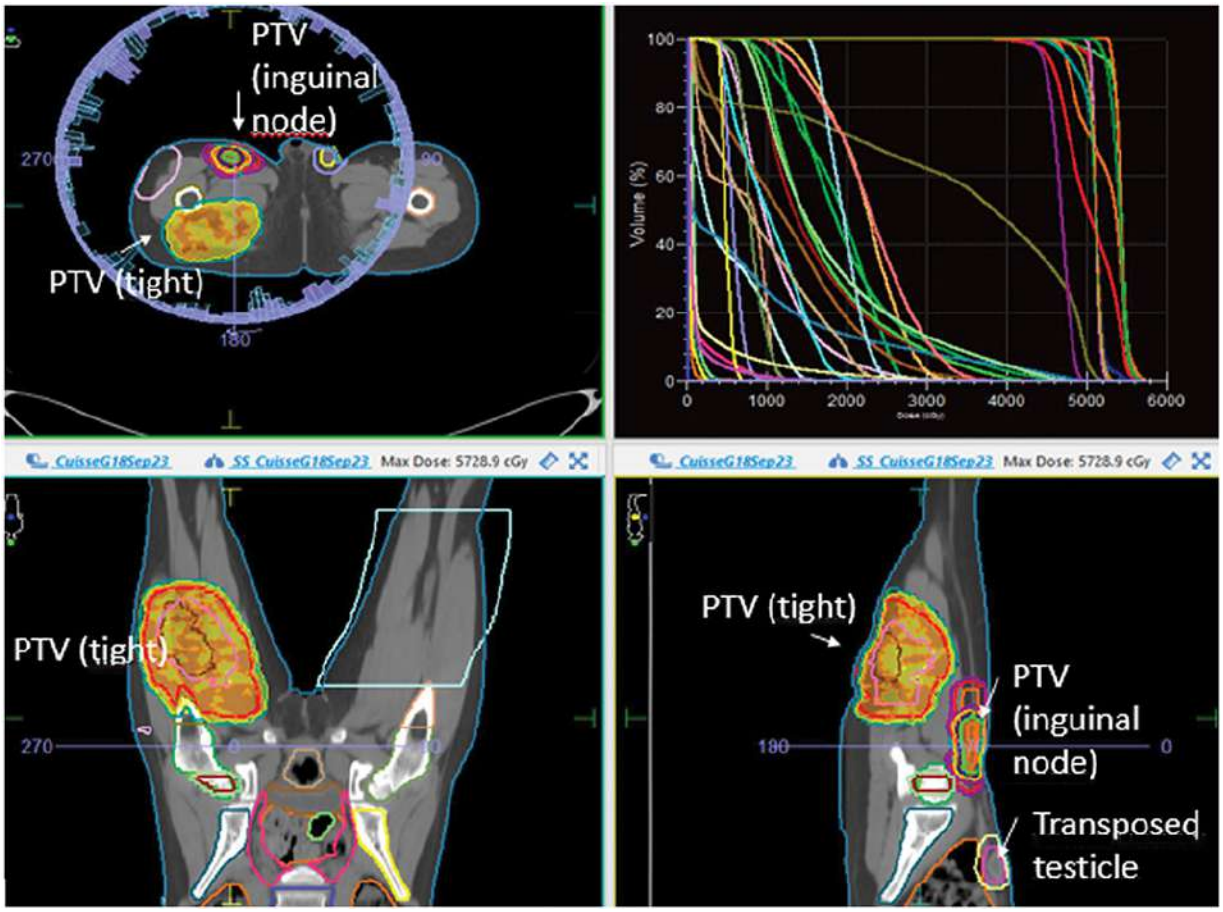

FIGURE 96.2 A 5-year-old boy was treated using preoperative radiotherapy (photons) for Ewing sarcoma of the tight and ipsilateral inguinal proven node involvement. Both primary planning tumor volume (PTV_tight) and PTV_inguinal nodes are represented. Testicles were transposed before radiotherapy to avoid radiation late toxicity.

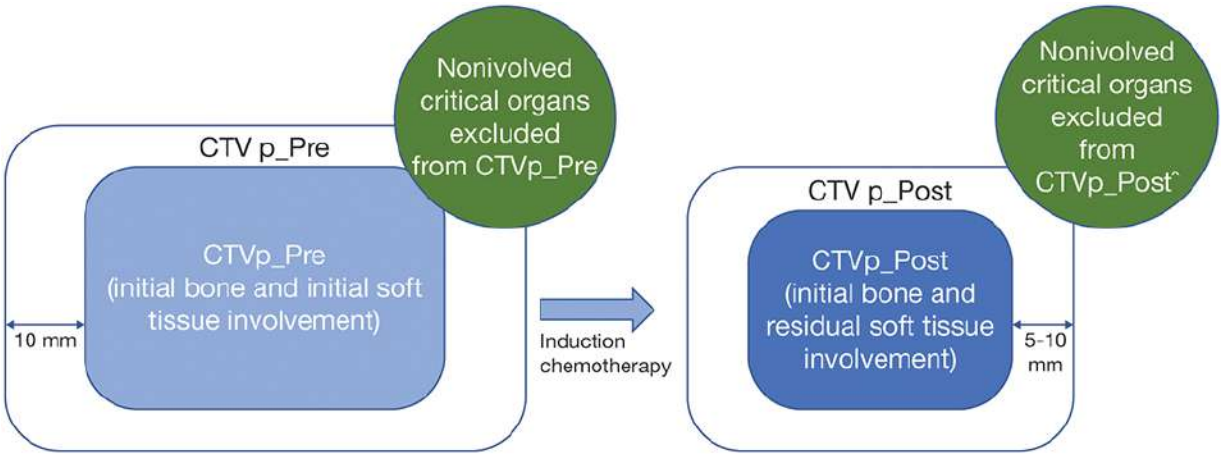

FIGURE 96.3 The concept of volume delineations. Gross tumor volume (GTVp_Pre) is defined as the visible tumor on imaging at its maximal extent (using computed tomography [CT], fluorodeoxyglucose positron emission tomography/CT, bone and magnetic resonance imaging scans, as available) prior to any chemotherapy or surgery. Clinical target volume (CTVp_Pre) should encompass any sites of potential microscopic extension of GTVp_Pre, or of contamination by GTVp_Pre. Margin to CTVp_Pre should be GTVp_Pre + 1 cm isotropic (except in limbs: proximal and distal margin of 15 mm), respecting unviolated anatomic margins to tumor spread. "Pushing borders" within body cavities are not included in the CTV.

Adjuvant Radiotherapy

A total dose between 45 versus 54 Gy depending on the anticipated risk for local recurrence is usually delivered (ie, INTER-EWING trial).

In the COG trials, a dose of 50.4 Gy (1.8 Gy once a day) is given if postoperative RT is indicated, mainly in case of microscopic positive margins. The most recent COG study (AEWS1031) did not consider histologic response as an indication for radiation, but it did inform the size of the RT treatment margins.[33]

Doses in the range of 30 to 44.8 Gy at 1.8 Gy a day have also been reported to be effective for subclinical disease.[44,46]

Preoperative Radiotherapy

The total dose for preoperative RT is usually ranging between 50.4 and 54 Gy (1.80/fr) in a single phase. If there are concerns about organ tolerance or wound healing, a reduction of dose to 36 to 45 Gy can be considered.

Radiation on Metastatic Sites

Local Therapy of Lung Metastasis

WLI is given independent of metastatic response to induction chemotherapy. The recommended WLI total dose is usually 12 to 15 Gy in young children or 15 to 18 Gy in older patients (>14 years). This is usually delivered at 1.5 Gy per fraction daily.

Residual metastasis after chemotherapy is often considered for metastasectomy or extra boost using stereotactic technique, particularly if the number of metastasis is less than 3.

SBRT can be used instead of surgery to treat inoperable or nonresectable residual lung mets after chemotherapy. Doses for SBRT boost are typically 30 to 35 Gy in five fractions, depending on the number and sites of lung metastasis.

Poor responders to induction chemotherapy whose lung metastasis cannot be removed probably still benefit from WLI.[85]

Local Therapy of Bone Metastasis

A dose of around 50 Gy to the metastatic bone site can lead to 91% LC rates at 3 years, as seen in an MSKCC study.[86] The same study concluded that this benefit declines with a number of metastasis more than five. SBRT to metastatic sites less than 5 cm is effective, well tolerated, with the advantage of a short treatment time. A retrospective study of 14 pediatric patients with 27 EWS or osteosarcoma lesions were treated with 40 Gy using SBRT in five fractions reported a 2-year LC rate of 85% and a low toxicity rate.[87] A Swedish study in patients with adult sarcoma reported also excellent results after SBRT in 46 patients with 136 metastatic sarcoma lesions. Overall response rate was 88% with a median follow-up of 21 months. The LC rate for the 14 EWS cases was 75%.[88] Several ongoing trials recommend the use of SBRT on EWS metastasis.[89] The St Jude EWS trial (NCT01946529) recommends RT to metastatic sites at week 19 and allows to use SBRT with 30 Gy in six fractions. The COG AEWS1221 (NCT02306161) recommended local therapy for metastasis after the completion of consolidation chemotherapy and allows for the use of SBRT with 40 Gy in five fractions.

Both INTER-EWING-1 trial and iEuroEwing trial also recommend a systematic treatment of extrapulmonary mets providing a limited number of

lesions, including SBRT when feasible.

Radiotherapy After High-Dose Chemotherapy With Busulfan

Because of the high risk of toxicity of the association of RT and HDCT including busulfan (BuMel), both indications should be early discussed in multidisciplinary meetings.

In case of patients receiving BuMel before RT, the total dose can be limited (generally at 45 Gy), whereas the dose constraints to major critical organs have to be strictly respected to avoid severe toxicity. Using conventional fractions, RT doses will not exceed 30 Gy to the spinal cord[90] and 45 Gy on a small volume of the gastrointestinal tract, including the bowel, colon, rectum, stomach, and duodenum.[91] Large irradiated lung volumes should be also avoided. Hemithoracic lung or whole-lung RT is not recommended in first-line treatment after HDCT-BuMel, because of the risk of respiratory toxicity. Spacer devices can be discussed in the pelvis to displace the bowel away from treatment volumes.

Modern external beam radiation techniques, such as intensity-modulated radiotherapy (IMRT) techniques, volumetric modulated arc therapy (VMAT), or proton therapy should be used to spare critical organs as much as possible in this situation. For patients who receive HDCT-BuMel, RT should begin later; especially when organs such as spinal cord, lung, or bowel need to be exposed to RT. In general, RT should commence at least 10 weeks after BuMel-HDCT delivery.[53,92,93]

Fractionation

Standard fractionation delivers 1.8 to 2 Gy per fraction, 5 days a week.

Twice-a-day RT has been used in several trials. To treat EWS, radiation oncologists at the University of Florida used 1.2 Gy twice a day to a total dose of 50.4, 55.2, or 60 Gy, depending on the tumor response to induction chemotherapy, and showed that late effects could be decreased while maintaining good LC, even for large primary tumors.[94,95] In CESS 86, doses of 1.6 Gy twice a day to a total of 60 Gy were given, although not in a continuous course. The Italian SE-91 trial also used 1.6 Gy twice a day to a total of 60.8 Gy, but in a continuous course. The CESS 86 trial showed no advantage for the accelerated hyperfractionated approach, but the early

results of SE-91 were promising with regard to LC.[45,96] Both of the latter regimens would be theoretically expected to increase late effects, but this remains unproven.

Radiation Volumes

The POG 8346 trial showed, in a randomized manner, that the traditional approach of irradiating the entire marrow cavity was not necessary.[76] Although "tailored" fields are the standard of care today, attention to the requisite volume is critical to obtaining maximal control rates; geographic miss has been a frequent source of failure in cooperative group studies.[76,97] Three-dimensional treatment planning, an appropriate immobilization, and cone-beam CT guidance are essential.

Gross tumor volume (GTV1/GTVp_Pre) is defined as the visible tumor on imaging at its maximal extent (using CT, FDG-PET/CT, bone and MRI scans, as available) prior to any chemotherapy or surgery.

Clinical target volume (CTV1, or CTVp_Pre) should encompass any sites of potential microscopic extension of GTV1/GTVp_Pre, or of contamination by GTV. The inclusion of metallic prostheses, drain sites, and surgical scars (if feasible and no extra toxicity is anticipated) are discussed, but the benefit is unclear. Margin to CTV should be GTV + 1 cm isotropic, respecting unviolated anatomic margins to tumor spread. "Pushing borders" within body cavities should not be included in the CTV.

The concept of internal target volume should be implemented when applicable (mobile targets), especially in thoracic or abdominal sites.

Planning target volume (PTV1, or PTVp_Pre) is defined from CTV1/CTVp_Pre, with a margin to account for day-to-day setup variation. This will vary according to tumor location in the body and the used immobilization and is specific to individual institutions. PTV1/PTVp_Pre will be typically CTV1 + 0.3 to 1.0 cm.

The boost is delivered to the residual tumor volume (GTV2/GTVp_Post) at the time of RT plus a 0.5 to 1 cm margin to CTV2/CTVp_Post. Any initial bone or BM abnormalities in the primary bone should be included in GTV2/GTVp_Post. CTV2/CTVp_Post does not need to include scars and drain sites. It should take into account anatomic barriers to tumor spread,

such as facial boundaries and bone. PTV2/PTVp_Post will be typically CTV + 0.3 to 1.0 cm.

The use of MRI is essential to identify the tumor extent, at the diagnosis and after the induction chemotherapy. PET-CT may be helpful for planning.

Extremity tumors may require sparing of at least a 1- to 1.5-cm strip of normal tissue to prevent lymphedema (corridor), aiming for a V20 50% or more constraint (D1.0 mL ≤ 50 Gy). An effort ought to be made in order to spare adjacent growth plates and joints without compromising adequate target coverage.[36]

With the high doses of cyclophosphamide or ifosfamide given in consolidation chemotherapy regimens for Ewing tumor, it is important to minimize the dose to the bladder.

Radiotherapy in Special Sites

Ribs

Rib lesions should be treated conformally with a minimum of lung and heart in the high-dose field. However, rib primary tumors often present with pleural effusion.

In the EICESS 92 trial, the 7-year rate of EFS was 63% with hemithorax RT versus 46% without.[47] Claren et al. recently confirmed that pleural effusion at diagnosis and incomplete resection were both independent risk factors for survival in localized tumor of the rib. Eighty-two French patients, with median age 13.6 years and median follow-up 8.4 years, were treated in EE99 protocol and reviewed. Five-year PFS was 69%. Pleural effusion and incomplete surgical resection (R1 or R2) were independent prognostic factors for PFS and OS. In case of initial pleural effusion, documented or not, OS was 27% without RT versus 68% after RT (P = .01).[98]

For very small pleural effusions that are considered to be reactive, ipsilateral hemithorax RT may be judged not to be necessary, particularly in young children. Doses between 12 to 15 (young children) and 15 to 18 Gy (older patients) are typically prescribed.

Spine

The type of local treatment remains a pending question in this site.

The standard dose for vertebral lesions used to be 45 Gy due to the limited dose to spinal cord and led historically to limited LC. As an example, a French cohort of 75 patients with localized spinal EWS treated between 1988 and 2009 was reported. Local treatment modality was surgery and RT in 50 patients, RT alone in 19, and surgery alone in 6. After a 7-year median follow-up, the 5-year LC, EFS, and OS were 78.0%, 57.0%, and 70.0% (95% confidence interval: 59.1-81.0), respectively.[99]

Modern techniques including VMAT or protons allow nowadays to increase the dose of RT beyond 50.4 Gy for tumors adjacent to the spinal cord to standard doses of 55.8 Gy for tumors below the spinal cord. In a large retrospective American study including 59 patients with spine EWS, the 5-year estimate of local failure by tumor site was low (3.6%), with no statistically significant difference in local failure incidence by local treatment modality (surgery vs definitive RT).[100]

HDCT-BuMel should not be given before RT for spinal lesions if RT dose to the spinal cord is expected to be over 30 Gy, because of the increased risk of myelitis.[90]

Treatment for Relapses

The prognosis after relapse is poor, with a 5-year OS of only 13% for patients recurring after treatment in the CESS 81, CESS 86, and EICESS 92 studies. Patients experiencing either late (>2 years) or isolated localized relapses fared slightly better, with 5-year OS 24% to 30%.[2,101] Relapse occurring only at the local site warrants aggressive attempts at salvage.[101] To date, no standard treatment has been defined in relapsed EWS. Patients who relapse only with lung metastases can sometimes be salvaged with additional chemotherapy and WLI. Resecting or treating the lung metastases with SBRT, if there are fewer than four lesions, may also be beneficial.[102] Patients with late pulmonary relapses fare better than those with early relapses.[103] Patients who relapse with bone metastases, however, are essentially incurable with current available therapies.

Positive response rates have been reported in retrospective studies and/or phase II trials, including topotecan-cyclophosphamide,[104] temozolomide-irinotecan,[105] gemcitabine-docetaxel,[106] and high-dose ifosfamide.[107] A recent international multiarm “rEEcur” trial (multistage randomized phase

II/phase III trial) comparing these four regimens was recently reported. High-dose ifosfamide was shown to be more effective in prolonging survival than the other combinations.[108]

The role of HDCT for relapsed tumors, which respond to second-line therapy, is controversial, with both positive and negative results reported in retrospective and single-arm studies.[92] A systematic review on the role of HDCT for children and young adults with relapsed EWS concluded that most studies using HDCT/autologous stem cell transplantation (aSCT) as consolidation regimen showed improved survival benefits compared to conventional chemotherapy.[109] Randomized controlled studies are highly needed to determine the true clinical benefit of HDCT followed by aSCT in patients with relapsed EW.

SEQUELAE OF TREATMENT

Treatment for EWS has been reported to have an actuarial complication rate of 70% at 35 years.[110] Paulino et al reported that 10 (53%) of 19 patients receiving RT alone, 4 (25%) of 16 receiving surgery alone, and 2 (40%) of 5 undergoing combined surgery and RT therapy had significant late effects.[111]

More recently, a retrospective chart review of 101 pediatric patients reported the most common complications were musculoskeletal abnormalities (50%) and cardiac toxicity (28%).[112] Neither study included loss of function related to planned surgical resection as a complication.

The most common skeletal complication of RT is abnormal growth and development of the irradiated tissues. RT can cause premature closure of active epiphyses, producing growth deficits and limb-length discrepancies. The degree of discrepancy depends on the RT dose, patient's age, and epiphysis radiated. Because 65% of leg growth is from the distal femoral (37%) and proximal tibial (28%) epiphyses, typical RT doses to the knee in boys younger than 14 years of age and girls younger than 12 years of age will usually cause a severe enough leg-length discrepancy to require intervention.[113] Deficits of 2 to 6 cm can usually be managed by a shoe lift; larger deficits require surgical treatment.

Approximately 15% of long bone lesions develop pathologic fractures at some time in their course, 5% at diagnosis, and 10% after RT, although

approximately one-third of the latter are caused by tumor recurrence or occasionally a secondary malignant neoplasm (SMN).[114] Whether the fracture is disease or treatment related, the most common site is the femur, particularly the proximal femur. RT-related fractures usually occur within 24 months after treatment but can be much later. Doses below 40 Gy using once-a-day doses of 1.8 to 2.0 Gy appear to have a very low risk, as does a hyperfractionated approach using 1.2 Gy twice a day from 50.4 to 55.2 Gy.[114,115] Extremity weakness, decreased range of motion secondary to fibrosis, pain in the extremity (particularly in the early morning), discoloration of the skin, and lymphedema can also occur after RT, even with careful planning and sparing of an adequate strip of tissue. Sarcomas, often osteosarcoma, are the most common second tumor, and the risk for increased dose therapy has been reported as 1% to 5% at 20 years.[112,116-118]

The Italian Sarcoma Group Experience followed 543 patients with EWS, treated between 1983 and 2006. Fifteen patients (2.8%) experienced secondary cancer. The cumulative 10- and 20-year incidence was 3.4% ± 0.9% and 4.7% ± 1.6%, respectively. The most common SMN in the EWS group was RT-induced osteosarcoma ($n = 6$).[119]

The British Childhood Cancer Survivor Study reported cause-specific mortality and risk of secondary neoplasms for 664 bone sarcoma survivors.[120] Beyond 25 years of follow-up, the risk of dying from all causes was comparable to the general population. In contrast, before 25 years, the risk was 12.7-fold than expected. Survivors were 4 times more likely to develop a secondary cancer than expected (bone and breast mainly), but the excess was restricted to 5 to 24 years postdiagnosis.

Retrospectively analyzed data from 4,518 patients with EWS treated in five consecutive trials from the CESS group were also reported.

The latency period between EWS and the secondary cancer was 8.4 years for solid tumor and 2.4 years for hematologic secondary malignancy ($P < .001$). The cumulative incidence of SMNs increased over time from 4% at 10 years to 14% at 30 years. An increased risk at radiation doses greater than 60 Gy was reported.[121]

The quality of life of 618 long-term survivors of EWS was reported by Ranft et al. Median observation time was 12.9 years from primary diagnosis. Survivors were less active than control subjects; however, the recommended level for an active lifestyle was achieved. This study

demonstrated that overall survivors of EWS were able to return to normal activity levels with minor limitations. Pelvic tumor location was the major inferior disease-specific prognostic factor as well as older age at diagnosis and female sex.[122] About 10% patients develop significant pulmonary dysfunction after WLI.[123,124]

FUTURE CONSIDERATIONS

Although the 5-year survival rate of patients with EWS appears to have improved since 1970, almost half of all patients diagnosed with Ewing tumor die of it within 10 years.[3] Outcomes for patients with metastatic disease other than lung and recurrent EWS especially remain poor with current strategies.[112]

Recent international trials have defined the better induction chemotherapy regimen for all the patients, but the limits of intensification have probably been reached with the presently available drugs.

For patients with localized disease receiving modern chemotherapy, more information is needed to estimate the probability of local progression. Traditional factors (eg, primary tumor site, modality of local therapy, patient age, histologic response) may no longer apply, and thus local disease risk stratification is a challenge. Accurate risk stratification is critical to identify which patients would benefit from treatment intensification (eg, radiation dose escalation) and de-escalation (radiation avoidance). Moreover, comparative data on toxicity and function following LC with radiation, surgery, or a combination thereof are largely absent. Within each group, subtypes of local therapy are unexplored: Outcomes based on specific surgical technique and radiation modality, such as IMRT and proton therapy, are important topics for future investigation. Future studies should prospectively collect these data to aid individualized decisions surrounding local therapy. The question whether treatments other than chemotherapy (ie, immunotherapy, targeted treatments) could be safe and efficient is crucial for high-risk patients (metastatic situations and recurrences); several trials will evaluate them in the next future (NCT05830084). The most promising targeted therapies are those acting on the microenvironment and are under research.[4] In addition, the question of maintenance treatment is also under debate and will be also randomized in two next trials (INTER-EWING 1

[EudraCT number 2021-005061-41], and iEuroEwing trial [EudraCT number 2019-004153-93]).

Future COG LC efforts are focused on risk stratification to help guide local therapy de-intensification and intensification. Future European LC efforts are also focused on practice homogenization and prospective quality control to improve local treatment data.

In patient with metastases at diagnosis, treating all metastases with RT or surgery appears to be promising for these high-risk patients. SBRT is promising, particularly in patients with oligometastatic disease. Feasibility and toxicity have to be prospectively evaluated to assess the benefits of such strategies.

International harmonization efforts are also ongoing (ie, Harmonization International Bone Sarcoma Consortium (HIBiSCus), Euro-Ewing consortium) to pool our strengths in these rare tumors, both in systemic treatments and in local strategies.

CHAPTER 97

Lymphomas in Children, Adolescents, and Young Adults

Sarah A. Milgrom, James E. Bates, Matthew D. Hall, Jamie E. Flerlage, Sharon M. Castellino, and Louis S. Constine

Childhood lymphomas comprise a broad spectrum of cancers with a range of prognoses. A challenge in management is to optimally balance treatment intensity with its attendant toxicity. Historic treatment with large radiation fields and high radiation doses, although effective, caused unacceptable morbidities in children, such as impaired musculoskeletal development, increased risks of secondary benign and malignant neoplasms, and cardiopulmonary and other organ toxicities. The introduction and refinement of effective systemic therapies enabled reductions in radiation field sizes and doses. In addition, modern radiation techniques have been incorporated into standard management, further reducing the radiation dose to normal tissues.

Modern research aims to tailor therapy to maximize efficacy and minimize treatment-related toxicity. There is a focus on risk and response adaptation to intensify therapy in children with an unfavorable prognosis and de-escalate treatment in those with a favorable prognosis. Thoughtful application of radiation therapy (RT) maintains a critical role in risk- and response-adapted treatment algorithms for pediatric lymphomas, given its efficacy.

HODGKIN LYMPHOMA

Hodgkin lymphoma (HL) constitutes a class of diseases that arise in both children and adults. Although histologic similarities between adult and pediatric subtypes exist, there are differences to suggest that the biology is only partially shared. For example, the clinical presentations vary in terms of gender ratio, distribution of histologic subtypes, hypotheses of etiology, role of Epstein-Barr virus (EBV), and prognosis.[1] Historic therapies, though effective for disease control, caused substantial cumulative morbidity in children.[2,3] Since patients were often cured, survivors of pediatric HL who were treated with historic approaches have served as models for understanding the long-term toxicity of RT and chemotherapy. A strong desire to avoid the toxicities associated with high-dose, extended-field RT prompted the first generation of studies examining combined modality therapy using lower radiation doses and/or smaller fields with the expectation that multiagent chemotherapy could eradicate microscopic disease.[4-9] The elevated rates of secondary malignancies attributed to alkylating agents led to the second generation of investigations using doxorubicin-containing chemotherapy regimens to reduce doses of alkylating agents.

Outcomes of children and adolescents with HL have improved over time, and 5-year survival rates now exceed 90%.[10] Today's treatment of children with HL employs multiagent chemotherapy regimens and nuanced RT approaches to mitigate long-term toxicity. Risk- and response-adapted treatment approaches are now widely employed: Patients receive varying intensities of chemotherapy with or without low-dose RT, with many contemporary studies using treatment response to guide elimination of RT in appropriately selected patients.[11-17] Future directions will aim to identify and subsequently integrate biologic markers to tailor therapy in patients with either very good or very poor outcomes.

Epidemiology

In the United States, childhood HL is the eighth most common cancer in children (ages 0-14) and the most common malignancy of adolescence (ages 15-16).[10] Although non-Hodgkin lymphoma (NHL) is slightly

more common than HL in children younger than 14, comprising 6% versus 4% of all cancer diagnoses, HL is more common than NHL in adolescents, constituting 15% of new cancer diagnoses compared to 8%.

There is marked variation in the international incidence of HL, with an inverse relationship between the occurrence of the childhood and young adult forms of the disease.[18,19] Countries with a high incidence of childhood HL generally demonstrate a low incidence of young adult HL and vice versa. Early and intense exposure to infectious agents has been speculated to increase the risk for the childhood form of HL.[20,21]

The childhood form of classic HL (cHL) usually occurs in children older than 10 years and is rare in children younger than 4 years. The incidence is associated with male gender, increasing family size, and decreasing socioeconomic status.[22-25] In the United States, Caucasians have the highest overall incidence rates for both males and females, but the male gender association of childhood HL is strongest in Black and Hispanic patients.

In contrast to childhood HL, adolescent and young adult cHL is associated with a higher socioeconomic status, smaller family size, and later birth order.[21-23] There is a roughly equal incidence between adolescent males and females.[26] Similarities between HL and paralytic poliomyelitis suggest that delayed exposure to an infectious agent may be a risk factor for the development of young adult HL, with the risk of oncogenesis increasing with later age of infectious exposure.[23] Interestingly, there also seems to be an association between exposure to children at nursery school and daycare and decreasing risk of young adult HL, most likely by facilitating early childhood exposure to common infections and promoting maturation of cellular immunity.[21]

Nodular lymphocyte–predominant HL (NLPHL) is a less common subtype compared to cHL, representing approximately 5% of pediatric HL diagnoses. It is associated with a much higher incidence in males, Caucasians, and younger children (<10 years), and it does not have a strong association with income or birth order.[27]

Pathologic Classification

As in adults, pediatric HL follows the World Health Organization (WHO) classification into two major groups of HL: cHL and NLPHL. Distinctions between groups are made according to their biologic and clinical features.[28,29] cHL is further subclassified into nodular sclerosing (NS), mixed cellularity (MC), lymphocyte-rich (LR), and lymphocyte-depleted (LD) histologies based on their unique morphologies. The most prevalent subtype in North America is NS cHL. NLPHL has a better outcome, and treatment typically varies from that of cHL. Of note, this category of lymphoma is called NLPHL in the WHO,[28] but it is labeled nodular lymphocyte–predominant B-cell lymphoma (NLPBL) by the 2022 International Consensus Classification.[29]

The relative distribution of the subtypes differs in younger children compared with adolescents and adults.[25,30] Although NS is the most common subtype in all age groups, it constitutes a significantly larger proportion of cases of adolescents (77%) and adults (72%) than in children younger than age 10 (44%). Conversely, MC subtype is more common in younger children (33%) than in adolescents (11%) or adults (17%). Similarly, NLPHL is more common in children younger than 10 years (13%) than in adolescents (8%) and adults (5%). LD subtype is rare in all age groups.[25]

Biology

Pediatric HL and NHL arise from the germinal center of lymph nodes. HL is unique among the lymphomas because the malignant Reed-Sternberg (RS) cells in cHL and lymphocytic-and-histiocytic (L-and-H) cells in NLPHL account for less than 1% of the tumor cell population. Identical immunologic gene rearrangements in RS and L-and-H cells support their origin from a single transformed B cell that subsequently undergoes monoclonal expansion.[31-33] There are two distinct immunophenotypes of HL, which distinguish the differentiation of HL into WHO's classifications of cHL and NLPHL.[28] The first immunophenotype associated with cHL is characteristic of RS cells that consistently express CD30 and often express CD15 with weak PAX5 expression.[28] The second immunophenotype associated with NLPHL

is characteristic of L-and-H cells that consistently express CD20 and J chain and do not express CD30 or CD15.[33,34]

Considerable evidence suggests an etiologic role of EBV in the pathogenesis of both childhood and young adult HL.[35,36] Early serologic studies linked EBV to HL.[35,36] Delayed early adolescent exposure to EBV is frequently associated with the development of infectious mononucleosis, and studies show an increased risk of HL in patients diagnosed with infectious mononucleosis.[37-42] In addition, increased EBV antibody titers have been observed in patients with HL several years prior to their HL diagnosis.[43] The incidence of EBV-associated HL varies by age, gender, ethnicity, histologic subtype, geography, and regional economic level.[36] EBV-positive tumor genomes are more frequent in children younger than 10 years and in those who live in low-income countries.[36] EBV positivity is most common in MC and LD cHL and is observed in approximately 80% of children aged 0 to 14 years with these subtypes. Tumors of children with NS HL were found to be EBV positive in nearly 40% (childhood HL) and 20% (young adult HL) of cases.[36]

The association of lymphoma with inborn errors of immunity is increasingly recognized. HL is also associated with inherited (eg, ataxia-telangiectasia)[44] and acquired (eg, human immunodeficiency virus [HIV]) immunodeficiencies, and EBV appears to be an important cofactor in the development of HL in these patients.[45] There is familial clustering of HL with concordance in siblings who have an over 4-fold increased risk of developing HL.[46] As high as a 99-fold increased risk in monozygotic twins of patients with HL has been reported, with no increased risk in dizygotic twins.[47] These familial cases of HL suggest a genetic predisposition to the disease.[48]

Clinical Presentation

Most pediatric patients with HL present with cervical lymphadenopathy.[49] The typical clinical presentation includes the indolent onset of lymphadenopathy, compressive symptoms due to a mediastinal mass, and/or systemic (“B”) symptoms. The lymph nodes are often fixed, firm, and painless. Mediastinal involvement is present in 76% of adolescents but in only 33% of children aged 1 to 10 years.[49] If mediastinal lymphadenopathy is present, it may be associated with a nonproductive cough, respiratory distress, or other symptoms of tracheal or bronchial obstruction or with superior vena cava (SVC) syndrome, but patients have relative clinical stability due to the slow growth and ability to accommodate compromise with collaterals. While disease may spread below the diaphragm, isolated infradiaphragmatic HL is rare, occurring in less than 5% of patients. Central nervous system (CNS) involvement is extremely rare.[50]

As a result of cytokine production by the RS cells, one-third of patients have one or more B symptoms at diagnosis. These include recurrent unexplained fevers greater than 38.3 °C during the previous month, drenching night sweats, or weight loss of more than 10% of body weight in the 6 months preceding diagnosis.[49,51] Other cytokine-mediated systemic symptoms may include anorexia, pruritus, fibrosis, eosinophilia, thrombocytosis, plasmacytosis, and immunodeficiency.[52]

Diagnostic Workup

The investigations required for accurate staging and diagnosis of childhood lymphomas are summarized in Table 97.1. The diagnosis of HL is made based on morphology, immunohistochemistry, and flow cytometry reviewed by experienced lymphoma pathologists. When appropriate, molecular studies may be needed for further characterization. The diagnosis is facilitated through an excisional lymph node biopsy to provide adequate tissue for evaluation of the malignant RS and L-and-H cells and of the characteristic architectural changes associated with the specific histologic subtypes. Although less desirable, core-needle biopsy can be considered when excisional biopsy is not possible; however, lack of adequate tissue may result in failure to obtain the diagnosis from a core- needle biopsy specimen.[53]

TABLE 97.1 INVESTIGATIONS REQUIRED FOR ACCURATE STAGING AND DIAGNOSIS OF CHILDHOOD LYMPHOMAS

History and Physical Examination

B symptoms (unexplained recurrent fever, drenching night sweats, weight loss >10% body weight within 6 mo)
Examination of lymph node regions, liver, spleen
Blood Work
Complete blood count with differential
Liver and renal function panels
Erythrocyte sedimentation rate (ESR)
Lactate dehydrogenase (LDH)[a]
C-reactive protein (CRP)
Imaging Studies
Chest radiograph[b]
Neck, chest, abdominal, and pelvis CT scan
Fluorine-18 FDG-PET imaging
Excisional or Incisional Biopsy
Morphology (fixed)
Immunohistochemistry
Immunophenotypic analysis (fresh or fixed)[a]
Cytogenetics (fresh)[a]
Molecular analysis (fresh or fixed)[a]
FISH for specific translocation (fresh or fixed)[a]
Immunoglobulin gene rearrangements (fresh or fixed)[a]
Bone Marrow Examination (Bilateral Aspirates and Biopsies) in Some Cases[a]
Cerebrospinal Fluid Examination (Cell Counts and Cytology) in Some Cases

CT, computed tomography; FDG-PET, fluorodeoxyglucose positron emission tomography; FISH, fluorescence in situ hybridization; NHL, non-Hodgkin lymphoma.

[a]NHL only.

[b]Chest x-ray is necessary if cross-sectional imaging is unavailable, or if needed to assess for mediastinal bulk according to a clinical trial's definition.

Adapted from Shad A, Magrath I. Non-Hodgkin's lymphoma. *Pediatr Clin North Am*. 1997;44(4):863-890. Copyright © 1997 Elsevier. With permission; Gross TG, Perkins SL. Malignant non-Hodgkin lymphomas in children. In: Pizzo PA, Poplack DG, eds. *Principles and Practice of Pediatric Oncology*. 6th ed. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2011:663-682.

A detailed history should evaluate the age, sex, and presence or absence of B symptoms, each of which may alter the management of a child with HL. Fatigue, pruritus, and alcohol- induced pain should be noted. Although these symptoms do not direct treatment, their recurrence may be an early indication of disease relapse. Physical examination involves a detailed lymph node evaluation, including assessment of Waldeyer ring, as well as assessment for splenomegaly and/or hepatomegaly. Laboratory evaluation should include a complete blood count with white blood cell differential and platelet count, erythrocyte sedimentation rate (ESR), albumin, renal and liver function tests, and lactate dehydrogenase (LDH). Evaluation for risk of HIV should be considered, as should a more detailed immunologic profile in younger children.

Imaging of the chest is required to assess for sites of thoracic involvement and for mediastinal bulk. Many protocols, including those run by the Children's Oncology Group (COG), define mediastinal bulk as a mass measuring 33% or more of the maximum intrathoracic cavity on an upright posterior-anterior chest radiograph (CXR). CXR is highly concordant with chest computed tomography (CT) for the detection of mediastinal bulk.[54,55] It is possible that CT-based definitions of mediastinal bulk are stronger predictors of relapse than CXR-based definitions.[55] CT, rather than CXR, is increasingly used to define bulk, with

common definitions including mediastinal masses larger than 10 cm and nonmediastinal masses larger than 6 cm. Even if a CXR is used to assess for mediastinal bulk, a contrast-enhanced CT is necessary in all patients to assess for subcarinal, hilar, and cardiophrenic lymphadenopathy, as well as extranodal disease sites including the pleura, chest wall, or pericardium, which may influence management.[56]

Infradiaphragmatic disease is assessed by a CT scan of the abdomen and pelvis with oral and intravenous contrast to distinguish lymphadenopathy from other structures. CT evaluation of the abdomen and pelvis may be limited, however, with suboptimal contrast administration or in children who lack retroperitoneal fat. In such cases, magnetic resonance imaging (MRI) may provide better assessment of disease involvement in the retroperitoneal lymph nodes.

Essentially all cases of HL demonstrate ^{18}fluorine-fluorodeoxyglucose ([18]F-FDG) avidity, and thus [18]F-FDG positron emission tomography (PET) is required as standard staging for HL.[57,58] The use of PET in addition to CT scans results in a change in disease stage in 10% to 30% of patients, more often upstaging.[59] In addition, PET-CT is critical for monitoring treatment response,[57,58] particularly in cases with persistent radiographic abnormalities[60] or "rebound" thymic growth after completion of therapy.[61] Splenic and hepatic involvement by HL is suggested by the presence of enlarged organs with areas of abnormal density on CT or MRI scans, as well as increased [18]F-FDG uptake on PET scans. Splenic enlargement alone, without nodular densities, does not necessarily indicate splenic involvement.

Traditionally, bone marrow biopsy (BMB) was standard in lymphoma staging; however, PET-CT has a high negative predictive value to exclude marrow involvement in HL.[62] Therefore, in the setting of PET-CT, BMB can be restricted to patients with unexplained cytopenias and a PET that is negative for marrow involvement.[57]

Staging Systems

Children and adults with HL are staged according to the system devised at the Ann Arbor Staging Conference in 1970 and revised at the Cotswolds meeting, as summarized in Table 97.2.[63] Patients are typically treated based on limited (stages I and II, nonbulky) or advanced (stage III or IV) disease, with stage II bulky classified as limited or advanced based on other prognostic factors. Stratification into prognostic groups has varied across and within pediatric consortia by study.[64]

TABLE 97.2 COTSWALDS MODIFIED ANN ARBOR STAGING SYSTEM

Stage	Definition
I	One nodal group or lymphoid organ (eg, spleen, thymus)
IE	Local extension from one nodal group to an extranodal site
II	Two or more nodal groups, same side of diaphragm
IIE	Two or more nodal groups, extension from a nodal group to an extranodal site, same side of diaphragm
III	Nodal groups on both sides of the diaphragm
IIIS	Nodal groups on both sides of the diaphragm, splenic involvement
IIIE	Nodal groups on both sides of the diaphragm, localized extension from a nodal group to an extranodal site
IIISE	IIIS and IIIE criteria
IV	Disseminated involvement of one more extranodal organs (eg, lung, bone, bone marrow, liver) with or without nodal involvement
Modifications	
A	Absence of B symptoms
B	Presence of B symptoms
X	Bulky disease[a]
E	Extranodal extension
S	Splenic involvement

Positron emission tomography-computed tomography used to define extent of disease in Hodgkin lymphoma. Tonsils, Waldeyer ring, and spleen are considered nodal tissue.

[a]Bulky definition varies across protocols but most commonly as a mass of more than one-third of the maximum intrathoracic diameter or extramediastinal mass greater than 6 to 10 cm.

Derived from Lister TA, Crowther D, Sutcliffe SB, et al. Report of a committee convened to discuss the evaluation and staging of patients with Hodgkin's disease: Cotswolds meeting. *J Clin Oncol*. 1989;7(11):1630-1636.

Prognostic Factors

A discussion of prognostic factors in pediatric HL is complicated for several reasons. First, prognostic factors such as disease stage, bulk, and biologic aggressiveness are frequently codependent.[65] Second, identification of baseline prognostic factors is confounded by the impact of therapy, with higher intensity therapies negating previously determined adverse risk factors, and the changing climate of novel therapies.[66] Third, different institutions and cooperative groups have employed various risk stratification schemes within pediatric HL protocols, and within these determinations, patients with early-stage disease have different prognosticators than patients with advanced-stage disease.[65]

The following are some generalizations regarding prognostic variables derived from both adult and pediatric data:

- *Stage of disease* is the most significant prognosticator of treatment outcome. Advanced-stage disease, particularly stage IV disease with multiple organ involvement, confers an inferior prognosis with conventional therapy.[67,68]
- *Bulk of disease* reflects the volume of involvement at each site. Bulky mediastinal adenopathy has historically been associated with an increased risk of disease recurrence, particularly when disease is managed with RT alone.[69-72] Bulky mediastinal adenopathy has been defined using a variety of definitions, most commonly as a mass of more than one-third of the maximum intrathoracic diameter on a posteroanterior CXR.[72-75] Other common definitions include a ratio of the mediastinal mass to the intrathoracic width at T5-6 measuring greater than 1/3,[76] or transverse diameter of greater than 10 cm,[77] 5 cm,[78] or 6 cm[79,80] depending on the protocol. In Europe, bulk is defined as a tumor volume of at least 200 mL estimated using an ellipsoid formula ($V = (xyz)/2$, where x, y, and z are the diameters of the mass in three dimensions).[11,12,17]
- *Systemic or B symptoms*, defined as unexplained fever, drenching night sweats, or unintentional weight loss, result from cytokine secretion. These reflect biologically more aggressive disease and are associated with an increased risk of relapse compared with the absence of such symptoms.[51,68]
- *Abnormal levels of serum markers*, including ESR, hemoglobin, serum albumin, and white blood cell count, are negative prognostic factors.[65,68] These are confounded by increased tumor volume, so it is unclear if elevated serum markers are independently prognostic for more malignant biology of disease.[65,68]
- *Histologic subtype* may correlate with prognosis. Patients with NLPHL have superior outcomes compared to cHL histologies. LD histology confers a worse outcome than the other cHL subtypes, but it is rare.[72] MC has a favorable prognosis when early stage, but a higher relapse risk when advanced stage.
- *Patient age* is a determinant of outcome with children younger than 10 to 15 years of age experiencing superior event-free (EFS) and overall survival (OS) compared to adolescents.[25,30,81]
- *Response to initial therapy* is a prognostic factor,[82] with a rapid early response (RER) associated with superior disease control. Early treatment response was the foundation for trials of response-based conventional therapy that are discussed later. Methods used for response assessment have varied across studies. A five-point score known as the Deauville criteria is a reproducible approach to evaluate response by PET-CT and is now being applied as a standard reporting criterion in both pediatric and adult HLs.[57,83] The Deauville score is defined as follows:
  - 1: No FDG-avidity

- 2: FDG-avidity ≤ mediastinal blood pool
- 3: FDG-avidity > mediastinal blood pool but ≤ liver
- 4: FDG-avidity moderately > liver
- 5: FDG-avidity markedly > liver or new site(s) of disease
- X: New lesion that is not attributable to lymphoma

*Note that the growth of disease or new lesions seen on imaging during therapy are rare, and other reasons for their development should be considered. A biopsy is not needed prior to continuation of prescribed therapy.

There is a prognostic risk scoring system for pediatric HL that is treated with modern era combined modality therapy. This system was defined based on a retrospective analysis of the COG study AHOD0031 that analyzed response-based therapy in intermediate-risk patients. The Childhood Hodgkin International Prognostic Score (CHIPS) allocates one point each for fever, stage IV disease, albumin less than 3.5 g/dL, and large mediastinal adenopathy (defined as mass of more than one-third of the maximum intrathoracic diameter on CXR). CHIPS was highly predictive of EFS, and it identified a subset (CHIPS 2 or 3) that comprised 27% of intermediate-risk patients with inferior outcomes (EFS <80%) with conventional ABVE-PC (doxorubicin, bleomycin, vinblastine, etoposide, prednisone, cyclophosphamide) who may benefit from early intensification of therapy.[84]

General Management

Given the high cure rates and lifespan of pediatric HL survivors, individualized risk for treatment-related late morbidity must be considered when selecting therapies. Historically, extended-field RT to curative doses that could exceed 40 Gy produced the first cures in patients with HL. In children with early-stage disease confirmed by surgical staging, 5-year disease-free survival (DFS) rates following extended-field RT ranged from 60% to 80% when treated with RT alone.[6,85,86] For patients with advanced-stage disease, the development of non–cross-resistant chemotherapy combinations provided the first effective therapy; however, the specific chemotherapeutic combinations have changed as their gonadotoxic and leukemogenic properties have become better understood. Treatment approaches of the past involving large radiation fields and toxic alkylating chemotherapy are no longer used; the observed late morbidity and mortality caused by these treatments have steered the management of pediatric HL to balance the efficacy and toxicity of contemporary combined modality regimens.

Modern trials for the treatment of pediatric HL are summarized in Tables 97.3 and 97.4 and reflected in national guidelines specific to pediatric HL. Current management paradigms involve a risk- and response-adapted approach. Therapy typically involves multiagent chemotherapy followed by low-dose RT for bulky, slowly responding, or residual disease, as summarized in Table 97.5. The development of this treatment approach is discussed later.

TABLE 97.3 SUMMARY OF CONTEMPORARY LOW-RISK PEDIATRIC HODGKIN LYMPHOMA TRIALS

					Percent Outcome (Years)	
Reference	Patients (*n*)	Stage	Chemotherapy	Radiation (Gy), Field	DFS, EFS, or RFS	Overall Survival
Euronet-PHL-C1[11]	440	IA, IB, IIA	2 OEPA	CR, no RT	86 (5)	99 (5)
	273			<CR, 19.8 IF ± 10.8 boost	87 (5)	98 (5)
COG AHOD0431[87]	175	IA, IIA	3 AV-PC	CR, no RT	80 (2)	100 (2)
	100			<CR, 21 IF	88 (2)	
SJCRH HOD05[88,89]	49	I, II	4 VAMP	CR, 15 IF	95.2 (10)	100 (10)
	61			<CR, 25.5 IF	84.5 (10)	93 (10)

Reference	Patients (*n*)	Stage	Chemotherapy	Radiation (Gy), Field	Percent Outcome (Years)	
					DFS, EFS, or RFS	Overall Survival
GOPH-HD-2002[17]	62	IA, IB, IIA	2 OEPA (boys) or 2 OPPA (girls)	CR, no RT	93 (5)	100 (5)
	126			<CR, 19.8-35 IF	92 (5)	100 (5)

AV-PC, Adriamycin, vincristine, prednisone, cyclophosphamide; CR, complete response; DFS, disease-free survival; EFS, event-free survival; IF, involved field; OEPA, Oncovin, etoposide, prednisone, Adriamycin; OPPA, Oncovin, procarbazine, prednisolone and Adriamycin; RFS, recurrence-free survival; RT, radiation therapy; VAMP, vincristine, amethopterin, mercaptopurine, prednisone.

TABLE 97.4 SUMMARY OF CONTEMPORARY INTERMEDIATE- AND HIGH-RISK PEDIATRIC HODGKIN LYMPHOMA TRIALS

Reference	Patients (*n*)	Stage	Chemotherapy	Radiation (Gy), Field	Percent Outcome (Years)	
					DFS, EFS, or RFS	Overall
EuroNet-PHL-C1[12]	514	IIE, IIB, I III, IV	2 OEPA + COPP vs COPDAC (2 for IR, 4 for HR)	AR at ERA, no RT	90 (5)	99 (5)
	773			<AR at ERA, 19.8 modified IFRT +/− 10.8 boost	87 (5)	98 (5)
COG-AHOD1331[13]	289	IIIB, IVA, IVB	5 ABVE-PC vs	LMA or SRL, 21 Gy ISRT	82 (3)	99 (3)
	298		5 BV-AVE-PC		92 (3)	98 (3)

GPOH-HD-2002[17]	139	IE, IIB, IIEA/B,	2 OEPA/OPPA + 2 or 4 COPP/COPDAC	19.8 IFRT ±15.2 boost	88 (5)	100 (5)
	239	IIIEA/B, IIIB, IV			87 (5)	95 (5)

ABVE-PC, Adriamycin, bleomycin, vincristine, etoposide, prednisone, cyclophosphamide; AEPA, Adcetris (brentuximab vedotin), etoposide, prednisone, Adriamycin; AR, adequate response; COPDAC, cyclophosphamide, Oncovin, prednisone and dacarbazine; COPP, cyclophosphamide, Oncovin, prednisone and procarbazine; CR, complete response; DFS, disease-free survival; EFS, event-free survival; ERA, early response assessment; IFRT, involved field; ISRT, involved-site radiation therapy; LMA, large mediastinal adenopathy; OEPA, Oncovin, etoposide, prednisone, Adriamycin; OPPA, Oncovin, procarbazine, prednisolone and Adriamycin; RFS, recurrence-free survival; RNRT, residual node radiation therapy; RT, radiation therapy; SRL, slowly responding lesion.

TABLE 97.5 RECOMMENDED TREATMENT APPROACH IN CLASSIC PEDIATRIC HODGKIN LYMPHOMA

Clinical Presentation	Stage[a]	Recommended Treatment Approach
Low risk Localized disease and absence of "B" symptoms, bulk, or extranodal extension	IA, IIA	**Recommended therapy** 2-4 cycles non–cross-resistant chemotherapy (OEPA, VAMP, COPP-ABV, AV-PC) Response-based low-dose ISRT (1,500-2,550 cGy) **Other considerations** If complete response after 2 cycles of OEPA and absence of bulk or elevated ESR, RT

Clinical Presentation	Stage[a]	Recommended Treatment Approach
		may be omitted[11]
Intermediate risk Localized disease with bulk (mediastinal ratio ≥33%; lymph node mass ≥6-10 cm), B symptoms, and/or extranodal extension. Advanced stage without B symptoms or extranodal disease	I/IIA with bulk, IB, IIB, IE, IIE, IIB[a], IIIA	**Recommended therapy** 3-6 cycles dose-intensive, non–cross-resistant chemotherapy (OEPA/COPDAC, ABVE-PC) Response-based low-dose ISRT (1,500-2,550 cGy) **Other considerations** If rapid early response after 2 cycles and complete response after 4 cycles of ABVE-PC, RT may be omitted[16]
High risk Stage II with B symptoms and bulk. Advanced stage with B symptoms and/or extranodal disease	IIB[a], IIIB, IV	**Recommended therapy** 4-6 cycles of dose-intensive, non–cross-resistant chemotherapy (OEPA/COPDAC/, ABVE-PC, BV-AVE-PC) Response-based low-dose ISRT (1,500-2,550 cGy) **Other considerations** If rapid early response after 2 cycles and absence of mediastinal bulk, RT may be omitted after 5 cycles Bv-AVE-PC[13] Immunotherapy may be considered based on emerging data.

Involved-site radiation therapy (ISRT) is the recommended RT technique. In treatment centers where prechemotherapy, postchemotherapy, and radiation simulation imaging are all obtained in the same position with the radiation simulation immobilization device, then involved-node radiation therapy (INRT) can be used instead of ISRT.

ABV, doxorubicin, bleomycin, and vinblastine; ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; ABVE-PC, doxorubicin, bleomycin, vinblastine, etoposide, prednisone, cyclophosphamide; AEPA, brentuximab vedotin, etoposide, prednisone, and doxorubicin; AV-PC, doxorubicin, vincristine, prednisone, and cyclophosphamide; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; Bv-AVE-PC, brentuximab vedotin, doxorubicin, vinblastine, etoposide, prednisone, cyclophosphamide; CAPDAC, cyclophosphamide, brentuximab vedotin, prednisone, dacarbazine; COPDAC, cyclophosphamide, vincristine, prednisone, dacarbazine; ISRT, involved-site radiation therapy; OEPA, vincristine, etoposide, prednisone, and doxorubicin; VAMP, vinblastine, doxorubicin, methotrexate, and prednisone.

[a]Different studies and cooperative groups have used various risk stratification schemes. When recommending therapy according to a particular protocol, reviewing the inclusion criteria for that study is recommended. For example, patients with stage IIB disease have been variably treated as intermediate or high risk. Some studies use associated risk factors, such as weight loss, bulk disease, and extranodal extension, for further risk stratification.

Combination Chemotherapy

The first effective systemic therapy for HL was MOPP (mechlorethamine, vincristine, procarbazine, prednisone).[90-92] This regimen was associated with ovarian failure in women, infertility in both sexes, and a high rate of secondary acute myeloid leukemia (s-AML).[93,94] The cumulative risk of secondary malignancy is 4% to 8% after MOPP-based therapy,[95] with the incidence peaking 5 to 10 years after treatment.[96] A regimen substituting cyclophosphamide for mechlorethamine (COPP) was associated with a lower incidence of s-AML.[95]

Subsequently, an alternative regimen using ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) was shown to result in superior disease control compared to MOPP.[97,98] This change shifted the toxicity pattern, because the side effects of bleomycin and doxorubicin are pulmonary and cardiovascular injury, respectively, and the risk increases when these agents are combined with RT that delivers dose to the lungs and heart.[71,99,100] Anthracycline exposure confers a dose-dependent risk of cardiotoxicity[101]; therefore, one approach to reduce the risk of cardiomyopathy is to limit the anthracyclines for pediatric HL to a cumulative dose of 250 mg/m^2, particularly in the case of favorable-risk disease. Bleomycin- induced pulmonary toxicity is manifested as a chronic pneumonitis or pulmonary fibrosis and typically occurs at doses exceeding 400 U/m^2.[102] Most modern pediatric HL regimens use doses in the range of 60 to 100 U/m^2. Such doses may result in subclinical pulmonary restriction and

diffusion defects, but toxicity can be exacerbated by thoracic RT. Serial pulmonary function tests including diffusing capacity for carbon monoxide are recommended, and if a significant decline from baseline is observed, bleomycin may be held.[103]

To reduce the treatment-related toxicities associated with six cycles of either MOPP or ABVD, strategies alternating the two regimens, and using fewer cycles of each, were developed. The combined ABVD and MOPP regimens used for children produced excellent disease control with diminished toxicity.[104,105]

Etoposide, a topoisomerase II inhibitor, was incorporated into treatment regimens to intensify therapy for unfavorable HL and serve as an alternative to alkylating agents to reduce the risk of gonadal toxicity.[106-109] There is a risk of secondary leukemia with topoisomerase II inhibitors due to a different pathogenesis than alkylator-related s-AML,[110] and the risk is compounded by the use of multiple topoisomerase II inhibitors. For example, in one POG trial that used dexrazoxane (a topoisomerase II inhibitor) as a cardiac protectant during treatment with ABVE or ABVE-PC, there was an unacceptably high rate of s-AML attributed to the use of multiple topoisomerase II inhibitors.[111] Risk of s-AML is low when the etoposide dose is limited to 5.0 g/m^2 or less.

Using a different multiagent chemotherapy regimen, gender- adapted therapy has been considered, given the differing susceptibility to infertility caused by procarbazine in boys compared to girls. The German Society for Paediatric Oncology and Haematology (GPOH) evaluated a gender-adapted approach according to which boys received OEPA (vincristine, etoposide, prednisone, doxorubicin) to limit alkylator exposure, whereas girls received OPPA (vincristine, procarbazine, prednisone, doxorubicin) substituting procarbazine for etoposide.[17,112,113]

Therapy for children, adolescents, and young adults with HL continues to be refined. Newer systemic agents are emerging, such as brentuximab vedotin (Bv), an antibody-drug conjugate that combines an anti-CD30 antibody with a synthetic tubulin disruptor and thereby targets CD30, which is ubiquitous in cHL. The anti-programmed death-ligand 1 (PD-L1) and anti-PD-L2 drugs exploit the abundance of programmed cell death protein 1 ligands associated with alterations in chromosome 9p24.1 in HL that allows immune evasion of the tumor.

Frontline regimens that are used for pediatric HL today include the following:

- AV-PC (doxorubicin, vincristine, prednisone, cyclophosphamide)[87]
- ABVE-PC[15,16]
- Bv-AVE-PC (brentuximab vedotin, doxorubicin, vincristine, etoposide, prednisone, cyclophosphamide)[13]
- OEPA[11,17]
- OEPA/COPDAC (cyclophosphamide, vincristine, prednisone, dacarbazine)[12,17]
- AEPA/CAPDAC (brentuximab vedotin, etoposide, prednisone, doxorubicin/cyclophosphamide, brentuximab vedotin, prednisone, dacarbazine)[14]
- N-AVD (nivolumab, doxorubicin, vinblastine, dacarbazine)[114,115]
- Bv-AVD (brentuximab vedotin, doxorubicin, vinblastine, dacarbazine)[114,115]

Modern Techniques of Radiation Therapy

Commensurate with the use of increasingly effective chemotherapy, there has been a more tailored approach to RT, with significant reductions in prescription doses and irradiated volumes, as shown in Figure 97.1. The RT technique progressed from extended fields, which included total lymphoid, mantle field, and pelvic radiation, to involved-field (IFRT) volumes, which encompassed involved lymph node regions or compartments based on bony anatomic landmarks. IFRT included not just the involved lymph nodes but also the entire lymph node region including adjacent uninvolved lymph nodes.[116] Today, involved-site radiation therapy (ISRT) or involved-node RT (INRT) is the standard, accepted approach for

defining treatment volumes. This modern, highly individualized approach targets only the lymph nodes or tissues that were initially involved by lymphoma. It takes into consideration imaging advances, including high-quality PET-CT scans, three-dimensional (3D) and 4D treatment planning with CT scanning, conformal radiation techniques, and image guidance, dramatically improving upon IFRT that was based on 2D treatment planning.

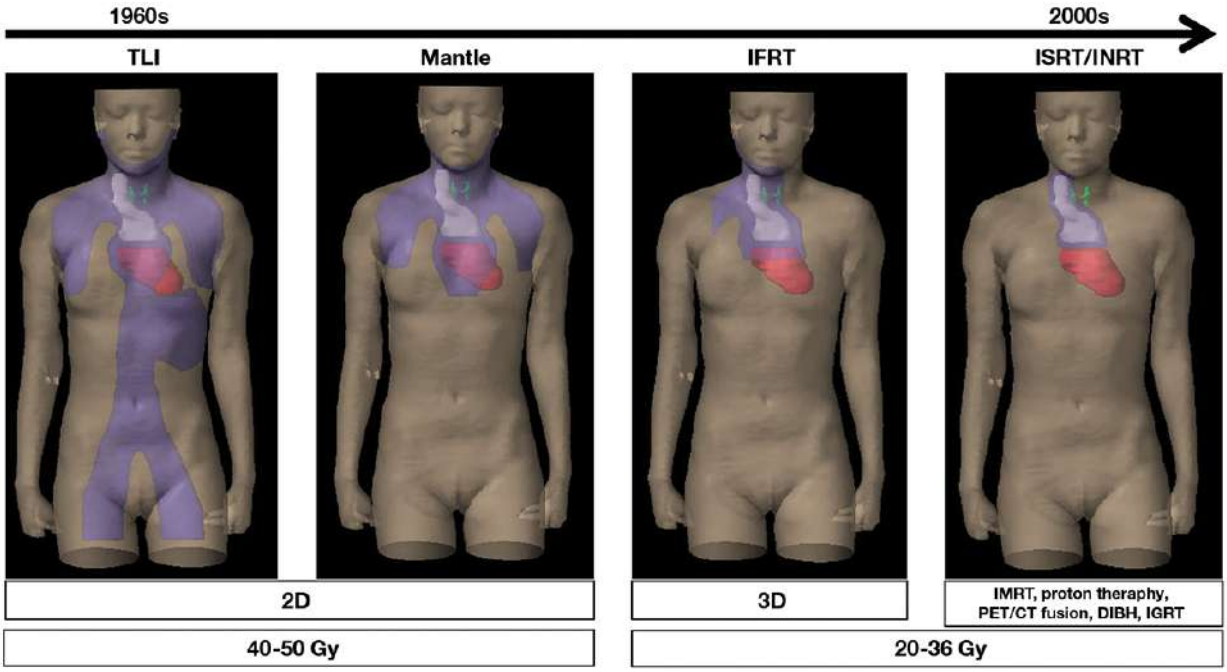

FIGURE 97.1 Evolution of the radiation therapy fields, doses, and techniques that have been used for lymphomas. Purple: irradiated volume; white: site of involvement by lymphoma; red: heart; green: thyroid. 2D, two-dimensional radiation planning; 3D, three-dimensional radiation planning; DIBH, deep inspiration breath-hold; IFRT, involved-field radiation therapy; IGRT, image-guided radiation therapy; IMRT, intensity-modulated radiation therapy; ISRT/INRT, involved-site radiation therapy/involved-node radiation therapy; PET/CT, positron emission tomography/computed tomography; TLI, total lymphoid irradiation. (Reprinted from Milgrom SA, Bakst RL, Campbell BA. Clinical outcomes confirm conjecture: modern radiation therapy reduces the risk of late toxicity in survivors of Hodgkin lymphoma. *Int J Radiat Oncol Biol Phys*. 2021;111[4]:841-850. Copyright © 2021 Elsevier. With permission.)

A review of relapse patterns after chemotherapy in patients with HL supported the reduction in radiation field sizes. The observation that recurrence occurs most often in initially involved sites[117] suggests that chemotherapy is sufficient to treat microscopic disease, so RT can be limited to sites of initial gross involvement. Thus, with sophisticated imaging techniques, a concerted effort to scan patients in the radiation treatment position, and more accurate RT delivery, the practice of INRT emerged as an effort by the European Organisation for Research and Treatment of Cancer and Group d'Etude des Lymphomes de l'Adulte (EORTC-GELA) investigators to customize delivery of RT to the radiographically involved regions.[118,119] Such reduction in treatment volumes is feasible largely because of PET scanning. FDG-PET identifies involved lymph nodes that were radiographically occult on CT scans. As such, prechemotherapy PET is necessary to delineate the full extent of disease.[120]

The efficacy of the smaller INRT target volumes was first demonstrated in retrospective studies and then in a large, prospective cooperative group trial by the EORTC-GELA.[121-123] Thus, RT fields that target only the nodes and tissues of initial gross disease involvement have become the accepted standard-of-care RT technique for HL. Paramount to successful INRT is the acquisition of pre- and postchemotherapy CT and PET scans with the patient in the treatment position for RT. In North America, ISRT, in contrast to INRT, is accepted as the standard conformal therapy. ISRT is an extension of INRT that provides greater flexibility

for patients without prechemotherapy imaging performed in the RT treatment position,[124] as is common in North America.

Radiation Simulation

When possible, CT simulation for the treatment of children with HL should be carried out with intravenous contrast to best delineate nodal stations and differentiate nodes and masses from vessels. Oral contrast may be helpful for the treatment of abdominal and pelvic tumors. 4D CT can assess for target motion and aid in the selection of appropriate margins to account for respiratory movement. If the patient is able to participate with breath-hold techniques, deep inspiration breath-hold at the time of simulation and treatment can allow for significant sparing of the heart and lung.[124] In older children, techniques such as respiratory gating may also be useful to minimize the impact of respiratory motion.

Careful consideration of immobilization can offer significant advantages by increasing setup reproducibility, translating into smaller margins needed for setup uncertainty with the planning target volume (PTV). In addition, thoughtful patient positioning may aid in reducing the dose to normal tissues. For example, when treating the axillae, positioning the arms above the head can reduce dose to the lungs. However, positioning of the arms above the head may not be recommended in patients who are still growing because the axillary lymph nodes then move into the vicinity of the humeral heads, which should be blocked in growing children. Also, breast doses in female pediatric patients may be lower with akimbo, rather than raised, arm positioning.[125] Thus, the position chosen involves weighing concerns regarding tumor volume coverage and dose delivered to adjacent organs at risk.

Radiation Therapy Target Delineation

Guidelines for INRT and ISRT have been published to aid the radiation oncologist in defining treatment volumes.[124] The principles of target volume delineation for INRT and ISRT are largely the same, with differences in the quality and accuracy of prechemotherapy imaging. The margins for ISRT are larger to allow for uncertainties in contouring the clinical target volume (CTV) when prechemotherapy imaging is not performed in the RT treatment position. For both approaches, the pre- and postchemotherapy PET and CT, ideally obtained in the treatment position using the planned immobilization devices, should be fused with the simulation CT in the RT planning system. The gross tumor volume (GTV), CTV, internal target volume (ITV) when relevant, and PTV should be delineated using all available imaging information on contrast-enhanced CT and PET-CT as shown in Figure 97.2 and described as follows:

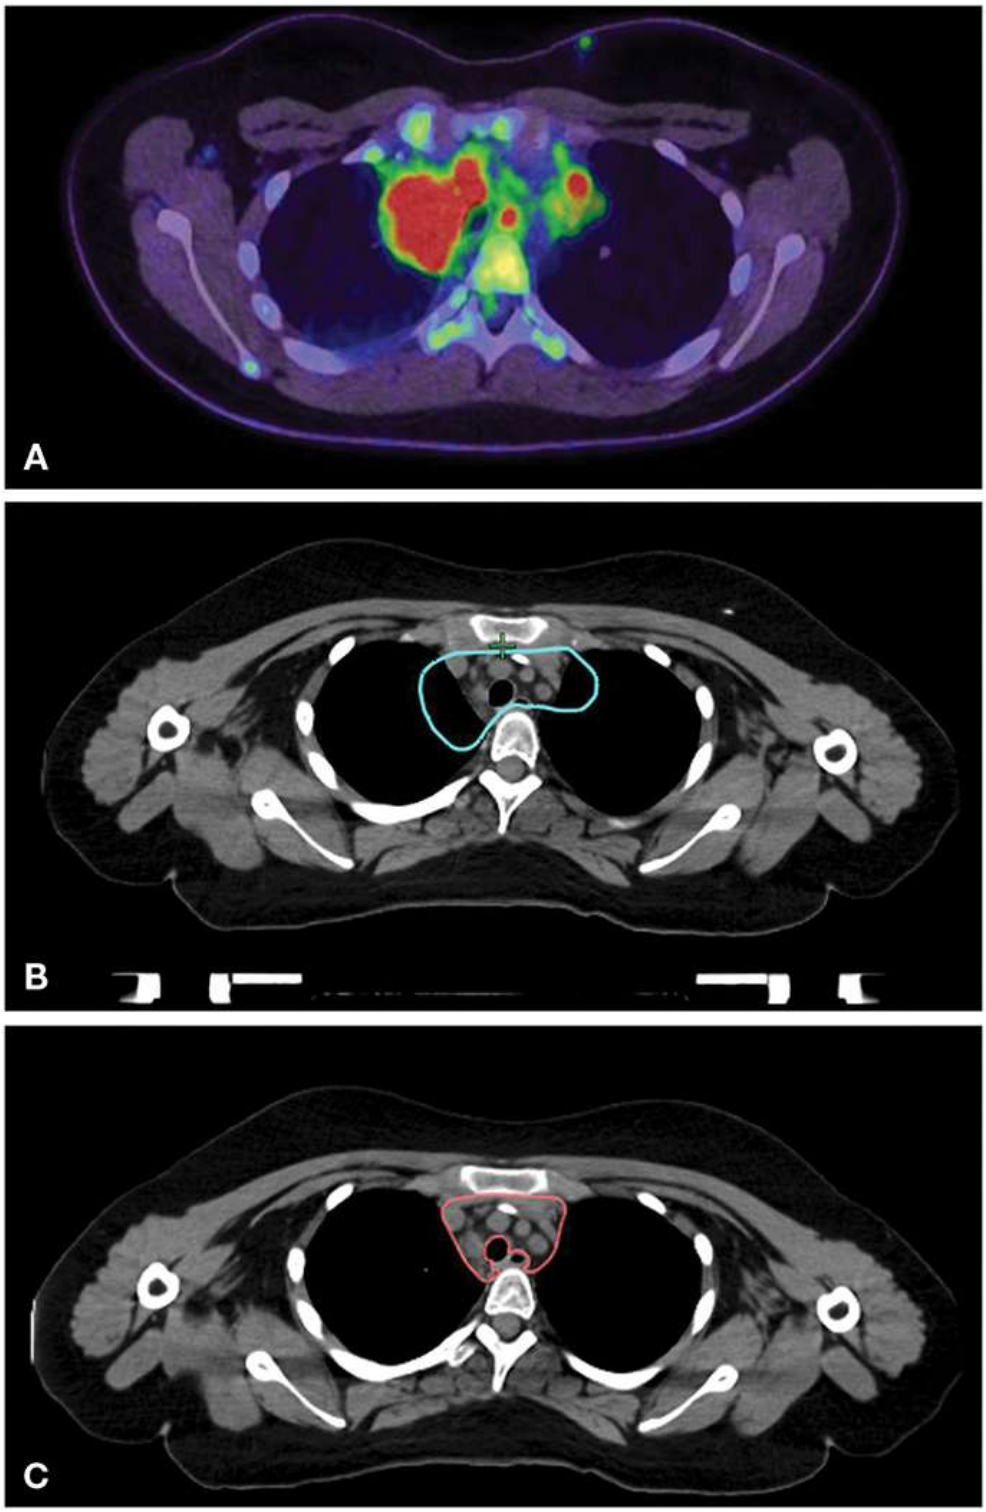

FIGURE 97.2 Illustration of involved-site radiation therapy target volumes informed by the prechemotherapy positron emission tomography (PET)/computed tomography (CT) scan. A. The prechemotherapy PET/CT scan demonstrates fluorodeoxyglucose-avid superior mediastinal disease. B. The prechemotherapy gross tumor volume (blue) encompasses the site of disease at diagnosis. C. The clinical target volume (CTV) contour (pink) encompasses the site of disease at diagnosis, accounting for anatomic changes that occurred with chemotherapy; for example, the CTV does not include lung tissue that was displaced by, but not invaded by, the mediastinal mass initially.

- Prechemotherapy GTV: GTV contoured on prechemotherapy CT and PET scans.
- Postchemotherapy GTV: GTV contoured on postchemotherapy CT and PET scans.
- CTV: A volume encompassing the superior and inferior extent of the prechemotherapy GTV with the radial extent respecting overtly uninvolved, normal structures (ie, lungs, kidneys, muscles) based on clinical judgment. The CTV should also take into account the quality and accuracy of imaging, pattern or spread of disease, changes in the volume of disease since imaging, risk of subclinical involvement, and nearby structures. Nodal volumes that are more than 5 cm apart can be treated as separate fields and do not need to be connected volumes. The CTV for ISRT will generally be larger than that for INRT because of the lack of optimal imaging information. If RT is used as the sole treatment modality, as in NLPHL, the CTV should be more generous because microscopic disease is likely more extensive in the absence of treatment with chemotherapy.
- ITV: Target motion should be accounted for using an ITV as defined by the International Commission on Radiation Units and Measurements as the CTV with a margin to consider organ motion for an individual patient.[126] A 4D CT simulation can be useful to obtain the ITV margins. With free breathing, respiratory motion may be significant in the chest or upper abdomen, so margins of up to 1.5- to 2-cm may be necessary.
- PTV: This margin should account for uncertainty in setup based on patient factors or immobilization that varies across institutions.

Radiation Therapy Dose

The dose of RT prescribed is guided by the intensity of the chemotherapy regimen used in combined modality approaches. Typical doses in the current era of low-dose RT are 15 to 30 Gy.[2,11-17,88] In North America, the COG has used a dose of 21 Gy in 14 fractions. Sites of partial response after completion of chemotherapy may receive an additional boost of 9 to 19 Gy (total 30-40 Gy).[13,15,16] On the current COG study for early-stage disease, AHOD2131, a slightly higher ISRT dose of 30 Gy is recommended, since RT is reserved for patients with less chemosensitive disease based on a slow early response (SER) to two cycles of ABVD chemotherapy (NCT05675410).

Radiation Therapy Planning

Given the risk of late effects in this patient population, children should be treated with the most conformal radiation approach that is reasonably available to them, typically either advanced photon-based techniques, such as intensity-modulated RT (IMRT) and volumetric modulated arc therapy, or proton therapy. While concerns existed previously that the "low-dose bath" with IMRT plans may increase the risk of second cancers in survivors, this is not borne out in data from 300 children treated at Memorial Sloan Kettering Cancer Center with a median follow-up of 11.2 years. The solid second malignant neoplasms that developed in these children were predominantly within the high-dose regions.[127] Before proton therapy was widely used, concerns were raised regarding potential increased second cancer risk due to neutron contamination, but no clinical evidence has arisen to date to support this possibility. For example, data from the University of Florida regarding 1,713 children treated with double- scattered proton therapy allay some of those fears. In their series, the absolute excess risk for a second cancer was 1.5 per 1,000 person-years, and all second tumors in children without genetic predisposition syndromes occurred in the high-dose region.[128] Proton therapy may offer the advantage of reduced doses to normal surrounding tissues and reduced integral dose.[129] Therefore, proton therapy may be particularly useful in cases where the target volume extensively contacts the heart or lungs, given the potentially additive effect between chemotherapy- and RT-related late toxicity to those tissues. Proton therapy may also be favored in the setting of prior RT targeting an adjacent area.

As always, we should strive to limit normal tissue doses to levels that are as low as reasonably achievable. Data suggest that the volume of tissue exposed even to low-dose radiation may be associated with the risk of toxicity in this population. For example, a radiation dose of 4 Gy or more to the breast

tissue has been associated with an increased risk of secondary breast cancer in survivors of HL.[130] Similarly, the volume of normal tissue receiving a dose of 5 Gy has been associated with the risk of pneumonitis[131] and late cardiac disease.[132]

Complications of Radiation Therapy

Acute Effects

The side effects of RT are related to the treated site and dose. Because doses used in pediatric HL are low, acute toxicities are typically limited. For supradiaphragmatic sites, the most common toxicities include temporary altered sense of taste, xerostomia, esophagitis, low posterior scalp epilation, skin erythema, and, occasionally, dyspepsia, nausea, and vomiting, depending on the anatomic location treated. Acute effects of para-aortic irradiation may include nausea, vomiting, and abdominal cramping. Fatigue is also reported by some patients, independent of anemia. Patients treated with larger fields may be subject to bone marrow suppression, the severity of which may be influenced by the systemic regimen preceding radiation.

Late Effects

Patients with HL have excellent prognoses, so the late effects of therapy are a critical concern. Studies of survivors who were treated for HL as children with historic, extended radiation fields have shed light on the potential late effects of RT.

Musculoskeletal

Impaired growth of bones and muscles is a potential long-term consequence of RT. The impact on growth is most severe with doses greater than 20 Gy, large fields, and prepubertal age at the time of RT. For example, decreased height was observed in young children who were treated with high doses and large fields (eg, total lymphoid irradiation that included most of the spine), and interclavicular shortening and hypoplasia of the neck muscles occurred when prepubertal children were irradiated to the neck.[133] Impaired musculoskeletal growth and development is modest with the low doses used in modern pediatric HL treatment strategies.[134] Avascular necrosis of the femoral or humeral heads is possible, but rare if appropriate shielding is employed. Radiation to the mandible in young children may result in dental abnormalities, such as stunted tooth development, incomplete calcification, premature apical closure or eruption, and root tapering with apical constriction.[135]

Cardiovascular

Cardiac sequelae, including pericarditis, pericardial effusion, valvular thickening, biventricular dysfunction, diastolic dysfunction, and coronary artery disease, may be observed after irradiation of the heart.[136,137] Increased mortality risk because of premature coronary artery disease and acute myocardial infarction has been demonstrated in patients who received mediastinal radiation doses greater than 30 Gy with historic RT treatments before 20 years of age.[119] Radiation-specific factors that influence the risk of cardiotoxicity include the total radiation dose to the heart, the volume of the heart exposed, and the dose per fraction.[138-144] In addition, other treatment and patient-specific factors contribute to the risk of radiation-associated cardiotoxicity. For example, the incidence of cardiotoxicity is higher in patients who received both anthracyclines and RT compared to RT alone.[137,141] In a recent review, every 100 mg/m^2 of anthracycline exposure was equivalent to a 10.5 Gy increase in mean heart dose with respect to late cardiac risk.[145] In addition, conventional cardiac risk factors, such as dyslipidemia, hypertension, and smoking, are independently associated with late cardiotoxicity in survivors.[138-141]

The risk of late cardiac toxicity is lower in survivors treated for HL in more recent decades compared to those treated with historic approaches, and a reduction in radiation dose to the heart has contributed significantly to the decline in cardiac toxicity incidence.[139] Using modern, conformal techniques, dose to the heart can be calculated and constrained in order to minimize the risk of long-term cardiac injury. Modern techniques enable radiation oncologists to consider more modern and aggressive dose constraints.

Recently, it has been shown that mean doses to individual cardiac substructures may better predict the risk of specific late cardiac diseases than mean dose to the entire heart[146]—work is ongoing to identify the best dose constraints to minimize cardiac risk in this patient population.

Pulmonary

The incidence of acute and subacute radiation-associated pneumonitis and late pulmonary fibrosis is low; however, the use of bleomycin can increase the risk.[147,148] It is manifest clinically in restriction defects and reduced diffusion capacity on pulmonary function tests. With advanced radiation planning, dose to the lungs should be limited, using constraints specific to the lymphoma population.[131] These low lung doses, in combination with contemporary regimens that eliminate or reduce the dose of bleomycin, result in a low risk of pulmonary toxicity.

Thyroid

Thyroid dysfunction may result from neck or upper mediastinal irradiation and most often is manifested by an elevated serum concentration of thyroid-stimulating hormone (TSH) indicative of primary thyroid failure. Constine et al noted an increased serum TSH in 4 (17%) of 24 children who received mantle doses of 26 Gy or less and in 74 (78%) of 95 who received higher than 26 Gy. Approximately one-fourth of these children had a concomitant low thyroxine level. In this series, 36% of children experienced spontaneous improvement in thyroid function.[149]

In a Childhood Cancer Survivor Study (CCSS), thyroid abnormalities were self-reported by 34% of patients in an era of extended-field RT. Hypothyroidism was the most common thyroid disturbance, with a relative risk of 17.1 ($P < .0001$) compared with sibling controls. Risk factors for hypothyroidism include increased dose of radiation, older age at diagnosis of HL, female sex, and Caucasian race.[150] However, work from the CCSS has also demonstrated a lower risk of hypothyroidism with lower radiation doses that are typical of modern HL treatment.[151,152]

The incidence of hypothyroidism varies, but it is directly related to radiation dose. No threshold radiation dose has been observed that is associated without a risk of hypothyroidism.[153] Therefore, thyroid exposure should be minimized when feasible to reduce the risk of hypothyroidism, and dose constraints specific to the lymphoma population should be used.[154,155]

Pelvis

Gonadal toxicity, including infertility and impaired secretion of sex hormones, is a potential complication of pelvic RT. In women, irradiation of the pelvis can affect the ovaries, resulting in premature menopause or impaired fertility. In a report by the Late Effects Study Group, 42% of female survivors of HL treated with alkylating agent chemotherapy and subdiaphragmatic radiation had experienced menopause by 31 years of age, compared with 5% of control subjects.[156] In childhood cancer survivors who continued to have spontaneous menses more than 5 years after their cancer diagnosis, the cumulative incidence of nonsurgical menopause was 8% by 40 years of age, representing a 13-fold higher risk compared with a sibling control group. Risk factors for premature menopause included exposure to increasing doses of ovarian radiation, increasing exposure to alkylating agents (based on the number of agents and cumulative dose), and diagnosis of HL.[157] In an effort to preserve ovarian function, the ovaries can be transposed via oophoropexy to increase their distance from the site to be irradiated. Normal pregnancies, without increased risk of fetal spontaneous abortion or birth defects, have been reported after pelvic irradiation.[158]

In boys irradiated to the pelvis, oligospermia is common, but it is reversible in most cases if the radiation dose scattered to the testes is low.[159] Permanent oligospermia may occur, however, after higher dose testicular irradiation.[159] Alkylating agent chemotherapy may also impact fertility. Several investigations have demonstrated that fertility is compromised in boys treated with gonadotoxic chemotherapy combinations like COPP, even when the cycles of alkylating agent chemotherapy are limited.[112,160] Anthracycline-based regimens such as ABVD (or a similar hybrid) are associated with

recovery of spermatogenesis after a temporary period of azoospermia.[161,162] In the modern treatment era, risk-adapted strategies seek to reduce or eliminate gonadotoxic treatments, resulting in excellent potential to preserve fertility in boys.[17] For male patients at risk of infertility, early oncofertility counseling and discussion of sperm banking are recommended.

Secondary Malignant Neoplasms

Survivors of HL are at risk for developing secondary malignancies including leukemias and solid tumors, most commonly breast, thyroid, bone, and soft tissue cancers. The risk of leukemia, which exhibits a peak frequency in the first 5 to 10 years after treatment, is associated primarily with the use of alkylating agents and etoposide.[163,164] In contrast, the risk of developing a second solid tumor increases with time after therapy, with a latency usually exceeding 10 years from diagnosis, and the risk is associated with radiation dose and field size.[165] In survivors treated with historical radiation approaches, the 15-year actuarial risk of second malignant neoplasms ranged from 8% to 15%.[96,103,130,163,164,166-169]

Several studies revealed an increased ratio of observed to expected second tumors for female survivors compared with males.[170-172] A large portion of this risk in females results from breast cancer. This increased risk of breast cancer is related to the patient's pubertal status at the time of RT and to the radiation dose and field size.[173,174] Historical extended fields included a substantial amount of breast tissue that was exposed to full-dose RT. Based on data from survivors who were treated with historic radiation techniques, a female survivor of HL who was treated at 25 years of age with thoracic RT of 40 Gy or greater, without alkylating agents, had an estimated cumulative risk of breast cancer of 1.4%, 11.1%, and 29.0% by 35, 45, and 55 years of age, respectively.[173] Breast tissue exposure was most significant when the axillae were irradiated in a typical mantle field, as opposed to the mediastinal and hilar region.

With modern RT, breast exposure is lower, translating into a reduced risk of secondary breast cancer. The practice of prophylactically irradiating the axillae is no longer performed, and, thus, the volume of breast tissue exposed to RT using ISRT or INRT approaches is substantially less. Using CT-based planning, the breast tissue can be contoured as an avoidance structure and dose to the breasts can be minimized, a practice that was not used with older radiation approaches. The risk of secondary breast cancer is lower in survivors who receive RT using modern techniques. In a population-based study of female survivors of HL who received treatment before 50 years of age, the risk of secondary breast cancer was significantly elevated after historic mantle RT; however, after modern "small field" RT, the risk was no greater than after chemotherapy alone.[175] Similarly, several other studies have demonstrated that smaller RT field sizes are associated with a lower risk of secondary breast cancer in survivors.[175-177]

As described earlier, historic, high-dose, large-field RT was associated with an elevated risk of serious, late adverse events.[3,96,130,137,140,141,177-183] This risk has declined significantly with temporal changes in the therapeutic management of HL.[184] Evolution in the use of RT has contributed, and decreased risks of late effects have been associated with reductions in RT dose and field size.[184] These findings support the use of the contemporary risk- and response-adapted treatment algorithms that are described later.

Modern Risk- and Response-Adapted Therapy for Classic Hodgkin Lymphoma

Contemporary therapy for pediatric HL using either chemotherapy alone or combined modality therapy produces long-term DFS in 85% to 100% of patients.[11-17,88,89] Multiagent chemotherapy alone is an effective treatment approach for many patients with pediatric HL[8,9,99,185-187] A chemotherapy alone paradigm eliminates the risk of radiation-specific toxicities; however, regimens may require more cycles and/or higher doses of chemotherapy, placing patients at an increased risk of chemotherapy-related toxicity. Furthermore, chemotherapy alone may be less effective than combined modality therapy for the treatment of higher risk disease.[9,188]

The sequence of therapy in the setting of combined chemotherapy and RT generally utilizes chemotherapy as the first modality. This allows assessment of chemotherapy response, maximization of the amount of systemic treatment, and shrinkage of disease, enabling more limited radiation fields. Rarely,

focal RT prior to chemotherapy is necessary because of significant symptoms, such as airway compression or symptomatic SVC syndrome. Typically in this setting, a low dose of radiation is used to palliate symptoms while maintaining the ability to deliver RT with curative intent later, if needed.

Current recommendations for therapy follow a risk- and response-adapted approach. Risk factors at presentation include B symptoms, mediastinal and peripheral lymph node bulk, extranodal extension of disease, and higher Ann Arbor stage. The most recent COG risk stratification defines patients into risk groups as follows:

- Favorable risk: stages IA and IIA without bulk
- Intermediate risk: stages I to IIA with bulk, I to IIAE, I to IIB, and IIIA
- High risk: stages IIB with bulk, IIIB, and IV

In Europe, the EuroNet cooperative group most recently has categorized patients into treatment groups (TGs) as follows[108]:

- TG-1: stages IA/B and IIA, without bulk 200 mL or higher or ESR 30 mm/h or greater
- TG-2: stages IEA/B, IIEA, IIB, IIIA, and IA/B and IIA with bulk 200 mL or higher or ESR 30 mm/h or greater
- TG-3: stages IIEB, IIIEA/B, IIIB, or IVA/B

The response to chemotherapy as assessed on CT and FDG-PET after two cycles of therapy is a significant prognostic factor.[189] As a result, a series of trials have explored if early response during conventional chemotherapy can be used to guide a reduction or intensification of therapy, as described later and summarized in Table 97.5. In addition, imaging at interim time points or at the end of planned chemotherapy can be used to direct the use of consolidative RT in disease that is less sensitive to chemotherapy alone.

Low-Risk Classic Hodgkin Lymphoma

Low-risk disease is defined differently by various clinical trial groups,[64] but it generally comprises patients with localized stages I and II disease without adverse prognostic features like bulk or B symptoms. Treatment typically involves two to four cycles of chemotherapy with or without low-dose ISRT. Patients with low-risk disease are the natural group in which to consider de-escalation of therapy because of their excellent outcomes.

In some regimens, RT has been dose reduced or eliminated based on a favorable response to chemotherapy. Early investigations of response-based therapy in the French Society of Pediatric Oncology MDH90 trial included 202 children with stage I/II HL.[106] Patients were treated with four cycles of vinblastine, bleomycin, etoposide, and prednisone and then a CT was obtained to assess response to therapy. A good response was defined as at least a 70% reduction in tumor size. Good responders received 20 Gy RT to initially involved fields. The remaining patients (poor responders) were given one or two more cycles of chemotherapy and were evaluated after each cycle. If they remained poor responders, then RT was administered to 40 Gy. If the response after additional chemotherapy exceeded 70%, then they received 20 Gy to involved fields. Eighty-five percent of patients were good responders, and the overall 5-year OS and EFS of the entire cohort were 97.5% and 91.1%, respectively. These results were comparable to the prior French Society of Pediatric Oncology (MDH82) in which all patients received chemotherapy consisting of alkylating agents and anthracyclines followed by RT.[190]

The GPOH successfully omitted RT in patients with early-stage disease who achieved a complete response (CR) to chemotherapy. This group pioneered the use of risk- and gender-adapted chemotherapy, according to which males received OEPA to limit alkylator exposure, and females received OPPA. After two cycles, a CR was defined as a volume reduction of 95% or more and 2 mL or less residual volume. In the GPOH-HD 95 trial, 20% of patients in TG-1 fell into this category of complete responders and were assigned to receive no RT. There was no difference in outcome between favorable-risk patients treated

with chemotherapy alone and those treated with combined modality therapy. Notably, the cohort consisted of cHL and NLPHL.[188] These outcomes were confirmed in the GPOH-HD 2002 study that excluded patients with NLPHL. In this study, for patients in TG-1, RT was omitted if they achieved a CR after two cycles of OEPA or OPPA, as defined in the prior GPOH-HD 95 study. All other patients were treated with IFRT to 19.8 Gy. A boost was given if less than 75% tumor reduction was noted (total 30 Gy) or residual disease measured greater than 100 mL (total 35 Gy). In TG-1, 5-year EFS was 92% and was similar in patients who did not receive RT (93%) and those who did receive RT (92%).[17]

The subsequent EuroNet-PHL-C1 incorporated PET for response assessment. The study investigated whether RT can be omitted in patients with an adequate anatomic and metabolic response to OEPA. Patients with newly diagnosed stage IA, IB, and IIA cHL were assigned to TG-1. They received two cycles of OEPA. Then, patients with an inadequate response by PET/CT received IFRT to a total dose of 19.8 Gy, whereas patients with an adequate response were observed. An adequate response was defined as at least 50% reduction in tumor volume and FDG-avidity that did not exceed mediastinal blood pool uptake (for residual volumes ≥2 cm in maximum diameter) or background uptake (for residual volumes <2 cm in largest diameter). The primary objective of the study was to maintain a 5-year EFS rate of 90% with omission of RT in patients with an adequate response to OEPA. In an intention-to-treat analysis of the 440 patients who achieved an adequate response, 5-year EFS was 86.5% (95% confidence interval [CI]: 83.3-89.8), which was just below the 90% target rate. In a per- protocol analysis of patients with an adequate response, 5-year EFS was 87.1% (95% CI: 83.9-90.3), which met the 90% target rate. In the 273 patients with an inadequate response who received RT, 5-year EFS was 88.6% (95% CI: 84.8-92.5), for which the 95% CI included the 90% target rate. Patients with risk factors, defined as ESR 30 or greater or bulky mass 200 mL or greater, were found to have an increased risk of disease relapse. Based on this finding, the protocol was amended so patients with these adverse features were assigned to TG-2. The authors concluded that RT could be omitted in patients with early-stage cHL and an adequate response to OEPA, but patients with risk factors might need more intensive treatment.[11]

In addition, several North American studies have demonstrated excellent results using response-adapted combined modality therapy for favorable-risk HL. Investigators from Stanford University Medical Center, St Jude Children's Research Hospital, and Dana-Farber Cancer Institute reported results using a nonalkylator regimen, VAMP (vinblastine, doxorubicin, methotrexate, and prednisone), for children with clinical stage I/II, nonbulky HL, including cHL and NLPHL.[89] Following four cycles of VAMP, patients were treated with 15 Gy IFRT if they achieved a CR or 25.5 Gy if they had a partial response after two cycles of VAMP. At a median follow-up of 9.6 years, 5- and 10-year EFS rates were 92.7% and 89.4%, respectively.

The POG evaluated the feasibility of combined modality therapy using four courses of DBVE (doxorubicin, bleomycin, vincristine, and etoposide) followed by IFRT to 25.5 Gy to treat stages IA, IIA, and IIIA HL.[136] At a median follow-up of 8.4 years, nearly all patients (98%) achieved a complete remission, and 6-year OS and EFS rates were 98% and 91%, respectively. This DBVE regimen was used by the POG and the COG to support reduction of chemotherapy via an early response-based treatment algorithm evaluated on P9426.[191] Patients received only two courses of DBVE if they achieved an early CR (45% of all patients) versus four courses of DBVE if they were slower responders. All patients were treated with IFRT to 25.5 Gy. Five-year OS and EFS were 98% and 88%, respectively.

The CCG trial 5942 compared a chemotherapy-alone regimen to a risk-adapted combined modality treatment approach with low-dose IFRT in low-risk disease achieving a CR. Patients were treated with COPP/ABV. Those achieving a CR to chemotherapy were randomized to receive low-dose IFRT or no further therapy. Given a significantly higher number of relapses in patients who were treated with chemotherapy alone, the trial was terminated early.[192] Of note, this trial used less intensive chemotherapy compared to most contemporary trials.

To better select low-risk patients with cHL who may benefit from the omission of RT, the COG AHOD0431 single-arm study incorporated interim PET-CT when possible to assess disease response and identified a group of very early responders (negative PET scan after one cycle, PET1) who may have

favorable outcomes even without adjuvant RT. Two hundred and eighty-seven stage IA/IIA patients were treated with three cycles of AV-PC. Those who achieved a CR after three cycles received no further therapy, whereas partial responders received 21 Gy IFRT. In the initially reported results, 2-year OS was 100%; however, 2-year EFS for those with CR to chemotherapy and no RT was 80% compared to 88% in those with partial response who received IFRT ($P = .11$). A subset analysis suggested the utility of PET1 in identifying patients who may be treated without RT after three cycles of AV-PC. Of the patients with a CR who did not receive RT, the 2-year EFS rate for those with a positive/equivocal PET1 versus those with a negative PET1 was 65% compared to 87% ($P = .005$). Similarly, 2-year EFS in partially responding patients with a positive/equivocal PET1 versus a negative PET1 was 82% versus 96% ($P = .047$).[193] The 4-year EFS rate was 79.9% overall, with superior EFS in those with a partial response or stable disease who received RT (82.8%) compared to those with a CR who did not receive RT (77.5%), although this difference was not statistically significant. The 4-year OS rate was 99.6%, emphasizing the efficacy of salvage therapy in this patient population. The value of PET1 persisted with longer follow-up. Patients with a negative PET1 had a significantly improved 4-year EFS (88.2% vs 68.5%).[87] These data highlight the importance of the interim FDG-PET scans when evaluating early-stage, low-risk patients for response-adapted therapy.

Intermediate-Risk Classic Hodgkin Lymphoma

Patients with stages IA and IIA disease with unfavorable features, including bulk and extranodal extension, and with stage IIIA disease are grouped into an intermediate-risk category. Treatment typically involves four cycles of chemotherapy and possible low-dose ISRT based on the risk factors and response to chemotherapy. As in low-risk disease, RT is generally dose reduced or eliminated based on a favorable response to chemotherapy.

In the GPOH-HD 2002 study, all patients received two cycles of chemotherapy (OEPA for males and OPPA for females), then intermediate-risk patients (TG-2) received two cycles of COPP for females and COPDAC for males. Subsequently, patients in TG-2 were treated with IFRT to 19.8 Gy with possible boosts as described earlier. In TG-2, 5-year progression-free survival (PFS) was 93%.[17]

In the EuroNet-PHL-C1 study, patients in TG-2 received two cycles of OEPA, then two cycles of COPP or COPDAC. RT was omitted for patients with an adequate response at early response assessment after two cycles of OEPA, with an adequate response defined as at least 50% reduction in tumor volume and PET negativity. All other patients received RT to 19.8 Gy targeting all initially involved sites of disease, with possible boosts as described earlier. In both adequate responders who did not receive RT and inadequate responders who were scheduled for RT, 5-year EFS was approximately 90%. The authors concluded that RT can be omitted in patients with an adequate early response to therapy, when consolidated with COPP or COPDAC.[12]

North American cooperative groups have completed two trials to evaluate a response-based approach. The first, POG9425, evaluated the prospect of reducing the number of chemotherapy cycles based on response to therapy.[107] The second, AHOD0031, evaluated a regimen to omit RT in patients with a RER and CR to chemotherapy and to intensify therapy for those with an SER.[16]

In POG9425, intermediate- and high-risk patients received three or five cycles of ABVE-PC followed by 21 Gy regional (mantle, para-aortic, or pelvic) RT for RER and SER, respectively. There was no difference in EFS between the two groups, demonstrating the efficacy of a response-based approach.[107]

The COG study AHOD0031 was a randomized trial comparing standard and response-based treatment for omission of RT or augmentation of systemic therapy in intermediate-risk cHL and NLPHL. Early response to therapy was assessed by CT scan, and CR status was determined by CT and gallium or FDG-PET scan. All 1,712 patients received two cycles of ABVE-PC followed by early response assessment. At this time point, an RER was defined as a reduction in tumor size by at least 60% in the product of the perpendicular diameters or return to normal size. Patients with an RER received two additional cycles of ABVE-PC followed by a second response assessment. At this point, a CR was defined as at least 80% reduction in the product of the perpendicular diameters, no extramediastinal mass larger than 2 cm in

maximum diameter, and PET or gallium negativity. Patients with an RER and subsequent CR were randomized to receive 21-Gy IFRT or no further therapy. Patients with an RER who did not have a CR were nonrandomly assigned to receive IFRT. Patients with an SER were randomized to either two additional cycles of ABVE-PC or intensified therapy with dexamethasone, etoposide, cisplatin, and cytarabine (DECA) followed by an additional two cycles of ABVE-PC. All patients with an SER received 21-Gy IFRT after chemotherapy. Four-year EFS rates were 85% overall, and 86.9% for patients with an RER versus 77.4% for those with an SER ($P < .001$). The 4-year OS for the entire cohort was 97.8%, and 98.5% for patients with an RER versus 95.3% for those with an SER ($P < .001$). The 4-year EFS rate was 87.9% for patients with an RER/CR randomized to receive IFRT versus 84.3% for those randomized to no IFRT ($P = .11$).[16] Thus, the results of AHOD0031 suggest that early response to chemotherapy is a powerful predictor of outcome that can help optimize subsequent treatment and that RT may be omitted for patients with an RER and CR after four cycles of ABVE-PC.

As PET was emerging at the time of the AHOD0031, FDG-PET was not required, but an interim PET after two cycles of ABVE-PC (PET2) was obtained in 1,135 (66%) patients, of whom 746 were eligible for the two random assignments in the study. Of the 550 patients with available PET2 imaging who had an RER/CR, there was no difference in EFS with versus without IFRT in those with a negative PET2 (86.7% vs 87.3%; $P = .87$) or a positive PET2 (83.1% vs 78.1%; $P = .80$). Of the 196 patients with SER with available PET2 results, there was no difference in EFS in patients treated with versus without DECA when PET2 was negative (90.1% vs 85.6%; $P = .54$). However, among patients with SER and PET2-positive results, EFS was marginally superior with DECA versus without DECA (70.7% vs 54.6%; $P = .05$).[16] A secondary analysis of PET response after two cycles of ABVE-PC demonstrated that PET may further assist with treatment optimization.

In a secondary analysis of the patterns of failure of AHOD0031, relapses commonly occurred in previously involved disease sites (94% of relapses) and within the irradiated fields, suggesting that INRT or ISRT target volumes may be sufficient and that larger IFRT volumes might not be necessary. In addition, recurrences occurred in both bulky and nonbulky initial sites of disease, suggesting that in intermediate- risk HL, irradiation of bulky sites alone may not be the optimal treatment strategy.[194]

High-Risk Classic Hodgkin Lymphoma

The criteria for high-risk HL are typically restricted to stage III or IV disease, often with “B” symptoms and/or extranodal extension to contiguous structures. Historically, chemotherapy was administered over the course of 6 to 8 months on a twice-monthly schedule.[7,8,107,195,196] An alternative strategy condenses the chemotherapy component of treatment into 3 to 5 months to enhance dose intensity and reduce the risk of developing resistant disease. RT for high-risk HL is variable and protocol dependent.

As in the cases of other risk groups, there is increasing interest in developing a response-adapted treatment approach for children with high-risk HL. In the GPOH-HD 95 trial outlined previously, RT was omitted in patients achieving a CR after OEPA-COPP chemotherapy.[197] PFS for high-risk patients who experienced a CR and did not receive RT was significantly lower than in patients without a CR who received RT ($P = .01$). This study highlighted the need for more refined criteria and modalities for response assessment than those used on GPOH-HD 95 to successfully identify patients for whom treatment RT may be omitted.[197]

The subsequent GPOH-HD 2002 and EuroNet-PHL-C1 studies, described earlier, established less gonadotoxic chemotherapy regimens and omission of RT in patients with an adequate early response to therapy.[12,17] In the most recent trial, EuroNet-PHL-C1, described earlier, patients in TG-3 received two cycles of OEPA, then four cycles of COPP or COPDAC. RT was omitted for patients with an adequate response after two cycles of OEPA; patient with an inadequate early response received RT to 19.8 Gy targeting all initially involved sites of disease, with possible boosts as described earlier. In both adequate responders who did not receive RT and inadequate responders who were scheduled for RT, 5-year EFS was approximated 90%.

An assessment of a dose-intense, response-based regimen using BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) in children with high-risk disease was evaluated in the COG 59704 trial. Females with a rapid response received four cycles of COPP/ABV following BEACOPP without IFRT, and males received two cycles of ABVD and IFRT. All patients with a slow response received four additional cycles of BEACOPP and IFRT. A high 5-year EFS rate of 94% was achieved, and the 5-year OS rate was 97%. However, significant acute hematologic toxicity was observed, and two patients developed secondary leukemia.[195]

The COG AHOD0831 trial evaluated a risk- and response-adapted approach for high-risk disease. Patients were treated with two cycles of dose-dense ABVE-PC and then assigned to one of two consolidation therapy regimens based on response to induction therapy. Patients with an RER received two more courses of ABVE-PC. Those with an SER received intensification of therapy with the addition of two cycles of ifosfamide/vinorelbine followed by two courses of ABVE-PC. Patients with a continued response after completion of chemotherapy proceeded to risk-adapted RT (21 Gy in 14 fractions IFRT) delivered only to sites of initially bulky disease or SER. With this approach, 4-year EFS was 91.9%, below the ambitious, projected rate of 95%. Five-year OS was 95%. Of particular note, 8 of the 11 SER patients with persistent PET-positive lesions at the end of chemotherapy had clinical evidence of active disease by either biopsy or further progression at that site, emphasizing the value of PET-CT scans in this patient population.[15] With this treatment strategy, most relapses occurred in initially involved sites that were neither bulky nor FDG avid after two cycles of chemotherapy and, therefore, were not treated with RT.[198] These findings suggest a role for refinement of strategies to optimally identify which patients and disease sites may benefit from RT.

To examine the efficacy of the antibody-drug conjugate Bv, AHOD1331 randomized children with stage IIIB, IVA, or IVB disease to ABVE-PC or Bv-AVE-PC for five cycles. All children were evaluated by a PET-CT scan after two cycles of therapy, and disease sites with a Deauville score of 4 or 5 were deemed "slowly responding lesions." Children received 21-Gy ISRT targeting initially bulky mediastinal disease, regardless of early response, and targeting slowly responding lesions. An additional 9-Gy boost was given if the final PET after all five cycles of systemic therapy had a Deauville score of 3 to 5. Children receiving Bv experienced significantly improved 3-year EFS (92.1% vs 82.5%, $P < .001$). However, driven by protocol-specified RT to all large mediastinal adenopathy, there was no difference in utilization of RT by study arm (53.4% vs 56.8%). There was also no difference in OS at 3 years (99.3% vs 98.5%).[13]

A similar open-label single-arm study was completed at St Jude (SJCRH HLHR13). In this study, pediatric patients with stage IIB, IIIB, or IV disease were treated with AEPA/CAPDAC, with the vincristine of OEPA/COPDAC replaced with Bv or "Adcetris." RT, using limited "residual node RT," was given at the end of chemotherapy only to nodal sites that did not achieve a CR after two cycles of therapy. A CR at early response assessment was defined as a Deauville score of 1 to 3 and 75% or more reduction in the product of the perpendicular diameters. In this cohort, 35% of patients achieved a CR after two cycles and avoided RT. For the total cohort, the 3-year EFS was 97.4% and 3-year OS was 98.7%.[14]

The ongoing EuroNet-PHL-C2 trial (NCT01026220) is also evaluating a risk-stratified and response-adapted approach in children with high-risk HL. Using the Deauville score for PET response assessment, patients with an adequate response after two cycles of initial OEPA chemotherapy will not receive RT and those with an inadequate response at this time point (Deauville ≥4 or <50% volume reduction in a bulky site) will receive modified (smaller field) IFRT to 19.8 Gy with a 10-Gy boost to sites with Deauville 3 or higher at the end of all chemotherapy. All intermediate- and high-risk disease will be treated with consolidation chemotherapy based on randomization between two and four cycles of standard COPDAC-28 (cyclophosphamide, vincristine, prednisone, dacarbazine) or intensified DECOPDAC-21 (doxorubicin, etoposide, cyclophosphamide, vincristine, prednisone, dacarbazine). This study will evaluate (a) whether intensified DECOPDAC-21 consolidation chemotherapy improves EFS as compared to standard COPDAC-28 in early responders and (b) if DECOPDAC-21 combined with RT restricted to sites that remain FDG-PET positive at the end of all chemotherapy has comparable EFS compared to COPDAC-28 plus RT as in the EuroNet-PHL-C1 trial.

Nodular Lymphocyte–Predominant Hodgkin Lymphoma

NLPHL is typically indolent, with a favorable prognosis and OS rates of close to 100%. It typically presents as localized, early-stage disease. Relapses can occur many years after the end of therapy, with 10- and 15-year cumulative relapse rates of 4.8% and 8.3%, respectively. Relapsed disease is curable, and OS rates are near 100% in patients with or without relapsed disease.[199] Historically, patients with NLPHL have been treated on protocols for patients with cHL; however, there are several reports in the adult and pediatric literature suggesting that they can be cured with less aggressive therapies. Adult patients with localized disease are typically treated with RT alone to 30 to 40 Gy.[200,201] However, given the concern for late toxicity of RT in children, alternative strategies are typically used in the pediatric population.

Surgery has been considered a treatment approach for localized pediatric NLPHL that is amenable to complete resection without the need for radical lymph node dissection. Removal of just a focal lymph node(s) is sufficient. A meta-analysis of French, United Kingdom, and German trial series showed that surgery alone was a feasible option for localized disease and yielded a long-term relapse-free survival rate of 67%.[202] The COG AHOD03P1 study prospectively evaluated 52 stage IA patients who were observed after surgery only.[203] Five-year EFS was 77%, with 13 patients experiencing relapse. Twelve of these relapses were stage IA, occurring at the initially involved site or in adjacent nodes or nodal regions; one relapse was stage IIA. Nine of these patients received salvage chemotherapy with AV-PC, all achieving a CR.[203]

In patients whose disease is not amenable to complete resection, low-dose chemotherapy is an effective treatment option. On the COG study AHOD03P1, patients with unresected stage IA or IIA NLPHL were treated with three cycles of AV-PC. Patients with less than a CR received 21 Gy IFRT. Of 135 patients treated with AV-PC, only 11 had less than a CR and received IFRT. Five-year EFS was 88.8% and OS was 100%.[203]

The EuroNet conducted a clinical trial to prospectively validate a “watch-and-wait” approach for children with completely resected disease and low-dose chemotherapy for patients with residual disease after resection, and the results are pending publication (EuroNet-PHL-LP1, NCT01088750).

Refractory or Relapsed Hodgkin Lymphoma

Treatment failures in pediatric cHL typically develop within the first 3 years; however, late relapses have been reported, particularly in patients with NLPHL. The most common site of relapse following risk-adapted therapies remains an initially involved site of disease.[194,198] Generally, positive prognostic factors include a nodal site of relapse (rather than extranodal), early stage at relapse (rather than advanced), longer duration from initial treatment until relapse, favorable histology, and robust response to first-line salvage chemotherapy. The selection of the most appropriate salvage regimen is based on whether a complete remission was achieved, the durability of the remission, the extent of disease at relapse, and the intensity of the frontline therapy given. Treatment options include standard-dose chemotherapy, high-dose chemotherapy followed by autologous stem cell transplantation, clinical trials, or palliative therapy. In addition, newer agents such as Bv and nivolumab are reinduction therapy options for relapsed/refractory cHL.[204,205] RT may be incorporated into any of these strategies. When pursuing autologous stem cell transplantation, RT may also be used pre- or post-transplant depending on the clinical scenario.[206]

Because of the excellent outcome for most children and adolescents with HL, investigations regarding salvage strategy have been limited. For high-risk relapses, a combination of ifosfamide and vinorelbine for pediatric patients in first relapse was studied by the COG on the AHOD00P1 study. This regimen showed a very good overall response rate of 72% and allowed for good stem cell mobilization for future autologous stem cell transplantation once remission was achieved.[207] Similarly, ifosfamide, gemcitabine, and vinorelbine was shown to be an effective salvage regimen with an overall response rate of 100% and excellent stem cell mobilization in relapsed/refractory pediatric HL.[208] In addition, Bv and gemcitabine is a highly active combination for pediatric patients with primary refractory or high-risk relapsed HL, with a CR rate of 67% based on modern response criteria.[205]

A risk-based approach for relapsed pediatric HL was recently proposed and evaluated.[209] CheckMate 744 was a phase II trial of children, adolescents, and young adults with relapsed/refractory HL that explored a risk-stratified, response- adapted strategy. Patients with a late recurrence and limited-stage relapsed disease were stratified into the low-risk group, whereas patients with an early recurrence or extranodal disease or B symptoms at relapse were classified as standard-risk group. All patients received nivolumab plus Bv; those without a complete metabolic response then received Bv plus bendamustine intensification. Patients in the standard-risk cohort who achieved a CR proceeded to consolidation with high-dose chemotherapy and autologous stem cell transplantation. In the standard-risk cohort, a complete metabolic response was achieved in 94% of subjects, 1-year PFS was 91%, and toxicities were limited.[204] Patients in the low-risk cohort were eligible for transplant-free consolidation with RT alone. Early results for the low-risk cohort demonstrated 3-year EFS and PFS rates of 87% and 95%, respectively, suggesting that these patients may be effectively salvaged without the need for high-dose chemotherapy with autologous stem cell transplant.[210]

Future Investigations

To build on the current era of risk- and response-adapted trials in pediatric HL, future studies will focus on refining baseline and longitudinal prognostic factors. Novel features that may improve risk stratification include PET volumetric parameters[211-213] and circulating tumor DNA burden.[214] In addition, accurate identification of patients at high risk of treatment-related toxicity may one day influence tailored treatment recommendations. For example, preliminary data suggest genetic risk factors for the development of radiation-associated breast cancer[215] and anthracycline-induced cardiotoxicity.[216] Such research will enable future clinicians to develop personalized treatment recommendations that are informed by both disease and host factors. Newer drugs may offer great efficacy with less toxicity. Current studies are moving novel agents, such as Bv and checkpoint inhibitors, into upfront treatment. With future study, these agents, as well as patient stratification using recently identified disease and host risk factors, will contribute to the decades-old goal of maintaining outstanding disease control while minimizing treatment-associated toxicity for children with HL.

NON-HODGKIN LYMPHOMA

Childhood NHLs are a heterogeneous group of malignancies with variable histopathology, sites of origin, and clinical manifestations. In contrast to HL, childhood NHLs are rapidly growing, diffuse, high grade, and poorly differentiated. Extranodal involvement is common, and dissemination occurs early and often.[217] This is in striking contrast to adult NHL, in which low- and intermediate-grade nodal disease predominates.[218] The common low-grade lymphomas seen in adults, such as follicular lymphomas (FLs) and marginal zone lymphomas, are extremely rare in children. These differences in pathology and clinical behavior between children and adults explain the markedly different clinical presentations, staging practices, and treatment strategies between age groups.

