It has been well reported that pediatric patients are more sensitive to brainstem toxicity following RT as compared to adult patients and are treated to lower dose threshold.[96,147] Haas-Kogan et al[148] reviewed the outcomes of symptomatic brainstem toxicity from the three largest U.S. pediatric proton centers as part of a National Cancer Institute workshop on PT for children. The overall incidence of toxicity was 2.4% and the actuarial rate of grade ≥2 brainstem toxicity was successfully reduced from 12.7% to 0% at one center after adopting modified radiation guidelines, which included reducing the brainstem goals to D(0.1 mL) to <56.6 GyRBE, D(10%) <55.4 and D(50%) <52.4.[147] Guidelines for treatment planning and current consensus brainstem constraints for PT were presented from each group and note they are more conservative than what is currently being used for adult patients with skull base tumors. Note that these OAR constraints differ substantially from that provided in Table 54.7 for adult practice patterns from Mayo Clinic Florida.

ESTHESIONEUROBLASTOMA

Esthesioneuroblastoma (ENB), also referred to as olfactory neuroblastoma (ONB), was first described by Berger and Luc.[149] They are thought to arise in the olfactory receptors in the nasal mucosa or the cribriform plate of the ethmoid bone. The olfactory nerves perforate grooves in the ethmoid bone in the cribriform plate and continue into the subarachnoid spaces, accounting for the high incidence of intracranial extension.[149]

Epidemiology

ENB constitutes 3% of all endonasal neoplasms and 0.3% of all upper aerodigestive tract malignancies, and over 1,000 cases have been reported in the world literature.[149] There appears to be a slight male predominance, and 80% of patients in SEER database from 1973 to 2014 were White.[150] The age distribution was unimodal, with ENB most frequently occurring in the fifth to sixth decades of life. Only 8% of all ONBs are diagnosed prior to 25 years of age.

Natural History

Although others thought that ENB was of ectodermal origin, most observers believe the tumor to be of neuroectodermal origin in the olfactory epithelium.[149] Most of these tumors occur high in the nasal cavity or in the lateral wall adjacent to the ethmoid. The tumor may spread to the opposite ethmoid bone, superiorly to the frontal sinus and anterior cranial

fossa; posteriorly to the sphenoid sinus, nasopharynx, and base of the skull; laterally to the orbits, forward to the frontonasal angle; or inferiorly to the nasal cavity and antrum (Figure 54.14). Lymphatic spread may be to the subdigastric, posterior cervical, submaxillary, or preauricular nodes, as well as to the nodes of Rouvière. The exact incidence of distant metastases is uncertain; it has been stated to be as high as 50%, but this rate is influenced by the use of chemotherapy in high-risk patients.

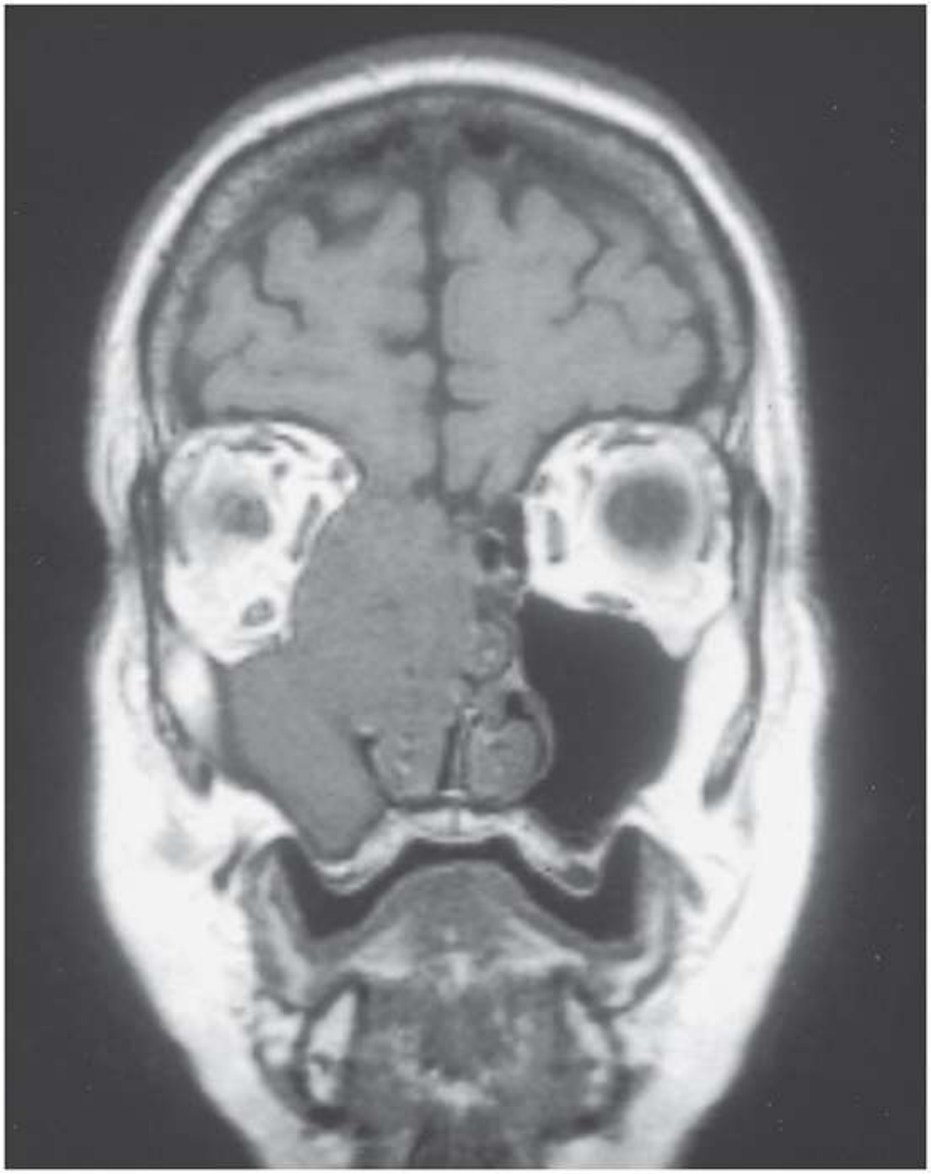

FIGURE 54.14 Coronal magnetic resonance imaging scan showing a large soft tissue mass and bone destruction in the right ethmoidal maxillary sinuses and nasal cavity secondary to extensive (Kadish stage C) esthesioneuroblastoma.

Clinical Presentation

These tumors tend to be friable and bleed easily. The most common clinical symptoms are epistaxis and nasal blockage. Patients may also have local pain or headache, visual disturbances, rhinorrhea, tearing, proptosis, or swelling in the cheek.[151] The symptoms may be associated with a mass in the neck.

Diagnostic Workup and Staging

Physical examination may show the inferior aspect of a polypoid friable mass in the nasal cavity. Ocular findings or a mass in the nasopharynx may be present. With early lesions, CT or MRI may show only nonspecific opacification, soft tissue swelling, and, occasionally, bone destruction.[152] Octreotide is a somatostatin analog that, when coupled to a radioisotope, produces a scintigraphic image of NETs expressing somatostatin type 2 receptors. Octreotide scintigraphy may be useful in confirming the preoperative diagnosis of certain H&N NETs, such as PGs, Merkel cell carcinomas, medullary thyroid carcinomas, and ENBs. Bustillo et al[153] carried out a retrospective study that compared the results of octreotide scintigraphy with the histopathologic diagnosis in 74 patients with H&N NETs. Of the 60 patients undergoing evaluation for suspected PG, octreotide scintigraphy was correctly positive in 36 of 37 patients with PG and correctly negative in 19 of 23 patients who did not exhibit PG (sensitivity of 97% and a specificity of 82%). There were 14 patients in the nonparaganglioma group. Octreotide scintigraphy detected or diagnosed locoregional recurrences in two with ENB.

Table 54.6 outlines the suggested diagnostic workup. CT provides the best information about the tumor and its local invasion into surrounding bone structures.[154] MRI allows an estimate of tumor spread into surrounding soft tissue areas, such as the anterior cranial fossa and the retromaxillary space. PET-CT (preferred) or bone scintigraphy scan is useful in detecting distant metastases.

The expansile tendency of ONB is characterized by bowing of the sinus walls. The destructive aspect is manifested as tumor replacing the turbinates, septum, and sinus walls with extension into contiguous areas (Figures 54.14 and 54.15). The density or signal and enhancement characteristics are nonspecific of ONB.

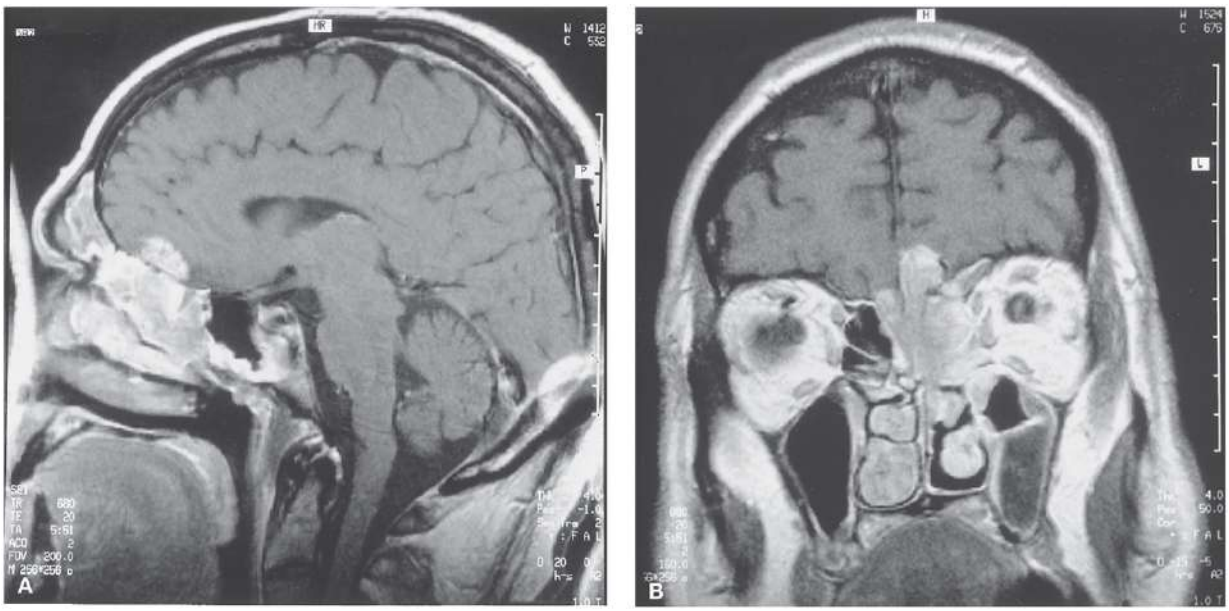

FIGURE 54.15 Sagittal (A) and coronal (B) views of preoperative magnetic resonance imaging of a 56-year-old patient who was initially seen with a Kadish stage C tumor involving left nasal cavity and extending intracranially. (From Chao KSC, Kaplan C, Simpson JR, et al. Esthesioneuroblastoma: the impact of treatment modality. *Head Neck*. 2001;23[9]:749-757. Copyright © 2001 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Although dopamine β-hydroxylase and catecholamines are produced by these tumors, their measurements or vanillylmandelic acid excretion levels have not proven clinically useful.

A staging system has been proposed by Kadish et al[151] (Table 54.11).

TABLE 54.11 KADISH SYSTEM FOR STAGING OF ESTHESIONEUROBLASTOMA

Stage	Characteristic
A	Disease confined to the nasal cavity
B	Disease confined to the nasal cavity and one or more paranasal sinuses
C	Disease extending beyond the nasal cavity or paranasal sinuses; includes involvement of the orbit, base of the skull or intracranial cavity, cervical lymph nodes
D	Distant metastatic sites

From Kadish S, Goodman M, Wang CC. Olfactory neuroblastoma: a clinical analysis of 17 cases. *Cancer.* 1976;37(3):1571-1576.

Pathologic Features and Prognostic Factors

ENBs are polypoid, frequently reddish, soft, and vascular tumors with neuroblasts and neurocytes. ENBs contain epithelial components serving as a supporting stroma and have a nerve component that corresponds to the olfactory cells. Rosettes are the main feature, consisting of several rows of cells arranged around the central area.[149] ENBs may be confused with lymphoma or anaplastic carcinoma and have diffuse, regular distribution.

ENBs contain many fibrils, which fill the central space of the rosette (called a pseudorosette). It has been suggested that the presence of chromaffin granules indicates a derivative from primitive neural crest cells. ENB must be distinguished from other poorly differentiated neoplasms, including sinonasal undifferentiated carcinoma (SNUC), which is derived from the Schneiderian epithelium. SNUC lacks rosettes and intercellular fibrils.[155]

Extension of the primary tumor based on the Kadish staging system[151] has been identified as the most important determinant of treatment outcome, although this was not confirmed by Chao et al[156] High-grade tumors had worse outcome in the reports from the Mayo Clinic and the University of California, Los Angeles (UCLA).[157]

Argiris et al[158] found that in 16 patients with ENB, 11 of whom had Kadish stage C and 8 (50%) had brain involvement at presentation. Craniofacial resection was performed in 13 (81%) patients; 14 received either preoperative or postoperative therapy (RT in 11 and chemotherapy in 4). The actuarial 5-year survival was 60% and disease-free survival 33%, with a median follow-up of 4.3 years. The first site of failure was locoregional alone in 10 of 12 patients who progressed, and in 6 patients involved the brain or the meninges. Two patients were successfully salvaged.

Hyams[159] proposed a histologic grading system for ENB in which grade I tumors have an excellent prognosis and grade IV tumors are uniformly fatal. The Hyams grading system predated advanced craniofacial techniques, extensive use of immunohistochemistry, and the recognition of SNUC as a distinct entity. Miyamoto et al[160] in a retrospective review of 12 patients with ENB and 14 with SNUC, used the Kadish clinical stage and Hyams histopathologic system. Kadish staging was available for 26 patients (2 patients with stage A tumors; 7 with stage B, and 17 with stage C). Of the eight evaluable patients with Kadish stage A or B tumors, six remained disease free for more than 2 years compared with only five of seven Kadish stage C tumors. Slides were available for Hyams grading in 21 patients (2 patients with grade I tumors, 4 with grade II, 4 with grade III, and 11 with grade IV). They concluded that both the Hyams grading and the Kadish staging system can be used as independent predictors of outcome. Papadaki et al[161] analyzed 18 formalin-fixed paraffin-embedded ONB specimens (12 primary tumors and 6 recurrences or metastases) from 14 patients and concluded that p53 point mutation does not play an important role in the initial development of ONB; however, p53 wild-type hyperexpression may occur in subsets, show local aggressive behavior, and have a tendency for recurrence.

Choby et al[162] performed a multicenter, case-control study incorporating Hyams grade into the existing staging systems. A total of 256 patients were included. They found that adding this variable to known ONB staging systems was better able to estimate disease progression. In fact, the novel Kadish staging system, patients with stage VI disease were nearly 7 times as likely to experience disease progression as patients with stage I disease.

General Management

Surgery alone (SA) (including endoscopic technique) appears to be adequate treatment for small, low-grade tumors in which negative surgical margins can be obtained. A complete resection with preservation of neurovascular structures is achievable by either EEA or craniofacial approaches. Endoscopic endonasal techniques have gained in use because of the reduced postoperative hospital stays, minimally invasive technique, and reduced complication rates with comparable oncologic outcomes for the appropriate patient population.[163] Those with more extensive local-regional disease benefit from surgery and adjuvant irradiation. Patients with locally advanced disease or high-grade tumors should receive aggressive treatment with combined modalities, such as surgery, RT, and chemotherapy.[154,164]

Dias et al[165] reported on 35 patients with ENB treated with GTR through a transfacial approach with postoperative RT in 11 patients, craniofacial resection and postoperative RT in 7, exclusive RT in 14, craniofacial resection alone in 1, and a combination of chemotherapy and RT in two patients. RT median dose was 48 Gy. Craniofacial resection plus postoperative RT provided a better 5-year disease-free survival rate (86%) compared with the other therapies ($P = .05$). The 5-year DSS rate was 64% and 43% for the low- and high-grade tumors, respectively ($P = .20$). At 5 and 10 years, disease-free survival was 46% and 24%, respectively, and OS was 55% and 46%, respectively.

Monroe et al[166] described treatment results in 22 patients who received RT for ENB. The modified Kadish stage was stage A in 1 patient, stage B in 4 patients, stage C in 15 patients, and stage D in 2 patients. Treatment modalities included primary RT in 6 patients, preoperative RT in 1 patient, postoperative RT after craniofacial resection in 12 patients, and salvage RT in 3 patients treated for recurrence after surgery. Elective neck RT was performed in 11 of 20 patients (2 patients had cervical metastases at presentation for RT). Rates of local tumor control, cause-specific survival (CSS), and absolute survival at 5 years were 59%, 54%, and 48%, respectively. The CSS rate at 5 years was lower after primary RT (17%) than after craniofacial resection and postoperative RT (56%). Cervical metastases occurred in 6 (27%) of 22 patients. No neck recurrences occurred in 11 patients treated with elective neck RT compared with four neck recurrences in 9 (44%) patients not receiving elective neck RT ($P = .02$). Their data and review of the current literature suggest a higher cervical failure rate than previously recognized; elective neck RT seems to correlate with improved nodal tumor control and should be considered in the treatment of ENB.

Gruber et al[167] described 28 patients with ENB treated with RT (median dose 60 Gy). In 13 patients, total tumor resection (recommended by the authors) was performed. Chemotherapy (cisplatin, etoposide, cyclophosphamide, and vincristine) combined with RT was used in five patients. With a median follow-up of 68 months, 54% of the patients were free of local tumor progression (51% at 10 years). Disease-free survival at 10 years was 25%.

Ozsahin et al[168] described the results of treatment in 13 European and North American centers for 77 patients with ONB, 11 with Kadish stage A, 29 with stage B, and 37 with stage C; 56 patients had surgery, 44 with total tumor excision. All but 5 patients received

RT (50% with 3DCRT) and 21 had chemotherapy. With a median follow-up of 72 months, locoregional tumor control (LRC) was 62%, disease-free survival 57%, and OS 64%. Patients having total tumor resection or receiving ≥54 Gy had better OS than those treated with lower doses. Six of the patients treated with RT (56-70 Gy) developed grade 3 or 4 late complications (five osteonecrosis and one retinopathy).

Sperry et al[169] treated 30 patients with ENB (70% with Kadish stage C) with surgery in 27 (52% craniofacial resection), combined with postoperative RT in 75.9% and chemoradiation in 23%. Local tumor failure at 5 years was 43.6%, and regional failure was 15.7%. The 5-year disease-free survival was 40.7% and OS was 80%.

Madani et al[170] published a report on 84 patients (73 with primary and 11 with local recurrent) sinonasal tumors, 9 of which were ENB, treated with IMRT (median dose 70 Gy in 35 fractions). Mean D50 was 37.2 Gy to the optic chiasm, 49.4 Gy to ipsilateral optic nerve, 47.1 Gy to contralateral optic nerve, and 37.7 and 28.4 Gy to the retina.

Sharrett et al[171] described treatment results in 75 patients with H&N ENB. The median follow-up was 105 months (range 6-539). The majority of the patients were men (64%), with a median age of 50.7 years at the time of diagnosis. A total of 77% had advanced-stage disease (Kadish stage C). All patients received RT; 88% was postoperative and 12% was definitive. The median RT dose was 60 Gy (range 42-70). Twenty (26.6%) patients received chemotherapy. The 5- and 10-year LC rates were 96% and 93%, whereas the 5- and 10-year LRC were 87% and 68%, respectively. Ninety-three percent of patients were free from distant metastasis at 5-year follow-up and 81% at 10 years. Half of the total recurrences were after a 5-year follow-up. The 5- and 10-year OS rates were 87% and 74%; the 5- and 10-year DSS were 93% and 84%, respectively. On univariate analysis, younger age was associated with better RFS, DSS, and OS. On multivariate analysis, younger age was the only independent prognostic factor for improved RFS ($P = .03$), DSS ($P < .0001$), and OS ($P < .0001$). The authors recommend surgery followed by postoperative RT and chemotherapy for advanced ENB.

Modesto et al[172] described their experience in 43 patients with biopsy-proven ENB, in two groups one of 26 and the other of 17 patients treated at separate institutions. Five patients had stage A at diagnosis (confined to nasal cavity), 13 stage B (tumor extending into paranasal sinuses), 16 stage C (beyond the paranasal sinuses), and 9 stage D (cervical lymph node involvement) according to the modified Kadish classification. Neoadjuvant platinum-based chemotherapy was administered to 24 patients, leading to a 70.8% response rate (6 complete and 11 partial). A total of 31 (72%) patients were treated by surgery, and 39 (90.6%) underwent RT. Among them, 11 (28.2%) patients were treated using IMRT. The median dose was 64 Gy (range 30-70 Gy). Twelve (28%) patients received bilateral cervical lymph node irradiation (LNI) (median dose 57 Gy, range 50-66 Gy). Nine (21%) patients received platinum-based concomitant CRT. Three patients received platinum-based adjuvant chemotherapy. After a median follow-up of 77 months, the 5-year OS was 65% and the 5-year PFS 58%. Twelve (28%) patients developed locoregional relapse, mostly within the first 2 years (five locally, two regionally, and five both locally and regionally). The major prognostic factor was the modified Kadish stage

with 3-year survival rates of 100% for Kadish A-B versus 48% for stage C and 22% for stage D. After adjustment for tumor stage, neither neoadjuvant chemotherapy nor LNI seemed predictive for LRC or survival. Interestingly among initial stage B and C patients (N = 29), two of them (7%) presented an isolated cervical lymph node relapse, and none occurred among patients previously treated by elective or adjuvant LNI.

Because of the tumor location, good prognosis, and generally younger age at diagnosis, PT has become increasingly utilized for the treatment of ENB. Nishimura et al[173] reported on 14 patients with ONB treated with proton beam (65 GyRBE in 2.5-GyRBE fractions) and 6 patients combined with surgery, sometimes combined with chemotherapy. With a median follow-up of 40 months, 5-year local PFS was 84%, disease-free survival 71%, and OS 93%.

Dagan et al[174] reported on 84 adult patients without metastases receiving primary (13%) or adjuvant (87%) treatment with PT for sinonasal cancers, of which 23% were ONB. Advanced stage (T3 in 25% and T4 in 69%) and high-grade histology (51%) were common. Surgical procedures included endoscopic resection alone (45%), endoscopic resection with craniotomy (12%), or open resection (30%). Gross residual disease was present in 26% of patients. Most patients received hyperfractionated PT (1.2 GyRBE) twice daily, 99%) and chemotherapy (75%). The median PT dose was 73.8 GyRBE, with 85% of patients receiving more than 70 Gy. The median follow-up was 2.4 years for all patients and 2.7 years for living patients. Local tumor control, neck control, freedom from distant metastasis, disease-free survival, CSS, and OS rates were 83%, 94%, 73%, 63%, 70%, and 68%, respectively, at 3 years. The 3-year LC rate was 61% for primary RT and 59% for patients with gross disease. Late toxicity occurred in 24% of patients (with grade 3 or higher unilateral vision loss in 2%).

Akimoto et al[175] reported on 339 patients with nonsquamous cell cancer in the H&N, of which 63 were ONBs, treated with protons. The median follow-up was 64 months. OS, PFS, and LC rate for all patients at 5 years were 61.2%, 36.8%, and 71.2%, respectively, and OS and LC were 86.2% and 79.0% for ONBs, respectively. Among all patients, 254 (75%) were not suited for photon RT because doses to OARs exceeded tolerance dose in the evaluation of dose-volume histogram. However, OS at 5 years of these patients was 65.5%. Regarding treatment morbidity, 34 (10%) patients developed grade 3 or 4 late toxicities, such as brain injuries and neuropathy. None experienced grade 5 toxicities.

Suefuji et al[176] reviewed outcomes following CIRT in a subanalysis of the Japan Carbon-Ion Radiation Oncology Study Group (J-CROS). Twenty-one patients with T4 ENBs treated with CIRT were retrospectively reviewed. With a median follow-up period of 39 months, the 3-year OS and LC rates were 88.4% and 83.0%, respectively. Grade 4 late toxicity was observed in three patients, including ipsilateral optic nerve disorder (n = 2) and ipsilateral retinopathy (n = 1).

Chemotherapy for ENB consists of platinum-based regimens in combination with cyclophosphamide, vincristine, and, occasionally, doxorubicin. It is usually used with surgery and/or RT and most commonly for the treatment of locally advanced disease, high-grade tumors, patients with recurrence, younger patients, or neoadjuvantly for those

deemed to be inoperable.[149,177] Brisson et al[177] reviewed the 636 patients from the SEER registry, of which 195 of whom received chemotherapy. They showed that with propensity score matching and inverse probability of treatment weighting, there was inferior OS and CSS for patients who received chemotherapy compared to those who did not. On subgroup analysis, those patients who did not undergo surgery and were treated with chemotherapy and/or RT (hazard ratio [HR] 0.3, $P < .001$) had the most impact. Because of the nature of retrospective SEER registry studies, it is difficult to eliminate selection bias from those who received a trimodality therapy but also suggests that patients who are considered nonsurgical candidates may benefit from the addition of chemotherapy.

Elective Neck Treatment

Recurrence is frequent and occurs in 40% to 50% of cases with long intervals to relapse, which can occur over 5 years from the initial therapy.[178] Although the sites of metastases are widely variable and often atypical, Beitler et al[156] found cervical node metastasis to be as frequent as local recurrence. Davis and Weissler[179] compiled a retrospective review of patients and found that the cumulative cervical metastasis rate reached 27% (55/207 patients). Noh et al,[180] in a report of 19 patients with ENB treated with combinations of surgery, RT, and/or chemotherapy, noted that 4 patients with high-risk factors received elective neck RT (45-70 Gy). There were no cervical node failures in 5 patients with Kadish stages A and B, 3 of 10 in patients with Kadish stage C treated surgically, and 0 in 9 receiving chemotherapy.

Peacock et al[181] reported on 53 patients with ENB in the H&N; 42 (79%) underwent craniofacial resection as the definitive surgical treatment, 28 (53%) patients underwent surgery and ART (ART group) to the primary site only, and 25 (47%) SA as treatment for the primary site (SA group). The median follow-up was 84.5 months for the ART group and 93 months for the SA group. Following initial treatment, the 5-year actuarial survival was 89% for the ART patients and 75% for the SA patients; the 5-year local RFS was 89% for the ART patients and 63% for the SA group. The 5-year cervical lymph node metastasis-free survival was 80% for the ART patients and 75% for the SA patients. Among the 18 patients with delayed cervical lymph node metastases, 10 underwent salvage neck surgery and RT, 5 had SA, and 3 did not have surgery or RT, because of distant metastases or other comorbidities. Four patients recurred in the neck following salvage treatment. With a median follow-up time of 31 months, the 2-year RFS estimate was 85% versus 74% following salvage treatment. Thus, the 5-year delayed cervical lymph node metastasis rate in patients with ENB and a clinically N0 neck undergoing local treatment is 23%. The delayed lymph node metastases were effectively salvaged in the majority of patients. The authors proposed that patients with ENB and a clinically N0 neck should not undergo elective neck RT as part of their initial treatment in order to avoid acute and late toxicity.

Ni et al[178] reviewed long-term outcomes of 143 who underwent salvage therapy for ENB at the Mayo Clinic. This series included approximately one-third of patients who had regional recurrences. Salvage therapy for the entire cohort was shown to be effective as

subsequent 5-year OS was 63%. Subsequent recurrences were not infrequent, however, and tended to occur at shortened intervals compared to initial disease progression.

Jiang et al[182] reviewed 71 patients from MD Anderson Cancer Center to evaluate the role of elective nodal irradiation (ENI) in clinically N0 patients. With a median follow-up of over 6.5 years, among N0 patients, 11 patients without ENI developed isolated neck recurrences. None of these 13 patients who received ENI recurred regionally. While ENI was associated with significantly improved regional nodal control at 5 years (100% for ENI vs 82%, $P < .001$), there was no difference in OS or disease-free survival. The authors concluded that although ENI significantly reduces the risk of cervical nodal recurrence in patients with clinically N0 necks, this did not translate to a survival benefit.

Yin et al[183] published a retrospective analysis of 116 patients with naïve ENB treated in China. According to the Kadish stage classification, 20% (23 patients) presented with stage B and 79% (92 patients) with stage C. Thirty-two patients showed cervical lymph node metastasis in the initial staging. Among 84 patients with N0 disease, the management of neck in 80 patients with Kadish stage B/C was available, with treatment modalities consisting of primary RT in 27 patients, preoperative RT in 10, postoperative RT in 40, and SA in 3. Fifty patients were treated with ENI and 30 without any prophylactic neck treatment. Thirty-two of 116 (28%) patients were N positive at the time of initial diagnosis, most frequently involving the level II lymph nodes (81%), followed by level IB (53%), level III (28%), and the retropharyngeal nodes (RPNs) (25%). Rates of OS, disease-free survival, and regional relapse-free survival at 5 years were 77%, 71%, and 98%, respectively, for patients treated with ENI, compared with 62%, 50%, and 75% for those without neck treatment. The regional failure rate was 2% for patients with ENI compared with 23% without neck treatment, and distant failure rates were 20% in the ENI group versus 27% in the untreated neck group. Neck recurrence occurred in 7 of 30 patients who were without neck treatment, all relapsed in level IB or level II. The authors concluded that the treatment target of ENI should at least cover the bilateral upper and middle neck, namely, level IB-III and RPNs.

As noted, because of the low incidence of cervical lymph node metastasis (≤10%) in early-stage ENB, elective irradiation of the neck or a dissection is not indicated. However, in patients with Kadish stage C disease, the cervical metastatic rate climbed to 44% (25/57 patients). As stated previously, Monroe et al[166] observed cervical node metastasis in 6 (27%) of 22 patients. In 11 patients treated with elective neck RT, no recurrences were noted, in contrast to 4 (44%) of 9 patients not receiving elective neck RT. Thus, with advanced-stage disease, cervical nodes may be initially managed by irradiation, radical neck dissection, or a combination of both. Zanation et al[184] recommend salvage of neck metastases occurring 6 months or more after treatment of the primary site to be treated with combined surgery and RT. They showed a clear disease-free survival advantage (59% vs 14%) in patients with combined modality therapy versus single modality in the salvage setting.

Hollen et al reviewed 26 patients with untreated nasal cavity ENB at the University of Florida.[185] For patients with Kadish stages B and C, ultimate neck control was 100% at 5

years for patients who received ENI versus 69% among those not receiving ENI ($P < .05$).

In summary, the risk of subclinical disease is high, with regional recurrence rates approaching 30% to 40% at 10 years from initial therapy for high-grade tumors (Kadish stages B and C). ENI is an effective therapy for reducing nodal relapse to less than 5%; however, given the additional acute and late toxicity with prophylactic irradiation, controversy exists over the optimal treatment strategy and sequencing as multiple studies show that salvage of isolated nodal relapse is highly effective and may not lead to differences in OS compared to upfront ENI.

Radiation Therapy Techniques

Treatment techniques are similar to those described for the treatment of paranasal sinuses (see Chapters 48). When combined therapy is used, preoperative doses of 45 Gy and postoperative doses of 50 to 60 Gy are indicated, depending on the status of the surgical margins. Doses of 65 to 70 Gy are delivered with irradiation alone in patients with inoperable or subtotally resected tumors at 1.8 to 2.0 Gy per treatment.[154,157,174] Contrast-enhanced CT or MRI scans before initiation of treatment are crucial to demarcate the extension of the tumor and delineation of normal anatomy.[186] Because of the proximity of ENB to the optic nerves, the optic chasm, and the brainstem, the precision of treatment setup, target volume definition, and dose homogeneity dictate tumor control and the sequelae of treatment. High doses per fraction (exceeding 2 Gy) increase the possibility of late sequelae, such as blindness and bone and brain necrosis. Some institutions use hyperfractionation 1.2 Gy twice daily when treating tumors adjacent to the optic apparatus.[154,187] IMRT and particle therapy, including both proton and heavy ions, provide excellent outcomes for the treatment of ENB (Figure 54.16). Special attention should be directed to reduce unnecessary irradiation to ocular structures, including optic nerve(s) and chiasma. While not indicated for all cases as previously discussed, when delivered ENI should include the primary nodal echelon, which includes levels 1B and II and the retropharyngeal lymph nodes.

FIGURE 54.16 Representative proton therapy plan covering the primary site and lymph node volumes to a total dose of 54 GyRBE with proton therapy. This technique minimizes the dose to developing brain tissue, cochlea, and oral cavity. PTV, planning target volume. (From Drescher NR, Indelicato DJ, Dagan R, et al. Outcomes following proton therapy for pediatric esthesioneuroblastoma. *Pediatr Blood Cancer*. 2024;71[2]:e30793. Copyright © 2023 Wiley Periodicals LLC. Reprinted by permission of John Wiley & Sons.)

Of note, attention to be made to the CTV extension along the dural, in particular for tumors with intracranial extension. Yu et al[188] reviewed 38 patients from a single-institutional retrospective series. Over half of the patients had intracranial extension at diagnosis. The dura was the most commonly involved site of relapse, and the 8-year dural disease-free survival was 57% versus 90% (P = .017) with and without intracranial extension. After dural recurrence, the median survival time was 42 months; however, salvage treatments were effective in rare cases of isolated low-volume recurrence.

Results of Therapy

Surgery and Irradiation

Platek et al,[189] in an analysis of SEER data (1973-2005) of 135 cases of ONB, noted that 59% of the patients were treated with surgery and RT, 23% with surgery only, 12% with RT only, and 6% with neither. No data on chemotherapy administration were available. The 5-year survival with surgery plus RT was 66%, with surgery only 51%, with RT only 26%, and with other therapy 34% (P = .003).

RT is an important component in the management of ENB, but the optimal sequence when integrated with surgery is unknown. Eden et al[190] observed no significant difference in survival whether preoperative or postoperative irradiation was given, but suggested improved local tumor control with preoperative irradiation. Technical factors may have contributed to a higher incidence of postoperative RT failures because three of five postoperative cases received <50 Gy; all three patients were treated with a single anterior field, which gives less homogeneous dose distribution throughout the treatment volume.

Foote et al[157] updated the experience of the Mayo Clinic. Seventeen patients had disease confined to the nasal cavity or paranasal sinuses (Kadish stages A and B), and 32 patients had more advanced disease. Treatment included either gross total resection alone or combined with RT. The 5-year actuarial survival, disease-free survival, and local tumor control rates were 69.1%, 54.8%, and 65.3%, respectively. Local tumor control was improved in patients who received postoperative irradiation (55.5 Gy), even after complete tumor resection.

Levine et al[191] conducted a retrospective review of 35 patients; 6% of them presented with cervical metastasis, and ultimately 25.7% developed cervical metastases. Fourteen percent of the patients had a local recurrence at an average of 6 years after diagnosis, and in 37%, at least one episode of metastatic disease occurred. The disease-free survival was 80.4% at 8 years. CNS complications occurred in 25.7% of patients, orbital complications in 22.9%, systemic post-treatment problems in 20%, and chemotoxic sequelae in 18%.

Eriksen et al[192] carried out a retrospective review of 13 patients with ENB (Kadish stage A 1 patient, stage B 5 patients, and stage C 7 patients). The 5-year disease-free survival was 51%. Forty-six percent of the patients experienced relapse, and despite intensive salvage therapy, median survival after recurrence was only 12 months.

Chao et al[193] reported on 25 patients with ENB (Kadish stage A in 3 patients, stage B in 13 patients, C in 8 patients, and modified D in 1 cervical nodal metastasis patient); 17 patients were treated with surgery and RT, 6 with irradiation alone, and 2 with surgery only. Eight patients received neoadjuvant chemotherapy. The median follow-up was 8 years. The 5-year actuarial OS, disease-free survival, and local tumor control rates were 66.3%, 56.3%, and 73%, respectively. Kadish stage was not a significant prognosticator for local tumor control or disease-free survival. Five-year local tumor control was 87.4% for combined surgery with RT and 51.2% for irradiation alone. Two patients with Kadish stages A and B disease underwent surgical resection alone; both failed locally. In contrast, only three of nine patients with Kadish stage A or B disease who received ART had a local recurrence. With ART, the surgical margin status did not influence local tumor control.

Chemotherapy and Irradiation

Eden et al[190] described results in 16 patients with stage A or B disease and 24 patients with stage C disease treated with irradiation (median dose 50 Gy) and surgery for stage A and B diseases, with the addition of chemotherapy (cyclophosphamide and vincristine) for stage C disease. Actuarial survival rates at 5 and 10 years were 78% and 71%, respectively. Locoregional failure developed in 15 of 40 patients; 68% of the failures were locoregional (including the brain, neck, facial bone, and sinus). They had no recurrences at the primary tumor bed; all recurrences were either outside the irradiation field or at distant sites.

Preoperative neoadjuvant therapy may provide a valuable complement to radical resection if there is expected high morbidity with surgery.[194]

Konuthula et al[195] analyzed 90 patients with Kadish stages C and D ENB in the NCDB, with 55% treated with definitive radiation (RT) (median dose 59.4 Gy) and 45% receiving chemotherapy. The mean follow-up was 57.1 months. There was no difference in 5-year

survival between the patients who received RT and those treated with RT and chemotherapy (74.8% vs 64.4%). There was also no difference in survival between whether a clinically node-negative neck was treated with RT (72.9% vs 67.0%).

Sequelae of Treatment

Treatment sequelae depend on the dose of irradiation and the location and extent of disease. Reported severe toxicities that can occur when treating sinonasal tumors include bone necrosis, brain necrosis or abscess, blindness, or painful eye reactions requiring enucleation. This is because of the sensitive adjacent normal tissues and the extensive surgeries and high doses indicated. Some studies note that the risk of severe grade 3+ toxicity regardless of radiation modality approaches one-quarter of patients.[154,196] A summary of studies evaluating late visual impairment is shown in Table 54.12.

TABLE 54.12 STUDIES REPORTING TREATMENT OUTCOME AND LATE GRADE 3 VISUAL IMPAIRMENT AFTER CONFORMAL RADIOTHERAPY THERAPY FOR SINONASAL TUMORS

Author (Reference)	Number of Patients	Treatment	Median Dose (Gy)	Follow-Up (Months)	Local Control (Year)	Overall Survival	Grade 3 Visual Morbidity

IMRT, intensity-modulated radiation therapy; NR, no report; PT, proton therapy; S, surgery.

Modified from Madani I, Bonte K, Vakaet L, Boterberg T, De Neve W. Intensity-modulated radiotherapy for sinonasal tumors: Ghent University Hospital update. *Int J Radiat Oncol Biol Phys*. 2009;73(2):424-432. Copyright © 2009 Elsevier. With permission.

Simon et al,[205] in 13 patients with olfactory ENB treated with surgery and RT, noted that one patient lost vision as a result of glaucoma and radiation retinopathy after 67.3 Gy in 34 fractions. One patient treated with 61.8 Gy in 34 fractions developed a visual field defect and optic atrophy and also had a nasal cutaneous fistula. One patient sustained intraoperative rupture of the ocular globe and subconjunctival hemorrhage.

Lucas Jr et al[206] reported on a small series of pediatric patients treated with proton RT. Four patients developed radiation- related late toxicities, including endocrine dysfunction, two cases of grade 2 retinopathy, and one case of grade 3 optic neuropathy.

Drescher et al[164] described the outcomes of 15 pediatric patients treated with PT. Serious late toxicity included major reconstructive surgery (n = 2), symptomatic retinopathy (n = 3), cataracts requiring intervention (n = 2), chronic otitis media requiring antibiotics (n = 2), chronic keratoconjunctivitis requiring antibiotics (n = 2), hypothyroidism requiring hormone replacement (n = 2), and in-field basal cell skin cancer (n = 1).

NASOPHARYNGEAL ANGIOFIBROMA

Epidemiology

Juvenile nasopharyngeal angiofibroma (JNPAF) is found more frequently in young pubertal boys; it has been shown to contain androgen receptors[207] and, occasionally, to regress with estrogen therapy. Hwang et al,[208] in 24 nasopharyngeal angiofibromas, detected androgen receptors in 18 (75%) of 24 cases, whereas only two (8.3%) were positive for progesterone. None of the 24 cases was positive for antibodies to estrogen.

The tumor is believed to originate from the posterior-lateral wall of the nasal cavity where the sphenoidal process of the palatine bone meets the horizontal ala of the vomer and the roof of the pterygoid process because it is always involved.[209] Other investigators agree, because the involution of tumor after irradiation usually occurs in this direction.[210]

JNPAF comprises <0.05% of H&N tumors. Patient's age at presentation ranges from 9 to 30 years, with a median of 15 years. Females comprise <4% of the total cases.[211]

Clinical Presentation and Pathology

Symptoms usually occur 2 to 48 months before diagnosis. The most common complaints are nasal obstruction or epistaxis, followed by nasal voice or discharge, cheek swelling, proptosis, diplopia, hearing loss, and headaches.[212] Nasopharyngeal angiofibroma may initially extend into the nasal fossae and maxillary antrum and push the soft palate downward and then through the pterygopalatine fossa and superoanteriorly through the inferior orbital fissure or laterally through the pterygomaxillary fissure to the cheek and temporal regions.[211]

Beham et al,[184] in a study of 32 cases of JNPAF, noted that most of the tumor vessels, which lacked elastic laminae, were characterized by vascular walls of irregular thickness and variable muscle content. In places, endothelial cells were separated from the stroma by only a single attenuated layer of contractile cells; in some more fibrotic hyaline areas, the stromal cells displayed reactivity for smooth muscle actin. The irregularity of the vascular walls, together with the lack of elastic laminae and stromal fibers, explains the pronounced tendency for hemorrhage in these lesions.

Differential diagnosis includes fibrosarcoma, rhabdomyosarcoma (RMS), chronic sinusitis, arteriovenous malformation, lymphangioma, neurofibroma, pleomorphic adenoma, lymphoma, pyogenic granuloma, polyps, and hemangioma.

Diagnostic Workup

After the history and physical examination, CT scans or MRI with and without contrast should be obtained. Characteristic findings are a mass in the posterior nasal or pterygopalatine fossa and bone erosion in the sphenopalatine foramen and extension to the pterygoid plate. The pattern of enhancement in this highly vascular tumor is diagnostic, and many investigators believe carotid angiograms are unnecessary after CT diagnosis of the lesion, unless embolization, which is also controversial, is contemplated. CT scans are especially helpful in regions involving thin bony structures (paranasal sinuses, orbits) and MRI to evaluate the nasopharynx and parapharyngeal space, including special resolution of soft and nervous tissues and intracranial extension.[186,209,211]

Seventy-two patients with JNPAF were evaluated with CT or MRI.[186] Origin of the tumor was in the pterygopalatine fossa at the aperture of the pterygoid (vidian) canal. The tumor extended posteriorly along the pterygoid canal, with invasion of the cancellous bone of the pterygoid base and greater wing of the sphenoid in 60% of the patients. The inability to remove the tumor in toto was principally due to deep invasion of the sphenoid; 93% of recurrences occurred with this type of tumor extension.

Biopsies are not indicated in all patients because of the potential for severe hemorrhage. It is important to perform a biopsy of the lesion when the clinical picture (sex, age, location, and behavior of the lesion) is not consistent with JNPAF because some lesions have proven to be sarcomas or chronic sinusitis.[209] While rare, cases of fibrosarcoma have been reported in patients in their 40s.[213]

Staging and Prognostic Factors

Staging schemes have been proposed by Chandler et al,[209] a radiographic staging system by Sessions et al,[210] and a more detailed anatomic system by Radkowski et al[214] In a retrospective review of 44 cases of JNPAF, invasion of the skull affected two-thirds of the patients, and the rate of recurrence was 27.5%.[215] Extensions to the infratemporal fossa, sphenoid sinus, base of pterygoids and clivus, the cavernous sinus (medial), foramen lacerum, and anterior fossa were correlated with more frequent recurrence.[216]

General Management

Optimum management of these patients remains controversial, and the decision of whether surgery or RT should be used depends, in part, on the initial extent of the disease. In patients with extracranial tumors,[215] surgery is the treatment of choice and yields near-zero mortality or any long-term morbidity.[217] Tumor extension to the posterior infratemporal fossa or intracranially is associated with a higher risk of recurrence.[218]

Residual tumor in symptom-free patients should be kept under surveillance by repeated CT scanning, because involution may occur. For patients with recurrent, unresectable tumor with symptoms or progression, RT may be used if further surgical resection is either highly morbid or technically not feasible.[211,212,217] When there is intracranial tumor extension (seen in about 20% of patients), the risk of surgically related death increases.

Some investigators consider preoperative intra-arterial tumor vessel embolization at the time of diagnostic bilateral carotid angiography, claiming a decrease in operative bleeding.[219] Salvage with embolization of polyvinyl alcohol has been described.[220] Others have reported anecdotal evidence of partial regression with the use of estrogens, believed to be the result of feedback inhibition of the pituitary's production of gonadotropin-releasing hormone.

Although RT is equally effective in extracranial tumors, the low but existing risk of secondary malignancies should limit its use to the more advanced tumors only, such as those involving the orbital apex or the base of the skull in which curative resection with low morbidity is unlikely.[211] In the experience of Cummings et al[212] covering 20 years, only two radiation-related malignancies were noted (one skin, one thyroid).

Radiation Therapy Techniques

Conformal techniques are recommended with either IMRT or PT. Because of the young age of the patient and excellent survival, techniques to reduce integral dose such as protons should be considered when available. Positive microscopic margins or history or recurrence in the setting of radiographic complete resection are not indications for RT. CTV is defined as the entire pterygopalatine fossa and inferior orbital fissure on the ipsilateral side plus 5 to 10 mm expansion of the GTV in all directions edited to anatomic boundaries of tumor spread (Figure 54.17). The recommended tumor dose ranges from 30 to 36 Gy at 1.8 to 2 Gy per treatment. Doses of 36 Gy provide approximately 90% tumor control. Focal boosts to 40 to 50 Gy in 20 to 28 fractions in 5 weeks can be considered to areas of gross residual tumor for select cases.[211] Target definitions and treatment approaches used at the Mayo Clinic Florida are summarized in Table 54.13.

TABLE 54.13 TREATMENT OPTIONS FOR THE MANAGEMENT OF JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

Indication for RT	Visible tumor on CT or MR scans in a situation where curative resection with low morbidity is unlikely
RT dose	36 Gy at 1.8 Gy per treatment. May consider boosting gross tumor to 40-45 Gy in selected cases for patients > than age 18 y and no gross tumor abutting the optic apparatus
RT technique	In most cases, photon-based IMRT; can consider proton therapy to reduce integral dose
GTV	Visible tumor on CT and MRI
CTV	CTV = the entire pterygopalatine fossa and inferior orbital fissure on the ipsilateral side plus 10 mm expansion from the GTV edited for barriers to tumor spread. There is no elective nodal irradiation.
PTV	CTV plus 3 mm based on institutional practice and daily CBCT image guidance

Current treatment practice at the Mayo Clinic Florida.

CBCT, cone-beam computed tomography; CTV, clinical tumor volume; D(0.1 mL), maximum dose to 0.1 mL; D_{max}, maximum dose; GTV, gross tumor volume; IMRT, intensity-modulated RT; MRI, magnetic resonance imaging; PTV, planning tumor volume; RT, radiation therapy.

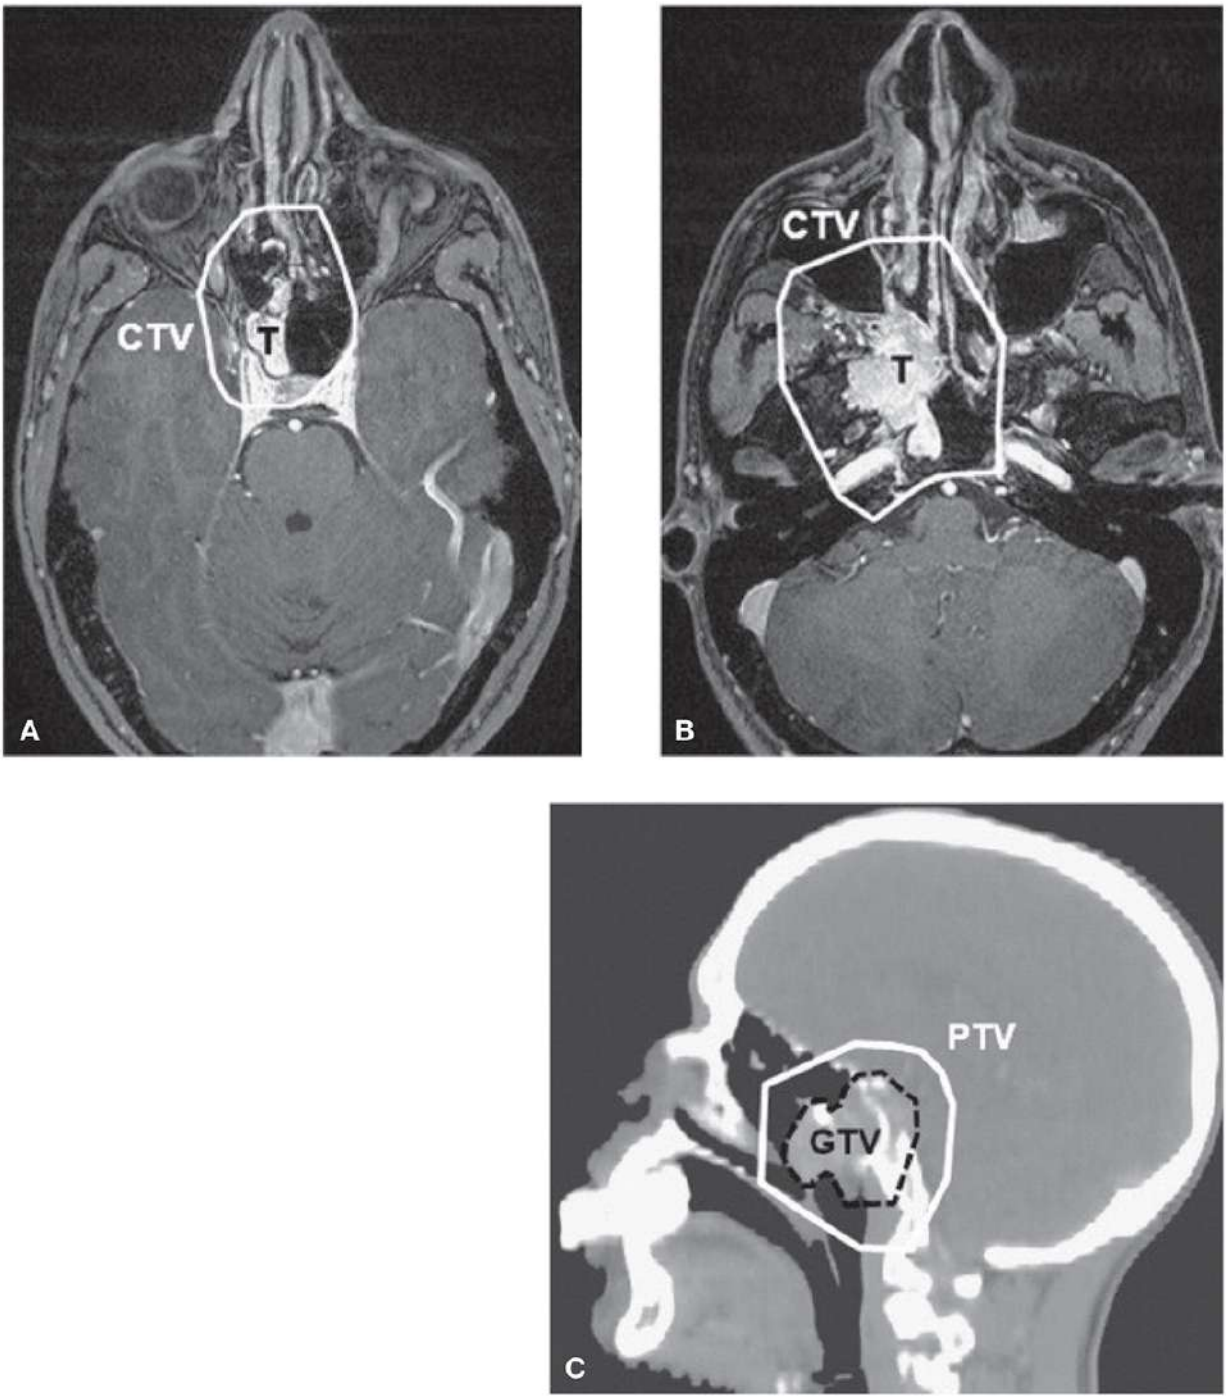

FIGURE 54.17 (A and B) The contrast-enhanced, T1-weighted magnetic resonance scan fused to simulation computed tomography (CT) scan (C). In A and B, the tumor is bright white, indicating that it is highly vascular. In (A), the tumor (T) involves the right side of the sphenoid sinus and the posterior portion of the inferior orbital fissure and nasal cavity. In (B), the tumor (T) epicenter is in the pterygomaxillary fossa and the tumor involves the medial portion of the infratemporal fossa and the posterior portion of the nasal cavity. The white line in (A and B) is the CTV, which puts a margin of a least 1 cm on the gross tumor volume (GTV) in areas where there is no barrier to tumor spread. When tumor involves a portion of the sphenoid sinus, we cover the entire sinus in the CTV. **C** is the midline sagittal reconstruction CT image showing the GTV and PTV (CTV + 1 mm). CTV, clinical tumor volume; PTV, planning target volume. (Reprinted from Amdur RJ, Yeung AR, Fitzgerald BM, Mancuso AA, Werning JW, Mendenhall WM. Radiotherapy for juvenile nasopharyngeal

angiofibroma. *Pract Radiat Oncol*. 2011;1[4]:271-278. Copyright © 2011 American Society for Radiation Oncology. With permission.)

The advantages of IMRT for the treatment of extensive or recurrent JNPAF were described in three patients on whom the tumor affected the base of the skull, pterygopalatine, infratemporal fossae, posterior orbit, and nasopharynx.[219] Tumor dose varied from 34 to 45 Gy. Chakraborty et al[221] treated eight patients with IMRT for stage III tumors (median dose 39.6 Gy). LC at 2 years was 87.5%, and toxicity was minimal (persistent rhinitis in one patient). Significant sparing of the surrounding OARs was obtained. No grade 3/4 toxicities were experienced.

Results of Therapy

In a surgical report, 18 patients were treated with gross tumor excision; two cases with intracranial involvement required a combined neurosurgical-otolaryngologic approach.[222] Recurrent intracranial disease was detected by MRI in three patients, who were treated with 35-, 36-, and 45-Gy external beam irradiation. Extracranial tumor recurrences were reexcised in seven patients. All patients (followed up with serial MRI) are living without evidence of active disease.

Cummings et al[212] treated 42 patients primarily with irradiation and 13 for postsurgical failures; all except six had biopsies. Nine had stage IV disease according to Chandler's staging system. Dose was 30 to 35 Gy in 14 to 16 fractions over a 3-week period. Follow-up ranged from 3 to 26 years. The control rate was 80% and was equivalent for all dose ranges. Of 11 recurrences, 8 were controlled by a second course of irradiation and 3 by surgery. These tumors regress slowly, with 50% still present at 12 months. At 24 months, 23% of tumors were still present, and half of those recurred. Of the complete responders, only 1 of 33 had a recurrence.

At the Mallinckrodt Institute of Radiology, Fields et al[223] reviewed the authors' experience with 13 patients: 11 surgical failures and 2 primarily treated with irradiation. Intracranial extension was noted in 38% of patients. Follow-up ranged from 40 to 173 months. Doses ranged from 36 to 52 Gy, with a median of 48 Gy (1.8-2 Gy per fraction, 5 days a week). The control rate was 85%; patients failing irradiation were salvaged with embolization. Late morbidity was primarily xerostomia and dental decay.

Ungkanont et al[224] described results in 20 patients treated before 1974 and 23 treated between 1975 and 1993: 31 had surgery (18 with preoperative embolization), 3 had irradiation, 7 received chemotherapy (4 combined with surgery), and 2 were observed. Disease-free survival was 67%; 28% of patients survived with residual tumor, and 4.6% died of surgical complications. Roche et al[225] treated 15 patients with JNPAF with various maxillofacial surgical resections, combined with Gamma Knife radiosurgery in 2 patients and external RT in 4 patients. With a median follow-up of 108 months, 12 patients were tumor free and 2 had no progression. All patients had normal or near-normal quality of life.

Tumor regression usually occurs slowly after either irradiation[212] or chemotherapy[226]; therefore, the presence of tumor up to 2 years after treatment is not an invariable sign of failure unless it is symptomatic or progressing. McAfee et al[227] treated 22 patients with JNPAF with definitive RT (30-36 Gy); with a median follow-up of 12.7 years, 20 (91%) patients had tumor control. The two patients failing were salvaged with surgery. No major treatment morbidity was noted. Kasper et al,[228] in nine patients treated with RT (30-35 Gy), observed 25% to 50% initial tumor regression within 1 year. Eventually, seven of the patients had complete clinical tumor regression, but on CT or MRI, only two of seven had no residual disease.

The management of large JNPAF with intracranial extension is complex. In 18 patients with JNPAF, preoperative MRI, embolization of feeding branches from the external carotid artery, and attempted complete resection were used in seven patients with intracranial disease[222]; serial MRI scans were used for follow-up. Intracranial disease that was persistent or recurrent and demonstrated subsequent growth was irradiated (35-45 Gy) or reexcised.

Wiatrak et al[229] reported on three patients with extensive intracranial extension treated primarily with RT doses of 36.6, 40.0, and 50.4 Gy, respectively, without surgical tumor resection. Although there was no complete resolution of the tumors, significant improvement of symptoms was obtained without serious sequelae.

Ochoa-Carrillo et al[230] reported on 31 patients treated with surgery or RT. Surgery was the treatment chosen in patients with stage II and III diseases, whereas RT was the treatment in stage IV, but it had low effectiveness, indicating the need to carefully investigate the value of surgical approaches in these tumors. RT (30-55 Gy) was administered to 16 patients: seven with stage III persistent or recurrent tumor, and eight patients as initial treatment for stage IV disease. The disease-free interval of patients with stage III and IV diseases was 80.3% and 19%, respectively, after 36 months of follow-up.

Tranbahuy et al[231] reported on seven patients with juvenile angiofibroma who underwent direct tumoral embolization. This technique induced marked devascularization and necrosis of the tumor. No neurologic sequelae were encountered.

Goepfert et al[226] reported on five patients with aggressive nasopharyngeal angiofibromas recurrent after extracranial resection and irradiation who were treated with chemotherapy. Doxorubicin (60 mg/m^2 intravenous push for 1 day) and dacarbazine (250 mg/m^2 intravenous drip for 5 days) were given, with courses being repeated every 3 to 4 weeks. In a second regimen, vincristine, dactinomycin, and cyclophosphamide were administered at usual doses. Excellent tumor regression was noted in all patients. Patients were disease free at 2, 3, 6, and 10 years.

Amdur et al[211] reported the outcomes of 24 patients treated with RT. The standard dose in the first half of the series was 30 Gy in 22 treatments (1.43 Gy/treatment), but was increased to 35 to 36 Gy at 1.8 Gy/treatment because increased recurrences with the lower dosing regimen. Elective nodal coverage was omitted and all recurrences were at the primary site within 5 years of completing therapy. While LC was 77% with those who received <32 Gy versus 91% with those treated with 35 to 36 Gy. All recurrences

following RT were successfully salvaged with surgery, and no patient had a significant growth abnormality or second tumor.

Sequelae of Therapy

Most investigators agree that surgical morbidity and mortality increase with intracranial extension of the tumor. The most common RT sequelae include delayed growth secondary to hypopituitarism and decreased bone maturation.[232]

Malignant degeneration in JNPAF undergoing RT has been occasionally reported,[233,234] and there are several documented cases of radiation-induced sarcomas in these patients.[212,235] Spagnolo et al[235] reported on four patients treated with irradiation who later developed sarcoma. Cummings et al[212] reported two neoplasms developing 13 and 14 years after irradiation; one was a basal cell carcinoma and the other metastatic thyroid carcinoma. Both patients are alive without disease. Two patients developed cataracts.

Mucosal Melanomas

Primary mucosal melanomas (MMs) of the H&N area constitute 2% to 8% of the cases seen each year in the United States.[236] They compose approximately 1% of all melanomas and about half arise in the H&N. They occur more commonly in countries such as Japan, where MM is found in 22% to 32% of patients with malignant melanoma. Most occur in the fifth to seventh decades of life; they are extremely rare in the first two decades (0.6% of MMs).[237] A review by Batsakis[238] of 204 MMs showed 56.4% to be from the upper respiratory tract and 44% from the oral cavity and pharynx. Nasal cavity or paranasal tumors comprise <1% of malignant melanomas and 2% to 9% of H&N melanomas.[239] Pigmentation may precede the lesion in up to 28% of patients for more than 1 year.[240] In the oral cavity, the most common location is the hard palate (up to 80%), followed in order of decreasing frequency by the upper gingiva and lower gingiva.

Diagnostic Workup

Summary diagnostic workup is found in Table 54.6.

An excisional biopsy should be performed when feasible with incisional or punch biopsy an acceptable alternative.[241] Batsakis[238] found that one-third of these lesions were amelanotic, and Hoki et al[239] noted that 25% were amelanotic.

Metastatic melanoma to the mucosa of the H&N area is less common. It can be differentiated from primary tumors by the presence of normal tissue between subepidermal tumor and the basal layer of melanocytes.[238] PET-CT should be used to identify metastases because of its high sensitivity in detecting both regional lymph node involvement and distant metastatic spread.

Management and Results of Therapy

Primary management is surgical resection. Because some have shown over one-third of patients may have associated adjacent pigmentation, some investigators recommend prophylactic excision of all adjacent melanocytic nevi. Results with irradiation are comparable with those of surgical series, with most patients having distant progression. Because of the poor survival of these patients because of distant metastases and not locoregional failure, primary RT with salvage surgery is an alternative for MMs of the H&N.[242] ENI is not indicated in all patients, as only few develop nodal metastasis.[243]

In a review of the Japanese literature, Umeda et al[244] found a local tumor control rate for stage I and II diseases of 58% (7/12) in surgically treated patients with oral melanomas and a minimum follow-up of 3 years. Similar rates of failure have been reported, even with radical en bloc excisions (20%-42%). Because the main cause of treatment failure is distant metastases and because almost no patient has clinically evident nodal metastases at presentation, an elective neck node dissection is not consistently recommended. This subject is still controversial, as 30% to 60% of patients may later develop nodal disease.[245]

Harwood and Cummings[246] treated 12 cases and added 12 cases from the literature for a total of 24 patients and 25 lesions. Local tumor control was achieved in 11 of 24 (9-54 months' follow-up). Six of seven tumors treated with 4-Gy fractions or larger were controlled, versus 5 of 18 treated with smaller fractions. Saigal et al[243] treated 17 patients with MMs (sinonasal tract in 11, oral cavity in 6) with surgery (16 combined with RT) and 1 with RT. Seven patients received adjuvant immunotherapy. With a median follow-up of 35.2 months, local tumor control at 5 years was 81%, disease-free survival 44.5%, and OS 51.5%.

Krengli et al[247] reported on 74 patients with upper aerodigestive tract MMs (31 nasal and 12 oral), 17 treated with SA, 42 with surgery and RT (median dose 60 Gy, 2-Gy fractions), 11 with RT alone, and 4 with chemoimmunotherapy. At 3 years, the local recurrence was 43% with SA and 29% with surgery plus RT. Grade 3 mucositis was noted in nine patients.

Kingdom and Kaplan[248] described results in 13 patients with MM of the nasal cavity and paranasal sinuses treated with surgical resection. Eight had microscopically negative margins. Seven patients received postoperative irradiation (30-62 Gy). The neck was treated in three patients with doses of 30 to 50 Gy. The local tumor recurrence rate was 85% (11/13), with a mean interval from primary tumor treatment to recurrence of 16 months. Metastatic neck disease developed in two patients and distant metastases in four. Patients receiving postoperative irradiation had increased disease-free interval and prolonged survival. Negative surgical margins were not predictive of a more favorable outcome. The investigators recommend resection of tumor with negative margins and postoperative irradiation for the treatment of all patients with mucosal malignant melanoma.

Zenda et al[249] treated 14 patients with H&N MMs using protons (60 Gy in 15 fractions, 3 fractions per week). With a median follow-up of 36.7 months, the 3-year local tumor control was 85.7% and OS 58%. The most frequent failure site was the cervical nodes (six patients). Two patients developed late decreased visual acuity.

Immunotherapy

Actionable mutations in melanoma including KIT mutations, TRK fusions, and BRAF mutations are under investigation. Checkpoint inhibitors have become a mainstay in therapy for cutaneous melanoma. Their role in MM is uncertain and not well studied, and both the indications and sequencing with surgery and radiation are still under investigation.[250]

D'Angelo et al[251] performed a pooled analysis of 889 patients who received immunotherapy, of which 86 (10%) had MM. Of those who received nivolumab monotherapy, the median PFS was 3.0 months, and objective response rates were 23.3%. Median PFS in patients treated with nivolumab combined with ipilimumab was 5.9 months with objective response rates of 37.1%. The incidence of grade 3 or 4 treatment-related adverse events rates was similar between the mucosal and cutaneous cohorts and roughly 4-fold higher for combination therapy as compared to monotherapy.

Lechner et al[252] performed an international multicenter retrospective analysis of 505 sinonasal MM cases from 11 international institutions. There was a statistically significant survival benefit for patients who received ART, compared with those who underwent SA (HR = 0.74) and immune checkpoint blockade for the management of recurrent or persistent disease, with or without distant metastasis, conferred longer survival (HR = 0.50, $P = .04$).

Abiri et al[253] reviewed over 1,900 cases of MM in the NCDB. Surgery with immunotherapy was associated with greater OS than SA (HR 0.672; $P = .036$). Surgery and immunotherapy (HR 0.425; $P = .024$) and combination with RT (HR 0.594; $P = .045$) were associated with superior OS than surgery with radiation.

Heavy Particles

Three prospective analyses[254-256] have been conducted on MM treated with CIRT. Patients have generally been treated with 16 fractions to a dose of 57.6 to 70.4 GyE with 2-year LC rates of 80% to 90%, with acceptable anticipated toxicity based on the extent and location of the primary tumor. A representative literature summary is included in Table 54.14.

TABLE 54.14 REPRESENTATIVE LITERATURE SUMMARY OF OUTCOMES FOLLOWING CARBON THERAPY FOR MUCOSAL MELANOMA

Yanagi et al[256] reported on 72 patients at Chiba who received doses from 52.8 to 64 GyE over 16 fractions in 4 weeks. With a median follow-up of 49.2 (range, 16.8-108.5) months, the 5-year LC rate was 84.1% and the 3- and 5-year OS rates were 46.1% and 27.0%, respectively. No acute or late toxicities of grade 3 or higher were reported. A 2011 analysis from Jingu et al[254] reviewed 37 patients who received a total 57.6 GyE over 16 fractions. After a median follow-up of 19 months, the 3-year LC, distant metastasis-free survival, and OS rates were 65.3%, 37.6%, and 88.1%, respectively. Toxicities were not reported. MRI minimum apparent diffusion coefficient was a prognostic factor for survival.

More recently, in 2019, Takayasu et al[255] from Gunma published their prospective experience treating 21 patients with MM of the H&N to doses between 57.6 and 64.0 GyE over 16 fractions. After a median follow-up of 15.5 months, the 3-year LC, PFS, and OS rates were 92.3%, 37.0%, and 49.2%, respectively. Regarding serious toxicities, eight

patients developed either grade 3 mucositis (2 patients; 10%), thrombocytopenia (1 patient; 5%), or leukopenia (5 patients; 24%). No patient developed a serious (grade 3 or higher) late toxicity.

Several other retrospective outcomes studies in the treatment of MM with carbon ion therapy were published between 2014 and 2019.[237,257,258] The most recent multicenter study from the J-CROS—which includes investigators from NIRS, Hyogo, Gunma, and HIMAT—is an update of patients reported in earlier series. In this 2017 multicenter study of various H&N histologies, multicenter study from the J-CROS, but this one focused on MM patients alone, Koto et al[237] reported on 206 patients treated with a total 57.6 GyE over 16 fractions. With a median follow-up of 22 months (range, 1-132), the authors reported 5-year LC, PFS, and OS rates of 72.3%, 27.2%, and 44.6%, respectively. A total of 27 grade 3 toxicities and 7 grade 4 toxicities were reported, including ipsilateral blindness (n = 5), mucosal ulcer (n = 1), and a second malignancy in the irradiated volume (n = 1). No late toxicities of grade 3 or higher were reported.

SARCOMAS OF THE HEAD AND NECK

Natural History

Sarcomas account for <1% of malignant neoplasms in the H&N. The histology is complex and requires immunochemical analysis, including angiosarcoma, chondrosarcoma, hemangiosarcoma, leiomyosarcoma, liposarcoma, malignant fibrous sarcoma, neurofibrosarcoma, osteosarcoma, RMS, malignant schwannoma, and synovial sarcoma. Fibrosarcoma, angiosarcoma, leiomyosarcoma, and RMS are the most common types, but this varies in published reports. Distribution of these sarcomas was 33% in the scalp or face, 26% in the orbit or paranasal sinuses, 14% arising from upper aerodigestive tract including the larynx, and 27% in the neck. Synovial sarcomas are rare soft tissue malignancies in the H&N region, accounting for 3% to 5% of H&N tumors. Histologic, immunohistochemical, and characteristic chromosomal translocation findings are necessary for diagnosis. The poor prognosis of this sarcoma justifies radical surgery with postoperative radiation.[259-261]

Radiation-induced sarcoma of the H&N is a rare long-term complication of treatment. The rarity of this tumor is reflected in the very few series reported in the English language medical literature.[262,263] When they do occur, most appear at least 10 years following RT. There is a possibility of a postirradiation sarcoma whenever a suspicious lesion is seen, regardless of the amount of time that has passed since RT was administered. The original pathology should be reexamined to ensure that the original tumor was diagnosed correctly.

The incidence of radiation-induced sarcomas of the H&N is, however, likely to increase due to progressive aging of the population combined with improved survival in patients with H&N cancer. This problem can be extremely challenging, and the overall outlook has been reported to be very bleak. Patel et al[262] reviewed 69 cases reported in the English medical literature since 1966 and pooled this information with their experience in treatment of 10 patients. This group was compared for survival with 124 patients with a diagnosis of H&N sarcoma registered on the Head and Neck Sarcoma database at the

Royal Marsden Hospital. There was no site prediction for radiation-induced sarcoma of the H&N, but malignant fibrous histiocytoma was the most common pathologic diagnosis. The period of latency between initial RT and diagnosis ranged from 9 to 45 years, with a median of 17 years. Surgery was the mainstay of treatment, and follow-up ranged from 6 months to 15 years with a median of 48 months. The actuarial 5-year disease-free survival rate in these patients was 60%.

Clinical Presentation and Diagnostic Workup

Clinical presentation varies with the primary site of disease. Tumors arising from the aerodigestive tract usually present with nasal bleeding, a palpable mass in the neck, or difficulty in swallowing or breathing. In tumors arising from the base of the skull or the nerve sheath, cranial nerve deficit is the most common presentation. Diagnostic workup follows that of soft tissue sarcomas of other sites in the body. With early lesions, radiographs or CT may show only nonspecific opacification, soft tissue swelling, and, occasionally, bone destruction. Table 54.6 outlines the suggested diagnostic workup. MRI, especially with gadolinium contrast, may be used as a supplement or alternative to CT scanning.[262,264] A CT scan of the chest is indicated to complete the staging workup to assess for distant metastasis.

The American Joint Committee on Cancer staging system for soft tissue sarcomas is based on histologic grade, the tumor size and depth, and the presence of distant or nodal metastases. The staging system applies to all H&N soft tissue sarcoma subtypes, with the exception of angiosarcoma, RMS of the embryonal and alveolar subtype, Kaposi sarcoma, and dermatofibrosarcoma protuberans.[265]

Prognostic Factors

Prognostic factors for predicting local recurrence or disease-free survival include anatomic site, treatment modality, tumor histology and grade, tumor size, extension of disease, lymph node metastasis, and surgical margins.[266-268]

A report from Royal Marsden Hospital showed anatomic location and treatment modality to be independent prognostic factors for local recurrence; tumors of the head had a better local RFS than did those of the neck.[267] Patients treated with a combination of surgery and RT had a better RFS than did those treated with surgery or irradiation alone. The only significant independent prognostic factor for OS was the implementation of definitive surgery versus biopsy. In the abovementioned report, the prognostic impact of tumor stage and grade did not reach statistical significance. In contrast, Tran et al[269] reported that 90% of patients with low-grade tumors were free of disease versus only 16% with high-grade lesions.

Bentz et al[270] reviewed 111 patients with H&N sarcoma; median duration of follow-up was 51 months; the actuarial 5-year relapse-free survival, DSS, and OS were 55%, 52%, and 44%, respectively. By multivariate analysis, size and grade significantly influenced all survivals, whereas margin status additionally influenced relapse-free survival.

In 109 soft tissue sarcomas of all sites, a French study demonstrated that quality of the surgery was one of the most important variables for predicting local recurrences. Tumor size, surgical margins, presence of tumor necrosis, and adequacy of the excision correlated with metastasis-free survival.[271]

General Management

Surgery is the preferred initial treatment modality for sarcomas; however, it is often difficult to achieve complete resection of the tumor, and a high recurrence rate has been observed with SA.[272] Extracapsular enucleation of the tumor results in 90% local recurrence because of the presence of microscopic pseudopodia, which tend to grow through the pseudocapsule into the surrounding tissue, and the presence of skipped lesions some distance from the main tumor mass. Pathologic analysis of the surgical bed often discloses microscopic extension of tumor. Farhood et al,[273] in a review of 176 cases of adult H&N sarcomas, reported that the pathologic margins of surgical specimens obtained by wide local excision were positive in >50% of cases. This resulted in inferior OS for sarcomas of the H&N when compared with extremity sarcomas.[274] Wide local excision, with a 5-cm margin around the pseudocapsule in extremity sarcomas, is associated with better outcome, although approximately 20% will have local recurrence. The criteria for surgical resection are impractical for H&N sarcomas because of anatomic limitations[275]; wide local excision is rarely possible because the tumors extend beyond the confines of origin and in the proximity of vital neurovascular structures. Some retrospective studies have suggested improved local tumor control when combined surgery and external irradiation are used. In 130 patients with soft tissue sarcomas of the H&N treated with SA at Royal Marsden Hospital, the overall 5-year survival was 50%; local tumor control was only 47%, and local recurrence was the cause of death in 63% of cases. Patients treated with combined modality treatment (surgery and irradiation) had less extensive surgery, yet local RFS was longer.[267]

Synovial sarcoma in the H&N is rare. In a report of 36 patients, Al-Daraji et al[276] noted there was a predilection for the parotid and the temporal regions, and nine involved skeletal muscle. Of 29 patients followed for a median of 14 years after surgical treatment, 11 were alive and tumor free.

A multidisciplinary discussion before the initiation of treatment is required to formulate the best approach for radiation delivery, surgical technique, and mode of reconstruction.

Radiation Therapy

RT, by external beam or brachytherapy, plays an important adjunctive role in disease management, especially for tumors where en bloc resection with negative margin is not possible.[277] Chemotherapy regimens are available for soft tissue neoplasms, primarily designed to improve local tumor control.[278]

A systematic review of RT trials was performed by the Swedish Council of Technology Assessment in Health Care.[279] This synthesis of the literature on RT for soft tissue

sarcomas is based on data from five randomized trials. Moreover, data from 6 prospective studies, 25 retrospective studies, and 3 other articles were used. In total, 39 scientific articles were included, involving 4,579 patients. The results were compared with those of a similar overview from 1996, which included 3,344 patients. There was evidence that ART improves local tumor control in combination with conservation surgery with negative, marginal, or minimal microscopic positive surgical margins. There are still insufficient data to establish that preoperative RT is favorable compared to postoperative RT in patients presenting primarily with large tumors. The preoperative setting results in more wound complications; however, this rate may be lower when compared to historic rates from extremity soft tissue sarcoma.[280] There is also no randomized study comparing external beam RT and brachytherapy.

Radiation Therapy Techniques

General principles for RT of H&N sarcomas are similar to those of soft tissue sarcomas. Complete coverage of the surgical bed and scar with adequate margins (2-5 cm) is required.[277] However, because of the proximity of critical and radiosensitive organs (eyes, spinal cord, brainstem), highly conformal techniques such as IMRT or particles are indicated to avoid seriously compromising target coverage to meet normal tissue constraints. Techniques similar to those used in epithelial tumors of the H&N can be applied to sarcomas. In general, 50 to 60 Gy is needed for postoperative adjuvant irradiation, and an additional 10- to 15-Gy boost is recommended if the surgical margins are close (≤3 mm) or involved by tumor. Some institutions prefer preoperative irradiation of 45 to 50 Gy. Special attention should be directed to limiting the dose to critical structures. The use of highly conformal radiation techniques such as particle therapy or IMRT (Figure 54.18) allows for optimization of target coverage and sparing of OARs. Target definitions and treatment approaches are summarized in Table 54.15 for patients with soft tissue sarcomas of the H&N. This table does not apply to those with RMS, Ewing sarcoma, and angiosarcoma, nor does it include bone tumors such as chordoma, chondrosarcoma, or osteosarcoma. For those, refer other sections within this chapter and text.

TABLE 54.15 TREATMENT OPTIONS FOR POSTOPERATIVE RADIOTHERAPY FOLLOWING GROSS TOTAL RESECTION OF ADULT SOFT TISSUE SARCOMA[A] OF THE HEAD AND NECK

Indication for RT	Preoperative: Consider preoperative for deep, bulky, or high-grade tumors. In addition, in situations when the tumor is abutting critical organs at risk or if there is uncertainty over expected surgical margins Postoperative: High grade AND >5 cm, R1/R2 resection (low or high grade), scenarios where surgical salvage of local recurrence will not be possible or high risk of morbidity
Preoperative RT dose	Prescription dose 50 Gy in 25 treatments
Postoperative RT dose	R0 resection: 60-64 Gy (1.8-2.0 Gy per fraction) R1 or R2 resection: 66-70 Gy (1.8-2.0 Gy per fraction) We do not currently hypofractionate for head and neck sarcomas, but early clinical investigations are ongoing.

ENI	No ENI: Node negative or when adding ENI significantly increases the risk of acute toxicity or a late complication. Yes ENI: This is rare and only considered in cases of positive nodes or histologies at high risk for nodal spread. ENI dose: 50 Gy at 2 Gy per fraction. In patients with a positive node, we include the area of positive adenopathy in the high-risk target volume and boost to approximately 60 Gy.
RT technique	In most cases, photon-based IMRT; can consider proton therapy to reduce integral dose
GTV	Fuse T1 contrast and T2 sequences from MRI (preferable in treatment position) to treatment planning scan. Define GTV by visible tumor on CT and MRI.
CTV	Resection bed plus 1-2 cm edited for anatomic boundaries to tumor spread
PTV	CTV plus 3 mm based on institutional practice and daily CBCT image guidance

Current clinical practice at the Mayo Clinic Florida for soft tissue sarcoma.

CBCT, cone-beam computed tomography; CTV, clinical tumor volume; ENI, elective nodal irradiation; GTV, gross tumor volume; IMRT, intensity-modulated radiotherapy; PTV, planning tumor volume; R0, margin negative; R1, margin microscopically positive; R2, gross residual tumor.

[a]Soft tissue histologies other than rhabdomyosarcoma, Ewing sarcoma, and angiosarcoma. This does not include bone sarcomas, such as chordoma, chondrosarcoma, and osteosarcoma.

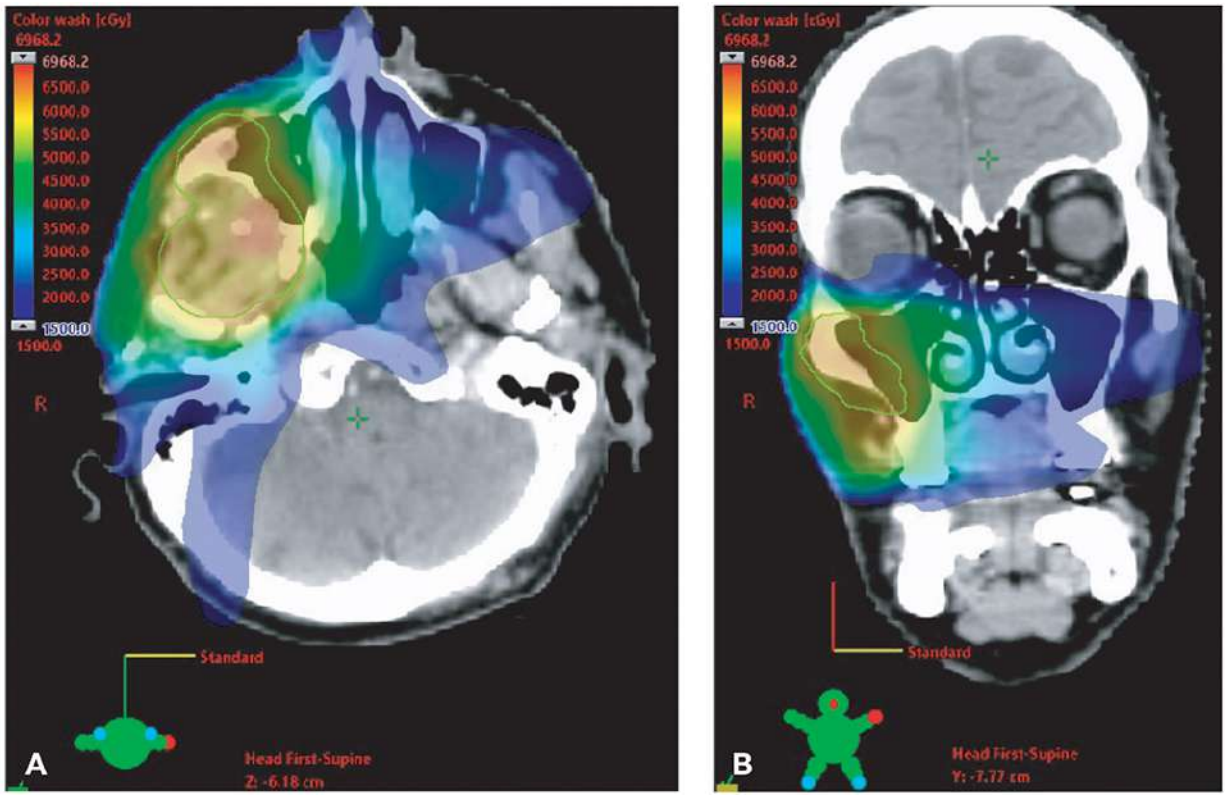

FIGURE 54.18 Representative intensity-modulated radiotherapy (IMRT) plan showing an axial (A) and coronal (B) color wash dose distribution from a computed tomography planning scan of a right maxillary sinus solitary fibrous tumor being treated postoperatively to 60 Gy. The planning target volume is shown in green. Highly conformal techniques such as IMRT allow for reduction in dose to the optic apparatus. Results of Therapy

Because of the propensity for sarcomas to invade the surrounding tissues, complete surgical clearance may be difficult. In a series from UCLA, attempted en bloc resection left residual tumor at the surgical margins in 52 of 127 patients.[269] The incidence of local recurrence was high (60%) with SA.

In a retrospective report of 73 patients with sarcomas of the H&N treated at Princess Margaret Hospital, the 5-year CSS was 62%, with a local recurrence rate of 41% and a distant metastasis rate of 31%.[264] Extension to adjacent structures, high-grade tumor, and tumor >10 cm were associated with poor survival. Gross residual tumor after surgery was also associated with a high local recurrence rate (75%) despite the addition of RT. Patients with clear surgical margins or only microscopic involvement fared much more favorably and had a similar local tumor control rate (74% and 70%, respectively), provided adjuvant irradiation was given. Because of the difficulty in obtaining wide surgical margins, 68% of the patients died as a result of uncontrolled local disease. These data substantiate the importance of surgical margins as well as the contribution of adjuvant irradiation.[144]

Colville et al[275] reported on 41 male and 19 female patients treated with H&N soft tissue sarcomas, with an overall 5-year survival of 60%. Twenty-five patients had SA, 20 had surgery and pre- or postoperative RT, and 15 received nonsurgical treatment. With a mean follow-up of almost 4 years, the 5-year local tumor control was 56% in the surgical group and 40% in the nonsurgical group (more advanced and aggressive tumors). The 5-year survival was 70% and 40%.

Penel et al[281] recorded their experience with 28 adult H&N soft tissue sarcomas. The most common subtype was RMS (seven cases). Twenty-two patients presented with previous inadequate resection performed elsewhere before admission. Nineteen patients had surgery (complete resection in 13 cases). Associated treatments were neoadjuvant chemotherapy, adjuvant chemotherapy, and postoperative RT in 4, 3, and 10 cases, respectively. The 2-year OS rate was 56%. Wolden et al[282] treated 28 patients with H&N RMS using IMRT (50-55 Gy in 1.8 Gy fractions) combined with chemotherapy. With a median follow-up of 24 months, local tumor control was 95% and 3-year survival 100%. McDonald et al[283] treated 20 children with RMS in the H&N with IMRT (median dose 50.4 Gy, 1.8 per fraction). With a median follow-up of 29 months, the 3-year local tumor control was 100% and survival 76%.

Pandey et al[284] reported on 22 cases of H&N sarcomas (the neck, lower jaw, tongue, cheek, scalp, and maxilla were the most common sites affected). None of the patients had palpable neck nodes or distant metastasis at presentation. All the patients were treated with primary surgical resection, followed by adjuvant treatment in 14 cases (63.6%). After a median follow-up of 14.5 months, two patients died, six developed local recurrence, four developed metastatic disease, and another patient developed a second primary sarcoma. The overall 5-year survival was 80%, whereas the 5-year disease-free survival rate was 24.1%.

Barker et al[285] published a review of 44 patients with nonmetastatic soft tissue sarcoma in the H&N. The most common tumor histologies included malignant fibrous histiocytoma

(15 patients), angiosarcoma (9 patients), fibrosarcoma (6 patients), and leiomyosarcoma (6 patients). The median OS for all patients was 79 months. The actuarial 5-year local tumor control was 55% and was highly correlated with the extent of surgical excision: 25% for subtotal resection or debulking, 65% for wide local excision, and 100% for radical excision. Local tumor control at 5 years was 60% for patients treated with both surgery and RT, 54% for SA, and 43% for radiation alone. ART significantly improved the LC rates (from 25% to 54%) for patients with close (<2 mm) or positive surgical margins. Of 14 patients with locoregional failure in whom salvage was attempted, 9 (64%) were rendered disease free.

Moalikyar et al[286] reported on 40 patients with H&N sarcomas, histologies including undifferentiated pleomorphic sarcoma (9), fibrosarcoma (6), chondrosarcoma (6), angiosarcoma (5), spindle cell sarcoma (3), osteosarcoma (3), and others (7). Tumor sites were the scalp or skin (11), mandible or temporomandibular joint (9), skull base or paranasal sinuses (9), neck (6), or upper airways (6). Histologic grade was low for 13, intermediate for 5, high for 17, and unavailable for 5. All patients underwent gross total tumor resection: 22 (57%) treated with SA, whereas 18 (43%) patients received surgery and postoperative RT. At a median follow-up of 14.9 months, the 2-year OS, LRC, and distant metastasis control were 68%, 73%, and 74%, respectively. Positive margins significantly reduced both 2-year LRC (52% vs 84%; $P = .01$) and OS (42% vs 81%; $P = .004$). The addition of ART did not improve 2-year LC (70% vs 77%; $P > .05$) or OS (58% vs 79%; $P > .05$). However, among the subgroup of patients with positive margins, the use of RT improved 2-year OS (73% vs 0%; $P = .03$) without an associated LC benefit. Similarly, improved 2-year OS was identified for high-grade tumors treated with RT (73% vs 0%; $P = .03$) with no associated LC benefit. Sarcomas of the skull base or paranasal sinuses demonstrated significantly worse 2-year LC (28% vs 86%; $P = .0002$) and OS (0% vs 83%; $P = .001$) than other evaluated subsites.

Huang et al[287] extracted data from 1,525 patients from the SEER database with diagnosis of H&N sarcoma treated between 1973 and 2010. Selected patients had no prior malignancies and no distant metastatic disease. The most common histology was fibrohistiocytic tumors (18.6%), followed by unspecified sarcomas (15.5%), blood vessel tumors (14.0%), liposarcomas (12.1%), and leiomyosarcomas (11.6%). Most tumors were nonspecifically coded as connective tissue of the head, face, and neck (60.3%). After that, the most common site was the skin/scalp (19.6%), followed by nasal cavity/paranasal sinus (4.6%) and oral cavity (3.9%). Of the cohort, 576 (37.8%) patients received RT in addition to surgery.

With a median follow-up of 48 months, the 5-, 10-, and 15-year OS rates were 64%, 49%, and 42%, respectively. The median OS in patients treated with surgery and RT was 82 months, which was inferior to that of 139 months in patients with surgery only ($P < .001$). Multivariate analyses showed that age >60, regional stage, high grade, and tumor size >5 cm were factors associated with worse survival. RT seemed to improve OS, but that result was not statistically significant (HR 0.90, $P = .247$).

Further analyses showed that patients with high-grade tumors had an improved OS by RT (HR 0.78, $P = .017$). The median survival was 59 months in patients with RT versus 45 months in those patients without RT. There was no significant difference in OS among patients with low-grade tumors by RT.

Brandmaier et al[288] also analyzed the SEER database for local H&N cancers diagnosed between 1990 and 2011 that included an array of 12 sarcoma subtypes totaling 1,046 patients. Tumor size and staging data were limited. For all patients with H&N sarcoma, the SA cohort had a 5-year OS of 65.4% compared to 53.3% for patients receiving surgery and ART ($P = .0009$). The 5-year CSS in the surgery cohort was 82.4% compared to 64% in patients receiving surgery and ART ($P < .0001$). Age >75 years was a negative prognostic factor for CSS, relative to age 20 to 39, with an HR of 1.61 ($P = .033$). High-grade histology was also a negative prognostic factor for CSS; grade 3 tumors had an HR of 8.0 relative to grade 1 ($P < .0001$). Among patients with grade 3 sarcomas, those receiving SA had a 5-year OS of 48.2% versus 43.7% for those receiving surgery and RT ($P = .81$).

Among a smaller subset of stage T1N0 grade 3 sarcomas, the 5-year OS for SA was 61.1% versus 51.6% for surgery and RT ($P = .89$). The CSS for the two groups was 77.5% and 71.6%, respectively ($P = .99$).

The authors hypothesized that ART could be beneficial for grade 3 H&N sarcomas, regardless of tumor stage or margin status.

Mahmoud et al[289] using the NCDB evaluated RT utilization pattern and outcome of adjuvant therapies in 2,096 patients with nonmetastatic H&N sarcomas diagnosed between 2004 and 2012, who underwent tumor resection. Chi-square test assessed the cohort that included 1,366 males and 730 females with a median age of 62 years (range: 18-90). Fibromatous sarcoma (20%) and high grades (36%) were the most common histology and grade, respectively. RT delivery was significantly more frequent in high-grade, large tumors with positive surgical margins. At a median follow-up of 36 months, RT use did not impact survival nor did CT, which was delivered in 260 patients. Restricting the survival analysis to 752 high-grade patients, the 5-year OS improved from 43% to 54%, with RT delivery reducing mortality HR by 36% ($P < .001$).

Their analysis showed that ART may improve survival in high-grade H&N sarcomas and that chemotherapy may not be beneficial.

Reported results of treatment of soft tissue sarcomas are summarized in Table 54.16.

TABLE 54.16 TREATMENT RESULTS OF ADULT SOFT TISSUE SARCOMAS OF THE HEAD AND NECK

[a]Series based on adults and children, excluding angiosarcomas.

Particles

Because of the dosimetric and potential biologic enhanced effects with particle therapy, protons or heavy ions have been more commonly used for H&N bone and soft tissue sarcomas. Hug et al[293] reported on 27 patients treated at Massachusetts General Hospital in Boston (18 primary and 9 recurrent sarcomas of the H&N close or abutting critical structures with 160-MeV protons; mean dose 68.5 GyE in 2.1-GyE fractions). Local recurrence was seen in eight (29%) patients and regional recurrence in six (22%) patients. Tumor grade had a significant impact on outcome. One patient developed Lhermitte sign and another hypothyroidism.

Jingu et al[294] described results in 27 patients with H&N unresectable bone and soft tissue sarcomas, treated with carbon ions (57.6, 64.0, or 70.4 GyE in 16 fractions). The 3-year local tumor control was 91.6% and survival 72%. Therapy was well tolerated. A comparison with historical results showed that local tumor control rate with 70.4 GyE was significantly higher than that with 57.6 or 64.0 GyE (3-year, 91.8% vs 23.6%, $P < .0001$). Furthermore, the OS with 70.4 GyE tended to be higher than that with 57.6 or 64.0 GyE (3-year, 74.1% vs 42.9%, $P = .09$).

Tumor Characteristics and Prognosis

Several series have shown that tumor grade and size dictate the outcome of patients with H&N sarcomas, such as leiomyosarcoma, RMS, and malignant fibrous sarcoma.[261,267,268,271] Farhood et al,[273] in a review of 176 adult H&N sarcomas, found that only 20% of the patients with high-grade tumors were alive 10 years after treatment, compared with 88% of patients with low-grade tumors.

Some series have reported that chondrosarcoma is not a radiosensitive tumor and that RT has no role in its treatment. However, modern reports have demonstrated efficacy of high-dose RT for patients with this histology. Hasegwa et al[295] performed a retrospective analysis of 32 patients with grade I or II skull base chondrosarcoma treated at the Mayo Clinic. Fourteen (44%) underwent upfront RT, whereas 18 (56%) were followed with serial MRI alone. Of the patients who received upfront ART, the 5-, 10-, and 15-year

cumulative freedom was 100%, 100%, and 67%, in those who received RT as compared to 64%, 64%, and 64%, respectively, in those who underwent upfront surveillance. While RT reduced the risk of early recurrence, this was not statistically significant (P = .250) and many of these patients were salvaged as the 10-year DSS was 95% with no difference between either cohort (P = .50).

Weber at el.[95] reviewed the outcomes from 151 patients treated with proton-based therapy for skull base chondrosarcoma. The 7-year LC rate was 93.6%. Figure 54.19 shows an example illustration of preoperative and postoperative chondrosarcoma status post near-total resection who received postoperative pencil-beam PT.

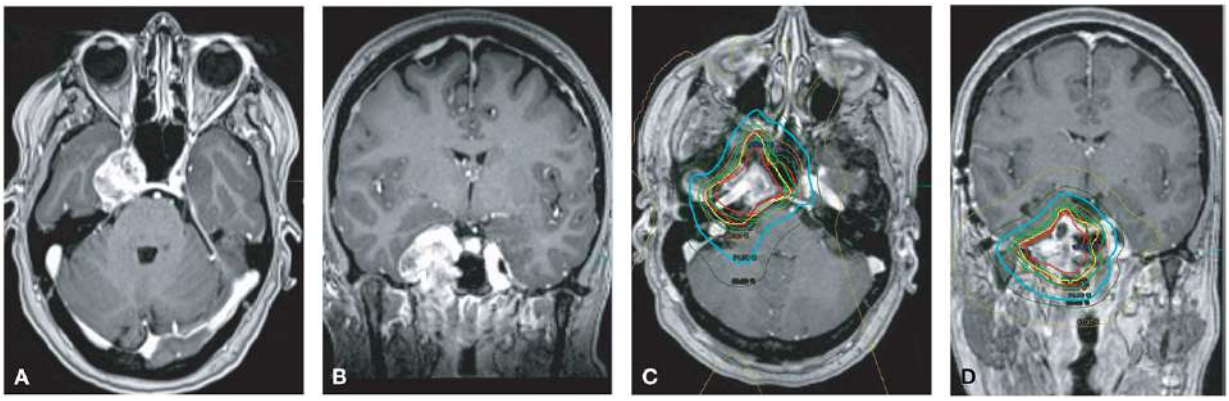

FIGURE 54.19 Preoperative T1-weighted magnetic resonance imaging (MRI) with contrast axial (A) and coronal (B) sequences showing a right petroclival chondrosarcoma. This patient underwent a near-total gross resection and received 70.2 GyRBE using a three-field pencil-beam scanning proton technique showing axial (C) and coronal (D) planning MRI co-registered to the planning computed tomography simulation. The planning target volume is shown in red. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Catanzano et al[296] reviewed 427 patients with a histologic diagnosis of chondrosarcoma in the NCDB. They found that 680 received a form of RT (13%). The multivariate proportional hazards analysis controlling for various patient, tumor, and treatment variables, including RT dose and modality, demonstrated that while overall RT was not associated with improved survival (HR 0.96, 95% CI 0.76-1.20), when examining just the patient cohort with positive surgical margins, RT trended toward improved survival (HR 0.81, 95% CI 0.58-1.13). When comparing advanced and conventional RT modalities, advanced RT was associated with significantly decreased mortality (HR 0.55, 95% CI 0.38-0.80). Modern advanced conformal RT may present a treatment option for certain patients, particularly in selected high-risk patients, particularly those with residual disease or a high risk of morbidity from recurrence related to either the tumor's location or the salvage intervention.

Osteogenic sarcoma of the H&N has a pattern of recurrence different from similar tumors elsewhere in the body. H&N osteosarcomas are usually high grade; they have a very high incidence of local recurrence but a lower risk of distant metastases. Several studies have used adjuvant irradiation and chemotherapy, which commonly results in

improved LRC and survival. Tran et al[269] reported a 73% 5-year survival rate in patients with osteogenic sarcoma of the H&N treated with high-dose preoperative irradiation followed by wide surgical excision.

Chemotherapy

The role of either routine preoperative or adjuvant chemotherapy to improve disease-free survival in sarcoma of the H&N is controversial. There are notable exceptions such as with synovial sarcoma, RMS, Ewing sarcoma, mesenchymal chondrosarcoma, osteosarcoma, and some cases of poorly differentiate chordoma where chemotherapy has demonstrated efficacy. Unlike with soft tissue sarcomas of the extremities, in which distant metastasis is the most common cause of death, the majority of deaths in sarcomas of the H&N are associated with local failure. Approximately half of the distant metastases were detected after local recurrence occurred.[264] Chemotherapy did not appear to affect local tumor control. With the noted exceptions, adjuvant chemotherapy for H&N sarcomas should be given only in a clinical trial setting.[85,278]

CHAPTER 55

Neck Cancer, Including Carcinoma of Unknown Primary

William M. Mendenhall, Anthony A. Mancuso, Robert J. Amdur, Rui P. Fernandes, and Peter T. Dziegielewski

ANATOMY

The locations of the various lymph node groups in the head and neck are shown in Figure 55.1.[1] Under normal conditions, the right and left lymphatic networks do not shunt from one side to the other.[2] The following discussion focuses on mucosal squamous cell carcinomas (SCCs) unless otherwise specified.

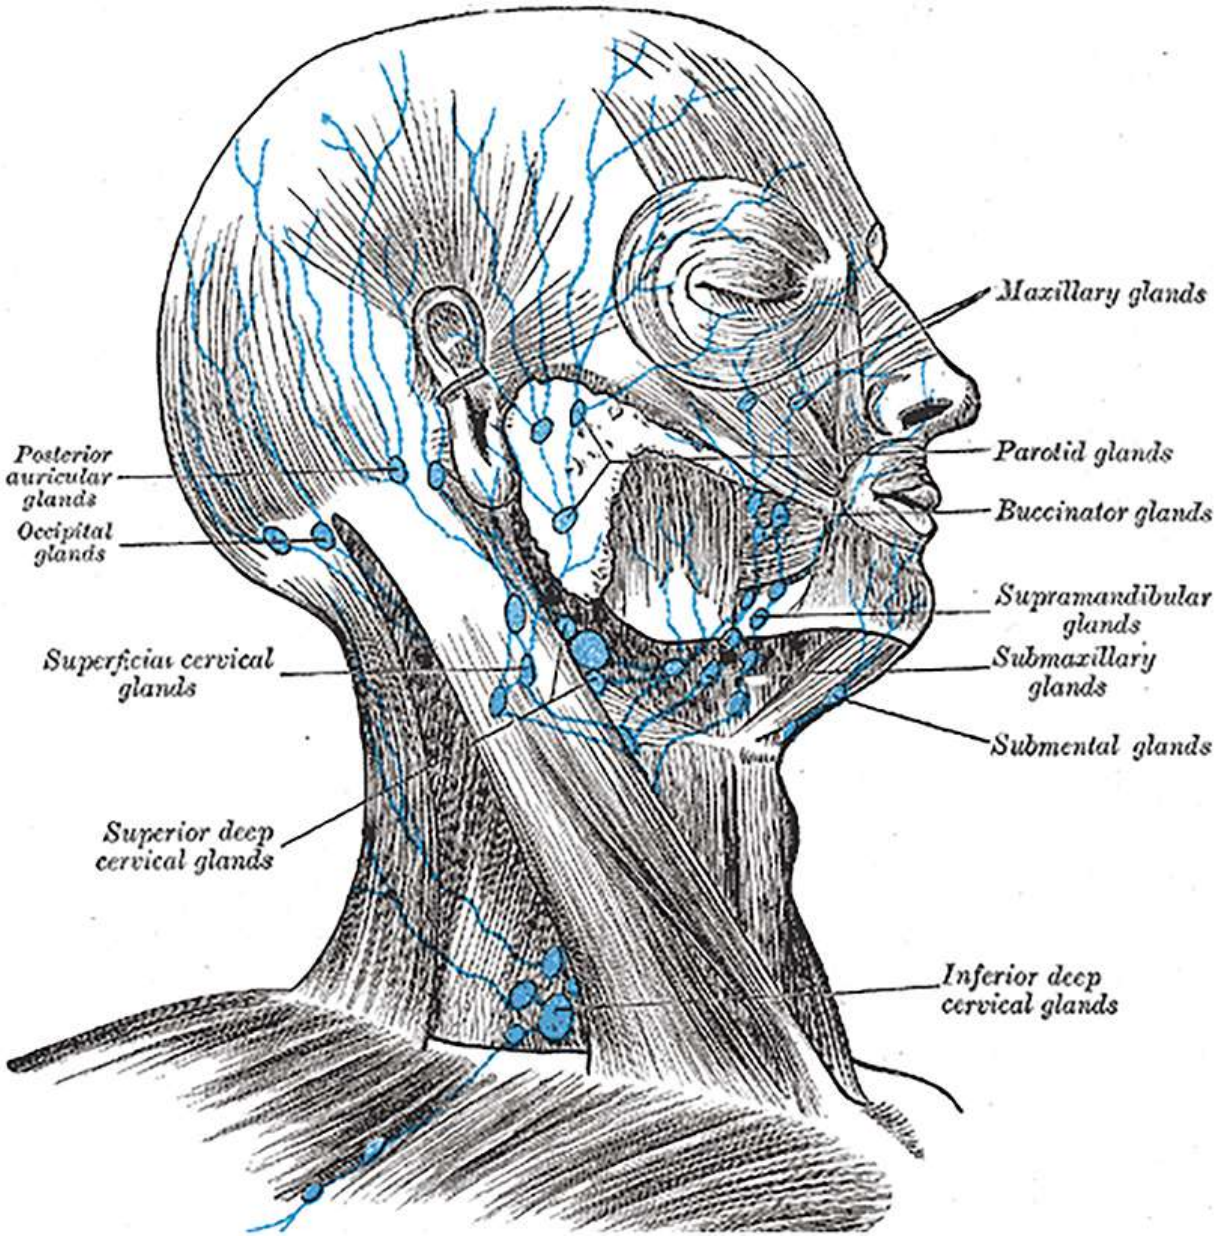

FIGURE 55.1 Arrangement of lymph nodes in the head and neck. (Redrawn from Rouvière H. *Anatomie Des Lymphatiques de L'homme*. Masson; 1932:10.)

The internal jugular chain (IJC) lymph nodes lie adjacent to the internal jugular vein and extend from the skull base to the clavicle. The most superior group of lymph nodes in this chain lies near the base of the skull in the posterior aspect of the lateral pharyngeal space and is often referred to as the parapharyngeal or junctional lymph nodes. These lymph nodes lie deep in the sternocleidomastoid muscle, the posterior belly of the digastric muscle, and the tail of the parotid gland. The remaining IJC lymph nodes

are artificially divided into the subdigastric, middle jugular, and lower jugular groups.

The spinal accessory chain (SAC) lymph nodes are distributed along the course of cranial nerve XI. The superior nodes of the SAC blend with the upper IJC nodes. The supraclavicular lymph nodes merge laterally with the SAC lymph nodes and medially with the lower IJC lymph nodes.

There are typically three to six submandibular lymph nodes. They may be either preglandular or postglandular; there are no lymph nodes in the substance of the submandibular gland. Adjacent to these nodes are also the perifacial lymph nodes, which lie next to the facial artery and vein around the marginal mandibular nerve. The submental lymph nodes lie in the midline between the anterior bellies of the digastric muscles, anterior and superior to the hyoid bone, and superficial to the mylohyoid muscle. There are typically one to three nodes in this area. The lateral retropharyngeal lymph nodes lie within the retropharyngeal space, which is bounded anteriorly by the pharyngeal constrictor muscles, superiorly by the skull base, and posteriorly by the prevertebral fascia. They are usually found at the level of the C1 and C2 vertebral bodies but may be found as inferiorly as C3. The medial retropharyngeal nodes are small, inconstant intercalated nodes that are located near the midline and empty into the lateral retropharyngeal lymph nodes.

The neck nodes are divided into levels as follows: level I, submental (IA) and submandibular (IB) nodes; level II, upper internal jugular nodes, from the skull base to the level of the hyoid bone divided by the spinal accessory nerve into levels IIa (anterior to the nerve) and IIb (posterior to the nerve); level III, middle internal jugular nodes, from the level of the hyoid bone to the omohyoid muscle; level IV, inferior internal jugular nodes, from the level of the omohyoid muscle to the clavicle; level V, divided by the spinal accessory nerve into levels Va (superior to the nerve) and Vb (inferior to the nerve); and level VI, central neck nodes, bounded by the hyoid bone, the sternum, and the common carotid arteries. Included in level VI are the paratracheal, pretracheal, precricoid (Delphian), and tracheoesophageal groove nodes.[3]

NATURAL HISTORY

The risk of lymph node metastases is influenced by the location of the primary tumor, histologic differentiation, size of the lesion, and the availability of capillary lymphatics.[4-7] The estimated risk of subclinical disease in the clinically negative neck as a function of the primary site and tumor (T) stage is shown in Table 55.1.[4] Previously unirradiated recurrent lesions have a higher risk of lymphatic involvement than untreated lesions. Moreover, their spread is less predictable. Previous irradiation of the lymphatics likely reduces the risk of lymph node metastases.

TABLE 55.1 DEFINITION OF RISK GROUPS

Group	Estimated Risk of Subclinical Neck Disease (%)	Stage	Site
I: Low risk	<20	T1	Floor of mouth, retromolar gingiva, trigone, palate, buccal hard mucosa
II: Intermediate risk	20-30	T1	Oral tongue, soft palate, pharyngeal wall, supraglottic larynx, tonsil
		T2	Floor mouth, oral of retromolar tongue, gingiva, trigone, hard palate, buccal mucosa
III: High risk	>30	T1-4	Nasopharynx, pyriform sinus, base of tongue
		T2-4	Soft palate, pharyngeal wall, supraglottic larynx, tonsil
		T3-4	Flour of mouth, oral retromolar tongue, trigone, gingiva, hard palate, buccal mucosa

Reprinted from Mendenhall WM, Million RR. Elective neck irradiation for squamous cell carcinoma of the head and neck: analysis of time–dose factors and causes of failure. *Int J Radiat Oncol Biol Phys*. 1986;12(5):741-746. Copyright © 1986 Elsevier. With permission.

The relative incidence of clinically positive lymph nodes in the neck by anatomic site and T stage is shown in Table 55.2.[5] The most commonly involved lymph nodes in the head and neck are the level II lymph nodes, followed by the level III lymph nodes. Lesions that are well lateralized almost always spread first to the ipsilateral neck nodes. Lesions on or near

the midline as well as lateralized base of the tongue and nasopharyngeal lesions may spread to both sides of the neck.

TABLE 55.2 CLINICALLY DETECTED NODAL METASTASES ON ADMISSION CORRELATED WITH T STAGE

Primary Site	T Stage	N0 (%)	N1 (%)	N2-3 (%)
Oral tongue[a]	T1	86	10	4
	T2	70	19	11
	T3	52	16	31

[d]T stage defined by MacComb et al.

[e]T stage defined by Chen and Fletcher.

Modified from Lindberg R. Distribution of cervical lymph node metastases from squamous cell carcinoma of the upper respiratory and digestive tracts. *Cancer*. 1972;29(6):1446-1449.

Patients who have clinically positive lymph nodes on the ipsilateral side of the neck may be at risk for contralateral lymph node spread if the metastatic masses produce significant obstruction of the lymphatic trunks. In addition, patients who have undergone previous surgery on one side of the neck develop shunting of lymph across the submental region to the opposite side of the neck. When contralateral lymph node metastases occur,

the level II lymph nodes are most frequently involved, followed by the level III and level IV lymph node groups.

As tumor grows within a lymph node, the node becomes indurated and more rounded and enlarges. Tumor eventually extends through the capsule of the lymph node and invades the surrounding structures. Extension to neurovascular bundles is common and may produce a mass that is fixed to palpation. The incidence of tumor involvement and the likelihood of capsular penetration as a function of lymph node size are shown in Table 55.3.[6]

TABLE 55.3 RELATIONSHIP BETWEEN NODE SIZE, THE PRESENCE OF TUMOR IN THE NODE, AND CAPSULAR PENETRATION IN 519 NODES

	Size of Node (cm)				
	1	2	3	4	≥5
Number of nodes	177	183	84	17	58
Percentage positive	33	62	81	88	100
Percentage positive capsular with penetration	14	26	49	71	76

The risk of lateral retropharyngeal lymph node involvement is related to the primary site and neck stage[7]; the medial retropharyngeal nodes are almost never the site of metastatic disease. The incidence of positive retropharyngeal nodes based on pretreatment computed tomography (CT) and, in selected cases, magnetic resonance imaging (MRI) is shown in Table 55.4.[7]

TABLE 55.4 INCIDENCE OF POSITIVE RETROPHARYNGEAL NODES FOR VARIOUS PRIMARY SITES AND CLINICAL NECK STAGES (794 TUMORS)

	Clinical Neck Stage		
Primary Site	**N0 Neck (%)**	**N+ Neck[a] (%)**	**Overall (%)**
Nasopharynx	2/5 (40)	12/14 (86)	74
Pharyngeal wall	6/37 (16)	12/56 (21)	19
Soft palate	1/21 (5)	6/32 (19)	13
Tonsillar region	2/56 (4)	14/120 (12)	9
Pyriform or sinus postcricoid area	0/55 (0)	7/81 (9)	5
Base of tongue	0/31 (0)	5/90 (6)	4
Supraglottic larynx	0/87 (0)	4/109 (4)	2

[a]N+ are neck nodes clinically involved (stages N1-3B).

DIAGNOSTIC WORKUP

Physical Examination

The patient is examined in the sitting position, the examiner behind the patient with one hand on the occiput to flex the patient's head forward and the other hand on the side of the neck to be examined. To examine the IJC lymph nodes, which lie deep to the sternocleidomastoid muscle along the internal jugular vein, place the thumb and index finger around the sternocleidomastoid muscle in the form of a "C" and then gently proceed from the sternal notch to the angle of the mandible. Both sides of the neck should not be examined simultaneously. The level Ib and level Ia nodes may be evaluated by direct palpation of these areas as well as by a bimanual examination with the index finger placed on the floor of the mouth.[8]

The following features of metastatic lymph nodes should be recorded: anatomic location, size, consistency, mobility, and clinical impression as to whether the node is involved with cancer.

Radiographic Evaluation

CT, MRI, fluorodeoxyglucose-positron emission tomography (FDG-PET), and ultrasound may be used to evaluate cervical metastatic disease.[9] At the University of Florida, CT remains the primary method of examination of most carcinomas arising in the upper aerodigestive tract and the regional lymphatics. MRI is the primary study only in patients with nasopharyngeal malignancies. MRI may also be used in patients who are allergic to intravenous contrast medium. Ultrasound has been used mainly in Europe to evaluate the cervical nodes. FDG-PET may be used to evaluate equivocal suspicious lymph nodes if the results of the scan would alter the treatment plan. Positive nodes <1 cm will not be reliably detected on a PET scan. FDG-PET remains unproven with regard to improving accuracy rates over those available with properly performed and interpreted CT.

Small metastases may be seen as lucent foci in normal-sized nodes. Such metastases have been identified and surgically confirmed in nodes as small as 6 to 8 mm; however, most subclinical disease in normal-sized nodes remains undetected on CT. FDG-PET has a marginal capability to improve CT in detecting the subclinical disease in small (<1 cm) nodes.

Lucent foci in normal-sized nodes must be differentiated from hilar fat or volume-averaging artifacts. As the metastasis grows, the node becomes more spherical than elliptical. Areas of necrosis are almost always present in nodal metastases larger than 2 cm. As the metastasis enlarges, the capsule of the node becomes hyperemic and is seen radiographically as contrast-enhanced rim. When the capsule becomes indistinct and irregular along its outer margin, it is highly suggestive early of capsular penetration. Continued growth causes obliteration of the fat planes surrounding the nodes. Finally, no clear plane of normal tissue lies between the mass and the adjacent structures, at which point the clinician usually notes fixation (Figure 55.2). Penetration of the prevertebral fascia and fixation to the scalene muscles are uncommon in untreated patients. Largely necrotic nodes may be negative on FDG-PET examinations.

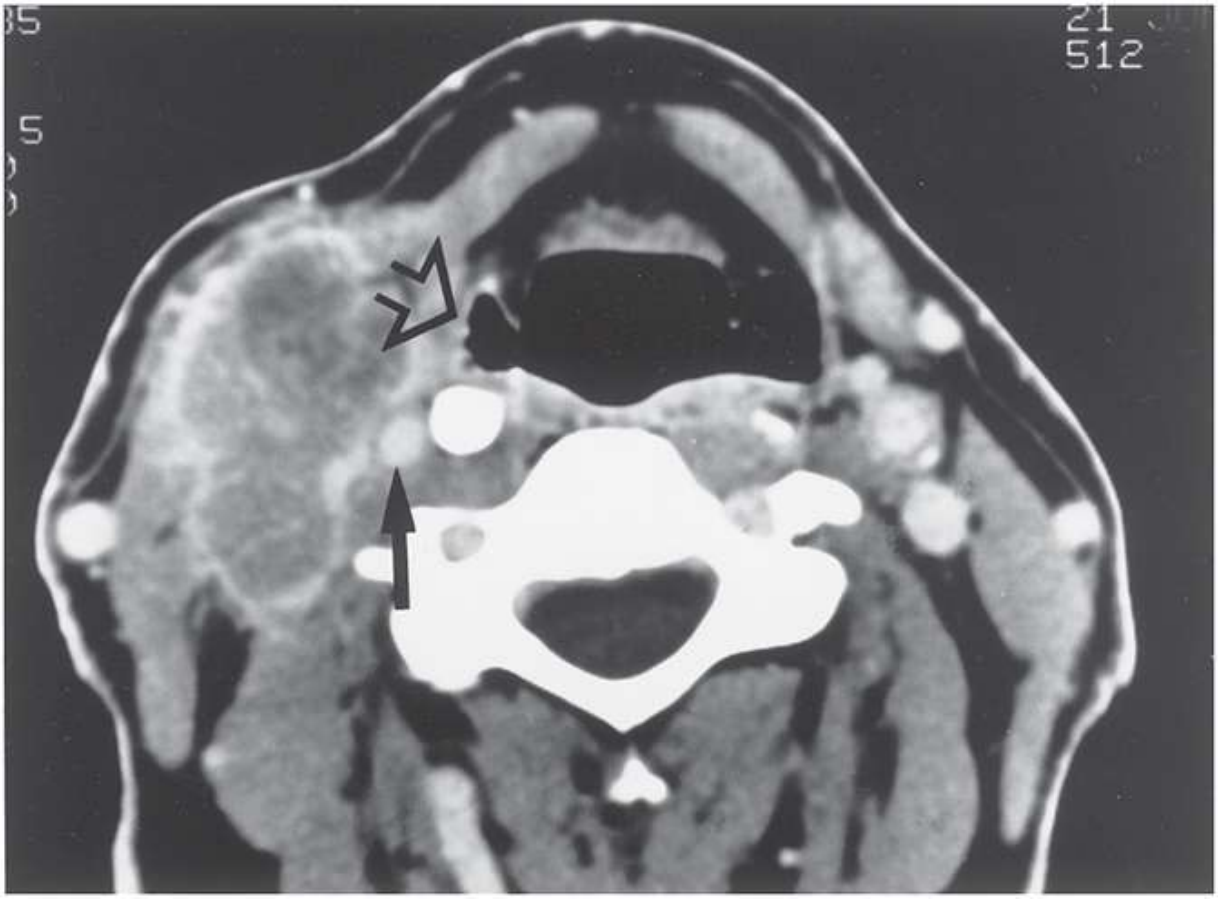

FIGURE 55.2 T1 squamous cell carcinoma of the lateral wall of the right pyriform sinus (open arrow) and a fixed N3B neck node that abuts but does not surround the carotid artery (solid arrow).

If a node shows evidence of capsular penetration and envelops more than 50% of the circumference of the carotid artery, clinical evidence of fixation to the artery is likely. Ultrasound and MRI may prove useful in evaluating tumor extension to the carotid, as suggested by CT. MRI tends to be better at excluding extension to the neurovascular bundle when it is suspected on CT, whereas ultrasound can help show invasion of the vessel wall, thus confirming focal extension to the artery.

STAGING

The staging systems shown in Table 55.5 are those of the American Joint Committee on Cancer (AJCC).[10] Because all University of Florida data presented in this chapter were analyzed using the 1983 AJCC staging

system,[11] both the 1983 and 2017 systems are outlined in Table 55.5. Stage N3C in the 1983 system is rare and should alert the clinician to search for another primary lesion. The 2017 AJCC staging system classifies bilateral or contralateral nodes not more than 6 cm in diameter as N2C; N3 is defined as a metastasis in a lymph node more than 6 cm in diameter.[10] The AJCC nodal staging system for head and neck cancer has not changed appreciably since the 1997 edition. The AJCC nodal staging for nasopharyngeal carcinoma differs from other head and neck primary sites and will be discussed in the chapter devoted to that topic.

TABLE 55.5 1983 AND 2017 AMERICAN JOINT COMMITTEE ON CANCER STAGING FOR NECK LYMPH NODES

Stage	Definition
1983 Stage	
NX	Nodes cannot be assessed.
N0	No clinically positive nodes
N1	Single clinically positive homolateral node 3 cm or less in diameter
N2	Single clinically positive homolateral node more than 3 cm but not >6 cm in diameter or multiple clinically positive homolateral nodes, none >6 cm in diameter
N2A	Single clinically positive homolateral node >3 cm but not >6 cm in diameter
N2B	Multiple clinically positive homolateral nodes, none >6 cm in diameter
N3A	Clinically positive homolateral node(s), one >6 cm in diameter
N3B	Bilateral clinically positive nodes (in this situation, each side of the should neck staged be separately N3B) (ie, left, N23; right, N1)
N3C	Contralateral node(s) clinically positive only
2017 Stage	
NX	Regional lymph nodes cannot be assessed.
N0	No lymph regional node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and extranodal extension (ENE)(−)
N2	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−); or metastases in multiple ipsilateral nodes,

Stage	Definition
	none larger than 6 cm in greatest dimension and ENE(−); or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension, ENE(−)
N2a	Metastasis in single ipsilateral or contralateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)
N2b	Metastasis in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2c	Metastasis bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); or metastases in a single ipsilateral node ENE(+) or multiple ipsilateral, contralateral, or bilateral nodes, any with ENE(+)
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b	Metastasis in a single ipsilateral node ENE(+) or multiple ipsilateral, contralateral, or bilateral nodes, any with ENE(+)

SURGERY

Historically, surgical treatment of neck lymphatics involved radical neck dissection. This involves the removal of lymph nodes in levels I to V along with the spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein. This is seldom performed today, as many studies have demonstrated that structures not involved by cancer in the neck can be preserved without sacrificing survival. The only indication to remove nonlymphatic structures in the neck (nerves, muscles, internal jugular vein, etc) is the direct involvement of the structure by a cancerous node.

Modified radical neck dissection, or functional neck dissection, involves the removal of lymph nodes in levels I to V with preservation of at least one of the following structures: spinal accessory nerve, sternocleidomastoid muscle, or internal jugular vein. This approach is used when the nodal burden is advanced with high-risk spread to level V or invasion of nonlymphatic structures.

The most commonly performed surgical neck treatment of neck lymphatics is now the selective neck dissection. This approach involves

preserving all nonlymphatic structures and only removing the high-risk lymphatic levels. The advantage of this approach is that it maintains function, minimizes morbidity, and does not compromise oncologic treatment. The levels to be removed are determined by the site of cancer. Levels I to III are addressed for oral cavity cancers. Levels II to IV are included for the treatment of oropharyngeal, laryngeal, and hypopharyngeal cancers. If nodes suspicious for metastases are encountered in areas outside the planned neck dissection, the selective neck dissection should be converted to a modified radical neck dissection.

Bilateral neck dissections may be performed simultaneously or separately (staged) in patients with bilateral neck disease as long as one internal jugular vein can be preserved. If both the internal jugular veins need to be sacrificed, at least one should be reconstructed with a vein graft (eg, saphenous vein or femoral vein). If both the internal jugular veins are left sacrificed, the patient is at high risk of cerebral edema, extreme facial edema, and, potentially, blindness.

Complications of Neck Dissection

Complications of neck dissection include hematoma; seroma; lymphedema; wound infection; wound dehiscence; skin flap necrosis; chyle leak; damage to cranial nerves V, VII, X, XI, and XII; internal jugular vein rupture; and carotid rupture. The incidence of complications is higher when neck dissection is combined with resection of the primary lesion or when it follows a course of radiation therapy (RT). The postoperative mortality rate for unilateral neck dissection after RT was 3% for patients treated between 1964 and 1982.[12] This figure is now <1%.

The incidence of postoperative complications in a series of patients treated with RT to the primary lesion and neck followed by unilateral or bilateral neck dissection(s) is shown in Tables 55.6[12] and 5.7.[13] Two of 10 patients undergoing a staged bilateral neck dissection experienced a moderately severe complication compared with 4 of 40 patients undergoing a simultaneous bilateral neck dissection. None of the 10 patients who underwent a staged bilateral neck dissection experienced a severe complication, compared with 6 of 40 (15%) patients who underwent a simultaneous bilateral neck dissection ($P = .24$).[13]

TABLE 55.6 POSTOPERATIVE COMPLICATIONS OF UNILATERAL NECK DISSECTION AFTER IRRADIATION TO THE PRIMARY LESION AND NECK (143 PATIENTS)

Complications	Number of Complications	Number of Second Operations to Repair Complication	Death
Salivary fistula	1	0	0
Wound breakdown	23	15	0
Bleeding	2	1	1
Pneumonia	2	0	1
Orocutaneous fistula	1	1	0
Lymphatic fistula	2	0	0

Taylor et al[14] analyzed the incidence of moderate (2+) and severe (3+) wound complications in a series of 205 patients who underwent a planned unilateral neck dissection after RT at the University of Florida. RT was given once daily in 123 patients, twice daily in 80 patients, and with both techniques in the remaining 2 patients. The incidence of wound complications increased with total dose and dose per fraction (Figure 55.3).

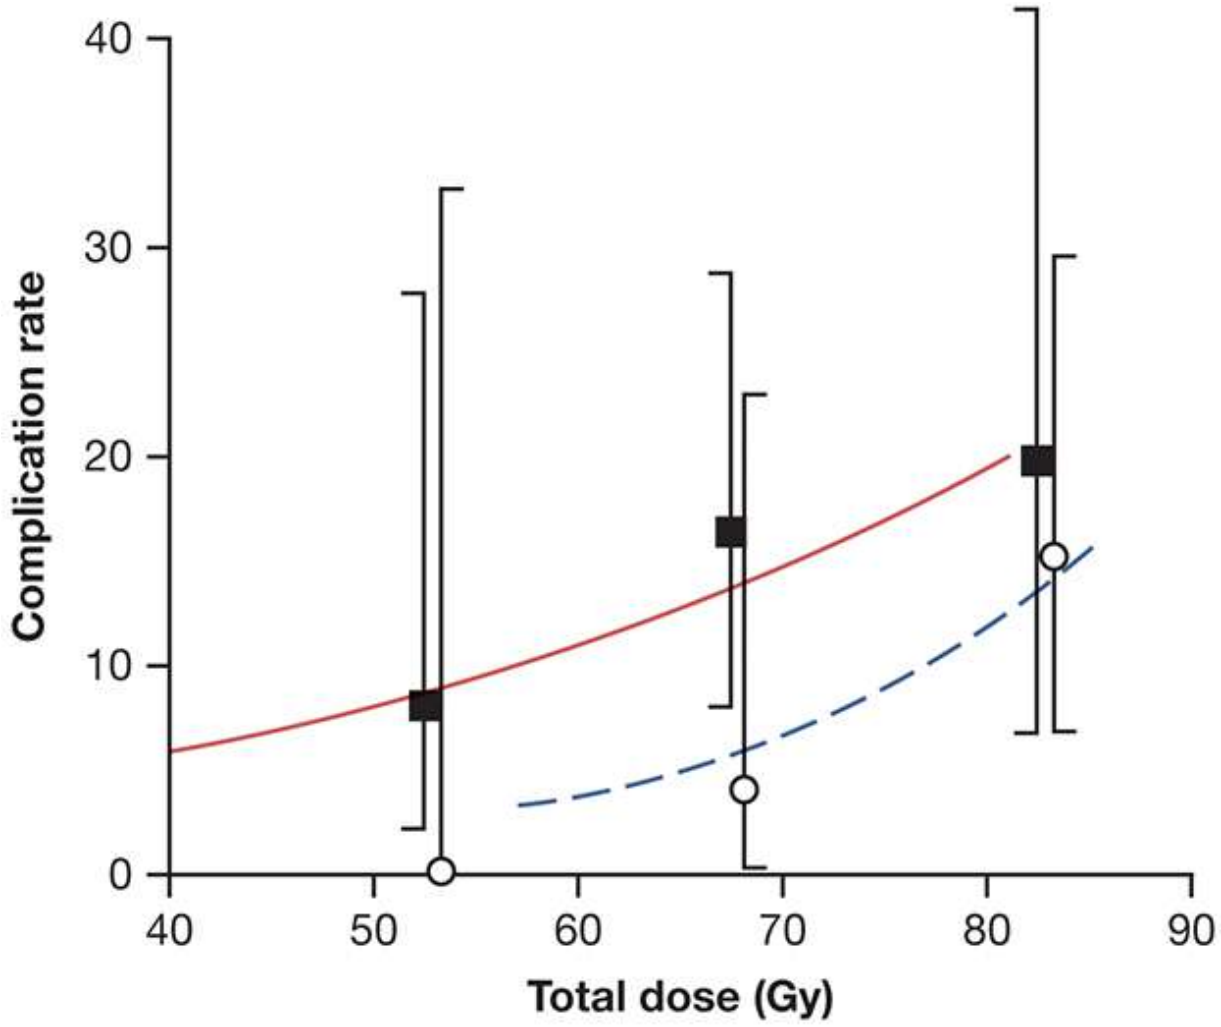

FIGURE 55.3 Complication rate (2+ or 3+) versus total dose. Separate analysis for once a day (filled square, solid curve) and twice a day (circle, dashed curve). Data are plotted at the midpoints of the range 45 to 60, 60 to 70, and 75 to 90 Gy. Error bars denote 95% confidence intervals. The curves are the results of separate logistic regression analysis. RADIATION THERAPY

RT may be used in the treatment of cervical lymph node metastases as elective treatment when there are no palpable lymph nodes, as the only treatment for clinically positive lymph nodes,[15] or as preoperative or postoperative treatment in combination with neck dissection for clinically positive lymph nodes.[16]

The regional lymph nodes are considered in the treatment planning of the primary lesion. With clinically negative neck nodes, treatment planning depends on the estimated risk of subclinical disease in the nodes. With clinically positive lymph nodes, the plan is influenced by the number of lymph nodes, size, and location.

Elective Radiation Therapy of Cervical Lymph Nodes When the Primary Tumor Is Treated by Radiation Therapy

Factors that influence the decision to irradiate the neck electively are site and size of the primary lesion, histologic grade, difficulty in neck examination, relative morbidity for adding lymph node coverage, likelihood of the patients returning for follow-up examinations, and suitability of the patient for a neck dissection if the tumor appears in the neck at a later date. Patients in whom the primary lesion is to be treated by RT, who have clinically negative nodes, and in whom the risk of subclinical disease is 15% to 20% or greater receive elective neck irradiation to a minimum dose equivalent to 45 to 50 Gy over 4.5 to 5 weeks (see Table 55.1). Patients with lesions arising in the lip, nasal vestibule, nasal cavity, or paranasal sinuses have a low risk of subclinical neck disease, and the neck is not treated electively unless the lesion is recurrent, advanced, or poorly differentiated. Similarly, the risk of occult neck disease is essentially 0% for T1 and 1.7% for T2 glottic carcinomas, and elective neck RT is not indicated.[17,18]

The lateral treatment portals used to encompass cancers in the oropharynx, supraglottic larynx, and hypopharynx include the upper jugular and often the midjugular chain lymph nodes. RT portals used for primary lesions of the oral cavity, nasopharynx, glottis, nasal cavity, and paranasal sinuses must be enlarged to include the lymph nodes. The treatment portals for irradiation of the cervical lymph nodes must be designed in such a way as to minimize additional mucosal irradiation. A common error in irradiating oropharyngeal and nasopharyngeal cancers is to enlarge the lateral (primary) portals inferiorly to unnecessarily include all of the larynx in the lateral portals (Figure 55.4).[19] Because the midneck is smaller in circumference than the upper neck, the total dose and dose per fraction are higher in the larynx than along the central axis of the beam, leading to

double trouble. Although a field junction through a positive node(s) may be avoided with intensity-modulated radiation therapy (IMRT), the larynx still receives a substantially higher dose compared with a separate anterior low neck portal with a midline laryngeal block junctioned at the thyroid notch (Figures 55.5 to 55.7).[20] Treating an unnecessarily large field increases the acute and late effects of RT and, by increasing the risk of an unplanned split, reduces the probability of disease control.[19,20]

FIGURE 55.4 Carcinoma of the base of the tongue: large radiation portals. A. Parallel-opposed lateral portals include the primary lesion, larynx, hypopharynx, most of the cervical spinal cord, and the upper portion of the trachea and cervical esophagus. Treatment through this portal tangentially irradiates the skin of the anterior neck unnecessarily. If an anterior field is not used to irradiate the low neck, the inferior border of the lateral field may be placed near the clavicle (dashed line). B. Anterior low neck portal. The wide midline tracheal block partially shields the low internal jugular lymph nodes, which are located adjacent to the trachea. The supraclavicular lymph nodes, which are less likely to be involved with tumor than the low jugular nodes, are adequately covered. C. Central axis dosimetry at the level of the base of tongue primary lesion. The contours were obtained from a RANDO phantom using parallel cobalt-60 fields weighted equally. The base of tongue tumor is outlined, and the tumor dose is specified at 97% of the maximum dose. D. Off-axis contour through the larynx. The minimum dose to the entire larynx is 104% of the maximum dose specified at the central axis, and the maximum dose on this off-axis contour is 113%. If the base of tongue tumor dose is specified as 50 Gy at 2 Gy per fraction, the minimum larynx dose is 53.61 Gy at 2.14 Gy per fraction, and the maximum larynx dose is 58.25 Gy at 2.33 Gy per fraction. If the tumor dose is specified as 60 Gy at 2 Gy per fraction, the minimum larynx dose is 64.33 Gy at 2.14 Gy per fraction, and the maximum larynx dose is 69.9 Gy at 2.33 Gy per fraction. (Reprinted from Mendenhall WM, Parsons JT, Million RR. Unnecessary irradiation of the normal larynx. *Int J Radiat Oncol Biol Phys*. 1990;18[6]:1531-1533. Copyright © 1990 Elsevier. With permission.)

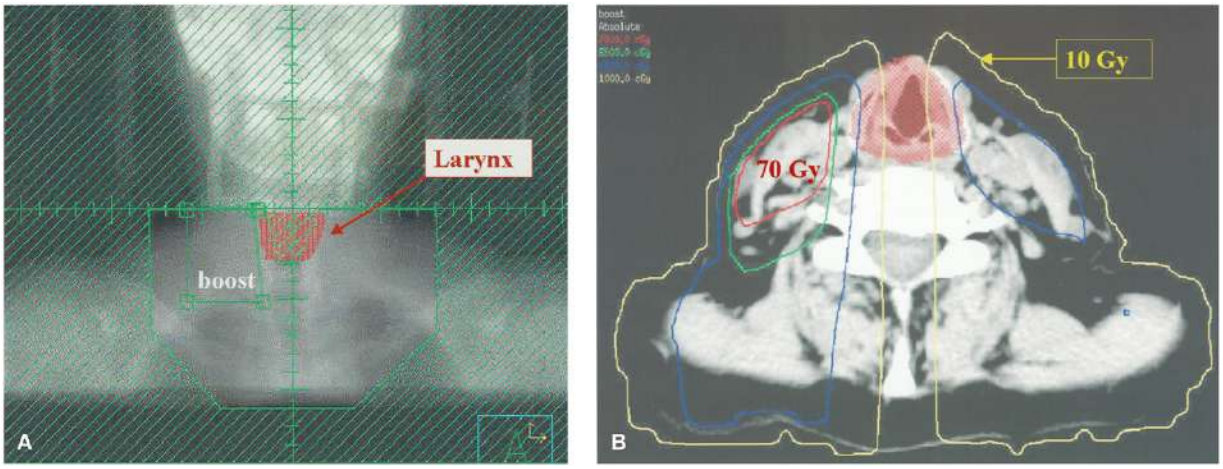

FIGURE 55.5 Laryngeal dose in a model patient with a stage T2N2b carcinoma of the tonsil with positive nodes on the right side at the level of the larynx. The primary site is irradiated with either intensity-modulated radiation therapy or lateral opposed fields. The cervical lymphatics inferior to the primary site fields are treated with an anterior low neck field. A. Digitally reconstructed radiograph of the low neck fields. The larynx was contoured and appears as a red color-wash structure. The larynx is shielded with a narrow midline block that does not cover the entire width of the larynx. In this model patient, the entire low neck field received 50 Gy and then the field size was reduced to boost the positive nodes on the right of the larynx to 70 Gy. Irradiation was given with a 6-MV photon beam with source to axis distance of 100 cm. B. Axial dose distribution at the level of the true vocal cords showing that the dose to the central portion of the larynx is extremely low when the larynx is shielded in the anterior low neck field. (From Amdur RJ, Li JG, Liu C, Hinerman RW, Mendenhall WM. Unnecessary laryngeal irradiation in the IMRT era. *Head Neck*. 2004;26[3]:257-264. Copyright © 2004 Wiley Periodicals. Reprinted by permission of John Wiley & Sons.)

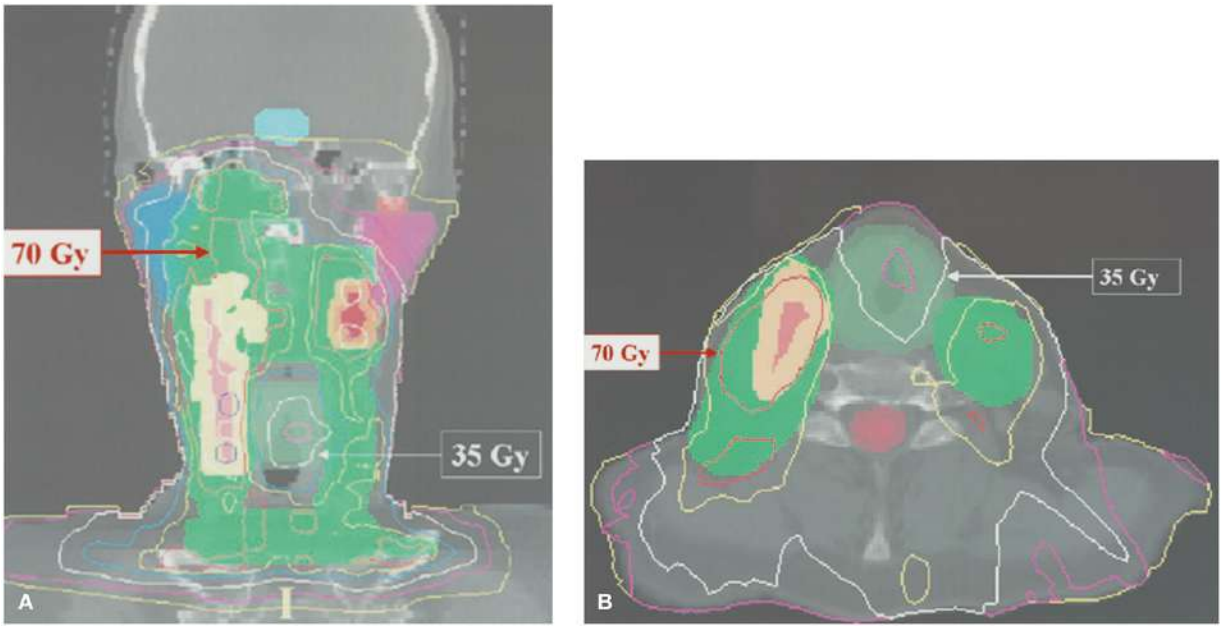

FIGURE 55.6 Dose distribution using intensity-modulated radiation therapy as described in the text to treat the model patient with a stage T2N2b carcinoma of the tonsil with positive nodes on the right side at the level of the larynx. The plan was optimized to minimize the dose to the larynx while delivering 70 Gy to gross disease and 59.4 Gy to areas at risk for subclinical disease. A. Coronal projection near the middle of the larynx. B. Axial projection at the level of the true vocal cords. A comparison of Figures 55.5B and 55.6B shows that sparing of the central portion of the larynx is shielded in an anterior low neck field. (From Amdur RJ, Li JG, Liu C, Hinerman RW, Mendenhall WM. Unnecessary laryngeal irradiation in the IMRT era. *Head Neck*. 2004;26[3]:257-264. Copyright © 2004 Wiley Periodicals. Reprinted by permission of John Wiley & Sons.)

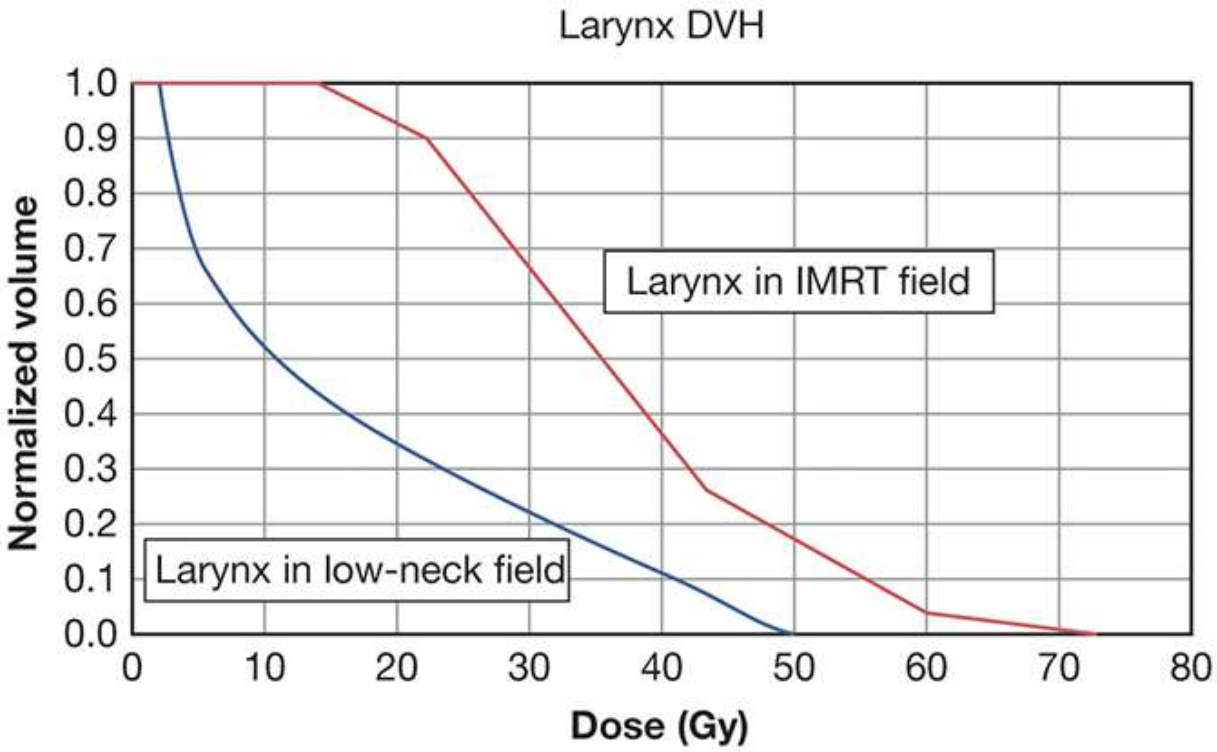

FIGURE 55.7 Dose-volume histogram (DVH) of the larynx for the model patient described in Figures 55.5 and 55.6. The red line is the DVH when the larynx is included in the intensity-modulated ration therapy (IMRT) fields shown in Figure 55.6. The blue line is the DVH when the larynx is shielded in the anterior low neck field shown in Figure 55.5. There is a major difference in the portion of the larynx that receives an extremely low dose. For example, when the larynx is included in the IMRT fields, the entire larynx receives more than 10 Gy, whereas when the larynx is shielded in the low neck field, approximately 45% of the larynx receives <10 Gy. (From Amdur RJ, Li JG, Liu C, Hinerman RW, Mendenhall WM. Unnecessary laryngeal irradiation in the IMRT era. *Head Neck*. 2004;26[3]:257-264. Copyright © 2004 Wiley Periodicals. Reprinted by permission of John Wiley & Sons.)

IMRT may be used to treat patients if there is a goal that can be achieved to reduce the toxicity of irradiation. These goals are usually parotid sparing to reduce the risk of long-term xerostomia, avoiding a low neck match in patients with a low-lying larynx, and improved coverage of the poststyloid parapharyngeal space in patients with nasopharyngeal cancer.[21] If one or more of these goals cannot be achieved, the patients may be better off being treated with conventional RT because of the disadvantages of IMRT, which include increased risk of a marginal miss, less homogeneous dose distribution, and increased cost and complexity.[21]

Elective neck irradiation for early oral cavity lesions includes the level Ib and level II lymph nodes. The level III and level IV lymph nodes are treated

as well by using a narrow anterior field. For primary lesions located in the oropharynx, nasopharynx, supraglottic larynx, and hypopharynx, the lower neck nodes are also routinely included. The low neck is treated with a single anterior field (Figure 55.8). A tapered midline larynx or trachea shield is added to protect the spinal cord, the larynx, and the pharynx. For primary lesions lying below the thyroid notch, a small midline tracheal block 1-cm wide is placed in the low neck field, to shield the trachea, esophagus, and spinal cord.

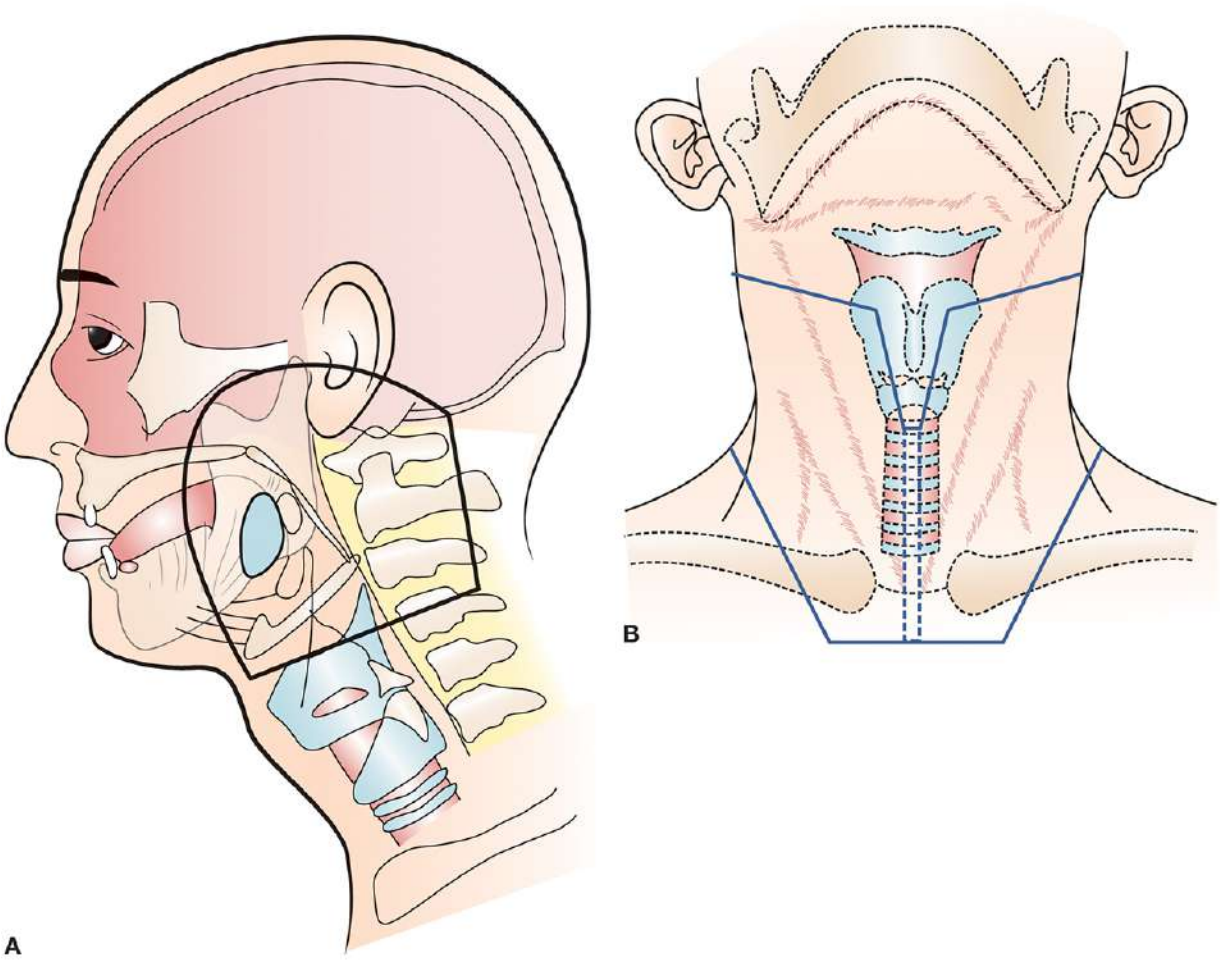

FIGURE 55.8 Lateral and anterior fields are used to irradiate a patient with a carcinoma limited to the base of tongue. A. Parallel-opposed fields include the primary lesion with a 2- to 3-cm inferior margin. The lower border of the field is placed at the thyroid notch and slants superiorly as the junction line proceeds posteriorly as the junction line proceeds posteriorly. This substantially reduces the amount of mucosa larynx and spinal cord included in the primary treatment portals. B. En face low neck portal with tapered midline larynx and tapered midline larynx block. It is not necessary to treat the supraclavicular fossa unless clinically positive nodes are found in that particular hemineck. A 5-mm midline tracheal block may be placed in the low neck portal (dashed line). (Reprinted from Mendenhall WM, Parsons JT, Million RR. Unnecessary irradiation of the normal larynx. *Int J Radiat Oncol Biol Phys*. 1990;18[6]:1531-1533. Copyright © 1990 Elsevier. With permission.)

Treatment of Clinically Positive Cervical Lymph Nodes When the Primary Tumor Is Treated by Radiation Therapy

The dose required to control a clinically positive lymph depends on the size of the lymph node[15,22] and whether concomitant chemotherapy is

administered. Relatively recent data suggest that advanced disease has a better chance of cure after altered fractionation or concomitant chemotherapy.[23] Patients treated at the authors' institution routinely receive hyperfractionation or simultaneous integrated boost (SIB) combined with weekly cisplatin 30 mg/m^2. SIB consists of 70 Gy in 35 fractions over 30 treatment days in 6 weeks with one twice-daily fraction during the last 6 weeks with a minimum 6-hour interfraction interval. The high-risk planning treatment volume (PTV) receives 70 Gy at 2 Gy per fraction, intermediate-risk PTV receives 63 Gy at 1.8 Gy per fraction, and the standard-risk PTV receives 56 Gy at 1.6 Gy per fraction. Positive nodes receive approximately 70 to 74 Gy, regardless of the size or rate of regression.

The decision to add a neck dissection after RT for multiple unilateral positive nodes or bilateral lymph node disease is individualized and is based on the diameter of the largest node, node fixation, and number of clinically positive nodes in the neck. If clinically positive lymph nodes disappear completely during RT, the likelihood of control by RT alone is improved and a neck dissection may be withheld.[24-27] Peters et al[28] reported on 100 node-positive patients with SCC of the oropharynx treated with concomitant boost RT between 1984 and 1993 at the MD Anderson Cancer Center (Houston, TX). Sixty-two patients had a complete response (CR) in the neck and received no further therapy. Three (5%) patients subsequently developed an isolated recurrence in the neck, and four (6%) patients developed a recurrence in the neck in conjunction with other sites of relapse. The 2-year neck disease control rates did not vary significantly with pretreatment nodal size: ≤3 cm, 87%; and >3 cm, 85%. The incidence of subcutaneous fibrosis was similar following RT alone compared with another group of patients who underwent a neck dissection in addition to RT. Johnson et al[29] reported on 81 patients with node-positive stages III and IV SCC of the head and neck treated with concomitant boost accelerated hyperfractionated RT at the Medical College of Virginia (Richmond). Fifty-eight (72%) patients had a CR in the neck and were followed; three (5%) patients subsequently developed an isolated recurrence in the neck and one additional patient developed recurrent cancer in the neck and in the primary site. The 3-year neck disease control rates were 94% for nodes ≤3 cm compared with 86% for those >3 cm.

Both of these series of patients received aggressive altered fractionated RT, and it is unclear whether these data can be broadly extrapolated to patients with head and neck cancer from a variety of head and neck primary sites that are treated less aggressively. It is also unclear whether the addition of concomitant chemotherapy results in a lower likelihood of needing a neck dissection. However, multiple subsequent studies evaluating neck control rates either after RT alone or combined with chemotherapy suggest that the likelihood of an isolated failure in the neck is low if there is a CR after treatment.[16,30-34]

The authors' policy at the University of Florida has changed to the extent that we now evaluate patients with clinically positive nodes with a CT 4 weeks after RT or a PET-CT at 3 months and withhold neck dissection in the subset of patients with a CR thought to have ≤5% risk of residual disease.[35-42] Liauw et al[38] evaluated a series of 550 patients treated with definitive RT at the University of Florida between 1990 and 2002; 341 (62%) patients underwent a post-RT planned neck dissection. CT images obtained at approximately 4 weeks post-RT were reviewed for 211 patients; radiographic complete response (rCR) was defined as no nodes >1.5 cm and no focal abnormalities such as focal lucency, enhancement, or calcification.[32] The outcomes are depicted in Table 55.8. Thirty-two patients had an rCR and were followed and did not undergo a neck dissection; the neck control rate was 97%. Recent data published by Yeung et al[35] suggest that for those who have a partial response to RT, neck dissection may be safely limited to only those levels that remain suspicious after RT. Post-RT selective neck dissection likely results in improved quality of life.[43] PET-CT is obtained 3 months after completion of RT to minimize the risk of a false-positive scan; those with a negative PET-CT are followed, the remainder undergo a neck dissection. Goenka et al[41] reported on 302 patients with node-positive oropharyngeal SCCs treated with IMRT and concomitant chemotherapy at the Memorial Sloan Kettering Cancer Center between 2002 and 2009. Patients underwent a PET-CT following treatment to assess response. A clinical and rCR was observed in 260 (86.1%) patients and were observed. The neck control rate was 97.7%. Three of four patients who recurred in the neck were successfully salvaged. Patients who underwent a neck dissection had the following rates of pathologically visible tumor: PET-CT positive, 52%; and PET-CT negative, 25%.