Epidemiology

In the United States, approximately 800 children and adolescents younger than 20 years of age are diagnosed with NHL every year, compared to 60,000 adult cases. According to the Surveillance, Epidemiology, and End Results Program of the National Cancer Institute, NHL accounts for about 8% of all cases of childhood cancer.[219] Compared to HL, NHL is more common in very young children and less common in adolescents. The incidence of NHL is higher in males than in females (ratio of 3-1) and in Caucasians than in African Americans (ratio of 1.5-1).

Although NHL is associated with several genetic and environmental factors, its cause and pathogenesis remain unclear. A small proportion of cases are seen in association with inherited immunodeficiencies (eg, Wiskott-Aldrich syndrome, X-linked lymphoproliferative disease [XLP], ataxia-telangiectasia, and

common variable immunodeficiency) or acquired immunodeficiencies (eg, HIV infection or immunosuppressive therapy in patients receiving solid organ or bone marrow transplants).[217] Given these associations, a comprehensive medical and family history should be obtained at diagnosis with referral to a geneticist for any concerns; treatment is influenced by certain syndromes, such as XLP in which allogeneic bone marrow transplantation is needed, and implications for testing siblings should be considered.

Geographic variation exists in the incidence and pathogenesis of NHL. For example, EBV infection is present in the majority of endemic Burkitt tumors in equatorial Africa, but it occurs in only 10% to 15% of sporadic cases outside Africa. Data suggest a significant role for EBV in lymphomagenesis leading to the development of the same oncogenic chromosomal translocations as those observed in non–EBV-associated sporadic cases of Burkitt lymphoma (BL).[220-222] EBV infection is also associated with the development of post-transplant lymphoproliferative disease, a B-cell disorder seen in patients after solid organ or hematopoietic stem cell transplantation.[223,224]

Pathologic Classification

Pediatric NHL cases are divided into four major histopathologic subtypes based on morphology and immunophenotype: (a) Burkitt leukemia or lymphoma; (b) lymphoblastic lymphoma (LL), including B-cell LL (B-LL) and T-cell LL (T-LL); (c) large B-cell lymphoma, including diffuse large B-cell lymphoma (DLBCL) and primary mediastinal (thymic) large B-cell lymphoma (PMBCL); and (d) anaplastic large cell lymphoma (ALCL).[217] The distribution of histologies is shown in Table 97.6.

TABLE 97.6 CLINICAL CHARACTERISTICS OF CHILDHOOD NON-HODGKIN LYMPHOMA

Histologic Subtype	Proportion of Cases (%)	Most Common Sites of Presentation
Burkitt lymphoma	35-40	Abdomen or head and neck
T-lymphoblastic lymphoma	15-20	Mediastinum
B-lymphoblastic lymphoma	3	Cutaneous masses, isolated nodes, and bone
Diffuse large B-cell lymphoma	15-20	Nodes, abdomen, and bone
Primary mediastinal B-cell lymphoma	1-2	Mediastinum
Anaplastic large cell lymphoma	15-20	Skin, nodes, and bone

The classification of NHL by the WHO was updated in 2016[225] and increasingly incorporates immunophenotype and cytogenetics into diagnostic, prognostic, and therapeutic decision-making. Several noteworthy changes with respect to pediatric NHL exist in the updated WHO classification. Pediatric-type FL became a distinct subtype from adult variants.[217,225,226] It is characterized by large, expansile, highly proliferative follicles that often have prominent blastoid follicular center cells, rather than classic centroblasts, and lack MYC, BCL6, and BCL2 rearrangements; however, BCL2 protein may be expressed. Large B-cell lymphoma with IRF4 rearrangement, which commonly occurs in children and young adults, was added as a new provisional entity. Most of these cases have IG/IRF4 rearrangements, some with BCL6 rearrangements, but they uniformly lack BCL2 rearrangements. These lymphomas typically occur in Waldeyer ring and/or cervical lymph nodes and are more aggressive than other pediatric-type FL. Burkitt-like lymphoma with 11q aberration was added as a provisional entity to distinguish a subset of lymphomas that have more complex karyotypes, lack MYC rearrangements, and have lower levels of MYC expression than BLs. Instead, this subtype is notable for chromosome 11q changes with proximal gains and telomeric losses, but the clinical course appears similar to BL.[227,228]

The identification of large numbers of monoclonal antibodies directed against surface antigens permitted subclassification of many NHL subtypes according to immunophenotype, as summarized in Table 97.7.[229] Thorough evaluation of histology and immunophenotype is critical to the diagnosis,

prognosis, and selection of therapy. Cytogenetic analysis and identification of molecular markers provide a more precise means to characterize these tumors and will likely provide insights into pathogenesis and potential novel therapeutic approaches.

TABLE 97.7 IMMUNOPHENOTYPIC, CYTOGENETIC, AND MOLECULAR MARKERS OF PEDIATRIC NHL

Histology and Frequency

Clinical Presentation

The clinical presentation of NHL varies according to the site of involvement, but often children present in distress. A mediastinal mass is present in 25% of children with NHL and is commonly associated with T-LL, DLBCL, and PMBCL.[230] Due to the rapid onset of the mediastinal masses, they often cause respiratory symptoms (eg, cough, wheezing, shortness of breath, and orthopnea) due to airway compression and can cause neck, face, and upper extremity swelling due to obstruction of the SVC. Hemodynamic compromise may also occur because of pericardial effusions. Due to rapid tumor growth, patients may experience an acute decline in 12 to 24 hours without initiation of therapy.

The NHL subtypes have typical presentations. For example, the majority (50%-70%) of children with precursor T-LL present with rapidly enlarging neck and large mediastinal lymphadenopathy and pleural effusions.[231,232] However, children and adolescents with precursor B-LL tend to have limited disease in sites such as skin, bone, and peripheral lymph nodes.[233] DLBCL frequently presents with nodal disease, although bone involvement is also relatively common.[231,234] PMBCL typically presents with signs and symptoms related to a large mediastinal mass and, often, pleural effusions.

Sites of involvement differ in sporadic compared to endemic BL. In sporadic BL, the abdomen is the most common site of disease involvement, and patients often present with abdominal pain, distension, a palpable mass, nausea, vomiting, and gastrointestinal bleeding. Bone marrow involvement is seen in about 20% of patients with sporadic BL.[235] However, in endemic BL, jaw involvement is most common, and bone marrow involvement is rare.[236]

ALCL may be systemic or cutaneous. In systemic disease, peripheral, mediastinal, and intra-abdominal nodal involvement, extranodal disease, and B symptoms are common. A translocation resulting in the fusion of the anaplastic lymphoma kinase (*ALK*) gene to one of several partners occurs in more than 90% of patients. Conversely, primary cutaneous ALCLs usually lack the ALK translocation, remain confined to the skin, and follow a more indolent course.[217]

Diagnostic Evaluation

Tissue diagnosis, imaging, and often BMB should be completed expeditiously to determine the extent of disease. Histology, immunophenotype, karyotype, and molecular studies are vital to identifying the optimal treatment plan, which should be initiated urgently due to the rapid growth rate of most pediatric NHL.[217] It is, therefore, critical that an adequate quantity of tissue be obtained at biopsy by performing an excisional biopsy, ideally, or a core-needle biopsy, if an excisional biopsy is not possible. Steroid use before a biopsy may be necessary in the case of a symptomatic mass to achieve clinical stability, but it may result in rapid shrinkage and necrosis, complicating the establishment of a tissue diagnosis.[237,238] Therefore, every attempt should be made to obtain a biopsy before steroids are administered. If steroids must be started emergently, then a biopsy should be obtained as soon as possible to have the greatest chance at making a diagnosis.

BMB has been a standard component of NHL staging and diagnosis (ie, Burkitt leukemia vs lymphoma or T-LL and B-LL vs acute lymphoblastic leukemia [ALL]). In DLBCL, FDG-PET-CT has been shown to be more sensitive for detecting marrow involvement than BMB, but PET may miss low-volume disease when less than 10% to 20% of the marrow is involved.[239,240] Therefore, in pediatric patients with DLBCL, FDG-PET-CT indicating bone marrow involvement is typically sufficient for diagnosis, and BMB may not be required. If the PET is negative for bone marrow involvement in DLBCL, however, a BMB should be recommended, particularly if the presence of bone marrow disease would influence management. For all other NHL histologies, a 2.5-cm unilateral BMB, along with immunohistochemistry and flow cytometry, is still considered standard practice because there are not conclusive data guiding the utility of PET.[57,58]

PET-CT is strongly encouraged for staging FDG-avid NHL.[57,58] Contrast-enhanced CT is indicated for all non–FDG-avid histologies. The FDG-avidity of the different NHL subtypes is summarized in Table 97.8.

TABLE 97.8 FDG-AVIDITY OF NHL ACCORDING TO WHO CLASSIFICATION

Histology	Number of Patients	FDG Avid (%)
HL	489	97-100
DLBCL	446	97-100

Laparotomy is no longer indicated for staging of lymphomas. MRI may be helpful in detecting disease at specific sites, particularly the CNS, and should be considered in appropriate cases.

Staging Systems

The Ann Arbor staging system,[63] commonly used in adult NHL, has limited prognostic value in pediatric NHL because of the often-disparate clinical presentation and disease course in children, the higher incidence of extranodal primary sites and CNS involvement, and the infrequent evolution into frank leukemia. The Lugano lymphoma staging classification similarly focuses on adult lymphomas.[57] In the 1980s, the Murphy/St Jude Children's Research Hospital staging system was introduced specifically for pediatric NHL. This system incorporates the extent of disease and clinical patterns.[217] Since the introduction of the Murphy/St Jude staging system, the pathologic classification of NHL has changed significantly. New subtypes of pediatric NHL have been identified, some of which display unique patterns of organ involvement, including the mucosa, skin, bone, ovary, and kidney. Therefore, a Revised International Pediatric NHL Staging System Classification was developed by a multidisciplinary,

international consortium that incorporates new histologic entities, extent of extranodal dissemination, and modern diagnostic methods and imaging techniques, as shown in Table 97.9. This revised staging system will enable more precise, reproducible comparisons of treatment efficacy across cooperative groups.[241]

TABLE 97.9 STAGING AND GROUPING SYSTEM FOR CHILDHOOD NON-HODGKIN LYMPHOMA

Stage	Murphy Staging System[218]	International Pediatric Non-Hodgkin Lymphoma Staging System[241]
I	Single EN tumor or single anatomic N area, excluding the mediastinum or abdomen	Single tumor excluding the mediastinum or abdomen (N; EN; B or S: EN-B, EN-S)
II	Single EN tumor with regional lymph node involvement Two or more N areas on the same side of the diaphragm Two single EN tumors + regional node involvement on the same side of the diaphragm Primary GI tract tumor (usually in ileocecal area), + involvement of associated mesenteric nodes only	Single EN tumor with regional node involvement Two or more N areas on the same side of the diaphragm Primary GI tract tumor (usually in ileocecal area), + involvement of associated mesenteric nodes, that is completely resectable (if malignant ascites or extension of tumor to adjacent organs, it should be regarded as stage III)
III	Two single EN tumors on opposite sides of the diaphragm Two or more N areas above and below the diaphragm All primary intrathoracic tumor (mediastinal, pleural, thymic) All extensive primary intra-abdominal disease including disease with spread via lymphatics to para-aortic and retroperitoneal nodes via intraperitoneal dissemination to form implants and plaques along the mesentery or peritoneum, or by direct infiltration of structures adjacent to primary tumor. Ascites may be present, and complete resection of all gross tumor is not possible. All paraspinal or epidural tumors, regardless of other tumor sites	Two or more EN tumors (including EN-B or EN-S) above and/or below the diaphragm Two or more N areas above and below the diaphragm Any intrathoracic tumor (mediastinal, hilar, pulmonary, pleural, or thymic) Intra-abdominal and retroperitoneal disease, including liver, spleen, kidney, and/or ovary localizations, regardless of degree of resection (except primary GI tract tumor [usually in ileocecal region] involvement of associated mesenteric nodes that is completely resectable) Any paraspinal or epidural tumor, regardless of whether other sites are involved Single B lesion with concomitant involvement of EN and/or nonregional N sites
IV	Any of the above with initial CNS or BM involvement (<25% blasts)	Any of the above findings with initial CNS involvement (stage IV CNS), BM (stage IV BM), or both (stage IV combined) based on conventional methods
Group Classification in the B-Cell Lymphomas[242]		
A	Completely resected stage I or completely resected abdominal stage II lesions	
B	All cases not eligible for group A or group C (Murphy stage III and non-CNS stage IV)	
C	Any CNS involvement and/or bone marrow involvement ≥25% blasts. For CNS involvement, one or more of the following applies: 1. Any L3 blasts in CSF 2. Cranial nerve palsy (if not explained by extracranial tumor) 3. Clinical spinal cord compression 4. Isolated intracerebral mass 5. Parameningeal extension: cranial and/or spinal	

B, bone; BM, bone marrow; CNS, central nervous system; CSF, cerebrospinal fluid; EN, extranodal; N, nodal; S, skin.

Prognostic Factors

Stage is the most important prognostic factor in childhood NHL and accounts for other known prognostic variables, including tumor burden and site of involvement.[241] Other important prognostic factors in NHL include LDH level at diagnosis and CNS involvement. Biologic characteristics including the presence of 13q abnormalities, MYC/8q24 rearrangement in DLBCL, and minimal disseminated disease and minimal residual disease in BL may also be prognostic.[243,244] As most pediatric NHL subtypes are high grade and

aggressive, few reports support the role of histologic subtype as a prognostic factor. Response to therapy is also being investigated,[245] and attempts are being made to standardize pediatric NHL response criteria.[246]

Treatment of Non-Hodgkin Lymphoma

OS of children with NHL was poor before the advent of multiagent chemotherapy in the mid-1970s.[247] Even in cases with localized disease based on the optimal staging of the time, cure rates as low as 20% were reported. In most cases, early systemic dissemination of disease already occurred. In modern regimens, chemotherapy is the primary therapeutic modality for all histologies and stages of childhood NHL. The dramatic improvement in the overall rate of survival in childhood NHL can be attributed not only to the development of highly effective, multiagent chemotherapy regimens, but also to the systematic evaluation of these diseases and their treatment by pediatric cooperative group clinical trials. EFS rates exceeding 90% in patients with limited disease (Table 97.10) and 70% in those with extensive involvement (Table 97.11) are now reported.[242,248-276]

[a]Excludes patients with CNS-positive disease and those who had insufficient response on day 33.

[b]Includes DLBL, follicular lymphoma, and mucosal-associated lymphoid tissue lymphoma.

Burkitt Leukemia or Lymphoma

As a result of several consecutive prospective trials, outcomes for BL have dramatically improved.[242,245,248,249,252,263,266,275,276] Treatment consists of 2 to 6 months of multiagent, cyclophosphamide-based chemotherapy. The current paradigm has been established through collaborative efforts across consortiums such as the French Society of Pediatric Oncology and French-American-British (FAB), Lymphomes Malins B (LMB), and the Berlin-Frankfurt-Munster studies.[242,245,248,249,252,263,266,275,276] Since BL

frequently occurs in lower income countries, treatments have been adapted to balance toxicity, efficacy, and cost. OS rates are now greater than 90% in the developed world for advanced BL, and more than half of patients can be cured using resource-adapted protocols in low- and middle-income countries.[280,281] Relapses most commonly occur within the first year of therapy.

In non–resource-constrained health systems, standard frontline therapy for advanced BL is based on the FAB/LMB96 regimen[245] with cyclophosphamide, vincristine, prednisone, high-dose methotrexate, doxorubicin, and cytarabine. Although 20% to 25% of patients present with advanced-stage disease involving the bone marrow and/or CNS, this treatment approach results in EFS of approximately 90%. Of note, involvement of more than 25% of the marrow by Burkitt is classified as Burkitt leukemia, which is treated using a high-risk BL treatment paradigm. High-dose methotrexate with or without high-dose cytarabine and intrathecal methotrexate with or without cytarabine provide effective CNS prophylaxis and treatment for high-risk and CNS-positive disease, eliminating the need for CNS irradiation.[242,245,248,249,252,263,266,275,276] Testicular involvement at diagnosis is uncommon but may occur in about 5% of children with disseminated BL and Burkitt-like NHL.[282] Testicular disease does not confer an inferior prognosis, and disease is still curable with intensive combination chemotherapy alone. Local surgery or radiation is not needed.

BL, like DLBCL, expresses CD20. As such, recent studies added the anti-CD20 monoclonal antibody, rituximab, into multiagent chemotherapy. In 2004, the COG implemented ANHL01P1, a pilot study evaluating the toxicity of adding rituximab to standard therapy for patients with newly diagnosed, pediatric BL and DLBCL.[283] Survival rates were similar to the 4-year reported EFS in patients treated with FAB/LMB96 therapy.[245] In a multicenter European phase II study, 136 pediatric patients with newly diagnosed B-cell NHL received one dose of rituximab in an upfront window prior to starting standard chemotherapy to assess the possibility of a future phase II trial to test if rituximab could substitute for chemotherapy. A response rate of higher than 65% was set for the classification of favorable activity of rituximab; although this ambitious rate was not met, 41% of patients experienced disease improvement after a single dose of rituximab.[278] The International B-NHL ritux 2010 trial randomized patients with stage III disease and elevated LDH or stage IV disease to intensive LMB/FAB chemotherapy with or without six doses of rituximab. The authors identified a significant improvement in EFS with rituximab (3-year EFS 94% vs 82%, $P = .00096$). Thus, the addition of rituximab to intensive chemotherapy should be considered the current standard of care for these patients.[279]

Diffuse Large B-Cell Lymphoma

The treatment of DLBCL follows the same protocols as BL in pediatric and young adult patients. Follow-up for patients with DLBCL, however, should be focused on the possibility of comparatively later relapses, which may occur up to 3 years after treatment.[242,263,276] Rituximab combined with intensive chemotherapy is considered standard of care in DLBCL as in BL based on ANHL1131.[279]

Primary Mediastinal B-Cell Lymphoma

PMBCL most commonly occurs in adolescents and young adults. Since the disease biology appears similar across age groups, the common adult treatment regimens are used in pediatric patients, including rituximab, cyclophosphamide, doxorubicin, and prednisone (R-CHOP) and dose-adjusted etoposide, doxorubicin, and cyclophosphamide with vincristine, prednisone, and rituximab (DA-EPOCH-R). Of note, treatment with DA-EPOCH-R obviated the need for RT in adult patients with PMBCL.[284] DA-EPOCH-R was evaluated in an intergroup trial of children and adolescents with newly diagnosed PMBCL, but the 4-year EFS in 46 patients was only 69.6% (95% CI 55.2-80.9),[285] which is lower than the EFS observed in adults.[284] Treatment of PMBCL with FAB/LMB96 chemotherapy resulted in an EFS of 70%.[286] The current intergroup study ANHL1931 (NCT04759586) is exploring whether the addition of nivolumab will improve cure rates when compared to chemo-immunotherapy alone. On ANHL1931, ISRT is used for (1) patients enrolled on the R-CHOP plus RT arm and (2) patients with a Deauville 4 or 5 response at the

completion of systemic therapy, with the presence of disease confirmed by biopsy. The ISRT dose is 30 Gy, with a possible boost of 9 to 15 Gy to residual FDG-avid sites.

Lymphoblastic Lymphoma

LL consists of both precursor T-LL and B-LL NHLs, with the majority (80%-90%) being T-LL. A BMB is required to distinguish between ALL and LL by the extent of bone marrow involvement. T-LL generally presents at an advanced stage with a mediastinal mass and occasionally bone marrow involvement. B-LL is more commonly localized and presents in various locations, including the bones, skin, soft tissues, and peripheral nodes.[287] Treatment follows an ALL-based paradigm with the addition of high-dose methotrexate and/or intrathecal injections for CNS prophylaxis,[254,288,289] rather than CNS RT.[253,290] These regimens include early intensified multiagent chemotherapy consisting of vincristine, prednisone, L-asparaginase, doxorubicin, cytarabine, cyclophosphamide, and high-dose methotrexate, followed by maintenance chemotherapy for 2 years.[253,254,269,270,277,288,289,291-294] In localized B-LL and T-LL treated with such intensive therapy, OS rates are 90% or better. In AALL1231, receipt of bortezomib significantly improved both 4-year EFS and OS in patients with T-LL, although no significant difference was observed in ALL.[295] Following relapse, the outcomes of patients with B-LL and T-LL remain mediocre. Novel agents, such as daratumumab, have demonstrated activity in T-LL and may be promising to consider as first-line therapy for T-LL and T-ALL in the future.[296]

Anaplastic Large Cell Lymphoma

ALCL presents in either a systemic or primary cutaneous form. Systemic ALCL is frequently associated with “B” symptoms and extranodal disease. Advanced systemic ALCL has been treated with short-pulse chemotherapy, proven effective in B-cell lymphomas, or with modifications of high-risk ALL protocols.[256,257,274] Long-term EFS ranges from 65% to 75%[250,255-257,297,298]; however, recurrences are comparatively more responsive to salvage therapies than relapsed disease in other NHL subtypes.[217] Treatment of recurrent ALCL involves chemotherapy followed by hematopoietic stem cell transplantation or weekly vincristine and yields survival rates of more than 90%.[255,256,299-301]

Role of Radiation Therapy

With the development of the current multiagent chemotherapy regimens in many NHL subtypes, the role of RT for local control of primary tumors and CNS prophylaxis is limited. At present, cranial irradiation is generally only indicated in patients with symptomatic CNS lymphoma, particularly if unresponsive to frontline chemotherapy, or in the event of CNS relapse.[302]

The role of consolidative RT for PMBCL is often considered. Adult data suggest that consolidative RT should be recommended in PMBCL after R-CHOP, but that it is generally not indicated following a complete metabolic response to DA-EPOCH-R. Given the poorer outcomes of PMBCL treated with DA-EPOCH-R in children compared to adults, the role of consolidative RT is less clear. At present, the authors recommend that consolidative RT to a minimum of 30 Gy be strongly considered in patients with PMBCL if they are treated with R-CHOP chemotherapy or if they have an incomplete response following any induction chemotherapy regimen.[284,303,304]

Historically, consolidative RT was included in the treatment of primary lymphomas of the bone.[259] An early trial randomized children and young adult patients with limited-stage NHL to receive RT or no consolidation after chemotherapy and demonstrated that consolidative RT was not needed in many patients with early-stage NHL. In this trial, however, all patients with primary lymphoma of the bone received 37.5 Gy and were not included in the randomization.[259] Given the rarity of these entities, the patterns of failure of all early-stage primary lymphomas of the bone treated on three consecutive POG studies were examined to determine the impact of RT on outcomes. Across the three studies, a total of 31 patients with primary bone lymphomas were analyzed, with 7 receiving combined modality therapy and 24 receiving

chemotherapy alone. In this analysis, no patient developed a local relapse, suggesting that NHL of the bone may be treated with chemotherapy alone.[305]

RT should be considered for relapsed or refractory disease, either as part of combined modality therapy with definitive intent or as palliation when appropriate. Selected patients with NHL may benefit from urgent RT for symptomatic mediastinal disease, spinal cord compression, pain, and symptomatic CNS lymphoma.

Pediatric patients with relapsed or refractory disease following frontline chemotherapy often receive high-dose chemotherapy and stem cell rescue as part of salvage therapy.[306] RT to limited site(s) of residual or relapsed disease may be beneficial in combination with hematopoietic cell transplantation and generally should use a dose of 30 to 36 Gy. Emergent palliative radiation to control symptoms of SVC syndrome, airway impingement, spinal cord compression, and orbital proptosis can produce dramatic and rapid responses, typically within 48 hours of treatment. In general, these regimens using daily fractions of 2 to 3 Gy or twice-daily treatments of 1.2 to 1.5 Gy are efficacious. For symptom control, total doses as low as 4 Gy can lead to relief.[307,308] Higher doses to 20 to 30 Gy may be more appropriate for cranial nerve deficits and other situations in which durable disease control is important.[308,309] Corticosteroids, ideally after the diagnosis is confirmed by biopsy, can also lead to dramatic tumor responses in NHL.

Future Investigations

Future pediatric NHL trials will aim to identify and incorporate novel therapies into frontline and salvage regimens, including targeted agents, monoclonal antibodies, and immunotherapies. Small patient numbers for individual NHL histologies and the rarity of patients developing relapsed/refractory disease are the most daunting obstacles to clinical trial design and implementation. Despite these limitations, considerable progress has been achieved in identifying potential targets and utilizing novel therapies in pediatric NHL. For example, ALCL arises from T cells but strongly expresses CD30, leading to the evaluation of Bv in a phase II study of adults and pediatric patients with relapsed or refractory ALCL with promising response rates.[310] Given that most pediatric patients have ALK-positive disease, ALK inhibitors may also be promising agents in ALCL.[311] CD20 is commonly expressed in DLBCL and BL, and rituximab is now employed during frontline therapy; next-generation anti-CD20 monoclonal antibodies may be reasonable to evaluate in DLBCL and BL, as well.[312] Immunotherapy will also be further explored in NHL and is part of the current COG study in PMBCL. Ultimately, these therapies may reduce treatment intensity and chemotherapy-related toxicities and may improve efficacy.

CHAPTER 98

Retinoblastoma

Beate Timmermann and John T. Lucas, Jr

Retinoblastoma is a malignant embryonal tumor of the eye that exclusively occurs during childhood. It originates from the retina in the early years of life. Various treatment modalities are available depending on the degree of spread and other factors. In general, eye-preserving therapies or surgery (enucleation), if necessary, are combined with adjuvant therapies.

EPIDEMIOLOGY

With an incidence of 1 in 15,000 to 20,000 live births worldwide, retinoblastoma is the most common eye tumor in children.[1] Approximately 8,000 new cases are diagnosed worldwide each year,[2,3] primarily in children aged under 5 years. The median age at diagnosis is 2 years.[1] Incidence is higher in low- and middle-income countries (LMICs) with an estimated 1,300 to 4,000 cases annually, compared to approximately 200 to 300 cases in the United States and around 500 cases in Europe.[4]

Retinoblastoma can present as unifocal (single tumor) or multifocal (many tumors). Approximately 60% of all retinoblastomas affect one eye (unilateral disease), while 40% affect both eyes (bilateral disease). All bilateral and multifocal forms are hereditary.

Survival rates for retinoblastoma vary greatly such that in high-income countries (HICs), almost all retinoblastoma cases survive, whereas in LMICs, the mortality rate can reach up to 70%.[4] The discrepancy is primarily due to differences in the time of diagnosis. In HICs, the tumor is often detected before critical structures of the eye are affected. In LMICs, diagnosis frequently occurs when there are signs of invasive disease, leading to a higher risk of local and distant metastasis.[5] While some patients with metastatic disease are still curative, those with involvement of the central nervous system (CNS) are rarely curable.

PATHOGENESIS

Retinoblastoma is a cancer characterized by small, round cells. These cells have large, deeply stained nuclei and minimal cytoplasm. Although retinoblastoma arises from retina cells and the retina is part of the CNS, retinoblastomas are not assigned to the CNS tumors.[6] Tumor cells grow around feeding blood vessels, forming a cuff-like structure. As they extend beyond the vascular supply, they become necrotic and calcified.[7] Retinoblastoma is a fast-growing eye cancer that can spread within and outside the eye (Figure 98.1). Intraocular retinoblastomas can affect only the retina or spread to structures such as the choroid, ciliary body, anterior chamber of the eye, and/or the optic nerve head. The tumor can grow into the vitreous (endophytic) or develop into the subretinal space while growing toward the choroid (exophytic).[8] The extent of disease, including seeding, is crucial for treatment decisions. Seeding can be localized, limited, or massive and nondiscrete and either described as subretinal or within the vitreous cavity. Diffuse infiltrating growth has also been described.[8] Retinoblastoma may extend beyond the eye into the bulb wall and spread to the tissue around the eye, referred to as an orbital retinoblastoma. In addition, the tumor can spread locally and regionally along the optic nerve, via the cerebrospinal fluid (CSF) space into the CNS, or through the bloodstream to the bone marrow, lymph nodes, or other parts of the body.[7,9]

Typically, undifferentiated tumor cells are more prevalent in retinoblastoma, and differentiation does not significantly impact the prognosis. However, tumors can exhibit varying levels of photoreceptor differentiation, resulting in the formation of rosettes at the cellular level. Flexner- Wintersteiner rosettes comprise a circular arrangement of columnar cells with eosinophilic cytoplasm and nuclei located peripherally around a central lumen. This lumen is lined by a refractile membranous structure corresponding to the outer limiting membrane of the retina. The

lumen is lined by a refractile membranous structure that corresponds to the outer limiting membrane of the retina. Homer-Wright rosettes are formed by cells surrounding a central structure known as the fibril tangle, which consists of their own projections. While these two types of rosettes can also be found in other neural tumors, their simultaneous occurrence is specific to retinoblastoma.[7,9] Fleurettes are curved cell accumulations composed of inner rod and cone segments. They are notably associated with the benign precursor of retinoblastoma, known as retinoma.[7]

GENETICS

Retinoblastoma arises from retinal progenitor cells carrying biallelic mutations of the retinoblastoma tumor suppressor gene *RB1*. Gene inactivation occurs according to the two-hit model, which was first described by Knudson in 1971.[10] To date, more than 2,500 *RB1* gene mutations are known. Most of these mutations are in the 180 kb of the coding region of the gene, but they can also affect the promoter and intron regions.[11] No clear hot spots exist. The mutations are distributed over the entire gene, which is localized on chromosome 13q14.2.[8] The *RB1* gene encodes the retinoblastoma protein (pRB), a phosphoprotein expressed in all human tissues. In the cell cycle, pRB regulates the transition from G1 to S phase by blocking the interaction of the transcription factors E2F and DP with DNA. In response to mitogenic stimuli, pRB becomes hyperphosphorylated, removing the blockade and enabling active transcription by E2F and DP. Mutations that impair pRB function lead to uncontrolled entry into the S phase, resulting in increased cell cycle activity and uncontrolled cell growth, which, in turn, leads to tumorigenesis. In addition, pRB function is associated with differentiation, chromatin remodeling, genomic stability, apoptosis, and epigenetic processes.[7,12,13-23] pRB dysfunction causes dysregulation of many tumor suppressor pathways.

Retinoblastoma exists in two forms: hereditary and nonhereditary. The hereditary form accounts for 30% to 40% of retinoblastoma cases. It is characterized by a germline mutation in one allele of the *RB1* gene, which is present in all cells of the child's body at birth. Prior to tumorigenesis, this germline mutation is followed by a somatic mutation in the second *RB1* allele in a retinal progenitor cell, leading to gene inactivation. In 25% of

patients, the germline mutation is inherited autosomal dominantly from one parent; otherwise, it arises during germ cell development.[8] If the mutation occurs later in development, postconception, it may lead to mosaicism, indicating that only some of the body cells carry the mutation.[24] Hereditary retinoblastoma typically presents early, with a median age of 15 months, and often manifests multifocally and bilaterally. However, 10% to 20% of unilateral cases are also based on a germline mutation.[25] Hereditary retinoblastoma is associated with an increased risk of developing second primary cancer, such as osteosarcoma, soft tissue sarcoma, malignant melanoma of the skin, or neuroectodermal tumors.[26,27] External beam radiotherapy (EBRT) further elevates this risk both inside and outside the radiation field.[28-30]

Nonhereditary retinoblastoma is the more common variant and develops as a result of random somatic mutations in both *RB1* alleles of a single retinal progenitor cell. It usually occurs as a solitary focus in one eye. The median age for nonhereditary retinoblastoma is 24 months.[4,31] In rare cases, patients with unilateral retinoblastoma develop new intraocular tumor foci in the opposite eye 2 to 18 months after diagnosis, a condition termed *metachronous retinoblastoma*. This phenomenon is suggested to be associated with family history, early age at diagnosis, tumor multifocality, and oncogenic mutations in the tumor.[32,33] Trilateral retinoblastoma describes a situation where bilateral retinoblastoma coexists with a third, intracranial tumor (Figure 98.2). The reported incidence is 5% to 15% of bilateral cases, although a recent analysis excluding studies with small cohorts estimates a lower incidence.[34] Importantly, this scenario does not represent CNS metastatic disease. The intracranial component is most commonly located in the pineal region, and less frequently in the suprasellar region. Extremely rare cases with both pineal and suprasellar locations are termed *quadrilateral retinoblastoma*.[8]

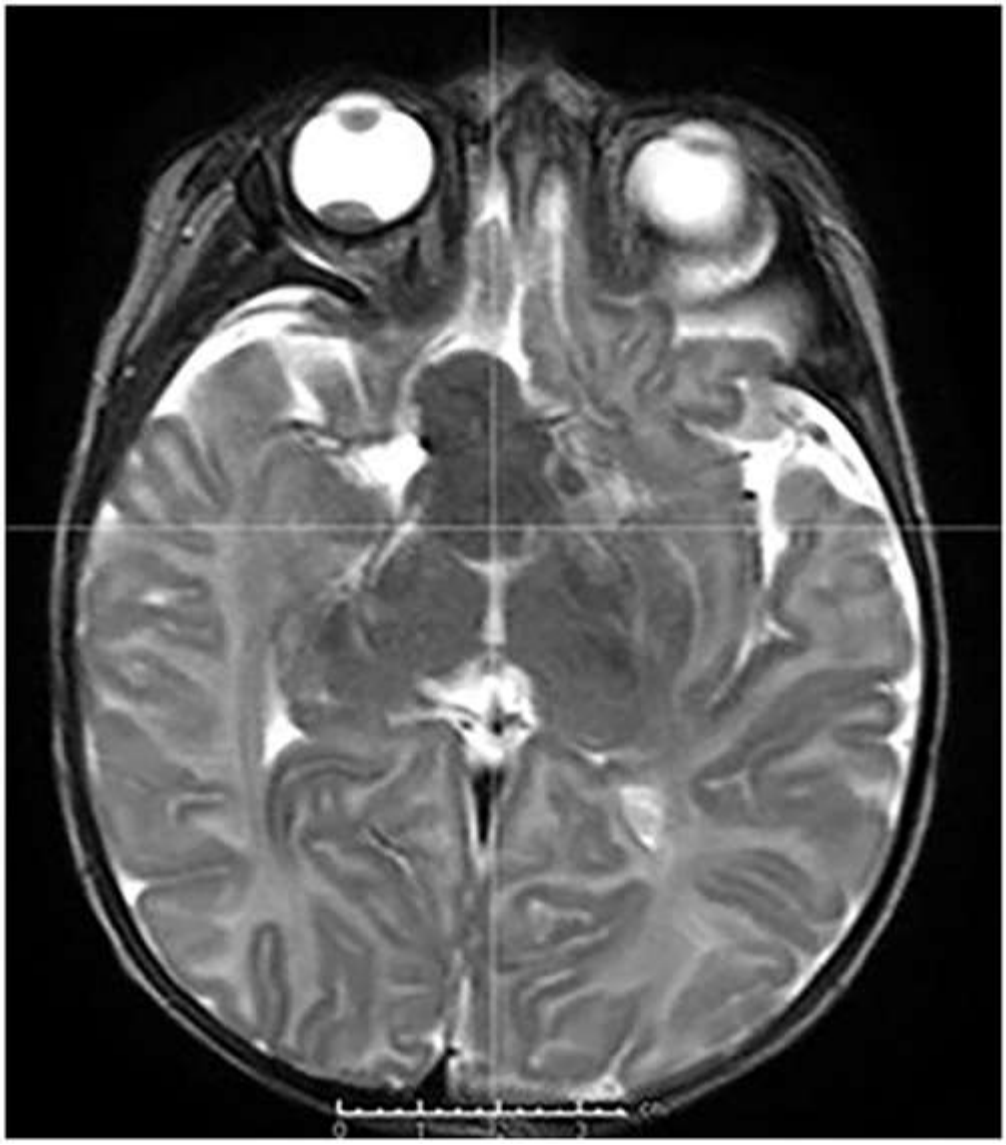

FIGURE 98.2 Transversal view of a T2-weighted magnetic resonance imaging of a trilateral retinoblastoma in suprasellar region.

Beyond *RB1* Gene Mutation

Tumorigenesis involves several stages. In addition to *RB1* gene inactivation, other genetic and epigenetic changes contribute to the development and progression of retinoblastoma. Recurring genetic changes in the epigenetic modifier genes *BCOR* (BCL6 corepressor) and *OTX2* (orthodenticle homeobox 2) have been identified.[35,36] A distinct pattern of genomic gains on chromosomes 1q, 2p, and 6p and loss on 13q and 16q has also been detected in retinoblastoma. Oncogenes and tumor suppressor

genes such as *KIF14* (kinesin family member 14, 1q), *MDM4* (murine double minute 4, 1q), *MYCN* (2q), *DEK* (6p), *E2F3* (E2F transcription factor 3, 6p), *CDH11* (cadherin 11, 16q), and *RBL2* (RB transcriptional corepressor like 2, 16q) are located in these regions.[36-39] Epigenetic dysregulation, including DNA methylation, histone modifications, and noncoding RNAs, also plays a significant role in retinoblastoma tumor formation and metastasis.[35,39] For instance, aberrant methylation of certain promoters, such as *MGMT* (methylguanine methyltransferase), *RASSF1A* (Ras association domain family member 1), *CASP8* (caspase 8), and *MLH1* (MutL homolog 1), contributes to the disease.[39-41] Dysregulation of microRNAs, including *let-7*, *miR-24a*, and the *miR17-92* cluster, is also observed in retinoblastoma.[39] In addition, long noncoding RNAs may act as potential modulators in retinoblastoma progression and metastasis.[42]

CLINICAL PRESENTATION AND DIAGNOSIS

The most common early symptoms of retinoblastoma are leukocoria (also known as "cat's-eye reflex") and strabismus (Figure 98.3A). However, this is not usually an abnormality at birth; rather, the signs develop between 6 months and 2 years of age. Other, less common signs of retinoblastoma include inflammation in various areas of the eye and orbit, mydriasis, microphthalmia, buphthalmos, neovascular glaucoma, uveitis, hyphema, and iris heterochromia. Proptosis (bulging of the eye) and periorbital swelling are symptoms of advanced retinoblastoma.[7,8,43-45]

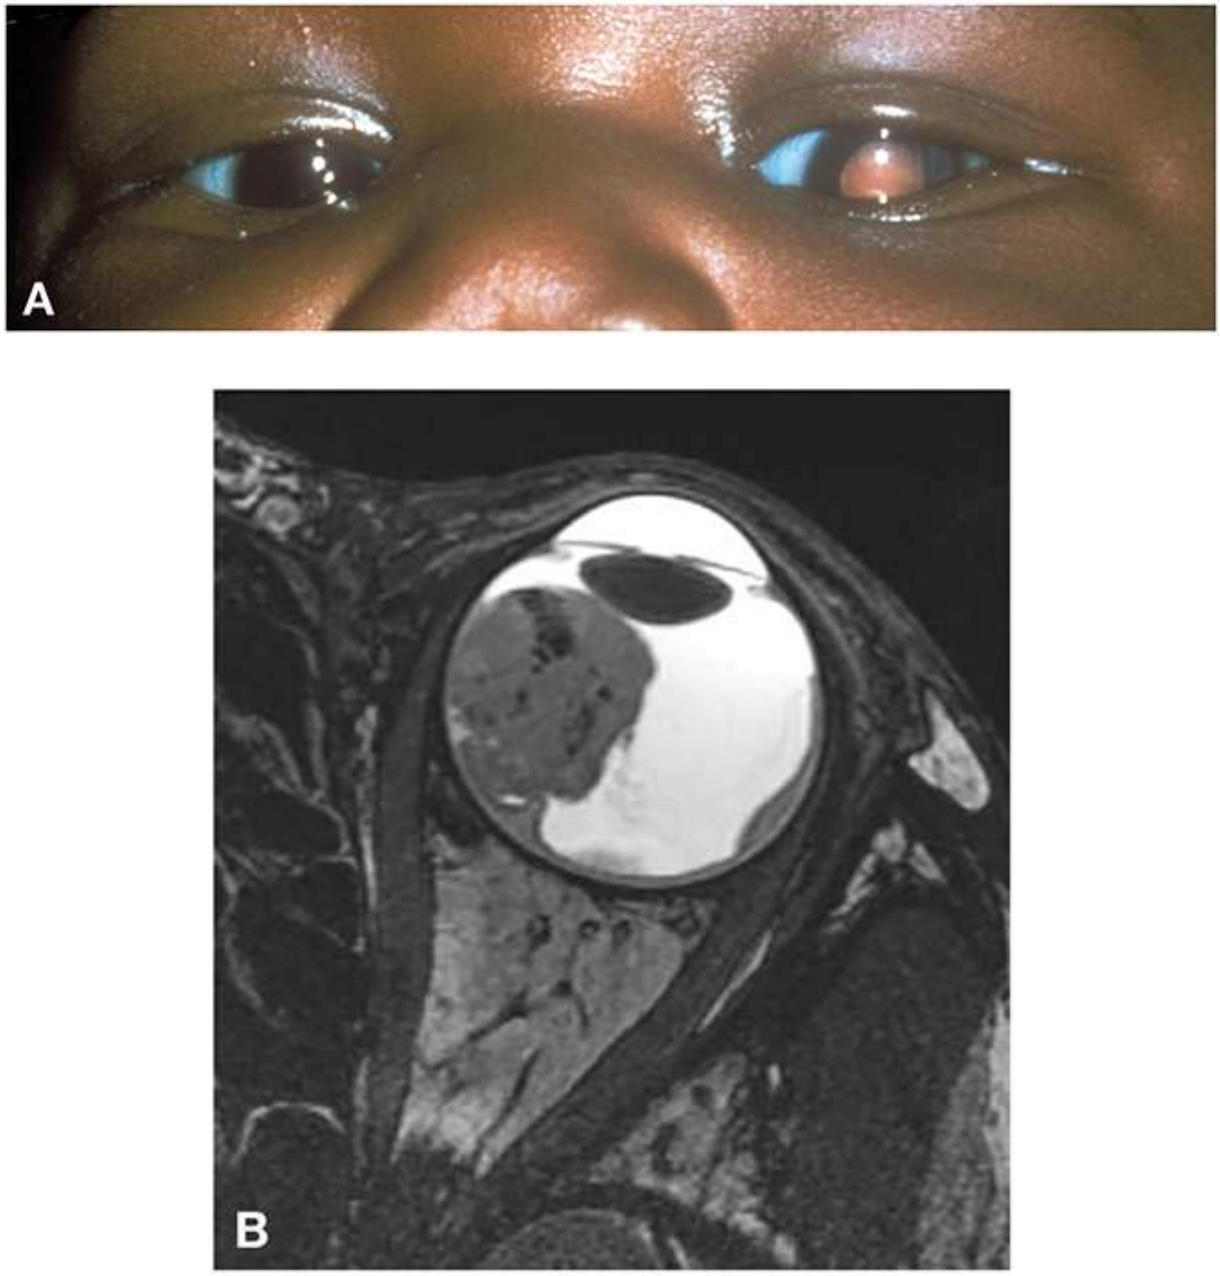

FIGURE 98.3 Diagnosis of retinoblastoma. A. Leukocoria flash-lit photographs ("cat's-eye"). B. T2-weighted magnetic resonance image showing the nasally located retinoblastoma with discrete vitreous seeding and contralateral retinal detachment.

Diagnosis of retinoblastoma is based on clinical features and not on histopathology. A biopsy is obsolete as it can lead to seeding and extraocular spread along the needle tract. Molecular testing of tumor tissue is only performed after enucleation.[46] It is crucial that tumors are diagnosed as early as possible, as this maximizes the prognosis for survival as well as

the chance of preserving vision and reduces the need for chemotherapy, radiotherapy, or enucleation.

The diagnosis of retinoblastoma requires several examinations. If retinoblastoma is suspected, a detailed medical history of the patient and their family is first taken to enable a focused examination. This is followed by clinical examinations under anesthesia (EUA) with a fully dilated pupil and mechanical dilation of the sclera for complete visualization of the entire retinal surface. The use of imaging techniques plays an important role here. Wide-angle retinal images and ultrasound examinations, as well as magnetic resonance imaging (MRI) examinations of the orbit and brain, are performed. Ophthalmoscopy, sonography, and orbital MRI are used to assess intraocular masses, retinal detachment, and calcification (see Figure 98.3B). The cranial MRI provides information on extrascleral extension, infiltration of the optic nerve, metastasis, and the presence of a pineoblastoma. In some cases, a computed tomography (CT) scan may also be conducted, but usually, efforts are made to avoid this radiation exposure, especially in hereditary forms. In the case of an extraocular retinoblastoma, a bone marrow aspiration and a lumbar puncture are also performed to rule out systemic metastasis.[9,44] Once the diagnosis has been confirmed, the parents receive detailed counseling on treatment options, followed by genetic counseling and diagnostics for all family members.[47]

Staging and Risk Classification

Retinoblastoma is classified based on several factors, including tumor size, location within the eye, extent of seeding, severity of retinal detachment, signs of increased intraocular pressure, neovascularization, and hemorrhage. Various classification systems exist for both intraocular and extraocular retinoblastoma (Figure 98.4, Tables 98.1 and 98.2). The historically first grouping system, known as the Reese-Ellsworth classification,[48] was initially designed to predict the outcome of radiotherapy (see Table 98.2). However, with the shift in therapeutic approaches from radiotherapy to chemotherapy, other staging systems have emerged.

TABLE 98.1 COMPARISON OF RETINOBLASTOMA STAGING SYSTEMS

AJCC Clinical and Pathologic Staging Eighth Edition[49]		IIRC[50]	ICRB[51]	IRSS[52]	SJCRH[53]

Currently, intraocular retinoblastomas are categorized into subgroups A to E according to the International Intraocular Retinoblastoma Classification system[50] and its modified version, the International Classification of Retinoblastoma.[51]

For extraocular retinoblastoma, extensive staging procedures are necessary to determine the appropriate treatment approach. These cases are classified according to the International Retinoblastoma Staging System developed by Chantada et al.[52] Enucleated retinoblastomas are divided into four stages (I-IV), while stage 0 includes all cases treated conservatively without enucleation. In addition, a staging system for vitreous seeding has been developed.[54-56]

Analogous to other types of cancer, retinoblastomas are also classified using the tumor node metastasis (TNM) system of the American Joint Commission on Cancer, currently in its eigh[th] edition.[49] The TNM system combines information on both intraocular and extraocular diseases. Based

on clinical characteristics, the tumor stage is initially determined for each eye, and subsequently, the patient is assessed with regard to the most advanced eye. Radiology plays an important role in this process.

Differential Diagnosis

The diagnosis of retinoblastoma is challenging, with a misdiagnosis rate of 10% to 40% based on histopathologic analysis after enucleation and 16% to 53% based on clinical examination.[44,57] The most common differential diagnosis is Coat disease. Other simulating lesions include congenital cataract, choroiditis, persistent fetal vasculature, astrocytic hamartoma, intraretinal hemorrhage, retinal detachment, retinopathy of prematurity, retinal astrocytoma, retinoma, toxocariasis, Bloch-Sulzberger disease, retinal dysplasia, and Patau syndrome.[9,44,45,58]

Risk Factors

Early diagnosis of retinoblastoma is an important prognostic factor, as the stage of the tumor is predictive for survival and preservation of vision (Figure 98.5). Socioeconomic differences in individual countries significantly impact prognostic outcomes. In HICs, retinoblastoma is considered a curable tumor, with a survival rate of more than 90%. In LMICs, the prognosis for retinoblastoma is significantly worse, with survival rates of approximately 70% and 40%, respectively.[43,59] Histopathologic risk factors are invasion of the choroid, the anterior chamber, the sclera, and infiltration of the optic nerve to varying degrees. Invasion of the choroid and sclera favors hematogenous spread, while infiltration of the optic nerve increases the risk of CNS metastases. Extraocular extension significantly reduces the chance of cure and increases mortality rates.[60-62] Furthermore, genetic predisposition increases the risk of developing multifocal bilateral and trilateral retinoblastoma in the first years of life. The risk of second primary cancers later in life is elevated with hereditary retinoblastoma, especially if EBRT has been performed.[63]

GENERAL MANAGEMENT

Retinoblastoma is a fast-growing tumor with a risk of extraocular spread to the orbit cavity, into the CNS, and other organs. Untreated, retinoblastoma disease is usually fatal. However, with a proper approach, it is curable.

When the diagnosis is made early enough, that is, when the disease is still limited to the eye (intraocular retinoblastoma), the survival probability is 99.2%.[67] In recent decades, even in cases of extraocular retinoblastoma without metastases, curative treatment with acceptable sequelae has been provided. However, metastatic disease has an unfavorable prognosis, particularly in CNS dissemination.[64]

For retinoblastoma treatment, various treatment options or their combination are available, such as surgery (enucleation), focal nonradiation therapies (laser photocoagulation, cryotherapy, hyperthermia), focal radiation therapy (plaque brachytherapy), chemotherapy, and EBRT.[68] Systemic chemotherapy administers vincristine, etoposide, and carboplatin.[69] Targeted chemotherapies (intra-arterial or intravitreal) administer agents directly to the eye. During enucleation surgery, an artificial eye is implemented, aiming to improve quality of life of the affected children.[70,71]

The overall treatment approach for retinoblastoma is complex. Fortunately, retinoblastoma cells are sensitive to chemotherapy and radiation. In cases of advanced extraocular disease, the approach is similar to multidisciplinary approaches used for pediatric brain tumors. However, traditionally, ophthalmologists primarily manage patients with retinoblastoma, rather than pediatric oncologists. To achieve the best possible outcomes, close communication and interdisciplinary review of findings are mandatory. Thorough documentation of the disease extent at diagnosis, response during therapy (Figure 98.6), and prior to other local treatments is of utmost importance. Treatment should occur in specialized centers. The typically young age of the child must be considered within diagnostic and therapeutic treatment. Ophthalmologic examinations and treatments are performed under anesthesia, requiring an experienced anesthesia team.

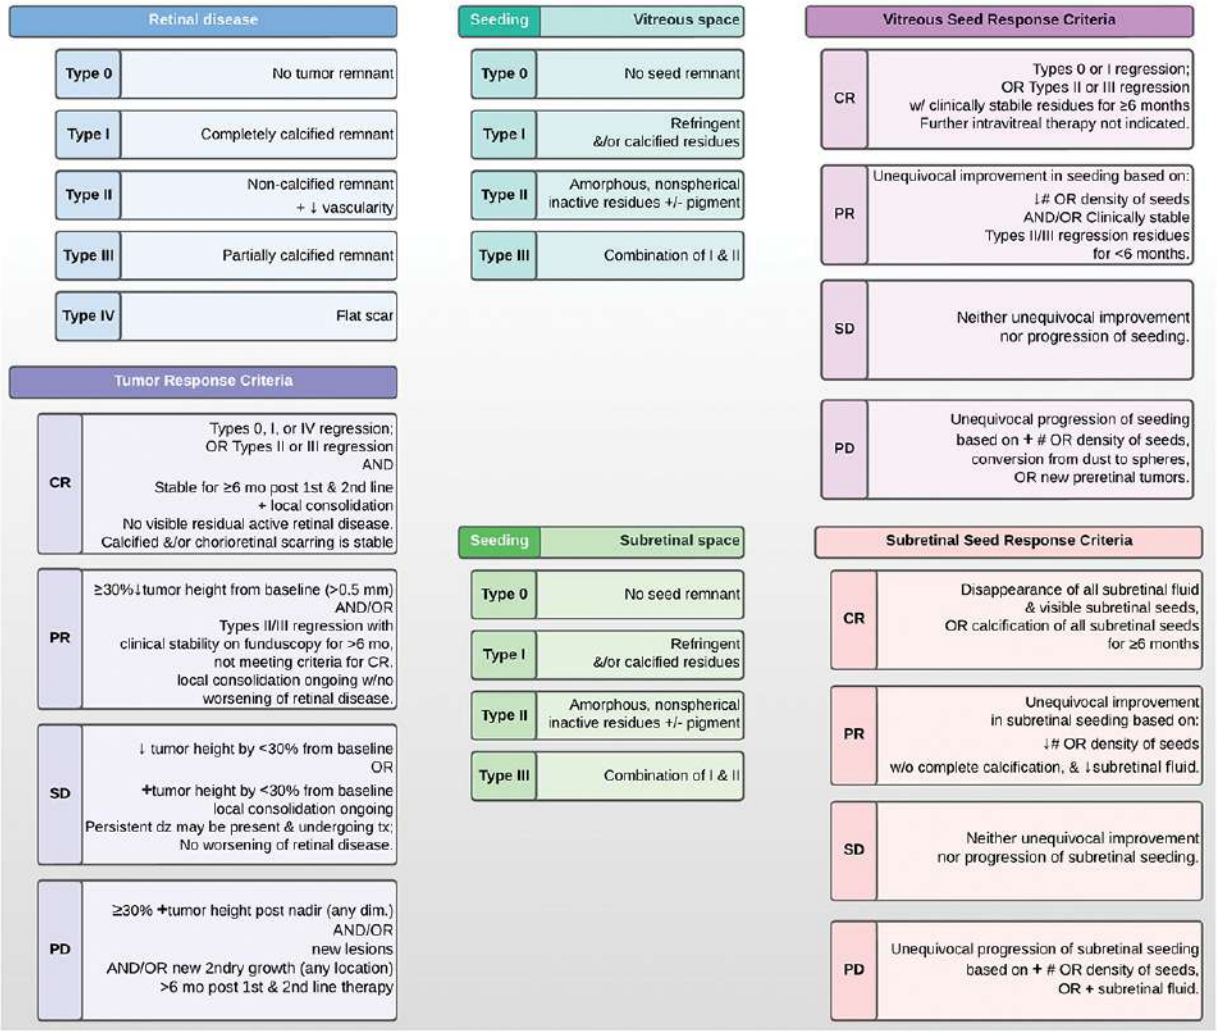

FIGURE 98.6 RB-RECIST criteria and response type for retinal tumors, and vitreous and subretinal seeds.[72] +, plus; ↓, decrease; CR, complete response; PD, progressive disease; PR, partial response; SD, stable disease.

The primary goal of treatment is to achieve a cure, that is, to save the patient's life, and the secondary goal is to preserve the eye and vision. Furthermore, preventing second primary cancer is a crucial objective, especially in hereditary diseases. Therefore, the risk of second primary cancer must be considered when planning comprehensive treatment, particularly in the context of radiation therapy. Decisions regarding the extent of treatment depend significantly on staging and laterality.

The intensity of treatment varies based on the extent of the disease, histopathologic features, genetics, and the patient's age. Treatment decisions also consider factors such as the availability of treatment options,

medications, specialists, and other resources, which can vary depending on a population's income level.[2] For developing countries, evidence-based treatment guidelines from various cooperative groups exist.[73-76] Currently, a collaboration between St Jude Global and the International Society of Pediatric Oncology (SIOP) is developing an adapted resource and implementation application guideline[77] with recommendations for the global management of unilateral retinoblastoma across all resource settings.[77]

General Approach in Intraocular Retinoblastoma

In the context of intraocular retinoblastoma, first-line therapy offers several treatment options, including focal therapy, chemotherapy, and surgery (Table 98.3). EBRT no longer plays a significant role in first-line treatment for intraocular retinoblastoma due to concerns about ionizing radiation exposure in patients with retinoblastoma (see Chapters 1).

TABLE 98.3 INDICATIONS FOR RADIATION THERAPY IN RETINOBLASTOMA

	Brachytherapy	External Beam Radiation Therapy
Intraocular RB	**Plaque Brachytherapy**	**Highly Conformal Radiation Therapy**
First-line treatment	*Not routine, rare indication* • Unsuitable for other focal therapies • Incomplete response with other local therapy • Eligibility criteria (tumor size and localization)	*No role* —
Second-line treatment	*Routine indication* • Unilateral RB after local treatment failure • PR to CTx and nonirradiative focal therapies	*Not routine, rare indication* • Globe preservation of remaining eye in bilateral RB ("last" eye) after prior contralateral eye enucleation • Select high-risk RB (eg, diffuse vitreous seeding)
Contraindications	• Vitreous seeding (>2 mm of tumor surface) • Dimensions unsuitable (depth, width)	• Lack of useful vision

	Brachytherapy	External Beam Radiation Therapy
Intraocular RB	**Plaque Brachytherapy**	**Highly Conformal Radiation Therapy**
	• Involvement of anterior chamber	
Extraocular RB	**Orbital Brachytherapy**	**Highly Conformal Radiation Therapy**
First-line treatment	*No role* —	*Common indication* • Part of multimodality approach as adjuvant therapy • Regional spread: lymphatic involvement • Intracranial metastatic disease (CSI, trilateral disease) • Extracranial metastatic disease (bone, soft tissue)
Second-line treatment	*Rare indication* • Recurrence in the bony orbit after prior EBRT	*Rare indication* • Palliation
Contraindications	• Gross orbital extension • Positive optic nerve margin	—

ant., anterior; CSF, cerebrospinal fluid; CSI, craniospinal irradiation; CTx, chemotherapy; EBRT, external beam radiation therapy; RB, retinoblastoma.

Whenever feasible, patients receive conservative treatment without the need for enucleation. Over the past decade, chemoreduction strategies have emerged to initially reduce extensive tumor volume before implementing focal therapy in children with residual useful vision.[68,69] Intra-arterial chemotherapy or intravenously (IV) administered chemotherapy is now considered the first-line therapy for early-stage retinoblastoma. In addition, nonirradiative focal therapies such as laser photocoagulation, cryopexy, and hyperthermia have demonstrated promising disease control rates, favorable vision preservation, and an acceptable toxicity profile. For small tumors, focal therapies alone may suffice. In selected cases (eg, small, isolated tumors distant from critical structures), plaque brachytherapy is a viable treatment option.[68,78]

Enucleation, while resulting in a cure for unilateral intraocular disease, comes at the cost of complete vision loss. Therefore, enucleation is reserved as salvage treatment when initial focal therapy failed. However, specific clinical features, such as neovascular glaucoma, nonfunctional eyes, and anterior disease, may necessitate primary enucleation.[68] Enucleation allows for histopathologic evaluation of the tumor, revealing features such as massive choroidal invasion, focal choroidal invasion, and/or optic nerve invasion.[79] This assessment informs decisions regarding adjuvant therapy in advanced retinoblastoma, with the goal of preventing further spread and metastasis.

Surgery remains the primary treatment worldwide for retinoblastoma.[68] However, in LMICs, conservative treatment for unilateral disease has been relatively infrequent until now. This is partly because retinoblastoma tends to be diagnosed at an advanced stage in these countries. Consequently, the affected eye is often enucleated in developing nations.[80] Nevertheless, even in low-income settings, there is an increasing trend toward using intense chemotherapy and focal therapies to avoid enucleation. In specific situations, such as buphthalmos, neoadjuvant therapy becomes necessary to facilitate subsequent surgery.[80] In resource-limited countries, the absence of pathologic review may influence treatment decisions, which are then based on clinical investigations.[80]

Apart from enucleation, plaque brachytherapy serves as an option for residual tumors located near the optic nerve and macula, potentially as a second-line treatment.[81] While EBRT is typically avoided, proton beam therapy (PBT) may hold promise even as a first-line therapy for highly selected patients with advanced disease.[82]

For children with retinoblastoma in both eyes (bilateral disease), doctors consider the severity of the tumors in each eye to decide on the best treatment, along with the factors mentioned earlier.[68] If other treatments are not effective or are not possible, EBRT can be used as a last resort to avoid removing the eye (enucleation) in cases where the cancer inside the eye is getting worse, coming back, or resisting other treatments.

This consideration is particularly relevant in bilateral disease scenarios where only one eye remains after enucleation of the other eye.

General Approach in Extraocular Retinoblastoma

When retinoblastoma spreads beyond the eye, it can affect various areas. This includes the outer layer of the eye (sclera), surrounding tissues, the optic nerve, and even distant sites like the CSF, bloodstream (hematogenous spread), and lymphatic system. Fortunately, due to early detection, this spread of retinoblastoma is uncommon in developed countries.

Orbital Disease

Achieving a cure for children with isolated orbital disease is feasible through conventional therapies, including enucleation. In cases of unilateral orbital retinoblastoma, enucleation serves as the preferred first-line treatment. However, due to the risk of metachronous contralateral disease, enucleation is often delayed in unilateral cases, especially among very young children.

The approach to extraocular disease involves starting multiagent systemic chemotherapy to address CNS invasion, when necessary. This is followed by enucleation and subsequent chemotherapy. Orbital EBRT completes the local treatment. It is administered either after enucleation or delayed until the completion of systemic therapy (see Table 98.3). Historically, brachytherapy implants have been used in collaboration with ophthalmologic oncology surgeons following enucleation.[83] However, EBRT is now more commonly employed to prevent recurrence. In cases of subsequent recurrence within the bony orbit after prior EBRT, orbital brachytherapy may be considered. When the optic nerve and locoregional lymph nodes are involved, EBRT is indicated to prevent further spread via the CSF and lymphatic system.

Metastatic Disease

Patients with extraocular metastatic retinoblastoma require intensive multimodality therapy, including high-dose chemotherapy, stem cell rescue, and EBRT to metastatic sites. In addition to orbital radiation therapy, radiation therapy of other sites may be indicated in cases of disseminated disease. The prognosis for patients with CNS metastases is extremely poor, while those with non-CNS metastases have a potential for cure, with an

approximate 80% survival rate.[64] In cases of CNS dissemination, craniospinal axis irradiation (CSI) is the typical approach.[64] Patients with limited CNS extension along the optic nerve and/or chiasm without leptomeningeal disease may represent a potentially curable subset of CNS metastatic disease (stage IVb).[84] If a patient does not respond to standard chemotherapy, palliative radiotherapy can be offered to preserve function and improve quality of life.

Trilateral Disease

Trilateral retinoblastoma is a rare condition in patients with heritable retinoblastoma characterized by the presence of unilateral or bilateral intraocular retinoblastoma and an intracranial primitive neuroectodermal tumor, most frequently located in the pineal gland but can also occur in the suprasellar region.[85,86] This advanced stage of retinoblastoma necessitates a multimodality treatment approach, including intensive chemotherapy, with or without stem cell rescue, and radiation therapy.[87] In cases of localized intracranial disease without CSF spread, local EBRT is recommended. However, trilateral retinoblastoma often presents with leptomeningeal involvement. Therefore, CSI with a sequential local boost is the recommended approach.

HISTORY OF RADIATION THERAPY FOR RETINOBLASTOMA

While enucleation has always been considered the gold standard for disease control, the adverse impact on vision, cosmesis, and quality of life prompted providers to consider EBRT. In fact, the first examples of the use of EBRT date back to Hilgartner in 1903[88] and Verhoeff in 1921.[89,90] EBRT became the preferred means of preserving vision and preserving the globe, and in fact, early staging systems such as the Reese-Ellsworth staging system[48] were used to assess the probability of vision preservation following radiotherapy. While even its first applications were associated with vision preservation, the late effects of therapy were becoming readily apparent as even Verhoeff's patient developed a lid basal cell carcinoma. These early experiences and our mounting knowledge of the late effects of radiotherapy resulted in providers shifting preference for nonirradiative local therapies, which had the potential to offer disease control and preserve

the globe and vision. As early as the 1930s, Moore and colleagues utilized radioactive seeds to treat patients with retinoblastoma.[91] This offered substantially less exposure, similar disease control, and a comparably less morbid late effect profile. This approach matured to the Stallard method in the mid-1960s[92] such that intervening nonirradiative methods such as diathermy went by the wayside due to their excessive complications. As systemic therapy approaches became available, chemoreduction techniques were pioneered by Kupfer and colleagues[93] and were increasingly used to facilitate less extensive local therapy procedures and vision preservation. Chemoreduction cleared the path for both nonirradiative and irradiative focal therapies. Irradiative techniques such as episcleral plaque brachytherapy were heavily utilized to either consolidate or definitively treat small foci of retinoblastoma tumors in the absence of vitreous seeding. Other nonirradiative techniques soon emerged like Xenon arc photocoagulation, which was first used in the late 1950s by Schwickerath.

Alternative means of administering chemotherapy have also had a substantial impact on the need for radiotherapy. Intravitreal chemotherapy has been used as early as the 1990s for heavily pretreated eyes as a means of avoiding enucleation.[94] Periocular injections for advanced eyes were used in combination with other local therapies to facilitate globe preservation as early as 2004.[95] Meanwhile, EBRT application for RB significantly decreased from 30.5% to 2.6% between 1980 and 2000.[96] Still, other providers explored more directed approaches to deliver systemic therapy with the selective ophthalmic infusion of chemotherapy.[97] Recent clinical trials illustrate the potential for topotecan plaques to potentially supplant the use of episcleral plaque radiotherapy. While the clinical experience is early, the first results have been presented by Morganstern and Gallie at SIOP 2023.[98] Topotecan is also being explored for administration for the control of CNS disease with intrathecal (IT) administration as this is an unmet need for patients with stage IVb who almost uniformly succumb to their disease.

In the late 1940s, Robert R. Wilson, a physicist postulated the idea of using protons for clinical applications,[99] although its use was only for limited areas/body sites at select locations in the use throughout the 1950s. As proton therapy technology has evolved, it is increasingly applied for the treatment of childhood cancers. Today, proton therapy is generally accepted

as the preferred means of EBRT in retinoblastoma, when required in cases of either globe preservation or in cases of extraocular spread.

RADIATION THERAPY TECHNIQUES

Choice of radiotherapy technique for retinoblastoma varies by setting, indication, and resources.

Intact Globe: Vision Preservation

Delayed, Consolidative, or Salvage Episcleral Plaque Brachytherapy

While episcleral plaque brachytherapy utilization of either incompletely responding (non–type 1 and non–type 4 regression patterns[100]) lesions or as consolidation for high-risk localized disease,[101] its utilization has been and will continue to be reduced secondary to the evolution of other nonirradiative local therapies (cryotherapy, thermotherapy, laser, etc) and alternative means of administering systemic therapy (topotecan plaque, periocular injection chemotherapy, intra-arterial chemotherapy) (see Figure 98.6). Regardless, there will likely continue to be select circumstances where episcleral plaque brachytherapy is the only remaining potential option that preserves vision and offers favorable disease control.

Typically, episcleral plaque brachytherapy is used for tumors ≤15 mm at the base and ≤10 mm in thickness. EUA performed by an oncologic ophthalmologist is needed for determining the proper dimensions and location for treatment planning. Typically, the thickness is estimated using a B- ultrasound scan, although CT and/or MRI can be complementary and aid three-dimensional (3D) planning. RetCam images obtained at the time of EUA can be co-registered with CT and/or MRI by specialty planning groups like EyePhysics to ease improved localization and improved organ sparing (optic nerve, macula, lens, etc). 3D planned cases can also facilitate calculation of approximate suture coordinates for plaque placement by the ophthalmologist in lieu of difficult transillumination at the time of the brachytherapy procedure for smaller tumors. The treating radiation oncologist and oncologic ophthalmologist should review serial fundus

diagrams to ensure that the appropriate lesion is targeted when 3D approaches are utilized.

The choice of the plaque type/model will depend on the availability and preferred supplier of the treatment radiation oncologist. While historically Collaborative Ocular Melanoma Study (COMS) plaques standardized the application of episcleral plaque brachytherapy for small retinal/choroidal tumors, their dimensions and dosimetry are not optimal for application in children.[102] More recent designs have been shown to reduce integral dose, provide improved organ at risk sparing, and target coverage. When choosing the plaque size/dimensions, the treating provider should ensure that the entirety of the tumor base is covered entirely with a tumor-free margin of 1 to 2 mm on all sides (Figure 98.7). When the relationship between the chosen plaque and tumor does not meet the prior criteria, the next largest plaque template should be chosen. One exception to the prior statement is when the tumor closely approximates the optic nerve (ie, juxtapapillary tumors). In these situations, the plaque may be trimmed or notched around the optic nerve so that the posterior edge of the plaque lies between the optic nerve and the posterior edge of the tumor.

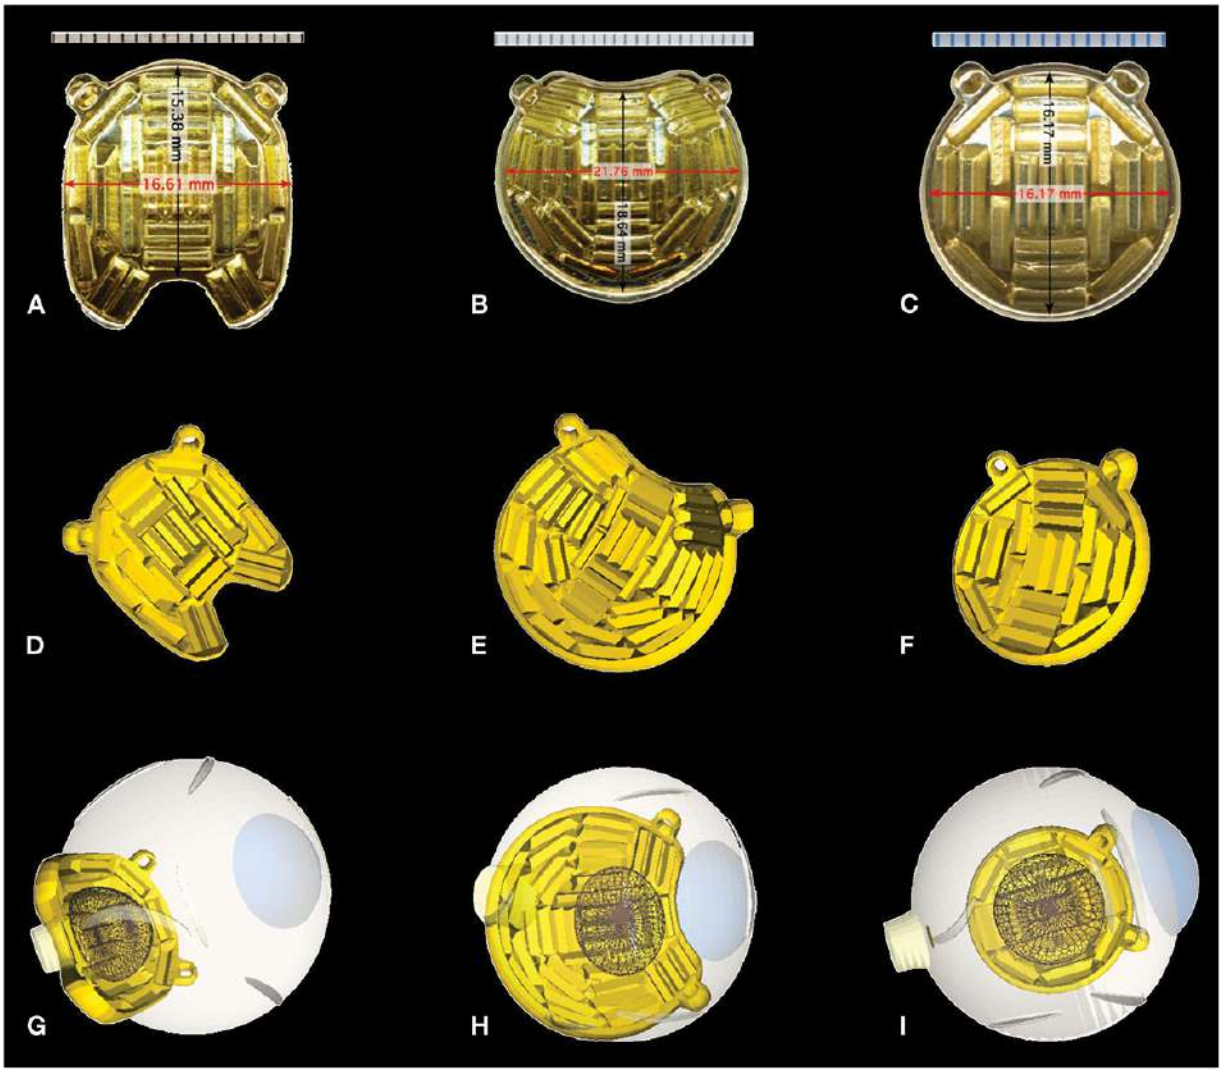

FIGURE 98.7 Representative episcleral plaque designs. A-C. Notched, limbus, and circular plaques respectively. D-F. Three-dimensional reconstructions of the plaque used in plaque simulator planning software. G-I. Representative placement of each plaque adjacent to the optic nerve (G), lens (H), and typical unobstructed globe location (I). (Adapted with permission from Melvin Astrahan, PhD, Eye Physics LLC. Available from https://www.eyephysics.com/)

Prescribing radiotherapy with episcleral plaque radiotherapy requires knowledge regarding the aforementioned dimensions, radionuclide choice, tumor location, and planned treatment dates/duration. Radiation is prescribed to the apex of the tumor, regardless of whether TG-43U or model-based dose calculation methods are utilized.[103] When tumors are thinner than 5 mm, the prescription depth is 5 mm. The sclera is assumed to be 1 mm thick, so this is added to the prescription depth. When the plaque

design requires a seed carrier that adds to the distance between the seeds and the tumor, this thickness should be added to the prescription depth (ie, silastic carrier in COMS plaques). While vitreous seeds are a contraindication for successful episcleral plaque radiotherapy, approximating seeds are not, and these should be added to the prescription depth when present. The total tumor dose ranges from 36 to 45 Gy, with 40 Gy being the most commonly used dose. A representative plan is shown in Figure 98.8. The dose rate at the prescription point should be ≥35 cGy/h but <65 cGy/h. Generally, tumors are treated over 3 to 5 days to facilitate placement removal at the beginning and end of a week, although it is frequent that providers will place a plaque to facilitate treatment over the weekend. The choice of radionuclide will depend on isotope availability and tumor characteristics. Iodine-125 (^{125}I) is the most commonly utilized isotope and, in general, is favored for thicker tumors over palladium-103 (^{103}Pd) and ruthenium-106 (^{106}Ru), which are preferred for thinner tumors (Figure 98.9). Prior treatment planning calculations used for COMS plaques have ignored the effect of the gold backing on scatter, attenuation, and shielding effects of the collimating lip. Recent analyses indicated that these should be taken into account as they may facilitate clinically significant reduction of doses to eye structures of interest.[104] As such, some providers have recommended that these adaptations be incorporated in future versions of the existing American Association of Physicists in Medicine TG43 brachytherapy formalism.[105]

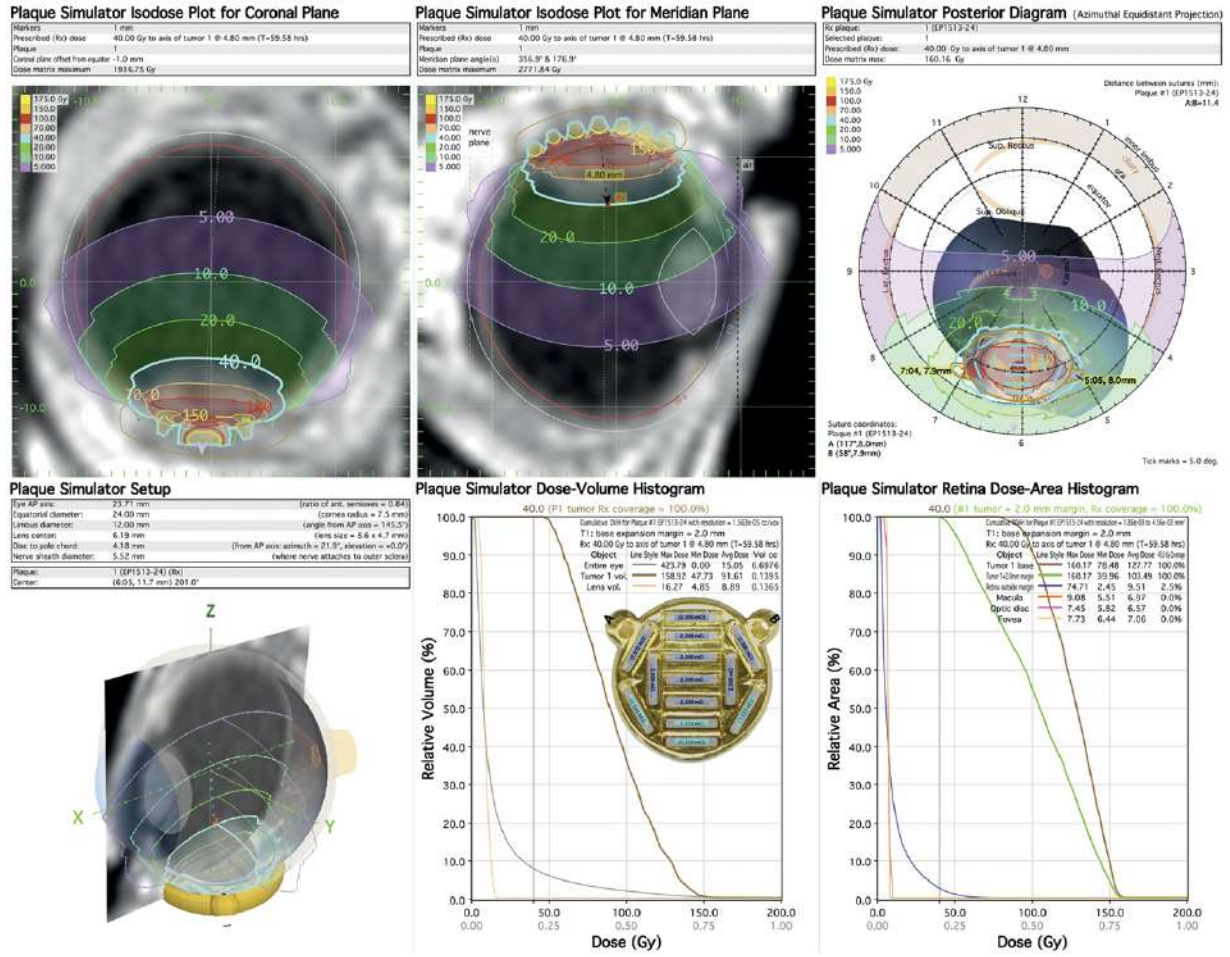

FIGURE 98.8 Representative episcleral plaque brachytherapy plan. The two top left panels are representative coronal and meridian plane depictions of the plaque with adjacent tumor with corresponding isodose lines. An azimuthal equidistant projection is shown in the top right adjacent with the optic nerve sheath represented centrally. A three-dimensional depiction of the plaque localized on the globe is shown in the bottom left. The bottom right two figures depict coverage of the tumor and organs at risk for the represented case. Finally, in the middle bottom portion of the figure is the representative plaque with ^{125}I seeds of varying strengths. (Reprinted with permission from Melvin Astrahan, PhD, Eye Physics LLC. Radionuclide	Half-life	Energy	HVL(mm lead)
^{60}Co	5.26 yr	1.17 & 1.33 MeV	11
^{192}Ir	73.8 d	0.136-1.06 MeV	2.5
^{125}I	**59.4 d**	**~28 keV**	**0.025**
^{103}Pd	17 d	~21 keV	0.008
^{106}Ru	368 d	~1.4 MeV	12

FIGURE 98.9 Plaque radionuclide comparison. Comparison of commonly used radioisotopes in brachytherapy planning including ^{192}Ir (left), ^{103}Pd (middle), and ^{106}Ru all relative to ^{125}I. The table depicts the half-life, energy, and half-value layer (HVL) (mm lead) for each radioisotope.

While treatment volumes and organ at risk definitions are not needed for 1D planning, these may be incorporated into 3D plans to facilitate improved tumor coverage, and visual structure dose sparing (see Figure 98.8). When 1D methods are utilized, dose reporting should be completed according to Krintz et al.[104] When 3D methods are used, target coverage, organ at risk doses, and plan quality should be assessed according to Fili et al.[106]

Several locations may be challenging for plaque placement (see Figure 98.7). When the application of plaque brachytherapy is the last line of salvage, anterior hemispheric plaques may be preferable for iris or ciliary body lesions as these may limit lens dose. Given that this may result in an increased dose to the trabecular meshwork of the eye, any signs of increased intraocular pressure should be promptly evaluated clinically. Juxtapapillary tumors are also challenging, and in these cases, a notched plaque is preferred. In these applications, seeds are inserted into notched plaque sites such that the posterior edge of the plaque lies between the optic

nerve and the posterior edge of the tumor. Varying source strengths may allow for some dose modulation across critical structures such that maximal vision preservation may occur.

Plaque placement takes place in an operating room under the direction of an ophthalmologic oncologist under general anesthesia. The procedure typically consists of lesion visualization, transillumination for localization, tumor margin marking, occasional muscle release (if necessary), plaque application, and stitching (two-three) followed by 3 to 5 days of treatment. Immediately following the procedure, plaque placement safety procedures should be tightly adhered to. This includes careful confirmation of the directive, activity calculations, proper shielding, and subsequent survey of the room and patient to account for all sources of radioactivity. Generally, one-two excess seeds are ordered to be assayed locally prior to implantation. Outpatient care is typically recommended unless the child is expected to encounter pregnant women or persons less than 18 years of age. Lead shielding is typically placed over the treated eye and should be worn at all times. The patient should sleep in their own bed when the plaque is in place and avoid touching the eye (aided by the shield). As long as the guidelines are followed, caregivers can stay with their child for as long as needed. However, they will usually be given a radiation badge as a precaution. The patient's family should be provided with the contact information for the treating radiation oncologist in case of a medical emergency or if the plaque becomes dislodged.

External Beam Radiotherapy

EBRT to the retina and vitreous cavity is infrequently provided for patients with an intact globe. The most common indication is in a patient with bilateral disease with prior enucleation and one remaining eye with useful vision (see Table 98.3, Figure 98.10). In these cases, the optimal vision preservation outweighs the potential late effects concerns associated with treating a patient with a germline *RB1* mutation. The choice of modality and technique for these cases is predicated on minimizing treatment exposure to any uninvolved tissue to limit the potential for out-of-field complications. Total dose is usually 40 to 50 Gy, given with a 1.8 or 2 Gy single dose. Typically, proton therapy is preferred, and a single lateral field may offer

the best balance between vision preservation, disease control, and limited late effects. Unless extrascleral extension is documented, the radiation target is either the posterior aspect of, or the entirety of the globe and should be defined as the clinical target volume (CTV). The gross tumor volume (GTV) is defined as the visible imaging defining the extent of the retinal tumor. The anterior chamber may be excluded from the CTV if no anterior disease is present and sufficient immobilization is available. The setup/immobilization appropriate planning target volume (PTV) should be defined by the treating institutional physics team.

Colored lines represent respective isodoses. Plans are generated using the treatment planning system RayStation.

Extraocular Disease

A range of indications for radiotherapy are possible for extraocular disease (see Table 98.3). In cases of extrascleral spread, the entirety of the bony

orbit should be targeted at the CTV and either a wedged pair or single lateral proton therapy field should be used for treatment (Figure 98.11). Total dose of orbital EBRT is usually 40 to 50 Gy in conventional fractionation. If protons are not available, a volumetric arc therapy (VMAT)/intensity-modulated radiation therapy (IMRT)/arc therapy plan is preferred and should have objectives set to minimize the integral dose, approximating brain, contralateral face, and eye. In cases of positive optic nerve cut margins, a similar volume is treated with the exception that the CTV should extend beyond the apex of the orbit to the chiasm. A similar beam arrangement for proton and photon therapy is appropriate to that of the prior example. Lymph node spread is rare but may require treatment of the perifacial and/or neck nodes. In these cases, treatment targets may need to be split into two different regions, which are adequately targeted by different beam arrangements that minimize radiation exposure. Recent trials target the entirety of the lymph node station as the CTV in case of positive lymph nodes while the GTV is defined as any pathologic unresected lymph nodes within that region. Again, proton therapy is preferred, but when not available, IMRT/VMAT/arc therapy are reasonable alternatives.

Metastatic Disease

Intracranial Metastatic Disease

CSI is infrequently used in retinoblastoma unless the patient has stage IVb disease and has completed their systemic therapy without evidence of progression. Typically, response-adapted dosing has been used, but the

existing treatment paradigms are arranged such that CSI is delayed. As a result, most patients progress prior to the application of CSI. While ARET0321 allowed for patients in complete response to abstain from CNS-directed radiotherapy, the high failure rate and progression prior to EBRT preclude this approach from being used in routine practice as active systemic therapy approaches are not adequate to address intracranial disease. This is an unmet need in stage IVb retinoblastoma, and while some groups are evaluating the use of IT topotecan to maximize disease control, their efficacy is unknown, and as such, this approach is not considered standard. While target volume delineation and treatment technique for CSI are beyond the scope of the present chapter, general principles in CSI volume delineation were published by the SIOP-Europe brain tumor group.[107] CSI doses between 23.4 and 36 Gy are typically recommended depending on age. CSI can be followed by a local boost to the primary or spinal and intracranial metastases (total dose 36-49.6 Gy to focal spinal sites; 45-49.6 Gy to focal intracranial sites). A CSI plan using protons irradiation in a patient with metastatic trilateral retinoblastoma is presented in Figure 98.12. Multiphase treatment plans are needed when there is contemporaneous high-risk orbital disease following enucleation, trilateral disease, and/or extracranial metastatic sites.

CSI volume (total dose 35.2 Gy [RBE1.1]) with a sequential boost to the intracranial tumor bed including residual tumor (cumulative dose 55 Gy [RBE1.1]; PTV in dark blue), and boost to metastatic sites (up to 49.6 Gy [RBE1.1]; PTVs in pink and orange). Plans are generated using the treatment planning system RayStation. PTV, planning target volume.

Extracranial Metastatic Disease

Consolidative extracranial metastatic site–directed radiotherapy was the response adapted on the last clinical trial. While patterns of failure analysis of these data have not been completed, patients in complete response were permitted to omit radiotherapy to metastatic sites. Of those who had metastatic site EBRT omitted following complete response, 14.3% experienced treatment failure, while no patients in partial response (PR) who received consolidative radiotherapy failed.[64] At present, the lack of detailed patterns of failure analysis precludes the omission of metastatic site EBRT for complete response. As such any patients with a PR at a metastatic site should undergo 36 Gy of radiotherapy at 1.8 Gy per fraction to the lesion with a 5-mm expansion to CTV and expanded setup/imaging appropriate PTV.

RESULTS OF THERAPY

Reporting of individual patient outcomes is confounded by the evolution of staging and risk stratification schemes (see Figure 98.4, Tables 98.1 and 98.2). Treatment outcomes according to several staging systems are shown in Figure 98.5. Outcomes following therapy for retinoblastoma by stage and treatment approach for high-risk stage 1, non–high-risk stage 1, and various stages of retinoblastoma with extraocular spread are shown in Figure 98.5D. Outcomes in LMICs show profound inequality relative to HIC

counterparts.[108] While death due to disease in lower stages is rare in HICs, LMIC 3-year overall survival is just 50%, and improving access to care and aiding infrastructure for early diagnosis are key to improving outcomes in this setting and as such remote screening and diagnostic approaches are being piloted.[47]

SEQUELAE OF RADIATION THERAPY

Episcleral Plaque Brachytherapy

The short-term side effects of episcleral plaque brachytherapy are largely related to the placement and removal of the plaque and include soreness, swelling, and bruising. The long-term side effects of brachytherapy potentially include blurry vision, dry eye, cataracts, retinal detachment, glaucoma, loss of eyelashes, tear duct problems, and bleeding into the eye — although the probability of many of these potential side effects will vary heavily and depend on the location of the tumor and preceding therapy.

Orbital Brachytherapy

The acute and late side effects of orbital brachytherapy are poorly characterized, given the rarity of the application. Given that brachytherapy is the most conformal radiotherapy delivery option, it is anticipated that dose to the surrounding bony orbit is reduced, which may have implications for bony symmetry and reduced risk for second primary cancer (Table 98.4), although proximal seed/catheter doses may be increased such that acute effects may be more pronounced. Dissecting the contribution of orbital brachytherapy-related side effects from preceding insult (surgical or external beam related) may also be challenging.

Orbit/Eye External Beam Radiotherapy

Short-term complications are more prominent with the use of EBRT and typically more protracted compared to episcleral plaque brachytherapy. Acute side effects may include radiation dermatitis, tearing, local swelling, flushing, and eye irritation. While symptoms may persist for several weeks following therapy, generally, these resolve within a month of completion. Long-term side effects may include dryness and inflammation in and around the cornea, changes in vision secondary to swelling under the retina with associated detachment, poor eye alignment, bleeding into the vitreous space, cataracts, and increased intraocular pressure. Given the young age at treatment, anatomic developmental issues are also possible and include underdevelopment of the socket and surrounding bony ridges and can be

exacerbated by EBRT.[113,114] While hypoplasia of the orbit is frequently attributed to radiotherapy, it is well recognized that enucleation alone can result in a similar extent of orbital hypoplasia due to the lack of mass effect exerting pressure on the surrounding bony socket.[115] In fact, post–enucleation socket syndrome may become more pronounced as the child ages and additional procedures may be required to attain favorable cosmesis.[115,116] The most feared complication is that of second primary cancer, which can occur anywhere in the treated field and is more common in patients with known germline predisposition. While formal comparisons between photon and PBT are limited, the reduced integral dose is presupposed to result in a decline in the incidence and potential severity of some complications, although the extent of this reduction will be heavily dependent on patient and disease-related factors.

Regional/Nodal External Beam Radiotherapy

Short-term side effects are expected to be comparable to other EBRT applications regarding radiation dermatitis and local swelling with a few exceptions. Parotitis, mucositis, esophagitis, and cheilitis are possible, which may lead to anorexia, nausea, weight loss, and vomiting. Long-term side effects associated with neck radiotherapy include thinning skin, reduced subcutaneous tissue thickness, shoulder/neck asymmetry, hypothyroidism, xerostomia, dental complications, and second primary cancers.

Craniospinal Radiotherapy

CSI side effects are numerous and typically associated with significant morbidity in young patients.[117] However, the prognosis associated with stage IVb is poor, and disease control without CSI is rare.

FUTURE THERAPEUTIC APPROACHES AND RECENT CLINICAL TRIALS

Retinoblastomas are the most common intraocular tumors arising in early childhood and represent a particular challenge for optimal treatment.

Future therapeutic improvements require close collaboration of all involved disciplines. Apart from the young age of the patient, multiple classification systems, various complex clinical situations in difficult local therapy locations (anterior segment or link to CNS via optic nerve, etc), limited evidence for multiple treatment approaches as well as substantial differences concerning incidences and treatment availability worldwide, make therapy very challenging. In developing countries, national health care systems have limited financial resources and infrastructure. Currently, cross-border cooperative groups are developing evidence-based treatment guidelines to address these obstacles. Various existing classification systems impede the comparison of previous results. Therefore, harmonization regarding the use of one uniform system will be crucial. Further adaptations regarding more detailed subgroup classification are proposed to improve prognostic value.[118] In future, noninvasive prognostic biomarkers like circulating tumor DNA will complement staging examinations early (ie, prior enucleation).[119] After enucleation, prognostic biomarkers will also supplement histopathologic analysis.

Contemporary high conformal techniques, such as PBT, may enable limiting radiation fields, potentially decreasing the risk of second primary cancer, even in hereditary retinoblastoma. Regarding radiotherapy doses and volumes, there are still many open questions to be addressed in the future. Only international studies will be able to generate sufficient data due to the rarity of disease. Regarding systemic therapy, targeted therapies or new drug discoveries in immunotherapy or gene therapy may add to the treatment efficacy for patients with retinoblastoma. When establishing any innovative therapy, outcomes must be evaluated in interdisciplinary clinical trials.

Current and future approaches to retinoblastoma therapy will likely continue to optimize the route and means of administration of chemotherapy in place of other local therapies. Current therapeutic approaches being investigated in both institutional and cooperative group trials are testing a range of means of administering local chemotherapy, including, but not limited to, selective ophthalmic intra-arterial chemotherapy, periocular injection chemotherapy (subtenon or subconjunctival), chemotherapy-impregnated episcleral plaques, intravitreal chemotherapy, and IT chemotherapy (for advanced disease).

Routes of administration like intravitreal chemotherapy will be essential for evaluating whether cytotoxic chemotherapy such as melphalan or topotecan can successfully clear vitreous seeding without compromising vision in advanced eyes. Ongoing trials are evaluating either intravitreal chemotherapy alone or in combination with systemic and local therapies (ClinicalTrials.gov identifiers NCT04681417, NCT04455139, NCT02866136, NCT01899066, NCT05504291, NCT01558960, NCT02792036, and NCT04990271). If successful, this could reduce the already small number of patients with bilateral retinoblastoma who have had prior enucleation requiring globe-directed radiotherapy for their remaining functional eye and has the potential to further improve the globe salvage rate.

Intra-arterial chemotherapy can be administered using a broad range of methods. The first example likely dates back to 1954 when Algernon B. Reese injected the alkylating agent, triethylene melamine, into the internal carotid artery for treatment of retinoblastoma.[120] This concept was improved upon by Yaman and Kaneko who introduced selective ophthalmic artery infusion.[97] In this technique, a micro-balloon catheter is positioned in the ophthalmic artery, allowing targeted drug delivery.[121] Currently, three principal chemotherapies are being evaluated—melphalan, topotecan, and carboplatin (ClinicalTrials.gov identifiers NCT04564521, NCT04342572, NCT03935074, NCT01393769, NCT01293539, NCT01151748, and NCT00901238). This technique has shown significant promise in reducing the systemic toxicity (ie, myelosuppression) of cytotoxic chemotherapy in very young children, and recently published trials such as that published by Wen et al demonstrated that in advanced unilateral disease, intra-arterial chemotherapy resulted in a dramatic increase in the progression-free globe salvage rate relative to conventional IV systemic chemotherapy.[122] The use of intra-arterial chemotherapy was associated with a ~20% increase in the overall globe salvage rate and had comparable overall survival to conventional chemotherapy. While intra-arterial chemotherapy rates of ophthalmic artery occlusion are rare (<5%), as many as one in five patients will develop ophthalmic artery stenosis. Extended reports of these outcomes are needed to evaluate the long-term impact on vision and globe salvage.

However, others are evaluating whether active systemic therapy agents such as topotecan can be impregnated in a carrier for local episcleral

delivery akin to what is done with episcleral plaque brachytherapy. Early results indicate that penetration into the vitreous is within a therapeutic range and has low systemic toxicity with favorable overall response rates.[123] Whether this will supplant the episcleral plaque brachytherapy remains unclear.

Finally, recent results of studies in patients with extraocular retinoblastoma demonstrate that there are unmet needs for patients with stage IVb disease. Given the early age at presentation, many providers are reluctant to provide even dose-reduced CSI for disease within the CNS. Furthermore, existing paradigms such as ARET0321 have shifted the application of radiotherapy to the completion of all other therapies such that most patients with CNS disease have progressed prior to the appropriate timepoint for administration.[50] As such, novel approaches are needed. At least three ongoing studies are evaluating the use of IT chemotherapy to mitigate the risk of CNS failure and hopefully at least stabilize the disease until the child is both a little older and has completed the rest of their systemic therapy (ClinicalTrials.gov identifiers NCT04903678, NCT03475121, and NCT02870907).

CHAPTER 99

Rare Tumors in Children

Cheng-Chia Wu and Matthew Krasin

Many rare childhood tumors are comparable to those that occur in the adult population and require a similar therapeutic strategy, with particular attention given to late sequelae. There are groups of rare tumors, however, diagnosed predominantly in children and require specific treatment strategies including radiotherapy.

NASOPHARYNGEAL CARCINOMA IN CHILDHOOD

Nasopharyngeal carcinoma (NPC) is a rare malignant tumor in childhood and adolescence (<1% of pediatric malignancies). The frequency differs greatly by geographic area: 1 case per 100,000 in Europe, the United States, and Australia; 10 per 100,000 in North Africa; and 80 per 100,000 in South China, Malaysia, and Greenland. Interestingly, although the absolute numbers are lower in nonendemic countries (the United States, Turkey, and Israel), childhood NPC is 6% to 18% of all cases of NPC (childhood and adult) compared to less than 1% to 2% in endemic countries/regions (southern China, Southeast Asia, and the Mediterranean basin).[1] A study from 2016 found that NPC in children has a different demographic distribution relative to adults and is associated with low socioeconomic status, rural location, and more advanced disease at presentation.[2] The fifth edition of the World Health Organization divided NPC into three distinct classification groups: nonkeratinizing squamous cell carcinoma (NK-NPC); keratinizing squamous cell carcinoma (K-NPC); and basaloid squamous cell carcinoma. NK-NPC is further subdivided into two categories, undifferentiated or differentiated.[3]

Most pediatric NPC cases are undifferentiated. As in older patients, Epstein-Barr virus is associated with this type of NPC in addition to certain human leukocyte antigen haplotypes/alleles (A2 Bsin2, Aw19, Bw46, and

B17). The virus is found in the tumor cells and not in the surrounding lymphocytes. Antibody and antigen titers are useful for both diagnosis and follow-up (Table 99.1).[4] The association between dietary factors and NPC has been suspected in China and seems to be confirmed in a case-control study published by Jia et al.[5]

TABLE 99.1 ANTIGEN AND ANTIBODY EPSTEIN-BARR VIRUS (EBV) TITERS

	IgG VCA	Ig EA	IgM VCA	IgA VCA	IgA EA	EBNA
Naive patient	0	0	0	0	0	0
Immune patient	Mild	0	0	0	0	Mild
Burkitt lymphoma	Raised	Raised	0	0	0	Raised
AIDS	Very raised	Raised	0	0	0	0
NC	Very raised	Very raised	Mild	Raised	Raised	Very raised

AIDS, acquired immunodeficiency syndrome; EA, early antigen (active disease); EBNA, EBV-associated nuclear antigen (cellular immunity); Ig, immunoglobulin; NC, nasopharynx carcinoma; VCA, vision capsid antigen (immune status).

Clinical Presentation

The incidence of NPC is bimodal. First occurrences are seen in late adolescence/early adulthood (ages 15-24) with a second peak later in life (ages 65-79),[6] with a higher incidence in males (2.75:1). The disease is in part associated with EBV infection, and there is a significantly higher incidence in endemic regions including Southwest Asia, Mediterranean region, North Africa, Greenland, and Alaska. Typically, the initial presentation can range from painless mass in the upper neck, nasal obstruction, epistaxis, otitis, cranial nerve palsy, and neck and facial pain. The tumor usually originates in the fossa of Rosenmüller, followed early on by locoregional extension, including extensive pharyngeal involvement and often bone, lung, and cervical lymph node metastases.

On clinical examination, bilateral lymphadenopathy and cranial nerve palsies are found; a nasopharyngeal mass can be seen by direct or indirect nasopharyngoscopy, and sometimes, a protruding mass can be seen in the oral cavity.

The diagnostic workup must include a cranial and neck computed tomography (CT) scan with contrast, magnetic resonance imaging (MRI), and positron emission tomography- computed tomography or chest CT. Pathologic confirmation is obtained by biopsy. More recently, EBV DNA load has been tested. Commonly used staging systems are the tumor-node-metastasis (TNM)/American Joint Committee on Cancer (AJCC), Kyoto, and Ho classifications. The Ho and Kyoto systems are based on topographic extension; the more commonly used TNM/AJCC classification is based on tumor volume and CT information.[7]

Treatment

In adult NPC, T1N0M0 disease is treated with radiotherapy (RT) alone. For locally advanced NPC, concomitant RT and chemotherapy with cisplatin followed by adjuvant (cisplatin and 5-fluorouracil) is the standard of care.[8,9] More recently, phase III clinical trial showed survival benefits with neoadjuvant induction gemcitabine and cisplatin and has been accepted as the standard of care for locally advanced disease.[10] Because of the scarcity of pediatric NPC cases, it is difficult to perform randomized studies in the pediatric age group. Based on adult trials, multimodality treatment is generally accepted as the standard of care for children for Stage II or greater with potentially RT alone for Stage I.[11] Children's Oncology Group (COG) study ARAR0331 treated pediatric patients with NPC with induction chemotherapy with cisplatin and 5-fluorouracil followed by concurrent chemoradiation with cisplatin. Radiation planning was response based with dose de-escalation depending on outcome. The single-arm phase II study enrolled 111 patients. The study had a 5-year event-free survival (EFS) of 84.3% and overall survival (OS) of 89.2%. When divided by stage, patients with Stage IIb, III, and IV disease had EFS of 100%, 82.8%, and 82.7%, respectively. The cumulative incidence estimates of local, distant, and combined relapse in 5 years were 3.7%, 8.7%, and 1.8%, respectively. This has largely been the US standard approach for treating pediatric NPC.[12] Interestingly, there is much interest in further decreasing the radiation dose with the addition of immunotherapy. In Germany, pediatric patients with NPC are treated with induction chemotherapy and concurrent chemoradiation followed by a year of interferon-β. All patients received 45

Gy to the primary tumor, involved node, and the subclinical regions. Patients with complete response received a boost to 54 Gy, whereas patients with incomplete response received a boost to 59.4 Gy.[13] The EFS and OS for these pediatric and young adult patients with locoregionally advanced NPC were 93.6% and 96.7%, respectively, after a median follow-up of 73 months. This has since led to the design of two clinical trials exploring the use of immune checkpoint inhibitors in the setting for NPC.[14]

Radiation Therapy

Adult patients with NPC are typically treated to 70 Gy in the setting of gross disease. A dose-response relationship for local control with a threshold of 60 Gy has been reported in a number of series.[15-17] However, Habrand et al[18] reported interesting results with lower doses of radiation therapy (50 Gy) in patients with a good response to chemotherapy. With the results from ARAR0331 and the German study, there is evidence that dose de-escalation is feasible in pediatric patients with induction and concurrent systemic therapies. Following the COG induction therapy schema, patients are treated with 45 Gy to the high-risk nodal stations, the nasopharynx and high-risk regions, and the primary tumor. In the setting of complete or partial response, 61.2 Gy is delivered to the entire nasopharynx and residual enhancing tumor and residual lymph node. For patients with stable disease, they receive 70.2 Gy using the same approach.

Late Effects

Given the rarity of pediatric NPC, many reported patient side effects are based on historic radiation techniques. With modern- day techniques including proton therapy and intensity- modulated radiation therapy (IMRT), the true incidence is likely lower. Similarly, with a reduction in radiation dose due to induction chemotherapy response, the anticipated radiation-induced side effects are likely lower. Xerostomia is the main side effect of treatment, followed by dental caries, trismus, muscular atrophy and fibrosis, nerve palsies, and endocrine dysfunction resulting from pituitary irradiation. Significant auditory late toxicity and sporadic cases of visual morbidity, secondary to RT with or without cisplatin-based chemotherapy, have been reported.[19] The St. Jude retrospective analysis

reported a rate of 8.5% of subsequent malignancies 8.6 to 27 years after treatment.[20]

OTHER HEAD AND NECK TUMORS

Carcinoma of the Oropharynx and Salivary Glands

Schwaab et al[21] reported the largest pediatric series, with only 2% squamous cell carcinoma among 380 head and neck tumors. The more frequent sites of disease are the tongue, lip, tonsil, palate, and salivary glands. Cigarette smoking or use of smokeless tobacco has been shown to be an etiologic factor for adolescent tongue carcinoma.[22] For other sites, passive smoking, poor oral hygiene, or genetic predispositions (xeroderma pigmentosum [XP] or retinoblastoma) have been suggested.

Special attention must be paid to laryngeal carcinoma because some of the cases may develop from juvenile papillomatosis, a benign condition of the aerodigestive tract that may undergo malignant degeneration. Guidelines for surgery and radiation therapy are the same as those for adults. Combined chemotherapy and radiation can be attempted for organ conservation.[23] The node area to treat does not differ from adults and must follow the Gregoire definition.[24] Psychological support and rehabilitation programs are an essential part of the comprehensive treatment for children who undergo major surgical resection.

Human papillomavirus (HPV)-positive oropharyngeal cancer is not a significant problem in this age group, as HPV exposure is associated with sexual activity. However, in one series, the HPV prevalence in the oral cavity/oropharynx of children was 1.9%.[25] This should help guide vaccine recommendations that may help reduce the incidence of HPV-positive disease in the future.

Esthesioneuroblastoma

Esthesioneuroblastoma is a malignant tumor arising from the olfactory nerve in the upper nasal cavity. Intracranial extension is common at the time of diagnosis. Esthesioneuroblastoma is mostly seen in patients in their 20s or 60s. Positive S100 and neuron-specific enolase stains combined with negative epithelial markers strongly suggest a neurogenic origin.[26] The

clinical presentation includes nasal obstruction, loss of smell, epistaxis, and, sometimes, enlarged cervical lymph nodes. Bony structures are often involved, as well as the ethmoid and maxillary sinuses. The most commonly used staging/grouping system is by Kadish et al[26] and is based on the degree of local tumor extension. Tumors are also graded according to the Hyams system.[27]

There is no universally agreed-upon standard of care. For localized disease, tumors are resected, if possible. Because of the high risk of recurrence, postoperative RT is usually offered and has been shown to reduce recurrence risk. Earlier studies have shown local control can be obtained in more than 75% of cases.[28] Eich et al[29] and Broich et al[30] recommend combined surgery and RT in all stages. Demiroz et al[31] reviewed 26 patients treated between 1995 and 2007. The relapse rate for patients treated with surgery alone was 29% versus 0% for those treated by surgery and postoperative radiotherapy. The recommended dose is 50 to 60 Gy.

More recently, for previously untreated disease, Hollen et al showed local control rates at 5 years of 79%. The age range for these 26 patients was 3 to 82 years.[32] One large retrospective study from China examined long-term outcomes for 113 patients from 1979 to 2014. The majority of patients were Kadish stage C, and they were treated with multimodality therapy and different sequencing including 51 who received preoperative radiotherapy. The local control for preoperative RT followed by surgery was 91% at 5 years.[33]

Elective neck irradiation or dissection is not typically advocated because less than 10% of early-stage cases exhibit nodal involvement. However, node metastases are frequent if the tumor extends beyond the paranasal sinuses, and Hollen et al[32] show that elective nodal irradiation reduces the risk of regional relapse for stage B and C disease. Therefore, lymph node dissection or prophylactic irradiation may be considered under certain clinical circumstances. Chemotherapy has yet to be accepted as part of routine first-line treatment for early-stage disease, although responses to chemotherapy have been reported.[34] It can reduce tumor volume prior to surgery or RT and can be used for palliative purposes in advanced cases. Promising results with cyclophosphamide, doxorubicin, vincristine, *cis*-platinum, and etoposide, combined with RT and stem cell support, have

been reported by Mishima et al.[35] They obtained eight complete responses in 12 Kadish stage C and D patients. Neoadjuvant concurrent chemoradiotherapy as preoperative treatment for locally advanced esthesioneuroblastoma has been reported by Sohrabi et al[36] with very promising results.

Recently, data evaluating the role of proton therapy have begun to accumulate. Lucas et al retrospectively evaluated eight patients (4-21 years old), most of whom were treated with different surgery, chemotherapy, and RT sequencing; however, all received proton treatment (59.4-70 GyE). The results are encouraging with a 5-year OS of 87.5% and local control of 100% with acceptable toxicities.[37] Drescher et al[38] reported similar rates of disease-free survival (86%) with doses in the 54 Gy (microscopic) and 66 Gy (gross disease) range. They did note a spectrum of local regional effects that were identified during long-term follow-up.

Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibroma (JNA) is a malignant vascular tumor most often arising from the posterior lateral wall of the nasopharynx in adolescent males. The lesion tends to extend into the nasal cavities, maxillary and sphenoid sinuses, orbit, and infratemporal fossa. Several classifications have been proposed, but the classification of Radkowski et al[39] appears to be the most appropriate, at least for surgical purposes (Table 99.2). Common symptoms are epistaxis, cheek swelling, a visible orbital tumor, and cranial nerve palsies. JNA is more frequent in patients with familial adenomatous polyposis. A mutation in the cluster region of the APC gene was reported in several studies, suggesting that JNA is perhaps a familial adenomatous polyposis tumor.[40,41]

TABLE 99.2 STAGING CLASSIFICATION FOR JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

Stage	Description
Ia	Limited to the nose and/or nasopharynx
Ib	Same as Ia, but with an extension into one or more paranasal sinuses
IIa	Minimal extension through the sphenopalatine foramen, into and including a minimal part of the medial most part of the pterygomaxillary fossa

Stage	Description
IIb	Full occupation of the pterygomaxillary fossa, displacing the posterior wall of the maxillary antrum forward; lateral and/or anterior displacement of branches of the maxillary artery; superior extension may occur, eroding orbital bones.
IIc	Extension through the pterygomaxillary fossa into the cheek and temporal fossa or posterior to the pterygoid plates
IIIa	Erosion of the skull base with minimal intracranial extension
IIIb	Erosion of the skull base with extensive intracranial extension with or without cavernous sinus invasion

Dustri-Verlag Dr. Karl Feistle GmbH & Co. KG.

Treatment consists of surgery for small lesions, often with preoperative embolization or hormone therapy. Surgery carries a risk of significant operative blood loss. For localized JNA, the cure rate obtained by surgery alone can be as high as 90%. Resection with negative margins is required because inadequate margins will result in a high local failure rate.[42] Minimally invasive endoscopic resection has been proposed for early-stage JNA. Lesions limited to the nasal cavity and/or nasopharynx or lesions with minimal extension through the sphenopalatine foramen are suitable for this procedure. A craniofacial approach is recommended for lesions extending into the pterygoid plates.[43,44] For tumors with intracranial extension, there are recent data demonstrating near-total tumor resections with good outcomes.[45] Radiation therapy is used either as adjuvant treatment or as sole treatment in locally advanced lesions extending into unresectable areas. IMRT has been successfully applied in unresectable and recurrent tumors.[46] A wide range of doses has been used, but there is no evidence that doses of greater than 36 Gy are advantageous. Chakraborty et al[47] treated eight patients with IMRT with a median dose of 39 Gy. The local control rate was 87% with a mean follow-up of 2 years. Mallick et al[48] looked at long-term outcomes for patients treated with RT for refractory residual or unresectable disease from 1990 to 2012, with a median dose of 30 Gy and showed a 10-year progression-free survival of 70.7%. Cataract and growth retardation have been reported.[49] There is no role for cytotoxic chemotherapy in JNA. The role of antiangiogenic agents is speculative, although a recent complete molecular profile suggests other potential targets.[50]

LUNG CANCER

Bronchogenic Carcinoma

Pediatric bronchogenic carcinoma is extremely rare, and its management does not differ from that of adults. Most of the tumors occur during adolescence. Histology is more frequently undifferentiated adenocarcinoma or carcinoid tumors rather than squamous cell carcinoma.

Of 230 cases of primary pulmonary neoplasms of childhood reviewed by Hartman and Shochat,[51] less than 25% were bronchogenic carcinoma. The survival rate was very similar to that of adults, stage for stage. Treatment strategies of these patients should be similar to adults.