Mehanna et al[42] reported on a prospective trial where 564 node-positive patients were randomized to chemoradiation followed by PET-CT and either planned neck dissection (282 patients) or observation in the event of a CR (282 patients). Patients in the latter group underwent fewer neck dissections: the 2-year survival rates were comparable.

TABLE 55.8 PREDICTIVE VALUE OF POSTRADIOTHERAPY COMPUTED TOMOGRAPHY FINDINGS AT 4 WEEKS IN THE HEMINECK CORRELATED TO NECK DISSECTION PATHOLOGY (*N* = 193 HEMINECKS)

	NPV		PPV	
Findings	**Number/Total Number**	**Percent**	**Number/Total Number**	**Percent**
Any lymph node >1.5 cm	85/118	72	24/75	32

If a neck dissection is planned to follow RT in patients with clinically positive lymph nodes, the preoperative dose varies with the size and location of the lymph node, fixation, and response to RT. Preoperative doses

of 50 Gy are sufficient for mobile lymph nodes 3 to 4 cm in size, but 60 Gy or more is recommended for 5- to 6-cm nodes and for fixed nodes. Lymph nodes measuring 7 to 8 cm are almost always fixed to adjacent structures and often require doses of 70 to 75 Gy for the surgeon to achieve a complete resection. If the lymph node lies behind the plane of the spinal cord, electrons may be used to boost the dose after the primary fields have been reduced off the spinal cord after 45 to 50 Gy.[12] Alternatively, IMRT may be employed. Patients in whom the decision is made to add a neck dissection after completion of RT receive full-dose irradiation to the clinically positive neck nodes because the decision depends on the response to RT.

Another technique commonly used for boosting the dose to the neck mass after spinal cord tolerance has been reached, and the treatment to the primary lesion has been completed is opposed anterior and posterior fields with wedges. The final dose to the neck node (not to the entire neck) may be 70 to 80 Gy without exceeding the spinal cord tolerance (Figure 55.9). The anterior and posterior wedge-pair technique is preferable to an appositional electron boost field because high energy electron beams increase the skin and mucosal dose.

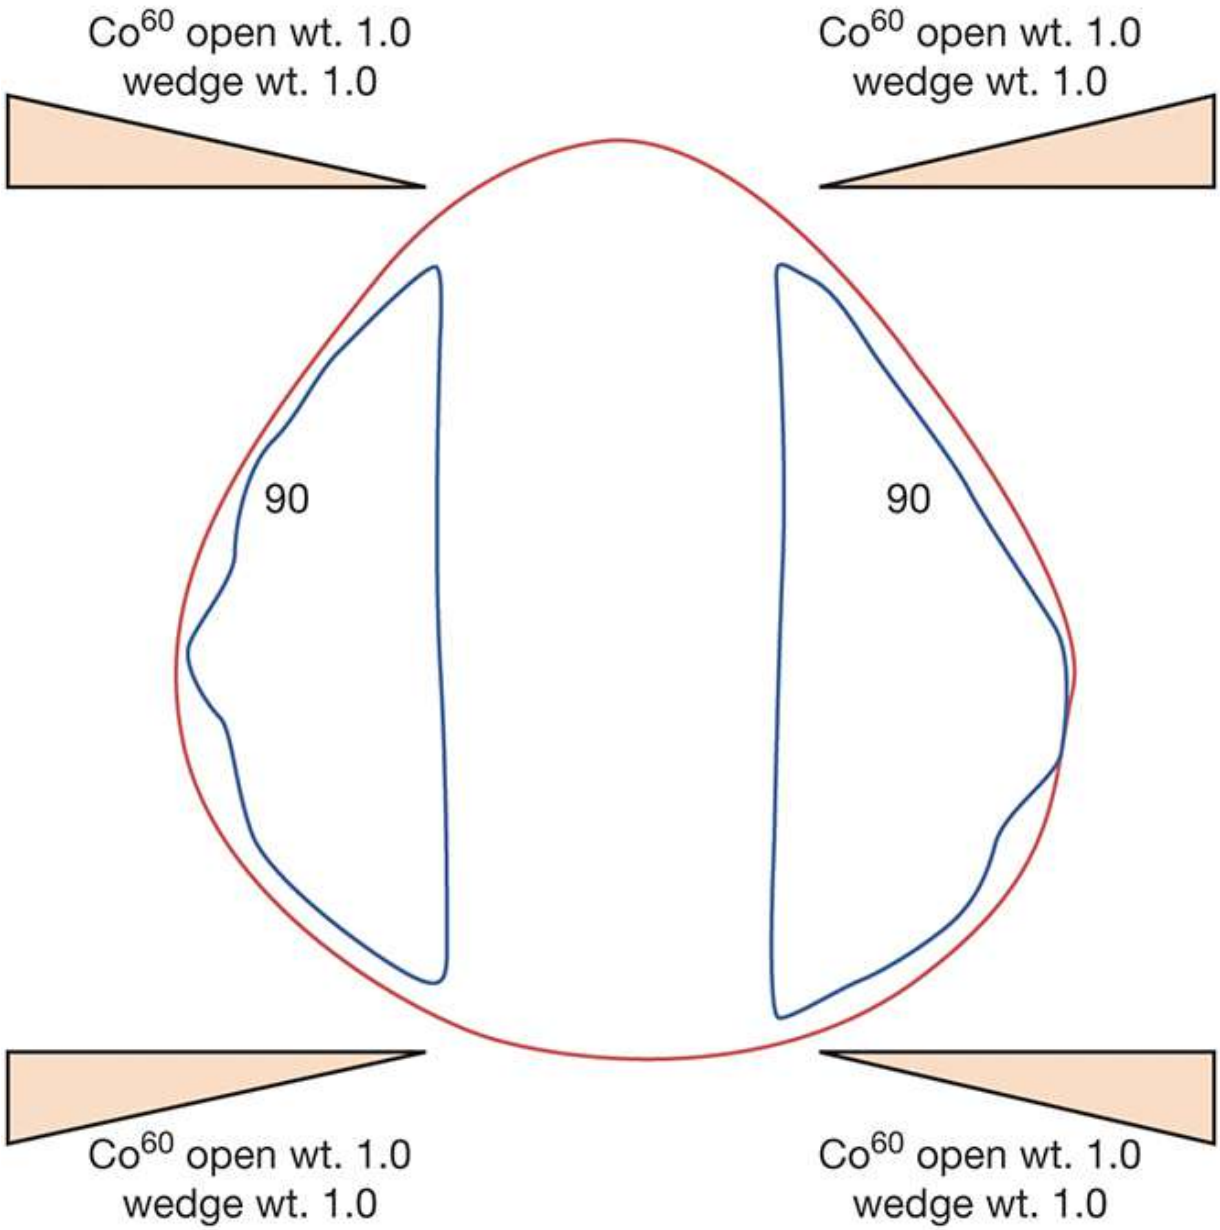

FIGURE 55.9 Dose distribution for anterior and posterior wedge cobalt-60 portals, both fields weighted 1.0.

When the cervical lymph nodes are located superficially, sometimes within 1 cm from the skin or fixed to it, treatment with high energy photon beams (≥6 MV) may underdose these nodes. Treatment should be initiated with cobalt-60 or 4-MV x-rays for the initial 45 to 50 Gy, after which a higher energy photon beam can be used to continue RT of the primary tumor if the neck nodes are clinically negative or if a neck dissection is planned to follow RT (Figure 55.10). Parallel-opposed 6-MV x-ray beams

may adequately treat the upper neck nodes included in the primary treatment fields; however, the supraclavicular nodes in the en face low neck field may be underdosed with a 6-MV beam in very thin patients. Although electrons alone may be used to treat cervical nodes, it is preferable to combine them with photons because of the high surface dose with high electron energies. The use of both 20-MeV electrons and 17-MV x-rays is compared with treatment by 20-MeV electrons alone in a patient with a lateralized lesion of the oropharynx (Figure 55.11).[44] The addition of the 17-MV x-rays to the 20-MeV electrons decreases the surface dose while still adequately irradiating the cervical nodes that are within the primary field. The addition of the x-ray beam also produces a dose distribution that is less affected by bone than that from the electron beam alone.

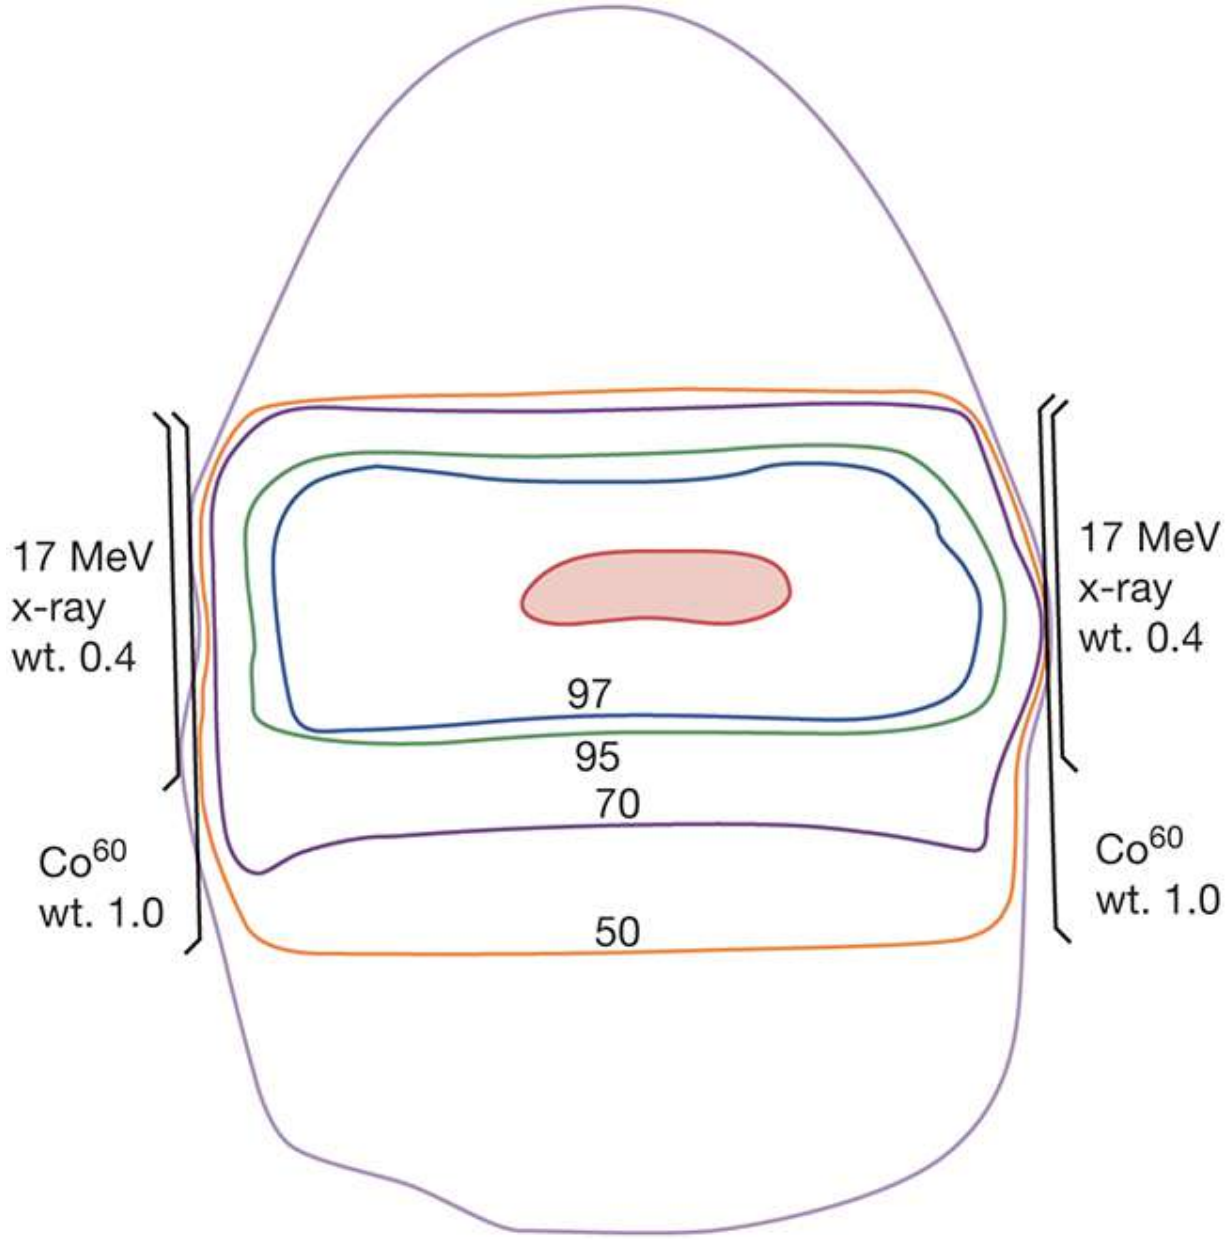

FIGURE 55.10 Dose distribution for parallel-opposed cobalt-60 portals, each weighted 1.0, with reduced 17-MV x-ray portals, each weighted 0.4.

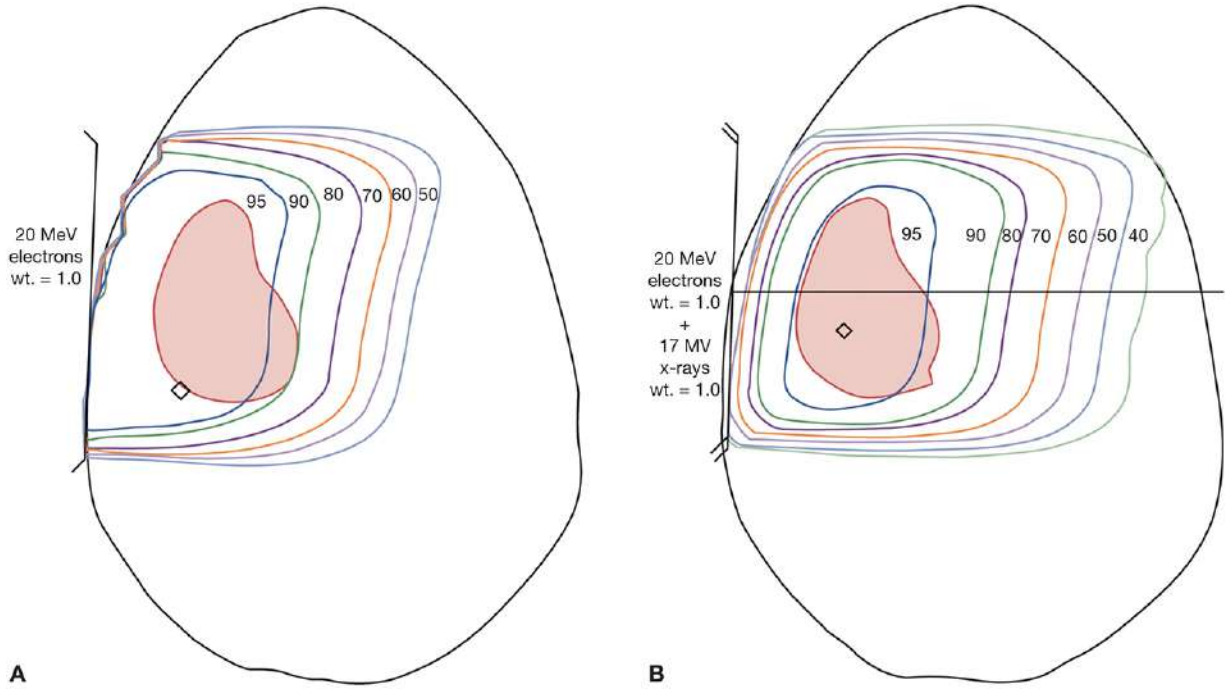

FIGURE 55.11 A. Dose distribution for 20-MeV electrons, field size 8.5 cm by 8.5 cm, SSD 100 cm. B. Dose distribution for 20-MeV electrons, field size 8.5 cm by 8.5 cm, and 17-MV x-rays, field size 7 cm by 7 cm, SSD 100 cm for both. The given doses are weighted 1 to 1. The addition of the 17-MV x-ray beam reduces the surface dose and gives a dose distribution that is affected less by bone. SSD, source to skin distance. (Reprinted with permission from Bova FJ. Treatment planning for irradiation of head and neck cancer. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach*. 2nd ed. J.B. Lippincott; 1994:306.)

Large lymph nodes may not show much regression during the course of RT but often show significant regression from completion of treatment to the time the patient returns for neck dissection, usually after 4 to 6 weeks. The mass frequently has a thick capsule that facilitates its removal at the time of neck dissection.

Patients with bilateral neck disease require individualized treatment planning jointly by the radiation oncologist and the surgeon. If the disease is minimal on one side, RT alone may be used to control the disease on that side of the neck, and a neck dissection may be used on the side with more disease. If a major bilateral disease is present, bilateral neck dissection should follow RT.

Complications of Neck Irradiation

The complications of neck irradiation include subcutaneous fibrosis and lymphedema of the larynx and submentum. The latter complications may be minimized by sparing an anterior strip of skin when designing the parallel-opposed lateral portals used to encompass the primary lesion. The probability of complications is directly related to the radiation dose with little, if any, morbidity observed with the doses used for elective radiation therapy of the neck.

Complications of neck treatment in patients who receive RT in conjunction with resection of the primary lesion and a neck dissection are essentially the same as those occurring after neck dissection. However, they occur with an increased incidence depending on the RT dose and extent of surgery.

Treatment of the Neck After Incisional or Excisional Biopsy

Open biopsy of a clinically positive neck node before definitive treatment potentially spills tumor cells along tissue planes that may not be removed with a radical neck dissection. McGuirt and McCabe[45] reported that incisional or excisional biopsy of positive neck nodes before definitive surgery increased the risk of neck failure and worsened the prognosis for patients with SCC of the head and neck. Parsons et al[46] reported their experience with incisional or excisional biopsy of positive neck nodes followed by RT as the initial step in the treatment of the patient; these data were updated by Mack et al.[47] After excisional biopsy of a single lymph node, RT alone to the primary lesion and to the neck resulted in a 95% rate of neck control.[47] If residual disease remained in the neck after biopsy, RT followed by neck dissection was more successful than RT alone for controlling neck disease (Table 55.9).

If the primary lesion is to be treated surgically, the patient's neck is typically treated with a completion neck dissection followed by RT. If the primary lesion is to be treated with RT, the patient is treated with RT. If there is no palpable disease remaining in the neck after excisional biopsy of a positive node, the neck may be treated with RT alone. If an incisional biopsy of the node has been performed (leaving gross disease) or if other positive nodes remain after an excisional neck node biopsy, a completion neck dissection is performed with removal of skin over the biopsy site as well as any other structures involved by cancer. RT follows the surgical procedure. The dose of RT preceding a neck dissection depends on the amount of gross disease in the neck and the degree of fixation.[1]

TREATMENT OF THE NECK AFTER SURGERY

Patients treated surgically generally undergo resection of the primary cancer and a unilateral or bilateral neck dissection depending on the location and extent of the primary and presence and extent of positive neck nodes. Indications for postoperative RT include positive or close (<5 mm) margins, initially positive margins with negative separately submitted margins, extracapsular extension, multiple positive nodes, lymphovascular space invasion, perineural invasion, bone or cartilage invasion, extension into the soft tissues of the neck, invasion of the apex of the pyriform sinus, and

subglottic extension of 1 cm or more. The highest risk indications are positive margins and extracapsular extension and require the addition of concomitant cisplatin during the course of postoperative RT. Because of the risk of increased radioresistance due to tumor cells being in potentially hypoxic tissues, the minimum dose is 60 Gy at 2 Gy per once-daily fraction. Areas at higher risk may be boosted to doses in the range of 66 to 70 Gy. Alternatively, patients at particularly high risk may be treated with hyperfractionation at 1.2 Gy per twice-daily fraction to doses up to 74.4 or 70 Gy in 35 fractions over 6 weeks treating twice daily once weekly for the last 5 weeks of RT. Consideration may be given to treating the primary site alone if the neck nodes are pathologically negative. Postoperative RT is not employed for the sole indication to electively treat the clinically negative neck in lieu of a neck dissection. Patients with a clinically negative neck who will require postoperative RT may forego a neck dissection and the neck irradiated in conjunction with the primary site.

RESULTS OF TREATMENT

Clinically Negative Nodes

Elective neck dissection and elective neck irradiation are equally effective in controlling subclinical disease. The decision whether to use surgery or RT for the purpose of electively treating the neck nodes depends on the method used to treat the primary lesion. Patients with a relatively early primary lesion and clinically negative nodes should be treated with one modality. Patients whose primary lesion is treated surgically may undergo an elective neck dissection, and those whose primary lesion is to be treated with RT should be considered for elective neck irradiation. Patients who develop a local recurrence on a metachronous second primary after RT for an SCC with a cN0 neck in whom the neck has been irradiated may be treated with surgery to the primary site alone and the neck observed because the likelihood of subclinical disease in the cervical lymphatics is <10%.[48,49]

The results of elective neck irradiation at the University of Florida for patients with SCC of the head and neck in whom the primary lesion was controlled are shown in Table 55.10.[4,50] Patients were divided into three risk categories based on the estimated risk of subclinical disease in the neck as follows: group I, low risk (<20% likelihood of occult disease); group II,

moderate risk (20%-30% risk of occult disease); and group III, high risk (more than 30% likelihood of occult disease). There were six neck failures (21%) in 28 patients who did not receive elective neck irradiation and eight neck failures (5%) in 162 patients who received elective neck irradiation. Of the eight failures in patients receiving elective neck irradiation, two occurred within the irradiation fields, one at the field margin, and five in out-of-field areas. No correlation was found between the rate of tumor control in the first-echelon lymph nodes and the irradiation dose for doses ranging from 40 to 55 Gy or greater.[4] Only one failure occurred in the first-echelon lymph nodes, and this was after 48 Gy in 25 fractions using continuous-course irradiation.[4] The low neck, defined as that part of the neck located below the treatment portals used to treat the primary lesion, received either 50 Gy in 25 fractions or 40.5 Gy in 15 fractions, specified at D_{max} (0.5 cm depth). Both dose fractionation protocols were equally effective in sterilizing subclinical disease in the low neck.[51] Elective neck irradiation is equally efficacious for SCC arising from various head and neck primary sites.

TABLE 55.10 CONTROL OF DISEASE IN THE CLINICALLY NEGATIVE NECK WITH ELECTIVE NECK IRRADIATION (NUMBER CONTROLLED/NUMBER TREATED)

Risk Group	No ENI (%)	Partial ENI (%)	Total ENI (%)
I (<20%)	13/15 (87)	16/17 (94)	1/1 (100)
II (20%-30%)	6/9 (67)	34/38 (89)	10/11 (91)
III (>30%)	3/4 (75)	32/33 (97)	61/62 (98)

ENI, elective neck irradiation.

Reprinted from Mendenhall WM, Million RR. Elective neck irradiation for squamous cell carcinoma of the head and neck: analysis of time-dose factors and causes of failure. *Int J Radiat Oncol Biol Phys*. 1986;12(5):741-746. Copyright © 1986 Elsevier. With permission.

In patients in whom primary failure occurs in addition to failure in the clinically negative nodes, the chances of surgical salvage are poor. In patients in whom the primary lesion is controlled and in whom failure develops in the initially negative neck, the chances of salvage with neck dissection are approximately 60%.

Although elective neck irradiation significantly reduces the risk of neck recurrence, there is no definite evidence that it improves survival. It would be necessary to conduct a large randomized trial to detect a survival difference, if one exists. Another problem is that the first-echelon lymph nodes are often included in the treatment portals used to treat the primary lesion so that it is often impossible to avoid at least partial elective neck irradiation. Therefore, such a trial would have to be restricted to primary sites where the portals would have to be enlarged to electively irradiate the neck or to patients treated with elective neck dissection rather than elective neck irradiation. Vandenbrouck et al[52] and Fakih et al[53] have conducted randomized trials comparing elective neck dissection with no elective neck treatment for patients with oral cavity carcinoma and oral tongue cancer, respectively. No survival advantage was noted for patients undergoing elective neck dissection in either study. However, because of the small number of patients in both trials, it is likely that even if a survival difference existed, it would have been missed. Subsequently, a randomized trial was conducted at the Tata Memorial Hospital (Mumbai) where 596 patients with T1-T1 N0 SCCs of the oral cavity were randomized to resection of the primary and observation of the neck or to resection of the primary and elective neck dissection. Those in the latter group had significantly improved overall survival at 3 years (80% vs 68%; $P = .01$).[54]

Dearnaley et al[55] reported on a series of 148 patients treated with an interstitial implant, either alone or combined with external-beam RT, for cancer of the tongue or floor of the mouth. Of 131 patients with negative neck nodes at diagnosis, 59 (45%) received elective neck irradiation to a dose of 40 Gy or greater. A multivariate analysis showed that elective neck irradiation significantly improved survival and reduced the risk of dying of cancer. Piedbois et al[56] reported a series of 233 patients with T1-2N0 carcinoma of the oral cavity treated with interstitial iridium brachytherapy: 123 patients received no elective neck treatment, and 110 patients underwent elective neck dissection. Patients who received an elective neck dissection tended to have more advanced primary lesions. Although the ultimate rates of neck control were similar, a multivariate analysis showed that elective neck dissection was significantly associated with improved survival.

Clinically Positive Nodes

The incidence of treatment failure in the neck by N stage and treatment category has been reported by the MD Anderson Cancer Center (Table 55.11) and the University of Florida (Table 55.12 and Figure 55.13).[57,58] In patients in whom the neck is treated with combined modalities, RT precedes surgery when the primary site is to be treated with irradiation or when the node is incompletely resectable. Surgery precedes RT when the primary site is to be treated operatively and the nodes are resectable.

When the initial treatment is surgery, a neck dissection is sufficient treatment for patients with a single positive lymph node <3 cm unless there is extracapsular spread of disease. RT may be added for control of subclinical disease in the contralateral side of the neck (Table 55.14).[57] The presence of multiple positive nodes in the surgical specimen is an indication for postoperative RT of the neck, especially when positive nodes are found at more than one level.[6,59,60]

Olsen et al[61] reported a series of 284 patients who underwent neck dissection at the Mayo Clinic for pathologic stages N1 and N2 SCC of the head and neck; no patient received adjuvant therapy. Neck recurrence-free survival rates at 5 years were as follows: N1, 76%; N2, 60%; and overall, 69%. A multivariate analysis showed that four or more positive nodes (P = .005), invasion of lymphatic or vascular spaces (P = .003), invasion of soft tissue (P = .0008), and a desmoplastic stromal pattern (P = .0001) were significantly associated with an increased risk of recurrence in the neck.[61]

The postoperative dose prescribed is usually 60 Gy in 30 fractions to 65 Gy in 35 fractions over 6 to 7 weeks for patients with negative margins; higher doses may be prescribed when residual disease is present in the neck.[59,62,63] If RT is to be added after surgery, it is usually initiated within 4 to 6 weeks after the operation, although it has been reported that a delay to 10 weeks is not associated with an increased risk of neck failure.[59]

The rate of control for neck nodes treated with RT alone as a function of node size, treatment scheme, and dose is shown in Table 55.14. RT alone is sufficient for patients with N1 (up to 2 cm) disease as long as the fraction size (2 Gy) and the total dose are sufficient.[36] RT followed by neck dissection has provided better rates of disease control than RT alone for patients with more advanced neck disease. The rate of neck disease control for patients treated with twice-daily RT, alone or followed by neck dissection, is shown in Figure 55.12 and shows a significant improvement in the control rates when neck dissection was added in selected cases.[64,65] As shown in a multivariate analysis by Ellis et al,[66] the addition of neck dissection after RT is independently related to a significantly decreased risk of disease-specific death. At least 50 Gy should be given preoperatively to the lymph nodes, although doses vary according to the size and degree of fixation of the lymph node. For example, large, fixed lymph nodes require

70 to 75 Gy of preoperative RT (Table 55.15). The likelihood of disease control in each side of the neck treated with irradiation and neck dissection is decreased when the node is fixed before treatment or when residual tumor is found in the pathologic specimen (Tables 55.16 and 55.17).[12] No difference is seen in the rate of control as a function of the interval between RT and neck dissection when comparing patients who have surgery within 6 weeks with those who have neck dissection more than 6 weeks after RT.[12] If a local recurrence occurs, prior combined treatment of the neck does not diminish the chance of successful surgical salvage of the patient.[67] The likelihood of disease control at the primary site was not found to be related to neck stage at diagnosis in patients treated with RT alone or followed by neck dissection at the University of Florida[68]; this finding is different from what others have reported.[69]

Results After Incisional or Excisional Biopsy

Patients who have undergone an incisional or excisional biopsy of a metastatic lymph node before referral do not have an increased risk of neck failure or a decreased cure rate if RT is the next step in treatment.[46] The likelihood of control and the cure rate are probably diminished if an operation without prior RT follows an incisional or excisional biopsy of a metastatic neck node because of the risk that the biopsy procedure disseminated tumor cells into tissues not removed by neck dissection.[45]

Ellis et al[66] reported on 508 patients with 660 positive heminecks treated at the University of Florida with RT alone or followed by a planned neck dissection. Pretreatment node biopsy did not influence the outcome when RT was the next step in treatment (see Table 55.9).[66] The results of the forward stepwise log-rank tests of prognostic factors for predicting time to recurrence are shown in Table 55.18.[66]

TABLE 55.18 PROGNOSTIC FACTORS, IN ORDER OF THEIR IMPORTANCE, FOR PREDICTING THE TIME TO OCCURRENCE OF VARIOUS EVENTS

Event	Rank Order	Factor	Level of Significance
Recurrence in neck (*n* = 660 heminecks)	1	Increasing *N* stage	*P* = .0001
	2	Treatment neck of with RT alone	*P* = .0001
	3	Fixed nodes	*P* = .0001
	4	T stage[a]	*P* = .0350
Death with disease present (*n* = 508 patients)	1	Recurrence above clavicles	*P* = .0001
	2	Increasing *N* stage	*P* = .0003
	3	Fixed nodes	*P* = .0053
	4	Treatment of with neck RT alone	*P* = .0121
For occurrence of distant metastasis (*n* = 508 patients)	1	Recurrence above clavicles	*P* = .0001
	2	Increasing *N* stage	*P* = .0003
	3	Fixed nodes	*P* = .0704
	4	Nodes below thyroid notch	*P* = .1023

RT, radiation therapy.

[a]This factor is thought to be correlated with the censoring pattern.

Zenga et al[70] reported on 45 patients from 1998 to 2012 who underwent open biopsy for human papillomavirus (HPV)-positive oropharyngeal cancer. All patients underwent definitive surgical treatment. Disease-specific survival was 98% versus 99% in a control group who did not undergo an open biopsy. Only 7% of the open biopsy group were found to have dermal metastases in the excised skin. It is known that hypoxic tissues, such as a scar, are increasingly resistant to RT. Thus, excision of the biopsied area along with a neck dissection will improve the efficacy of adjuvant RT. This study questions the idea that previous open biopsy

adversely affects patient outcomes in this subset of patients. Neck dissection is an effective primary treatment for previously violated neck nodes. However, an adjuvant dose of RT with 60 to 70 Gy is needed to minimize recurrence rates.

CERVICAL LYMPH NODE METASTASIS WITH UNKNOWN PRIMARY TUMOR

In a small percentage of patients with enlarged cervical lymph nodes, the primary lesion cannot be found, even after extensive evaluation.[71-73] Patients with enlarged lymph nodes in the upper neck have a good prognosis when treated aggressively, compared with those with enlarged lymph nodes in the low IJC or supraclavicular fossa. The latter patients are more likely to have primary lesions located below the clavicles, which carry a much worse prognosis. The majority of patients have either SCC or poorly differentiated carcinoma. Those with adenocarcinoma almost always have a primary lesion below the clavicles, although, if the nodes are located in the upper neck, one must exclude a salivary gland, thyroid, or parathyroid primary tumor. This section deals with patients presenting with SCC or poorly differentiated carcinoma in the upper or middle neck.

Patients should be evaluated with a thorough physical examination, including careful evaluation of the head and neck. A needle biopsy of the lymph node should be performed. After chest roentgenography, a CT or MRI of the head and neck is obtained to detect an unknown primary lesion arising from the mucosa of the head and neck. It is unclear whether FDG-PET scans may identify primary lesions that would not otherwise be identifiable.[74] The available data suggest that some patients will benefit from these studies. Direct laryngoscopy and examination under anesthesia are performed with directed biopsies of the nasopharynx, tonsils, base of the tongue, and pyriform sinuses, and of any abnormalities noted on CT or MRI or suspicious mucosal lesions noted at laryngoscopy. Patients with adequate lymphoid tissue in their tonsillar fossae should undergo at least an ipsilateral tonsillectomy. The likelihood of bilateral tonsillar carcinomas is probably less than 5% and may prompt some surgeons to perform bilateral tonsillectomy. If a contralateral tonsillar malignancy is missed and the patient is treated with an ipsilateral field arrangement for an ipsilateral

tonsillar cancer, salvage treatment would probably be compromised. The diagnostic evaluation for the patient with cervical metastasis from an unknown head and neck primary lesion is summarized in Table 55.19. The results of a diagnostic evaluation for an unknown primary site in 236 patients at the University of Florida are depicted in Table 55.20.[75] Overall, 132 primary sites were discovered in 126 (53%) patients and were most often located in the oropharynx: tonsillar fossa, 59 (45%); base of the tongue, 58 (44%); pyriform sinus, 10 (8%); pharyngeal wall, 3 (2%); and supraglottic larynx, 1 (1%).[75]

TABLE 55.19 DIAGNOSTIC WORKUP FOR CERVICAL LYMPH NODE METASTASES: UNKNOWN PRIMARY TUMOR

General
History
Physical examination
Careful examination of neck and supraclavicular regions
Examination oral of cavity, pharynx, and larynx (indirect laryngectomy)
Radiographic Studies
Chest roentgenogram
Computed tomography or magnetic resonance imaging of head and neck (special attention to nasopharynx, pharynx, and larynx)
Laboratory Studies
Complete cell blood count
Blood chemistry profile
Direct and Laryngoscopy-Directed Biopsies
Nasopharynx, tonsils, base of tongue, pyriform and sinuses, any suspicious abnormal or mucosal areas
Fine-needle aspirate or core needle biopsy of the cervical node
Tonsillectomy

Some patients may be cured with treatment directed only to the involved area of the neck[76]; however, the authors usually irradiate the nasopharynx and oropharynx as well as both sides of the neck. The hypopharynx and larynx were irradiated as well until 1997 when it was decided to eliminate them because they are rarely the site of the primary cancer and because irradiation of these sites significantly increases the morbidity of treatment. It is not necessary to irradiate the oral cavity unless the patient has submandibular adenopathy, in which case the authors either do a neck dissection and observe the patient or irradiate the oral cavity and oropharynx and not the nasopharynx. Patients are treated with parallel-opposed fields at 1.8 Gy per fraction to a midline dose of 64.8 Gy with a reduction of the spinal cord at 45 Gy tumor dose (Figure 55.13). An alternative is to use IMRT to spare the contralateral parotid gland in patients with ipsilateral neck nodes. The lower neck is treated through a separate en face anterior field. IMRT may be used if patients have unilateral neck disease to reduce the dose to the contralateral parotid.

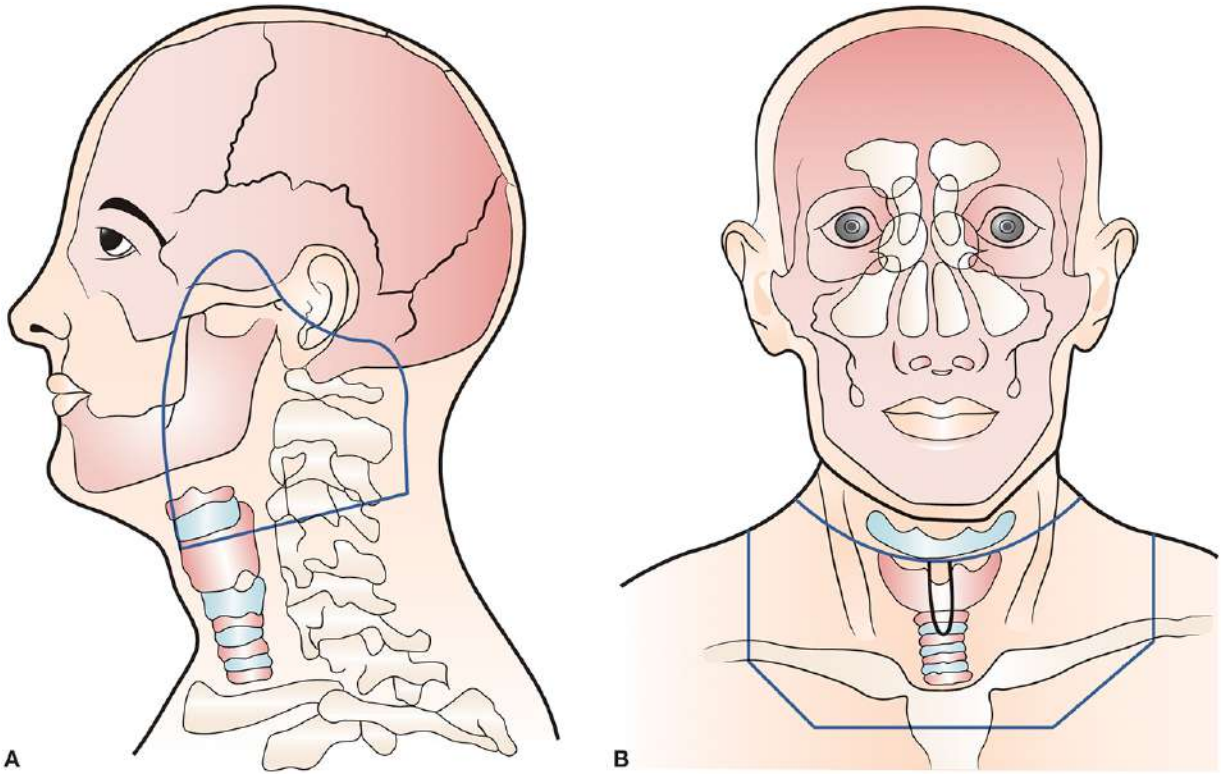

FIGURE 55.13 Radiation therapy portals used starting from 1997 to treat head and neck mucosal sites and upper cervical lymph nodes (A) and lower cervical and supraclavicular lymph nodes (B). The inferior border for lateral portals is placed at the superior anterior border of the thyroid cartilage, shielding the hypopharynx and larynx. (Reprinted from Erkal HS, Mendenhall WM, Amdur RJ, Villaret DB, Stringer SP. Squamous cell carcinomas metastatic to cervical lymph nodes from an unknown head-and-neck mucosal site treated with radiation therapy alone or in combination with neck dissection. *Int J Radiat Oncol Biol Phys*. 2001;50[1]:55-63. Erkal et al[72] reported on patients 126 with treated curative intent at the University of Florida between 1964 and 1997 with follow-up for at least 2 years. RT was delivered to head and neck mucosal sites and both sides of the neck in 119 patients and to the neck alone in 7 patients. Twelve (10%) patients developed SCC in a head and neck mucosal site at 0.5 to 10.9 years (median, 1.8 years) after treatment. The 5-year results were as follows: head and neck mucosal failure, 13%; neck node control, 78%; distant metastases, 14%; absolute survival, 47%; and cause-specific survival, 67%. Wallace et al[77] reported a combined series of 179 patients treated at the University of Florida (139 patients) and the University of Wisconsin (40 patients). The 5-year mucosal control rate was 92%; the head and neck mucosa was irradiated in 174 (97%) patients. For the subset of 28 patients where the

mucosal RT was limited to the nasopharynx and oropharynx, the 5-year mucosal control rate was 100%. De Leo et al[78] subsequently reported on 50 patients treated with the larynx-sparing technique described above between 1997 and 2019 at the authors' institution; none of these patients developed a head and neck mucosal SCC after receiving RT.

Colletier et al[79] reported on 136 patients treated with neck dissection followed by RT to head and neck mucosal sites and bilateral lymph nodes. Six percent of patients developed carcinomas in head and neck mucosal sites within RT portals, and 4% of patients developed carcinomas in head and neck mucosal sites outside the RT portals. The absolute survival rate at 5 years was 60%. The authors recommended RT to head and neck mucosal sites. Reddy and Marks[80] reported on 16 patients with RT to ipsilateral lymph nodes and 36 patients with RT to head and neck mucosal sites and bilateral lymph nodes. The authors concluded that RT reduced the rate of developing carcinomas in head and neck mucosal sites. For patients with no RT to head and neck mucosal sites, the rate of developing carcinomas in head and neck mucosal sites was 46% and the absolute survival rate at 5 years was 47%. For patients treated with RT to head and neck mucosal sites, the rates were 8% and 53%, respectively. Grau et al[81] reported on 273 patients treated with curative intent at five cancer centers in Denmark between 1975 and 1995 with surgery alone (23 patients), RT to the ipsilateral neck either alone or combined with surgery (26 patients), and RT to the neck and head and neck mucosa either alone or combined with surgery (224 patients). The ipsilateral oropharynx unintentionally received some RT in patients treated to the ipsilateral neck alone, depending on the treatment technique. The 5-year rates of freedom from failure in the head and neck mucosa were as follows: surgery alone, 45%; RT with or without surgery to the ipsilateral neck, 77%; and RT to the head and neck mucosa with or without surgery, 87%. The oropharynx, particularly the base of the tongue, was the most common location of mucosal site failure.

The incidence of subsequent mucosal primary lesions was compared by Erkal et al[82] for 1,112 patients with a known primary site (oropharynx, hypopharynx, and supraglottis) and a series of 126 patients treated for an unknown primary site at the University of Florida. The incidence of subsequent mucosal head and neck cancer was similar for both groups, suggesting either that mucosal irradiation significantly reduced the risk of

primary site failure or that patients with unknown primary sites have a much lower risk of a second primary head and neck cancer developing subsequently (Figure 55.14).[72]

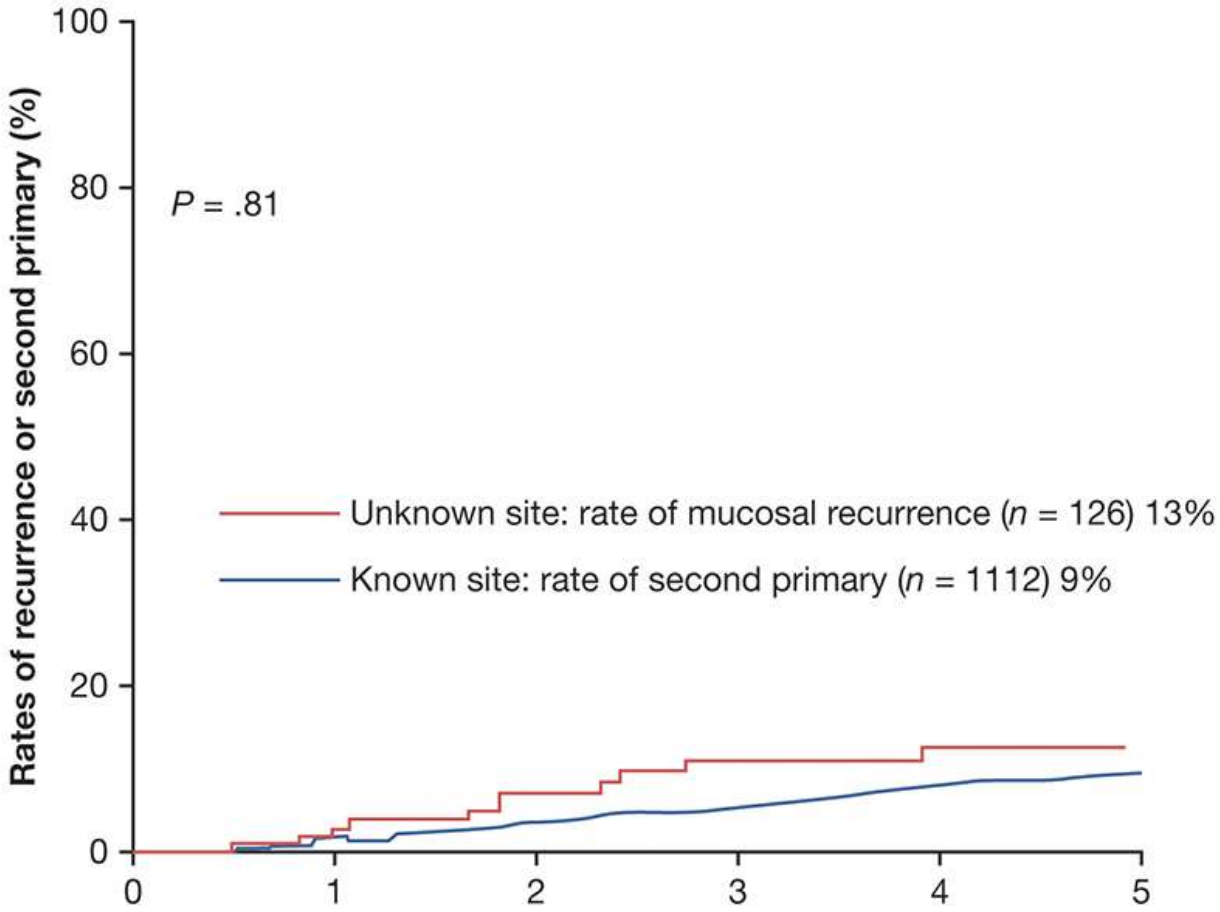

FIGURE 55.14 The rate of developing carcinomas in head and neck mucosal sites for patients treated for carcinomas with an unknown head and neck mucosal site compared to the rate of developing metachronous carcinomas in head and neck mucosal sites for patients treated for carcinomas with a known head and neck mucosal site. (Reprinted from Erkal HS, Mendenhall WM, Amdur RJ, Villaret DB, Stringer SP. Squamous cell carcinomas metastatic to cervical lymph nodes from an unknown head-and-neck mucosal site treated with radiation therapy alone or in combination with neck dissection. *Int J Radiat Oncol Biol Phys*. 2001;50[1]:55-63. Copyright © 2001 Elsevier. With permission.)

A subset of patients presenting with SCC metastatic to the neck nodes from an unknown head and neck primary site are treated with palliative intent because of the poor medical condition, extensive nodal involvement, or distant metastases at presentation. Treatment of the neck depends on the extent and location of the adenopathy. Forty of 166 (24%) patients were

treated palliatively at the University of Florida between 1964 and 1997.[83] Treatment was delivered to the neck alone to a dose of 30 Gy in 10 fractions over 2 weeks or 20 Gy in 2 fractions with a 1-week interfraction interval. The nodal response rate was 65%, and the symptomatic response rate was 57% at 1 year. The 1-year absolute and cause-specific survival rates were 25%.

The main complications of RT for patients treated for an unknown head and neck primary tumor are xerostomia, dysphagia, and neck fibrosis. The complications of treatment of the neck, which have been discussed previously, depend on whether chemotherapy and/or neck dissection is added.[83]

An alternative approach to carcinoma of unknown primary of the neck involves transoral surgery: transoral robotic surgery (TORS) or transoral laser microsurgery (TLM). The TORS approach involves using the surgical robot to access difficult-to-reach areas of the oropharynx to take more thorough directed biopsies. With the robot, the surgeon performs bilateral tonsillectomy/extended tonsillectomy as well as lingual tonsillectomy/base of tongue shaves. Moreover, if a primary is found on inspection or frozen section, the surgeon may perform a resection at the same time. Typically, a selective neck dissection (levels II-IV) is performed in conjunction with the TORS procedure. Durmus et al[84] reported on the initial experience of this method at the Ohio State University. In 77% of patients, the primary site was identified; 76% of tumors were found in the palatine tonsils and 24% in the base of the tongue. Seventy-seven percent of these patients underwent complete resection with negative margins. Adjuvant treatment was delivered as indicated, with 59% of patients able to avoid chemotherapy. Other studies have demonstrated similar results, with the primary being found in 72% to 90% of cases versus 25% to 57% of cases using traditional biopsy techniques.[85] Kang et al summarized the TORS approach for carcinoma of unknown primary (Figure 55.15).

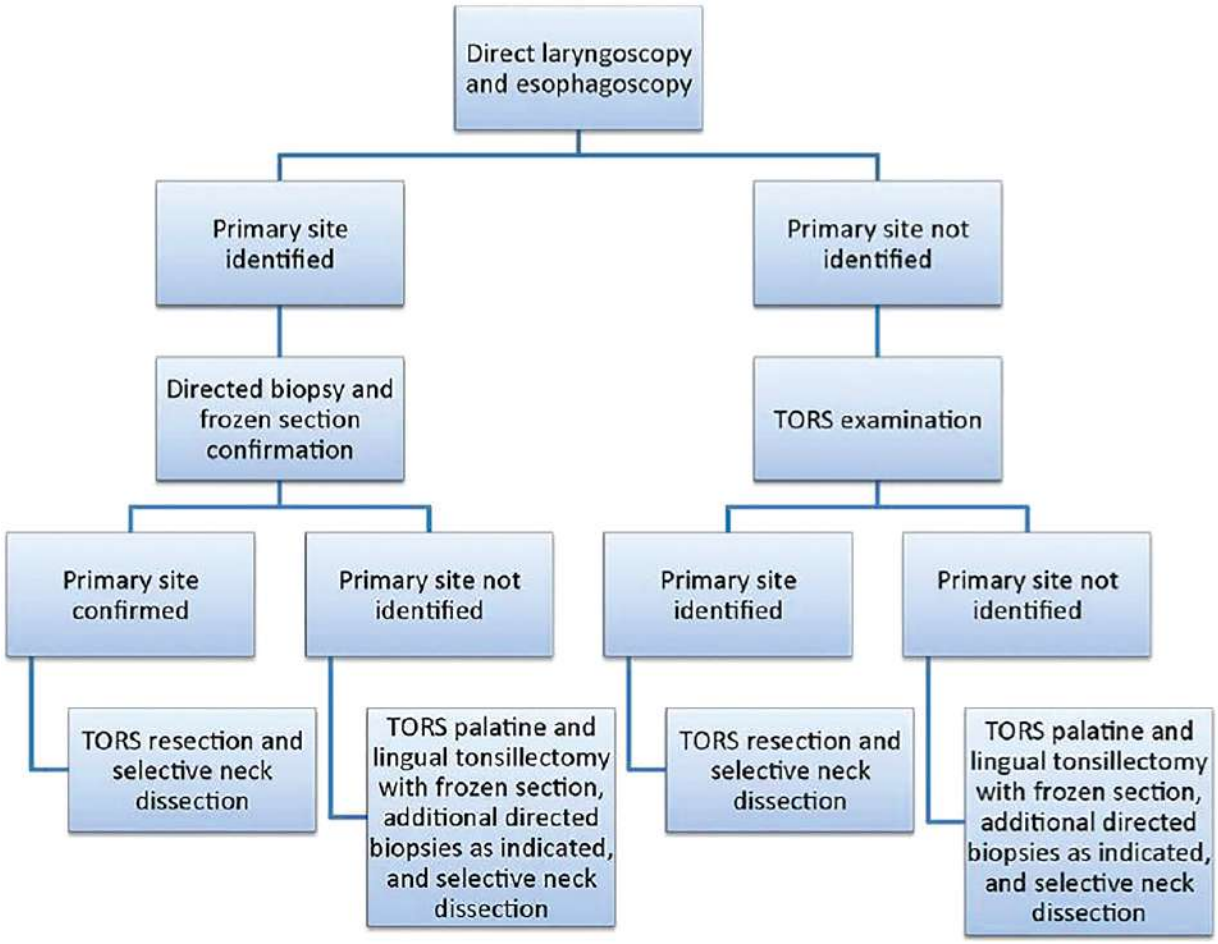

FIGURE 55.15 Treatment paradigm for carcinoma of unknown primary metastatic to cervical lymph nodes. TORS, transoral robotic surgery. (From Kang SY, Dziegielewski PT, Old MO, Ozer E. Transoral robotic surgery for carcinoma of unknown primary in the head and neck. *J Surg Oncol*. 2015;112[7]:697-701. Copyright © 2015 Wiley Periodicals. Reprinted by permission of John Wiley & Sons.)

Another transoral technique, TLM, utilizes a laser instead of the electrocautery of the TORS approach. Graboyes et al[86] reported the largest series of carcinoma of unknown primary worked up and treated with TLM. Eighty-nine percent of patients had the primary site identified. The approach also involves palatine tonsillectomy and base of the tongue resections as well as selective neck dissection. Twenty-six percent of patients who were treated with the TLM approach managed to avoid RT altogether.

There are several advantages to identifying the primary site in patients presenting with carcinoma of unknown primary of the neck. When the

primary site is elucidated, RT can be tailored to a smaller field and lower dose, thus reducing the morbidity of RT. Some have contended that conventional RT for carcinoma of unknown primary, when the primary site is not found, can lead to grade 3 dysphagia in 50% of patients.[87] This has not been our experience when the targeted mucosal sites are limited to the oropharynx.[71,77] If the primary site is completely resected, adjuvant treatment may be avoided or deintensified. However, because the majority of these patients have an oropharyngeal primary, it is likely that the HPV-positive nonsmokers could safely have their treatment deintensified without respecting the primary site. Functional outcomes for this approach are excellent with a 4.5% gastrostomy rate at 1 year and return of quality of life to pretreatment baseline or better.[85] Perhaps even more significant is the potential survival advantage provided when the primary site is identified and treated appropriately.[86,88-90]

CHAPTER 56

Thyroid Cancer

Robert J. Amdur and Roi Dagan

BASIC THYROID ANATOMY AND PHYSIOLOGY

Gross Anatomy

The thyroid gland is located in the central anterior neck at the cervical-thoracic junction (Figure 56.1). The bulk of the gland is located immediately anterior and inferior to the thyroid cartilage. It has two lateral lobes connected by a central isthmus. Approximately 50% of individuals have a pyramidal lobe that extends superiorly from the central aspect of the gland, which is a remnant of the gland's embryologic origin, the thyroglossal duct. The average adult thyroid gland measures approximately 5×5 cm^2 and weighs 10 to 20 g.

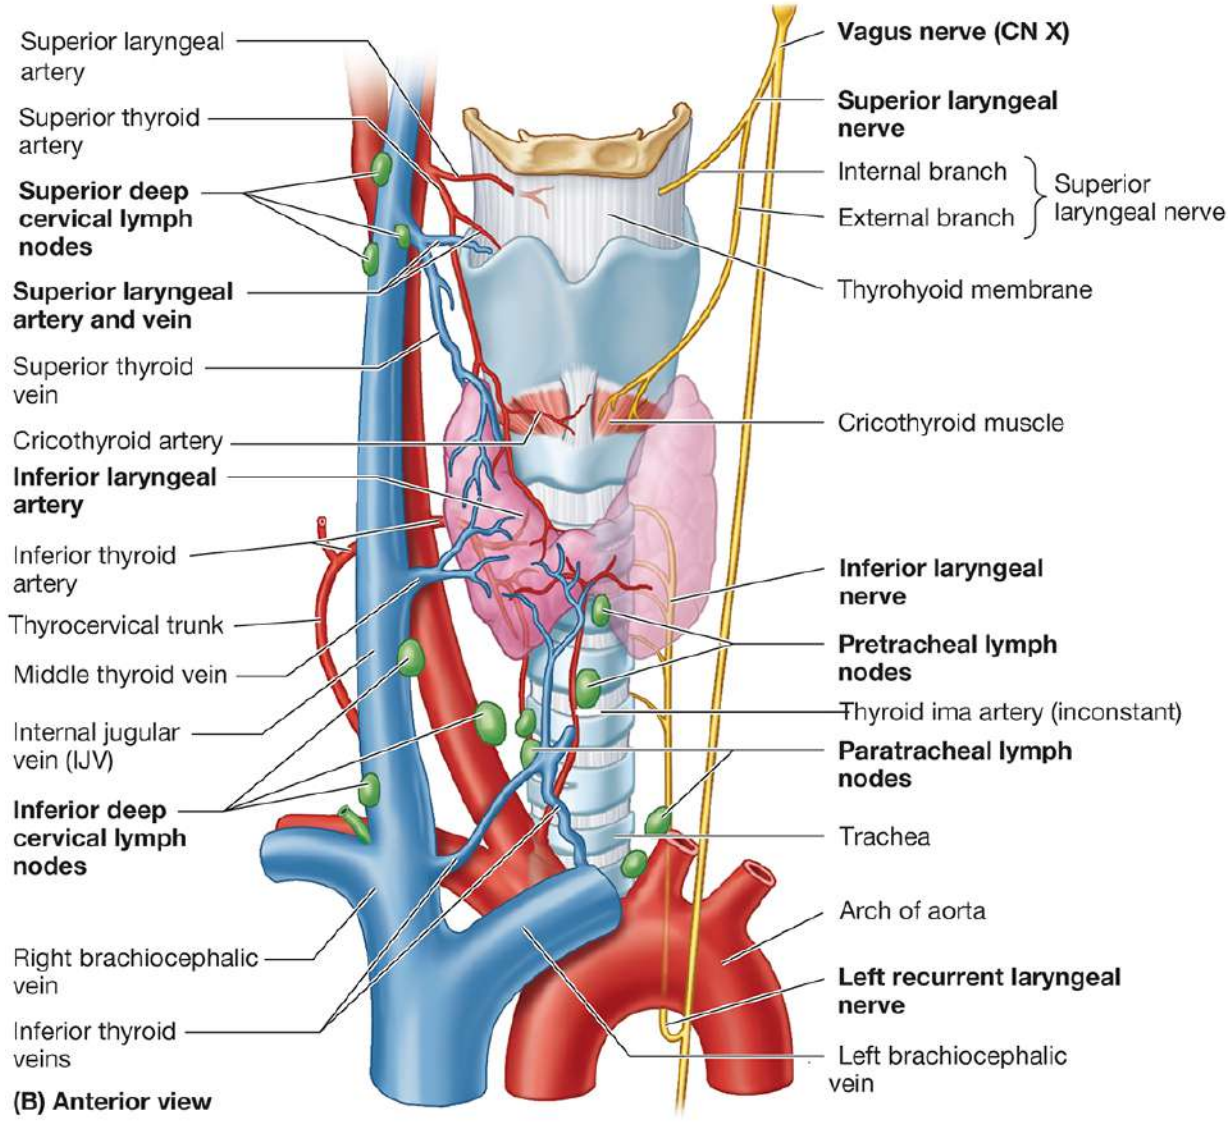

FIGURE 56.1 Anatomic location of the thyroid gland relative to the larynx, major vessels, and draining lymphatics. (Reprinted with permission from Agur AMR, Dalley AF. *Moore's Essential Clinical Anatomy*. 7th ed. Wolters Kluwer; 2024:620.)

The location of the gland in the central neck and its relation to critical structures explain the presenting symptoms of advanced neoplastic processes arising from the thyroid as well as potential complications of thyroid surgery and radiotherapy (Figure 56.2). The lateral lobes extend superiorly to the level of the midthyroid cartilage overlying the larynx and inferiorly to the sixth tracheal ring. The gland wraps around 75% of the tracheal circumference, posteriorly encroaching on the esophagus. The lateral extent is just medial to the common carotid arteries. The recurrent laryngeal nerves, sympathetic trunks, vagus, and phrenic nerves are all found immediately posterior to the gland, and the gland is

anteriorly bound by the strap muscles. Parathyroid glands are located posterior to the thyroid gland and vary in location and number.

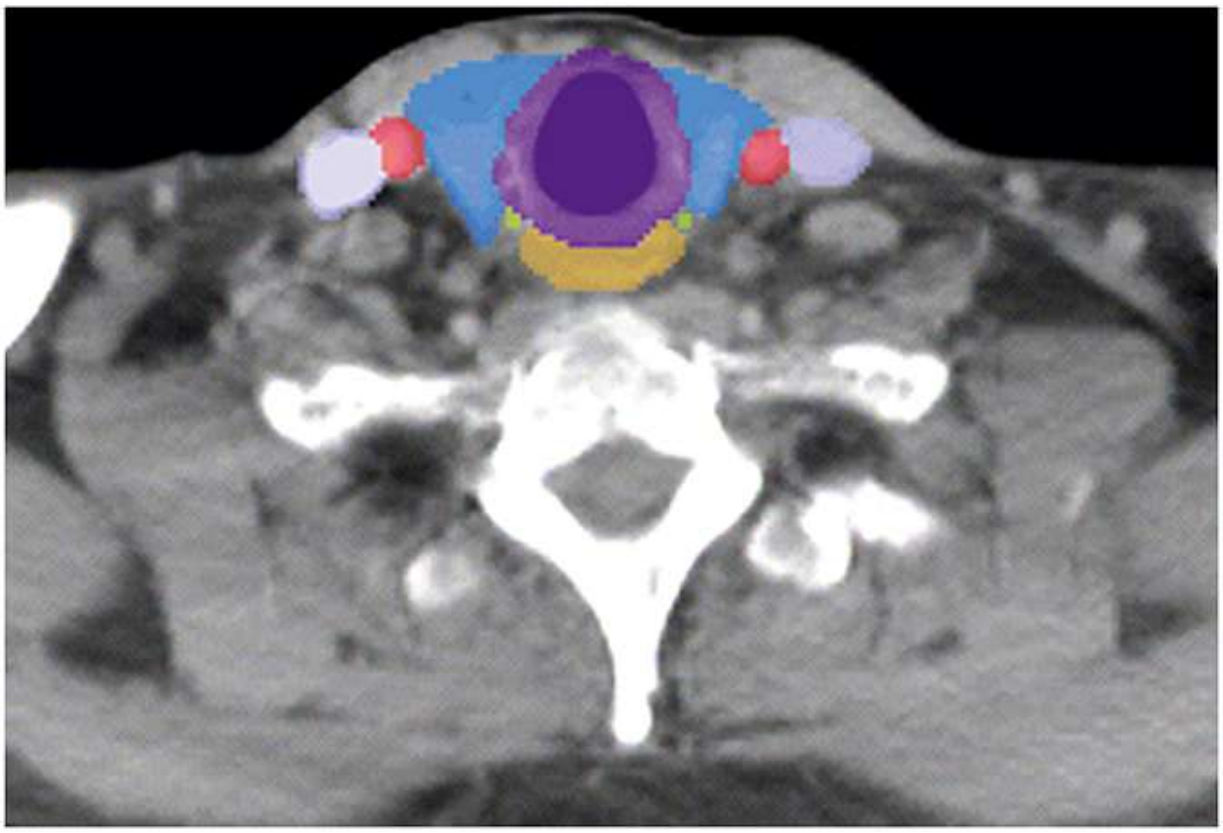

FIGURE 56.2 Anatomy of the thyroid gland. Contrast-enhanced axial computed tomography slice at the level of the bottom of the cricoid cartilage (purple) showing the position of the thyroid gland (blue) relative to the esophagus (orange), carotid arteries (red), jugular vein (lavender), and the approximate position of the recurrent laryngeal nerves (yellow green).

Vasculature and Lymphatics

The arterial blood supply to the thyroid gland is provided by the paired superior thyroid arteries (branches of the external carotid arteries) and inferior thyroid arteries (branches of the thyrocervical trunk from the subclavian arteries). Venous blood drains via the paired superior and middle thyroid veins to the internal jugular veins and from the inferior thyroid veins to the subclavian and innominate veins. There is a dense lymphatic network draining the gland in multiple directions, and bilateral involvement of lymph node metastases is common. According to the American Joint Committee on Cancer's (AJCC) eighth edition of the *AJCC Cancer Staging Manual*, the first-echelon nodes for thyroid cancer metastases are located in level 6 (the central or "visceral" compartment) between

the hyoid bone and the thoracic inlet.[1] Specifically, these are the paralaryngeal, paratracheal, and prelaryngeal (Delphian) nodes. Second-echelon nodal spread is to the mid- and lower cervical nodes (levels 3 and 4), supraclavicular nodes, upper mediastinal nodes (level 7), and, to a lesser extent, the upper cervical nodes (level 2). Level 1 (submental and submandibular) lymph nodes are rarely involved.

Spread of thyroid cancer to the retropharyngeal nodes is unusual, but we see positive retropharyngeal nodes in patients with many positive nodes in the lateral cervical stations and with advanced-stage disease at the primary site. With thyroid cancer, the positive retropharyngeal nodes are often in the more inferior portion of the station (Figure 56.3).

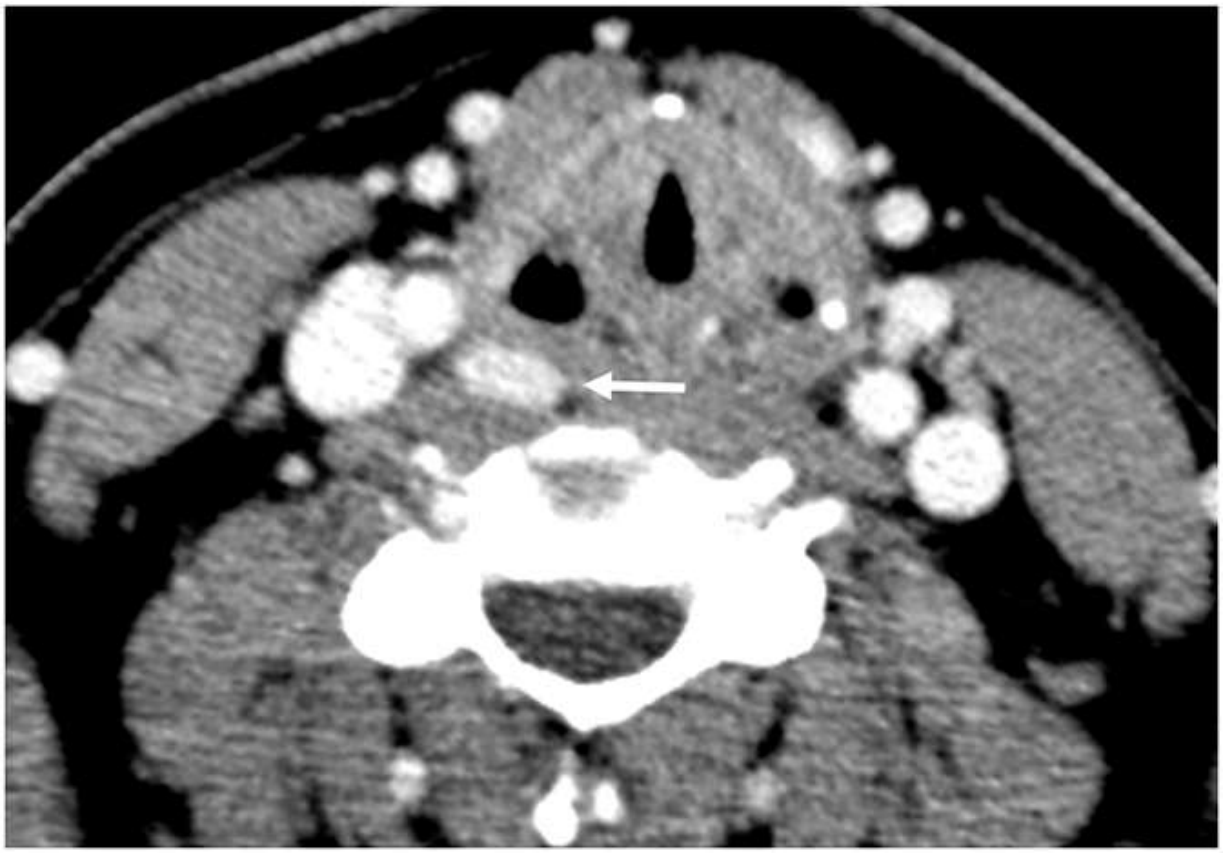

FIGURE 56.3 Axial computed tomography image with intravenous contrast at the level of the false vocal cords in a patient with papillary thyroid cancer. The arrow points to a retropharyngeal node. Metastatic cancer in this node explains the avid enhancement from iodinated contrast.

Microscopic Anatomy

Microscopically, the normal thyroid gland consists of numerous lobules comprising individual follicles forming the structural and functional unit of the

gland (Figure 56.4). The supporting stroma and vasculature are intertwined around the follicles. Each follicle consists of a single layer of cuboidal surface epithelium comprising thyroid follicular cells surrounding a central lumen-containing colloid, a substance rich in thyroglobulin (Tg). Separate from the follicular epithelium are the parafollicular cells, or C cells, which are neural crest–derived cells containing granules of calcitonin. The thyroid gland is incompletely surrounded by a connective tissue capsule.

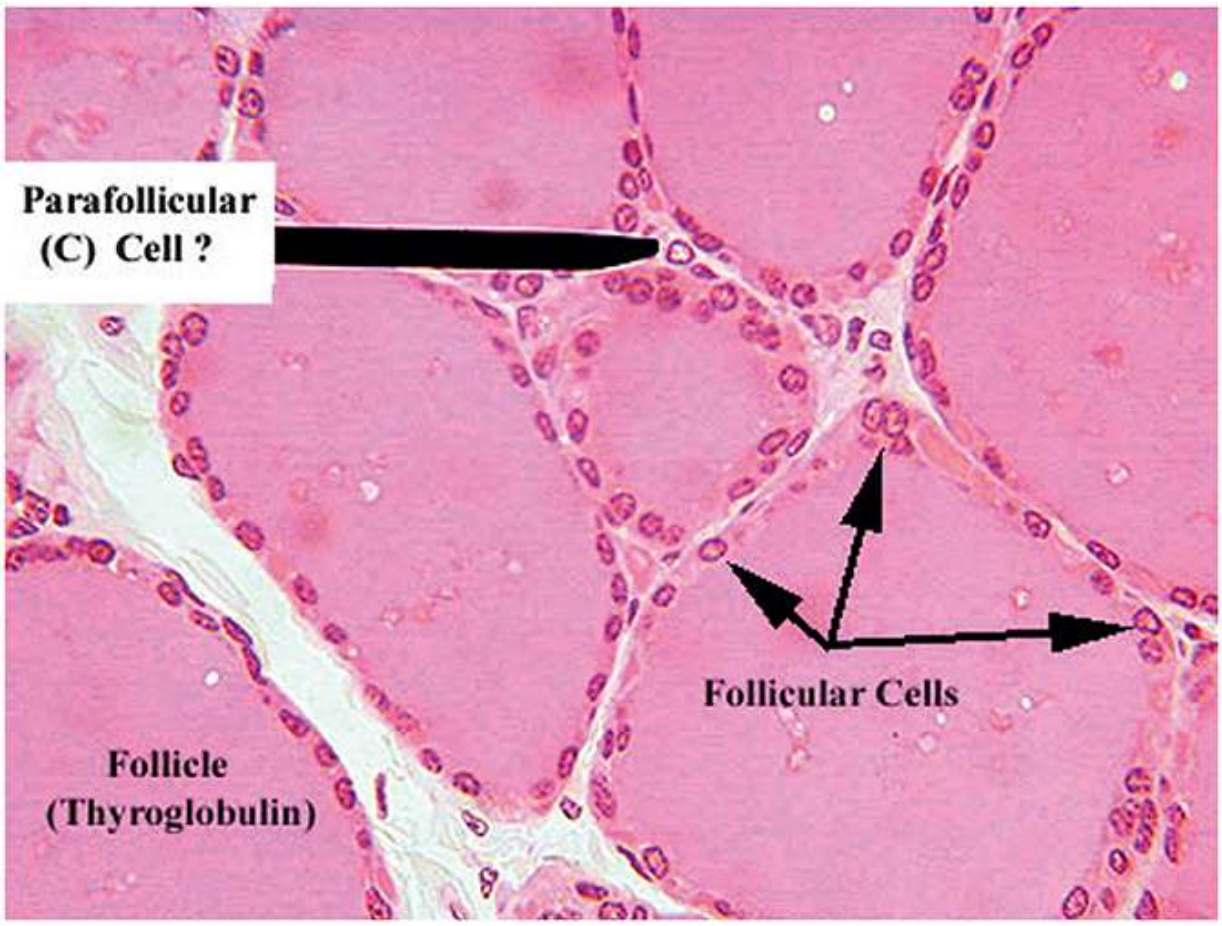

FIGURE 56.4 Thyroid follicle. Thyroid follicular cells produce thyroglobulin and thyroid hormone. Thyroid cells, which are normally located in the thyroid follicles and in perifollicular regions, synthesize and secrete calcitonin. (Reprinted by permission from Springer: Mazzaferri EL, Amdur RJ. Thyroid and parathyroid physiology. In: Amdur RJ, Mazzaferri EL, eds. *Essentials of Thyroid Cancer Management (Cancer Treatment and Research)*. Springer; 2005:7-17. Copyright © 2005 Springer Science+Business Media.)

Physiology

The primary physiologic role of the thyroid gland is the production of thyroid hormone, which plays an important role in metabolic homeostasis. A secondary

role is the production of calcitonin, a hormone involved in calcium homeostasis. The follicular cells of the thyroid gland synthesize and secrete Tg and thyroid hormone in two biologically active forms, thyroxine (3,5,3′,5′-iodothyronine or T_4) and triiodothyronine (3,5,3′-iodothyronine or T_3). It is useful to consider T_4 as the storage and transport form of thyroid hormone and T_3 as the metabolically active form. Most circulating thyroid hormone is bound to thyroxine-binding globulin. In peripheral tissues, where thyroid hormone executes its endocrine function, T_4 is rapidly converted to the more active form T_3 by the action of T_4 monodeiodinase. T_3 is transported to the nucleus where it binds to specific nuclear receptors and interacts with regulatory genes, influencing their expression. The gene products ultimately increase the cell's basal metabolic rate, protein synthesis, catecholamine effects, and growth of long bones and play an essential role in metabolism of proteins, fats, and carbohydrates. Thyroid hormone exerts its endocrine function on virtually all cells in the body.

Iodine is a critical component of thyroid hormone and is essential for thyroid function. The recommended daily intake is 150 μg, and at least 50 μg of daily intake is necessary to prevent deficiency, resulting in a goiter. The follicular cells of the thyroid gland possess a unique ability to actively uptake and concentrate iodine. The sodium iodine symporter (NaIS) actively transports sodium and iodine against an electrochemical gradient across the cell membrane in an energy-dependent fashion. This transmembrane protein is stimulated by thyroid-stimulating hormone (TSH or thyrotropin), which is synthesized in the anterior pituitary. Functional NaIS is present on malignant follicular cells seen in multiple variants of differentiated thyroid cancer (DTC). The unique ability to concentrate iodine within these malignant cells makes radioactive iodine (RAI), such as iodine-131 (I-131), a potent targeted therapy. The central role of TSH in driving the internalization of iodine within follicular thyroid cells is exploited in preparation for I-131. To increase the efficacy of I-131 therapy, T_4 deprivation, a low-iodine diet, and administration of recombinant human TSH (rhTSH) can be used to increase the effects of TSH on follicular thyroid cells (see the section on preparing patients for I-131). NaIS is also present in the parotid glands, breast tissues, gastric mucosa, and nasolacrimal ducts, placing them at risk for injury from I-131 therapy.

Upon entering the follicular cells, iodine is transported across the apical membrane and oxidized to a form that binds to tyrosyl residues of Tg, a large (660 kDa) glycoprotein synthesized by the follicular cells. Iodinated Tg becomes the main component of the intraluminal colloid stores of the thyroid follicles. T_3

and T_4 are synthesized by the coupling of iodinated tyrosine. They remain attached to the Tg until leaving the gland. TSH stimulation results in endocytosis of colloid droplets from the lumen into the follicular cells where it is hydrolyzed and releases Tg, T_4, and, to a lesser degree, T_3 into the circulation. Malignant differentiated follicular cells retain this function. Thus, serum Tg becomes a unique tumor marker after thyroidectomy and thyroid remnant ablation.