Pleuropulmonary Blastoma

Pleuropulmonary blastoma (PPB) is the most common malignant lung tumor in children. Up to 90% of type I, II, and III are diagnosed in children 7 years of age or younger.[52] PPB was often mixed with pulmonary blastoma until it was accepted that PPB is purely a pediatric tumor. The main histologic difference between pulmonary blastoma and PPB is the absence of epithelial carcinomatous components in PPB; PPB consists of mesenchymal stroma only. The tumor usually begins in pulmonary tissue, but it can also originate in the pleura or mediastinum.[53] According to the Dehner et al[54] classification, three pathologic features can occur: cystic (type I), mixed cystic and solid (type II), and solid (type III). According to the International Pleuropulmonary Blastoma Registry (IPPBR), the 5-year OS rates are 91%, 71%, and 53% for types I, II, and III, respectively, with the PPB type shown to be the strongest predictor of outcome.[55,56] A germ line mutation in DICER1, leading to a loss of function, is the known cause of the majority of PPB cases.[57] Messinger et al concluded that surveillance of DICER1 carriers may be reasonable to detect PPB before it progresses. Patients with DICER1 pathogenic variants are associated with other malignancies as well.[52] Some reports described PPB association with a preexisting pulmonary cyst.[58] It is unclear whether PPB arises in preexisting malformation or whether PPB induces cystic lesion formation. The report from the IPPBR showed that great vessel or cardiac extension is present at diagnosis in 3% of cases.[59]

Clinically, PPB exhibits no specific symptoms. The usual presentation is cough, thoracic pain, and fever. Respiratory impairment is unusual. Radiologic findings depend on the extent of the cystic component (Figure 99.1). The standard treatment is surgery alone with chemotherapy included, and RT is used in a minority of cases.

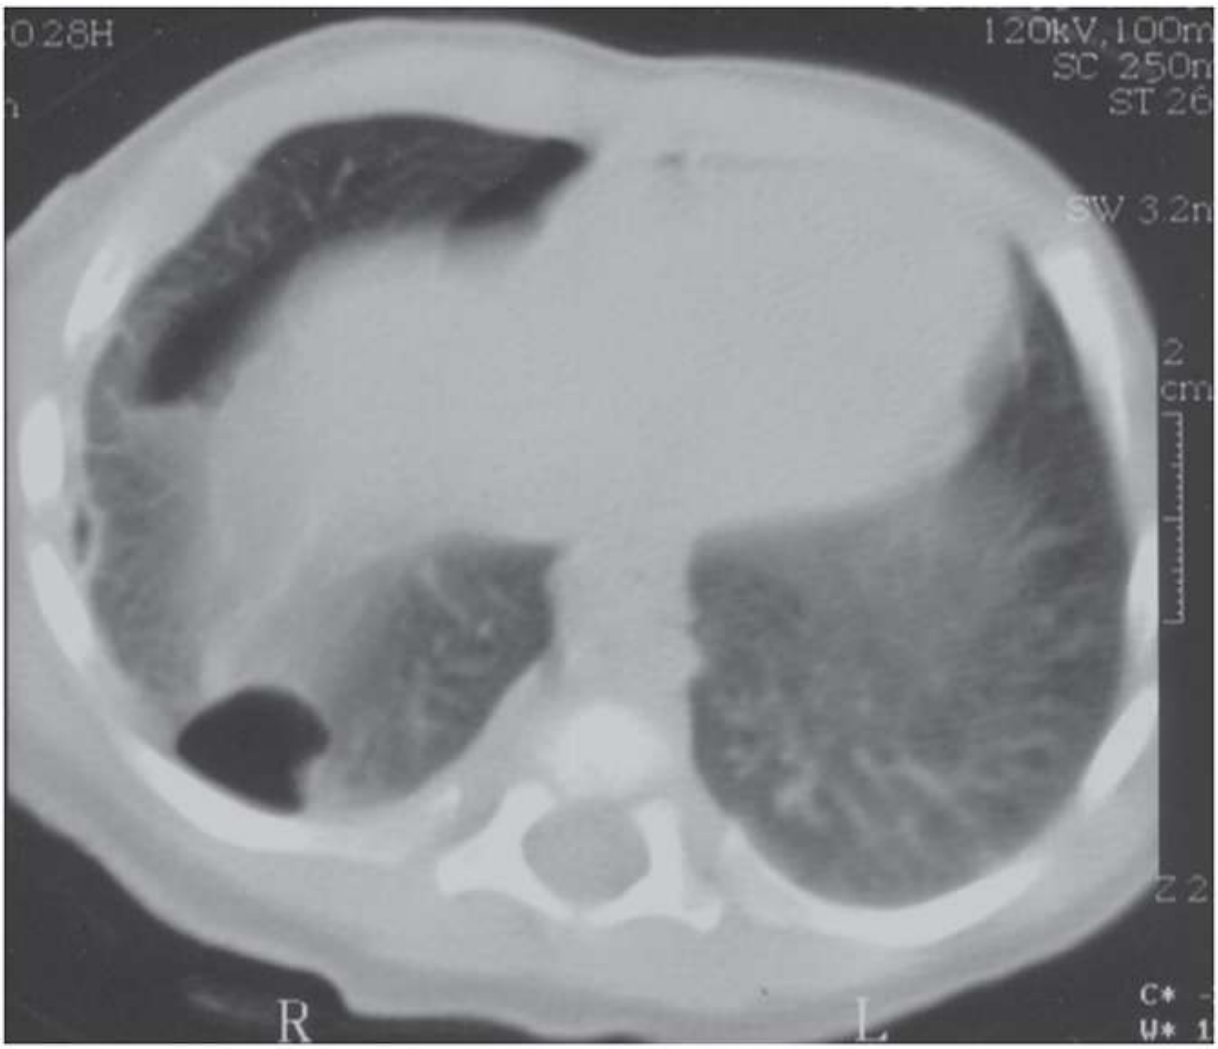

FIGURE 99.1 Pleuropneumoblastoma in a 1-year-old girl.

Priest et al reported an only 8% survival rate at 5 years among 50 patients[60]; however, large cohorts described earlier showed superior outcomes. Multimodal therapy with surgery followed by chemotherapy and RT (10.5 Gy) has been reported[61]; however, the IPPBR study examining the largest patient cohort demonstrated no benefit from adjuvant radiotherapy.[56]

The value of chemotherapy is somewhat controversial for type I PPB. Because of higher metastatic potential, multiagent combinations such as actinomycin D, cyclophosphamide, cisplatin, etoposide, doxorubicin, and vincristine have been used in type II and III PPB.[53,62-65] Long-term survival can be achieved for patients treated with surgery and chemotherapy; however, the optimal combination of chemotherapy drugs or their direct impact on outcomes is less clear. Current plans by the COG include the proposed study, ARAR2331, that will explore the use of camptothecins as window therapy and during consolidation and maintenance. This is in hopes of reducing local relapse and central nervous system (CNS) metastatic spread. Furthermore, this study will help standardize the approach to types I and Ir PPB. Lastly, it will also explore the use of circulating tumor DNA as a prognostic biomarker for Types I, II, and III PPB.[52]

BREAST TUMORS

Malignant breast tumors account for less than 1% of all childhood cancers and less than 0.1% of all breast cancers.[66-68]

A review of adolescents seen at the MD Anderson Cancer Center during a 40-year period identified breast cancer in 16 patients younger than 20 years of age.[69] Ten patients had primary adenocarcinoma of the breast, four had cystosarcoma phyllodes, and two had breast metastases from other primary tumors. Four of the 16 patients had a family history of breast disease. Roisman et al[70] reported seven female patients, ages 14 to 17 years, who were treated in various hospitals in Israel for malignancy of the breast between 1967 and 1989. There were two cases of undifferentiated carcinoma with positive axillary lymph nodes, two cases of cystosarcoma phyllodes, one case of rhabdomyosarcoma, and two cases of malignant lymphoma, one of them Burkitt type. Umanah et al[71] reported 1 case (1.2%) of an invasive ductal carcinoma among 84 breast tumor materials from patients aged 10 to 19 years in a Nigerian city.

Ultrasonography is the most appropriate initial investigation in any adolescent patient with a breast mass because dense breast tissue adversely affects the quality of mammography.[72] MRI is recommended for diagnosing breast cancer when conventional imaging is complex and indeterminate, especially in young patients with dense mammographies.

Juvenile secretory carcinoma of the breast is rare and was first described by McDivitt and Stewart[73] in 1966 in seven girls ages 3 to 15 years, all of whom had a benign clinical course. The tumor cells are characterized by abundant mucin- and mucopolysaccharide-containing materials.[74] Hormonal receptors are generally negative.[75] Local tumor excision alone may be adequate therapy, although simple and radical mastectomies have also been used.

The histology and patterns of the spread of adenocarcinoma of the breast in children and adolescents are similar to those in adults. Because most publications refer to isolated cases, neither a consensus of opinion nor specific guidelines exist with regard to treatment. In general, principles of clinical management established for adults should be adopted. Because recurrences were found in 25% of patients treated with excisional biopsy alone, this seems inadequate, and a simple mastectomy with axillary lymph node dissection should probably be performed.[76] Sentinel lymph node biopsy offers an approach to stage the axillary lymphatic drainage, with a lower complication rate than formal dissection.[77] On the other hand, McDivitt and Stewart[73] believed that the disease tends to run a relatively favorable course and that radical therapy is therefore unnecessary. Hartman and Magrish[78] considered it important to avoid RT in young children, and instead, they recommended radical mastectomy. A multidisciplinary approach is necessary to review the risks, benefits, and long-term toxicities associated with treatment decisions.

Inflammatory carcinoma of the breast is extremely rare in children. There have been case reports of primary lymphoma, rhabdomyosarcoma, adenoid cystic carcinoma, radiation- induced sarcoma, and cystosarcoma phyllodes of the breast in children.

Cystosarcoma phyllodes appears as a large breast mass; in 25% of cases, it is bilateral. Norris and Taylor[79] were the first to separate benign from malignant lesions in this disorder. The distinction is based on tumor size, stromal invasion, cellular atypia, degree of mitotic activity, focal calcification, and/or patterns of infiltration. Metastases occur in the lungs and bones. Lymph node metastases are extremely rare. Simple or wide local excision or simple mastectomy, with rare local recurrences, may adequately treat histologically benign lesions. In malignant cystosarcoma phyllodes, some authors recommend radical mastectomy with or without axillary

lymph node dissection, and others are in favor of simple mastectomy.[80,81] The use of RT and postoperative chemotherapy in cystosarcoma phyllodes is controversial. These modalities should be reserved for locally advanced, palliative, and disseminated cases.

Rhabdomyosarcoma of the breast, either primary or metastatic, is rare. Billroth reported the first case of primary rhabdomyosarcoma in a 16-year-old girl in 1860.[82] In a series of 108 patients younger than 20 years of age with this malignancy, Howarth et al[83] reported seven patients who had metastatic tumors to the breast with primary rhabdomyosarcoma located on an extremity or buttock. Six of the seven patients had alveolar histology. Rhabdomyosarcoma of the breast and other sarcomas of the breast are treated primarily by surgery followed, in most cases, by adjuvant radiation and chemotherapy.

Breast metastases in the pediatric age group include hepatocarcinoma, non-Hodgkin lymphoma, rhabdomyosarcoma, Hodgkin disease, neuroblastoma, and adenocarcinoma.[84]

GASTROINTESTINAL TUMORS OF CHILDHOOD

Gastrointestinal tract malignant tumors are relatively rare in children. Carcinoid and hepatobiliary tumors are the most common.[85] Others are adenocarcinoma, lymphoma, and leiomyosarcoma. More common are benign tumors such as hamartoma, leiomyoma, neurofibroma, and hemangioma.

Esophagus

In most cases, an esophageal tumor is of epithelial origin, either squamous cell carcinoma or adenocarcinoma. Rarely, sarcomas may develop in the esophagus (leiomyosarcoma, carcinosarcoma, and malignant schwannoma). Malignization of a chemical injury to the esophagus has been described.[86] Carcinoma of the esophagus may develop in association with Barrett esophagus and Cornelia de Lange syndrome.[87,88] McGill et al[89] reported on a 16-year-old 3-year survivor of gastroesophageal junction cancer following resection and chemotherapy. The most common benign tumor of the esophagus in the pediatric age group is leiomyoma; desmoid and teratoma

may also occur. The management of esophageal cancer in the pediatric age group follows the same guidelines of treatment as in adults.[90]

Stomach

Adenocarcinoma is extremely rare, representing less than 0.05% of pediatric gastrointestinal malignancies; it may arise in association with Peutz-Jeghers syndrome.[91] *Helicobacter pylori* infection also appears to be a risk factor.[92] In children, the prognosis is exceedingly poor with a median survival of 5 months.[93] A report from 2015 described an *H. pylori*– positive antral tumor in a 16-year-old boy.[94]

Non-Hodgkin lymphoma is the most frequent gastric malignancy in the pediatric age group, followed by leiomyosarcoma and leiomyoblastoma.[95] The management of non-Hodgkin lymphoma follows the treatment guidelines of non-Hodgkin lymphoma in adults. There is also some evidence that primary gastric Burkitt lymphoma may also be associated with *H. pylori*.[96]

Leiomyosarcoma of the stomach is treated primarily with surgery. Postoperative irradiation is given to patients with a high risk of local recurrence (such as positive surgical margins or extension into the retroperitoneum).

As in the adult age group, subtotal gastrectomy with resection of associated lymph nodes is the treatment of choice for children with gastric carcinoma. No data are available on adjuvant radiation-chemotherapy in the pediatric age group. In adults, multiple randomized studies have shown a benefit to adjuvant chemoradiotherapy compared to chemotherapy alone if the patient has a D2 dissection with positive lymph nodes.[97] A sandwich regimen of chemo, surgery, and chemotherapy has also demonstrated a progression-free and OS benefit.[98] More recent studies with modern chemotherapy with fluorouracil plus leucovorin, oxaliplatin, and docetaxel (FLOT) have shown better outcomes.[99]

Radiotherapy guidelines are similar to those for the adult age group. At the time of RT planning, attention should be given to vital structures such as the spinal cord, kidneys, small bowel, and liver. During treatment, acute side effects may occur, such as nausea, weight loss, and fatigue.

Several combination chemotherapy regimens have been used in the adjuvant setting and for locally advanced or metastatic gastric carcinoma. Over 20% of gastric cancers and up to 33% of gastroesophageal junction tumors show HER2 overexpression.[100] There is interest in exploring the role of trastuzumab.[101]

Small Bowel

According to the Surveillance, Epidemiology, and End Results (SEER) data, the incidence of malignant small intestine tumors is low in patients younger than 30 years of age.[102] The most common malignancy of the small intestine in children is non-Hodgkin lymphoma. Sarcomas of the small bowel and carcinoids may also develop in children. Small intestine adenocarcinoma may develop spontaneously or in association with Peutz-Jeghers syndrome.[103]

Treatment guidelines are similar to those of the adult age group. Adjuvant radiation can be given after surgery for duodenal sarcomas or adenocarcinomas arising in the segment fixed to the retroperitoneum or for palliative purposes such as for pain or bleeding.

Colorectal Cancer

Carcinoma of the rectum and the large bowel is rare in children and adolescents. Recent SEER data for 2014 record a rate of around 0.4 per 100,000 for patients younger than 20 years of age.[104] Young patients with long-standing ulcerative colitis have an increased risk of developing colorectal cancer.[105] Several genetic conditions may also be associated with colorectal carcinoma in childhood and adolescence. These include familial polyposis, Turcot syndrome, Oldfield syndrome, and Gardner syndrome.[100,102-104,106-110] The genetic events associated with the development of colorectal carcinoma in familial adenomatous polyposis syndrome, from epithelial proliferation, through the formation of adenomas, to the sequential development of colorectal malignancy, have been described by Vogelstein et al,[111] and more recently, the associated mutations have been well characterized.[112]

Similar to the adult age group, signs and symptoms of colorectal cancer are related to the segment of the large bowel where the tumor is located.

Because of its rarity in the pediatric and adolescent age groups, diagnosis of colorectal carcinoma is often delayed, and patients usually present with acute symptoms that necessitate urgent laparotomy. Colorectal cancer in the young is usually diagnosed at an advanced stage, with metastases involving the omentum, peritoneum, mesenteric lymph nodes, liver, ovaries, and sometimes lungs, brain, and bones, and therefore, it carries a poor prognosis.[113]

Colorectal carcinoma is diagnosed by direct fiberoptic colonoscopy. Radiographic studies include barium enema with air contrast, CT scan, and radioisotope studies (fluorodeoxyglucose– positron emission tomography [FDG-PET]) to determine metastatic spread. Preoperative carcinoembryonic antigen (CEA) level is important both as a prognosticator and for follow-up purposes. CA19-9 has been less valuable, although some tumors produce CA19-9 without CEA production.

Adenocarcinoma of the colorectum may be well, moderately, or poorly differentiated. The mucinous variety and signet cell types are associated with an extremely poor prognosis. Mucinous adenocarcinoma is the most common histotype in the pediatric age group.[114] Unlike adult patients, in whom 60% of colonic cancers are located within 25 cm of the anus and in whom the rectum and sigmoid are also common sites for mucinous adenocarcinoma, tumors in children are probably more evenly distributed in all parts of the colon.[115] In a series reported by Andersson and Bergdahl,[116] the most common area was the transverse colon (39%). In a series of 20 patients reported by Karnak et al[117] from Turkey, the rectosigmoid area was the most frequent site of location of the primary tumor (65%, the same as in adults). Another series from St. Jude's evaluated 24 adolescents with colorectal, 21 of whom had poorly differentiated mucin-producing adenocarcinoma.[118] The disease-free survival reported was extremely poor.

Surgery alone is the primary and most effective treatment for early-stage colorectal carcinoma. Because of late diagnosis, the rate of complete resection has been less than optimal in children. In the series of Karnak et al,[117] complete resection was possible in only 6 of 20 patients. The surgical guidelines are similar to those of adult patients. Similarly, the use of chemotherapy and RT follows the guidelines of the adult age group with Sauer et al,[119] demonstrating superiority for preoperative chemoradiotherapy for T3, T4, or node-positive rectal cancer. Special attention should be given

to radiochemotherapy sequelae on the reproductive system, as both the ovaries and testes are exquisitely radiosensitive.

More recently, there have been emerging data demonstrating that adult patients with deficient DNA mismatch repair or microsatellite instability respond to immunotherapy targeting the PD1/PD-L1 immune checkpoint axis.[120] COG, in cooperation with Alliance, is exploring the role of chemotherapy alone versus chemotherapy and anti-PD-L1 immune checkpoint inhibitor for patients with Stage III colon cancer with deficient DNA mismatch repair or microsatellite instability.[121]

Appendix

The most frequent malignant tumors of the appendix in the pediatric age group are carcinoids. These tumors are usually diagnosed incidentally during surgery for acute appendicitis or during other abdominal surgery. Complete surgical removal is the treatment of choice.[122]

Pancreas

Pancreatic tumors are rare in children. The most important types are functional tumors, pancreatoblastomas, and solid papillary epithelial neoplasms.[123,124] The adult form of pancreatic adenocarcinoma rarely occurs in children.

Functional islet cell tumors are characterized by their hormonal activity. The diagnostic procedures and management follow the same guidelines set for adults.

Pancreatoblastoma, a rare tumor, accounting for 25% of pancreatic cancer in children younger than 10 years old, has an annual incidence of 0.004 per 100,000 persons.[125] The mean age of diagnosis is 5.[126] The European Cooperative Study Group for Pediatric Rare Tumors analyzed 20 patients diagnosed between 2000 and 2009.[127] The tumor is characterized by adenocarcinomatous tissue with ductal cells, acinar cells, squamoid corpuscles, and sometimes islet cell differentiation. These tumors stain positively by periodic acid–Schiff, α-trypsin, and α-keratin and in many cases can be associated with increased levels of α-fetoprotein (AFP).[128-130] Familial adenomatous polyposis and Beckwith-Wiedemann syndrome are associated with neonatal cases.[126] The SEER database from 1973 to 2004

reports 10 cases, and the United Kingdom National Registry of Childhood Tumors reports 11 cases.[131]

In most cases, the tumor is located in the head of the pancreas. In patients with a solitary noninfiltrative tumor, complete local resection without radical pancreatoduodenectomy is recommended. Unlike patients with local disease, in whom local resection can be curative, in many other cases, the tumor is clearly malignant, with porta hepatis or vascular invasion, local recurrences, and nodal and disseminated metastases. The prognosis for these patients is very poor. For unresectable diseases, neoadjuvant chemotherapy may be recommended with adjuvant chemotherapy to follow resection.

Radiation therapy is used in the postoperative setting, in locoregional recurrences, and in the neoadjuvant setting. A dose of 40 to 50 Gy is recommended.[130,132] Technical guidelines of RT planning are similar to those of the adults. Intraoperative RT for recurrent disease has also been used.

Chemotherapy has been used for unresectable tumors, to treat metastatic disease, or in the adjuvant setting.[126,133,134] Because the disease is so rare, it is impossible to set firm guidelines and treatment policies for chemotherapy in pediatric pancreatoblastoma; however, there are case reports of long-term survival and tolerance of aggressive surgical and chemotherapy regimens for locally advanced disease.[135] There is also evidence that a combination of vinorelbine and oral cyclophosphamide may be effective for relapsed disease.[136]

Papillary cystic tumors of the pancreas, also known as Frantz tumors or solid pseudopapillary tumors, are usually encapsulated lesions that can develop throughout the pancreas. They are characterized by cystic or pseudocystic spaces surrounded by residual solid tissue. Only 15% of these tumors are malignant, and they usually occur in female patients at a mean age of 24 years at diagnosis.[137]

These tumors usually present as an upper abdominal mass. Unlike other malignant pancreatic tumors, their prognosis is excellent after complete surgical excision.[138] In a retrospective analysis, Hwang et al showed that CT scan findings of an increased solid component indicated the disease was more likely to be malignant and a more radical resection should be recommended.[139]

The adult type of pancreatic adenocarcinoma is extremely rare in the pediatric and adolescent age groups. Signs and symptoms are similar to those of adult carcinoma of the pancreas.[132] These tumors are managed according to guidelines of treatment set for adult patients with surgery for resectable disease.

Hepatobiliary Tumors

Hepatobiliary tumors are the most common neoplasms of the gastrointestinal tract to occur in children. They constitute 0.5% to 2% of pediatric cancer in Europe and in the United States. Hepatocellular carcinoma (HCC) occurs more frequently in Saharan Africa and Asia.[71,140,141] This geographic clustering may be explained by the high rates of hepatitis B infection and hepatitis B serum antigen positivity.[142] This is supported by the dramatic decrease in the rate of HCC in Taiwan from 10% to 1% 10 years after a nationwide hepatitis B vaccination program was launched.[143]

Benign hepatic tumors are more frequent than malignant tumors in young children. In older children, malignant tumors become more common. Benign tumors are classified according to the cell of origin: mesenchymal (hemangioma, hemangioendothelioma, hamartoma, peliosis hepatis) or epithelial (cysts, focal nodal hyperplasia, adenoma).[144] On rare occasions, radiation therapy may be used for the treatment of hemangiomas.

Malignant tumors of the liver are classified according to the tissue of origin, with hepatocellular tumors (hepatoblastoma [HBL] and HCC) most common, constituting 75% to 90% of primary hepatic malignant tumors of childhood. Other tumors include malignant mesenchymoma, undifferentiated embryonal sarcoma, primary hepatic malignant tumors with rhabdoid features, leiomyosarcoma, angiosarcoma, hepatic sinusoid tumors, carcinoid, and non-Hodgkin lymphoma.

Bile duct adenocarcinoma (cholangiocarcinoma) is extremely rare before the age of 30. This tumor has been associated with certain rare congenital biliary anomalies, ulcerated colitis, cystic fibrosis, and sclerosing cholangitis.[144] The liver is also a common site for metastatic disease.

Of the malignant tumors of the liver in childhood, HBL is the most common. HBL occurs almost exclusively in small infants, although isolated

instances in older children and in young adolescents have been reported. These tumors occur more frequently among males.

HBL is associated with Beckwith-Wiedemann syndrome, familial adenomatous polyposis, and congenital anomalies like hemihypertrophy and cleft palate, Wilms tumor, and glycogen storage diseases.[145-147] Although the association between HBL and Beckwith-Wiedemann syndrome indicates abnormalities on chromosome 11 and loss of heterozygosity of 11p, increased incidence of HBL in families with familial adenomatous polyposis indicates abnormalities of chromosome 5q.[147,148] More recently, it has been shown that familial adenomatous polyposis cases with HBL are associated with germ line mutations of APC, located on 5q. However, the sporadic cases of HBL instead demonstrate mutations in the Wnt-β-catenin pathway.[149] Others have shown that activation of the telomerase gene, TERT, and MYC expression are associated with the more aggressive HBL phenotypes.[150]

The presenting signs and symptoms are distension of the abdomen, anorexia, vomiting, anemia, fever, and jaundice. Isosexual precocity secondary to human chorionic gonadotropin (HCG) secretion or testosterone production by the tumor can be seen in some cases.[151]

Serum AFP produced by the embryonal endoderm is increased in 84% to 90% of patients with HBL.[152] HCG and cystathionase may also serve as tumor markers.[153] Histologically, HBLs (Figure 99.2) are frequently composed of combinations of epithelial, mesenchymal, poorly differentiated, cholangioblastic and other cell types (Table 99.3). Over the years, through the collaboration of multiple cooperative groups—including COG, International Childhood Liver Tumors Strategy Group (SIOPEL), Gesellschaft fur Padiatrische Onkologie undHamatologie (GPOH), and Japanese Study Group for Pediatric Liver Tumors (JPLT)—new prognostic definitions have been created. In the United States, COG AHEP0731 is a multicenter phase 3 trial, in which patients are stratified into four risk groups: very low risk, low risk, intermediate risk, and high risk. The risk stratification is based on Evans surgical stage, Histology, and AFP level at diagnosis. Patients received risk-adaptive therapy: very low risk will be treated with surgery only, low risk will be treated with surgery and regimen T (two adjuvant cycles of cisplatin, 5-FU, and vincristine), intermediate risk will be treated with surgery and regimen F (perioperative doxorubicin in

addition to cisplatin, 5-FU, and vincristine), and high risk will receive regimen H (vincristine, irinotecan, and temsirolimus in an upfront window to assess for response rate followed by perioperative doxorubicin, cisplatin, 5-FU, and vincristine).[154] Recent results for the Low-Risk stratum showed that two cycles of adjuvant chemotherapy resulted in a 4-year EFS of 92% and a 5-year EFS of 88%. In the setting of High-Risk HBL, the addition of temsirolimus did not improve the response rate in patients treated with vincristine and irinotecan alone.[155] Further results are pending. The role of radiation for HBL is not clearly defined at this time. Radiation treatment has been used in the inoperable or metastatic setting with various degrees of success.[156]

TABLE 99.3 HISTOLOGIC CLASSIFICATION OF HEPATOBLASTOMA[323]

Classification	Microscopic Features	Clinical Features
Epithelial		
Fetal		
Pure Fetal	Well differentiated and uniform	More favorable
Crowded	Mitotically active	Often mixed with other subtypes
Pleomorphic	Nuclear pleomorphism	Seen post therapy
Embyronal	Angulated nuclei	Mixed with other subtypes
Macrotrabecular	Cells growing in trabeculae	Unclear prognosis
Small-cell	Small cells with no architecture	Aggressive, low to normal alpha fetoprotein levels
Cholangioblastic	Small duct formation	Differentiate from other cholangioblastic tumors
Mixed epithelial and mesenchymal	Blastoma, osteoid, muscle sometimes mixed with neuroectoderm and endoderm	20-30% of cases, prognosis unclear

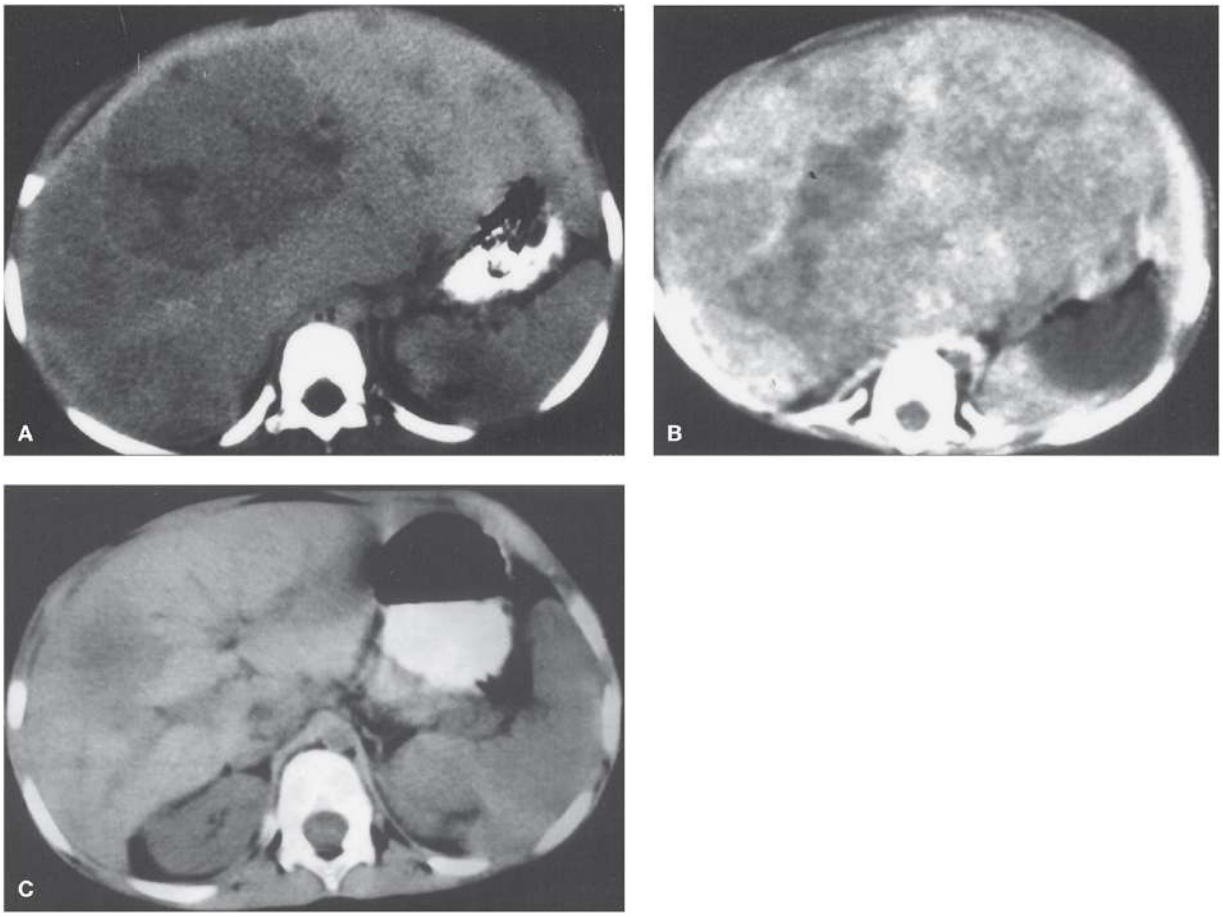

FIGURE 99.2 A 7-year-old girl with hepatoblastoma at diagnosis (A), after one cycle of chemotherapy (B), and after four cycles of chemotherapy before right hepatic lobectomy (C).

HCC is the second most common primary malignant liver tumor in the pediatric age group and accounts for about one-fourth to one-third of hepatic malignancies. Although reported in children as young as 21 months, most reports indicate that HCC usually develops in early adolescence.[157,158] This is in contrast to HBL, which occurs primarily in infancy and is seldom seen in children older than 3 years. Similar to HBL, HCC occurs mainly in males.[159,160] The fibrolamellar carcinoma variant of HCC occurs mainly in young adults around the age of 20 years but has also been reported in childhood.[161,162]

Approximately 25% of HCC cases in childhood are associated with cirrhosis secondary to biliary atresia, Fanconi anemia, glucose-6-phosphatase deficiency, and hereditary tyrosinemia.[163] The most important known etiologic factor for HCC is the high incidence of maternal

transmission of the hepatitis B surface antigen in Africa and Asia.[164,165] Other etiologic factors include exposure to aflatoxins, hepatic fibrosis, anabolic steroids, inherited disorders of metabolism, membranous obstruction of the inferior vena cava, and possibly ethanol abuse.[141,160] However, these etiologic factors apply mostly to HCC in the adult age group. In adult Black South African patients, deletions of alleles on chromosome 17p and P53 (codon 249) have been identified[166,167]; the exact molecular mechanisms responsible for the development of HCC are not known.

Similar to HBL, two-thirds of children with HCC have an elevated AFP.[168] AFP levels are high in healthy newborns and drop rapidly by the age of 1 month and should not be detectable by age 2 years.[169] Initial AFP level is a significant prognostic factor: In a study performed by the Radiation Therapy Oncology Group,[170] the mortality in HCC was 1.8 times higher in patients with strongly positive AFP. AFP is an indicator of tumor growth and can serve as a valuable marker of response to therapy. After complete tumor resection, the AFP level should return to normal within 2 months.[171] Increasing levels of AFP during the follow-up period after surgery indicate local recurrence or metastatic disease.[168]

The Children's Cancer Study Group intergroup and Pediatric Oncology Group (POG) staging systems for primary malignant liver tumors are based on resectability and on the histologic subtype (Tables 99.4[172] and 99.5[173]).

TABLE 99.4 INTERGROUP STAGING SYSTEM FOR LIVER TUMORS

Stage	Description
I	Complete resection
IA	Favorable histologic features
IB	Unfavorable histologic features
II	Microscopic residual, negative nodal involvement, and no spilled tumor
IIA	Residual in liver
IIB	Extrahepatic residual
III	Gross residual, nodal involvement, or spilled tumor
IIIA	Nodal involvement or tumor spill but tumor completely resected
IIIB	Gross tumor not completely resected

Stage	Description
IV	Metastatic disease (as per evaluation immediately before first cycle of chemotherapy)
IVA	Primary tumor completely resected
IVB	Primary tumor not completely resected

TABLE 99.5 PEDIATRIC ONCOLOGY GROUP STAGING SYSTEM FOR PRIMARY MALIGNANT LIVER TUMORS

Stage	Description
I	Complete resection achieved
II	Microscopic residual tumor remaining
III	Gross residual tumor remaining
IV	Metastatic disease present at diagnosis

Modified from Bowman LC, Riely CA. Management of pediatric liver tumors. *Surg Oncol Clin N Am*. 1996;5(2):451-459. Copyright © 1996 Elsevier. With permission.

Successful therapy of localized HBL or HCC depends mainly on the feasibility of complete surgical excision.[174] Up to two-thirds of patients with HBL have resectable tumors at presentation because these tumors are usually unifocal and encapsulated. Cure can be achieved in one-third of the successfully operated patients, typically those with fetal HBL.[145,175]

In contrast, only 30% of the cases of HCC are suitable for complete resection at the time of diagnosis because of the multifocal involvement or size. From 50% to 75% of the fibrolamellar variant of HCC is amenable to complete resection at the time of presentation.[156,176] In principle, tumor resectability is determined by the tumor size, the existence of bilobar involvement necessitating the resection of more than three liver segments, vascular invasion, or metastatic spread. Patients with advanced disease who are not suitable for primary surgery may be considered for neoadjuvant preoperative cytoreductive chemotherapy. In these cases, the diagnosis can be based on clinical presentation; on imaging findings, including FDG-PET

scan[177] and tumor markers; or on tissue diagnosis obtained via open biopsy or CT/ultrasound-guided needle biopsy, although there are some concerns that a needle biopsy may cause a significant hemorrhage. Preoperative cytoreductive chemotherapy can reduce the size of the tumor in the majority of patients with HBL and in a significant percentage of patients with HCC, rendering them resectable. A variety of chemo regimens exist, including cisplatin, vincristine, and 5-fluorouracil,[178] the camptothecin analogues topotecan and irinotecan; oxaliplatin; and liposomal doxorubicin (Doxil).[174] Sorafenib, a tyrosine kinase inhibitor, is available for unresectable HCC. In animal models of pediatric HCC, sorafenib has shown promising efficacy.[179] A phase II trial also demonstrated a good toxicity profile for sorafenib in children.[180] Bevacizumab has shown a survival benefit in a phase II trial.[181,182] In one center's experience, bevacizumab plus conventional platinum-based chemotherapy was effective and safe.[183] If resectability cannot be achieved using chemotherapy, there is still a chance to render unresectable tumors resectable by radiotherapy.[156] The perioperative mortality of hepatic lobectomy is on the order of 5% to 10% in specialized centers applying improved surgical techniques, modern methods of anesthesia, and state-of-the-art postoperative intensive care.[184]

Surgical resection of pulmonary metastases can be attempted if they persist after chemotherapy and if the primary tumor can be completely resected. Patients who are successfully operated on for Stage I disease and later develop a solitary lung metastasis are also suitable for metastasectomy.

Total hepatectomy and liver transplantation can be attempted in unresectable HBL (about 10% after chemotherapy) and HCC (>50% are unresectable at diagnosis), with the tumor confined to the liver without penetration of the capsule and in the absence of lymph node and distant metastases. The OS is between 50% and 83%, with a minimum follow-up of 2 years. The best outcome was achieved in patients with a good response to chemotherapy who had a "first-line transplant" (ie, not after an unsuccessful attempt at resection).[174,185-187]

Although it has been used preoperatively and postoperatively in children with HBL and HCC, radiation therapy has a limited role in curative management. Transarterial radioembolization (TARE) has been used in adult patients with HCC to offer tumor local control. TARE usually requires a mapping process and a treatment process. ^{99m}Technetium-labeled

macroaggregate albumin is used to map the liver prior to treatment to assess for possible deposition of the microsphere in extrahepatic regions.[188] More recently, the use of TARE as a bridging therapy to help reach surgical resection has been explored.[189,190] Historically, standard fractionated radiation schemes have been tested, but with the usage of stereotactic body irradiation (SBRT) for adult HCC, the role of SBRT for HCC in pediatric patients has been explored. This includes utilizing SBRT as a bridging therapy for diseases with central biliary obstruction or nodal involvement.[191,192] More data are needed at this time.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH), a dendritic disorder, is believed to affect fewer than 1 in 200,000 children; however, any age group can be affected.[193]

Other terms for LCH include histiocytosis X, eosinophilic granuloma, Letterer-Siwe disease, and Hand-Schüller- Christian disease; however, the preferred term is LCH.

The pathogenesis is not completely understood, but excessive production of interleukin-1, interleukin-17a, prostaglandin, and metalloproteases MMP9 and MMP12,[194] as well as of prostaglandin E_2, has been demonstrated in the affected bone. These factors can play a major role in osteoclast activation. Controversy exists regarding whether the clonal proliferation of LCH cells results from a malignant transformation or is the result of an immunologic stimulus. Regardless of the mechanism responsible for the clonal proliferation, the primary treatment, if necessary, involves chemotherapeutic agents. Select chemotherapeutic drugs also have immunomodulatory activity. The diagnosis of LCH is based on a histologic and immunophenotypical examination of tissue. The main feature is the morphologic identification of the characteristic Langerhans cells. In addition, LCH stains positive for CD1a, langerin (CD207), and S100.[195] The expression of langerin confirms the presence of Birbeck granules, the cytoplasmic organelles typically found in Langerhans cells.[196]

In children older than 2 years, the disease is less aggressive, with widespread bone granulomas causing pain, otitis, diabetes insipidus (42%), and exophthalmos. Eosinophilic granuloma is characterized by bone

involvement only and with symptoms related to the location of the granuloma. CNS involvement is possible; most frequently, meningeal and pituitary lesions occur, but intraparenchymal lesions, especially hypothalamic and cerebellar, can also be encountered.

Staging procedures include a skeletal survey (rather than an isotopic bone scan). Many prognostic scores have been proposed, all based on the extent of disease, age at diagnosis, and demonstrable organ dysfunction. Cases are classified into the following groups[197]:

- **Single system**
  - Unifocal or multifocal organ system involvement
  - Unifocal or multifocal bone involvement
  - Skin
  - Lymph node
  - Hypothalamic/pituitary/CNS
  - Other (eg, thyroid)
- **Multisystem**
  - Involvement of greater than or equal to two organs or systems

Treatment decisions are based on whether the high- or low-risk organs are involved and whether the disease is a single system or multisystem. Many cases of LCH are indolent or resolve spontaneously. Aggressive treatment therefore should not be given if there is no organ dysfunction. International efforts during the last 20 years have shown that combination therapy with vinblastine/prednisone is an effective therapy for multisystem LCH. There is the potential of adding mercaptopurine for high-risk LCH.[195] Trials conducted by the Histiocyte Society confirmed this regimen as standard therapy for multisystem LCH with and without risk organ involvement.[198,199]

Risk organs and their involvement were defined according to modified Lahey criteria as follows[200]:

- Hematopoietic: Anemia and/or leukopenia and/or thrombocytopenia
- Liver: Enlargement greater than 3 cm below the costal margin, dysfunction, or both

- Spleen: Enlargement greater than 2 cm below the costal margin
- Lung: Typical changes via high-resolution CT, histopathologic diagnosis, or both

Local Therapy

Various local therapies have been explored. Those include local steroid injection, various forms of surgical intervention, and radiotherapy.[201] The POG 8047 study demonstrated that a similar control rate can be achieved (70%-90%) with biopsy, curettage, or tumor excision.[202] Wide excision is recommended for expendable bones (clavicle, ribs) and biopsy for other sites. Curettage is not indicated if there is a risk of instability (cervical vertebra, femoral neck) or if a poor cosmetic or orthopedic outcome is likely.

Radiation therapy was widely used in the 1960s but is no longer indicated in the large majority of cases. Radiation therapy could be discussed in a case of resistant cerebral location. Tumors are very radiosensitive; however, a wide range of doses has been reported for the treatment of LCH (2.5-50 Gy).[203-206]

It appears that 9 Gy for bone lesions and 15 Gy for soft tissues will result in very high response and local control rates; however, they may still be consequential for children and should be only considered in selected cases. Typically, for pediatric cases, radiation is avoided; however, in the setting in which RT is needed, a low dose of 6 to 10 Gy is preferred to limit secondary malignancy.[201,207]

ENDOCRINE TUMORS

Adrenocortical Carcinoma

Adrenocortical carcinoma (ACC) accounts for 0.2% of childhood cancer, and in 75% of the cases, it occurs in children younger than 5 years, more commonly in females.[208-212] Half of ACCs are associated with Li-Fraumeni syndrome.[121] ACC is sometimes associated with Beckwith-Wiedemann syndrome and hemihypertrophy.[213]

Children with ACC may present with abdominal pain and a palpable mass. More than 75% of the tumors are functional, secreting one or more

hormones: androgens, cortisol, aldosterone, or estrogens. The most common presenting sign is virilization, with deepening of the voice, hirsutism, premature pubic hair, clitoromegaly, phallumegaly, excessive muscular development, and advanced bone age. Pure Cushing syndrome (moon face, plethora, hypertension, striae, weight gain, acne, and "buffalo hump") is rare in children. Feminization or aldosterone- secreting tumors are also rare.[211]

Urinary 17-ketocorticosteroids and 17-hydroxycorticosteroids are usually elevated, with steroid production not influenced by adrenocorticotropic hormone suppression.

Diagnostic imaging studies include CT and/or MRI. It is sometimes difficult to separate ACC from adenoma. However, at presentation, most carcinomas are greater than 6 cm and calcified, whereas benign adenomas are small and nonfunctional. A characteristic echogenic star pattern can be seen on ultrasonography, and a CT scan shows an inhomogeneous tumor with irregular contrast material. Recently, the use of 18-FDG-PET has been shown to be effective in discriminating between benign and malignant adrenal lesions.[214,215] Because both benign adenomas and ACC may exhibit abnormal mitoses and cellular and nuclear pleomorphism, malignancy is determined by the finding of capsular penetration, invasion of the inferior vena cava up to the right atrium, lymph node, and distant metastases.[208]

Generally, the prognosis of ACC depends on disease presentation and can range from 30% to 70% 5-year survival.[216-219] In COG ARAR0332, a single-arm risk-stratified study was performed. Patients with Stage I ACC were treated with surgery alone. Stage II patients were treated with adrenalectomy and retroperitoneal lymph node dissection. Stage III or IV patients were treated with mitotane and chemotherapy. Rodriguez- Galindo et al reported their results, and the 5-year EFS for Stages I, II, III, and IV disease were 86.2%, 53.3%, 81%, and 7.1%, respectively. The 5-year OS rates were 95.2%, 78.8%, 94.7%, and 15.6%.[220] Repeat complete resection of local recurrences and discrete metastatic lesions can improve survival.[221]

The literature on adjuvant radiation therapy after resection of ACC is scarce and relatively old and consists of a small series or case reports.[222] There is no standardized role for RT for pediatric ACC; however, there is interest to utilize RT for local therapy in the setting of advanced ACC.[222]

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Pheochromocytoma and paraganglioma are rare tumors of childhood and adolescence.[223-227] Pediatric pheochromocytoma occurs usually between 8 and 14 years of age, more frequently in males. More than 90% of all pheochromocytomas in adults, and 70% of pheochromocytomas in children, originate in the adrenal gland, but the tumor can occur at any site in the sympathetic chain, most commonly below the diaphragm. The most common sites of occurrence of extra-adrenal pheochromocytoma are the superior para-aortic region, between the diaphragm and the lower renal poles, in the paraganglia, the organs of Zuckerkandl, and the bladder. Extra-abdominal tumors may develop in the brain, thorax, and the bladder.[223,226,228,229] Approximately 10% of all patients with pheochromocytoma are children, but several characteristics distinguish them from their adult counterparts. Unlike pheochromocytomas of the adult age group, children with pheochromocytoma have a higher incidence of bilaterality, a higher association with the multiple endocrine neoplasia (MEN) syndromes, and a lower incidence of malignant neoplasms.[223,228,230,231]

Familial pheochromocytoma is associated with other endocrine tumors in the MEN IIA and IIB syndromes.[228,232-234]

In addition to the familial syndrome of isolated pheochromocytomas, pheochromocytomas in the pediatric age group can be associated with other inherited diseases, such as von Hippel-Lindau disease (retinocerebral angiomatosis), tuberous sclerosis, and von Recklinghausen neurofibromatosis.

Malignant pheochromocytomas occur in 10% of the pediatric cases of pheochromocytoma. The definition of malignancy is based on biologic and clinical behavior and not on histologic features alone.

Pheochromocytoma is responsible for 1% of cases of childhood hypertension, which, unlike the situation in adults, is sustained and not paroxysmal. Other signs and symptoms include diaphoresis, flushing, fatigue, headache, and convulsions.[235]

Adrenal pheochromocytomas produce epinephrine and norepinephrine, but most extra-adrenal pheochromocytomas produce only norepinephrine.

Urinary epinephrine, norepinephrine, metanephrine, and vanillylmandelic acid values remain the gold standard for biochemical screening of pheochromocytoma. On some occasions, urinary catecholamine levels may be normal, whereas serum levels are elevated. Imaging studies include ultrasonography, CT scan, and/or MRI. Iodine-131 metaiodobenzylguanidine (MIBG) scan provides the most accurate and direct method of diagnosing adrenal, extra-adrenal, or metastatic pheochromocytoma because MIBG, which has a molecular structure similar to that of norepinephrine, is actively concentrated and stored in catecholamine storage vesicles of pheochromocytoma cells.[223,228,236-238]

Surgery is the definitive therapy. The most significant reduction in preoperative and postoperative mortality has come from the control of perioperative hypertension using α- and β-blockers.[28,239]

External-beam irradiation is used for palliation of lymph nodes, bone, brain, and spinal cord metastases. High-dose iodine-131 MIBG has been used with modest results in metastatic disease. Streptozotocin or cyclophosphamide, vincristine, and dacarbazine may produce modest decreases in catecholamine secretion in patients with malignant pheochromocytoma. Patients with malignant pheochromocytoma require chronic medical control of their elevated blood pressure by α and β blockade or inhibition of catecholamine synthesis with α-methyl-para-tyrosine.[240-242]

THYROID CARCINOMA

Thyroid carcinoma accounts for 1% to 1.5% of all cases of cancer in the pediatric and adolescent age groups, with between 0.4 and 1.5 cases per million, 2 to 3 times as frequent in girls as in boys.[243] After the April 26, 1986, Chernobyl nuclear reactor accident, a remarkable incidence increase was observed in children exposed to radioactive iodine (RAI) fallout.[244,245] The incidence of thyroid cancer in Belarus and Ukraine began to rise sharply from 1989 to 1990: in adults, the number of new cases increased 2- to 3-fold; and in children younger than 20 years of age, and particularly during the first 5 years of life, the number of new cases increased 20- to 30-fold.[244] Almost all new pediatric cases were papillary tumors (94%-98%), with a relatively high incidence of lymph node (65%) and lung (5%)

metastases at presentation (Table 99.6). Lubin et al[246] reported pooled data from nine cohort studies of childhood external radiation exposure and thyroid cancer with individualized dose estimates, more than 1,000 irradiated subjects, or more than 10 thyroid cancer cases, with data limited to individuals receiving doses less than 0.2 gray.

TABLE 99.6 HISTOLOGIC TYPES OF CHILDHOOD THYROID CANCER

Type	Frequency (%)	Characteristics
1. Differentiated carcinoma		
a. Papillary carcinoma	70-80	Infiltrative and multicentric; lymph node metastases in 70%-90% of cases; hematogenous spread (mainly lung) in 5%-10% of cases
b. Follicular carcinoma	16-20	Vascular invasion
2. Medullary carcinoma	Rare	Occurs in isolation, but more frequently associated with one of the MEN syndromes; usually aggressive and can be fatal
3. Undifferentiated carcinoma	Rare	Aggressive, usually fatal within 6 months of diagnosis
4. Insular carcinoma	Very rare	A variant of the poorly differentiated carcinoma; aggressive, poor prognosis

MEN, multiple endocrine neoplasia.

Estimates of threshold dose ranged from 0.0 to 0.03 gray, with an upper 95% confidence bound of 0.04 gray. The increasing dose-response trend persisted for more than 45 years after exposure, was greater at younger age at exposure and younger attained age, and was similar by sex and number of treatments.

For pediatric patients, 85% of childhood thyroid cancers are papillary thyroid cancers (PTCs), with the remainder divided between follicular thyroid cancer (FTC) and medullary thyroid cancer. PTC is a tumor named for its papillary growth pattern, although the defining diagnostic criteria are actually the nuclear features of neoplastic cells. In addition to enhanced screening, the important factor contributing to the increased incidence of

PTC is the increase in diagnosis of a variant of PTC known as the follicular variant of PTC (FVPTC). Among the two main subtypes, infiltrative (or nonencapsulated) and encapsulated, encapsulated FVPTC (EFVPTC) has increased in incidence by an estimated 2- to 3-fold over the past two to three decades and makes up 10% to 20% of all thyroid cancers currently diagnosed in Europe and North America.[247,248] A recent international, multidisciplinary, retrospective study of patients with thyroid nodules diagnosed as EFVPTC, including 109 patients with noninvasive EFVPTC observed for 10 to 26 years and 101 patients with invasive EFVPTC observed for 1 to 18 years, found that thyroid tumors currently diagnosed as noninvasive EFVPTC have a very low risk of adverse outcome and should be termed as noninvasive follicular thyroid neoplasm with papillary-like nuclear features.[249] This reclassification will affect a large population of patients worldwide and result in a significant reduction in psychological and clinical consequences associated with the diagnosis of cancer.[250]

FTC are typically unifocal and have a risk for hematogenous spread. They are subdivided into microscopic or no capsular invasion versus widely invasive FTC.[251] Medullary carcinomas are rare, tend to be more aggressive than the differentiated carcinomas, and can be fatal. They are associated with the immunoreactive thyrocalcitonin marker. Because of the aggressive clinical course, experts advocate genetic testing to identify affected individuals with specific mutations in the ret oncogene that predict MEN syndromes. Those individuals could be candidates for prophylactic thyroidectomy at an earlier age than if the increase in serum calcitonin was used to identify C-cell hyperplasia or early carcinoma. At present, genetic testing should be performed at birth in children suspected of having the MEN IIA syndrome and no later than 1 year of age for those with possible MEN IIB.[252-254]

Children with thyroid cancer are commonly euthyroid and usually present with a thyroid nodule or palpable cervical lymph node. Conventional radiographs may show calcifications in the region of the thyroid gland (psammoma bodies). An iodine radionuclide scan may show a cold nodule.

Paradoxically, despite the fact that 70% to 80% of patients present with regional lymph node involvement and approximately 20% have distant

metastases at diagnosis, the prognosis of differentiated thyroid cancer (DTC) in children and adolescents is excellent.[254-256]

Thyroid carcinoma is treated primarily by surgery. The extent of surgery for the primary tumor (subtotal lobectomy, lobectomy, total thyroidectomy) and involved lymph nodes (node picking, modified or radical neck dissection) is controversial.[257]

The arguments in favor of total thyroidectomy include the multifocality of the tumor, decrease in neck recurrences, the ability to use serum thyroglobulin as a tumor marker after radical surgery, and the ability to detect pulmonary metastases by RAI scan earlier. The arguments for more limited surgery are mainly the increased complication rate of radical surgery, with apparently no clear survival advantage.[253-255,258-260]

The use of RAI for routine ablation of remaining thyroid tissue after surgery in patients without any known metastatic disease is another area of controversy. However, many support the administration of RAI in this setting because of the high incidence of nodal and systemic metastases of thyroid cancer in the young.[261] Unlike adult thyroid cancer where RAI is routinely used, RAI in pediatric patients has risks for developing secondary malignancies. The American Thyroid Association (ATA) guideline for pediatric DTC stratifies patients by risk. ATA pediatric low-risk patients are initially treated with thyroid-stimulating hormone (TSH)-suppressed thyroglobulin. For ATA pediatric intermediate and high-risk patients, a postoperative TSH-simulated thyroglobulin and diagnostic whole-body (DxWBS) scan are recommended. ^{123}I should be used for DxWBS when possible. RAI is recommended for pediatric patients with iodine-avid persistent locoregional or nodal disease that cannot be resected or with known or presumed iodine-avid distant metastatic disease.[262,263]

Side effects of RAI include nausea, xerostomia, taste alterations, increases in caries, stomatitis, candidiasis, glossalgia, hypogeusia, thyroiditis, and gastrointestinal discomfort.[264,265] Potential and rare long-term complications include myelosuppression, leukemia, bladder cancer, salivary cancer, gastric cancer, breast cancer, and infertility. These complications occur rarely with today's treatment doses and protocols.[261]

Exogenous thyroid hormone is given to suppress TSH production and to decrease the probability of tumor recurrence. Exogenous thyroid hormone

is also given as replacement therapy to keep the patients euthyroid despite thyroidectomy.[258,266,267]

External-beam irradiation in children with DTC is indicated for unresectable primary tumor or cervical or mediastinal lymph nodes that do not take up RAI. It also has a role in advanced locoregional disease, with extensive extrathyroid extension, or where there is gross residual tumor after attempted surgical excision, or when definitive resection has not been possible. Although external-beam irradiation is useful for palliative therapy of advanced or metastatic disease, the lack of randomized controlled studies makes its role as part of initial adjuvant treatment controversial, and it is rarely indicated for microscopic residual disease. Radiotherapy, with or without chemotherapy, can be administered in children with anaplastic thyroid carcinoma.[256]

The volume of irradiation is designed according to operative and pathologic findings and can range from whole-neck and upper mediastinal irradiation to just treating the thyroid gland or thyroid bed. CT-based planning, with proton therapy or IMRT, is advocated to allow the administration of curative doses (in the range of 55-70 Gy) to the target volume without compromising spinal cord tolerance. This can be achieved by a variety of techniques.[268]

In the Mayo Clinic series, survival rates for children did not differ significantly from those of matched controls at 20 to 30 years.[269] In the Royal Marsden series,[258] the median OS was 53 years, and the median survival for patients who developed recurrence was 30 years. The only presenting feature predictive of poorer survival was the presence of metastases at diagnosis. According to a study reported by the Surgical Discipline Committee of the Children's Cancer Group, the OS for children presenting with distant metastases was 100% at 10 years. The progression-free survival rate was 76% at 5 years and 66% at 10 years. In a series of 14 children with PTC and pulmonary metastases treated at the Mayo Clinic[267] by various surgical procedures, RAI, external-beam irradiation (one patient), and suppressive hormone therapy, at a mean follow-up time of 19.3 years, 50% were alive completely free of disease and 50% were alive and asymptomatic with residual pulmonary disease.

GERM CELL TUMORS

Gonadal or extragonadal germ cell tumors (GCTs) represent less than 2% of pediatric cancer. The tumor is the result of neoplastic transformation of primitive germ cells or totipotent embryonal cells (Figure 99.3).[270] The GCTs can arise from the brain to the sacrococcygeal region, with the most common site presentation in the testis, ovary, sacrococcygeal region, retroperitoneum, and mediastinum. Aberrant migration can explain unusual tumor sites.[271] The Children's Oncology Group evaluated the link between a family history of cancer and pediatric GCT in a case-control study of 274 cases. The risk of GCT decreased among female cases with a family history with onset before 40 years but increased for boys, especially for those with a family history of melanoma.[272] The most frequent cytogenetic abnormality is the isochromosome 12p for both gonadal and extragonadal GCT, except for children younger than 3 years of age at diagnosis. Klinefelter syndrome can be associated with GCT in boys.[244] Intracranial GCTs are discussed in Chapters 90.

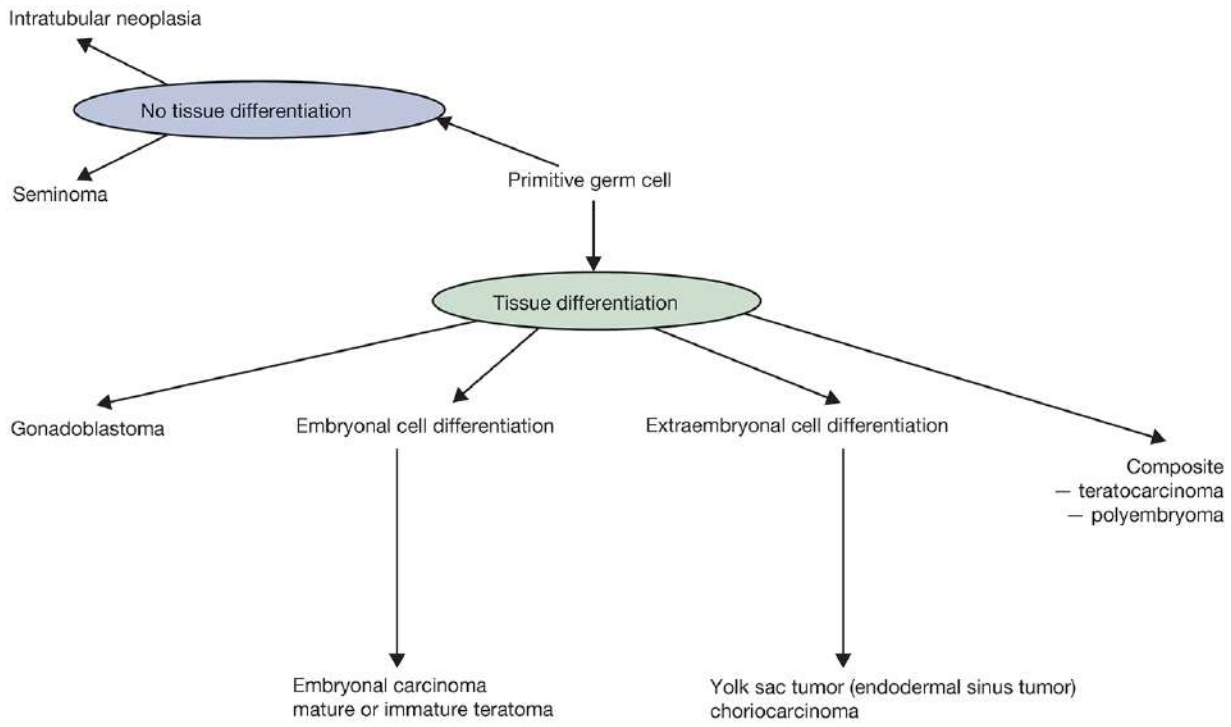

FIGURE 99.3 Classification of germ cell tumors.

Clinical Presentation

Abdominal pain, abdominal distension, and sacrococcygeal or buttock swelling are the frequent presenting signs.[273] Staging includes imaging both the primary tumor and the most frequent sites of metastatic dissemination (lungs, liver, brain, and bone). Serum AFP, *β*-HCG, lactate dehydrogenase, CEA, and placental alkaline phosphatase levels are mandatory prior to the initiation of any treatment. Serum AFP level must be interpreted according to patient age (level >1,000 mg/mL is normal until the age of 1 month). Clinical markers are strongly correlated with some histologic features (Table 99.7); however, high AFP levels can be detected in infectious diseases of the liver, and increased *β*-HCG levels can be associated with malignancies other than choriocarcinoma. The half-life time of AFP is 5 to 7 days and that of *β*-HCG is 24 to 36 hours. Both are very useful tools for predicting and monitoring treatment response, progression of disease, and relapse.[274]

TABLE 99.7 GERM CELL TUMOR AND CLINICAL MARKERS

Tumor Type	*β*-HCG	AFP	LDH	CEA	PLAP
Embryonal carcinoma	+	+		+	
Mature teratoma					
Immature teratoma	+	+	+	+	
Yolk sac tumor		+++	+	+	
Choriocarcinoma	+++		+		
Germinoma	+		+	+	+++

AFP, *α*-fetoprotein; *β*-HCG, beta-human chorionic gonadotropin; CEA, carcinoembryonic antigen; LDH, lactate dehydrogenase; PLAP, placental alkaline phosphatase.

Treatment

Their cure rate is high and strongly correlated with adherence to strict treatment guidelines.

Surgery is the standard treatment for mature teratomas and sacrococcygeal tumors (with complete removal of the tumor and the coccyx), but it may be combined with chemotherapy to limit the extent of irradiation. Surgery is often the first treatment for malignant gonadal GCT: orchiectomy with high inguinal ligation or ovariectomy with careful

peritoneal cavity exploration. Lymph node dissection is not recommended in early-stage GCT, especially in germinomas. Second-look surgery can be indicated in cases of residual disease (clinical or biochemical) after chemotherapy.

Since the introduction of cisplatin-based chemotherapy, the survival rate of GCT has risen from 60% to 90%,[275] and regimens used are similar to those used in the adult age group. Carboplatin is often used to reduce late toxicities.[276] The rate of decline of serum tumor markers has demonstrated prognostic significance and must be used in the management of poor-risk patients.[277] Although GCTs are in general sensitive to radiation and are used in the adult setting, RT is rarely indicated for pediatric patients due to known late effects. Even in advanced cases of ovarian dysgerminoma, careful surgical staging followed by conservative resection and chemotherapy without RT results in an OS rate as high as 85% without compromising the possibility of future pregnancy.[60] There is no indication for RT after complete response in extragonadal GCT. For Stage IA ovarian dysgerminoma, conservative surgery is the gold standard, even in a case of incomplete staging, and chemotherapy is given only in the event of relapse, according to the last Italian group report.[278]

BENIGN VASCULAR TUMORS

Hemangiomas

Infantile hemangiomas, congenital hemangiomas, and Kaposiform hemangioendotheliomas constitute vasculoproliferative tumors. They are subdivided based on the presence or absence of endothelial cell glucose transporter 1 (GLUT1) isoform protein. Infantile hemangioma is the most common benign vascular tumor in children and affects approximately 40% of all infants. The skin, subcutaneous, and soft tissue of the head and neck are the site of origin in 60% of patients, followed by the trunk, extremities, and viscera (eg, liver, lung, gastrointestinal tract).

In some cases, their development can be associated with adverse cosmetic effects, unacceptable symptoms, and organ compression that, in certain cases, could be life threatening. Such cases require therapy. There are two distinct types of hemangiomas: dynamic lesions, which include cellular hemangiomas, capillary hemangiomas, and cavernous

hemangiomas; and adynamic lesions, which include port-wine stains, telangiectasias, and venous lakes. Vascular malformations are subdivided into two major groups, low or slow flow and high or fast flow.[279]

Treatment of infantile hemangiomas depends on the location and number of lesions as well as associated symptoms. Laser therapy is available for skin ulceration, the most frequent complication. For hemangiomas with symptoms, including thrombocytopenia or hypothyroidism, as well as heart failure caused by numerous hepatic hemangiomas, treatment is typically started with antiangiogenic drugs (propranolol, steroids, and less often vincristine) followed by gradually more aggressive treatments, such as embolization and rarely surgery. External-beam RT was used in the past for patients not responding to steroids or interferon. Total doses of 300 to 750 cGy, and rarely exceeding 1,000 cGy, at 10 to 20 cGy per fraction could achieve good local control.[280] Higher doses (30-40 Gy) are used in older patients for large and progressive lesions to achieve lasting local control.[281] However, radiation therapy in the treatment of hemangiomas has fallen out of favor because of concerns for potential late effects, like scarring, bone growth abnormalities, dental and periodontal problems, and secondary neoplasms, and is rarely used anymore.

Special attention must be given to the Kasabach-Merritt syndrome (KMS) (Figure 99.4), which is defined as a combination of cutaneous vascular abnormalities with or without visceral involvement and thrombopenia because of intravascular coagulopathy. KMS is associated only with Kaposi-like hemangioendothelioma or tufted angioma. Kaposi-like hemangioendothelioma must be distinguished from infantile hemangioma, which disappears spontaneously.[282,283] These are alarming hemangiomas with life-threatening lesions (mediastinum, lower extremities, abdomen), either because of compression or secondary to a thrombocytic coagulopathy or high-output cardiac failure. Cavernous hemangiomas can be located in the epidural space and cause spinal cord compression. Surgical resection is the standard treatment.[284]

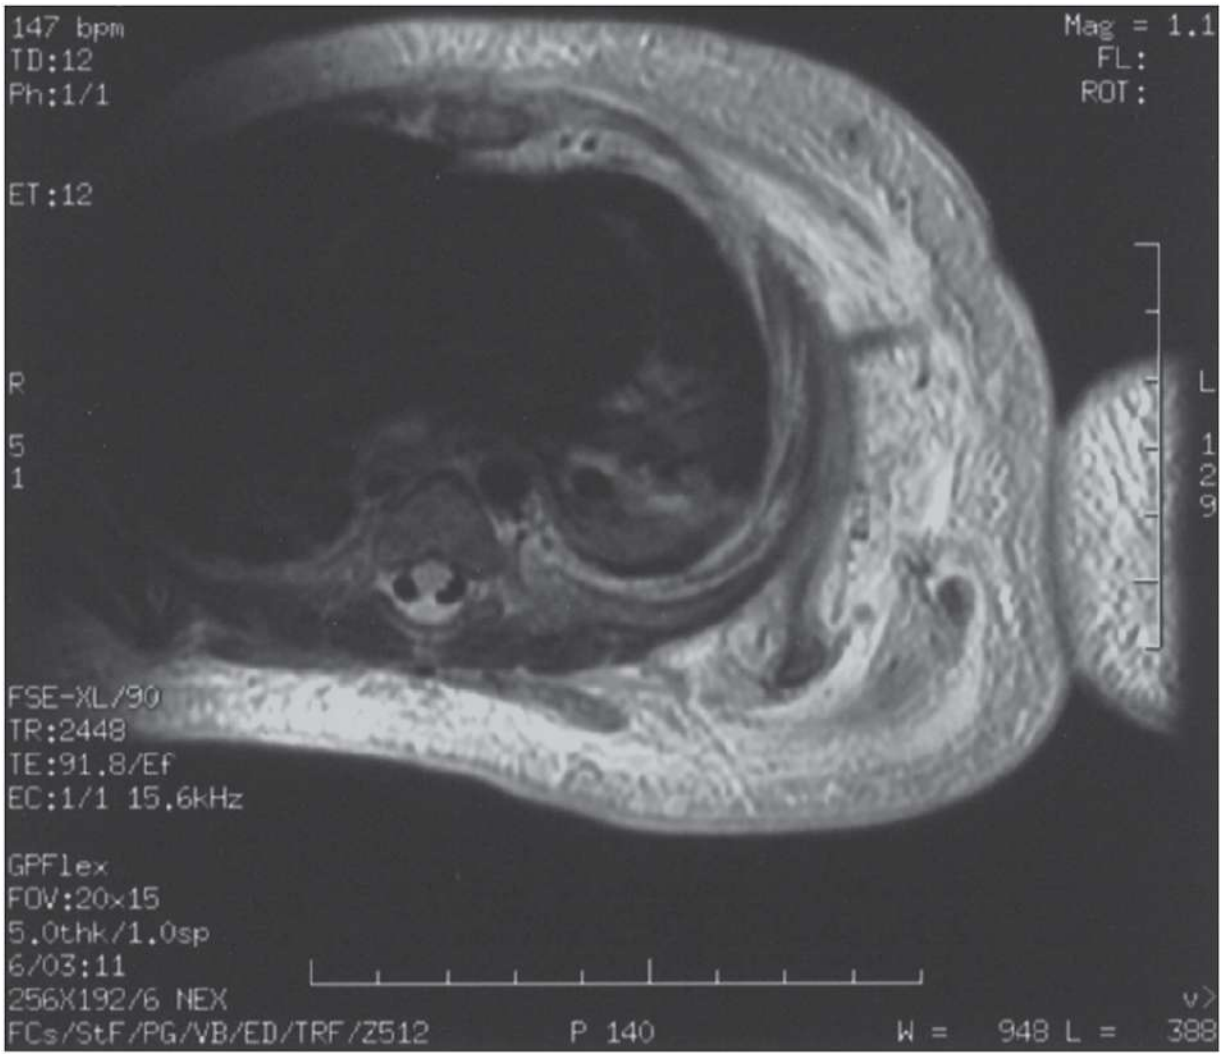

FIGURE 99.4 Kasabach-Merritt syndrome. Massive left hemithorax infiltration and involvement of the left arm.

Radiotherapy is used in a rare setting for unresectable cases and should be considered very cautiously because of its late effects. A dose of 10 Gy in 10 fractions can be given; it is not mandatory to encompass the whole hemangioma in the target volume.[285,286]

Lymphangiomas

Histologically, lymphangiomas are a benign proliferation of lymph vessels. Four types are recognized: capillary lymphangiomas, cavernous lymphangiomas, cystic hygromas, and hemangiolymphangioma. Surgery is the treatment of choice.

Special attention must be given to the Gorham syndrome, also known as the bone-vanishing syndrome or massive osteolysis of bone.[287] Gorham syndrome is a bone hamartoma with various percentages of lymphangioma and hemangioma, characterized by well-margined osteolytic scattered lesions that progressively affect the cortex, with no respect for joint boundaries (Figure 99.5). All bones can be affected (vertebrae, ribs, scapula). Progression is unpredictable, from spontaneous remission to bone absorption and sometimes even death. The prognosis is very poor when pleural or visceral involvement develops. Some encouraging results have been reported using antiresorptive therapy such as calcitonin or biphosphonates.[288] Although RT is the last resort for the patient, encouraging results have been reported for patients with chylothorax and in patients with rib, thorax, and vertebral body involvement. The usual dose is approximately 18 Gy to the hemithorax. Affected bones have been treated to approximately 40 Gy with good response.[289]

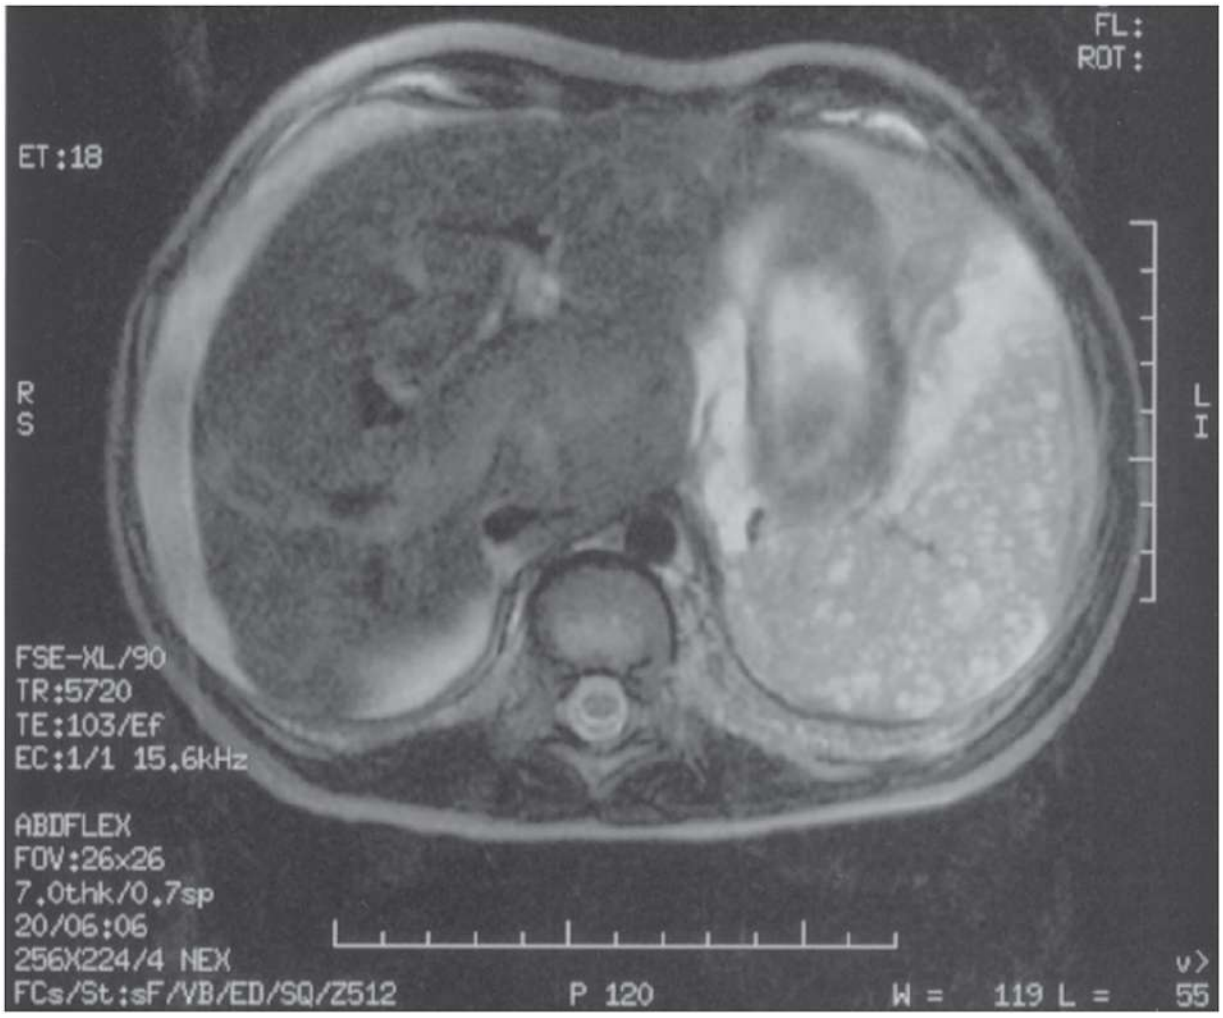

FIGURE 99.5 Gorham disease in a 3-year-old girl. Diffuse lymphangiomatosis affecting pelvic bones, ribs, spleen, and liver.

DESMOPLASTIC SMALL ROUND CELL TUMOR

Desmoplastic small round cell tumor (DSRCT) was first described in 1989.[290] It is a rare aggressive neoplasm with typical clinical, histologic, karyotypic, and biologic characteristics. DSRCT mainly affects male adolescents and young adults, but it sometimes occurs in young females. Clinically, patients present with a bulky abdominal or pelvic mass, but intracranial, testicular, renal soft tissue, and bone DSRCTs have also been described.[291-294]

The tumor is characterized by a desmoplastic stroma with circumscribed tumor cells and encased nests of primitive undifferentiated cells. The

tumoral cells express epithelial (keratin, EMA), conjunctival (vimentin), muscular (desmin), and neuroendocrinal markers.

Reciprocal translocation (11:22) (p13:q12) has been described, which results from a fusion between the terminal part of the Ewing sarcoma gene and the carboxy terminus part of the Wilms tumor gene (WT1).[295]

The DSRCTs are highly chemosensitive, but the prognosis is still poor. Kretschmar et al[296] reviewed 101 cases of DSRCT: after 2 years, only two patients were still alive, and the median survival was 17 months. Newer agents including tyrosine kinase inhibitors, mTOR inhibitors, immune checkpoint inhibitors, and others are being explored.

The treatment approach for DSRCT is largely multimodality therapy including intensive chemotherapy even including high-dose chemotherapy with stem cell transplant, debulking surgery, and adjuvant radiotherapy. This disease often presents with intraperitoneal implants, and imaging studies, whether CT or MRI, typically underestimate the extent of disease found during surgery.[297] Patients are treated with upfront chemotherapy followed by aggressive surgical excision. Following maximal excision, patients are then treated with adjuvant whole abdominal irradiation to 30 Gy and treatment to 54 to 55.8 Gy for residual gross disease. One alternative to the use of whole abdominal irradiation is the use of hyperthermic intraperitoneal chemotherapy, and some studies have tried to combine the two therapies.[297]

NONMELANOMA SKIN CANCER

Basal and squamous cell carcinomas are rare in children and adolescents. When they occur in the pediatric and adolescent age groups, there is usually an underlying predisposing genetic disorder, such as basal cell nevus syndrome (BCNS) or Gorlin-Goltz syndrome and XP. Basal and squamous carcinomas have also been reported to arise in nevus sebaceous[298] and after radiation for benign or malignant conditions.[299,300]

BCNS or Gorlin-Goltz syndrome[301] is an autosomal dominant disorder with variable penetrance characterized by a “coarse face” with hypertelorism and frontal bossing, multiple basal cell carcinomas presenting at a young age, pits on the palms and soles, skeletal abnormalities (eg, bifid ribs, hemivertebrae, fusion of vertebral bodies), jaw cysts, epidermic cysts

and hamartomas, oculoneurologic abnormalities, and ectopic calcification of the falx cerebri and other structures. Skin lesions located in the head and neck tend to invade the deep structures. Several patients with BCNS were reported to have developed medulloblastoma at early childhood and ovarian fibromas.[138,301-305]

Mutation of the human homologue of the *Drosophila*-patched (PTC) gene is considered the molecular defect in BCNS.[306] The Gorlin-Goltz syndrome is a unique example of the genetic-environmental interaction for the production of malignancies: children treated for medulloblastoma by craniospinal irradiation developed multiple skin cancers in the irradiated area, an unusual and special illustration of multihit mutagenesis, suggesting that RT should probably be omitted or limited in children with BCNS.[307]

XP is an extremely rare, autosomal recessive inherited disease characterized by abnormal pigmentation and a greater than 1,000-fold increase in nonmelanoma skin cancer (basal cell carcinoma and squamous cell carcinoma) on sun-exposed skin. Patients with XP are also at a significant risk of developing melanoma.[307,308] Neurologic abnormalities such as areflexia and mental retardation are sometimes associated with XP.

The genetic abnormality underlying XP leads to defects in nucleotide excision repair of ultraviolet-induced DNA damage.[307,309,310]

Skin cancer in affected children is treated by standard techniques (such as surgery, cryosurgery, and chemosurgery). There should not be any contraindication to using RT to treat skin cancer or any other malignancy in patients with XP because ionizing radiation damage is normally repaired in these patients.[311]

MALIGNANT MELANOMA

Childhood melanoma can present in an atypical manner that does not fit the traditional clinical findings for adult melanoma: **a**symmetry, irregular **b**orders, **c**olor variation, **d**iameter greater than 6 mm, and lesion evolution. For these reasons, it can sometimes delay diagnosis. Sometimes childhood melanoma is associated with large congenital nevocytic nevi, dysplastic nevus syndrome, immunosuppression, transplacental malignant melanoma, and XP. Pediatric malignant melanoma should be distinguished from

juvenile melanoma or Spitz nevus characterized by a relatively benign course and long-term survival.[312-314]

The management of childhood melanoma follows the guidelines set for adult patients.[315] The prognosis is related to the Breslow or Clark thickness of the primary lesion and nodal status. Chemotherapy regimens usually have poor activity against melanoma in adults. However, St. Jude Children's Research Hospital (SJCRH) reported a complete or partial response in 8 of 18 (44%) pediatric patients receiving cyclophosphamide, vincristine, and dacarbazine.[316] Immunotherapy has been explored with promising results. Given the favorable results with the use of interferon α-2b in adults, 15 patients younger than 18 years of age with Stage III melanoma, defined as having a primary tumor thickness greater than 4 mm or having lymph node or in-transit metastases, were included in an SJCRH feasibility study.[317] Another group from Toronto used the high-dose interferon in children with metastatic disease.[318] Most of the patients in both studies did complete their therapy with some alterations in dosage because of toxicity. Intergroup Study of Cancer and Leukemia Group B, Children's Oncology Group, Eastern Cooperative Oncology Group, and Southwest Oncology Group (S0008) studied the role of biochemotherapy, which provided statistically significant improvement in recurrence-free survival (RFS) but no difference in patients with OS with high-risk melanoma.[319] Targeted therapies, such as BRAF and MEK inhibitors that are approved for the treatment of patients with advanced melanoma who harbor *BRAF* V600E mutation–positive tumors, result in a significant survival advantage compared to chemotherapy.[320]

Drugs blocking immune checkpoints, such as cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) and the programmed cell death protein 1 (PD-1), have been used to enhance antitumor immunity and have become the standard of care.[321,322] Overall, the pediatric age group represented a very small proportion of patients studied for systemic therapy. Therefore, treatment plans for children are mainly extrapolated from adult studies.

Radiotherapy has a role mainly in the palliation of metastatic disease or in locally advanced lesions. Again, data here should extrapolate from the adult literature; however, high-dose per fraction regimens will need to be evaluated with caution because of toxicity concerns.

PART N

Benign Diseases

CHAPTER 100

Nonmalignant Diseases

Simon A. Brown, Jerry J. Jaboin, Tony Y. Eng, Jose Bazan, and Charles R. Thomas, Jr

Benign diseases generally include a class of localized tumors or growths that have a low potential for progression and do not invade surrounding tissue or metastasize to distant sites. Pathologically, they are composed of well-differentiated cells that are considered nonmalignant and usually do not require any treatment. However, clinically, not all benign diseases have benign consequences. Some untreated benign diseases can produce bothersome mass or secretory effects. Others can be locally aggressive and cause secondary debilitating symptoms. For example, Graves ophthalmopathy (GO) can lead to local pain and visual impairment without therapeutic intervention,[1] a hormonally active pituitary adenoma may cause growth abnormality in addition to blindness,[2] and desmoid tumors can be locally persistent after surgical resection and grow uncontrollably similar to their malignant counterparts.[3]

Documented empirical use of radiation in imaging and the treatment of benign diseases or conditions occurred soon after the discovery of x-rays by Wilhelm Röntgen in 1895.[4] Between 1920 and 1960, over a million Americans, mostly young adults and children, received x-ray treatments to the head and neck region for benign conditions.[5] The efficacy of painless x-ray treatment led to the treatment of many benign conditions with radiation: acne, body hair, scalp ringworm, enlarged tonsils, enlarged thymus, enlarged neck lymph nodes, whooping cough, and others. Radiation therapy

(RT) was used in some instances due to a lack of effective alternative therapies.

Over the past decades, advances in medical and surgical therapies have provided new treatment options for many diseases. With improved awareness of late radiation sequelae on normal tissue, particularly radiation carcinogenesis, the use of RT for the treatment of benign conditions has gradually declined. However, with modern RT techniques and a better understanding of radiobiology, judicial use of radiation provides good local control with minimal toxicity and relief of associated symptoms.

THE HISTORIOGRAPHY OF THE RADIATION THERAPY OF NONMALIGNANT DISEASES

From the dawn of RT, in the late 19th and early 20th centuries, ionizing radiation was used in all manner of malignant and nonmalignant diseases. The early textbooks of RT are filled with case descriptions and photographs of these attempts.

In the English-language literature, three textbooks of the past 60 years are particularly deserving of note in this field. The first was by a radiologist practicing at the Hunterdon Regional Medical Center in Flemington, Stephen B. Dewing. His textbook, *Radiotherapy of Benign Disease* (Charles C. Thomas, Publisher; 1965), is beautifully written with clear and thoughtful prose and is awash with commonsense advice. As a largely single-author book, Dr Dewing's voice is clearly present.

Twenty-five years later, a book of tabulations of the use of RT for benign disease with brief summary paragraphs was published. Stanley E. Order and Sarah S. Donaldson's *Radiation Therapy of Benign Diseases*: *A Clinical Guide* (Springer-Verlag; 1990) explained to its readers what was available from single case reports and small clinical series to inform practice.

Eighteen years later, the magisterial book edited by M.H. Seegenschmiedt, H.-B. Makoski, K.-R. Trott, and L.W. Brady was published. *Radiotherapy for Non-Malignant Disorders; Contemporary Concepts and Clinical Results* (Springer; 2008) comprehensively reviewed the available literature, compared and contrasted experiences from different countries, and put in perspective what was known and what was not known and the state-of-knowledge of mechanisms of actions.

If available from used booksellers, all three books merit a place on the bookshelf of interested radiation oncologists. The Order and Donaldson book has appeared in a subsequent edition.

THE INFLUENCE OF NATIONAL CONTEXT ON PATTERNS OF PRACTICE

A distinctive feature of RT use for nonmalignant disease is the substantial influence of the country of practice on treatment patterns. If one reviews the literature for the treatment of adult bronchogenic carcinoma or childhood medulloblastoma, one may find differences in the nuances of RT dose or the sequencing of surgery, RT, and chemotherapy, but the basic principles of treatment remain broadly consistent across economically developed nations.

In contrast, the willingness to employ RT for nonmalignant disease varies significantly depending on national context. Utilization is more common in Eastern and Central Europe, declines in Western Europe (including the United Kingdom and Ireland), and is used sparingly in North America.

In the United States, although some practitioners advocate for an expanded role of RT in nonmalignant disease—and occasionally frame this as a "resurgence"—this overlooks the long history of such applications, which extends over a century. Hesitancy among American and Canadian radiation oncologists is shaped by concerns regarding the strength of supporting evidence, reliance on retrospective clinical series rather than prospective randomized trials, and the potential for late toxicities, including secondary malignancies. As Leer and colleagues noted in their international survey, concerns have also been raised that efforts to secure reimbursement may, in some cases, have outpaced the generation of rigorous clinical data evaluating safety and efficacy.[6]

RADIOBIOLOGIC EFFECTS ON BENIGN DISEASES

The precise radiobiologic mechanisms of radiation effects on benign diseases are not well defined. Radiation is believed to work through complex multicellular interactions that affect different cell types in our body system.[7,8] Specific cellular and functional mechanisms depend on the specific disease and site. Although most benign lesions have no known stimuli or causes, some benign lesions may be triggered by trauma, as seen

in keloid formation after body piercing or heterotopic bone formation after surgery. In conditions that arise following trauma, local inflammation and repair occur, often characterized by excess stimulation of growth factors and accelerated cellular proliferation. For example, in the development of keloids, fibroblast proliferation is responsible for most of the hyperproliferative process. Even with the lower doses commonly used in benign diseases, RT is clinically effective in inhibiting cell proliferation and suppressing cell differentiation without inducing cell death as is typically seen with tumoricidal doses of radiation. Yet, radiation can induce apoptosis in selected target cells by influencing the expression of cytokines in macrophages, leukocytes, endothelial cells, and other cells, thereby modulating the inflammatory cascade.

Among the major sites of radiation effects are the blood vessels; vascular endothelial cells respond rapidly to radiation damage by upregulating the cytokine-mediated cellular reactions responsible for inflammatory tissue response. Low-dose irradiation (total dose <12 Gy using #1.0 Gy per fraction) exerts anti-inflammatory effects on the endothelial cells of capillaries and mononuclear cells of the immune system.[9]

Cell adhesion molecules, including selectins, are mobilized to the cell membrane and disrupt capillary permeability, allowing the inflammatory cells (lymphocytes, macrophages, monocytes) to migrate into the interstitial space. The anti-inflammatory effect is attributed to the modulation of cytokine and adhesion molecule expression on the activated endothelial cells and leukocytes. These cells are known to be radiosensitive. They express pro-inflammatory cytokines (eg, interleukin-1 [IL-1], IL-6) or necrosis factors (eg, tumor necrosis factor-α [TNF-α]) that influence the complement cascade and inflammatory reaction. IL-1 stimulates the production and release of pro-inflammatory prostaglandins, leading to a change in the synthesis of inducible nitric oxide synthetase.

The radiation-induced modulation of nitric oxide production and oxidative burst in activated macrophages and native granulocytes leads to modification of the immune response, inflammatory process, and clinical analgesic effects.[10] Although endothelial cells possess a high proliferative potential and are sensitive to radiation damage at high doses, they are not prone to rapid mitotic radiation death at low doses.

Chronic inflammatory processes are triggered by antigen-antibody reactions and mediated by mononuclear peripheral blood cells in the immune system. Ionizing radiation helps suppress some of the cell populations, such as T lymphocytes, in the inflammation process or modulate their effects. While low doses of radiation can exert an anti-inflammatory response, high doses of radiation as used in malignant tumors can elicit pro-inflammatory effects and fibrotic change in normal tissue.[11] At higher single or total doses, endothelial cell damage can lead to sclerosis and obliteration of blood vessels. In vascular disorders such as hemangiomas or arteriovenous malformations (AVMs), high radiation doses may induce occlusion of pathologic vessels. In addition to inhibition of cell proliferation, cell killing may play a part in the management of benign meningiomas, pituitary adenomas, or neuromas where higher, tumoricidal doses of radiation may be required. In summary, the normal balance within the inflammatory and proliferative milieu, when altered, can result in the growth of benign lesions, which may or may not become clinical entities that require intervention.

RISK OF SECOND MALIGNANCIES

The induction of cancer or genetic defects by radiation exposure is attributed to stochastic effects where there is no absolute threshold level of radiation exposure below which cancer induction or genetic effects will not occur. Increasing the radiation dose or the volume of exposure will increase the probability that a cancer or genetic effect may eventually occur with long enough follow-up. Sometimes, the effects of radiation are difficult to separate from the inherent genetic effects. For example, in patients with retinoblastoma, the *Rb1* gene plays an important role in developing radiation-induced sarcomas.[12,13] In a study of 384 patients with retinoblastoma treated with radiation, the actuarial risk for developing sarcoma in the treatment field 18 years after treatment was 6.6%.[12] In another study of 693 patients, the cumulative risk for any sarcoma 50 years after RT was 13.1%.[13] Although most sarcomas were within the irradiated fields, 18 out of 69 sarcomas developed outside the treatment fields. Rb1 mutations appear to confer a genetic predisposition to developing sarcomas, especially after radiation exposure.

The risk of the induction of secondary tumors was overestimated in the past.[14] More recently, Trott and Kamprad used the epidemiologic data from long-term follow-up studies on patients treated with RT for benign diseases to estimate the risk of cancer induction.[15] Taking all known modifying and organ-specific factors into account, including radiation doses and volume irradiation, the estimated absolute lifetime risk for sarcoma induction was less than 0.0001% for 1 Gy and a 100-cm^2 field. Table 100.1 lists the absolute lifetime risk for other malignancies.

TABLE 100.1 THE ESTIMATED ABSOLUTE LIFETIME RISK FOR MALIGNANCIES AFTER RADIATION THERAPY FOR BENIGN DISEASES

Types	Absolute Lifetime Risk
Skin (basal cell carcinoma)	0.1% for 100-cm^2 field
Osteosarcoma	< 0.0001% for 1 Gy and a 100-cm^2 field
Leukemia	1% for 1 Gy TBI
Brain tumor	0.2% after 20 Gy for endocrine orbitopathy
Thyroid carcinoma	1% per Gy for children < 10 y
Breast carcinoma	5% for one breast, 1 Gy, age < 35 (<3% for age 35-45)
Lung carcinoma	1%. within 25 y after a mean lung dose of 1 Gy

TBI, total body irradiation.

Jansen et al applied the effective dose concept and estimated the carcinogenic risk in patients after RT of benign diseases (heterotopic ossification [HO], omarthritis, gonarthrosis, heel spurs, and hidradenitis suppurativa).[16] Special risk-modifying factors, including age at exposure and gender, were taken into account. For an average-aged population, the estimated number of radiation-induced fatal tumors was between 0.5 and 40 persons per 1,000 patients treated. The range of effective doses was also found to be large (5-400 mSv). In addition to age and gender, the individual risk also depended on individual inherent sensitivity, anatomic site, type of disease, and treatment technique, such as dose and fractionation. The International Commission on Radiological Protection estimates that cancer incidence due to ionizing radiation increases linearly and is about 5.5% per Sv.[17] Thus, for a patient exposed to 20 mSv—the typical limit for radiation

workers per year—irradiation increases the lifetime cancer risk by about $0.020 \times 5.5\ Sv^{-1} = 0.1\%$.[8]

INDICATIONS FOR RADIOTHERAPY

Most benign diseases can be classified as inflammatory, degenerative, hyperproliferative, or functional. Therefore, therapeutic approaches vary widely due to the paucity of well-controlled prospective therapeutic clinical trials. Radiation treatment of benign diseases is less commonly used in the United States than in some other parts of the world, where variation in indications and treatment schedules is institutionally based.[18] Within Germany, a pattern of care study revealed significant geographic and institutional differences.[19] Most radiation treatments for benign diseases are delivered in the low-dose range (<10-15 Gy).

Degenerative processes in tendons, ligaments, and joints can cause pain by chronic inflammation and trigger secondary functional impairment of the involved musculoskeletal system. Although radiation does not halt the degenerative process, it may reduce inflammation and provide partial or complete pain relief. This clinical effect is well established in reports of osteoarthritis (OA), synovitis, and bursitis, where low-dose RT has improved the function of affected joints.[19,20]

Benign diseases may have a significant effect on self-image and self-esteem because of cosmetic appearance (eg, facial keloids, juvenile angiofibroma) or a lasting impact on quality of life (QoL) because of chronic pain or other secondary symptoms (eg, heterotopic bone, macular degeneration). When benign diseases become locally invasive with aggressive growth, therapeutic intervention can prevent or limit functional loss of organs. In rare cases of large hemangiomas with associated thrombocytopenia and consumption coagulopathy (Kasabach-Merritt syndrome), potentially fatal complications can occur, and timely therapeutic intervention can be lifesaving.[21]

Although there is a lack of an international consensus, the German Working Group on Radiotherapy of Benign Diseases published its consensus guidelines for RT of nonmalignant diseases. The guidelines were to serve as a starting point for quality assessment, prospective clinical trials, and outcomes research.[8,20,22-24] In brief, treatment is indicated when benign

diseases are symptomatic or potentially symptomatic. When other methods are unavailable or have failed, RT should be considered. As medical professionals, we remain mindful of therapeutic gain and potential treatment side effects and complications. A thorough risk-benefit analysis is always pertinent. Organ-specific acute and chronic toxicities, including potential effects on fertility and induction of secondary tumors in the future, must be explained to and discussed with patients, especially those who are young and have a long life expectancy. Informed consent that is required for all medical interventions is certainly required for the treatment of benign diseases and should be obtained prior to the delivery of RT.

The current chapter covers some of the more common benign conditions that we encounter in the practice of radiation oncology. Details on the therapeutic approaches and data on radiation dose regimens for different benign diseases are summarized in the individual corresponding sections.

BENIGN NEOPLASMS OF THE BRAIN, HEAD, AND NECK

Nonmalignant tumors of the central nervous system and neck can lead to severe, life-threatening symptoms due to pressure and mass effect on critical structures from tumor growth. However, depending on growth rate and location, the surrounding tissue may adapt leading to a delay in the clinical diagnosis.

The role of RT in the following nonmalignant tumors of the brain, head, and neck is addressed in the following chapters:

Meningioma: Chapters 40

Pituitary adenoma: Chapters 41

Craniopharyngioma: Chapters 40 and, briefly, in Chapters 41

Vestibular schwannoma (acoustic neuroma): Chapters 16 and 40

Chordoma: Chapters 54

Glomus tumor/chemodectoma/paraganglioma: Chapters 54

Juvenile nasopharyngeal angiofibroma: Chapters 54

Langerhans Cell Histiocytosis (Histiocytosis-X)

Background and Clinical Aspects

Langerhans cell histiocytosis (LCH) is a rare disorder that affects approximately 300 individuals with a higher incidence in children (3-5 per million) than adults (1-2 per million). Age is an important prognostic factor, with children having better outcomes than adults. In the past, it was felt that children younger than 2 years were felt to have a poor prognosis, but recent data from the LCH-II study now refute that point.[25]

The disease is due to an accumulation and/or proliferation of cells that phenotypically resemble the Langerhans skin cell and can cause tissue damage by the production of cytokines and infiltration. The actual Langerhans cell is a myeloid dendritic cell that expresses the same antigens (CD1a and CD207) as the Langerhans skin cell.[26] On electron microscopy, Birbeck granules are the classic finding.

LCH encompasses a spectrum of diseases with varying clinical presentations. The most common form is called eosinophilic granuloma, which typically affects bones, most commonly the skull, long bones, and spine. Other forms include Hand-Schüller-Christian disease (involving multiple organs) and Letterer-Siwe disease (a severe multisystem form that is more common in infants). Patients are typically stratified into groups based on the extent of disease: single-system disease at a single site, single-system disease involving multiple sites, or multisystem disease. The clinical presentation is dependent upon the sites of the disease. Involvement of the skeletal system is the most common site for children and may manifest as pain, palpable mass, motion deficit, or chronic otitis in the case of mastoid or middle ear involvement. Bony lesions from LCH are predominantly lytic in appearance, and the skull is the most frequently involved bony structure.

Cutaneous involvement affects primarily the skin of the scalp and groin and resembles a seborrheic dermatitis. Patients with cranial involvement (posterior pituitary or hypothalamus) may present with diabetes insipidus (DI). The disease may also involve the cervical lymph nodes. Pulmonary involvement is more typically seen in adults. Hepatomegaly, splenomegaly, bone marrow infiltration, and involvement of the gastrointestinal tract are further potential sites of disease.

Evaluation of a patient suspected of having LCH involves a complete history and physical examination, including routine laboratory work such as complete blood count with differential. The biopsy of affected tissues, such as bone, skin, or lymph nodes, is often necessary to identify the

characteristic Langerhans cells and confirm the diagnosis, including determination of druggable mutations. In addition, imaging studies like x-rays, computed tomography (CT) scans, or magnetic resonance imaging (MRI) are performed to assess the extent and location of the disease (Figure 100.1). Patients with symptoms of DI should undergo a water restriction test, while a skeletal survey with or without a bone scan is useful for assessing potential lytic lesions. For patients with skull, orbital, or mastoid involvement, CT of the head is recommended, and MRI of the head is indicated for those with DI or suspected brain parenchymal disease involvement. In cases of pulmonary involvement, a CT of the chest is performed, and an MRI of the abdomen is conducted for patients with palpable hepatomegaly or splenomegaly. Overall, the diagnosis of LCH relies on a combination of clinical, radiologic, and pathologic findings to accurately identify and characterize the disease.

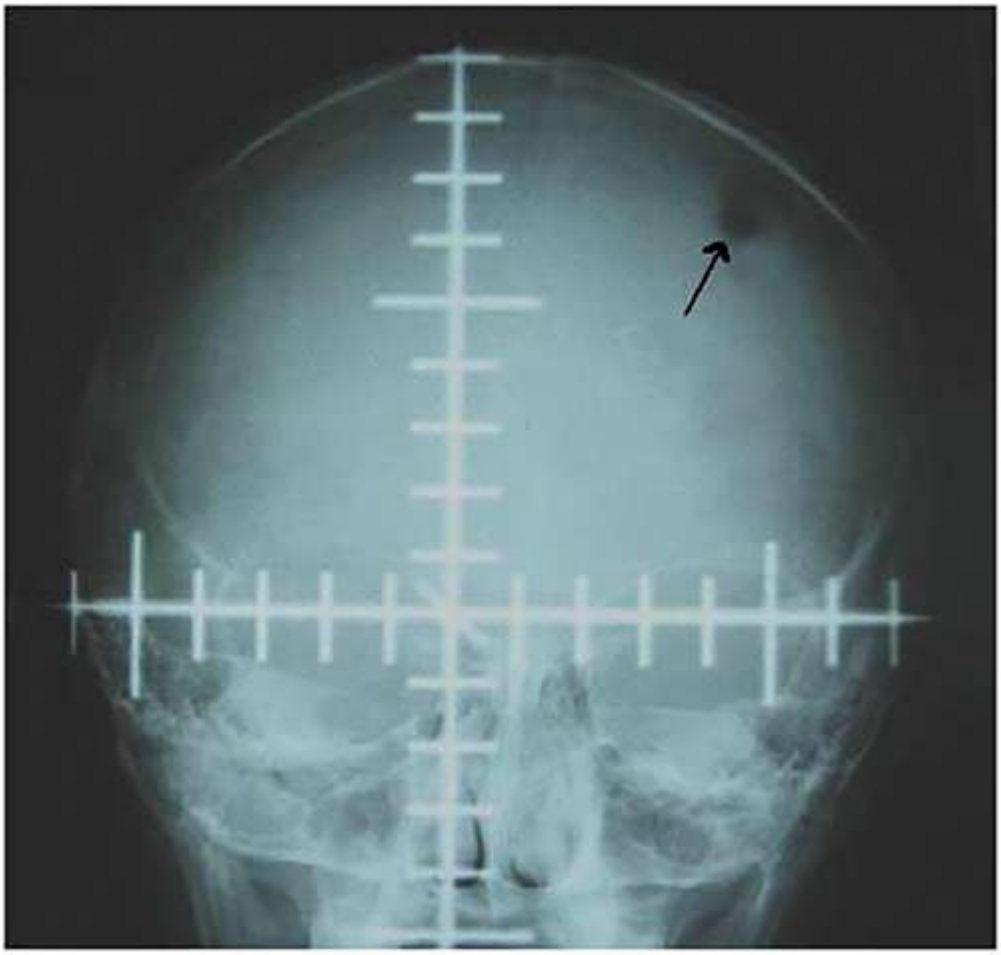

FIGURE 100.1 A typical punched-out skull lesion in a 10-year-old boy with histiocytosis. (Reprinted from Eng TY, Abugideiri M, Chen TW, et al. Radiation therapy for benign disease: arteriovenous malformations, desmoid tumor, dupuytren contracture, graves ophthalmopathy, gynecomastia, heterotopic ossification, histiocytosis. *Hematol Oncol Clin North Am*. 2020;34[1]:205-227. Copyright © 2019 Elsevier. With permission.)

Surgery

Surgery plays a limited role in the treatment of LCH. It is primarily used in specific situations where there is a localized and accessible lesion that can be surgically removed. Asymptomatic lesions may be observed. Treatment options include curettage, excision, or intralesional steroid injection for patients with a single bone lesion or a soft tissue mass that can be excised without causing significant functional or cosmetic impairment. The goal is to completely remove the affected tissue to achieve local disease control. Response rates with curettage or excision alone range from 70% to 90%.[27] It is important to note that surgery alone is not considered curative for LCH.

Due to the systemic nature of the disease and the potential for involvement of multiple organs, a comprehensive treatment approach is necessary.

Systemic Therapy

Single-system multifocal bone disease may be effectively treated with corticosteroids or chemotherapy, such as vinblastine. For skin-only disease, topical nitrogen mustard and methotrexate are considered effective treatments. For patients with multisystem disease with symptoms (fever, pain, failure to thrive) or organ dysfunction, treatment with systemic therapy is indicated. In LCH-II, a study conducted on patients with LCH, all participants initially received treatment with prednisone and vinblastine. They were then randomly assigned to receive additional intensification with or without etoposide. The group that received intensification showed superior rapid response rates and decreased mortality rates compared to the standard arm.[25,28]

For children with DI, exogenous antidiuretic hormone (ADH) (vasopressin) is used as a treatment. Overall, the treatment approach for LCH involves a combination of therapies tailored to the individual patient, which may include chemotherapy (such as vinblastine and steroids), targeted therapies (such as BRAF inhibitors for patients with specific mutations), and immunotherapy.

Radiation Therapy

RT is a safe and effective measure for providing symptom palliation and local control of LCH involving the bone.[29] However, due to the excellent response rates to nonradiotherapeutic measures, the role of RT in the treatment of LCH bony lesions has decreased. Indications for RT to bony sites include relapse after surgery, no signs of clinical healing after other interventions, pain relief, potential compromise of critical structures from an expansile lesion (ie, cord compression), or if the bony site is not amenable to other local therapies. Collapsed vertebral lesions should not be irradiated unless they are painful. Controversy still remains regarding the role of RT in the management of DI. In a retrospective series from MGH, 14 of 17 patients with DI received irradiation to the hypothalamic-pituitary axis.[30] Only two of these patients had a complete response (cessation of

ADH therapy), and no patients had a partial response. When the decision is made to treat, three-dimensional (3D) RT should be the technique of choice.

The target volume for patients with bony disease should encompass the abnormality seen on imaging with a small margin. For children, low doses on the order of 5 to 10 Gy given in 1.5 to 2 Gy daily fractions should be sufficient to control most bony lesions. Higher doses can be used in adults. In a study of 80 patients irradiated up-front or as salvage therapy with a median total dose of 15 Gy, 77% achieved a complete remission and 12.5% achieved a partial remission. The long-term control rate was 80%.[31] The University of California, Los Angeles found local control rates of 88%, with doses ranging from 6 to 15 Gy for previously untreated lesions and 8 to 15 Gy for recurrent lesions.[32]

The target volume for patients receiving treatment for DI should encompass the hypothalamus and pituitary gland. The recommended prescribed dose is 15 Gy in 1.5-Gy daily fractions. In a report from the Mayo Clinic, 36% of 28 evaluable patients responded to RT.[33] The response rates were 60% (3/5 patients) in those treated with more than 15 Gy compared to 30% (7/23 patients) treated with doses of less than 15 Gy. Six patients had a complete response to therapy, five of whom received treatment within 14 days from diagnosis of DI.

VASCULAR DISORDERS

Vascular disorders are broadly categorized into vascular tumors, most commonly benign hemangiomas, and vascular malformations, including AVMs and cavernous hemangiomas. Radiosurgery has emerged as an important and common treatment option for AVMs. While radiation was used commonly in the past to treat hemangiomas in children, the recognition of late effects associated with RT, especially secondary malignancies, has rendered this practice less common.

AVMs are covered later, and hemangioma/Kasabach- Merritt syndrome is addressed in Chapters 99.

Arteriovenous Malformations

Background and Clinical Aspects

Intracranial AVMs are congenital vessel abnormalities consisting of conglomerations of dilated arteries and veins with a resultant lack of a normal capillary bed. The nidus is a tangle of vessels connected by one to several fistulas with a risk of rupture. The overall prevalence is low, affecting approximately 18 in 100,000 individuals, with the age at presentation typically between 20 and 40 years.

Clinical concern comes from the high risk of bleeding, estimated to be 2% to 4% per year. Approximately 50% of patients present with hemorrhage and 50% present with nonfocal (headache, nausea) symptoms or incidentally found focal neurologic deficits. The risk of death per bleed is up to 10%, and approximately 30% have serious morbidity associated with each bleed.

Diagnostic imaging includes angiography, which is invasive but allows for full grading of the AVM according to the Spetzler-Martin scale,[34] which is predictive of hemorrhage risk. MRI, MR angiography, and CT angiography are noninvasive, and complementary studies may be used to visualize the AVM.[34]

Surveillance

A randomized trial of unruptured brain AVMs entitled the ARUBA trial was performed to help determine the role of surgical intervention versus medical management. Two hundred twenty-three patients were available for outcome analysis at the time the cohort reached 33 months of follow-up. The risk of death and stroke was significantly lower in the medical management group (hazard ratio [HR]: 0.27, confidence interval [CI], 0.14-0.54).[35] The findings have been controversial, as there have been concerns about halting of the trial early, small patient numbers, and nonstandard treatment approaches. However, it stands as the largest trial of its kind in this space.

Surgical Management

The goal of any therapy for AVM is to completely obliterate the nidus to decrease the cumulative bleeding risk. Complete microsurgical excision provides immediate cure but carries a risk of intraoperative bleeding, ischemic cerebrovascular accident, infection, and death. Surgery is

particularly indicated for AVMs in superficial, noneloquent regions of the brain. Endovascular therapy (embolization) is typically not curative but is frequently used to decrease the risk of intraoperative bleeding.[36] The best success of monotherapy with embolization is in small AVMs with a single draining vein.[37] There is a theoretically increased risk of hemorrhage or neurologic complication postembolization, and increasingly very selective embolizations are being performed to mitigate risk. Historically, embolization has been performed to decrease the size of the nidus before planned RT, but there have been data suggesting that preradiosurgery embolization negatively impacts the obliteration rate.[38,39]

Radiation Therapy

Stereotactic radiosurgery (SRS) is the radiation modality of choice for the treatment of AVMs. SRS is indicated mostly for lesions in deep or eloquent regions of the brain and is particularly safe and successful for lesions that are less than 3 cm. Unlike surgery, the time to obliteration ranges from 1 to 4 years after SRS, so the patient remains at a continued bleeding risk. Even with time, Maruyama et al demonstrated that the bleeding risk is not completely eliminated but reduced by approximately 88%.[40] Overall, the obliteration rate is 80% by 3 years for lesions that are 3 cm or smaller. For larger lesions, the angiographic obliteration for large AVMs is significantly reduced, with a mean approximating 66%.[41]

Based on the Flickinger dose-response data, typical prescriptions for the treatment of AVM are 21 to 22 Gy prescribed to the 50% isodose line (IDL) for frame-based radiosurgery (Table 100.2).[42] The prescription should be lowered for AVMs near the brain stem or larger lesions (> 3 cm). For Linac-based SRS, prescriptions generally range from 16 to 24 Gy in a single fraction to 20 to 22 Gy in two fractions for spinal AVMs (Figure 100.2).[43]

TABLE 100.2 FLICKINGER PREDICTED RATES OF IN-FIELD AVM OBLITERATION BASED ON THE MINIMUM DOSE WITHIN THE TARGET VOLUME

Minimum Dose to Target (Gy)	Predicted AVM Obliteration Rate (%)
27	99

AVM, arteriovenous malformation.

Adapted from Flickinger JC, Pollock BE, Kondziolka D, Lunsford LD. A dose-response analysis of arteriovenous malformation obliteration after radiosurgery. *Int J Radiat Oncol Biol Phys*. 1996;36(4):873-879. Copyright © 1996 Elsevier. With permission.