A feedback loop between the thyroid, pituitary, and hypothalamus regulates thyroid hormone synthesis and secretion. Thyrotropin-releasing hormone (TRH) is synthesized in the hypothalamus, and its primary function is to increase the secretion of TSH in the pituitary. Both T_3 and T_4 in turn inhibit TRH release and TSH secretion.

CLASSIFICATIONS OF THYROID CANCER

Correct pathologic classification of thyroid carcinoma is fundamental to the appropriate clinical management of the malignancy.[2] A system of classification that the authors find useful for clinical practice is shown in Table 56.1 and discussed below. The cell of origin, cytologic features, and growth morphology determine the pathologic classification. All carcinomas of the thyroid gland are derived from the follicular epithelium, except medullary thyroid carcinoma (MTC), which is derived from the parafollicular C cells. Capsular invasion is important in the pathologic diagnosis of certain thyroid carcinomas. The diagnosis of papillary thyroid carcinoma (PTC) is entirely predicated on the presence of diagnostic nuclear features and does not require invasive growth, while follicular carcinoma (FC) requires the presence of capsular or vascular invasion. Other rarely encountered malignant neoplasms of the thyroid gland include thyroid lymphoma and sarcomas. These two entities are not discussed in this chapter and are better evaluated and managed under paradigms detailed in the chapters on lymphoma and sarcoma.

TABLE 56.1 CLASSIFICATION OF THYROID CANCER BY CELL OF ORIGIN

Follicular epithelial cell
Well-differentiated thyroid cancer (DTC)
Papillary thyroid carcinoma (PTC)
Classic
Follicular variant
Oncocytic variant
Unfavorable variants
Diffuse sclerosing
Tall cell

Columnar cell
Hobnail
Follicular thyroid carcinoma (FTC)
Classic
Hürthle cell (oncocytic) carcinoma
Poorly differentiated thyroid cancer (PDTC): insular carcinoma
Undifferentiated thyroid cancer: anaplastic carcinoma

Parafollicular C cell

Medullary carcinoma

Differentiated (Follicular-Derived) Thyroid Carcinoma

The two major subgroups comprising DTC are PTC and FC.[2] They are distinguished mainly by cytologic features: In PTC, cytology is diagnostic of malignancy, whereas in FC, the diagnosis of malignancy requires evidence of tumor invasion through the tumor (not the thyroid) capsule. It is for this reason that PTC is usually diagnosed by fine-needle aspiration (FNA), but diagnosis of FC usually requires at least a lobectomy.

Papillary Thyroid Carcinoma

The distinguishing features of PTC include nuclear enlargement, hypochromasia, intranuclear cytoplasmic inclusions (nuclear pseudoinclusions), nuclear grooves, and distinct nucleoli. After formalin fixation, nuclei may appear pale, optically clear, and resemble "Orphan Annie's eyes." PTC is strongly lymphotropic, and multicentric disease within the parenchyma of the gland is often present secondary to early lymphatic spread. All PTC stain strongly for Tg.[3-5]

In its classic variant, PTC has a tumor architecture comprising branching papillae with fibrovascular cores. The follicular variant of PTC differs from the classic variant by its follicular growth pattern; however, it retains the nuclear features diagnostic of PTC. The oncocytic variant of PTC has the morphology of oncocytomas elsewhere in the body with abundant pink cytoplasm. From the clinical standpoint, the distinction between classic, follicular, and oncocytic subtypes of PTC is not important because they are treated the same way and have similar prognoses. The unfavorable variants of PTC have a worse prognosis than the above three subtypes.

Diffuse sclerosing is a rare form of PTC, with histologic features of extensive sclerosis, lymphocytic infiltrate, and psammoma bodies. A greater percentage of patients with diffuse sclerosing PTC present with extrathyroidal extension or distant metastases. Likewise, tall cell, columnar, and hobnail variants are commonly associated with poor prognostic features, such as advanced age, large

tumor size, aggressive histologic features with early invasion, and distant metastases. The distinguishing feature of tall cell PTC is that at least 70% of the carcinoma is composed of cells that are at least twice as tall as they are wide because of abundant cellular cytoplasm. Columnar and hobnail cell variants are rare. These carcinomas histologically show striking nuclear stratification, usually with papillary architecture. However, the usual nuclear features of PTCs may be absent; therefore, some pathologists prefer to classify columnar and hobnail cell variants as poorly differentiated carcinomas.

Follicular Carcinoma

FC, like PTC, is a DTC of follicular cell origin. This malignant thyroid neoplasm lacks the cytologic features of PTC. These carcinomas show evidence of thyroid follicle formation and are usually well circumscribed with a defined tumor capsule.[2] They are grossly indistinguishable from follicular adenomas. The diagnosis of FC is dependent on the presence of one of two histologic features: (a) tumor invasion through the entire tumor capsule or (b) tumor invasion into a blood vessel located in the tumor capsule or immediately outside the tumor capsule. Minimally invasive forms of FC may present a pathologic challenge and often require serial sectioning to find evidence of capsular or vascular invasion, while widely invasive forms of FC are obviously invasive tumors on both gross and microscopic evaluation.

Hürthle Cell (Oncocytic) Carcinoma

The more general term for Hürthle cell carcinoma is oncocytic carcinoma of the thyroid (not to be confused with the oncocytic variant of PTC). Some references classify Hürthle cell carcinoma as a subtype of follicular thyroid cancer, but more recent molecular studies suggest it is a separate entity.[2,6]

Hürthle cells are large and contain abundant granular eosinophilic cytoplasm. Hürthle cells may be seen in both benign and other non-Hürthle cell malignant neoplastic lesions; however, at least 75% of the tumor must be composed of Hürthle cells to designate it Hürthle cell carcinoma. Similar to FC, Hürthle cell carcinoma requires the presence of capsular or vascular invasion to classify it as a malignant neoplasm.

Poorly Differentiated Thyroid Carcinoma (Insular Carcinoma)

These follicular epithelial cell–derived tumors are intermediate between DTC and undifferentiated, or anaplastic, thyroid cancer (ATC). Both their histologic

appearance and biologic behavior are more aggressive than DTC.[2] They tend to be widely invasive, and many will extend beyond the gland. Insular carcinoma is characterized by tumor cells that are arranged in discrete nests separated by a fibrous stroma. Microscopically, they are usually solid with some evidence of follicle formation. Mitoses and necrosis are often present. The presence of more differentiated areas of tumor admixed with insular carcinoma suggests that the latter represents "dedifferentiated" tumors.

Undifferentiated Thyroid Carcinoma (Anaplastic Carcinoma)

ATC is the most aggressive form of thyroid carcinoma. Most patients are diagnosed at the age of 65 years or above.[2,7] ATC originates from the thyroid follicular epithelium but shows little to no evidence of histologic differentiation. This tumor is defined as much by its clinical behavior as its histologic appearance. When diagnosed, most ATCs are widely invasive, replacing most if not all of the normal-appearing gland, and freely infiltrate the perithyroidal tissues. They are usually accompanied by bulky metastatic lymphadenopathy and distant metastatic spread. Gross pathologic evaluation is characterized by widely infiltrative disease with areas of necrosis and hemorrhage. Various microscopic patterns have been described, including small cell, spindle cell, giant cell, squamoid, or pleomorphic. They are hypothesized to be lesions that have dedifferentiated from more benign differentiated follicular neoplasms.

Medullary Thyroid Carcinoma

MTC does not originate from the follicular epithelial cells, but from the parafollicular C cells, which are neural crest–derived cells whose function is to produce calcitonin. Cases are seen sporadically (80%) or in association with familial multiple endocrine neoplasia (MEN IIa, MEN IIb, and pure familial MTC) syndromes. Multifocal and bilateral MTCs are usually seen in patients with MEN, but, otherwise, familial and sporadic MTCs are indistinguishable. Grossly, these tumors are well circumscribed and nonencapsulated. Microscopically, tumors can have different appearances, including patterns that mimic other types of thyroid tumors. The most common pattern is of solid growth or nests similar to insular carcinoma. Amyloid, which is present in approximately 80% of cases, is a characteristic feature of MTC. Calcitonin stains are usually positive and specific for MTC, but up to 20% of cases may not stain for calcitonin; therefore, other neuroendocrine markers such as chromogranin may be useful.

Classification Based on the Capacity to Concentrate Iodine

Different pathologic classes of thyroid carcinoma concentrate iodine to various degrees. This characteristic is central to management decisions because the ability to concentrate iodine presents a useful therapeutic target. Table 56.2 presents a classification system that categorizes cancers based on whether they always concentrate iodine, infrequently concentrate iodine, or never concentrate iodine. Papillary carcinoma and FC (with the exception of the more aggressive variants) usually concentrate iodine. The follicular variant of papillary cancer has the same avidity for iodine as papillary cancer with classic morphology. Therefore, from the treatment standpoint, the distinction between these types of DTCs is not important. The aggressive variants of papillary carcinoma and Hürthle cell carcinoma can concentrate iodine, but to a lesser degree than the classic morphologies. In fact, there is often no measurable iodine uptake in metastases of these tumors. Anaplastic and medullary cancers never concentrate iodine to a clinically useful degree.

TABLE 56.2 CLASSIFICATION OF THYROID CANCER BASED ON THE ABILITY TO CONCENTRATE IODINE

Usually concentrate iodine to a degree that may be curative
Papillary thyroid carcinoma
Classic
Follicular variant
Oncocytic variant
Follicular thyroid carcinoma
Classic
Often do NOT concentrate iodine to a degree that is curative
Unfavorable variants of papillary thyroid carcinoma
Diffuse sclerosing
Tall cell
Columnar cell
Hobnail
Hürthle cell (oncocytic) carcinoma
Rarely concentrate iodine to a degree that is curative
Poorly differentiated thyroid carcinoma: insular carcinoma
Never concentrate iodine to a degree that is curative
Anaplastic carcinoma
Medullary carcinoma

EPIDEMIOLOGY OF THYROID CANCER

The most recent report of thyroid cancer incidence using the Surveillance, Epidemiology, and End Results database was published in 2017 with data from 1974 to 2013.[8]

DTC accounted for about 90% of total thyroid cancer cases, with 90% of these being papillary carcinoma. The approximate distribution of thyroid cancer cases by sex, race, and histology was as follows: female, 75%; White, 80%; papillary, 84%; follicular, 11%; medullary, 2%; and anaplastic, 1%. Distribution by age was <20 years, 2%; 20 to 39 years, 31%; 40 to 59 years, 42%; 60 to 79 years, 22%; and ≥80 years, 3%.

Between 1974 and 2013, the incidence of thyroid cancer tripled, from ~4.5 to 14.4 per 100,000 individuals with almost the entire increase attributable to PTC. These findings are explained by the fact that the large increase in thyroid cancer diagnosis is from the detection of early-stage tumor on neck ultrasound (US) and other imaging studies. The extent of cancer at diagnosis was distributed as follows: localized, 59; regional, 33%; and distant, 5%.

Radiation-Induced Thyroid Cancer

Exposure to ionizing radiation is an established risk factor for thyroid nodules and cancer. Well-recognized data come from survivors of atomic bombs in Hiroshima and Nagasaki and the nuclear reactor accident in Chernobyl.[9-15] A recent analysis of the 59,687 atomic bomb survivors in the Life Span Study demonstrated a total of 24.5% of cases of thyroid cancer in this cohort were attributed to radiation exposure with a strong dose response.[13] Women and young children appeared to be most susceptible. An estimated additional 1,000 cases of thyroid cancer throughout Europe have been attributed to the Chernobyl accident.[15] An increased risk of thyroid cancer has also been attributed to exposure to therapeutic radiation in children treated for Hodgkin lymphoma, tinea capitis, enlarged tonsils, and enlarged thymus.[16-18] Radiation-induced thyroid cancer is pathologically indistinguishable from spontaneous forms of the disease and is not associated with more aggressive biology or poorer prognosis.[19-22]

Familial Medullary Thyroid Carcinoma

Twenty-five percent of cases of MTCs are hereditary. All patients with MTC should be screened for familial disease, and genetic testing is considered the standard of care for all first-degree relatives of patients with newly diagnosed MTC. Heritable forms of MTC are associated with the familial MEN syndromes

(MEN IIa, MEN IIb, and pure familial MTC) and have their own unique epidemiology. These disorders are inherited in an autosomal dominant manner due to a germline point mutation in the *RET* gene on chromosome 10q11.2. Men and women are affected equally, given the pattern of inheritance. These patients typically present with bilateral and multifocal tumors compared to sporadic forms of MTC. The aggressiveness and age of onset of familial MTC differ depending on the specific genetic mutation. Prophylactic thyroidectomies are increasingly being performed on patients at risk for developing MTC.[23]

CLINICAL MANIFESTATIONS OF THYROID CANCER

The most common presentation of thyroid cancer is an asymptomatic thyroid nodule found incidentally by the patient, clinicians, or on an imaging study performed for other reasons.[24,25]

Alternatively, locally advanced thyroid cancer presents with symptoms from involvement of the critical structures intimately associated with the thyroid gland, massive cervical lymphadenopathy, or metastatic disease. These patients present with symptoms such as hoarseness from tumor compression of the recurrent laryngeal nerve, airway compromise, dysphagia or respiratory symptoms, and pain and weight loss resulting from metastatic dissemination.

DIAGNOSTIC EVALUATION OF THYROID CANCER

Laboratory Studies

All patients with thyroid nodules should undergo a serum TSH in addition to basic metabolic, renal, and liver function tests and a complete blood count. Other lab tests, such as Tg, T_3, and T_4, are commonly obtained but are rarely useful in the initial management of thyroid cancer. Serum calcitonin can be measured during the initial evaluation of patients with MTC and is essential during follow-up for these patients.

Ultrasound and Ultrasound-Guided Fine-Needle Aspiration

Neck US with Doppler and US-FNA are the standard diagnostic approaches for evaluating thyroid nodules, both palpable and incidentally detected on imaging. US-FNA has several benefits in the evaluation of thyroid nodules over other means of obtaining a tissue diagnosis: (1) the technique is minimally invasive and is usually performed as an outpatient procedure; (2) the operator can visually verify that the biopsy needle is in the nodule(s) of suspicion; and (3) it allows for

evaluation of nonpalpable nodules and, in the setting of cystic lesions, lowers the rate of inadequate specimens. Cervical US is also an important staging tool because it is effective in identifying lymph node metastases and extrathyroid extension.[26-30]

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) commonly detect otherwise clinically occult thyroid nodules. Malignancy is likely with either imaging technique when there are findings of a mass with extrathyroidal extension, lymph node metastases, or both. In this setting, the studies are useful in presurgical planning by establishing the extent of extraglandular tumor and helping the surgeon determine the need for extended neck dissections (Figures 56.5 and 56.6). MRI is superior to CT for establishing the local extent of a known cancer, because it will more clearly show esophageal or tracheal invasion (Figure 56.6).[31] MRI is indicated in the presence of hoarseness, stridor, dysphagia, or other clinical signs of locally extensive thyroid cancer that cannot be adequately assessed by US.

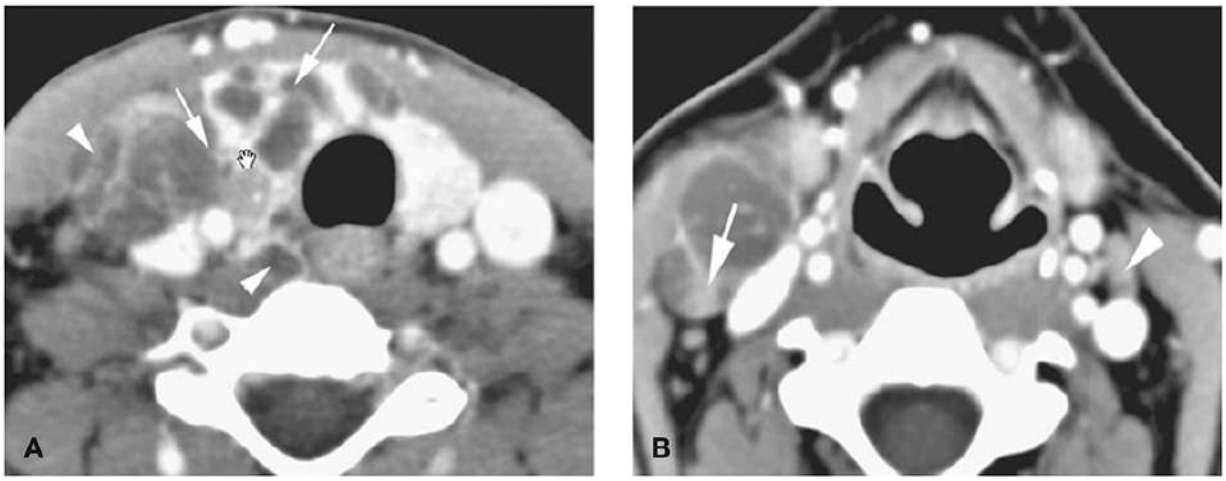

FIGURE 56.5 A patient presenting with a neck mass. A. Computed tomography image showing the mass to be due to a primary papillary thyroid carcinoma coming into contact with a related level 4 metastatic lymph node (arrows). The lymph node at level 4 and in the tracheoesophageal groove is shown by the arrowheads. B. A section more superiorly shows level 3 adenopathy that is multicystic in a pattern typical but not necessarily diagnostic of papillary thyroid carcinoma. There is upper level 4 cystic adenopathy with an enhancing mural nodule (arrow)—a morphology suggesting of thyroid carcinoma. A contralateral enhancing positive node with a focal low-density defect (arrowhead) is also present. (Reprinted with permission from Mancuso AA, Mendenhall WM, Vaysberg M. Thyroid: nodules and malignant tumors. In: Mancuso AA, ed. *Head and Neck Radiology*. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2010:1457-1481.)

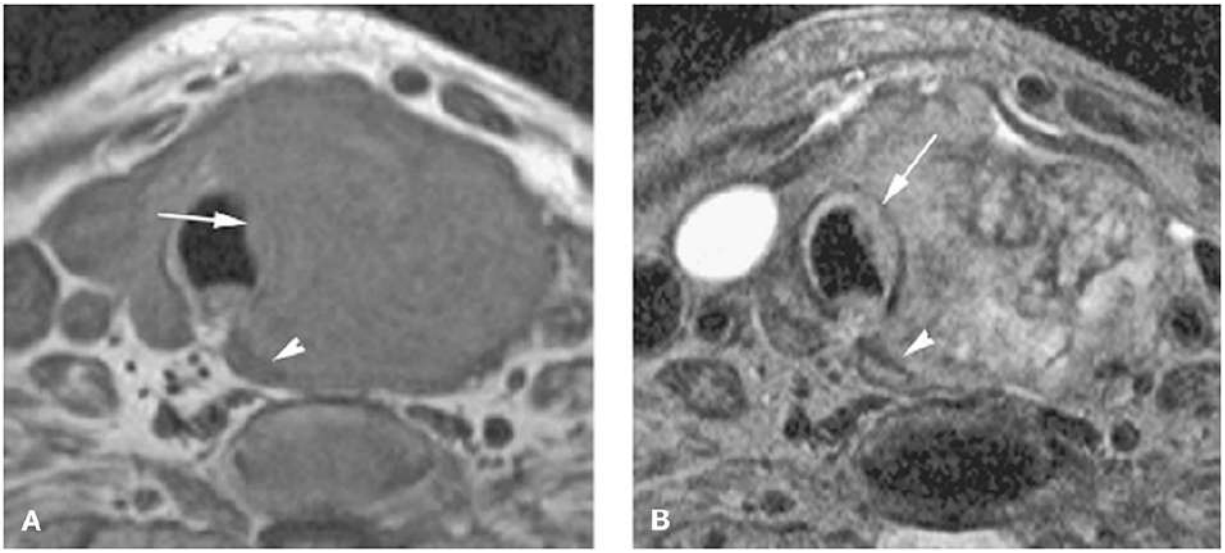

FIGURE 56.6 A patient demonstrating the value of magnetic resonance in the detection of invasion of the trachea and cervical esophagus, especially as it pertains to treatment planning. This patient has anaplastic carcinoma of the thyroid gland. In (A), T1-weighted images show distortion of the trachea (arrow) and esophagus (arrowhead), but it is difficult to determine whether invasion is present. In (B), the T2-weighted image shows obvious growth of tumor replacing the normal signal of cartilage of the trachea with growth on both sides of the cartilage (arrow) as well as replacement of the normal muscular wall signal of the cervical esophagus (arrowhead), indicating esophageal wall invasion. (Reprinted with permission from Mancuso AA, Mendenhall WM, Vaysberg M. Thyroid: nodules and malignant tumors. In: Mancuso AA, ed. *Head and Neck Radiology*. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2010:1457-1481.)

A major downside to CT is that useful imaging of the neck requires contrast enhancement, which can interfere with subsequent I-131 therapy. Because of their high concentration of iodine, CT contrast agents can seriously compromise the effectiveness of therapeutic I-131. When patients receiving iodinated contrast agents require I-131, therapy should be delayed in order to achieve adequate efficacy. In selected cases, a noncontrasted CT of the chest may be indicated to evaluate the presence of mediastinal and lung metastases, but, generally speaking, it is not necessary to perform a CT before primary therapy of most DTCs.

Nuclear Medicine Studies

The four major nuclear medicine studies related to thyroid cancer evaluation with iodine isotopes are radioactive iodine uptake (RAIU), thyroid scan, diagnostic whole-body scan (DxWBS), and post-treatment whole-body scan (RxWBS). Table 56.3 summarizes the characteristics of each of these studies.

TABLE 56.3 NUCLEAR IMAGING STUDIES USED IN THE MANAGEMENT OF DIFFERENTIATED THYROID CARCINOMAS

Study	Isotope	Diagnostics	Results	Purpose	Comment
Radioactive uptake (RAIU) study	Usually I-123 (200-400 μCi)	Counts are measured over the low neck 2-24 h after administration.	Not an image but a number. Normal findings after near-total thyroidectomy are 0.5%-3%.	Quantifies the ability of thyroid tissue and cancer to concentrate iodine and estimates the amount of remaining normal and malignant tissue. RAIU is required by federal regulation before outpatient therapy with I-131.	Performed the week before I-131 administration when prepared with T_4 deprivation and on the day of the second injection when prepared with rhTSH
Diagnostic whole-body scan (DxWBS)	I-131 (1-3 mCi) or I-123 (1.5-3 mCi)	The entire body is imaged with a gamma camera ~3 d after I-131 administration.	Records images of the distribution of radioactive iodine throughout the entire body	To detect residual cancer or normal thyroid tissue	Patients should be prepared with a low-iodine diet and TSH elevation. The value of this study is controversial. We do not use this study to plan treatment or monitor cancer status.
Post-treatment whole-body scan (RxWBS)	I-131, 30-250 mCi (therapeutic dose range)	Same as DxWBS but performed ~7 d after I-131 administration	Same as DxWBS	After remnant ablation, it documents the quality of treatment and identifies unsuspected nodal and	False positives are the only downside and their impact is mitigated when interpreted in the appropriate

Study	Isotope	Diagnostics	Results	Purpose	Comment
				distant metastases. When normal thyroid tissue has been previously ablated, it identifies cancer that is I-131 avid.	clinical context.
Thyroid scan	I-123, I-131, or Tc-99	Same basic procedures as RAIU, but the thyroid is imaged with a gamma camera.	Results are an image of the thyroid.	Used in the evaluation of thyroid nodules to determine if the nodule is functional (ie, “hot” or “cold”)	Thyroid scan is included in this table so that it is not confused with RAIU or whole-body scans. Thyroid scans are not used to plan cancer treatment or post-treatment surveillance.

rhTSH, recombinant human thyroid-stimulating hormone; TSH, thyroid-stimulating hormone.

RAIU tests are used to quantify the RAI-concentrating ability of remnant thyroid tissue after thyroidectomy. This value is required by federal regulation for outpatient I-131 therapy.

Thyroid scans produce images of the thyroid’s ability to concentrate iodine and have a historical use in the evaluation of thyroid nodules, characterizing them as functional (“hot”) or nonfunctional (“cold”). The authors do not use thyroid scans in the workup or management of patients with thyroid cancer.

The typical DxWBS involves a total body image several days after administering approximately 3 mCi of I-131 or I-123. The current value of a DxWBS in thyroid cancer management is controversial. Some experts use a DxWBS to determine the therapeutic dose of I-131 in a patient being treated for thyroid cancer. Some experts use a DxWBS as part of the surveillance program following initial treatment. A comprehensive discussion of the issues related to DxWBS is beyond the scope of this chapter. The main arguments against doing

DxWBS are low sensitivity, stunning of residual cancer cells, and unnecessary radiation exposure. The bottom line is that reasonable people will disagree about the role of DxWBS in thyroid cancer management. The authors do not use DxWBS to stage or monitor patients with thyroid cancer and have not ordered a DxWBS in over 5 years.

An RxWBS should be done in every patient who receives a therapeutic dose of I-131. The optimal interval between administration and scan in most patients is approximately 7 days. The primary purpose of an RxWBS is to detect gross residual disease in the regional lymphatics or in distant sites and to determine if known disease concentrates iodine.

Fluorodeoxyglucose-positron emission tomography (FDG-PET) is another nuclear medicine study that is commonly used to detect metastatic disease, but the predictive value of PET in thyroid cancer is controversial.[32,33]

TSH stimulation increases the accuracy of FDG-PET in most types of DTC. A prospective trial comparing FDG-PET studies during thyroid hormone suppression to studies after administration of rhTSH showed increased detection of occult metastases in the stimulated studies.[34] Some insurers will not reimburse for FDG-PET for thyroid cancer without prior documentation of follicular-derived thyroid cancer with a suppressed or stimulated Tg over 10 ng/mL and a negative DxWBS.[35]

OUTCOME AND PROGNOSTIC FACTORS

The AJCC staging system documents the major prognostic factors that determine disease-specific survival after diagnosis of thyroid cancer (Table 56.4 and Figure 56.7). There are major differences in the staging system from prior versions and from the many prognostic models from other groups. The remainder of this subsection discusses some of the issues that deserve additional explanation.

TABLE 56.4 AMERICAN JOINT COMMITTEE ON CANCER (AJCC) EIGHTH EDITION (2017) TNM STAGING SYSTEM FOR THYROID CANCER

Papillary, follicular, poorly differentiated, Hürthle cell, and anaplastic thyroid carcinoma

Primary tumor (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
T1	Tumor ≤2 cm in greatest dimension limited to the thyroid
T1a	Tumor ≤1 cm in greatest dimension limited to thyroid
T1b	Tumor >1 cm but ≤2 cm in greatest dimension limited to the thyroid

Papillary, follicular, poorly differentiated, Hürthle cell, and anaplastic thyroid carcinoma

T2	Tumor >2 cm but ≤4 cm in greatest dimension limited to the thyroid
T3	Tumor >4 cm limited to the thyroid, or gross extrathyroidal extension invading only strap muscles
T3a	Tumor >4 cm limited to the thyroid
T3b	Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumor of any size
T4	Includes gross extrathyroidal extension
T4a	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
T4b	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size
Regional lymph node (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No evidence of locoregional lymph node metastasis
N0a	One or more cytologically or histologically confirmed benign lymph nodes
N0b	No radiologic or clinical evidence of locoregional lymph node metastasis
N1	Metastasis to regional nodes
N1a	Metastasis to level VI or VII (pretracheal, paratracheal, or prelaryngeal/Delphian, or upper mediastinal) lymph nodes. This can be unilateral or bilateral disease.
N1b	Metastasis to unilateral, bilateral, or contralateral lateral neck lymph nodes (level I, II, III, IV, or V) or retropharyngeal lymph nodes
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

Prognostic stage groups

Differentiated

When age at diagnosis is …	And T is …	And N is …	And M is …	Then the stage group is …
<55 y	Any T	Any N	M0	I
	Any T	Any N	M1	II
≥55 y	T1	N0/NX	M0	I

Recurrence Versus Survival

Many discussions of treatment for thyroid cancer are controversial. A major reason for disagreement is an inability to agree on the outcome end point. The major options are as follows: overall survival (an event is death from any cause), disease-specific survival (an event is death from thyroid cancer), relapse-free survival (an event is cancer recurrence), and local-regional control (an event is cancer recurrence in the thyroid bed or regional neck nodes).

Most types of thyroid cancer have an indolent growth rate such that patients live many years with uncontrolled tumor. An additional complicating factor is that DTC shares with prostate cancer the feature of exhibiting a highly specific serum marker of tumor activity. Serum Tg level is to DTC what prostate-specific

antigen is to prostate cancer. Therefore, with most forms of thyroid cancer, there is also the debate about biochemical versus clinical evidence of cancer control.

Most major studies of outcome of thyroid cancer use either overall or disease-specific survival as the outcome end point. The major limitation of these survival end points is that they do not reflect the morbidity from tumor recurrence that does not cause death. Psychological stress from living with recurrent cancer or uncertainty about cancer cure is substantial,[36,37] and there is physical morbidity that comes from additional diagnostic testing and salvage therapy. This limitation runs through almost every major debate about thyroid cancer treatment because the difference between recurrence and survival results is usually large. Figure 56.8 shows the key figure from a classic study demonstrating this concept.

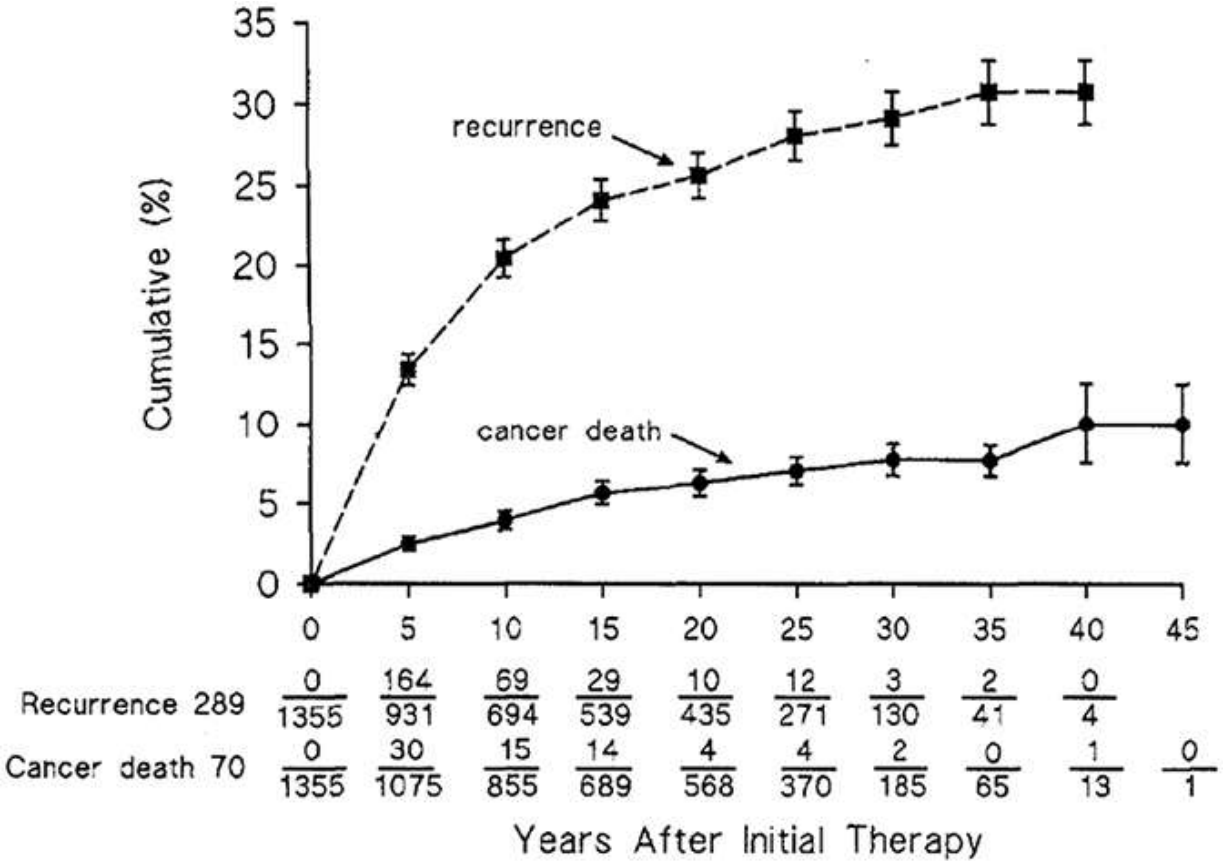

FIGURE 56.8 Tumor recurrence and cancer deaths in 1,355 patients treated for follicular and papillary thyroid carcinoma. (Reprinted from Mazzaferri EL, Jhiang SM. Long-term impact of initial surgical and medical therapy on papillary and follicular thyroid cancer. *Am J Med*. 1994;97[5]:418-428. Copyright © 1994 Elsevier. With permission.)

In this chapter, we do not present specific studies related to a treatment recommendation in a specific situation. Summarizing specific studies would

make this chapter unacceptably long, and it would not end with definitive answers. For this reason, our approach is to list the major guideline references (Table 56.5) and summarize their opinions in some of the major treatment situations. These major guidelines contain a long list of references of the specific studies that inform the discussion topic.

DTC, differentiated thyroid cancer; EBRT, external-beam radiation therapy.

Age

Age is a major prognostic variable in the AJCC staging systems. The current AJCC system dichotomizes staging based on age under 55 years versus 55 years and above. Age is a major factor in all outcome studies because of the consistent finding that younger patients do better than older patients, especially those in the older adult age groups. Of course, the prognostic effect of age is really a continuous variable, but it is more useful for treatment decisions to force a dichotomous breakpoint. But, the major limitation of this approach to age is that it ignores the data that young children (<12 years old) do worse than young adults.[38] The explanation for this difference may be that young children present with more advanced-stage disease at diagnosis, frequently with distant metastases.[39,40]

Unfavorable Variants of Papillary Thyroid Cancer

The most important prognostic factor for disease recurrence and cancer mortality is the histologic classification. Survival following diagnosis is long for most stages of papillary and follicular thyroid cancer with classic histology. The term *unfavorable variant* usually refers to subtypes of papillary carcinoma called tall cell, hobnail, or diffuse sclerosing. Most studies show that the prognosis of an unfavorable variant is substantially worse than with classic histology of a similar stage.[41,42] Note that follicular variant PTC is not unfavorable, meaning that the prognosis is similar for a given stage of follicular variant PTV and classic histology PTC.

Hürthle Cell Carcinoma

There is major disagreement about the prognosis of Hürthle cell carcinoma relative to other forms of DTC such that some authors recommend a separate staging system. A summary of this debate is beyond the scope of this chapter. A paper from our group summarizes the main issues and presents our data on the subject.[43]

Positive Surgical Margin

A positive surgical margin is an important prognostic factor in most cancer situations. But microscopic margin status is not a factor in the American Thyroid Association (ATA) treatment guidelines. Data on the independent significance of a microscopic positive margin in DTC are scarce. Some studies suggest that a positive margin warrants more aggressive treatment,[44] but the most respected study on this subject concludes that a positive margin does not affect the

recurrence rate following standard treatment.[45] As with many other debates in thyroid cancer, the studies evaluate different end points. In the Memorial Sloan Kettering series, the end point is clinical recurrence (visible tumor recurrence) without discussion of biochemical recurrence data.[45] Our view is that a microscopically positive margin should be taken into account such that we are reluctant to recommend observation, regardless of other factors.

Number of Positive Lymph Nodes

The prognostic importance of positive neck nodes from DTC has been a major controversy for decades. The AJCC staging system reflects the conclusion that the distinction between no positive nodes and at least one positive node has some importance, but stage does not change based on the number of positive nodes (see Table 56.4). In patients with positive nodes, guidelines from the ATA do not change treatment recommendations based on node number.

Our opinion is that these guidelines undervalue the significance of many positive nodes in predicting outcome and making treatment decisions. Multiple studies show that multiple positive nodes constitute a powerful negative prognostic factor. A publication from our group summarizes published data on this subject.[46] We take the number of positive nodes into account when making treatment decisions (Table 56.6).

TABLE 56.6 EMPIRIC I-131 DOSING FOR TREATMENT OF DIFFERENTIATED THYROID CANCER FROM THE UNIVERSITY OF FLORIDA DEPARTMENT OF RADIATION ONCOLOGY

Adjuvant treatment soon after total thyroidectomy (No prior I-131 treatment and no visible tumor)	
Observation[a] (No I-131 treatment)	**All must be present:** pT1-2, pN0-1a, M0 ≤3 positive nodes No extranodal extension Negative margin Postop Tg[b] <1.0 ng/mL
30 mCi	All other scenarios
100 mCi	**If any are present:** pT3b ≥4 positive nodes ENE that is not extensive[c] Positive margin and postop Tg[b] ≥1.0 ng/mL
200 mCi	**If any are present:** pT4 Extensive ENE[c]

M1 (with the exception of large-volume disease)

For recurrent tumor based only on serum thyroglobulin level (no visible disease) following at least one prior I-131 treatment

Observation without additional I-131 is always a reasonable option.
We recommend observation when life expectancy unrelated to thyroid cancer is <5 y or when the risk of additional I-131 treatment is high: renal insufficiency, peripheral blood count deficiency, or substantial dry eye from prior I-131 treatment.
Our usual dose when treating recurrent tumor based only on serum thyroglobulin level is 100 mCi.

Other situations of recurrent tumor following at least one prior I-131 treatment

The range of scenarios in the category is wide: distant metastasis, small-volume unresectable disease in the neck, and gross total resection of neck disease with a high risk of recurrence based on pathologic findings: positive margin, soft tissue invasion, multiple positive nodes, and extranodal extension.
We usually do not give I-131 treatment in this setting when the risk of I-131 treatment is high (major renal insufficiency, peripheral blood count deficiency, or dry eye problems).
When we treat with I-131 in this setting, our usual dose is 100-200 mCi.

There are differences between these guidelines and those of the American Thyroid Association.

[a]Observation is always reasonable, and we explain this as part of the discussion of treatment options.

[b]Serum thyroglobulin (Tg) value obtained ≥6 weeks after thyroidectomy with any level of thyroid-stimulating hormone. The 1.0-ng/mL Tg threshold is only applicable in the absence of anti-thyroglobulin antibodies.

[c]Extranodal extension (ENE) of tumor beyond the node capsule. We do not have a definition of "extensive" in this setting.

From 8th edition (2017) of the AJCC staging system.[1]

Extranodal Extension

Extranodal extension of metastatic tumor is an important prognostic factor in most types of cancer. In thyroid cancer, this factor is not included in the AJCC staging system nor in the factors that determine treatment in the ATA guidelines. However, there is evidence that extranodal extension predicts a higher recurrence rate in patients with DTC.[47] We take extranodal extension into account when making treatment decisions (see Table 56.6).

Distant Metastases

A unique feature of thyroid cancer is that patients with extensive distant metastases from DTC may be cured with I-131 therapy and most experience long-term survival.[48] Treatment of distant metastases depends on the specific situation, and the scenarios vary so greatly that further discussion is beyond the

scope of this chapter. The consensus guidelines listed in Table 56.5 address the treatment of distant metastases across various situations.

SURGICAL MANAGEMENT OF THYROID CANCER

Surgery is the primary treatment of localized thyroid cancer of all histologies. A total thyroidectomy is the preferred oncologic procedure, but the consensus guidelines listed in Table 56.5 describe scenarios where lobectomy is acceptable.

It is critical to understand that even a total thyroidectomy leaves residual thyroid tissue that will have major implications for subsequent therapy and disease monitoring. The clearest evidence of residual thyroid tissue after total thyroidectomy is seen in postoperative I-131 thyroid studies, which nearly always show uptake in the region of the thyroid bed. The presence of residual thyroid tissue in this setting is not a sign of incomplete surgery, but a matter of practicality. The ligament connecting the posterior surface of the thyroid capsule to the trachea harbors microscopic nests of thyroid tissue and is rarely completely resected in order to reduce the risk of tracheal injury. Second, the recurrent laryngeal nerve is embedded in thyroid tissue at the point where the nerve enters the larynx, and it is not possible to remove all of this thyroid tissue without injuring the nerve and compromising voice quality and laryngeal function.

Several important complications can arise from thyroidectomy. The most common are recurrent laryngeal nerve injury (temporary 30% and permanent 2%) and hypoparathyroidism (temporary 5% and permanent 0.5%).[49]

Neck Dissection in Differentiated Thyroid Cancer

As with squamous cell carcinomas, a modified radical neck dissection is done for thyroid cancer when there is a visible or palpably positive node. However, elective neck dissection (removal of lymphatic regions at risk for subclinical disease) is generally not performed for DTC, unlike primary surgery for most other head and neck cancers. Despite a high incidence of subclinical lymph node involvement in even small DTCs, elective neck dissection is not included in the initial surgical approach because the results without neck dissection have been good.[50]

An ongoing controversy is the role of central (level 6) node dissection as part of the thyroidectomy procedure. The consensus guidelines listed in Table 56.5 summarize this controversy. In our opinion, thorough dissection of the central compartment is not necessary in the absence of clinically suspicious nodes at the time of surgery.

MANAGEMENT OF DIFFERENTIATED THYROID CANCER WITH RADIOACTIVE IODINE

Bioconcentration of Radioactive Iodine

I-131 for DTC is one of the most successful targeted therapy in oncology. The iodine-concentrating capacity of benign and neoplastic thyroid tissue makes most thyroid carcinomas amenable to I-131 therapy. I-131 is taken up by thyroid tissue, including DTC of follicular epithelial origin, at a rate 6.6 times more than most tissues in the body. The biologic half-life in extrathyroidal tissue is 12 days compared to 80 days for thyroid tissue (Table 56.7).

TABLE 56.7 PHYSICAL, BIOLOGIC, AND EFFECTIVE HALF-LIVES ($T_{½}$) OF I-131

Tissue	Physical $t_{½}$	Biologic $t_{½}$	Effective $t_{½}$
Thyroid	8 d	80 d	7.3 d
Extrathyroidal	8 d	12 d	8 h

Radioactive Decay of Iodine-131

I-131 is produced from the fission of uranium atoms during the operation of nuclear reactors or in the detonation of nuclear bombs. I-131 decays by negatron emission (β-minus decay) to xenon-131 (Xe-131). A neutron from the I-131 nucleus converts to a proton, and an electron (β particle) is emitted from the nucleus. This first transition results in a β particle with a range of energies from 250 to 800 keV. These β particles are the reason I-131 is able to deliver targeted cytotoxicity. Because electrons of this energy range will deposit their energy within a millimeter, only the cells taking up the I-131 are affected.

In the second decay step, unstable Xe-131 decays to stable xenon, releasing a photon with an energy of 364 keV. This product is therapeutically undesirable, because the photon will travel far from the source where iodine is concentrated. It contributes very little cytotoxicity to thyroid cancer cells and increases the total body dose; however, it is this photon emission that makes iodine useful for diagnostic imaging.

Goals of Radioactive Iodine Therapy for Differentiated Thyroid Cancer

Broadly speaking, the two basic purposes of adjuvant I-131 are (a) thyroid remnant ablation and (b) adjuvant therapy for residual microscopic disease. Ablation of the remaining thyroid tissue facilitates the use of serum Tg as a very

sensitive and specific marker for disease persistence after primary therapy. I-131 may increase the chance of cancer cure by destroying cancer cells remaining in the operative bed, occult lymph node metastases, and distant metastases.

Dose of Radioactive Iodine (I-131) to Treat Differentiated Thyroid Cancer

There are two main approaches to selecting the dose of I-131 for remnant ablation or treatment of known residual DTC: empiric and dosimetric. With the empiric method, all patients with the same disease risk factors get the same dose. With the empiric method, patients undergo tests of iodine metabolism to customize the dose based on individual physiology. It is beyond the scope of this chapter to discuss the many dosimetric approaches that have been described in the literature. The bottom line is that today most experts recommend empiric dosing in the absence of renal insufficiency or multiple prior I-131 treatments.

Table 56.6 summarizes the indications and dose of I-131 that we currently use in our program. There are differences between these guidelines and those of the major published guidelines.

Preparing Patients for Iodine-131 Treatment

Appropriate preparation for I-131 therapy is critical to obtaining the optimal desired effect of therapy, whether for remnant ablation or adjuvant therapy residual disease. There are many elements to consider when deciding how thorough to be. Table 56.8 summarizes how we prepare patients in our program. These factors are discussed in detail in the consensus guidelines from the ATA.

TABLE 56.8 PREPARATION OF PATIENTS FOR I-131: GUIDELINES FROM THE UNIVERSITY OF FLORIDA DEPARTMENT OF RADIATION ONCOLOGY

Component	Description	Comments
Low-iodine diet	A diet that is low in iodine (≤50 μg/d) for 2 wk before, and 2 d after, I-131 administration. Diet instructions are available at www.thyca.org.	The purpose of a low-iodine diet is to deplete the total body iodine stores to a degree that maximizes the uptake of I-131 by thyroid tissue and thyroid cancer.[70,71]
Intravenous iodinated contrast exposure	Iodine contrast, as used with computed tomography (CT) scans, results in a large amount of iodine stored in interstitial tissues.	In patients who have received intravenous iodinated contrast within 3 mo of the planned date of therapeutic I-131 administration, we measure the urine iodine level 1-2 wk

Component	Description	Comments
		before the planned date of administration (see below).
Urinary iodine measurement	Total body iodine level is determined by the amount of iodine in the urine. The gold standard is a 24-h urine specimen, but we use a spot urine sample because it is more convenient for the patient.	Ideally, urine iodine is ≤50 μg/L before cancer treatment with I-131. When we suspect inadequate iodine depletion, we measure urine iodine 1-2 wk before the planned date of I-131 administration, on day ≥7 of a low-iodine diet. If the urine iodine is ≤150 μg/L, we administer I-131 as planned. If the level is higher, we delay administration, with the patient on a low-iodine diet for as long as we think it will take to adequately deplete total body iodine stores. It is ideal to recheck the urine iodine concentration, but we do not do this when the initial value was <300 μg/L.
rhTSH instead of T_4 deprivation	rhTSH 0.9-mg intramuscular injection twice (2 d and 1 d) before I-131 administration	Compared to T_4 deprivation, rhTSH injections avoid the problems of hypothyroidism and result in less total body radiation exposure but may decrease the potency of I-131 cancer treatment. Also, the cost of rhTSH may not be covered by the patient's insurance. We use rhTSH in all adults when the patient can afford the cost. We do not use rhTSH in children as it is not FDA approved in children and because children tolerate hypothyroidism better than adults do.
T_4 deprivation instead of rhTSH	Stop all thyroid hormone (usually levothyroxine, T_4) replacement for as long as it takes to raise the TSH level to ≥30 μU/mL by the day of I-131 administration. Ideally, pretreatment testing and the administration date should be scheduled well in advance. For this reason, our standard program is to stop thyroid hormone replacement 6 wk before the planned date of I-131 administration because TSH is almost always >30 μU/mL after ~5	Compared to rhTSH, T_4 deprivation may make I-131 treatment more effective because hypothyroidism decreases urinary excretion of I-131 and thus increases biologic half-life. Another advantage of T_4 deprivation is that it does not have the cost of rhTSH injections. But, T_4 deprivation causes the physiologic problems of hypothyroidism and results in a higher total body radiation dose. We use T_4 deprivation, instead of rhTSH, in adults who cannot afford rhTSH. We use T_4 deprivation in all

Component	Description	Comments
	wk of deprivation when we check it 5-10 d before the planned date of administration.	children because rhTSH is not FDA approved in children and because children tolerate hypothyroidism better than adults do.
Lithium	The recommended dose of lithium carbonate is ~20 mg/kg/d (usually 300 mg 3 times a day) for 7 d, beginning 5 d before I-131 administration. At this dose, serum lithium concentration should be measured on day 4 and/or 5 (therapeutic range 0.6-1.2 mEq/L). We have found it difficult to get serum lithium results back in a timely manner. For this reason, in standard-size patients, we often use an empiric dose of 300 mg twice a day and do not check serum levels.	Lithium increases radiation dose in target tissue by increasing iodine retention time preferentially in normal and malignant thyroid cells.[72,73] We use lithium in most patients who do not have a published contraindication, including psychiatric problems, dementia, seizure disorder, cardiac arrhythmia, renal insufficiency, hepatic impairment, hypo- or hypernatremia, and any of these medications: diuretic, antidepressant, nonsteroidal anti-inflammatory drugs, seizure medication, and calcium channel blockers. In patients who are at high risk for tumor recurrence, we often stop contraindicated medications for the week of lithium treatment or administer lithium without stopping the medication.
Stopping T_4 for 4 d with the rhTSH program	Discontinue thyroid hormone replacement 3 d prior to, and the day of, I-131 administration in patients prepared with rhTSH injections.	Thyroid hormones contain iodine. Stopping thyroid hormone replacement for a short time before I-131 administration may increase the efficacy of treatment by augmenting the low-iodine diet.[74] We stop T_4 for 4 d in all patients prepared with rhTSH injections.
Scopolamine	Scopolamine transdermal patch of 0.33 mg/24 h. Apply patch behind your ear as soon as you get up in the morning on the day of I-131 administration. Remove the patch 48-72 h later. Dispense 1 patch. No refills.	Scopolamine is an antimuscarinic that decreases stimulation of the salivary glands. Less salivary stimulation may decrease iodine uptake and thus decrease radiation dose to the salivary glands from I-131 therapy. We use scopolamine in all patients without major contraindications such as angle-closure glaucoma, pyloric obstruction, or serious dementia.
Sour candy	Do NOT eat sour candy for ~3 d after I-131 administration.	Some programs recommend sucking on sour candy during the first few days after I-131 administration. The

Component	Description	Comments
		idea behind sour candy is that stimulating salivary production "washes" iodine out of the saliva glands. One of the few studies on this issue suggested that sour candy INCREASES the radiation dose to the saliva glands.[75] For this reason, we give the patient instructions to NOT chew gum, suck on any type of candy, or eat spicy food for 3 d after I-131 administration.
T_3 during T_4 deprivation	Triiodothyronine (T_3, liothyronine sodium) 25 µg orally twice a day starting the day of discontinuation of T_4, and stopping 2 wk before the day of I-131 administration	T_3 has a much shorter half-life than T_4. The idea behind administering T_3 is to decrease the fatigue and other symptoms of T_4 deprivation. We do not use T_3 because a formal study failed to show a quality of life benefit.[76]
Diagnostic whole-body scan (DxWBS)	Total body image ~3 d after administration of I-131 (1-3 mCi) or I-123 (1.5-3 mCi) with TSH ≥30 µU/mL	Some experts use this study to determine the therapeutic dose of I-131. We do not perform this study.

FDA, U.S. Food and Drug Administration; T_3, 3,5,3′-iodothyronine; T_4, 3,5,3′,5′-iodothyronine; TSH, thyroid-stimulating hormone.

Outpatient Management of Iodine-131

Grigsby et al[51] described the pattern of radiation exposure in 65 household members of 30 patients treated with I-131. The mean dose to family members was well below regulatory standards at 0.24 mSv, and the maximum dose was 1.11 mSv. The Nuclear Regulatory Commission (NRC) has issued guidance on the release of patients following I-131 treatment for thyroid cancer, and a copy of all material related to the issue can be found on the NRC website. Major recommendations were issued in 1997 (NRC Regulatory Guide 8.39) and have largely remained in place. Several minor subsequent recommendations have been issued, most recently in early 2011 under 10 CFR 35.75.[52] Overall, the recommendations are intended to keep the exposure to the public "as low as reasonably achievable."

Risks of I-131 Therapy

A therapeutic dose of I-131 exposes all tissues in the body to ionizing radiation. For this reason, I-131 may damage any tissue in the body and may cause the formation of all types of benign and malignant tumors. The risk of toxicity from I-131 treatment for thyroid cancer depends on the administered dose, the patient's physiology related to iodine metabolism, the sensitivity of the patient to ionizing radiation, tumor burden, tumor location, and the ability of tumor cells to concentrate iodine.

A discussion of all possible acute and late toxicities that have been reported following I-131 treatment will not be useful to most clinicians. Table 56.9 is a version of the consent document that we use to explain the main side effects and complications of I-131 therapy.

TABLE 56.9 SIDE EFFECTS AND RISKS OF I-131 THERAPY: CONSENT DOCUMENT LANGUAGE FROM THE UNIVERSITY OF FLORIDA DEPARTMENT OF RADIATION ONCOLOGY

The most common temporary side effects from I-131 treatment

Swelling of the saliva glands or neck: It is common to experience mild pain and swelling of the saliva glands that are located near the jawbone. This discomfort usually goes away in 3-5 d.

Taste change: It is common to experience a change in the way food tastes. Taste usually returns to normal within 3 wk after taking I-131.

Nausea: Some patients have nausea—possibly with vomiting—for 1-3 d after taking I-131. Take the nausea medication that we give you as often as you need it.

The main serious and permanent problems that may occur after I-131 treatment

Decrease in saliva and tears causing dry mouth, tooth decay (cavities), and dry eyes:
The risk of these problems depends mainly on I-131 dose and the status of your saliva and tear glands.

Bone marrow damage causing infection, bleeding, and problems from anemia:
The risk of these problems depends mainly on I-131 dose and the status of your bone marrow.

I-131 can cause cancer to develop in the future:
We will try to estimate the risk of cancer from I-131 is your situation.
A publication with a formula is second primary malignancies patients with in thyroid cancer.
A website for cancer risk calculation is https://radiationcalculators.cancer.gov/radrat

Damage to testicles or ovaries: I-131 therapy may cause early menopause if you are a woman and impotence and other problems if you are a man. The chance that you could get these problems depends on your age and dose of I-131.
I-131 therapy may decrease your fertility or ability to produce a normal baby. You should definitely not get pregnant if you are a woman, or get a woman pregnant if you are a man, for at least 6 mo after I-131 therapy.

To decrease the chance of problems, do these things:

Do not wear contact lenses for 3 d after receiving I-131.

Stay well hydrated for 3 d after taking I-131: Drink enough fluid so that you need to urinate every few hours. This will decrease radiation exposure to your saliva glands, bladder, and other organs.

Have at least one bowel movement each day for 3 d after taking I-131: Eat prunes or take a laxative, such as Dulcolax 15 mg, as needed.

Avoid things that stimulate saliva production for 3 d after taking I-131: Do not chew gum, use smokeless tobacco, or suck on candy.

EXTERNAL-BEAM RADIOTHERAPY FOR THYROID CANCER

Indications for External-Beam Radiotherapy for Differentiated Thyroid Cancer

There are no randomized control trials defining the indications for external-beam radiotherapy (EBRT) in thyroid cancer. The European Multicentre Study on Differentiated Thyroid Cancer trial was planned as a prospective multicenter trial to evaluate the benefit of adjuvant EBRT in locally advanced DTC. Patients with pT4 disease with or without lymph node metastases and no known distant metastases who underwent total thyroidectomy, I-131, and TSH suppression were to be randomized to EBRT or observation. The trial closed prematurely, however, as only 16% of patients consented to be randomized to EBRT. The trial was converted to a prospective cohort study, and subsequent results failed to define the role of EBRT in this population.[53-55] Therefore, recommendations for EBRT are based on institutional retrospective experiences. Table 56.10 summarizes indications for EBRT from our department and the major consensus guideline publications.

TABLE 56.10 INDICATIONS FOR EXTERNAL-BEAM RADIOTHERAPY FOR DIFFERENTIATED THYROID CANCER

Age	University of Florida	ATA Guidelines[35]	AHNS Guidelines[56]
Age ≤18 y	Painful metastases or impending normal tissue damage from a growing tumor not amenable to other treatment	No child-specific guidelines	No child-specific guidelines
Age >18 y with visible, unresectable neck disease	Most situations where surgery is not able to remove all visible tumors with acceptable morbidity, but age is a factor.	Recommendation 71 [C22]: EBRT is considered for local-regional recurrence that is not surgically resectable,	EBRT is recommended for patients with gross residual or unresectable local-regional disease, except for patients <45 y old with limited gross

Age	University of Florida	ATA Guidelines[35]	AHNS Guidelines[56]
	Due to the increased risk of complications from EBRT in young patients, we usually treat small-volume (<2 cm^3), unresectable residual tumor in the neck in patients <55 y old with I-131 without EBRT if the patient is I-131 naive. We do not use EBRT if I-131 may be curative or elevated Tg is the only sign of disease.	particularly in patients with no evidence of distant disease.	disease that is I-131 avid.
Age >18 y: *Adjuvant treatment soon after thyroidectomy*	Most cases with stage T_4 primary tumors or nodal metastases with extensive extranodal extension, but age is a factor. We often do not give adjuvant EBRT in patients <55 y old with risk factors for microscopic residual tumor. We do not use EBRT if I-131 may be curative or elevated Tg is the only sign of disease.	There is no role for routine adjuvant EBRT to the neck in patients with DTC after initial complete surgical removal of the tumor.	EBRT should not be used routinely as adjuvant therapy after complete resection of gross disease.
Age >18 y: *After gross total resection of recurrence following initial therapy*	Same as for adjuvant EBRT after thyroidectomy	No guidelines in the absence of unresectable disease	After complete resection, EBRT may be considered in select patients older than 45 y old with a high likelihood of microscopic residual disease and a low likelihood of responding to I-131. This scenario may occur in the setting of gross extrathyroidal extension or with revision surgery for

External-Beam Radiotherapy Technique

Techniques for treating metastatic disease will vary by site, tumor burden, and clinical circumstances; therefore, this chapter only discusses the technique used for treating the primary site and nodal regions.

CT simulation is used for treatment planning with patients positioned supine with arms at their side and the neck extended such that the mandible is at 90° with respect to the treatment couch. An Aquaplast (WFR/Aquaplast Corporation) mask, custom head holder, and shoulder straps are used to immobilize the head and neck and to depress the level of the shoulders. Bolus material should be applied over scars on the neck. Intravenous contrast may be helpful in defining target volumes and normal tissue structures, but this is contraindicated if I-131 is being considered within the next 3 months. Axial CT images are acquired from above the skull base to the middle of the chest. Although not necessary, preoperative image sets may be fused to treatment planning CT scans to aid in target definitions. Historically, conventional anterior- posterior/posterior-anterior or lateral fields have been described to treat thyroid cancer, often requiring custom bolus materials to ensure homogeneous dose distributions. Because the target volume straddles the level of the shoulder and, in nearly all cases, contains concavities with envaginated critical normal tissues, we treat all thyroid cancer cases with intensity-modulated radiotherapy (IMRT). We do not routinely bolus neck scars because the tangential beams in the IMRT plan deliver a high dose to the skin of the low neck.

External-Beam Radiotherapy Dose and Target Guidelines

Table 56.11 lists the major publications from the modern era with dose and target volume information related to EBRT with curative intent for thyroid cancer. Table 56.12 summarizes the guidelines that we use.

TABLE 56.12 EXTERNAL-BEAM RADIOTHERAPY NECK TARGET VOLUME AND DOSE GUIDELINES FOR THYROID CANCER FROM THE UNIVERSITY OF FLORIDA

Standard fractionation with moderate risk of recurrence: 60/54 Gy prescriptions

We use this program when our indication for EBRT is met and there is NO evidence of visible residual tumor, extranodal extension of tumor, or surgical margin <0.5 cm.
CTV 60 Gy at 2 Gy = Postoperative areas thought to be at high risk for recurrence. These include areas where recurrent tumor was resected plus a 1-cm margin edited for anatomic boundaries to tumor spread, and dissected nodal stations with pathologically positive nodes.
CTV 54 Gy at 1.8 Gy = Undissected nodal stations that we judge to be at >10% risk of recurrence
PTVs = CTV + 0.3 cm

Standard fractionation with high risk of recurrence: 70/63/56 Gy prescriptions

We use this program when our indication for EBRT is met and there is visible residual tumor, extranodal extension of tumor, or surgical margin <0.5 cm.
CTV 70 Gy at 2 Gy = Visible residual tumor and/or postoperative areas with close margin or extranodal extension, plus a 1-cm margin edited for anatomic boundaries
to tumor spread
CTV 63 Gy at 1.8 Gy = Dissected nodal stations with pathologically positive nodes
CTV 56 Gy at 1.6 Gy = Undissected nodal stations that we judge to be at >10% risk of recurrence
PTV = CTV + 0.3 cm

Stereotactic body radiation therapy (SBRT)

We use neck SBRT for small-volume (<2 cm^3) visible disease in situations where we judge the risk of treating a larger volume to be unacceptable. We do not have criteria for choosing the 50 vs 35 Gy schedules.
A single target volume: CTV = GTV, PTV = CTV + 0.2 cm
Dose to 95% of PTV = 50 Gy at 5 Gy (10 treatments) or 35 Gy at 7 Gy (5 treatments)

EBRT, external-beam radiotherapy; CTV, clinical target volume; GTV, gross total volume; PTV, planning target volume.

Sequencing of External-Beam Radiotherapy and I-131 Treatment

When there are indications for both EBRT and I-131 treatment, there is the question of sequencing. There is no high-quality study specific to this question. In the words of the American Head and Neck Society Consensus guidelines, "There is no consensus on the optimal sequence of EBRT and I-131."[56]

The argument for starting with EBRT is that it often minimizes delay to starting adjuvant treatment. The argument for starting with I-131 is concern that EBRT will "stun" cancer cells in a way that decreases uptake of I-131.

We individualize the decision based on the projected delay to administering I-131 treatment and the likelihood that I-131 treatment will increase the chance of cure. In most cases, we deliver EBRT first.

THYROID-STIMULATING HORMONE SUPPRESSION FOR DIFFERENTIATED THYROID CANCER

A common practice in the management of DTC is administration of supratherapeutic doses of T_4 in an effort to drive the TSH below detectable limits (<0.1 mIU/L), thereby decreasing stimulation of residual benign and malignant follicular- derived thyroid cells. There is in vitro evidence that TSH-receptor stimulation is sufficient to initiate thyroid tumorigenesis.[57] A large retrospective series of patients with DTC with 30 years of follow-up showed that, compared with no adjunctive therapy, treatment with TSH suppression with T_4 resulted in a 50% reduction in cancer deaths (6% vs 12%).[58] Another study showed that the degree of TSH suppression (TSH ≤0.05 mIU/L vs ≥1 mIU/L) was associated with improved relapse-free survival.[59]

A major limitation to TSH suppression is the associated toxicity as these patients experience subclinical and even overt thyrotoxicosis. As such, these patients are prone to bone demineralization and cardiac abnormalities, including tachyarrhythmia, conduction abnormalities, increased contractility, ventricular hypertrophy, systolic and diastolic dysfunction, and even cardiac death.[60] Nevertheless, a meta-analysis with over 4,000 patients with DTC demonstrated that the relative risk of major adverse clinical events was 0.73 ($P < .05$) favoring a "likely" or "questionable" benefit to TSH suppression in 15 of 17 trials.[61] The authors concluded that TSH suppression is justified following initial therapy for DTC. The authors recommend TSH suppression to just below 0.1 mU/L for

patients with high-risk thyroid cancer, while maintaining the TSH at or slightly below the lower limit of normal (0.1-0.5 mU/L) in patients at low risk of recurring.

CHEMOTHERAPY AND TARGETED AGENTS FOR DIFFERENTIATED THYROID CARCINOMA

There are two settings where chemotherapy or targeted systemic therapy is indicated: adjuvant treatment or treatment for recurrent or metastatic disease for which surgery, EBRT, or I-131 treatment is not a reasonable option.

The ATA's statement summarizes the view of most experts regarding the adjuvant situation: "RECOMMENDATION 61: There is no role for routine systemic adjuvant therapy in patients with DTC (beyond I-131 and/or TSH suppressive therapy using [levothyroxine])."[35]

There is no standard treatment for DTC that is not likely to respond to surgery or radiation therapy. Traditional systemic cytotoxic therapies have no significant role because of poor response rates.[62] Recent advances in targeted therapeutics have opened new doors for effective systemic therapy for recurrent or metastatic disease that is unresponsive to I-131. Most of the agents currently under investigation target specific pathways involved in cellular proliferation through inhibition of tyrosine kinase receptors and angiogenesis through inhibition of vascular endothelial growth factor receptors. This is a rapidly evolving area. Section C41 of the ATA guidelines summarizes the status of this issue as of late 2015.[35]

MANAGEMENT OF MEDULLARY THYROID CARCINOMA

All patients with MTC should be tested for *RET* mutations, including sporadic cases. Genetic screening and testing are also indicated. Similar to follicular epithelial-derived DTC, the initial primary management of localized MTC is total thyroidectomy, which is the only completely effective therapy. Central neck dissection should be performed in all cases, and compartment-oriented lateral neck dissection is indicated when clinically involved. There is no role for adjuvant I-131 therapy. All patients should be followed with serum calcitonin levels as this presents a sensitive and specific marker for the extent of residual disease.

MTC is uncommon, and most of the time it behaves as an indolent disease where long survival with uncontrolled tumor is common. For these reasons, there

are few studies on the role of EBRT. The American Head and Neck Society consensus document is currently the best summary of this issue.[23]

Traditional cytotoxic systemic therapies have been ineffective in the management of metastatic or recurrent MTC; however, recent advances in therapies targeting the *RET*-tyrosine kinase receptors have shown promising preclinical and early clinical results.[63-67]

MANAGEMENT OF ANAPLASTIC THYROID CARCINOMA

The ATA guidelines explain the major issues and relevant literature related to the diagnosis and treatment of ATC.[68]

Complete surgical excision should be the goal of initial therapy, when feasible. However, surgery should be avoided when complete excision is not possible as debulking does not improve outcomes. There is no therapeutic role for I-131.

The great majority of patients with ATC present with poor performance status and locally advanced disease such that gross total resection is not possible. For this reason, the goal of treatment in most ATC cases is palliation.

Patients with good performance status and no evidence of distant metastases should be offered aggressive treatment with maximum safe resection and EBRT, with or without concurrent chemotherapy. There is no consensus on the EBRT fractionation program, but a recent study of the National Cancer Database showed that survival was better when the EBRT total dose was 60 to 75 Gy as compared to lower doses.[69] In our program, we usually use the 70/63/56 Gy program described in Table 56.12.

The most aggressive approach is to combine EBRT with chemotherapy involving a taxane, anthracycline, platin, or a combination of all. In our program, we rarely use chemotherapy with EBRT for ATC due to the high toxicity of combination therapy in this setting.

CHAPTER 57

Lung Cancer

John Kang, Michael T. Milano, Marco Schwarz, Rafael Santana-Davila, Ramesh Rengan, and Jing Zeng

EPIDEMIOLOGY

In 2020, lung cancer accounted for 11.4% (2.2 million) of the total cases of cancer worldwide. In the United States, lung cancer is the second most common cancer and the most common cause of cancer-related death in both men and women. The American Cancer Society projects 238,340 people being diagnosed with lung cancer in 2023 and 127,070 deaths.[1] A similar number of people in the United States die from lung cancer as from breast, prostate, and colorectal cancers combined. The incidence and mortality rates for men began to drop around 1990, and a slight drop in the incidence and mortality rates has only recently been observed for women. The lag in the trend of declining lung cancer rates in women compared with men reflects historical differences in cigarette smoking between the sexes; cigarette smoking in women peaked about 20 years later than in men. Sex, racial, and sociodemographic disparities exist in the incidence and mortality for lung cancer with rates highest in men, particularly those residing in counties with low income and education level, and particularly in African Americans.

Voluntary or involuntary cigarette exposure accounts for 80% to 90% of all cases of lung cancer. Indoor radon exposure is now considered the second leading cause of lung cancer in the United States. Other known risk factors for lung cancer include exposure to occupational and environmental carcinogens, such as asbestos, arsenic, and polycyclic aromatic hydrocarbons.

ANATOMY

The lungs are situated on each side of the mediastinum, which contains the heart, trachea, esophagus, and great vessels. The lungs are conical in shape with an apex projecting upward into the neck for approximately 2 to 3 cm above the clavicle, a base sitting on the diaphragm, a costal surface along the chest wall, and a mediastinal surface that is molded to the heart and other mediastinal structures. Visceral pleura covers the lungs, and parietal pleura covers the inside of the chest cavity. The lungs are freely suspended but are rooted to the mediastinum by the structures emerging from the hilum.

The lungs are divided into distinct lobes—three lobes within the right lung and two lobes and the lingula within the left lung. The right lung is divided into the upper, middle, and lower lobes by the oblique (major) and horizontal (minor) fissures. The oblique fissure runs forward and downward from approximately the level of the fifth thoracic vertebral body to the diaphragm, dividing the lungs into upper and lower lobes. The horizontal fissure separates the right middle from the right upper lobe, fanning out forward and laterally from the hilum. The middle lobe is thus a small, triangular lobe bounded by the horizontal and oblique fissures and actually rests on the diaphragm. The left lung is divided by only the oblique fissure into two lobes—the upper and lower lobes. The lingula, located in the left upper lobe, is homologous to the right middle lobe and also touches the diaphragm.

The trachea bifurcates at the carina, which lies at the junction between the manubrium and body of the sternum, into the right and left main bronchi. Each main bronchus divides into lobar bronchi, each supplying a lobe of the lung. Although the lingula is in the left upper lobe, the lingular bronchus is considered by many a

lobar bronchus. Each lobar bronchus divides into smaller bronchi that form the bronchopulmonary segments. These segments are pyramidal in shape, with an apex toward the lung root and a base at the pleural surface. Structures entering each bronchopulmonary segment (ie, bronchus and artery) tend to lie centrally. Structures leaving the segment (ie, veins and lymphatics) lie in the periphery of the segment within the connective tissue that separates the segments. Segmental bronchi divide into bronchioles, continue to branch, and eventually form the alveoli, where blood-gas exchange occurs.

The main lymphatic drainage for each bronchopulmonary segment follows the vasculature and airways toward the hilum, where it ultimately drains into the mediastinum. However, the rich network of lymphatics within the thorax leads to complex variability in drainage patterns.

The International Association for the Study of Lung Cancer (IASLC) developed a lymph node map that reconciles differences among older maps and provides precise anatomic definitions for all lymph node stations.[2] The IASLC lymph node map has been endorsed by the American Joint Committee on Cancer (AJCC) and incorporated into the staging manual. The IASLC lymph node map designates 14 lymph node levels compartmentalized into intrapulmonary, hilar, and mediastinal zones that have prognostic implications and are utilized in common clinical practice.

CLINICAL PRESENTATION AND PATTERNS OF SPREAD

Signs and symptoms of lung cancer directly reflect the patient's local, regional, or distant pattern of spread. Lung cancer spreads locally by direct extension of the primary tumor, regionally via involvement of the thoracic lymphatics, and distantly via invasion into vascular channels leading to hematogenous spread. From cases registered to the Surveillance, Epidemiology, and End Results (SEER) program (https://seer.cancer.gov/statfacts/html/lungb.html), ~20% of lung cancers are localized to the primary site at initial diagnosis, ~20% have regional lymph node involvement and/or direct extension of the primary cancer outside the lung, and more than 50% present with distant metastases (and ~5% are with unknown/unrecorded stage). Small cell lung cancer (SCLC) has a greater propensity to present in more advanced stages.

Intrathoracic Spread

There is a wide range of symptoms attributable to intrathoracic mass effects from lung cancer. Tumor invading or compressing the airways accounts for common symptoms of cough and dyspnea, with more extensive airway invasion resulting in possible stridor or hemoptysis. Dyspnea may also arise from atelectasis, post– obstructive pneumonia, or a pleural or pericardial effusion. Potentially life-threatening hemoptysis can result from tumor eroding into blood vessels. Patients can experience pain from tumor invasion or spread into the mediastinum, parietal pleura, or chest wall. A central primary tumor or mediastinal lymph node can impinge upon the recurrent laryngeal nerve (either along its course under the aortic arch on the left or in the supraclavicular region on the right), which can cause hoarseness. Phrenic nerve impingement may initially produce hiccups, and progressive damage can produce unilateral paralysis of the diaphragm with shortness of breath. See the section "Superior Vena Cava Syndrome" for more details.

Obstruction of the superior vena cava (SVC) from primary tumor or mediastinal lymphadenopathy commonly causes a sensation of fullness in the head and dyspnea. Physical findings include jugular venous distension and, occasionally, swelling of the face and arms.

Primary tumors arising within the superior sulcus may produce the classic Pancoast syndrome (more common with non–small cell lung cancer [NSCLC] vs SCLC) manifested by shoulder pain, Horner syndrome, and brachial plexopathy. See the section "Superior Sulcus Tumors and Pancoast Syndrome" for more details.

Distant Extrathoracic Spread

Contralateral lung, liver, bone, adrenals, and brain are the most frequent sites of distant disease; however, lung cancer can spread to any part of the body and cause symptoms from tumor mass effect or alterations in the microenvironment around the metastatic site (which may contribute to metastasis-related bony pain). For some metastatic sites, such as adrenal or liver, symptoms are not common, particularly in the setting of nonbulky disease. For other sites, such as the eloquent brain, metastases (even of relatively small size) can

result in debilitating symptoms. Brain metastases can also cause generalized symptoms of headache, nausea, or seizure, though could also be asymptomatic in some patients.

Paraneoplastic Syndromes

Paraneoplastic syndromes are characterized by specific signs and symptoms that are likely mediated by humoral factors secreted by tumor cells or by an immune response against the tumor. These uncommon syndromes often resolve with treatment of the cancer, though could persist and require ongoing management. Examples of paraneoplastic syndrome are discussed in the subsequent section.

Cushing Syndrome

Ectopic production of adrenocorticotropic hormone (ACTH) can cause Cushing syndrome. Typical signs and symptoms include muscle weakness, weight loss, hypertension, hirsutism, osteoporosis, hypokalemic alkalosis, and hyperglycemia. Cushing syndrome is relatively common in patients with SCLC or carcinoid tumors.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion results in hyponatremia. Approximately 10% of patients who have SCLC exhibit SIADH, and SCLC accounts for approximately 75% of all SIADH. Symptoms include headache, muscle cramps, anorexia, and decreased urine output. If left untreated, cerebral edema can develop, leading to mental status changes, coma, seizures, and respiratory arrest.

Hypercalcemia

Hypercalcemia in patients with lung cancer may be attributable to the secretion of a parathyroid hormone–related protein, calcitriol, or other cytokines, including osteoclast-activating factors. In one study of 1,149 consecutive lung cancers, 6% of patients had hypercalcemia.[3] Among those with hypercalcemia, squamous cell carcinoma, adenocarcinoma, and SCLC were responsible for 51%, 22%, and 15% of cases, respectively. Symptoms of hypercalcemia include anorexia, nausea, vomiting, constipation, lethargy, polyuria, polydipsia, and dehydration. Renal failure, confusion, and coma are late manifestations.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is an autoimmune disorder characterized by muscle weakness of the limbs that improves with repeated testing, in contrast to myasthenia gravis, which worsens with repetition. Proximal muscles are predominantly affected, and patients complain of difficulty climbing stairs and rising from a sitting position. Approximately 3% of patients with SCLC exhibit LEMS, and SCLC accounts for approximately 60% of all LEMS.[4] The neurologic symptoms of LEMS precede the diagnosis of SCLC in more than 80% of cases, often by months or years.

Hypertrophic Osteoarthropathy

Hypertrophic pulmonary osteoarthropathy (HPO), most frequently associated with adenocarcinoma, is defined by clubbing and periosteal proliferation of the tubular bones. HPO is further characterized by a symmetrical, painful arthropathy that usually involves the ankles, knees, wrists, and elbows. A radiograph of the long bones shows characteristic periosteal new bone formation. A bone scan or positron emission tomography (PET) typically demonstrates diffuse uptake by the long bones.