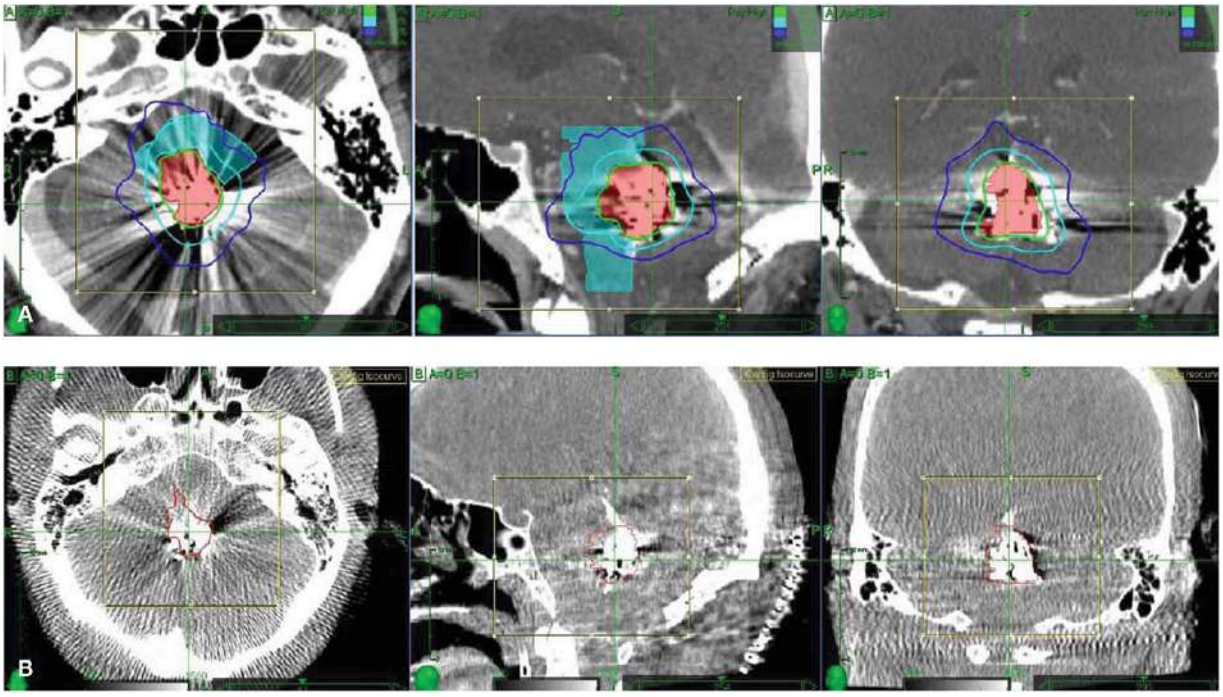

FIGURE 100.2 A. Stereotactic radiosurgery plan for an arteriovenous malformation (AVM) (red) in the dorsal pons treated with 22 Gy in two fractions. The prominent streak artifacts are present because of embolization 1 year prior to treatment. B. Computed tomographic angiogram of the same patient used to assist in defining the AVM nidus (red contour).

Finding the best approach for the management of large AVMs is ongoing. Over the past decade, hypofractionated, dose-staging, and volume-staging treatment schemas have all been attempted, and there are data suggesting that volume-staging approaches can yield the highest obliteration rates among these approaches. Treatment of less than 10-mL sections of the nidus volumes in 3- to 6-month periods has shown 5-year obliteration rates

between 35% and 58% and 10-year rates between 75% and 80% far outpacing the obliteration rates of the other two approaches.[44,45]

FUNCTIONAL DISORDERS

SRS is widely used for the treatment of benign tumors. However, a significant number of patients benefit from the use of SRS to treat functional disorders, such as trigeminal neuralgia (TN), tremors, and epilepsy. Over the past several years, there have been increasing reports of the use of SRS for the treatment of refractory psychiatric disorders, including obsessive-compulsive disorder (OCD) and major depressive disorder.

Trigeminal Neuralgia (Tic Douloureux)

Background and Clinical Aspects

TN is a common problem that affects approximately 15,000 patients each year in the United States, with a slight female predominance (1.5:1). The disorder is currently classified into type I and type II TN, which is based on pain characteristics, as opposed to the traditional classification system that divided patients into idiopathic TN versus secondary TN.[46-48] The classic form of the disease, type I TN, is described as sudden shocks of sharp, lancinating facial pain lasting anywhere from a few seconds to minutes with pain-free intervals. Patients with type II TN predominantly experience constant burning, aching, or throbbing pain, generally of lower intensity.[49] This system also carries prognostic significance, with patients with type I TN more likely to be pain free and have longer disease control than patients with type II TN after decompression.[46] Compression of the TN by an artery or vein within a few millimeters from the root entry zone is believed to account for more than 80% of cases, while the remainder can include benign tumors, cysts, or, rarely, a vascular malformation.[50-52] In addition, multiple sclerosis has also been associated with TN, though demyelination, plaques, and even vascular compression have been observed in these patients.[53,54]

The classic clinical feature is recurrent episodes of sudden, brief, severe, stabbing, or lancinating pain in the area of the trigeminal nerve sensory

distribution. It is most commonly unilateral, but some cases are bilateral. Common triggers for attacks include talking, chewing, brushing teeth, and cold air. The diagnosis is often suspected on the basis of the abovementioned clinical symptoms, but an MRI of the brain should be performed to rule out structural abnormalities that may be causing secondary TN.

Systemic Therapy

TN is first treated with pharmacotherapy, with carbamazepine being the most common and extensively studied agent. Oxcarbazepine is an option for patients who are unable to tolerate carbamazepine. Numerous other agents have been used to treat carbamazepine-refractory patients, including lamotrigine, neurontin, pimozide, tizanidine, and topiramate. Carbamazepine has been demonstrated to have complete or near-complete pain relief in 58% to 100% of patients in early clinical trials, and a more than 50% decrease in attacks achieved by more than 88% of patients. Those of East Asian and South Asian descent should be tested for the *HLA-B*15:02* allele as both carbamazepine and oxcarbazepine should be avoided unless benefits clearly outweigh the increased risk of developing Stevens-Johnson and/or toxic epidermal necrolysis.

Surgical Management

In patients who have medically refractory disease, microvascular decompression is the treatment of choice for immediate relief of symptoms. Pain relief is attained in 90% of patients and declines to 80%, 75%, and 73% by years 1, 2, and 5, respectively. This has the longest duration of pain control in surgical procedures.[51] Other options include rhizotomy with either radiofrequency ablation, glycerol injection, or balloon compression.

Radiation Therapy

SRS has emerged as a successful and minimally invasive procedure to treat classic TN. Treatment planning involves the fusion of a contrast-enhanced MRI with less than 1-mm axial sequences to the treatment planning CT scan. The target for SRS varies along the track of the trigeminal nerve. Potential targets described in the literature include the anatomic emergence

of the trigeminal nerve from the pons—proximal dorsal root entry zone (DREZ), the prepontine cistern slightly anterior of the DREZ—retrogasserian target, and the semilunar ganglion.[55-63] Typical doses using a frame-based radiosurgery platform range from 70 to 90 Gy prescribed to an isodose range from 50% to 100%, with prioritization of low doses to the brainstem for minimal toxicity. This dose range is largely based on a composite of trials originating from Kondziolka et al who prospectively assigned patients to low-dose (60-65 Gy) or high-dose (70-90 Gy) SRS and demonstrated higher rates of pain relief in the high-dose arm (72% vs 9% for patients treated with ≥70 vs <70 Gy).[57,63]

The durability of treatment and time to response depend on the dose distribution. The median time to treatment response varies from 2 to 4 months, with higher doses yielding better treatment response but increased chances of sensory neuropathy (facial numbness).[49,64-66] Flickinger et al prospectively randomized patients to 75 Gy targeted to a shorter (one isocenter) or longer (two isocenters) segment of the trigeminal nerve, demonstrating that treating larger segments of the nerve with higher doses is associated with delayed onset of facial numbness.[67] Although the rates of pain relief were surprisingly identical between the two groups, there was a trend toward a higher incidence of numbness or paresthesias in the two-isocenter patients, and overall, the nerve length irradiated was significantly correlated with the development of numbness and paresthesias. However, in a report by Adler et al, 46 patients received treatment with a frameless robotic radiosurgery platform to a 6-mm segment of the trigeminal nerve, with a mean marginal prescription dose of 58.3 Gy and mean maximal dose of 73.5 Gy.[68] In this cohort of patients, 85% experienced a complete response; and at a mean follow-up of 15 months, 96% reported excellent or good outcomes. Only 15% of patients experienced ipsilateral facial numbness.[69]

Epilepsy

Background and Clinical Aspects

Epilepsy is a disorder characterized by recurring seizures. It affects 0.5% to 1% of the population, and its etiology is unknown in most cases. The clinical presentation of patients with seizures is broad, depending on the

type of seizure and the area of the brain involved. Seizures are generally classified into simple versus complex (loss of consciousness) and generalized versus partial (affecting only one focus in the brain).

Systemic Therapy

Antiepileptic drugs are the treatment of choice for patients with epilepsy, and about half of those with a new diagnosis will become seizure free with their first prescription.[70] Therapy is typically not given until patients have had two or more unprovoked seizures, and generally, treatment is begun as monotherapy at lower doses that are slowly titrated up to a level of seizure freedom. Drug choice is based on several factors, including, not limited to, tolerability, comorbid conditions, factors affecting drug clearance or metabolism, cost/availability, and age. Furthermore, combination therapy for the management of intractable seizure activity is often employed when seizure freedom has not been achieved.

Surgical Management

Surgery is an option for patients who develop medically refractory disease.[71,72] Candidates for surgical management of seizure activity require delineation of a focal epileptogenic zone in which surgery can be performed that will not injure an eloquent brain region. Mesial temporal lobe epilepsy is generally the most common remediable and generally involves resection of the anterior temporal lobe (ATL) or selective amygdalohippocampectomy (SAH). There are no high-quality data comparing SAH and ATL, but they seem to have similar seizure control outcomes, approximating 50% to 60% 1 year rare to seizure-free outcomes.[73]

Radiation Therapy

SRS may be an alternative to surgery in medically refractory epilepsy for patients who are not surgical candidates. In a multi-institutional study, Regis et al treated 20 patients with SRS for intractable mesial temporal lobe epilepsy.[74] The mesial temporal lobe was treated to a dose of 24 to 25 Gy in a single fraction with Gamma Knife. At a follow-up of 2 years, 65% of the patients were seizure free. However, there was a 1-year lag between

treatment and maximal effect, and there was a transient increase in seizures before the seizures started to diminish. In a study by Barbaro et al, 30 patients were randomized to low-dose (20 Gy) or high-dose (24 Gy) radiosurgery targeting the amygdala, hippocampus, and parahippocampal gyrus.[75] At 3 years, the seizure-free rate was 67% among all patients, with a trend toward a higher response rate (77% vs 59%) and earlier response in the high-dose group. No serious toxicity was reported in the study.

The randomized controlled ROSE trial was a multi- national, randomized, single-blinded, controlled trial comparing radiosurgery (SRS, 24 Gy to the 50% IDL) versus open surgery (ATL) for mesial temporal epilepsy. The findings suggested that ATL had an advantage over SRS in 3-year seizure remission (78% vs 58%), with seizure remission taking 1 to 2 years and with a similar impact on memory and language outcomes. Unfortunately, the study was severely limited by patient numbers, only accruing 58 of the 234 cases needed to determine noninferiority.[76] In evaluating these outcomes in the context of the data, radiosurgery is a reasonable tool in the armamentarium for drug-resistant epilepsy.

Parkinson Disease

Background and Clinical Aspects

Parkinson disease (PD) results from the loss of dopaminergic neurons in the substantia nigra. It is a debilitating and progressive neurodegenerative disorder that affects approximately 1 million people in the United States. The hallmark clinical symptoms include masked facies, resting tremor, slow movements, shuffling gait, and muscle rigidity. Some patients also develop dementia as part of the disorder.

Systemic Therapy

Pharmacotherapy with dopamine agonists and other compounds is the treatment of choice for patients with PD. Most patients use levodopa (usually in the form of carbidopa-levodopa [Sinemet]) as initial therapy and with high efficacy and the lowest need to add on a secondary therapy as compared to other drugs.[77-79] Device-assisted therapies are available for continuous infusion approaches for medically refractory cases. The best studied are the continuous levodopa-carbidopa intestinal gel and the

continuous subcutaneous apomorphine infusion. These are not widely available currently. In addition, there is a positive clinical trial supporting the use of continuous subcutaneous foslevodopa-foscarbidopa.[79]

Surgical Management

Once refractory to medical therapy, surgery may be used to remove the overactive brain nuclei. Ideally, MRI-guided focused ultrasound (FUS) pallidotomy for those with motor fluctuations or dyskinesias favoring one side. For medication-refractory tremors, MRI-guided FUS thalamotomy is used.

Deep brain stimulation (DBS) is the most common invasive procedure used in medically refractory PD. The primary targets for DBS are the subthalamic nucleus, the internal globus pallidus (GPi), and the ventral intermedius nucleus (VIM). DBS of the VIM is only effective for tremor, while the other targets can impact bradykinesia and motor fluctuations as well. DBS has been effective in providing an improvement in motor movement and QoL as compared to the best medical therapy with 4 to 5 hours per day mean improvement in time without troubling dyskinesia.[80]

Radiation Therapy

Patients who are poor candidates for surgery may receive SRS for the treatment of medically refractory PD. To relieve tremor, the target is the nucleus intermedius (thalamotomy) with a dose in the range of 120 to 180 Gy. Evidence demonstrates long-term success rates of 80% to 90% in relieving symptoms from PD tremor, as well as essential and other types of tremors with a very low rate of permanent complications.[81-86]

Although radiosurgery has proven beneficial for tremors, mixed results have been found with regard to the treatment of PD-related akinesia/dyskinesia/rigidity. Treatment entails targeting the GPi (pallidotomy) with doses in the range of 120 to 180 Gy. Rand et al reported that four of eight patients received relief in rigidity with no serious complications.[87] However, Friedman et al achieved a response in only one of four patients, and dementia and psychosis developed in the only patient responder.[88] Young et al[89] treated 29 patients with SRS pallidotomy, with an

80% success rate at a mean follow-up of 2 years and only one (3.4%) complication at 9 months (homonymous hemianopia).

Psychiatric Disorders

Background and Clinical Aspects

Psychiatric disorders such as OCD, bipolar disorder, major depressive disorder, and subgroups of autism with pathologic aggression are debilitating illnesses. Radiosurgery has been used for the treatment of some of these psychiatric illnesses, with the majority of experience in patients with OCD. OCD is characterized by intrusive thoughts (obsessions) that lead to repetitive behaviors (compulsions).

Systemic Therapy

The combination of pharmacotherapy (ie, selective serotonin reuptake inhibitors) and behavioral therapy is the treatment of choice for patients with mood disorders and OCD. Surgical management and DBS are used for extreme and severe cases.

Radiation Therapy

Patient selection for the use of SRS to treat psychiatric disorders is complex. Friehs et al recommend that such patients must be enrolled on an institutional protocol after careful evaluation by a multidisciplinary team.[90] Similar strict criteria were used by Kondziolka et al.[91]

The treatment of OCD involves targeting the bilateral anterior capsules to a total dose of 120 to 140 Gy (Figure 100.3). Kondziolka et al delivered a maximum dose of 140 or 150 Gy to the anterior limb of the internal capsule in three patients.[91] At a minimum follow-up of 28 months, all patients noted significant functional improvements with no treatment-related complications. In a pilot study by Lopes et al, five patients were treated with SRS to a maximum dose of 180 Gy to the anterior limb of the internal capsule.[92] At 3 years, three patients had a complete response to treatment and one patient had a partial response based on changes in scores on an OCD assessment tool. Based on these findings, the group has opened a double-blind, randomized controlled study on the use of SRS to treat refractory OCD.[92]

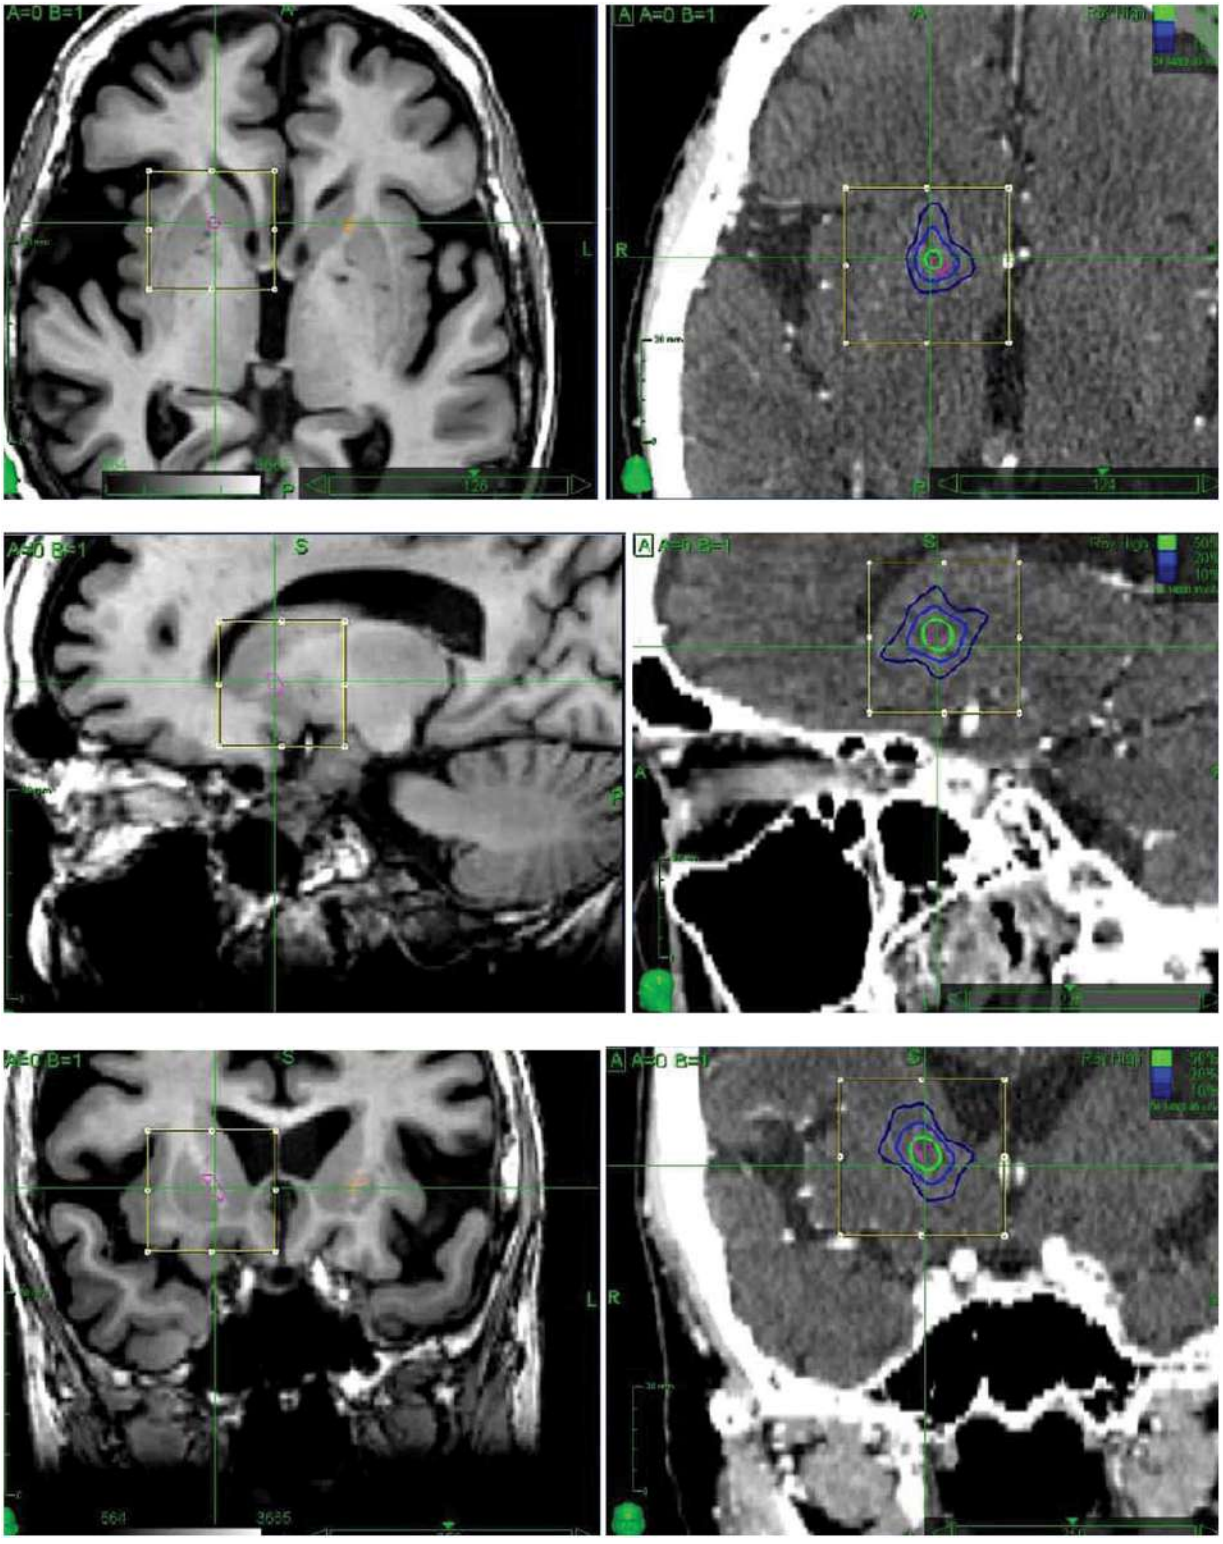

FIGURE 100.3 Stereotactic magnetic resonance imaging sequences (left) demonstrating the contoured anterior limbs of the internal capsule bilaterally and the corresponding treatment plan (right) for the right internal capsule for a patient with refractory obsessive-

compulsive disorder. The right internal capsule was prescribed 70 Gy to the 50% isodose line (140 Gy maximum dose) in a single fraction.

Radiosurgical capsulotomy in the same manner has been used to treat refractory depression (Figure 100.3). Findings include significant improvement in depression burden, decreased need for electroconvulsive therapy, decreased need for ketamine therapy, and decreased suicidal ideation with no reported neurologic decline or toxicity.[93,94]

In a small series from the Hospital Ruber in Spain, 10 patients with autism spectrum disorder with either pathologic aggression, dyscontrol, or activity of daily living–limiting OCD underwent SRS, with a significant improvement in behavior, symptoms, and QoL, though in 8 of 10 patients, there was a need for repeat treatment.[95]

While the efficacy of radiosurgery for movement disorders or severe pain has a reasonably clearly defined end point, radiosurgery for psychiatric disorders often does not, and there is, of course, a very troublesome history of the use of surgical interventions for psychiatric disease, particularly the use of frontal lobotomies. Before this area of clinical practice would be considered within the standard of care, rigorous investigations of the highest standards are called for at selected academic centers by multidisciplinary teams capable of conducting such work.

Cardiac Arrhythmias

Over the past 10 years, there has been an increasing interest in the use of RT for patients with refractory cardiac arrhythmias, now commonly known as stereotactic arrhythmia radioablation (STAR). There have now been several prospective clinical trials evaluating the use of STAR for patients with refractory ventricular arrhythmias, including ventricular tachycardia (VT) and ventricular fibrillation (VF). There are limited human studies regarding the role of STAR for atrial fibrillation (AF) perhaps in large part due to the fact that AF is a benign arrhythmia whereas refractory VT/VF are life-threatening.[96] In this regard, any studies of STAR for AF need to primarily focus on safety, both short term and long term, while efficacy end points are appropriate for patients with VT/VF as these patients have

limited treatment options and life expectancy. Herein, we focus on the use of STAR for ventricular arrhythmias.

VT is a life-threatening form of structural heart disease that occurs when there is electric reentry in areas of myocardial fibrosis, and the main treatment is with invasive catheter procedural techniques to find the areas of fibrosis with abnormal electrical activity and then apply thermal-ablative energy to these areas.[97,98] Since these invasive procedures may take several hours and require anesthesia often in patients with numerous comorbidities, STAR emerged as a potential noninvasive alternative. While the goal of STAR is similar to that of catheter ablation procedures in that the goal is to target surviving myocytes within the areas of myocardial fibrosis, the exact mechanism of action of STAR is not yet known.

To date, numerous small prospective studies and/or case series have evaluated the use of STAR for VT, with sample sizes ranging from 5 to 19 patients.[99-105] The largest series by Robinson et al. evaluated the safety and efficacy of STAR in 19 patients with refractory VT and found a reduction in VT or premature ventricular contractions in 94% of the evaluable patients (17/18).[104] A 2023 study from the Netherlands, termed the *STAR-NL1 study*, was the first prospective trial evaluating the use of STAR for VT in Europe.[105] In this study of six patients, STAR resulted in a 50% or more reduction in VT episodes in four of the six patients with a simultaneous tapering off of antiarrhythmic medications. The Europeans have formed a consortium of 31 clinical and research institutions as a large research network to systemically investigate the use of STAR for VT, with a goal of enrolling over 300 patients into the STAR treatment registry over the study period.[106]

The most common dose and fractionation is 25 Gy in a single fraction to the well-defined target. The definition of the target requires close collaboration with cardiology and requires various imaging studies as described by Robinson et al., including a cardiac CT scan, cardiac MRI, cardiac single-photon emission CT, 12-lead electrocardiogram during VT, and electrocardiographic imaging.[104] While the treatment appears to be well tolerated, several complications of STAR have been published, including one case of worsening mitral regurgitation,[103] one case of acute pericarditis,[104] two cases of delayed pericardial effusions,[104] one case of fatal gastropericardial fistula,[104] and two cases of radiation pneumonitis.[102] These

potential complications underscore the importance of selecting patients who have no or few alternatives for the treatment of recurrent VT and also emphasize why the use of STAR for benign arrhythmias, such as AF, should be limited to prospective protocols.

In summary, STAR is emerging as a potential noninvasive alternative to catheter ablation in select patients with refractory VT supported by a small, but growing body of literature. Well-designed, careful randomized trials are needed to help determine the true efficacy and toxicity of STAR.

Sialorrhea

Background and Clinical Aspects

Sialorrhea, from excess saliva production or inadequate saliva clearance, affects up to 80% of patients with PD and approximately 30% of patients with amyotrophic lateral sclerosis (ALS). The neurodegenerative process of ALS affects upper motor neurons of the anterior horn of the spinal cord with bulbar involvement seen in the later stages of the disease. A pseudobulbar palsy resulting in dysphagia and inability to control swallowing causes drooling and subsequent facial and skin irritation. Furthermore, the use of noninvasive ventilation, which has been shown to increase life expectancy and QoL for patients with ALS, is limited due to the risk of choking and pulmonary aspiration.[107]

Systemic Therapy

Medical management is not always effective and can come with side effects that have the potential to further complicate an already progressively debilitating disease state. Treatment consists of postural changes, repetitive swallowing, suctioning, botulism injections, surgery, and/or radiation.[108]

Anticholinergic drugs are the primary medications deployed in the management of sialorrhea. Scopolamine patches are thought to be the most effective and well-tolerated anticholinergic drugs in the management of sialorrhea. Oral anticholinergics are often discontinued due to systemic side effects, such as sedation and delirium. Glycopyrrolate has been shown to have a more favorable toxicity profile regarding central side effects and can also be administered subcutaneously.[107,109]

Botulism can be injected into the submandibular or parotid glands under ultrasound guidance. Because the duration of effect can range from 3 to 7 months, repeat injections are often necessary.[109]

Radiation Therapy

Electron-based and photon therapy are both techniques employed in delivering RT for sialorrhea. Photon therapy is typically delivered with parallel-opposed radiation targeting the inferior two-thirds of the bilateral parotids and the entire bilateral submandibular glands. Most common electron field arrangements target the entire bilateral submandibular and parotid glands. The durability of the treatment effect is variable, but the side effects of treatment are characteristic of patients receiving head and neck radiation. Guy et al compared the two treatment techniques and demonstrated longer durability and less acute toxicity (oral pain and mucositis) among patients treated with electron therapy.[110] A systematic review demonstrated median time to symptomatic improvement was 2 months, with efficacy ranging from 3 months to over 5 years.[108] Optimal treatment is likely a 3D conformal plan with a combination of mixed photon-electron beams using an oral cavity avoidance to minimize toxicity. Assouline et al treated 50 patients with a regimen of 20 Gy in four fractions or 10 Gy in two fractions, with 92% of patients achieving a complete response with no difference in toxicity.[111] In this cohort of patients, eight of nine patients treated with the lower dose regimen required a second RT course.

DISEASES OF THE EYE AND ORBIT

Ptyergium is addressed in Chapters 22 and 44.

Choroidal hemangioma is addressed in Chapters 44.

Reactive lymphoid hyperplasia/orbital pseudotumor is addressed in Chapters 44.

Age-Related Macular Degeneration

Background and Clinical Aspects

Age-related macular degeneration (AMD) is a progressive eye condition that affects the macula and is the leading cause of blindness in the developed world.[112] The development of AMD is dependent on age, with a prevalence of up to 35% in the eighth decade of life. AMD can be classified into two main types. The more common form is dry AMD, which accounts for about 80% to 90% of cases. It is characterized by the gradual thinning and breakdown of the macula over time. In this type, small yellow deposits called drusen may accumulate in the macula, affecting its function (Figure 100.4). On the other hand, wet AMD, although less common, is more severe and accounts for about 10% to 20% of cases. It involves the growth of abnormal blood vessels beneath the macula, which can leak fluid and blood, resulting in rapid and significant vision loss. AMD risk factors include age, genetics, smoking, race (more common in Caucasians), cardiovascular disease, and unhealthy lifestyle factors, such as obesity and poor diet. In the early stages, AMD may not exhibit noticeable symptoms. However, as the condition advances, individuals may experience distorted or impaired central vision. Reading and tasks requiring fine vision may become challenging. Color perception may decrease, and sensitivity to glare can increase. In addition, dark or empty areas may appear in the central vision.

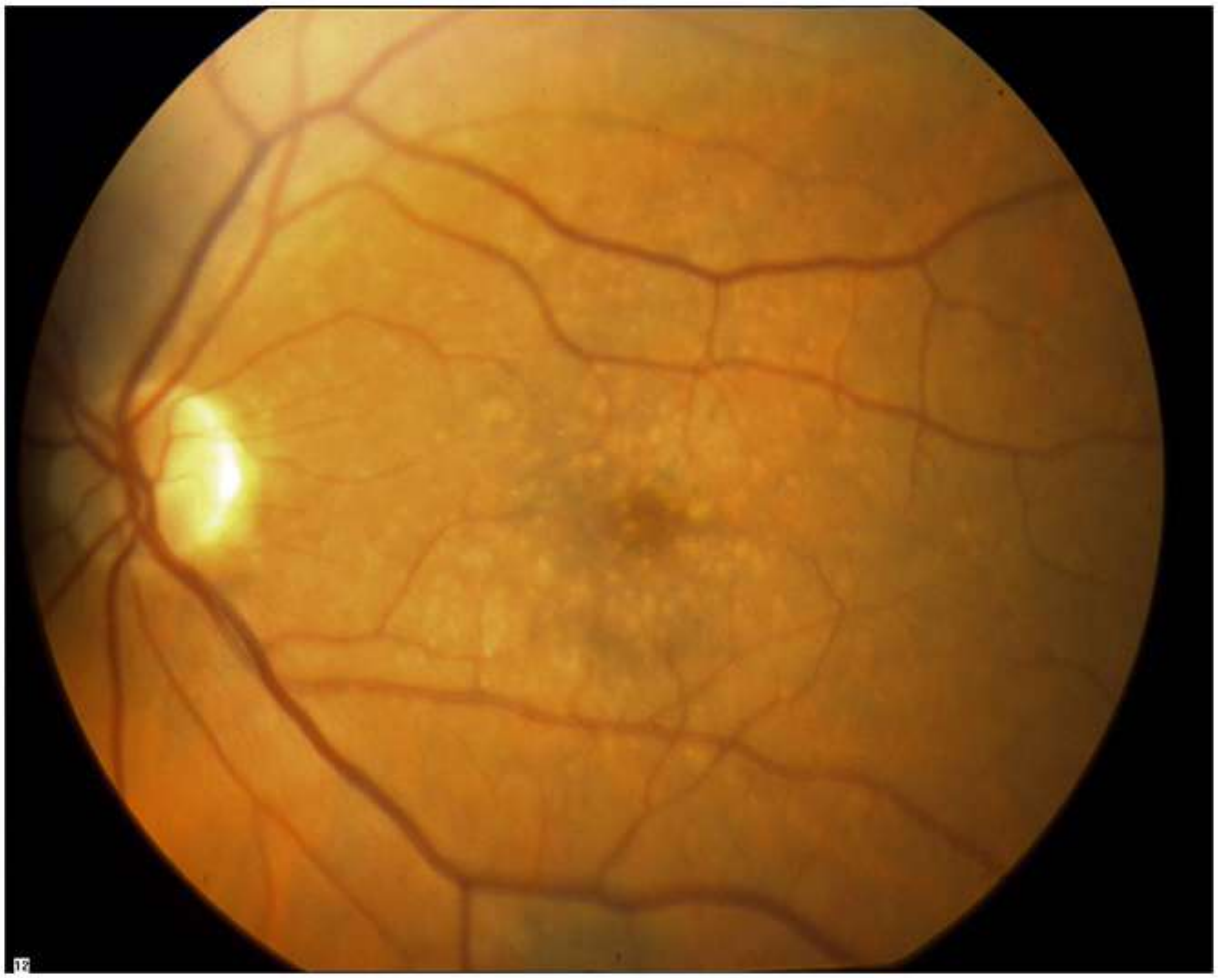

FIGURE 100.4 Macular degeneration with atrophic-appearing macula and surrounding drusen. (Reprinted from Eng TY, Abugideiri M, Chen TW, et al. Radiation therapy for benign disease: keloids, macular degeneration, orbital pseudotumor, pterygium, Peyronie disease, trigeminal neuralgia. *Hematol Oncol Clin North Am*. 2020;34[1]:229-251. Copyright © 2019 Elsevier. With permission.)

Management Overview

While there is currently no cure for AMD, treatment options are available to slow its progression and manage its effects, particularly for wet AMD. Intravitreal injections of anti-vascular endothelial growth factor (VEGF) medications can reduce abnormal blood vessel growth and leakage in wet AMD, stabilizing or improving vision.[113] In certain cases of wet AMD, vascular-targeted photodynamic therapy can selectively destroy abnormal blood vessels using a light-activated drug combined with laser therapy.[114]

External beam RT (EBRT) with photons or protons and brachytherapy have been used in the past to treat macular degeneration. Overall, the results

of RT in the management of this disease have been mixed. Most studies took place before the routine use of anti-VEGF and before the development of modern RT techniques, such as stereotactic radiation therapy (SRT).[115] A Cochrane meta-analysis in 2010 analyzed 14 randomized trials utilizing RT as a treatment for AMD and concluded that the review "does not provide convincing evidence that RT is an effective treatment for neovascular AMD."[116]

However, there is renewed interest in RT for AMD based on the results of the RT in Conjunction with Anti-VEGF Treatment for Patients with Wet AMD trial.[117] In this study, 230 participants who had received at least three injections with anti-VEGF therapy were randomized to 16 Gy, 24 Gy, or sham SRT. The primary end point was the mean number of pro re nata (PRN) intravitreal ranibizumab injections over 52 weeks. With 2 years of follow-up, patients who received 16 or 24 Gy had fewer PRN treatments compared to the sham SRT group. SRT was found to induce microvascular change, but this affected vision in only 1% of patients.[118] This trial supports SRT as a potential method to stop or slow down the visual loss associated with continued intravitreal injections of anti-VEGF therapy.

Graves Ophthalmopathy

Background and Clinical Aspects

GO (also referred to as Graves orbitopathy, thyroid eye disease, Basedow disease, or Parry disease) is an autoimmune disorder affecting the musculature of the orbits. It is commonly associated with an overactive thyroid (hyperthyroidism). The presence of activated T lymphocytes leads to an inflammatory reaction secondary to the release of cytokines. It is estimated that up to 50% of patients with Graves disease will develop orbitopathy, but 10% of patients are euthyroid and some are hypothyroid at presentation.[1] Smoking is the greatest risk factor for the development of GO and also predicts a poorer response to therapy.

A multidisciplinary team including an ophthalmologist, endocrinologist, and radiation oncologist should be involved in the evaluation of the patient with GO. Clinical features of patients with GO include proptosis (measured by the Hertel exophthalmometer on physical examination), photophobia, upper eyelid retraction, periorbital edema (due to the accumulation of

collagen and hyaluronin, which attract water), conjunctival erythema, tearing, and visual impairment (Figure 100.5). Patients may complain of a "gritty" sensation in their eyes. Several classification systems are available to document the extent of disease, including SPECS Ophthalmic Index (Table 100.3), which assigns a score of 1 to 3 on the basis of six categories: ***S***oft tissue involvement, ***P***roptosis, ***E***xtraocular movements, ***C***orneal involvement, and ***S***ight (visual acuity).

TABLE 100.3 SPECS CLASSIFICATION SYSTEM FOR GRAVES OPHTHALMOPATHY

Clinical Feature	Grade 1 (1 Point)	Grade 2 (2 Points)	Grade 3 (3 Points)
S (soft tissue involvement)	Minimal objective symptoms: redness, chemosis, slight periorbital edema	Moderate objective symptoms: redness, chemosis; moderate periorbital edema	Severe objective symptoms: conjunctival exposition, prominent periorbital edema
P (proptosis)	>20-23 mm	24-27 mm	>27 mm
E (eye muscle dysfunction)	Rare diplopia; none in primary position	Frequent diplopia; moderate mobility impairment	Severe constant muscular dysfunction
C (corneal involvement)	Slight corneal changes and no symptoms	Prominent corneal changes and moderate symptoms	Keratitis or other severe eye symptoms
S (sight loss)	20/25-20/40	20/45-20/100	>20/100

SPECS, ***S***oft tissue involvement, ***P***roptosis, ***E***xtraocular movements, ***C***orneal involvement, and ***S***ight (visual acuity).

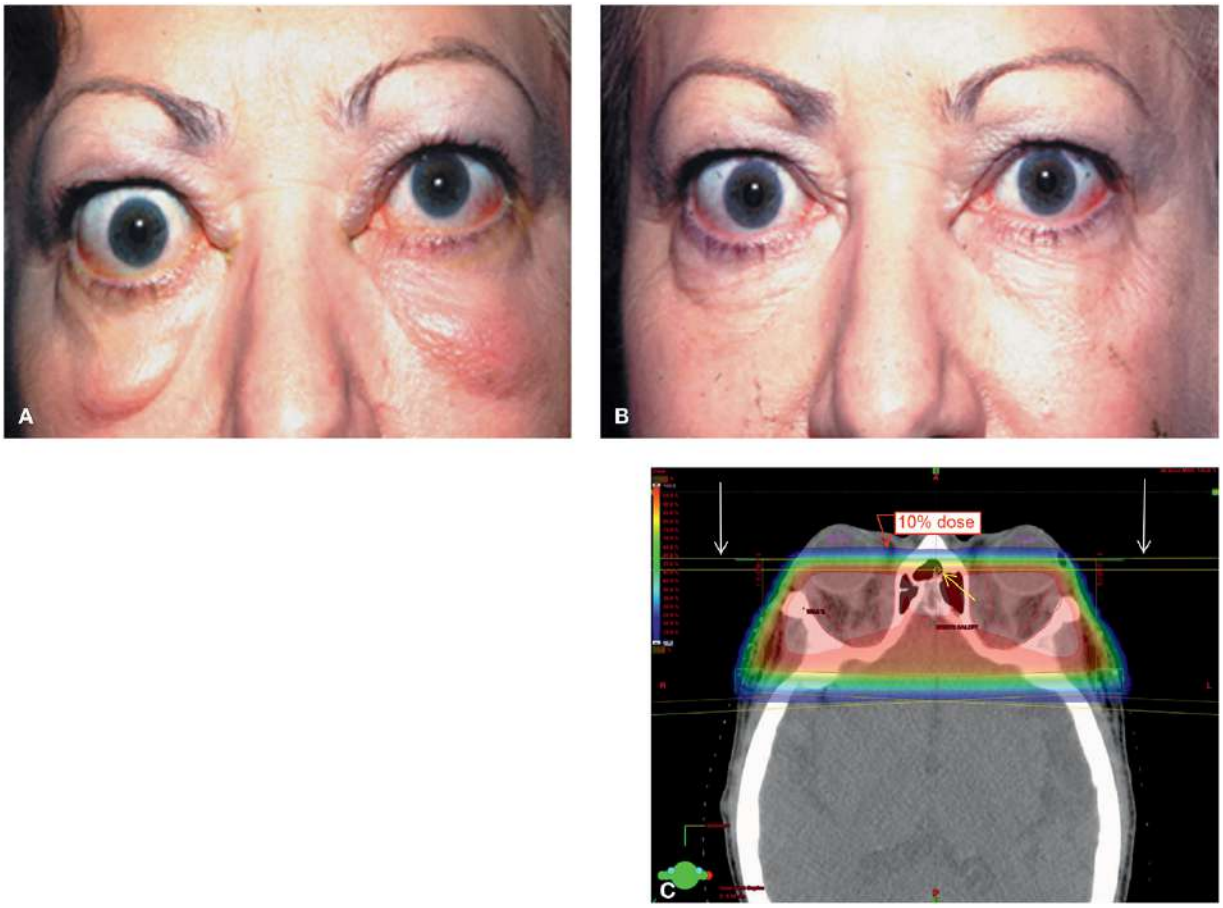

FIGURE 100.5 A 50-year-old woman with Graves ophthalmopathy before (A) and after (B) treatment with corticosteroids and radiotherapy for prominent eyelid edema and strabismus. C. Three-dimensional conformal radiotherapy treatment plan for a patient with Graves ophthalmopathy. The isocenter (yellow arrow) is placed a few mm posterior to the lenses (magenta), and the opposing fields are beam split anteriorly (white arrows). The extraocular muscles are contoured in red. The color wash display demonstrates that <10% of the dose reaches the lens.

Imaging studies, such as CT or MRI, will demonstrate abnormalities, including enlargement of the extraocular muscles and fatty infiltration, in 70% to 80% of cases.[1] The most commonly involved muscles include the inferior and medial rectus muscles.[118]

Management Overview

Treatment options for GO include glucocorticoids (GCs), orbital RT, and surgery (orbital decompression, eye muscle surgery, eyelid surgery). Smokers should be encouraged to quit. Prior to the initiation of treatment, the patient's thyroid function should be normalized. Radioiodine therapy,

but not antithyroid drugs, may cause worsening of GO, especially in smokers.[119,120] Once thyroid function is stabilized, the treatment of GO depends upon the severity of the disease.

Systemic Therapy

GCs are a mainstay of treatment for GO. Immediate treatment with high-dose steroids (intravenous [IV] or oral) is required for patients whose vision is threatened by optic neuropathy.[121] GCs may also be used to treat patients with moderate-to-severe active ophthalmopathy.[121] In a double-blind randomized trial, 28 patients with moderately severe GO were treated with a 3-month course of oral prednisone and sham irradiation, and 28 received retrobulbar irradiation (20 Gy) and placebo capsules, oral prednisone, and RT appeared to be equally effective as initial treatment in patients with moderately severe GO.[66]

Surgery

In the event that GCs fail to improve optic neuropathy, urgent orbital decompression is necessary.[122,123] Another indication for urgent orbital decompression is exposure keratopathy not relieved by local measures.[122]To improve extraocular muscle function and cosmesis, other procedures such as strabismus surgery and lid surgery may be performed. It is recommended that the GO be inactive for at least 6 months before pursuing these procedures.[122]

Radiation Therapy

RT has shown to be an effective treatment option for palliating clinical symptoms in GO, although some conflicting data on the efficacy of RT for GO exist.[66,123-126] Indications for RT in the management of GO have been outlined by Donaldson and McDougall and include (Table 100.4) inducing clinical regression, improving functional deficits, improving cosmesis, and avoiding side effects of other treatments.[127]

TABLE 100.4 CLINICAL GUIDELINES FOR USE OF RADIOTHERAPY IN GRAVES OPHTHALMOPATHY (GO)

Radiotherapy Goal	Precondition/Indications	Contraindications
Induce clinical regression	*Pretherapeutic diagnostics*: evidence of autoimmune thyroid disease; CT/MRI	Stable GO without clinical progression
Reduce/eliminate functional deficits	*Ophthalmologic diagnostics*: documented progressive disease	Lack of euthyroid
Improve cosmetics/aesthetics	*Subjective/objective findings*: evidence of functional deficits and disorders	"Cosmetic" indication alone without functional impairment
Avoid/decrease undesired effects of other measures	*Exclusion of risk factors*: no other eye disease (ie, diabetic retinopathy)	No consent to planned therapy

CT, computed tomography; MRI, magnetic resonance imaging.

RT is generally administered with 3DRT. Both orbits, including the entire length of the extraocular muscles, are treated to a total dose of 20 Gy in 2-Gy fractions using opposed lateral fields with the isocenter placed a few millimeters posterior to the lenses using a beam-split technique (see Figure 100.3).

For patients with progressive GO, retrospective data suggest that orbital RT is an effective treatment modality. Marquez et al reviewed the records of 197 patients treated at Stanford, all of whom received 20 to 30 Gy to the bilateral retrobulbar region.[128] Outcomes assessed included SPECS score and patient satisfaction. There was a 96% overall response rate and 98% patient satisfaction rate, with the largest improvements in soft tissue findings (89%), extraocular muscle dysfunction (85%), and corneal abnormalities (96%). In a later study, Matthiesen et al. reported on 211 patients who received orbital RT between 2000 and 2010 for GO.[129] Overall, 97% of patients had stabilization of disease and 84% reported symptomatic improvement. Steroids were discontinued in 98% of patients who received them as initial therapy. A subset of 14 patients received orbital reirradiation for persistent symptoms, with 5 achieving a complete response

and 9 having disease stabilization. These 14 patients did not experience increased toxicity compared to the rest of the cohort.[129]

There have been limited data comparing the effectiveness of low-dose versus high-dose RT. In a recent study of 127 patients with stage III/IV GO who received 20 Gy in 2-Gy fractions versus 4.8 Gy in 0.8-Gy fractions, with a median follow-up of 9.0 years, 63.8% of the patients experienced an improvement in symptoms after RT, irrespective of the use of low dose or high dose. However, low-dose RT required retreatment more frequently (13.1% vs 1.7%).[130]

BENIGN DISEASES OF SOFT TISSUE AND BONES

General Overview of Inflammatory Conditions of Joints and Tendons

The role of RT in the treatment of benign inflammatory conditions involving the joints and/or tendons is controversial. OA, tendonitis, bursitis, rotator's cuff syndrome, and tennis elbow are examples of inflammatory conditions for which RT has been used in the past. These soft tissue syndromes may result from repetitive activities that cause overuse or injury to the joint areas, incorrect posture, stress on the soft tissues due to an abnormal or poorly positioned joint or bone, or other conditions such as autoimmune diseases or infection.

Although the cause of each disorder may be different, the clinical presentation and general treatment plan are frequently similar. Symptoms include pain, swelling, or inflammation in the tissues and structures around a joint, such as the tendons, ligaments, bursae, and muscles. Treatment generally involves a combination of exercise, lifestyle modification, and analgesics. If pain becomes debilitating, joint replacement surgery may be used to improve the QoL. In rare instances, low-dose RT (<10-15 Gy) can be employed. The low dose required to improve symptoms suggests the possible mechanism of action for RT, as shown in Table 100.5.

TABLE 100.5 RADIATION THERAPY MECHANISM OF ACTION DOSE CONCEPTS

Mechanisms of Action	Single Dose (Gy)	Total Dose (Gy)
Cellular gene and protein expression (eg, eczemas)	<2.0	<2

Mechanisms of Action	Single Dose (Gy)	Total Dose (Gy)
Inhibition of inflammation in lymphocytes (eg, in orbital pseudotumor)	0.3-1.0	2-6
Inhibition of fibroblast proliferation (eg, in keloids)	1.5-3.0	8-12
Inhibition of proliferation in benign tumors (eg, in desmoids)	1.8-3.0	45-60

Osteoarthritis

OA, the most common joint disorder, is a chronically debilitating musculoskeletal disorder, which predominately affects older people. It presents with pain associated with cartilage destruction, bone modification, and structural changes of the capsule and synovia. Symptoms are caused by reactive inflammation of the joint surface and joint capsule lining (synovia). Risk factors include age; genetic predisposition; bone fracture or joint injury, whether by an accident of overuse from work or sports; and increased body mass index.[131] The incidence of OA is expected to rise worldwide due to an aging population and the increasing prevalence of obesity compared to previous decades.

Systemic Therapy

Hunter and Lo provide a general overview of the diagnosis, investigation, and treatment of OA.[69] The treatment of early OA is intended to reduce the primary symptoms of joint pain and stiffness, with the goal of maintaining and improving the functional capacity of the affected joint(s).[132] Exercise, weight reduction, and joint braces have shown some success at unloading damaged joints and improving symptoms.[133] For OA of the hip and knee, exercises that strengthen muscles and improve aerobic condition are most effective.[134]

Oral analgesics are the mainstay of treatment for OA. While acetaminophen is frequently offered due to its relative safety and efficacy, a nonsteroidal anti-inflammatory drug (NSAID) may be added or substituted.[135] NSAIDs can be used in patients with symptomatic OA of the hand, hip, or knee. The goal is to administer the lowest effective dose for the shortest duration. The use of stronger analgesics, such as weak opioids

and narcotics, may be considered when other methods have been ineffective or if certain drugs are contraindicated.[133] Glucosamine and chondroitin sulfate are over-the-counter remedies that are frequently used to reduce pain, but their efficacy has not been proven.[136] Corticosteroids and other analgesics may be injected directly into the joint; injections may temporarily reduce swelling and pain. Acupuncture and other complementary and alternative treatment modalities have been used, but their efficacy is unproven.[84]

Surgery is reserved for patients with severe OA and those who have not responded to noninvasive therapies. Total or partial joint replacement is most commonly used for OA involving the knee, hip, and shoulder and is considered when structural damage is visible on x-rays. However, there are modern surgical procedures that can obviate or delay the need for joint replacement, including osteotomies and joint resurfacing.[85] Joint fusion or arthrodesis may be used to treat arthritis of the spine, ankles, hands, and feet. Arthroscopy, or arthroscopic surgery, is a minimally invasive surgical procedure that can be used to examine and treat the interior surface of a damaged joint. Arthroscopic procedures can help relieve pain for a short time and allow the joints to move better. While arthroscopy may delay the need for joint replacement surgery, it does not improve the arthritis itself.[86]

Radiation Therapy

In nonsurgical candidates, low-dose RT may be considered if pharmacotherapy has failed. RT can lead to freedom from pain and improved joint function.[137] Several single-institution studies have been published that report long-term pain relief and functional gain in 50% to 75% of patients. In Germany, a pattern of care study investigated the use of RT for the treatment of OA of the knee (gonarthrosis) from the years 2006 to 2008.[138] Almost 80% of institutions in Germany used RT to treat OA in the 2-year period analyzed. Treatment of 4,544 patients was performed annually at 188 institutions. The median total dose was 6 Gy (range 3-12 Gy), with a median single dose of 1 Gy (0.25-3 Gy). Long-term clinical outcomes were available in 5,069 cases. The majority of patients experienced pain reduction for at least 3 months, but pain management for up to 12 months was reported. In 30% of patients, a second course of RT

was used for inadequate pain response or early pain recurrence.[138] Micke et al published a prospective study on older patients with gonarthrosis using a similar RT regimen, demonstrating a good analgesic effect of low-dose RT with minimal side effects.[139]

As with arthroscopy, radiation may reduce pain and pain-related dysfunction, but it does not improve the arthritis itself. Due to its efficacy and relative safety, RT may provide an alternative to conventional conservative treatment for patients who are not surgical candidates.

Gorham-Stout Syndrome

Gorham-Stout syndrome, also known as disappearing bone disease or massive osteolysis, is a rare bone disorder of unknown etiology. It is characterized by progressive proliferation of small blood or lymph vessels, resulting in destruction and resorption of the bone matrix. The symptoms are nonspecific but include muscular weakness, limb tenderness, and pathologic fracture occurring with minimal trauma. Involvement of the cervical spine or skull base could be fatal. Case reports indicate limited efficacy of systemic therapies, such as zoledronic acid and interferon-alpha.[140,141] RT has also been used.[142] Heyd et al completed a national patterns-of-care study and literature review that summarized the scant data available for this rare disorder.[143] The 38 articles listed therein provide evidence from the treatment of 44 patients and show that conventionally fractionated EBRT (total dose of 36-45 Gy) may prevent disease progression in 75% to 80% of cases.

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis or tenosynovial giant cell tumor is a rare proliferative disorder of synovial tissue. Symptoms include sudden onset, unexplained joint swelling, and pain that frequently involves a single joint. The knee and foot are most commonly affected, but there are reports of shoulder, hand, and hip involvement.[144] Decreased motion, joint stiffness, and increased pain occur as the disorder progresses. Surgical resection with either synovectomy or joint replacement is the treatment of choice.[145]

RT is indicated in cases of diffuse, bulky disease resulting in bone destruction or in the rare instance of multiple recurrences after resection.

Although intrasynovial injection of radioactive isotopes postoperatively has been used in the past for high-risk patients,[146] most institutions use EBRT. RT to a dose of 36 to 50 Gy has been effective.[23,147,148] MRI is essential for delineating disease pre- and postoperatively. The final dose of RT should be tailored to the amount of residual disease.[149]

Vertebral Hemangiomas

Hemangiomas are benign proliferations of blood vessels that can affect any tissue and are typically asymptomatic. About 50% of hemangiomas involving the vertebral body are associated with pain and, therefore, may require treatment. Treatment options include surgical resection or more conservative interventions such as transarterial embolization, vetebroplasty, or intralesional injections.[150] RT either alone or postoperatively has been successful in reducing pain caused by vertebral hemangiomas.[151] In a German multicenter trial, a total of 84 patients with 96 symptomatic lesions were irradiated for symptomatic vertebral hemangioma. At a median 68-month follow-up, 90% of patients had either complete or partial pain relief. Radiation doses 34 Gy or greater resulted in significantly improved pain relief. A total radiation dose of 36 to 40 Gy delivered in 2 Gy per fraction was recommended.[152]

DISEASES OF CONNECTIVE TISSUE AND SKIN

Desmoid Tumors

Background and Clinical Aspects

Desmoid tumors (also called aggressive fibromatosis or deep musculoaponeurotic fibromatosis) are benign tumors of connective tissue that arise from muscle fascia, aponeuroses, tendons, and scar tissue. They are slightly more predominant in females and tend to occur during the third and fourth decades of life, although children and the older patients can be affected. In the general population, desmoids are rare; the estimated incidence is 2 to 4 per million per year. Genetic factors, trauma, and/or surgery predispose to the development of desmoids. Most desmoids arise sporadically, with 85% of cases associated with *CTNNB1* gene mutation in the Wnt/β-catenin signaling pathway. Mutation in the *APC* genes results in

desmoid tumors affecting 10% to 20% of patients with familial adenomatous polyposis (FAP) and is a manifestation of Gardner syndrome.[153,154]

Tumors can develop anywhere in the body, but most commonly involve the trunk/extremity, abdominal wall, and intra-abdominal sites, including the bowel and mesentery. Approximately 30% of patients with desmoid tumors have a history of prior desmoid tumors.[155,156] Sporadic cases commonly involve the extremities, the shoulder girdle, and the buttock.[157] In patients with FAP, intra-abdominal desmoids predominate and tend to be associated with surgical sites and anastomoses following colectomy.[158] Desmoid tumors in women can occur during or after pregnancy; they may be associated with high estrogen states. Women who have been pregnant are more likely to have abdominal desmoid tumors that develop within 10 years of the last pregnancy.[159]

Desmoids are locally aggressive and commonly have a high rate of recurrence, even after complete resection. Diagnostics workup with MRI helps to estimate size and infiltration into other organs and should be obtained prior to incisional biopsy for diagnostic confirmation.

Systemic Therapy

Observation is a viable option for stable, asymptomatic desmoids. Treatment is indicated for symptomatic patients, if there is a risk to adjacent structures, or to improve cosmesis. Complete surgical resection of the tumor with negative microscopic margins is the treatment of choice for most desmoid tumors. Due to the size and infiltrative nature of extra-abdominal desmoids, resection may result in significant morbidity, requiring skin grafting or flap reconstruction. Desmoid tumors have a high rate of recurrence following even complete surgical removal. A recent meta-analysis of 1,295 patients demonstrated that the risk of recurrence in patients with positive surgical margins was almost 2-fold higher.[160] While resection does not alter survival in most patients, given the histologically benign nature of desmoids, the overall surgical strategy should still be an attempt at complete removal using function-preserving surgical approaches to minimize major morbidity (functional and/or cosmetic).[161]

While extra-abdominal desmoid tumors can generally be treated effectively with local therapy, surgical intervention tends to be counterproductive in intra-abdominal variants, especially the ones associated with FAP. In some instances, systemic therapy may achieve significant and durable cytoreduction, obviating the need for resection. Patients with desmoid tumors have been treated with NSAIDs. The most widely used NSAID for the treatment of desmoid tumors is sulindac. Hormonal agents such as tamoxifen, raloxifene, and progesterone have been used, often in combination with NSAIDs. Tamoxifen has been used most widely and is typically prescribed at doses similar to those used for breast cancer (10 mg daily). Much higher doses (120 mg daily) have been recommended,[162] but high-dose tamoxifen is difficult to tolerate, and there is no evidence to suggest that higher doses of tamoxifen are better than lower doses.

A variety of palliative chemotherapeutic regimens have been used.[163-165] With the waxing and waning natural history of desmoids, it is difficult to say whether systemic therapy provides much benefit over observation. In one series, 142 patients presented with either a primary (n = 74) or recurrent (n = 68) desmoid tumor. Eighty-three patients were treated with observation alone, and 59 received either hormone therapy or chemotherapy. There was no statistically significant difference in progression-free rates between the two groups.

Desmoid tumors also respond to the tyrosine kinase inhibitor imatinib.[166,167] The response is thought to be due to the expression of one of Gleevec molecular targets, platelet-derived growth factor receptor, on desmoid tumors.[168] Phase II clinical trials have demonstrated the efficacy of imatinib in the treatment of progressive and recurrent aggressive fibromatosis. While response rates are low, the 2-year progression-free rate in responders is about 50% with a favorable toxicity profile.[167,169] Kasper et al prospectively administered imatinib (800 mg/daily) to patients with desmoid tumors not amenable to R0 resection without significant function loss and demonstrated a 2-year progression arrest rate of 45%.[169]

Intralesional injections[170] and radiofrequency ablation[171] have also been used. Although the techniques led to some tumor shrinkage, the experience to date is limited, and the long-term results are not yet known.

Radiation Therapy

RT is a viable option for inoperable patients and may also be used in combination with surgery or chemotherapy. Spear et al retrospectively compared the efficacy of surgery alone, radiation alone, and combined modality therapy (radiation and surgery) in the treatment of desmoid tumors.[172] Five-year local control rates among surgery, RT, and combined modality groups were 69%, 93%, and 72%, respectively. More recently, Janssen et al performed a meta-analysis on the influence of surgical margin and adjuvant RT on local recurrence and found that RT reduces the risk of recurrence in patients with microscopically positive resection margins.[159] The association of adjuvant RT benefit was even stronger for resection of recurrent tumors with positive margins. Of note, adjuvant RT for patients with negative margins did not affect recurrence rates.

The general recommended radiation dose for inoperable or recurrent desmoids is 60 to 65 Gy.[23] However, long-term results at another institution show increased post-treatment toxicity in patients who receive RT doses greater than 56 Gy.[160]

Young age (# 30 years) was also associated with increased late toxicity. In a retrospective study of 30 patients under the age of 30, younger age (<18) was associated with inferior local-regional control following RT. Although actuarial control rates were better with RT doses of 55 Gy or higher, almost 50% of patients experienced grade 3 to 4 complications, including pathologic fractures, impaired range of motion, pain, and in-field skin cancers.[173,174] Since long-term results suggest that unresectable tumors respond to 56 Gy with a 75% expectation of local control, the lower dose may be more appropriate in this population.

When an R0 resection is not possible, doses of 50 to 60 Gy postoperatively should be given to improve local control. RT is often not considered for intra-abdominal tumors because the dose and increased field size increase the risk of bowel injury. Due to the complexities involved in managing the disease, a multidisciplinary approach must be taken.[175]

Peyronie Disease

Background and Clinical Aspects

Peyronie disease (PYD) (also known as “induratio penis plastica”) is a chronic inflammatory connective tissue disorder involving the penile tunica albuginea that results in tissue proliferation and the development of hard plaques, most commonly on the dorsal surface of the penis. These may cause a curvature, indentation, and changes in the length or circumference of the penis while erect. Symptoms may lead to difficult intercourse, penile pain, and erectile dysfunction.

PYD affects up to 10% of men, although a recent population-based study suggests the condition may be underreported in the United States.[176] While PYD can affect teenagers, men between the ages of 40 and 70 are mostly affected, with a peak incidence at 50 years of age. The cause is unknown but is often associated with prior penile trauma. Diabetes mellitus and arterial and venous vascular disease are risk factors, along with an assumed genetic predisposition. Slow progression over several months is typical, with spontaneous remission occurring in less than 15% of men.[177]

Systemic Therapy

Results of nonsurgical treatment of PYD are mixed and controversial.[178,179] Some success has been reported with vitamin E supplementation, but results have not been confirmed in larger studies.[180] A combination of vitamin E and colchicine may delay disease progression.[181] Other agents that specifically target inflammatory pathways have also shown mixed benefit, including tumor growth factor-β1 inhibitors,[182] coenzyme Q10,[183] and sildenafil, among others.[184] Topical therapies have largely been ineffective, but penile injection with verapamil or collagenase, intended to break up scar tissue formed by the inflammation, has shown some efficacy.[185] Physical therapy and extracorporeal shock treatments have also had limited benefit.

Surgical options for PYD are complex procedures that should only be performed by experienced urologists and are reserved for patients not responding to other therapies.[186] Although the nonsurgical treatments discussed may not reliably treat the disease, they can be used to stabilize the scarring process and may result in some reduction of deformity. A combination of nonsurgical techniques may have even more efficacy.[187]

Radiation Therapy

The largest experience with the use of RT in the treatment of PYD has been in Europe. Retrospective studies report varied symptom improvement with the use of RT in terms of pain, curvature reduction, plaque volume, and sexual functioning.[189] These data also suggest that any benefit of RT is best in the treatment of early stages of disease, when radio-responsive inflammatory cells and fibroblasts are still active. RT in later stages of PYD once the plaques have fully formed is thought to yield worse outcomes.

The current recommendation for RT in PYD is a total dose of 10 to 20 Gy in daily single fractions of 2 to 3 Gy using a direct ventral field. The penis lays on the scrotum, and a lead or polyethylene layer is placed between the scrotum and penis to shield the testes. Orthovoltage, low-energy photons and/or electrons may be used. One retrospective study from the Netherlands indicated that low-dose RT, either 13.5 Gy (9 × 1.5 Gy, three fractions per week) or 12 Gy (6 × 2 Gy, daily fractions), resulted in pain relief in the majority of the 179 patients evaluated.[189] Sexual dysfunction was a reported side effect, although this is confounded by the underlying disease.

As experimental models improve our understanding of the pathogenesis of PYD, the use of RT for plaque development in this highly complex vascular organ may further decline, given concerns regarding radiation-induced vascular fibrosis and the development of more effective therapies.[190,191]

Dupuytren Contracture

Background and Clinical Aspects

Dupuytren contracture, also known as Morbus Dupuytren (MD) and Morbus Ledderhose (ML) depending on the involvement of the hands or feet respectively, is a connective tissue disorder that affects the palmar or plantar fascia. Some authors estimate the global prevalence of Dupuytren disease to be between 3% and 6%. Incidence increases after the age of 40, and the condition affects men more often than women. A genetic predisposition along with a number of environmental factors (smoking, alcohol use) can lead to local ischemia and free radical release, which

stimulates fibroblast proliferation and cytokine production, particularly IL-1.

In the early stage, subcutaneous nodules appear, which may be fixed to the overlying skin. As the disease progresses, cords develop and become visibly predominant. With further progression, the cords reach the periosteum of the bones and lead to the characteristic appearance of palmar or plantar contraction. The fourth/fifth phalanges of the hand (MD) or the first/second toes of the foot (ML) are the most commonly affected digits (Figure 100.6). With increased thickening of the fascia and progressive contracture, the fingers and toes begin to curl, resulting in significant functional deficits, for example, difficulty grabbing (MD) or walking (ML).

FIGURE 100.6 Dupuytren contracture of both hands and the left foot.

Surgical management

Excision of diseased cords and fascia via limited or selective fasciectomy is widely considered the gold standard treatment for Dupuytren

contracture.[192,193] A 20-year review of open surgery for Dupuytren contracture showed that major complications occurred in 15.7% of cases and that wound complications were seen in 22% of cases.[194] Even with excellent surgical resection, relapse is common, with a 30% to 50% recurrence rate at 3 years.

Modern minimally invasive techniques have substantially reduced the complication rates. Percutaneous needle fasciotomy is a technique where cords are weakened through the insertion and manipulation of a small 25-gauge needle mounted on a 10-mL syringe.[195] The procedure is performed under local anesthesia, and patients may return to full usage of the affected limb within 24 hours. Since the cords and nodules are not fully excised, minimally invasive surgery has an even higher recurrence rate that surgical excision. A randomized study comparing percutaneous needle fasciotomy with limited fasciectomy showed an 85% recurrence rate after 5 years with the minimally invasive procedure.[196]

During the early stage of Dupuytren, medication (steroids, allopurinol, nonsteroidal vitamin E) may provide benefit, but the effects are temporary. Collagenase *Clostridium histolyticum* injections (CCH) are the Food and Drug Administration–approved nonsurgical treatment option for adult patients with Dupuytren contracture with a palpable cord. Injections of this collagenase enzyme weaken the cords through the breakdown of the peptide bonds in collagen, which subsequently allows for finger manipulation and release of contractures.[197-199] While CCH has proven to be a useful minimally invasive technique for patients with later stage DC, recurrence rates of 35% at 3 years of follow-up have been reported.[199,200]

Radiation Therapy

RT is currently used in the treatment of Dupuytren exclusively for early-stage patients (who have a <10-degree deformity) and is considered standard of care for the prevention of Dupuytren progression. Low-dose RT hinders fibroblast proliferation and the cascade of inflammatory markers that induce collagen formation and fibroblast differentiation into fibronectin. Many studies have demonstrated patient-reported effectiveness of radiation, preventing further Dupuytren progression with minimal toxicity.[201-204] Adamietz et al reviewed 176 hands treated with low-dose RT.

Of those patients with less than 5-degree deformity, 82% had a patient-hand reported disease progression-free survival at the 10-year follow-up. Betz et al retrospectively reviewed 208 hands treated with low-dose radiation and found that patients with less than 5-degree deformity had an 87% patient-hand reported disease progression-free survival at the 13-year follow-up. Most recently in 2015, a prospective study by Schuster et al published the largest U.S. patient-reported outcomes after low-dose radiation for early-stage Dupuytren.[205] In this study, 45 patient-hands received low-dose radiation via electrons directed en face. After 31 months, 94% of surveyed patients reported the RT was successful with minimal toxicity.

Seegenschmiedt et al performed a randomized clinical trial comparing the safety and efficacy of two different dose regimens and an untreated control group.[201] Group A received 10 × 3 Gy (30 Gy) via a split course (5 × 3 Gy) repeated at intervals of 12 weeks; in group B, patients were treated with 7 × 3 Gy (21 Gy) delivered over 2 weeks. Regardless of the dose regimen, approximately 90% of treated patients had stable or improved disease. After a mean follow-up of 8 years, the extension deficit increased in 35% of the control group, in 7% of the 21 Gy group, and in only 4% of the 30 Gy group. Acute toxicity was more pronounced in group B, but long-term toxicity was comparable and included dryness, desquamation, skin atrophy, and altered sensation. The results of this study indicate that prophylactic RT is well tolerated by patients and effective at preventing disease progression. The 30-Gy regimen may be superior.[23] Irrespective of the dose regimen, the target volume should include palpable or detectable nodules and cords surrounded by a 3- to 5-mm margin; appropriate immobilization and shielding of unaffected joints are required (Figure 100.7).

Keloids and Hypertrophic Scars

Background and Clinical Aspects

Keloids are excessive tissue proliferation around scars after skin injury from surgery, heat, chemical burns, inflammation (eg, acne), or even spontaneous proliferation. They differ from hypertrophic scars by their typical infiltrative growth pattern, causing local pain and inflammatory reactions, and sometimes long-term progression; hypertrophic scars show thickening without surrounding reaction and can flatten spontaneously. Keloids appear mainly in the upper body and in regions with high skin tension (eg, sternum, earlobes). The cause is still unknown, although there is a genetic and race-specific predisposition that can already be noted during adolescence. Keloids at the earlobe after piercing are typical. In

some patients, the resulting lesions are severely disfiguring and painful (Figure 100.8). Recurrence is common after treatment.

FIGURE 100.8 A. Keloid behind left earlobe. B. Status of keloid following resection plus 4 × 4 Gy radiotherapy.

Systemic Therapy

Silicone bandages, pressure dressings, and cryosurgery have all been used to treat keloids with varying efficacy.[206,207] Intralesional injections remain the first-line therapy for most keloids. Corticosteroids, 5-fluorouracil, and verapamil have all been directly injected into keloid lesions with symptom improvement. Up to 70% of patients respond to intralesional corticosteroid injection with flattening of keloids, although the recurrence rate is high in some studies (up to 50% at 5 years).[208]

Surgical excision may be indicated if injection therapy alone does not result in improvement. In patients treated with excision alone, recurrence rates range from 45% to 100%[209]; therefore, excision is typically combined

with perioperative or postoperative injections of either triamcinolone or interferon.[208]

Radiation Therapy

RT should be considered in cases of repeat recurrences postoperatively or where there is a high risk of recurrence (eg, marginal resection, large lesion, unfavorable location). Primary RT can be considered in instances where resection would result in functional impairment and in actively proliferating disorders within about 6 months after the triggering trauma. Because proliferating fibroblasts and mesenchymal and inflammatory cells are the target cells for RT, fully matured keloids have minimal response to RT alone. Prophylactic RT immediately following excision (within the first 24 hours) is most effective and reduces the risk of recurrence to 15% to 25% in most series.

Among different modalities for postexcisional RT, brachytherapy was found to have a lower recurrence rate when compared to electron and x-ray therapy by meta-analysis.[210] The target volume is limited to the scar plus a 1-cm margin; lead shielding can be constructed to protect normal tissue. An analysis of multicenter data on the use of postoperative RT for earlobe keloids showed that a higher dose per fraction and the use of deeper penetrating electrons were preferable to standard 2-Gy fractionation schemes.[211] A retrospective review of 124 patients with 250 keloids treated with postoperative RT to a biologically equivalent $dose_2$ of 35 to 36 Gy_2, 48 to 52.5 Gy_2, and 60 to 72 Gy_2 demonstrated a recurrence rate of 10% (P = .007), 8.9% (P = .16), and 1.6% (P = .02), respectively.[212] Common side effects include erythema and changes in skin pigmentation.

Heterotopic Ossification

Background and Clinical Aspects

HO is a common complication of total hip arthroplasty, hip trauma, or acetabular fracture. HO occurs when the soft tissues around the bone become ossified. Following trauma, primitive mesenchymal cells in the surrounding soft tissues are transformed into osteoblastic tissue that then forms mature bone. The hip is the most common joint affected; HO

typically occurs around the femoral neck and adjacent to the greater trochanter. The risk factors for the development of HO are unknown. The incidence is greater in men, and HO occurs in more than 80% of patients who have a history of ipsilateral or contralateral HO. It is also more common in patients with a known history of OA, ankylosing spondylitis, and Paget disease.[213] Hip stiffness is the primary symptom, and the diagnosis is made radiographically. Pain is typically not associated with HO.

Systemic Therapy

The treatment for HO is surgical excision followed by some form of HO prophylaxis. Prophylaxis is only applied to patients at high risk for developing HO. A meta-analysis showed that NSAIDs are effective in reducing the risk of postoperative HO.[214] Indomethacin is the most commonly used nonselective NSAID for HO prophylaxis. Indomethacin is a prostaglandin synthase inhibitor that also suppresses mesenchymal cells. The limited data available have not shown a clear benefit to the use of selective cyclooxygenase-2 (COX-2) inhibitors in HO prophylaxis.[215,216] Kan et al performed a meta-analysis comparing selective NSAIDs (COX-2 inhibitors) and nonselective NSAIDs versus placebo in HO prevention. Efficacy was the same among the two classes with similar rates of discontinuation from gastrointestinal side effects.[217] Bisphosphonates have been used for prophylaxis because they delay the mineralization of osteoid and appear to have some efficacy in preventing HO if used at the appropriate time. In one study, the cost of bisphosphonate use was prohibitive for routine use when compared to indomethacin.[218]

Radiation Therapy

External beam radiation is an effective method for the prevention of HO after total hip arthroplasty. Prophylactic RT for the prevention of HO has been used since the 1970s. A single fraction of 700 or 800 cGy to the at-risk region (Figure 100.9) is recommended and should be delivered in the perioperative period, either preoperatively (within 4 hours) or postoperatively (within 72 hours).[24] Typically, an anteroposterior/posteroanterior field size measures 14 × 14 cm^2, with the

cranial field border approximately 3 cm above the acetabulum and the caudal field border encompassing two-thirds of the proximal implant. The dose is prescribed to the body midplane.[24]

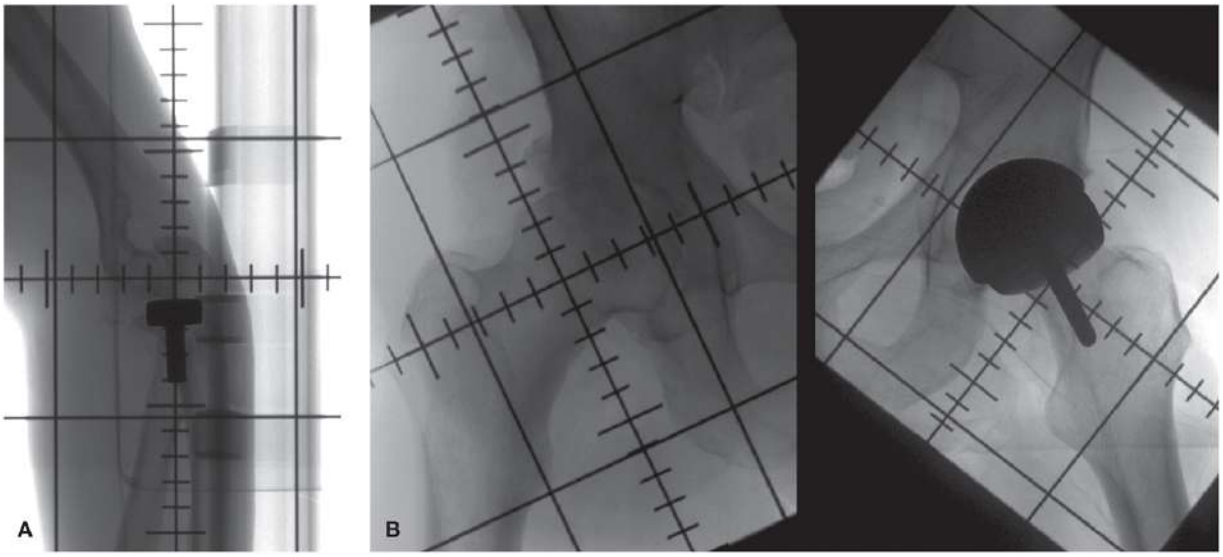

FIGURE 100.9 Typical treatment field for heterotopic ossification (HO). A. Field setup for elbow after radial head replacement. B. Field setup of acetabulum with active HO and after hip arthroplasty.

When comparing RT and NSAIDs, there is no clear benefit for the use of one modality over another. A prospective, randomized study demonstrated that RT and indomethacin are both effective in the prevention of postoperative HO.[219] Although one meta-analysis of seven randomized studies concluded that RT is more effective compared to NSAIDs for HO prophylaxis,[220] a separate analysis of nine studies involving 1,295 patients found no statistically significant difference between the two.[221] An economic analysis using the same nine studies and the meta-analysis suggest that RT is not cost-effective when compared to the use of NSAIDs.[222] This analysis has yet to be validated. Further data suggest the cost of NSAIDs approaches the cost of administering RT when considering costs of treatment failure and treatment-induced morbidity.[223]

Plantar Fasciitis

Plantar fasciitis is characterized by pain in the heel and the bottom of the foot. Typically, the pain is most severe with the first steps of the day or following rest. The pain is often exacerbated by bending the foot and toes up toward the shin.

This disease has acquired an impressive number of names in addition to plantar fasciitis. Alternative names include painful heel spur, Kalkaneussporn (calcaneal spur), policeman's heel, heel spur syndrome, plantar or dorsal heel spur, Haglund exostosis, achillodynia or calcaneodynia, jogger's heel, tennis heel, and subcalcaneus bursitis.[224]

The plantar fascia is a thick, broad, inelastic band of fibrous tissue on the plantar surface of the foot. It is attached to the calcaneus and then fans out to attach to the metatarsal bones in the area of the ball of the foot. The anatomy of the plantar fascia, along with a possible explanation for plantar fasciitis, has been artfully described by Micke et al[224]:

> Because the normal foot has an arch, this tight band of tissue (plantar fascia) is at the base of the arch. In this position, the plantar fascia acts like a bowstring to maintain the arch of the foot…. Pathophysiologically, excessive stretch of the plantar fascia can result in microtrauma…. This microtrauma, if repetitive, can result in chronic inflammation and degeneration of the plantar fascia. (Reprinted by permission from Springer: Micke O, Ernst-Stecken A, Mücke R, Seegenschmiedt MH. Calcaneodynia: plantar and dorsal heel spur/heel spur syndrome. In: Seegenschmiedt MH, Makoski HB, Trott KR, Brady LW, eds. *Radiotherapy for Non-Malignant Disorders*. Springer; 2008:296-297. Copyright © 2008 Springer-Verlag Berlin Heidelberg.)

Indeed, the use of the word *fasciitis* implies that the core issue in this disease is inflammation. That is far from clear. This has led some writers to propose yet another name for the disease, *plantar fasciosis*, an agnostic term that does not imply that the crux of the problem is inflammation.

The most commonly invoked alleged mechanism of action of RT in the treatment of plantar fasciitis is that it damps down the local inflammatory process. This mechanism is, of course, a hollow explanation if, indeed, inflammation does not play an important role in many cases. Furthermore, as with many nonmalignant diseases in which local RT is asserted to be useful in treating inflammation, proponents are left with having to explain why inflammatory cells outside the field of radiation do not pour into the treated area after each fraction of radiation. They usually respond by

making claims that the inflammatory cascade and/or antigen presentation are disrupted by ionizing radiation.

In his 1965 textbook *Radiotherapy of Benign Disease*, Dewing classified "calcaneal spurs" as a "sterile inflammatory condition."[225] He wrote,[225]

> Whether the lesion is primarily a plantar fasciitis or is combined with a periostitis can probably never be determined in a given case. The title "painful calcaneal spur" is certainly a misnomer, for the bony spur itself is not primarily the seat of the disorder (or the pain). Many such spurs are seen in asymptomatic persons, and surgical resection of a spur is often quite ineffective in relieving the symptom. The practical problem, however, is pain, and there is no adequate specific therapy.

Many patients get better with supportive care. Among the long list of therapies are various forms of physical therapy, oral and locally injected drugs, extracorporeal shock wave therapy, and a wide variety of types of surgery.

The end point of the clinical studies on RT relies on patient-reported symptoms. The possibility of a placebo effect is real. About 25 papers, dating from the 1950s forward, have been invoked to allege that RT at a total dose of 90 to 150 cGy in three to five treatments, or 5 Gy in 5 weeks, or 7 to 7.5 Gy in one to five treatments, or 3 to 6 Gy fractionated over 2 weeks is helpful with response rates of 65% to 100%. Patients are typically irradiated 2 to 3 times per week. The largest volume of data is from Germany.[224-227]

The subject cries out for rigorous clinical investigation driven by science rather than an urge to find another billable procedure for RT. Reporting that "I treated a patient and he got better" or, even worse, "I treated a celebrity patient and he got better" brings to mind the old clinical adage that "In medicine, the pleural of clinical anecdote is not data."

OTHER CONDITIONS IN WHICH RADIATION THERAPY HAS BEEN EMPLOYED

Solid Organ Transplantation

The first human-to-human heart transplant, performed by Dr Christiaan Barnard in South Africa in 1967, included local field irradiation of the transplanted donor heart as part of the immunosuppressive program.[228] Low-dose fractionated RT was used at many centers in the 1960s to 1980s

in an attempt to forestall rejection of cardiac and renal allografts. Total lymphoid irradiation was investigated for a potential role in creating a sustained immunosuppressive state for heart, liver, and kidney allografts and xenografts. There were some notable successes in experimental models of xenografts.[229-232]

The evaluation of more powerful and less toxic chemical immunosuppressives and the development of genetically engineered pigs have made the use of EBRT for human solid organ allografting and xenografting largely of historical interest, but it remains possible that as xenografting evolves, there may once again be an impetus to investigate RT's usefulness in certain situations.

Alzheimer Disease

Because of the aging population in the economically developed world, societies face the growing effect on morbidity, mortality, economic costs, and social stress of a rising incidence of Alzheimer disease. In view of the largely unsatisfactory attempts to reach a consensus on the pathophysiology of this disease and the lack of efficacy of therapy, it is not surprising that some investigators have turned to EBRT in experimental animal models and clinical studies. For example, in a clinical investigation of five patients with Alzheimer dementia irradiated with 2 Gy/fraction of whole-brain irradiation for five fractions, Rogers et al reported results with a positive safety profile and suggested cognition was stabilized or improved by the treatment.[233] The authors offer, as mechanisms of action for this possible benefit of RT, the reduction of amyloid and tau burden, as well as decreased neuroinflammation.[233-236]

One can expect, in the coming years, further laboratory and clinical studies in this disease regarding the use of RT.

SECTION V

Palliative and Supportive Care

CHAPTER 101

Palliation of Brain Metastases

Hua-Ren R. Cherng, Mark Mishra, Roy A. Patchell, William F. Regine, and Young Kwok

BRAIN METASTASIS

Brain metastasis is a very common diagnosis, with an annual incidence of approximately 170,000 to 300,000 cases. Brain metastasis represents the most common intracranial lesion in adults, occurring at a median time of 8.5 to 12 months from primary diagnosis. The rising incidence of brain metastasis is likely in part from a combination of increasing survival from recent advances in therapy and a greater availability and use of magnetic resonance imaging (MRI). The most common primary site is the lung followed by the breast (Table 101.1).[1-4]

TABLE 101.1 EPIDEMIOLOGY OF BRAIN METASTASIS

Primary Site	
Lung	20%-50%
Breast	5%-20%
Small cell lung cancer	15%
Melanoma	7%-10%
Renal cell carcinoma	4%-6%
Colon	2%-5%
Relevant Facts	
Median survival	<1 y
Mean age	60 y
Annual U.S. incidence	>170,000
Clinical incidence	30%

Clinical Presentation, Diagnosis, and Prognosis

The majority of patients present with neurologic signs and symptoms (Table 101.2).[1,5] Although differential diagnoses such as an abscess or a stroke must be considered, new-onset neurologic symptoms in a patient with known cancer should always be presumed to be from brain metastasis until proven otherwise.

TABLE 101.2 CLINICAL PRESENTATION OF BRAIN METASTASIS

Symptom	Percentage of Patients
Headache	24-53
Mental Disturbance	14-32
Motor weakness	20-40
Cerebellar Dysfunction	7-26
Seizures	12-22
Speech problems	14

From Lagerwaard FJ, Levendag PC, Nowak PJ, Eijkenboom WM, Hanssens PE, Schmitz PI. Identification of prognostic factors in patients with brain metastases: a review of 1292 patients. *Int J Radiat Oncol Biol Phys*. 1999;43(4):795-803; and Posner JB. Brain metastases: 1995. A brief review. *J Neurooncol*. 1996;27(3):287-293.

Patients presenting with acute neurologic signs and symptoms will likely undergo an initial noncontrast computed tomography (CT) due to its ease of completion and ability to rule out life-threatening etiologies. However, contrast-enhanced MRI represents the most sensitive imaging modality to detect brain metastases, especially for identifying small lesions, which can have a significant effect on the patient's prognosis and treatment course.

Most brain metastases are located in the cerebral hemisphere (80%) at the junction of gray-white matter. While there are no pathognomic MRI characteristics of brain metastases, they generally tend to be T1 iso- or hypointense and T2 hyperintense and enhance with contrast administration.[6,7] Full systemic workup (eg, positron emission tomography and CT) should be promptly initiated if brain metastasis is the presenting event.

Performance status and extracranial disease status have consistently been shown to impact prognosis. Gaspar et al[8] reported on the Radiation Therapy Oncology Group (RTOG) experience of 1,200 patients. This analysis revealed three recursive partitioning analysis (RPA) classes, with the RPA class I (Karnofsky performance score [KPS] ≥70, controlled primary, age <65 years, no extracranial metastases), class II (not meeting requirements of class I or III), and class III (KPS <70) having median survivals of 7.1, 4.2, and 2.3 months, respectively. This class scheme has subsequently been validated using the patient cohort from RTOG 91-04.[9] Contemporary series have further refined the class division by incorporating disease-specific prognostic factors, thereby creating and validating a diagnosis-specific graded prognostic assessment (DS-GPA) index to estimate survival outcomes with brain metastases.[10]

Corticosteroids

Initial therapy for suspected or confirmed brain metastases should promptly start with corticosteroids (eg, dexamethasone or methylprednisolone), which effectively improve edema and neurologic deficits in approximately two-thirds of patients within 24 to 48 hours.[11] The only randomized trial evaluating steroid dosage was reported by Vecht et al.[12] This trial included two successive groups of patients. The first group (n = 47) evaluated 8 versus 16 mg/day initial dexamethasone doses, with tapering schedules over 4 weeks. The second group (n = 49) evaluated 4 versus 16 mg/day of initial dexamethasone, with continuation of these doses for 28 days before tapering. The patients were scheduled for whole brain radiotherapy (WBRT) and concurrent ranitidine. All arms had similar KPS improvements at 7 days (54%-70%) and 28 days (50%-81%). The study concludes that 4 mg/day of dexamethasone (with a taper over 4 weeks) is the preferable

regimen. One should be cautious, however, in interpreting the results of this study. Patients in the 4 mg/day arm had to have the medication be reinstituted at a higher rate than the patients in the 8 or 16 mg/day arms. Furthermore, the arm with the greatest improvement in the KPS was the 16 mg/day arm when this was tapered over 4 weeks, compared with any of the other arms. It can be argued that higher KPS improvement arose from the maximal anti-inflammatory effects of the initial higher doses, with the 4-week taper minimizing the late toxicity associated with corticosteroids.

A reasonable corticosteroid regimen in patients with brain metastases is a 10-mg intravenous (IV) or oral bolus, followed by a 4 to 6 mg every 6 to 8 hours of dexamethasone equivalent dose (with a concurrent proton-pump inhibitor; PPI), before this is tapered in a clinically cautious manner. The trial by Vecht et al, however, did demonstrate that 4 mg/day (eg, 2 mg twice daily) of dexamethasone is probably acceptable in select, symptomatic patients with minimal mass effect. In asymptomatic patients with little peritumoral edema or mass effect, initial corticosteroids may be reserved until the first sign of neurologic symptoms.

Anticonvulsants

Patients may present to the radiation oncologist already started on prophylactic anticonvulsants. This represents one of the most preventable causes of neurocognitive decline in patients with brain tumor, given the known negative impact on quality of life and neurocognition with anticonvulsants. In a study of 156 patients with low-grade glioma (85% experiencing a seizure), Klein et al[13,14] analyzed the impact of antiepileptic treatment on quality of life and neurocognitive function. This study convincingly demonstrates the significant correlation between the use of anticonvulsants (even with the lack of seizures) and a decrease in quality of life and neurocognitive function.

Based on four negative randomized trials, the American Academy of Neurology in 2000 recommended that prophylactic anticonvulsants not be initiated in patients with newly diagnosed brain tumor who have not experienced a seizure.[15] This recommendation continues to be relevant as there has now been a fifth randomized trial that has shown no benefit in newly diagnosed brain tumors.[16]

Whole Brain Radiotherapy

WBRT continues to be a standard of care in select patients with diffuse brain metastasis (≥5 brain metastases). WBRT is well known to provide improvement in neurologic symptoms with overall response rates of 70% to 93%.[17] Unfortunately, there exists no agreement on the optimal dose and fractionation schedule for WBRT, despite numerous studies designed to determine the optimal delivery. Table 101.3 summarizes selected randomized fractionation studies.[18-22] A total of 30 Gy in 10 fractions or 37.5 Gy in 15 fractions continue to remain the standard for a vast majority of patients receiving WBRT.[2] As reported by Nieder et al, the radiographic overall response rate with this fractionation scheme is 59% (24% complete response [CR] and 35% partial response [PR]).[23]

[a]18 Gy/3 split course with another 18 Gy/3 within 1 month.

[b]32 Gy in 1.6Gy twice-daily hyperfractionation to the whole brain followed by boost of 22.4 Gy in 1.6 twice-daily hyperfractionation to visible lesions with a 2-cm margin.

[c]40 Gy in 1.0 Gy twice-daily hyperfractionation for the entire course of therapy.

For patients with poor performance status and/or uncontrolled extracranial disease burden, a shorter fractionation scheme (eg, 20 Gy in 5 fractions) can be considered. For this patient cohort, a supportive care–alone strategy may also be considered. The phase III randomized, noninferiority QUARTZ (Quality of Life after Treatment of Brain Metastases) trial compared the quality-adjusted life years (QALY) between optimal supportive care (OSC) alone and OSC plus WBRT (20 Gy in 5 daily fractions) for patients with non–small cell lung cancer (NSCLC) with brain metastases unsuitable for resection or stereotactic radiotherapy (SRT). OSC consisted of dexamethasone titrated based on patient's symptoms as well as patient access to palliative care clinicians and nurses. The results revealed a difference in mean QALY of 4.7 days (46.4 QALY days for OSC + WBRT vs 41.7 QALY days for OSC), which was within the prespecified noninferiority margin of 7 days. Overall survival (OS) was not significantly different between randomization arms (OSC + WBRT: 9.2 weeks vs OSC alone: 8.5 weeks). Subgroup analysis suggested a survival benefit in favor of OSC plus WBRT for patients younger than 60 years, KPS 70 or higher, and controlled extracranial primary.[24] However, serious concerns about patient selection, methodology, and trial design have been pointed out.[25,26] Therefore, while WBRT may be omitted in select patients with very poor prognosis, it still remains an important therapeutic strategy.

Historically, WBRT has been frequently cited as the major cause of neurocognitive decline in patients with cancer. One of the most misinterpreted studies on this subject is the Memorial Sloan-Kettering Cancer Center experience reported by DeAngelis et al[27,28] who reported an

11% risk of radiation-induced dementia in patients undergoing WBRT for brain metastasis. The 11% figure is very misleading. Of the 47 patients who survived 1 year after WBRT, 5 (11%) patients developed severe dementia. When these five patients were examined, all were treated in a way that would significantly increase the risk of late radiation toxicity (ie, large daily fractions and concurrent radiosensitizer). Three patients received 5- and 6-Gy daily fractions, while the fourth patient received 6-Gy fractions with concurrent Adriamycin. Only one patient received what is considered a standard radiation fractionation scheme (ie, 30 Gy in 10 fractions), but this patient received a concurrent radiosensitizer (lonidamine). *No* patient who received the standard 30 Gy in 10 fractions WBRT alone experienced dementia.

In addition, this trial did not address the potential neurocognitive changes in patients who received WBRT resulting from any underlying disease progression.[29,30] Li et al have attempted to further elucidate the true incidence of WBRT-related neurocognitive changes while controlling for brain metastasis response. All patients received WBRT in 30 Gy in 10 fractions and were subjected to a battery of neurocognitive tests monthly for 6 months and then every 3 months thereafter until death. The neurocognitive tests covered domains of memory, verbal fluency, and executive function. In addition, patients underwent serial MRI with the summed volume of up to 6 brain metastases used for assessment of good or poor response. Good or poor response was defined as reduction of the summed volume at 2 months being more than 45% or less than 45%, respectively. The results revealed that volume regression was associated with the preservation of neurocognitive function, primarily in the domains of executive function and fine motor coordination. Tumor volume changes, however, had a weaker association with preservation of memory function (recall and delayed recall), which were domains most susceptible to changes from WBRT use.[31]

The RTOG subsequently completed RTOG 0933 and RTOG 0614, evaluating the role of hippocampal avoidance WBRT (HA-WBRT) and use of WBRT plus memantine, respectively, in an effort to preserve memory-related dysfunction as was identified by Li et al.[31] RTOG 0933 was a phase II trial comparing the 4-month decline in Hopkins verbal learning test (HVLT)-DR (delayed recall) scores with HA-WBRT (30 Gy in 10 fractions)

relative to a historical control group receiving standard WBRT (30 Gy in 10 fractions). HA-WBRT resulted in a mean decline of 7% in HVLT-DR scores from baseline to 4 months, which was significantly lower than the mean decline of 30% for historical controls.[32] RTOG 0614 was a phase III placebo-controlled trial randomizing patients to WBRT (37.5 Gy in 15 fractions) with or without 24 weeks of memantine administration. The primary end point was the effect of memantine use on DR at 24 weeks, which trended in favor of memantine use, though was not statistically significant (P = .059). The use of memantine, nonetheless, resulted in superior results in various other domains, including delayed recognition, executive function, and processing speed.[33] These results prompted the trial NRG Oncology CC001, which evaluated the role of WBRT with or without HA in patients all of whom receive memantine.

Hippocampal Avoidance Whole Brain Radiotherapy

Based on preclinical and clinical studies including RTOG 0933, NRG Oncology CC001 was developed to investigate the role of HA-WBRT in a phase III trial. This trial assessed the impact of WBRT with HA and memantine on reducing the risk of cognitive failure, defined as decline using the reliable change index on at least one of the cognitive tests (HVLT-R [total recall, DR, delayed recognition], Controlled Oral Word Association [COWA], Trail-Making Test [TMT] Parts A and B), after brain irradiation. HA-WBRT plus memantine significantly lowered the risk of cognitive failure (hazard ratio [HR] 0.74, P = .02) compared to WBRT with memantine, and this effect was sustained on longer term follow-up (HR 0.74, P = .016).[34,35] Importantly, there were no significant differences in OS, intracranial progression-free survival (PFS), toxicity, or perihippocampal failures. There was less deterioration in executive function at 4 months and learning and memory at 6 months. Patient-reported outcomes including symptom burden and symptom interference also favored the WBRT with HA arm. Confirmatory results of the neuroprotective benefits of HA were demonstrated in two additional smaller phase II trials: Yang et al compared HA-WBRT and conformal WBRT and found that memory decline at 6 months was improved with hippocampal techniques.[36] Westover et al evaluated hippocampal-sparing whole brain irradiation with simultaneous

integrated boost and found a 10.6% mean decline in HVLT-R DR at 3 months, which was significantly improved compared to historical outcomes.[37] Given these neuroprotective data, WBRT with HA is the new standard of care for patients with diffuse brain metastases and no lesions within a 5-mm margin around the bilateral hippocampi.

Targeted Agents as an Alternative to Whole Brain Radiotherapy in Non–Small Cell Lung Cancer

Historically, the use of systemic chemotherapy for control of NSCLC brain metastasis has been limited by the poor penetration of these agents through the blood-brain barrier (BBB). However, with a greater understanding of the BBB and the many oncogenic drivers present in NSCLC, contemporary targeted therapies have begun to play a larger role in the management of brain metastases. Epidermal growth factor receptor (EGFR) mutations as well as anaplastic lymphoma kinase (ALK) rearrangements, which occur in 15% to 20% of advanced NSCLC cases,[38] represent two commonly targeted mutations. Zimmerman et al, identified a brain metastasis response rate of 74% to 89% with the use of EGFR tyrosine kinase inhibitors (TKIs).[39] Similarly, Rusthoven and Doebele noted response rates of 36% to 67% with next-generation TKIs, such as alectinib, in ALK-positive NSCLC brain metastases.[40] Magnuson et al have reported the largest pooled multi-institutional analysis to date evaluating the optimal sequencing of EGFR-TKIs and radiation therapy in patients with EGFR-mutant NSCLC brain metastases. TKI-naïve patients who had developed brain metastases underwent one of three treatment regimens: stereotactic radiosurgery (SRS) followed by EGFR-TKI, WBRT followed by EGFR-TKI or EGFR-TKI followed by SRS, or WBRT at the time of intracranial progression. At baseline, patients receiving up-front EGFR-TKI had smaller (<1 cm) and less symptomatic intracranial disease. Median OS for the up-front SRS, WBRT, and EGFR-TKI arms was 46, 30, and 25 months, respectively ($P <$ .001). Both up-front SRS and WBRT use were independently associated with improved OS relative to up-front EGFR-TKI. The use of up-front SRS or WBRT was also associated with a trend toward lower risk of intracranial progression, highlighting the potential for inferior outcomes with deferral of early radiotherapy.[41] On the contrary, Gerber et al found equivalent survival

outcomes with the use of up-front EGFR-TKI or WBRT in patients with EGFR-mutant brain metastases.[42]

More recently, osimertinib, a third-generation EGFR-TKI, was shown to have high intracranial penetration and efficacy as demonstrated in a subset analysis of the FLAURA trial.[43,44] Patients in this trial were randomly assigned to osimertinib or standard EGFR-TKIs (gefitinib or erlotinib). A preplanned central nervous system (CNS) PFS primary objective was performed, which demonstrated a significant improvement in CNS PFS (HR 0.48, $P = .014$). CNS objective response rates were 91% and 68% in patients with CNS lesions in the osimertinib and standard EGFR-TKI groups, respectively (odds ratio [OR] 4.6, $P = .066$). In patients with measurable and/or nonmeasurable CNS lesions, response rates for the same groups were 66% and 43%, respectively (OR 2.5, $P = .011$). A phase III randomized clinical trial is currently open to accrual (NCT05236946), in which patients with oncogene-mutated NSCLC and asymptomatic brain metastases are randomized to up-front cranial radiation and TKI versus TKI and observation/delayed cranial radiotherapy to assess the superiority of early versus delayed brain radiation in these patients.

Similarly, the ADAURA trial randomized patients with resected EGFR-mutated NSCLC to receive osimertinib or placebo and demonstrated significant improvements in disease-free survival (HR 0.20, $P < .001$) and CNS disease–free survival consisting of CNS disease recurrence or death (HR 0.18, $P < .0001$) with osimertinib on initial primary analysis at 24 months.[45] CNS recurrences were rare in the osimertinib-treated patients (1%) versus 10% in the placebo arm. In the updated analysis by Herbst et al, the estimated probability of observing CNS recurrence at 36 months was 2% in the osimertinib arm and 13% in the placebo arm; CNS DFS continued to be significantly improved with osimertinib at 48 months (HR 0.24).[46]

There have also been multiple studies examining ALK-positive targeted therapies in NSCLC. The ALEX trial randomized patients with previously untreated advanced ALK-positive NSCLC to receive alectinib or crizotinib. The primary end point was investigator-assessed PFS; time to CNS progression was a secondary end point. Time to CNS progression was significantly longer with alectinib (HR 0.16, $P < .001$), and the cumulative incidence rate of CNS progression was 9.4% at 12 months (compared to

41.4% for crizotinib).[47] In the CROWN phase III study, patients were randomly assigned to lorlatinib or crizotinib in patients with ALK-positive NSCLC. Lorlatinib substantially reduced the 12-month cumulative incidence of CNS progression in patients with (7% vs 72%) and without (1% vs 18%) brain metastases at the time of enrollment, as compared to crizotinib.[48]

Immunotherapy in the Treatment of Brain Metastases

The use of immunotherapy for brain metastases has also increased over the past several years. Goldberg et al ran a phase II trial in which patients with NSCLC and at least one brain metastasis that was not previously treated (≥5 mm, <2 cm) or was progressing after prior RT received pembrolizumab 10 mg/kg every 2 weeks.[49] Patients were divided into two cohorts (cohort 1 for those with programmed cell death ligand 1 [PD-L1]) ≥ 1%; cohort 2 for those with PD-L1 <1% or unevaluable. The primary end point of the trial was the proportion of patients achieving response (either PR or CR) in the CNS. In all, 29.7% of patients in cohort 1 had brain metastasis response, which met the trial's prespecified success criteria; 10.8% of patients had stable disease, while 43% had CNS progression. The median duration of response in the patients who achieved response was 5.7 months. The authors commented that the extracranial response rates to programmed cell death protein 1 axis inhibitors in other studies were comparable to the CNS response rate in this study. Similarly, a pooled analysis of KEYNOTE-001, KEYNOTE-010, KEYNOTE-024, and KEYNOTE-042 demonstrated in patients with PD-L1 tumor proportion score (TPS) 1% or higher and TPS 50% or higher, the overall response rate was 33.9% with pembrolizumab compared to 14.6% in the chemotherapy arm.[50]

Surgical Resection

Surgical resection can aid in obtaining a pathologic diagnosis of intracranial lesions, provide immediate relief of tumor mass effect (Figure 101.1), and may cure a small percentage of patients with single or solitary lesions. On the other hand, radiation typically takes several days to work. Radiobiologically, 30 Gy in 10 fractions to a solid tumor (excluding radiosensitive tumors) is not adequate to achieve long-term tumor control.

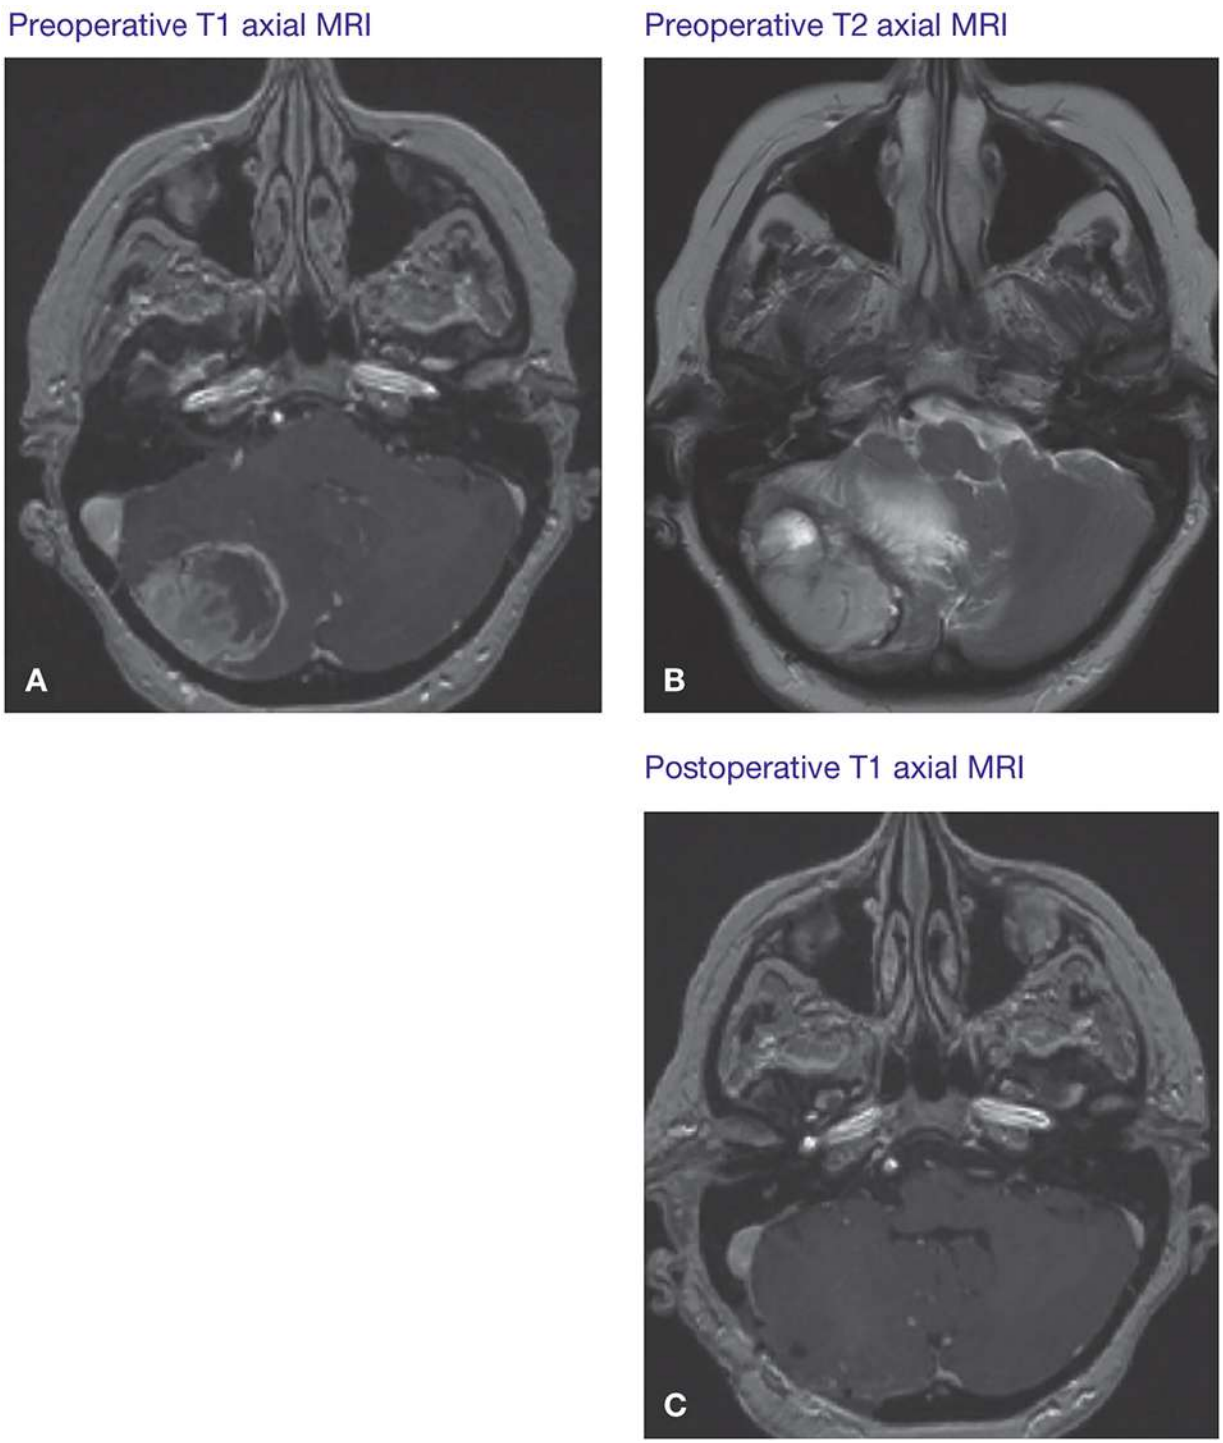

FIGURE 101.1 A. Six months after definitive therapy for stage IIIB non–small cell lung carcinoma (NSCLC), a patient presented with progressively worsening headache, nausea, vomiting, and coordination difficulties. Preoperative T1 gadolinium-enhanced axial magnetic resonance imaging (MRI) demonstrates a large, necrotic right cerebellar mass. B. Preoperative T2 axial MRI reveals large area of vasogenic edema, with resultant mass effect causing fourth ventricular compression and hydrocephalus (not shown). C. Patient was taken immediately for a craniotomy, and a gross total resection was achieved.

Pathology revealed metastatic NSCLC. Postoperative T1 gadolinium-enhanced axial MRI reveals no residual tumor, decompression of the mass effect, and reexpansion of the fourth ventricle.

Given that up to 50% of brain metastases can present as a single lesion, there has been historical interest in evaluating the role of surgery in the management of brain metastases.[51] There have now been three phase III trials testing the hypothesis that surgical resection of single-brain metastasis is potentially beneficial. All three trials included patients with either a single lesion, defined as the presence of only one intracranial lesion regardless of the extracranial disease status, or a solitary lesion, defined as the intracranial lesion being the only site of metastatic disease. Table 101.4 summarizes the three trials.[52-54] The studies by Patchell et al[53] (KPS ≥70) and Noordijk et al[54] (World Health Organization grade #2) included better performance status patients compared with the Mintz et al[52] study (KPS ≥50), which may have contributed to the differences in the outcomes between these studies. In addition, 45% of patients in the study by Mintz et al had extracranial metastases, as compared to 37.5% and 31.7% in the studies by Patchell et al and Noordijk et al, respectively. Similarly, as highlighted by Noordijk et al, the survival benefit to the addition of surgery to WBRT was most pronounced in patients with inactive or stable extracranial disease, with no survival benefit present for patients with active or progressive extracranial disease. The results of these studies suggest that surgical resection should be reserved for lesions causing life-threatening complications, requiring pathologic confirmation, or in patients with good performance status (ie, KPS ≥70) and controlled extracranial disease burden.

Radiosurgery Boost Trials

Radiosurgery provides a suitable alternative to conventional surgery. The three aforementioned randomized trials of surgical resection were all performed before the widespread availability of SRS. Although no randomized trials have been performed comparing surgery with SRS, SRS boost appears to provide at least comparable, if not improved, local control rates (80%-90% when combined with WBRT). Therefore, in the setting of

limited intracranial disease burden, unless emergent surgery is warranted, SRS alone or as a boost can serve as a noninvasive alternative. In addition, while two of the three aforementioned surgery trials have shown a survival benefit in single-brain metastasis, there have been no randomized trials addressing the role of surgery for multiple lesions. In contrast, three randomized trials have assessed the efficacy of SRS boost in the treatment of multiple metastases (Table 101.5).

The first randomized trial was reported by Kondziolka et al[56] from the University of Pittsburgh. This small study was stopped early at a planned interim analysis of 60% patient accrual because the authors reported having found a large difference in the primary end point of 1-year local control in favor of SRS (92% vs 0%; $P = .0016$). Unfortunately, the study used nonstandard end points to measure recurrence, defining it as *any* increase in the lesion size on MRI. Furthermore, no attempt was made to control for steroid use, radiation changes, or other factors that might produce small fluctuations in the lesion size on MRI. Median OS was not significantly different between arms (WBRT alone: 7.5 months vs WBRT + SRS: 11 months, $P = .22$). Therefore, this study is difficult to interpret.

Chougule et al[57] from Brown University reported the second trial, although this has to date only been published in abstract form. This trial had three treatment arms and randomized patients to treatment with SRS alone, SRS plus WBRT, or WBRT alone. This trial suffers from several methodological problems. Although the authors conclude that the survival times among the treatment arms were similar and that patients treated with SRS experienced superior local control, no probability values are given. Furthermore, 51 patients had surgical resection for at least one symptomatic brain metastasis prior to entry into the study, and no attempt was made to stratify for previous surgery. The inclusion of the surgically resected patients effectively made this a six-arm trial and, therefore, the size of this trial was not large enough to support a meaningful analysis. Finally, the radiation doses used in the SRS arms cannot be considered conventional because the peripheral dose was not individualized based on the tumor size or volume.

In the third study, RTOG-95-08, inclusion was limited to 1 to 3 metastases, with a maximum diameter of 4 cm for the largest lesion with additional lesions not exceeding 3 cm. WBRT dose was 37.5 Gy in 15 fractions, whereas SRS boost dose was lesion size based in accordance with the results of RTOG 90-05. The primary end point was OS, which was not statistically different between the WBRT plus SRS and WBRT-alone arms (6.5 months and 5.7 months, respectively; $P = .1356$), although the SRS boost improved the survival in the subgroup (planned analysis) of patients with single metastasis.[55] For secondary end points, the local control and performance measures were higher in the SRS boost arm, but this did not translate into a lower death rate from neurologic progression. Multiple unplanned subgroup analyses were completed, and an OS benefit with SRS boost was found in several subgroups that included patients with RPA class 1, tumor size 2 cm or larger, and NSCLC or metastatic squamous histology from any site. Unfortunately, these subset analyses were not planned or prespecified, and the probability values needed for significance should have been adjusted for inflation of the type I error. When this was done, none of these subgroup analyses showed a positive benefit for SRS. On the other hand, this trial did demonstrate that SRS boost is associated with lower edema and corticosteroid use, countering a commonly held notion that SRS

actually increases the edema risk. However, regarding the major end points for multiple metastases, this study should be considered a negative trial.

More recently, Sperduto et al completed a secondary analysis of RTOG 95-08 to determine the efficacy of SRS boost with patients restratified by DS-GPA scores. Their secondary analysis predominantly included lung cancer primaries (84%). The results revealed an OS benefit to SRS boost in patients with DS-GPA scores of 3.5 to 4, irrespective of the number of metastases (WBRT alone: 10.3 months vs WBRT + SRS: 21 months, P = .05). No survival benefit for SRS boost was observed with DS-GPA scores less than 3.5. These results should be interpreted with caution, however, given the small sample size and potential nonrandom selection of patients in the secondary analysis.[58]

In conclusion, although it would seem SRS boost WBRT is indicated (from RTOG-95-08 and from the extrapolation of surgical resection data) in patients with a single metastasis, it is difficult to justify its use (ie, WBRT + SRS boost) when multiple trials have failed to demonstrate the benefit of WBRT after local therapies like surgery or SRS.

Postoperative or Postradiosurgery Radiotherapy

A historic controversy in the treatment of brain metastasis has been the role of WBRT postoperatively or post-SRS. In a multi-institutional retrospective SRS study, Sneed et al argued for the omission of up-front WBRT because this does not compromise OS.[59,60] Regine et al reported on 36 patients with planned observation after initial SRS alone. Even with close follow-up with examinations and high-resolution MRIs, 47% of patients experienced brain failure, with 71% and 59% experiencing symptomatic relapse and neurologic deficits, respectively.[61] It was also felt that the omission of up-front WBRT may have even more serious consequences for patients with more radioresistant tumors, such as renal cell carcinoma (RCC). The Eastern Cooperative Oncology Group protocol E6397 was a phase II trial that evaluated SRS alone in radioresistant tumors (RCC, melanoma, sarcoma). Manon et al[62] reported a 6-month total brain failure rate of 48.3% with 6-month local failure within the SRS volume of 32.2%. The authors concluded that routine avoidance of WBRT should be approached judiciously.[62] Unfortunately, none of this previous generation of studies

analyzed the consequences of recurrences and WBRT with modern neurocognitive testing.

There have been now multiple phase III trials that have assessed the use of postoperative or postradiosurgery radiation (Table 101.6). Patchell et al[63] evaluated up-front WBRT (50.4 Gy in 28 fractions) versus observation in resected metastatic lesions with a primary end point comparing local and distant intracranial control rates. The results demonstrated that surgical resection without WBRT led to a failure rate at the original site and distant brain/leptomeningeal recurrence of 46% and 37%, respectively. In comparison, surgical resection with up-front WBRT led to a significantly lower failure rate at the original site and distant brain/leptomeningeal recurrence of 10% and 14%, respectively. More importantly, 44% of the patients in the surgery-alone arm died as a result of neurologic sequelae from brain failure as compared to 14% of patients receiving up-front WBRT ($P = .003$). OS was not significantly different between arms (surgery alone: 43 weeks vs surgery + WBRT: 48 weeks, $P = .39$). The results of this study have been frequently misinterpreted in the literature. Some have justified the withholding of up-front WBRT based on the fact that this study demonstrated equivalent survivals. In fact, this study was designed with brain tumor recurrence rate as the primary end point and not OS. To show an OS difference, this trial needed to enroll over 2,000 patients. This study met its primary end point and confirmed the importance of postoperative WBRT in preventing brain failure and death from neurologic causes.

[d]Decline >1 SD from baseline on at least 1 of 7 cognitive tests at 3 months.

[e]Drop in Hopkins Verbal Learning Test–Revised score at 4 months.

Given the long-term cognitive impact attributed to WBRT, however, contemporary series have evaluated the efficacy of postoperative SRS as an alternative to up-front WBRT. Brown et al reported the results of the phase III NCCTG N107C/CEC.3 trial, which randomized patients to postoperative SRS versus postoperative WBRT.[69] Patients with one resected metastatic brain lesion and a resection cavity 5.0 cm or less in maximal extent as well as up to 3 unresected metastases were included in this trial. They were then randomly assigned to postoperative single-fraction SRS (12-20 Gy, dose determined by surgical cavity volume) or WBRT (30 Gy in 10 fractions or 37.5 Gy in 15 fractions). The remaining unresected lesions also received SRS. The coprimary end points of this trial were cognitive deterioration–free survival and OS. Cognitive deterioration–free survival was defined as a drop of greater than 1 standard deviation (SD) from baseline in at least one of the six cognitive tests. Cognitive deterioration–free survival was significantly longer after SRS to the surgical cavity compared to WBRT (median 3.7 vs 3.0 months, HR 0.47, $P < .0001$). At 6 months, cognitive deterioration in patients who had cognitive evaluation was statistically more frequent ($P = .00031$) in the WBRT arm (85%) versus the SRS arm (52%); this held true for all cognitive domains. OS was similar in both arms (median OS 12.2 months in WBRT arm vs 11.6 months in SRS arm, HR 1.07, $P = .70$). However, SRS was associated with a quicker time to intracranial progression as compared to WBRT (median 6.4 vs 27.5 months, HR 2.45, $P < .0001$). In addition, 6-month surgical bed control was significantly lower with SRS (80.4% vs 87.1% with WBRT, $P = .00068$); this difference was even more pronounced at 12 months (60.5% vs 80.6%).

In addition, Mahajan et al prospectively evaluated local tumor control rates of resected metastases receiving postoperative cavity SRS versus

observation in 1 to 3 brain metastases.[70] All lesions not resected received definitive SRS. Secondary objectives included distant brain control and OS. The results revealed 1-year local control rates for observation and postoperative SRS of 43% and 72%, respectively (P = .015). Smaller tumors demonstrated greater 12-month local control (91% for tumors #2.5 cm, 40% for tumors >2.5 and #3.5 cm, and 46% for tumors >3.5 cm, P = .0002). One-year freedom from distant brain failure with observation and postoperative SRS was 33% and 42%, respectively (P = .35). Similarly, OS did not differ with the use of postoperative cavity SRS (observation: 18 months vs postoperative SRS 17 months, P = .24).

Therefore, these data strongly suggest that postoperative SRS should be done over WBRT.

There have now been multiple phase III trials that have evaluated the role of SRS alone versus the addition of WBRT. In the Japanese Radiation Oncology Study Group JROSG-99-1 phase III trial of one to four lesions, the SRS-only arm experienced increased 1-year total brain recurrence rate (46.8% in WBRT + SRS cohort vs 76.4% in the SRS-alone cohort; P < .001), increased 1-year rate of distant brain relapse (P = .003), and increased 1-year local tumor failure (P = .002). This resulted in more frequent use of salvage therapy (P < .001) in the SRS-alone arm.[64] Furthermore, the average time until Mini-Mental State Examination (MMSE) deterioration was significantly longer for the combined arm (16.5 vs 7.6 months; P = .05).[71] Median OS did not differ between groups (WBRT + SRS: 7.5 months vs SRS alone: 8 months, P = .42). Despite no OS benefit for the entire group, this study demonstrates the importance of WBRT in decreasing brain failure, corroborating the findings of the Patchell et al[63] study.

Subsequently, this group has performed a secondary analysis evaluating the outcomes of post-SRS WBRT in non–small cell lung primaries restratified by DS-GPA. Significantly increased median OS was observed with DS-GPA score of 2.5 to 4 (WBRT + SRS: 16.7 months vs SRS alone: 10.6 months, P = .04), whereas no survival differential was observed with DS-GPA scores less than 2.5. No significant difference in neurocognitive function, as assessed by the MMSE, was observed at baseline or during follow-up for WBRT plus SRS or SRS-alone arms for DS-GPA scores of either less than 2.5 or greater than 2.5.[72] The results of the secondary

analyses of the RTOG 95-08 and JROSG-99-1 trials, therefore, indicate that patients with brain metastases from NSCLC primary with favorable DS-GPA scores may benefit more from combined treatment (WBRT + SRS) than either treatment alone. Future prospective examination of this conclusion is warranted.

Muacevic et al[65] randomized patients with single-brain metastasis patients (KPS ≥70, size #3 cm, stable systemic disease) to SRS alone versus resection plus WBRT. While this trial is not exactly an SRS with or without WBRT trial, it addresses the benefit of WBRT to local therapies. Those randomized to SRS alone experienced worse distant (P = .04) recurrences, but there were no differences in neurologic death rates or OS.

The results of EORTC-22952-26001 have been reported with the primary end point of evaluating duration of functional independence.[66] In this study, patients with 1 to 3 brain metastases underwent local therapy with either surgery or SRS and were then randomized to the addition of WBRT versus observation. WBRT did not improve the duration of functional independence or OS but was associated with a significant decrease in 2-year local and distant brain relapse rate versus observation with either surgery or SRS. This resulted in a 16% decrease in the risk of neurologic death. Although there was no difference in the duration of functional independence between the two arms, the authors conclude that this is likely due to a variety of factors, including the subjective definition of functional independence, the routine use of MRI rendering the majority of recurrences as asymptomatic, and the potential impact of systemic progression on performance status.

Brown et al randomized patients with 1 to 3 brain metastases less than 3 cm to SRS alone or SRS and WBRT in the NCCTG N0574 Alliance Study.[67] The primary end point of this trial was cognitive deterioration, defined as a decline in greater than 1 SD from baseline on at least one of seven cognitive tests at 3 months. Secondary end points included tie to intracranial failure, quality of life, functional independence, long-term cognitive status, and OS. Data revealed that there was less cognitive deterioration at 3 months with SRS alone as compared to SRS plus WBRT (63.5% vs 91.7%, respectively, $P < 0.001$). Quality of life was also higher at 3 months with SRS alone ($P = 0.002$). Local control was improved with the addition of WBRT (90.1% vs 72.8% in SRS-alone arm at 1 year, P = .003)

as was 1-year distant brain control (92.3% vs 69.9.%, $P < .001$). Time to intracranial failure was significantly shorter for SRS alone compared with SRS plus WBRT ($P < .001$), though there was no difference in OS (10.4 months for SRS-alone patients vs 7.4 months for SRS + WBRT patients, $P = .92$).

Chang et al[68] reported on a series of 58 patients with 1 to 3 brain metastases randomized to SRS with or without WBRT. The primary end point of the study was neurocognitive function, which was assessed using the Hopkins Verbal Learning Test–Revised at 4 months after therapy. They found that patients receiving combined therapy were more likely to have a decline in learning and memory function at 4 months compared with patients who did not receive WBRT. The median survival was 15.2 months for the SRS-alone group and 5.7 months for the WBRT/SRS group ($P = .003$). However, the local (100% vs 67%; $P = .012$) and distant (73% vs 45%; $P = .02$) brain control rates were worse in the SRS-alone group compared with the WBRT/SRS group. There are multiple criticisms of this study worth noting.[73] First, because the primary end point was neurocognitive function, the authors did not stratify by baseline neurocognitive function or other factors known to impact neurocognition. Second, the authors chose a single test at a single time point. Ideally, a whole battery of tests should be performed at multiple time points to adequately assess the trend of something as complex as neurocognition. Most importantly, the combined arm inexplicably had a shorter survival, contrary to the four previously mentioned trials that demonstrated equivalent survivals. The median survival of 5.7 months was within 2 months of the primary end point mark, which classically falls within the time point of progressively worsening cognition seen in patients who are terminally ill [74,75] The superior survival in spite of inferior local and distant brain control is unprecedented and can possibly be explained by an improper randomization that is possible in a small study.

In summary, four of the five phase III local with or without WBRT trials unequivocally show a meaningful benefit of WBRT in terms of preventing neurologic deaths or brain failure. However, there has been no demonstrated OS benefit with the addition of WBRT. In light of the potential added neurotoxicity of WBRT, it is critical for radiation

oncologists to help patients navigate through the risks and benefits of additional WBRT after local therapy with surgical resection or SRS.

Radiosurgery for Multiple Brain Lesions

The Japanese Leksell Gamma Knife Society designed a prospective observational study (JKGK0901) to assess SRS treatment for 5 to 10 brain metastases.[76] At the time of initiation of this trial, major guidelines suggested that two to four metastases were the ideal number for SRS. This was a noninferiority prospective observational cohort study; 1,195 patients with 1 to 10 brain metastases were assigned to groups 1 (1 brain metastasis), 2 (2-4 brain metastases), and 3 (5-10 brain metastases). The primary end point was OS, with secondary end points of neurologic death, neurologic deterioration, local recurrence, distant brain failure, and maintenance of neurocognitive function, among others. Data revealed that patients with 1 brain metastasis (13.9 months) had significantly longer OS compared to those with 2 to 4 (10.8 months, $P = .0004$) or 5 to 10 (10.8 months, $P = .019$). However, the median OS was not statistically different in patients with 2 to 4 versus 5 to 10 metastases treated with SRS ($P = .78$, $P_{\text{noninferiority}} < .0001$), thereby meeting the primary end point of the study. There were no differences in preservation of neurocognitive function (defined as MMSE score decrease of <3 points from baseline) between the groups of patients with more than 1 brain metastasis. Other secondary end points were also not different between these same groups (local recurrence cumulative incidence, distant brain failure, and leukoencephalopathy). At longer term follow-up of 4 years, maintenance of cognitive function and post-SRS complication incidence did not differ among the aforementioned groups, thus supporting the noninferiority of SRS alone for patients with 5 to 10 brain metastases.[77]

The results of a randomized phase III trial of SRS versus WBRT for patients with 4 to 15 brain metastases were also recently presented.[78] Patients with 4 to 15 untreated brain metastases (up to 20 lesions allowed at time of treatment) were randomized to receive SRS (dosing per RTOG 9005) or WBRT (memantine strongly encouraged). The coprimary end points were memory function assessed by HVLT-R total recall at 4 months and local control. At 4 months, the SRS arm had increased Z-score in

HVLT-R total recall by 0.21 compared to a decreased of 0.74 Z-score in the WBRT arm (P = .041). Similarly, a statistically significant benefit with SRS was also seen at 1 (P = .033) and 6 months (P = .012). Significant improvements in composite neuropsychiatric scores were seen in the SRS arm at 1, 4, and 6 months. There were no differences in OS (median 7.8 months in SRS vs 8.9 months in WBRT arms, P = .59) nor in local control at 4 months (95% in SRS vs 87% in WBRT arms, P = .79). Notably, there was a significant shortening (P = .001) in time to initiation of systemic therapy favoring the SRS arm (1.7 weeks) versus the WBRT arm (4.1 weeks). The trial was terminated early due to the results of NRG CC001 (benefit of HA), but the authors concluded that SRS was associated with reduced neurocognitive decline and shorter time to systemic therapy, without any detriment in OS or local recurrence risks.

These data have laid the foundation for a currently-accruing phase III trial (CCTG CE.7) comparing HA-WBRT + memantine and SRS for patients with 5 to 15 brain metastases.

In summary, SRS can be considered a standard of care for patients with 4 to 15 brain metastases as opposed to up-front WBRT, but we await definitive results from the aforementioned trials, and especially the ongoing HA-WBRT versus SRS trial.

Treatment of Distant Brain Recurrences After Initial Radiosurgery

Modern series have demonstrated that rates of distant brain recurrences following SRS alone at 12 months can be as high as 40% to 60%. Many SRS trials to date have been focused on patients with newly diagnosed brain metastases, so the impact of multiple serial salvage SRS procedures on neurocognitive cognition or OS remains unknown. Brain metastasis velocity (BMV) defined as cumulative number of new brain metastases since up-front SRS/total time interval since up-front SRS at the time of distant brain relapse after up-front SRS has been shown to predict the risk of developing serial distant brain relapse after salvage SRS and has been corelated with survival and neurologic death.[79] Patients were classified by BMV into low (<4 new metastases since first SRS per year), intermediate (4-13 new metastases since first SRS per year), and high risk groups (>13

new metastases since first SRS per year). The use of BMV was subsequently validated in a multi-institutional dataset as a predictor of OS following initial SRS.[80] Median OS in this validation dataset was 12.5 months for BMV <4, 7.0 months for BMV 4 to 13, and 4.6 months for BMV >13 ($P < .0001$).

NRG BN009 is an ongoing phase III trial that is open to accrual. Patients with distant failure after initial SRS (either first or second relapse) will be randomized to receive SRS + HA-WBRT + memantine or SRS alone. The primary end point of the phase IIR will be time to neurologic death, and the end point of the phase III component is OS.

Preoperative Stereotactic Radiosurgery

Postoperative SRS/SRT has several potential drawbacks, including need for expansion of cavity in addition to occasional need for coverage of meninges and surgical tract. These can substantially increase the volume of normal brain that is irradiated. Preoperative SRS delivers radiation to intact brain metastases prior to planned resection. This often means that margin expansion is not required given these intact brain metastases are easily identifiable on preoperative imaging. Dose can often times be decreased with this approach. Preoperative SRS is also not contingent on clinical course after surgery, which may ultimately increase compliance rates. Finally, preoperative SRS can potentially reduce the likelihood of leptomeningeal disease associated with surgical spillage and perturbation, described as nodular meningeal disease, as opposed to classical leptomeningeal disease.

The PROPS-BM multicenter cohort study compiled patients from five institutions with brain metastases who had at least one lesion treated with preoperative SRS.[81] Most patients (98.8%) were treated with single-fraction SRS to a median dose of 15 Gy. Cavity local recurrence rates at 1 and 2 years were 15% and 17.9%, respectively while 1 and 2-year rates of meningeal disease were 6.1% and 7.6%, respectively. Only 10 out of 242 (4.1%) patients experienced grade 3 or higher postoperative surgical complications.

With the challenges of postoperative cavity SRS target delineation, need for larger treatment volumes, and concerns of meningeal disease in mind,

NRG opened the phase III trial (NRG BN012) which is comparing preoperative to postoperative SRS in patients with resectable brain metastases. The primary objective is time to composite adverse end point (defined as either local tumor progression in the surgical cavity, adverse radiation event, or nodular meningeal disease). Patients can have up to 4 brain metastases, one of which requires resection. This lesion must measure between 2 cm and 5 cm.

Small Cell Lung Cancer

Patients with small cell lung cancer were excluded from the landmark clinical trials that established SRS as the preferred treatment for limited brain metastases, and thus WBRT has remained the standard of care for these patients. However, there remain many patients who may be candidates for SRS especially when considering the quality of life and long-term neurocognitive advantages of avoiding WBRT.

The First-line Radiosurgery for Small-Cell Lung Cancer (FIRE-SCLC) cohort study has now been published.[82] This was a multicenter retrospective analysis of patients with small cell lung cancer brain metastases treated with SRS without prior WBRT or prophylactic cranial irradiation (PCI). 710 patients were included in the study; the median OS was 8.5 months and the median time to CNS progression was 8.1 months. Twelve-month competing risk estimate for local failure was 7.0% and for distant CNS failure was 41.6%. Propensity score-matched analyses comparing SRS with WBRT demonstrated that WBRT was associated with improved time to CNS progression (HR 0.38, $P < .001$) but not OS (median 6.5 months for SRS vs 5.2 months for WBRT, $P = .003$) or CNS PFS (median 4.0 months for SRS vs 3.8 months for WBRT, $P = .79$). These data are similar to the other SRS versus WBRT trial data that established SRS as a standard of care.

NRG CC009 is an ongoing phase III trial comparing SRS versus HA-WBRT for patients with 10 or fewer brain metastases from small cell lung cancer. The primary objective of this trial is to assess whether SRS relative to HA-WBRT + memantine prevents cognitive function failure as measured by cognitive decline on a battery of tests. OS and cumulative incidence of intracranial disease progression, neurologic death, and number of salvage procedures used to manage recurrent intracranial disease are secondary end

points. Until these data mature, selected patients with small number of metastases may be candidates for SRS.

For patients receiving PCI for small cell lung cancer, there have now been three phase III randomized studies assessing HA for neurocognitive protection. The PREMER study randomized 150 patients to standard PCI (25 Gy in 10 fractions) or to HA-PCI.[83] The primary objective was decline (defined as a decrease of ≥3 points from baseline) on the delayed free recall (DFR) on the Free and Cued Selective Reminding Test at 3 months. Decline on DFR was significantly lower (P = .003) in the HA-PCI arm (5.8%) compared with the PCI arm (23.5%). Incidence of brain metastases, OS, and quality of life were not significantly different between the arms. In contrast, in the multicenter NCT01780675 trial in the Netherlands, HA-PCI was not associated with a lower probability of cognitive decline.[84] This trial randomized 168 patients to standard PCI or HA-PCI with the same dosing fractionation. The primary end point of this trial was failure in total recall on the HVLT-R at 4 months, defined as a decline of at least five points from baseline. 29% and 28% of patients in the PCI and HA-PCI arms, respectively, showed decline on total recall on the HVLT-R at 4 months (P = 1.000). OS was not different between arms, nor was the cumulative incidence of new brain metastases at 2 years.

NRG CC003 was a phase IIR/III trial that was recently reported in an oral presentation form.[85] Patients were again randomized to PCI or HA-PCI. HVLT-R, TMT, and COWA tests were performed. The primary end points were noninferiority of 12-month intracranial relapse rate (phase II) and 6-month HVLT-R delayed recall failure, defined as using the reliable change index (phase III). For the phase IIR primary end point, HA-PCI had noninferior 12-month intracranial relapse rate (14.8% for PCI arm vs 14.2% for HA-PCI arm, P < .0001 to rule out inferiority). For the phase III primary end point, HA-PCI was not associated with a significant reduction in 6-month HVLT-R delayed recall deterioration (PCI 30.0% vs HA-PCI 26.0%, P = .31). However, HA-PCI did prevent neurocognitive function failure in any neuropsychiatric test (HR 0.77, P = .03). Again, there were no differences in OS (P = .19). Though the study did not meet its primary end point, the authors concluded that HA-PCI did significantly reduce the likelihood of neurocognitive function failure with noninferior intracranial relapse risk and similar OS. The final results and publication are pending.

Therefore, HA-PCI may be a reasonable treatment option especially if patients are concerned about neurocognitive toxicities of PCI, though the data remain mixed.

Repeat Whole Brain Radiotherapy

Occasionally, patients will fail in the brain after initial WBRT. Salvage surgery, SRS, or repeat WBRT should strongly be considered. Wong et al[86] reported on a series of 86 patients who underwent repeat WBRT. The median dose for the first course was 30 Gy in 10 fractions, while the median dose for the second course was 20 Gy. A total of 70% experienced neurologic improvement, with 27% experiencing complete neurologic resolution, while 43% had partial improvement after repeat WBRT. Median survival was 4 months after the second course of WBRT, with a retreatment dose of greater than 20 Gy associated with a significantly longer survival. Clinically significant radiation-related complications were rare.

Son et al[87] similarly reported on a series of 17 patients who underwent whole brain reirradiation. The median RT dose for the first course of treatment was 35 Gy in 14 fractions and for the second course 21.6 Gy in 1.8 Gy per fraction. The median survival time for all patients after retreatment WBRT was 5.2 months. In patients with stable extracranial disease, the median survival time after retreatment was 19.8 months compared with 2.5 months in patients with progressive extracranial disease. Eighty percent of patients experienced improved symptoms, with acute mild to moderate adverse reactions seen in 70.5% of patients.

Therefore, repeat WBRT is relatively safe and highly effective for recurrent or progressive brain metastases after initial WBRT. A minimum of 20 Gy in 1.8 to 2 Gy fractions should be given.

Concurrent Radiosensitizers

Although most patients with brain metastases ultimately succumb to systemic progression, a significant percentage will die from neurologic progression. Multiple randomized trials of concomitant radiosensitizers have been performed in an attempt to optimize brain control (Table 101.7).[88-97] No trial has demonstrated a survival advantage, although a few have demonstrated an increased response rate. The trials with temozolomide

show promise. Temozolomide is an oral alkylating agent with excellent CNS penetration. However, the findings of these relatively small trials need to be confirmed in a larger trial. Otherwise, a patient should be treated with a concomitant radiosensitizer only on a prospective trial.

Leptomeningeal Carcinomatosis

Leptomeningeal carcinomatosis (LCM) is a rare complication of multiple cancers, occurring in approximately 5% of metastatic cancer. A diagnosis of LCM portends a poor prognosis, with a medial survival of 2.3 to 4.7 months in modern series.[98] The most frequent cancers associated with LCM are lung and breast. In breast cancer, it is often seen in patients who have *HER2-neu* overexpression or infiltrating lobular histology.[99] In lung cancer, it is most commonly involved by NSCLC, with adenocarcinoma histology accounting for 50% to 78% of cases.[100]

The majority of patients present with signs and symptoms. According to the review by Gleissner and Chamberlain,[101] spinal symptoms (>60%) are the most common, followed by cerebral (50%) and cranial nerve symptoms (40%). Contrast-enhanced MRI is the radiographic modality of choice. The entire neuroaxis must be imaged if LCM is clinically suspected in a patient with a known malignancy as multifocal involvement is common. In most patients, the MRI will reveal leptomeningeal enhancement that is frequently associated with cranial nerve enhancement and gross tumor deposits. MRI can provide a diagnosis of LCM, with a sensitivity and specificity of 76% and 77%, respectively.[102] A radiographic diagnosis of LCM may be limited, however, in the setting of hematopoietic tumors as the rate of positive neuroimaging is approximately 50%, thereby requiring cerebrospinal fluid (CSF) cytology for confirmation.[98]

CSF cytology is also warranted in a setting when suspicion for LCM is high but MRI is equivocal. Multiple samples may need to be obtained because the initial yield of a lumbar tap may be only 50%.[101] Neurosurgery must be consulted to evaluate the need for (a) shunting if hydrocephalus is suspected and (b) placement of Rickham or Ommaya reservoir for possible intrathecal (IT) chemotherapy. Gleissner and Chamberlain[101] argue that CSF flow studies should be performed with indium-111 or technetium-99, because up to 40% of patients have abnormal CSF flow from gross tumor deposits that may disrupt adequate IT chemotherapy delivery. However, flow studies are not performed by many centers because gross tumor

nodules, most likely to cause flow disruption and not effectively treated by IT chemotherapy, are treated with radiation anyway. Thus, CSF flow studies typically do not change the overall management of patients with LCM who require treatment decisions to be made in an expedient manner.

There is no consensus on the optimal management of patients with LCM. This is mainly because of the lack of large published experiences, limited number of randomized trials, nonuniform treatment regimens in single-institution experiences, and inclusion of various primary tumor histologies in the clinical trials. However, most would agree that an aggressive treatment with radiation and appropriate chemotherapy are indicated in patients with good performance status. The optimal dose and fractionation schedule of radiation therapy delivered in the setting of LCM remains unknown; however, similar to WBRT and MSCC, 30 Gy in 10 fractions is the most typical scheduled used. In a large published experience on LCM from small cell lung cancer (n = 36), the dismal median survival of 1.3 months is a direct result of only 14 patients being offered some kind of therapy (n = 9 for radiation, n = 5 for chemotherapy).[103] In contrast, Chamberlain and Kormanik[104] in a series of patients with LCM from NSCLC (n = 32) treated patients prospectively with radiotherapy followed by IT chemotherapy. The median survival for the entire cohort was 5 months, while patients with normal CSF flow had a significantly longer median survival compared with patients with interrupted CSF flow (6 vs 4 months; $P < .05$). This suggests that an aggressive multimodality approach can produce survival times that are comparable to patients with multiple brain parenchymal metastases.

A phase II randomized trial assessing proton therapy and craniospinal irradiation (CSI) was recently published. Patients with NSCLC and breast cancers with leptomeningeal disease were randomized to proton CSI or photon involved-field radiotherapy (IFRT), which included WBRT and/or focal spine RT.[105] All patients received memantine. There was also an exploratory proton CSI cohort that enrolled patients with other solid tumors. At interim analysis, CNS PFS was significantly improved ($P < .001$) with proton CSI (median 7.5 months) compared to the photon IFRT arm (2.3 months); this led to early discontinuation of the trial. Moreover, there was a statistically significant ($P = .029$) OS benefit with proton CSI (9.9 months) versus photon IFRT (6.0 months), with no difference in the rates of grade 3

or 4 treatment-related adverse events. On multivariable analysis, proton CSI remained significantly associated with CNS PFS (HR 0.15, $P < .001$) and OS (HR 0.43, $P = .025$) improvements. The trial was not powered to evaluate differences in OS, and as such, a phase III randomized trial is in the works to validate these findings.

Most of the historic randomized clinical trials on patients with LCM from solid tumors have included IT methotrexate (MTX)-based regimens (Table 101.8).[106-110] The only trial that compared IT versus non-IT (ie, systemic) chemotherapy was reported by Boogerd et al[110] However, this negative trial only included patients with breast primaries. Glantz et al[109] reported that IT DepoCyt (cytarabine liposome injection) led to a greater median time to neurologic progression (8 vs 4 weeks; $P = .007$), although the OS was not statistically different. The only positive trial reported to date has been by Kim et al[106] from Seoul National University. Patients randomized to IT MTX, arabinofuranosyl cytidine, and hydrocortisone had a significantly longer survival than those randomized to IT MTX alone (18.2 vs 10.4 weeks; $P = .029$). Patients with adenocarcinoma of the lung in the multiagent arm had a significant, longer survival (23.9 vs 10.4 weeks; $P = .038$). Multiple other agents have been studied, but none have demonstrated significant responses. Targeted agents that cross the BBB should be used when appropriate.

TABLE 101.8 RANDOMIZED TRIALS OF SOLID TUMOR PATIENTS WITH LEPTOMENINGEAL CARCINOMATOSIS

Study	*N*	Histology	Arms[a]	RR[b] (%)	Median Survival	Survival (*P*-value)
Hitchins et al[107]	44	Solid tumors	IT MTX 15 mg	61	12 wk	.08

Boogerd et al[110]	35	Breast	IT chemotherapy[d]	41	18 wk	.32
			Non-IT chemotherapy	39	30 wk	

Ara-C, arabinofuranosyl cytidine; CSF, cerebrospinal fluid; DepoCyt, sustained-release cytarabine; IT, intrathecal; MTX, methotrexate; NS, not significant; RR, response rate; RT, radiotherapy.

[a]All studies allowed palliative radiation when necessary.

[b]RR determination by neurologic and CSF improvements as predefined by each study.

[c]Fourteen patients (19%) had lymphoma, the rest had solid tumors.

[d]All patients started with MTX and switched to Ara-C if no response.

There is ample evidence that focal radiation, such as WBRT or spinal radiation, provides added benefit to IT chemotherapy. This is particularly true in patients with bulky meningeal disease because IT chemotherapy only penetrates 2 to 3 mm. In the randomized IT chemotherapy trial reported by Hitchins et al[107] patients who received concurrent CNS radiation had a higher response rate compared with those who did not (73% vs 35% $P < .05$). Likewise, in the randomized trial reported by Kim et al[106] those who received concurrent CNS radiation had a significant higher neurologic response rate (81.5% vs 50.0% $P = .014$). There is a concern that concurrent radiation and IT chemotherapy could potentially increase toxicity. The vast

majority of patients, however, do not survive long enough to see the late neurologic toxicity manifest.

With the recent findings of the first prospective trial of RT for solid tumor leptomeningeal disease, there is now evidence of the potential benefits of proton CSI in terms of improved CNS PFS and potentially OS. It is premature to say that proton CSI should be a standard of care for patients with leptomeningeal disease at this time, but discussion with patients about the benefits and risks of this more aggressive treatment, as opposed to focal radiation, is warranted. Logistical considerations regarding proton CSI planning are also very important, especially since these patients are often symptomatic and need more urgent initiation of treatment. Phase III results are still awaited to more definitively define the role of radiation in the setting of leptomeningeal disease.

CONCLUSION

A significant percentage of patients with cancer will require palliative radiation therapy at some point during their natural history. On the basis of randomized data, patients with a limited number of brain metastases should be treated with local therapy such as surgery or SRS with or without whole brain irradiation, while those with numerous brain metastases should be treated, with whole brain irradiation alone. LCM continues to have an unfavorable prognosis, and the use of radiation therapy should be based on the palliation of individual signs and symptoms.

CHAPTER 102

Palliation of Vertebral and Spinal Cord Metastases

Emily MacDuffie and Joshua Jones

METASTASES TO THE SPINE

Metastatic tumors are the most common malignancy in the spine, with an estimated 30% of patients with solid cancer harboring spinal metastasis at the time of death and over 15% receiving a clinical diagnosis of spinal metastasis at some point after their cancer diagnosis.[1] Spinal metastases deserve special consideration as progression of spinal tumors can lead to pain, significant morbidity including numbness, weakness, loss of bowel and bladder continence, and the potential for the development of metastatic spinal cord compression (MSCC) in the future. Spinal metastases in about 10% of patients will progress to cause MSCC, resulting in symptoms that range from paresthesias to paralysis. Given the risk of permanent disability, MSCC is considered an oncologic emergency that warrants expedited treatment. Even in the absence of frank MSCC, spinal metastases should be evaluated by a multidisciplinary team due to the risk of spinal instability, including from pathologic compression fractures, which can be associated with significant pain and limited mobility. This chapter will discuss the epidemiology, pathology, evaluation, and treatment options for spinal metastases and their associated complications.

Spinal Cord Compression

In the United States, more than 20,000 cases of MSCC are diagnosed annually, and it is estimated to develop in approximately 5% to 10% of all patients with cancer.[2,3] MSCC is a devastating complication of cancer associated with complete loss of function below the level of the injury. It is considered a true medical emergency with immediate intervention required. Even with aggressive therapy, results can often be unsatisfactory. Although

most patients with MSCC have limited survival, up to one-third will survive beyond 1 year.[4] As such, and in the context of ever-evolving systemic therapies that are leading to lover survival for patients with metastatic disease, evaluation of prognosis is critical in determining appropriate treatment for patients with MSCC.

Pathophysiology

MSCC develops primarily in one of four ways: (a) continued growth and expansion of vertebral bone metastasis into the epidural space; (b) neural foramina extension by a paraspinal mass; (c) destruction of vertebral cortical bone, causing vertebral body collapse with displacement of bony fragments into the epidural space; or (d) rarely primary hematogenous seeding to the epidural space. Although complex, the most significant damage caused by MSCC appears to be vascular in nature as opposed to mechanical. Epidural tumor extension causes epidural venous plexus compression, which leads to intramedullary edema. This increase in vascular permeability and edema causes increased pressure on the small arterioles. Capillary blood flow diminishes as the disease progresses, leading to white matter ischemia. Prolonged ischemia eventually results in white matter infarction and permanent cord damage.[5] When symptoms are rapid and develop over hours to days, the likelihood of response decreases with time and urgent/emergent intervention is indicated. When symptoms develop more slowly over days or weeks, the injury is more likely related to direct compression and recovery is more likely.[6]

Clinical Presentation and Evaluation

Most patients with MSCC have a history of prior cancer diagnosis. Around two-thirds of MSCC cases have a diagnosis of breast cancer, lung cancer, or prostate cancer, each histology accounting for 15% to 20% of all cases.[7] This reflects the high natural incidence of these tumors and their propensity for osseous metastasis. Back pain is the most common presenting symptom (70%-94%), followed by weakness (61%-91%), sensory deficits (46%-90%), and autonomic dysfunction (40%-57%).[7] Presentation of new-onset back pain in patients with cancer should raise suspicion of vertebral involvement and prompt thorough physical exam and imaging workup.

Even without a prior cancer diagnosis, MSCC should be suspected in patients who present with progressively worsening back pain, incontinence, or paraplegia, especially in the high-risk population such as long-time smokers. Those presenting with MSCC at initial diagnosis are more likely to be subsequently diagnosed with cancers such as lung cancer, non-Hodgkin lymphoma, myeloma, or unknown primary origin.[7] The most common level of the MSCC involvement is in the thoracic spine (60%-80%), followed by lumbar (15%-30%) and cervical spine (<10%); however, multilevel involvement can be identified in 20% to 30% of patients, with the second site often asymptomatic. Providers should be aware that location of pain as described by patients does not reliably correlate to tumor location on imaging, further underscoring the need for accurate imaging.[8]

At initial presentation, computed tomography (CT) is often the first imaging study ordered to identify the etiology of symptoms, and it has a relatively high sensitivity and specificity for the detection of spinal cord compression (SCC).[9-11] However, full spine magnetic resonance imaging (MRI) is the gold standard to best delineate the extent and severity of compression[12] and should be ordered in conjunction with CT for patients with moderate to high suspicion of SCC. Because patients can have synchronous, multifocal MSCC, an MRI of the entire spine with and without contrast should be promptly performed in anyone suspected of having MSCC. High-resolution CT scan or CT myelogram of the spine should be performed for those with contraindications to MRI.

After images are obtained, scoring tools such as the Bilsky epidural spinal cord compression scale[13] can be used to estimate the severity of SCC and the Spinal Instability Neoplastic Score (SINS)[14] can be used to assess the stability of the bony spine (Figure 102.1; Table 102.1).

TABLE 102.1 SPINAL INSTABILITY NEOPLASTIC SCORE (SINS) SYSTEM

Component	Score
Location	
Junctional (O-C2; C7-T2; T11-L1; L5-S1)	3
Mobile spine (C3-6; L2-4)	2

Component	Score
Semirigid (T3-10)	1
Rigid (S2-S5)	0
Pain[a]	
Yes	3
Occasional pain but not mechanical	1
Pain-free lesion	0
Bone lesion	
Lytic	2
Mixed (lytic/blastic)	1
Blastic	0
Radiographic spinal alignment	
Subluxation/translation present	4
Deformity (kyphosis/scoliosis)	2
Normal	0
Vertebral body collapse	
>50% collapse	3
<50% collapse	2
No collapse with >50% body involved	1
None of the above	0
Posterolateral involvement of spinal elements[b]	
Bilateral	3
Unilateral	1
None of the above	0

The SINS represents a validated measurement of spine stability that requires clinical (pain scores) and imaging input (magnetic resonance imaging as well as evaluation of lytic vs blastic tumors). Scores of 0 to 6 indicate a mechanically stable spine, while scores of 7 to 12 represent a potentially unstable spine and scores of 13 to 18 represent unstable spinal pathology.

[a]Pain improvement with recumbency and/or pain with movement/loading of spine.

[b]Facet, pedicle of costovertebral joint fracture or replacement with tumor.

Reprinted with permission from Fisher CG, DiPaola CP, Ryken TC, et al. A novel classification system for spinal instability in neoplastic disease: an evidence-based

approach and expert consensus from the Spine Oncology Study Group. *Spine (Phila Pa 1976)*. 2010;35(22):E1221-E1229.

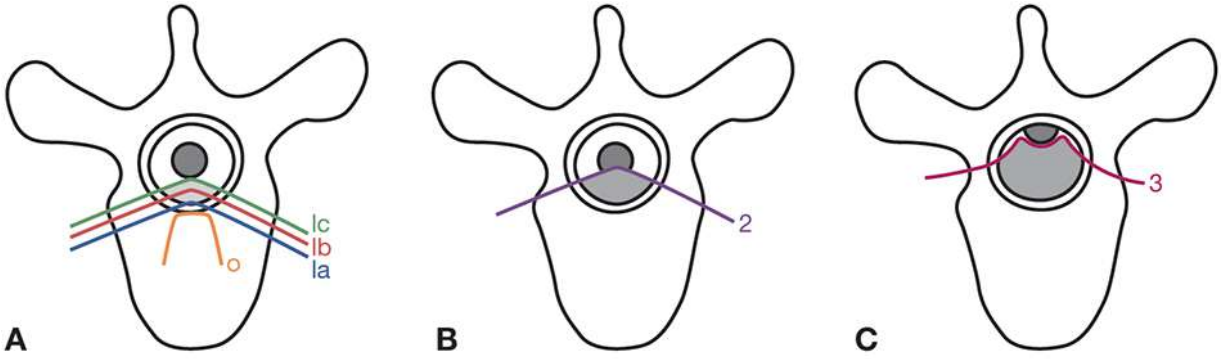

FIGURE 102.1 Epidural spinal cord compression grade. The "Bilsky" score or epidural spinal cord compression grade details extent of epidural tumor in patients with spinal metastases. T2-weighted axial magnetic resonance imaging represents the gold standard for evaluation of epidural tumor. A score of 0 represents no epidural tumor extension (bone-only disease). Score 1a represents epidural tumor extension without deformation of the thecal sac. Score 1b represents epidural tumor with deformation of the thecal sac, but without spinal cord abutment. Score 1c represents epidural tumor with defamation of the thecal sac and with spinal cord abutment. Score 2 represents epidural tumor with mass effect on the spinal cord (spinal cord compression), but with cerebrospinal fluid (CSF) visible around the spinal cord. Score 3 represents epidural tumor with complete spinal cord compression with no CSF visible around the spinal cord. (Reproduced with permission from Bilsky MH, Laufer I, Fourney DR, et al. Reliability analysis of the epidural spinal cord compression scale. *J Neurosurg Spine*. 2010;13[3]:324-328. An Open Access or Creative Commons publishing model conveys no rights to use this material in any format without written permission from the JNS Publishing Group.)

Treatment Algorithms

Options for the management of spinal metastases have expanded dramatically in recent years and include surgical decompression, minimally invasive separation surgery, external beam radiotherapy (conventionally fractionated radiotherapy or stereotactic radiotherapy), interventional spine techniques including kyphoplasty/vertebroplasty and ablative spine interventional techniques such as microwave ablation or cryoablation, systemic therapies such as chemotherapy, targeted therapies or immunotherapy, corticosteroids such as dexamethasone and bone-modifying agents such as bisphosphonates or RANK-L inhibitors. Given the potential high levels of morbidity when patients develop spinal cord compression, multiple treatment algorithms have been developed to guide

management of patients with spinal metastases. The Neurologic, Oncologic, Mechanical, Systemic (NOMS) framework incorporates neurologic, oncologic, mechanical, and systemic factors into clinical decision-making.[15] This score evaluates the neurologic tumor impact, including Bilsky epidural spinal cord compression grade and resulting neurologic symptoms, the oncologic factors of tumor radiosensitivity (eg, lymphoma, myeloma, small cell carcinoma are highly "radiosensitive," while melanoma and renal cell carcinoma are "radio-resistant"; Figure 102.2), mechanical stability as assessed by the SINS, and the patient's overall ability to tolerate surgical intervention or other treatments. These factors can be used to guide decision-making regarding the need for surgery, conventional or stereotactic radiotherapy. An alternative framework for the management of spinal metastases created by the International Spine Oncology Consortium is the LMNOP framework.[16-18] This framework evaluates the number and site of spinal levels involved by tumor (L), the mechanical stability (now incorporating SINS: M), the neurologic deficits and epidural extent of tumor (N), the oncologic parameters including radiosensitivity (O) and patient prognosis, preferences and response to prior treatment (P) (Table 102.2). While clinical decisions must be nuanced based on each patient's individual case, generally patients who have asymptomatic low-grade SCC or highly radiosensitive tumors can undergo radiotherapy alone, whereas those with high-grade SCC or spinal instability who can tolerate surgery should first undergo decompressive surgery, separation surgery, and/or stabilization surgery followed by postoperative radiation to optimize ambulatory and neurologic outcomes.

TABLE 102.2 LMNOP FRAMEWORK FOR THE MANAGEMENT OF SPINAL METASTASES

L: Number of spinal levels involved and location of disease in the spine
M: Mechanical instability, subsequently incorporating SINS
N: Neurology (including epidural tumor extension and neurologic deficits)
O: Oncology, incorporating tumor radiosensitivity
P: Patient fitness, prognosis, and response to prior therapy

SINS, Spinal Instability Neoplastic Score.

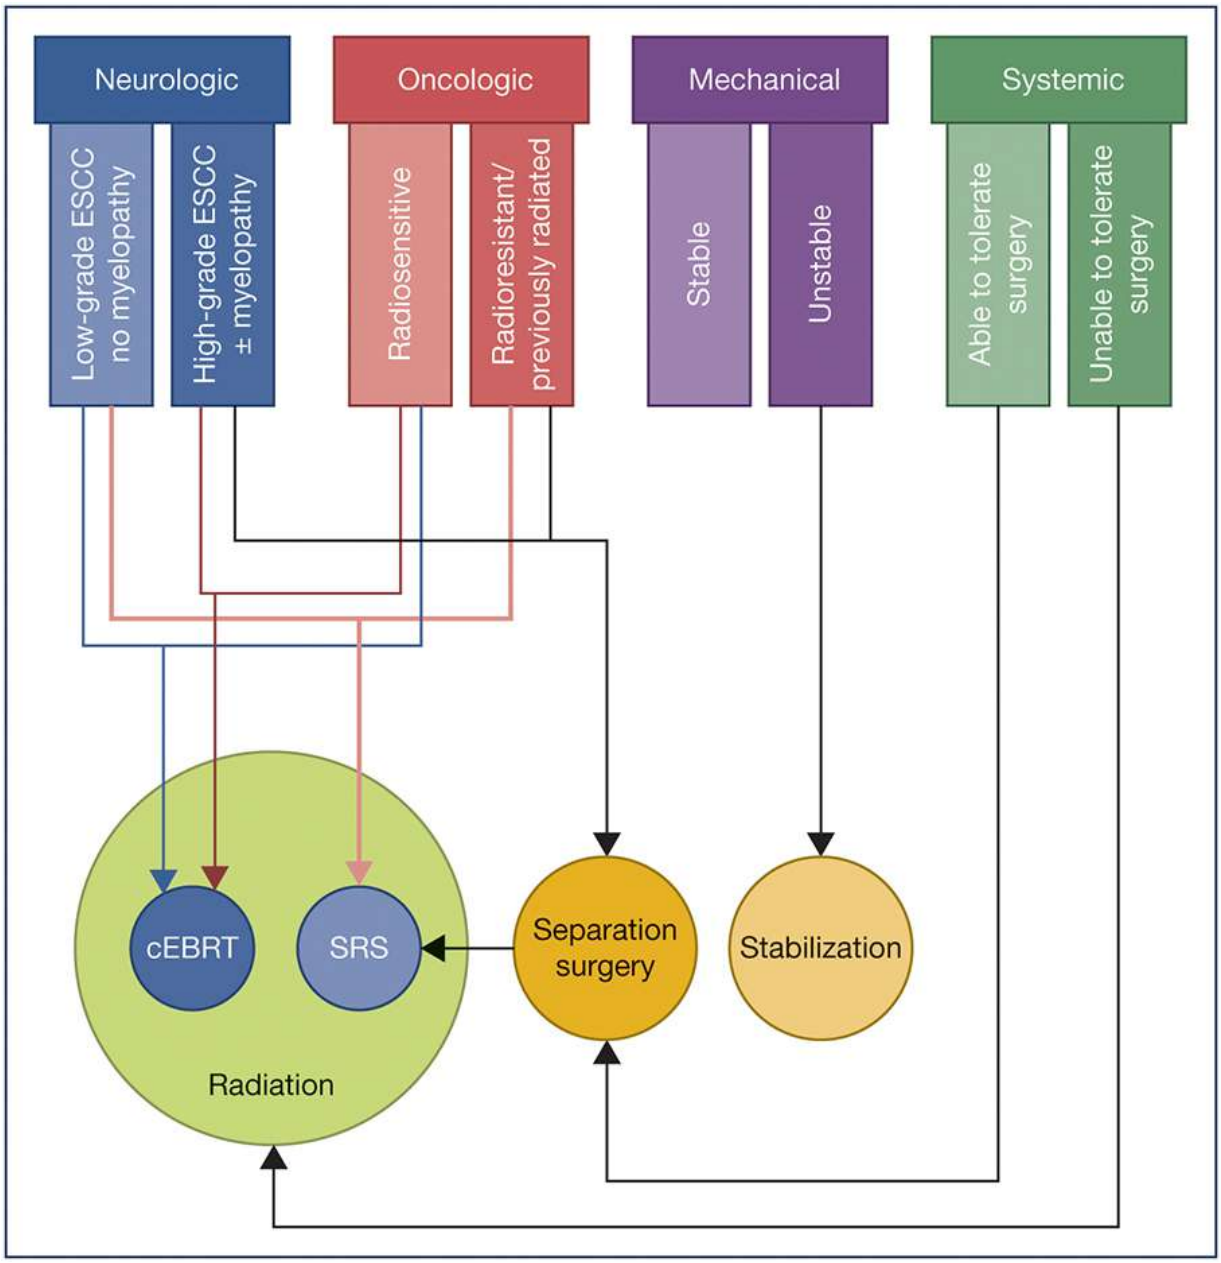

FIGURE 102.2 Neurologic, Oncologic, Mechanical, Systemic (NOMS) approach. The NOMS approach incorporates degree of spinal canal compression and degree of myelopathy (epidural spinal cord compression score) with the radiosensitivity of the tumor, the mechanical stability of the spine (SINS), and the patient's overall ability to tolerate surgery in an approach for evaluating optimal management of spine tumors. For the purposes of this approach, the following tumors were defined as radiosensitive: seminoma, lymphomas (all), myeloma and breast, prostate, ovarian and neuroendocrine carcinomas. The following tumors were defined as radioresistant: renal cell carcinoma, thyroid cancers, hepatocellular carcinoma, colon cancer, non–small cell lung carcinomas, sarcomas, and melanoma. cEBRT, conventional external beam radiotherapy; ESCC, epidural spinal cord compression; SRS, stereotactic radiosurgery. (From Laufer I, Rubin DG, Lis E, et al. The

NOMS framework: approach to the treatment of spinal metastatic tumors. *Oncologist*. 2013;18[6]:744-751. Reproduced by permission of Oxford University Press.)

Estimating Survival for Patients With Metastatic Spinal Cord Compression

Patients with spinal metastases and spinal cord compression can present with symptoms at any time point in the cancer trajectory, from initial diagnosis with a long anticipated survival to near end of life with days or weeks to live. As such, accurate prediction of survival is critical to determining the optimal treatment approach for patients with spinal metastases. Traditional scores predicting ambulatory status, neurologic outcomes, and survival have been developed to help with clinical decision-making for patients with spinal metastases including the Tokuhashi score, revised Tokuhashi score, the Tomita index, the Baur score, modified Baur score, Katagiri score, and van der Linden score.[19,20] In addition, multiple scores from Rades, both general scores for all histologies and various histology-specific scores, have been used to predict outcomes including survival-based retrospective evaluation of thousands of patients. Rades et al validated the use of a scoring system for patients treated with radiation alone by assigning 2 to 8 points for six prognostic factors: tumor type, interval between tumor diagnosis and MSCC, other bone or visceral metastases, ambulatory status, and duration of motor deficits.[21] The 6-month survival rates were 14% for those with 20 to 30 points, 56% for those with 31 to 35 points, and 80% for those with 36 to 45 points. Use of these tools may help guide physicians in selecting the appropriate intervention and length of a radiation course based on a patient's prognosis and potential for recurrence over their remaining lifetime.

More recently, machine learning algorithms have been utilized to predict 90-day and 1-year survival for patients with spinal metastases undergoing surgery. The Skeletal Oncology Research Group (SORG) has developed a machine learning algorithm that has been externally validated by multiple groups and predicts 90-day and 1-year survival for patients undergoing surgery for spinal metastases.[22-24] The group created a classic scoring algorithm, nomogram, and boosted algorithm with machine learning to evaluate survival for patients with spinal metastases. Factors that impact survival include age, performance status, primary cancer type, more than

one spinal metastasis, lung and/or liver metastasis, brain metastasis, any systemic therapy prior to surgery, white blood cell count, and hemoglobin levels. Regardless of which system is utilized, validated prognostic models should be incorporated into clinical decision-making for patients with spinal metastases.

Corticosteroids

Corticosteroids are a critical component of the management of MSCC. Administration is often indicated even prior to radiographic diagnosis if there is any suspicion of MSCC, as medications can be rapidly discontinued if a negative diagnosis is obtained. Corticosteroids effectively decrease cord edema and serve as an effective bridge to definitive treatment. In addition to multiple retrospective studies that have demonstrated their clinical efficacy, Sorensen et al[25] reported a randomized controlled study (n = 57) on the utility of high-dose corticosteroids before definitive radiotherapy in MSCC from solid tumors. The treatment arm consisted of 96 mg of intravenous (IV) bolus of dexamethasone followed by 96 mg oral per day for 3 days and a 10-day taper versus no corticosteroid therapy. This study demonstrated 3-month and 6-month ambulatory rates of 81% versus 63% and 59% versus 33% ($P < .05$), respectively, in favor of high-dose dexamethasone.

The optimal maintenance dose of corticosteroids has not been firmly established, but historical trials have shown little benefit to very high doses of dexamethasone as compared to moderate doses. An early trial by Vecht et al[26] comparing an IV loading dose of 10 to 100 mg followed by 16 mg daily showed equal efficacy in pain reduction. However, very high doses of corticosteroids are associated with significant side effects. The Sorensen et al[25] phase III study reported an 11% incidence of serious side effects for patients in the treatment arm. Heimdal et al[27] reported a 14.3% incidence of serious gastrointestinal (GI) side effects in patients treated with 96 mg of IV dexamethasone per day, including a fatal ulcer hemorrhage, rectal bleeding, and bowel perforations. No additional events were recorded after the dose was decreased to 16 mg/d for the remainder of the study, yet ambulatory rates did not decline on the lower dose. Other known side effects of corticosteroids include opportunistic infections, hyperglycemia, and neuropsychiatric disturbances, all of which may disrupt delivery of

oncologic care if severe.[28] Thus, appropriate dosing is important when balancing the benefits and risks of steroid administration.

In clinical practice, a loading dose of 10 mg of IV dexamethasone followed by a maintenance dose ranging from 8 mg every 12 hours to 4 mg every 6 hours is reasonable for patients presenting with MSCC. In clinical practice, it is reasonable to time dosing with diurnal cortisol releases (morning and early to late afternoon) to decrease side effects. Every 6-hour dosing should be reserved only for patients with severe myelopathic symptoms. Patients who can tolerate PO intake can be safely switched to an oral regimen after their initial IV loading dose due to the high oral bioavailability of corticosteroids. Although there are no strict recommendations regarding steroid tapers, after definitive treatment is underway (eg, decompressive surgery has been performed or radiotherapy has been initiated), it is reasonable to reduce by 2 to 4 mg every 3 to 6 days and discontinue within 2 weeks.

Patients initiated on steroids should also be considered for GI prophylaxis with a proton pump inhibitor (PPI) if they are anticipated to have a prolonged steroid course, taking nonsteroidal anti-inflammatory drugs (NSAIDs) concomitantly, or are hospitalized. No randomized trials utilizing PPIs in patients receiving corticosteroids exist, but extrapolations have been made from literature on chronic NSAID use, which mirrors steroid use in the similar disruption of mucosal-protective prostaglandins, and show that PPIs reduce the risk of peptic ulcer development.[29] Use of oral antacids is not recommended as they have not been shown to protect against injury. For patients who are anticipated to remain on 20 mg or more of daily prednisone equivalent dose (ie, 3.2 mg dexamethasone) for 4 weeks or more, prophylaxis for *Pneumocystis jiroveci* pneumonia (PJP) with trimethoprim/sulfamethoxazole or equivalent should be considered.[28,30] Patients with comorbid diabetes should monitor their blood sugar closely and be counseled that they may need to initiate or increase subcutaneous insulin administration while on steroids.

Surgery

Under the NOMS framework, patients who present with symptomatic cord compression, radiographic evidence of Bilsky grade 1a cord compression or

greater, a SINS suggesting spinal instability, radioresistant tumor histology, and fitness for surgery should be considered for surgical intervention and evaluated by a surgeon. In these patients, surgery has the potential benefit of immediate decompression of neurovascular structures and allowing for collection of tissue for pathologic examination. Consultation with a radiation oncologist is always warranted as patients will require radiotherapy as a component of their treatment regardless of surgical candidacy. Effective multidisciplinary teamwork is critical for the rapid evaluation and management of patients with MSCC.

The seminal phase III randomized trial from Patchell et al[31] that established the benefit of surgical intervention over radiation alone reported the efficacy of direct decompressive surgery in patients with MSCC (Table 102.3). The study compared radiation alone (standard 30 Gy in 10 fractions) versus circumferential decompressive and stabilization surgery within 24 hours of diagnosis followed by the same radiotherapy (within 2 weeks of surgery). The trial was prematurely terminated due to statistical improvement in ambulation outcomes in the surgical group. This trial demonstrated a statistically significant advantage to surgery for outcomes including regaining ambulatory function, maintenance of continence, maintenance of American Spinal Cord Injury Association (ASIA) scale and Frankel score (measures of spinal function after injury), median overall survival, and median mean daily dexamethasone and morphine equivalent doses.

TABLE 102.3 KEY FINDINGS OF A PHASE III STUDY OF PATIENTS WITH METASTATIC SPINAL CORD COMPRESSION[31]

	Surgery + Radiation (*n* = 50)	Radiation Alone (*n* = 51)	*P*
Primary endpoint			
Ability to walk posttreatment			
Rate	84% (42/50)	57% (29/51)	.001
Time[a]	122 d	13 d	.003
Secondary endpoints[a]			
Maintenance of continence	156 d	17 d	.016

	Surgery + Radiation (*n* = 50)	Radiation Alone (*n* = 51)	*P*
Maintenance of ASIA score[b]	566 d	72 d	.001
Maintenance of Frankel score[b]	566 d	72 d	.0006
Overall survival	126 d	100 d	.033
Other endpoints			
Mean daily morphine[c]	0.4 mg	4.8 mg	.002
Mean daily dexamethasone[c]	1.6 mg	4.2 mg	.0093
In patients ambulatory at study entry			
Ability to walk (maintaining)			
Rate	94% (32/34)	74% (26/34)	.024
Time[a]	153 d	54 d	.024
In patients nonambulatory at study entry			
Ability to walk (regaining)			
Rate	62% (10/16)	19% (3/16)	.012

[c]Converted into equivalent doses.

Critics have noted that patients in this trial were highly selected, and a matched pair analysis of patients with symptomatic MSCC by Rades et al[21] suggested that endpoints such as posttreatment motor function, ambulatory status, regaining ambulatory status, local control, and survival evaluated after radiotherapy alone appeared similar to those of surgery plus radiotherapy. However, further matched pair analysis of patients with radioresistant histologies did demonstrate superior outcomes for those who received surgical decompression prior to radiation compared to those who received radiation alone.[32] Notably, consistent with prior studies,[33] laminectomy did not demonstrate benefit in this study.

While surgical decompression has traditionally been the preferred surgical approach, new surgical approaches combined with stereotactic ablative radiotherapy may allow similar outcomes with a less invasive approach. Minimally invasive surgical (MIS) separation of tumor and spinal cord can allow for high-dose stereotactic body radiation therapy (SBRT) to be delivered while limiting the dose to the spinal cord. Recently, MIS techniques have been implemented in separation surgery and may show promise for patients who would otherwise not tolerate decompression. Echt et al[34] reported on a single-institution, retrospective comparative study of MIS versus open approach for separation surgery in patients with MSCC. They found that despite having a significantly older population, the MIS group had significantly reduced blood loss during surgery and there was a nonsignificant trend toward reduced time to starting radiation treatment. There were similar rates of local recurrence and hardware failure. In the future, this technique may allow for a broader inclusion of candidates for surgical intervention. Other types of MIS interventions include percutaneous cement augmentation (eg, kyphoplasty or vertebroplasty) or pedicle screw fixation, which can allow for stabilization of the spine followed by oncologic treatment with radiation, with reduced time required for postoperative healing.[35,36]

In summary, for appropriate patients with MSCC, direct surgical decompression, tumor debulking, and spinal stabilization can improve clinical outcomes compared to radiation alone. While there are no randomized phase III data comparing MIS to direct decompressive surgery, outcomes with MIS followed by SBRT may allow faster recovery and less disruption of systemic therapy. All patients should undergo postoperative radiation to prevent local recurrence and the subsequent risk of recompression or disruption of surgical hardware.

Radiotherapy

Palliative radiotherapy has been the standard of care in the treatment of patients with MSCC for many decades. Historically, 30 Gy in 10 fractions has been the most frequently employed fractionation schedule; however, a number of modern studies have suggested that shorter fractionation schemes can be equally effective in many scenarios.[4,37] In one of the largest

studies to date, Rades et al[38] reported a retrospective series of 1,304 patients with MSCC. The patients were separated into five schedules: 8 Gy × 1 in 1 day (n = 261, group 1), 4 Gy × 5 in 1 week (n = 279, group 2), 3 Gy × 10 in 2 weeks (n = 274, group 3), 2.5 Gy × 15 in 3 weeks (n = 233, group 4), and 2 Gy × 20 in 4 weeks (n = 257, group 5). All of the groups had similar posttreatment ambulatory rates (63%-74%) and motor function improvements (26%-31%). However, in-field recurrence rates were much lower for the protracted schedules. The 2-year in-field recurrence rates for groups 1, 2, 3, 4, and 5 were 24%, 26%, 14%, 9%, and 7% (P < .001), respectively. They recommend that a single fraction of 8 Gy should be used in patients with MSCC with limited survival expectations and that 30 Gy in 10 fractions should be used for all other patients.

Rades et al[39] followed up with a randomized trial comparing a short-course regimen (4 Gy × 5) to 30 Gy × 10 in patients with poor to intermediate survival prognosis, defined as having an estimated 6-month survival of 14% to 56% based on a validated scoring system. Primary endpoint was motor function response rate showing improvement or no progression of motor deficits at 1 month. Seventy-five percent of patients survived more than 1 month. One-month response rates were similar for both radiation regimens (87.2%-89.6%, P = .73). Both regimens also had similar effects on motor function at 3 and 6 months posttreatment. Ambulatory status at 1, 3, and 6 months was not significantly different between regimens. Local progression-free survival and overall survival (median: 3.2 months) were also similar for both arms. Based on the trial results, 4 Gy × 5 was deemed noninferior to 30 Gy × 10 and should be strongly considered for patients with poor prognosis in whom limiting treatment time and discomfort should be a high priority.

The SCORAD randomized trial reported by Hoskin et al[40] compared a single dose of 8 Gy radiotherapy with 20 Gy in five fractions with a primary endpoint of ambulatory response (grades 1 and 2, ie, able to ambulate with or without assistance) at 8 weeks posttreatment. While the primary endpoint did not meet the criterion for noninferiority for achieving ambulatory response status at 8 weeks (grade 1 or 2; P = .06), for all other time points of 1, 4, and 12 weeks, the threshold for noninferiority was met. Overall survival was not different between groups. This trial suggests that the use of single-fraction radiation for MSCC may be appropriate in a wider

variety of clinical scenarios than only for patients with very poor performance status.

Table 102.4 compares outcomes of the SCORE 2 and SCORAD randomized studies of radiotherapy alone for patients with MSCC.

TABLE 102.4 COMPARISON OF SCORE-2 AND SCORAD RANDOMIZED STUDIES OF DIFFERENT RADIOTHERAPY DOSE-FRACTIONATION SCHEDULES FOR PATIENTS WITH EPIDURAL SPINAL CORD COMPRESSION

Trial	Score-2, Rades et al[39]		Patchell et al[31]	
Treatment arm	400 cGy × 5	300 cGy × 10	300 cGy × 10 alone	Surgery + 300 cGy × 10
Ambulatory pretreatment	58 of 101 (57.4%) (w/ and w/o aid)	57 of 102 (55.9%) (w/ and w/o aid)	35 of 51 (68.6%) (aid not specified)	34 of 50 (64%) (aid not specified)
Median time, diagnosis to MESCC	>5 mo = 45.5% (46 of 101)	>5 mo = 50% (51 of 102)	7 mo	3 mo
Time motor symptoms to treatment	1-7 d: 45.5% 8-14 d: 25.7% >14 d: 28.7%	1-7 d: 45.1% 8-14 d: 26.5% >14 d: 28.4%	12 d	10 d
Ambulatory status posttreatment	61 of 96 (63.5%)	62 of 96 (64.6%)	57%	84%
Duration of ambulatory status after treatment	71.8% ambulatory, 44.9% with aid at 1 mo	72.0% ambulatory, 42.9% with aid at 1 mo	13 d (median)	122 d (median)
Overall survival (OS)	Median OS 3.0 mo	Median OS 3.7 mo	100 d	126 d

Multiple alternative approaches for patients with longer anticipated survival have been published, demonstrating potential benefit of dose escalation for patients with spinal cord compression and longer anticipated survival. In the RAMSES 01 phase II study, 22 patients were treated with dose-escalated intensity-modulated radiation therapy (IMRT) with either 15

× 2.633 Gy (41.6 Gy_{10}) or 18 × 2.33 Gy (43.2 Gy_{10}) and compared with a propensity-matched historical control group of 266 patients treated with 10 × 3 Gy.[41] The 15-fraction alternative was introduced during the COVID-19 pandemic. Spinal cord maximum dose was 101.5% of the prescription. The dose-escalated population had improved rates of local progression-free survival at 12 months compared with historical controls, a trend toward improved motor functions and similar overall survival and ambulatory rates. Two patients died during radiotherapy and, per protocol, were not included in the analysis. Twenty percent of patients had grade 2 toxicity and 4% had grade 3 toxicity (mostly diarrhea, esophagitis).[42]

The PRE-MODE trial examined 40 patients with spinal cord compression treated with 5 × 5 Gy (biologically effective dose [BED] equivalent to 10 × 3 Gy) using IMRT and compared them to propensity-matched historical controls treated with 5 × 4 Gy. Spinal cord maximum dose was kept to 101.5% of the prescription dose. The 6-month rate of local progression-free survival was 95.0% with improvement in local progression-free survival compared with the historical control. A total of 82.5% of patients were ambulatory after survival. Rates of motor function and overall survival were similar between the 5 × 5 Gy group and historical controls.[42]

SBRT is not usually offered in the setting of spinal cord compression given proximity of tumor to spinal cord and need to "underdose" the tumor to spare the spinal cord. However, a prospective study of 62 patients treated for 85 lesions with spinal cord compression and neurologic power scores of 4 or 5 showed improvement in neurologic function in 81% of patients. Patients were treated with doses ranging from 12 to 20 Gy in a single fraction and the maximum dose of the spinal cord was kept to 14 Gy. There was evidence of tumor regression with thecal sac patency improving from 55% to 76%.[43]

Stereotactic Body Radiation Therapy Versus Conventional Radiotherapy for Spine Metastases

Numerous prospective and retrospective single-arm studies suggest high rates of pain control and local control for patients treated with SBRT.[44] However, only three randomized studies have prospectively randomized patients to SBRT versus conventional palliative radiotherapy in the

management of patients with spine metastases. The SC.24 phase II/III study randomized 229 patients with spinal metastases who did not need surgical decompression to 24 Gy in two fractions SBRT versus 20 Gy in five fractions conventional palliative radiotherapy. Patients were included with SINS less than 12, Eastern Cooperative Oncology Group performance status 0-2, pain score more than 2 and 3, or fewer contiguous spinal segments. The primary endpoint showed improved complete pain response at 3 months (35% vs 14%) with persistence of improved pain control at 6 months. There was no difference in rates of compression fractures and no spinal cord toxicity through the course of the study.[45] Local control rates were higher with SBRT versus conventional palliative radiotherapy (2.8% vs 11.2% at 6 months, 6.1% vs 28.4% at 12 months, and 14.8% vs 35.6% at 24 months) and rates of reirradiation were higher at 1 year for conventional palliative radiotherapy (2.2% vs 15.8%).[46]

A phase II study randomized 55 patients to 24 Gy in 1 fraction SBRT versus 30 Gy in 10 fractions with the primary endpoint pain control at 3 months after radiotherapy. There was a trend toward improved pain control at 3 months and statistically significant improvement in pain control at 6 months and beyond. Compression fracture rates were 27% in the SBRT arm versus 5% in the conventional radiation arm.[47]

The NRG Oncology/RTOG 0631 study randomized 339 patients with painful spinal metastases to 16 to 18 Gy single-fraction stereotactic radiotherapy versus palliative radiotherapy of 8 Gy in a single fraction. Patients were not stratified by SINS. The primary endpoint of pain response at 3 months favored conventional external beam radiotherapy with 60.5% of patients achieving a pain response with cEBRT compared with 41.3% pain response with SRS. Performance status was the most significant factor influencing pain response. Compression fracture rates were 19.5% with SRS and 21.6% with cEBRT.[48]

A meta-analysis of these studies showed improved complete pain response with SBRT without improvement in overall response rates. There were no differences in overall survival or local progression according to the meta-analysis,[49] though the SC.24 study supplemental analysis showed improvement in local control and reirradiation for SBRT compared with cEBRT.[46]

There is no standardized response assessment for clinical evaluation of patients who have been treated with spine SBRT for spinal metastases. The Spine Response Assessment in Neuro-Oncology (SPINO) group has published two reports on the challenges in assessing clinical outcomes after treatment of spinal metastatic disease based on imaging, clinical outcomes, and patient-reported outcomes. Imaging responses can be difficult to interpret due to overlap between tumor and treatment effect signal on MRI. Pain relief can be difficult to assess—what is residual pain from tumor versus spinal stability? In this context, the first SPINO report evaluated the response outcomes used in various retrospective and prospective trials of spine SBRT.[50] The second report created recommendations for clinical evaluation of patients treated with SBRT for spinal metastases, both imaging and clinical responses[51] (Table 102.5).

TABLE 102.5 SPINO RESPONSE ASSESSMENT GUIDELINES FOR EVALUATION OF CLINICAL RESPONSE TO SPINE SBRT

Clinician-based measures	
Spinal stability	SINS
Epidural tumor extension	Bilsky grade
Neurologic assessment	AIS, MRC, 10-m walk test
Functional assessment	KPS, ECOG
Patient-reported outcomes	
Generic	EQ-5D or SF-36
Pain	BPI
Spine tumor specific	SOSGOQ or MDASI-SP

AIS, ASIA impairment scale; BPI, Brief Pain Inventory; ECOG, Eastern Cooperative Oncology Group; EQ-5D, EuroQol-5D; KPS, Karnofsky Performance Status; MDASI-SP, MD Anderson Symptom Inventory for spine tumors; MRC, Medical Research Council; SBRT, stereotactic body radiation therapy; SF-36, 36-Item Short Form Survey; SINS, Spinal Instability Neoplastic Score; SOSGOQ, Spine Oncology Study Group Outcomes Questionnaire; SPINO, Spine Response Assessment in Neuro-Oncology.

The American Society of Radiation Oncology (ASTRO) and the European Society of Radiation Oncology (ESTRO) have each published updated guidelines on the management of bone and spinal metastases. Based on the available data, ASTRO conditionally recommends surgery followed by radiotherapy for patients with spinal cord compression. ASTRO recommends 8 Gy in 1 fraction, 20 Gy in 5 fractions, 24 Gy in 6 fractions, or 30 Gy in 10 fractions for patients with spinal cord compression based on overall clinical status. ASTRO conditionally recommends 24 Gy in two fractions with SBRT rather than conventional palliative radiotherapy for patients with spinal metastases, no neurologic deficits, and who are eligible for SBRT, noting that other dose-fractionation schemes may be reasonable.[52]

ESTRO has published a systematic review and meta-analysis for patients treated with de novo spine SBRT. Sixty-nine studies demonstrated outcomes of 5,736 patients treated for 7,236 metastases with overall pain response rates of 83%, 1-year local control rate of 94%, but with high heterogeneity among studies. Pooled vertebral fracture rate was 9%, myelopathy rate was 0%, and pain flare rate was 6%, again with high heterogeneity among studies.[53]

Technical Considerations for Spine Stereotactic Body Radiation Therapy

The American Association of Physicists in Medicine (AAPM) has outlined safe practices for delivery of SBRT.[54] Specific technical expertise is required for safe delivery of stereotactic radiotherapy to the spine, including optimizing patient immobilization, definition of targets and organs at risk, managing patient setup, patient-specific quality assurance, and intrafraction motion. Consensus guidelines for contouring for spine SBRT have been published in the intact (Figure 102.3), postoperative (Figure 102.4), and sacrum SBRT settings (Figure 102.5).[55-57]

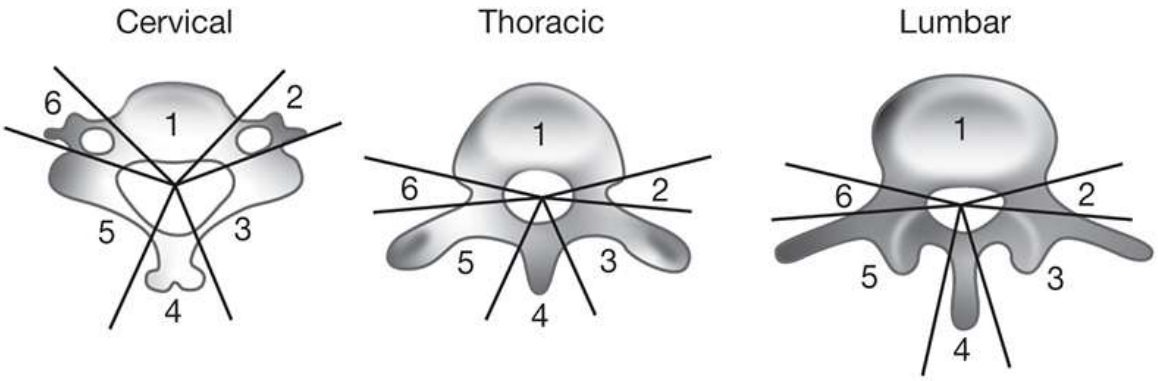

FIGURE 102.3 Consensus contouring guidelines demonstrate the need to cover adjacent spine segments. If a tumor is in a specific spinal segment, the immediately adjacent segment should be included in the target volume. (Reprinted from Cox BW, Spratt DE, Lovelock M, et al. International Spine Radiosurgery Consortium consensus guidelines for target volume definition in spinal stereotactic radiosurgery. *Int J Radiat Oncol Biol Phys*. 2012;83[5]:e597-e605. ESTRO guidelines further outline the specifics required for appropriate treatment with spine stereotactic radiotherapy. Essential to a spine SBRT program is collaboration between physicians, medical physicists, dosimetrists, radiation therapists, spine surgeons, neuroradiologists; use of adequate patient immobilization; MR simulation or fusion of a diagnostic MRI to evaluate target volumes and organs at risk including spinal cord and thecal sac; use of pretreatment imaging; and intrafraction patient analysis. Ideally, a six-degrees-of-freedom treatment couch should be utilized to account for pitch and role in patient daily setup.[58]

There are multiple references for tolerances of organs at risk in the management of patients undergoing spine SBRT. Mutually agreed upon

constraints should be established up-front prior to treatment planning; priority should be given to spinal cord/thecal sac constraints over tumor coverage to decrease the risk of myelopathy. The ASTRO guidelines have published sample single- and two-fraction constraints for patients undergoing spine SBRT (Table 102.6).

TABLE 102.6 SAMPLE CONSTRAINTS FROM THE ASTRO BONE METASTASIS GUIDELINES FOR ONE- AND TWO-FRACTION SPINE SBRT

	1 Fraction			
Organs at Risk	**Volume**	**Volume Max (cGy)**	**2 Fractions**	**Endpoint**
Spinal cord[a]	≤0.35 mL ≤10% of partial spinal cord ≤0.03 mL	1,000 1,000 1,400	N/R	Myelopathy

Pediatric Spinal Cord Compression

MSCC in the pediatric population differs from adult MSCC. Histologic subtypes commonly encountered in children (eg, neuroblastoma, Wilms tumor, and Ewing sarcoma) rarely occur in adults. In adults, most cases of MSCC are caused by direct invasion into the epidural space by metastatic vertebral body tumors, although, in children, most are caused by direct neural foraminal invasion, causing the characteristic "dumbbell" tumor. Chemotherapy plays a central role in the treatment of pediatric MSCC.[59]

Neuroblastoma is the most common histology of pediatric MSCC. Hayes et al[60] (nine cases of neuroblastoma and five cases of Ewing sarcoma) and Sanderson et al[61] (four cases of neuroblastoma) demonstrated that chemotherapy alone allowed complete recovery of spinal cord function in all cases. The French Society of Pediatric Oncology protocol NBL-90 included 42 nonmetastatic neuroblastoma patients with intraspinal extension and consequent MSCC.[62] All were treated with initial chemotherapy, and this resulted in intraspinal tumor shrinkage, avoidance of surgery, and neurologic deficit improvement in 58%, 60%, and 92% of the patients, respectively. Severe neurologic sequelae occurred in only six patients (15%).

Emergent surgery should be offered to any pediatric patient with rapid neurologic progression at initial presentation or while on chemotherapy. In most circumstances, this should be followed by definitive chemotherapy. In stable or mildly symptomatic patients, chemotherapy can obviate the need for surgery, which is often associated with long-term skeletal deformities. Radiation should be reserved only for those who require palliation for progressive disease after failure of multiple systemic regimens, those who progress neurologically despite the initial treatment with chemotherapy or surgery, and those who present with primary vertebral tumors (eg, primary vertebral Ewing sarcoma) in which definitive surgery is rarely feasible.

Intramedullary Spinal Cord Metastasis

Intramedullary spinal cord metastasis (ISCM) is rare, representing only 1% of all intramedullary tumors but being more greatly recognized as an entity given enhanced radiographic techniques. According to a review by Kalayci et al,[63] ISCM is most commonly secondary to a lung primary (54%), followed by breast cancer (11%). Although back pain is common in more than 90% of patients with MSCC, back or neck pain was seen in only 38% of patients with ISCM. However, high sensory deficits (79%), sphincter dysfunction (60%), and weakness (91%) are more common in ISCM. The most striking difference between ISCM and MSCC is the high incidence of synchronous brain metastasis (41%) in patients presenting with ISCM. This is not surprising when one considers the route of spread and the high incidence of lung primaries in patients with ISCM. An MRI of the brain should be obtained.

The treatment of ISCM should be approached very similarly to MSCC, except for the role of surgery. Most surgeons are reluctant to operate in ISCM because surgery carries a high morbidity rate. Corticosteroids as well as radiation therapy should be promptly initiated. Unfortunately, a diagnosis of ISCM portends a poor prognosis, with median survival of 1 to 5.5 months.[64]

Reirradiation

As patients with metastatic cancer live longer, more patients are developing symptomatic progression in previously irradiated fields. Similar algorithms for patient management to de novo radiotherapy are applicable, but special attention must be paid to spinal cord tolerance. Patients should be evaluated for prognosis, spine stability, degree of spinal cord compression, and prior dose of radiotherapy to the spinal canal.

A phase III randomized trial of patients requiring reirradiation for bone metastases included randomization for patients with spinal metastases to 8 Gy in one fraction or 20 Gy in eight fractions reirradiation. About 45% (single fraction) versus 51% (multifraction) of patients who underwent repeat irradiation had pain response, including patients with spine and non-spine bone metastases.[65] Thus, for patients with short anticipated survival, reirradiation with 8 Gy in one fraction or 20 Gy in eight fractions is reasonable for palliation of pain in patients with spinal metastases.

A retrospective review of patients receiving reirradiation who developed and did not develop radiation myelopathy was conducted to evaluate spinal cord tolerance to reirradiation. The authors used BED calculations with an α/β ratio of 2 and found that the risk of myelopathy is low (<3%) if the following factors are utilized: time between radiotherapy courses more than 6 months, cumulative effective dose to spinal canal less than 135.5 Gy (BED2), and neither course to spinal exceeding 98 Gy (BED2).[66]

Patients who have better anticipated survival may be candidates for SBRT in the reirradiation setting. No randomized comparisons of conventional palliative reirradiation versus SBRT have been conducted, but if a patient has a good anticipated survival, it is reasonable to consider dose escalation with SBRT. One retrospective study analyzed 60 patients treated with 24 Gy in three fractions versus 25 to 30 Gy in five fractions depending on tumor proximity to spinal cord. A total of 65% of patients had at least some pain relief and 93% of patients had stable disease at 9 months.[67] Thecal sac constraints have been evaluated in the spine SBRT reirradiation setting and are listed in Table 102.7.

TABLE 102.7 ASTRO BONE METASTASES GUIDELINE SUGGESTED THECAL SAC CONSTRAINTS FROM AN ANALYSIS OF SPINE SBRT REIRRADIATION

Prior Radiation Details		SBRT Reirradiation Dose Recommendations		
Prior Spinal Cord Total Dose	**Prior EQD2-2**	**Planned Number of Fractions**	**Acceptable Range of Reirradiation Total Dose**	**Recommended Thecal Sac Constraint (Dmax)**
2,000 cGy/5 fx-3,000 cGy/10 fx	3,000-3,750 cGy	1	1,600-1,800 cGy	900 cGy
4,000 cGy/20 fx-5,000 cGy/25 fx	4,000-5,000 cGy	1	Not recommended	Not recommended
2,000 cGy/5 fx-4,500 cGy/25 fx	3,000-43,000 cGy	2	1,600-2,400 cGy	1,220 cGy
5,000 cGy/25 fx	5,000 cGy	2	1,600-2,000 cGy	1,100 cGy
2,000 cGy/5 fx-4,500	3,000-4,300	3	1,800-2,700 cGy	1,450 cGy

Prior Radiation Details		SBRT Reirradiation Dose Recommendations		
Prior Spinal Cord Total Dose	Prior EQD2-2	Planned Number of Fractions	Acceptable Range of Reirradiation Total Dose	Recommended Thecal Sac Constraint (Dmax)
cGy/25 fx	cGy			
5,000 cGy/25 fx	5,000 cGy	3	1,500-2,400 cGy	1,250 cGy
2,000 cGy/5 fx-4,500 cGy/25 fx	3,000-4,300 cGy	4	2,400-3,600 cGy	1,620 cGy
5,000 cGy/25 fx	5,000 cGy	4	2,000-2,600 cGy	1,400 cGy
2,000 cGy/5-4,500/25 fx	3,000-4,300 cGy	5	2,500-3,000 cGy	1,800 cGy
5,000 cGy/25 fx	5,000 cGy	5	2,000-2,500 cGy	1,550 cGy

ASTRO, American Society of Radiation Oncology; Dmax, maximum point dose to an organ or tumor target; EQD2-2, dose calculation to an equivalent dose of 2 Gy with α-to-β ratio of 2; SBRT, stereotactic body radiation therapy.

CONCLUSION

Metastases to the spine require special care and consideration given the possibility of significant morbidity including loss of function from spinal cord compression. Prognostic algorithms should be utilized to assess anticipated overall survival and neurologic outcomes for patients with spinal metastases with promise from machine learning algorithms to help predict survival. The degree of epidural spinal cord compression and spine stability can be utilized in conjunction with the NOMS framework. Prognostic models should be used to assess likelihood of overall survival and neurologic outcomes. Surgical decompression should be considered for patients with an unstable spine or for patients with spinal cord compression and neurologic deficits. Dexamethasone should be utilized for patients with neurologic deficits and can help with pain control. Conventional palliative

radiotherapy with doses of 8 Gy in 1 fraction, 20 Gy in 5 fractions, 24 Gy in 6 fractions, and 30 Gy in 10 fractions can be utilized for pain control and to improve neurologic function. SBRT, particularly 24 Gy in two fractions, has shown improved complete pain responses compared to 20 Gy in five fractions. Care must be taken when using spine SBRT to ensure adequate patient setup, reproducibility, and adequate patient-specific quality assurance. In the reirradiation setting, conventional palliative radiotherapy can be utilized for pain control with respect to spinal cord tolerance. BED2 should be limited to 135.5 Gy_2 cumulative, 98 Gy_2 with each course and at least 6 months between courses. SBRT reirradiation should be considered for patients with recurrent/progressive spinal metastases with a good prognosis.

CHAPTER 103

Palliation of Bone Metastases

Alexander A. Harris, Michael Kharouta, Chirag Modi, and William F. Hartsell

BACKGROUND AND INCIDENCE

Metastatic disease to the bone is a common cause of pain and other significant symptoms that are detrimental to quality of life. The exact incidence of bone metastases is difficult to determine, but estimates are that >100,000 people in the United States will develop osseous metastatic disease annually, with a prevalence of more than 300,000 patients living with bone metastases.[1-3] The incidence of bone metastases varies significantly, depending on the primary site, with prostate, lung, renal, and breast cancers having the highest incidence.[4] Bone metastases may be found in up to 85% of patients dying from breast, prostate, or lung cancer. Other primary sites with a propensity for bone metastases include thyroid, melanoma, and kidney. On the other hand, primary gastrointestinal malignancy gives rise to bone metastasis in only 3% to 24% of patients with metastatic disease.[5,6] Some hematologic malignancies, including myeloma and lymphoma, can also cause significant pain and bone destruction.

The ultimate prognosis for patients with bone metastases is poor, with a median survival typically measured in months rather than years, although there may have been some changes in the recent past that will change these timelines. Overall survival depends on the primary site and the presence or absence of visceral metastases. Patients with bone metastases from lung cancer have short median survival durations of 6 months. However, patients with bone metastases from breast or prostate cancer may have significantly longer survival times. In patients with bone-only metastatic prostate or breast cancer, median survivals of 2 to 4 years have been reported.[7-9] Whether the survival time is only a few months or extends to multiple years, these patients will often require active treatment because of pain, difficulty with ambulation and immobility, hypercalcemia, pathologic fractures, neurologic deficits, anxiety, depression, spinal cord or nerve root compression, fatigue, insomnia or sleep disturbances, and general deterioration of quality of life.[5,10,11]

The axial skeleton is the most common site of bone metastasis, with metastasis most frequently occurring in the spine, pelvis, and ribs. The lumbar spine is the most frequent site of bone metastasis.[12-15] In the appendicular skeleton, the proximal femurs are the most common site of metastatic disease. The acral sites (feet and hands) are rarely involved. Certain skeletal sites are associated with specific types of metastatic cancer. For example, scapular metastases are seen more frequently from renal primaries.[16] Involvement of the skull is more common with breast primaries. The distal appendicular skeleton (tibia, fibula) and acral sites (especially the hands) are more common with lung primaries, and involvement of the toes is seen more commonly with genitourinary primaries.

The most common symptom of bone metastases is progressive pain that is well localized. Pain from the femur or acetabulum may worsen with weight bearing or ambulation. In contrast, pain from the inferior ischium or sacrum may be worse with sitting but less bothersome with ambulation. Although the pain is frequently localized, pain may radiate to other areas. This is most frequently seen with pain in the lower back, pelvis, or hips that may radiate down the legs. Pain that radiates does not necessarily indicate nerve impingement because radicular pain can also be caused by spasm of muscles that originate or insert near the area of disease (eg, pain in the hip radiating to the knee).

Bone metastases can present a risk to health and quality of life even if they do not initially present with symptoms. Locally destructive bone metastases can increase the risk of bone fracture. Fracture of certain bones can lead to significant sequelae and potentially shorten a patient's survival. Treatment of these

lesions, either with prophylactic surgical repair or prophylactic palliative radiation therapy (RT) can improve a patient functional status, improve patient mobility, and potentially improve overall survival.[17,18]

The concept of "oligometastases" was proposed by Hellman and Weichselbaum[19] in 1995. In brief, it describes how the clinical outcomes of patients with a small burden of metastatic disease may differ from the patients with a higher volume of metastatic disease. It then follows that these patients may benefit from different treatment paradigms. In these cases, the goals of treating with a limited number and low burden of bone metastases may shift away from the palliation of pain to improving cancer control.[20-23]

PATHOPHYSIOLOGY

There are primarily three types of cells within mature bone: osteocytes, osteoblasts, and osteoclasts. Osteoblasts originate from osteogenic cells, found in the periosteum or endosteum. The osteogenic cells differentiate into osteoblasts when there is a mechanical or chemical stimulus for remodeling or repair. The osteoblasts build bone by depositing collagen type I into the extracellular space. An inorganic complex of calcium and phosphate (hydroxyapatite) is laid down within this organic matrix to provide the strength and density of the bone. The osteoblasts then mature into osteocytes, which maintain the bone structure. Osteoclasts are multinucleated giant cells that originate from pluripotent hematopoietic bone marrow cells and adhere to the bone surface.[24] These cells create an acidophilic environment that causes dissolution of the hydroxyapatite crystals and proteolysis of the bone matrix.

The differentiation and activation of osteoclasts occur because of the effects of a group of proteins that are related to tumor necrosis factor, including osteoprotegerin, receptor activator of nuclear factor-κB (RANK), and the RANK ligand (RANKL). Osteoblasts, stromal cells, and activated T cells express and release RANKL. The RANKL binds to the RANK receptor on osteoclast precursors, which then induces the formation of mature osteoclasts. The destruction of bone by osteolytic metastases is mediated by the osteoclasts, not by the tumor cells. However, the factors that activate the osteoclasts are likely produced by the tumor cells, including RANKL, interleukin-1, interleukin-6, parathyroid hormone–related peptide, transforming growth factor β (TGF-β), and macrophage inflammatory protein 1α.[25-27]

Normal bone is constantly being remodeled in a cycle lasting about 120 to 200 days (3-6 months). For the first 20 to 40 days of the cycle, the bone is resorbed by osteoclasts. The bone is then rebuilt by osteoblasts during the next 100 to 150 days.[28]

The structure of the bone changes during growth and development. At the time of birth, all bones are immature, woven bone. Woven bone is more cellular, with no organized orientation to the collagen fibers of the bone. As bones age, the woven bone is absorbed and is replaced by lamellar bone. The lamellar bone is organized circumferentially around neurovascular canals. This cylindrical structure provides much more strength than the haphazard orientation of woven bone. Most adult bone is lamellar.

Adult bone has three distinct layers: cortical, cancellous, and bone marrow. The cortical bone is the dense, compact exterior portion of the bone. This portion of the bone comprises most of the mass and strength of the skeleton. Internal to the cortical bone is the porous, haphazard network of bone tissue known as cancellous bone, which is also known as trabecular or spongy bone. Inside the porous cancellous bone is the bone marrow. There are two different types of bone marrow, red marrow and yellow marrow. Red marrow produces red blood cells, white blood cells, and platelets. Red marrow is highly vascular. Yellow marrow produces fat, cartilage, and bone. Yellow marrow is scantly vascular. At birth, all marrow is red marrow, but as bone ages, red marrow is slowly replaced by yellow marrow.

In the adult body, there are five different types of bone: long, short, flat, sesamoid, and irregular bone. Long bones consist of the epiphyses, metaphyses, and a diaphysis. The diaphysis is the long shaft of the bone, consisting of a hard cortical exterior encapsulating a central cavity consisting of cancellous bone and bone marrow, known as the medullary cavity. The epiphyses are at the ends of the bone. These are composed of hyaline cartilage initially, which becomes ossified during puberty. The metaphysis is the area between the epiphysis and the diaphysis. Most of the bones of the limbs are made of long bones. Short bones are cuboid in shape and make up the bones of the wrist and ankle. Flat bones are thin and

curved bones. They make up the skull and sternum. Sesamoid bones are found suspended in tendons, such as the patella. Irregular bones are oddly shaped bones that contain a thin layer of cortical tissue surrounding an interior of active cancellous and bone marrow. The majority of the axial skeleton, including the spine and pelvis, is made up of irregular bones.

Metastases to the bone most often occur in the red marrow, which is found in highest concentration in the skull, irregular bones of the axial skeleton, and the medullary portion of the appendicular skeleton. This most often occurs by hematogenous spread but may occur by direct extension as well. Involvement of adjacent bone by direct extension (eg, mandibular involvement from an oral cavity cancer) does not necessarily imply that there is a higher likelihood of distant bone metastases and that its management is very different from that of bone metastases from hematogenous spread.

The relatively high proportion of hematogenous metastasis to bone compared with other sites in the body cannot simply be explained by blood flow, which is >30 times greater in the lung than in red bone marrow.[29] The predilection of certain tumor sites to metastasize to bone may be related to local growth factors in the bone, such as TGF-β, insulin-like growth factors I and II, fibroblastic growth factors, platelet-derived growth factors, preferential adherence to endothelial surfaces in certain bones by cell adhesion molecules, or chemotactic attraction from bone cells by osteocalcin or type I collagen.[5,24,30]

Bone metastases are often described as either osteolytic or osteoblastic. However, these are different representations of abnormalities in the normal bone remodeling process. Breast and lung cancers more commonly cause osteolytic-appearing lesions. Prostate and thyroid cancers more often have osteoblastic-appearing lesions. Only myeloma is associated with purely osteolytic lesions.[24] Most other tumors have a combination of osteolytic and osteoblastic components.

The mechanism of pain from bone metastases is not clearly understood. Possible mechanisms include mechanical instability, irritation of periosteal stretch receptors, tumor-directed osteoclast-mediated osteolysis, tumor cells themselves, tumor-induced nerve injury, production of nerve growth factor, or stimulation of other cytokine receptors.[2,7,31,32] Because the mechanisms of pain may be multifactorial, a combination of therapies may be superior to any one therapy alone.[31]

EVALUATION

The most common symptom associated with bone metastasis is pain. Therefore, the physical examination is an important step in evaluating a patient with bone metastases. The physical examination may help make decisions regarding appropriate subsequent imaging studies. Firm palpation will often elicit the specific area of pain, with “point tenderness” often pointing directly to the affected area in the bone. It is important to carefully evaluate the entire skeletal system with examination because intense pain at one site often masks subjective reports of pain at other sites. A careful physical examination may reveal hidden pain in other locations. A thorough neurologic examination is also important, especially in patients with spinal metastases, to carefully evaluate for the possibility of spinal cord, cauda equina, or nerve root compression.

Technetium-99m (Tc-99m) bone scintigraphy (nuclear medicine bone scan) is the best method for screening patients at risk for bone metastasis who may not present with bone pain. It is also useful to evaluate the extent of metastatic disease in the bone (Figure 103.1). Bone scintigraphy is an indicator of osteoblastic activity. Because multiple myeloma is frequently purely osteolytic, bone scans are less useful for evaluating the extent of disease in myeloma. Bone scintigraphy is not specific for metastatic disease, and positive findings must often be confirmed using other imaging studies. A confirmatory study is especially important in a weight-bearing bone, such as the proximal femur. False-positive readings may be seen in areas of arthritis, trauma, prior fractures, or Paget disease. In addition, the osteoblastic activity in healing bone after treatment may give the appearance of progressive disease. False-negative readings may occur in fast-growing, highly aggressive tumors, especially if these are mainly osteolytic.

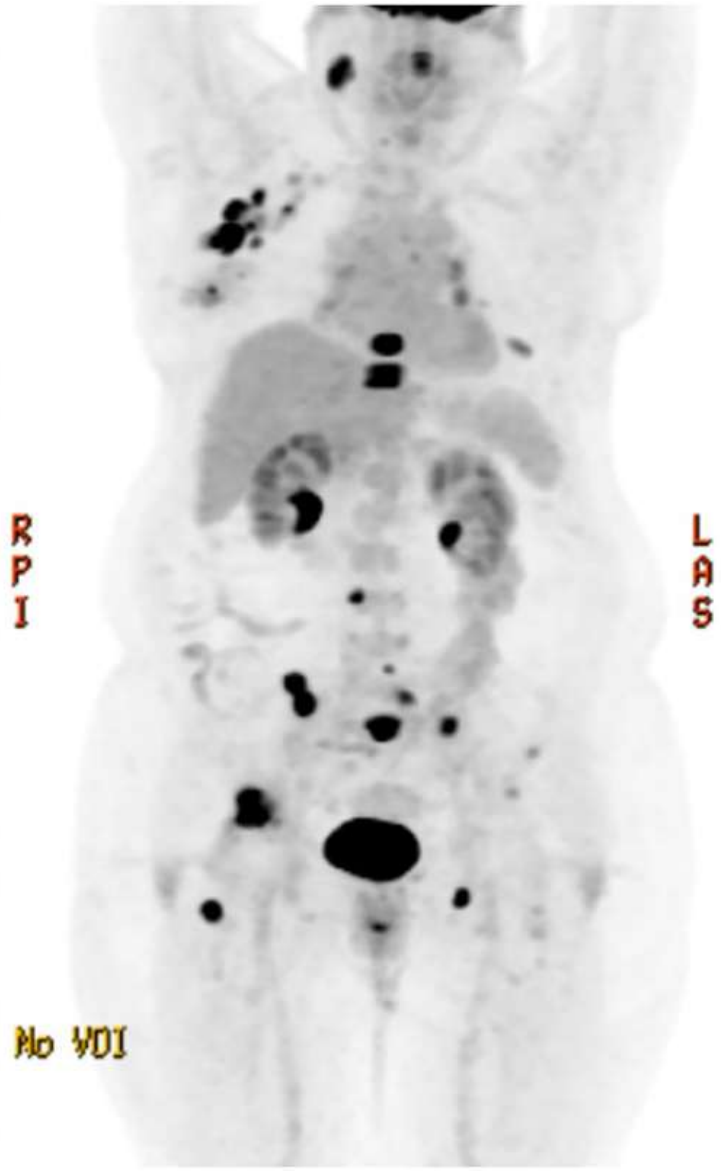

FIGURE 103.1 Nuclear medicine bone scan from a woman with metastatic breast cancer. The bone scan shows the abnormality in multiple osseous sites, as well as in the right breast and axilla.

For symptomatic patients with point tenderness or for patients with an abnormal bone scan, plain radiographs are typically the most appropriate first or next imaging study.[33] Radiographs are easy to obtain and inexpensive. The appearance of bone metastases on x-rays varies depending on the primary site and histology, with some appearing osteolytic and some osteoblastic. However, nearly all bone metastases have components of both osteolytic and osteoblastic processes. The primary disadvantage of plain radiographs is that small lesions are rarely seen. Approximately 30% to 50% of the bone mineral content must be lost before the lesion will be apparent on x-rays.

Computed tomography (CT) scans are more sensitive than plain radiographs and may be better able to localize the lesion within the bone. However, CT scans are more expensive and more time-consuming and may not be useful as a screening tool for skeletal metastasis. The CT may be useful in defining the extent of cortical destruction and helping to assess the risk of a pathologic fracture.[34] In addition, the CT scan may be used to guide needle biopsies to obtain a tissue diagnosis (Figure 103.2A, B). CT scans have

limited usefulness in detecting marrow involvement but are much better than plain radiographs at evaluating soft tissue extension of disease.

FIGURE 103.2 Images from a patient with metastatic prostate cancer. Nuclear medicine bone scan (A) shows uptake in the right pedicle of L4, seen as an osteoblastic lesion on axial computed tomography (B). This biopsy confirmed metastatic prostate cancer. The bone scan does not demonstrate the lesion in the L2 vertebral body, which is demonstrated on the sagittal (C) and axial (D) magnetic resonance images.

Magnetic resonance imaging (MRI) is better than plain radiography or nuclear medicine bone scintigraphy at assessing the involvement of trabecular bone and bone marrow, especially in the vertebral bodies (Figure 103.2C, D). The findings are typically best seen on T1 contrast-enhanced images and short-tau inversion recovery (STIR) images. Metastatic prostate cancer is visible as high-intensity lesions on the STIR images and is visible prior to its appearance on bone scintigraphy.[35] In addition, MRI scans are useful in determining the involvement of neurovascular structures. MRI scans are not useful as a screening tool for bone metastases because of the high cost and lengthy time of the examination. However, MRI scans may be more sensitive than bone scintigraphy in the vertebral body region. The sensitivity of MRI scanning has been reported as 91% to 100%, compared with 62% to 85% for bone scintigraphy.[35,36] In addition, MRI can help distinguish whether a vertebral body compression fracture is from malignancy or osteoporosis.

Positron emission tomography (PET) scanning evaluates areas of increased metabolic activity, most commonly using the 18-fluorodeoxyglucose (FDG) isotope. These scans are useful in detecting highly metabolic osteolytic bone metastases but are less sensitive for the less metabolically active osteoblastic metastases. In addition, precise determination of the location of lesions is difficult with PET scans, but the use of simultaneous CT scans allows for much better localization of the abnormal FDG uptake.[37] PET scans may be useful as a whole-body screening tool.[37,38] Comparative studies have shown PET scans to

be more sensitive than Tc-99m scintigraphy or whole-body MRI scans in detecting bone metastases.[39,40] There may be limitations in the sensitivity of PET scanning in certain areas such as the skull, where the intense physiologic metabolic uptake from the adjacent brain parenchyma may obscure small skull metastases. 18-FDG-PET scans have been used for many epithelial tumor types, but less frequently for prostate cancers. There are multiple new PET scan isotopes, which may be more sensitive and more specific for metastatic prostate cancer, including ^{18}F-NaF, ^{11}C-choline, ^{11}C-acetate, and ^{18}F-fluciclovine.[41] Cancer-specific PET scans, such as prostate-specific membrane antigen (PSMA) and Axumin PET scans for prostate cancer and Dotatate PET scans for neuroendocrine tumors, can identify bone metastases from these primaries with improved sensitivity and specificity.[42,43] These novel PET tracers have begun to be incorporated into randomized trials with encouraging results for the improvement of target delineation and patient outcomes.[22,44]

PAIN MANAGEMENT

The majority of patients with bone metastases will experience pain during their disease course. Controlling pain for a patient with cancer can significantly improve their quality of life. Pain management may be achieved either by debulking disease using cytotoxic therapy, modifying the bone/tumor microenvironment, or by symptomatic control with pharmacologic interventions.

Despite increasing understanding about the effective treatment of pain, patients with pain from bone metastases frequently have inadequate pain management. Barriers to pain treatment include physician underestimation of the patient's pain as well as reluctance by the patient to report the true level of pain.[45] In addition, concerns about opioid abuse and dependence may lead to undertreatment of cancer pain, either or both by the patient or by the physician. There is a significant discrepancy between the physician's estimate of pain and the pain level reported by the patient.[46] The use of a validated pain scale, such as the Brief Pain Inventory, gives the patient an opportunity to describe both the severity of pain and the interference it has with daily functioning in a manner that can be understood by both the patient and the physician.[45] This also allows for distinguishable comparisons of pain levels over time, to better assess the effectiveness of treatments.

Pain control can be achieved in the majority of patients using the World Health Organization analgesic ladder. Step I uses nonopioid analgesics, such as acetaminophen or nonsteroidal anti-inflammatory drugs; step II uses weak opioids, such as codeine; and step III uses strong opioids, such as morphine or oxycodone. These medications are increased as necessary until the patient is free of pain. Typically, the medications are given on a schedule ("by the clock") rather than waiting until a certain level of pain is reached ("on demand"). Using a scheduled approach, 70% to 76% of patients will have good pain relief.[47,48] Alternative, nonopioid medications such as gabapentin, pregabalin, or amitriptyline may be used for neuropathic pain. Antianxiety or antidepressant medications may also be of benefit in selected patients.

The opioid-based pain medications frequently cause constipation and may cause nausea. Patients using opioid medications should routinely be administered a fiber supplementation with or without a stool softener or osmotic laxative to minimize constipation. Other side effects of the opioid analgesics may include sedation, mental status changes, and mood changes.

SURGICAL MANAGEMENT

Surgical management of bone metastases is performed primarily to prevent or treat pathologic fractures. The goals of surgical intervention are to prevent or relieve pain, improve motor function, and improve overall quality of life. Treatment techniques are simpler and more effective when the procedure is performed prophylactically for an impending fracture rather than after the occurrence of a pathologic fracture. The risk of pathologic fracture depends on multiple factors, including the location and extent of the lesion; whether the lesion is osteolytic, osteoblastic, or mixed; and the primary cancer site.

Fractures of the weight-bearing bones are the most likely to cause significant functional deficits. The proximal femur may have a higher propensity for fracture than other sites, but some authors have suggested that the fracture risk in upper limbs is similar to the risk in the femur. Whether there is a difference in the risk of fracture, the peritrochanteric femur is the site most likely to cause serious morbidity, and therefore, the threshold for prophylactic intervention should be relatively low. The femur accounts for 65% of pathologic fractures requiring surgical intervention.[49] The humerus and vertebral bodies are also sites that require special attention because of the potential functional deficits from pathologic fractures.

The size of the bone metastasis is an important predictor of risk of fracture, especially with regard to the extent of cortical destruction. Various models have been used to predict the risk of pathologic fracture based on the size of the lesion. In series using plain radiographs, lesions ≥2.5 cm in the cortex of the femur were significantly more likely to fracture.[50] The proportion of cortical destruction is important as well. The risk of pathologic fracture of the femur begins to significantly increase when there is destruction of >50% of the cortex; the risk of fracture is 80% when >75% of the cortex is destroyed.[51] Femoral lesions with axial cortical destruction >30 mm had a 23% risk of pathologic fracture, compared with 3% risk of fracture for cortical destruction ≤30 mm.[52] The location within the bone is important as well. An experimental model has shown that the greatest reduction in strength of the femur occurs with lesions in the inferior and medial aspects of the femoral neck, and posterior lesions have the least impact (Figure 103.3).[53]

A

FIGURE 103.3 Anteroposterior (A) and oblique (B) radiographs of the right femur in a patient with metastatic breast cancer. Note the significant destruction of the posterior cortex from the proximal to mid-diaphysis of the femur, in a "moth-eaten" appearance.

A scoring system proposed by Mirels[54] has a 12-point scale based on the location of the lesion, pain, extent of cortical destruction, and radiographic appearance (Table 103.1). The risk of fracture is 15% for a score of 8 and 33% for a score of 9. He proposed that prophylactic fixation is indicated for a score of ≥9.

TABLE 103.1 MIRELS SCORING SYSTEM OF PREDICTION OF PATHOLOGIC FRACTURE RISK

Score	Pain	Location	Cortical Destruction	Radiographic Appearance
1	Mild	Upper limb	<1/3	Blastic
2	Moderate	Lower limb	1/3-2/3	Mixed
3	Severe	Peritrochanteric	>2/3	Lytic

A score is assigned for each of the four categories, and the sum of those scores is used to estimate the risk of pathologic fracture.
Adapted with permission from Mirels H. Metastatic disease in long bones: a proposed scoring system for diagnosing impending pathologic fractures. *Clin Orthop Relat Res*. 1989;(249):256-264.

The decision to proceed with surgery should be based on a number of factors, which include, but are not limited to, the estimated risk of pathologic fracture and overall life expectancy. For patients with a very limited life expectancy, surgery may not be indicated even if the risk of pathologic fracture is relatively high.[49] An approach utilizing clinical assessment, patient, and cancer-specific parameters, along with evidence-based prognostic models can be used to aid in identifying which patients are best served for surgical resection versus less or noninvasive approaches.[55-58]

Femoral fractures are the most common site of surgical correction. Fractures of the femoral neck can be managed by either total hip arthroplasty (which replaces both the femoral head and the acetabulum) or a proximal femoral endoprosthesis alone.[49] Fractures of the intertrochanteric area may be managed by open reduction and internal fixation without the use of a prosthesis. This may allow for better long-term gait because of the preservation of the hip flexor and adductor strength.[49] Lytic disease that extends below the intertrochanteric area is treated with a long intramedullary rod that provides stability throughout the length of the femur. If there is significant destruction of the greater trochanter and femoral neck or head in addition to subtrochanteric involvement, a prosthetic replacement would be more appropriate than a reconstruction nail.[59] Fractures of the distal femur may be managed either with a plate and compression screw or with an intracondylar nail and screws augmented by intramedullary methyl methacrylate cement. The latter method may reduce the risk of late failure of the repair, especially in patients receiving postoperative RT.[49]

Repair of pathologic fractures of the humerus may be more problematic because of the small intramedullary canal and because of the proximity of the radial nerve, which may require extensive dissection.[49] Pathologic fractures of the proximal humerus will frequently require prosthetic replacement.[49] Fractures in the diaphysis may be repaired with a compression plate and screws. An alternative is to use a segmental diaphyseal replacement prosthetic device, which involves a prosthetic device that can be cemented into an allograft.[59] Supracondylar fractures are difficult to manage because the shape of the bone is not conducive to a plate and screws; these lesions may require intramedullary rods inserted in a retrograde manner through both the medial and lateral condyles, supplemented by intramedullary cement.[49]

Most pathologic fractures of the pelvis do not require surgical intervention, except for those involving the acetabulum.[49] Repair of acetabular fractures may involve the use of a total hip acetabular prosthesis, but more extensive lesions may require reconstruction that transfers the load-bearing stresses into more structurally intact bone in the iliac bone or sacroiliac joint.[49]

Surgical intervention for bone metastasis typically does not address the underlying oncologic issue that initially put the patient at risk for fracture. If the underlying cancer is not addressed, there is a risk of worse functional outcomes as well as fixation failure. One study from the University of Kansas found that patients who received adjuvant RT to the site of surgical fixation were found to have improved function status and lower rates of repeat surgical interventions at the site, as well as longer overall survival, as compared to patients who received surgery alone.[17]

INTERVENTIONAL TECHNIQUES

Vertebroplasty is an effective method of palliating pain from vertebral body metastases, even in patients who have received prior RT.[60] Most patients experience pain relief within 48 hours. The procedure involves percutaneous injection of methyl methacrylate under CT or fluoroscopic guidance. Retropulsion of bone, epidural tumor, and collapse of the bone to less than one-third of its original height are relative contraindications to percutaneous vertebroplasty because of the risk of extrusion of the cement into the spinal canal, potentially causing neurologic complications. In some patients with epidural tumor,

percutaneous vertebroplasty can be performed safely and effectively with a relatively low risk of serious complications.[61,62] However, the procedure should be considered with some caution; in a systematic review of 987 patients, there were 5 deaths and 19 other serious complications.[63]

Kyphoplasty involves the percutaneous placement of a balloon-like device into a symptomatic spinal metastasis (most commonly into a fractured or compressed vertebral body).[64] The balloon is then inflated to restore the height of the vertebral body, and methyl methacrylate is subsequently injected into this cavity. This procedure may provide significant relief of pain and improve overall functioning, especially in patients with mechanical instability of the vertebral body.[65,66] Kyphoplasty may be a better option than vertebroplasty in patients with vertebral wall deficiency.[65]

An ablative procedure is frequently coupled with vertebroplasty or kyphoplasty.[67] Radiofrequency ablation (RFA) may be used to ablate the tumor but is most effective for tumors that are osteolytic or mixed osteolytic and osteoblastic. The RFA may not be as effective in tumors that are primarily sclerotic. Cryoablation may be used for larger lesions or those that are sclerotic. For both of these procedures, special attention to cord and nerve temperatures is required to minimize the risk of complications.