SCREENING, DIAGNOSTIC STAGING, AND WORKUP

Screening for Lung Cancer

Given the high mortality rate of lung cancer and that the majority of patients are diagnosed with advanced stage, identifying lung cancer at an earlier stage has the potential to improve outcomes. While screening trials

involving chest x-rays and/or sputum sampling failed to demonstrate a survival benefit, early trials of spiral computed tomography (CT) in lung cancer screening were promising[5] and set the groundwork for the landmark National Lung Screening Trial (NLST).[6] From 2002 to 2004, 53,454 participants between 55 and 74 years of age, with a history of cigarette smoking of at least 30 pack-years and not having quit smoking more than 15 years ago, were randomly assigned to three annual screenings with either low-dose CT (n = 26,722) or standard chest x-ray (n = 26,732). Screening with low-dose helical CT scans had a 20% relative reduction in risk of death caused by lung cancer (P = .004) and a 6.7% relative reduction in all-cause mortality (P = .02). A 2019 update of the NLST showed that with longer follow-up, the number needed to screen to prevent one lung cancer death remained unchanged, with similar rates of lung cancer incidence in both arms.[7] Similarly in the NELSON trial, patients between the ages of 50 and 74 years and who currently smoke or quit less than 10 years ago were randomly assigned to undergo CT screening at T0 (baseline), year 1, year 3, and year 5.5 or no screening.[8] Screening reduced lung cancer mortality by 24% (95% confidence interval [CI] 0.61-0.94; P = .01). As of 2021, the U.S. Preventive Services Task Force recommends "annual screening for lung cancer with LDCT in adults aged 50 to 80 years who have a 20 pack-year smoking history and currently smoke or have quit within the past 15 years."[9] The 2023 guideline from the American Cancer Society is the same except years since quitting is no longer an eligibility factor for people who formerly smoked.[10]

Diagnostic Workup

Outside of diagnosing lung cancer after an abnormal screening CT scan, or after an incidental finding during the workup of another problem (ie, cardiac arrest, chronic obstructive pulmonary disease exacerbation, or pneumonia), lung cancer is generally diagnosed when working up new symptoms (described earlier) and signs (ie, abnormal physical examination), particularly in patients with significant smoking history. An abnormal chest x-ray, showing a mass, obstruction or atelectasis, is often one of the first diagnostic findings of lung cancer. Nevertheless, all patients with suspected lung cancer (with or without an abnormal chest x-ray) should undergo a contrast-enhanced CT scan of the chest and upper abdomen to include the entire liver and adrenal glands. Suspicious CT findings warrant consideration of PET/CT imaging to optimally assess for the likelihood of lung cancer, although PET/CT scans are often performed only after pathologic diagnosis of lung cancer to better characterize the extent of extracranial disease.

While the sensitivity and specificity of PET in assessing mediastinal nodal metastasis is markedly superior to CT,[11] the potential for false positives and false negatives (particularly with smaller lymph nodes 16) necessitate lymph node tissue sampling (when feasible).

Percutaneous fine-needle aspiration (FNA) has long been used to obtain tissue for pathologic diagnosis of lung cancer. The U.S. guidance (ie, for supraclavicular lymph nodes or pleural effusions) or CT guidance (ie, for lung, liver, adrenal, or bone sites) is used to increase the diagnostic yield. For CT-guided lung biopsy, there is a ~25% risk of pneumothorax, though most resolve without intervention; only approximately 5% require a chest tube. A negative biopsy cannot rule out malignancy unless another benign diagnosis can clearly be established. Fiberoptic bronchoscopy enables visualization of the tracheobronchial tree and obtaining cytologic brushings and washings and biopsy of visible lesions. Navigational bronchoscopy utilizes a virtual map of the bronchial tree that is generated from a high-resolution CT imaging to potentially target lesions not accessible with standard bronchoscopy and may increase the diagnostic yield. For some peripheral lesions, navigational bronchoscopic biopsy and CT-guided percutaneous biopsy may both be feasible, and the decision-making on the optimal approach should involve a multidisciplinary discussion.

Fiberoptic endoscopy techniques can also be combined with ultrasound to aid in targeting mediastinal and hilar lymph nodes to biopsy. Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) can readily sample paratracheal (lymph node levels 2 and 4), subcarinal (level 7), or hilar lymph node stations (level 10). A prospective study comparing EBUS-TBNA with PET/CT scans revealed an accuracy of 98% and a sensitivity and specificity of 92% and 100%, respectively.[12] An esophageal approach known as transesophageal endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) can perform the same function, especially the sampling of mediastinal nodes that are posterior or inferior, such as the retrotracheal (lymph node station 3p), subcarinal (level 7), paraesophageal (level 8), and pulmonary ligament lymph nodes (level 9).

In skilled hands, mediastinoscopy remains the most accurate technique to assess upper and lower paratracheal (lymph node stations 2 and 4), prevascular (station 3a), retrotracheal (station 3p), subcarinal (station 7), and hilar lymph nodes (station 7), particularly for normal-sized nodes. Lymph nodes within the aortopulmonary window (lymph node station 5) and along the ascending aorta (station 6) are not accessible by standard mediastinoscopy techniques; however, they can be evaluated by anterior mediastinotomy (also known as the Chamberlain procedure) or video-assisted thoracoscopic techniques. Although considered the gold standard, mediastinoscopy does have a false-negative rate of approximately 10%. Furthermore, less invasive techniques such as EBUS-TBNA or EUS-FNA are often favored. Mediastinoscopy should be considered in situations where less invasive techniques are nondiagnostic. It is reasonable to forgo invasive staging of the mediastinum in patients with clinical stage I peripheral disease, particularly those with PET-positive primary tumors but no mediastinal uptake and no obviously enlarged nodes on CT.

Video-assisted thoracoscopy can also be used to reach mediastinal nodes not accessible by standard mediastinoscopy, EBUS-TBNA, or EUS-FNA techniques.

STAGING

Definitions of tumor, node, metastasis (TNM) for the eighth edition of the *AJCC Cancer Staging Manual* are shown in Table 57.1. The stage groupings are shown in Table 57.2.

TABLE 57.1 AJCC STAGING OF LUNG CANCER, EIGHTH EDITION

Tx	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy.
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (ie, not in the main bronchus)
T1mi	Minimally invasive adenocarcinoma: adenocarcinoma (≤3 cm in greatest dimension) with a predominantly lepidic pattern and ≤5 mm invasion in greatest dimension
T1a	Tumor is ≤1 cm in greatest dimension.
T1b	Tumor >1 cm but ≤2 cm in greatest dimension
T1c	Tumor >2 cm but ≤3 cm in greatest dimension
T2	Tumor >3 cm but ≤5 cm or having any of the following features: involves the main bronchus but without involvement of the carina; invades the visceral pleura; or associated with atelectasis or obstructive pneumonitis that extends to the hilar region, involving part or all of the lung
T2a	Tumor >3 cm but ≤4 cm in greatest dimension
T2b	Tumor >4 cm but ≤5 cm in greatest dimension
T3	Tumor >5 cm but ≤7 cm in greatest dimension or directly invading any of the following: parietal pleura, chest wall (including superior sulcus tumors), phrenic nerve, parietal pericardium, or separate tumor nodule(s) in the same lobe as the primary
T4	Tumor >7 cm or tumor of any size that invades diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina; separate tumor nodule(s) in an ipsilateral lobe different from that of the primary
N0	No regional lymph node involvement
N1	Involvement of ipsilateral intrapulmonary, or peribronchial, hilar lymph nodes
N2	Involvement of mediastinal or subcarinal lymph nodes
N3	Involvement of contralateral mediastinal or hilar lymph nodes. Involvement of ipsilateral or contralateral scalene or supraclavicular nodes
M0	No distant metastasis
M1	Distant metastasis present
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural or pericardial nodule(s) or malignant pleural or pericardial effusion
M1b	Single extrathoracic metastasis

M1c	Multiple extrathoracic metastases in one or several organs

PATHOLOGIC CLASSIFICATION

The four major classifications of lung cancer include (a) squamous cell carcinoma, (b) adenocarcinoma, (c) small cell carcinoma, and (d) large cell carcinoma. Historically, the most important histologic information to guide treatment for lung cancer was distinguishing between non–small cell and small cell carcinoma. However, in recent decades, specific systemic regimens (discussed later) have been shown to be more or less efficacious for certain lung cancer subtypes. Moreover, among patients with squamous cell carcinoma and adenocarcinoma, specific mutations can determine if there are molecular characteristics (ie, specific mutations) that can optimally guide therapy (targeted therapy is discussed in more detail later). Molecular testing can be performed from the sampled tissue, or from serum or blood (ie, liquid biopsy). The 2021 World

Health Organization (WHO) Classification of Lung Tumors has placed a greater emphasis on molecular characteristics.[13]

Prognostic and Predictive Factors

Prognostic factors, such as TNM stage, are those that predict clinical outcome independent of therapy, and predictive factors are those that predict response to a particular therapeutic regimen. The past decade has seen significant advances in our understanding of tumor-related prognostic and predictive factors. With the advent of novel immunotherapies and targeted systemic therapies specific for molecular subtypes of NSCLC (discussed later in the chapter), a subset of patients (even with metastatic disease) can experience prolonged progression-free survival (PFS) and overall survival (OS). Thus, having a "targetable" mutation predicts response to specific targeted agents. Objective assessment of performance status (ie, Karnofsky or Eastern Cooperative Oncology Group [ECOG] scales), and whether a patient experienced significant weight loss (generally >5%) in the 6 months preceding diagnosis have been shown in large trials to be among the factors most predictive of survival (along with TNM stage).[14] In addition, age, sex, and marital status have been shown to be prognostic for survival in a number of studies. Movsas et al[15] reported that baseline quality of life (QoL), as quantified by validated instruments, superseded performance status, age, sex, and other classic prognostic indicators for survival in a prospectively collected data set in patients enrolled on a Radiation Therapy Oncology Group (RTOG) clinical trial, suggesting that baseline QoL may be one of the most important predictors of long-term survival.

GENERAL MANAGEMENT OF NON–SMALL CELL LUNG CANCER

The management of NSCLC presents a formidable challenge. Oncologists must not only account for the stage and extent of disease spread at the time of diagnosis but also carefully weigh the impact of baseline pulmonary functional status and comorbidities on the patient's ability to tolerate treatment. NSCLC is an aggressive tumor of a vital organ that is poorly functioning at baseline in the majority of patients. Therefore, the final therapeutic approach must be tailored to the individual. The treatment principles presented in this section should be viewed as guidelines and not as a cookbook for the management of this disease.

For patients with stage I disease, the standard of care for patients who are surgical candidates is complete surgical resection with the possible addition of adjuvant chemotherapy for those patients who present with stage IB and high-risk disease, although there is significant controversy. For patients with stage I disease who are medically inoperable, stereotactic body radiation therapy (SBRT), also known as stereotactic ablative radiotherapy (SABR), is the standard of care. There are several trials investigating the use of immunotherapy for these patients.

For stage II, patients who are operable may be treated with surgery upfront followed by adjuvant chemotherapy and immunotherapy or with neoadjuvant perioperative chemoimmunotherapy; this is an area of active investigation. Patients who are inoperable may be treated as stage III if they have node-positive disease (N1) or stage I if they have node-negative disease (T2b or T3). Stage II is relatively uncommon and should be managed in a multidisciplinary setting.

For patients with stage III disease, a significant amount of controversy exists regarding optimal management. For select patients with stage III disease at diagnosis who are candidates for surgical resection, neoadjuvant chemoimmunotherapy or chemoradiotherapy is often used. For patients with unresectable stage III disease, the standard approach is concurrent chemoradiotherapy followed by adjuvant immunotherapy for fit patients or sequential chemotherapy and radiotherapy (RT) for patients who cannot tolerate concurrent treatment.

For patients with stage IV disease without significant local presenting symptoms or need for urgent radiation, systemic therapy is the standard initial treatment approach. When significant local presenting symptoms requiring radiation are present—SVC obstruction, hemoptysis, or cord compression—palliative RT can precede systemic therapy. A detailed discussion of the goals of care with consideration of early referral to hospice should be part of the initial treatment approach. Early introduction of palliative care into the standard

treatment paradigm in this setting not only improves QoL and reduces inappropriate hospitalization at the end of life but may also improve survival.[16]

In the next two sections, we divide the management for NSCLC into early and locally advanced stages. Early stage includes T1 to T2 N0 tumors, although some studies could include T3 tumors by size criteria, that is, 7 cm or less. Locally advanced stages include node-positive and large tumors T3 to T4.

MANAGEMENT OF EARLY-STAGE NON–SMALL CELL LUNG CANCER (T1 TO T2N0)

Preoperative Assessment

Patient selection is critical when an operative approach is being considered for the management of NSCLC. This includes an assessment of the clinical extent of disease, the predicted postresection pulmonary reserve of the patient, and preoperative cardiac clearance for the intended surgical procedure. Although there are no strict guidelines for operability, traditionally, patients are considered to be suitable for resection if their predicted postoperative forced expiratory volume in 1 second (FEV_1) is more than 60% and diffusing capacity for carbon monoxide more than 60%.[17] Patients who do not meet those criteria should undergo additional testing, including exercise test, or ventilation-perfusion imaging to determine the regional variance in pulmonary function, including the potential loss of functional lung tissue within the planned area of excision.

Resection for Early-Stage Lung Cancer

The standard of care for a patient with early-stage, node-negative lung cancer is surgical resection through either a lobectomy or pneumonectomy with mediastinal lymph node dissection. A trial from the Lung Cancer Study Group randomized 276 patients with T1N0 NSCLC to lobectomy versus limited surgical resection (either wedge resection or segmentectomy). In 1995, they reported a 17% risk of local recurrence with limited resection versus 6% with lobectomy ($P = .008$).[18] However, a nonrandomized trial by Okada et al[19] suggested sublobar resection did not confer worse local control versus lobectomy and afforded better postoperative lung function in appropriately selected patients with early-stage NSCLC. More recently, a pair of phase III trials established that sublobar resection has a role in small peripheral tumors. The Japanese Clinical Oncology Group (JCOG) 0802 trial randomized 1,106 patients with 2 cm peripheral NSCLC or less to lobectomy or segmentectomy, with segmentectomy improving 5-year OS from 91.1% to 94.3% in spite of having more locoregional recurrences (10.5% vs 5.4%).[20] The Cancer and Leukemia Group B (CALGB) 140503 trial randomized 697 patients with peripherally located, early stage (≤2 cm), with intraoperative confirmation of node-negative NSCLC.[21] With a median follow-up of 7 years, the disease-free survival (DFS) and OS were not significantly different between the groups, while lung function (specifically FEV_1 and forced vital capacity) was worse after lobectomy. Sublobar resection can be considered for small, peripheral, node-negative lung tumors.

Radiation for Early-Stage Lung Cancer

There appears to be no role for adjuvant RT after sublobar resection of early-stage NSCLC with negative surgical margins. The American College of Surgeons Oncology Group Z4032 study analyzed 222 patients who underwent sublobar resection as they were objectively deemed to be at high risk for lobectomy for early-stage (≤3 cm) NSCLC and were randomized to undergo or not undergo adjuvant intraoperative brachytherapy.[22] With a median follow-up of more than 4 years, the local recurrence and OS rates were similar between the two groups. Among 14 patients who were found to have positive margins at the staple line, the hazard ratio (HR) for local recurrence was 0.22 ($P = .24$) (an unplanned analysis) with brachytherapy. While not based on level 1 data, patients with positive surgical margins after sublobar resection or lobectomy are generally offered adjuvant RT to the staple lines or high-risk areas (if identified with staples by the thoracic surgeon). Gross residual disease should be treated with curative intent (depending on pathologic staging and sites of disease) if feasible.

Historically, early-stage NSCLC was treated with conventional fractionation to doses on the order of 70 Gy. Dose escalation trial allows safe delivery of doses up to 102.9 Gy to small peripheral tumors.[23] Based on fundamental radiobiologic principles, Fletcher[24] predicted that using conventional fraction sizes of 1.8 to 2

Gy, doses of 100 Gy or higher might be required for the sterilization of most NSCLC tumors. These doses are not routinely achievable with conventionally fractionated RT in the patient who is medically inoperable without excessive toxicity.

SBRT refers to the delivery of large doses of radiation to a small treatment volume, usually employing multiple beams, using a small number of fractions (usually five fractions or less). Application of SBRT in lung cancer was impractical until advanced imaging treatment delivery techniques were developed (Figure 57.1). Cancer control and survival outcomes from phase I and II studies of SBRT (discussed later) were markedly superior to conventionally fractionated radiation, although it was not clear how much benefit was derived from more modern cancer staging and treatment planning approaches. Thus, the Scandinavian SPACE study randomized 102 patients from 2007 to 2011 to SBRT (15 Gy × 3) versus conventionally fractionated RT (2 Gy × 35) and found similar PFS, OS, and local control.[25] The TROG 0902 CHISEL randomized 101 patients (21-01 randomization) from 2009 to 2015 to SBRT (18 Gy × 3 or 12 Gy × 4) versus conventionally fractionated RT (2 Gy × 30-33 or 2.5 Gy × 20).[26] While OS, PFS, and QoL were greater with SBRT, these differences were not significant. Notable differences between the CHISEL and SPACE studies include the dose fractionation used, use of PET staging (all patients in CHISEL, 65% in SPACE), performance status (ECOG ≤1 in CHISEL vs 24% in SPACE with ECOG >1), and use of four-dimensional (4D) CT and cone-beam CT (CBCT) (required for CHISEL and only used at few sites in SPACE).

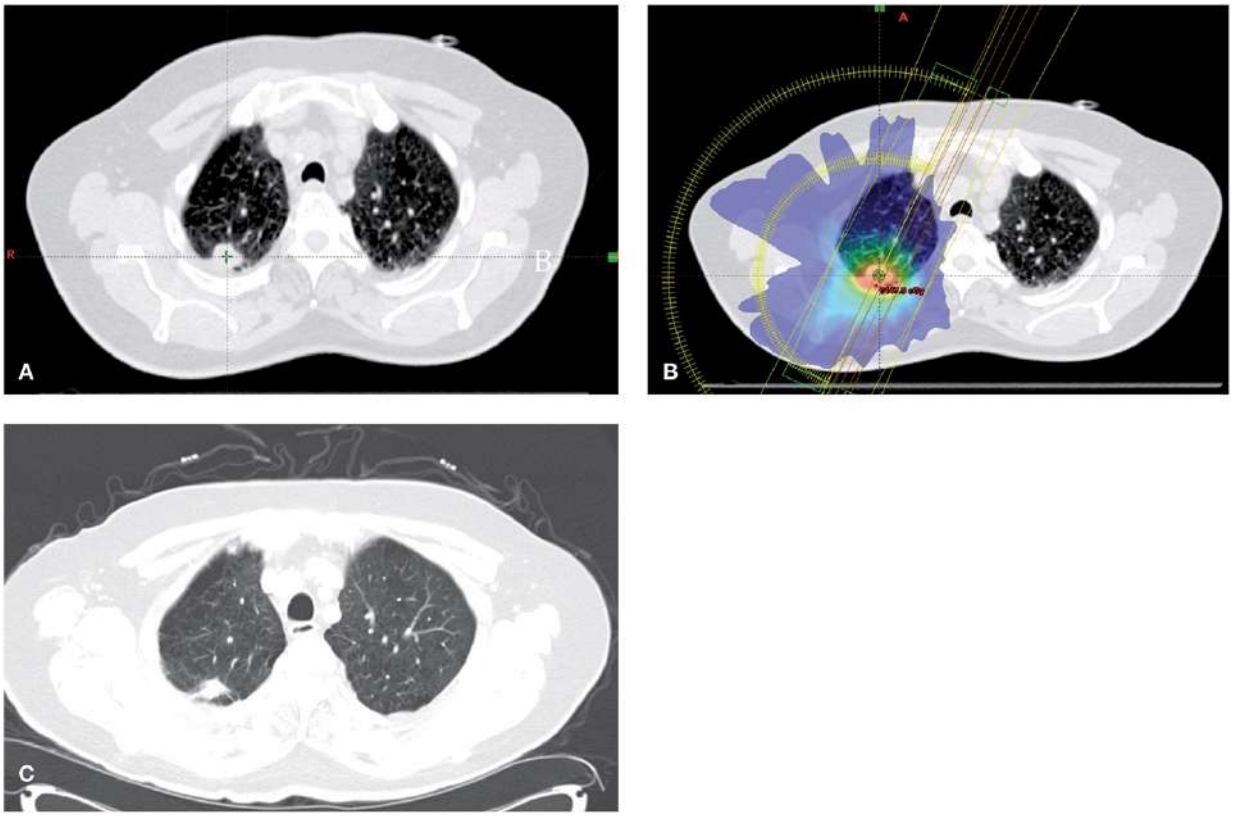

FIGURE 57.1 Stereotactic body radiation therapy (SBRT) in stage I non–small cell lung carcinoma (NSCLC). The patient was diagnosed as having T1N0M0 right upper lobe NSCLC and was treated with SBRT. A. Pretreatment tumor volume. B. Treatment plan with dose color-wash. C. Computed tomography showing response 6 weeks after treatment.

The CHISEL and SPACE studies were preceded by promising phase I and II data (discussed later) in patients with early-stage NSCLC who are medically inoperable or who opted against resection (Table 57.3). The phase I (n = 37 patients) and phase II (n = 70 patients) studies, from Indiana University, of three-fraction SBRT for early-stage NSCLC, established the excellent local control (~88% at 3-year) and survival outcomes after SBRT. Notably, their analyses also established the increased risks of high grade and fatal toxicity using

such an SBRT approach for targets within the 2 cm zone of the proximal bronchial tree.[27] The phase II RTOG 0236, which followed from these studies, demonstrated more than 90% 5-year tumor control and median survival of ~4 years after SBRT of 60 Gy in three fractions among 55 evaluable patients with peripheral early-stage NSCLC.[28,29] The RTOG 0915 phase III noninferiority study compared 34 Gy × 1 versus 12 Gy × 4 for peripheral early-stage NSCLC and showed no significant difference in rates of tumor control, OS, or adverse events.[30]

TABLE 57.3 PROSPECTIVE TRIAL OUTCOMES FOR PATIENTS WITH EARLY-STAGE NON–SMALL CELL LUNG CANCER RECEIVING STEREOTACTIC BODY RADIATION THERAPY

Authors (Years Enrolled)	Patients	Dose (Gy)	T Stage	3-y Local Control (%)	3-y Lobar Control (%)	3-y Overall Survival (%)
SBRT trials in inoperable patients						
Baumann et al (2003-2005)[265]	57	15 Gy × 3 to 67%	T1-T2	92	—	60
Fakiris et al (2002-2004)[266]	70	T1: 20 Gy × 3 to 80% T2: 22 Gy × 3 to 80%	T1-T2	88	—	43

[a]Estimated from overall survival figures.

While SBRT is the standard of care for early-stage NSCLC in patients not fit for surgery, its use in operable patients is much more controversial. The JCOG 0403[31] phase II nonrandomized trial showed 3-year OS of 60% and 77% in the inoperable (n = 64) and operable cohorts (n = 100), respectively. Thirty-one percent of deaths were attributed to lung cancer among inoperable patients, whereas 50% were attributed in the operable cohort. The RTOG 0618 phase II study of operable patients reported favorable local control (n = 1 in-field recurrence), 4-year DFS (57%), and 4-year OS (56%) after SBRT in 26 evaluable patients with medically operable early-stage (≤5 cm) NSCLC. Four patients (15%) developed SBRT-related grade 3 adverse events, and there were no grade 4 and 5 adverse events.[32] In response to these promising results, multiple prospective randomized trials comparing SBRT with surgery in resectable early-stage NSCLC were launched,[33-36] but failed to accrue enough patients and were subsequently closed. A pooled analysis from two of these trials (STARS and ROSEL) compared outcomes among 31 patients with stage I NSCLC 4 cm or less who underwent SABR versus 27 who underwent resection.[37] The median follow-up was 40.2 months for the SABR

group and 35.4 months for the surgery group. Estimated OS at 3 years was 95% (95% CI 85-100) in the SABR group compared with 79% (64-97) in the surgery group (HR 0.14, 95% CI 0.017-1.190, log-rank P = .037). Recurrence-free survival at 3 years was 86% (95% CI 74-100) in the SABR group and 80% (65-97) in the surgery group (HR 0.69, 95% CI 0.21-2.29, log-rank P = .54). A separate Revised STARS cohort[38] with 80 operable patients (no overlap with prior STARS) with tumors 3 cm or less and median 5.1 years of follow-up showed 5-year OS of 87% and 5-year PFS of 77%. Chang et al[38] posit several reasons for the improved survival of the patients in the Revised STARS cohort compared to RTOG 0618 in that they were younger, had smaller tumors, had better pulmonary function, were treated with modern SBRT technique, and overwhelmingly received EBUS, which was performed in 90% of the patients.

While based on a small pooled randomized and nonrandomized experiences, these data suggest that SBRT may be a viable noninvasive option for selected patients with early-stage operable NSCLC, particularly in those who may be at increased risk from surgical resection (Table 57.3). Data from the currently enrolling VALOR (NCT02984761) and STABLE-MATES (NCT02468024) trials will prove better comparative data.

It is challenging to treat early-stage NSCLC that is central (within 2 cm of the proximal bronchial tree) or ultracentral (with various definitions[39] but generally with gross tumor volume [GTV] or planning target volume [PTV] overlapping the proximal bronchial tree other mediastinal structures[40]) in location. The phase I and II RTOG 0813 enrolled 120 patients (100 evaluable for efficacy and 89 evaluable for toxicity) who received five-fraction SBRT for central early-stage NSCLC (with only 17% having ultracentral tumors defined as PTV overlap with mediastinal and/or pericardial pleura).[41] The maximum tolerated dose was 12 Gy × 5, with 7.2% experiencing dose-limiting toxicity. The HILUS study[42] enrolled 65 patients treated with an eight-fraction 56 Gy SBRT course with early-stage lung NSCLC located 1 cm from the proximal bronchial tree. Due to excessive risks of toxicity, the author concludes that the 7 Gy × 8 regimen should not be used for tumors within 1 cm of the main bronchi and trachea, and for other patients, the maximum dose (to 0.2 cc) to the main bronchi and trachea should be less than 70 to 80 Gy equivalent dose in 2-Gy fractions. From a follow-up pooled analysis of Expanded HILUS[43] (HILUS study participants plus patients added retrospectively), 3-year local control and OS rates were 84% and 40%, respectively. Thirty (13%) of 230 patients developed fatal five toxicity, of which bronchopulmonary bleeding occurred in 20. Significant factors associated with fatal hemoptysis and fatal toxicity included tumor compression of the tracheobronchial tree and maximum dose to the mainstem bronchi or bronchus intermedius, while the largest diameter of the gross target volume was not significant. In a separate analysis of 127 patients (mostly treated with eight-fraction SBRT), tumor location 1 cm or less from the trachea or main bronchi was a significant predictor of severe toxicity.[44] The SUNSET study reported less than 7% risks of grade 3 to 5 toxicity after 7.5 Gy × 8 for well-selected (no endobronchial obstruction) ultracentral (nonnodal) lung tumors for which the protocol required less than 120% maximum dose.[45]

The HyTEC report pooled data from 46 studies of SBRT for early-stage NSCLC, which allowed for modeling tumor control probabilities with respect to prescribed dose at the PTV periphery. For T1 to T2N0 NSCLC, the authors recommended 43 ± 1 Gy in three fractions, 47 ± 1 Gy in four fractions, and 50 ± 1 Gy in five fractions to "achieve the maximal local control rate."[46] With respect to SBRT treatment planning, dose heterogeneity with steep dose gradients minimizes the volume of normal tissue exposed to high doses and allows for high maximal doses (ie, 125%-150% of prescribed dose) within the target, which has been shown to correlate with better tumor control.[47] In treatment planning, particularly with central lesions, it is often advisable to underdose the target to meet normal tissue constraints[39,48]

Due to the success of immune checkpoint inhibitors (ICIs) in metastatic and locally advanced NSCLC, several trials are looking at incorporating immunotherapy into earlier stages. The MD Anderson I-SABR[49] phase 2 trial randomized 141 patients with stage I and IIA or recurrent NSCLC to SABR with or without concurrent and adjuvant nivolumab. At 33-month follow-up, immunotherapy improved 4-year event-free survival (EFS) from 53% to 77% (per protocol HR 0.38, P = .0056) at the cost of 15% immunologic grade 3 adverse events (no grade 3 pneumonitis). Many other trials are ongoing (KEYNOTE 867, SWOG/NRG S1914, NRG PACIFIC 4/RTOG 3515, ASTEROID).

MANAGEMENT OF LOCALLY ADVANCED NON–SMALL CELL LUNG CANCER

Operable Stage III Non–Small Cell Lung Cancer

Considerable controversy exists regarding the role of surgery in stage III NSCLC. In the 1960s and 1970s, patients with documented N2 disease were generally regarded as incurable and referred for nonoperative approaches. Martini et al[50] reported the outcome of 1,598 patients who underwent surgical resection, 706 of whom had mediastinal nodal involvement. Of these, 151 patients underwent complete surgical resection with mediastinal node dissection. Survival in patients with clinical stage I or II (pathologic N2) was favorable at 50% at 3 years. Survival in patients with obvious clinical N2 disease was extremely poor at 8% at 3 years. Martini et al[50] stated: "Very few patients with gross mediastinal nodal involvement benefit from resection. We believe that this group of patients should not be considered for thoracotomy unless innovative forms of treatment can be offered." Beyond gross mediastinal nodal involvement, multistation N2 disease and subcarinal nodal involvement are also shown in multiple series to be portend to poor outcomes.[51,52]

Based on these and similar results with surgical resection alone in stage III disease, neoadjuvant approaches were explored to facilitate surgical resection. However, significant controversy still exists regarding the role of surgical resection in stage III disease. A European Organisation for Research and Treatment of Cancer (EORTC) phase III trial randomized patients with biopsy-proven N2 disease who responded to induction chemotherapy to either resection or RT. Both arms showed similar median and 5-year OS for patients randomly assigned to resection versus RT at 16.4 versus 17.5 months and 15.7% versus 14%.[53]

Neoadjuvant (Induction) Therapy

Preoperative Systemic Therapy

With the advent of immunotherapy, the role of perioperative systemic therapy has been rekindled. The use of immunotherapy upfront has the theoretical advantage of a high neoantigen burden and an intact anatomy with improved draining lymph nodes that could result in better and more efficient antigen presentation and, therefore, priming of a more tumor-specific T cell.[54] Historically, studies of neoadjuvant cytotoxic chemotherapy were underpowered as these closed early as the adjuvant studies that accrued more rapidly demonstrated a survival advantage. A meta-analysis of 15 trials demonstrated an OS benefit of 5% at 5 years for neoadjuvant chemotherapy over surgery alone, which is similar to the benefit of the more traditional adjuvant treatment.[55] Neoadjuvant treatment has the potential advantage of facilitating a surgical procedure to abate the need for a more extensive resection, a higher probability of completion of planned systemic therapy, and providing prognostic information as the degree of pathologic response is associated with an improved outcome.

Several placebo-controlled phase 3 trials—CheckMate 816,[56] KEYNOTE 671,[57] and AEGEAN[58]—comparing induction chemotherapy with and without immunotherapy have been reported (Table 57.4). These studies have several differences, and as of this writing, there is neither a clearly defined optimal strategy nor is there a preferred ICI or a preferred chemotherapy backbone. Logistical challenges remain an important factor to consider; most of these trials excluded patients with the most common oncogene-driven lung cancer (epidermal growth factor receptor [EGFR] mutations and anaplastic lymphoma kinase [ALK] alterations) because these patients are less likely to benefit from immunotherapy. This point entails the need to have a presurgical histologic diagnosis with enough tissue to establish the presence of these abnormalities. The genetic testing turnaround time and often scant tissue available are frequent barriers to a timely initiation of neoadjuvant treatment. When faced with the decision to offer neoadjuvant treatment, the clinician and their patients also need to consider the chemoresistant nature of this disease. Neoadjuvant chemoimmunotherapy can lead to a response that prevents the need for a pneumonectomy, but this is not the goal of treatment, and therefore, patients should only be offered this strategy if the patient is likely to have a complete surgical resection even if there is no significant response.

TABLE 57.4 PHASE III TRIALS OF PERIOPERATIVE CHEMOIMMUNOCHEMOTHERAPY

Study	Population	Intervention	Control	Adjuvant Treatment	Primary End Point	Surgery	pCR	EFS	OS
CheckMate 816[56]	Stage IB-IIIA resectable NSCLC	Three cycles of nivolumab + chemotherapy	Chemotherapy alone	None dictated	EFS and pCR	83.2% vs 75.4%	24% vs 2.2%	31.6 vs 20.8 (HR 0.63; 97.38% CI 0.43-0.91)	NR vs NR (HR 0.57; 99.67% CI 0.30-1.07)
KEYNOTE 671[57]	Stage II, IIIA, or resectable IIIB	Four cycles of pembrolizumab + chemotherapy	Placebo + chemotherapy	Pembrolizumab for 1 year	EFS and OS	82.1% vs 79.4%	18.1% vs 4%	NR vs 17 (HR 0.58; 95% CI 0.46-0.72)	NR vs 45.5 (HR 0.72; 95% CI 0.56-0.93)

CheckMate 77T		Four cycles of nivolumab + chemotherapy	Placebo + chemotherapy	Nivolumab for 1 year	EFS	78% vs 77%	25.3% vs 4.7%	NR vs 18.4 (HR 0.58; 95% CI 0.42-0.81)	Not reported

CI, confidence interval; EFS, event-free survival; HR, hazard ratio; NSCLC, non–small cell lung cancer; NR, not reached; OS, overall survival; pCR, pathologic complete response.

Preoperative Chemoradiotherapy

The rationale for preoperative chemoradiotherapy is that surgical resection after chemoradiotherapy will optimize local control, thereby improving clinical outcomes in locally advanced disease. A phase II trial by the Southwest Oncology Group (SWOG) of induction chemoradiotherapy followed by surgical resection in 126 patients with stage IIIA/IIIB disease showed a promising 3-year survival of 26%.[59] Motivated by these results, an intergroup randomized phase III trial was initiated to determine the value of adding surgery to chemoradiotherapy in stage III disease with a primary end point of OS. Patients with stage T1 to 3 with pathologic proof of N2 NSCLC involvement (eg, biopsy) who were deemed to be potentially technically resectable were randomly assigned to concurrent induction chemoradiation to 45 Gy followed by surgery or the same induction chemoradiation with completion to 61 Gy.[60] The median OS was 23.6 months in the trimodality arm and 22.2 months in the bimodality group ($P = .24$). For those with pN0 status at thoracotomy, the median OS was 34.4 months. The median PFS was better in the trimodality arm (12.8 vs 10.5 months, $P = .017$). An unplanned, exploratory analysis suggested that patients who underwent lobectomy in the trimodality arm had improved survival compared to matched patients receiving chemoradiotherapy. One of the most important findings from this trial was the significant toxicity of right-sided pneumonectomy after induction chemoradiotherapy. Among the 29 patients who underwent a right pneumonectomy, there were 11 postoperative deaths (38%).[61] Overall, this trial did not demonstrate a survival benefit for the addition of surgery to chemoradiotherapy in patients with stage IIIA NSCLC.

Two phase III trials examined whether adding neoadjuvant radiation to induction chemotherapy would benefit PFS. The phase III German Lung Cancer Cooperative Group trial compared neoadjuvant chemotherapy, surgery, and postoperative radiation, versus neoadjuvant chemotherapy, twice-daily (BID) chemoradiation followed by surgery and a further radiation if positive margins.[62] Mediastinal downstaging

(46% vs 29%) and pathologic response (60% vs 20%) favored the neoadjuvant chemoradiation arm, but median PFS was no different at around 10 months. The SAKK 16/00 trial had a simpler design comparing induction platinum doublet chemotherapy to sequential platinum doublet followed by 44 Gy in 22 fractions. Similarly to the German trial, the median EFS was around 12 months in both arms.[63]

In conclusion, the role of neoadjuvant chemoradiotherapy in stage III NSCLC remains unclear, especially now in the era of preoperative chemoimmunotherapy, with induction chemotherapy preferred to neoadjuvant chemoradiation about 2:1 by institutions.[64]

Adjuvant Therapy

Postoperative Systemic Therapy

The strongest evidence for the use of adjuvant chemotherapy in patients with NSCLC comes from two meta-analyses. The 2008 Lung Adjuvant Cisplatin Evaluation meta-analysis, which pooled data from five large trials involving 4,584 patients, focused on the effectiveness of postoperative cisplatin-based chemotherapy in NSCLC.[65] The results showed an overall HR of death of 0.89 (95% CI 0.82-0.96) with chemotherapy, corresponding to 5-year absolute survival benefit of 5.4%. The benefit was seen in patients with stage II (HR 0.83, 95% CI 0.73-0.95) and IIIA disease (HR 0.83, 95% CI 0.72-0.94). For patients with stage IA, no study has found a positive effect of adjuvant treatment. For those patients with stage IB, the benefit was marginal and not statistically significant (HR 0.93, 95% CI 0.78-1.10). To determine whether adjuvant chemotherapy improves survival for stage IB, the CALGB 9633 randomized patients with pT2N0 NSCLC to observation or adjuvant chemotherapy. OS was similar in both arms with HR 0.83 (95% CI 0.64-1.08).[66] Subset analysis for tumors larger than 4 cm in diameter showed a benefit with HR 0.69 (95% CI 0.48-0.9). Adjuvant chemotherapy in these patients remains an area of controversy and should only be offered in select cases after a careful discussion of risks and benefits. The 2015 Cochrane meta-analysis by the Non-Small Cell Lung Cancer Collaborative Group analyzed individual patient data from 26 randomized clinical trials, involving 8,447 patients. The analysis demonstrated clear evidence of a benefit of adding chemotherapy after surgery (HR 0.86, 95% CI 0.81-0.92), with an absolute survival increase of 4% at 5 years.[67]

More recently, postoperative immunotherapy has been studied with both pembrolizumab and atezolizumab after chemotherapy found to be beneficial. The IMpower010 study was an open-label study of 1,005 patients with stage IB (tumors ≥4 cm) to IIIA NSCLC after mandatory platinum-based adjuvant chemotherapy who were randomized to atezolizumab versus best supportive care (BSC). The analysis followed a prespecified step that demonstrated that initial improvement in DFS compared to BSC alone. In patients with stage II to IIIA whose tumors had a programmed death-ligand 1 (PD-L1) staining of 1% or greater, the DFS was not reached in the investigational arm and was 35.3 months in those treated with BSC, HR for DFS was 0.66 (95% CI 0.50-0.88). Subset analyses showed that the greatest magnitude of DFS improvement was seen in patients with PD-L1 50% or greater, in whom an HR for DFS was 0.43 (95% CI 0.27%-0.68%) over BSC.[68] A final OS analysis is still pending at the time of this writing. Prespecified exploratory analyses published currently show showed an OS improvement in favor of atezolizumab in the stage II to IIIA PD-L1 50% population or greater (stratified HR 0.43, 95% CI 0.24-0.78).[69]

The KEYNOTE-091 (PEARLS) trial was a triple-blind adjuvant study of 1,177 patients with completely respected stage IB (tumors ≥4 cm) to IIIA NSCLC who were randomized to adjuvant pembrolizumab versus placebo. An interim analysis showed an improvement in median DFS from 42 to 53.6 months (HR 0.76, 95% CI 0.63-0.91, $P = .0014$). In contrast to the IMpower010 study, no benefit in DFS was seen in the PD-L1 tumor proportion score more than 50% population (HR 0.82, 95% CI 0.57-1.18).[70]

The percentage of patients with grade 3 adverse events or greater was 22% in IMpower010 and 34% in PEARLS. The rate of discontinuation of immunotherapy for adverse events was 18.2 and 22% in IMpower010 and PEARLS, respectively.

Patients with driver oncogenes were included in both adjuvant immunotherapy studies. Currently, however, we know that the value of immunotherapy in this patient population is small, and in contrast, patients may benefit from the use of adjuvant tyrosine kinase inhibitors (TKIs). The ADAURA study was a placebo-controlled trial for patients with resected NSCLC that harbored a deletion 19 or an L858R EGFR mutation.[71] In all, 682 patients with resected stage IB to IIIA disease were randomly assigned to receive 3 years of

adjuvant osimertinib or placebo after optional chemotherapy. The primary end point of the study was DFS, which was markedly improved in the experimental arm with overall HR of 0.18 (95% CI 0.10-0.33). The 5-year OS was 88% for those randomized to osimertinib versus 78% for those on placebo (HR 0.49; 95.03% CI 0.34-0.70). The OS benefit was consistent among subgroups, though a larger benefit was seen for those patients who had stage IIIA disease (HR 0.37, 95% Cl 0.20-0.64). This study has been heavily criticized because crossover to osimertinib—a therapy known to be markedly superior to its alternatives—was not mandated at the time of disease relapse, and therefore, only 38.5% of patients on the control arm whose disease had relapsed ever received osimertinib.[72] Despite this limitation, adjuvant osimertinib is the current standard of care for patients who present with these EGFR abnormalities. In patients with alteration in ALK, the ALINA study randomized 257 patients with resected stage IB to IIIA to either 2 years of alectinib or up to four cycles of adjuvant chemotherapy. A preliminary analysis showed a significant DFS benefit was seen in patients randomized to alectinib in both stage II to IIIA (HR 0.24, 95% CI 0.13-0.45) and intention-to-treat (ITT) populations (HR 0.24, 95% CI 0.13-0.43).[73]

It is unknown if these results can be extrapolated to other patients with rarer oncogene-driven mutations and it is unlikely that phase 3 results will ever be conducted in these subgroups given its rarity.

Postoperative Radiotherapy

The predominant pattern of intrathoracic failure after surgical resection is along the surgical stump or in the mediastinal nodes. Concern over locoregional failure led to investigations of postoperative radiotherapy (PORT) in completely resected stages II and IIIA NSCLC to reduce local recurrence.[74] The role of PORT has historically been controversial. In the Medical Research Council PORT meta-analysis, PORT was associated with a decrease in survival for patients with pN1 disease (attributed to excessive morbidity) and no difference in pN2.[75] Subsequent studies found support for PORT in pN2 disease. A SEER analysis of stage II/III resected NSCLC showed that PORT was associated with an improved 5-year OS for pN2 patients (27% vs 20%) but reduced OS for pN0 and pN1 patients.[76] A subset analysis of the Adjuvant Navelbine International Trialist Association trial[77] showed that in patients with pN2 disease, PORT was associated with improved median survival in both the chemotherapy (23.8 vs 47.4 months) and observation arm (median survival 12.7 vs 22.7 months). In contrast, PORT for pN1 was associated with improved survival only if no chemotherapy was given and worse survival if chemotherapy was given.

The hypothesis of PORT-benefiting pN2 disease was investigated in the European Lung Adjuvant Radiotherapy trial (LungART) and the Chinese PORT-C phase III trials. In LungART,[78] 501 patients (90% of those who currently smoke or formerly smoked) with pN2 disease after complete resection and nodal exploration were randomized to observation or PORT 54 Gy; 89% of PORT patients were treated with 3D conformal technique and 96% of patients received chemotherapy. In both arms, 3-year DFS and OS were similar at around 45% and 68%, respectively. While PORT was associated with a 50% decrease in mediastinal relapse, it was also associated with increased death, particularly cardiopulmonary deaths (8% vs 0%). In PORT-C,[79] 394 patients (45% of those who currently smoke or formerly smoked) with pN2 disease after complete resection and four cycles of platinum doublet chemotherapy were randomized to observation or PORT 50 Gy; 89% of PORT patients were treated with intensity-modulated radiotherapy (IMRT). Three-year OS was around 80% in both arms and 3-year DFS was also not statistically different at 40.5% with PORT and 32.7% with observation, though after preplanned analysis (stratified by the number of detected and positive lymph nodes), a statistically significant difference was found.

With two phase III trials in disparate populations both negative for the addition of PORT for pN2 disease, adjuvant radiation is not routinely recommended in patients with positive nodes following a *complete resection* and who are candidates for systemic therapy. Recent analyses suggest an association between increased heart dose and survival after PORT.[80] Further investigations into cardiopulmonary cause of death and the role for advanced radiation techniques are expected.

Postoperative Chemoradiotherapy

The ECOG 3590 randomized 488 patients with stage II and IIIA NSCLC and negative margins after surgery to RT either with or without four cycles of chemotherapy. RT in both arms consisted of 50.4 Gy in 28

fractions. There was no difference in local recurrence or survival between the two arms.[81] In current practice, concurrent chemoradiation is typically recommended in the adjuvant setting if gross disease was left behind at surgery, and variably recommended if microscopic disease was left behind at surgery.

Inoperable Stage III Non–Small Cell Lung Cancer

The current standard of care for inoperable stage III NSCLC is concurrent chemoradiation and adjuvant immunotherapy. Current trials are looking at incorporating immunotherapy earlier in treatment. The evolution of arriving at the current standard of care has been a fairy linear processing, starting from radiation alone in the 1980s, to the incorporation of sequential chemotherapy in the 1990s, to concurrent chemoradiation in the 2000s, and to sequential immunotherapy in the 2010s, and finally to the open question of concurrent immunotherapy in the 2020s.

Radiotherapy Alone

Most patients with inoperable locally advanced NSCLC will receive definitive thoracic RT as a part of their treatment strategy. Kubota et al[82] performed a randomized phase II trial in stage III NSCLC comparing chemotherapy with or without RT that showed an increase in 3-year survival from 3% to 29% with radiation. At present, definitive thoracic RT is part of the standard therapeutic approach for patients with unresectable locally advanced NSCLC. However, because of high local failure rates and the significant toxicity associated with this treatment, investigations have been performed to determine the optimal dose, treatment volume, and integration with chemotherapy.

Dose and Fractionation With Radiotherapy Alone

The RTOG 7301 phase III trial compared 40 (including with a split course), 50, and 60 Gy, delivered with conventional fractionation. The 60-Gy arm had the lowest local failure at 35% and was established as the standard of care.[83,84]

Motivated by these results, the RTOG moved to explore methods of escalating radiation dose while maintaining the therapeutic ratio through altered fractionation schedules. RTOG 8311 was a randomized phase I/II trial that compared doses from 60.0 to 79.2 Gy using 1.2 Gy fractions delivered BID. No significant differences in the toxicity were found, although in a subset analysis of good performance status patients, there was a dose response identified for survival that plateaued at 69.6 Gy, which became the standard altered fractionation regimen for subsequent RTOG trials.[85]

The progression of 2D to 3D conformal radiotherapy (CRT) in the early 1990s allowed increased conformal dose around the tumor. Bradley et al[86] demonstrated by multivariate analysis that GTV was strongly predictive of OS and cause-specific survival, suggesting that large-volume disease might require escalated doses of RT, if feasible. Rengan et al[87] found that even in patients with large stage III tumor volumes, local failures were reduced when treated to 64 Gy or more.

Starting in the early 2000s, multiple trials attempted to find maximum tolerated doses for hypofractionated radiation (ie, >2.0 Gy per fraction). A University of Wisconsin phase I dose escalation trial for 25 fractions evaluated doses from 57 to 85.5 Gy using IMRT.[88] Based upon their protocol-defined criteria, 63.25 Gy in 25 fractions was the maximally tolerated dose. Higher doses had concerning rates of grade 4 to 5 toxicities related to central and perihilar structures, such as the proximal bronchial tree.

A UT-Southwestern (UTSW) phase I dose escalation trial for 15 fractions evaluated doses from 50 to 60 Gy, with all arms being well tolerated and no association between fraction size and toxicity.[89] In a subsequent UTSW trial, patients were randomized to 60 Gy in 15 or 30 fractions to determine if the hypofractionated course would yield superior 1-year OS. No statistically significant difference was found in survival or toxicity outcomes.[90]

Taken together, these data suggest that dose escalation can be achieved safely in locally advanced NSCLC via novel hypofractionation and treatment delivery approaches. However, caution should be employed when considering hypofractionated regimens beyond 60 Gy per 15 fractions, particularly in ultracentral locations.

Volume of Radiation With Definitive Radiotherapy: Involved-Field Versus Elective Nodal Irradiation in Inoperable Stage III Non–Small Cell Lung Cancer

In the era of 2D RT for NSCLC, it was customary to include the elective nodal basin in the radiation portals for any patient receiving curative-intent RT, regardless of stage. There is ample evidence that the elective nodal basins can be safely omitted in stage I NSCLC in patients who have undergone modern clinical staging.[28,86] Although ^{18}FDG-PET/CT has become an indispensable tool for noninvasive staging of the mediastinum, studies have shown that FDG-PET may carry up to a 25% false-negative rate in lymph nodes less than 1 cm in the short axis.[11,91]

Motivated by this concern, several studies have examined the rate of elective nodal failure in patients treated with involved-field radiotherapy (IFRT) and have shown this to be a relatively rare event of less than 5% to 10%.[92,93] In the only prospective study of elective nodal irradiation (ENI) versus IFRT, Yuan et al[94] compared IFRT 68 to 74 Gy versus ENI 60 to 64 Gy, showing an increase in 2- and 5-year local control with IFRT of 8% and 15%, respectively (only statistically significant at the 5-year time point). In addition, Yuan et al demonstrated an improved OS rate at 2 years with IFRT (39.4% vs 25.6%, P = .048) and higher pneumonitis rates in patients treated with ENI (29% vs 17%, P = .044). Although interesting, this study has been criticized for the imbalances in the radiation dose delivered and lung V_{20} between the two arms. In a single-institution retrospective cohort comparison of patients receiving definitive 3DCRT for locally advanced NSCLC, Fernandes et al[95] analyzed 108 consecutive patients treated with either ENI (median dose 63.6 Gy) or IFRT (69.9 Gy). In a multivariable logistic regression analysis, the IFRT cohort had a lower risk of high-grade esophagitis (odds ratio [OR] 0.31, P = .036).

The incorporation of routine PET/CT for staging led to a phase 2 noninferiority trial PET-Plan/ARO-2009-09, which sought to determine whether planning using PET/CT could allow reduced target volumes. The trial randomized patients to chemoradiation planned using PET alone (PET-directed) compared to conventional planning (using PET, CT-size criteria, and ENI). The PET-directed arm mean dose was 67.3 Gy compared to 65.3 Gy for the conventional arm. One-year locoregional progression was noninferior in the PET-directed arm in both the per-protocol and ITT analysis, ranging from 14% to 17% compared to 29% to 30% in the conventional target arm. Invasive mediastinal sampling was per the treating physician.[96]

These studies support that IFRT can be employed in patients with locally advanced NSCLC without risk of significant compromise in clinical outcome and with possibly decreased side effects.

Combined Modality

Induction Chemotherapy

In locally advanced NSCLC, the dominant pattern of failure in these patients was through distant dissemination in about 75% to 80% of patients.[84] To address the issue of whether adding induction chemotherapy to radiation would improve survival in locally advanced disease, multiple phase III trials looked at adding induction chemotherapy before radiation regimens. CALGB 8433 randomized 155 patients with unresectable stage III NSCLC with excellent performance status and showed that chemotherapy increased median survival from 9.6 to 13.7 months (P = .0066).[97] Subsequently, RTOG 8808 randomized 490 patients and showed an improved median survival of 13.8 months with induction chemotherapy compared to 11.4 months with standard RT and 12.3 months with hyperfractionated RT (P = .03).[98] A similar Gustave-Roussy trial with more intense induction chemotherapy did show decreased distant metastases though the improvement in OS did not reach statistical significance (2-year OS 21% vs 14%).[99] Overall, these trials established the role of chemotherapy, in addition to radiation, in the management of unresectable stage III NSCLC (Table 57.5).

TABLE 57.5 SEQUENTIAL CHEMOTHERAPY VERSUS RADIATION THERAPY ALONE FOR LOCALLY ADVANCED NON–SMALL CELL LUNG CANCER

CT, chemotherapy; PV, cisplatin, vinblastine; RT, radiation therapy; VCPC, vindesine, cyclophosphamide, cisplatin, lomustine.

Concurrent Chemoradiotherapy

To determine the efficacy of chemotherapy radiosensitization, the EORTC performed a phase III randomized trial comparing concurrent cisplatin-based chemoradiation to RT alone. They demonstrated a clear survival benefit to chemotherapy radiosensitization that was attributed to improvement in local control, given no difference in distant metastases.[100] A Cochrane meta-analysis of 19 randomized studies and 2,728 patients compared concurrent chemoradiation with definitive radiation.[101] Concurrent chemotherapy improved the overall risk of death (HR 0.71) and overall PFS (HR 0.69) at the expense of increased acute toxicity, especially severe esophagitis with concurrent treatment (relative risk [RR] 4.96).

Concurrent Versus Sequential Chemoradiotherapy

Initial phase II trials suggested that concurrent chemoradiotherapy—with response rates of 75% to 85%—might be more effective than sequential chemoradiotherapy,[102,103] which was subsequently confirmed in phase III trials. Furuse et al[104] performed a phase III trial comparing concurrent chemoradiotherapy with mitomycin, vindesine, and cisplatin given at systemic doses to sequential chemotherapy and RT, showing improved survival with the concurrent approach (median survival of 16.5 vs 13.3 months and 5-year survival of 15.8% vs 8.9%). RTOG 9410 compared two different concurrent regimens (cisplatin and vinblastine with conventional RT, arm 1, or cisplatin and oral etoposide with hyperfractionated RT, arm 2) to a "standard" sequential regimen of cisplatin and vinblastine followed by conventional RT (arm 3). Comparing arm 1 to arm 3 (as per the study design), median survival times improved significantly (17 vs 14.6 months), as did 5-year survival (15% vs 10%) with an increase in acute grade 3 through grade 5 nonhematologic toxicities.[105] The survival in arm 2 was not significantly better than arm 1, although this intensive regimen was associated with much higher esophageal toxicity. A meta-analysis of six trials by Auperin et al[106] showed a significant benefit to concurrent over sequential chemotherapy and RT with an absolute increase in 3-year OS of 5.7% (from 18.1% to 23.8%) and in 3-year PFS of 2.9% (from 13.1% to 16.0%). Concurrent chemoradiotherapy decreased locoregional progression (34.1% to 28.1% at 3 years), although not distant progression. Again, this improvement in locoregional control came at the expense of greater acute toxicity for patients receiving concurrent chemoradiotherapy, with an increase in acute esophageal toxicity (grades 3 and 4) from 4% to 18% with an RR of 4.9 ($P < .001$).

Because of the increased toxicity with concurrent chemoradiation, especially acute esophagitis, there can be treatment delays that have been found to be detrimental in terms of radiobiologic efficacy.[107] Meta-analysis of RTOG trials with concurrent chemoradiation demonstrated that on multivariable analysis, there was a 2% decrease in OS for each additional day beyond 5 days from the planned end of treatment.[108] Appropriate patient selection and maneuvers to minimize toxicity are increasingly important to minimize the likelihood of treatment delays that can compromise the efficacy of concurrent therapy.

In summary, these studies established concurrent over sequential chemoradiotherapy as the standard approach for patients with good performance status and minimal weight loss, at the expense of greater toxicity to the patient, especially esophagitis.

Cytotoxic Platforms for Concurrent Chemoradiotherapy in Locally Advanced Non–Small Cell Lung Cancer

Several chemotherapy regimens that pair cisplatin or carboplatin with etoposide, vinorelbine, mitomycin, vindesine, irinotecan, paclitaxel, docetaxel, and pemetrexed have each been studied; unfortunately, few head-to-head trials comparing these agents have been conducted. There is no single regimen that could be considered standard. In North America, the most common prescribed regimens are either cisplatin and etoposide (EP) at systemic doses or carboplatin and paclitaxel administered weekly during RT. Unlike limited SCLC, where cisplatin is dosed at 60 mg/m^2 every 3 weeks and etoposide at 80 to 120 mg/m^2 daily × 3 both during and after radiation,[109] an alternative dose and schedule is generally used. There are abundant data from the SWOG and RTOG for a schedule that was ultimately phase III tested in RTOG 9309 and later by the Hoosier Oncology Group: specifically, cisplatin 50 mg/m^2 days 1 and 8, 29 and 36; and etoposide 50 mg/m^2 intravenously days 1 through 5 and days 19 through 33.[59,61,110] This schedule, while inconvenient, is tried and tested and generally safe. The carboplatin-paclitaxel regimen is administered weekly during radiation with a carboplatin dose of area under the curve (AUC) of 2 and paclitaxel at 40 to 50 mg/m^2. Prior to the era of immunotherapy after radiation was completed, two more cycles were administered 3 weeks apart using a higher (systemic) dosage of both agents (carboplatin AUC 6 and paclitaxel 200 mg/m^2). Given its favorable toxicity profile and superiority to gemcitabine in combination with cisplatin in advanced nonsquamous NSCLC, pemetrexed has been widely adopted in the metastatic setting, The PROCLAIM study randomized patients with stage III nonsquamous histologies to either EP or cisplatin with pemetrexed during definitive thoracic radiation.[111] After 598 patients were enrolled, the study was stopped early because of futility; no difference was observed between the two arms with respect to OS (26.8 vs 25 months, HR = 0.98, 95% CI 0.79-1.20, P = .83), median PFS (11.4 vs 9.8 months, HR, 0.86, 95% CI 0.71-1.04, P = .13), and response rates (35.9% vs 33%, P = .45). The only clear toxicity difference was a higher incidence of neutropenia for patients treated with EP (54.8% vs 44.5%, $P \leq .05$).

Given the lack of evidence for a “best” or preferred regimen, clinicians and patients need to decide which chemotherapy to choose based on other considerations, including histology (pemetrexed only useful for patients with nonsquamous histology), potential toxicities (eg, kidney injury for cisplatin, neuropathy for paclitaxel), and cost. It is important to remember that only patients who are treated with cisplatin-based regimens receive adequate systemic doses of chemotherapy. Although weekly carboplatin and paclitaxel are useful as a radiosensitizer, the doses of chemotherapy are unlikely to eradicate micrometastatic disease and are, therefore, likely inferior systemic treatment.

In patients who will receive high lung V_{20} (percentage of normal lung that will receive ≥20 Gy) more than 35% or in those with borderline pulmonary function or other comorbidities, many clinicians consider administration of chemotherapy first for two or even three cycles, followed by radiation alone or concurrent chemoradiation if there has been sufficient tumor shrinkage to allow a more reasonable RT treatment field. In those with minimal or no tumor shrinkage using this approach, some investigators omit concurrent chemotherapy during radiation to avoid untoward toxicity, proceeding with radiation alone. These patients are often much more symptomatic than those with smaller volume tumors, with postobstructive symptoms including wheezing, pneumonitis, and hypoxia, and often have compromised performance status. However, the one study to isolate the role of induction therapy prior to concurrent chemoradiation with paclitaxel and carboplatin failed to show a survival advantage compared to concurrent chemoradiation alone.[112]

Toxicity mitigation is another major challenge that has been inadequately addressed. Both acute esophagitis and long-term pneumonitis and pulmonary fibrosis are common complications of combined modality therapy. A meta-analysis demonstrated a 6-fold increase in short-term esophagitis, grade 3, or worse (18% vs 3%) in those receiving concurrent chemoradiation as opposed to asynchronous or sequential chemotherapy and radiation.[106] Randomized trials evaluating amifostine as an esophageal protectant failed to show a significant reduction in esophagitis rates.[113,114] Advances in technologies including proton therapy (PT) may help reduce

the severity and duration of acute and late esophageal and pulmonary effects. This is currently under investigation.

Immunotherapy After Radiation

The addition of immunotherapy to the treatment of lung cancer has been one of the most important developments in the treatment of this disease in the past decade. Immunotherapy using ICIs has changed the paradigm of treatment of lung cancer and many other malignancies. A detailed explanation of ICI is outside the scope of this review, and readers of this chapter are referred to many excellent reviews on this topic.

The PACIFIC trial was a phase 3, randomized, double-blind, placebo-controlled trial that demonstrated that the addition of a PD-L1 ICI after chemotherapy and radiation dramatically improved OS.[115] Seven hundred and thirteen patients who had not progressed after concurrent chemoradiotherapy were randomly assigned on a 2:1 ratio to receive either durvalumab or a placebo for 12 months. The final analysis of the trial showed that patients who received durvalumab had an improvement in PFS (median 16.8 vs 5.6 m, HR 0.52, 95% CI 0.42-0.65) and OS with a median of 47.5 versus 29.1 months with placebo (HR 0.72, 95% CI 0.59-0.89).[115] In exploratory analysis, the PFS and OS benefit was seen across all levels of expression of PD-L1, with the exception of OS in patients who had a negative expression of PD-L1 where the HR for OS was 1.15 (95% CI 0.75-1.75). In the United States, the use of durvalumab is approved by the Food and Drug Administration, independent of PD-L1 expression, whereas the European Medicine Agency approved it only in patients with a PD-L1 1% or greater. Immune-mediated adverse events of any grade were reported in 24.2% of patients treated with durvalumab. These were grade 3 or greater in 3.4% of patients with pneumonitis being the most common one.[116] For patients who are not candidates for concurrent chemoradiation, the PACIFIC-6 study was a trial that demonstrated that patients treated with sequential chemotherapy and radiation experience a comparable safety profile and an improved efficacy compared to historical controls treated without immunotherapy.[117] These trials included patients with mutation-driven NSCLC in very small numbers. The use of adjuvant immunotherapy in this subpopulation is currently a matter of controversy, as patients with advanced EGFR-mutated cancers have not shown to benefit from immunotherapy in phase 3 trials.[118] Furthermore, there is concern that starting a TKI shortly after the use of an ICI may increase the risk of TKI-associated pneumonitis. Therefore, the use of immunotherapy for patients with EGFR and ALK abnormalities is currently not recommended, though whether this applies to other driver mutations is a matter of intense debate and controversy.

Targeted Agents in Locally Advanced Disease

Identifying oncogene-driven NSCLC has led to the development of targeted therapy. This treatment has revolutionized the treatment and outcome of patients who have NSCLC that are driven by molecular abnormalities. Prior to the identification of molecular abnormalities, the use of targeted therapy with or after chemoradiation in all patients with NSCLC was not successful[119,120] and even detrimental as was in the case of the use of gefitinib, a TKI, which we now know is effective only in patients with EGFR mutations.[121] These studies underscore the need for biomarker designed clinical trials.

Unfortunately, the study of use of targeted agents in patients with molecularly driven NSCLC treated with chemoradiation has been proven extremely difficult. In patients with EGFR mutations, early-phase studies have proven the safety and preliminary efficacy of adding EGFR TKI to radiation.[122,123] RTOG 1306/Alliance 31101 aimed to compare standard chemoradiation versus induction erlotinib or crizotinib for 12 weeks followed by chemoradiation; this study was terminated because of poor accrual after 59 of 234 patients were accrued. The LAURA study (NCT03521154) is a global randomized study that evaluates if the addition of osimertinib after chemoradiation improves PFS compared to placebo in patients with stage III NSCLC with EGFR mutations.

For patients with other driver mutations, there is currently no data to guide us on whether targeted therapy should be added after chemoradiation.

Dose Escalation With Concurrent Chemoradiotherapy

Although concurrent chemoradiotherapy has emerged as the standard therapeutic approach for fit patients with unresectable locally advanced disease, suboptimal locoregional control necessitated investigations into dose escalation. Although phase II trials showed promise in dose escalation with concurrent chemotherapy,[124,125] RTOG 0617 showed a detriment to 74 Gy compared with 60 Gy, and 60 Gy remains the standard dose in stage III NSCLC treatment. RTOG 0617 was a 2 × 2 phase III trial of 544 patients to simultaneously examine the question of 60 versus 74 Gy concurrent chemoradiation with or without cetuximab in inoperable stage III NSCLC. At a median follow-up of 5.1 years, median survival was 28.7 months for patients who received standard-dose radiation and 20.3 months for those who received high dose (HR 1.35, 95% CI 1.08-1.69; $P = .0072$). Cetuximab did not improve survival and added severe toxicity (grade ≥3, 87.3% vs 71.2%, $P < .0001$). Both the radiation dose and cetuximab results crossed protocol-specified futility boundaries. There were no statistical differences in overall grade 3 toxic effects or greater between RT groups, though if esophagitis and dysphagia were combined, high-dose group experienced more of these toxicities (20.8% vs 7.3%, $P < .0001$). There were more treatment-related deaths in the high-dose radiation group (nine vs three patients). There were no differences in grade 3 pulmonary events or greater between treatment groups. Multivariable analyses in the RTOG 0617 reports[119,126] and related publications[127] have suggested that heart volume exposure (eg, V_5, V_{40}) are prognostic for survival. Multiple modeling efforts have attempted to define cardiac substructure-specific constraints, which is an area of active investigation.[128,129]

Superior Sulcus Tumors and Pancoast Syndrome

Superior sulcus tumors (SSTs) were first described in 1838 and the characteristic accompanying neurologic symptoms in 1932 by Dr Henry Pancoast. SSTs account for less than 5% of all lung cancer.[130] The most common symptom among patients with SST is pain in the shoulder attributable to direct invasion of the parietal pleura, vertebral body, ribs, or brachial plexus (Figure 57.2). Pain radiating down the ulnar aspect past the elbow indicates T1 nerve root involvement, whereas pain in the fourth and fifth digits indicates involvement of the C8 nerve root. There may be weakness or atrophy of the intrinsic muscles of the hand. Involvement of the stellate ganglion may manifest as Horner syndrome: the triad of ptosis, miosis, and hemifacial anhidrosis. Irritation or compression of the adjacent sympathetic chain may cause ipsilateral flushing and sweating of the face or reflex sympathetic dystrophy, a regional syndrome of burning neuropathic pain. Pancoast syndrome is a constellation of signs and symptoms, including shoulder/arm pain, Horner syndrome, and unilateral upper extremity weakness.

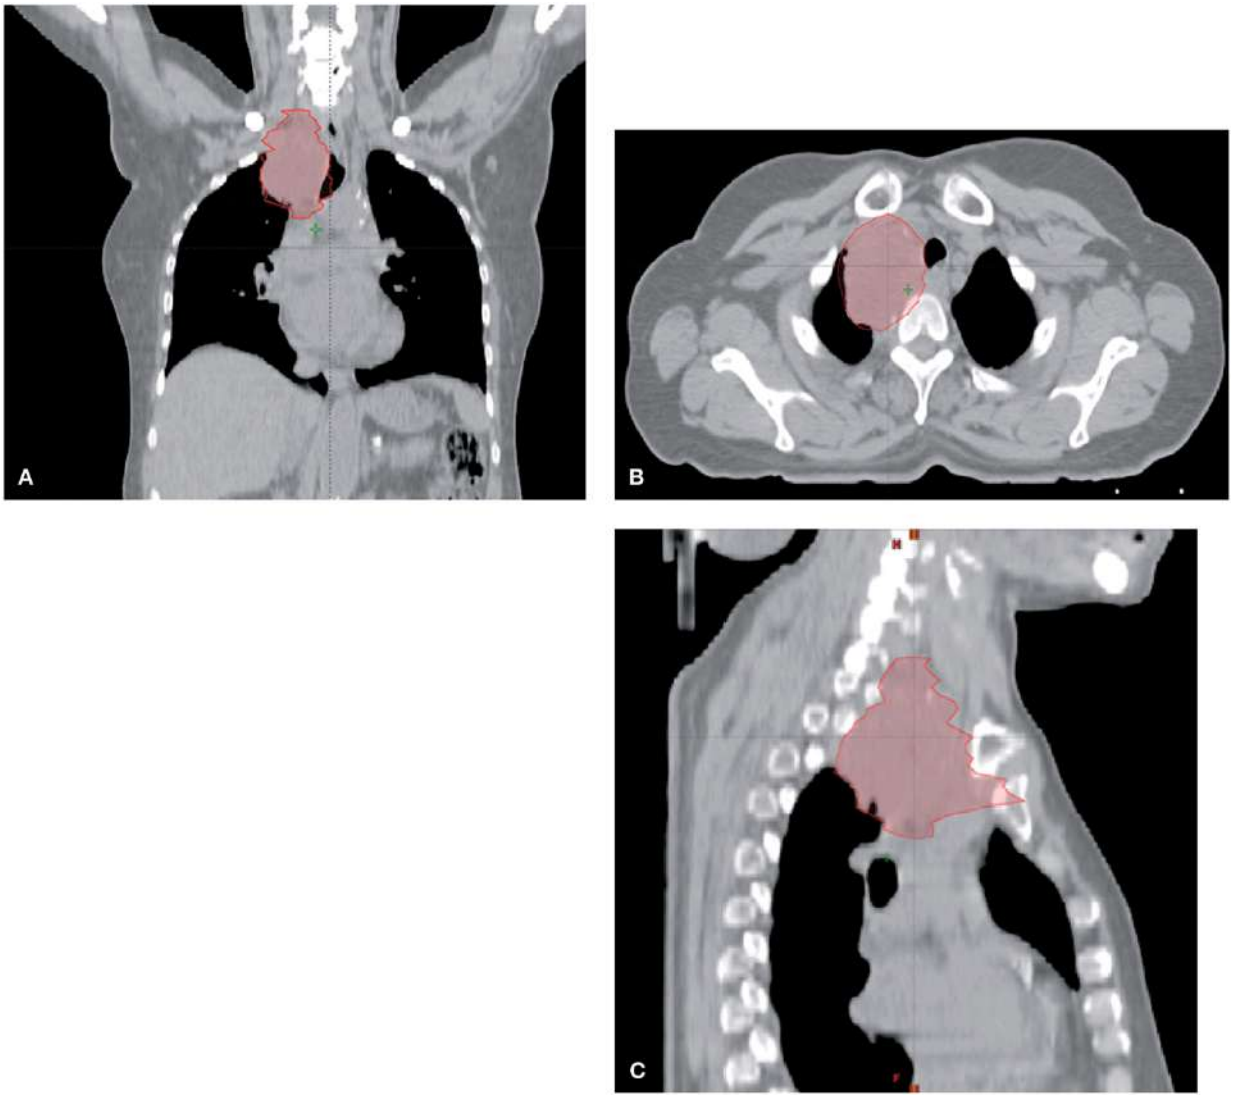

FIGURE 57.2 A 51-year-old person who has smoked formerly presented with right shoulder pain and right-sided Horner syndrome and was found to have an adenocarcinoma in the right superior sulcus. A. Coronal view with gross tumor volume (GTV) contoured. B. An axial view with GTV contoured. A 4-cm tumor is seen invading the mediastinum with displacement of the trachea. He underwent a staging evaluation including mediastinoscopy and was staged as T4N0M0. C. Sagittal view with GTV contoured showing vertebral body impingement. The patient was treated with radiotherapy with concurrent cisplatin and etoposide to 50 Gy and underwent resection with negative margins.

Determining the feasibility of resection is a critical decision point in the management of NSCLC SSTs. Because of the apical location of the tumor, invasion of the brachial plexus, vertebral bodies, and subclavian vessels is not uncommon and may preclude surgical resection as an option, magnetic resonance imaging (MRI) is recommended for determining involvement of these structures.

Multimodality Therapy for Superior Sulcus Tumors

SWOG 9416/Intergroup 0160 included 110 patients with T3 to 4, N0 to 1 SSTs. All patients were treated with neoadjuvant concurrent chemoradiation (45 Gy in 25 fractions with two cycles of cisplatin/etoposide), followed by surgery within 3 to 5 weeks, and then two further cycles of chemotherapy.[131] Eighty-eight patients (80%) underwent surgery, and 83 (76%) had complete resection. The 5-year OS was 44%. Sixty-one resected patients (56%) had a pathologic complete response to induction therapy, and their 5-year survival was

significantly better at 54%. The JCOG 9806 trial showed similar results with 76% of patients undergoing surgery and 5-year OS 56%.[132]

Patients with unresectable localized SSTs and those with stage III disease and bulky N2 (or N3) lymph nodes should be treated with definitive chemotherapy and radiation.[133,134] A retrospective analysis from the Netherlands examined the outcome of 49 patients with stage II or III SST who received 66 Gy with daily cisplatin (6 mg/m^2).[135] Nineteen patients had sufficient response to undergo resection, and in these patients, there was a 53% pathologic complete response rate. The 5-year OS was 18% in patients who received chemoradiotherapy and 33% in patients who were able to undergo surgery.

CURRENT RADIOTHERAPY TECHNIQUES AND FUTURE DIRECTIONS

The treatment of lung cancer presents unique challenges from the technical perspective, due to the combination of breathing motion, significant tissue heterogeneity, and, in some cases, the need for frequent treatment adaptation. All these challenges become even more severe when complex treatment techniques are used, such as SBRT or PT.

The developments of the past 10 to 15 years led to a large-scale availability of tools and techniques for adequate management of these technical difficulties. There are indications that the introduction of improvements such as adaptive therapy and daily alignment on tumor based on CBCT imaging had a measurable clinical impact.[136] SBRT has become the standard of care in inoperable stage I NSCLC, thanks to excellent results in local control and low toxicity.[137] At the same time, techniques such as SBRT require a high level of confidence in the accuracy of the overall treatment workflow,[138] and ensuring a high technical quality of treatments at a large scale is challenging. For instance, it has been shown that it is possible to generate lung SBRT plans that fulfill internal quality assurance criteria but are associated with an expected inferior outcome.[139]

Imaging for Treatment Planning

Accuracy in this phase of treatment preparation is crucial, as uncertainties in representing either the patient anatomy or the tissue density will in principle result in systematic errors. CT is the key imaging method to generate a 3D model of the patient's anatomy for treatment planning. The reproducibility of patient positioning should be maximized, which in the case of patients with lung cancer means achieving two goals:

1. Finding a good balance between patient comfort, so that the position can be maintained during the treatment sessions, and reproducibility, so that after imaging the patient position can be adjusted via small translations and/or rotations of the couch
2. Facilitating inter- and intrafraction regularity of breathing in terms of both motion amplitude and relation between external references (eg, the patient surface) and internal anatomy

The patient is typically scanned with both arms above the head, to maximize the degrees of freedom in choosing beam directions, and the scan should encompass the whole-lung volume, including the costophrenic recesses.

Several methods are available to describe the breathing motion in an image data set that will be then used in treatment planning.[140] The most common imaging approach is the respiratory correlated 4DCT, which represents the breathing motion in the region of interest via multiple intrinsically registered 3D data sets (typically 10). 4DCT helps inform a decision about the motion management approach, which is typically considered for patients with a target motion of more than 5 mm.[140] The 4DCT is also used to generate additional data sets for contouring and/or dose planning, such as the average, mid-ventilation,[141] and maximum intensity projection. These data sets retain some information about the breathing motion but are not associated with the computational burden of a 10-phase 4DCT. For treatments in free breathing, the most common data set for planning is the average CT, where the Hounsfield Unit value for each voxel is the average across the breathing cycle.

Systems for motion mitigation should be considered in case of large motion amplitude, with the caveat that for some of them, for example, breath-hold, reproducibility, and patient compliance may be an issue.

Target Definition and Planning Techniques

Gross Tumor Volume

Clinical macroscopic disease is defined as the GTV. The GTV in the patient with lung cancer is usually derived from a treatment planning CT or PET/CT obtained during quiet respiration. Intravenous contrast is usually not required for identification of the primary tumor unless it is located adjacent to the hilum or mediastinum. European Society for Radiotherapy and Oncology guidelines[142] recommend the preset lung window setting (W = 1,600, L = −1,600) to delineate tumors surrounded by lung parenchyma and the preset mediastinum window setting (W = 400, L = 20) to delineate lymph nodes and tumors invading the mediastinum. A PET/CT within 3 weeks of starting radiation is recommended to avoid stage migration with increasing time to treatment. Intravenous contrast may be valuable in identifying nodal disease. On CT, a short-axis diameter 1 cm or more is often employed for identification of pathologically involved nodes. However, this cutoff is unsatisfactory, having a relatively poor sensitivity of approximately 60% for correctly identifying nodal disease. Meta-analyses suggest that FDG-PET/CT sensitivity and specificity are around 80% and 90%, respectively, compared to CT at around 60% and 80%, respectively.[11,143] The gold standard for the identification of mediastinal nodal disease is through invasive staging. When feasible, the mediastinum should be pathologically staged through either cervical or mediastinoscopy EBUS-TBNA; this information should be incorporated into delineating the nodal GTV. Current studies investing incorporating systematic prechemoradiation nodal sampling suggest that EBUS-TBNA for treatment planning can decrease organ at risk doses as well improve coverage of PET-occult nodal disease.[144,145]

Clinical Target Volume

The clinical target volume (CTV) represents a volumetric expansion of the GTV to encompass microscopic disease. For the primary tumor, pathologically derived correlative data have shown that a 7- to 9-mm margin would encompass all microscopic disease in 90% to 95% of lung adenocarcinomas, whereas a 4- to 6-mm margin would be sufficient in 90% to 95% of lung squamous cell carcinomas.[146,147] A study by Meynard et al[148] using modern pathology techniques recommend primary tumor expansions of 7 and 4 mm margins for adenocarcinoma and squamous cell carcinoma, respectively. For nodal disease, surgical series have shown that a 3-mm margin will encompass 95% of the microscopic extranodal extension of disease in lymph nodes less than 2 cm. However, larger margins may be required for lymph nodes more than 2 cm.[149]

Planning Target Volume

In x-ray RT, geometrical uncertainties are taken into account during planning via the definition of a PTV, which is an expansion of the GTV/CTV with appropriate margins.[150] Planning margins should be defined for each treatment protocol considering these aspects: frequency of imaging for positioning (eg, daily vs weekly), type of imaging and alignment (eg, 2D projections and “bone match” vs 4D CBCT and “tumor match”), and motion management approach (eg, free breathing vs breath-hold). While the same positioning margins should be used for a population of patients treated with the same immobilization systems and imaging/alignment protocol, the margin for breathing motion should be defined at the level of the individual patient.

These additional issues should be considered while defining margins in lung cancer treatment:

1. Any choice of imaging method and volume definition is associated with uncertainties and trade-offs: For instance, the 4DCT is based on a few breathing cycles on a single day, which may not be fully representative of the intra- or even interfraction breathing motion.
2. Commonly used “margin recipes” can also incorporate breathing motion.[151] If one considers the breathing motion as a potentially source of systematic and random errors, the benefit of a 4DCT with respect to a 3DCT is even more evident, as it allows to remove the systematic uncertainty due to the periodic breathing motion. This will lead to a significant reduction in the margin needed to compensate for this component of the breathing motion. One the other hand, the breathing motion baseline may change, and this should be considered a source of systematic error.[141]
3. The margin depends also on the beam penumbra, which is shallower in the lung than in higher density tissue, and the PTV approach assumes that the motion of the CTV will not affect the PTV dose (“static

dose cloud approximation"). When the PTV encompasses a volume with significant tissue heterogeneities, the question of whether the PTV dose metrics are representative of the dose to the moving CTV does not have a simple answer. For instance, a study investigating the influence of GTV motion on SBRT dose distributions found that the dose to the moving GTV was closer to the dose of the static GTV and internal target volume (ITV) than to the PTV dose.[152] This resulted because the GTV had a higher density than the surrounding tissue and the dose distribution was essentially moving together with the GTV.

A detailed analysis of this aspects, in particular in the initial clinical implementation of complex techniques, will help define appropriate treatment margins and fully appreciate what improvements in the treatment workflow will contribute the most to margin reduction.[153]

The most common approach do define a margin for breathing motion in clinical practice is to use the 4DCT to define an ITV, which is the volume encompassed by the GTV/CTV throughout the breathing cycle (Figure 57.3).[154] This is the most expedient way to include a margin for breathing motion. This contour is then transferred to a 3D data set, typically the average CT, and planning is performed on a PTV defined as ITV plus an additional margin for setup error. The main disadvantage of the ITV is that it is a conservative approach with respect to target coverage that is ensured at the expense of a higher dose than strictly needed to healthy tissues in its proximity. By comparison, an analysis of 297 lung SBRT patients treated with a mid-ventilation–based PTV margin estimated that an ITV + 5 mm expansion would have resulted in a bigger PTV for 47% of the patients.[155] These two margin approaches have not been directly compared in the clinic, and they are both associated with high local control and low toxicity.

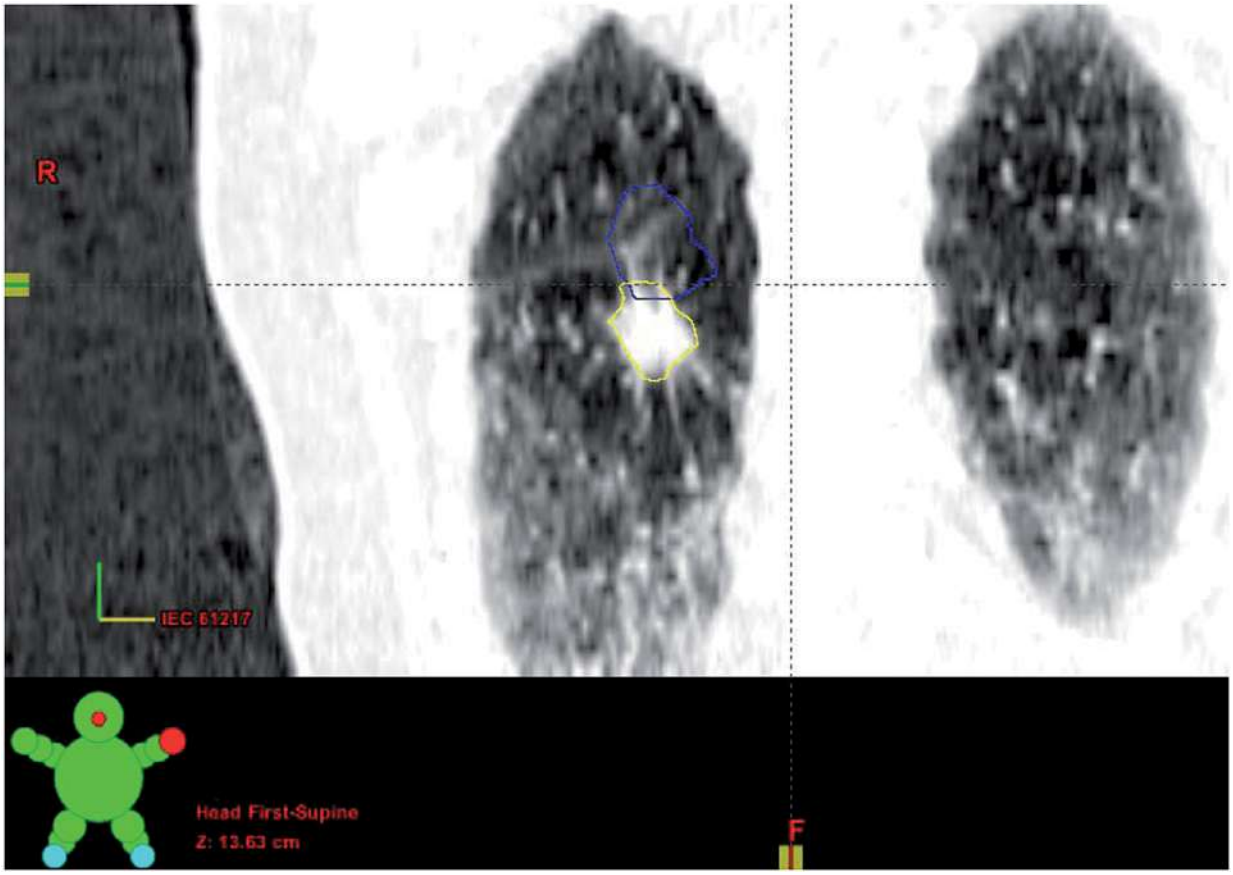

FIGURE 57.3 Tumor motion during a patient's normal respiratory cycle. The yellow wireframe shows the tumor position at full inspiration. The blue wireframe shows the tumor position at full expiration.

In some treatment planning software, it is possible to include the full 4D data set in treatment plan optimization, thus removing the need of a margin for the periodic breathing motion. This method also has the advantage of explicitly considering the dose perturbation due to breathing motion in the optimization process. However, this advanced planning approach also has disadvantages (eg, it is computationally more intensive and delineated contours should be available for all phases), and it is not the norm in clinical practice.

Treatment Planning

According to the tumor volume, shape, and location; the dose prescription; and the available beam technology, lung cancer is treated with techniques ranging from 3DCRT to static IMRT and volumetric-modulated arc therapy (VMAT).

3DCRT can be used to generate clinically acceptable dose distributions when the target volume has a regular shape, and the dose conformity requirements are not stringent. However, the quality of 3DCRT dose distribution drops significantly with large and/or irregularly shaped targets, where techniques using intensity modulation should be preferred.[156-158]

The first application of intensity-modulated treatments in lung relied on static field IMRT. Over the years, VMAT became the technique of choice for most patients, as it is typically associated with the same quality of dose distribution and a significantly lower beam delivery time.[159] The combination of VMAT and flattening filter free beams allows for an even faster delivery,[160] which positively affects patient comfort and reduces intrafraction motion.

Due to the radiation sensitivity of healthy lung tissue at low doses, the balance between dose conformality and normal tissue sparing may lead to different solutions in lung according to the specific clinical scenario. For instance, if the lung is the only dose-limiting organ, fewer beam directions, or narrower arcs, should be preferred: This approach will be associated with a lower lung volume receiving low-intermediate doses between 5 and 20 Gy, and it may be worth the cost of a slightly worse conformity. On the other hand, there are situations where the dose conformity should be maximized, for example, because a high dose is prescribed and the esophagus is adjacent to the target volume: This will in general lead to a plan with several beams, or broader arcs, that will result in a good conformity but also with a larger lung volume receiving a nonzero dose.

In intensity-modulated techniques, it is possible that the lung volume receiving low doses will be larger than in 3DCRT, due the increase in number of beams and in Monitor Units,[161] due to the presence of many small segments. This is not an inevitable consequence of using IMRT, which can generate lung dose distributions at least as good as 3DCRT in the low-dose region,[162] but rather the results of specific planning approaches. It is, therefore, important to carefully "drive" the optimization process in the desired direction, for example, by properly selecting the beam geometry, avoiding strict constraints on target dose uniformity, and limiting the contribution of small segments to the total dose. Generating a plan where most of the dose is delivered with larger segments will also reduce the dosimetric impact of interplay (see later).

Another aspect that should be considered with intensity-modulated techniques is the so-called interplay effect, that is, the interaction between the time structure of beam delivery via multiple segments and the breathing motion. This effect can, in principle, cause both "cold spots" in the target and "hot spots" in healthy tissues. Extensive literature data suggest that interplay is not a primary concern in conventional fractionation. In fact, given the significant random component of the phenomenon,[163] estimated dosimetric impact is limited to 1% to 2% over the treatment course. Dose perturbations may become more prominent in SBRT and when fast beam delivery with a flattening free filter is considered, though most studies suggest that the interplay effect is still not associated with a significant dose deterioration.[162] In selected critical cases, it would be useful to estimate the interplay effect for a specific plan and breathing pattern, but this feature is unavailable in most treatment planning systems.

Lung RT is challenging from the point of view of dose calculation due to the presence of multiple transitions between tissues of significantly different densities. This heterogeneity causes a lack of charged particle equilibrium and a dose "build up" or "build down"[164] that cannot be accurately modeled with simple algorithms. The scenario becomes even more complex in highly conformal techniques and SBRT, when small fields shaped by multileaf collimators are applied, thus requiring an accurate modeling of the beam upstream

of the patient surface. It has been shown that pencil-beam dose calculation algorithms may lead to clinically significant differences with respect to more accurate methods, not only in SBRT[165-168] but even with simple 3DCRT techniques.[169] Dose calculation algorithms such as convolution/superposition or Monte Carlo[170] should be used for all lung RT treatments and are a must for complex techniques.[138]

Readers are encouraged to reference dose constraints from QUANTEC for 3D radiation planning,[171] published trial protocols for IMRT planning,[126] and HyTEC for SBRT planning.[172]

Image Guidance, Treatment Monitoring, and Treatment Adaptation

Image guidance systems are essential to ensure reproducibility in patient positioning and thus allowing for smaller margins. Daily megavoltage or kilovoltage planar imaging can be used, but volumetric CBCT is necessary in case of highly conformal techniques or small margins, as it increases the setup accuracy[173] and it allows to move from a positioning based on bone anatomy to a "tumor match." If available, a 4DCBCT should be preferred, as there are indications that it reduces the interobserver variability in patient alignment.[174] When the target volume is composed by a primary tumor in the lung and lymph nodes in the mediastinum, their motion is in general different (eg, more motion in a lower lobe tumor and less motion in a superior paratracheal node). Consequently, the setup strategy may favor accuracy in one part of the target over the other, and this could be reflected in the planning margins.

Surface guidance is an additional imaging method based on nonionizing radiation that cannot replace a CBCT but can be used for patient prepositioning before imaging, patient monitoring during treatment, and providing a beam-triggering signal.[175]

Breath-hold and beam gating are treatment options for patients with large breathing motion, even though the theoretical advantages should be weighed against the additional uncertainties associated with these methods: Breath-hold reduces tumor motion and may lead to better normal tissue sparing, but reproducibility issues have been reported[176]; the vast majority of gating approaches rely on a surrogate breathing signal (eg, the patient surface), whose relation with the internal anatomy can vary.[140]

Lung cancer treatments are also affected by interfraction anatomy changes (eg, in tumor volume, or in the anatomy of the lung) that may benefit from treatment adaptation. The proportion of patients requiring adaptation depends on factors such as the fractionation schedule, applied margin, the positioning protocol, and the minimum dose difference that triggers replanning. As a consequence, different institutions may report rate of replanning as different as 7%[177] vs 27%.[178] A commonly reported obstacle to the widespread use of adaptive therapy are limited human resources and technical limitations.[179] RT equipment designed to facilitate adaptive protocols is becoming increasingly available, and this will likely lead to an increase in treatment adaptation also in lung cancer. The ARTIA-lung randomized trial is investigating whether daily adaptation may decrease toxicity in locally advanced lung cancer (NCT05488626).

Physics Aspects of Particle Therapy for Lung Cancer

Protons and heavier ions have a dose depth deposition characterized by a peak followed by a very sharp dose falloff. This makes them an interesting option for RT in general and for lung cancer. The main dosimetric benefit of PT in lung cancer is a lower dose to the lungs, heart (including substructures), and esophagus, even though the extent of sparing depends on several factors, including the beam delivery technique (Figure 57.4). Scattering techniques are not always superior to x-ray techniques (XRT), and this may be one of the reasons why in a clinical trial comparing IMRT and PT delivered with scattered beams (NCT0915005), the proton arm was not associated with better dose distributions in the lung.[180] Pencil-beam scanning (PBS) has superior dose shaping capabilities to both passive scattering and IMRT, and this translates into better dose distributions in both planning studies and clinical practice.[181]

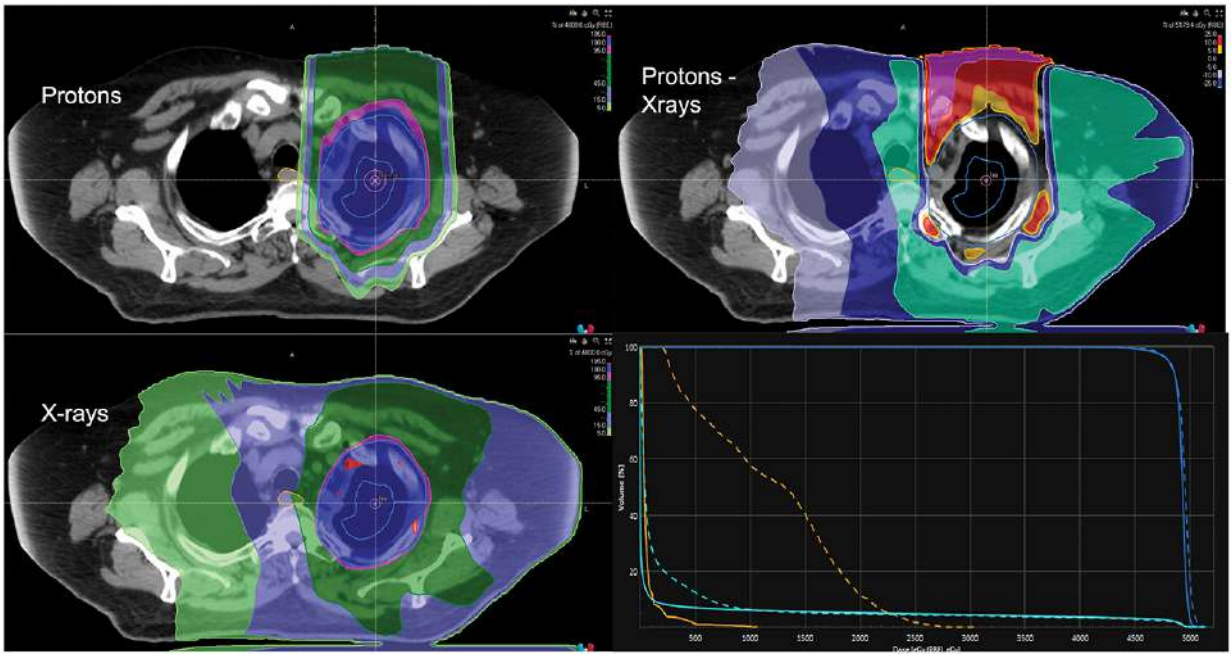

FIGURE 57.4 Comparison between a proton and a photon plan. The isodose levels correspond to 105%, 100%, 95%, 45%, 15%, and 5% of the prescribed dose. The dose differences are shown as the percentage of the prescription dose. Dose-volume histograms are shown for the planning target volume (darker blue), esophagus (orange), and lung (light blue). Solid and dashed lines are for the proton and the photon plan, respectively.

The very localized dose deposition of heavier charged particles is at the same time a strength and a potential weakness, as particle therapy dose distributions are in general more sensitive than XRT to uncertainties, such as patient positioning and breathing motion.[182] This sensitivity, combined with higher costs and reduced availability, means that only a small fraction of patients with lung cancer are treated with PT.

The increased sensitivity of proton dose distributions to intra- and interfraction changes in anatomy has two specific consequences in lung cancer treatment:

1. Treatment adaptation is more often necessary in PT than in XRT. In the NCT0915005 trial at MD Anderson, 29% of patients treated with PT needed plan adaptation versus 12% of those treated with IMXT.[183] A planning study suggested that up to 60% of the patients need treatment adaptation when PBS is used.[184] It is, therefore, recommended that patients with lung cancer treated with PT receive CT scans during the treatment course at regular intervals, for example, once a week, to verify the consistency between the planned and delivered dose.
2. The management of breathing motion is in general more critical than in XRT. The AAPM Task Group Report 290 on respiratory motion management in particle therapy[185] provides a detailed guideline on this topic. While some clinical scenarios (eg, a non-SBRT dose prescription combined with moderate breathing motion) can be safely planned on an average CT and treated in free breathing, more challenging situations require dedicated planning and delivery approaches. A robust optimization approach that considers not only setup and range error but also the breathing motion via multiple phases of the 4DCT should be the preferred approach. When this is not possible, an evaluation of the dose perturbation due to breathing motion should be performed, such as by recalculating the dose on all breathing phases. When possible, the time structure of PBS delivery should also be considered in plan evaluation, to assess the impact of interplay effects.

Pencil-beam dose calculation algorithms are inadequate for lung PT,[186] and Monte Carlo or methods of equivalent accuracy should be used in both plan optimization and final dose calculation.

For a systematic discussion of PBS treatments for thoracic tumors, the reader is referred to The Particle Therapy Cooperative Group consensus guidelines.[187]

METASTATIC NON–SMALL CELL LUNG CANCER

Basic Systemic Therapy Precepts

The treatment of metastatic NSCLC has continued to evolve. By the early 1990s, it was clear that platinum-based chemotherapy could prolong survival, improve symptom control, and yield superior QoL compared with BSC.[188] Over the past decade, the main advances in the treatment of patients with metastatic NSCLC have been the discovery of mutation-driven malignancies in a subset of patients, the advent of immunotherapy, and also active investigations into whether ablative doses of radiation can improve survival in patients with limited metastatic disease burden at the time of diagnosis or progression (Figure 57.5).

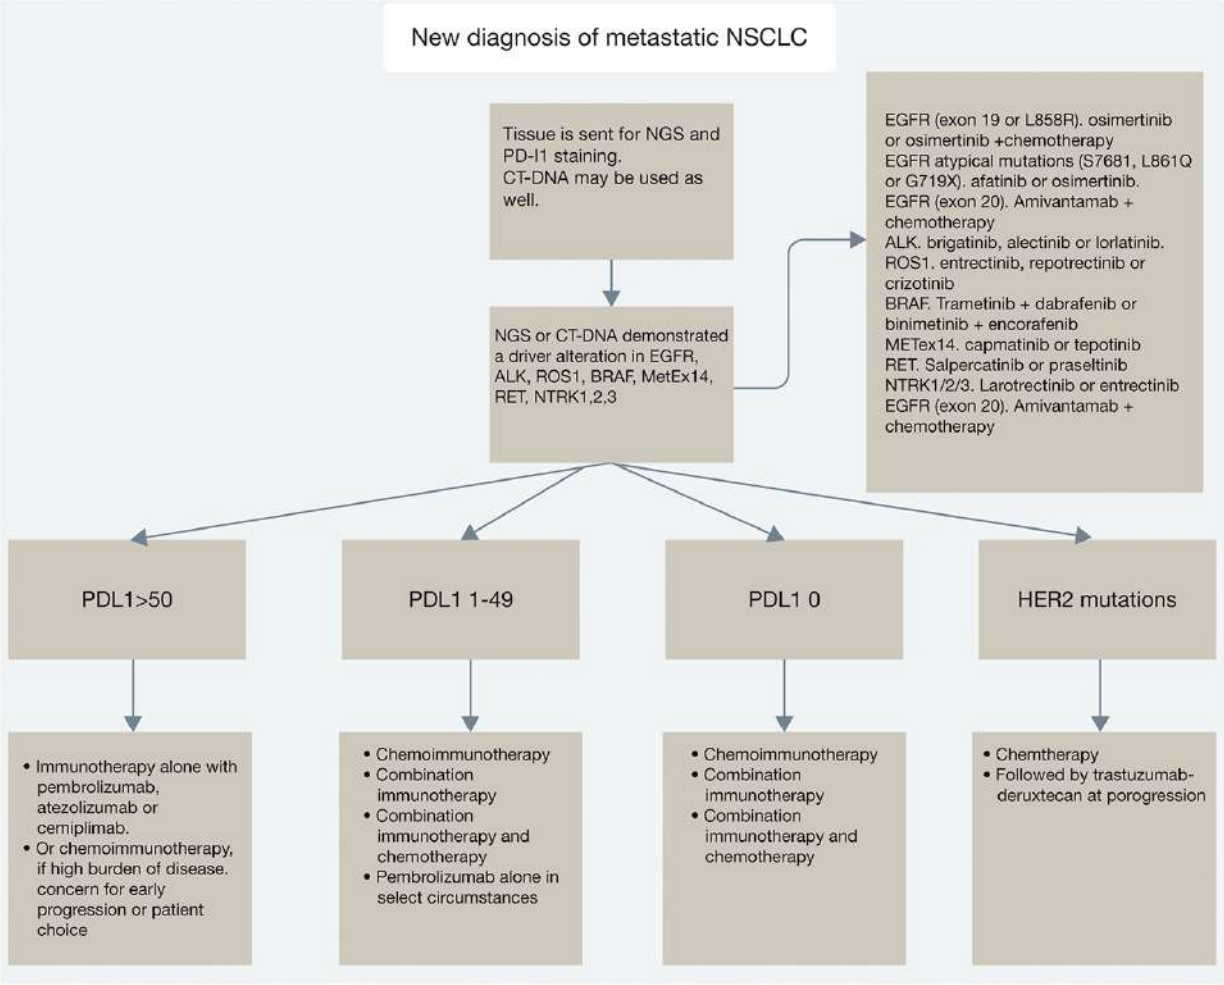

FIGURE 57.5 Molecular biomarker workup for a new diagnosis of metastatic non–small cell lung cancer (NSCLC) to decide on first-line systemic therapy. CT, computed tomography; EGFR, epidermal growth factor receptor; NGS, next-generation sequencing; PD-L1, programmed death-ligand 1.

Immunotherapy

Immunotherapy in the form of ICIs has dramatically changed the treatment paradigm for patients with a variety of malignancies. In NSCLC, treatment with PD-L1 inhibitors was first approved in patients with progressive disease after first-line chemotherapy; several trials demonstrated an improved outcome comparing ICI versus standard second-line chemotherapy (Table 57.6).[189,190]

TABLE 57.6 PHASE III TRIALS OF IMMUNOTHERAPY IN METASTATIC NON–SMALL CELL LUNG CANCER

Study	Intervention	Control	Population	ORR	PFS (mo)	OS (mo)
First-line PD-L1 monotherapy						
KEYNOTE 24[268]	Pembrolizumab	Doublet platinum chemotherapy	All NSCLC with a PD-L1 > 50%	46.1% vs 31.1%	7.7 vs 5.5 (HR 0.50; 95% CI 0.39-0.65)	26.3 vs 13.4 (HR 0.62; 95% CI 0.48-0.81)
KEYNOTE 042[191]	Pembrolizumab	Doublet platinum chemotherapy	All NSCLC with a PD-L1 > 1%	27.3% vs 26.7%	5.6 vs 6.8 (HR 0.79; 95% CI 0.70-0.89)	16.4 vs 12.1 (HR 0.79; 95% CI 0.70-0.89)
IMpower110[269]	Atezolizumab	Doublet platinum chemotherapy	All NSCLC with a PD-L1 > 1%	31.4% vs 32.1%	5.8 vs 5.6 (HR 0.72; 95% CI 0.60-0.86)	18.9 vs 14.1 (HR 0.85; 95% CI 0.69-1.04)
EMPOWER-Lung[193]	Cemiplimab	Doublet platinum chemotherapy	All NSCLC with a PD-L1 > 50%	46% vs 21%	8.1 vs 5.3 (HR 0.51; 95% CI 0.42-0.62)	26.1 vs 13.3 (HR 0.57; 95% CI 0.46-0.71)
First-line immunotherapy and chemotherapy						
KEYNOTE 189[195]	Pembrolizumab, carboplatin, and pemetrexed	Carboplatin and pemetrexed	Non-SCC	48.3% vs 19.9%	9 vs 4.9 (HR 0.50; 95% CI 0.42-0.60)	22 vs 10.6 (HR 0.60; 95% CI 0.50-0.72)
KEYNOTE 407[270]	Pembrolizumab, carboplatin, and taxane	Carboplatin and taxane	SCC	62.6% vs 38.4%	8 vs 5.1(HR 0.57; 95% CI 0.47-0.69)	17.1 vs 11.6 (HR, 0.71; 95% CI 0.58-0.88)
IMpower150[271]	Atezolizumab, carboplatin, paclitaxel, bevacizumab	Carboplatin, paclitaxel, bevacizumab	Non-SCC	63.5% vs 48%	8.4 vs 6.8 (HR 0.57; 95% CI 0.48-0.67)	19.5 vs 14.7 (HR 0.80; 95% CI 0.67-0.95)
Combination immunotherapy						
CheckMate 227[272]	Nivolumab, ipilimumab	Doublet platinum chemotherapy	All histologies <1% PD-L1	27.3% vs 23.1%	5.1 vs 4.7 (0.75; 95% CI 0.59-0.95)	17.4 vs 12.2 (HR 0.65; 95% CI 0.52-0.81)
			All histologies >1% PD-L1	35.9% vs 30%	5.1 vs 5.6 (0.79; 95% CI 0.67-0.94)	17.1 vs 14.9 (HR 0.77; 95% CI 0.66-0.91)
Combination immunotherapy and chemotherapy						
CheckMate 9LA[273]	Nivolumab, ipilimumab, doublet platinum chemotherapy	Doublet platinum chemotherapy	All histologies	38% vs 25%	6.4 vs 5.3 (HR 0.70; 95% CI 0.59-0.83)	15.8 vs 11 (HR 0.75; 95% CI 0.63-0.88)
POSEIDON[274]	Durvalumab, tremelimumab, doublet platinum chemotherapy	Doublet platinum chemotherapy	All histologies	38.8% vs 24.4%	6.2 vs 4.8 (HR 0.72; 95% CI 0.60-0.86)	14 vs 11.7 (HR 0.77; 95% CI 0.65-0.92)

CI, confidence interval; HR, hazard ratio; ORR, objective response rate; OS, overall survival; PD-L1, programmed death-ligand 1; PFS, progression-free survival; NSCLC, non–small cell lung cancer; NR, not reached; SCC, squamous cell cancer.

Subsequent studies focused on patients with treatment-naïve metastatic disease. In patients with high PD-L1 expression and no driver mutation, pembrolizumab, atezolizumab, and cemiplimab have demonstrated superior efficacy over chemotherapy alone.[191-194] Several programmed cell death protein 1 and PD-L1 inhibitors have also been paired with chemotherapy and demonstrated superior outcomes compared to patients treated with chemotherapy alone.[195-198] The choice in the first line of ICI alone, ICI with chemotherapy, or

combination immunotherapy is a complex decision that involves goals of care, willingness to accept toxicity risks, and a patient's support system. In patients without driver mutations (except for KRAS mutations) and PD-L1 expression greater than 50% with limited disease burden, ICI alone is an appropriate treatment that reduces the incidence of side effects compared to using chemoimmunotherapy. In patients with PD-L1 low tumors (0% to 49%), the preferred treatment option is chemoimmunotherapy or combination immunotherapy. ICI alone in patients with PD-L1 1% to 49% is likely inferior, although it is an acceptable option for patients who want to avoid adverse events from chemotherapy.

Molecular Determinants of Therapy

Another major advancement in the management of patients with metastatic NSCLC is the discovery that a fraction of patients with mostly adenocarcinomas has a driver genetic abnormality. Pharmacologically inhibiting this abnormality with targeted treatment is now the standard of care for these patients.

Epidermal Growth Factor Receptor

EGFR-activating mutations are found in approximately 10% to 15% patients with of lung cancer, with the most common mutations being exon 19 deletion or exon 21 L858R mutations. The activating mutations can be inhibited by TKI, which results in a decrease in the cancer burden.[199] The first-generation TKIs erlotinib and gefitinib were proven to be more effective than chemotherapy in several clinical trials. OS was not found to be different in the majority of this trials, likely because of crossover to an EGFR TKI in the majority of patients randomized to chemotherapy.[200,201] Second- and third-generation TKIs such as osimertinib were designed to address the development of a resistance mutation T790M, which impairs the binding of these TKIs to the EGFR. A phase III study compared osimertinib to either erlotinib or gefitinib, and this demonstrated improved efficacy, PFS, and OS for osimertinib.[202] Patients with EGFR mutations commonly have brain metastasis at presentation, and osimertinib also showed a higher central nervous system (CNS) response rate and CNS-specific PFS compared to the older TKIs. Recent trials have tested the hypothesis of whether adding chemotherapy to osimertinib is beneficial compared to osimertinib alone.[203] As of this writing, the results have showed an improvement in PFS at the cost of adverse events, and whether this will affect OS or if there is a specific population who benefits more (the presence of brain metastasis, higher burden of disease) to inform this more aggressive approach is a topic of controversy.[204]

ALK

ALK positivity defines a distinct molecular subset of NSCLC (3%-7%). Crizotinib was the first agent approved for ALK mutations, but PFS was short, and it had limited activity in patients with CNS metastasis. Currently, alectinib,[205] brigatinib,[206] and lorlatinib[207] have been shown to be superior to crizotinib and are the standard of care for these patients.

ROS1

The translocation between *ROS1* and other genes, the most common of which is *CD74*, occurs in 1% to 2% of NSCLC.[208] These fusions lead to the constitutive activation of *ROS1*. This activation can be inhibited with crizotinib,[209] entrectinib,[210] or reprotectinib.[211] Given the low incidence of ROS1 abnormalities, these agents have been approved based on open-label phase 2 studies. Crizotinib has low CNS activity; therefore, entrectinib and repotrectinib are preferred agents.

BRAF

BRAF can also act as an oncogenic driver in the presence of an activating mutation, the most common one of which is V600E, observed in 1% to 2% of lung adenocarcinomas.[212] In patients with this disease, inhibition of only the BRAF pathway is effective but leads to acquired resistance, most commonly through a bypass signaling via MEK, another protein in the same pathway. By combining a BRAF inhibitor with an MEK inhibitor, the pathway is blocked at two different points, which can overcome or delay the development of resistance. Encorafenib and binimetinib[213] have been approved for this disease.

Other Driver Mutations

Many targeted drugs are actively being investigated in the clinical trial testing. When feasible, patients with metastatic NSCLC should undergo molecular testing via a broad, panel-based approach, usually by next-generation sequencing. Other targetable mutations at this time include KRAS, MET exon 14, RET, HER2, and NTRK1/2/3.

Role of Radiation in Oligometastatic/Oligoprogressive Non–Small Cell Lung Cancer

Although survival for patients with metastatic NSCLC remains poor with 5-year OS of less than 10%, there is a subset of patients who have better prognosis and may benefit from aggressive local therapy, though identifying this subset has remained challenging. One subgroup that has consistently shown superior outcome is patients with limited systemic disease burden (oligometastatic disease), and this has been incorporated into the AJCC eighth edition staging system, with M1b being patients with a single site of extrathoracic metastasis. The exact definition of oligometastatic is still evolving and varies based on studies. An international analysis of 757 patients with NSCLC with one to five synchronous or metachronous metastases and a controlled primary (treated with curative-intent local therapy including surgery, SBRT, curative dose radiation, or some combination) showed 5-year OS of 29.4% for the entire population, with 5-year OS of 47.8% for the best risk group on recursive partitioning analysis in patients with metachronous disease, and 5-year OS of 13.8% in the worst risk group for patients with synchronous metastases and N1/N2 disease.[214] Beyond treating the primary lung tumor, aggressive radiation may also have a role in managing the oligometastatic sites. A multicenter, phase II trial randomized patients with synchronous metastatic NSCLC with three or fewer metastatic lesions after first-line systemic therapy to either local consolidative therapy (LCT) to all sites of disease +/− maintenance treatment or maintenance treatment alone.[215] LCT included surgery or radiation, and radiation was given with curative intent when possible. The study was terminated early after randomization of 49 patients due to improved median PFS in the LCT group. On long-term follow-up, the PFS benefit was durable at 42.2 months (95% CI 7.4-23.1 m) in LCT group versus 4.4 months (95% CI 2.2-8.3 m) in the maintenance group (P = .017). A similar randomized phase II trial with 29 patients with oligometastatic NSCLC from UTSW published a year later showed a similar improvement in PFS with aggressive radiation.[216] SABR-COMET was a randomized phase II trial of SABR versus standard of care that included patients with mixed histologies—including NSCLC—and one to five oligometastases with a controlled primary. Aggressive radiation improved OS and PFS compared to standard of care,[217] leading follow-up phase III trials (NCT03862911, NCT03721341). The SINDAS trial asked a similar question in patients with EGFR-mutated NSCLC, comparing TKI only against TKI plus radiation, showing an improvement in OS with addition of radiation.[218]

As systemic therapies improve, there is also a category of patients with “oligoprogressive” disease, who may have many sites of metastasis that are all responding to systemic therapy but one or a few sites of disease that are progressing. In this scenario, aggressive RT, such as with SBRT, to the sites of oligoprogressive disease can give patients more time on the targeted agent before having to switch systemic therapies. In published series of patients on erlotinib or crizotinib with four or fewer sites of extracranial progressive disease, ablative local therapy such as SBRT to the oligoprogressive sites can provide an additional 6 months or more of PFS on the same targeted agent.[219,220] The CURB trial was a phase II randomized trial of SBRT versus standard of care in patients with metastatic breast cancer or NSCLC who were oligoprogressive on first-line systemic therapy, with oligoprogression defined as five or less progressive lesions on PET/CT or CT.[221] The study was closed to accrual with 106 patients, before reaching the targeted sample size, after the primary efficacy end point was met during a preplanned interim analysis. For the 59 patients with NSCLC, median PFS improved from 2.2 to 10.0 months with SBRT, and the time to new systemic therapy was 11.0 months.

Conclusion

These are very exciting times for the treatment of metastatic NSCLC as significant advances have become available that are dramatically changing the paradigm of how we treat this disease. Systemic therapy options

are increasingly personalized for patients based on their cancer's molecular targets and biomarkers. As systemic therapies improve, there may also be an increasing role for local therapy in providing durable disease control.

PALLIATIVE RADIOTHERAPY

Given the propensity of lung cancer for locoregional recurrence and/or distant metastatic disease, RT plays an important role in the palliation of symptomatic disease in many patients with lung cancer. The most common sites of disease that require palliative RT include the thorax, bone, and brain. Intrathoracic disease and bone metastasis will be covered here. The reader is referred to Chapters 16, 101, and 102 for radiosurgery, palliation of brain metastases, and palliation of spine metastases, respectively, in the management of CNS metastases from lung cancer.

Palliation of Intrathoracic Disease

Symptoms from progression of intrathoracic lung cancer that may benefit from a course of palliative RT include cough, hemoptysis, chest wall pain, SVC syndrome, dyspnea from airway obstruction, and hoarseness from involvement of the recurrent laryngeal nerve. For intrathoracic disease, higher doses of radiation with biologic effectiveness dose greater than 35 Gy_{10} (eg, 30 Gy in 10 fractions) are recommended by meta-analyses[222] and ASTRO 2011 guidelines.[223] A 2018 update to ASTRO guidelines recommends the use of concurrent chemotherapy for patients with stage III NSCLC who are not suitable for curative therapy but have ECOG PS 0-2 with a life expectancy of at least 3 months.[224]

Endobronchial brachytherapy may provide relief for patients with endobronchial lesions causing obstruction or hemoptysis. With improvements in radiation technique and the ability to increase the therapeutic ratio through fractionation, external beam radiation is generally preferred to brachytherapy, though it may be reasonable to consider if an obstruction fails external beam radiation. The lesion to be treated should be visible by bronchoscopy and generally located in the trachea, mainstem, or lower lobe bronchi. This procedure requires the combined efforts of an interventional pulmonologist and brachytherapist. The pulmonologist performs fiberoptic bronchoscopy, placing an afterloading catheter within the airway adjacent to the tumor under direct visualization. In a retrospective study from MD Anderson Cancer Center involving 175 patients with lung cancer who received high-dose rate brachytherapy for metastatic or locally recurrent lung cancer, 115 (66%) patients demonstrated symptomatic improvement.[225]

Superior Vena Cava Syndrome

Lung cancer is the most common cause of SVC syndrome and accounts for approximately 80% of cases at diagnosis. If the SVC becomes obstructed because of an extrinsic mass, blood returns to the heart through collateral vessels to the azygos vein or inferior vena cava. Venous collaterals dilate over weeks so that the upper body venous pressure and resulting edema of the arm and face decrease over time. The severity of the symptoms is, therefore, attributable not only to the degree of SVC narrowing but also to the rapidity with which it develops. The characteristic signs include cyanosis, plethora, distention of subcutaneous veins, and edema of the head, neck, and arm. Patients may report dyspnea or cough. Rarely, severe and acute obstruction can result in cerebral edema or laryngeal stridor. The clinical course may be exacerbated by the development of a thrombus or the simultaneous tumor mass effect on the bronchi or heart.

Traditionally, SVC syndrome was viewed as a medical emergency. Accumulating experience, however, demonstrates that the course of SVC is rarely life-threatening.[226] Immediate intervention is warranted when the symptoms are life-threatening (eg, cerebral edema leading to altered mental status, stridor, or clinically significant hemodynamic compromise). Intravascular stenting provides the most immediate relief and can be accomplished even when there is complete obstruction. In the absence of life-threatening symptoms, the patient should be appropriately staged and biopsied and the underlying malignancy treated in a manner appropriate for its stage and presentation. The majority of patients with SVC syndrome attributed to SCLC will respond to systemic therapy and should start this as soon as the diagnosis is confirmed (see the section "Small Cell Lung Carcinoma"). For limited-stage SCLC, radiation can be added starting with cycle 2, which

also has the advantage of treating a smaller, postchemotherapy volume. Patients with NSCLC and SVC syndrome are less likely to respond to chemotherapy; thus, the threshold for starting radiation or placing an endovascular stent should be lower.

SMALL CELL LUNG CARCINOMA

In the United States in 2023, approximately 33,000 patients were diagnosed with SCLC, constituting approximately 14% of all lung cancer diagnoses. Over the past several decades, the proportion of SCLC among all lung cancer histologies has been decreasing, perhaps because of smoking cessation and the proliferation of low-tar cigarettes. Although there has been a modest but statistically significant improvement in 2- and 5-year survival in both limited- and extensive-stage diseases in recent decades, the outcomes are still extremely poor, particularly since the majority (approximately two-thirds) of patients present with extensive-stage disease with an expected 5-year survival of only 3%.

Pathology

The establishment of a firm pathologic diagnosis distinguishing SCLC from NSCLC variants such as carcinoma with neuroendocrine features and carcinoid is extremely important in this disease, as it can have a significant impact on management and clinical outcome. Histologically, SCLC is one of the small, round, blue cell tumors (along with neuroblastoma, rhabdomyosarcoma, Merkel cell carcinoma, etc) with scant cytoplasm and indistinct nucleoli. Cells are often molded together, and crush artifact is commonly noted after needle biopsy but is not pathognomonic. Almost all SCLC samples are immunoreactive to keratin and epithelial membrane antigen, and approximately 80% express thyroid transcription factor-1.[227] The majority of tumors will stain for neuroendocrine markers, including synaptophysin, neuron-specific chromogranin A, enolase, and CD56. Immunohistochemistry alone, however, cannot distinguish SCLC from small cell cancer of nonthoracic origin or from NSCLC with neuroendocrine differentiation. The WHO recognizes that SCLC can occur in a pure type or mixed with NSCLC in up to 30% of cases.

Prognostic Factors in Small Cell Lung Cancer

The most clinically important prognostic factor in SCLC is stage (limited vs extensive), with 5-year survival of approximately 30% for patients with local disease versus 3% for those with extensive disease.[1] Other clinical factors consistently reported to correlate with improved survival include good performance status, female gender, and normal lactate dehydrogenase levels at baseline.[228]

Staging Workup

As in patients with NSCLC, patients with SCLC should undergo a timely and efficient history, physical examination, and laboratory and radiographic evaluation. The history and physical should be performed with particular attention to signs and symptoms of paraneoplastic syndromes, including SIADH and elevated ACTH. Laboratory evaluation should include a complete blood count and comprehensive chemistry panel. Radiographic studies should include a CT scan of the chest and abdomen with intravenous contrast, with PET/CT for suspected limited-stage disease. All patients with SCLC, regardless of stage, should undergo a brain MRI with gadolinium or a head CT with contrast to evaluate for brain metastases. A diagnostic thoracentesis should be performed for any identified pleural effusion to determine the presence of malignant cells. The TNM staging system adopted by the AJCC is applicable to both NSCLC and SCLC. Most historical studies classified patients as having limited or extensive disease based on the 1973 Veteran Administration Lung Group staging scheme.[229] In this system, limited stage is defined as disease confined to the ipsilateral hemithorax, which can be safely encompassed within a tolerable radiation portal. Virtually all studies in limited disease exclude malignant pleural effusions due to the significant risk of pulmonary toxicity in a high-risk patient population with little chance of cure.

Clinical Presentation and Paraneoplastic Syndromes

Paraneoplastic syndromes are commonly encountered in lung cancer; however, the spectrum of paraneoplastic syndromes in SCLC is distinct from that observed in NSCLC. Neurologic paraneoplastic syndromes are more commonly encountered in SCLC and are thought to be primarily autoimmune in nature. LEMS is seen in 3% of all patients with SCLC at presentation and is characterized by proximal muscle weakness that improves with continued activity. This syndrome occurs when autoantibodies are generated against voltage-gated calcium channel receptors on the presynaptic membrane, impeding release of acetylcholine into the neuromuscular junction and resulting in muscular weakness. A wide variety of other rare autoimmune neurologic paraneoplastic syndromes have been described in SCLC, including encephalomyelitis, cerebellar degeneration, and retinopathy. SCLC can also elaborate hormonally active peptides including ACTH and vasopressin leading to Cushing syndrome and SIADH, respectively. Although SCLC is the most common tumor associated with SIADH, only 10% of patients meet the clinical criteria for SIADH. Similarly, only 5% of patients with SCLC present with Cushing syndrome. Despite the fact that paraneoplastic syndromes may lead to early identification and diagnosis of SCLC, some of these syndromes, such as Cushing, have been associated with poorer survival.[230] Treatment of the cancer will often, although not always, ameliorate the paraneoplastic syndromes.

General Therapeutic Precepts

Early-stage (ie, T1-2, N0) SCLC is diagnosed in less than 5% of incident cases. For these patients, definitive surgical resection is a potential therapeutic option. In a population-based study, lobectomy without adjuvant radiation was associated with an approximately 50% OS.[231] Given the propensity for early nodal dissemination with SCLC, invasive staging of the mediastinum should be performed prior to surgical resection. For patients who are medically inoperable, SABR could be used in place of surgery for early-stage, node-negative disease, with some clinical data showing efficacy.[232] After surgical resection or SABR, the primary mode of failure for these patients is distant dissemination. Therefore, adjuvant chemotherapy is recommended for all patients, even if node negative. Postoperative radiation is recommended if positive margins or nodal involvement is found at resection.

The majority of patients present with evidence of nodal or distant dissemination at the time of diagnosis. Multiagent chemotherapy, usually a platinum-based combination, is an essential part of therapy for these patients. For patients with limited-stage disease, the addition of thoracic radiation significantly improves survival and, therefore, is an integral of part their treatment regimen.[233-235] For patients with extensive- stage disease, first-line therapy now includes multiagent chemotherapy plus PD-L1 ICIs. In the preimmunotherapy era, consolidative thoracic radiation was found to be potentially beneficial for select good performance status patients who have complete resolution of their extrathoracic tumor burden after chemotherapy, to reduce the risk of intrathoracic failure.[236,237] The role of thoracic radiation is less certain in the era of immunotherapy for extensive-stage SCLC. Prophylactic cranial irradiation (PCI) is still a standard of care after systemic therapy for patients with SCLC, as this has been shown to provide a significant improvement in absolute survival for these patients.[238,239] However, the trials showing a benefit to PCI were conducted without routine MRI imaging, and there is also evidence PCI might not be beneficial for patients with no brain mets on MRI.[240] MRI brain surveillance is also an acceptable practice in place of PCI.

Chemotherapy for Limited-Stage Disease

EP for four cycles is the most common chemotherapy regimen used for limited-stage SCLC and has the most published clinical evidence.[109,241] For patients not eligible to receive cisplatin, there is clinical evidence that carboplatin can be used with similar rates of disease response and survival.[242] Cisplatin is associated with higher rates of nephropathy, neuropathy, hearing loss, and nausea/emesis, but carboplatin is associated with higher risks of myelosuppression.

Radiation Timing for Limited-Stage Disease

A randomized trial by the JCOG evaluated concurrent versus sequential chemotherapy and thoracic radiation in patients with limited-stage SCLC.[243] All patients received 45 Gy in 1.5-Gy fractions BID and were randomized to receive four cycles of cisplatin (80 mg/m^2 on day 1) and etoposide (100 mg/m^2 days 1, 2, and

3) every 4 weeks concurrent with RT (beginning day 2) or every 3 weeks sequentially before RT. Patients treated concurrently had longer median survival compared to patients treated sequentially: 27 versus 20 months. A meta- analysis by De Ruysscher et al[244] that included more than 2,300 patients from nine randomized trials evaluated the timing of RT when given concurrently with multiagent chemotherapy. When all trials were pooled together, "earlier or shorter" RT did not have a significant impact on OS compared with "later or longer" RT (HR 0.99, 95% CI 0.91-1.08, P = .78). However, if looking at trials with similar chemotherapy compliance rates between the arms, results were in favor of earlier radiation (OS HR 0.79, 95% CI 0.69-0.91). It is recommended to start radiation with cycle 1 or 2 of chemotherapy, unless radiation fields are very large at diagnosis, and more tumor shrinkage could significantly decrease radiation treatment toxicity.

Radiation Dose and Fractionation for Limited-Stage Disease

The optimal dose and fractionation scheme for concurrent chemoradiation for limited-stage SCLC is an area of active investigation. SCLC is highly radiosensitive, suggesting that hyperfractionation could be employed to reduce late normal tissue toxicity. It also has a high proliferative rate, arguing for accelerated treatment to counteract repopulation. Between 1989 and 1992, 417 patients were enrolled in a randomized, intergroup trial of concurrent accelerated hyperfractionated RT versus standard daily RT in patients with limited-stage SCLC.[109] All patients received four cycles of cisplatin (60 mg/m^2 on day 1) and etoposide (120 mg/m^2 on days 1, 2, and 3), and RT began with cycle 1. In the once-daily arm, patients received 45 Gy in 1.8-Gy fractions over 5 weeks. In the BID arm, patients received 45 Gy in 1.5-Gy fractions over 3 weeks. Patients who achieved a complete response were offered PCI. OS was significantly higher in the BID arm (26% vs 16% at 5 years), and local recurrence was significantly lower (36% vs 52%). There was a significant increase in grade 3 acute esophagitis (26% vs 11%) in the BID arm, with no difference in late toxicity.

Since the two arms of the abovementioned Turrisi trial do not have the same biologic equivalence, there has been immense interest on whether a BID radiation regimen would be superior to a daily regimen to a higher dose (ie, 60-70 Gy). The Concurrent Once-daily Versus Twice-daily Radiotherapy trial enrolled 547 patients between 2008 and 2013 at 88 centers worldwide, randomizing patients with limited-stage disease to 45 Gy BID or 66 Gy once daily.[245] The 2-year OS was not significantly different (56% for BID, 51% for once daily), and the rate of grade 3 or greater esophagitis was 19% in both arms. CALGB 30610/RTOG 0538 compared 45 Gy in 30 fractions over 3 weeks versus 70 Gy in 35 fractions.[246] A third arm was closed, which administered 61.2 Gy in 5 weeks per RTOG 0239. All patients received concurrent EP, and RT begins with cycle 1 or cycle 2. OS did not significantly differ between treatment arms (P = .594). Median OS was 28.5 months (95% CI 25.4-34.5) for 45-Gy BID compared with 30.1 months (95% CI 24.4-37.2) for 70-Gy once-daily RT. Grade 3+ esophageal toxicity was 16% in the 45-Gy BID arm and 17.5% in the 70-Gy once-daily arm. Rates of grade 3 dyspnea were low, 4% (12 patients) on the BID arm and 7% (21 patients) on the once-daily arm, and the only case of grade 4 dyspnea reported was on the BID arm. Both trials concluded that once-daily radiation is an acceptable alternative to BID radiation, although BID is still standard of care.

The high intrathoracic relapse rate observed in limited-stage SCLC after radiation had led to continued interest in dose escalation. Choi et al[247] conducted a phase I dose escalation study with both BID and once-daily arms. In the BID arm, 45 Gy in 30 fractions over 3 weeks was the maximum tolerated dose. In the once-daily arm, the dose was escalated to the maximum of 70 Gy in 35 fractions over 7 weeks without dose-limiting toxicity. More recently, Gronberg et al[248] investigated whether BID radiation to 60 Gy in 40 fractions improves survival over 45 Gy in 30 fractions. This randomized, phase 2 trial was done at 22 public hospitals in Norway, Denmark, and Sweden. All patients received chemotherapy and started radiation around cycle 2. Between 2014 and 2018, 170 patients were randomized. At 2 years, OS was 66% versus 39% favoring the 60 Gy group (OR 3.09, 95% CI 1.62-5.89; P = .0005). Overall, there was no difference in toxic effects between the 60-Gy group and the 45-Gy group. These results are encouraging and would benefit from additional clinical testing.

Radiotherapy Techniques for Limited-Stage Disease

There have been immense technological advances in the radiation treatment of lung cancer. While most of the clinical data are in NSCLC, SCLC could derive similar clinical benefits. Early-stage, node-negative SCLC

can be treated with SABR, following similar principles as NSCLC.[232,249] IMRT is increasingly used for node-positive lung cancer, with data in NSCLC suggesting superior clinical outcomes over 3D conformal radiation.[127] There are also small clinical series with proton radiation showing safety and efficacy.[250,251] Advanced technologies should be deployed as appropriate to deliver a high dose to the target and minimize dose to the normal tissues.

Radiotherapy Volume for Limited-Stage Disease

Limited-stage SCLC is frequently bulky at presentation, requiring large treatment fields to encompass all sites of intrathoracic disease. Therefore, induction chemotherapy has been employed to achieve cytoreduction of disease prior to initiation of thoracic RT. This approach raises the concern of potentially increasing the risk of marginal treatment failure if the postchemotherapy volume alone is included in the radiation portal. To address this question, the SWOG conducted a randomized study, enrolling 191 patients who had a partial response or stable disease after 6 weeks of induction chemotherapy. They were randomized to receive RT (48 Gy split course) to either the preinduction or postinduction volume.[252] There was no difference in local recurrence rates: 32% in the preinduction versus 28% in the postinduction arm. Careful retrospective studies of patients treated with preinduction or postinduction thoracic RT show that local failure is not significantly higher if smaller fields are used. Furthermore, most intrathoracic failures occur in the smaller postchemotherapy radiation field, arguing, as in locally advanced NSCLC, against the use of ENI.[253,254] Recent clinical trials in limited-stage disease have targeted gross disease, with some including the ipsilateral hilum regardless of involvement.[245,246]

Radiotherapy for Extensive-Stage Disease

Systemic therapy is the essential element in the treatment of patients with extensive-stage SCLC with good performance status; however, thoracic RT may play a role in selected patients. Based on the observation that patients have high rates of thoracic relapse after systemic therapy alone, a single-institution prospective randomized trial was undertaken in Yugoslavia.[236] In this trial, 209 patients with extensive disease were enrolled and treated with three cycles of EP. Of those, 110 patients who had a partial response in the chest and a complete response outside the chest were randomized to receive thoracic radiation with concurrent carboplatin and etoposide, followed by two cycles of EP, versus four further cycles of EP alone. All eligible patients received PCI. The thoracic radiation was delivered in 54 Gy in 36 fractions over 12 days. At 5 years, the OS was higher in the arm that featured thoracic radiation: 9% versus 4%.

Similarly in the chemotherapy era, the Dutch CREST trial tested 30-Gy thoracic radiation after platinum/etoposide in patients who had any response to chemotherapy.[237] Thoracic radiation was associated with a 2-year OS benefit (13% vs 3%, $P = .004$), but not a 1-year OS benefit, which was the primary end point of the study. After stratifying for intrathoracic disease after chemotherapy in a subsequent analysis, a significant difference in OS was seen in the 434 of 495 patients who had residual disease after chemotherapy (33% vs 26% at 1 year, 12% vs 3% at 2 years, $P = .044$).[255] Both of the abovementioned trials were conducted without immunotherapy as part of the systemic regimen, which is now standard of care in extensive-stage SCLC, and the benefit of thoracic radiation in this patient population is uncertain.

Beyond thoracic radiation, RTOG 0937 was a randomized phase II study in patients with metastatic SCLC with one to four extrathoracic sites of disease (excluding brain metastasis); patients were randomized to receive 45 Gy in 15 fractions to all sites of disease followed by PCI, versus PCI alone, after chemotherapy. The trial was closed for futility after an interim analysis of 86 patients.[256] With a median follow-up of 9 months, there was no significant difference in 1-year OS: 60% for PCI versus 51% for PCI and RT to thoracic and metastatic sites. There are ongoing studies to evaluate the role of thoracic and extrathoracic radiation in patients with extensive- stage disease, in the era of chemoimmunotherapy.

Prophylactic Cranial Irradiation and Radiation for Brain Metastasis

Brain metastases are present at diagnosis in approximately 20% of patients with SCLC. The brain is also a frequent site of failure after chemotherapy for extensive disease or chemoradiotherapy for limited-stage disease. Several randomized trials have addressed the value of PCI following a response to initial therapy and

have consistently demonstrated a decrease in the incidence of brain metastases. A meta-analysis reported the results of 987 patients treated in seven randomized trials enrolling between 1977 and 1995,[238] with 85% limited-stage patients and 15% extensive. All were randomized to either PCI or observation following a response to chemotherapy, and brain imaging was not required prior to PCI. At 3 years, PCI was found to significantly decrease the incidence of brain metastases (59% vs 33%) and significantly improve OS (21% vs 15%).

PCI in extensive-stage SCLC was studied in an EORTC trial,[239] randomizing 286 patients to either PCI or observation after any response to four to six cycles of chemotherapy. Brain imaging was not required prior to PCI. The 1-year cumulative incidence of brain metastases was significantly decreased in the PCI arm at 15% versus 40%, and 1-year OS was significantly increased in the PCI arm at 27% versus 13%. A similar Japanese randomized trial did not replicate these results; the trial was terminated after enrollment of 163 patients when an interim futility analysis determined that no benefit was possible. Patients were randomized after any response to chemotherapy, but unlike the EORTC study, brain imaging was done before enrollment. The median OS was not significantly different between the two arms with a trend toward worse survival in the PCI arm: 11.6 months for patients who received PCI versus 13.7 months for those who did not (HR 1.27, CI 0.96-1.68, $P = .094$).[240] Thus, the role of PCI in extensive-stage SCLC remains an ongoing controversy.

To help define the optimal dose and fractionation for PCI, an intergroup trial randomized patients with limited-stage SCLC who had achieved a complete response to chemoradiotherapy to standard dose, 25 Gy in 10 daily fractions, or high dose, 36 Gy in either 18 daily fractions or 24 BID fractions.[257] A total of 720 patients were randomized; at 2 years, the cumulative incidence of brain metastases was not significantly different between the two arms: 29% in the standard-dose arm versus 23% for high dose. There was poorer 2-year OS in the high-dose arm: 42% versus 36%. Patients enrolled in this trial participated in baseline and follow-up neuropsychological test batteries along with QoL assessments. Wolfson et al[258] reported an increased incidence of chronic neurotoxicity at 12 months after PCI in the 36-Gy cohort ($P = .02$). Taken together, these results establish 2.5 Gy in 10 fractions as the current preferred regimen to deliver PCI.

For patients with brain metastases, the standard of care therapy is whole-brain radiation to 30 Gy in 10 fractions. Studies have looked at the use of memantine and hippocampal avoidance (HA) radiation to decrease neurotoxicity from treatment with conflicting results. NRG CC001 randomized 518 patients with brain metastases from 2015 to 2018 to HA whole-brain radiation therapy (HA-WBRT) plus memantine or WBRT plus memantine. Risk of cognitive failure was significantly lower after HA-WBRT (adjusted HR 0.74, 95% CI 0.58-0.95; $P = .02$), with no difference in intracranial PFS and OS.[259] Patients on this trial did not have SCLC, but there has been extrapolation into the small cell patient population. Conflicting results regarding HA have been seen with PCI. PREMER is a phase III trial that randomized 150 patients with SCLC to PCI or HA-PCI.[260] The primary objective was delayed free recall at 3 months, which was better in the HA-PCI arm (5.8%) compared with the PCI arm (23.5%; OR 5, 95% CI 1.57-15.86; $P = .003$). The incidence of brain metastases, OS, and QoL were not significantly different. However, Belderbos et al[261] reported that in a multicenter, randomized phase 3 trial of 168 patients with SCLC, standard PCI versus HA-PCI of 25 Gy in 10 fractions did not find a lower probability of cognitive decline in patients with SCLC receiving HA-PCI compared with conventional PCI. No increase in brain metastases at 2 years was observed in the HA-PCI arm. NRG CC003 randomized 392 patients with SCLC to PCI or HA-PCI (25 Gy in 10 fractions) and also did not show a clear benefit to neuroprotection with HA-PCI.

Due to concerns of neurotoxicity, there has been increasing interest in stereotactic radiosurgery (SRS) for brain mets from SCLC. While the standard of care is still WBRT, there are now clinical reports of SRS for small cell brain mets, with favorable cranial control and survival.[262,263]

Systemic Therapy for Extensive-Stage Disease

For decades, in patients with adequate performance status, chemotherapy was the cornerstone of treatment for extensive- stage SCLC. Cisplatin or carboplatin plus etoposide was the recommended regimen.[242] This changed in 2018 with the results from IMpower133,[264] a double-blind, placebo-controlled, phase 3 trial to evaluate atezolizumab plus carboplatin and etoposide in patients with extensive-stage SCLC. Atezolizumab improved median OS from 10.3 to 12.3 months (HR 0.70, 95% CI 0.54-0.91; $P = .007$). In 2019, the

CASPIAN trial reported for patients with extensive-stage disease randomized to durvalumab plus EP; durvalumab plus tremelimumab plus EP; or EP alone, durvalumab plus EP was associated with a significant improvement in OS (HR 0.73, 95% CI 0·59-0.91; $P = .0047$) over EP alone. The current standard of care first-line systemic therapy for extensive-stage SCLC is now chemoimmunotherapy.

CHAPTER 58

Mediastinum and Trachea

Florence K. Keane, Annemarie Shepherd, Christopher S. Nabel, Ravi A. Chandra, Anneyuko Saito, Gregory A. Russo, Clifton D. Fuller, and Charles R. Thomas, Jr

MEDIASTINAL TUMORS

The mediastinum is a trapezoidal structure in the center of the thoracic cavity. It is bound by the sternum anteriorly, the vertebral column posteriorly, and the lungs and pleural laterally (Figure 58.1). The diaphragm forms the floor of the mediastinum, while the thoracic outlet at the first thoracic vertebra, its rib, and the manubrium form the roof.[1] Conceptually, it is helpful to divide the mediastinum into anterior, middle, and posterior compartments, but no anatomic barriers specifically separate these regions.[2-4] The anterior mediastinum is the space anterior to the pericardium and great vessels and is occupied by the thymus, lymph nodes, and small vessels, including branches from the internal thoracic chain. The middle mediastinum is composed of the heart, proximal great vessels, central airway structures, and lymph nodes. The International Thymic Malignancy Interest Group (ITMIG) have codified these anatomic boundaries into a series of computed tomography (CT)-based radiographic standards for aiding clinical diagnosis and research.[5]

Tracheal anatomy is depicted in Figure 58.2. The posterior mediastinum is posterior to the heart and great vessels and contains the sympathetic chain ganglia, vagus nerve, thoracic duct, and esophagus. Given the number of structures within the mediastinum, it is not surprising that a heterogeneous group of malignancies can arise in this location. Thymic, neurogenic, germinal, and mesenchymal tissues may all give rise to neoplasms. The malignancies that occur within the various compartments in the mediastinum are listed in Table 58.1.

TABLE 58.1 HISTOLOGIES OF TUMORS APPEARING IN THE VARIOUS COMPARTMENTS OF THE MEDIASTINUM

Anterior (Anterosuperior)	Middle	Posterior
Thymic tumors	Lymphomas	Lymphomas
Thymomas	Cysts	Neurogenic tumors
Thymic carcinomas	Bronchogenic	Peripheral nerves
Thymic cysts	Foregut	Malignant peripheral nerve sheath tumors
Carcinoids	Pericardial	Schwannomas
Thymolipomas	Thoracic duct	Neurosarcomas
Lymphomas	Meningoceles	Sympathetic ganglia
Hodgkin disease	Mesenchymal tumors	Ganglioneuroblastomas
Non-Hodgkin lymphomas	Tracheal tumors	Ganglioneuromas
Undifferentiated	Carcinomas	Neuroblastomas
Germ cell tumors	Cardiac and pericardial tumors	Paraganglia
Seminomas	Hernias	Paragangliomas
Nonseminomas	Hiatal	Mesenchymal tumors
Embryonal carcinomas	Morgagni	Endocrine tumors
Choriocarcinomas	Vascular tumors	Esophageal tumors and cysts
Mixed germ cell tumors	Ascending aortic	Hiatal hernias
Teratomas (dermoid cysts)	Transverse arch	Lateral thoracic meningoceles
Endocrine tumors	Descending aortic	
Parathyroid adenomas	Great vessels	
Thyroid tumors	Lymphadenopathy	
Mesenchymal tumors	Inflammatory	
Amyloid tumors	Granulomatous	
Castleman disease	Sarcoidosis

Incidence of Primary Mediastinal Tumors

Lymphomas represent the most common type of anterior mediastinal tumor and are discussed in a separate chapter. The malignancy with the next highest incidence—tumors of thymic origin—are rare and represent about 0.2% to 1.5% of all malignancies.[6] Thymic carcinomas are especially rare and account for only 0.06% of all thymic neoplasms.[7] The frequency and prevalence of primary mediastinal tumors seem to be increasing over time.[8-11] Adults generally develop thymic tumors and lymphomas, but they can also develop germ cell tumors and carcinomas.[11,12] Neurogenic tumors disproportionately develop in children.[9,13,14]

THYMOMAS

The thymus gland is an irregular lobulated lymphoepithelial organ in the anterior mediastinum. Embryologically, the thymus is derived from the endoderm of the lower portion of the third pharyngeal pouch and involutes during adulthood, gradually being replaced by adipose tissue. Its blood supply is from the internal mammary arteries, and its venous return drains to the innominate and internal thoracic veins. Its lymphatics drain into the lower cervical, internal mammary, and hilar lymph nodes.

The vast majority of thymic tumors are thymomas, 90% of which are found in the anterosuperior mediastinum; other variants occur in the middle and posterior mediastinum or neck.[15] Thymomas are epithelial tumors associated with an exuberant lymphoid component composed of immature cortical thymocytes. Although lymphomas, carcinoid tumors, and germ cell tumors can all arise within the thymus, only thymomas, thymic carcinomas, and thymolipomas arise from true thymic elements.

Epidemiology

Thymomas are exceedingly rare. The Surveillance, Epidemiology, and End Results (SEER) project reported the thymoma incidence in the United States to be 0.13 to 0.15 per 100,000 person-years.[16,17] For patients with associated myasthenia gravis, the peak age is in the fourth decade, whereas for patients without myasthenia gravis, the peak age is in the seventh decade or later.[17-23] According to the SEER data, the incidence of thymoma

increases into the eighth decade of age and then decreases.[24] Thymomas are more common in men than in women (P = .007) and are most common among Asians/Pacific Islanders (0.49/100,000 person-years).

Thymomas represent 20% of all mediastinal tumors in adults[4,12,25,26] and 15% in pediatric populations.[15] Furthermore, they are the most common tumor of the anterior mediastinum, accounting for about 30% of all such masses.[9-11,15,27,28] Though a precise causative factor has not been identified, associations of thymomas with Epstein-Barr virus, lymphoepitheliomas, radiation exposure, and cytogenetic abnormalities have been suggested.[29-35]

Natural History

Thymomas are generally characterized by an indolent growth pattern that can be locally invasive. The vast majority of thymomas are cytologically bland tumors, and approximately half of them are noninvasive.[11,23,36-46] Roughly one-third of thymomas are asymptomatic and found incidentally on the lateral component of chest x-rays.[42,43,47] Of the symptomatic thymomas, about 40% of cases present with symptoms relating to impingement of nerves and/or vessels by the intrathoracic mass, ranging from cough, chest pain, dyspnea, hoarseness, superior vena cava obstruction, and even tumor hemorrhage.[48] The remainder of symptomatic patients present with one of several paraneoplastic syndromes, the most common of which are myasthenia gravis, benign cytopenias, hypogammaglobulinemia, and polymyositis.[18,21,49-52]

Myasthenia gravis has the highest incidence among the par athymic syndromes and occurs in approximately 45% of patients with thymomas, with the reported prevalence in studies involving more than 100 patients ranging from 10% to 67%.[19,20,22,23,53,54] Conversely, only 10% to 15% of patients with myasthenia gravis have a thymoma; 60% of patients with myasthenia will have thymic lymphoid hyperplasia, and roughly 25% will have a normal thymus.[20,55-58] Thymectomy results in clinical improvement in most cases even when the thymus is normal.[59]

Myasthenia gravis is characterized by the presence of antibodies that react to nicotinic acetylcholine receptors in muscle and disrupt transmission at the neuromuscular junction or mediate receptor internalization.[55] The cardinal features are weakness and fatigability of skeletal muscles, with

most patients first experiencing fatigue in the ocular muscles followed by ptosis and diplopia, and later developing generalized weakness. More severe cases involve the proximal limb girdle muscles, and, in the worst cases, respiration can be limited.[60-62]

Other systemic symptoms occur in 5% to 10% of patients with thymomas as part of a constellation of autoimmune disorders. Souadjian and associates, in reviewing more than 500 cases of thymoma, noted that 71% were associated with systemic disease.[52] These include erythroid and neutrophil hypoplasia, pancytopenia, Cushing syndrome, DiGeorge syndrome, carcinoid syndrome, Lambert-Eaton syndrome, pernicious anemia, nephrotic syndrome, syndrome of inappropriate antidiuretic hormone hypersecretion, Whipple disease, lupus erythematosus, pemphigus, myotonic dystrophy, scleroderma, polymyositis, polyneuritis, myocarditis polyarthropathy, myotonic dystrophy, Sjögren syndrome, Addison disease, panhypopituitarism, sarcoidosis, hypogammaglobulinemia, ulcerative colitis, rheumatoid arthritis, Hashimoto thyroiditis, hyperthyroidism, hyperparathyroidism, and thyroid carcinoma.[15,63-66] Other miscellaneous diseases include hypertrophic osteoarthropathy and chronic mucocutaneous candidiasis.[65]

Several studies have also reported an excess risk of developing a second primary malignancy of approximately 15% among patients with thymoma, which is a reason why these patients mandate indefinite post-treatment surveillance.[49,50,52,67-69] An aberrant immune system is postulated to be a mechanism for the development of these metachronous malignancies.[70] The highest excess risk of subsequent malignancy appears to be for non-Hodgkin lymphoma, but thymoma patients are also at risk for upper foregut digestive system malignancies and soft tissue sarcomas.[24] Patients with higher grade and advanced-stage tumors seem to have the highest risk of metachronous extrathymic malignancies.[70]

The vast majority of thymomas are indolent, but if the tumors spread, they most commonly implant on regional pleural surfaces (the so-called “drop metastases”), which can progress to malignant pleural effusions.[18,71] Other mechanisms for metastases are uncommon for this histology. The rate of lymphogenous metastasis in a large database of 1,093 patients with thymomas was 1.8%, with 90% of positive lymph nodes located in the

anterior mediastinum.[72] Only rarely do thymomas spread hematogenously, though metastases have been reported in the liver, lung, and bone.[73]

Diagnosis

The radiographic presence of an anterior mediastinal mass is suggestive of a thymic tumor as these histologies account for the majority of masses in this location (see Table 58.1).[11] A clinical diagnosis of thymoma can sometimes be made based on the presence of an anterior mediastinal mass in conjunction with clear evidence of a parathymic syndrome, such as myasthenia. The absence of symptoms suggestive of lymphoma (fevers, weight loss, adenopathy) or tell-tale radiographic findings for rare histologies such as teratoma are further clues suggestive of a thymic malignancy.

Nonetheless, histologic confirmation is usually required to establish a definitive diagnosis. Biopsy can be performed via a fine-needle aspiration, bronchoscopy, mediastinoscopy, video-assisted thoracoscopy (VATS), or open biopsy. Historically, biopsies were assumed to be relatively contraindicated because of a concern for tumor spillage into the pleural space when the capsule was breached.[74,75] However, no cases of seeding of a needle tract or the biopsy site have been reported in recent series, and only three recurrences in thoracotomy scars have been reported.[76,77] In fact, multivariate analysis in one series of 136 patients being treated for thymomas showed better survival among patients who underwent biopsy before surgery ($P = .056$).[50] Therefore, many centers routinely obtain biopsy samples of anterior mediastinal tumors for histologic assessment.[20,49,76,78-81]

When thymoma is suspected or confirmed, the diagnostic workup begins with a careful evaluation of myasthenia gravis. Routine blood work for commonly associated syndromes should be done, with serum α-fetoprotein and β-human chorionic gonadotropin in men to rule out a germ cell tumor.[82] In addition to laboratory studies, imaging is a hallmark of thymoma diagnosis and treatment planning.

Plain film chest x-rays were historically the main diagnostic modality for identifying and measuring thymic tumors. Thymomas tend to appear as ovoid, smooth, and unilateral mass occupying the space between the thoracic inlet and the cardiophrenic angle.[83] More advanced presentations

may present an irregular border between the mediastinum and the lung, suggesting lung invasion, or elevation of the diaphragm if the phrenic nerve has been infiltrated.

Contrast-enhanced CT is the most common technique for visualization of thymomas and other anterior mediastinal masses.[45,84-86] Magnetic resonance imaging (MRI) can provide more detail when needed, delineating the musculoskeletal anatomy and neurovascular structures of the mediastinum.[87-89] MRI may also improve sensitivity for defining the soft tissue extent of the mass in addition to providing information regarding tumor grade and invasiveness beyond that which can be gleaned from CT. Common features indicative of a high-grade tumor include low T2-signal foci within the mass, the presence of mediastinal lymphadenopathy, an incomplete capsule, and/or inhomogeneous enhancement (Figure 58.3).[90,91]

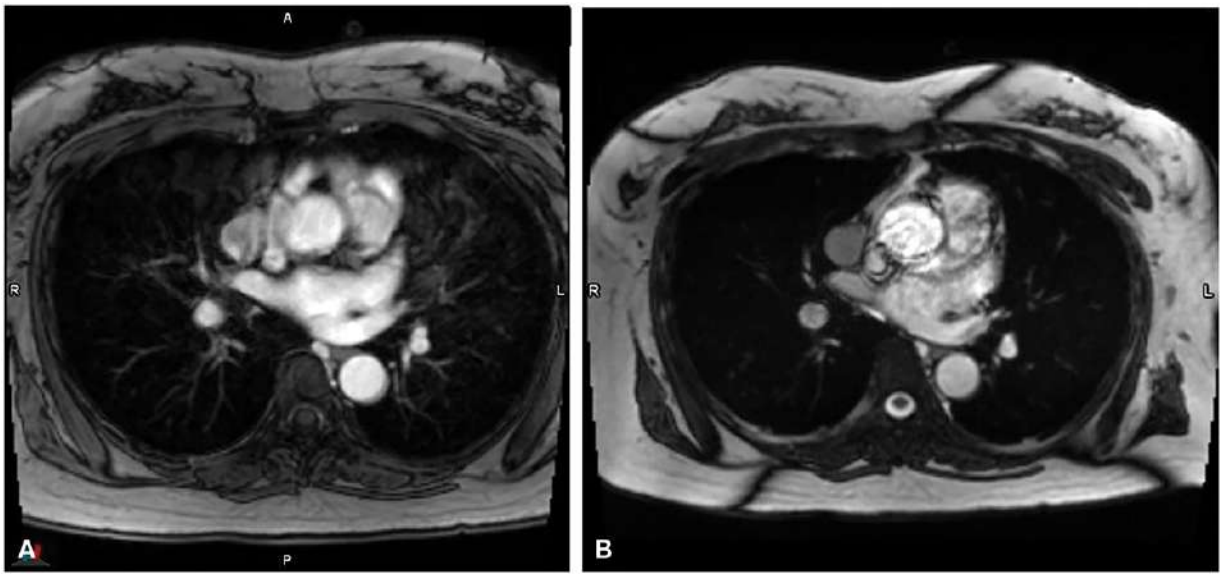

FIGURE 58.3 Magnetic resonance imaging of the chest for a patient with type AB thymoma. A. The lesion shows rapid enhancement on T1 postcontrast image. B. The lesion is T2 hyperintense compared with muscle on T2-weighted series.