These interventional procedures are often paired with RT to ensure that the underlying malignancy is addressed. An evidence-based review of the literature leads to ASTRO guidelines noting that, "… vertebroplasty and kyphoplasty for the treatment or prevention of cancer related symptoms does not obviate the need for EBRT in appropriate patients."[68]

SYSTEMIC TREATMENT

The rationale for using systemic therapy in the management of bone metastasis is compelling. The pathophysiology of bone metastasis involves hematogenous dissemination, and most patients with bone metastasis suffer from multiple synchronous sites of disease. In theory, administering systemic cytotoxic therapy should deliver palliative benefit by simultaneously addressing all sites of bone metastasis. A localized therapy such as external beam radiation may be most appropriate for palliation if symptoms are localized. On the other hand, systemic chemotherapy may offer palliative benefit if symptoms are diffuse or constitutional and the disease is widespread. The chemotherapy drugs are frequently given with bisphosphonates and corticosteroids, which may affect the response rates.

Measurement of response to systemic therapy has generally been with the same criteria used for solid metastatic tumors: a measurable radiographic change. This works well for lung and liver metastasis, but not as well for bone metastasis. For bone metastases, the definition of a complete response is complete disappearance of all lesions on radiographs for at least 4 weeks. This is unlikely to occur even if all tumor cells are eradicated. A partial response requires some recalcification of lytic lesions, which may not be evident for 6 months or more.[69] PET scans may be more accurate at assessing response in a timely manner but are too expensive to be used as a routine follow-up evaluation for bone metastases. Response to therapy for other modalities (ie, RT, bisphosphonates) is measured in terms of pain relief and quality-of-life measures. Unfortunately, there is not much literature on accurate and reliable response criteria to palliative systemic therapy for bone metastasis. Most of the studies of chemotherapy for metastatic disease involve patients with visceral as well as osseous metastases. The responses in terms of pain are typically reported for all patients, not just those with bone metastases, so pure bone metastatic pain is difficult to ascertain.

Tannock et al[70] recommended using more relevant end points of palliation. They performed a randomized trial of mitoxantrone plus prednisone versus prednisone alone for patients with hormone-refractory prostate cancer and pain. Improvement in pain was seen in 29% of patients receiving the chemotherapy, compared with 12% of those who received prednisone alone. In a subsequent study, they compared mitoxantrone and prednisone plus or minus clodronate for a similar group of patients. Most had mild pain at study entry (160/209; 77%), and the remainder had moderate pain scores. The patients with moderate pain who received chemotherapy and clodronate had a 58% response rate (≥2-point improvement in pain score) compared with 26% for those who received chemotherapy alone. The median

duration of pain response was 6 months. The TAX327 phase III trial was conducted in 1,006 men with hormone-resistant metastatic prostate cancer and randomized patients to receive prednisone combined with either docetaxel or mitoxantrone. The docetaxel arm showed an improvement in overall survival, lower cancer-induced bone pain, and better objective tumor response.[71]

In patients with bone metastasis, there is seldom reason to combine chemotherapy with concurrent RT because of the potential for increased toxicity when both modalities are delivered concurrently.

A number of hormonal therapies are available in the management of metastatic prostate and breast cancer. In properly selected patients, hormonal therapy has the potential for providing excellent palliation of metastatic disease with limited morbidity. In 1984, the Medical Research Council started a prospective, randomized trial in which 938 patients who either had asymptomatic metastatic prostate cancer or were not medical candidates for definitive therapy were randomized to immediate versus delayed hormone ablation therapy. Hormone ablation was achieved using either a luteinizing hormone–releasing hormone agonist or orchiectomy. This study showed that immediate versus delayed initiation of hormone ablation therapy in the subset of patients with metastatic prostate cancer helped to prevent serious complications from metastatic disease. Serious complications including pathologic fracture, spinal cord compression, development of extraskeletal metastases, and ureteral obstruction were 2-fold more frequent in patients whose hormonal therapy was deferred compared with patients who received immediate hormone ablation therapy.[72]

Osteoclast inhibitors are also often used in conjunction with other systemic treatments. The bisphosphonates are pyrophosphate analogs that bind to calcium phosphate with high affinity and are potent agents affecting bone resorption through osteoclast inhibition.[73] The nitrogen-containing bisphosphonates inhibit the key enzyme farnesyl diphosphate synthase in the mevalonate pathway.[74] This prevents the action of several additional enzymes required for bone resorption. The bisphosphonates include pamidronate, alendronate, ibandronate, risedronate, and zoledronic acid. Zoledronic acid is much more potent than the other bisphosphonates, in part because it also inhibits tumor cell adhesion to the extracellular matrix. There is evidence that the bisphosphonates also induce apoptosis in cancer cells.[75]

The initial studies of bisphosphonate usage were primarily in women with metastatic breast cancer. Pamidronate was evaluated in multiple randomized, prospective studies of women with osteolytic bone metastases from breast cancer. The Aredia Breast Cancer Study Group Protocols 18 and 19 enrolled women receiving either chemotherapy (P19) or hormonal therapy (P18). In the P18 study, 372 women were randomized to receive either placebo or pamidronate.[76] The primary end point was the prevention of "skeletal-related complications" (pathologic fractures, spinal cord compression, hypercalcemia, or the requirement for surgery or RT on bone). There were fewer skeletal-related complications in the pamidronate arm, but the benefit in reducing pathologic fractures and hypercalcemia was not significant until 18 to 24 months of treatment. The primary difference was that twice as many placebo patients required RT for palliation of pain, most often in the first 6 to 12 months. There was no difference in survival, although pain levels and serum markers of bone resorption were significantly lower in the group receiving pamidronate. In the P19 study, women with stage IV breast cancer who were receiving chemotherapy and had lytic bone metastasis were given placebo or pamidronate for 12 monthly cycles.[77] Patients in the pamidronate arm suffered fewer overall skeletal complications and had a greater median time to first skeletal complication when compared with patients in the placebo arm of the study. Women treated with pamidronate maintained better performance status and had less bone pain secondary to metastasis.

Rosen et al[78] evaluated 773 patients with bone metastases from solid tumors, including lung cancer, renal cell carcinoma, head and neck cancers, thyroid, and other primary sites (excluding breast and prostate cancer). They compared placebo with zoledronic acid in doses of either 4 or 8 mg given every 3 weeks for 9 months. The primary end point was the proportion of patients developing a skeletal-related event (SRE), including pathologic fracture, spinal cord compression, or the need for surgery or RT. The proportion of patients developing an SRE was 44% in the placebo group compared with 38% in the 4-mg

zoledronic acid group (P = .127) and 35% in the 8-mg group (P = .023). The time to the development of an SRE was significantly longer with zoledronic acid compared with placebo (230 vs 163 days; P = .017).

The Medical Research Council PRO4 and PRO5 were two prospective, randomized trials conducted to evaluate sodium clodronate in men with prostate cancer. Long-term data showed that sodium clodronate improved overall survival in men with metastatic prostate cancer who were starting hormone therapy, but there was no improvement in overall survival for men with nonmetastatic disease.[79]

Complications of supportive therapy with bisphosphonates include osteoradionecrosis (particularly of the jaw) and renal insufficiency.[80] The mechanism of bisphosphonate-induced osteoradionecrosis is not known. Risk factors include the intravenous use of pamidronate and zoledronic acid, duration of treatment of 36 months or longer, older age in patients with multiple myeloma, and need for periodontal procedures.[81] Bisphosphonates are not metabolized by the body and are excreted by the kidneys. Bisphosphonate therapy can lead to renal toxicity. The incidence of renal toxicity is 9% to 15% in trials when 4 mg of zoledronic acid is delivered intravenously for 15 minutes.[80] Moreover, the rate of renal toxicity depends on underlying renal disease, dose of bisphosphonate used, and duration of the infusion.

Another form of systemic therapy is the use of agents that target the RANK pathway. Denosumab is a human monoclonal antibody specific for the RANKL. The antibody binds to RANKL and thus inhibits the formation, activation, maturation, and survival of osteoclasts.[82] In randomized, prospective comparisons of denosumab with zoledronic acid in patients with metastatic breast or prostate cancer, denosumab was superior to zoledronic acid in delaying or preventing the time to SREs.[83,84]

RADIATION THERAPY

RT has been reported to be effective in palliating painful bone metastases, with partial pain relief seen in 60% to 90% of patients and complete pain relief in 30% to 50% of patients. These data are primarily from meta-analyses of studies using physician evaluation of pain. When patient evaluation of pain is used, pain improvement is seen in 60% to 80% of patients and complete pain relief is seen in 15% to 40% of patients.[85] The response to treatment depends on a large number of factors, including sex, primary site and histology, performance status, type of lesion (osteolytic vs osteoblastic), location of the metastases, weight-bearing versus non–weight-bearing site, extent of disease, number of painful sites, marital status, and level of pain prior to treatment. The effectiveness of the treatment also depends on the goal: palliation of pain, prevention of pathologic fracture, avoidance of future treatments, or local control of the disease. The doses required and volumes treated may be quite different for each of these goals. In addition to pain relief, other symptoms may also be relieved by RT. Patients who have improvement in pain after RT may also have improvement in emotional functioning, decreased insomnia, decreased constipation, and overall improvement in quality-of-life scores.[86] RT should be an integral part of palliative treatment for bone metastases to treat pain and prevent other symptoms.[68]

Local-field external beam RT is typically used for palliation of a few discrete areas of painful metastases (Figure 103.4). The first large randomized study evaluating different dose and fractionation schemes was the Radiation Therapy Oncology Group (RTOG) 74-02 trial.[87] Patients with solitary bone metastases were randomized to 40.5 Gy in 15 fractions versus 20 Gy in 5 fractions. Patients with multiple painful metastases were allocated to one of four treatment schedules: 30 Gy in 10 fractions, 15 Gy in 5 fractions, 20 Gy in 5 fractions, or 25 Gy in 5 fractions. The initial analysis by Tong et al[87] in 1982 showed no statistically significant difference in response rates between any of the treatment arms, with complete responses in 49% to 61% of patients. These results were questioned by Blitzer,[88] who reanalyzed the data using different criteria for complete response, which excluded patients who received repeat treatment, and defined complete response as no pain and no analgesic usage. With this adjustment in response definition, there was a significant difference in response favoring the longer treatment courses: 40.5 Gy in 15 fractions for the solitary metastases and 30 Gy in 10 fractions for multiple metastases. This was offered as evidence that higher doses were necessary for optimal palliation, even though one of the

highest biologic doses for multiple fractions (25 Gy in five fractions) had one of the lower response rates. This reanalysis highlighted the importance of retreatment in this group of patients, especially in those given lower total doses during the initial course of RT.

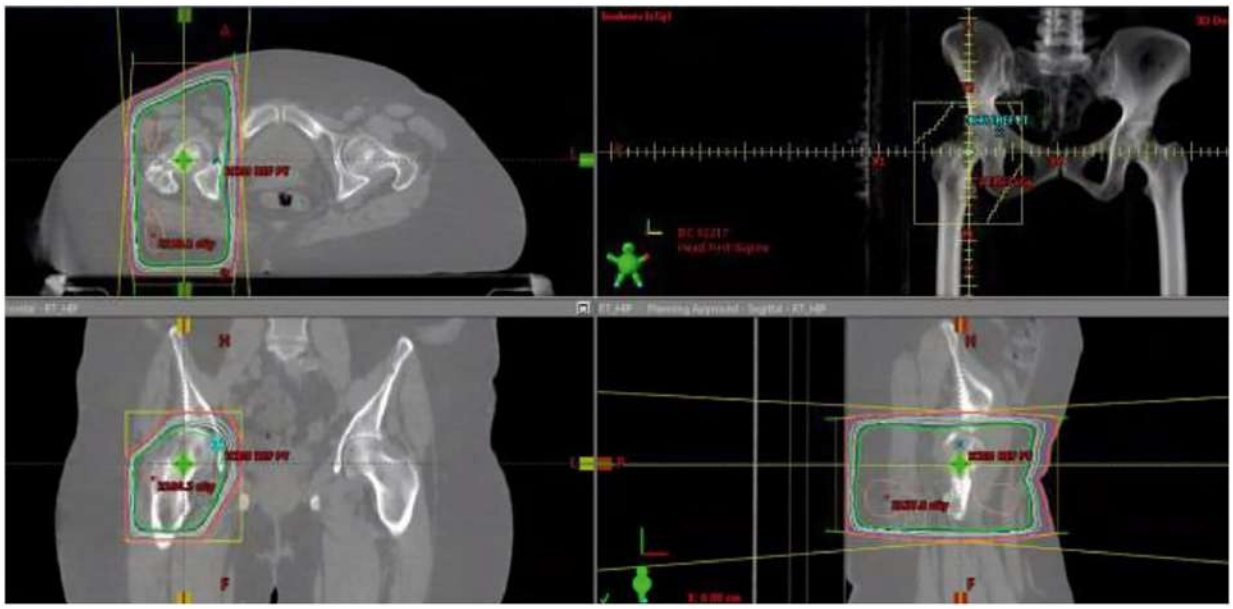

FIGURE 103.4 Isodose plan for a patient receiving radiation therapy to the right hip showing axial and coronal projections of the doses as well as a digitally reconstructed radiograph of the treatment fields.

There have been multiple randomized, prospective trials evaluating different dose and fractionation schemes.[87,89-101] Most of the earlier studies evaluated different multifraction treatment regimens (Table 103.2). No significant difference was seen between longer course treatments and the shorter duration, lower total dose treatment courses. Two randomized studies evaluated single doses of RT for palliation of bone metastases. Hoskin et al[102] randomized patients to 4 versus 8 Gy, and Jeremic et al[103] randomized patients to one of three dose levels, 4 versus 6 versus 8 Gy. In both of these studies, the 8-Gy arm was superior to 4 Gy, indicating that there is a threshold dose necessary to achieve adequate palliation. Most of the randomized trials during the past 15 years used a multiple-fraction treatment scheme as the control arm and a single dose of 8 to 10 Gy as the study arm (Tables 103.3 and 103.4).

TABLE 103.2 RANDOMIZED TRIALS WITH ≥100 EVALUABLE PATIENTS COMPARING MULTIPLE-FRACTION TREATMENTS FOR PALLIATION OF BONE METASTASES

[a]Proportion of patients with pathologic fractures after treatment.

[b]Response rates listed are for pain relief.

[c]A regimen of 30 Gy/10 was also allowed; 98% of patients received 20 Gy/5.

Two large studies compared single-dose treatment to longer courses of RT. The Dutch trial evaluated patients with bone metastases from solid tumors, primarily breast (39%), prostate (23%), and lung (25%); patients with metastatic melanoma and renal cell carcinomas were excluded.[101] The primary end point was patient-assessed pain relief, evaluated on an 11-point scale (0 = no pain, 10 = worst imaginable pain). A total of 1,171 patients were randomized to either 8 Gy in a single fraction or 24 Gy in six fractions. The painful areas had to be included in a single-treatment volume. The spine (36%) and pelvis (30%) were the two most common sites of treatment. The median pain score was 6.3, with a minimum score of 2. About half of the patients were receiving narcotic pain medications prior to randomization, and slightly more than half (53%) were receiving systemic therapy. The median survival after treatment was 30 weeks, with no difference between the two treatment groups. There was no difference in overall or complete response rates between the single-dose versus longer course treatment arms. Overall, 71% of patients achieved a response to therapy during follow-up, with 35% achieving a complete response. Most of the responses occurred within the first 4 to 6 weeks after treatment. Complete response rates were higher for patients with breast and prostate primaries than with lung or other primary sites (44% and 41% vs 21% and 16%).

There were two significant differences between the two treatment groups: retreatment rates and pathologic fracture rates. The rate of pathologic fracture in the treated area was 4% for the 8-Gy single-treatment arm compared with 2% for the 24 Gy/six fraction group. The median time to fracture was similar for the two groups at 21 and 17 weeks. Although there was a significant difference in pathologic fracture between the two groups, these rates are still relatively low. There was also a significant difference in retreatment rates between the two arms of the study, with a much higher likelihood of a second course of treatment in the single-treatment group. The group of patients receiving 24 Gy in six fractions initially was given a second course of treatment 7% of the time, whereas 25% of the 8-Gy single-fraction group was given retreatment. Retreatment occurred more commonly with lung/other tumors than with breast/prostate primaries. In addition, the retreatment was given at a lower pain score (median 6.8 for 8-Gy single-fraction compared with 7.5 for the multiple-fraction group) and at an earlier time (14 weeks after initial treatment compared with 23 weeks). This may indicate a greater willingness to reirradiate after a single dose of 8 Gy or more reluctance to give retreatment after a higher initial dose of RT.

The second large study of single-dose versus longer course treatment for palliation of bone metastases was RTOG study 9714, which was conducted in the United States and Canada.[92] This was limited to patients with painful bone metastases from breast or prostate primaries, with up to three painful sites allowed. Pain was evaluated using the Brief Pain Inventory, an 11-point scale. At the time of randomization, the patient was required to have a minimum pain score of 5 or a high narcotic pain medication requirement of the equivalent of >60 mg of morphine per day. More than 70% of the patients had severe pain at study entry (pain scores of 7-10). Patients were randomized to 8 Gy in a single fraction versus 30 Gy in 10 treatments. The median survival was 9.3 months. Overall toxicity rates were low, with fewer patients in the 8-Gy treatment group experiencing acute toxicity. There were no significant differences in complete (17%) and partial pain response rates (49%) between the two treatment groups. Complete pain and narcotic response (0 pain score and no narcotic pain medication use) were seen in 11%; these responses were all determined at the 3-month post-treatment evaluation. As in the Dutch trial, the rate of retreatment was higher in the 8-Gy treatment group, with 18% in that group receiving retreatment compared with 9% in the 30-Gy group. This disparity in the rate of retreatment occurred despite nearly identical rates of stable (26% vs 24%) or progressive pain scores (9% vs 10%) and similar rates of narcotic use between the two groups.

In contrast to the Dutch trial, there was no difference in the rate of pathologic fractures between the two groups (5% for 8 Gy vs 4% for 30 Gy). Further analysis of this study has shown that certain subgroups may benefit from the longer course of palliative RT. Konski et al[104] showed that although married men and both single and married women were more likely to receive retreatment after receiving 8 versus 30 Gy of palliative RT, there was no difference in retreatment rates among single men. The authors suggest that social support factors may significantly affect the ability of some patients to access repeat therapies for painful bone metastasis, especially as their health declines. Such subgroups of patients may benefit from the longer 10-fraction course of therapy.

These two large prospective, randomized trials comparing single-fraction to multiple-fraction palliative RT have similar results and help to clarify the role of palliative RT for bone metastases. The assessment of pain was performed by the patients rather than by physicians or other health care providers. The studies with the highest response rates generally used physician assessment of pain response. Even with patient assessment of response, the single-fraction treatment yields similar response rates to the longer course treatment. The patients in the Dutch trial were treated when their pain was in the moderate range, with only half on narcotic pain medications, compared with severe pain and high-dose narcotic pain medication for most of the patients entered on the RTOG trial. This may account for the higher rates of complete response on the Dutch trial. In the RTOG trial, the group of patients with a single area of pain or with moderate pain scores at the time of study entry had higher complete response rates. Thus, it appears that the outcome is much better if patients are treated with palliative RT earlier in the course of their bone metastases rather than waiting until pain is severe or narcotic pain medication requirements are significant. There was no difference in pain response whether the treated bone metastases were in the spine or in extremity sites. The rates of pathologic fracture after treatment are relatively low, but it is not clear whether higher doses provide greater protection from fractures. The rates of retreatment are significantly higher with the single-dose schedules, but there may be some physician bias partially accounting for this difference because the retreatment tends to be offered at an earlier time and at lower levels of pain following the single-dose treatment.

There have been multiple randomized, prospective trials in the past 40 years comparing shorter course, lower total dose treatment to the more “standard” longer course, higher dose treatment. Several conclusions are clear from these studies:

1. Single-dose treatments of 8 Gy provide similar pain relief to longer treatment regimens (30 Gy in 10 fractions or 20 to 24 Gy in five to eight treatments).
2. The retreatment rates are higher after short-course treatment by a factor of 2 to 3.
3. Response rates are lower when scored by the patient instead of by the treating physician.
4. Response rates are better when the initial pain scores are lower, that is, when the patients are treated for moderate pain rather than severe pain.
5. There is no consistent dose-response relationship for palliation of bone metastases.

The lack of a dose-response relationship suggests that the mechanism of initial pain relief is not a reduction in tumor burden but more likely a change in the local environment that has caused activation of bone resorption by osteoclasts.[2] This helps to explain the seeming paradox of similar pain improvement with single-dose treatment compared with higher total dose, longer course treatment. The treatment paradigm for bone metastases may be more analogous to treatments for certain benign conditions, such as prevention of heterotopic ossification or keloid formation. In those conditions, a single or few treatments are given to diminish the activation of osteoblasts or fibroblasts.

This mechanism of pain relief may also help to explain the higher rates of retreatment after single-dose 8-Gy treatment because there will be less cell kill with this dose compared with 30 Gy in 10 fractions. Thus, for patients with a longer lifespan, there is a greater opportunity for regrowth of the tumor, which may again affect the local milieu, causing osteoclast activation.

For patients with a poor performance status, difficulty making multiple trips for treatment, extensive nonosseous metastases, and/or a short life expectancy, the most appropriate treatment is a single fraction of 8 Gy. Even with a limited expectancy (<3 months), the majority of patients experience pain relief, and palliative RT should still be considered for those patients.[105,106] For patients with a longer life expectancy, bone-only metastases, and good performance status, a longer course of treatment (30 Gy in 10 fractions) may be more appropriate to minimize the risk of retreatment. For selected patients with a solitary bone metastasis ("oligometastasis"), an even higher dose of treatment may be indicated, although this must be tempered by potential weakening of surrounding normal bone.

The single large-fraction treatment may be more likely to cause a "flare" reaction, with a temporary increase in pain at the site of the metastases.[107] The risk of this side effect may be diminished by the use of anti-inflammatory medications, either corticosteroids or nonsteroidal anti-inflammatory medications. Although the risk of significant acute toxicity has been low in the randomized trials, another potential concern is the risk of nausea or emesis if a significant portion of the stomach is within the treatment field (eg, with a field covering the lower thoracic spine). It may be beneficial to give prophylactic antiemetics 1 to 2 hours before the treatment to minimize the possibility of this side effect.

For select patients who do not respond to the initial treatment course or for those with pain recurrence after an initial successful treatment, reirradiation to the painful metastatic sites can be administered.[108] Approximately 60% of retreated patients experienced an improvement of their pain, with 16% to 28% of patients experiencing a complete resolution of pain.[109] Patients also experienced an improved overall quality of life and decrease in pain associated functional limitations after retreatment of a painful bone metastasis.[110] A randomized, controlled, noninferiority study compared single-dose treatment to longer courses of RT for the retreatment of previously irradiated painful metastatic bone cancer. Four hundred and twenty-five patients were randomized to receive either 20 Gy over multiple fractions or 8 Gy over one fraction. The single-fraction course was found to be noninferior to the multiple-fraction course and resulted in a lower frequency of acute toxicity. There was no difference in pathologic fracture or spinal cord compression between these two groups.[108]

STEREOTACTIC RADIOSURGERY OR STEREOTACTIC BODY RADIATION THERAPY FOR BONE METASTASES

Stereotactic radiosurgery (SRS) has been evaluated for the treatment of bone metastasis, particularly in the spinal region. Indications for the use of SRS in treating vertebral body metastases vary, but the use of SRS is often considered in cases of pain, reirradiation, and ablation of oligometastatic or oligoprogressive disease.

A prospective, nonrandomized cohort study conducted at the University of Pittsburgh in 500 cases of spinal metastasis treated with single-fraction radiosurgery to a maximum intratumor dose of 12.5 to 25 Gy demonstrated long-term pain level improvement in 86% of cases. Long-term tumor control was demonstrated in 90% of cases when radiosurgery was used as the primary treatment modality.[111]

The RTOG 0631 is a phase II/III study evaluating the role of SRS for patients with spine metastasis. Patients on this trial were randomized to either single-fraction external beam radiation to 8 Gy or to single-fraction image-guided SRS to 16 Gy. The primary end point of this study was assessment of pain control at the treated site(s). The phase II portion of this study demonstrated the feasibility and accurate use of SRS to treat spinal metastases.[112] The primary end point of the phase III portion of the study compared the pain relief at the treated site(s) and improvement in quality of life between the two groups. The results demonstrated no difference in pain control at 3 months due to the lower pain control rate at 3 months.[113]

Another prospective phase 3 randomized trial compared 24 Gy in 1 fraction to 9 Gy × 3 stereotactic body radiation therapy (SBRT) to evaluate local control of oligometastatic disease.[114] One hundred and seventeen patients with 154 oligometastatic lesions (osseous or lymph node metastases) were randomized between the two groups with a median follow-up of 52 months. The cumulative incidence of local

recurrence for 24 Gy × 1 was 2.7% and that for 9 Gy × 3 was 9.1%. No differences in toxicity were observed, with the authors concluding the 24 Gy × 1 to be a superior ablative treatment.

In another regimen, Sahgal et al[115] compared 24 Gy in two fractions using SBRT compared to 20 Gy in five fractions using standard techniques. In the randomized controlled phase II/III trial, 229 patients with spinal metastases were treated with a median follow-up of 6.7 months. At 3 months, 35% of patients in the SBRT group versus 14% of patients in the conventional group had a complete response to pain (P = .0002). The SBRT dose was shown to be superior in improving the complete response to pain, and the authors suggested the dose-escalated RT to be appropriate in the palliative setting for symptom control.

In a prospective randomized phase II trial by Nguyen et al,[116] 160 patients with mostly non–spine bone metastases were randomized to receive single-fraction SBRT (12 Gy for lesions ≥4 cm and 16 Gy for lesions <4 cm) versus standard palliative RT (30 Gy in 10 fractions). SBRT resulted in a higher proportion of patients experiencing complete or partial pain response at 3 months (73% vs 49%, P = .04). The results of this trial suggest that SBRT should be considered for patients expected to have a relatively long survival.

There have been multiple contouring guidelines published for the use of SBRT in spinal metastases. The International Spine Radiosurgery Consortium developed guidelines for target volume delineation in the intact setting based on the extent of disease.[117] In the postoperative setting, Redmond et al[118] created consensus guidelines for common scenarios.

RADIATION, BONE PROTECTION, AND OSSEOUS REPAIR

External beam radiation has become standard of care for pain relief of symptomatic bone metastases, but it has been shown to impart benefits in select asymptomatic patient. One multicenter randomized trial by Gillespie et al[18] assigned patients to receive prophylactic RT to asymptomatic high-risk bone metastases and compared outcomes to patients receiving standard care. The primary outcome was SREs. In this trial, 78 patients with 122 high-risk bone metastases were enrolled with different primary malignancies. At 1 year, SREs occurred in 1.6% in the RT arm versus 29% in the standard care of arm (P < .001). In the RT arm, the results demonstrated significantly fewer hospitalized patients. At 2.5 years median follow-up, the RT arm also demonstrated a significant increase in overall survival.

The use of bisphosphonates with external beam RT may further improve the outcome in terms of bone repair and pain relief. A prospective trial by Vassiliou et al[119] evaluated 45 patients who received both external beam irradiation and monthly ibandronate for painful bone metastases from solid tumors. All of the patients had improvement in pain, with 57% complete responses and 43% partial responses when using the same response criteria as RTOG 9714. The average pain score decreased from 6.3 to 0.8, and opioid pain medication use decreased from 84% of the patients before treatment to 24% after treatment. Bone density in the area of the metastases increased by 73% by 10 months after treatment. A similar study using pamidronate and 30 Gy of external beam RT in women with painful bone metastases from breast cancer found that 88% of patients had complete radiographic response by International Union Against Cancer criteria.[120]

The majority of patients with osseous metastases have multiple lesions. Although focal RT is effective at palliating pain in a few sites, it cannot be used to treat widespread disease. Two techniques have been used to treat more diffuse metastases: hemibody irradiation and intravenous radiopharmaceuticals. Hemibody irradiation was used before there were effective targeted radiopharmaceuticals but is used much less commonly now. Systemic agents capable of treating the entire skeletal system, such as radiopharmaceuticals, may be a better option in treating patients with a high burden of osseous metastatic disease.

Radiopharmaceuticals

The concept of radiopharmaceutical treatment is compelling.[121] Calcium (and to a lesser extent phosphorous) analogs will preferentially accumulate in bone, especially in areas of active bone turnover. A radioactive isotope that is a β-emitter or low-energy γ source will allow localized treatment in the areas in which the radiopharmaceutical accumulates, thus minimizing side effects and giving an excellent therapeutic ratio. The radiopharmaceuticals are given in a single injection that is easily administered. The treatment can be combined with other modalities, including chemotherapy or external beam RT.

The first radiopharmaceutical used for the treatment of bone metastases was phosphorous-32 (P-32). Treatment with P-32 for diffuse bone metastases was successful in giving subjective pain relief but with unacceptable bone marrow toxicity. Other radioisotopes have been used for the palliation of diffuse osseous metastases with a better therapeutic ratio than P-32. Strontium-89 (Sr-89) is chemically similar to calcium and is deposited in the bone matrix, preferentially in sites of active osteogenesis. Sr-89 is a pure β-emitter with an energy of 1.4 MeV and a half-life of 50.6 days.[122] Samarium-153 (Sm-153) is primarily a β-emitter but also has a component of γ-emission, which is useful for imaging purposes. The Sm-153 ethylenediamine tetra-methylenephosphonic acid is concentrated in areas of high bone turnover, accumulating in areas of hydroxyapatite. The physical half-life of Sr-153 is 46.3 hours, but the biologic half-life is much shorter because about half of the compound is excreted in the urine within 8 hours of injection.[123] These isotopes accumulate in areas of osteoblastic activity, especially in areas of increased uptake on bone scintigraphy; for this reason, most of the patients entered on prospective trials have metastatic prostate cancer. Sr-89 and Sm-153 are used infrequently now and are becoming more difficult to obtain. There are multiple new radiopharmaceutical agents being investigated for the treatment of metastatic disease, which are increasingly better targeted, such as radium-223 (Ra-223) and lutetium-177 PSMA.

Radium-223

Ra-223 dichloride is a pharmaceutical that emits α-particles and selectivity targets bone metastases. The ALSYMPCA trial was a phase III, prospective randomized study of men with castrate-resistant prostate cancer with bone metastases. Patients were randomized to receive six injections every 4 weeks of either Ra-223 or placebo. The randomization was 2:1, with 614 patients receiving Ra-223 and 307 patients receiving placebo. The primary end point of the study was survival, which was significantly greater in the patients treated with Ra-223 (14.9 months) compared to placebo (11.3 months).[124] Multiple secondary end points were improved with the Ra-223 compared to placebo: (1) time to first symptomatic skeletal event (15.6 vs 9.8 months), (2) decreased risk of spinal cord compression, (3) lower use of external RT for bone pain, and (4) decrease in certain biomarkers (total alkaline phosphatase and lactic dehydrogenase, although there was not a statistically significant difference in prostate-specific antigen).[124,125] There was no difference between the groups in pathologic bone fractures or the need for orthopedic intervention. The rates of significant adverse events were low, as was the risk of myelosuppression, in the patients receiving Ra-223.[125] Ra-223 has been used concomitantly with abiraterone, enzalutamide, and denosumab in an open-label prospective but nonrandomized study, with relatively low significant toxicity rates (grade ≥ 3 hematologic toxicity was <10%).[126] The use of Ra-223 in combination with abiraterone resulted in excess toxicity in a randomized trial and is discouraged.[127] Ra-223 is the only bone-directed radionuclide, which has shown improvement not only in pain and quality of life but also in overall survival.

Lutetium-177

The VISION trial evaluated lutetium-177 (Lu-177)-PSMA-617 for the treatment of metastatic castration-resistant prostate cancer.[128] These were heavily pretreated patients (at least one androgen pathway inhibitor and at least one taxane regimen) who had PSMA-gallium-68 scans, which were positive for metastatic disease. Over 90% of the patients in the study had bone metastases. The patients were randomized in a 2:1 manner to either Lu-177-PSMA-617 at 7.4 GBq every 6 weeks for 4-6 cycles or to

standard care. Standard care, however, excluded Ra-223, chemotherapy, immunotherapy, or other investigational drugs. Patients on the Lu-177-PSMA-617 arm had significantly better overall survival, progression-free survival, objective response rates, and disease control compared to standard therapy, although with a higher risk of grade >3 adverse events (52.7% vs 38.0%). Several studies using Lu-177 in combination with immunotherapy or in lieu of more traditional therapies for metastatic prostate cancer have been initiated and initial results are promising, suggesting that its use may become increasingly more common.[129,130]

Patient Selection

Radiopharmaceuticals, specifically Ra-223, Sr-89, and Sm-153, are effective in providing pain relief for patients with diffuse osseous metastases. This is primarily true for metastases that have an osteoblastic component. In general, if a Tc-99m nuclear medicine bone scan shows localized areas of increased uptake, then radiopharmaceutical treatment is likely to be of benefit. An advantage of radioisotope treatment is that it can be combined with other modalities, such as external beam RT or chemotherapy. Because the targets of treatment are similar, treatment with bisphosphonates should not be given simultaneously with radioisotopes because this may reduce the efficacy of both medications. However, there is evidence that the Ra-223 can be given concomitantly with denosumab. Relative contraindications to therapy would be impaired renal or hepatic function or inadequate hematologic reserve.

Radiopharmaceuticals: Summary

Both Sr-89 and Sm-153 radiopharmaceuticals appear equally effective at palliating pain from bone metastasis; however, these radioisotopes are becoming increasingly difficult to obtain. Ra-223 offers not only palliation of pain but also the possibility of improved overall survival, at least in patients with castrate-resistant metastatic prostate cancer. Radiopharmaceuticals, not only in bone metastases, but in the management of visceral disease are continuing to grow. Newer radiopharmaceutical agents that have more specificity to bind to specific tumor parkers are continuing to be developed. These newer agents not only can palliate painful bone metastases but have the ability to provide more targeted RT to nodal and visceral metastases as well.[128] These radiopharmaceuticals add to the growing armamentarium of therapies designed to palliate pain and improve the quality of life of patients with bone metastasis from cancer.

CONCLUSION

Palliative RT is of significant benefit to patients with painful bone metastasis, with most patients experiencing relief in the magnitude of pain following treatment. Response rates to palliative RT for localized sites of pain are consistently higher than response rates from palliative systemic therapy, and palliative external beam RT remains the mainstay of treatment for clinically localized painful bone metastasis. Providing shorter, single-fraction palliative treatment schedules (ie, 8 Gy in a single fraction) for properly selected patients with bone metastasis can help better integrate palliative RT into the multidisciplinary management of patients with metastatic cancer and offer equivalent palliation compared with longer courses of palliative RT. Meanwhile, SRS can be used in treating challenging bone metastases when standard palliative doses may not be enough. Systemic targeted therapies offer yet another means to target painful sites of bone metastasis without limiting the ability to use localized external beam RT and systemic chemotherapy. The role of radiation in treating bone metastases will continue to grow as newer data are highlighting the benefits in treating select patients who have asymptotic bone metastasis.

CHAPTER 104

Palliation of Visceral Recurrences and Metastases and Treatment of Oligometastatic Disease

Alexander A. Harris, Michael Kharouta, Chirag Modi, and William F. Hartsell

The 5-year survival and overall cure rates for many cancers have significantly improved over the past 40 years. Unfortunately, there is still a large number of patients who develop recurrent or metastatic disease. The most common sites of metastatic disease are bones, brain, lungs, and liver. In addition, there are other visceral sites of recurrence or metastatic disease that may cause significant symptoms. Palliative radiation therapy (RT) for the treatment of bone and brain metastases is well established, with multiple randomized prospective trials evaluating best treatment practices. However, there is less information on the treatment of palliative radiation in treating visceral metastases and recurrences, although radiation oncologists recognize that RT is frequently effective at palliating symptoms in these settings.

The specific goals of treatment will depend on the symptoms, treatment site, functional status of the patient, and other patient-specific factors. The indications for treatment may include pain, visceral obstruction, bleeding, or other symptoms that negatively impact the quality of life. In general, this treatment is given with the goal of improving the quality of life, not the quantity of life. For some disease sites, this can be done with a very low-dose, short course of treatment. For other sites, this will require higher doses given to control the local disease.

Some visceral metastases will cause pain. For example, liver or adrenal metastases may cause significant pain. Splenic metastases from hematologic metastases may cause abdominal pain, early satiety, and abdominal distention. In contrast, pulmonary metastases rarely cause pain. Instead, these lesions may cause airway obstruction or hemoptysis.

Metastatic lesions in the gastrointestinal system may cause bleeding or obstructive symptoms (esophageal obstruction, gastric outlet obstruction, gastric bleeding, biliary obstruction, rectal obstruction). In addition to rectal obstruction, pelvic masses may cause ureteral obstruction, bleeding (vaginal, bladder, or rectal), or pain from involvement of the sacrum or sacral nerves.

There has been a revolution in the understanding of the metastatic process in the past decade. Traditionally, in solid tumor biology, cancer cells are thought to undergo some genetic change that potentiates them to grow into tumors and cause daughter cells to spread through the lymphatic or circulatory system to lymph nodes and distant sites. However, recent understanding of the epithelial-mesenchymal transition demonstrates that cancer cells develop embryonic stem cell–like properties that allow them to disseminate to distant sites. The microenvironment surrounding the primary tumor and metastatic sites can regulate the metastatic process. In addition, metastasis occurs much earlier than clinical detection of lymphadenopathy and radiographic or symptomatic evidence of the development of distant visceral disease.[1] Treatment of visceral metastases in the oligometastatic setting may allow for improved palliation and may also improve the overall survival (OS) in carefully selected patients.

PALLIATION OF HEAD AND NECK CANCER

Palliative RT for head and neck cancers is an essential treatment approach for patients who have locoregional disease recurrence or who are not candidates for curative therapy. The primary objective of palliative RT is to relieve debilitating symptoms, such as pain, dysphagia, and tumor ulceration, with minimal side effects, thereby improving the patient's quality of life.

The first and most important decision in treating these patients is to decide if treatment should be definitive or palliative. Candidates who may be best treated with palliative radiation over a definitive approach are often those with poor performance status, advanced age, uncontrolled medical comorbidities, recent prior radiation, organ dysfunction, and bulky tumors. Various nomograms can be used to help aid in the decision-making process.[2,3]

For patients who are best served with palliative RT, short courses of palliative radiation can be effective at reducing the tumor and associated pain, with objective response rates ranging from 40% to 80%.[4,5]

The QUAD shot regimen involves delivering 350 to 370 cGy twice daily (BID) for 2 consecutive days, repeated every 3 to 4 weeks. Studies have shown significant improvement in symptoms with minimal toxicities using this approach. In a study by Paris et al, the QUAD shot regimen demonstrated a 77% objective response rate, with most patients reporting subjective improvement in symptoms without major toxicities.[4] Corry et al reported a 50% objective response rate and a median OS of 5.7 months using a similar approach.[5] In another study by Lok et al, a higher number of QUAD shot cycles correlated with increased palliative response.[6]

Other fractionation schedules have also been explored and can provide a balance between high response rates with short, convenient treatment courses. The Hypo Trial treated patients deemed unsuitable for curative treatment to 30 Gy in five fractions, administering two treatments per week (at least 3 days apart). They found an objective response rate of 80%.[7] A regimen of 32 Gy delivered at 4 Gy per fraction biweekly in 126 patients with mostly stage IVB cancers showed a 74% treatment completion rate, a 42% response rate at the primary site of disease, and 55% at the site of nodal disease.[8] A retrospective study involving 21 patients used a 24 Gy in three-fraction regimen, delivering one fraction per week. This approach was effective in managing symptoms with a reasonable safety profile.[9] Another study of 32 patients deemed unfit for radical treatment due to poor performance status or advanced stage treated patients with 25 Gy in five fractions in 1 week. A significant portion of these patients had T4, N3, or M1 stage, and efficacy and tolerability were high, with only 13% of patients experiencing any grade 3 toxicities, no grade 4 or 5, and patients reporting equal or lower than baseline symptoms at up to 6 months post-treatment.[10] Another retrospective analysis with 65 patients used a higher dose regimen of 60 Gy in 20 fractions or 72 Gy in 24 fractions for a more aggressive approach in patients unable to tolerate continuous-course definitive chemoradiation, incorporating a mid-treatment break to manage toxicity, though feeding tube rates still reached 42%.[11] Several retrospective studies on the use of palliative stereotactic body radiotherapy (SBRT) have also been reported with good local control and toxicity rates. Siddiqui et al

reported a retrospective study of the treatment of 55 lesions in 44 patients with primary, recurrent, and metastatic tumors using either 13 to 18 Gy in a single fraction or 36 to 48 Gy in five to eight fractions, showing a 77% overall response rate.[12] Khan et al reported a similar study of 24 sites treated in 21 patients with de novo and recurrent head and neck cancers with SBRT using 35 to 48 Gy in five to six fractions with an overall response rate exceeding 90%.[13]

Proton therapy may be appropriate for some patients, especially since it limits dose to other normal tissues, which may have been previously irradiated. A single-institution study evaluated 242 patients with head and neck cancers in previously irradiated fields, who were treated with proton therapy for reirradiation. A significant proportion had salvage surgery before irradiation (40.5%), and 57% received concurrent chemotherapy. Approximately one-third were treated with "QUAD shot" treatment of 14.7 Gy_{RBE} in four fractions over 2 days, repeated every 2 to 4 weeks for a total of up to four cycles (median was three cycles, total dose of 44.4 Gy_{RBE}). The remainder of the patients were treated with more standard fractionation; the median dose of proton reirradiation in those patients was 70 Gy_{RBE}. Control rates and survival rates were significantly better in the fractionated arm, with 63% local control at 2 years, and a 1-year survival rate of 66.6%.[14]

These regimens showcase the diverse approaches in palliative RT, each with its specific benefits and considerations. Each regimen can be tailored to individual patient needs and treatment objectives. The choice of a specific regimen depends on various factors, including the patient's overall health status, the extent of the disease, and the primary symptoms to be alleviated. Though no consensus guidelines exist on optimal treatment volumes, it is generally recommended to select volumes that minimize toxicity from treatment while balancing the risk of untreated or undertreated disease causing symptoms in the future. While simpler techniques may minimize the time to treatment, intensity-modulated radiation therapy (IMRT) or protons should be considered in situations where it may otherwise be difficult to minimize treatment toxicity.

MALIGNANT LOWER AIRWAY OBSTRUCTION

The lower airway is generally defined as being below the first tracheal ring. Upper airway obstructions can be emergently treated with a tracheostomy. The lower airway can become compromised from either primary or metastatic malignancy. Patients may have intrinsic compression caused by an endobronchial tumor or extrinsic airway compression by a tumor mass in the lung parenchyma or bulky lymphadenopathy during the course of their illness. Clinical symptoms, bronchoscopy, and radiographic imaging are used to determine the extent of luminal obstruction. It is important to determine whether the airway obstruction is endobronchial or from external compression of the airway in order to select the most appropriate treatment. For intrinsic compression of a tumor mass growing inside the bronchial lumen, interventional bronchoscopy techniques offer immediate benefit in many patients. These interventional techniques can result in relief of dyspnea, decreased risk of postobstructive pneumonia, and improved functional status.[15-17] Either laser resection of tumor or endobronchial stent placement, along with RT, is effective in maintaining the patency of the lower airway.[18,19] The additional treatment of the airway can be given with either external-beam RT, endobronchial brachytherapy, or photodynamic therapy. Brachytherapy is typically the best option in patients who have recurred after prior external-beam RT. For endobronchial therapy, the recommended doses are 7.5 Gy × 3 or 10 Gy × 2.[20] In a prospective observational study, de Aquino Gorayeb et al utilized high-dose-rate endobronchial brachytherapy for palliation of malignant airway obstruction. The study protocol consisted of three fractions of 7.5 Gy weekly or biweekly, with over half of the patients having been previously treated with external-beam radiation. Of the 78 patients treated, 70% reported an improvement in performance status and 87% noted improvement of one or more of their presenting complaints (dyspnea, cough, infection, and/or hemoptysis). Of the patients who presented with one or more of the abovementioned symptoms, 57% noted improvement in their dyspnea, 34% noted improvement in their cough, 80% noted improvement in their infection symptoms, and 100% noted improvement in their hemoptysis.[21]

External-beam RT is typically used for the treatment of airway compromise caused by extrinsic compression of a bronchus. Endobronchial brachytherapy typically does not improve symptoms when there is external compression of the airways.[22,23] The highest doses from brachytherapy will

be given to the (relatively) normal mucosa of the airway, with a much lower dose to the extrinsic tumor that is causing the compression.

There is no standard fractionation scheme or total dose for palliative external-beam treatment for lung cancer. A review by Fairchild et al found the best results, in terms of palliation of symptoms, are achieved with relatively high doses of RT: 3 Gy per fraction to a total of 30 to 45 Gy, or 2 Gy per fraction to 50 to 60 Gy.[24] The trade-off is that there is a higher rate of acute esophagitis with these higher doses. The American Society for Radiation Oncology clinical practice guideline consensus statement recommends doses equivalent to 30 Gy in 10 fractions or greater.[25] For patients with a poor performance status or who have difficulty traveling for multiple treatments, shorter fractionation schemes such as 20 Gy in five fractions can be used. Very short regimens (17 Gy in two fractions or 10 Gy in one fraction) may be useful in certain situations; however, there are reports of radiation myelopathy with these regimens (17 Gy in two fractions).[25]

In most patients who receive RT for palliation of pulmonary symptoms, there is no benefit to the addition of chemotherapy. Combined chemotherapy and RT may improve response rates slightly, but with significantly greater acute toxicity.[25]

LIVER METASTASES

The liver is the most frequent site of distant metastatic disease from gastrointestinal tumors, especially colorectal, but also esophageal, stomach, and pancreatic cancers. The liver is also a frequent site of metastases from lung cancer, breast cancer, and melanoma. A patient with liver metastases may have symptoms of anorexia or early satiety, weight loss, nausea, right upper quadrant or epigastric pain, pruritis, jaundice, and fever.

For patients with few metastatic lesions in the liver and no evidence of extrahepatic metastases, 12% to 36% may be cured with surgical resection.[26] The risk factors associated with the best outcome are clear resection margins, low levels of carcinoembroyonic antigen, a single metastatic deposit, metachronous presentation of the liver metastasis, and node-negative disease (with the original primary).[26] Other liver-directed therapies can be used for patients with one or a few hepatic metastases,

including radiofrequency ablation, microwave coagulation therapy, transarterial chemoembolization, transarterial radioembolization, hypofractionated external-beam RT, and SBRT.[27]

Most patients with liver metastases are found to have multiple lesions, extrahepatic disease, or other risk factors that make them unsuitable for these surgical or ablative procedures. It is common for these patients to undergo multiple courses of systemic therapy prior to being seen and evaluated by a radiation oncologist. For many years, the only viable chemotherapy option for metastatic gastrointestinal tumors was 5-fluorouracil, often given in combination with leucovorin. More recently, multiple drug regimens including oxaliplatin or irinotecan have significantly improved the response rates and increased the median duration of survival. Targeted agents such as cetuximab or bevacizumab may improve the response rates even further. These new combinations have changed the goal of treatment from palliation to prolonging survival; with this new paradigm, the multiple drug regimens are given as neoadjuvant therapy with the goal of downsizing tumor bulk in order to facilitate a resection.[28] Hepatic arterial infusion of chemotherapy gives higher local concentrations of the chemotherapy agents and also gives higher response rates. A meta-analysis of hepatic arterial infusion chemotherapy for liver metastases demonstrated a significantly higher response rate but showed no improvement in survival duration.[29] Increasingly, these targeted agents are being paired with ablative radiation-based treatment to with a goal of improving outcomes.

The group of patients who are referred to a radiation oncologist for palliation of liver metastases tend to be the patients who have more medical comorbidities, a greater tumor burden, and who have been previously treated with multiple other therapies. Despite these poor prognostic factors, RT can be effective in palliating symptoms (Figure 104.1).[30]

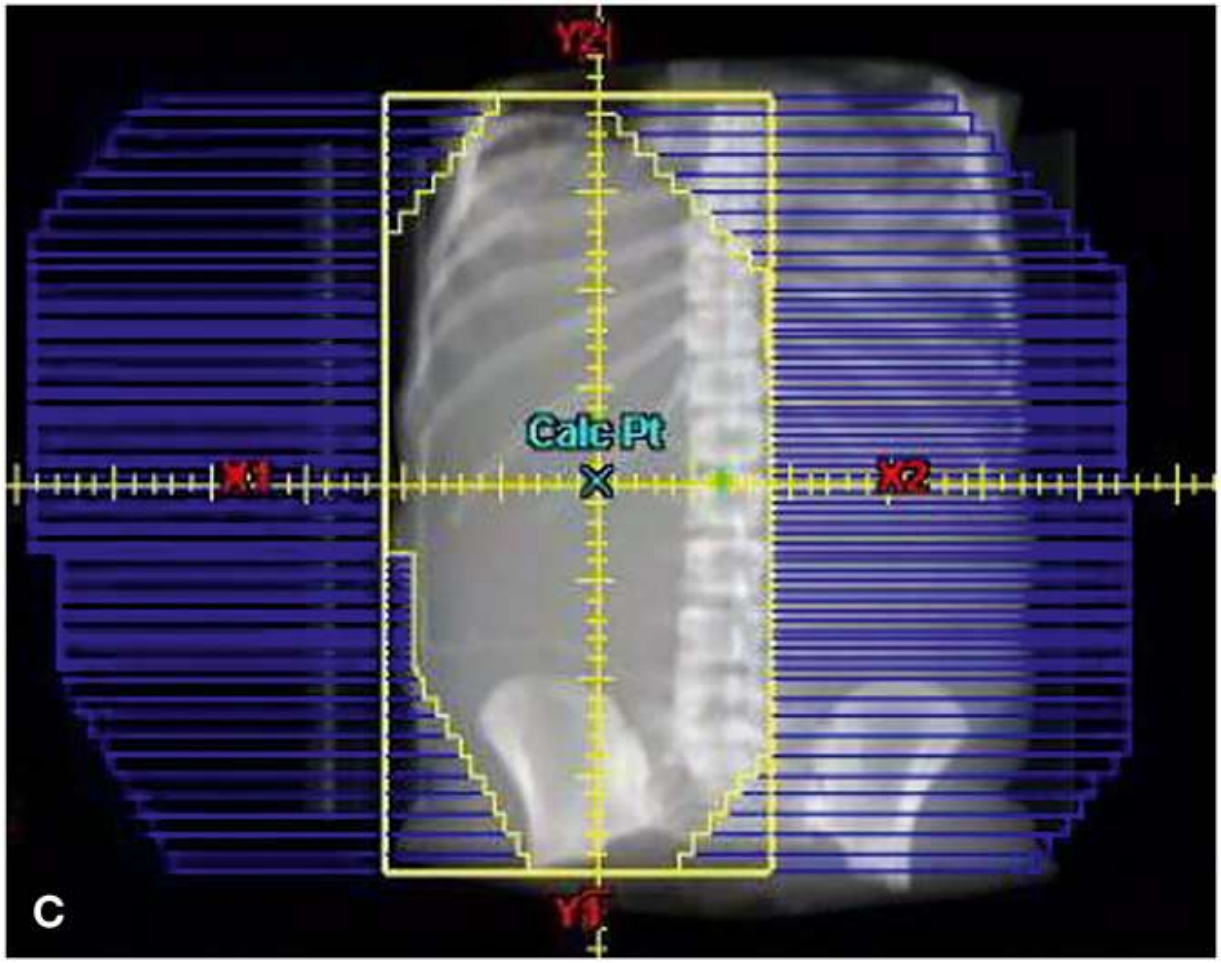

FIGURE 104.1 Axial (A) and coronal (B) isodose plots in a patient with diffuse metastases in an enlarged liver, causing significant pain. Treatment field is shown in (C). This patient was given 21 Gy in seven fractions and had significant improvement in pain within 4 weeks.

Palliative treatment of the liver is limited by radiation- induced liver disease (RILD). This toxicity becomes apparent 1 week to 3 months after treatment and may result in liver failure and death.[31] Both dose and volume of liver irradiated are important in avoiding RILD. For treatment of the whole liver, the threshold for RILD is approximately 30 Gy in 2 Gy fractions or 33 Gy in 1.5 Gy BID fractions.[32,33] The Radiation Therapy Oncology Group's trial RTOG-7605 evaluated multiple regimens in patients with multiple liver metastases: 30 Gy in 15 fractions, 25.6 Gy in 16 fractions, 20 Gy in 10 fractions, and 21 Gy in 7 fractions.[34] Improvement in symptoms was seen in 55% of the patients, with no difference among the four treatment regimens. A subsequent RTOG trial evaluated whole-liver RT with a dose of 21 Gy in seven fractions; patients were randomized to

receive either the radiation alone or the addition of misonidazole to the radiation.[35] There was minimal toxicity and a rapid symptomatic response in the majority of patients. Complete pain relief was reported in 54% of the patients, and 80% of the patients noted an improvement in pain following treatment. Overall, there was no significant benefit with the addition of misonidazole. The best response rates were seen in patients with colorectal primaries. Bydder et al[36] reported on a series of 28 patients treated with a hypofractionated regimen of 10 Gy in two fractions to the whole liver. The overall response rate was 54%, with two patients experiencing grade 3 toxicity (emesis and diarrhea). For patients where a shorter course of treatment may be best, a phase II trial showed that approximately half of patients treated with a single fraction of 8 Gy will experience measurable improvements in symptoms with a low rate of treatment-related toxicities.[37]

If a smaller portion of the liver is irradiated, higher doses can be given with low risk for RILD. A 5% risk of RILD is associated with 90, 47, and 31 Gy with uniform irradiation of one-third, two-thirds, and the whole liver, respectively. If the effective liver volume irradiated is less than 25%, doses greater than 100 Gy can be given with little risk of RILD.[38,39]

SBRT has been shown to be an effective and well-tolerated way to treat patients with a limited number of liver metastases. In one retrospective review of patients treated with a single fraction of SBRT (median dose 24 Gy) showed a high rate of local control, with 6- and 12-month control rates of 87% and 70%, respectively.[40] However, these control rates are likely improved with increasing doses and fractionation. In a dose-escalation study of UT Southwestern, Rule et al found that 2-year local control rates increased from 56% to 89% to 100% as treated dose increased from 30 Gy in three fractions to 50 Gy in five fractions to 60 Gy in five fractions. This was done with a low rate of toxicity in all arms, with no treatment-related grade 3+ toxicities reported.[41] These findings were further supported in a phase I/II study of SBRT in patient with limited number of liver metastases (one to three). Ablative radiation provided an in-field local control rate of 95% at 1 year and 92% at 2 years. The 2-year local control rate was noted to be higher (at 100%) in the treated tumors that were smaller than 3 cm in diameter. This was done with a low rate of grade 3 toxicities (2%).[42]

Selective internal radiation therapy (SIRT) is another option for patients with diffuse liver metastases. This technique involves the use of yttrium-90

(^{90}Y) glass or resin microspheres that are given through intra-arterial infusions into the liver. A phase III trial of patients with liver metastases from colorectal cancer evaluated intra-arterial floxuridine alone compared to intra-arterial floxuridine plus SIRT with ^{90}Y resin microspheres.[43] The patients who received SIRT had a significantly better overall response rate, time-to-tumor progression, and OS. The addition of SIRT did not increase grade 3 or 4 toxicity. SIRT can also be used to debulk liver metastases in an effort to later resect. One study showed that the addition of SIRT to chemotherapy in patients with liver metastases from colorectal primaries improved the rate of resectability of liver metastases over chemotherapy alone.[44]

In summary, patients with multiple symptomatic liver metastases may be palliated by whole-liver RT. Relatively low doses of 21 Gy in 7 fractions or 30 Gy in 15 fractions are generally well tolerated and provide symptomatic relief for the majority of patients. Treatment to high doses can be done, often with improved control or to convert an unresectable patient into a resectable one, if a smaller percentage of the liver is radiated.

BILIARY OBSTRUCTION

Malignant biliary obstruction may be caused by a tumor mass causing either extrinsic compression onto the bile duct or intrinsic compression from tumor progression within the bile duct lumen. This obstruction can lead to hyperbilirubinemia and jaundice, which can cause pruritus, anorexia, and weight loss. The biliary obstruction may be a life-threatening emergency. Emergent drainage of the bile duct is achieved initially by external stent or percutaneous drain placement. The stents are later converted to internal endoprostheses; however, these catheters typically only remain patent for 4 to 8 months.[45] The patency of these stents can be extended with the use of intraluminal brachytherapy, photodynamic therapy, or external-beam RT. Intraluminal brachytherapy extends stent patency and lengthens survival duration in patients with inoperable cholangiocarcinoma.[46,47] Although there are few data specifically for the use of external-beam RT for palliative treatment of recurrent, metastatic, or inoperable biliary disease causing obstruction, it may be of benefit especially for the treatment of extrinsic bile duct compression by a tumor mass.[48] One retrospective study showed that in

patients with metastatic cholangiocarcinoma, treating the primary tumor with high doses of RT along with chemotherapy not only improved symptoms of biliary obstruction but also prolonged OS (21 vs 9 months) as compared to a propensity score–matched cohort of patients from the same institution that received chemotherapy alone.[49]

PAINFUL ADRENAL METASTASES

The adrenal glands are a common site of metastatic disease from many types of cancer, primarily due to the rich blood supply of the adrenal gland. Lung cancer is the most common source of adrenal metastases. These metastases are frequently asymptomatic, but occasionally may cause pain. For patients with a good performance status and few sites of metastatic disease, surgical management may be appropriate. RT is also appropriate for palliative treatment.

Palliative RT typically has been given with conventional external-beam techniques. Soffen et al[50] reported the results in 16 patients with painful adrenal metastases treated with palliative RT. The majority of the patients received 30 Gy in 10 to 12 treatments. A response was seen in 12 (75%) of 16 patients, with 6 of those patients having complete response for the duration of their survival. Nearly half of the patients (44%) experienced nausea, which may have been related to the technique of treatment with anterior and posterior fields. No late toxicity was seen, but the median survival was only 3 months. A multicenter retrospective study assessed results from 134 patients treated with three-dimensional (3D) conformal (88%), IMRT (6%), or SBRT (6%) for adrenal metastasis from hepatocellular carcinoma. Treatment regimens ranged from 20 to 60 Gy (median of 45 Gy) with dose per fraction of 1.8 to 15 Gy (median 2.5 Gy). A complete response was seen in 6 patients, and a partial response was seen in 48 patients, for an objective response rate of 39%. Seventy-eight patients (55%) were noted to have stable disease.[51]

There are multiple reports evaluating the use of IMRT techniques or SBRT techniques for the treatment of adrenal metastases. Most of these patients were treated for asymptomatic adrenal metastases, rather than for palliation of symptoms. These treatments appear to provide a high rate of local control. SBRT studies have shown local control rates ranging from

73% to 100% after 1 year, with minimal toxicity.[52-54] These RT treatments may be appropriate for patients with limited volume disease (oligometastases) (Figure 104.2). In the palliative setting, there is a benefit with a dose of 30 Gy in 10 treatments using conventional techniques.

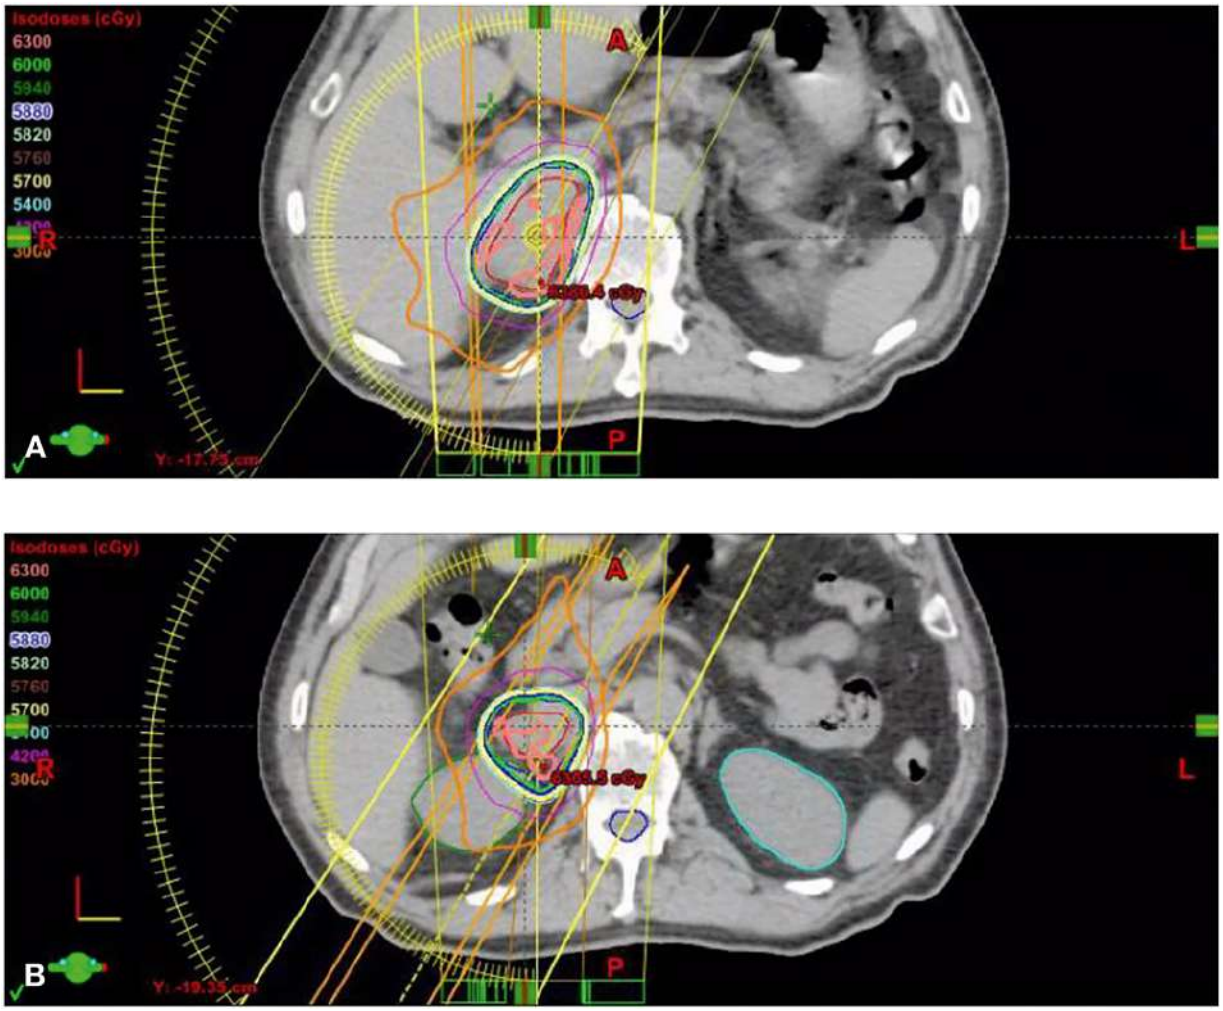

FIGURE 104.2 Axial isodose plots from superior (A) and inferior (B) aspect of stereotactic body radiotherapy fields for an adrenal metastasis. This patient was given 50 Gy in five fractions.

SPLENIC METASTASES

It is relatively uncommon for solid tumors to metastasize to the spleen. Splenomegaly is more often associated with hematologic malignancies and disorders, such as leukemia or myeloproliferative diseases. The spleen can become massively enlarged, causing pain, early satiety, nausea, or emesis.

These symptoms may also occur when the spleen is enlarged because of extramedullary hematopoiesis due to marrow failure.[55]

Treatment with RT can be very effective at reducing the size of the spleen and palliating the other symptoms associated with splenomegaly. The doses required for palliation of symptoms are much lower than the doses typically used for palliation of other visceral metastases. The response may be quite rapid as well, which necessitates evaluation of the field sizes on a frequent basis. The regimens frequently used include doses of 0.25 to 1 Gy given 2 to 3 times per week. It is important to evaluate blood counts on a frequent basis, since anemia and thrombocytopenia may occur rapidly with precipitous drops in the counts over a very short period. A typical regimen is the one reported by McFarland et al.[56] Their patients were treated twice weekly beginning at 0.5 Gy per fraction the first week, increasing to 0.75 Gy per fraction in the second week and 1 Gy per fraction on the third week. A complete blood count was obtained prior to each treatment. The total dose was typically less than 5 Gy. Even with these low doses, 14 of 16 patients had subjective improvement in their symptoms, and 12 of 16 patients had objective decrease in the splenomegaly.

A recent systemic review of palliative splenic radiation for the treatment of splenomegaly in the setting of hematologic malignancy showed that the treatment was effective at reducing splenic size, splenic pain, and improving cytopenias. Over the 27 articles reviewed, the average partial response rate was 85%, with 72% of the treatment courses resulting in splenic size reduction, 59% resulting in pain relief, and 78% resulting in improvement in cytopenia. Of the total of 766 treatment courses assessed, 33% resulted in acute toxicities, with the most common being a grade 3 to 4 leukopenia/neutropenia or thrombocytopenia. No long-term toxicities were noted.[57] Treatment of the spleen may cause an abscopal effect as well, with decrease in the size of involved lymph nodes distant to the treated spleen.[56]

VAGINAL BLEEDING OR DISCHARGE

Vaginal bleeding is a common symptom at diagnosis in several gynecologic tumors, especially cervical, uterine, and vaginal tumors.[58] The initial treatment should be with vaginal packing, but this often does not treat the underlying issue.[59] RT is also effective at controlling this type of vaginal

bleeding. A hypofractionated treatment course is typically used, usually with 2.5 to 4 Gy per fraction. A typical course of treatment would be 30 Gy in 10 fractions. Often, the bleeding will slow or stop after three to five treatments. The treatment can be continued to definitive doses at that point, using more standard fractionation of 1.8 to 2.0 Gy per fraction (Figure 104.3). An alternative method of palliating bleeding and vaginal discharge is to use a single large fraction of 10 Gy.[60-62] This will result in a high likelihood of reducing or stopping the bleeding, often within 24 to 48 hours of the first dose. This dose of 10 Gy can be repeated at 1-month intervals. The risk of complications increases when this dose is repeated a third or fourth time, so this should be limited to one to two fractions.[63]

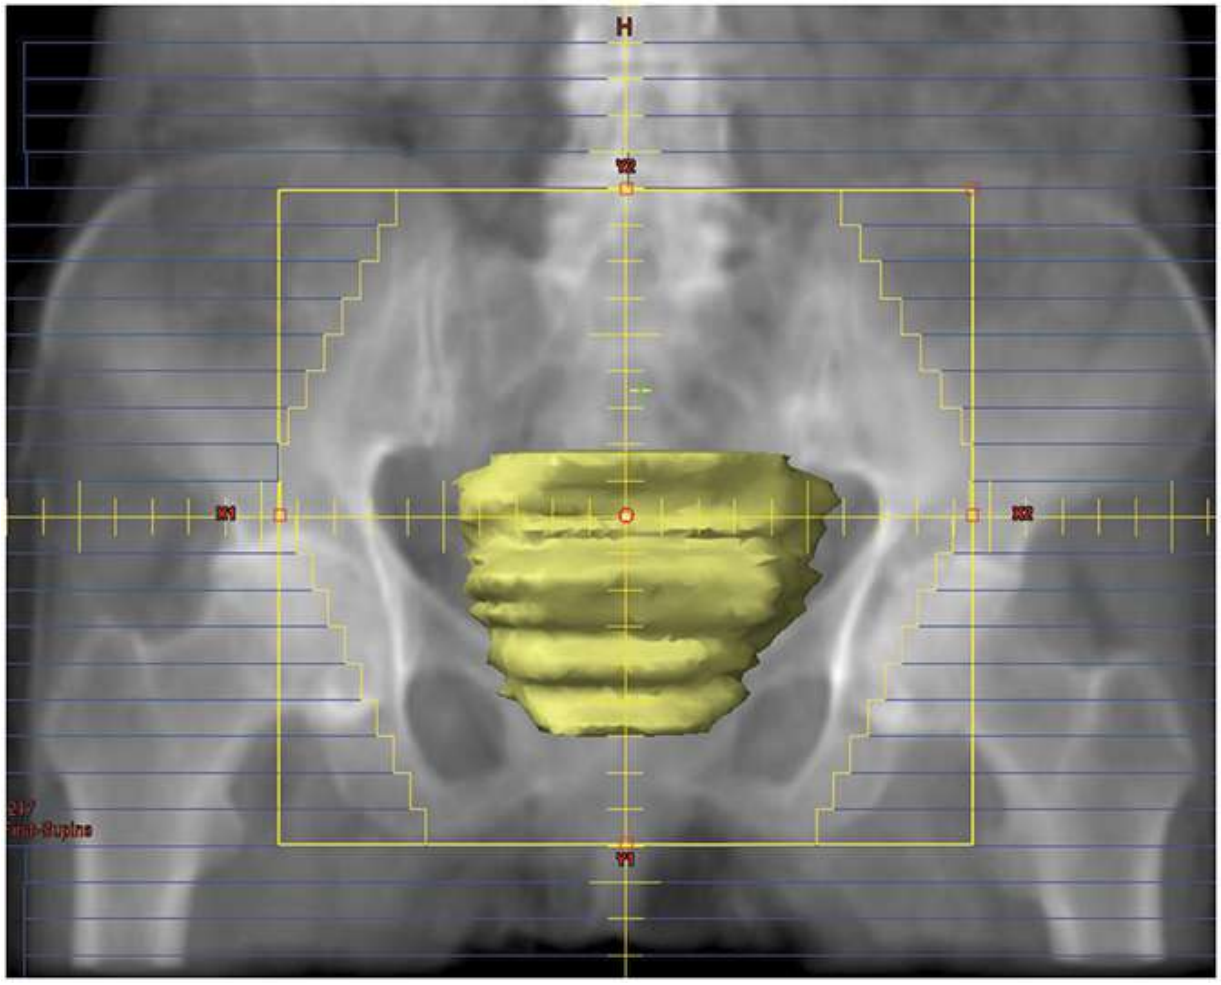

FIGURE 104.3 Digitally reconstructed anterior-posterior radiograph of a palliative pelvic field. This palliative field arrangement would be appropriate to treat a patient with hemorrhage from a cervical or bladder cancer.

PELVIC RECURRENCE

Recurrent pelvic malignancies may cause significant symptoms, including pain, bleeding, or obstruction. The choice of the appropriate palliative treatment depends on multiple factors, including the type and amount of prior treatment. In contrast to palliative treatment of other sites of recurrent disease, aggressive combined-modality treatment may provide the best chance of palliation of symptoms for recurrent pelvic malignancies.

Recurrent colorectal cancer may cause life-threatening problems from bowel obstruction. For most patients in this circumstance, surgical intervention is the most appropriate treatment. This may involve complete surgical removal of the disease, if possible, or a diverting colostomy to alleviate the symptoms of obstruction.[64] There is a high risk of perioperative complications in this group of patients, primarily because it is frequently difficult to perform an adequate bowel preparation prior to surgery.

Hydronephrosis and severe pain may be signs of a more advanced tumor and are relative contraindications to surgical resection.[65] The majority of patients with recurrent rectal cancers have posterior or posterolateral involvement of the pelvis, which makes surgery more difficult.[66] The presence of severe pain may indicate invasion of the sacrum or sacral nerve roots. Tumors that invade these structures are more difficult to resect completely. Melton et al[67] and Wells et al[68] reported that patients who underwent an aggressive surgical resection of locally recurrent rectal cancers had a high risk of significant complications. Patients who had sacral resection as part of the surgical treatment had a 42% risk of significant complications.[68]

Patients with bulky pelvic recurrences who have not previously received RT are appropriate candidates for combined chemotherapy and RT. A prospective randomized Danish trial evaluated RT alone (50 Gy in 25 fractions, with a boost of 10-20 Gy in 5-10 fractions) compared with the same RT with concomitant weekly bolus dose of 5-fluorouracil.[69] This treatment was given to patients with locally recurrent or inoperable rectal cancers. There was no improvement in survival with the addition of chemotherapy, but there was a higher rate of acute complications (33% with chemotherapy vs 13% with radiation alone). In several retrospective studies, the addition of chemotherapy was beneficial. Ito et al[70] reported on

30 patients with symptomatic intrapelvic recurrent rectal cancers. They noted a higher pain relief rate in the patients receiving chemotherapy (100% vs 77% for radiation alone) and a near doubling of the median survival time (7.8 vs 4 months). For these patients with locally recurrent rectal cancers, combined-modality therapy is usually recommended to improve the likelihood of local control.

Relatively high doses of RT are required for palliation of symptoms. A review by Wong et al[71] showed that total dose was important in achieving a response, with the highest responses seen in patients receiving 50 Gy or more. In their series, the patients with the best prognostic factors received higher doses, but the dose-response relationship was still predictive of local control and survival in a multivariate analysis. Bae et al[72] also found improvement in the rate and duration of symptom control in patients who received higher doses. They recommended a biologic effective dose greater of than 40 Gy_{10} when possible.

Patients who have received prior irradiation and subsequently develop locally recurrent rectal cancer are frequently treated with either surgery, chemotherapy, or a combination of the two. However, there are circumstances in which additional RT may be beneficial. The RT may be given as hyperfractionated external-beam radiation, intraoperative radiation therapy (IORT), or brachytherapy. Lingareddy et al[73] utilized hyperfractionation with 1.2 Gy BID to a median dose of 30.6 Gy for reirradiation of patients with locally recurrent rectal cancer; these patients had received full-dose pelvic RT as part of their initial treatment. They used limited fields for the reirradiation, excluding the bladder and small bowels. Most of the patients (90%) received concurrent 5-fluorouracil chemotherapy. There was improvement in pain in 65% of these patients and cessation of bleeding in 100%. The late toxicity of treatment was significantly lower in patients who received hyperfractionated treatment compared to single daily treatments (18% vs 47%). The most frequent late toxicities were small bowel obstruction (17%) and fistula formation (8%). An Italian prospective study evaluated patients with recurrent rectal cancer who had previously received RT.[74] Patients with biopsy-proven recurrent disease were given preoperative combined-modality treatment, with hyperfractionated RT (30.6 Gy using 1.2 Gy BID, followed by a 10.8-Gy

boost also with 1.2 Gy BID) and continuous infusion 5-fluorouracil. The patients were then evaluated for resection, and surgery was performed at 4 to 6 weeks following the chemoradiotherapy, when feasible. Fifty-one (86%) of the patients completed the preoperative treatment as planned, and 30 (50.8%) underwent resection. The overall median survival was 42 months, and the 5-year survival was 39%. Seven patients had late grade 3 toxicity, and there were no grade 4 toxicities.

An alternative treatment paradigm for patients with advanced pelvic malignancies mirrors the QUAD shot technique utilized in head and neck palliative RT. RTOG 8502 utilized a BID treatment technique to deliver four fractions of 14.8 Gy in 3.7 Gy per fraction over 2 days. This regimen was repeated every 3 to 6 weeks for a total of three cycles for a total dose of 44.4 Gy. Utilizing this technique, the authors found a 45% response rate for individuals who finished the recommended three courses of RT.[75]

SBRT has shown promising results for treating previously irradiated pelvic cancers; however, the majority of the literature is limited to small, single-institution studies.[76,77] Dewas et al[77] reviewed 16 patients with lateral pelvic recurrences of anal, rectal, endometrial, or bladder cancer. The patients received reirradiation of 36 Gy over six treatments to the lateral pelvic recurrence. The 1-year local control rate was approximately 50%, with a median disease-free survival of 8 months, with toxicities limited to grade 2 or below. Defoe et al[78] repor ted on 14 patients with presacral tumors from rectal cancer who received SBRT treatment after prior RT. The patients were retreated to a dose of 36 Gy over three fractions. Local control rates were 91% at 1 year and 68% at 2 years, with OS of 90% and 79%, respectively. Toxicities were limited to grade 2 or below. Jereczek-Fossa et al treated 34 patients with recurrent prostate cancer, localized to pelvic lymph nodes. The patients were retreated on average to 30 Gy over 4.5 fractions. About half of the treated patients received androgen deprivation therapy.[79] Biochemical response was noted in 84% of cases. In patients who received SBRT without androgen deprivation therapy, the biochemical response rate was 81%, with a complete prostate-specific antigen (PSA) response rate of 56%. Most toxicity was acute, with 18% of treated patients experiencing acute urinary toxicity and 3% experiencing acute rectal toxicity. Late urinary toxicity occurred in 20% of patients, and late rectal toxicity in 6%.

IORT may be useful in some patients with locally recurrent rectal cancer. The patients who may benefit from this treatment are those with locally advanced recurrent rectal cancer who have no evidence of metastatic disease. Haddock et al[80] reported on a series of 51 previously irradiated patients with recurrent rectal cancer who underwent maximal resection followed by IORT using electrons. The dose given was 10 to 30 Gy, with a median of 20 Gy. Thirty-seven patients received additional external-beam RT (median 25.2 Gy) following the surgery and IORT. The 2-year survival rate was 48%, but the 5-year survival rate was only 12%. The local control rate was 60% at 2 years, with a trend toward better local control in patients who received 30 Gy or more external-beam treatment in addition to the IORT (81% local control vs 54% for those who received no external-beam treatment or doses <30 Gy). The toxicity included peripheral neuropathy in 32% of patients and ureteral narrowing or obstruction in 14%.

Brachytherapy is another alternative method to deliver radiation dose to a relatively limited volume. Alektiar et al[81] reported on 74 patients with locally recurrent colorectal cancers. The patients underwent surgical resection of the recurrence, followed by high-dose rate intraoperative brachytherapy, with doses of 10 to 18 Gy. The 5-year OS rate was 23%, with a 5-year local control rate of 39%. The primary toxicity was peripheral neuropathy, which occurred in 16% of the patients. Patients with negative margins of resection had a higher likelihood of local control compared to those who had positive margins (43% vs 28%). Kolotas et al[82] evaluated palliative interstitial high-dose rate brachytherapy in a group of 38 patients. Only four of the patients had the catheters implanted intraoperatively; most were placed using computed tomography guidance, with the catheters implanted through the perineum or sacrum. This group of patients had bulky disease at the time of implant. The median survival was 15 months following brachytherapy, with most deaths caused by distant metastases. There was stable disease in 28 of 38 patients, with pain relief in 89.5% of patients.

In summary, palliative RT is effective in reducing pain or bleeding from recurrent pelvic malignancies. Because of the location and nature of pelvic recurrences, combined-modality treatment with chemotherapy, RT, and surgery may be needed. Relatively high doses of radiation may also be needed to provide the palliative benefits of treatment.

RADIATION THERAPY IN THE SETTING OF OLIGOMETASTATIC DISEASE

As reviewed in the preceding sections, the radiotherapeutic management of metastatic disease has historically been limited to palliation, typically utilizing relatively low overall doses and abbreviated treatment schedules. The goal of this approach has been to provide short- to moderate-term palliation, while limiting treatment-related toxicity and minimizing duration of therapy. Until recently, this paradigm has been generalized to nearly all patients staged as metastatic, with an essentially uniform treatment strategy applied to a widely heterogeneous group of patients, presentations, and disease biology. The paradigm shift of "curative" local therapy, including RT, for select presentations of "oligometastatic" disease, was first proposed by Weichselbaum and Hellman in a 1995 editorial.[83] According to this concept, select patients with controlled locoregional disease and a limited number of metastatic sites may theoretically be cured with definitive local therapy, especially in the setting of effective systemic therapy. During the era of Weichselbaum and Hellman's writing, limitations in RT technique precluded effective ablation of most sites of oligometastatic disease without significant toxicity. Furthermore, available systemic therapy was largely ineffective in eliminating microscopic systemic disease. Interval advances in highly conformal image-guided RT and the increased efficacy of systemic and molecular therapies have allowed for the translation of this theoretical concept into clinical investigation and practice.

Early investigations of definitive RT for metastatic disease included isolated metastatic liver disease.[84] Investigators at the University of Michigan first pioneered the paradigm of high-dose 3D conformal RT in a cohort of patients that included both primary hepatocellular carcinoma and hepatic metastasis, achieving acceptable local control and toxicity (Figure 104.4). With the advent of image-guided SBRT, the definitive treatment of isolated hepatic metastasis has been the focus of intense clinical investigation and practice.[85] A multi-institutional phase I and II trial of 47 patients with one to three liver lesions (each <6 cm in size) tested dose-escalated SBRT of 36 to 60 Gy in three fractions, reporting a 2-year local control of 92% for all lesions. Local control rates of 100% for lesions 3 cm or less and 77% for lesions greater than 3 cm were also achieved in the 60-

Gy cohort. With a median follow-up of 16 months, an OS of 20.5 months was reported, with no documented RILD and grade 3 toxicity or higher of 2%.[42] A pooled analysis of 65 patients from three institutions has also demonstrated an excellent efficacy and toxicity profile for SBRT in the definitive treatment of colorectal liver metastasis, recommending a prescription dose of at least 48 Gy for a three-fraction regiment for optimal local control.[86] More recently, Goodman et al evaluated the long-term safety and efficacy of SBRT treatment for oligometastatic liver disease. Eighty-one patients, with one to three liver metastases were treated with a median dose of 54 Gy in three to five fractions.[52] They found that local control was 94% after 33 months, and a partial or complete response was observed in 69% of lesions treated. Grade 3 liver toxicity occurred in 5% of the cases.[33] In a study conducted by Scorsetti et al, the long-term efficacy and safety of SBRT for unresectable liver metastases were evaluated. The trial involved 61 patients with 76 lesions, treated with a high dose of 75 Gy in three consecutive fractions. Key findings included a median OS of 27.6 months and local control rates of 94%, 78%, and 78% at 1, 3, and 5 years, respectively. The study concluded that SBRT is both effective and safe for treating unresectable liver metastases, highlighting the importance of patient selection and the timing of SBRT in the treatment pathway.[87]

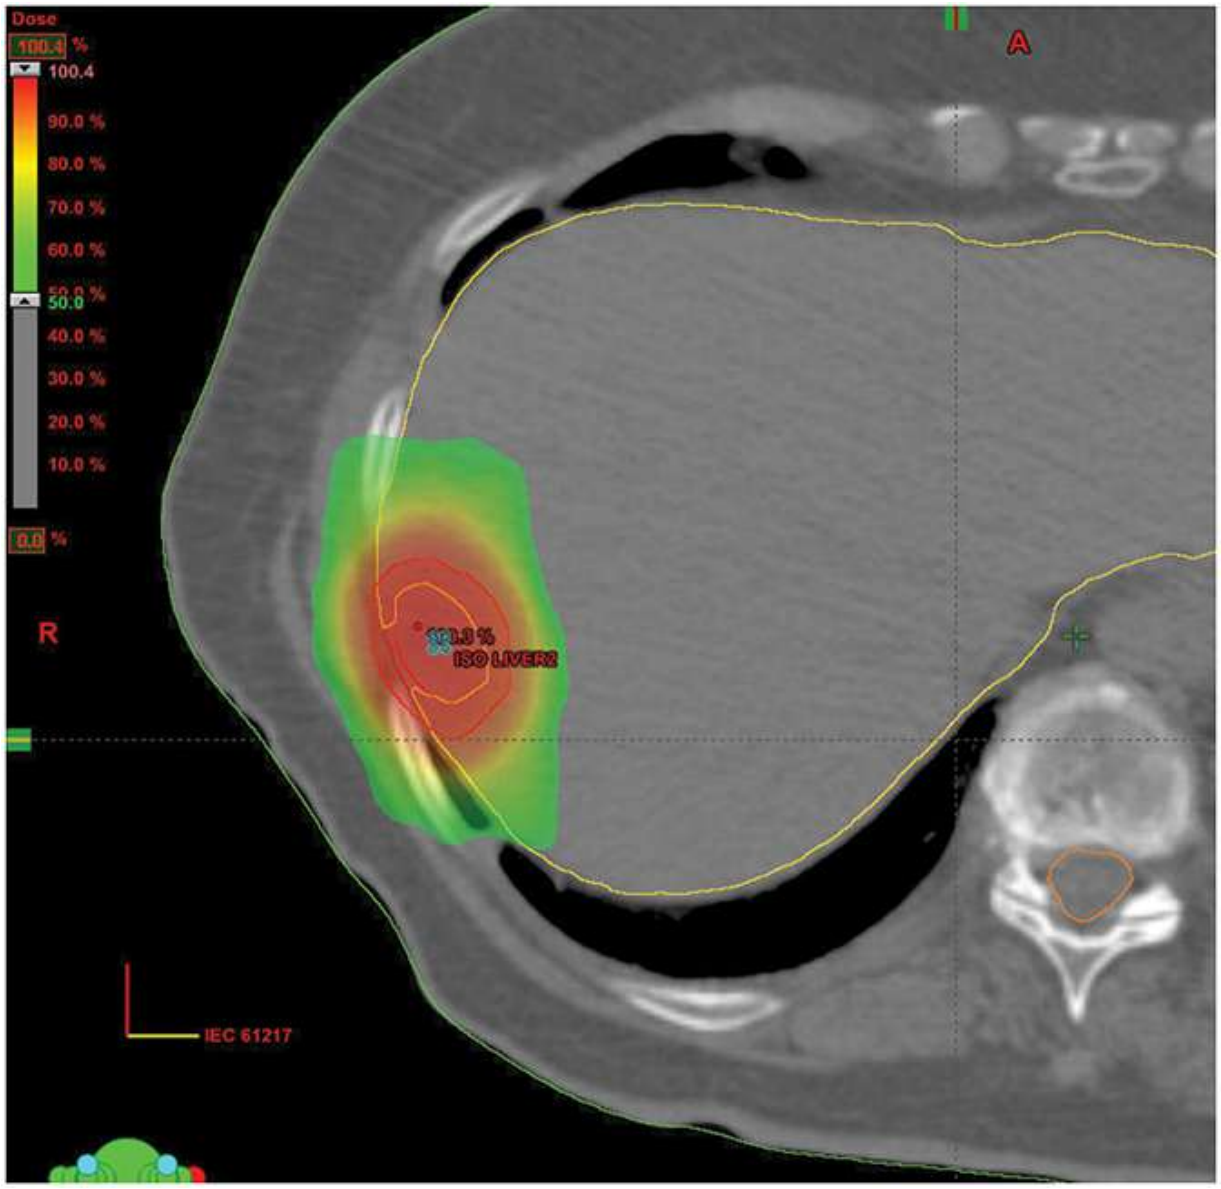

FIGURE 104.4 Axial computed tomography images showing the dose distribution from stereotactic body radiotherapy treatment of a liver metastasis.

With rapid advances in SBRT technique and experience, a number of modern trials on the treatment of oligometastatic disease have been initiated and reported. The phase II Stereotactic Ablative Radiotherapy for the Comprehensive Treatment of Oligometastases (SABR-COMET) trial, with its extended long-term outcomes, compared the outcomes of patients receiving standard palliative care (control arm) with those receiving SABR in addition to standard care (SABR arm), specifically targeting patients with one to five metastases and a controlled primary tumor. The 8-year follow-up

data revealed that the SABR arm exhibited significant improvements in OS and progression-free survival (PFS). Notably, the 8-year OS rate in the SABR arm was 27.2%, compared to 13.6% in the control arm. Moreover, 21.3% of patients in the SABR arm achieved survival beyond 5 years without recurrence, suggesting a potential shift toward a curative paradigm in select patient populations. In addition, the extended follow-up period reported no new major late toxicities, affirming the safety profile of SABR. Another noteworthy finding was the reduced utilization of cytotoxic chemotherapy in the SABR arm, indicating a potential for SABR in decreasing the need for more aggressive treatments in the long term.[88] Two phase III follow-up studies, SABR-COMET-3 and SABR-COMET-10, have been initiated to further explore the question of patient selection for metastasis-directed therapy using SABR, particularly by number of metastatic lesions.[89,90] Complementing these studies, the SABR-5 trial focused on the PFS and local control achievable with SABR in patients with up to five oligometastases.[91] This trial reported a median PFS of 15 months and local control rates of 93% and 87% at 1 and 3 years, respectively. Key prognostic factors influencing PFS included tumor diameter, performance status, and the number of metastases at the time of SABR. These findings, demonstrating notable outcomes in both PFS and local control, further reinforce the significant role of SABR in managing oligometastatic disease. The outcomes of these studies underscore the significant role of SABR in the management of oligometastatic disease, reinforcing its value in extending survival and maintaining quality of life.

The definitive SBRT treatment of oligometastatic disease involving the lung has also been the subject of numerous clinical reports.[92,93] A multi-institutional phase I and II trial of SBRT for lung metastases dose-escalated 38 patients with one to three lesions and cumulative maximal tumor diameters of less than 7 cm from 48 to 60 Gy in three fractions. A median survival of 19 months and local control rate of 96% at 2 years were achieved, while symptomatic radiation pneumonitis was uncommon (2.6%) and grade 3 toxicity or higher was reported as 8%.[94] A German multi-institutional pooled database of 700 patients with oligometastatic lung cancer treated with SBRT showed a 2-year local control rate of 81.2% and OS rate of 54.4%. Radiation-induced pneumonitis grade 2 or higher was observed in 6.5% of patients.[95]

The curative treatment of oligometastatic sites in addition to lung and liver has also shown promise in published clinical reports. In most series, the oligometastatic state has been defined as one to five sites of metastatic disease, with inconsistent application of primary disease status, overall disease volume, or maximal lesion size as constraints for oligometastatic disease (Figure 104.5). Investigators from the University of Chicago have reported a dose-escalation trial of 29 patients with one to five sites of metastatic disease, concluding that there was minimal toxicity and potential clinical benefit from this approach.[96] Another prospective study of 121 curative-intent SBRT with five or fewer oligometastatic lesions yielded 4-year survival rates of 28%, PFS of 20%, and local control of 60%.[97] Twenty-nine patients were alive and with no evidence of disease at last follow-up, leading the authors to conclude that "oligometastatic disease is a potentially curable state of distant cancer spread."

Other investigators have also examined the curative role of oligometastatic disease for specific primary sites of disease. Milano et al[98] examined the role of curative SBRT for 51 patients with metastatic breast cancer, concluding prolonged survival and possible cure for select patients with limited metastatic disease, as well as the utility of palliative-intent SBRT for symptomatic or potentially symptomatic sites. International guideline statements have also addressed the management of select patients with oligometastatic breast cancer in consensus recommendations, stating "a small but very important subset of metastatic breast cancer patients, for

example those with a solitary metastatic lesion, can achieve complete remission and a long survival."[99]

Similarly, the role of curative SBRT for the treatment of limited metastatic prostate cancer shows promise. Prospective studies have shown good rates of local and PSA control in limited boney and nodal metastatic disease.[100,101] The ORIOLE trial further substantiates this, demonstrating that SBRT significantly reduces disease progression at 6 months in patients with oligometastatic prostate cancer compared to observation alone (19% vs 61%).[102] This trial, which randomized patients in a 2:1 ratio to receive SBRT or observation, also indicated that SBRT improved median PFS and that complete consolidation of prostate-specific membrane antigen (PSMA) radiotracer-avid disease with SBRT decreased the risk of new lesions. Importantly, SBRT was found to induce a systemic immune response, suggesting its potential for enhancing disease control beyond the treated lesions.

In addition to metastasis-directed therapy, the HORRAD and STAMPEDE trials in patients with limited metastatic disease to the bones and lymph nodes investigated the benefit of treatment of the primary site.[103,104] A meta-analysis including these trials showed that for patients with less than five metastases, there was a 7% improvement in 3-year survival with the addition of prostate RT, and for all patients, there was approximately 11% biochemical PFS benefit, though no OS benefit.[105]

While initial studies of the treatment of oligometastatic disease show promising results, safety of these treatments has been a concern since inception of this concept. Several studies have now demonstrated the safety of this approach. The NRG-BR001 phase 1 trial was a critical study evaluating the safety of SBRT in patients with oligometastatic disease.[106] The trial focused on patients either with three or four metastases or with two metastases in close proximity in patients with non–small cell lung, breast, and prostate cancer, utilizing SBRT to target these lesions. The findings demonstrated the safety of this approach, with no incidents of treatment-related deaths. However, the occurrence of late grade 3 adverse events emphasized the importance of prolonged follow-up for patients with oligometastatic disease. These promising results led to the initiation of a successor phase II study, NRG BR-002. This randomized phase II/III study investigated the role of metastases-directed treatment (MDT) with SBRT or

surgical resection alongside standard of care systemic therapy (SOC ST) in newly diagnosed oligometastatic breast cancer. The trial enrolled patients with four or less extracranial metastases, who were randomized to receive either SOC ST alone or in combination with MDT.[107] The results indicated no significant improvement in PFS or OS with the addition of MDT. While there were fewer new metastases within the treated/index areas in the MDT arm, the overall outcomes did not support a substantial benefit of adding MDT to SOC ST in patients with oligometastatic breast cancer, and the trial did not proceed to phase III.[78]

Early reports have also documented the potential utility of curative SBRT for oligometastatic disease from gynecologic and non–small cell lung primary sites, as well as involved oligometastatic sites such abdominal nodal metastases and adrenal gland metastasis.[87,108-112] For additional information on the treatment of oligometastases for specific sites, refer to the specific disease site chapter for each site.

The abscopal effect is a phenomenon where local RT leads to regression of distant, nonirradiated tumors. This concept has garnered renewed interest in the context of modern immunotherapy and the oligometastatic paradigm. This effect is thought to be underpinned by the immunomodulatory impact of radiation, which can stimulate a systemic antitumor immune response. Historically considered too rare and unpredictable for therapeutic goals, the abscopal effect is now increasingly observed in conjunction with immune checkpoint inhibitors (ICIs). The integration of RT with ICIs has been demonstrated to enhance the abscopal response, suggesting a potential new avenue for treating metastatic disease. Originally identified in the early 1950s, this effect encapsulates the regression of nonirradiated distant tumors following RT to a specific site.[113] The synergy between RT and ICIs, such as antibodies against cytotoxic T-cell antigen 4, programmed cell death protein 1, and programmed death ligand 1, has been a focal point of recent research.[114] The underlying mechanism, though not fully elucidated, seems to involve the optimal induction of DNA double-stranded breaks by specific radiation doses, triggering an antitumor immune response through the cGAS-STING pathway.[115]

Clinical and preclinical studies have reported systemic abscopal effects when combining immunotherapy with RT.[116] Golden et al showed that concurrent treatment with RT and ipilimumab in a patient with metastatic

lung adenocarcinoma showed regression of disease at distant sites, with a post-treatment increase in tumor-infiltrating cytotoxic lymphocytes observed.[117] Preclinical studies have highlighted the variety of factors that can influence this phenomenon, mostly associated with modulation of cytotoxic T-cell behavior, and emphasize the importance of dosage and timing of both RT and immunomodulatory drugs in its promotion.[118] While the abscopal effect offers a promising avenue in cancer treatment, its rarity and unpredictability remain challenges. Ongoing research aims to understand the mechanisms driving this effect, and many modern trials exploring the treatment of oligometastatic disease include biomarkers with the hope of improving patient stratification and treatment planning.

In summary, local therapy, particularly using advanced techniques such as SBRT, may be beneficial in selected patients with a small number of metastatic sites; these patients should be treated on prospective trials in order to obtain a better understanding of the appropriate use of this technology.

CHAPTER 105

Cancer Pain: Assessment and Management

Ellen Kim and Tracy A. Balboni

The most common cancer-related symptom that radiation oncologists are called upon to assess and manage is cancer-related pain. More than half of patients undergoing radiotherapy (RT) experience pain.[1] Notably, majorities of patients and physicians feel that patients' pain is suboptimally controlled,[2] highlighting the need for oncologists to have a comprehensive understanding of and facility with cancer pain assessment and management.

PAIN AS A MULTIDIMENSIONAL CONSTRUCT

Pain is a complex symptom that is dynamically related to physical, emotional, social, and spiritual aspects of illness and quality of life. For example, the young parent with metastatic cancer who is struggling emotionally with concerns of how this will impact young children may experience bone pain heralding progressive disease with much greater intensity than a patient who has experienced acceptance of illness. Dame Cicely Saunders, founder of the modern hospice movement, termed this comprehensive concept, "total pain" (Figure 105.1).[3] Such an approach is critical to holistic pain assessment and management, addressing the multidimensionality of pain and drawing upon multidimensional resources for its mitigation. In the patient example above, physical strategies to address pain, such as pharmacologic agents and palliative RT, should be considered together with psychosocial/spiritual assessment and care as part of a comprehensive approach to pain management, an approach discussed further in Chapters 106. Such an approach is fostered by multidisciplinary management of patients with cancer pain, including palliative and psychosocial specialists, social work, and chaplaincy.

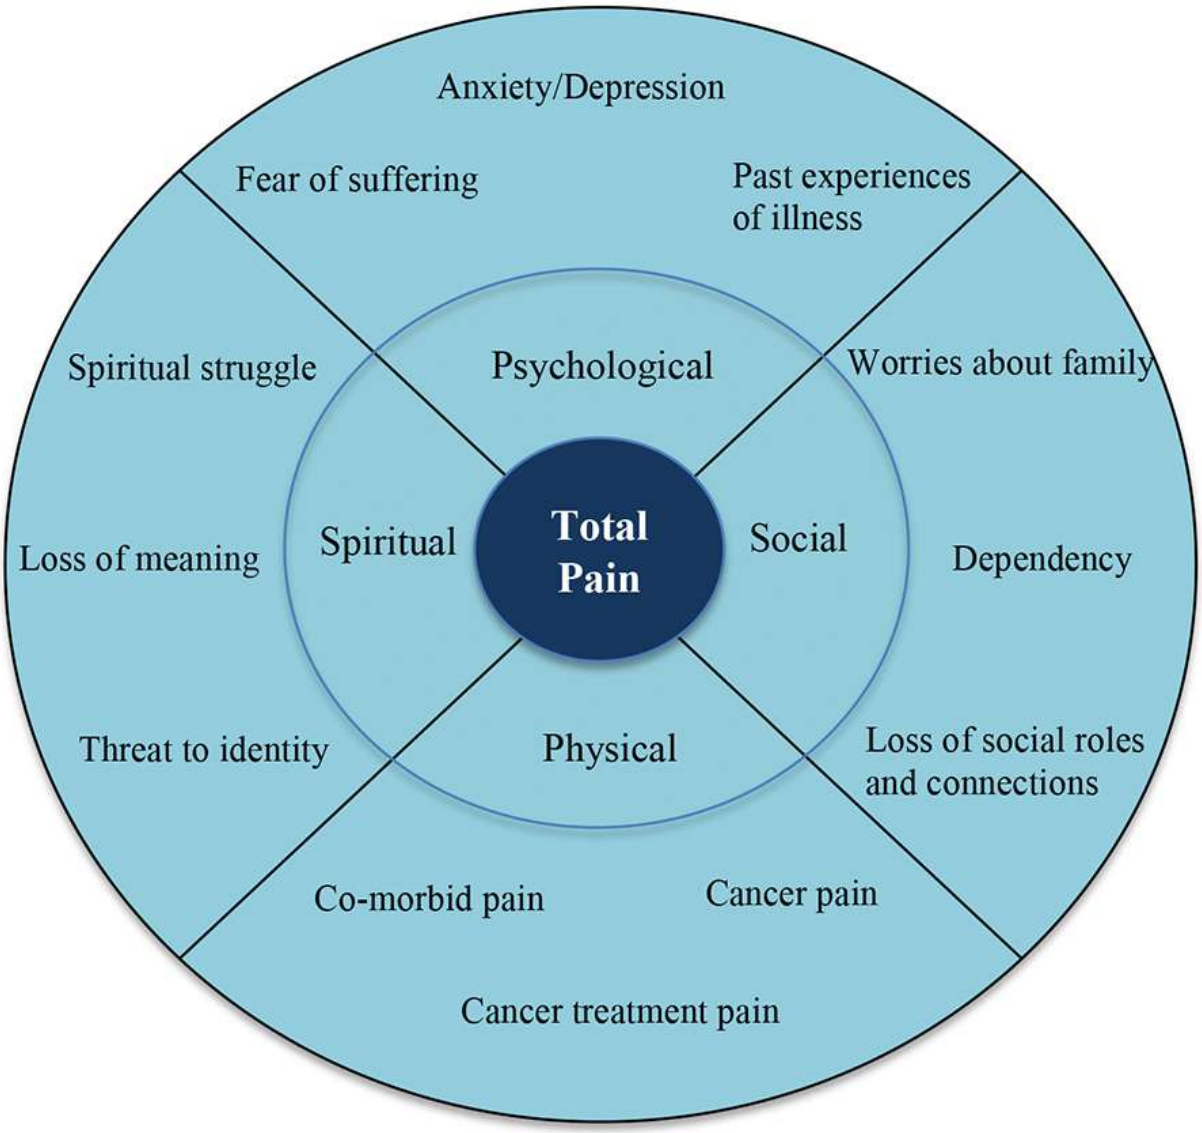

FIGURE 105.1 Dame Cicely Saunders conceptual model of total pain, with examples of factors contributing to the physical, psychological, social, and spiritual pain domains. (Derived from Saunders C. The treatment of intractable pain in terminal cancer. *Proc R Soc Med*. 1963;56[3]:195-197.)

PHYSICAL ETIOLOGIES OF CANCER-RELATED PAIN

Though cancer can be asymptomatic within the normal tissues, symptoms arise once sufficient disruption of normal tissues has occurred, with pain being the most common manifestation. Cancer pain has been hypothesized to be multifactorial in its etiology (Figure 105.2).[4] It is hypothesized to arise from induction of local inflammatory cytokines within the microenvironment with recruitment of inflammatory cells. These, in turn,

promote sensitization and activation of primary afferent neurons. In addition, cancer pain can arise from mechanical disruption and/or mass effect on normal tissues. This includes normal tissue destruction resulting in pain, such as lytic disease causing bone instability as well as local tissue compression or expansion resulting in pain, such as back pain from malignant spinal cord compression or capsular stretch pain from extensive liver metastases.

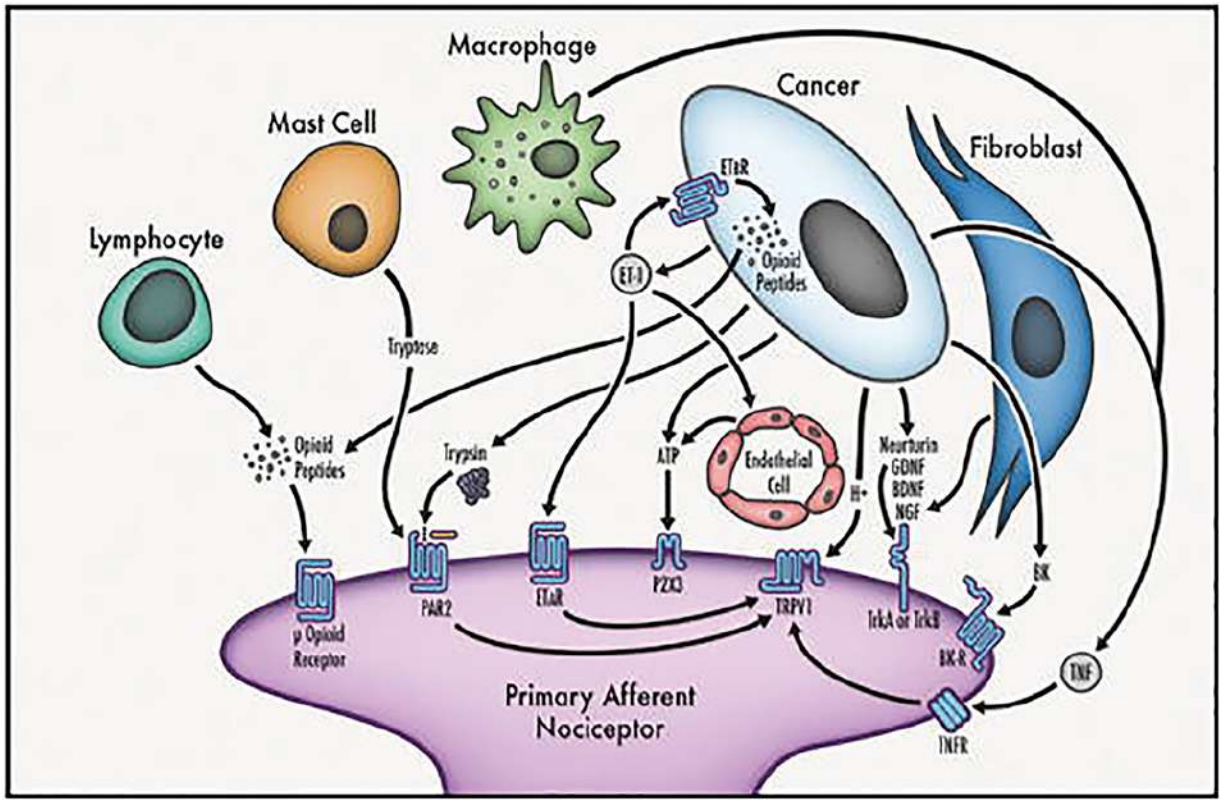

FIGURE 105.2 Schmidt model of the mechanisms of cancer pain. Cancer cells are hypothesized to secrete mediators that sensitize and/or activate primary afferent neurons within the local microenvironment. Cancer cells are posited to secrete chemoattractants that recruit lymphocytes, mast cells, macrophages, and fibroblasts that secrete mediators modulating cancer pain. BDNF, brain-derived neurotrophic factor; BK, bradykinin; BK-R, bradykinin receptor; ET-1, endothelin-1; ET_AR, endothelin A receptor; ET_BR, endothelin B receptor; GDNF, glial-derived neurotrophic factor; NGF, nerve growth factor; PAR2, protease-activated receptor 2; TrkA, tyrosine kinase receptor A; TrkB, tyrosine kinase receptor B; TRPV1, transient receptor potential vanilloid 1. (From Schmidt BL. The neurobiology of cancer pain. *Neuroscientist*. 2014;20[5]:546-562. Copyright © 2014 SAGE Publications. Reprinted by permission of SAGE Publications.)

Cancer-related pain can also result from the delivery of RT and subsequent complications to normal tissues. Acutely, irradiation of normal tissues with a rapid growth rate causes cell death and triggers a cascade of cytokines and thrombotic and growth factors, propagating local painful reactions.[5,6] Examples include RT-related mucositis and dermatitis. RT can also cause pain because of late or chronic tissue damage such as fibrosis and damage to local microvasculature. Pain management in the setting of acute RT toxicities typically requires a strategy conducive to dynamic pain management needs, including rapid uptitration with gradual downtitration of pain interventions, as symptoms resolve. In the setting of pain related to the long-term effects of RT, pain management strategies should reflect the frequent long-term nature of these pain syndromes, given that they often are caused by permanent damage to normal tissues.

This chapter provides an overview of cancer pain assessment, management, and guidelines critical to the practice of radiation oncology. RT is often a valuable component of a treatment plan for cancer-related pain, given its efficacy in palliating symptomatic cancers involving bone, nerves, and other soft tissues.[7] The application of RT for the palliation of cancer-related pain and other symptoms is covered in their respective chapters elsewhere in this book.

Types of Cancer-Related Pain

Pain is generally classified as nociceptive or neuropathic or can present as a combination of these pain types. For example, lumbar vertebral body involvement at L1 with tumor compressing the L1 exiting nerve root can cause both local somatic pain (eg, mid to lower back pain) because of bone involvement by tumor as well as referred neuropathic pain down the L1 dermatomal distribution to the lateral hip. Nociceptive pain refers to the nervous system response that is proportional to the tissue damage initiating the response. Nociceptive pain is subcategorized into somatic pain and visceral pain depending on the location and symptoms of the painful stimulus. Somatic pain generally is a local response to damage to normal tissues, such as skin, muscle, or connective tissue. It often presents as a dull or achy pain that is localizable to its source. Conversely, visceral pain is typically due to irritation of viscera (eg, colic from gallstones) and may be

difficult to localize, though it can also have a somatic component. Visceral pain often is characterized as a dull, sharp, and/or cramping pain.

Neuropathic pain results from irritation and activation of peripheral or central nerves. Patients may complain of burning, shooting, tingling, or numbness, which generally occurs along a nerve distribution.[8] Neuropathic pain can result in pain out of proportion to the pain stimulus where there is abnormal pain processing by the peripheral or central nervous system.

Cancer Pain Assessment

All patients should be screened for pain at each point of clinical contact. Typically, screening is performed with the 0 to 10 pain intensity scale. A comprehensive pain assessment should be performed at initial consultation and at each subsequent evaluation of their ongoing pain management. A comprehensive pain assessment is critical for determining the etiology of pain and for informing strategies for symptom management, both pharmacologically and with local interventions such as RT. Each type of pain syndrome is amenable to treatment with different modalities. For example, localized, somatic pain may be better treated with nonsteroidal anti-inflammatory drugs (NSAIDs) and/or with opioid medications, whereas neuropathic pain may be more effectively managed with anticonvulsants or antidepressants with or without opiates.

Comprehensive pain assessment should include assessment of the following factors, captured in the acronym “PAINED” to aid in application to clinical practice. Place (P) is assessment of the location of pain, including any pain radiation. Activators (A) are determining factors that make the pain worse, such as positions (eg, lying down), actions (eg, walking), or time of day. Intensity and interval (I) are assessment of the intensity of the pain, typically assessed with the 0 to 10 pain scale from 0 (none) to 10 (worst possible pain) together with the interval of time the pain has been present; this includes assessment of changes in pain intensity over time. Asking about the range of pain intensity and intensity changes with aggravating factors can also be informative. Nullifier (N) is assessment of those factors that reduce pain, including analgesics (with full assessment of analgesic types used and quantity), positions and activities reducing pain, or other practices (eg, meditation). Effect (E) is assessment of the effect of

pain on daily activities, including activities of daily living and additional activities important to the patient (eg, being able to pick up a grandchild). Finally, description (D) is assessment of the quality of the pain in the patient's own words (eg, dull, stabbing, aching, burning).

Assessment of the patient goals for pain management (eg, activity goals) and evaluation of risk factors for opioid misuse and diversion are also important to determine an optimal strategy for pain management. Risk factors include a prior history of drug or alcohol abuse, family history of substance abuse, history of psychiatric disorders (eg, anxiety, depression, post-traumatic stress disorder), history of legal problems or incarceration, and age <45 years. In patients with risk factors, referrals to clinicians with experience in managing pain in high-risk patients, such as palliative medicine specialists, should be considered. All patients given opiates should be educated regarding safe use, storage, and disposal of opiates. Furthermore, opioid contracts—statements signed by the patient regarding the appropriate use of opioids, commitment to opioid safety, and nonmisconduct—are often performed at the time when long-acting opioids are required. Finally, opioid prescribing should include review of the patient's prescription history with the local state prescription monitoring program.

Cancer Pain Management

A comprehensive pain assessment guides the application of workup and treatment strategies. For example, a patient with metastatic cancer and low back pain radiating to the lower extremities should have a magnetic resonance imaging (MRI) of the spine to assess for possible etiology of cord/cauda compression, with the treatment strategy based on the etiology. Wherever possible, the etiology of the pain should be addressed (eg, RT for bone metastasis–related pain) in addition to pharmacologic intervention. The roles of RT in alleviating cancer-related pain are addressed elsewhere. Herein, guidelines to approach pharmacologic and other non–cancer-directed therapies to alleviate pain are outlined.

GUIDELINES FOR PAIN MANAGEMENT

Many national and international organizations have developed guidelines for pain management. Despite variations in the details, the principles and approaches are consistent across guidelines. The World Health Organization (WHO), American Pain Society (APS), and other national consensus guidelines are discussed here.

WHO pain ladder. The WHO guidelines for analgesic management of cancer pain, first described in the early 1980s,[9,10] consist of a three-step approach that has been validated in clinical trials.[11] Despite some debate on its effectiveness,[12] it establishes a widely practiced, stepwise approach in the treatment of various levels of pain severity.

The first tier involves the use of nonopiate medications, primarily NSAIDs (Table 105.1). These medications include acetaminophen, nonspecific cyclooxygenase inhibitors (including ibuprofen, diclofenac, and aspirin), and cyclooxygenase-2 inhibitors (celecoxib).[13] NSAIDs are considered the first group of medications to administer. If the patient's pain persists or worsens, the second tier adds a weak opioid in addition to the nonopiate. Finally, continued treatment for worsening pain includes the addition of a strong opioid to replace the weak opiate, the third tier (Table 105.2).

TABLE 105.1 GUIDE TO COMMON NONOPIATE MEDICATIONS AND STARTING DOSES FOR ADULTS

Medication	Starting Dose (Maximum Daily Dose in mg)
Acetaminophen	500, 3-4 × day (4,000)
Nonsteroidal anti-inflammatory drugs	
Aspirin	325, 3-4 × day (4,000)
Ibuprofen	200, 3 × day (2,400)
Naproxen	250, 2 × day (1,250)
Ketorolac	IV 15-30 up to 4 doses
Diclofenac	50, 3 × day (150 mg)
Specific COX-2 inhibitors	
Celecoxib	100, 2 × day (400-800)

COX-2, cyclooxygenase-2; IV, intravenous.

TABLE 105.2 GUIDE TO COMMON WEAK AND STRONG OPIOID MEDICATIONS AND POTENTIAL STARTING DOSES

Opioid	Starting Dose	PO Conversion (mg)	IV Conversion (mg)
Weak			
Tramadol	50 mg PO 2-3 × day	—	—
Codeine	30 mg PO 4-6 × day	—	—
Hydrocodone	5 mg PO 4-6 × day	—	—
Strong			
Morphine	15 mg PO 4-6 × day	30	10
Hydromorphone	2-4 mg PO 4-6 × day	8	2
Methadone	2.5-5 mg PO 2-3 × day	2	1
Fentanyl	Transdermal 25 μg/d	NA	0.2
Oxycodone	5-15 mg PO 4-6 × day	20	NA

Opiate medication must be titrated for adequate pain relief and minimal side effects. For the strong opiates, equivalent doses for conversion are given, with methadone IV as the base dose of 1 mg. The conversion factors can be used to change PO or IV doses among the different opiates (ie, 2 mg of PO methadone is roughly equivalent to 30 mg of PO morphine). Similarly, 2 mg of PO methadone is equivalent to 1 mg of IV methadone. When changing from one opiate to another, a reduction factor is sometimes applied (usually 25%-50% of the original medication's dose) because of less tolerance to the new medication. For example, if a patient is using 60 mg of PO morphine every 4 hours, an equivalent oxycodone dose may be 40 mg × a 50% reduction, leading to 20 mg every 4 hours.

IV, intravenous; NA, not applicable; PO, by mouth.

Five simple principles are recommended to make the pharmacologic treatments effective: (a) Oral administration of analgesics should be used whenever possible; (b) analgesics should be given at regular intervals; (c) analgesics should be prescribed according to pain intensity as evaluated with a pain scale; (d) dosing of analgesics should be adapted to the individual; and (e) analgesics should be prescribed with a constant concern for detail.[14]

Over time, adaptations of the WHO ladder have been proposed. In refractory pain or crises of chronic pain, a fourth step may be considered. This fourth step includes invasive techniques such as nerve blocks, neurolysis, or surgical or other interventions.[9,15] Adjuvant medications

including steroids, anxiolytics, antidepressants, hypnotics, anticonvulsants, antiepileptic-like gabapentinoids (gabapentin and pregabalin), membrane stabilizers, sodium channel blockers, *N*-methyl-D-aspartate receptor antagonists, and cannabinoids may be used in the treatment of neuropathic pain.[16,17]

APS and other national consensus guidelines. Although the WHO guidelines are a good initial step in pain management, other organizations have expanded these strategies to improve treatment for cancer pain. These guides provide initial medication dosages, the addition of adjuvant medications, and information on appropriate dose increases, allowing the radiation oncologist to further develop pain management skills.

The 2005 APS *Guideline for the Management of Cancer Pain in Adults and Children* contains detailed discussions of cancer pain management algorithms, pharmacologic strategies, co-analgesics, psychological strategies, supportive therapy, integration of nonpharmacologic and pharmacologic treatments, physical strategies, nerve blocks, surgical strategies, RT, chemotherapy, and pain management in special populations. It also discusses patient education and the importance of patients' adherence to the pain management plan as well as how to improve quality of care in pain management.[18]

The latest national consensus guidelines for adult cancer pain outline the following principles: (a) Patients should be screened for pain at each point of contact; (b) pain intensity must be quantified and quality described by the patient whenever possible; (c) a formal comprehensive pain assessment must be performed for new or worsening pain; (d) pain management plans should employ optimized disease-specific therapies, rely on multidisciplinary input as appropriate, anticipate and minimize pain management side effects (eg, opioid-related side effects), involve patients in the development of treatment plans and goals, and address the multidimensional impacts of pain on patients and families; (e) reassessment of pain intensity must be performed at specified intervals to ensure that the therapy selected is having the desired effect; (f) education must be provided to the patient to ensure understanding of anticipated side effects and of safe use and disposal of opiates and other analgesics; and (g) all patients should be screened for potential opiate misuse, abuse, or diversion and include the

use of prescription monitoring programs as directed by state government requirements. The guidelines provide specific suggestions for dosing of NSAIDs, opioids, and co-analgesics, as well as titrating and rotating of opioids, escalating opioid dosage, managing opioid adverse effects, and deciding when and how to proceed to other techniques/interventions for the management of cancer pain.

Role of Oncologists and Pain Specialists in Managing Cancer-Related Pain

Radiation oncologists, together with other oncology clinical practitioners, are responsible for assessing and managing pain for their patients by utilizing the guidelines as noted above. However, this raises the question of when to call upon palliative medicine or acute pain specialists in pain management. Randomized trials have shown a quality of life benefit of early involvement of palliative medicine clinicians in the care of cancer patients, and hence, the American Society of Clinical Oncology recommendations call for the early integration of palliative care into standard oncology care.[19] Oncologists should have a low threshold to call upon palliative care providers to guide pain management strategies, particularly in the setting of refractory pain, complex pain syndromes, and/or difficult-to-manage side effects. Integration of palliative medicine into oncology care, and when to refer patients to palliative medicine specialists, is discussed in more detail in Chapters 106.

Routes of Administration

Chemotherapy, surgery, and RT often produce significant side effects that can limit oral administration of pain medications. Furthermore, cancer-related pain can be so severe that acute pain management requires hospital admission and intravenous (IV) pain medication administration. Both opiate and nonopiate pain medications come in formulations that can be delivered via nonoral routes, such as transdermal, IV, or rectal. When changing from oral to another delivery mode, care must be taken to give equipotent analgesic doses. Conversion charts for opioids are readily available in the literature.[20] When switching opiate agents, a 25% to 50% dose reduction should be applied to account for incomplete cross-tolerance between

distinct opioid agents. Such complicated pain management scenarios may require an inpatient stay and/or the assistance of pain management specialists.

Opiate Side Effects

Treating a patient's pain is a balance of maximizing analgesic effects and minimizing side effects.[21] Common opioid side effects include gastrointestinal (constipation, nausea, and emesis), respiratory (decreased respiratory rate), dermatologic (pruritus and dry mouth), and peripheral/central nervous system (myoclonus, sedation, hallucinations, and seizures) effects.

General management strategies include the pharmacologic treatment of the side effects. These include the standard inclusion of strategies to mitigate constipation, such as high water intake, dietary fiber, and a daily regimen of stool softeners and laxatives. Consideration of peripherally acting opioid antagonist methylnaltrexone is made in the case of constipation refractory to these measures. Nausea can be mitigated through the use of antiemetics, though care must be taken in the use of antiemetics that can cause constipation, such as ondansetron. Another important opiate side-effect mitigation strategy is to reduce the dose of opiates required to achieve analgesia through the use of adjunctive medications for pain management, including agents such as glucocorticoids, anticonvulsants, and antidepressants. These medications are discussed further in the next section. A third strategy is opioid rotation as some opiate side effects such as pruritis and myoclonus can be mitigated by rotating to another opioid agent. Opioid rotation should follow the principles of an approximate 25% to 50% dose reduction based on an equianalgesic table, given incomplete cross-tolerance of different opiate agents.

Adjuvant Therapies and Interventions for Pain Management

Using the WHO ladder, pain related to cancer can be managed with oral medications in 70% to 85% of patients.[11,22] At any point on the WHO analgesic ladder, adjuvant therapy can be initiated to supplement NSAIDs and opioid treatment. Benefits of adjuvant therapy include the use of

medications tailored to specific causes of nociceptive responses (ie, neuropathic pain) and reduction of opiate side effects.

Adjuvant Therapies in Neuropathic Pain

Because neuropathic pain is often not responsive to opioid medications unless high doses are applied, other classes of medications are often prescribed.[23] Glucocorticoids (eg, dexamethasone) are effective for the short-term management of tumor-related neuropathic pain and are often the initial agent of choice when managing neuropathic pain while awaiting an anticipated response to palliative RT. Dexamethasone is usually preferred in oncology due to its favorable balance of glucocorticoid (anti-inflammatory and analgesic) to mineralocorticoid properties (eg, fluid retention), longer half-life allowing for less frequent dosing, and availability in both oral and IV formulations.[24] If glucocorticoids are insufficient to control neuropathic pain, and/or palliative RT does not sufficiently resolve neuropathic pain symptoms, typically anticonvulsants or antidepressants are considered.

Anticonvulsants such as gabapentin, carbamazepine, and pregabalin are effective in managing neuropathic symptoms.[8] Both gabapentin and pregabalin are renally excreted and have minimal drug-drug interactions, which renders these medications effective first-line treatments for neuropathic pain.[8] Like anticonvulsants, antidepressants are a broad category of medications that stabilize neurons involved in neuropathic pain. Tricyclic antidepressants in low doses, such as amitriptyline, have been well studied and can be effective for pain relief.[25] Serotonin reuptake inhibitors and newer classes of antidepressants, including selective serotonin and norepinephrine reuptake inhibitors (milnacipran, duloxetine, and venlafaxine), are less well studied but are often prescribed for neuropathic pain. Because many patients with neuropathic pain experience depression or anxiety, antidepressants may play a dual treatment role and improve the efficacy of pain control.[26]

Topical agents can also be effective in the management of neuropathic pain and often have minimal side effects. These include capsaicin cream and transdermal lidocaine, both found to be effective in the management of neuropathic pain.[26-28]

Muscle relaxants are another class of agents that can be used in both neuropathic pain and other pain syndromes. Because painful muscle spasm can add to the pain etiology in both neuropathic and other pain syndromes (eg, somatic pain from vertebral body fracture), muscle relaxants can have a role in mitigating pain in this setting. Agents typically used include baclofen and cyclobenzaprine.

Finally, agents that antagonize the NMDA (*N*-methyl-D-aspartate) receptor are also considered in the management of neuropathic pain; however, prescription of these medications is typically limited to pain specialists. The NMDA receptor has a role in modulating pain signals throughout the nervous system. Methadone is a long-acting opioid receptor antagonist, which is hypothesized to also act as an NMDA receptor antagonist, preventing morphine tolerance and NMDA hyperalgesia effects.[29] Ketamine, a specific NMDA receptor antagonist, is also employed by pain management specialists to relieve cancer and neuropathic pain, especially refractory pain.[30]

Other adjuvant analgesic drug classes used in cancer therapy include local anesthetics, steroids, muscle relaxants, benzodiazepines, α-adrenergic agonists, and bisphosphonates.[30] In recent years, there has been a resurgence in clinical trials of cannabis extracts and analogs in the treatment of refractory cancer pain.[31] Many of these medications are used in specific pain syndromes, which may be useful for the radiation oncologist (Table 105.3).

TABLE 105.3 COMMON ADJUVANT MEDICATIONS WITH STARTING DOSAGES AND COMMON SIDE EFFECTS

Medication	Starting Dose (PO Unless Otherwise Specified; mg)	Significant Side Effects
Antidepressants		
Amitriptyline	10-25 at night	Cardiac, CNS
Nortriptyline	10-25 at night	Cardiac, CNS
Venlafaxine	37.5 every day	CNS
Duloxetine	60 every day	Nausea, somnolence
Anticonvulsants		

Medication	Starting Dose (PO Unless Otherwise Specified; mg)	Significant Side Effects
Gabapentin	100, 3 × day	CNS, sedation
Carbamazepine	100, 2 × day	Bone marrow, liver, CNS
Pregabalin	75, 2 × day	CNS, sedation
Topicals		
Lidocaine 5%	1-3 patches for 12 h	CNS, cardiac
Capsaicin	0.025% cream	Burning
Muscle relaxants		
Baclofen	5, 3 × day	CNS
Cyclobenzaprine	5, 3 × day	Drowsiness, dry mouth
Tizanidine	2 every night (4 mg tid)	Weakness, dry mouth
***N*-Methyl-D-aspartate antagonist**		
Ketamine	Intravenous infusion	Hallucinations, CNS

CNS, central nervous system; PO, by mouth; tid, three times a day.

INTERVENTIONAL PAIN MANAGEMENT STRATEGIES

Although most cancer pain can be managed medically, some patients require interventional procedures to achieve pain relief. Such interventions include neuroablative techniques and implantable neuroaxial drug delivery devices. These strategies should be considered in patients with refractory pain despite pharmacologic management via traditional administration routes (eg, oral) escalated according to WHO guidelines or among patients with severe side effects despite optimization of pharmacologic agents.

Neuroablative Techniques

Neuroablative techniques can be excellent options for patients who have pain along discrete nerve distributions when chronic and/or insufficiently controlled by conventional systemic pharmacologic management. Interventional pain management specialists offer a myriad of neurolytic

procedures that can be highly efficacious and can reduce or even obviate the need for systemic pharmacologic pain medications.

Common nerves targeted include intercostal nerves for thoracic chest wall or abdominal wall pain, maxillary and mandibular nerves for facial pain, and median branch nerves for facet arthropathy.[32] Cryoanalgesia techniques apply subzero temperatures to induce Wallerian degeneration of neurons while allowing normal regrowth of axons. Radiofrequency techniques use heat to induce nerve damage. Chemical neurolysis can be achieved with phenol or alcohol preparations.

Pain signals initiating from the perineal, pelvic, and abdominal regions may be transmitted via visceral afferents following the sympathetic nervous system. Along with these fibers, the sympathetic nerves coalesce at specific ganglia (impar, superior and inferior hypogastric, and celiac plexus). At these sites, image-guided neurolytic procedures can be performed.[33] When pain fibers are destroyed in this process, the associated region is also sympathetically denervated.

Implantable Neuroaxial Drug Delivery Devices

Implantable neuroaxial drug delivery devices are indicated when oral opioid doses are escalated without sufficient pain relief and/or when side effects are intolerable.[34] Either semipermanent epidural systems or permanent intrathecal delivery systems can be used to deliver local anesthetic and opiate medications in low concentrations to appropriate spinal cord root levels.[35] The benefits of these methods include decreased side effects than systemic pain pharmacologic agents and often superior pain control.[36]

Electrostimulation techniques may also be applied to disrupt the flow of pain signals in the spinal cord. Transcutaneous electrical nerve stimulation (TENS), spinal cord stimulation at thoracic and lumbar regions, and deep brain stimulation at the thalamus or motor cortex can interfere with the conduction of pain signals.[37] The stimulation of large motor fibers inhibits the conduction of pain signals by small nerve fibers and has shown efficacy for various pain syndromes.[38]

Neurosurgical techniques are generally reserved for refractory pain and specific indications. Plexus root avulsions may be responsive to dorsal root entry zone lesioning, but the indications and success rates are limited.[39]

More specific lesions at the spinal cord and central nervous system (eg, thalamotomy and deep brain stimulation) have also been used with variable success and significant side effects.[40] Finally, various chemoneurolytic medications can be delivered intrathecally for the destruction of specific nerve roots or parts of the spinal cord for the treatment of refractory cancer pain.[41]

Finally, electroanalgesia involves a noninvasive strategy of electrical disruption of pain signals from a locus of pain to reduce pain perception. The most common types include TENS and scrambler therapy. A recent review[42] suggests some potential for benefit in chronic pain management, including in cancer-related pain,[43] though further research is required.

COMPLEMENTARY THERAPIES

Conventional medical regimens may not satisfactorily treat cancer-related pain syndromes. Several complementary modalities such as hypnosis, biofeedback, massage, music therapy, mind-body exercises, and dietary supplementation have been shown to reduce anxiety and chronic pain,[44] yet more multi-institutional, randomized controlled trials are needed to confirm their efficacy in this setting.[45]

Acupuncture is perhaps the most extensively studied alternative method for pain control.[46] Acupuncture can relieve both acute pain (eg, postoperative dental pain) and chronic pain (eg, headache, osteoarthritis).[47-49] Acupuncture also appears effective against cancer-related pain. A randomized, placebo-controlled trial tested auricular acupuncture for patients with cancer pain despite medication. Pain intensity decreased by 36% at 2 months from baseline in the treatment group, a statistically significant difference compared with the two control groups for whom little pain reduction was seen.[50] Most patients in this study had neuropathic pain, which is often refractory to conventional treatment. Neurophysiologic studies show that acupuncture-induced analgesia appears to be mediated by endogenous opioids and other neurotransmitters.[51] Functional brain imaging studies suggest that acupuncture also modulates the affective-cognitive aspect of pain perception.[52] Correlations between functional MRI signal intensities and analgesic effects induced by acupuncture have been reported.[53]

SPECIFIC SCENARIOS FOR THE RADIATION ONCOLOGIST

The following section identifies some common pain scenarios and syndromes specific to the setting of radiation oncology and proposes strategies for their management. As previously noted, radiation oncologists are generalist palliative care providers who should readily reach out for the expertise of pain specialists (eg, palliative medicine and anesthesia pain services) to ensure optimal pain control and quality of life for their patients.

Pain During Radiotherapy Planning and Treatment

Radiation oncologists regularly encounter patients who cannot tolerate RT positioning secondary to pain. The first goal should be to optimize treatment positioning and to decrease time on the treatment table to minimize pain. Often, simple modifications in treatment setup (eg, cushion under the knees and/or neck), where feasible without compromising radiation delivery, can greatly mitigate incident pain. Next, overall pain management using the aforementioned guidelines should be optimized. Premedication with additional dosing of the breakthrough pain agent such as short-acting opiates approximately 1 hour prior to the simulation or treatment should be performed to anticipate incident pain. Not infrequently, patients will require IV pharmacologic management as an inpatient and hence IV premedication can be given. For such inpatients with severe pain, pain specialists should be involved to optimize pain management using specialized strategies. Among patients with pain that is severe only with the positioning and who may become overmedicated with traditional short-acting opiates, fast-acting opiates can also be considered. For example, transmucosal preparations of fentanyl are optimal because of their pharmacologic properties of fast onset and resolution of effect.

Mucositis and Proctitis

Pain associated with mucositis (up to 75% of patients treated with radiation) can be debilitating and, if not sufficiently controlled, may result in treatment delays and/or dose limitations of RT.[54] Pain control strategies for patients with mucositis follow the aforementioned pain management guidelines but with some adaptations, given the particular needs of this

patient population. Topical analgesics, such as viscous lidocaine preparations (eg, 1:1:1 solution of magnesium and aluminum hydroxide, diphenhydramine, and lidocaine), can provide relief from incident pain when swallowing.[55] When systemic pain management is required, often, liquid short-acting opiate preparations and transdermal long-acting agents (eg, fentanyl patch) are required, given difficulty swallowing pills. Mucositis prevention and management will be discussed in greater detail in Chapters 106.

Similar to oral mucosa, the rectum is susceptible to acute and chronic proctitis, with patients typically presenting with tenesmus and rectal pain. In addition to systemic pain control, topical-directed therapies are often used in this setting, including hydrocortisone topical preparations and the use of sucralfate.[56] Management of constipation and diarrhea is also critical in these patients as either can worsen local irritation. Acute proctitis in the setting of RT most often heals within several weeks of RT completion without clinical sequelae, but particularly among patients receiving high-dose RT to the rectum, chronic proctitis can occur. These patients have chronic mucosal irritation that can be painful with rectal mucosal thinning and aberrant blood vessel formation that can result in rectal bleeding. Novel therapies, including hyperbaric oxygen and laser therapy, have been used successfully to heal rectal mucosa and reduce associated symptoms.[57-59]

Plexopathy

Nerve plexopathies are a frequent problem encountered by radiation oncologists, often because of tumor involving the nerve plexus. This scenario is typically managed with RT directed at the culprit tumor site for palliation together with the aforementioned pharmacologic processes for managing neuropathic pain. Though less common, RT can also cause plexopathies. Similar to muscle fibers, nerve bundles exposed to dose equivalents of more than approximately 60 Gy in 2 Gy fractions undergo significant decreases in large nerve fiber density.[60] Significant pain may ensue months to years after RT, especially in the brachial plexus distribution.[61] Rates of radiation-induced plexopathy range from 1% to 5% in selected patient populations. Among these patients, 10% will have complicated pain syndromes.[62] Treatments involve physical and

occupational therapy, together with pain management strategies, generally overseen by a pain specialist. Typical strategies include multimodality pain regimens (opioid and neuropathic pain medications as previously discussed), with consideration of interventional pain procedures and other novel interventions.[63]

Radiation-Related Muscle Spasm

Muscle fibers, once thought to be radioresistant, may undergo significant change, especially months to years after radiation exposure.[64] One-time muscle exposures to 10 to 20 Gy or fractionated doses >55 Gy are associated with myokymia, pain, and decreased muscle strength and range of motion.[65] Specific cancer locations susceptible to muscle complications include head and neck cancers and soft tissue cancers (eg, Ewing sarcoma).[65] Treatment regimen includes early physical therapy and orthopedic exercises and pharmacologic therapy such as muscle relaxants, such as baclofen or cyclobenzaprine. Novel treatments involve the use of botulinum toxin injected in small doses (15-25 units) into the muscle to relieve contracture or spasm.[65,66]

SUMMARY

Pain is a common problem in patients with advanced cancer. RT is frequently utilized to treat pain caused by the underlying cancer. A multimodal management approach should be applied, starting with oral analgesics administered according to clinical practice guidelines, with simultaneous attention to the psychosocial and spiritual aspects of pain and illness. For patients who experience refractory pain despite medical management according to pain management guidelines, pain specialists (eg, palliative medicine and/or anesthesia pain services) should be involved and specialty pain interventions (eg, interventional procedures) considered, where applicable. Complementary therapies may be helpful in some patients, although their efficacy has not been definitively established.

CHAPTER 106

Palliative and Supportive Care

Ellen Kim and Tracy A. Balboni

DEFINITIONS

The National Consensus Project defines *palliative care* as "beneficial at any stage of a serious illness, palliative care is an interdisciplinary care delivery system designed to anticipate, prevent, and manage physical, psychological, social, and spiritual suffering to optimize quality of life for patients, their families and caregivers."[1] Palliative care may be delivered in a variety of settings including inpatient and outpatient care as well as throughout the patient's disease course, from the initial diagnosis to the end of life. The National Consensus Project has defined eight domains of palliative care (Table 106.1) critical to quality palliative care provision.

TABLE 106.1 DOMAINS FROM THE NATIONAL CONSENSUS PROJECT GUIDELINES

NCP Domain	Domain Description
Domain 1: Structure and Processes of Care	This domain addresses interdisciplinary team engagement and collaboration with patients and families, with an emphasis on developing a comprehensive palliative care assessment and plan, ensuring continuity of care across healthcare settings, and planning for care coordination. Clarity and specificity of interdisciplinary composition, team member qualifications, necessary education, training, and support are described. This section includes quality assessment process and parameters for continuous quality improvement. Emotional support for the interdisciplinary team is also defined as part of a goal of building resilient teams. Finally, palliative care model sustainability and growth are also addressed.
Domain 2: Physical Aspects of Care	This domain addresses the assessment of physical symptoms with appropriate, validated tools and the multidimensional management of symptoms with pharmacological, interventional, behavioral, and complementary interventions. Explicit policies for the treatment of pain and symptom management and safe prescribing of controlled medications are recommended.
Domain 3: Psychological and Psychiatric Aspects of Care	This domain addresses the collaborative assessment process for psychological concerns and psychiatric diagnoses. Essential elements are described and include patient–family communication on assessment, diagnosis, and treatment options for common conditions in context of respect for goals of care of the patient and family. The domain also includes description and required elements of a bereavement program.

NCP Domain	Domain Description
Domain 4: Social Aspects of Care	This domain addresses interdisciplinary engagement and collaboration with patients and families to identify, support, and capitalize on patient and family strengths. The essential elements of a palliative care social assessment are defined. The role of the professional social worker is described.
Domain 5: Spiritual, Religious, and Existential Aspects of Care	This domain defines spirituality and describes assessment, access, and staff collaboration in attending to spiritual concerns throughout the illness trajectory. Requirements for staff training and education are set forth, and responsibility of the interdisciplinary team—including a chaplain—to explore, assess, and attend to spiritual issues of patients and families are discussed. Spiritual and religious rituals and practices to promote comfort are promoted.
Domain 6: Cultural Aspects of Care	This domain sets forth how the interdisciplinary team can deliver care that is respectful of patient and family cultural beliefs, values, language, and communication preferences. This domain aims to ensure care that is culturally respectful in terms of the care environment, care policies and procedures, and care practices.
Domain 7: Care of the Patient at the End of Life	This domain highlights communication and documentation of signs and symptoms of the dying process for the patient, the family, and involved health providers. Meticulous assessment and management of patient pain and other symptoms and attention to family guidance as to what to expect in the dying process and post death period are emphasized. Bereavement support, beginning with anticipatory grief, is emphasized, together with social, spiritual, and cultural aspects of care throughout the dying process.
Domain 8: Ethical and Legal Aspects of Care	This domain addresses global ethics, legal considerations, screening and assessment, and treatment decision making. Global ethical principles (e.g., autonomy, beneficence) are set out. Team competencies in identifying and resolving commonly encountered ethical issues are described. The importance of seeking guidance from ethical committees is also emphasized. Within legal considerations, the complex legal and regulatory issues in palliative care are acknowledged. There is also an emphasis on the necessity of and access to expert legal counsel when navigating intricate and sensitive legal and regulatory issues in palliative care. Guidelines for screening and assessment for patient preferences and goals are set forth, including advance care planning. Finally, for treatment and ongoing decision-making, the interdisciplinary team is to follow patient-centered goals within the applicable laws and standards of practice.

Of note, until a paradigm shift in the late 2000s, palliative care was often considered synonymous with hospice and end-of-life care.[2] Lingering misunderstandings from both patients and providers can interfere with palliative care engagement.[2]

Palliative care delivered in definitive cancer care settings is at times separately referred to as "supportive care." Furthermore, in some cancer care settings, regardless of the treatment intent, the term "supportive care" is used. To ensure clarity and comprehensiveness, this chapter defines "palliative and supportive care" as care that addresses the biopsychosocial and spiritual dimensions of patient quality of life throughout the cancer care continuum.

EVIDENCE AND CLINICAL GUIDELINES

In the oncology setting, there is a strong body of evidence supporting the integration of specialty palliative care into oncology care. The American Society of Clinical Oncology (ASCO) set forth the 2012 ASCO Provisional Clinical Opinion based on the randomized controlled trial (RCT) by Temel et al.[3] This study of 151 patients with advanced lung cancer randomized to receive either concurrent palliative care at the time of diagnosis or usual care showed that integration of palliative care into oncology care resulted in better quality of life and fewer depressive symptoms. In addition, despite receiving less aggressive medical interventions, patients randomized to early palliative care had longer median survival.[3] A survival benefit was also seen in the ENABLE III trial, which randomized patients to early or delayed palliative care. Survival at 1 year was 63% for patients who enrolled early versus 48% for those who enrolled 3 months later.[4] Subsequent RCT, meta-analysis, and systematic reviews have suggested that palliative care interventions either improve or have no effect on survival[5]; reassuringly, they have not suggested a negative effect on survival.[6] Caregivers may also experience lower levels of depression and stress burden with early enrollment.[7] In the realm of everyday life, early consultation can improve symptom severity and ongoing quality of life for patients.[8] These studies clearly demonstrate that early initiation of palliative care has wide-ranging benefits for both patients and caregivers.

Multiple models have been proposed to strategize effective palliative care using health care ecosystem resources efficiently, though each country faces different challenges due to different resources, needs, and financial structures of health care systems.[9-11] Multiple studies have demonstrated the value of palliative care interventions by reducing patient and hospital costs while improving care quality.[12]

Based on these findings and others, ASCO, the American Cancer Society, the Institute of Medicine, the European Society for Medical Oncology (ESMO), and the World Health Organization have all called for the early integration of palliative care in the treatment of patients with cancer.[2,13] Providing palliative care is not limited to one clinical specialty; multidisciplinary care is optimal for addressing all

domains of palliative care.[14] The 2017 ASCO Clinical Practice Guidelines call for oncologists to act as generalist providers of palliative and supportive care.[15] Specific to radiation oncology, radiation oncologists provide specialty expertise in the use of radiation therapy (RT) for the management of cancers, both definitively and palliatively. Together with this specialist role, radiation oncologists must have a basic competency in addressing the aforementioned domains of palliative and supportive care that can arise at all phases of cancer treatment.[2] Palliative medicine teams may then be viewed as corresponding specialist providers working in tandem with the oncology team. Notably, some cancer care centers do not have ready access to palliative care teams. Telemedicine has the potential to help reduce the impact of the limited access to palliative care specialists[16,17] but may worsen health inequities,[17] and the unmet need has been predicted to worsen.[18] In this setting, the oncology care team is called upon to gain more in-depth facility in providing palliative and supportive care. Though advocacy for the establishment of palliative medicine resources is needed, care teams in those settings are encouraged to seek out continuing medical education experiences that deepen palliative and supportive care knowledge. Organizations such as the American Society for Radiation Oncology, the ASCO, and the American Academy of Hospice and Palliative Medicine sponsor educational opportunities for oncology clinicians using a variety of formats, such as online or conferences. Leaders in U.S. residency education are discussing how to train residents to provide palliative and supportive care beyond simply delivering palliative radiation.[19,20] As demonstrated in the other chapters in this section (Section IV), palliative radiation is becoming more sophisticated and more integral to symptom management in patients with cancer.

As generalist providers of palliative care, oncologists have a role in the initial screening, assessment, and management of several palliative care domains, including physical, psychological, social, and spiritual aspects of quality of life. To this end, patient-reported outcome measures (PROMs) are surveys that allow patients to comprehensively and systematically report and rate their symptoms and psychosocial/spiritual distress. PROMs aid in informing when clinicians are needed to provide additional supportive care and interventions to improve symptom control and overall patient well-being.[21] A trial of electronic integration of PROMs in patients with metastatic cancer demonstrated improved measures of quality of life[22] and a significant survival benefit with the addition of PROMs, with results guiding supportive care intervention.[22] These findings point to the need for the standard integration of PROMs in oncology settings as a means of screening patients for palliative and supportive care needs.

In the ensuing sections, we review common palliative and supportive care issues that arise in the radiation oncology setting and strategies for their management. These include fatigue (both cancer and radiation related), weight loss and cachexia, radiation-induced salivary gland injury, radiation-related mucosal injury, radiation-induced nausea and vomiting, radiation-related diarrhea and other intestinal injury, radiation-induced skin injury, and radiation-related genitourinary injury, including male and female sexual function. Given its frequency and complexity, cancer pain management is addressed with a dedicated chapter (see Chapters 105). Radiation oncology clinicians can be expected to provide more in-depth expertise and management for common palliative supportive care issues that arise among their patients. Palliative and supportive care issues with which radiation oncologists have less familiarity (eg, psychosocial and spiritual issues) should be addressed with established screening tools such as PROMs that provide thresholds to prompt referrals to specialty providers for intervention.

CONSTITUTIONAL SYMPTOMS

Cancer-Related Fatigue

Cancer-related fatigue (CRF) affects a majority of patients with a cancer diagnosis including those receiving active treatment as well as cancer survivors.[23] CRF is generally defined as tiredness due to cancer or cancer treatment that interferes with normal functioning. The national consensus guidelines recommend screening for CRF in all patients undergoing treatment for cancer at regular intervals with simple age-appropriate measures, such as rating their degree of fatigue in the past 7 days on a 0 to 10 rating scale. CRF is often multifactorial and can be related to the cancer treatments themselves (including RT and chemotherapy), tumor burden, and upregulation pro-inflammatory cytokines, including interleukin-1 (IL-1), IL-6, and tumor necrosis factor-α (TNF-α).[24,25]

Screening for CRF in all patients undergoing treatment for cancer is recommended at regular intervals with simple age-appropriate measures, for example, asking adults, “How would you rate your fatigue on a scale of 0 to 10 over the past 7 days?” For those with fatigue score of 4 or greater, a more focused history should be obtained with an emphasis on possible contributing or related factors, including disease status, pain, medication side effects, emotional distress, sleep disturbances, hypothyroidism, anemia, nutritional deficits, and comorbidities.[26]

Primary management of CRF should be focused on correcting any of these contributing factors. Nutrition deficits and imbalance often occur and may be overlooked in these patients. Weight, caloric intake, fluid intake, electrolyte

abnormalities, and micronutrient deficiency from an imbalanced diet should be identified and nutritional counseling provided. One of the most common causes of fatigue is inadequate and/or poor-quality sleep. Control of stimulus, optimization of sleep environment, control of symptoms (pain, fever, dyspnea) and side effects, treatment of sleep-related breathing disorders such as sleep apnea, and promotion of sleep hygiene are all important. Massage therapy to reduce tension and stress is often helpful. The patient should be counseled on self-monitoring of fatigue levels, energy conservation techniques, and the use of distraction. Simple behavioral changes in daily life, such as setting priorities, pacing daily activities, delegating as much as possible, scheduling activities at times of peak energy, and structuring a daily routine to promote quality of sleep, can go a long way to reduce fatigue. Emotional and psychosocial support should also be provided.

Many nonpharmacologic interventions have proven successful in managing CRF. A meta-analysis of 113 studies examined the effect of exercise, psychological interventions, and pharmacologic interventions for CRF.[27] This analysis showed a significant reduction in fatigue scores in patients with cancer with both exercise and psychological interventions but not with pharmacologic interventions. Specifically, there is randomized evidence in support of the use of yoga in reduction of CRF in patients being treated for breast and colorectal cancer.[28,29] Massage therapy by a therapist or a lay person may improve CRF, with the strongest evidence among patients with breast cancer.[30] Cognitive behavioral therapy has been found to be effective in the treatment of CRF in a randomized trial of cancer survivors,[31] and other psychosocial interventions such as mindfulness-based stress reduction and supportive-expressive therapies have also been shown to be beneficial after treatment.

Pharmacologic interventions can also be implemented in carefully selected patients for whom nonpharmacologic interventions are not effective.[32] Short-term uses of glucocorticoids such as dexamethasone and methylprednisolone have been evaluated in several randomized trials. Dexamethasone 4 mg twice daily for 14 days was compared to placebo in 84 patients with advanced cancer showed short-term improvement in fatigue scores, quality of life, and physical well-being.[33] A separate randomized trial of methylprednisolone 32 mg daily for 14 days was also compared to placebo, again showing short-term improvement in fatigue.[34] However, long-term use of glucocorticoids is limited by their significant side-effect profile including hyperglycemia, psychological symptoms including anxiety and agitation, insomnia, gastrointestinal (GI) bleeding, and adrenal insufficiency upon withdrawal.[35,36]

Psychostimulants such as methylphenidate and modafinil have also been evaluated in CRF with conflicting results. A meta-analysis of five RCTs (298

patients) in the treatment of CRF showed improvement in fatigue scores with methylphenidate over placebo but not in cognition or quality of life and with increased rates of vertigo, anxiety, nausea, and anorexia.[37] Modafinil was compared to placebo in 208 patients with advanced lung cancer showing no difference in fatigue, depression, sleepiness, or quality of life.[38] In general, these medications should only be considered in patients refractory to more established treatment modalities, and a referral to palliative care should be strongly considered in these cases.

Radiotherapy-Associated Fatigue

RT can also be directly responsible for worsening fatigue in patients with cancer. Radiation-related fatigue is often difficult to distinguish from generalized CRF resulting from multiple aforementioned etiologies. A review of CRF showed prevalence was 50% to 75% at cancer diagnosis, 80% to 96% during chemotherapy, and 60% to 93% during radiation treatments.[23] RT fatigue has been demonstrated in patients treated to multiple different body sites, including treatment for prostate, breast, and head and neck cancer. Radiation-associated fatigue typically is shorter in duration and less severe than chemotherapy-generated fatigue. Compared with women who received adjuvant radiation, women receiving adjuvant chemotherapy were more than twice as likely to develop fatigue during the course of therapy.[39] In a prospective study of 28 men receiving radical external beam radiation with androgen deprivation therapy (ADT) for prostate cancer, the prevalence of moderate-to-severe fatigue increased from 7% at baseline to 32% at completion of radiation. Fatigue significantly interfered with walking ability, normal work, daily chores, and enjoyment of life, but only at the end of radiation. Improvement occurred after completion of treatment but remained higher than baseline at 6.5 weeks of follow-up.[40] Similar results are seen in studies of patients with breast cancer. In 38 women alive with no evidence of disease 2.5 years after adjuvant radiation for localized breast cancer, there was no significant difference between chronic fatigue levels after radiation and pretreatment values.[41] In another cohort of patients with breast cancer, during and for 3 months after adjuvant radiation for breast cancer, fatigue increased from 33% to 93% and gradually improved during the following 3 months.[42] In patients with advanced cancer, fatigue levels initially worsened with radiation, stabilized at week 8, and returned to baseline by week 27.[43]

The size of the RT field also relates to the likelihood of developing fatigue. For example, patients treated with whole-breast RT are more likely to experience fatigue compared to those treated with partial-breast RT.[41] In addition, in a survey

of patients with brain metastases treated with whole-brain radiation or radiosurgery, 69% of patients receiving whole-brain radiation experienced severe fatigue and problems with cognition. Only 5% of radiosurgery patients reported fatigue.[44] Furthermore, the degree of radiation-associated fatigue may depend not only on the cumulative whole-body dose/volume but also on which organs at risk (OARs) are exposed, such as the brainstem/cerebellum.[45,46]

Cancer-Related Weight Loss and Cachexia

Weight loss and anorexia are a commonly encountered problem among patients with cancer and have been associated with poor overall survival.[47] Cancer-related cachexia is a distinct category within weight loss and anorexia categorized by a metabolic syndrome associated with a pro-inflammatory state resulting in loss of muscle with or without associated loss of fat. This syndrome can occur even in the absence of decreased caloric intake or malabsorption.[48] Increases in IL-1, IL-6, and TNF-α have all been associated with increased protein catabolism, resulting in skeletal muscle breakdown and a worsening cachexia syndrome.[49] The exact definition and diagnostic criteria for cancer-related cachexia have been previously ill-defined. An international panel of experts published a definition and classification of cancer-related cachexia in 2011, defining *cachexia* as "patients who have more than 5% loss of stable body weight over the past 6 months, or a body mass index less than 20 kg/m^2 and ongoing weight loss of more than 2%, or sarcopenia and ongoing weight loss of more than 2%."[50]

The data regarding the optimum treatment of cancer- related cachexia are limited. Patients with cachexia should be managed by a multimodality approach with an emphasis on identifying potentially reversible factors. Although there is mixed evidence on intensive nutritional intervention, all patients with cancer-related cachexia should be evaluated by a nutritionist for advice on diet modification and liquid meal supplementation.[50,51] Dietary counseling has been shown to improve outcomes in selected populations.[52] Patients should be encouraged to take in multiple smaller, calorie-dense meals throughout the day.[51] Liquid meal supplements seem to have the greatest impact if they are taken in between, rather than with meals, with a reduction in early satiety and improved overall caloric intake.[53]

Patients with cancer tend to have a higher protein turnover. Adequate protein intake is critical in patients undergoing cancer treatment. Daily intake of 1.5 to 2.0 g of protein per kilogram of ideal body weight generally maintains a positive nitrogen balance. Caloric intake helps maintain the weight. Between 30% and 90% of total calories can come from carbohydrates. Fat provides energy, serves as a

vehicle for other nutrients, and performs other important biologic functions. It usually makes up around 30% of the content in enteral formulas. Vitamins, minerals, and other micronutrients should be included. Sufficient water intake is required to offset the 2.5-L daily fluid loss. Body weight and serum markers (albumin, transferrin, and prealbumin) can be monitored to assess whether the nutritional support is adequate.[54,55] In patients with moderate-to-severe radiation-induced oral mucositis or esophagitis, oral nutritional support can be challenging. Tube feeding bypasses the injured tissues and provides direct access to the absorption surface. Nasogastric or nasojejunal tubes enable short-term access. For longer term access (>30 days), gastrostomy, gastrojejunostomy, and jejunostomy tubes can be placed endoscopically, radiologically, or surgically. Percutaneous endoscopic gastrostomy is increasingly the method of choice, often placed prophylactically when severe upper GI toxicity is anticipated.[56-59] Gastrostomy tube placement is not without risk. Some series suggest a 17% morbidity rate. In 3% of patients, serious complications such as peritonitis, sepsis, perforation, and dislodgement were reported.[60,61] For patients with reflux esophagitis, gastroparesis, aspiration pneumonia, or limited stomach volume, a jejunostomy tube may be placed instead. The feeding tube should be cared for properly to prevent displacement or malfunctioning, such as clogging.

When adequate nutrition intake can be achieved, enteral intake is preferred to parenteral support because it uses and helps maintain the existing alimentary functions. It is less expensive, safer, and associated with fewer side effects. However, in patients without a functioning GI tract because of obstruction, poor GI motility, intractable vomiting, severe diarrhea, short bowel syndrome, or severe pancreatitis, total parenteral nutrition may be appropriate. Implementation of total parenteral nutrition requires special expertise and is done in a concerted manner between the cancer-treating team and the nutrition support team.[62,63]

Pharmacologic interventions have also been studied to improve appetite, weight gain, and quality of life in patients with cancer-related cachexia, particularly those who have failed intensive nutritional support. Short-term uses of glucocorticoids (such as prednisone and dexamethasone) have shown modest benefits in improving appetite and weight gain but do not seem to improve quality of life and can result in significant side effects such as hyperglycemia, psychological side effects such as anxiety and agitation, insomnia, adrenal insufficiency, and GI bleeding.[35,36] Megestrol acetate, a progestin with antiandrogen activity, has also been shown to modestly improve appetite compared to placebo in randomized trials at a dose of 800 mg/daily.[64] A head-to-head comparison of megestrol acetate and dexamethasone showed them to be equivalent in the induction of weight gain.[36] Dronabinol, a cannabinoid, which has been examined for the treatment of nausea

and anorexia, has not been shown to be superior to placebo in inducing weight gain in patients with cancer and has been shown to be inferior to megestrol acetate.[65] In general, short-term use of glucocorticoids and more sustained use of megestrol acetate can be considered for the management of cachexia in patients who have failed conservative nutritional management.

SALIVARY GLAND INJURY: XEROSTOMIA

Xerostomia, the subjective experience of dry mouth, is among the most common complaints experienced by patients with cancer treated with RT to the head and neck area. It is caused by salivary gland dysfunction as a result of damage in the field of radiation. Histologically, irradiated salivary glands demonstrate acinar atrophy and chronic inflammation. Inflammatory changes and fibrosis are observed in periductal and intralobular areas, whereas the ductal system remains relatively intact.[66,67]

Salivary dysfunction develops immediately and predictably. A 50% to 60% decrease in salivary flow occurs during the first week. As RT continues and the total radiation dose increases, salivary function decreases accordingly in a dose-dependent manner. After initial deterioration, a recovery phase may be seen, with patients reporting reduced xerostomia even though salivary flow remains depressed. This may result from adaptation to the sensation of xerostomia and compensatory response from surviving functional glandular tissues. However, salivary function usually continues to decline for 6 to 8 months after therapy, and many patients show no recovery even at 12 months.[68,69] In some patients, xerostomia may be permanent.

In addition to oral discomfort, radiation-induced salivary gland injury contributes to systemic problems, including loss of appetite, chronic esophagitis, gastroesophageal reflux, and sleep disruption because of the need for frequent mouth moistening and subsequent polyuria.[70] The lubricating, buffering, and antimicrobial effects of saliva maintain the integrity of oral tissue (dental and mucosal). Saliva also assists in speech, taste perception, mastication, bolus formation, and swallowing.[71] Decreased salivation can lead to dental caries, periodontal diseases, a shift of oral flora, poor tolerability to dental prosthesis and inflammation, and atrophy and ulceration of mucosa. As a result, radiation-induced xerostomia has a debilitating impact on health and overall quality of life in patients and survivors with head and neck cancer.[72]

Xerostomia Prevention

The extent of radiation-induced salivary dysfunction is influenced by radiation field, radiation dose, and initial volume and function of the salivary gland. Several approaches have been developed to prevent or minimize injury to salivary glands. They include salivary gland transplantation, intensity-modulated radiation therapy (IMRT), and amifostine therapy.[73] In several earlier studies, surgical transfer of submandibular glands into the submental space prior to RT resulted in the prevention of xerostomia.[74-77] A 2-year follow-up showed that 83% to 92% of patients reported no or minimal xerostomia.[77,78] Advances in three-dimensional (3D) conformal RT and IMRT make it possible to conduct gland-sparing RT. Several studies showed that both subjective and objective measures of salivatory function are preserved. Limiting the mean dose of the parotid glands to 26 Gy or less decreases the risk of long-term xerostomia. Local treatment failure rates do not appear to be compromised by the use of salivary gland-sparing IMRT.[79-84]

Intravenous (IV) amifostine, a thiol-containing radioprotectant, administered at 200 mg/m^2 daily 15 to 30 minutes before irradiation, reduced acute and chronic xerostomia in an open-label phase III study.[85] Antitumor treatment efficacy was preserved; however, oral mucositis was not reduced. Nausea, vomiting, hypotension, and allergic reactions were the most common side effects.[86] Subcutaneous administration of amifostine has been explored for reduced side effects.[87-89] A multicentered phase III randomized trial failed to show that subcutaneous amifostine is superior to IV amifostine in terms of patient compliance or efficacy.[90] Other agents are less promising. Pilocarpine during RT was compared to salivary gland transfer in the prevention of xerostomia and found to be inferior.[91,92] Cevimeline, a muscarinic agonist, was evaluated in RCT with conflicting results.[93,94]

Management of Radiation-Induced Xerostomia

Current treatment of radiation-induced xerostomia includes dietary and oral hygiene, saliva substitution, or stimulation of salivation by moistening agents or medications.[73,95,96] Cold, tepid, soft food and beverages are preferred. Hard, spicy foods should be avoided. In patients without residual salivary function, saliva substitutes are used to relieve xerostomia. Water is commonly used and preferred by patients. Other types of mouthwash such as saline, bicarbonate, glycerol, or commercial formulations are available. Artificial saliva has been designed to mimic natural saliva. It may contain carboxymethylcellulose, porcine and bovine mucin, or xanthan gum. In patients with residual salivary function, increased flow of natural saliva can be achieved by stimulation with chewing gum, sugarless

candies, menthol, acid, vitamin C, or lozenges developed to provide antimicrobial enzymes.

Several sialagogues, defined as systemic salivary gland stimulants, have been tested with mixed results. They are typically muscarinic agonists, such as pilocarpine, bethanechol, carbachol, or cevimeline. Other classes of agents include neostigmine, physostigmine, nicotinic acid, potassium iodide, bromhexine (a mucolytic), and anethole trithione.[67] Current data support the use of pilocarpine. Further studies are needed to determine the long-term efficacy and safety of cevimeline and bethanechol.[73]

The most extensively studied pharmacologic treatment for xerostomia is pilocarpine. Oral administration at 5 to 10 mg, 3 times daily, is the standard regimen. Several randomized, double- blind, placebo-controlled trials have shown the clinical efficacy and safety of pilocarpine in treating radiation-induced xerostomia.[97,98] In a multicenter study, 54% of the 207 study subjects reported a reduction in the overall severity of xerostomia. Only 25% of those receiving a placebo reported improvement. Speaking ability improved in 33% of patients receiving pilocarpine versus 18% of those receiving placebo. Saliva production also improved, but this did not correlate with subjective symptom relief.[97] In another multicenter trial that involved 162 patients, both subjective symptom and objective measurement of saliva flow improved significantly in those receiving pilocarpine versus placebo. Best results were obtained with continuous treatment for 8 to 12 weeks.[99]

Some patients require pilocarpine treatment for 2 months or longer to achieve maximum effect. Sweating, the most common side effect, is experienced by 37% to 65% of patients. In one study, 6% and 29% of patients in the 5- and 10-mg groups, respectively, dropped out because of the adverse effects.[97] Because of the cholinergic activity of pilocarpine, it is not recommended for patients with cardiovascular disease, and it is contraindicated in patients with narrow-angle glaucoma and uncontrolled asthma.[100]

Acupuncture has been shown to stimulate saliva production.[101-103] It even has shown benefit in pilocarpine-resistant xerostomia.[104] Patients with more severe symptoms appear to benefit more from acupuncture treatment.[105] Acupuncture given concurrently with RT was shown to significantly reduce xerostomia and improve quality of life.[106] Yet, an acupuncture-like transcutaneous electrical nerve stimulation given concomitantly with radiation failed to do the same.[107] Acupuncture appears to modulate the function of the autonomic nervous system, which may stimulate salivary gland function and induce salivary flow.[108-111] Functional magnetic resonance imaging (MRI) changes in the brain were associated with acupuncture treatment.[112] In summary, acupuncture appears to be a

low-risk intervention that offers a potential future treatment for radiation-induced xerostomia.[73,113]

MUCOSAL INJURY: ORAL MUCOSITIS, NAUSEA AND VOMITING, DIARRHEA, AND OTHER GASTROINTESTINAL TOXICITY

RT causes mucosal injury. When such injury occurs in the oral cavity, as commonly seen in patients irradiated at the head and neck area, it is called *stomatitis* or *oral mucositis*. When the injury occurs in nonoral alimentary tract mucosa, it presents as esophagitis, gastritis, enteritis, colitis, or proctitis. These injuries manifest as pain, dysphagia, odynophagia, nausea, vomiting, and diarrhea, typically described as GI toxicity. Mucosal injuries by radiation appear to share the same underlying molecular pathogenesis, regardless of anatomic location.[114-116] Some favor the terminology of *alimentary mucositis* to describe the hierarchy and constellation of toxicity to the oral and GI mucosa.[117] Depending on the site of irradiation, dosage, and fractionation, patients' risks of mucositis vary. More than 50% of patients receiving radiation to the head and neck, abdomen, or the pelvis will experience moderate-to-severe mucositis. Stem cell transplant recipients who received total-body irradiation have more severe and prolonged symptoms.[118] Finally, medical judgment is also necessary to consider a differential including the development of a new condition with symptoms similar to radiation-induced mucosal toxicity, such as ulcers, gastroesophageal reflux disease, irritable bowel disease, or irritable bowel syndrome.

Recent research indicates that the pathogenesis of mucositis is not simply the result of nonspecific epithelial cell death. Rather, it may involve a more complex pan-tissue process.[119-121] The complexity of the pathogenesis of mucositis reflects the dynamic interactions of all of the cell and tissue types that comprise the epithelium and submucosa. Genetic predisposition, circadian variables, epithelial type and characteristics, and local microbial environment all play a role in determining the risk of mucosal injury.[122-124] Novel therapies are being developed based on these new findings.[123,125]

A practice guideline developed in 2004 by the Multinational Association of Supportive Care in Cancer (MASCC) and International Society of Oral Oncology (ISOO) was most recently updated in 2020.[120,126] These guidelines provide an excellent and evidence-based reference in the prevention and management of chemotherapy and RT-related mucositis.

Oral Mucositis Prevention

Basic oral care is the foundation of care for oral mucositis. There is a lack of evidence supporting one protocol over another. Therefore, feasibility, adherence, performance, and outcomes are more important than the use of specific agents. Three randomized and three nonrandomized trials showed that implementation of a systematic protocol improved outcome.[127-132] Protocols consisting of brushing, flossing, bland rinses, and moisturizers should be implemented for all patients. An interdisciplinary approach to oral care (nurse, physician, dentist, dental hygienist, dietician, pharmacist, and others as relevant) is preferred. Dental examinations and treatment are important prior to the start of cancer therapy, especially for those with head and neck cancer, and should continue throughout active treatment and follow-up.[133]

Radiation treatment techniques to minimize radiation dose to the mucosa, though trade-offs between target coverage and acute and late side effects, must be considered.[46] Beyond avoidance of the mucosa with radiation fields, various pharmacologic agents have been tested. Topical benzydamine, a drug with anti-inflammatory, analgesic, and antimicrobial effects, has been shown to reduce the frequency and severity of oral ulcers and pain in an RCT.[134] It inhibits the production of pro-inflammatory cytokines, including TNF-α.[134,135] Chlorhexidine failed to prevent radiation-induced oral mucositis (Figure 106.1).[136-138]

FIGURE 106.1 A, B. Radiotherapy-induced oral mucositis.

Studies testing amifostine for oral mucositis have been disappointing. Although it appeared useful in the prevention of xerostomia, inconsistent results have been reported for its use for oral symptoms.[139] New classes of agents are being investigated. A commercially available oral lozenge of probiotic *Streptococcus salivarius* K12 colonized the oral cavity and produced bacteriocin-like inhibitor substance to significantly reduce grade 3 to 4 mucositis in a prospective randomized trial, though it may cause flatulence or dyspepsia.[140] Recombinant

human keratinocyte growth factor-1 (palifermin) was shown to reduce mucositis in patients with hematologic malignancies receiving high-dose chemotherapy and total-body irradiation with autologous stem cell transplantation.[141] Palifermin reduces the incidence of severe oral mucositis in patients with head and neck cancer receiving definitive chemoradiotherapy and delays the onset of severe symptoms when compared to placebo. Yet, the differences are not significant after multivariate analysis.[142] Its use in non–stem cell transplantation settings is not recommended based on current data.

Multiple other agents for oral mucositis prevention are in various phases of development and testing. These include epidermal growth factor, transforming growth factor-β, glucagonlike peptide-2, lactoferrin, anti-inflammatory amino acid decapeptide, recombinant human interleukin 11, and insulin-like growth factor-1.[143] Others include natural product and dietary supplements such as glutamine, PV701 (milk- derived protein extract), several vitamins (A, B_{12}, E), folate, aloe vera (a plant extract), probiotics, and curcumin, an extract from turmeric. Thus far, studies of these agents are not of sufficient quality to support a recommendation regarding their use.

Oral Mucositis Treatment

Pain management is an important component of the management of oral mucositis. Most studies were done in the setting of chemotherapy-induced mucositis, instead of radiation-induced oral mucositis. Systemic and topical analgesics are used, as are coating agents. The use of opioids, nonopioids, and adjuvant medications is covered in more detail in Chapters 105. These agents can be given via oral, transmucosal, transdermal, or IV routes. The use of topical agents is widespread in practice, with practices and institutions using their own favorite formulation. Typically, these are compounded mixtures with nicknames such as “magic mouthwash.” Common ingredients include viscous lidocaine, diphenhydramine, and Maalox. Despite their popularity, there is little evidence supporting their effectiveness.[138,144-149] Doxepin rinses have also been evaluated for the treatment of oral mucositis and were recommended in the MASCC/ISOO 2014 guideline.[150] However, the MASCC/ISOO 2020 guideline currently suggests benzydamine mouthwash for the treatment of RT-associated oral mucositis.[150]

Gastrointestinal Mucositis Prevention

Several medications have been shown to significantly reduce the frequency and severity of radiation-induced GI mucositis, which usually presents as diarrhea and pain. Depending on the location, the GI mucositis may be termed *esophagitis*,

enteritis, *colitis*, *proctosigmoiditis*, or *proctitis*. External beam irradiation to the pelvis as part of treatment for prostate, rectal, or cervical cancer produces lower GI injury in the majority of patients. Acute side effects include pain, melena or hematochezia, diarrhea, and rectal urgency during or shortly after the radiation course.[151] Chronic side effects months to years later can lead to strictures, ulcerations, or fistulas.[151]

Radiation modality, planning, and delivery should try to minimize the dose to GI structures. The transition from 3D to IMRT treatments improved late GI toxicity in patients with prostate and gynecologic cancer.[152-154] Proton therapy seems to have similar or worse GI toxicity than IMRT, at least among patients with prostate cancer.[155,156] Studies of prostate cancer treatments have demonstrated consistent dose-volume relationships with grade 2 or higher rectal toxicity with dose 60 Gy or greater.[157] Improvements in immobilization, simulation (eg, 4D, breath hold, gating), placement of devices (fiducials, hydrogel spacers),[158-160] patient instruction (eg, NPO or dietary modification, visualization of respiratory guidance, bowel and bladder preparation), and daily image guidance (computed tomography, MRI, intrafractional imaging)[161,162] can all contribute to improved dosimetry and potentially reduce GI toxicity, through smaller margins on both targets (planning target volume) and OAR (planning risk volume). However, these changes must be made cautiously in a scientific manner to avoid compromising tumor control.[163]

In an RCT of pelvic irradiation, sulfasalazine 1 g orally twice daily reduces GI toxicity from 93% to 80% and diarrhea from 86% to 55% when compared with placebo. Grade 4 diarrhea was reduced from 16% of the patients to none.[164] Amifostine is an antioxidant that appears to protect normal cells from radiation injury preferentially to cancer cells.[165] But the evidence of amifostine's efficacy seems mixed.[123,131-133,139,166-168] Furthermore, IV amifostine is not without side effects. A small randomized phase 3 trial has suggested selenium supplementation during pelvic radiation for uterine/cervical cancer can reduce moderate-to-severe diarrhea.[169]

Other agents that did not show significant benefit include glutamine,[167] oral sucralfate,[170,171] rectal administration of sucralfate,[172] and other anti-inflammatories commonly used in ulcerative colitis, such as 5-aminosalicylates,[173] mesalazine,[174] and olsalazine.[175] They should not be used to prevent radiation GI toxicity.

Gastrointestinal Mucositis Treatment

Nausea and Vomiting

In addition to measures discussed here that aim to treat the underlying pathology of radiation-induced mucosal injury, symptomatic treatment should also be provided.

Radiation-induced nausea and emesis tend to be undertreated. Factors that influence radiation-induced emesis include single and total dose rate, fractionation, field size and irradiated volume, site of irradiation and organs included in the radiation field, patient positioning, radiation technique, energy and beam quality, previous or simultaneous influencing therapy, and general health status of the patient.[176] Evidence-based practice guidelines developed by national organizations differ in specific recommendations and in, when recommendations apply, reflecting the limited amount of high-level evidence available to date. The updated guidelines from the MASCC and ESMO[177] and ASCO[178] are summarized in Table 106.2.

TABLE 106.2 GUIDELINES FOR PREVENTION AND TREATMENT OF RADIATION-INDUCED NAUSEA AND VOMITING

	Risk			
	High	**Moderate**	**Low**	**Minimal**
MASCC/ESMO risk category	Total body	Upper abdomen, craniospinal	Brain, H&N, thorax, pelvis	Breast, extremities
MASCC/ESMO recommendation	Prophylaxis with 5-HT_3 receptor antagonists + dexamethasone	Prophylaxis with 5-HT_3 receptor antagonists + optional dexamethasone	Rescue with dexamethasone, a dopamine receptor antagonists, or 5HT_3 receptor antagonists	Rescue with dexamethasone, dopamine receptor antagonists, or 5-HT_3 receptor antagonists
ASCO risk category	Total body	Upper abdomen, craniospinal	Brain, H&N, thorax, pelvis	Breast, extremities
ASCO recommendation	Ondansetron 8 mg oral or 0.15 mg/kg IV once or twice a day on days of radiation with first dose daily before radiation and every 1 d after radiation, or granisetron 1-2 mg oral or 0.01 mg/kg IV once daily on days of radiation before radiation and every 1 d after	Ondansetron 8 mg oral or 0.15 mg/kg IV once or twice a day on days of radiation with first dose daily before radiation, or granisetron 1-2 mg oral or 0.01 mg/kg IV or tropisetron 5 mg oral or IV once daily on days of radiation before radiation; and	Ondansetron 8 mg oral or 0.15 mg/kg IV as breakthrough, or granisetron 1-2 mg oral or 0.01 mg/kg IV as breakthrough; or dexamethasone 4 mg oral or IV as breakthrough (titrate up as needed to a maximum of 16 g oral of IV daily); prochlorperazine 5-10 mg oral or	Ondansetron 8 mg oral or 0.15 mg/kg IV as breakthrough, or granisetron 1-2 mg oral or 0.01 mg/kg IV as breakthrough; or dexamethasone 4 mg oral or IV as breakthrough; or prochlorperazine 5-10 mg oral or IV or metoclopramide 5-20 mg oral or

	Risk			
	High	Moderate	Low	Minimal
	radiation; and dexamethasone 4 mg oral or IV once daily on days of radiation before radiation and every 1 d after radiation	dexamethasone 4 mg oral or IV once daily before radiation for the first 5 d of	IV or metoclopramide 5-20 mg oral or IV as breakthrough (titrate up as needed to maximum 3-4 administrations daily)	IV as breakthrough

5-HT_3, 5-hydroxytryptamine 3; ASCO, American Society of Clinical Oncology; H&N, head and neck; MASCC, Multinational Association of Supportive Care in Cancer; RT, radiotherapy.

Diarrhea

Symptomatic management of radiation-induced diarrhea is similar to that of chemotherapy-induced diarrhea.[179,180] Diarrhea usually occurs during the third week of fractionated abdomen or pelvic RT. Guidelines were developed by an expert panel and updated in 2004.[181]

For mild-to-moderate diarrhea, the initial management should include dietary modifications.[182] Patients should eat small, frequent, protein-rich meals. Adequate fluid intake (35 mL/kg/day) is necessary. Liquids should be taken primarily between meals. Soluble fibers such as oats, pectin, guar, and psyllium help retain stool consistency. Spices, alcohol, caffeine, high-osmolar beverages, and high-lactose food should be avoided.[182]

Loperamide remains the mainstay of pharmacologic treatment. It should be started at 4 mg followed by 2 mg every 4 hours or after every unformed stool (maximum 16 mg/day). Unlike in chemotherapy, where loperamide may be discontinued after initial response, standard doses of loperamide should be continued for the duration of radiation. This is because the long duration of fractionated radiation may cause repeated injury to the intestinal mucosa. The dose is increased to 2 mg every 2 hours if the diarrhea persists for more than 24 hours.

If diarrhea has not resolved after another 24 hours on the higher dose of loperamide, the drug should be continued and a second-line agent, such as tincture of opium (paregoric), an antimotility agent, can be added. Diphenoxylate and atropine can also be used, although they do not have as favorable a side-effect profile as loperamide. Mesalamine or corticosteroid enemas can help reduce the frequency of bowel movement and discomfort.[151] Sodium butyrate enemas can also effectively treat acute radiation proctitis.[183] For chronic proctitis, patients can

consider sucralfate enemas, formalin, mesalamine or glucocorticoid suppositories, short-chain fatty acid enemas, or hyperbaric oxygen therapy.[151,184] For rectal bleeding, argon beam plasma coagulation is very effective, but complications can include rectal ulcerations or fistula formation.[151] Surgery should be reserved for very severe complications. There is no evidence to support ozone therapy, metronidazole, or other endoscopic treatments, such as bipolar electrocoagulation, radiofrequency ablation, or Nd-YAG laser.[151]

Patients with diarrhea may require outpatient evaluation and IV fluid. Antibiotics and complete stool and blood workup are usually not necessary in the absence of signs of dehydration or infection. Octreotide and glutamine have been studied and found of no benefit.[185,186] Probiotic supplementation showed beneficial effect in the prevention and treatment of radiation-induced diarrhea in animal studies, but high-quality clinical studies are lacking. If diarrhea is severe, persistent, or complicated, hospitalization may be considered.[181]

SKIN INJURY: ACUTE DERMATITIS AND CHRONIC SKIN CHANGES

Radiation-induced skin injury can lead to acute dermatitis or chronic skin changes.[187,188] These changes can occur at both the entrance and exit sites of the irradiation beam. Severity is determined by the dose, fractionation, beam, volume, and surface area. Patient-specific factors such as poor nutrition status, preexisting vascular condition or connective tissue disease, excessive skin folds, and genetics also play a role.[189] The pathophysiology is a combination of direct radiation injury and a subsequent inflammatory response. Free radicals from ionizing radiation cause alteration of DNA, proteins, lipids, and carbohydrates. Epithelial basal cells, vascular endothelial cells, and Langerhans cells are damaged. A cascade of pro-inflammatory cytokines, thrombotic factors, growth factors, and other molecules is activated.[190]

Acute skin changes may become visible after 10 to 14 hours. Grade 1 changes include mild generalized erythema and dry desquamation, pruritus, scaling, dyspigmentation, and hair loss. After 4 or 5 weeks of RT and radiation doses to the skin of 40 Gy or greater, grade 2 dermatitis may develop, with tender or edematous erythema, moist desquamation in skin folds, and considerable pain. They tend to peak 1 to 2 weeks after the last treatment and start healing 3 to 5 weeks after radiation. Complete healing may take 1 to 3 months. Occasionally, dermatitis may progress to grade 3, characterized by confluent moist desquamation, or even grade 4, with ulcers, hemorrhage, and necrosis.[187,191] Chronic changes may develop months or years after the initial exposure. Postinflammatory hypopigmentation or hyperpigmentation, textural changes (xerosis and hyperkeratosis), loss of hair

follicles and sebaceous glands, atrophy, telangiectasia, or subcutaneous fibrosis are among the manifestations. Fibrosis can result in tissue retraction, pain, and limitation of movement. The scalp appears more tolerant to radiation injury than the skin of the face, neck, trunk, and extremities. The affected skin can be predisposed to ulcers and skin breakdown.[192,193] In some patients, radiation recall dermatitis may occur. This happens when a patient who has completed radiation encounters a drug and develops skin reaction similar to an acute radiation dermatitis. The offending drugs are usually cytotoxic agents. Radiation recall dermatitis is probably due to local cutaneous immunologic responses to the challenging agent.[194]

Mild acute dermatitis is treated symptomatically. Washing with water, gentle cleansing with a mild agent, wearing loose, nonbinding clothing, and avoidance of irritants, antiperspirants, and ultraviolet exposure all help. When erythema and dry desquamation occur, creams or ointments (petrolatum-based, castor oil, balsam of Peru, trypsin, trolamine) can be used. Topical sucralfate or hyaluronic acid was shown to be efficacious in some controlled studies.[195,196] In a phase III study in patients with breast cancer receiving postoperative RT, an extract from the calendula plant significantly reduced the occurrence of moderate-to-severe acute dermatitis from 63% to 41% when compared with trolamine, a nonsteroidal agent.[197] Other topical agents containing aloe vera, D-panthenol, almond, or chamomile can also be tried. The use of these agents is supported only by uncontrolled studies or anecdotal evidence.[198,199]

The value of topical antioxidants has not been established, and topical steroids are controversial, with research producing conflicting results. There are concerns of infection and skin atrophy, known side effects of topical steroids. At best, steroids may ameliorate the symptoms, but they do not prevent the dermatitis.[200] Topical ascorbic acid lotion (vitamin C) did not show discernible benefit for the prevention of radiation dermatitis.[201]

When acute dermatitis becomes severe, usual wound care should be applied to the erosions and ulcerations. Key measures are keeping the site clean and moist, pain management, protection from contamination, debridement, and infection control.[193,202] During radiation treatment, hydrogel dressings, hydrocolloid dressing, burn pads, or foam dressings can be applied. If the wound is infected, ionic silver powder, topical antibiotics, cadexomer iodine, or maltodextrin powder can be added. Referral to wound care specialists should be made in these cases.[198] In recent years, more specific agents have been investigated, such as topical granulocyte-macrophage colony–stimulating factor, tacrolimus, pimecrolimus, and platelet-derived growth factor, though these are not included in the standard of care.[187]

Chronic skin changes from radiation injury are more challenging to treat. Chronic fibrosis is associated with a high incidence of skin breakdown and infection. A team approach should be adopted that includes wound care, physical therapy, deep massage, and pain management to address cosmetic and quality-of-life issues. Pentoxifylline appears to have an antifibrotic effect. Oral pentoxifylline (800 mg/day) and vitamin E (1,000 IU/day) for 6 months significantly reduce radiation-induced fibrosis.[203] Prophylactic use of pentoxifylline significantly reduces late skin changes, fibrosis, and soft tissue necrosis in a randomized controlled study, possibly through its protective effect against vascular pathology.[204] Intramuscular liposomal copper or zinc superoxide dismutase, subcutaneous interferon-γ, or hyperbaric oxygen therapy has also been used. Persistent radiation-induced alopecia may occur particularly after greater scalp radiation dose or proton therapy and may be improved with topical minoxidil or surgical procedures.[205]

GENITOURINARY TRACT INJURY

Urinary Symptoms

Irradiation to the pelvic region as part of treatment for cancer of the prostate, uterus, ovary, cervix, rectum, or urinary bladder can cause urinary problems because of injury to the mucosa, vasculature, and smooth muscles.[206,207] Acute reactions occur within 3 to 6 months of treatment. Chronic changes occur later. Acute reactions present as dysuria, frequency, and urgency. Strictures or fistula can develop during the years following RT.[208,209]

Once infection is ruled out, symptomatic relief with phenazopyridine is usually the first-line treatment for acute symptoms. It is given at 200 mg orally, 3 times a day. Phenazopyridine accumulates in the urine essentially unchanged and acts as a topical analgesic within the bladder. Patients should be warned that phenazopyridine turns the urine into a bright orange color and can stain clothing. If the symptoms are not adequately relieved, antispasmodics can be added. Oxybutynin or flavoxate helps relax the smooth muscles and reduces urinary urgency and frequency.[210] Tolterodine is a cholinergic antagonist that is also effective for overactive bladder. It causes less dry mouth, but its response rate is lower.[211] Trospium was documented to improve symptoms in radiation-induced cystitis and is significantly better tolerated than immediate-release oxybutynin.[212]

Intravesical infusion of hyaluronic acid or chondroitin sulfate, injection of botulinum toxin A into bladder wall, and hyperbaric oxygen therapy have shown benefit.[213-216] IV WF10 (tetrachlorodecaoxide), an immunomodulator, was reported

to be beneficial.[217,218] In patients with severe pain, aggressive pain control with opioids may be needed.

Symptomatic management of chronic changes is similar to that of acute reactions. Dilatation or placement of a permanent catheter may be required for significant obstruction. Patients not responding to less aggressive treatment may be candidates for reconstructive surgery to repair the stricture, sphincter failure, or fistula.

Female Sexuality

High-dose radiation to the pelvis causes varying degrees of sexual dysfunction related to injury to the ovaries and vagina.[219,220] Ovarian failure as a result of pelvis irradiation leads to postmenopausal changes. Acute injury occurs during the course of RT and the following few months. It usually presents as vaginal and vulvar mucositis, pain, and ulceration. Chronic changes develop more than 3 months after the completion of treatment and include fibrosis, loss of elasticity and sensation, susceptibility to trauma and infection, postcoital bleeding, and dyspareunia.[221-224]

Maintenance of local hygiene, aggressive treatment of infection, and regular dilatation of the vaginal canal help reduce the acute reaction. Hormone replacement therapy and application of lubricants for mucosal dryness can be used to treat acute injury. To prevent chronic changes, the use of vaginal dilators, lubricants, and supplemental estrogen was shown to be helpful. When fibrosis is established, treatment may require more drastic measures, such as hyperbaric oxygen therapy or surgical reconstruction. Although these are common options in clinical practice, the level of evidence supporting their use varies.[219]

Most studies of the use of topical estrogen showed benefit.[225,226] Radiation causes damage to the epithelium, which may persist for another 3 to 6 months after therapy. Topical estrogen promotes epithelial regeneration. Benzydamine is an anti-inflammatory that also has analgesic, local anesthetic, and antimicrobial effects. It can be applied topically to achieve a higher local tissue concentration. It reduced both subjective symptoms and objective observation of vaginal mucositis.[227,228] There have been several uncontrolled studies of hyperbaric oxygen therapy in the treatment of established necrotic wound resulting from perineal and vaginal radiation; the strength of evidence is modest.[229,230] In women with severe radiation damage, such as perineal defect or obliteration of the vagina, reconstructive surgery may be considered.[219]

Male Sexuality

When planning radiation for prostate cancer, its effect on male sexual function must be considered and discussed with the patient. Although the rate of erectile dysfunction (ED) is lower in patients receiving RT versus radical prostatectomy, sexual dysfunctions remain one of the most important post-treatment quality of life issues.[231,232] A survey showed that 68% of men aged 45 to 70 years were willing to trade off a 10% or greater advantage in 5-year survival to maintain sexual potency.[233] Onset of ED is gradual, usually beginning about 6 months post-treatment and continuing to deteriorate for 4 years.[234]

Radiation does not appear to reduce testosterone production or cause pelvic nerve injury.[235] In addition to psychological reasons, vascular changes after radiation appear to be the predominant cause of postradiation male sexual dysfunction. As such, smoking and hypertension are risk factors.[236,237] With external beam radiation, the rates of ED vary from 7% to 72%, a wide range attributed to the differing study populations. Brachytherapy is associated with 2% to 89% of ED.[238] Diminished sexual desire, decreased orgasmic pleasure, and a reduced ejaculation volume are other problems reported by patients.[239]

The rising use of ADT for the treatment of intermediate-risk, high-risk, and metastatic prostate cancer has also had a dramatic impact on male sexuality. Rapid drops in testosterone brought on by the initiation of ADT can cause decrease or result in the complete loss of libido and sexual desire in up to 90% of men being treated for prostate cancer as well as physical and emotional changes such as weight gain, gynecomastia, genital shrinkage, depression, and emotional lability.[240] Sexual side effects related to ADT can begin almost immediately and can last for several years after completion of therapy. A quality-of-life analysis of a prospective, definitive prostate cancer trial demonstrated that at 2 years after completion of the therapy, 75.4% patients receiving 4 to 8 months of ADT in conjunction with definitive RT stated that their ability to function sexually was poor or very poor versus only 44.0% treated with RT alone.[241] Patients and their partners are often unprepared for the profound side effects related to ADT. In a survey of 79 patients and their partners recently prescribed ADT, 30% to 50% were unaware that low of libido, ED, and genital shrinkage were possible side effects of ADT. Care should be taken by physicians to communicate all of these side effects to both patients and their partners and to facilitate consultation with couple counseling, sex therapy, and men's health clinics when appropriate.

Treatment of postradiotherapy sexual dysfunction should take a multidisciplinary approach, including psychosocial evaluation and counseling, pharmacologic intervention, and exploration of the use of mechanical devices.[238,242] The mainstay of pharmacologic treatment is phosphodiesterase inhibitors in patients with arteriogenic ED. A randomized double-blinded, placebo-controlled,

crossover trial suggests a positive response to sildenafil. Yet, the overall response rate is low. Only 21% of patients improved during sildenafil treatment, but not during placebo treatment.[243] Tadalafil has also been found to be beneficial in this patient population.[244,245]

Intracavernosal injection of prostaglandins or phentolamine papaverine is also effective. For patients who are refractory to pharmacologic intervention, implantation of a penile prosthesis can be considered. Minimal intraoperative and postoperative complications and an excellent patient satisfaction rate were reported.[246] Vacuum devices are another option.

SUMMARY

Palliative and supportive care is an integral component of cancer care, as reflected in national and international cancer care guidelines. Palliative and supportive care includes the role of oncologists, including radiation oncologists, as generalist palliative care providers who assess and initially address patient physical and psychosocial-spiritual issues. Specialty palliative care and other practitioners (eg, social work, psychiatry, chaplains) are regularly integrated for specialized palliative and supportive care needs. In addition to cancer-related pain (addressed in Chapters 105), patients with cancer frequently present to radiation oncologists with CRF, weight loss and cachexia, xerostomia, oral mucositis, nausea and vomiting, diarrhea and other intestinal injury, dermatitis, and genitourinary toxicities. Hence, radiation oncologists must be equipped to mitigate these issues with strategies, such as radiation planning techniques, and be facile with their assessment and management.

CHAPTER 107

Management of Radiation Side Effects

Shirin Sioshansi, Gavin Jones, and Paul Rava

This chapter is organized by organ system affected rather than by cancer site treated. For example, lymphedema from breast cancer radiation is listed under the lymphatic system, and osteoradionecrosis (ORN) of the mandible is listed under the skeletal system. The text outlines the presentation, symptoms, referrals, and interventions with existing supporting data, and the tables summarize medication management. Secondary malignancies and side effects unique to the pediatric population are beyond the scope of this chapter.

NERVOUS SYSTEM

See Table 107.1 for an overview of the medical management of radiation toxicity to the nervous system.

TABLE 107.1 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE NERVOUS SYSTEM

Radiation Toxicity	Timing	Medical Management

Neurocognitive decline	Late	• Memantine (Namenda) 10 mg bid for 24 wk (memantine is titrated upward as tolerated by 5 mg/d per wk to the maximum dose of 20 mg/d)[16]
		  • Advise tapering dose by 50% q2-4 wk until 5 mg daily and then discontinue.
		  • Dose modifications required for patients with renal insufficiency

Fatigue and somnolence syndrome	Acute or late	• Methylphenidate (Ritalin, Class II) 10-20 mg PO bid-tid • Ritalin LA 20 mg PO q am; increase 10 mg q wk to 60 mg qd max • Armodafinil (Nuvigil, Class IV) 50-150 mg (older) or 250 mg q am (non-older)

Radiation Toxicity	Timing	Medical Management
		• Modafinil (Provigil, Class IV) 100 mg (older) or 200 mg PO q am (non-older)
Edema	Acute or late	• Dexamethasone (Decadron) 4-8 mg PO qd (morning dosing preferred to reduce insomnia with a gradual taper as tolerated monitoring for symptoms)[424]
Radiation brain necrosis	Late	• Dexamethasone (Decadron) 4-8 mg PO qd (morning dosing preferred to reduce insomnia; titrate and taper as tolerated monitoring for new/recurrent symptoms)[424] • Bevacizumab 1-15 mg/kg q2-3wk[425] • 5-Loxin 150 mg PO bid[42]
Seizure	Acute or late	Newer antiepileptics • Levetiracetam (Keppra) 500-750 mg bid; max 3,000 mg qd • Pregabalin (Lyrica) 50 mg tid; increase to 200 mg tid max • Topiramate (Topamax) 200 mg bid; weekly increase 50 mg bid to 800 mg bid max Older antiepileptics • Divalproex (Depakote ER) initial 10-15 mg/kg/d. Titrate upward 5-10 mg/kg/d in weekly intervals for optimal response; max 60 mg/kg/d. • Phenytoin (Dilantin) 100 mg tid initially, increase 100 mg q2wk to desired response (usually 300-600 mg); once stabilized, change to extended-release daily. • Carbamazepine (Tegretol) 200-600 mg bid

Nausea	Acute	Antiemetics
		• 5-HT3 receptor antagonists
		  • Ondansetron (Zofran) 8 mg PO q8h
		  • Also available as Zofran ODT (orally disintegrating tablet)
		  • Granisetron (Kytril) 2 mg tablet PO 1 h within XRT
		• Phenothiazine
		  • Prochlorperazine (Compazine) 5-10 mg PO q6-8h
		  • Promethazine (Phenergan) 12.5-25 mg PO/PR q4-6h
		Benzodiazepine

Radiation Toxicity	Timing	Medical Management
		• Lorazepam (Ativan) anticipatory 1-2 mg PO 45 min prior to XRT, adjunct to antinausea medications 0.5-1 mg PO tid Anti-inflammatory • Glucocorticoids, eg, dexamethasone (Decadron) 2-4 mg PO q8h Appetite stimulation: • Dronabinol (Marinol) 2.5-10 mg PO q6-8h
Myelitis	Subacute to late	• Dexamethasone (Decadron) 4-8 mg PO q am (with gradual taper) • Lowest effective dose should be used to minimize side effects. Patients who do not respond within days should be tapered off.[424]
Brachial plexopathy	Late	• NSAIDs • Gabapentin (Neurontin) 300-600 mg qd to tid • Pregabalin (Lyrica) 50 mg tid; increase to 200 mg tid max

bid, 2 times daily; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, oral; PR, by rectum; q, every; qd, everyday; tid, 3 times daily; XRT, radiotherapy.

Fatigue, Radiation-Induced Cognitive Decline

Radiation-induced cognitive decline (RICD) is a multifactorial toxicity, with a number of external confounding variables that make precise identification and qualification challenging. These include, but are not limited to, completion of accurate baseline neurocognitive testing, tumor-related deficits, concurrent medications, and comorbid neuropsychiatric conditions (such as dementia, depression, and anxiety), all of which independently and collectively contribute to cognitive functioning. Moreover, many patients with primary or secondary central nervous system malignancies have historically experienced limited long-term survival, restricting the capacity to observe and study post-treatment cognitive functioning over an extended time frame.

RICD may evolve in a “biphasic” pattern, with subacute transient decline peaking at the 4-month post-treatment interval, followed by a late, irreversible phase of impairment that is apparent anywhere from months to years later. Notably, approximately 50% of patients who receive partial- or whole-brain radiation experience RICD within 6 months of completion of radiotherapy (RT).[1,2] The pathophysiology of RICD appears to involve microvascular damage, neuronal loss, and demyelination/white matter changes, which may manifest as fatigue, diminished attention, working verbal and spatial memory, attentive capacity, informational processing speed, and novel problem-solving abilities.[3,4]

Physicians should refer all patients suspected of having RICD to certified neuropsychologists for formal evaluation. While the Mini-Mental Status Examination has been used historically for this purpose, this tool—which was developed to screen for dementia—has largely been supplanted by more sophisticated methodologies.[5-7] Patient compliance with such intense neurocognitive assessment may be challenging, especially in the setting of clinical deterioration. To help overcome this, the RTOG has formulated neurocognitive tests and a quality-of-life instrument with an estimated completion time of 30 minutes.[3,8]

Radiographic imaging is largely corroborative for RICD. Whole-brain and partial-brain radiation is associated with reductions in hippocampal volume, dose-dependent temporal-limbic cortical atrophy, and white matter T2 and fluid attenuated inversion recovery changes on magnetic resonance imaging (MRI), findings that are not uniformly apparent and oftentimes do not correlate to neurocognitive function.[9-12] Although functional MRI and positron emission tomography (PET)-based imaging are evolving for neurocognitive disorders, their utility in assessing RICD has not been established.

Various treatment strategies exist to help mitigate the risk of RICD, particularly in the setting of intracranial metastatic disease. The adoption of stereotactic radiosurgery (SRS), in which a number of selected brain lesions could be effectively targeted in a single treatment with preferential sparing of intervening healthy brain tissue, has been shown in multiple trials to more effectively preserve normal neurocognition without apparent decrement in overall survival.[13-15] For this reason, SRS has largely supplanted whole-brain RT (WBRT) as the first preferred first-line

treatment of patients with a limited number of brain metastases, even though rates of regional intracranial recurrence are higher with SRS than with WBRT.

When WBRT is necessary, the addition of memantine, *N*-methyl-D-aspartate receptor antagonist delays time to cognitive decline when taken both concurrently and as maintenance.[16] The mechanism may be similar to that of dementia. Hippocampal avoidance WBRT (HA-WBRT) in appropriate patients also appears to be associated with less cognitive decline when compared to WBRT alone.[17] The use of these two modalities together—HA-WBRT and memantine—has been investigated in a phase III randomized trial, with improvement in time to cognitive failure and fewer associated cognitive symptoms, memory complaints, and symptom interference as compared to the WBRT with memantine arm.[18] Both HA-WBRT and memantine are considered standard practice for the treatment of brain metastasis per ASCO-SNO-ASTRO guidelines published in 2021.[19]

The acetylcholinesterase inhibitor donepezil prescribed for mild-to-moderate Alzheimer dementia may be of some utility in patients with notable memory deficits, although data supporting its use in this setting are somewhat mixed.[20,21] Care should be maintained in prescribing this medication, given its common associated gastrointestinal side effects (nausea, vomiting, diarrhea) and contraindications (eg, QT-interval prolongation, bradycardia, asthma, or pulmonary disease).[22,23] Methylphenidate has also been suggested for patients with diminished attentive capacity as their predominant RICD- associated symptom, although phase III data supporting its use in the adult population are lacking, and the medication also carries with it many associated side effects and contraindications (cancer-related anorexia, monoamine oxidase inhibitor use, prior seizure disorder among others) limiting its broad applicability in this setting.[24]

Neurocognitive rehabilitation represents an alternative or complementary approach in which patients undergo cognitive and/or compensation training to help recuperate certain mental capacities and/or better accommodate to new functional deficits.[25]

Cerebral Edema

Patients undergoing intracranial irradiation for primary brain tumors, benign lesions, or metastasis may experience acute side effects of headache, nausea, vomiting, and temporary worsening of preexisting neurologic deficits. These symptoms are often indicative of worsening peritumoral vasogenic edema.

Patients without evidence of significant mass effect or herniation on imaging may be managed conservatively with low-dose dexamethasone or prednisone.[26] The starting dose and taper regimen should be individualized based upon the severity of the patient's symptoms, clinical response, and physician discretion. Treatment goal is to provide symptomatic relief with a quick taper if achievable to minimize unwanted effects of high-dose steroids. If unable to taper successfully, the lowest effective dose should be used. Potential side effects associated with glucocorticoid therapy include mood changes, agitation, sleep disturbance, myopathy, hyperglycemia, and gastrointestinal upset. All patients with prior diagnosis of diabetes mellitus should have their blood glucose levels routinely monitored. Gastric prophylaxis with proton pump inhibitors (PPIs) or additional form of antisecretory therapy should be provided.

Radionecrosis

Cerebral radiation necrosis (RN) is a late side effect of RT, presenting after 6 months and frequently 1 to 2 years following completion of treatment and —in keeping with the so-called "vascular injury" versus "glial injury" theory of RN—is presumed to result from direct injury to surrounding cerebral vessels. Radiation-induced damage to local arterioles and venules proceeds through a complex biologic process that culminates in luminal narrowing and occlusion by which local tissue ischemia, edema, and parenchymal cell death result.[27,28] Nevertheless, the precise mechanisms and pathophysiology underlying RN have not been entirely elucidated, and some controversy exists over the role of additional immunologic and pro-inflammatory mediators.

Estimates of the natural incidence of RN have ranged from 5% to 50%, contingent upon multiple treatment parameters, including total radiation dose, dose/fractionation, volume, and use of radiosensitizing agents.[29-32]

Although most patients with RN are asymptomatic, some may present with signs and symptoms associated with increased intracranial pressure (headaches, lethargy, nausea/vomiting, and seizures) with or without additional anatomically correspondent focal neurologic deficits.[27,33]

Differentiating post-treatment brain tissue necrosis from tumor progression based upon computed tomography (CT) or conventional MRI of the brain alone is challenging. Radiographically, RN has an anatomic predilection to form within periventricular white matter or deep-seated brain regions. Nevertheless, supposedly characteristic, visually descriptive findings of perilesional edema and contrast enhancement have a low positive predictive value for RN, frequently necessitating the use of more sophisticated tools for clarification.[34] Diffusion-weighted imaging may be helpful, though has similar limitations.[35]

MR spectroscopy can be used to evaluate the metabolic composition of lesions, with increased choline-creatinine and choline-*N*-acetyl aspartate ratios suggestive of tumor recurrence and elevated lipid lactate peaks that are more characteristic of RN.[36] MR perfusion studies can better characterize the relative cerebral blood volume and hemodynamics in areas of concern.[37] PET with carbon-11 methionine, fluoro-1 thymidine, and fluoroethyltyrosine exploit the differential uptake of amino acid by tumor when compared with normal brain parenchyma.[38-40] Each of these imaging modalities is beset by inherent limitations.[41] Unfortunately, the accuracy for imaging to confirm whether the changes reflect necrosis or recurrent tumor remains quite poor and often requires symptom management with follow-up imaging to ultimately define the process.

Surgical exploration with biopsy represents the “gold standard” for confirmation of RN versus tumor progression and may be therapeutic in patients with significant associated edema. Nevertheless, this approach has obvious limitations, the most obvious being that many intracranial lesions that are treated with SRS are deemed surgically inaccessible ab initio, such that excision may render the patient neurologically impaired or incapacitated. Moreover, histopathology from surgically resected lesions post-RT often reveals an admixture of residual viable/nonviable tumor cells and necrotic tissue, for which unequivocal classification is problematic.

The management of RN is largely dependent on the presence of associated symptoms. For patients with radiographic evidence of RN alone,

the condition may self-resolve without the need for additional intervention, and continued surveillance is considered appropriate.[41] For others with mild-to-moderate symptoms, initiation of low-dose oral corticosteroids with gradual taper may result in improvement. Nonsteroid conservative management can include pentoxifylline and vitamin E. When these fail, recent studies suggest a benefit to 5-Loxin (*Boswellia serrata*), an inhibitor of vascular endothelial growth factor (VEGF) expression.[42] Patients with steroid-refractory symptomatic RN may be considered appropriate candidates for antiangiogenic therapy with the VEGF inhibitor bevacizumab. The precise mechanism by which bevacizumab helps reduce RN is unknown, but its efficacy as a form of RN treatment has been corroborated by a number of different studies.

For patients who remain symptomatic with RN in spite of conservative management, surgical resection may be indicated, although initial concerns regarding operative morbidity remain. Laser interstitial thermal therapy (LITT) is an emerging novel technique of some promise; LITT treatment involves stereotactic placement of a laser fiber and generation of elevated temperatures with MR thermometry to effectively "ablate" both necrotic or viable tumor tissues and can hasten steroid taper.[43-45] Additional treatment with heparin, warfarin, oral pentoxifylline, vitamin E, and hyperbaric oxygen (HBO) have all shown benefit in small case series but remain investigational at present as evidence to support their broad applicability in the management of RN is limited.[46-48] In addition, one should be hesitant to recommend HBO if there is any concern for a viable tumor.

Myelitis

Acute radiation myelopathy (Lhermitte syndrome [LS]) describes a descending electric shock–like sensation radiating from the nape of the neck to the distal limbs that is often precipitated by neck flexion.[49] LS is believed to be secondary to axonal denudation of the ascending sensory neurons of the spinal cord. LS most frequently presents from 3 to 6 months following spinal irradiation. The development of LS has been associated with higher spinal cord V40 and mean doses, although additional evidence has accrued that inhomogeneous dose gradients along the axial plane of the spinal cord may contribute to its development.[50,51] However, dose and

volume metrics do not fully explain the phenomenon since LS can develop with low-dose radiation for pediatric lymphoma or ipsilateral neck treatment with conformal avoidance of the spinal cord.

LS is generally transient, self-resolving, and does not reliably progress to chronic radiation myelopathy; patients with persistent or progressive symptoms merit additional workup to rule out neoplasm or other neurologic or structural etiologies (eg, multiple sclerosis, subacute combined degeneration, cervical spondylosis).[52-54]

Chronic radiation myelopathy is a far more serious, typically irreversible neurologic sequela of prior spinal irradiation, which presents months to years following completion of RT.[55,56] The pathophysiology of chronic radiation myelopathy is complex and poorly understood but is believed to implicate direct glial cell injury and vascular damage, resulting in small vessel ischemia.[57,58] Symptoms of chronic radiation myelopathy vary in both extent and severity depending on the region of the spinal cord that is affected. These range from mild peripheral sensory paresthesias or motor weakness, to upper motor neuron signs (eg, spasticity, clonus, hyperreflexia), Brown-Sequard syndrome, fecal and urinary incontinence, and complete paraparesis or paraplegia below the distal to the designated compromised spinal level.

Chronic radiation myelopathy remains a diagnosis of exclusion with requisite clinical correlation, and competing demyelination, rheumatologic, infectious, and paraneoplastic etiologies must be considered to be ruled out per clinical judgment.[58] MRI may be helpful in corroboration and can demonstrate supporting characteristics of spinal cord atrophy, T2 hyperintensity, and focal contrast enhancement, but these findings remain nonspecific. Primary prevention of chronic radiation myelopathy is paramount; care should be exercised to minimize therapeutic radiation maxima within the treatment field and respective appropriate spinal cord dosimetric constraints, which are dose and fractionation dependent. While some series suggest interval symptomatic improvement over extended longitudinal follow-up, the condition is typically considered permanent.[55,58]

The management of chronic radiation myelopathy is largely supportive, and limited evidentiary data exist to support improvements associated with any particular therapy. Treatment parallels that of brain radionecrosis—oral corticosteroid therapy. Anti-VEGF therapy with bevacizumab and HBO

have also been suggested to support tissue recovery, but all such therapies remain under investigation at this time.[59,60]

Brachial plexopathy is rare, with a reported incidence between 1% and 4%, and typically manifests 1 to 4 years following completion of RT.[61] Radiation-induced brachial plexopathy is presumed secondary to direct radiation-induced damage to the nerves via a mechanism of glial cell injury, Schwann cell demyelination and ischemia, and/or as a result of extrinsic compression from supraclavicular and axillary fibrosis.[62] Patients may experience neurogenic upper extremity and axillary pain as well as progressive sensory and motor deficits of the affected limb.

The diagnosis of radiation-induced brachial plexopathy remains a diagnosis of exclusion, with primary concern for disease recurrence in the neck and/or axilla. CT and MRI may be useful to assess the anatomy of the brachial plexus and correlate the presence or absence of a distinct mass.[63,64] MRI findings of radiation-induced plexus changes have been described in conflicting terms of both T2 sequence hypointensity relative to surrounding muscle and T2 hyperintensity with infiltration and swelling.[63,65] Electromyography can be used to assess nerve conduction with myokymia and is strongly associated with radiation-induced brachial plexopathy, but not diagnostically sufficient without other supportive findings.

As with most other radiation-induced neurologic toxicity, primary prevention through appropriate treatment planning and delivery is paramount. Radiation-induced brachial plexopathy is a dose-dependent toxicity, which varies with fractionation. Care should be exercised to minimize therapeutic radiation hot spots within the structure and utilizing various fractionation schema to encourage sublethal repair as a means to reduce risk when necessary.

Management of radiation-induced brachial plexopathy is largely supportive and consists of physical therapy, and medical management with nonnarcotic analgesics, neuropathic pain medications, anticonvulsants, tricyclic antidepressants, gabapentinoids, and selective serotonin-norepinephrine reuptake inhibitors may be of utility.[66] More severe cases may be appropriate candidates for narcotic pain medication and surgical exploration with neurolysis to release the plexus and associated vasculature from perineural scar tissue and fibrosis.[67] Additional investigational management techniques include the use of pulsed radiofrequency ablation

and hyperbaric oxygen therapy (HBOT).[66,68] Unfortunately, and importantly, once symptomatic brachial plexopathy develops, medical management has limited effectiveness to control symptoms that dramatically alter patient lifestyles.

VISUAL SYSTEM

See Table 107.2 for an overview of the medical management of radiation toxicity to the visual system.

TABLE 107.2 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE VISUAL SYSTEM

Radiation Toxicity	Timing	Medical Management
Ocular inflammation	Acute	Cortisporin ophthalmic (combination steroid and antimicrobial): Apply ointment or 1-2 gtts q3-4h. • Note: Do not use >5-10 d.
Dry eye	Late	Tear replacement agents • Refresh (OTC) 1-2 gtts to affected eye qid • Tears Naturale (OTC) 1-2 gtts prn • Visine (OTC) usually 1-2 gtts to affected eye qid • Lacrisert insert as directed qd, box of 60 unit doses, plus applicators • Note: Consider for severe dryness. Cyclosporine emulsion (Restasis) 1 gtt q12h
Optic neuropathy	Late	Triamcinolone 4-mg intravitreal injection Bevacizumab 1.25-mg injection q6-8wk[426]

gtts, drops; OTC, over the counter; prn, as needed; q, every; qd, everyday; qid, 4 times daily.

Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Xerophthalmia

Radiation-related damage to the lacrimal and/or meibomian glands can result in xerophthalmia. Patients with radiation-related xerophthalmia may

present with a subjective "dry eye" sensation, in addition to conjunctival irritation and chemosis.

Lacrimal shielding or avoidance should be offered to all patients when appropriate as a form of primary prevention, and the lacrimal glands may be contoured as organs at risk (OARs) to minimize integral radiation dose. Preservative-free artificial tears or ocular lubricants may be administered to help supplant diminished lacrimal and mucus production. Ophthalmologic interventions include temporary or permanent surgical punctal occlusion and tarsorrhaphy.[69,70]

Cataracts

The lens remains the most radiosensitive structure of the eye due to the high mitotic rate, and cataracts—a disease of progressive clouding of the lens—is a well-recognized late effect of RT. The development and latency of radiation-induced cataracts appear to be dose dependent, and most patients who develop radiation-induced cataracts will present with impaired vision 2 to 3 years following RT.[71] Treatment is concordant with non–radiation-induced cataracts, with extracapsular cataract extraction followed by prosthetic lens replacement.

Retinopathy and Maculopathy

Radiation retinopathy (RR) and radiation maculopathy (RM) are additional dose-dependent late sequelae of prior RT to the orbit, which typically present 6 months to 3 years following treatment.[72] Patient-related risk factors include prior diabetes, hypertension, coronary artery disease (CAD), pregnancy, concurrent chemotherapy, pretreatment tumor size, and larger irradiated retinal area in the posterior ocular fundus.[73]

Clinical features of RR and RM may be occult in the early stages of the disease requiring testing with measures such as dilated fundoscopic examination to identify characteristic changes.[73,74]

Currently, there is no well-defined treatment for RR and RM, and therapy is largely directed at visual stabilization and prevention of progressive future vision loss. All such patients should be referred to ophthalmology for definitive assessment and management: Therapeutic interventions have

included laser photocoagulation, local injections of anti-VEGF agents, intravitreal triamcinolone acetonide, and dexamethasone implants.[73]

Optic Neuropathy

Radiation optic neuropathy (RON) is a severe late complication of radiation to the optic apparatus (left and right optic nerves, optic chiasm), which results in acute, painless typically monocular visual impairment and/or blindness. The pathogenesis of RON is believed to be similar to that of cerebral RN, such that delayed ischemia and neuronal injury result from radiation-induced vasculopathy and local inflammation (RN).[75] The diagnosis of RON remains a diagnosis of exclusion; primary suspicion for recurrent or residual neoplasm should be considered first and foremost.

Damage to the optic apparatus is a function of the total dose received, dose/fractionation regimen, and volume of optic nerve/chiasm irradiated. Symptoms of RON usually manifest within months to years upon completion of RT, with an average onset of 18 months after treatment.[76] Patients may report sudden changes in visual acuity, loss of normal color perception, or other more specific patterns of optic or chiasmatic visual defects, including, but not limited to, central scotoma or bitemporal hemianopia.[77]

The prognosis of RON is relatively poor, and the majority of affected patients will have a final visual acuity of 20/200; radiation treatment planning, which preferentially avoids excess radiation dose or therapeutic radiation maxima (hot spots) within the optic nerves and optic chiasm, is prudent to reduce the risk of RON.[78] The optimal management of RON is controversial and limited by the paucity of randomized data to guide recommendations but parallels that of RN. Oral corticosteroid therapy with low-dose dexamethasone has been recommended and is generally worth consideration for patients with mild-to-moderate symptoms. Anti-VEGF therapy with bevacizumab, therapeutic oral anticoagulation, angiotensin-converting enzyme inhibitor (ACEI), and HBO have also been suggested, but all such therapies remain under investigation.[75,77]

AUDITORY SYSTEM

See Table 107.3 for an overview of the medical management of radiation toxicity to the auditory system.

TABLE 107.3 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE AUDITORY SYSTEM

Radiation Toxicity	Timing	Medical Management
Eustachian tube edema	Acute or subacute	Decongestant • Pseudoephedrine (available *behind* the counter without a prescription) 1 PO q6h Short-course steroids • Methylprednisolone (Medrol Dosepak) 4 mg tablets PO as directed over a 6-d taper • Dexamethasone (DexPax) 1.5 mg PO as directed, 6-, 10-, and 13-d tapering dose packs
External otitis	Acute	Tympagesic otic solution: Fill canal q4h, place stopper.

PO, oral; q, every.

Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Ototoxicity

Radiation-related hearing loss may proceed via two primary mechanisms: disruption in normal mechanical propagation of sound from the external auditory canal to the cochlea, resulting in "conductive hearing loss," or direct damage to the cochlea and/or acoustic nerve itself, resulting in "sensorineural hearing loss" (SNHL). These two forms of radiation-induced ototoxicity are not mutually exclusive, and patients who receive cranial or head and neck irradiation are at risk.

Radiation-induced conductive hearing loss may derive from any process extending from the pinna to the ossicles. Radiation-induced otitis media with effusion (OME) is the most common culprit, but additional processes include, but are not limited to, external auditory canal stenosis, middle ear fibrosis, tympanic membrane sclerosis, and ossicular necrosis.[79-81] These findings are best appreciated on direct otoscopic examination, or through dedicated CT or MRI.

Many cases of OME resolve over time and can be managed conservatively.[82] Apart from this self-limiting condition, the evaluation of conductive hearing abnormalities and consideration of therapy for radiation-induced conductive hearing loss is highly nuanced and complex; all patients should be referred to a dedicated otolaryngologist or neuro-otologist for diagnosis and management. Additional interventions such as tympanocentesis, myringotomy, tympanostomy tube insertion, intratympanic steroid injections, and implantation of osseointegrated hearing aids—in addition to other sophisticated forms of functional middle ear surgery—may be necessary.[81]

SNHL is a dose-dependent toxicity, occurring in approximately one-third of patients who receive significant radiation dose to the middle ear. Patients may present with deficits in sound discrimination, volume, and tinnitus; Radiation-related SNHL often affects higher frequency hearing and is typically progressive over time.[81]

Treatment for SNHL is limited. Prevention remains the most effective management. The use of concurrent or adjuvant cisplatin should be judiciously limited to patients for whom chemotherapy is clearly indicated, as this chemotherapy regimen may further contribute to ototoxicity. Conventional hearing aids may be employed, with cochlear implant reserved for those patients with profound deficits or total deafness.[79]

VOCAL SYSTEM

Dysphonia

Vocalization is a complex process involving not only the generation of intermittent airflow pulses by the glottic larynx but also proper articulation and resonance through the oropharynx, oral, and nasal cavities.[83] Radiation-induced changes to any of these structures may affect a patient's phonation, including vocal strain, diminished vocal projection and volume, diminished pitch variability, and increased hoarseness or "breathiness."[84]

Any patient presenting with dysphonia should be evaluated for residual, recurrent, or secondary primary neoplasm. In addition, as these patients may have a history of tobacco use, a lung tumor should also be considered with hoarseness developing from external compression of the recurrent laryngeal nerve.

Visualization of the larynx may reveal vocal fold lesions, paresis, or cord paralysis but has relatively poor sensitivity to detect more subtle vibratory glottic abnormalities.[84] Videostroboscopy, videokymography, and high-speed videolaryngoscopy allow for more detailed evaluation of the mucosal wave of glottic vibration.[85,86]

Speech therapy remains the primary treatment modality for voice rehabilitation and has been associated with beneficial effects on communication function and quality-of-life domains.[87,88] Symptoms of vocal cord paralysis can be improved with local injections or procedures that medialize the cord.

DIGESTIVE SYSTEM

See Table 107.4 for an overview of the medical management of radiation toxicity to the digestive system.

TABLE 107.4 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE DIGESTIVE SYSTEM

Radiation Toxicity	Timing	Management
Oral, pharyngeal, or esophageal mucositis	Acute	Baking soda mouthwash: 1-3 tsp gargle and spit, >4 to 6 qd • Mix 1 tbsp baking soda, 1 tbsp salt, 1 quart water Cepacol lozenges prn, max 12 per d Orabase paste (20% Benzocaine, OTC): Apply prn. Ulcerease (OTC topical anesthetic): 2 tsp swish and swallow or spit prn • Mix with ice chips for posterior pharyngitis. Triple mix 1:1:1: Benadryl elixir, Maalox: viscous, Xylocaine 2%, 2 tsp PO 10 min qac and qhs Sucralfate solution (Carafate): 2 tsp swish and swallow qid Gelclair swish in oral cavity 1 min, spit; avoid eating or drinking for 1 h, use up to tid Lidocaine • Xylocaine oral spray 10% PO prn (10 mg per dose) • Xylocaine viscous 2% 2 tsp PO swish and swallow/spit prn • Note: may mix 2% viscous lidocaine 1:1 with liquid antacid (Maalox or Mylanta) to improve coating Miracle mouthwash 2 tsp PO swish and spit/swallow qid

Radiation Toxicity	Timing	Management
		• Mix 60 mL tetracycline oral suspension (125 mg/5 mL), 30 mL Mycostatin oral suspension (100,000 U/mL), 30 mL hydrocortisone oral suspension (10 mg/5 mL), and 240 mL Benadryl syrup (12.5 mg/5 mL) RadiCare oral wound rinse 15 mL swish/gargle qid Doxepin hydrochloride 0.5% mouthwash (or 25 mg/5 mL water solution) swish for 30-60 sec, then spit within 1 h of radiation[427]
Thrush	Acute	Mycelex troche: Dissolve lozenge in mouth, 5 per d × 14 d. Nystatin suspension 5 mL swish well for 2 min and swallow qid; or dissolve 2 lozenges orally bid; through 2 d postclinical resolution. fluconazole (Diflucan) 200 mg PO day 1, then 100 mg PO qd × 7 d (if candida recurs, repeat for 21 d)
Sialadenitis	Acute	NSAIDs • Ibuprofen 200-800 mg PO q6h • Naproxen (Naprosyn) 500-750 mg PO initially, then 250-500 mg PO q6-12h If associated with temp >101°F, add antibiotics.
Xerostomia	Acute to late	Saliva substitutes • Artificial saliva (OTC): Apply to oral mucosa prn. • Aquoral 2 sprays PO tid-qid prn • Moi-Stir (OTC) spray prn • Mouth Kote 1% (OTC) 5 mL PO gargle, swish, hold for 1 min, then spit • Note: combination moisturizer/lubricant Salivary stimulants • Pilocarpine (Salagen) 5 mg PO tid initially; consider 10 mg PO tid prn (12 wk required to assess efficacy) • Cevimeline (Evoxac) 30 mg PO tid Xerostomia can be exacerbated by candidiasis, anticholinergic drugs, opioids, decongestants, antidepressants, anxiolytics, and antidiarrheals.
Thickened saliva/gag response	Acute to late	Guaifenesin (Mucinex) 600-1,200 mg PO bid Baking soda mouthwash 1-3 tsp gargle and spit, >4 to 6 qd • Mix 1 tbsp baking soda, 1 tbsp salt, 1 quart water Scopolamine patches (Transderm Scop): Apply to skin behind ear, 2-3 d per patch.