The use of ^{18}F-fluorodeoxyglucose positron emission tomography (PET) is expanding for visualizing several types of malignancies, including thymoma. In the mediastinum, the results of PET can be confounded by the physiologic uptake of fluorodeoxyglucose by the thymus in children and young adults.[92-95] Nevertheless, this imaging modality has continued to

show promise for disease detection and for evaluating prognosis. Recent studies have shown that not only can PET improve the sensitivity of diagnosis, but it also can be helpful for establishing the grade of the disease and for distinguishing thymoma from thymic carcinoma, as the latter tends to have significantly higher metabolic activity.[96-100] In terms of distinguishing between lower and higher risk thymomas, maximum standardized uptake value may lack sensitivity, though some emerging data suggest that homogeneously distributed uptake is more characteristic of lower risk thymomas (types A, AB, and B1).[101]

In one provocative study in which 49 patients with thymic tumors underwent PET imaging, the rate of fluorodeoxyglucose uptake was compared with the expression of several biologic markers, including GLUT1, GLUT3, HIF-1α, vascular endothelial growth factor (VEGF), microvessel density, CD31 and CD34, p53, and bcl-2. The authors found a direct correlation between fluorodeoxyglucose uptake on PET and expression of GLUT1, HIF-1α, VEGF, and p53 as well as microvessel density, and several of these markers also correlated with tumor grade.[102] Predicting the presence of HIF-1α may also be germane to therapeutic strategies that seek to match radiation dose to the presence of hypoxia and its associated radioresistance in the tumor microenvironment.[101]

These findings are important because they imply that metabolic response may be a viable marker for measuring treatment efficacy. Figure 58.4 demonstrates PET findings from a patient with locally advanced thymoma treated with trimodality therapy. Indium 111-octreotide, carbon-11 methionine, and gallium-67 citrate, two other nuclear medicine agents, have also been reported to show some activity for thymic malignancies, but utilization of these modalities has been limited by their lack of sensitivity in distinguishing benign conditions such as thymic hyperplasia from frank neoplasia.[83,103]

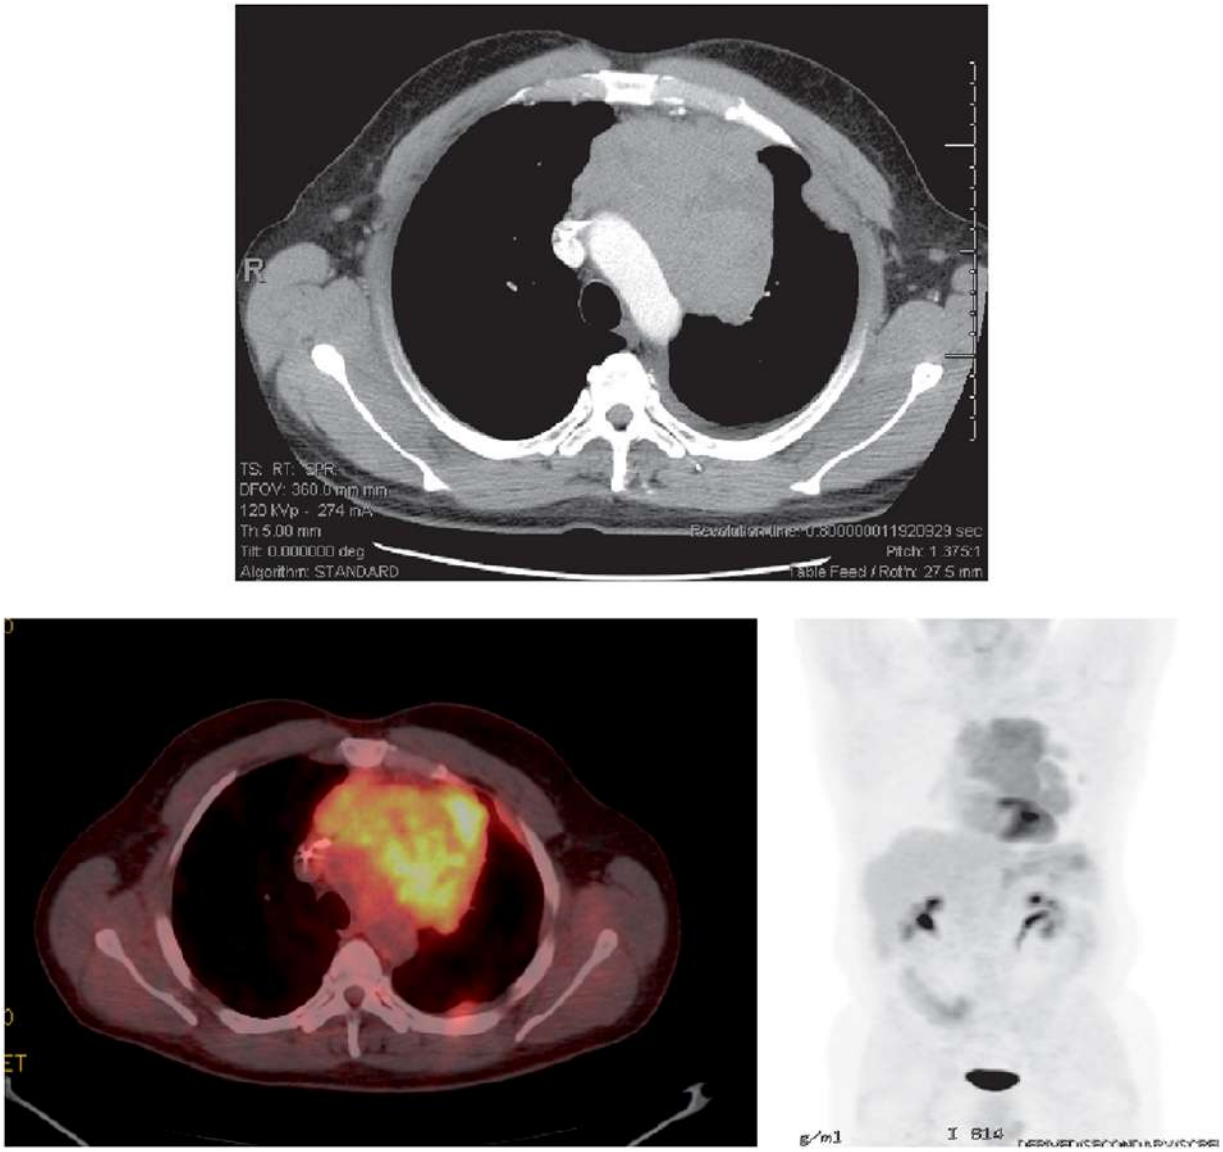

FIGURE 58.4 Positron emission tomography (PET) scanning in thymic malignancies. PET imaging has been shown to aid in delineating the extent of disease and assessing for metastases.

Pathologic Classification

The varied appearances and the frequent absence of classic malignant features have made thymomas challenging to classify pathologically. Disagreements on the prognostic importance of certain pathologic features have led to multiple proposed classification systems (Table 58.2). Indeed, even simple terminology such as “invasive versus noninvasive” or “benign versus malignant” has not accurately captured clinical behavior.

Recurrences and metastases after resection have been reported in all large series,[19,20,104-106] regardless of disease stage or histologic subtype.[18-20,22,23,44,49,50,105-113] Ultimately, even bland-appearing, noninvasive thymomas have the fundamental characteristics of a malignant tumor in their ability to recur and metastasize.

TABLE 58.2 THYMOMA CLASSIFICATION SYSTEMS

Bernatz et al[114]	Muller-Hermelink and Kirchner[115]	Suster and Moran[711]	WHO[123]
Spindle cell	Medullary	Thymoma, well differentiated	Type A
–	Mixed		Type AB
–	Predominantly cortical		Type B1
Lymphocyte rich	Cortical		Type B2
Lymphoepithelial			
Epithelial rich	Well-differentiated thymic carcinoma	Atypical thymoma	Type B3
–	High-grade thymic carcinoma	Thymic carcinoma	Type C

WHO, World Health Organization.

A historical perspective of thymoma classification systems is illustrative of the challenges of pathologic classification for thymoma. The earliest system, proposed by Bernatz, identified four categories based on the predominant cell type: lymphocytic, epithelial, mixed, and spindle cell.[114] In practice, this classification system is poorly correlated with clinical prognosis. Verley and Hollman later also identified four categories: spindle or oval, lymphocyte rich, differentiated epithelial cell rich, and undifferentiated epithelial.[105] The first three types are cytologically bland, whereas the fourth category includes pleomorphic tumors with high numbers of mitoses and atypia, which are also considered thymic carcinoma. Unfortunately, this categorization also did not correlate well with prognosis.

A third classification system based on work by Muller-Hermelink and associates based classification on the different subsets of epithelial cells found in the thymus: cortical, medullary, mixed cortical and medullary, and

well differentiated.[115] Although this system was widely used, again no consistent correlation between epithelial cell morphology and clinical prognosis has been validated.[116] Although some associations have been found, such as cortical thymomas behaving more aggressively and being more often associated with myasthenia gravis, several multivariate analyses have shown that the Muller-Hermelink classification system is not an independent predictor of survival, casting doubt on the link between this histologic classification and prognosis.[18,21,78-80,105,109,116-120] Another confounder for these classification schemes is that they do not consistently correlate with other schemes.[116] Concordance rates for thymomas classified independently by a panel of pathologists were often as low as 35% within one system, although two small studies demonstrated 78% concordance when using the Muller-Hermelink classification system.[121,122] The poor correlation between the histopathology of thymomas and their potential for aggressive malignant behavior or systemic syndromes underlines the need for a consistent and predictive classification system,[45] The current system—the World Health Organization (WHO) classification—represents an important step in this direction, though further refinement that perhaps includes a molecular component will likely be required.

The WHO classification, first proposed in 1999 and currently in its fifth iteration as of 2021, is similar to the Muller-Hermelink system but recognizes six different types of thymic tumors (A, AB, B1, B2, B3, C; see Table 58.2).[123-125] Type A tumors are composed of neoplastic oval or spindle-shaped epithelial cells without atypia or lymphocytes. Type AB is similar to type A, but with foci of lymphocytes. Type B tumors consist of plump epithelioid cells that can be subdivided into three subtypes defined by increasing proportions of epithelial cells and increasing atypia. Type B1 tumors resemble normal thymic cortex with areas similar to thymic medulla. Type B2 tumors have scattered neoplastic epithelial cells with vesicular nuclei and distinct nucleoli among a heavy population of lymphocytes; perivascular spaces are prominent, and a palisading effect of tumor cells along the perivascular spaces may be present. Type B3 is composed of predominantly round or polygonal epithelial cells exhibiting mild atypia admixed with a minor component of lymphocytes; thus, this type resembles what others have described as well-differentiated thymic carcinoma. Thymic carcinomas are designated type C tumors and have

cytologic atypia and a cytoarchitecture resembling carcinoma that is distinctively unlike normal thymus tissue.[126]

Concordance rates among different pathologists using the WHO system were reported to be 90% and 95% in two independent studies.[127,128] The most clinically distinct subtypes are type B3, formerly known as well-differentiated thymic carcinoma, and type C, thymic carcinomas. The clinical characteristics associated with the other WHO subtypes still vary considerably, but the WHO system at least seems to correlate well with Masaoka stage (Table 58.3) in studies in which patients were analyzed with the WHO system.[126] The vast majority of type A and AB tumors are Masaoka stage I or II, and the B subtypes tend to resemble the higher Masaoka stages.[126]

TABLE 58.3 MASAOKA STAGING SYSTEM FOR THYMOMAS

Stage		Description
I		Macroscopically completely encapsulated, with no microscopic capsular invasion
II	a	Macroscopic invasion into surrounding mediastinal fatty tissue or mediastinal pleura
	b	Microscopic invasion into the capsule
III		Macroscopic invasion into surrounding organs
IV	a	Pleural or pericardial implants/dissemination
	b	Lymphagenous or hematogenous metastases

Adapted from Masaoka A, Monden Y, Nakahara K, Tanioka T. Follow-up study of thymomas with special reference to their clinical stages. *Cancer*. 1981;48(11):2485-2492. Copyright © 1981 American Cancer Society. Reprinted by permission of John Wiley & Sons.

With regard to prognosis, the WHO system has been found to have independent prognostic value for disease-specific survival, with only two small studies indicating that stage was the only prognostic variable.[126] Most of the prognostic value of the WHO classification is attributable to type C having distinctly worse survival,[129-131] but even studies that excluded type C could demonstrate WHO type as having independent prognostic value.[131,132]

More recent pathologic studies have provided intriguing insights into prognostic histologic features. In one such study by Shim and colleagues

that involved assessing the effect of stromal lymphocytic infiltration in thymic carcinoma,[133] patients with low levels of $CD4^+$ lymphocytes and $CD20^+$ lymphocytes within the tumor stroma were found to have lower survival rates, and various combinations of $CD4^+$, $CD8^+$, and $CD20^+$ cells were particularly predictive of worse survival outcomes. These authors concluded that these lymphocytes may work together to suppress cancer progression and that combinations of them may be useful for stratifying patients in terms of long-term prognosis.[133]

Molecular Characterization

During the past several years, pathologic classification systems for several thoracic malignancies have been refined by the incorporation of molecular markers, including expression of subtype-specific markers at the RNA/protein level and identification of somatic mutational alterations in tumor DNA. These findings have tried to bridge the gaps between the histology of normal cortical and medullary epithelium and the genetic alterations present in tumors, and these efforts remain a work in progress with room for ongoing improvement.[134] Inspired by the efforts to identify targeted therapies in other nonthymic malignancies, several studies have shown elevated expression of the epidermal growth factor receptor (EGFR) in large percentages of thymic malignancies, similar to what is observed among non–small cell lung cancer (NSCLC) and other epithelial cancers.[135-138] However, increased EGFR expression in thymoma is rarely associated with accompanying mutations,[139-141] and targeted EGFR inhibitors have not shown consistent improvements in thymic tumor response or disease control rates.[142-144] Other signaling pathways that often show overexpression are the VEGF,[145] IGF-1R,[146] and KIT pathways,[147,148] although, again in most circumstances, the overexpression takes place mainly in thymic carcinomas rather than thymomas. Beyond expression targets with therapeutic relevance, a recent study has identified frequent POU2F3 expression in thymic carcinoma with squamous differentiation.[149] POU2F3 has recently emerged as a molecular subtype of small cell lung cancer and may represent a dependency for tumor growth.[150]

Patterns of somatic mutational alterations have been well defined with array-based comparative genome hybridization and next-generation

sequencing. Two major findings have been described, largely in a mutually exclusive manner. For patients with type A and AB thymomas, point mutations in general transcription factor II-I are present in upward of 80% of cases and associated with improved overall survival.[151,152] The mutations are missense variants (p.L424H) that are unique to thymoma and not observed in other malignancies, thought to alter expression of transcriptional targets though ultimately incompletely understood. Type A and AB thymomas are also associated with expression of a large microRNA cluster on chromosome 19 associated with the PI3K pathway with unclear therapeutic relevance.[153] By contrast, copy number alterations are frequently observed in B-subtype thymomas and thymic carcinoma.[154] Alterations are typically low-level gains without amplifications. Some alterations are shared between thymoma and thymic carcinoma (such as 1q gain, 3p loss, and 6 loss), while others can demonstrate a mutually exclusive relationship between histologies (such as 7p or 7q gain in thymoma and 8q24 gain and 16q loss in thymic carcinoma).

These historical findings have been validated in a project from the Cancer Genome Atlas Project to molecularly subtype thymic epithelial tumors using a data set of 120 patients using multi-omic approaches incorporating DNA mutational analysis, messenger RNA (mRNA) expression, and somatic copy number alterations.[155] This tour de force analysis identified four distinct molecular subtypes that largely reflected the known WHO subtypes. The first two were characterized, respectively, by G2F2I mutation or mRNA clusters associated with T-cell signaling expression. The next two subtypes were characterized by the presence or absence of chromosomal stability based upon somatic copy number. These subtypes were associated with disease-free and overall survival. As in other malignancies like breast cancer, the identification of molecular subtypes holds promise for novel strategies in the identification of targeted therapies, though no efforts have been successful to date.

Staging

The most commonly used staging system for thymomas was published by Masaoka and associates in 1981 (Table 58.3).[107,156] Staging is based on the extent of either macroscopic or microscopic invasion into structures

including the thymoma capsule and surrounding mediastinal structures at the time of surgery. Other groups have tried to improve upon the Masaoka system. For example, the French Groupe d'Etudes des Tumeurs Thymiques classification (Table 58.4) incorporates completeness of resection, which may be of prognostic value but does not allow patients to be compared independent of treatment factors.[157]

TABLE 58.4 GROUPE D'ETUDES DES TUMEURS THYMIQUES (GETT) THYMOMA STAGING SYSTEM

Stage		Description
I	a	Encapsulated tumor, completely resected
	b	Macroscopically encapsulated tumor, completely resected Surgeon suspects mediastinal adhesions and potential capsular invasion.
II		Invasive tumor, completely resected
III	a	Invasive tumor, subtotal resection
	b	Invasive tumor, biopsy only
IV	a	Distant pleural implants or supraclavicular metastasis
	b	Distant metastasis

It is a testament to the robustness of Masaoka classification system that it has persisted nearly unchanged for 30 years. But despite its popularity, areas of ambiguity have persisted, especially with regard to the Masaoka system's tendency to incorporate both clinical and pathologic data. For instance, some clinicians have questioned the precision with which one can assess that a "tumor is adherent to but not breaking through mediastinal pleura." After all, the mediastinal pleura is not typically in the pathologic specimen.[158] Therefore, a group headed by the ITMIG proposed a new staging classification in 2013 based upon TNM staging principles.[159] The T-stage—which still drives staging does not distinguish between encapsulated and unencapsulated tumors. Staging is broken down as the presence or absence of microscopic invasion into mediastinal fat (T1a), invasion into mediastinal pleura (T1b), pericardium (T2), "more resectable" organs (T3),

and “less or unresectable” organs (T4).[160] Although it remains to be seen whether this staging system can provide better prognostic information above historical staging systems, at the very least, it provides a standard template for communication among physicians and for the design of collaborative trials, an essential contribution by the staging system for the investigation of a rare disease like thymoma. There are challenges in using the new TNM staging system to make decisions regarding the need for adjuvant radiation therapy as the data on the role for adjuvant radiation therapy are predominantly based on the Masaoka staging system. Table 58.5 is a helpful tool to extrapolate Masaoka staging system[156] to the TNM staging system in order to help with making recommendations for adjuvant therapy.[161]

Prognostic Factors

The two factors that have consistently demonstrated prognostic value in multivariate analyses in large studies are tumor invasiveness (ie, disease stage) and completeness of resection.[18,19,21,22,36-38,43,49,50,78,104,107,162-165] Disease stage has proved important for prognosis in every large study.[18-20,22,23,44,49,50,104,107,166] Mean overall survival rates at 15 years are 78% for those with stage I disease, 73% stage II, 30% stage III, and 8% for stage IV disease (Table 58.6).[19] At 10 years, mean disease-free survival rates are 92% for those with stage I disease, 87% stage II, 60% stage III, and 35% for stage IV (recurrence rates are summarized in Table 58.7).[19,22,104,117,165]

The extent of resection is the other major factor consistently identified as being prognostic in thymic malignancies.[19,49,50,167-169] Patients for whom complete (R_0) resections can be done have significantly better survival than do those with R_1 or R_2 resections.[107,170] R_0 resections are almost always possible for stage I tumors, but resectability rates decrease on average to 50% for stage III tumors.[20,23,44,107]

As mentioned previously, the WHO histology classification was found to be independently associated with prognosis. Major studies reporting

analyses of stage, histology, and resection status as independent predictors of survival in thymic tumors are summarized in Table 58.8. Other potential prognostic factors are tumor size and the presence of symptoms.[18,49,109] Interestingly, although bulky tumor size was classically defined in terms of a 10-cm threshold, a more recent publication of 154 consecutive patients with thymic epithelial tumors treated in the modern era (2000-2014) demonstrated that a size greater than 4 cm was associated with worse relapse-free survival, even among patients with stage I disease.[171] With regard to symptoms, older series reported that patients with parathymic syndromes such as myasthenia gravis and other autoimmune diseases fared worse than those without such syndromes,[46,49,165] but this finding has not been replicated in newer series.[19,22,23,50,79,80,107,109,163,172-174] Indeed, some studies have found survival to be better for patients with myasthenia gravis,[20,50,175] perhaps because of earlier detection of thymomas.[49,176-178] A study published in 2005 indicated that myasthenia gravis, present in 25% of 1,089 patients from Japan,[54] did not affect 5-year overall survival rates among patients with stage III disease. For patients with stage IV disease, 5-year overall survival rates were 85.1% for patients with myasthenia gravis versus 63.9% for patients without. R_0 resection was accomplished in a significantly higher proportion of patients with myasthenia gravis (60%) than those without it (38%).

[b]Overall survival instead of disease-free survival.

Another potential prognostic factor is patient age. Patients older than 30 to 40 years may have a better prognosis than younger patients.[18,78,165] Thymomas in children seem to follow a more malignant course than those in adults.[179] Fortunately, malignant thymomas in children are extremely rare.[180]

General Management

The number of treatment modalities that have shown activity for thymoma are numerous and include surgery, radiation, cytotoxic chemotherapy, immunotherapy, and targeted agents. The optimal utilization and sequencing of these treatments is not well defined by randomized prospective trials. Therefore, treatment selection for these tumors can be daunting. The ITMIG, therefore, advocates that patients with thymic epithelial tumors are best served in a setting in which multimodality consultation can occur prior to initiation of treatment.[181] The authors agree that multidisciplinary consultation is critical to achieve best outcomes.[182]

Surgery

Surgical resection is the mainstay of treatment for thymomas. A complete en bloc surgical resection (R_0) remains the treatment of choice for all thymomas, regardless of invasiveness, except in rare, advanced cases with extensive intrathoracic or extrathoracic metastasis. Fortunately, the vast majority (90%-95%) of thymomas are localized.[183] Operative mortality rates average 2.5% (range 0.7%-4.9%).[18-20,23,44,49,104,184] Resectability rates for stage I thymomas should approximate 100%, but those rates vary widely for higher stage thymomas: 43% to 100% (mean 85%) for stage II, 0% to 89% (mean 47%) for stage III, and 0% to 78% (mean 26%) for stage IV.[104]

Because the completeness of resection is such an important prognostic factor, an aggressive surgical approach is justified to remove as much of the lesion as possible at surgery. If residual microscopic disease is suspected of

being present (an R_1 operation), metallic clips should be placed to help delineate the radiation field. Whether subtotal resections are beneficial is controversial, with some authors demonstrating better survival when debulking takes place before adjuvant radiation therapy[20,23,53,107,108,165] and others finding no benefit from debulking over biopsy alone.[19,20,23,49,78,157,165,175,185] One large study found significant differences in 5-year survival rates among patients undergoing subtotal resection versus biopsy only (64% vs 36%) but little difference in 10-year survival rates, suggesting that any benefit may be only in intermediate- term survival.[53] Resection for thymomas should include a lymph node dissection, including dissection of the deep thymic region (N2) lymph nodes for more advanced tumors.[186]

Traditional surgical techniques for patients with stage I thymic tumors produce 5-year survival rates in excess of 90%, with survival rates decreasing slightly at 10 years,[20,23,66] and with local recurrence rates of less than 5%. For stages II and III disease, recurrence rates after surgery alone range from 10% to 47%. In a study of more than 100 patients previously treated for thymoma, causes of death were as follows: 38% were related to thymoma (range 19%-58%), 9% to postoperative causes (range 2%-19%), 22% to myasthenia gravis (range 16%-27%), 9% to other autoimmune diseases (range 2%-19%), and 29% to unrelated causes (including other cancers) (range 8%-47%).[18-20,22,23,44,50,105,108,117,165] Recurrence rates are summarized in Table 58.7.

The use of minimally invasive techniques including VATS thymectomy and robotic thymectomy has come into use over the past decade. Video-assisted techniques are generally accepted for benign conditions of the thymus, but their appropriateness in oncologic settings is a matter of active investigation. A Japanese center reported on using this procedure to treat 35 patients with clinical stage I thymoma from 1998 to 2009.[187] The authors reported the technique to be safe, with no perioperative deaths and three minor complications. Disease in 20 of the 35 patients was upstaged to Masaoka stage II or III at the time of surgery. At an average follow-up time of 65 months, one patient had experienced recurrence in the bilateral lung.[187] Similarly, a Polish group reported on 24 patients operated on for thymoma with VATS, which resulted in no operative mortality and one

bleeding complication.[188] Finally, a Chinese center reported on comparative outcomes between 15 patients with early-stage thymoma with myasthenia gravis treated with VATS and 18 patients treated with the trans-sternal technique. The VATS patients achieved similar perioperative morbidity and significantly better neurologic outcomes, although the authors noted that selection bias may have influenced the latter finding as the open sternotomy patients had, on average, more advanced tumors.[189]

Despite this promising safety profile, it is an open question whether the oncologic outcomes will be the same as open procedures. Nakagiri et al compared 45 patients with early-stage thymoma who underwent VATS thymectomy with 29 patients who underwent open sternotomy.[190] They noted that all three cases of pleural recurrence occurred in the VATS group. Their conclusion was that VATS was oncologically feasible but that the technique should be favored for patients for whom en bloc resection is likely; special caution should be exercised for large or cystic tumors, for which the risk of capsular injury and tumor spillage is high.

Robotic surgical techniques have also become an accepted approach at specialized centers. The potential advantages of robotic techniques include increased rates of preserved pulmonary function, improved cosmesis, and higher rates of patient compliance because of the minimally invasive nature of the surgery.[191] The improved visualization and versatility of the robotic technique may allow for increased radicality of thymectomies by allowing surgeons to achieve resections in challenging anatomies such as patients with tumor located between the aorta and innominate vein or in those with encasement of the left phrenic nerve.[192]

Several institutions have explored the use of robotics in thymectomy, and a few studies have been published. Rückert et al demonstrated the feasibility of this technique for patients undergoing thymectomy for myasthenia gravis.[193] That same group of investigators then published a retrospective cohort study comparing robotic and nonrobotic thoracoscopic thymectomy and found that rates of remission of myasthenia gravis were actually higher for patients who had received a robotic thymectomy; the authors attributed this finding to the potential for improved mediastinal dissection with the robotic technique.[194] A survey of the utilization of robotic techniques published in 2013 revealed that nearly 3,500 robotic

thymectomy cases had been performed at approximately 100 centers worldwide.

Finally, surgeons have recently asked whether patients with early-stage thymoma and no evidence of myasthenia may be served by thymomectomy (removal of the tumor alone, akin to a wide local excision) rather than complete thymectomy. Tseng et al reported on a cohort of 95 patients treated at a Taiwanese center between 2002 and 2011.[195] Forty two patients underwent thymomectomy, while 53 underwent complete thymectomy. As expected, patients undergoing thymomectomy had lower morbidity and shorter hospitalizations. Intriguingly, after a median follow-up of 57 months, neither the rate of tumor recurrences nor myasthenia neurologic outcomes were significantly different in the two groups. A separate retrospective series of thymomectomy with or without extended thymectomy for patients with stage I or II thymomas did not report a difference in tumor recurrence rates with a more limited resection.[196] As these are nonrandomized retrospective studies with limited patient numbers and length of follow-up, the results should be interpreted with caution. Nevertheless, minimizing not just surgical technique, but also the surgical target itself, is a compelling subject for further inquiry.

The appropriate use of these newer surgical techniques and surgical paradigms will clearly evolve as more evidence is collected on their safety and oncologic efficacy. Publication of long-term outcomes and development of clinical trials, whenever possible, will be critical for defining the role of these novel approaches in the spectrum of thymic malignancies.

Patterns of Failure

The pattern of failure in the overwhelming majority of thymomas is locoregional: 81% of recurrences are local, 9% are distant, and 11% are both.[18,19,44,49,105,106] Figure 58.5 demonstrates that, although recurrences in a radiation field are rare, a significant number of intrathoracic recurrences are observed along pleural surfaces.[197]

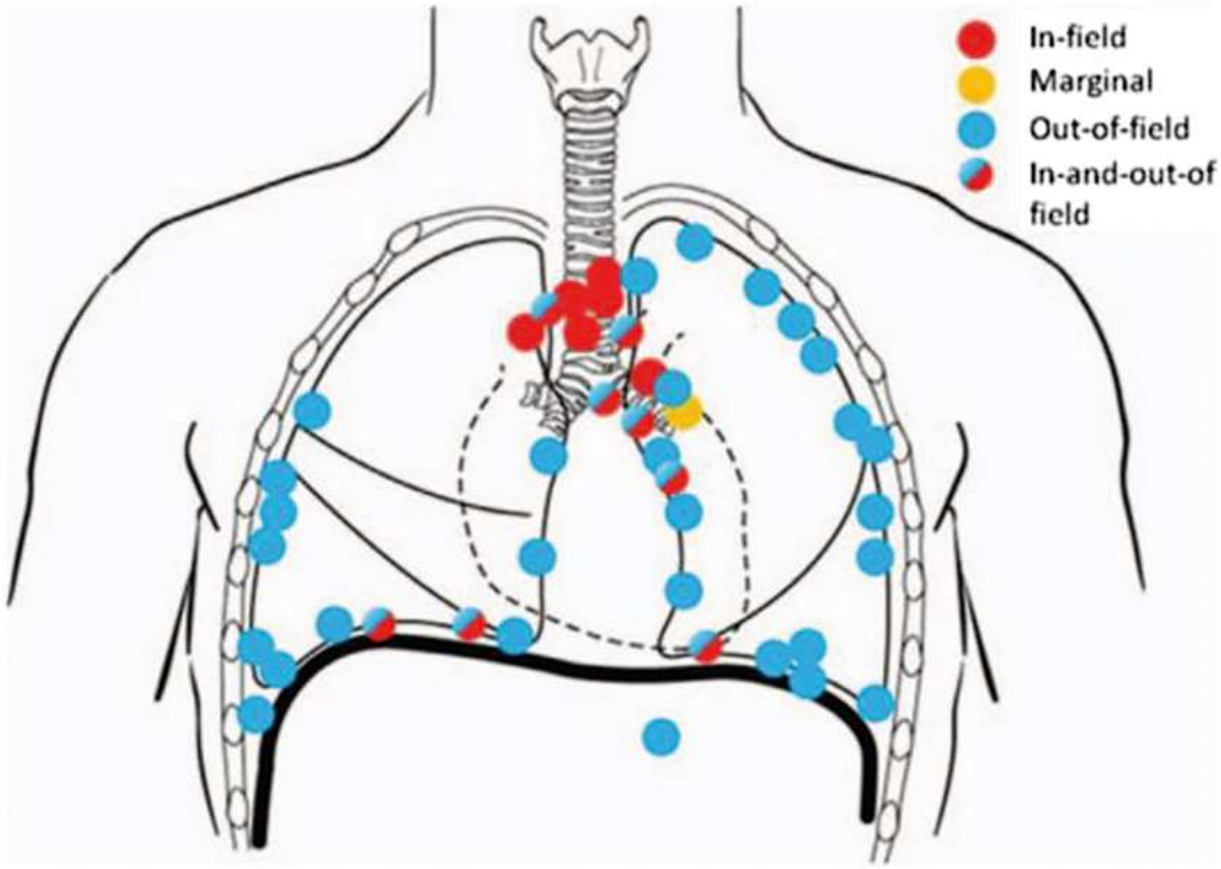

FIGURE 58.5 Graphical illustration of failure patterns following radiotherapy for stages II to IV thymoma. (Reprinted from Rimner A, Gomez DR, Wu AJ, et al. Failure patterns relative to radiation treatment fields for stage II-IV thymoma. *J Thorac Oncol*. 2014;9[3]:403-409. Copyright © 2014 International Association for the Study of Lung Cancer. With permission.)

Most recurrences arise within 3 to 7 years,[18-20,49,50,106] but recurrence has been documented as late as 32 years after the initial resection.[44,56,173,198,199] Given the tendency for late recurrences, patients require at least two decades of follow-up after potentially curative therapy.

If technically feasible, the traditional recommendation for recurrence has been surgery and adjuvant radiation.[77,106,200] Most recurrences (50%-75%) are operable, and of those that are operable, the reported rates of a successful R_0 resection range from 45% to 71%.[49,77,104,106,201] Patients with a recurrence after an R_0 resection generally experience acceptable short- and long-term results,[77,200] with 10-year actuarial survival rates ranging from 53% to 72%[77,104,106,202]; 10-year survival rates after an incomplete resection, by contrast, range from 0% to 35%.[19,77,104,106,202]

Despite the historical tendency to reresect operable recurrences, some emerging data suggest that this recommendation for reresection should be tempered by the high rate of additional recurrences. In one study from Memorial Sloan Kettering Cancer Center, of 25 patients who experienced recurrent disease after initial resection, 11 (44%) had disease that was amenable to reresection. In that same study, 50% of patients undergoing surgery for recurrent disease had an R_0 resection, but 82% of these patients still experienced a second recurrence. The authors concluded that "despite the historical enthusiasm for re-resection … reoperation should be considered only in selected patients."[203]

When recurrent disease is unresectable, radiation and chemotherapy have been used with modest results: 5-year overall survival rates reportedly range from 25% to 50%, with poorer longer term survival.[20,49,104,106,201,204]

Radiation Therapy

Adjuvant Radiation After Complete Resection

Recurrence rates for stage I thymomas after an R_0 resection are so low that radiation is considered unlikely to offer improvement.[205] More commonly, radiation therapy is offered as an adjuvant treatment for patients with resected stage II and III thymomas or those with incompletely resected tumors. However, patterns of care studies demonstrate significant controversy around these indications; some centers recommend adjuvant radiation for all patients,[23,108] others recommending adjuvant radiation for stage II and III thymomas,[19,66,81,157,165] and still others recommending radiation only after an incomplete resection.[53,157,165] The reason for this diversity of opinions is that the evidence regarding adjuvant radiation is retrospective, and, because of the rarity of thymoma, studies span many decades. Nonetheless, because disease stage and completeness of resection are such important prognostic factors, analyses of adjuvant radiation have tended to focus on these factors.

For completely resected stage II thymoma, studies have been mixed with regard to local control benefit of adjuvant radiotherapy, with some studies showing trends toward better local control after adjuvant radiation, others finding no difference in recurrence rates, and one series reporting worse results with adjuvant radiation.[53,106,206-209] A report by Chang et al of patients

with completely resected stage II or III thymoma demonstrated similar overall survival rates but improved disease- free survival rates with adjuvant radiation therapy (93% with radiation vs 70% without).[206] In counterpoint, Berman and associates found that the local recurrence rate among 74 patients after complete resection for stage II disease was only 3% and was not affected by receipt of adjuvant radiation.[207] Utsumi et al reported similar findings in a study of patients with stage I or II completely resected disease.[208] Finally, a SEER analysis of 901 patients showed no clear benefit from adjuvant radiation for patients with completely resected disease.[209] Some studies have sought to fine-tune the pathologic indications for adjuvant radiotherapy in stage II disease with additional high-risk features beyond capsular invasion. For instance, Haniuda and colleagues found that patients with fibrous adhesion to the mediastinal pleura without microscopic invasion benefited the most from postoperative therapy[210]: Recurrence rates among patients with such adhesion were 36.4% versus 0% among those without adhesion.

Similar to the literature for stage II disease, there are mixed findings in the literature regarding the role of adjuvant radiation after R_0 resection for stage III thymoma. Traditionally, the literature has consisted of small retrospective studies showing excellent local control after radiation but unclear survival benefit with conflicting results. An illustrative example of a positive result in terms of local control is an early study by Urgesi and colleagues, who reported no in-field recurrences and only three out-of-field recurrences among a cohort of 33 stages III and IVa patients treated with surgery and radiation.[163] Similarly, Ogawa reported on 103 patients with stages I to IV thymoma treated with postoperative radiation and found a 100% in-field control rate.[211] And yet the impact of local control benefit on survival outcomes has not been borne out in some single-institution studies. For instance, Shen and colleagues reported on 83 patients with completely resected stage II and stage III thymic epithelial tumors and found no survival benefit to adjuvant radiation in this group.[212]

Studies using large population-based databases to assess the role of postoperative radiotherapy have reported mixed results. The Japanese Association for Research on the Thymus Database Study published its findings on postoperative radiotherapy for stages II to III thymoma in 2015

using the records of 2,835 registered patients. In multivariate analysis comparing those who either did or did not receive adjuvant radiation, the study found no benefit to radiotherapy for either relapse-free survival or overall survival.[213] Furthermore, subgroup exploratory analysis failed to identify factors among the stage III patients that could reliably predict a benefit to adjuvant radiation.

In contrast to the Japanese study, three population-based analyses found an association with adjuvant radiation with improved outcomes. Weksler et al reviewed the outcomes of 798 patients with stage III thymoma in the SEER database. In multivariate analysis, postoperative radiation therapy after surgery was associated with improved disease-free survival, but not with overall survival.[214] Jackson and colleagues reported on a population cohort of 4,056 patients in the National Cancer Database with all stages of thymoma and found that adjuvant radiation was associated with improved overall survival after adjustment for other clinical factors. Subgroup analysis found that this benefit was most pronounced in patients with stages IIB to III disease and with positive margin.[215] Lastly, an analysis of 1,263 patients in the ITMIG database who had undergone complete resection of a stage II or III thymoma found a 7% improvement in the 10-year overall survival among those given postoperative radiotherapy (86% vs 79%, P = .002).[216] Furthermore, the association of radiotherapy with overall survival was significant after multivariate adjustment.

The dose-response relationship is also a matter of contr oversy in the literature. Harnath and colleagues found that doses in excess of 50 Gy were associated with improved disease- free and overall survival among 27 patients diagnosed with thymic epithelial tumors and treated with adjuvant radiation. However, Fan et al reviewed the cases of 53 patients who underwent complete resection of stage III thymoma followed by radiation (range 28-60 Gy) and found to clear dose-response relationship.[217]

Even if local control is achieved, it is not evident that distant or regional recurrences or overall survival are clearly impacted by adjuvant radiation.[49,53,218-220] The North American thoracic intergroup of the National Clinical Trials Network proposed a randomized clinical trial for thymoma to further clarify the role of postoperative radiotherapy for resectable disease (as well as the impact of neoadjuvant or induction systemic therapy for unresectable or borderline thymoma), but CTEP ultimately rejected the

proposal as not being of sufficient priority for investment of NCI resources to support such an effort. Until a randomized controlled trial rigorously addresses the controversy around postoperative radiotherapy for completely resected tumors, we recommend that treatment for stage II or III disease should be made on an individual basis and should consider risk factors such as frank pleural or pericardial invasion, tumor grade, and comorbid conditions.

Decisions on the use of postoperative radiotherapy also need to carefully consider the potential long-term toxicities of radiotherapy in this population. Due to the location of the thymectomy bed extending over the heart, there can be significant exposure of the heart and cardiac substructures, including the left main and left anterior descending artery. The impact of cardiac adverse events on outcomes has been well documented in NSCLC[221,222] and breast cancer.[223]

We, therefore, strongly recommend that proposed treatment strategies be discussed in a multidisciplinary setting before the final recommendation is made. Ultimately, the evidence for adjuvant is limited by its largely retrospective character; a strong emphasis on designing and completing randomized controlled trials[224] (NCT02633553, NCT02014805) is needed to settle the role of adjuvant radiation in more definitive manner. For incompletely resected tumors, radiotherapy is often considered to be an important adjunctive treatment for addressing residual disease. Although rigorous prospective evidence is unavailable for this clinical scenario, retrospective analyses have observed very low rates of mediastinal failure among patients with gross residual disease treated with adjuvant radiation.[39,163,225]

Radiation as Neoadjuvant Therapy

Radiation has been proposed as a neoadjuvant strategy to reduce tumor burden and improve resectability, especially for cases involving gross invasion of critical structures.[36,110,166,226-230] Response rates of up to 80% have been reported, and a theoretical decrease in the potential for tumor seeding during surgery has been proposed as well.[20,39,165,226] The rates of R_0 resections after neoadjuvant radiation for stage III thymoma can be as high as 53% to 75%,[110,230] which are favorable compared with the typical 50%

rate of R_0 resections of stage III thymomas.[19,22,23,39,49,81,107,157] Ten-year survival rates do not seem to be better after preoperative radiation, but to date, studies evaluating this approach have been small.[110,229,230] For patients recommended to receive neoadjuvant (preoperative) radiotherapy, the authors recommend consideration of platinum-based radiosensitizing chemotherapy.

Radiation as Definitive Therapy

Radiation therapy alone has been used for patients who cannot undergo surgery because of medical conditions, or those for whom surgical resection is not possible, with modest results. Arakawa and associates reported that 7 of 12 patients presenting with unresectable tumors treated with primary radiation therapy were still alive at follow-up times ranging from 1 to 5 years.[231] Ciernik and associates reported a 5-year survival rate of 87% for a small group of patients with stages III and IV disease who underwent radiation without resection,[225] and Jackson and colleagues found 10-year survival rates of 44% for patients who received radiation after biopsies or incomplete resections.[232] As for the use of radiation for recurrent disease, Urgesi and others reported on comparative outcomes of 21 patients with intrathoracic recurrences, of whom 11 were able to undergo resection/debulking and 10 were treated with radiotherapy alone.[201] The 7-year survival rate of 70% was similar for those treated with radiation alone and for those treated with surgery and adjuvant therapy. The standard dose for definitive radiotherapy ranges from 60 to 70 Gy in 2 Gy fractions, largely extrapolating from the principles of radiotherapy for NSCLC. Improvements in radiotherapy planning and treatment delivery have also increased interest in the use of hypofractionated radiotherapy with image guidance, including stereotactic body radiation therapy, to decrease the time under treatment while minimizing potential short and long-term toxicities. A single-institution prospective study of SBRT[233] in this population included 32 patients with thymoma or thymic carcinoma. In all, 56.3% of patients had IVA or IVB disease. The response rate was 96.9%, median progression-free survival (PFS) was 28 months, and local control rate was 81.25%. Treatment was well tolerated. Although combined modality therapy is often still prioritized for patients with unresectable thymoma,

these improvements in treatment planning and delivery provide an intriguing potential management option for selected patients.

Chemotherapy

Platinum-based chemotherapies serve as the backbone for combination regimens typically used in the first-line setting. Preferred regimens combine cisplatin and adriamycin, either in combination with cyclophosphamide or cyclophosphamide and vincristine. For patients with underlying cardiac risk factors where an anthracycline may be contraindicated, cisplatin/etoposide and carboplatin/paclitaxel are other acceptable regimens. Thymomas can be chemotherapy with overall response rates greater than 50%.[69,174,234-242] However, duration of response is often limited with median responses ranging from 12 to 18 months. Whether chemotherapy influences long-term survival is more difficult to assess. In one retrospective analysis of 90 patients, chemotherapy reduced the rates of metastases to the lung, pleura, or other sites by half (17% vs 38%, $P < .05$). All of those patients were high risk with stage III or IV tumors treated with radiation and partial or no resection.[165] Another study reported a nonsignificant trend toward better disease-free survival from the addition of chemotherapy.[185]

As is true for the literature on the effects of radiation, most of the series describing the use of chemotherapy are small, single-arm studies with approximately 20 patients owing to disease rarity. The absence of randomized control arms limits direct comparisons, exacerbating the typical caveats associated with cross-trial comparisons. The accepted primary end point for efficacy is overall response rate, which is not a validated surrogate for overall survival or PFS, typically accepted as gold standard for outcomes in systemic therapies. In addition, some studies of systemic chemotherapies predate the implementation of the current WHO guidelines for tumor subtyping, applying histologic classifications no longer in use. Most importantly, no retrospective studies have been able to describe any prognostic biomarkers for the likelihood of response to platinum-based chemotherapy regimens, preventing any efforts to stratify regimen selection on a patient-by-patient basis.

The most promising use of chemotherapy is in the neoadjuvant setting. Like preoperative radiation, chemotherapy seems to render tumors more

suitable for complete resection. An early investigation suggested that neoadjuvant chemotherapy was associated with improved survival for patients with stage III or IVa thymomas.[178] This hypothesis was more rigorously tested in a phase II prospective trial by Park et al: 27 patients with radiographic evidence of stage III or IV thymic malignancies were enrolled (9 were thymoma and 18 were thymic carcinoma).[243] After induction therapy with docetaxel/cisplatin, 19 of the 27 patients underwent surgery and 15 among the 19 achieved a complete resection, which represents 55.6% of the intent-to-treat population. Overall survival at 4 years were 92.9% and 62.2% among those who did and did not achieve complete resection, respectively, though statistical significance was not achieved (possibly as a result of the small numbers involved). This study serves as evidence that tumor resectability can potentially be improved with a course of systemic chemotherapy.

Aside from cytotoxic agents, cytostatic agents can also be beneficial, often with a more tolerable side-effect profile. This is best exemplified with somatostatin analogs (eg, octreotide) and high-dose corticosteroids.[244,245] In one prospective study, two courses of glucocorticoid therapy before surgery led to a 47% response rate among 17 patients with resectable thymomas.[246] This therapy seems to work by exploiting the ability of corticosteroids to induce apoptosis in $CD4^+$ $CD8^+$ immature thymocytes. Another prospective study by the Eastern Cooperative Oncology Group enrolled 42 patients with unresectable, advanced thymic malignancies for whom octreotide scans were positive. Patients were treated with octreotide with or without prednisone. Two patients had complete responses and ten had partial responses, which led the investigators to conclude that octreotide alone had modest activity and that prednisone improved the overall response rate.[247] Similar cytostatic agents include pemetrexed[248] and everolimus.[249] Though overall response rates were only 25% and 9.4%, respectively, disease control rates of 75% and 94%, and median PFS remained 12.1 and 16.6 months, respectively. For prednisone, octreotide, and everolimus, treatment may provide an additional immunosuppressive benefit in patients with paraneoplastic disease.

Targeted therapies, which seek to take advantage of aberrations in signaling pathways, have been investigated in small series for thymic malignancies. Early studies have focused on c-KIT, EGFR, IGF-1R, and

VEGF angiogenesis and histone deacetylation pathways.[141,250,251] Phase I/II trials with agents targeting receptors in these pathways, like those with EGFR- and IGF-1R–targeted agents, have been largely disappointing.[252,253]

Ultimately, a better understanding of tumor biology coupled with studies involving larger numbers of patients is necessary to advance targeted therapies in thymoma.

Immunotherapies are an intriguing therapeutic modality in thymoma, given the role of the normal thymus in promoting immunologic self-tolerance and frequent association with clinical paraneoplastic syndromes including myasthenia gravis. Two studies have evaluated the anti-programmed cell death protein 1/programmed death ligand 1 (PD-1/PD-L1) immune checkpoint inhibitors pembrolizumab[254] and avelumab[255] in a limited number of patients. While both studies featured response rates greater than 25%, clinical responses were invariably associated with grade 3 and 4 immune-related adverse events. Most concerning were the frequent associations with immune-related myocarditis causing complete heart block in two patients. These results may reflect the primed state for antigen cross-presentation and elicitation of adaptive immune responses. To this point, similar associations with paraneoplastic syndromes were seen in the phase 2 study of the IGF-1R inhibitor cixutumumab.[256] Current guidance is to avoid immune checkpoint blockade in thymoma outside the clinical trial setting.

Combined Modality Therapy

Some evidence exists to suggest that multimodality treatment can improve both resectability and long-term survival among patients with stage III or IV thymomas; typical combinations include neoadjuvant chemotherapy followed by surgery and postoperative radiation, chemotherapy, or both. Prospective trials of preoperative combination chemotherapy have been undertaken at several institutions[78,239,241,243,257,258]; the regimens in all cases included cisplatin with some combination of cyclophosphamide, doxorubicin, vincristine, prednisone, or epirubicin. Reported response rates to these regimens range from 62% to 100% (Table 58.9); R_0 resections were possible in 57% to 82% of cases; and pathologic complete response rates ranged from 4% to 31%. Overall survival rates at 5 years (57%-95%) were quite favorable for unresectable stage III or IV thymoma.[78,239,241,257,259] In

many of these studies, most if not all patients received postoperative radiation (Table 58.9), and the results seem superior to historical results from patients who underwent surgical resection alone. In summary, multimodality therapy consisting of preoperative combination cisplatin-based chemotherapy followed by surgery and postoperative radiation can produce excellent results. Although anthracycline-based chemotherapy is preferred for induction chemotherapy, for those patients who cannot tolerate anthracycline- based chemotherapy, induction chemoradiation with cisplatin and etoposide may be a reasonable alternative as determined by two prospective pilot studies by Korst et al[260] and Tamiya et al,[261] in which all patients were able to undergo resection.

TABLE 58.9 OUTCOMES AFTER COMBINED MODALITY THERAPY FOR THYMOMAS

Study	Institution	*n*	Pre-op Chemo	Adjuvant Therapy	% Response	% R_0	% pCR	% 5-Y Survival
Lucchi et al[178]	Pisa	36	Csiplatin, vp, epi	RT and chemo	67	78	6	65 (est)
Venuta et al[78]	Rome	25	Cisplatin, vp, epi	RT and chemo	–	80	4	80
Kim et al[241]	MD Anderson	22	Cyclo, doxo, cisplatin, pred	RT and chemo	77	82	18	95
Rea et al[239]	Padua	16	Cyclo, doxo, cisplatin, vin	RT or chemo	100	69	31	57
Yokoi et al[719]	Tochigi	17	Cyclo, doxo, pred	RT and chemo	93	12	7	81
Kunitoh et al[258]	JCOG	23	Cisplatin, vin, doxo, vp	RT	62	69	14	85
Park et al[243]	Seoul	27	Docetaxel, cisplatin	RT, chemo, or both	63	79	NR	79.4 (4 y OS)

cyclo, cyclophosphamide; doxo, doxorubicin; epi, epirubicin; pCR, pathologic complete response; pred, prednisone; R_0, complete resection; vin, vincristine; vp, etoposide.

Modest results have also been obtained from the combination of chemotherapy plus definitive radiation therapy for unresectable thymoma. A prospective intergroup study[234] reported a 5-year survival rate of 52.5% for 26 patients (96% Masaoka stage III), who were treated with cisplatin, doxorubicin, and cyclophosphamide followed by radiation therapy using a two-dimensional (2D) radiation technique to 54 Gy in 1.8 Gy/fraction from 1983 to 1995 for patients with unresectable thymomas. The median survival time was 93 months. A more recent prospective phase 2 study by Fan et al[262] reported a 5-year survival rate of 56% for 56 patients (75% Masaoka stage IVB) who were treated with definitive concurrent chemoradiation with cisplatin, etoposide, and 60 Gy in 2 Gy/fraction using intensity-modulated radiation therapy (IMRT) with an objective response rate of 85.7%. Next-generation studies in this patient population will likely test a hypofractionated approach.

Radiation Therapy Dose

Radiation doses given for thymoma have ranged from 30 to 70 Gy, most often given in standard 1.8- to 2.0-Gy fractions. Typical postoperative doses are 45 to 50 Gy, with higher doses for positive surgical margins (54 Gy) or gross disease (60-70 Gy). Dose-response effects have been difficult to determine owing to the retrospective nature of most published studies; one study did not identify a dose response,[263] but two others did.[185,264] One systematic review[265] failed to identify optimal doses in the postoperative and definitive settings due to the paucity and heterogeneity of published data.

Radiation Targets

The radiation approach and targets is dependent on the intent of treatment. Full descriptions of radiation therapy definitions, reporting guidelines, and targets and techniques for thymic malignancies are detailed in two papers by Gomez et al and developed with the ITMIG.[266,267] As radiation planning techniques have evolved, the trend in treating thymic tumors, like NSCLC, has been toward the use of involved-field techniques. Because thymomas do not routinely spread via the lymphatic system, the draining nodal distributions do not need to be included in the radiation fields.[106] In general,

neoadjuvant or definitive radiation therapy is delivered a clinical tumor volume consisting of the entire extent of gross disease as visualized on imaging with a further clinical tumor margin (1-2 cm) to account for microscopic infiltration. Extending the clinical tumor margin into the lung parenchyma is generally unnecessary.

When radiation is to be given as adjuvant therapy, the radiation treatment fields are designed to treat any residual gross disease and the surgical bed. This region is defined based on the pretreatment images, with the field generally encompassing the surgical field that can be defined by the placement of surgical clips and preoperative imaging that delineates the superior-inferior extent of disease before treatment. Again, a clinical tumor margin is added to account for infiltration beyond the area previously occupied by gross tumor.

It is highly advisable to review the treatment volumes for adjuvant radiotherapy with the operating surgeon to ensure that all areas of concern for recurrence are addressed. Likewise, the surgeon can aid the radiation oncologist by placing radio-opaque clips at the time of surgery to help define the tumor bed and other areas of interest. It is especially critical to mark in this way regions known to harbor an unresected positive margin based on frozen section or wherever there is a high expectation of margin positivity on permanent section.

There is evidence that these principles of delineation lead to good interobserver consensus; an investigation by Holliday and colleagues sought to measure interobserver variability by comparing contours among seven radiation oncologists given a pilot data set for a preoperative and postoperative case.[268] Their results showed exceptional agreement in the preoperative contours, although lower agreement was observed in the postoperative setting, further highlighting the benefit of multidisciplinary involvement that includes the surgeon for these cases.

Thymic tumors have a propensity to spread to the pleura. Radiation can be directed at pleural targets for palliation and to prolong disease control in select cases. A phase II study by Wang et al[269] treated patients with unresectable pleural metastases that progressed on chemotherapy with IMRT to 30 to 50 Gy in 2 Gy/fractions. This regimen was safe when one course of radiation was delivered and the control rates were higher with 50 Gy. Unfortunately, 93.5% of patients developed out-of-field failures,

indicating that only targeting areas of known pleural metastases is not sufficient in preventing future progression. In theory, hemithoracic intensity-modulated pleural radiation (IMPRINT) could be beneficial in thymic malignancies because of their tendency for drop metastases along the pleural surfaces. This technique has been assessed in several studies. In one such study, Sugie et al[270] reported findings from 60 patients with stages I to IV invasive thymoma, 48 of whom had been treated with fields limited to the mediastinum to a dose of 30 to 64 Gy and the other 12 given hemithoracic radiation therapy to a dose of 11.2 to 16 Gy. Although the toxicity of the extended-field (hemithoracic) radiation was acceptable and seemed to produce modest improvements in pleural dissemination rates, no differences were found in overall survival between the two techniques.[271] Other small studies have also tested hemithoracic radiation to doses of 15 to 20 Gy, and some have had promising results.[272-274] However, these studies were small and primarily retrospective. Ultimately, the dose that can be delivered safely in hemithoracic therapy is probably not sufficient for controlling microscopic disease, which typically requires 40 to 45 Gy. However, conformal techniques such as IMRT and proton therapy may allow further dose escalation as being studied in current investigations (ClinicalTrials.gov Identifier: NCT05354570).

Radiation Modalities and Simulation Techniques

CT-based treatment planning is essential for targeting the tumor and for accurate dosimetry of critical structures. In the modern era, 4D techniques or deep inspiratory breath-hold (DIBH) to manage respiratory motion are also helpful for ensuring coverage of the target as well as optimizing avoidance of organs at risk. As is true for all thoracic and mediastinal tumors, the major critical structures include the spinal cord; lung parenchyma; the heart and associated substructures, including the pericardium, cardiac chambers, and coronary arteries; esophagus; bronchus; and trachea. The guidelines to be followed to minimize dose to these structures are the same as those used in the treatment of lung cancer. Table 58.10 lists common dose constraints for radiation therapy, with or without chemotherapy, for mediastinal malignancies. These constraints were derived from a Quantitative Analysis of Normal Tissue Effects in the Clinic

Consensus analysis published in 2010.[275-278] Any deviations from these dose constraints should be reviewed in a radiation quality assurance setting and discussed with the patient before treatment is begun.

TABLE 58.10 STANDARD-DOSE CONSTRAINTS USED IN RADIATION THERAPY FOR THORACIC MALIGNANCIES

Organ at Risk	RT Alone	Chemo and RT	Chemo and RT Before Surgery
Spinal cord	D_{max} <45 Gy	D_{max} <45 Gy	D_{max} <45 Gy
Lung	Mean dose ≤ 20 Gy V_{20} ≤ 40%	Mean dose ≤ 20 Gy V_{20} ≤ 35% V_{10} ≤ 45% V_5 ≤ 65%	Mean dose ≤ 20 Gy V_{20} ≤ 30% V_{10} ≤ 40% V_5 ≤ 55%
Heart	V_{30} ≤ 45% Mean dose <26 Gy	V_{30} ≤ 45% Mean dose <26 Gy	V_{30} ≤ 45% Mean dose <26 Gy
Esophagus	D_{max} ≤ 80 Gy V_{70} < 20% V_{50} < 50% Mean dose<34 Gy	D_{max} ≤ 80 Gy V_{70} < 20% V_{50} < 40% Mean dose <34 Gy	D_{max} ≤ 80 Gy V_{70} < 20% V_{50} < 40% Mean dose <34 Gy
Kidney	20 Gy < 32% of bilateral kidney	20 Gy < 32% of bilateral kidney	20 Gy < 32% of bilateral kidney
Liver	V_{30} ≤ 40% Mean dose <30 Gy	V_{30} ≤ 40% Mean dose <30 Gy	V_{30} ≤ 40% Mean dose <30 Gy

D_{max} = maximum dose; V_x = percent volume of organ receiving *x* dose.

From Marks LB, Bentzen SM, Deasy JO, et al. Radiation dose-volume effects in the lung. *Int J Radiat Oncol Biol Phys*. 2010;76(3 suppl):S70-S76.

Major advances in radiation delivery over the past decade have led to great improvements in both the conformality and therapeutic ratio of radiation for thoracic malignancies. IMRT has been shown to allow the dose to normal structures to be reduced relative to that from 3D conformal radiation and to allow accurate target localization.[279-285] Indeed, a recent study of 496 patients with locally advanced, unresectable NSCLC demonstrated that the more advanced technique (4D CT with IMRT) led to lower rates of high-grade radiation pneumonitis and better overall survival compared with 3D simulation and 3D conformal therapy.[286] Although

similar comparisons for thymic malignancies have not been done because of the rarity of this disease as well as the paucity of respiratory movement of the superior anterior mediastinum, the same principles would be expected to apply, given the mediastinal location of these tumors and hence their close proximity to the lungs, heart, and esophagus.

Another treatment modality, proton beam therapy, has shown promise for reducing the dose to normal structures while maintaining adequate doses to the tumor target in NSCLC.[279,287-294] Indeed, the dose distribution properties of proton therapy, specifically the "Bragg peak" that minimizes dose distal to the tumor, are well suited for anteriorly located thymic tumors. Proton therapy has been shown to produce greatly reduced doses to critical structures in mediastinal lymphoma, which often presents in the same anterior location as thymic malignancies, compared with photon-based techniques.[295] Vogel and colleagues tested this hypothesis by comparing double-scattered proton beam plans to IMRT plans for 22 consecutive patients requiring treatment for thymic malignancies. They confirmed that proton beam therapy resulted in statistically significant reductions in dose to the heart, lungs, left ventricle, and spinal cord and that the baseline risk of major cardiac events was increased by 135% after IMRT and 74% after proton therapy ($P = .04$).[296] This same group as well as Mercado et al[297] published the first clinical results with proton therapy for patients with thymic malignancies, revealing low toxicity rates and acceptable recurrence rates. As these studies are small and either retrospective or from prospective registry data, further investigation via rigorous, prospective clinical trials will be essential in determining if the dosimetric benefits of proton beam therapy (Figure 58.6) translate to clinical benefits.

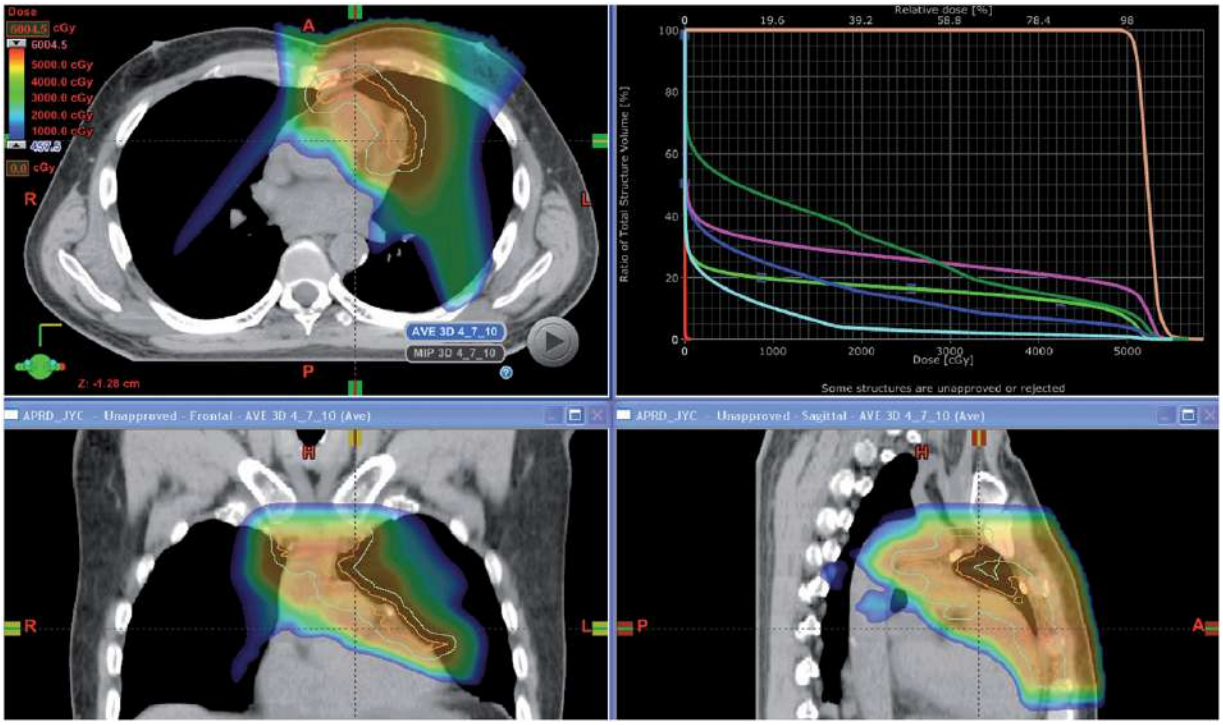

FIGURE 58.6 Axial, sagittal, and coronal views of a typical proton plan for postoperative treatment of thymoma. Surrounding structures including the lungs, heart, and esophagus have significantly diminished radiation exposure with this approach, as illustrated in the dose-volume histogram.

Regardless of treatment modality, we recommend that all treatment simulations for patients with thymic tumors take place while the patients are supine, and well immobilized with their arms above their head, to maximize the number of potential beam arrangements. We recommend that 4D CT scans be obtained at the time of simulation to assess the motion of the tumor during respiration. If 4D CT scanning is not available, we recommend either a slow helical scan to encompass all phases of the breathing cycle or that CT images be obtained at full inspiration (DIBH) and expiration to assess the extremes of respiratory motion.

THYMIC CARCINOMA

Natural History and Diagnosis

Thymic carcinomas are considerably less common than thymomas. Like thymomas, thymic carcinomas are thought to arise from the thymic epithelium and typically appear in the anterosuperior mediastinum. The

clinical behavior of thymic carcinoma is quite different from that of thymoma; they are generally more aggressive and have a higher propensity for capsular invasion, pleural involvement, and extrathoracic metastatic proliferation. Because of these features, thymic carcinoma often presents as advanced disease, and its 5-year survival rates are much poorer than for thymomas.[53,298,299]

Clinically, thymic carcinoma can present as cough, dyspnea, pleuritic chest pain, phrenic nerve palsy, or superior vena cava syndrome.[298,300,301] Associated paraneoplastic syndromes have been observed occasionally, though these are less commonly seen compared to thymoma.[301-303] CT scans often demonstrate an irregular mass with necrotic, cystic, or calcified regions.[300,304-306] In about 80% of cases, thymic carcinoma shows radiographic evidence of invasion into adjacent structures in the mediastinum, and mediastinal lymphadenopathy is evident at presentation in about 40%.[301,307-309] Distant metastases to regional lymphatics, bone, liver, kidney, and lung are also common clinical features.[301,310-312] Therefore, bone scanning, MRI, PET with 18F-flourodeoxyglucose or 11C-labeled methionine, and single-photon emission computed tomography have been used for both staging and evaluation of response to therapy.[92,313-316]

Historically, thymic carcinomas have been classified as type C thymic tumors in the WHO classification, and disease staging is often done with the Masaoka clinical staging system for thymomas and now with the official TNM staging system.[107,317] Most thymic carcinomas are undifferentiated high-grade lesions with anaplasia and marked cellular atypia, lacking the histologic features of a normal thymus[318]; others may be of adenocarcinomatous, sarcomatous, squamous, basaloid, mucoepidermoid, or lymphoepithelial-like histology.[300,319,320] Some thymic carcinomas are associated with multilocular thymic cysts, which are acquired lesions of the thymic gland associated with an inflammatory reaction. Recent studies have demonstrated the importance of thorough sampling of thymic cysts to rule out underlying carcinoma.[321]

Because histologic grade is one of the most significant indicators of prognosis, a revised histologic classification has been proposed that broadly divides thymic carcinomas into high-grade or low-grade lesions.[322] Tumors in the low-grade histologic group are characterized by a relatively favorable clinical course and a low incidence of local recurrence and metastasis.[323-325]

High-grade variants of thymic carcinoma are more lethal, with frequent metastases to regional lymph nodes, bone, liver, and lung.[306,326] In a recent study by Gao et al[327] of 127 patients with thymic carcinoma treated with complete surgical resection and adjuvant radiation therapy, the most common sites of failure were distant/nodal (32.3%), pleural (22%), and local (15%).

In addition to grade, extent of surgical resection, Masaoka stage, TNM stage, and receipt of adjuvant therapy are also associated with improved survival[328-331]; interestingly, the specific histology of thymic carcinoma, just as in thymoma, does not appear to reliably confer an impact on survival. Stage IVb patients with lymph node–only metastases may have better outcomes than those with distant metastatic disease at presentation, a result that may be driven by the possibility of curative resection in some of these patients.[332]

General Management

Owing to the paucity of prospective data with this rare tumor, the ideal therapeutic regimen is unknown. Current management strategies borrow from the principles of treating NSCLC. Thus, an aggressive multimodality approach is often employed, which includes the consideration of primary surgical resection, neoadjuvant or adjuvant cisplatin-based chemotherapy, and postoperative radiation therapy.

Although incomplete resection does not necessarily preclude long-term survival if multimodality platinum-based therapy is used,[333] complete resection is nevertheless the cornerstone of treatment.[328-331] The recently published American Radium Society (ARS) Appropriate Use Criteria[334] for thymic carcinomas recommended against the use of minimally invasive thymectomy for thymic carcinoma due to the infiltrative nature of these tumors. Reflecting multiple other single- institution studies, Takeda and colleagues observed a median survival time of 57 months for patients with completely resected thymic carcinomas versus 13 incomplete resection.[335] A multi-institutional study of patients with thymic carcinoma showed that the 5-year survival rates of total resection, subtotal resection, and inoperable groups were 67%, 30%, and 24%, respectively.[53] Likewise, a large series of 1,042 cases from the combined European Society of Thoracic Surgeons

(ESTS) and ITMIG databases reported overall survival rates for R0, R1, and R2 groups were 70%, 55%, and 42%, respectively.[330] In light of this consistent finding in multiple data sets, complete resection of the primary tumor is a fundamental recommendation.

The routine addition of lymph node dissection is more controversial, though it has merited attention because of the higher rate at which thymic carcinomas spread to regional lymph nodes in comparison to thymomas. Park et al retrospectively reviewed 37 patients with thymic carcinoma who were divided into four groups: no node dissection, N0 by limited dissection, N0 by extensive dissection, and N1 by dissection of any type.[336] Among the 29 patients who underwent node dissections, 6 (20.7%) were found to harbor nodal metastases. Furthermore, patients who underwent no dissection or node negative after limited dissection had outcomes that were inferior to those who were node negative after an extensive dissection. These results suggest that an extensive dissection may impart more accurate staging and better prognostic information. Though this intriguing study requires confirmation in larger investigations, it raises an intriguing hypothesis that routine lymph node dissection may improve outcomes either by the therapeutic effect of completely excising gross disease or by providing better guidance for necessary adjuvant therapies.

The role of radiotherapy for thymic carcinoma is not well defined, again owing to the rarity of the disease and the absence of prospective clinical trials. Although radiotherapy should be considered in all cases of thymic carcinoma, there is limited evidence that omission in completely resected, early-stage disease may be feasible. A small investigation of four patients fitting this characterization who were treated with radical surgery alone found that all four were alive and free from relapse at a median follow-up of 72 months (range, 12-167 months).[337]

Most single-institution retrospective studies have reported on outcomes withed adjuvant radiation therapy, typically to a dose of 40 to 70 Gy delivered in standard fractionation (1.8- to 2.0-Gy fractions).[263,324,335,338-341] In one such series of 26 patients treated with surgery and postoperative radiation without chemotherapy, Hsu and associates observed a 5-year overall survival rate of 77% for all patients,[341] 82% for patients with completely resected tumors, and 66% for those with subtotally resected tumors. The 5-year local control rate was 91% with a median radiation dose

of 60 Gy. In another study of 40 patients given either surgery and adjuvant radiation or definitive radiation therapy with or without chemotherapy, Ogawa and associates reported complete resections in 16 patients; moreover, no local recurrences were observed among the patients with complete resection who had received adjuvant radiation of at least 50 Gy.[324] Kondo and colleagues observed no survival benefit from adding adjuvant radiation to surgical resection in a retrospective multi-institutional study of 186 patients, although the authors did note that the retrospective nature of the study and its small subgroup sizes precluded any definitive conclusions.[53]

Investigators of the ESTS database reported on 229 patients treated with thymic carcinoma between 1999 and 2010. Compared to patients receiving surgery alone, a significant survival advantage was observed among patients receiving surgery and postoperative radiotherapy. Ahmad and colleagues went further to study the combined ESTS and ITMIG databases to create a cohort of 1,042 thymic carcinomas, 60% of whom received adjuvant radiotherapy. In their multivariable analysis, attaining R0 resection and administration of radiotherapy were the only variables associated with prolonged overall survival (hazard ratio for radiotherapy, 0.45).[330]

In aggregate, these studies seem to indicate that local control is improved with radiation and that a survival benefit may also accrue. The quality of the evidence, however, is limited by its retrospective nature and vulnerability to selection bias. As is true for all mediastinal tumors, better knowledge will depend on conducting randomized clinical trials. The formation of international collaborations such as the ESTS and the ITMIG is reassuring developments, as they will likely underpin the design and completion of such trials. The ARS Appropriate Use Criteria recommend against the use of elective nodal irradiation when treating thymic carcinoma definitively or adjuvantly after surgical resection. In addition, the panel[334] recommended the use of proton therapy or IMRT for thymic carcinoma to maximize radiation conformity and reduce radiation exposure to the heart and lungs.

The use of adjuvant cisplatin-based chemotherapy has shown significantly beneficial effects in several studies.[234,342,343] In one such study, Nakamura and associates treated 10 patients with unresectable thymic carcinoma with platinum-based protocols, with or without radiation therapy, and observed a median survival time of 11 months.[343] Yoh and others

reported excellent preliminary results (ie, a 42% response rate) from the use of weekly cisplatin, vincristine, doxorubicin, and etoposide for the treatment of advanced tumors.[344] Other studies have shown favorable responses from various combinations of cisplatin, etoposide, ifosfamide, doxorubicin, nedaplatin, cyclophosphamide, and vincristine.[234,235,342-346] Finally, although data are limited, some centers advocate combined chemoradiation in select circumstances for thymic carcinoma, particularly after R1 or R2 resections.[347]

Molecular pathways may provide a new avenue for treatment. Exploratory studies have shown the association of thymic carcinoma with certain mutations (VEGF,[145] IGF-1R,[146] and KIT pathways).[147,148,348] These approaches have struggled to obtain validation in larger cohorts of patients.[349] High expression of KIT at the immunohistochemical (IHC) level in the absence of frequent activating point mutations may explain increased responses to the multikinase-targeted inhibitors sunitinib[350] and lenvatinib,[351] with overall response rates upward of 26% and 40% and PFS of 7.2 and 9.3 months, respectively. The greatest improvement in systemic therapies for thymic carcinoma has come with immune checkpoint blockade. Two phase 2 studies have demonstrated overall response rates in the 20% to 25% range, all in patients with a tumor PD-L1 IHC staining of greater than 50%.[254,352] Responses may last for several years, but the vast majority of patients will experience recurrence and may respond to rechallenge.[353] As in thymoma, immune-related adverse events can be a series and often follow a similar clinical spectrum with myositis/myasthenia gravis/myocarditis overlap.

Because of the rarity of thymic carcinoma, few treatment recommendations can be made; however, it seems clear that for patients with resectable disease, complete surgical resection is the preferred initial therapeutic intervention.[53,104,335,354,355] For patients with unresectable lesions, neoadjuvant chemotherapy, with or without thoracic radiotherapy, seems reasonable. Ultimately, after complete resection, the most important prognostic factors are the initial disease stage and tumor grade. Five-year survival rates for patients with higher disease stage and higher grade neoplasms range from 15% to 20%, whereas for patients with low-grade, localized disease those rates can range from 80% to 90%.[322,326] The addition

of adjuvant therapies for patients with poor prognostic factors should be made on an individual basis in the context of a multidisciplinary review.

THYMIC CARCINOID

Thymic carcinoid (neuroendocrine) tumors of the thymus are very rare, accounting for less than 5% of all neoplasms of the anterior mediastinum. They originate from normal thymic Kulchitsky cells, which belong to the amine-precursor-uptake-and-decarboxylation group.[356] Thymic carcinoid tumors are often confused with thymomas because of similarities in their clinical behavior. Most patients with thymic carcinoids are men aged 30 to 50 years; the male-to-female ratio is 3 to 1.[357] Roughly half of thyroid carcinoids are associated with endocrine disorders such as MEN-1 (multiple endocrine neoplasia type 1) or secondary Cushing syndrome.[358-360]

Thymic carcinoids can present with symptoms related to compression of normal structures (chest pain, dyspnea, cough, hoarseness, superior vena cava syndrome)[356,361] or with no symptoms.[360] These tumors are best evaluated by CT or MRI for visualizing local invasion of the surrounding structures (pericardium, great vessels, pleura, sternum) and metastases within or outside the thorax. Most thymic carcinoids detected in radiographic studies are already advanced, commonly metastasizing to regional lymph nodes. Metastases are present in up to 40% to70% of patients within 8 years of the initial diagnosis,[362,363] which may explain the poor prognosis associated with these tumors.

The Masaoka staging system for thymoma has been used for staging thymic carcinoids.[107,357] The WHO system classifies the pathology of thymic carcinoids into typical carcinoid, atypical carcinoid, large cell neuroendocrine carcinoma, or small cell carcinoma,[123,124] and a system proposed by Klemm and Moran classifies these tumors as well differentiated (low grade), moderately differentiated (intermediate grade), or poorly differentiated (high grade).[364] Notably, neither grading nor other histologic variables have shown a consistent association with prognosis.[357]

Complete surgical resection is the preferred method of treatment, although recurrence is common. Incomplete resections followed by adjuvant radiation, chemotherapy, or both seem to provide some benefit without increasing morbidity or mortality.[360,362,365,366] Distant metastases to

bone, liver, or skin occur in 30% to 40% of cases.[367] Despite aggressive treatment, the prognosis in most cases is poor. According to one report, the overall 5-year survival rate was 31%, and all 14 patients expired within 9 years.[361] A more recent analysis of 205 patients from the combined ESTS and ITMIG databases was more reassuring with a reported 5-year survival rate of 68%, although this result should be tempered by the observation that 39% of patients experienced recurrence in this time frame.[363] Similar to the other thymic malignancies, overall survival was influenced primarily by the Masaoka stage and completeness of resection. Neither chemotherapy nor radiotherapy showed statistical significance with regard to overall survival benefit. Thymic carcinoids associated with MEN-1 are especially lethal; in one study, the 5-year survival rate for patients with thymic carcinoids without associated endocrinopathy was about 70% but was only 35% for those with an endocrinopathy.[360,361,368]

OTHER RARE TUMORS OF THE THYMUS

Thymoliposarcoma was first described by Havlicek and Rosai in 1984.[369] This rare and distinctive entity is considered the malignant counterpart of thymolipoma. Thymoliposarcomas have appeared in adults aged 36 to 77 years, with a slight female predominance. Unlike its thymolipoma counterpart, thymoliposarcoma is not associated with myasthenia gravis. It grows by expansion and has a relatively low risk of distant metastasis in the absence of histologic dedifferentiation. Complete surgical resection or subtotal resection with adjuvant radiation therapy has been used for local control.[369,370]

MALIGNANT MEDIASTINAL GERM CELL TUMORS

Epidemiology

Primary extragonadal germ cell tumors account for 2% to 5% of all germ cell tumors.[371,372] About two-thirds of these tumors occur in the anterior mediastinum,[373-375] making the mediastinum the most common site of primary extragonadal germ cell tumors among young adults, mostly male.[376] Similar to gonadal sites, these can include teratomas, seminomatous tumors, and nonseminomatous tumors; the former is the most common mediastinal

germ cell tumor.[377] Benign teratomas arise from germ cell elements, but they are not included in this discussion because they are not malignant and surgical resection is often curative (immature teratomas are rare and aggressive with poorer outcomes). Germ cell tumors contribute about 10% of all malignant mediastinal tumors and about 2% of mediastinal neoplasms.[378] In a pooled analysis of 341 patients with mediastinal germ cell tumors treated at 11 cancer centers over a 20-year period, the median age of presentation was 33 years for seminomatous tumors and 28 years for nonseminomatous tumors.[379,380]

Primary extragonadal germ cell tumors have several observed associations. Klinefelter syndrome has been documented in patients with mediastinal germ cell tumors, but not in patients with testicular germ cell tumors.[381-384] In one study, up to 20% of patients with mediastinal germ cell tumors were found to have the Klinefelter karyotype (47,XXY).[385,386] Several unusual malignant processes are associated with nonseminomatous germ cell tumors, including hematologic malignancies such as acute myeloid leukemia, acute nonlymphocytic leukemia, acute megakaryocytic leukemia, myelodysplastic syndrome, and malignant histiocytosis.[386-390]

Natural History

Primary extragonadal germ cell tumors arise along midline structures of the body extending from the pineal gland, through the mediastinum and retroperitoneum, to the presacral areas. The origin of these primary extragonadal germ cell tumors remains controversial,[391-393] but presumably, they arise from germ cells that migrate along the urogenital ridge during embryonic development.[386,394] Because the embryologic urogenital ridge extends from C-6 to L-4, malignant transformation of displaced germ cells can give rise to primary germ cell tumors outside the gonads.