Radiation Toxicity	Timing	Management
		Lorazepam (Ativan) 0.5-2 mg 3 times daily
Dental prophylaxis	Late	Fluoride toothpastes • Biotene dry mouth toothpaste bid-tid brushing • Note: contains antibacterial enzymes, fluoride, natural Xylitol • GelKam fluoride toothpaste, brush 10 min bid Provident fluoride toothpaste, brush 10 min bid

Esophagitis	Acute	Topical
		• 2% viscous lidocaine by itself or in suspension with antiacids and mucosal protective agents (sucralfate) administered qac for temporary relief
		  • Triple mix 2 tsp PO 10 min qac and qhs, 1:1:1 Benadryl elixir, Maalox: viscous, Xylocaine 2%
		  • Note: Anesthetic lasts ~20 min; may repeat once during meal.
		• Sucralfate (Carafate) 2 tsp swish and swallow qid
		Antisecretory medications: proton pump inhibitors:
		• Omeprazole (Prilosec) 20 mg PO qd
		• Pantoprazole (Protonix) 40 mg PO qd
		• Esomeprazole (Nexium) 20-40 mg PO qd
		Antifungals if suspect component of candidiasis (especially with steroid therapy):
		• Nystatin suspension 5 mL swish well for 2 min and swallow qid
		• Fluconazole (Diflucan) 200 mg PO day 1, then 100 mg PO qd, × 7 d; if candida recurs, repeat for 21 d

Gastritis and duodenitis	Acute	Topical
		• 2% viscous lidocaine by itself or in suspension with antiacids and mucosal protective agents (sucralfate) administered prior to meals for temporary relief. See esophagitis section for dose information.
		Antisecretory medications
		• Proton pump inhibitors. See esophagitis section for dose information. Consider doubling the recommended doses for erosive gastritis.
		• H_2-receptor blockers
		  • Ranitidine (Zantac) 50 mg PO bid or 300 mg PO qhs
		  • famotidine (Pepcid) 10-20 mg PO bid

Radiation Toxicity	Timing	Management
		Non-NSAID analgesic • Hydrocodone/acetaminophen elixir 15 mL PO q4h Promotility agent • Metoclopramide (Reglan, generic) 10-20 mg PO q4h Antispasmodic • Hyoscyamine (Levsin) 0.125-0.25 mg PO/SL tid-qid

Nausea/vomiting	Acute (within hours)	Antiemetics
		• 5-HT3 receptor antagonists
		  • Ondansetron (Zofran) 8 mg PO q8h
		  • Also available Zofran ODT (PO disintegrating tablet) and Zuplenz (PO dissolving film)
		  • Granisetron (Kytril) 2 mg tablet PO 1 h within XRT
		• Phenothiazine:
		  • Prochlorperazine (Compazine) 5-10 mg PO q6-8h
		  • Promethazine (Phenergan) 12.5-25 mg PO/PR q4-6h
		• Benzodiazepine: lorazepam (Ativan) anticipatory 1-2 mg PO 45 min prior to XRT, adjunct to antinausea medications 0.5-1 mg PO tid
		Anti-inflammatory
		• Glucocorticoids, eg, dexamethasone (Decadron) 2-4 mg PO q8h
		Appetite stimulation: dronabinol (Marinol) 2.5-10 mg PO q6-8h
		Promotility: metoclopramide (Reglan) 10-20 mg PO q4h

Anorexia	Acute	• Dronabinol (Marinol) 2.5-10 mg PO q6-8h
		• Mirtazapine (Remeron) 7.5-15 mg nightly
		• Megesterol (Megace) 800 mg qd
		  • Contraindicated in older patients
		• Prednisone 10-40 mg qd
		  • Contraindicated in older patients
		• Zinc—may improve taste

Enteritis	Acute	Antidiarrheal medications • Loperamide (Imodium A-D) 1-4 mg PO q am, then 2 mg PO prn, 1-4 mg qd-bid as prophylaxis prn; max 16 mg/d • Diphenoxylate/atropine (Lomotil) ½-2 tablets or 10 mL PO initially or q am, then 1 after each loose stool prn,

Radiation Toxicity	Timing	Management
		diphenoxylate 2.5 mg/atropine 0.025 mg per tablet or per 5 mL; max 8 tablets or 40 mL/d Bile acid sequestrants • Cholestyramine (Questran) 1 packet or 1 scoopful mixed per directions PO qd initially; may increase to 1-2 packets or scoopfuls PO bid, 1 scoop (9 g) or 1-g packets contain 4 g cholestyramine (mix dose with at least 2 oz water)
Pancreatic exocrine insufficiency	Chronic	Pancrelipase (Pancrease) 400-2,500 units/kg/meal
Hemorrhoidal inflammation	Acute	Topical analgesic • ELA-Max 5 Anorectal Cream (5% lidocaine): Apply to intact skin. Topical anti-inflammatory treatment: creams and ointments for external hemorrhoids; suppositories for internal hemorrhoids • Hydrocortisone rectal suppository (Anusol-HC) 1 PR bid-tid • Hydrocortisone (Proctocort) 30 mg suppository 1-2 bid PR or 1% cream apply bid-qid PR • Hydrocortisone 10% (Cortifoam) 1 PR qd-bid • Rectal Rocket 1 PR qhs × 5 d (custom formulation or hydrocortisone 5%, lidocaine 2.5% [or 5%], nifedipine 0.3% [to 0.4%]) Mesalamine (Canasa) rectal suppository 1 PR bid-tid

Proctitis	Acute	Antidiarrheal: See enteritis section for medications and dose information.
		Stool softeners
		• Docusate sodium (Colace) 1-3 capsules daily prn
		Anti-inflammatory topical treatments: See hemorrhoidal section for medication and dose information.
		Antiflatulents
		• α-Galactosidase enzyme (Bean-O) 5 drops or 3 tablets q 3 servings
		• Simethicone variable dosing, see individual products:
		  • Gas-X (regular, extra strength, max strength)
		  • Maalox (regular and max strength)
		  • Phazyme

bid, 2 times daily; NSAIDs, nonsteroidal anti-inflammatory drugs; OTC, over the counter; PO, oral; PR, by rectum; PRN, as needed; tbsp, tablespoon; tsp, teaspoon; q, every; qac,

before meals; qd, everyday; qhs, every night; qid, 4 times a day; SL, sublingual; tid, 3 times daily; XRT, radiotherapy.

Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Xerostomia

Xerostomia refers to the subjective sense of dry mouth from the lack of adequate saliva production. Major salivary glands, which include the parotid, submandibular, and sublingual glands, ordinarily produce approximately 90% of normal salivary output in both a stimulated (parotid) and unstimulated (submandibular, sublingual) capacity. Due to their location, these structures often receive a collateral radiation dose in head and neck cancer treatment, from which decreased salivary production and altered salivary composition may result. The constituent aspects of saliva are varied: While the liquidity of saliva helps with lubrication to facilitate normal food bolus formation and articulation of speech, additional components (enzymes, bicarbonates, macromolecule proteins and mucins, calcium ions, phosphates, and immunoglobulins) confer additional benefits, including control of dental plaque formation, bone mineralization, and antimicrobial function. As such, sequelae of xerostomia include dysphagia, dysarthria, inadequate enteral intake, predisposition to dental caries, and oral cavity infection.[89]

Xerostomia may affect upward of 60% of patients who receive external beam treatment to the head and neck.[89,90] Temporary xerostomia may be appreciated within 1 week of initiation of RT, often peaking within 6 to 7 weeks of conventionally fractionated treatment, with gradual recovery over a 2- to 3-year time frame.[91,92] Typical manifestations of xerostomia include subjective sense of oral dryness, the presence of viscous and ropy secretions, tacky appearance of the gingiva and buccal mucous membranes, oral cheilitis, and intolerance to oral appliances/prostheses.[89] Given the frequency with which xerostomia is seen in patients with head and neck cancer, the clinical threshold for diagnosis should remain low, and additional testing beyond patient report and visual examination of the oral cavity and oropharynx is rarely necessary.

Preventive measures include conformal avoidance during planning as well as the use of the radioprotector amifostine and, in selected patients, submandibular gland transfer. The various preclinical data regarding the use of amifostine are conflicting, and concerns regarding amifostine utility in the modern era of intensity-modulated RT (IMRT)- or volumetric modulated arc therapy (VMAT)-based treatment delivery, the inconvenience associated with its intravenous administration, and related side effects (hypotension, nausea, vomiting, allergic reaction) have limited its clinical use.[93-96] Submandibular gland transfer has shown benefit over pilocarpine in preventing xerostomia in a prospective trial, but as a technique is limited to patients who are appropriate surgical candidates, for whom neoplastic involvement of the prospectively transposed gland is minimal and can have the submental region safely omitted from radiation fields.[97-100] Additional studies have analyzed transfer of the submandibular to the parotid region, or temporary relocation to the forearm prior to native reimplantation.[101,102]

Patients who develop xerostomia during treatment should be encouraged to maintain adequate oral hydration, as baseline dehydration may exacerbate symptoms. Frequent small sips of water or the use of ice chips may help mitigate the subjective sense of xerostomia and help prevent associated dysphagia and odynophagia with oral intake of food. Additional lifestyle modifications may include the use of humidifiers and avoidance of consuming dry, highly absorbent foods (crackers, breads, meats) without supplementary liquid to accompany them.

Prompt initiation of an oral rinsing and gargling regimen with either a dilute solution of saline and sodium bicarbonate or dilute 25% hydrogen peroxide 4 times daily is suggested. Each of these rinse solutions provides exogenous hydration of the oral cavity and oropharyngeal mucosa and aids in the maintenance of oral hygiene with certain antimicrobial properties. In particular, the effervescence of both the baking soda and peroxide components of these rinses assists in manual mucus clearance, which may be particularly helpful in patients with tenacious secretions.[92] Additional mucolysis may be achieved with the expectorant, guaifenesin. Over-the-counter alcohol-based mouthwashes should be avoided.

Sialagogues such as pilocarpine, cevimeline, and bethanechol are muscarinic-cholinergic agonist parasympathomimetic agents that stimulate salivary tissue; prior series suggests that approximately 50% of patients

experience some degree of postradiation xerostomia relief with the use of pilocarpine, although other studies suggest more modest overall benefit.[96,103-108] Nevertheless, this class of medication is associated with traditional anticholinergic side effects, such as sweating, tachycardia, flushing, lacrimation, and dizziness, and are contraindicated in patients with prior diagnoses of asthma, acute iritis, or glaucoma.[96] Caution should also be exercised for those with chronic obstructive pulmonary disease and/or prior cardiovascular disease. Moreover, their functional gains cease if treatment is discontinued, necessitating lifelong therapy for effect.[96,109] Nonpharmacologic stimulation of salivary production with the use of sugar-free candy, lozenges, or chewing gum may provide some relief to patients with reserve levels of parotid function. Extraoral and intraoral electrostimulation to the parotid gland (via transcutaneous electrical nerve stimulation) and to the buccal mucosa are newer techniques of salivary induction but remain investigational.[110,111] Acupuncture has also shown utility in alleviating postradiation xerostomia in selected studies, although robust evidentiary support of this technique is limited, and the lack of randomized trial data—coupled with the profound heterogeneity of its delivery—limits acceptance of acupuncture as a primary form of treatment.[96,112,113]

Lastly, mucosal lubricants and artificial salivary substitutes may be offered to patients for whom stimulation of salivary secretion is ineffective. These substances—which typically consist of minerals, preservatives, flavorings, and methylcellulose or methacrylate viscous base agents—come in a wide variety of formulations; application of one product over another may be based on patient preference.[103] These substances do not replace the antimicrobial and immunogenic function of native saliva. Specialized toothpastes/dentifrices and/or fluoride- or chlorhexidine-based mouthwashes may be prescribed by the dental provider.[89]

Dysgeusia and Ageusia

RT to the head and neck region may result in alteration of taste perception (dysgeusia) or loss of taste (ageusia) in upward of 80% of patients. Dysgeusia and ageusia appear to be a dose-dependent toxicities; of the various taste perceptions (sweetness, bitterness, saltiness, sourness, and

savoriness, aka "*umami*"), umami appreciation has a lower dose threshold of loss than the remaining four tastes.[114] Nevertheless, this does not appear to be borne out clinically, as alterations in or loss of bitter and salty discrimination are the most commonly reported symptoms following head and neck RT.[115] All five taste types typically decline by the fifth week of conventionally fractionated radiation, with maximum impairments seen in the fourth to fifth weeks, and gradual improvement 11 weeks following initiation of RT and substantial recovery by 3 to 9 months thereafter.[116]

Attempts to minimize excess radiation dose to the nasal mucosa and oral tongue should be attempted in the radiation treatment planning process, as preferential sparing of these tissues can preserve normal gustatory function.[117] Unfortunately, pharmacologic interventions directed at restoring normal gustation and olfaction in the post-RT setting have been disappointing.[118,119] Trials of amifostine have also proven underwhelming, with one study suggesting that dysgeusia is actually *more* frequent among patients who receive this cytoprotective agent.[120,121]

For any given patient presenting with taste disturbance, evidence of oropharyngeal infection (ie, candidiasis), which can often confound a diagnosis of dysgeusia, should be ruled out or if present, treated appropriately. Patients with dysgeusia and ageusia are at elevated risk for poor oral intake and malnutrition. Comprehensive evaluation and management under the care of a registered dietician are suggested. In severe cases, nutritional supplementation and enteral feeding with gastrostomy or jejunostomy tube may ultimately still be required.

Oropharyngeal Mucositis/Oral Infection

Oral mucositis represents one of the most common and prominent side effects of head and neck RT, affecting upward of 90% of patients who receive radiation treatment for this indication, with frequency and severity increased by the use of concurrent chemotherapy or altered fractionation schemes.[122,123] The rapid rate of cellular turnover of the mucosal basal epithelial layer makes it particularly susceptible to radiation-induced damage. Additional patient-related risk factors that appear to contribute to the development of mucositis include advanced age, poor oral hygiene, preexisting xerostomia, and baseline malnutrition.[124]

Symptoms of mucositis most often present in the third week of RT and may be associated with early discontinuation and suboptimal treatment-related survival outcomes. As mucositis develops and progresses, patients often develop significant pain and dysphagia that limit appropriate oral intake. Mucositis can also contribute to symptoms of dysgeusia and dysphagia, further compounding challenges with feeding and speech production.

Primary prevention of mucositis largely consists of appropriate treatment planning and delivery in which the regions of high dose within the oral and oropharyngeal mucosa are avoided or minimized as feasible.[125] The use of intraoral positioning systems (colloquially referred to as "bite blocks"), in addition to dental rolls and/or wax bolus, may effectively increase the effective oral cavity surface area spared, provide a greater degree of anatomic separation between tissues, and help absorb backscatter radiation dose generated by metallic dental implants or fillings.[126]

Optimization of oral hygiene prior to RT is similarly important, and we encourage all patients to initiate an oral rinsing and gargling regimen with a dilute solution of saline and sodium bicarbonate (one tablespoon salt, one tablespoon baking soda, mixed in one quart of water) with the start of radiation treatment (see section "Xerostomia"). Alcohol-based, over-the-counter mouthwashes should be avoided, and chlorhexidine mouth gargles —which are often recommended as the prevention of chemotherapy-induced mucositis—are not suggested in the setting of RT.[127] Pretreatment dental evaluation and extraction with a formal dental provider should be a standard part of care.

In spite of prophylactic measures, comorbid fungal, viral, and bacterial oral infections due to epithelial mucosal barrier breakdown are common. Oral and oropharyngeal *Candida* infections are optimally managed first via the use of topical antifungal solutions (nystatin swish and swallow, clotrimazole troches dissolved, or miconazole mucoadhesive buccal tablets).[128,129] Caution should be maintained as certain nystatin suspensions contain supplementary sugars that can contribute to the formation of dental caries and appear to be associated with poor taste and gastrointestinal upset.[130] Patients with moderate or severe disease, or candidiasis refractory to these first-line oral solutions, should be treated with oral fluconazole. Herpetic vesicular eruption and ulceration may arise especially in the

setting of immunosuppression and should be managed with oral acyclovir or valacyclovir.[131]

Once radiation-related mucositis is apparent, certain dietary and behavioral modifications should be undertaken to help minimize discomfort. Patients should be counseled to avoid smoking, caffeine, or alcohol consumption and to adopt a diet devoid of spicy, acidic, temperature extreme, and texturally sharp or rough food items. Softened toothbrushes and specialized dentifrices may be used to help minimize abrasion.

Topical anesthetics including lidocaine, benzocaine paste, and 2% viscous xylocaine may be strategically used prior to meals to alleviate discomfort. These anesthetics may be used in isolation or, in the case of lidocaine, as part of a "Miracle," "Magic," or "Triple-Mix" mouthwash elixirs; such solutions often contain diphenhydramine and aluminum hydroxide/magnesium hydroxide antacid, with or without the addition of oral tetracycline, mycostatin, and hydrocortisone components. Doxepin mouth rinses can be used to accomplish the same effect, although this may be associated with stinging, burning, unpleasant taste, and drowsiness due to a certain degree of systemic absorption and antihistaminergic action.[132] Various mucoadhesive hydrogels are available and function to form a synthetic, palliative, and protective barrier to damaged oral and oropharyngeal mucosa that ameliorates both the onset and course of symptomatic mucositis, although honey—which also has inherent antimicrobial properties lacking in synthetic products—has been investigated for the same indication with encouraging results.[133,134]

Even with the utilization of any of these mixtures, additional pain control is often required in the form of oral narcotic medication or 0.2% morphine mouthwashes, and patients with severe symptoms may require temporary radiation treatment breaks to allow for appropriate healing.[135,136] Nutritional support of patients with mucositis is paramount, and many patients will require gastrostomy or jejunostomy tube placement to help prevent significant malnutrition and weight loss, even with appropriate mucositis management.

Dysphagia

Radiation-associated dysphagia refers to impaired swallowing efficiency and safety following RT.[137] The physiologic process of swallowing includes four distinct phases: an oral preparatory phase, an oral phase, a pharyngeal phase, and an esophageal phase. As such, radiation-related dysphagia is multifactorial, with many potential mechanical-structural, anatomic sources, neurologic mediators, and disparate contributing toxicities being involved.[138]

Patients who are expected to proceed with head and neck radiation should undergo formal evaluation with a dedicated speech and language pathologist (SLP) prior to initiation of treatment, even in the absence of swallow-related symptoms. Pretreatment baseline levels of subclinical (silent) aspiration are common and are often exacerbated by radiation treatment.[139]

Primary prevention of radiation-associated dysphagia requires treatment planning that minimizes radiation dose to susceptible structures—such as the oral cavity, larynx, pharyngeal wall/pharyngeal constrictor muscles, and esophagus.[140] Implementation of proactive swallowing therapy—that commences prior or concurrent to the advent of RT—is associated with improved rates of functional swallowing, mouth opening, and dysphagia-related quality of life in multiple series.[141-143]

Appropriate management of additional contributing toxicities (eg, fluids, oral hydration for patients with xerostomia) may further reduce apparent swallowing impairment. Nutritional support in the form of altered food textures, thickened liquids, and purees tailored to the nature of underlying dysphagia should be provided under the guidance and supervision of both a registered dietician and SLP. Prophylactic gastrostomy tube placement in the head and neck population continues to remain controversial; certain data are suggestive of benefit, and other studies show prolonged rates of percutaneous endoscopic gastrostomy-tube dependence and delay in resumption of normal oral-enteral alimentation.[144-146]

Referral to a registered dietician early in the course of treatment is paramount for guidance regarding nutritional needs. There are a variety of oral supplement nutritional drinks available that can support appropriate caloric and macro- and micronutrient needs. Typically, feeding tubes (gastric tube, jejunostomy feeding tube, gastrojejunostomy feeding tube) are recommended for patients receiving RT who are malnourished and who

are expected to be unable to ingest or absorb adequate nutrition over for more than 7 to 14 days. Fluid and electrolyte supplementation may be necessary in patients with vomiting, diarrhea, or ostomy drainage.

Radiation Esophagitis

Acute symptoms of radiation esophagitis often present 2 to 3 weeks following initiation of conventionally fractionated radiation and may include globus sensation, dysphagia, odynophagia, or substernal discomfort. Additional symptoms, such as hematemesis from esophageal bleeding, perforation, fistula, or esophageal obstruction in the setting of acute radiation esophagitis, are comparatively less common.[147,148]

Management of acute radiation esophagitis includes behavioral and dietary modifications, as well as utilization of topical anesthetics for relief. Patients should be counseled to avoid smoking or alcohol consumption and to adopt a relatively bland diet devoid of spicy, acidic, excessively dry, fatty, and temperature extreme hot or cold foods that may aggravate odynophagia or gastroesophageal reflux.[149] Multiple small-volume semisolid meals spaced throughout the day are preferable to the consumption of large meals, with further caloric supplementation as needed to meet daily requirements. Topical 2% viscous lidocaine, either by itself or in suspension with additional antacid (magnesium aluminum hydroxide) and mucosal coating protective (sucralfate) agents, is the common formulation that may be swallowed by the patient for symptomatic relief[150]; such elixirs may be strategically administered prior to meals. Additional therapies include anti-inflammatory and narcotic agents for analgesia, antisecretory agents such as PPIs (omeprazole, pantoprazole) and H_2-blockers (ranitidine) to mitigate underlying gastroesophageal reflux, and antifungal therapy (nystatin suspension, fluconazole) for those patients with esophageal candidiasis. Feeding tube placement and intravenous hydration may be required for those unable to maintain food and fluid intake per os. Symptoms of acute radiation esophagitis are usually self-limiting and resolve within 2 to 4 weeks after completion of therapy.

Chronic radiation esophagitis may present as early as 3 months following completion of radiation, with a median onset of 6 months following treatment.[151,152] Progressive fibroblast and inflammatory infiltration of the

irradiated esophageal mucosa may result in progressive dysmotility, stricture, and/or fistula. Esophageal strictures are typically managed with endoscopic dilation combined with acid suppression therapy.[153] Development of symptomatic esophageal fistula can be a life-threatening complication with a poor prognosis, one requiring expedient evaluation and potential surgical correction if feasible.[154]

Gastritis/Duodenitis

Radiation gastritis commonly includes symptoms such as nausea, vomiting, dyspepsia, epigastric discomfort, abdominal pain, and/or cramping and may present both during an active course of radiation or up to 1 year after completion of therapy.[152] As with radiation esophagitis, upper endoscopy is the diagnostic modality of choice for radiation gastritis.

Nausea and vomiting are frequent side effects of RT to the abdomen both as a component of radiation gastritis and as a distinct clinical entity in isolation; moreover, radiation-induced nausea and vomiting (RINV) and can manifest in the immediate hour(s) following completion of a given radiation fraction.[155] It is suggested that patients fast or consume minimal amounts of food or drink at least 2 hours prior to receipt of RT targeting the stomach, as the presence of gastric contents and active digestion may predispose to RINV. Common antiemetics used to prevent or mediate nausea and vomiting include 5-HT3 receptor antagonists such as ondansetron, followed secondarily by phenothiazine-class medications such as prochlorperazine or chlorpromazine. Additional glucocorticoids, such as dexamethasone, may also have an antiemetic role in more refractory cases of RINV.[156] Lorazepam or dronabinol may also help with nausea and/or appetite stimulation.

Further management of the symptoms of radiation gastritis includes the use of antisecretory therapies (PPIs omeprazole, pantoprazole; H_2-receptor blocker ranitidine) and gastric mucosal protective agents (sucralfate), with consideration of non–nonsteroidal anti-inflammatory drug (NSAID)-based analgesics, promotility agents (metoclopramide), and antispasmodics (hyoscyamine) for those with abdominal pain and/or cramping. Patients with hemorrhagic gastritis require comprehensive assessment by gastroenterology and medical stabilization in the setting of acute upper

gastrointestinal bleeding and ultimately may submit to similar endoscopic therapies for hemostasis (eg, argon plasma coagulation [APC]) as those patients with radiation esophagitis.[157] Gastric outlet obstruction is often treated with serial endoscopic balloon dilation, similar to esophageal stricture.

Radiation duodenitis presents with similar symptoms as radiation gastritis, although additional symptoms such as loose stools and diarrhea may be present. Suggested medical management of mild-to-moderate acute radiation duodenitis consists of antisecretory therapies (H_2-blockers, PPIs) and non–NSAID-based analgesics for pain. Agents such as sucralfate appear to have less demonstrable benefit for patients with radiation-induced small bowel toxicity than those with gastritis.[158] Patients with concern for duodenal ulceration or bleeding require upper endoscopy.

Radiation Enteritis

Radiation enteritis is a comprehensive term that describes secondary damage to the small and/or large intestines resulting from prior abdominopelvic irradiation, with symptoms including, but not limited to, nausea and vomiting, abdominal bloating, abdominal pain, excessive flatus, diarrhea or loose stools, and malabsorption. Additional symptoms, such as hematochezia or melena due to intestinal bleeding, partial or complete bowel obstruction from the development of adhesive disease, sepsis from perforation, or enteric fistula, may also be present but are more rare.

The temporal development of radiation enteritis can be both acute (#3 months after RT) and chronic (>3 months after RT). In concert with the aforementioned symptoms, the diagnosis of radiation enteritis can be corroborated by abdominal CT or MR enterography. These studies typically show bowel wall thickening or mucosal hyperenhancement. Direct visualization with upper endoscopy and/or colonoscopy with biopsy may provide macroscopic and microscopic confirmation of postradiation changes and absence of other factors.

Initial management of acute radiation enteritis includes behavioral and dietary modifications. Patients who develop mild-to-moderate diarrhea are suggested to adopt a low-fiber, low-fat diet.[159,160] Any offending medications with laxative effects should be discontinued and appropriate hydration

maintained. The antidiarrheal agent loperamide is a preferred first-line therapy for those without signs or symptoms of bowel obstruction.[161] Additional antidiarrheal therapies include diphenoxylate/atropine and bile acid sequestrants (cholestyramine, colestipol, colesevelam), which effectively chelate elevated intraluminal levels of bile salts that are not absorbed by the affected bowel mucosa. For patients with small intestinal bacterial overgrowth, tailored antibiotic therapy and correction of micronutrient (vitamin B_{12}, fat-soluble vitamins, iron, thiamine) deficiency should be completed.[162]

Chronic radiation enteritis may present as early as 3 months following completion of radiation, with a median onset of 8 to 12 months following treatment.[152] In addition to the aforementioned symptoms, progressive fibrosis and ischemia of the irradiated bowel may result in intestinal dysmotility, fibrosis, adhesions, ulceration, stricture, and/or fistula development. Patients with small or large intestinal bleeding require endoscopic intervention for hemostasis. For those presenting with evidence of bowel obstruction, nonoperative management with nasogastric decompression, intravenous hydration with electrolyte replacement, and parenteral nutrition are preferred.[163] Surgical approaches for chronic radiation enteritis should be reserved for cases that are severe and refractory to medical treatment.

Pancreatitis/Pancreatic Insufficiency

Radiation-induced acute pancreatitis is an exceptionally rare toxicity of upper abdominal radiation, although this clinical entity has been described in select case reports.[164] Management of radiation-related acute pancreatitis should follow the typical paradigm of supportive therapy with goal-directed fluid resuscitation, analgesia, and temporary bowel rest until enteral nutrition can be resumed and a normal diet advanced.

Chronic radiation pancreatitis resulting from prior abdominal RT has also been described, with endocrine and exocrine pancreatic insufficiency resulting in varying degrees of steatorrhea, macronutrient and micronutrient deficiency, unintentional weight loss, and/or glucose intolerance.[165-169] Any clinical suspicion of chronic pancreatic insufficiency in patients with prior

abdominal radiation should prompt referral to gastroenterology and/or endocrinology for further workup and management.[170]

Radiation-Induced Liver Disease

Radiation-induced liver disease (RILD) is a significant and potentially life-threatening complication of RT to the abdomen. RILD typically occurs 4 to 8 weeks following completion of radiation, with an incidence that appears dependent on cumulative radiation dose, volume of irradiated liver, and baseline hepatic function, among other factors.

Patients who develop classic RILD present with fatigue, abdominal pain, and distension due to hepatomegaly and anicteric ascites. Serum alkaline phosphatase levels are elevated, while bilirubin and transaminases are normal. The current model of pathogenesis suggests classic RILD is caused by veno-occlusive disease and retrograde congestion resulting from radiation-induced fibrosis of the central vein lumina.[171] Nonclassic RILD arises in patients with baseline underlying liver disease. Patients with nonclassic RILD often present with signs of jaundice, and laboratory values often show markedly elevated alanine and aspartate aminotransferase levels.[172] Unfortunately, while the pathophysiologic characteristics of RILD are well described, the mechanisms involved with the development and evolution of RILD remain unknown.

Mild elevations in transaminases or alkaline phosphatase can be transient and self-limiting and should be periodically reevaluated for resolution. For patients with persistent elevation in alkaline phosphatase or transaminases beyond 6 months, referral to a hepatologist is prudent. The only treatments for RILD are supportive and include diuretics for edema, therapeutic paracentesis for ascites, and steroids for hepatic congestion.

Biliary Stricture

A rare but potentially severe late effect after treatment to the liver and biliary system is radiation-induced stricture of the bile duct. Affected patients may present with symptoms of obstructive jaundice, and findings are corroborated on laboratory workup with conjugated hyperbilirubinemia. Management of radiation-induced biliary stricture is similar to that of any nonmalignant biliary stricture: Balloon dilation, stenting, or surgical bypass

is indicated to relieve symptoms of cholestasis and prevent the development of ascending cholangitis, Gram-negative septicemia, and hepatic abscesses.[173-175]

Radiation Proctitis

Radiation proctitis (RPr) is a comprehensive term that describes the development of rectal symptoms secondary to radiation damage to the sigmoid colon and rectum, including, but not limited to, diarrhea, fecal urgency, fecal incontinence, rectal pain, excess flatus, fecal mucus, tenesmus, and/or hematochezia. The temporal development of RPr can be both acute (#3 months after RT) and chronic (>3 months after RT). Given that the term "proctitis" is felt by some to be a misnomer that inaccurately suggests the condition is one of chronic inflammation, chronic radiation proctitis (CRP) is alternatively referred to as "rectal proctopathy" or "pelvic radiation disease."[176] In addition, "radiation-associated vascular ectasias" has been proposed for those patients whose postradiation rectal pathology consists primarily of bleeding from affected vasculature.[177] In concert with the aforementioned symptoms, the diagnosis of RPr is established with direct visualization of the rectal mucosa—often demonstrating telltale changes of telangiectasias, fibrosis, and pallor. Biopsy is typically not recommended in cases of acute radiation proctitis (ARP) due to concern for increased risk of bleeding and subsequent fistula formation.[178]

ARP is typically self-limiting, with symptoms of ARP resolving after discontinuation of radiation. Supportive measures with appropriate hydration, antidiarrheal (loperamide), and/or antigas (simethicone) medication may be used as needed.

CRP is a far more consequential sequela of pelvic irradiation and is associated with significant morbidity. The median onset of CRP is 8 to 12 months postradiation but can occur as late as 30 years after treatment. Three types of CRP exist: inflammation predominant, bleeding predominant, and mixed, which represents a combination of the former two types in varying degrees. Bleeding predominant is not only the most common form but also the most likely to resolve over time. Optimization of bowel function and fecal consistency with dietary modification, fiber supplementation, or laxative use is suggested as a first step to help prevent traumatic bleeding

associated with the passage of indurated stool. Additional noninvasive therapies include the use of antioxidant vitamin A/E/C or metronidazole 400 mg 3 times daily for 30 days.[179,180] Sucralfate enemas are the most well-accepted medical option for CRP and appear to provide cytoprotection to the rectal mucosa by stimulating local prostaglandin production. Their use for patients with CRP has been associated with a 77% improvement rate in bleeding grade in one series.[181,182]

Endoscopic therapies may be reserved for patients with bleeding-predominant CRP with severe or recalcitrant symptoms. APC is a commonly employed technique to ablate superficial hemorrhagic vasculature within the rectum and remains the best studied technique in the treatment of bleeding CRP.[183] Nevertheless, the widespread use of APC may be limited by its cost and availability. APC treatment requires antecedent colonic lavage, and the treatment itself can be associated with rectal side effects, such as pain, ulceration, and stricture.[184,185]

Topical formalin, which functions as a local sclerosant and chemical cauterizing agent, is sometimes used as an alternative to APC in CRP management. As compared to APC, formalin therapy is comparatively inexpensive and widely available. The success rate of formalin in the long-term management of CRP appears highly variable, ranging from 27% to 100%, a fact likely attributable to differences in technique of application and chemical concentration. Much like APC, however, concerns about severe formalin-related toxicity, such as fistula and necrosis, remain.[182,186,187]

HBOT to increase neovascularization and facilitate mucosal healing remains an option for patients with persistent symptoms after ablation, although data from only one randomized clinical trial support its use in CRP.[188,189] However, HBOT should only be used in patients with no evidence of active malignancy. Lastly, surgical treatments such as local excision, urinary and fecal diversion, and coloanal J-reservoir construction are considered last resorts for patients with CRP, due to concern for poorly vascularized tissues and low healing rates in patients with prior pelvic irradiation.

Inflammation-predominant RPr may be managed with loperamide, fiber supplementation, and stool-bulking agents. Rectal betamethasone or rectal hydrocortisone may also be of additional utility.[190]

Anal Toxicity

Patients undergoing pelvic irradiation for lower gastrointestinal malignancies or gynecologic malignancies may experience additional anal toxicity. Symptoms often overlap with those of rectal toxicity and may include diarrhea, tenesmus, fecal incontinence, and/or hematochezia. Additional symptoms specific to anal toxicity in particular include anal pain and perianal skin reaction with pruritus, erythema, and variable extent of desquamation.[191,192]

Management of acute anal toxicity consists of supportive care with dietary modification and antidiarrheal agents as needed. Patients with perianal pain and radiation skin reaction (see section "Integumentary") traditionally benefit from the use of barrier creams and frequent sitz baths, either with lukewarm water alone or with dilute solutions of baking soda or astringent aluminum acetate. Sitz baths accomplish mutual goals of both improved anal hygiene and direct analgesic effect on the irritated anal and perianal epithelium. Additional pain control may be achieved with narcotic pain medication; corticosteroid and lidocaine suppositories have also been trialed for local analgesia but remain investigational.[193]

Additional late anal toxicity includes the development of chronic fecal incontinence, anal ulceration, anal stricturing/ stenosis, and fistula formation.[194] Chronic fecal incontinence may be managed with a mixture of antidiarrheals and stool bulking agents, as well as pelvic floor strengthening exercises and biofeedback techniques carried out by specialist practitioners or community teams.[195]

Mild-to-moderate cases of anal stricture are managed conservatively with the regulation of stool transit by dietary fiber supplementation and manual dilation, while more severe cases of anal stenosis merit surgical correction with sphincterotomy or anoplasty.[196] The feasibility of complex anorectal fistula repair is highly variable and patient dependent, as surgical concerns exist regarding appropriate postsurgical healing.[197,198] As such, diverting colostomy may represent a final but necessary resort for refractory cases of anal sphincter dysfunction, fistulae, or stricture otherwise not amenable to other forms of amelioration.[199]

RESPIRATORY SYSTEM

See Table 107.5 for an overview of the medical management of radiation toxicity to the respiratory system.

TABLE 107.5 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE RESPIRATORY SYSTEM

Radiation Toxicity	Timing	Medication Management
Pneumonitis	Subacute	NSAIDs • Ibuprofen 200-800 mg PO q6h • Naproxen 500-750 mg PO initially, then 250-500 mg PO q6-12h • Indomethacin 25 mg bid-tid initially; max 200 mg/d Advance to prednisone with a gradual taper • Prednisone 40-60 mg/d (or 1 mg/kg/d) with slow taper over 4-8 wk with close monitoring of symptoms[424]
Bacterial pneumonia	Acute or late	Outpatient pneumonia with immune compromise or comorbidities: moxifloxacin or combination of azithromycin and amoxicillin/clavulanate • Moxifloxacin (Avelox) 400 mg PO qd • Azithromycin (Z-Pak) 500 mg PO qd day 1, then 250 mg PO qd × 4 d • Amoxicillin/clavulanate (Augmentin) 250-500 mg PO tid or 875 mg PO bid If aspiration suspected Clindamycin 150-450 mg PO tid-qid
Cough	Acute or late	• Guaifenesin (Mucinex DM) 600-1,200 mg PO bid • Benzonatate (Tessalon) 100-200 mg PO q8h
Hiccups	Acute or late	• Baclofen 5-20 mg PO tid; titrating up at 2-d intervals • Note: antispastic muscle relaxant • Metoclopramide (Reglan) 10-20 mg PO q4h • Chlorpromazine (Thorazine) 25 mg IV or IM, or 50 mg PO tid (range 25 mg PO tid to 50 mg PO qid); maintenance 10 mg 50 mg PO tid
Sinusitis	Acute	To promote sinus drainage • Guaifenesin (Mucinex) 600-1,200 mg PO bid • Pseudoephedrine (available “behind” the counter without a prescription) 1 PO q6h For infection

Radiation Toxicity	Timing	Medication Management
		• Amoxicillin/clavulanate (Augmentin) 250-500 mg PO tid or 875 mg PO bid • Levofloxacin (Levaquin) 500-750 mg qd • Ciprofloxacin (Cipro) IR 250-750 mg q 12 h or XR 500-1,000 mg qd

bid, 2 times daily; IM, intramuscular; IV, intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, oral; q, every; qd, everyday; qid, 4 times a day; tid, 3 times daily.

Radiation-Induced Lung Injury

Radiation-induced lung injury (RILI) is a comprehensive term that refers to any damage to lung parenchyma as a result of therapeutic irradiation and is most often defined in terms of its acute (radiation pneumonitis: RPn) and chronic (radiation fibrosis [RF]) manifestations. Although described separately, both RPn and RF arise from the same underlying physiologic process, often evolving as a stepwise series of five clinicopathologic phases: early phase, latent phase, exudative phase, intermediate phase, and fibrotic phase.[200] The pathologic changes underlying the RILI are characterized by progressive alveolar epithelial and endothelial degeneration, culminating in fibroblast infiltration and collagen deposition within the pulmonary interstitium.[201]

Traditionally, RPn occurs anywhere from 4 to 12 weeks after radiation, although its origin as an "acute" phase of RILI suggests that the development of any radiation-induced pulmonary toxicity within a 6-month time frame following RT constitutes RPn.[202,203] In cases of acute RILI, patients may present with exacerbation of preexisting respiratory symptoms or new-onset dyspnea, cough, chest pain, low-grade fevers, and/or malaise. Less common, more severe signs include tachypnea, labored respirations with evident hypoxemia, and abnormal findings on pulmonary auscultation (eg, pulmonary friction rub, rales).[200]

Initial workup of RILI consists of direct patient evaluation followed by dedicated chest imaging with plain film chest radiograph and/or chest CT.

Chest radiographs may show hazy opacification and infiltrates in the distribution of the prior radiation portal, although, in the modern era of IMRT and VMAT delivery, the "straight line" test in which abnormal pulmonary densities conform to the confines of a distinct geometric border is no longer as valid an indicator of RPn as previously.[204] Furthermore, changes outside the prior radiation field—potentially due to infection, atelectasis, obstruction, or additional immune-mediated hypersensitivity reaction—may also be apparent, further confounding the diagnosis.[205]

Ideally, RPn risk should be minimized through diligent radiation planning by limiting normal irradiated lung tissue volume and dose according to established metrics (such as lung V20 and mean lung dose). Nevertheless, once present, the mainstay of treatment for RPn consists of supportive therapy and corticosteroids. Patients with mild symptoms can be treated with NSAIDs (ibuprofen, naproxen, indomethacin) and antitussives (dextromethorphan, codeine), as needed.[92] For other individuals presenting with moderate-to-severe symptoms, glucocorticoid therapy is suggested; oral prednisone (ideally 1 mg/kg/day, often suggested at a maximum dose of 60 mg/day) is considered a reasonable starting dose, with slow taper over a period of 3 to 12 weeks based on symptomatic reassessment and improvement. Starting dose and taper schedule needs to balance the needs of the individual patient with regard to respiratory symptoms as well as unwanted effects attributed to high-dose and long-term steroid use. Reinitiation or change in taper regimen may be necessary for patients with recurrent or recalcitrant symptoms. *Pneumocystis jirovecii* prophylaxis with trimethoprim-sulfamethoxazole or inhaled pentamidine may be considered when prednisone is administered.[200,201] Patients who present with severe symptoms or hypoxemia often require more aggressive management and should be evaluated for hospitalization, intravenous methylprednisolone 2 to 4 mg/kg/day, supplemental oxygen therapy, and other forms of respiratory support as needed. Patients who are diagnosed and managed appropriately with RPn generally have favorable outcomes, and pulmonary function may be expected to recover within an 18-month time frame from completion of therapy.[206]

RF represents the end stage of RPn, and while certain medications such as ambroxol, pentoxifylline, amifostine, and ACEIs have been suggested as potential mediators and attenuators of the progression of RPn to RF,

radiation-induced lung fibrosis is currently resistant to all known pharmacologic interventions.[207-210] Pirfenidone, a medication used to treat idiopathic pulmonary fibrosis, has also been suggested as a potential prophylactic therapy to prevent RF, although its use for this indication remains completely investigational at present.[211] Patients with established RF should be managed supportively under the supervision of a dedicated pulmonologist.

As immune checkpoint inhibitor use increases in patients who have previously received thoracic radiation, it will be a challenge to differentiate checkpoint inhibitor–mediated pneumonitis from radiation-related pneumonitis.[212] The pathways involved in this process are under current investigation, although both seem to mediate damage through cytokine secretion (interleukin-1β, interleukin-6, interleukin-17, and interferon-γ) promoting the process of lung inflammation.[213] Initial management depends on the severity of symptoms and findings but includes considering discontinuing immune checkpoint inhibitor followed by a similar steroid regimen and supportive care.

Radiation Recall Pneumonitis

Recall radiation pneumonitis (RRP) is an acute inflammatory response seen in previously irradiated but otherwise quiescent lung tissue that typically occurs with the advent of new antineoplastic systemic therapy (most notably taxane and anthracycline chemotherapeutics).[201,214] Confounding direct cause and effect in these cases lies in that many of these agents have an inherent risk for pneumonitis even when patients have no history of radiation treatment to the lungs. In addition, RRP has been described in patients with a prior history of thoracic RT who suddenly discontinue steroids prescribed for an alternative medical indication, unmasking latent RPn in the process.[215] The onset of RRP can occur anywhere from hours to days following initiation of the offending agent, and the intervening time between receipt of RT and development of RRP can be years in duration.[216] Management of symptomatic RRP generally consists of discontinuation of the inciting therapy in question, with additional treatment per standard RPn paradigms as earlier.

Bronchial Stenosis/Obstruction/Fistulae

Symptomatic narrowing of the tracheobronchial tree has been reported in patients treated with conventionally fractionated radiation, endobronchial high-dose rate (HDR) brachytherapy, a combination of external beam RT (EBRT) and HDR brachytherapy, and, more recently, stereotactic body radiation therapy (SBRT).[217-221] Lobar bronchi appear more susceptible to bronchial stenosis as compared to mainstem and intermediate bronchi, although these findings do not necessarily correspond to clinically apparent pulmonary toxicity.[222]

Patients with symptomatic manifestations of bronchial stenosis may present with new-onset or progressive dyspnea, cough, and/or wheezing. CT imaging of the chest may reveal radiation-induced changes in major, lobar, segmental, and/or subsegmental bronchial caliber, but direct visualization of the tracheobronchial tree with diagnostic bronchoscopy is gold standard. Patients may benefit from therapeutic bronchoscopy with endobronchial balloon dilation and/or endobronchial stenting.[223,224]

Radiation-induced bronchial fistulae are rare and, depending on the anatomic location of the sinus tract in question (eg, bronchopleural, bronchomediastinal, broncho- esophageal), may result in severe sequelae, such as empyema and mediastinitis. As with bronchial stenosis, CT imaging of the chest and direct bronchoscopic evaluation are indicated. Management is difficult, with mortality rates associated with pulmonary fistulae being very high. Management is not standardized but typically consists of appropriate antimicrobial therapy and attempted closure of the fistulizing tract. Smaller fistulas (<3-8 mm in size) may be amenable to seal with various occlusive materials.[225-228] Larger fistulae may require placement of coils, Amplatzer devices, or endobronchial stents.[229-231] Surgical intervention includes attempted closure with pedicled muscle flaps or free flaps, although the risk of an operation in previously irradiated and poorly vascularized tissue must be considered.[232,233]

CARDIOVASCULAR SYSTEM

Cardiovascular toxicity resulting from radiation treatment may manifest in a variety of ways, as radiation may induce changes in the different tissues and

structural components of the heart. See Table 107.6 for an overview of the medical management of radiation toxicity to the cardiovascular system.

TABLE 107.6 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE CARDIOVASCULAR SYSTEM

Radiation Toxicity	Timing	Medication Management
Pericarditis	Acute	NSAIDs • Ibuprofen 200-800 mg q4-6h, 3,200 mg/d max • Naproxen 250-500 mg q12h, 2,500 mg/d max • Indomethacin 25-50 mg q8-24h

NSAIDs, nonsteroidal anti-inflammatory drugs; q, every.
Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Pericarditis

Radiation-induced pericardial disease has a temporal development that includes both acute and chronic manifestations.[234] Symptoms of acute pericarditis, such as chest pain and fever, may result within days of radiation exposure, and pericardial effusions, either developing during acute pericarditis or in isolation, can present weeks to months following initial treatment.[235-238] Further workup of presumed pericardial toxicity may consist of electrocardiogram (ECG), transthoracic echocardiogram, and/or cardiac markers; classic findings such as diffuse ST elevation on ECG may help secure a diagnosis of pericarditis when clinical suspicion is present. Most cases of acute pericarditis secondary to radiation treatment are self-limiting with supportive therapy and the use of NSAID as well as colchicine providing relief of pain and resolution of inflammation, with steroids reserved as second-line agents in refractory cases.[239-242] Patients who have a pericardial effusion resulting in hemodynamic compromise may require pericardiocentesis.[243] With a latency period of 10 years, constrictive pericarditis represents the most severe, chronic form of radiation-induced pericardial disease. Pericardiectomy serves as the definitive therapy for this condition.[244]

Coronary Artery Disease

CAD may represent the most common radiation-induced cardiovascular toxicity, with clinical manifestations typically present 10 to 30 years after initial radiation exposure.[245] Radiation-induced injury to the intima of the coronary arteries can initiate an inflammatory cascade leading to atheromatous plaque formation. The extent of CAD in affected patients can manifest across a spectrum of severity and presentation, ranging from asymptomatic, incidentally noted instances of coronary stenosis, to life-threatening cases of acute coronary syndromes.[246,247] Examining the effect of radiation dose to independent cardiac substructures on the development of CAD remains an active area of interest within the field of radiation oncology; while mean heart dose has been associated with a proportional increase in the risk of ischemic heart disease, certain series have correlated the risk of major cardiovascular events (unstable angina, heart failure, myocardial infarction, coronary revascularization, and cardiac death) to radiation dose received by the left anterior descending artery.[248,249] The presence of additional comorbid conditions and factors, including preexisting hypertension, hyperlipidemia, and active smoking history, increases the risk of developing CAD.[250]

Valvulopathy

Valvulopathy and valvular dysfunction represent an additional chronic complication of radiation, with a median interval incidence of approximately 20 years following initial exposure. The left-sided mitral and aortic valves are most frequently affected, and progressive fibrosis, thickening, and calcifications of the valvular apparatus may result in structural incompetence with stenosis and/or regurgitation.[251] Similar interstitial fibrotic changes within the myocardium result in ventricular wall stiffening with systolic and diastolic dysfunction, cardiomyopathy, and/or heart failure. Cardiac arrhythmias, such as bundle branch block, may result when electrical signal propagation through the cardiac conduction system is similarly affected by radiation-induced fibrosis.[252,253]

In general, although no specific cardiovascular screening guidelines exist for patients with prior receipt of RT, echocardiography is largely considered a first-line imaging modality for radiation-induced cardiovascular toxicity

due to its noninvasive nature and widespread utility in the assessment of multiple aspects of cardiac anatomy and physiology. Further assessment with ECG, cardiovascular CT, CT coronary angiography, cardiac stress testing, cardiac MRI, and measurement of serum biomarkers such as brain natriuretic peptide may also play a role in the diagnosis of these patients.[254,255]

The management of these and other radiation-related cardiovascular toxicities is largely in keeping with non–radiation- related cases of the same clinical entities, the details of which are beyond the scope of this text. All patients, following radiation that involves the heart and major vasculature, should be well informed regarding late risks of CAD with recommendations for a heart-healthy diet, regular exercise, appropriate primary care follow-up and as-needed blood pressure control, diabetes management as well as the addition of lipid-lowering agents, such as statins as necessary. Smoking cessation should be encouraged. For more complicated management, it is recommended that a cardiologist be intricately involved in post-treatment care.

Vascular Effects

Similar to breast and thoracic treatment, RT that targets disease in the brain and head and neck has the potential to affect local vasculature with the carotid arteries, most commonly described as at risk for stenosis and an antecedent to cerebrovascular accident (CVA).[256] Dose-dependent inflammatory effects within the vessel substructure result in atheroma development following the same cascade of events previously described for CAD.[257] The effect is stochastic without a threshold dose and becomes more probable when patients are greater than 5 years from treatment completion.[258] A large cohort study with post-treatment ultrasound analysis showed 2-, 5-, and 10-year asymptomatic stenosis rates to be 8.9%, 17%, and 29.6%, respectively.[259] Symptomatic stenosis rates for patients in this same study were reported as 1.8%, 5.1%, and 10.1%. Although a “no radiation” control was not included, longitudinal studies have reported rates of 1% to 5% (age 70-79) for asymptomatic stenosis in the general population.[260] Even high-risk populations (those with reported cardiovascular risk factors) have less than 5% prevalence of asymptomatic

stenosis.[261] The time frame for the event is unfortunately well beyond most typical cancer-specific follow-up schemes; therefore, vascular effects are likely under-identified with delayed management in the community. We typically follow up patients with a 2-year post-treatment carotid ultrasound and 5-year interval imaging from that point. However, current guidelines do not include a history of head and neck radiation as a factor to support asymptomatic screening.[262] Cardiovascular risk reduction as previously described for CAD represents current management to reduce risk. When significant or symptomatic stenosis develops, invasive procedures need to be considered, which include carotid endarterectomy and stenting. In certain situations, procedural intervention for asymptomatic stenosis may reduce the risk for CVA and transient ischemic attack.

URINARY SYSTEM

See Table 107.7 for an overview of the medical management of radiation toxicity to the urinary system.

TABLE 107.7 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE URINARY SYSTEM

Radiation Toxicity	Timing	Pharmaceutical Management

Cystitis	Acute and late	If UA negative for infection: Treat with analgesics or antispasmodics.
		Analgesics
		• Phenazopyridine (Pyridium, or OTC Azo-Standard) 200 mg PO tid
		• If insufficient advance to
		  • Prosed DS (combination of local analgesic, antiseptic, and parasympatholytic) 1 tab qid
		  • Note: Contraindicated in glaucoma, urinary bladder neck obstruction, pyloric or duodenal obstruction, or cardiospasm; do not use with sulfonamides; formulation includes atropine.
		  • Pentosan (Elmiron) 100 mg PO qd-tid
		Antispasmodics
		• Oxybutynin (Ditropan XL) 5-10 mg qd; increase 5 mg qd weekly to 30 qd max
		• Darifenacin (Enablex) 7.5 mg, advancing to 15 mg PO qd

Radiation Toxicity	Timing	Pharmaceutical Management

		• Solifenacin (VESIcare) 5 mg, advancing to 10 mg PO qd
		• Tolterodine (Detrol LA) 4 mg PO qd
		• Flavoxate (Urispas) 100-200 mg PO tid-qid
		• If symptoms persist, consider:
		  • Hyoscyamine (Levsin) 0.125-0.25 mg PO/SL tid-qid
		  • Levsinex TIMECAPS 0.375-0.75 mg PO bid-tid
		  • Hyoscyamine, phenobarbital, atropine, scopolamine (Donnatal Extentabs) 1 PO bid (to tid) belladonna/opium (B&O Supprettes, Class II) 1 supprette PR qd-qid, 15A: 30 mg opium, 16.2 mg belladonna, 16A: 60 mg opium, 16.2 mg belladonna
		If UA and culture reveal infection: 7-14 d course of antibiotics based on culture sensitivity analysis
		• 1st line
		  • Trimethoprim/sulfamethoxazole (Bactrim, Bactrim DS): 2 regular or 1 DS tablet PO bid, regular 80 mg/400 mg; DS 160 mg/800 mg
		• 2nd line
		  • Amoxicillin/clavulanate (Augmentin) 500/125 mg tid
		  • Cephalexin (Keflex) 500 mg qid
		  • Ciprofloxacin (Cipro) 250-750 mg PO bid; Cipro XR 500-1,000 mg PO qd
		  • Levofloxacin (Levaquin) 500-750 mg qd
		  • Nitrofurantoin (Macrobid) 50-100 mg qid

Hemorrhagic cystitis	Late	For pain: pentosan (Elmiron) 100 mg PO qd-tid Consider radiation fibrosis protocol with pentoxifylline and vitamin E for 3-6 mo: • Pentoxifylline (Trental) 400 mg PO tid with meals • Note: Do not use if history or cerebral or retinal bleeding. • Vitamin E (tocopherol) 1,000 IU PO qd

Prostatitis	Acute	Treat with urinary obstruction modifier.
		• For BPH or radiation edema: α-1 blockers: Note Flomax, Rapaflo, and Uroxatral carry less potential for hypotension compared to Hytrin and Cardura.
		  • tamsulosin (Flomax) 0.4-0.8 mg 30 min after same meal qd
		  • Note: may be tapered to a prn schedule
		  • Silodosin (Rapaflo) 4-8 mg PO with same meal qd
		  • Alfuzosin (Uroxatral) 10 mg PO following same meal qd

Radiation Toxicity	Timing	Pharmaceutical Management

		• Doxazosin (Cardura XL) 4 mg qd; increase to 8 qd after 3-4 wk
		• Terazosin (Hytrin) 1 mg qhs initially; increase stepwise to 2 mg, 5 mg, 10 mg (the target dose) qhs
		  • Note: may cause significant hypotension at the beginning of treatment; initiate at bedtime checking blood pressure routinely.
		• For BPH alone: 5α reductase inhibitor (antiandrogen therapy)
		  • Dutasteride (Avodart) 0.5 mg qd
		  • Finasteride (Proscar) 5 mg qd
		For severe symptoms, use a combination of α-1 blocker and 5α reductase inhibitor.
		• Dutasteride/tamsulosin (Jalyn) 1 tab post same meal qd
		For bacterial prostatitis, treat with 28 d of levofloxacin or 3 mo of Bactrim (refer to cystitis section above for dosing).

BPH, benign prostatic hyperplasia, OTC, over the counter; PO, oral; PR, by rectum; PRN, as needed; qd, everyday; qid, 4 times a day; qhs, every night; tid, 3 times daily; UA, urinalysis.

Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Radiation Nephropathy

The kidneys are inherently radiosensitive organs, with EBRT and radionuclide therapies shown to result in radiation damage causing progressive loss of renal function.[263,264] Radiation is also known to contribute to renal artery stenosis, independent of its effect on renal parenchyma.[265]

Acute radiation nephropathy presents with an onset of 6 to 12 months following radiation exposure, while chronic renal failure resulting from chronic radiation nephropathy takes years to develop. Patients with radiation nephropathy may experience hypertension as well as symptoms consistent with advanced renal failure (lethargy, edema, headaches, and dyspnea).[266] Imaging with a technetium-labeled diethylene triamine penta-acetic acid scan can detect a decrease in glomerular filtration rate, and

dimercaptosuccinic acid scintigraphy can show a decline in renal tubular function following RT.[267]

Renal protection with appropriate shielding, and/or radiation planning with dedicated renal dose constraints, is paramount and can reduce the incidence of radiation nephropathy. As with any patient with kidney disease, all patients presumed to have radiation nephropathy should be evaluated and followed by a dedicated nephrologist. Once present, treatment of radiation nephropathy consists primarily of the management of hypertension with ACEIs or angiotensin II receptor antagonists.[266] Patients with anemia may also respond to human recombinant erythropoietin.[268] Additional medication to manage fluid overload and hyperkalemia may be utilized as needed.

Radiation Cystitis

Radiation cystitis is a comprehensive term that describes the development of "irritative" bladder symptoms associated with receipt of pelvic irradiation, such as increased frequency of urination (polyuria, nocturia), increased urgency, incontinence, and/or discomfort with urination (dysuria). In clinical instances where significant blood is present in the urine (hematuria), the term "hemorrhagic cystitis" (HC) may be used. Much like RPn, the temporal development of radiation cystitis can be both acute (#3 months after RT) and chronic (>3 months after RT). Acute radiation cystitis is more common, with a reported incidence of up to 50% in one selected series, while chronic radiation cystitis is thought to affect approximately 5% to 10% of patients, with an event-free interval ranging anywhere from months to years after completion of treatment.[269,270]

As with most radiation-associated side effects, radiation cystitis remains a diagnosis of exclusion and can be easily mislabeled or conflated with alternative etiologies. Chemical exposure can also result in cystitis, and for those patients currently receiving or having received chemotherapy in the past, it is nearly impossible to accurately discern whether radiation or these other systemic chemotherapeutics (eg, oxazaphosphorines [ifosfamide, cyclophosphamide], doxorubicin, busulfan) serve as the primary inciting culprit. Given such a broad differential, any patient either receiving pelvic radiation or with a prior history of pelvic radiation presenting with new or

worsening “irritative” urinary symptoms should undergo workup with urinalysis and urine culture. A more thorough evaluation with urine cytology, dedicated upper tract imaging (CT urogram, retrograde pyelogram), and cystoscopy may also be indicated.[271]

Most mild-to-moderate cases of acute radiation cystitis can be sufficiently managed with anticholinergic medication, such as oxybutynin chloride. Mirabegron represents a potential second-line option. Patients presenting predominately with bladder spasms may benefit from the use of hyoscyamine or flavoxate hydrochloride. Dysuria may be alleviated with phenazopyridine hydrochloride, although patients should be cognizant that this medication results in orange discoloration of the urine and ideally should be used 2 to 3 times per week at maximum. Blood in the urine in the acute setting is typically mild and self-limiting, but significant, worsening, or persistent hematuria beyond a 6-week timeframe warrants further urologic workup and dedicated cystoscopy.

Patients presenting with mild-to-moderate symptoms of chronic radiation cystitis often also respond to these above-mentioned measures, although the total duration of medication use in the long-term merits further consideration, and periodic reassessment of symptoms without medication is prudent. It is our opinion that any patient presenting with severe urinary symptoms greater than 3 months following completion of pelvic RT should undergo prompt evaluation by urology to rule out other abnormalities, such as stricture, ulcer, vesicular fistula (discussed later), and/or secondary malignancy.

HC represents the most concerning and potentially severe form of chronic radiation cystitis. Initial conservative management of HC usually consists of hydration, continuous bladder irrigation, and blood transfusion as indicated with additional supportive and corrective measures (eg, reversal of coagulopathy) that address factors potentially contributing to the bleeding. Additional intravesical and extravesical therapies such as alum, silver nitrate, aminocaproic acid (Amicar), prostaglandins, or formalin may be administered. If hematuria continues despite this, patients may require cystoscopy with clot evacuation and/or fulguration of hemorrhagic sites within the bladder. Lastly, in patients with refractory and intractable cases of HC, HBO, vesical artery embolization, or urinary diversion with or without cystectomy may be necessary.[271] Diversion of urine from the

bladder—that is defunctionalizing the bladder—can serve as an effective treatment for refractory bleeding. In patients who are not suitable candidates for ileal conduit diversion, bilateral nephrostomy tubes can be placed to divert urine.

Prostatitis

Lower urinary tract symptoms, such as polyuria, dysuria, urinary hesitancy, weak urinary stream, or urinary straining, resulting from prostate-only irradiation are often a consequence of inflammation of the prostatic stroma rather than of the entirety of the bladder mucosa. Such instances of "benign prostate obstruction" may be managed with α-adrenergic receptor antagonists so as to allow for more facile passage of urine.[272] While first-generation selective α-1 adrenergic receptor antagonists (prazosin, alfuzosin) are effective for this purpose, they require twice-daily dosing. As such, prostate-selective second-generation agents, such as tamsulosin 0.4 mg, are preferable and can be used up to twice daily if needed.[273] Silodosin 8 mg daily remains an additional option if a patient's polyuria is otherwise refractory to tamsulosin. While effective, terazosin and doxazosin are associated with a more significant risk of hypotension, a side effect that may be potentiated by concurrent use of phosphodiesterase type 5 inhibitors (PDE5-I) (sildenafil, vardenafil) used for erectile dysfunction (ED).[272,274]

Urethritis, Stenosis

Urethral strictures resulting from prior pelvic irradiation are relatively infrequent, occurring in approximately 3% of patients with prostate radiation,[275,276] and appear to be most common in the setting of prior HDR brachytherapy or in patients treated with combined modalities of brachytherapy and external beam radiation.[277,278] Symptoms can often mimic benign prostatic hypertrophy symptoms, including decreased urinary stream, acute urinary retention, split urinary stream, and increased postvoid residual. Flexible cystoscopy is diagnostic. Usually, additional characteristics of the stricture are needed to plan treatment, and a retrograde urethrogram can help delineate the length and location of the stricture. Urethral stricture can be seen in the postprostatectomy salvage radiation setting, with the combination of tissue ischemia from both the surgery itself

and the radiation serving as contributing factors. Treatment options for urethral stricture are largely interventional, including minimally invasive dilation and endoscopic urethrotomy with or without drug eluting balloon placement. Urethral reconstruction (urethroplasty) or urinary diversion may be appropriate for more severe cases.[279] Postradiation strictures tend to be more challenging to treat, often with the need for tissue transfer, due to the loss of healthy vascularized tissue.

FEMALE REPRODUCTIVE SYSTEM

See Table 107.8 for an overview of the medical management of radiation toxicity to the female reproductive system.

TABLE 107.8 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE FEMALE REPRODUCTIVE SYSTEM

Radiation Toxicity	Timing	Medication Management
Vulvar and vaginal mucositis	Acute	• Betadine-medicated douche (povidone-iodine 10%; OTC): 2 tbsp concentrate to 1-quart warm water qd • Betadine-medicated gel (povidone-iodine 10%, OTC): 1 applicator full qhs; may apply externally as well • Betadine-medicated vaginal suppositories (povidone-iodine 10%, OTC): insert intravaginally qhs • Replens vaginal moisturizer (OTC): one applicator q2-3d prn • Lidocaine: Apply to affected area prn for topical anesthesia, 2.5% ointment, 4% and 5% cream. • EMLA cream (lidocaine 2.5%, prilocaine 2.5%): Apply topically prn.
Bacterial vaginosis	Acute or chronic	Topical antibiotics • Metrogel vaginal (0.75%) 1 applicator qd-bid × 5 d • Cleocin vaginal ovules (clindamycin) 1 ovule intravaginally qhs × 3 d Oral antibiotics • Metronidazole (Flagyl) 375-500 mg PO bid • Flagyl ER 750 mg PO qd × 7 d

Radiation Toxicity	Timing	Medication Management
Vaginal candidiasis	Acute or chronic	Topical antifungals • Miconazole (Monistat) 100 mg intravaginally qd × 7 d or 200 mg qd × 3 d • Clotrimazole (Mycelex) cream or vaginal tablets qd × 1, 3, or 7 d • Butoconazole (Femstat-3) qd-q3d, cream (× 3 d) or extended-release cream (× 1 d) If refractory to topical, try oral antifungal medication: • Fluconazole (Diflucan) 150 mg PO × 1 d; if refractory, 100 mg qd × 14 d
Premature menopause	Subacute	In patients with cancer who are ER-negative, consider hormone replacement therapy[428]
Hot flashes	Subacute	For mild symptoms: vitamin E 800-1,000 IU qd For severe symptoms • Paroxetine (Paxil CR) 12.5 + mg PO qd • Venlafaxine (Effexor XR) 75 mg PO qhs (titrate upward from 37.5 mg) • Clonidine patch (Catapress TTS) 0.1 mg patch q week • Methyldopa (Aldomet) 250 mg PO bid If refractory to above • Gabapentin (Neurontin) 300 mg qd × 3 d, then 300 mg tid or titrate down to effective level • Medroxyprogesterone (Depo Provera) 150 mg IM q 3 mo • Megesterol (eg, Megace) 20 mg PO bid initially; 10 mg qd or qod once responsive
Vaginal atrophy, dryness, dyspareunia	Late	Vaginal moisturizers can be used several times a week to maintain vaginal health. • Replens vaginal moisturizer (OTC): 1 applicator q2-3d prn • Hyaluronic acid vaginal lubricants should be applied prior to penetration/intercourse. • Water- or silicone-based lubricants are recommended. • Petroleum-based lubricants are not recommended (increase the risk of infection and can damage latex condoms). • Avoid lubricants with perfumes or flavors as these can be irritating.

Radiation Toxicity	Timing	Medication Management
		Low-dose vaginal estrogen is available in creams (Estrace, Premarin), tablets, and rings (Estring, Femring).[429] • Associated with minimal serum estrogen elevation Selective estrogen reuptake inhibitor: • Ospemifene (Osphena)[430]
Hypoactive sexual desire disorder	Late	Flibanserin 100 mg PO qhs[430]

OTC, over the counter; PO, oral; PRN, as needed; tbsp, tablespoon; q, every; qd, everyday; qhs, every night; tid, 3 times daily.

Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Vaginal Mucositis

Vaginal toxicity and sexual dysfunction are common for women undergoing radiation treatment of gynecologic malignancies. Selected series suggest that the highest incidence of postradiation sexual dysfunction may be seen in women undergoing multimodal treatment for cervix cancer.[280-282]

Acute vaginal mucositis is a presumptively underreported toxicity of radiation, and as such, estimates of its true incidence are difficult to ascertain. Affected patients may present with symptoms of vaginal burning, pruritus, pain, dyspareunia, and/or variable degrees of bleeding.[283] Speculum examination may reveal erythematous vaginal mucosa with variable extent of edema, ulceration, and overlying exudate; serosanguinous discharge with pooling in the posterior aspect of the vaginal canal may also be present. Clinicians should maintain a low threshold of suspicion for infectious candidal vaginitis in patients with thick, adherent white vaginal discharge, or bacterial vaginosis in patients with copious gray, thin malodorous vaginal discharge. Either of these clinical entities may develop secondarily in patients undergoing active radiation treatment and are typically treated with topical antifungals (clotrimazole, miconazole) or antibiotics (metronidazole, clindamycin), respectively.[92]

Management of noninfectious causes of vaginal mucositis is largely in keeping with the management of vulvar mucositis, and the two conditions

are often comorbid. Patients are suggested to maintain appropriate hygiene of the genitalia and perineum through frequent use of lukewarm water sitz baths. Additional cleansing of the vaginal canal directly with medicated douching of dilute hydrogen peroxide, or povidone-iodine 10% solution, also has therapeutic utility.[92,284,285] Glycerin and mineral oil–based moisturizers (Remedy cream) and topical lidocaine and/or prilocaine ointments may be applied to provide more focal relief in bothersome and symptomatic areas.[92]

Vaginal Ulceration, Necrosis, Fistula

More rarely, patients may develop more chronic sequelae of vaginal ulceration, necrosis, and/or fistula formation after completion of RT. Vaginal necrosis may appear as a small region of mucosal whitening and hypopigmentation, progressing to diffuse, "glassy" edema of the affected mucosa with exudate.[286] This often results within 15 months after completion of treatment and, if limited in extent, may resolve spontaneously or after conservative management with hydrogen peroxide vaginal douching and/or antimicrobial therapy.[287] Biopsy should be completed in equivocal cases to rule out residual disease or recurrence, although this must be weighed against concern for delayed vaginal wound healing and further tissue injury. For more severe cases, pentoxifylline, HBO, or surgical intervention with debridement may be required.[286]

Rectovaginal fistula or vesicovaginal fistula development is an additional chronic complication that may present with the passage of urine, flatus, or feces from the vaginal canal, among other locoregional symptoms such as incontinence, pain, burning, and/or bleeding. The diagnosis and treatment of vaginal fistulae is complex, and any patient suspected to have vaginal fistula should be promptly referred for surgical assessment.[288,289] Careful consideration is made of the extent of fistula and its anatomic location; conservative, nonsurgical management in patients with small or asymptomatic fistula may be attempted, while more severe but appropriately operable cases may require surgical closure of the fistula with interposition of a pedicled tissue flap.[290]

Vaginal Stenosis

Vaginal stenosis is a well-recognized late side effect of pelvic irradiation. Affected patients may present with symptoms of sexual dysfunction, including dyspareunia, vaginismus, and postcoital bleeding as early as 3 to 6 months following completion of therapy. Pelvic examination may demonstrate progressive loss of elasticity of the vaginal mucosa with the variable extent of intracavitary adhesions and occlusion, and the act of gynecologic examination itself may be prohibitively uncomfortable for affected patients.[291]

Although limited primary data support its use, management of vaginal stenosis generally consists of insertional vaginal dilator use, both for prophylaxis and as an active treatment.[292] The principle of dilation, either through regular penetrative coitus or with an appropriately sized physical dilator, is to maintain patency of the vaginal canal through manual expansion of surrounding tissues and lysis of adhesions.[293] Despite its commonplace adoption and ubiquity, no consensus exists on the frequency and overall duration of dilator use, and care must be taken in select patients to avoid the potential adverse psychological impact associated with manual dilation.[292] Many suggest utilization of vaginal dilators 3 to 5 times weekly, followed by a progressive tapering schedule with continual assessment of patient tolerance and compliance. Discontinuation of dilation may be considered when patients are no longer experiencing discomfort during vaginal examination at follow-up 1 to 2 years post-treatment, although some practitioners suggest continual dilation indefinitely.[92,293]

Sexual Interest/Arousal Disorder

Some patients who received pelvic radiation may develop sexual interest/arousal disorder. Diagnosis involves meeting any three of the following criteria: reduced interest in sexual activity, reduced sexual/erotic thoughts or fantasies, reduced initiation of sexual activity and typically unreceptive to a partner's attempts to initiate, reduced sexual excitement/pleasure during sexual activity in 75% to 100% of sexual encounters, reduced sexual interest or arousal in response to any internal or external sexual cues, or reduced genital or nongenital sensations during sexual activity in 75% to 100% of sexual encounters.[294] Referral to a

psychotherapist, or a provider who specializes in cognitive behavioral therapy or sexual psychoeducation is recommended.

Ovarian Failure and Infertility

RT is a well-known cause of premature ovarian failure (POF), early-onset menopause, and infertility. The degree of ovarian impairment subsequent to radiation is multifactorial and dependent on a number of separate variables, including total dose received by the ovaries, the dose and, fractionation regimen employed, the total pelvic irradiation volume, and uniquely, the patient's age at the time of treatment.[295-298] Of the various cell types (eg, theca, granulosa, oocyte) that are found within the ovary, germ cells appear to be the most inherently radiosensitive; the apparent dose required to kill half of all human oocytes (LD_{50}) is 2 Gy or less.[299] Since the number of ovarian primordial follicles decreases with age, older women are more susceptible to radiation-induced POF than younger women, such that the effective sterilizing dose associated with radiation at birth is 20.3 Gy, while at 30 years, the value is 14.3 Gy.[300]

All patients who desire to preserve fertility through cancer treatment should be referred to fertility specialists, and it is recommended that any patient who has a greater than 30% chance of losing fertility from subsequent cancer therapy should receive some form of fertility preservation counseling.[301]

Oophoropexy is a well-established surgical procedure that manually relocates the ovaries outside the prospective radiation field in an attempt to preserve gonadal function and potential fertility in premenopausal patients. In oophoropexy, both ovaries are laparoscopically transposed from the prospective radiation field without compromising the blood supply to the ovary or torsing the infundibulopelvic ligament.[302-305] Once transposed, the placement of radiopaque clips intraoperatively may allow for facile identification of the ovaries as OARs during CT simulation and treatment planning. Importantly, oophoropexy should only be considered in patients for whom the risk of occult ovarian metastasis is low. While oophoropexy may help maintain normal ovarian endocrine function, it is also important to recognize that transposition does not obviate the potential deleterious impact of radiation on the uterus and cervix—consequences that might

otherwise preclude normal fertilization and pregnancy in and of themselves, separately.

Additional modern techniques, such as embryo cryopreservation, immature or mature oocyte preservation, and ovarian tissue cryopreservation, also exist for patients who wish to preserve their fertility prior to RT. A detailed explanation of these techniques is outside the scope of this text. Nevertheless, as mentioned previously, each of these procedures carries with it unique requirements, benefits, and limitations that merit nuanced assessment and understanding prior to recommendation for a given individual who will undergo RT. Other newer investigation techniques, such as in vitro follicle culture, appear promising, although further research is required prior to their widespread adoption.[306]

For patients who do subsequently develop radiation-induced ovarian failure, significant vasomotor symptoms (VMS) and genitourinary symptoms of menopause (GSM) may ensue and confer a negative impact on quality of life.[307]

Hot flashes are the most frequently reported VMS of menopause, occurring in upward of 80% of women. While lifestyle modifications may be adequate to mitigate mild VMSs, patients with moderate-to-severe hot flashes often benefit from estrogen replacement therapy; this may be delivered via oral, transdermal, and cutaneous formulations.[308,309] For those who are not appropriate candidates for hormonal replacement, additional medications such as selective serotonin uptake inhibitors (SSRIs: paroxetine, citalopram, escitalopram) and selective norepinephrine uptake inhibitors (SNRIs: venlafaxine, desvenlafaxine) may be used to help mitigate VMSs. For patients who cannot tolerate SSRI or SNRI therapy, further consideration may be made for other tertiary pharmacologic agents, including gabapentin, pregabalin, clonidine, and fezolinetant, a novel neurokinin-3 receptor antagonist.[310,311]

Initial lines of therapy for GSM consist of local, nonhormonal vaginal moisturizer creams and lubricants, which can help mitigate dryness associated with mucosal atrophy. Vaginal moisturizers are recommended to be used routinely, while lubricants are generally reserved for sexual activity. For those patients with moderate GSM or symptoms otherwise refractory to moisturizers and lubricant therapy alone, additional vaginal estrogen applications may be of utility. Although levels of systemic estrogen

absorption from these local therapies are generally felt to be minimal, some caution may be warranted in patients with hormone-dependent malignancies, and an individualized discussion regarding the risks and benefits of topical estrogen for these women, based on their disease pathology and symptom severity, is suggested.[312,313] The use of vaginal estrogen therapy may be employed for patients also receiving concurrent systemic hormone replacement therapy, but with persistent atrophic vaginal symptoms.

MALE REPRODUCTIVE SYSTEM

See Table 107.9 for an overview of the medical management of radiation toxicity to the male reproductive system.

TABLE 107.9 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE MALE REPRODUCTIVE SYSTEM

Radiation Toxicity	Timing	Medication Management
Erectile dysfunction	Late	Phosphodiesterase-5 inhibitors • Tadalafil (Cialis) 10 mg qd prn (range 5-20 mg) as single dose or 2.5 mg qd (up to 5 mg qd) for continuous dosing • Vardenafil (Levitra) 10 mg PO prn (range 5-20 mg) • Avanafil (Stendra) 100 mg qd prn (range 50-200 mg) • Sildenafil (Viagra) 50 mg qd prn (range 25-100 mg)
Male hot flashes	Late	Antidepressant • Venlafaxine (Effexor XR) 75 mg PO qhs Progestional agents • Medroxyprogesterone (Depo-Provera) 150 mg IM q 3 mo • Megestrol (Megace) 20 mg PO bid, 10 mg qd or qod once responsive

IM, intramuscular; PO, oral; PRN, as needed; qd, everyday; qhs, every night; qod, every other day.

Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Erectile Dysfunction

ED is a well-recognized toxicity associated with pelvic irradiation, particularly following definitive radiation for prostate cancer. Impotence may develop anywhere from 8 to 16 months following completion of treatment, with an estimated prevalence of around 34% at 1 year that approaches 50% at 5 years.[92,314] Clinical evaluation of patients with suspected RIED generally consists of comprehensive history and physical, with particular attention to a detailed sexual history that appropriately addresses the severity, timing, and duration of sexual dysfunction as it pertains to receipt of radiation treatment.[315] Additional offending medications contributing to impotence should be discontinued and potential psychological contributors elucidated. PDE5-Is (tadalafil, vardenafil, avanafil, sildenafil) represent the general first-line treatment for radiation-induced ED. This class of medications work by inhibiting the PDE5 enzyme found within the smooth muscle of corporal penile tissue and thereby enhance the erectile, vasodilatory effects of endogenous nitric oxide.[316] PDE5-Is are generally safe, well tolerated, and efficacious.[317] Importantly, however, cavernosal nerve activation is required to initiate the physiologic cascade that mediates the effect of this medication class, and therefore, PDE5-I use is most effective in those individuals with some preexisting level of neurovascular preservation and prior capacity for sexual stimulation. In addition, PDE5-Is are contraindicated with the concurrent use of α-adrenergic and nitrate medications; the combination of both classes of medication may result in significant vasodilation and hypotension and should, therefore, be avoided whenever possible.[316]

Vacuum erection devices (VEDs) may also be employed in the management of RIED. These instruments function by exerting negative external pressure on the penile tissue, allowing for passive engorgement of blood that is maintained through the presence of external constriction ring that prevents blood outflow.[318,319] While VEDs are associated with high rates efficacy in instantiating on-demand erections, long-term compliance of this therapy may be limited by the mechanical procedure required for its use and unnatural feeling.[320,321]

Patients with persistent RIED refractory to the above- mentioned interventions should be referred to urology for further evaluation and management. In addition, second- and third-line therapies for RIED may

include intracavernosal injections, transurethral suppositories, and penile prosthesis.[320]

Oligospermia, Azoospermia, and Infertility

The development of radiation-induced male gonadal toxicity is similarly multifactorial and dependent on a number of separate variables, including total dose, dose and fractionation regimen employed, patient age, and target cell population. Of the various cell types (eg, Sertoli, Leydig, germ) that are found within the testis, germ cells also appear to be the most inherently radiosensitive. Significantly, the process of spermatogenesis is such that developing germ cells become progressively more resistant to single doses of radiation with increasing degree of maturation: that is, single doses as low as 0.1 Gy may temporarily compromise spermatogenesis via damage to spermatogonia, 2 to 3 Gy can damage the more mature spermatocytes, and doses in excess of 6 Gy may be necessary to deplete spermatids and incite permanent azoospermia.[322-325] This graded radioresistance, coupled with the prolonged time of the germ cell maturation process itself, explains the relatively unique, temporally dependent process of both radiation-induced male infertility and recovery by which lower, but increasingly fractionated doses can have a more deleterious effect on sperm production than higher, single doses of radiation. Leydig cells of the testis are otherwise less sensitive to the damaging effects of irradiation, and doses of 12 to 20 Gy are typically required for clinically relevant impairments in testosterone production.[326-329] See the endocrine section for information regarding testosterone replacement therapy.

Again, we suggest that all patients who desire to preserve fertility through cancer treatment should be referred to fertility specialists. Sperm cryopreservation—in which a semen sample is collected from a patient prior to receipt of RT and frozen in preservation—represents one of the most common methods of fertility preservation. The freezing process allows for up to 15 years of storage, with success rates of up to 40% in the use of subsequent in vitro fertilization.[330,331]

SKELETAL SYSTEM

Trismus

Trismus refers to restriction in range of motion of the jaw. The condition of trismus is thought to result from progressive radiation-induced fibrosis of the pterygoid muscles, masseter, and temporomandibular joint, leading to involuntary muscular fiber contracture and ankylosis. Patients may present with subjective sense of "lockjaw," jaw pain, jaw clicking, muscle spasm, difficulty chewing, and/or dysarthria.

Patients with radiation-induced trismus may benefit from intensive physiotherapy in which regular opening, closing, and lateral movement of the mouth are completed at regular intervals via an exercise protocol.[332] Numerous trismus appliances exist for this purpose, including externally or internally activated devices such as threaded tapered screws, tongue spatulas, and/or dynamic bite openers.[333,334] In spite of the many different appliances and techniques that exist, no clearly superior strategy for conservative management of trismus exists; most exercise regimens and rehabilitation devices appear to have similar effectiveness, and more importance remains with patient adherence to the utilized therapy.[335] Physical therapy can also help lessen edema, soften fibrous tissue, improve range of motion and muscle strength, and restore circulatory efficiency.[336]

More severe and extreme cases of trismus may require surgical intervention with coronoidectomy, myotomy tissue release, or scar tissue resection followed by free flap reconstruction.[337]

Osteoradionecrosis of the Mandible

ORN of the mandible is a sequela in which hypovascular, devitalized bone is openly exposed for a minimum of 3 months.[338] Radiation to the head and neck region is believed to induce an obliterative endarteritis of osseous and overlying soft tissue that results in progressive hypoxia and eventual necrosis; the otherwise limited, tenuous blood supply to the mandible and relatively high collateral doses to this region—particular in the primary treatment of oral cavity cancer—make it particularly susceptible to radionecrosis as compared to other at-risk adjacent bone (eg, maxilla).[339] Moreover, the phenomenon of ORN is frequently heralded by mechanical insult or traumatic injury (ill-fitting dentures, dental extractions), in which appropriate wound healing is impaired.[340] ORN is a dose-dependent toxicity in which total dose, maximum dose, and volume of mandibular irradiation

are important; smoking, preexisting poor dentition and oral hygiene, and the use of bisphosphonates represent additional identifiable patient-related risk factors.[341-346]

The incidence of ORN following RT to the head and neck approaches 3% to 8% and often develops anywhere from 2 to 4 years following treatment.[343,347,348] Patients with mandibular ORN traditionally present with a painful, nonhealing lesion or ulcer of the oral cavity. Additional ancillary symptoms may include expectoration of bone fragments, tooth luxation, periodontal disease, halitosis, trismus, dysarthria, dysesthesia, or anesthesia in the distribution of the inferior alveolar nerve. Depending on the severity of the condition, secondary osteomyelitis of adjacent bone, pathologic mandibular fracture, and/or osseous fistula may also ensue.[349] Biopsy of the wound in question is important to definitely rule out recurrent or residual malignancy.[350] Additional imaging studies may aid in diagnosis, including panoramic mandibular radiograph and CT of the head and neck, demonstrating radiolucencies and cortical bone disruption, respectively.

The risk of ORN is best mitigated through appropriate radiation treatment planning that minimizes excess radiation dose to the mandible, and avoidance of unnecessary oral trauma. Preradiation dental extractions are preferred to postradiation dental extraction, and for this reason, any patient who is anticipated to undergo head and neck radiation should have formal dental evaluation prior to initiation of RT.[340] Once present, asymptomatic or mildly symptomatic cases of ORN may be managed conservatively with appropriate pain control, good oral hygiene (frequent saline irrigation), antimicrobial therapy, and/or minimal dental interventions as needed; filing, smoothening, and debridement of sharp, exposed bone and bony fragments can be performed to prevent aggravation and injury of adjacent buccal, gingival, and lingual tissue.[351,352] Patients with more significant symptoms, symptoms refractory to first-line conservative therapies, or with substantial evidence of necrosis merit formal evaluation by otolaryngology and are instead treated via invasive surgical approaches (wound debridement, sequestrectomy, decortication, or radical mandibular surgical resection and microvascular reconstruction).[353]

The role of HBOT in mandibular ORN is conflicting and controversial. Conclusive data supporting HBO's benefit in this setting are lacking. HBO treatments are time-consuming, often consisting of 30 consecutive daily

sessions, each of which is approximately 90 minutes in duration.[354] As such, many refrain from routine HBO use in the modern era, recommending therapy on a case-by-case basis for those with persistent ORN in spite of conservative management and/or more aggressive surgical approaches as earlier.[355] Pentoxifylline and tocopherol (vitamin E) therapy has shown therapeutic promise as synergistic antifibrotic agents to help treat refractory ORN, although adoption of this regimen awaits further prospective randomized data.[356]

Osteoradionecrosis of the Femur (Aka Avascular Necrosis)

ORN of the femur may result from prior pelvic irradiation via a mechanism that is presumed commensurate with that of both mandibular ORN and pelvic insufficiency fracture (PIF): namely, progressive vascular obliteration that results in local ischemia, bony matrix remodeling, and structural weakening that predisposes to fracture or collapse. Patients with ORN of the femur may, therefore, present with more overt symptoms of hip, groin, thigh, and/or buttock pain and limited mobility than other patients with occult, asymptomatic PIF.[357]

Initial, conservative therapeutic management may consist of analgesia with nonsteroidal anti-inflammatory agents, limitation or avoidance of weight bearing, and biophysical therapy to improve motion and gait.[358] Surgical interventions for cases of hip ORN are based on preoperative staging criteria and may include femoral core decompression or bone grafting for early stages versus total hip arthroplasty for more advanced stages.[359] ORN of the humeral head has also been reported in the breast radiation literature, and workup/management is similar.

Costochondritis

RT to the breast, chest wall, lung, or mediastinum may also precipitate costochondritis, as evidenced by tenderness of the costochondral junctions in anatomic areas corresponding to prior treatment fields. A paucity of data exists regarding the frequency and management of this toxicity in the setting of RT, although treatment is generally supportive: simple analgesia with NSAIDs, and topical heat or ice application for similar purposes when the overlaying skin is otherwise intact, is usually sufficient. Rarely,

escalation to additional narcotic pain medication, use of local anesthetic injections, or corticosteroids may be necessary.[360] Some case series have reported instances of necrotic, secondarily infected radiation-related costochondritis in patients with postoperative breast cancer requiring surgical debridement.[361] See Table 107.10 for an overview of the medical management of costochondritis.

TABLE 107.10 MEDICAL MANAGEMENT OF RADIATION-INDUCED COSTOCHONDRITIS

Radiation Toxicity	Timing	Medication Management
Costochondritis	Acute	NSAIDs • Ibuprofen 200-800 mg q4-6h, 3,200 mg/d max • Naproxen 250-500 mg q12h, 2,500 mg/d max

NSAIDs, nonsteroidal anti-inflammatory drugs; q, every.
Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Pelvic Insufficiency Fracture

PIFs are a well-recognized late side effect of pelvic RT. The process of pelvic irradiation is believed to cause progressive osteoblast reduction in the bone matrix, fatty marrow replacement, and obliterative ischemia of osseous tissue, and PIFs are believed to occur when normal biomechanical stresses overwhelm the compromised integrity of this structurally weakened, inelastic bone.[362,363] The reported rates of insufficiency fracture incidence vary widely in the historic literature—from levels less than 1% to as high as 89%—and are most frequently associated with RT for gynecologic malignancies. More modern estimates place the crude incidence of PIFs around 15%, with a median time to diagnosis between 8 and 39 months.[364]

Patients with PIFs will most often present with complaints of intractable pain in the region of the lumbar spine, sacrum, hips, groin, or pelvis, which may or may not radiate distally to the legs. These symptoms may be exacerbated by weight bearing.[365] Other patients may remain entirely asymptomatic, such that the diagnosis of PIFs is made on the basis of

radiologic imaging alone. The sacrum and pubis are the most common sites of PIFs.[364]

Prevention of PIFs is largely directed at modification and mediation of risk factors; individuals with osteoporosis should undergo appropriate screening, evaluation, and management with reversal of secondary causes of osteoporosis when indicated. Vitamin D and calcium supplementation may be necessary.

Currently, there is little consensus regarding the treatment of radiation-induced PIFs, and these patients are best managed in a multidisciplinary setting including orthopedic surgeon and endocrinology. Conservative approaches are typically suggested initially, through the use of analgesics and appropriate mobilization, with assisted ambulation, transfers, and weight bearing as tolerated. The role of bone-directed antiresorptive agents, such as bisphosphonates, in the setting of acute fracture remains unclear. Operative intervention with sacroplasty or internal fixation may be considered for those who fail medical and nonoperative therapies.[365]

Another common location for radiation-related insufficiency fractures includes ribs in the setting of thoracic SBRT and breast irradiation and is typically managed conservatively with pain management and rest.

INTEGUMENTARY SYSTEM

See Table 107.11 for an overview of the medical management of radiation toxicity to the integumentary system.

TABLE 107.11 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE INTEGUMENTARY SYSTEM

Radiation Toxicity	Timing	Medication Management
Dermatitis	Acute	Moisturizers used to prevent and treat: Aquaphor, Calendula, Calmoseptine, Miaderm, etc Domeboro compresses: Dissolve 1 tablet or packet in 1-pint water and apply moist (not wet) soak 20 min tid-qid. Topical analgesics: Aquaphor/Xylocaine 5% ointment, topical lidocaine 2.5% ointment and 4% or 5% cream, EMLA (lidocaine 2.5%, prilocaine 2.5%)
Pruritus	Acute	Topical steroids: hydrocortisone 1% (OTC), betamethasone 0.05%, desoximetasone cream

Radiation Toxicity	Timing	Medication Management
		0.25%, 0.05%, ointment 0.25% Sarna sensitive (OTC, 1% hydrocortisone; 1% pramoxine)
Miliaria rubra aka inflammation of sweat glands	Acute	Topical steroids: hydrocortisone 1% (OTC), betamethasone 0.05%, desoximetasone cream 0.25%, 0.05%, ointment 0.25%
Moist desquamation	Acute	Silvadene cream 1% or SilverMed (OTC): Apply to affected area tid. Mupirocin applied 3 times daily. Domeboro compresses: Dissolve 1 tablet or packet in 1-pint water and apply moist (not wet) soak 20 min tid-qid prior to topical ointments/creams. Nonstick adhesive pads (eg, Tefla) or hydrocolloid and hydrogel wound dressings
Ulceration/slow healing	Subacute or late	In addition to the above-mentioned skin care, consider debridement with saline or MPM wound and skin cleanser. Capillary bed stimulant: Xenaderm (Balsam of Peru, trypsin, and castor oil) applied bid-tid. Pentoxifylline 400 mg PO tid with vitamin E 1,000 IU PO qd
Wound infection		For minor/superficial open wound infections • OTC Bacitracin or Polysporin • Advance to Silvadene 1% or mupirocin For uncomplicated subcutaneous involvement • Trimethoprim/sulfamethoxazole (Bactrim DS) 1 PO bid • Cephalexin (Keflex) 250-500 mg PO q6h For patients who are diabetic or infections of the groin and perineum, add • Clindamycin 150-450 mg PO q6h If pseudomonas is suspected • Ciprofloxacin 250-750 mg PO bid or XR 500-1,000 mg PO qd • Levofloxacin 500-750 mg qd
Fungal/yeast infection		OTC: Terbinafine (Lamisil) applied bid or Lotrimin antifungal applied bid if refractory try naftifine 1% applied qd or fluconazole 200 mg day 1, then 100 mg qd.
Herpetic infections		For herpes simplex

Radiation Toxicity	Timing	Medication Management
		• Valacyclovir 1 g bid × 7 d • Acyclovir 200 mg PO 5 times daily × 10 d For herpes zoster • Valacyclovir 1 g tid × 7 d • 800 mg PO 5 times daily × 7-10 d
Capsular contracture around breast prostheses	Late	Leukotriene antagonist Singulair 10 mg qd for 3 mo Trental 400 mg tid with vitamin E 1,000 mg qd for 6 mo
Fibrosis	Late	Trental 400 mg tid with vitamin E 1,000 mg qd for 6 mo Pravastatin 40 mg daily

bid, 2 times daily; OTC, over the counter; PO, oral; q, every; qd, everyday; qid, 4 times a day; tid, 3 times daily; XE, extended release.

Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Radiation Dermatitis

Radiation dermatitis is one of the most common and conspicuous side effects of RT, such that 90% or more of patients will experience some extent of radiation-related skin reaction.[366] Acute radiation changes include erythema, dry desquamation, moist desquamation, poor wound healing, skin necrosis, and/or ulceration. Chronic radiation dermatitis may arise from months to several years after treatment and may present as hypo- or hyperpigmentation, skin fibrosis/scarring, skin atrophy, and telangiectasias.

The recommendations for the management of radiation dermatitis are somewhat discordant across multiple series of national and international guidelines, as there is a relatively narrow window of medications or interventions that can be strongly supported on the basis of level 1 evidence; some paradigms of approaches to therapy are based on clinical practice.[367] Topical steroids such as beclomethasone, hydrocortisone 1%, or mometasone furoate 0.1% appear to decrease the risk of patient-reported symptoms and moist desquamation.[368] A number of additional topical agents have been investigated as prophylaxis for radiation dermatitis, all with either weak or contradictory data to support their use: petroleum-based ointments, ascorbic acid, almond oil or olive oil, triethanolamine, silver

sulfadiazine, calendula cream, barrier films, silver nylon dressing, and sucralfate.[369]

Patients with common terminology criteria for adverse effects (CTCAE) grade 1 radiation dermatitis are characterized as having faint skin erythema and peeling.[370] Such patients can be managed with general precautionary advice, with maintenance of appropriate skin hygiene and moisturization with hydrophilic ointments. Patients with notable irritation and pain may benefit from the use of Aquaphor/xylocaine ointment 5% mixture for soothing.[92]

Grade 2 and 3 radiation dermatitis includes those with moderate redness and swelling with thinning of skin folds, or skin thinning more than 1.5 cm across not limited to folds, with severe swelling.[370] Treatment generally consists of focal dressings—usually silicone foam bandage, hydrogel, or hydrocolloid—over areas of exposed skin to help minimize insensible fluid loss, prevent secondary superinfection, and accelerate normal skin repopulation and reepithelialization. Additional use of Silvadene cream and Burow solution soaks (aluminum sulfate tetradecahydrate/calcium acetate monohydrate astringent) may be helpful.[92]

Any patient with evidence of skin infection or cellulitis should begin topical (mupirocin) and/or systemic therapy with antibiotics. Patients with grade 3 dermatitis may require treatment breaks to allow for appropriate healing. Grade 4 radiation dermatitis is defined by skin necrosis or ulceration of the full thickness of the dermis, from which spontaneous bleeding may occur.[370] Skin necrosis is typically described as leathery in texture, yellow in appearance, and adherent.[371] Patients who develop ulceration should have appropriate wound debridement and irrigation to keep the skin and soft tissue clean and free of debris.[92] Grade 4 radiation dermatitis is relatively rare and should be treated on a case-by-case basis; more conservative management may consist of silver sulfadiazine cream, capillary stimulation with Balsam of Peru/trypsin/castor oil, and covering with a hydrocolloid or hydrogel, although most patients require specialized wound care. More severe and refractory cases may merit surgical intervention, with methods including advanced reconstructions with skin flaps or artificial skin.[372,373] HBO has been used for chronic nonhealing skin ulceration or necrosis, although well-designed clinical trial data to substantiate the efficacy of HBO in this setting have not been completed.[374]

The therapies for chronic radiation dermatitis are more limited, and we suggest a formal evaluation by dermatology and/or plastic surgery for patients with persistent, bothersome sequelae. Again, the use of rehabilitative care and deep friction manual massage has been suggested to help manually dissipate scar tissue and fibrosis with softening over time. Trials of pentoxifylline and vitamin E have shown promise in managing cutaneous radiation-related fibrosis and scarring, although the therapeutic effect required prolonged administration over years, which may limit patient adherence.[375] Additional options for skin or soft tissue fibrosis that have been suggested include liposomal-encapsulated superoxide dismutase injections and fractional laser therapy, both of which also remain investigational at present.[376,377] Patients with breast cancer with post-treatment telangiectasias have been treated with multiple pulsed dye-laser treatments with satisfactory cosmetic results.[378,379]

Mastalgia, Post-Breast Surgery Pain Syndrome

Patients who are receiving whole- or partial-breast RT may experience worsening mastalgia, often experienced as the onset of sharp, shooting, shock-like sensations, referred to as “zinger pains” or “zingers.” Radiation may also increase the frequency or conspicuity of such pain, which may otherwise normally be present in the postoperative period.

Little randomized data exist to guide a formalized process of workup or management of such patients, given the ubiquity, and generally self-limiting nature of this form of mastalgia. All such patients should have additional competing etiologies of breast pain—including mastitis, cellulitis, seroma, or hematoma formation—ruled out through physical examination and dedicated imaging as necessary, per clinical judgment. Analgesia with NSAIDs is typically a sufficient treatment for zinger pain, with escalation to additional opioid medication or neuropathic pain medications if relief is not achieved by more conservative regimens.

Patients may also experience “post-breast surgery pain syndrome” (PBSPS), a more chronic form of neuropathic pain in the absence of disease recurrence, which persists for greater than 3 to 6 months. PBSPS, previously referred to as postmastectomy pain syndrome—is a comprehensive diagnosis that includes a variety of conditions including

phantom breast pain, pain resulting from intercostobrachial nerve injury, or neuroma formation, all of which may be exacerbated by prior breast or chest wall RT, likely through mechanisms of perineural and intraneural fibrosis. Younger patient age at the time of surgery appears to be associated with this syndrome, which is often accompanied by symptoms of persistent hyperesthesia, hypoesthesias, and numbness of the affected breast or chest wall.[380,381] Given the wide variety and potentially multifactorial causes of PBSPS, these patients often require multidisciplinary evaluation between surgical oncology, plastic surgery, and pain management specialists. Identification of the underlying etiology of pain is paramount for appropriate treatment, which may include neurolysis, autologous fat grafting, topical capsaicin cream, tricyclic antidepressant, and/or antiepileptic neuropathic pain medications.[380-382]

Breast Fibrosis/Contracture

Radiation-induced breast or chest wall fibrosis typically presents 4 to 12 months following completion of RT, and affected patients may experience symptoms, such as breast shrinkage and induration, breast contraction, delayed wound healing, and/or diminished range of motion of the upper extremity.

The risk of radiation-induced breast or chest wall fibrosis does appear to be impacted by the nature of prior breast oncologic surgery and reconstruction. Immediate, rather than delayed, breast reconstruction may be preferred by patients and surgeons alike in its ability to lessen the psychological impact of mastectomy, better concord to preoperative quality of life, eliminate need for second operation and anesthesia, and obviate risks associated with resection of irradiated tissue. Unfortunately, this approach of immediate reconstruction is also associated with increased risk of complications. Irradiation of a foreign body, whether a tissue expander or breast implant—is associated with increased rates of toxicity and cosmetic side effects, including fat necrosis, breast volume loss, and capsular contracture. These side effects exist irrespective of impact on postmastectomy radiation techniques. Unfortunately, such toxicity does not appear to be avoided with the use of retropectoral implants or when the prosthesis is covered by a tissue flap.[383-388] This recommendation also exists

for transverse rectus abdominis muscle flap reconstruction, where higher incidences of complication are noted with immediate versus delayed reconstruction.[389] As such, increasing consensus exists for delayed reconstructive techniques in which breast reconstruction is performed several months following completion of postmastectomy radiation.[390] Delayed-immediate reconstruction also exists, by which the mastectomy skin envelope is preserved with a tissue expander that is deflated during RT and later inflated and replaced by a tissue flap.[386]

Additional preventive efforts include the use of prophylactic oral pentoxifylline and vitamin E for at least 6 months in selected high-risk patients (ie, those undergoing reconstruction). Multiple trials have demonstrated significant benefits in various fibrosis-related end points associated with this form of medical management, including direct measurement of tissue compliance of the irradiated breast or chest wall.[391-393] Additional isolated randomized trials have investigated reducing RF with the use of deep friction massage/endermotherapy and kinesiotherapy, which have the ability to manually break down fibrotic tissue, improve muscular elasticity, and conserve a functional range of motion.[393-395]

LYMPHATIC SYSTEM

Lymphedema of the Extremities

RT-related peripheral lymphedema may affect both the upper and lower extremities, although is most frequently associated with upper extremity lymphedema in the setting of prior breast RT, and lower extremity edema in the setting of prior gynecologic RT.

The risk of radiation-related upper and lower extremity edema is compounded by prior surgery; the extent of axillary surgery is a known risk factor of breast cancer–related lymphedema (BCRL), such that axillary lymph node dissection may quadruple the risk of BCRL than sentinel lymph node biopsy.[396] Similarly, the extent of pelvic lymph node dissection appears to increase the risk of lower extremity lymphedema in endometrial cancer.[397] The greater extent of prior radiation fields (supraclavicular, posterior axillary, internal mammary nodal coverage) also increases the risk of BCRL, with additional independent risk factors including elevated body mass index (BMI) at the time of cancer diagnosis, and preexisting cellulitis.

Symptoms of radiation-related extremity lymphedema typically present months to years following surgery and may include notable extremity edema with restriction of clothing in the affected leg or arm, subjective sense of heaviness of the affected extremity, and/or pain. Screening for population at risk is suggested, which requires objective limb measurements both at baseline and regular intervals over time—potentially as often as every 6 to 12 months for up to 3 years. BCRL is typically defined as a relative volume change of 10% or more, or weight-adjusted change of 10% or more, greater than 3 months after surgery.

Preventive measures include judicious use of radiation, management of obesity and maintenance of a healthy BMI, and exercise of the affected limb. Any potential soft tissue infection should be addressed before radiation treatment. Additional precautionary actions include preferential avoidance of blood pressure cuffs or venipuncture and the use of compression hosiery during air travel: nevertheless, some feel that these risk-reducing recommendations were initially adopted based on the preponderance of precaution and that there is a lack of robust data to support their widespread adoption or efficacy.[398]

Once peripheral lymphedema is present, all patients are recommended to meet with a certified lymphedema therapist for evaluation and treatment. Again, these licensed professionals may assist patients with complete decongestive therapy with serial bandaging and manual lymphatic drainage and can provide instruction on appropriate home exercises to increase range of motion and mobility. Once patients have experienced adequate lymphedema reduction, a “maintenance phase” of therapy may be ensured with the use of additional compression garments and self-directed manual lymphatic drainage.[396,399,400]

Lymphedema of the Head and Neck

Lymphedema of the head and neck is well-established but likely underreported late toxicity; it is believed that upward of 75% of patients who receive prior head and neck irradiation will experience some form of local lymphedema and that many patients have some preexisting form of lymphedema even prior to treatment due to local tumor involvement and inherent lymphatic disruption.[401]

External lymphedema may be appreciated by visual examination of the head and neck showing visible swelling of the skin and soft tissue, and the patient may report notable cosmetic changes in the face, submental, submandibular, neck, and shoulder regions, as well as a subjective sense of tightness and limited cervical range of motion. Internal lymphedema requires direct examination and/or flexible endoscopy of the upper aerodigestive tract and is evinced by turgidity of the mucosa and underlying soft tissue of the oral cavity, pharynx, and/or larynx. Depending on its anatomic location, internal lymphedema may result in dysphagia, dysarthria, dysphonia, and wheezing with concern for potential airway compromise and need for tracheostomy.[402,403]

Most patients with lymphedema can be managed through approaches of education, complete decongestive therapy, stretching exercises, and appropriate skin care. Minimizing select postures and body positions, for instance, may help mitigate gravity-dependent reducible edema in certain locations. Manual lymph drainage and compression therapy may help return lymph back into the circulatory system, facilitating the regression of soft tissue swelling and preventing the deposition of fibrofatty scar tissue that results in permanent neck fibrosis.[404] Various pneumatic compression devices may also aid in this purpose.[405] Qualified physical and occupational therapists trained in lymphedema management may assist patients with decongestive therapy and can provide instruction on appropriate home exercises to increase range of motion and mobility. Surgical revascularization attempts via lymphaticovenous anastomosis appear promising, but remain investigational in this setting.[406,407] Patients with overt neck fibrosis may benefit from the use of pentoxifylline.[408]

ENDOCRINE SYSTEM

See Table 107.12 for an overview of the medical management of radiation toxicity to the endocrine system.

TABLE 107.12 MEDICAL MANAGEMENT OF RADIATION TOXICITY OF THE ENDOCRINE SYSTEM

Radiation Toxicity	Timing	Medical Management
Hypopituitarism	Late	Endocrine supplementation
Hypothyroidism	Late	Levothyroxine supplementation titrated based on TSH level
Premature menopause	Subacute	In patients with ER-negative cancer, consider hormone replacement therapy.[428]
Testosterone deficiency	Late	Testosterone replacement therapy • Testosterone gel (Androgel) 1.62% 40.5 mg (2 pumps or 1 packet) applied to shoulders and upper arms daily (dose adjusted to maintain testosterone levels between 350 and 750 ng/dL)[423] Lack of evidence for use in patients with prostate cancer[421]

ER, estrogen receptor; TSH, thyroid-stimulating hormone.
Dziuk T. *Commonly Prescribed Medications in Radiation Oncology*. 11th ed. https://www.texasoncology.com/getmedia/ddb81e5b-0532-4200-b25e-20a538cd9221/Commonly-Prescribed-Medications-in-Radiation-Oncology.pdf

Hypopituitarism

Patients who receive cranial irradiation, total body irradiation, and radiation to the nasopharynx or skull base are at risk for hormone deficiency secondary to hypothalamic and pituitary injury, with decreased production of growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), and gonadotropins (luteinizing hormone and follicle-stimulating hormone). Central obesity due to hypothalamic damage, in which patients experience appetite dysregulation and significant weight gain, may also result, presumably through a mechanism of impaired leptin and insulin homeostasis.[409,410]

Early detection and treatment of radiation-induced endocrinopathy are particularly important in the pediatric population, where appropriate hypothalamic-pituitary axis function is implicated in meeting age-appropriate milestones of growth, physical and mental development, and psychosocial attainment.[411] Radiation dose, age at treatment, and length of time from irradiation are independent predictors of endocrinopathy within this cohort.[411]

The diagnostic criteria for classification of radiation-induced endocrinopathy are distinct for each hormone and may take both laboratory

values and clinical factors into account. GH appears to be the most sensitive of the anterior pituitary hormones to the effects of radiation, such that GH deficiencies following RT are most common. The incidence of radiation-induced ACTH and TSH deficiencies is much lower, although discrepancies exist in the literature regarding the exact descending sequence of hormones that are most-to-least commonly affected and may in fact be distinct between pediatric and adult populations.[412]

Strategies that help minimize radiation dose to the hypothalamus and pituitary gland, such as proton beam therapy, may be employed to help mitigate the risk of radiation-induced endocrinopathy. Once present, hypopituitarism is generally irreversible and progressive; all patients at risk for hypopituitarism should be evaluated by a dedicated endocrinologist prior to initiation of RT, where pretreatment levels of key hormones and implicated hormone mediators may be obtained and followed longitudinally over time. Requisite long-term hormone replacement is the primary form of treatment, and patients may also require stress doses of steroids in instances of acute insult or illness.[413]

Hypothyroidism

Primary radiation-induced hypothyroidism is defined as low level of blood thyroid hormone due to direct insult to the thyroid gland, often as a result of head and neck irradiation. This is important to distinguish from *secondary* radiation-induced hypothyroidism, which occurs after hypothalamic or pituitary damage precludes the normal production of TSH (see section "Hypopituitarism"). Thyroid hormone deficiency in primary hypothyroidism is indicated by a serum level of TSH (thyrotropin) elevated above the upper limit of normal: 4 mU/L is a typical reference value.[414]

The presentation of hypothyroidism is quite variable. Patients with clinically overt hypothyroidism may develop symptoms such as fatigue, cognitive slowing, weight gain, cold intolerance, brittle hair or hair loss, xerosis, decreased wound healing, constipation, myalgias, and/or soft tissue edema. Pediatric hypothyroidism can also result in significant growth retardation and developmental delay. Subclinical hypothyroidism, however, is generally symptomatically occult and suggested only by elevated serum TSH values with normal serum T4 (thyroxine).[414]

More modern, comprehensive estimates suggest a higher incidence of radiation-induced hypothyroidism in the range of 40% to 50%, which is likely owing to improved routine modern screening practices; the incidence of hypothyroidism based solely upon the presence of clinical symptoms is low, with a mean value of approximately 5%.[415] Radiation-induced hypothyroidism typically manifests months to years after RT, with a median onset of 1 year.[416] Female sex, decreased thyroid volume, and receipt of multimodal therapy (surgery, chemotherapy) have been associated with increased risk of radiation-related hypothyroidism.[415]

Radiation-induced hypothyroidism is treated with synthetic T4 (levothyroxine), which represents standard replacement therapy. A few different formulations of synthetic T4 exist, including liquids, tablets, and gel capsules that are taken without food.[417] All patients with hypothyroidism merit evaluation by a dedicated endocrinologist or other appropriate medical practitioner, as management will require continual monitoring and potential dose adjustment every 8 to 12 weeks based on serum TSH concentration and amelioration of preexisting symptoms.[418,419]

Radiation-Induced Premature Menopause

Protecting the ovaries from off-target collateral radiation with the use of appropriate treatment planning and delivery techniques is ideal. Nevertheless, in most cases of pelvic malignancies requiring RT, the natural anatomic proximity (and inherent mobility) of the ovaries to the uterus, cervix, bladder, and rectum makes achieving this goal challenging, even with modern OAR-sparing IMRT. To this end, oophoropexy is a well-established surgical procedure that manually relocates the ovaries outside the prospective radiation field in an attempt to preserve gonadal function and potential fertility in premenopausal patients.

For patients who do subsequently develop radiation-induced ovarian failure and premature menopause, significant VMSs and GSM may ensue and confer a negative impact on quality of life.[307]

Hot flashes are the most frequently reported VMS of menopause, occurring in upward of 80% of women. They are characterized by a sudden flush of warmth that envelops the torso and face before radiating to the remainder of the body and often last for only a few seconds or minutes

before self-resolving. While lifestyle modifications may be adequate to mitigate mild VMSs, patients with moderate-to-severe hot flashes often benefit from estrogen replacement therapy; this may be delivered via oral, transdermal, and cutaneous formulations.[308,309] Importantly, estrogen replacement should not be administered to those with a history of estrogen-based, hormone-dependent malignancies (eg, estrogen receptor–positive breast cancer), and individuals with an intact uterus will require coadministration of progestins to decrease the risk of endometrial proliferation and neoplasia. Additional hormone replacement contraindications include use in patients with a prior history of deep venous thrombosis and/or clotting disorder, CAD, and chronic liver disease, among other factors and comorbidities.[420] As such, it should be mentioned that a particular patient's candidacy for and selection of hormone replacement therapy should only be determined by a dedicated medical practitioner who specializes in reproductive medicine (obstetrician/gynecologist, reproductive endocrinologist) and is well acquainted with the patient's prior cancer history.

GSM vulvovaginal atrophy may manifest with symptoms such as vulvar burning, pain, dryness, and concomitant dyspareunia.[309] Refer to the female reproductive section for more details on the management of these symptoms.

Patients treated with pelvic radiation may develop low testosterone levels. Typical presentation may include reduced libido, decreased spontaneous erections, testicular atrophy, loss of body hair, low bone mineral density, gynecomastia or breast discomfort, and hot flashes. Less specific symptoms include fatigue, depression, and muscle atrophy. Chemical confirmation with serum morning total testosterone levels is the initial diagnostic test. If total testosterone is near the lower limit of normal, an additional test of free or bioavailable testosterone level is recommended. Referral to an endocrinologist is advised. Androgen replacement therapy may be subsequently recommended for men with symptoms to improve sexual function, maintain secondary sex characteristics, improve muscle mass and strength, elevate bone mineral density, and enhance general well-being.

Although there is a lack of data on the safety of androgen replacement therapy in patients with previously treated prostate cancer, it is generally

not advised out of a principle of caution.[421] Androgen replacement therapy is also not advised in patients with a history of breast cancer, palpable prostate nodules, prostate-specific antigen levels greater than 4 ng/mL, men at high risk for prostate cancer, hematocrit more than 50%, severe sleep apnea, severe lower tract urinary symptoms with an International Prostate Symptom Score of greater than 19, or poorly controlled heart failure.[422] Treatment consists of testosterone gel applied to the shoulder and upper arms (locations that will not be direct contact with other people) daily with dose adjustments to maintain testosterone levels between 350 and 750 ng/dL.[423]