Because primary gonadal germ cell tumors can spread to the retroperitoneum and mediastinum,[374,386] the diagnostic workup must be thorough to avoid overlooking an occult gonadal primary. Although primary mediastinal germ cell tumors have the same morphologic and histologic appearance as those of the testes, primary germ cell tumors of the mediastinum are more aggressive and have a poorer prognosis.[395-397]

Primary mediastinal seminomatous germ cell tumors are sensitive to radiation and chemotherapy, but nonseminomatous tumors are less vulnerable to treatment and are considered poor-risk diseases in all staging systems.[397,398] Such tumors are often invasive at the time of diagnosis, and approximately half of such tumors will present with distant metastases, most often to the lung.[379] TP53 mutations are also associated with reduced overall survival.[399]

Tumor markers can aid in the diagnosis of mediastinal germ cell tumors; serum α-fetoprotein levels are elevated in 75% of patients (median, 2,500 ng/mL) at diagnosis, and β-human chorionic gonadotropin and lactate dehydrogenase levels are elevated in about 50% of patients at presentation.[379] Pure seminomatous histologies are less likely to be associated with biomarker elevation, although occasionally a modest rise in β-human chorionic gonadotropin can be observed.

Clinical Presentation

As is true for other mediastinal tumors, local symptoms are usually caused by tumor compression or invasion of adjacent structures. Primary extragonadal germ cell tumors present with clinical symptoms in many cases,[400] with dyspnea (25%), chest pain (23%), cough (17%), fever (13%), weight loss (11%), vena cava occlusion syndrome, and fatigue/weakness (6% each) being the most common.[379,401,402] These tumors may be asymptomatic in other cases,[403] with incidental diagnosis.[404,405] Roughly one-third of seminomatous mediastinal germ cell tumors present with metastases at diagnosis. The cervical lymph nodes are enlarged in about 25% of such cases, but abdominal lymphadenopathy has also been present. Distant metastases from nonseminomatous germ cell tumors are even more common, with rates of 85% to 90% in prior series but in more recent series about 50% at diagnosis.[379,406-409]

Diagnostic Workup

Mediastinal germ cell tumors are usually readily detected on chest x-rays, with most masses noted in the anterosuperior mediastinum. CT scans of the chest, abdomen, and pelvis are essential to evaluate the mass and to screen for metastases and lymphadenopathy. A careful physical examination and

testicular sonography should be performed to rule out an occult primary gonadal tumor. As mentioned earlier, tumor marker assessment can be helpful for diagnosis, evaluating treatment efficacy, and surveillance.[11,410-412] Thus, the determination of baseline tumor marker levels both before treatment is begun and after treatment is completed is essential.

The initial diagnosis of mediastinal germ cell tumors is usually reached through a combination of findings from CT, radiography, sonography, and tumor marker measurements. Whether PET or MRI has a place in the management of these tumors is unclear. In some instances, the tumor marker findings are sufficient to classify the lesion as an extragonadal nonseminomatous germ cell tumor without histologic confirmation, but false-positive β-human chorionic gonadotropin levels have been reported.[413,414] Histopathologic analysis can often be done easily via fine-needle aspiration and cytologic staining for tumor markers. Biopsy samples should be obtained whenever possible because both the choice of treatment and prognosis depend greatly on histology.[413,414]

Prognostic Factors

The most important prognostic factor for mediastinal germ cell tumors is histologic type. Seminomas are highly curable, but nonseminomatous germ cell tumors, despite advances in therapy, are associated with poor PFS and overall survival. The presence of metastases with tumors of either histologic type is also associated with adverse PFS and overall survival. In nonseminomatous tumors, elevated β-human chorionic gonadotropin levels are associated with inferior overall survival.[379] Nomograms have been developed to aid in prognostication.[415]

General Management

Seminomatous Tumors

Seminomas are quite sensitive to both radiation therapy and chemotherapy, and thus, all patients with tumors of seminomatous histology should be treated with curative intent, even in the presence of metastatic disease. The choice of treatment has evolved with the development of cisplatin-based

chemotherapy regimens, and most patients should be initially treated with systemic chemotherapy.[416]

Historically, mediastinal seminomatous tumors (like all mediastinal tumors) were treated surgically.[386,417] Complete radical resection can be considered in some cases if it is technically feasible and if the patients do not want radiation or chemotherapy. Definitive radiation replaced surgical resection for localized mediastinal seminomatous germ cell tumors, with long-term survival rates of 60% to 80% achieved even for those with bulky tumors.[372,386,389,417] Before the advent of platinum-based chemotherapy, radiation therapy had the advantage of being more tolerable and less toxic, and relapses could be effectively treated with systemic chemotherapy.[372] However, cisplatin-based chemotherapy has eclipsed radiation; in an early application of this approach, Einhorn and colleagues at the University of Indiana reported a complete response rate of 63% lasting a median duration of 18 months for 19 patients with disseminated seminoma treated with cisplatin-based chemotherapy.[418] In more modern series, the response to primary systemic chemotherapy is favorable for 92% of patients, and 5-year overall survival rates exceeding 90% are standard.[419,420]

Residual radiographic abnormalities after the completion of chemotherapy for bulky mediastinal seminomas are not uncommon, but the management strategy in such cases is still controversial. In the vast majority (80%-90%) of such cases, the residual masses represent dense fibrosis with no viable tumor.[386,421-423] Some clinicians have advocated surgical resection or biopsy of all postchemotherapy masses larger than 3 cm,[87,422-424] and others recommend close follow-up in such cases, with early intervention if the mass enlarges on chest x-ray or CT scan and resection, radiation, or salvage chemotherapy reserved for progressive disease.[386,389,423,425] Whether PET is useful for predicting viable tumor is debatable and under investigation.[426,427] Even though seminomas are extremely sensitive to radiation therapy, radiation therapy delivered to residual masses after chemotherapy has not shown a significant benefit.

Circumstances in which radiation may be appropriate include patients who refuse chemotherapy, in whom chemotherapy is contraindicated, or who likely harbor viable residual disease after chemotherapy based upon highly suspicious imaging findings or pathologic confirmation. Radiation doses and treatment techniques for mediastinal seminomatous germ cell

tumors have varied.[428-433] Doses as low as 30 Gy and as high as 50 Gy have been recommended.[378,430] Given the absence of unambiguous clinical trial guidance, radiation dose should be adjusted based on the size of the lesion, the history of chemotherapy exposure, and the clinical circumstance. Because the disease is infiltrative and susceptible to nodal involvement, the entire mediastinum was traditionally encompassed with anteroposterior-posteroanterior fields with CT guidance. In the prechemotherapy era, the use of smaller portals was associated with marginal relapses,[429] and in fact the clinical target volume for definitive radiation alone often electively covered the supraclavicular, cervical and para- aortic lymph nodes.[411,428,431,434] Extrapolating from the experience with prophylactic treatment of para-aortic nodes in testicular seminomas, one could assume that the contiguous lymphatic drainage sites for a mediastinal primary could be treated effectively with 20 Gy with minimal morbidity.[435]

In conclusion, cisplatin-based combination chemotherapy can consistently produce 5-year overall survival rates in excess of 90% for mediastinal seminomas. However, for selected patients, definitive radiation therapy has produced local tumor control rates of 89% to 100% and long-term survival rates of 60% to 80%.[378,386,429,431,436]

Nonseminomatous Germ Cell Tumors

The primary treatment for nonseminomatous germ cell tumor is intensive cisplatin-based chemotherapy, but surgical resection of all residual masses after first-line chemotherapy is recommended whenever technically possible, either as a one-stage or as a sequential procedure.[437-440] Chemotherapy regimens should include either cisplatin and etoposide or cisplatin, etoposide, and bleomycin. Patients whose tumors respond well to initial chemotherapy followed by complete resection of any residual mass can have excellent outcomes, but the outcome for patients who do not respond to primary therapy is poor, as salvage therapy is rarely effective.[397]

The role of radiation therapy in nonseminomatous germ cell tumors is not clear. Radiation may be useful for unresectable residual masses, given the relatively high rate of persistent viable tumor and the poor success rates of salvage therapy. Nonseminomatous germ cell tumors are in fact radiosensitive, but they require higher doses than seminomatous tumors.

Akin to other solid tumors, doses of 60 Gy or more may be necessary to achieve disease control.[441]

Before the cisplatin-based chemotherapy era, fewer than 5% of patients with mediastinal nonseminomatous germ cell tumors survived.[411] Since that time, long-term disease-free survival rates have varied from 45% to 72% in studies using cisplatin-based combination chemotherapy followed by surgery.[379,397,442] Several salvage regimens have been used for disease that progresses during or after initial chemotherapy, but unfortunately, long-term survival rates for patients with relapsed mediastinal germ cell tumors are less than 10%.[379,397,443,444] Thus, surgical resection and even radiation therapy may be appropriate in select cases to augment chemotherapy or as an alternative treatment modality when no further chemotherapy is available. As with other disease sites, there is intense interest in the use of immune-modulatory agents in the management of these tumors.[445]

MEDIASTINAL MESENCHYMAL TUMORS

Epidemiology

True mediastinal mesenchymal lesions are exceedingly rare tumors. Retrospective series suggest that 2% to 8% of all mediastinal lesions are primary mesenchymal tumors; extrapolation of these values puts the estimated incidence at approximately 0.1 to 0.2 per million.[11,446-448] More than half of mediastinal mesenchymal tumors are vascular or lymphatic in origin, with the rest composed of unusual histologic variants.[449] The age predilection depends on the specific histologic subtype.[49,405,446-448,450]

Clinical Presentation and Workup

Mesenchymal lesions can arise in any of the three mediastinal compartments. Mesenchymal tumors that present in children seem to be more malignant than those presenting in adults.[450,451]

Mediastinal mesenchymal lesions can reach impressively large sizes before detection, typically presenting with symptoms such as chest pain and dyspnea. At least one series suggests that symptomatic presentation is a harbinger of malignant character, with 80% of patients with malignant disease presenting with symptoms versus 44% of patients with benign

masses.[11] An accurate histopathologic diagnosis is critical.[450] Tissue for these analyses can be obtained via mediastinoscopic biopsy, fine-needle aspiration, or endoscopy. Disease can be staged according to the American Joint Committee on Cancer staging system for soft tissue tumors.

Tumors of Adipose Tissue

Lipomas are the most common adult benign tumor; however, mediastinal lipomas are rare, representing 1.6% to 2.3% of all mediastinal tumors.[449,452-454] Mediastinal lesions can occur either in isolation or multiples and may mimic cardiomegaly or pleural effusion on a chest x-ray. They are usually well circumscribed and encapsulated but can grow to a large size before detection.[455,456] For example, a lipoma 40 cm × 25 cm × 15 cm in size and 3.78 kg in weight has been reported.[457] Though these tumors can be quite large and cause significant compressive symptoms [458-460] gross total resection is almost always curative.[13,461-464] Technically, lipomas are considered "benign" tumors, but those that are growing or causing symptoms should be referred for surgical resection.

In contrast to lipomas, liposarcomas consist of immature fat cells with malignant histology and behavior. The fifth WHO Classification of Tumors of Soft Tissue and Bone divided liposarcoma into five clinicopathologic and genetic subtypes: well-differentiated liposarcoma (WDLS)/atypical lipomatous tumor (ALT), de-differentiated liposarcoma, myxoid/round cell liposarcoma, pleomorphic liposarcoma, and myxoid pleomorphic liposarcoma.[465] WDLS/ALT and de-differentiated liposarcoma account for 50% to 60% of all liposarcomas. All the subtypes can arise in the mediastinum. WDLS/ALT is low-grade malignancy that mostly arises in the extremities, inguinal region, and retroperitoneum. De-differentiated liposarcomas are WDLS containing a nonlipogenic sarcomatous component that could be low or high grade. These tumors often arise in the retroperitoneum, followed by the extremities. Myxoid liposarcomas represent for nearly 20% to 30% of the liposarcomas. These tumors are the least common types of liposarcomas in adults but are common in children; also, these are the least common types of liposarcoma arising in the mediastinum. Pleomorphic liposarcomas account for less than 5% of liposarcoma. These are typically high-grade, poorly differentiated tumors,

which most commonly occur in the extremities. Myxoid pleomorphic liposarcomas are rare and aggressive tumors. Retrospective studies have supported the WHO classification.[466-468]

Distinguishing lipomas from liposarcomas can be difficult histologically; liposarcomas are distinguished by size heterogeneity, hyperchromatic nuclei, and eosinophilic cytoplasm.[469] Primary mediastinal liposarcomas often appear in the posterior portion of the mediastinum. Anterior mediastinal liposarcomas are possible albeit rare.[470] Tumors often appear to be encapsulated and well circumscribed, even when invasion is present (Figure 58.7), giving rise to the term "pseudocapsule." In one historical review, survival times for patients with well-circumscribed lesions ranged from 3 to 17 years, whereas patients with grossly invasive tumors died within 2 years.[471] As is true for all sarcomas, the prognosis depends on the histologic grade.[472,473]

FIGURE 58.7 Computed tomography scan (left) and intraoperative photograph (right) of a primary mediastinal liposarcoma filling right thoracic cavity. The recommended treatment for this malignancy is aggressive surgical resection with adjuvant radiation therapy and consideration of systemic therapy. (From Wiedemann D, Schistek R, Gassner E, Antretter H. Mediastinal liposarcoma. *J Card Surg*. 2011;26[2]:162-164. Copyright © 2010 Wiley Periodicals. Reprinted by permission of John Wiley & Sons.).

Like other sarcomas, optimal treatment consists of surgical resection and adjuvant radiation therapy.[441,474] ALT is more indolent, and a marginal resection technique should be employed to minimize surgical morbidity. For

ALT/WDLS, if en bloc resection with negative margins is achieved, radiotherapy is not indicated.[475] In one report that reviewed 91 patients with ALT/WDLS, positive surgical margins were associated with a higher risk of local progression, suggesting that reresection or adjuvant radiotherapy could be considered for patients with positive surgical margins.[476] For example, in one series, patients with positive margins received a 14 to 20 Gy boost to the high-risk area. For myxoid liposarcoma, a dose reduction to 36 Gy can be considered.[477]

Tumors of Lymph Tissue

Tumors arising from the vascular or lymphatic components of the mediastinum make up the bulk of the remaining mediastinal mesenchymal lesions.[446-448] Lymphangiomas and hemangiomas are morphologically similar under light microscopy, and the presence of red blood cells or chyle within the tumor lumen often serves as a primary diagnostic aid.[461] Localized lymphangiomas are rare; less than 1% are located only in the mediastinum. More commonly, these are located in the neck, and approximately 10% have mediastinal extension.[478] A cystic lymphangioma is illustrated in Figure 58.8.[479]

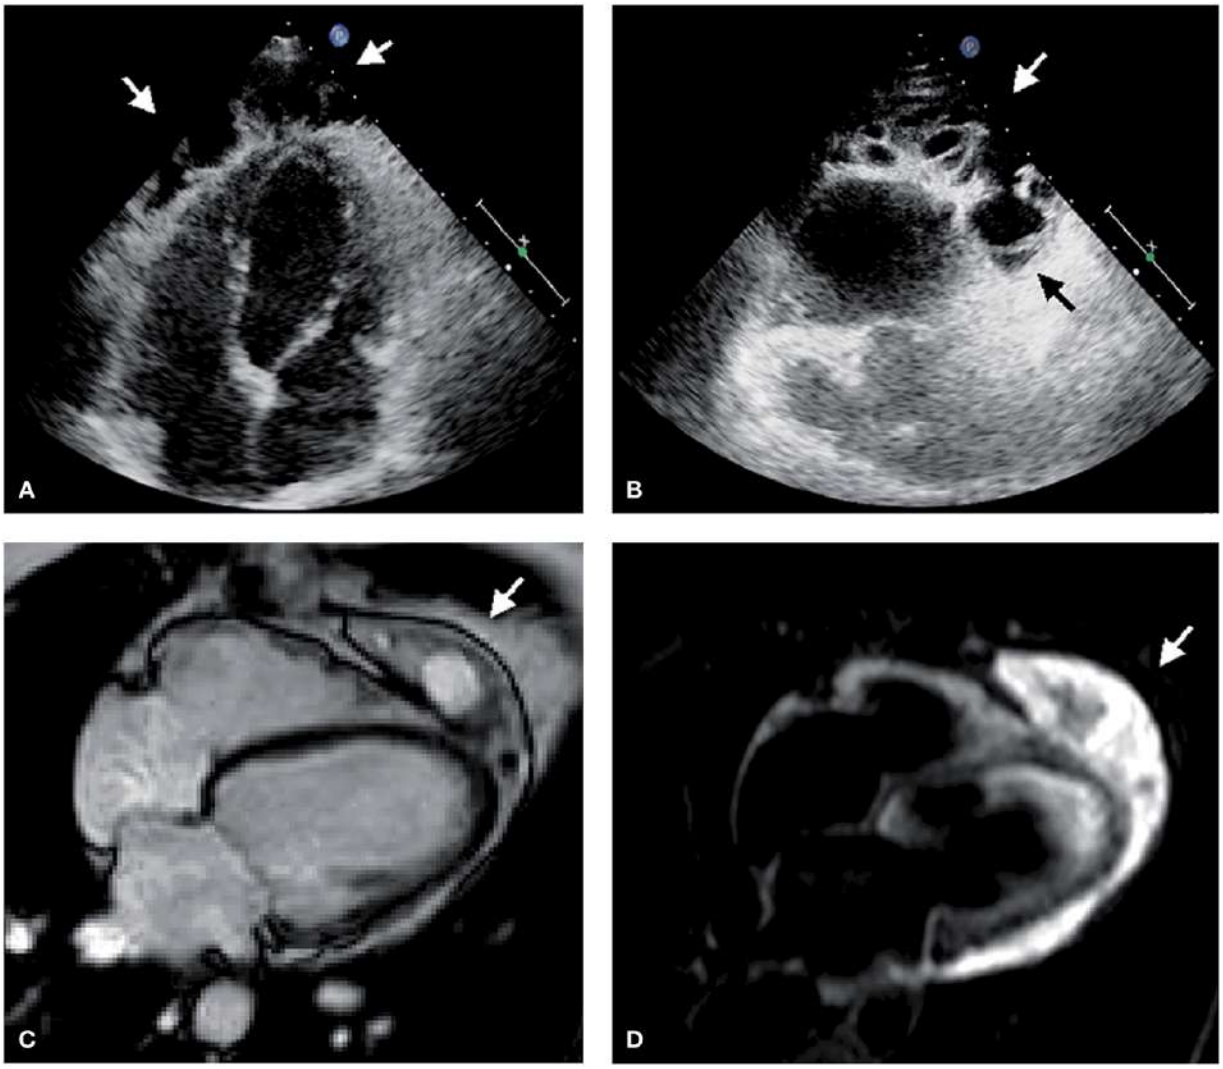

FIGURE 58.8 Echocardiographs (top) and cardiac magnetic resonance images (bottom) of mediastinal lymphangioma. The patient presented with palpitations and was found to have a cystic lymphangioma surrounding both ventricles from the apex to the left atrioventricular groove. The arrows are pointing to the tumor. (Reprinted from Conte G, Aldrovandi A, Reverberi C, Cademartiri F, Ardissino D. Mediastinal cystic lymphangioma. *J Am Coll Cardiol*. 2011;57[16]:e207. Copyright © 2011 American College of Cardiology Foundation. With permission.)

Lymphangiomatosis, which is characterized by synchronous widespread lymphangiomas, is a rare benign condition and accounts for 0.7% to 4.5% of mediastinal tumors. The majority of patients (~90%) have tumors in the neck and axilla and present by the age of 2 years.[480,481] By contrast, pure mediastinal-type tumors are rare and usually not discovered until adulthood

due to the relative lack of associated symptoms.[482] Younger age and mediastinal or pulmonary involvement carry a poor prognosis.[461,483-491]

Lymphangiosarcoma seems to be a malignant variant of lymphangiomas and should be treated like other soft tissue sarcomas, with the optimal treatment being full extirpation.[492] In the largest reported retrospective series of 25 patients with mediastinal and cervicomediastinal lymphangiomas, survival rates were excellent after surgical resection alone, and only one patient died of a complication from lymphangioma.[493] Lesions arising from the low thoracic duct with symptomatic chylothorax have a higher risk of recurrence after surgical resection. Low-dose adjuvant radiotherapy of 15 to 20 Gy in 10 to 12 fractions following surgery was reported to be effective in preventing recurrence in patients with refractory symptoms.[494]

Tumors of Vascular Tissue

Mediastinal mesenchymal lesions of endothelial origin include hemangiomas, hemangioendotheliomas, and hemangiopericytomas. Many of these tumors have an indolent course, but hemangiopericytomas are notable for having both malignant and benign presentations. Malignant hemangiopericytomas have high rates of metastasis at presentation. Hemangiomas can be capillary or cavernous; cavernous hemangiomas (ie, angiomyomas or hamartomas) are distinguished from capillary hemangiomas by the presence of smooth muscle. Hemangiomas and hemangioendotheliomas are typically well circumscribed. Hemangioendotheliomas contain the hallmark cytoplasmic Weibel-Palade bodies.[495,496]

Hemangiopericytomas arise from the capillary pericytes of Zimmerman.[497] Although most are indolent, recurrence and metastases have been observed many years after resection.[498] Retrospective studies suggest that high mitotic rates and proliferative indices may portend malignant behavior.[499,500] Nevertheless, long-term survival is still possible with aggressive treatment of metastatic disease.[501] Surgery remains the mainstay of therapy and is often curative.[502] Because of their benign nature, hemangiomas or hemangioendotheliomas should not be treated with radiation.[502] An endoscopic approach has been proposed for several types of

intrathoracic tumors including benign hemangiomas and should be explored further.[503] Radiation remains an option for incompletely resected hemangiopericytomas.

Miscellaneous Mediastinal Mesenchymal Lesions

A mélange of other mediastinal mesenchymal lesions have been reported, usually of musculoskeletal or connective tissue origin, with the former typically appearing within the posterior mediastinum and the latter typically appearing in the anterior mediastinum.[449,484,504] These lesions have been treated with surgical excision and, occasionally, postoperative radiation therapy, depending on the histology and clinical presentation.[446-449,505-509]

MEDIASTINAL NEUROGENIC TUMORS

Epidemiology

Neurogenic tumors of the thorax are generally classified by their neural cell of origin, including tumors of the nerve sheath (schwannomas and neurofibromas), autonomic ganglion (ganglioneuromas and neuroblastomas), and paraganglion (paragangliomas and pheochromocytomas). Most neurogenic lesions arise in the posterior mediastinum. Indeed, they are the most common cause of a posterior mediastinal mass and account for roughly one quarter to one-third of all mediastinal neoplasms[9,11,510-512]

Neurogenic neoplasms are rare, with an incidence of 0.5 per million in adults.[11] Neuroblastoma, an aggressive variant of neurogenic tumors, occurs primarily in children[513] and appears in the mediastinum in about 20% of cases. This condition is covered in the pediatric malignancy section of this book. Neuroblastomas are more common in male Caucasians, whereas other malignant neurogenic tumors occur at equal rates in both sexes.[514-516]

Paragangliomas are rare tumors that arise from extra- adrenal paraganglia and can be either functional (catecholamine secreting) or nonfunctional.[517,518] Most of these tumors are benign and surgical resection is usually curative, but about 10% of patients are reported to have malignant tumors[519] and germline mutations are suggested to have an association with

this. The higher rate of malignancy is reported to be associated with SDHB germline mutations[520,521]

The most common neurogenic tumors in adults are benign schwannomas and neurofibromas, often presenting in the setting of neurofibromatosis type 1 (NF-1), an autosomal dominant neurocutaneous disorder, with an estimated birth incidence of 1 in 2,500.[499] Individuals affected with NF-1 are at increased risk of developing both benign and malignant tumors. The most common benign tumor in individuals with NF-1 is neurofibroma, a heterogeneous benign peripheral nerve sheath tumor.[522,523] Neurofibromas can occur as discrete focal cutaneous or subcutaneous growths, as intraforaminal spinal tumors, or as plexiform tumors. Plexiform neurofibromas are composed of the same cell types as dermal neurofibromas but have an expanded extracellular matrix and a rich vascular supply.[524] In one study of 125 patients with NF-1, plexiform neurofibromas were clinically visible in 32%.[525] Schwannomas often originate from the intercostal or sympathetic nerves and can become quite large before being detected.[461] Surgery is the mainstay of treatment, but the possibility of achieving an R0 resection depends on the extent of locoregional disease. Few local recurrences are reported, and long-term local control rates are nearly 100%.[511,514,526-529] In adults, most malignant mediastinal neurogenic tumors are malignant peripheral nerve sheath tumors (MPNSTs). Individuals with NF-1 carry a heightened risk of developing MPNSTs, with a lifetime risk of almost 7.5% to 15%.[530,531] Because most NF-1–associated MPNSTs arise within preexisting plexiform neurofibromas, individuals with NF-1 and plexiform neurofibromas warrant increased surveillance. For MPNSTs, adjuvant irradiation to a dose of 60 Gy or more or brachytherapy is reported to show improved local control of disease.[532]

With regard to anatomic origin, it is reported that MPNSTs were located in the trunk in 40% to 51% of the patients studied.[516] Patients with NF-1 were 22-27% of the patients had NF-1. The median age at presentation of the MPNST tends to be younger in patients with NF-1[487,533]

Natural History and General Management

In up to 80% of cases, mediastinal neurogenic tumors present as an asymptomatic, incidentally found mass (Figures 58.9 and 58.10). In some cases, these masses can grow slowly enough to involve nearly the entire hemithorax before detection.[515,534,535] Large or rapidly growing lesions can cause chest pain and nerve dysfunction (including Horner syndrome) from compression.[536] Proximal organs such as the vagus or phrenic nerves, esophagus, trachea, and cardiac chambers may be involved by direct extension or via the nerve sheath.[537-545] Local invasion and bony destruction are common.[546] Distant metastases were reported to present in 26% of patients at diagnosis.[547,548] Because MPNSTs are difficult to detect before they infiltrate nearby structures (making surgery difficult) and metastasize, the prognosis is poor.[549] Malignant triton tumors, an extremely rare subtype of MPNSTs, have aggressive biologic behavior and, therefore, the prognosis is very poor.[550]

Management of malignant mediastinal neurogenic tumors requires a multidisciplinary approach similar to the management of adult soft tissue sarcomas. High-resolution CT (Figure 58.11) is essential, as is MRI (Figure 58.12), to evaluate the neural and spinal anatomy if involvement is suspected.[551] A definitive pathologic diagnosis is often reached after surgical intervention[552]; examples of histologic slides of a schwannoma and a neurofibroma are shown in Figures 58.13 and 58.14, respectively. Histologic examination often reveals nuclear atypia, mitotic figures, cellularity, typical Antoni A and B areas, and tumor necrosis; these findings, in combination with positive IHC staining for S-100 protein and negative staining for smooth muscle markers such as desmin, are suggestive of a nerve sheath origin. Of these features, the factor most reliably correlated with malignancy is a mitotic figure of 5 or more in 50 high-power fields.

Scattered background mast cells and entrapped axons are also present (original magnification 100×). (Courtesy of David Sauer, MD.)

Surgical resection is the mainstay of therapy. An R0 resection should be attempted but is often difficult for mediastinal tumors because of impingement on surrounding structures and, in the case of neurofibromas, the risk of drastic neurologic deficits. Advances in surgical technique, including minimally invasive approaches such as VATS surgery, are available but should be undertaken only by experienced thoracic surgeons.[553-555]

As is true for the treatment of soft tissue sarcomas, radiation appears to improve local control for MPNSTs when combined with surgery. One series reported on 134 patients with MPNSTs treated at the Mayo Clinic between 1975 and 1993.[532] Only 25 of those patients had mediastinal tumors, a

resection with a negative margin was possible for 68%, which was an improvement over a historical series showing an R0/R1 rate of only 55% for mediastinal MPNSTs.[556] About half of the patients received radiation as a part of initial treatment, and the median cumulative radiation dose, including external beam irradiation, brachytherapy, and intraoperative radiation therapy, was 60 Gy. At 5 years, the overall survival rate was 52% and the local tumor control rate was 51% for the entire group of patients.

Prognostic factors for overall survival found to be significant in multivariate analyses were surgical margin status and history of radiation. Prognostic factors for local control were surgical margin status, radiation dose, and the use of intraoperative radiation or brachytherapy. The use of radiation with a dose of 60 Gy or higher as a part of the initial treatment showed statistically significant improvement of local control, whose rates were improved from 50% to 87% at 3 years and from 50% to 73% at 5 years (P = .021), but regarding overall survival, there was not statistically significant improvement.

Other evidence supporting the use of radiation after surgery for MPNSTs comes from a review of 205 patients with localized MPNSTs at all body sites treated over a 25-year period at the Istituto Nazionale per lo Studio e la Cura dei Tumori in Milan, Italy.[516] That study reported a disease-specific mortality rate of 53% at 10 years for the patients with tumors in the trunk. Of these, 44% of the patients had received radiation therapy. Variables found to be significant in multivariate analyses for survival included tumor site (head and neck or trunk tumor location has higher disease-specific mortality), tumor size (>12 cm), surgical margin status, and the use of adjuvant radiation (P = .016). Eventual distant metastasis development was seen in 42% of patients, the vast majority of which were pulmonary.

Planning and delivery of external beam radiation therapy for MPNSTs is facilitated with the use of modern approaches, including 3D conformal radiation, IMRT, and image-guided radiation using onboard imaging approaches. Patients with these tumors, which are complicated to manage, should be treated at centers with extensive multidisciplinary experience in thoracic and paraspinal neoplasms. Radiation treatment after surgery for microscopic disease should be given at a minimum dose of 60 Gy in 30 fractions, similar to the adjuvant dose given in other soft tissue sarcomas. Given the close proximity of the posterior mediastinum to the spinal cord,

careful attention should be paid to immobilization and the use of image guidance techniques. Although placing the patient in the prone position may reduce the distance from the localization points to the treatment volume, the patient must be able to rest comfortably in the same position throughout the treatments. Daily onboard imaging with stereoscopic guidance can ensure daily accuracy. IMRT is often necessary to provide a concave dose distribution around the spinal cord. In cases of gross residual disease, higher doses may be beneficial but can be challenging to deliver, given the constraints on exposure of normal tissues.

For patients with unresectable disease, radiation can be delivered either alone or with chemotherapeutic agents that are typically used for soft tissue sarcomas. Few agents are effective for MPNSTs, and treatment regimens usually include doxorubicin or ifosfamide.[557] Finally, significant progress has been made in recent years in elucidating the molecular genetics and biology of MPNSTs, especially in patients with NF-1. A variety of genetic alterations have been reported in MPNSTs, but it is yet unclear whether any of them are causally related to tumorigenesis or can be exploited for treatment effect.[558] As is true for the treatment of soft tissue sarcomas, radiation appears to improve local control for MPNSTs when combined with surgery. The findings from 134 patients with MPNSTs treated at the Mayo Clinic between 1975 and 1993.[532] Only 25 of those patients had mediastinal tumors, a resection with a negative margin was possible for 68%, which was an improvement over a historical series showing an R0/R1 rate of only 55% for mediastinal MPNSTs.[556] About half of the patients received radiation as a part of initial treatment, and the median cumulative radiation dose, including external beam irradiation, brachytherapy, and intraoperative radiation therapy, was 60 Gy. At 5 years, the overall survival rate was 52% and the local tumor control rate was 51% for the entire group of patients.

Prognostic factors for overall survival found to be significant in multivariate analyses were surgical margin status and history of radiation. Prognostic factors for local control were surgical margin status, radiation dose, and the use of intraoperative radiation or brachytherapy. The use of radiation with a dose of 60 Gy or higher as a part of the initial treatment showed statistically significant improvement of local control, whose rates were improved from 50% to 87% at 3 years and from 50% to 73% at 5

years (P = .021), but regarding overall survival, there was not statistically significant improvement.

Other evidence supporting the use of radiation after surgery for MPNSTs comes from a review of 205 patients with localized MPNSTs at all body sites treated over a 25-year period at the Istituto Nazionale per lo Studio e la Cura dei Tumori in Milan, Italy.[516] That study reported a disease-specific mortality rate of 53% at 10 years for the patients with tumors in the trunk. In cases of gross residual disease, higher doses may be beneficial but can be challenging to deliver, given the constraints on exposure of normal tissues.

TRACHEAL CARCINOMAS

Tracheal neoplasms are quite rare, contributing to fewer than 0.5% of all tumors.[559] Most of the information available to date is derived from pooled

population-based data sets or single-institution series involving a variety of treatment regimens. Review of the largely retrospective data has revealed several patterns: First, surgical resection is the cornerstone of therapy; second, local recurrence is a major pattern of failure resulting in morbidity and mortality; and third, adjuvant radiation seems to have some positive effect on outcomes.

Demographics

Primary tracheal malignancy is exceedingly uncommon, accounting for approximately 0.1% to 0.4% of all diagnosed malignancies.[560] Epidemiologic data from the SEER project estimate an incidence of 0.2 per 100,000 persons in the United States; the true incidence of tracheal carcinomas is likely even lower.[38] Traditionally, adenoid cystic carcinomas (formerly known as cylindromas) were considered the most common tracheal neoplasms, but recent reports suggest that the most prevalent histology worldwide is squamous cell carcinoma (60%-90%).[561] Other less common histologies include neuroendocrine tumors (glomus tumors, granular cell carcinomas, and small cell carcinoma),[562-566] sarcomas (chondrosarcoma and myxofibrosarcoma),[567,568] and glandular tumors (acinic cell carcinoma).

Tracheal cancer affects roughly twice as many men as women; estimates of incidence from the SEER database are 0.2 per 100,000 for men and 0.1 per 100,000 for women.[569] The male-to-female ratio is 23:1 for squamous cancer but is closer to 1:1 for adenoid cystic carcinomas.[570] Although squamous cell carcinoma is associated with tobacco exposure, data are mixed regarding the association of tobacco with adenoid cystic carcinoma.[571] Squamous cell variants typically present during the sixth decade of life, whereas adenoid cystic carcinomas seem to present at younger ages. Other histologies include carcinoid, carcinosarcoma, granular cell tumor, hemangioma, neurogenic tumors, chondroma, and chondrosarcoma.[572-618]

Anatomy

The trachea is a fibrocartilaginous tube connecting the larynx superiorly and the mainstem bronchi inferiorly. The esophagus, thyroid, parathyroid,

and trachea are derived from the same out-pouching of the embryonic foregut; the lungs arise from terminal tracheal buds.

In adults, the trachea is 12 cm long; its diameter is slightly larger in men (2.3 cm) than in women (2.0 cm). In cross section, the organ is "C" or "U" shaped. The upper border lies around the sixth or seventh cervical vertebra, and the lower border around the fourth (full expiration) or sixth (full inspiration) thoracic vertebra. Each centimeter of trachea contains about two cartilaginous rings. The posterior aspect of the trachea is membranous and is intimately associated with the esophagus. Three branches of the inferior thyroid artery supply blood to the upper half of the trachea and connect to the superior thyroid artery, which contributes small vessels that run from the tracheal wall adjacent to the thyroid isthmus. The bronchial arteries supply blood to the lower trachea and carina. Arterial branches interdigitate between each cartilaginous ring (see Figure 58.2).

Natural History

Tracheal carcinomas can present with a variety of symptoms, including cough, dyspnea, dysphagia, and hemoptysis.[600,619] Tracheal tumors tend to be evenly distributed between upper, mid-, and lower trachea.[620] Yang and colleagues reported cough to be the most common symptom (present in 72% of patients), followed by dyspnea (66%), stridor (39%), hemoptysis (39%), and dysphonia (31%).[621] Adenoid cystic carcinomas in particular are often first mistaken for asthma, which is often treated as such until "refractory" obstructive symptoms are evaluated with bronchoscopy, typically after numerous "normal" chest radiographs.[618,619,622-631] Hemoptysis is more likely to be the presenting symptom of squamous cell carcinoma,[621,632] and dysphagia is considered an ominous sign.[633] In one study of nonadenoid cystic/nonsquamous tracheal tumors, benign tumors presented with dyspnea, whereas malignant tumors were associated with hemoptysis.[575]

In 40% to 50% of cases, adenoid cystic carcinomas are diagnosed with metastases,[634] but survival is relatively long despite the presence of such metastases.[632,635-638] In one series, the median survival time for such patients was 37 months,[570] and the median reported survival from the time of diagnosis was approximately 5 years.[561,621] When these tumors spread, they

almost always do so in distant nodes rather than in the locoregional paratracheal lymph nodes. Local recurrence is the predominant form of treatment failure and can appear 10 or more years after treatment.[639-641]

Unlike adenoid cystic carcinoma, squamous cell carcinoma has a much more aggressive course, with reported median survival times of only 6 to 12 months depending on resectability.[19,632,633,637,642-647] The disease often presents with local extension via paratracheal lymph nodes (in ~30% of cases) and distant metastases.[648]

The clinical course and natural history of other pathologic variants of tracheal tumors are difficult to accurately characterize because of the scarcity of reported findings. Adenocarcinomas and sarcomas are thought to have poor prognoses.[575,611,613,617,649-662] Granular cell tumor, carcinoid, lymphoma, leiomyoma, and small cell carcinoma all have variable prognoses, yet they seem to be less aggressive than the squamous carcinomas, adenocarcinomas, or sarcomas.[575]

Staging and Prognostic Factors

No system for staging tracheal neoplasms has been universally accepted or adopted. One staging system proposed by Licht and colleagues does not seem to have predictable prognostic value.[47] In some studies, lymph node involvement does not seem to have a significant adverse effect on prognosis,[19,621,648] although an epidemiologic analysis showed an association between nodal status and survival outcomes.[663] The size and location of the tumor seem to be important because of the extent of surgical resection necessary to remove the tumor and higher postoperative mortality associated with carinal resection.[622,663,664]

In 2004, Bhattacharyya proposed a staging system, wherein stage I is defined as T1N0 disease, stage II as T2N0, stage III as T3N0, and stage IV as T4N0 or any N1 disease (Table 58.11).[663] A similar system, with minor modifications, was used by Webb and colleagues in evaluating the experience at MD Anderson Cancer Center.[561] Subsequently, Macchiarini proposed a more elaborate staging model that draws from experience with other thoracic malignancies.[559] In 2022, Piórek et al proposed a simplified TNM classification where both T and N classifications correlated with survival in patients treated surgically, whereas only T-stage correlates with

survival for patients treated palliatively. This difference is likely owing to a high likelihood of morbidity and mortality from local versus systemic symptoms[665] (Table 58.10). However, at this time, it remains to be seen which system will be broadly implemented by clinicians or validated with large-scale clinical data sets.

TABLE 58.11 STAGING SYSTEMS FOR TRACHEAL CARCINOMA

Bhattacharyya Staging System[626]

Primary Tumor (T)		
T1	Primary tumor confined to the trachea; size <2 cm	
T2	Primary tumor confined to the trachea; size >2 cm	
T3	Spread outside the trachea but not to adjacent organs or structures[a]	
T4	Spread to adjacent organs or structures[a]	
Tx	Unknown or cannot be assessed	
Regional Lymph Nodes (N)		
N0	No evidence of regional nodal disease	
N1	Positive regional nodal disease	
Nx	Unknown or cannot be assessed	
Anatomic Stage/Prognostic Groups		
Stage		
I	T1	N0
II	T2	N0
III	T3	N0
IV	Any	N1
IV	T4	Any
Macchiarini Staging System[559]		
Primary Tumor (T)		
Tx	Cannot be assessed	
Tis	Any tumor without invasion	
T1a	<3 cm limited to mucosa	
T1b	≥3 cm limited to mucosa	

Bhattacharyya Staging System[626]

T2	Any tumor that invades cartilage or adventitia		
T3	Any tumor that invades trachea or larynx		
T4a	Any tumor that invades carina or main bronchus		
T4b	Any tumor that invades neighboring structures		
Regional Lymph Nodes (N)			
Nx	Regional lymph nodes cannot be assessed		
N0	No evidence of node metastasis		
N1	Local nodes positive (N1a < 3 cm; N1b ≥ 3 cm)		
Upper third	Highest mediastinal nodes; upper paratracheal nodes, prevascular and retrotracheal		
Middle third	Upper paratracheal nodes; prevascular and retrotracheal; lower paratracheal nodes; para-aortic nodes (ascending aorta or phrenic)		
Lower third	Upper paratracheal nodes; prevascular and retrotracheal; subaortic nodes (aortopulmonalis window)		
N1A	1-3 positive nodes in upper third		
N1B	>3 positive nodes in upper third		
N2	Regional nodes positive		
Upper third	Lower paratracheal nodes; subaortic nodes (aortopulmonalis window)		
Middle third	Highest mediastinal nodes; subaortic nodes (aortopulmonalis window)		
Lower third	Upper paratracheal nodes; pulmonary ligament		
Distant Metastasis (M)			
Mx	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Metastasis to nodes other than N1 and N2		
M2	Distant metastasis (eg, lung)		
Anatomic Stage/Prognostic Groups			
Stage			
0	Tis	N0	M0

In addition to clinical staging, molecular genetic analysis may prove important in future characterization and treatment of tracheal cancers. Kieran reported a single case of tracheal adenoid cystic carcinoma with NOTCH1 mutations successfully treated with nirogacestat, an experimental NOTCH1 inhibitor.[666]

General Management

Bronchoscopy is essential for the diagnosis of tracheal malignancies and for preoperative surgical planning.[619,667-669] In an acute respiratory compromise, rigid bronchoscopy (see Figure 58.2) may be indicated to "core out" the tracheal neoplasm.[622,670,671] In one series of 56 patients reported by Mathisen and Grillo, rigid bronchoscopy led to improved airway symptoms in 90% of cases, with 5% experiencing mild, easily controlled bleeding.[672] Photodynamic therapy may hold promise as a means of local treatment for palliation of symptoms or definitive management of superficial early lesions.[673] Esophagoscopy is suggested for all patients to rule out esophageal invasion. A CT scan of the chest is indicated to aid in the

evaluation of tumor extension, resectability, involvement of lymph nodes, and pulmonary metastases,[600,619,669,674-678] and coronal reconstruction can be helpful to evaluate tracheal wall thickening and extraluminal extension.[679] Virtual bronchoscopy can be useful to get a complete characterization of tracheal and tumor anatomy to facilitate surgical planning.[680]

Treatment Approaches

Resectability is universally associated with lower mortality in reported series[19,637,667,681] and as such is the initial strategy for most tracheal primaries.[559,646,648,667,675,682-684] Resection rates vary, however, by institutional and national practice, from 10% to over 65% based on the above-cited studies. Historic registry data from the Netherlands demonstrated a resection rate of 12%[642]; however, a recent update[685] suggests that 24% underwent resection in 2000 to 2005 (vs 58% who received radiotherapy). Contraindications to resection depend in large part on the preference of the surgeon; for example, Pearson recommends tracheal resection for at least some patients with adenoid cystic carcinoma with low-burden pulmonary metastases, yet many would consider such cases unresectable.[570,634,686] Regardless, many tracheal carcinomas are either improperly classified (eg, nontracheal primaries with tracheal extension) or systematically undertreated surgically.[685]

Most patients undergoing surgery have a median sternotomy and cervical collar excision, although extensive subglottic or high tracheal disease may require cervical exenteration with mediastinal tracheostomy.[634,640,648] Margins may of necessity be compromised to ensure a functioning airway. Technical advances in surgical procedures such as complete mobilization of the right hilar ligament, detachment/implantation of the left hilum, mobilization of the cervical trachea, and techniques for carinal resection/reconstruction and intrapericardial dissection have improved the likelihood of an R_0 resection.[342,664,681,687] Other surgical techniques like VATS are also reported in a limited number of cases.[688,689] Gaissert and colleagues reported improvements in both complete resection rates (from 68% to 82%) and in-hospital mortality (declining from 21% to 3%) with the increasing use of such techniques over a 40-year period.[636,682]

After resection, postoperative radiation is usually recommended.[561,636,637,667,668,671,682] Pathologic features such as completeness of resection, involvement of the thyroid gland, and lymphatic invasion have clearly been shown to have prognostic value,[690] and postoperative radiotherapy is routinely recommended for all patients at many institutions.[561,690] Preoperative radiotherapy has also been attempted, but fewer reports of this experience have been published. In aggregate, several small retrospective series seem to show a benefit for adjuvant radiation (Table 58.12). Chow and colleagues found that patients who underwent resection plus adjuvant radiation had a median survival time of 61 versus 16 months for those who received only surgery.[691] Regnand and others found that 31 patients who had had a complete resection with adjuvant radiation had seemingly better 5-year survival rates than did 27 patients without adjuvant radiation (74% vs 53%), but this apparent difference was not statistically significant.[19]

TABLE 58.12 RESULTS OF RESECTION WITH ADJUVANT IRRADIATION FOR PRIMARY TRACHEAL CARCINOMA

Study and Reference	Histology	Treatment	Median Survival Times or Rates

R_0, complete resection; $R_{1,2}$, incomplete resection; RT, radiation therapy.

[a]A minority of these patients received surgery alone.

Postoperative radiation seems to be effective for incompletely resected disease as well, with 5-year survival rates of 45% for such patients versus 0% for patients who did not receive radiation ($P < .05$).[19] Webb and colleagues, describing the experience at MD Anderson, demonstrated a statistically significant improvement in survival for patients given adjuvant radiotherapy rather than chemoradiation; however, no difference in survival was found between adjuvant radiotherapy and surgery alone.[561] In the largest series reported to date, 191 patients consecutively treated at the National Cancer Center, China, Wang and colleagues used postoperative radiation therapy for positive margins and salvage radiation therapy after local failure. In their series radiation, therapy has significant impact in both settings, with disease-free survival of 55 and 31 months, respectively, after the use of radiation therapy.[692] The results of studies of definitive therapy for tracheal tumors are summarized in Table 58.13.

HDR, high-dose rate; LDR, low-dose rate; RT, radiotherapy.

[a]One treatment-related death in patient receiving 60 Gy RT + 53 Gy LDR Ir-192.

Radiation has also been used as monotherapy for unresectable tumors and is the only independent risk factor for survival in these patients.[693] Results are best when doses have exceeded 60 Gy.[643,694,695] Mornex and associates found that the 5-year survival rate decreased from 12% for those receiving at least 56 Gy to 5% for those receiving lower doses.[696] However, Chow and others caution against giving doses higher than 60 Gy, as three of six patients in their study given doses in excess of 60 Gy had severe complications requiring surgical intervention, for example, tracheoesophageal fistula, esophageal stricture, and severe tracheal

crusting,[691] whereas none of the six patients treated with less than 60 Gy in that study had late side effects. Other authors have corroborated the concern of high doses contributing to the risk of complications.[697] Still, Chow and colleagues noted significantly better local control among patients who received greater than 50 Gy as adjuvant therapy and greater than 60 Gy as definitive therapy.[691] By way of comparison, Fuwa and colleagues reported reasonable results with a novel endoluminal-centering catheter; the median dose delivered to the group as a whole was 91 Gy (given as external beam radiation with low-dose rate 192Ir brachytherapy). Only one treatment-related death was reported 1 year after therapy in a patient who had received a total dose of 113 Gy.[698] Harms and colleagues, using median doses of 60 Gy delivered by external beam radiation plus 15- to 18-Gy brachytherapy boosts, reported minimal rates of severe (grade 3-4) toxicity (8% of 25 patients).[699] Exploratory studies of fast neutrons for locally advanced adenoid cystic carcinomas have been reported; in the University of Washington experience with endoluminal brachytherapy, fast neutrons were considered feasible and toxicity acceptable.[700] A summary of the experience with radiation as monotherapy for primary tracheal neoplasms is given in Table 58.11.

Combined chemoradiotherapy without resection has been attempted at some institutions, usually for nonsquamous tumors, with mixed results.[561,632,701,702] In general, patients with squamous cell carcinoma have fared poorly, and those with small cell carcinoma or lymphoma have done better.[47,561,621,703]

Radiation Techniques

No evidence is available to suggest that adjuvant radiation therapy is not beneficial in tracheal malignancies; however, any postoperative radiation should not be begun before 30 to 45 days after surgery to allow sufficient wound healing. Modern CT-based 3D conformal or intensity-modulated radiation techniques should be used. Case reports and small series using proton therapy[704] and carbon ion therapy[705] are also reported. Aggressive treatment is warranted to prevent airway obstruction, even when the intent is palliative.[696] External beam doses should be about 60 Gy for fully resected disease,[561] with a boost considered for squamous cell lesions with

high-risk features.[690] In a series of 32 patients treated for tracheal cancers reported by Zeng and colleagues in 2020, higher boost doses, up to 68 Gy, resulted in improvement in PFS compared to patients getting lower or no boost dose (5-year PFS 44% vs 13%). They did not observe increases in grade 3 or higher toxicity. Radiation therapy techniques included 2D, 3D, and IMRT.[706]

An intraluminal boost technique allows the dose to be increased (and, theoretically, local control to be increased as well) with minimal added acute or late side effects.[645,691,699,707-709] Standard constraints on organs at risk should be observed in all cases.[275,276,278,710] Intraluminal brachytherapy is also useful for palliative treatment. Skowronek and colleagues, in a study of patients treated with 10 to 30 Gy in one to three fractions, found that high-dose brachytherapy as monotherapy led to prolonged survival and improved quality of life.[709] In patients with locally extensive disease, the gravest complication of radiation therapy is the development of a tracheoesophageal fistula, which can be difficult if not impossible to avoid. For patients with emergent airway obstruction, rigid bronchoscopy should be performed instead of urgent radiotherapy.

The role of elective nodal irradiation for tracheal carcinoma is uncertain. As mentioned earlier, nodal status does not seem to have prognostic significance; even cervical adenopathy was not associated with poorer outcome.[621] Given the low proclivity for lymphatic spread of adenoid cystic carcinomas, the choice to avoid elective nodal irradiation for this variant is certainly reasonable. Because local recurrence is the major factor influencing survival, nodal and regional failure patterns are not a main concern. Yet if mediastinal or cervical nodes are seen on radiographic or pathologic examination, or if worrisome pathologic risk features[690] are discovered at surgery, radiation to these regions should be considered.

CONCLUSION

Primary tracheal cancer is quite rare and, in most cases, is of squamous or adenoid cystic histology. The optimal management strategy for these tumors seems to be a combined modality approach incorporating surgical resection and postoperative radiation. For localized disease, the role of chemotherapy, either alone or concurrent with radiation, is unknown.

CHAPTER 59

Esophageal Cancer

Brian G. Czito and Christopher G. Willett

Less than 20% of patients diagnosed with esophageal cancer are cured, with approximately half of patients presenting with unresectable or metastatic disease. This chapter reviews the natural history and treatment of esophageal cancer, including anatomy, risk factors, patterns of spread and recurrence, staging, results of current therapeutic approaches, radiation planning techniques, toxicity data, and future treatment strategies.

ANATOMY

The esophagus is a thin-walled, hollow tube approximately 25 cm in length. It is lined with stratified keratinized squamous epithelium, extending from the cricopharyngeus muscle at the level of the cricoid cartilage superiorly to the gastroesophageal (GE) junction inferiorly. The lower one-third (5-10 cm) of the esophagus may contain glandular elements. Replacement of the stratified squamous epithelium with columnar epithelium is referred to as Barrett esophagus, often occurring in the lower one-third. The Z line refers to the endoscopically visible junction of the squamous and glandular epithelium. The esophageal wall is composed of three layers: the mucosa, submucosa, and muscularis propria (Figure 59.1). The mucosal layer contains the epithelium, lamina propria, and muscularis mucosae. The epithelium is separated from the lamina propria by a basement membrane. In the portion of the esophagus containing columnar-type epithelium, the muscularis mucosae may consist of two layers. The mucosa may be divided into distinct layers, including M1 (epithelium), M2 (lamina propria), and M3 (muscularis mucosae). Similarly, the submucosal layer may be divided into inner (SM1), middle (SM2), and outer (SM3) layers. The muscularis propria consists of a circular inner layer and longitudinal outer layer. The adventitia (periesophageal connective tissue) lies directly on the muscularis propria.[1] No serosa is present, facilitating extraesophageal spread of disease.

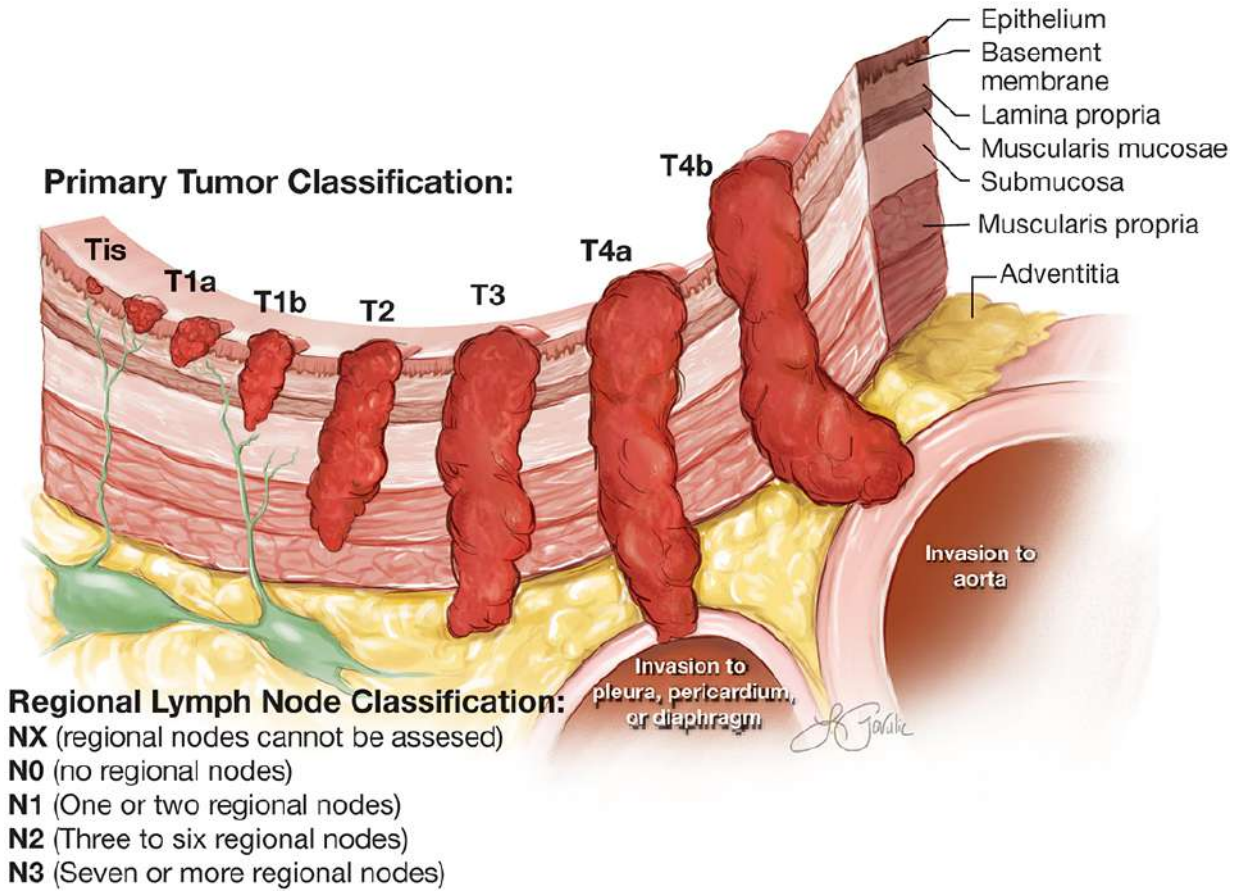

FIGURE 59.1 Diagram of esophageal wall. (Reprinted with permission from American College of Surgeons, Hunt KK, Katz MHG, Veeramachaneni N. In: Alliance for Clinical Trials in Oncology, ed. *Operative Standards for Cancer Surgery: Vol 2: Thyroid, Gastric, Rectum, Esophagus, Melanoma*. Wolters Kluwer; 2019:313.)

Although somewhat arbitrary, the esophagus is frequently divided into cervical and thoracic components. The most recent American Joint Committee on Cancer (AJCC) report divides the esophagus into four regions: cervical, upper thoracic, midthoracic, and lower thoracic (Figure 59.2).[1] The cervical esophagus lies within the neck and begins at the cricopharyngeus muscle (approximately the C7 level or 15 cm from the incisors) and extends to the thoracic inlet (at approximately the T3 level or at ~20 cm from the incisors [the level of the suprasternal notch]). The thoracic esophagus extends from approximately the level of T3 (beginning at about 20 cm) to T10 or T11.[1,2] The upper thoracic esophagus is bordered superiorly by the thoracic inlet and inferiorly by the lower border of the azygos vein, extending from approximately 20 to 25 cm. Radiographically, tumors in this location would be located between the sternal notch and azygos vein. The middle thoracic esophagus extends from the lower border of the azygos vein to the inferior pulmonary veins, extending from approximately 25 to 30 cm. The lower thoracic esophagus extends from the inferior pulmonary veins to the stomach and is inclusive of the GE junction, typically extending from approximately 30 to 40

cm. Endoscopically, the GE junction is often defined as the point where the first gastric fold is encountered, although this may be a “theoretical” landmark. The location of the GE junction can be accurately defined histologically as the squamocolumnar junction. In the most recent AJCC staging system, cancers with an epicenter in the lower thoracic esophagus or GE junction or within the proximal 2 cm of the stomach (ie, cardia) and extending up to the GE junction or esophagus are staged as an adenocarcinoma of the esophagus. If the epicenter is more than 2 cm distal to the GE junction, these are classified as stomach cancers. Useful landmarks in reference to endoscopy include the carina (~25 cm from the incisors) and GE junction (~40 cm from the incisors).

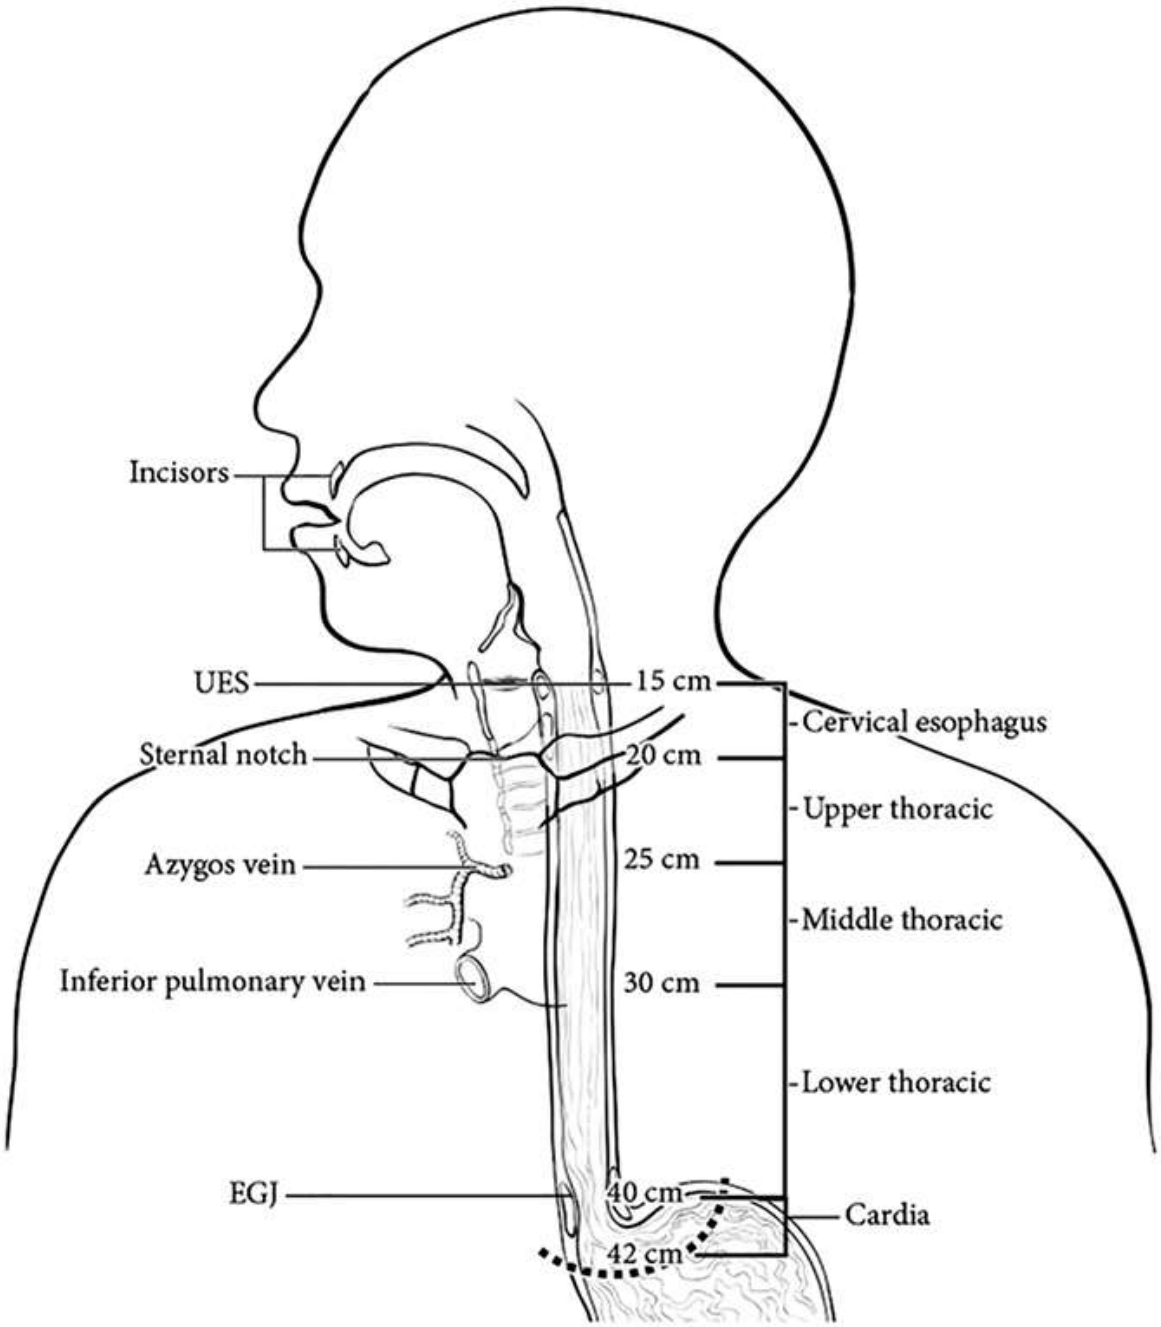

FIGURE 59.2 Anatomy of the esophagus. Note the lengths of various segments of the esophagus as measured from the upper central incisors. EGJ, esophagogastric junction; LES, lower esophageal sphincter; UES, upper esophageal sphincter. (From Rice TW, Gress DM, Patil DT, Hofstetter WL, Kelsen DP, Blackstone EH. Cancer of the esophagus and esophagogastric junction—major changes in the American Joint Committee on Cancer eighth edition cancer staging manual. *CA Cancer J Clin*. 2017;67(4):304-317. Copyright © 2017 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.)

Rudiger Siewert et al[3,4] characterized cancer *involving the GE junction* according to the location of the tumor (Figure 59.3). If the tumor center is located from more than 1

cm up to 5 cm above the GE junction (Z line), the tumor is classified as a type I adenocarcinoma of the distal esophagus. If the tumor center is located within 1 cm cephalad to 2 cm caudad to the GE junction, it is classified as type II. If the tumor center is located more than 2 cm below the GE junction, the tumor is classified as type III. Only Siewert type I/II tumors would be staged as esophageal cancer in the most recent AJCC staging system. However, locally advanced/bulky tumors can make it difficult to accurately distinguish where tumors originated in relationship to the GE junction.

Lymphatic Drainage

The esophagus has an extensive, longitudinal interconnecting system of lymphatics. The esophageal lymphatic network is primarily located within the submucosa (Figure 59.4); however, channels are also present within the lamina propria, facilitating spread of even superficial cancers of the esophagus involving the mucosa. In addition to these longitudinal lymphatics, intramural lymphatics may traverse the muscularis propria, facilitating tumor spread to regional lymphatic channels and paraesophageal nodes. Supporting this, autopsy series have demonstrated a high incidence of directly draining channels extending from the submucosa lymphatics into the thoracic duct, facilitating systemic spread. Lymph can travel the entire length of the esophagus before draining into lymph nodes,[2] and thus, the entire esophagus is at potential risk for lymphatic involvement. Up to 8 cm or more of "normal" tissue can exist between gross tumor and micrometastases "skip areas" secondary to this extensive lymphatic network.[5] In

addition, as many as 71% of frozen tissue sections scored as margin negative by conventional histopathology show involvement by lymphatic micrometastases with immunohistochemistry.[6] Lymphatics of the esophagus drain into nodes that usually follow arteries, including the inferior thyroid artery, the bronchial and esophageal arteries, and the left gastric artery (celiac axis).[7]

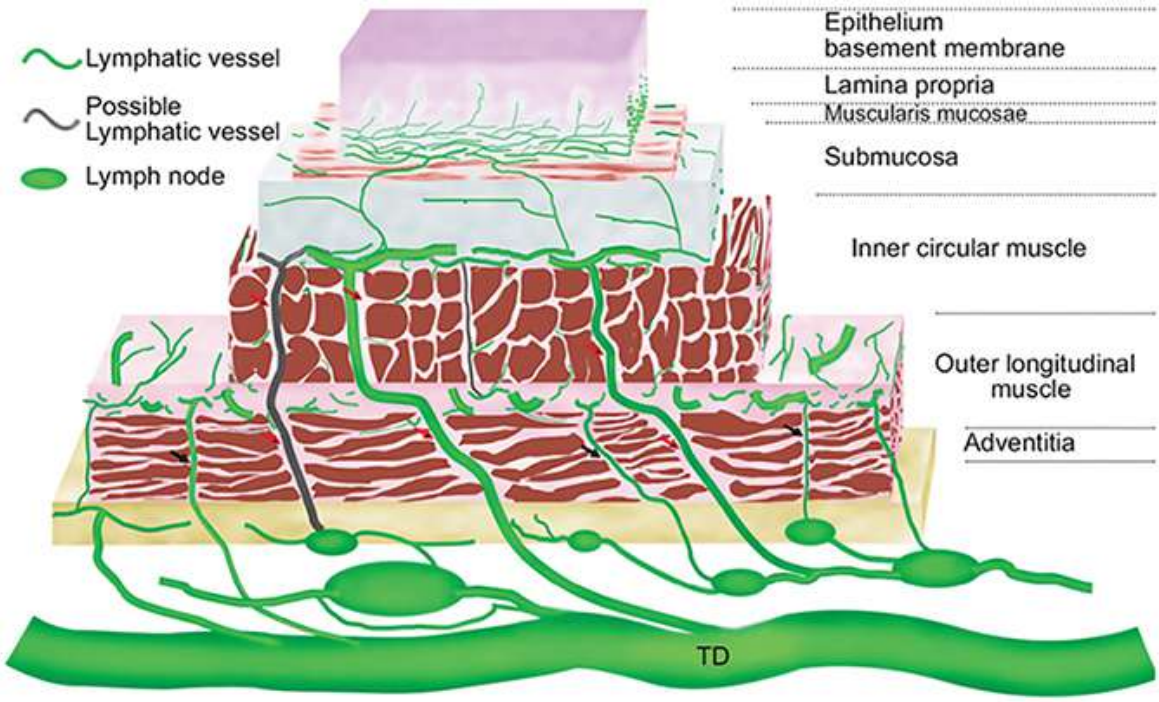

FIGURE 59.4 Lymphatics are found in virtually all layers of the esophagus except epithelium and basement membrane, primarily running longitudinally in the lamina propria and submucosa and more radially in the intermuscular space. More superficial lymphatics generally connect to the submucosa, which can subsequently drain directly to the thoracic duct or regional lymph nodes (including paraesophageal). Similarly, there can be direct lymphatic drainage to the intermuscular lymphatic plexus within the muscularis propria. Adventitial lymphatics can also drain to local regional lymphatics as well as the thoracic duct. (From Wang Y, Zhu L, Xia W, Wang F. Anatomy of lymphatic drainage of the esophagus and lymph node metastasis of thoracic esophageal cancer. *Cancer Manag Res*. 2018;10:6295-6303. EPIDEMIOLOGY AND RISK FACTORS

Esophageal carcinoma accounts for approximately 6% of all gastrointestinal malignancies. In 2025, there will be an estimated 22,070 new patients diagnosed with esophageal cancer in the United States and 16,250 deaths. Worldwide, in 2020, an estimated 604,000 esophageal cancer cases and 544,000 deaths occurred. Five-year survival worldwide for esophageal cancer ranges from 15% to 25%.[8] Most cases occur in males, at a rate of 4:1 relative to females.[9-11]

The incidence of esophageal carcinoma varies according to geography. Most cases of esophageal cancer occur in less developed countries. Nearly 80% of cases and deaths

occur in Asia. Worldwide, squamous cell carcinoma accounts for 90% of all disease. In contrast, adenocarcinoma is more common in developed countries.[8] The highest incidence of esophageal cancer occurs in Linxian, China, Russia, and the Caspian region of Iran. The incidence in these regions is 100/100,000 persons. What is often referred to as the "esophageal cancer belt" extends from northern Iran through the Central Asian republics to north-central China. In areas such as northern France, Kazakhstan, and South Africa, the incidence can be as high as 50 to 99/100,000. Although the reasons for the geographic discrepancy are unknown, some reports have linked the arid climate and alkaline soil with these high-risk areas, as well as the ingestion of nitrosamines, and inversely to the consumption of riboflavin, nicotinic acid, magnesium, and zinc.[12,13] In the United States, the incidence rate among males is less than 5 per 100,000. Over the last 20 years, there has been an increase in the incidence of adenocarcinoma at a rate of 5% to 10% per year.[14] In 1987, adenocarcinoma was reported to represent 34% and 12% of esophageal cancers in White men and women versus 3% and 1% for African American men and women, respectively.[14] As of 1998, esophageal adenocarcinoma accounted for almost 55% of all diagnosed cases in White men, and in the United States, the rates of adenocarcinoma now exceed those of squamous cell carcinoma, accounting for 80% of esophageal cancers in the United States.[8] African American men are more frequently diagnosed with squamous cell carcinoma.[14-16]

Important risk factors for esophageal cancer include sex, race, alcohol consumption, smoking, obesity, economic and social status, and dietary (tea and coffee consumption, low consumption of fruits and vegetables, and micronutrients) and genetic factors.[17,18] In North America and Western Europe, alcohol use and tobacco use are the major risk factors for squamous cell carcinoma, accounting for 80% to 90% of cases.[19] Reports have described the relative risk of esophageal cancer by the amount of alcohol and tobacco consumed, including a relative risk of 155:1 when consuming more than 30 g/day of tobacco along with 121 g/day of alcohol.[20]

Diets low in fruits, vegetables, and animal products result in marginal deficiencies in vitamins and trace elements and are associated with the development of squamous cell carcinoma.[21] Patients with Plummer-Vinson (Paterson-Kelly) syndrome, a condition characterized by iron deficiency anemia and low riboflavin levels, are at an increased risk for oral cavity, hypopharyngeal, and esophageal cancer. In addition, dietary intake of nitrosamines, nitrosamides, and *N*-nitroso compounds and exposure to polyaromatic hydrocarbons have been implicated in esophageal carcinoma. Examples of nitrate-rich foods include pickled vegetables, alcoholic beverages, cured meats, and fish. Betel quid chewing in Taiwan and India has been implicated as a potential cause as well.[22-24] Thermal irritation from consumption of hot beverages, soup, and food and physical irritation due to loss of teeth (poor oral hygiene) have been implicated in some studies. The role of human papillomavirus 16 and 18 has been linked to squamous cell carcinoma in some geographic areas although these results are inconsistent.[24]

Other risk factors associated with esophageal carcinoma include achalasia and tylosis. Achalasia of long duration (25 years) is associated with a 5% incidence of squamous cell carcinoma.[25,26] Patients with tylosis (hyperkeratosis of the palms and soles and papilloma of the esophagus) have a reported 38% risk in developing esophageal cancer at a mean age of 45 years.[27] In addition, carcinoma of the esophagus occurs in 2% to 4% of patients with head and neck cancer.

Risk factors leading to the development of adenocarcinoma of the esophagus are increasingly understood. Most esophageal adenocarcinomas tend to arise from the metaplastic columnar-lined epithelium known as Barrett esophagus.[28] Severe and long-standing GE reflux disease has clearly been shown to be a significant risk factor for Barrett esophagus, which may lead to adenocarcinoma. It has been estimated that patients with long-standing severe reflux have a 44-fold risk of developing adenocarcinoma.[29] Tobacco use is a more moderate risk factor for adenocarcinoma development. Smokers appear to have a 2- to 3-fold greater risk for developing esophageal adenocarcinoma than do nonsmokers.[30,31] The relative risk of esophageal adenocarcinoma persists even after three decades following smoking cessation, in contrast to a significant decline in similar patients with squamous cell carcinoma.[32] Obesity has also been linked to a 3- to 4-fold risk of adenocarcinoma, possibly because of an increased risk of reflux.[33] This is particularly pertinent to central obesity (visceral fat).[34] It has been estimated that a middle-aged patient with Barrett esophagus has a 10% to 15% risk of developing esophageal adenocarcinoma during their lifetime, although other reports have suggested this risk may be overstated.[35]

Although many risk factors are associated with esophageal carcinoma, few studies have demonstrated a causal relationship leading to pathogenesis. Montesano et al[36] reported possible genetic abnormalities involved in the genesis of esophageal cancer. In addition, possible differences in mechanisms of pathogenesis for squamous cell carcinoma and adenocarcinoma were described. Genetic abnormalities in squamous cell carcinoma include p53 mutations and multiple allelic losses at 3p and 9q, with amplification of cyclin D1 and epidermal growth factor receptor (EGFR). These mutations lead to cell hyperplasia, low- and high-grade dysplasia, and, ultimately, squamous cell carcinoma. In contrast, genetic abnormalities in adenocarcinoma include overexpression of p53; multiple allelic losses at 17p, 5q, and 13q; and amplification and overexpression of EGFR and human epidermal growth factor receptor 2 (HER-2). These abnormalities may be involved in the stepwise development of Barrett esophagus, dysplasia, and, ultimately, adenocarcinoma. These differences suggest that squamous cell carcinoma and adenocarcinoma have different series of genetic mutations as etiologies, but these abnormalities occur in 23% to 94% of tumors studied. Whole exome sequencing has identified mutations in p53 and the cyclin-dependent kinase inhibitor CDKN2, as well as multiple other known tumor-associated genes, in both adenocarcinoma and squamous cell carcinoma. Next-generation sequencing has identified frequent genomic alterations of CCND1 and SOX2 and/or *TP53* genes in

esophageal squamous cell carcinoma (more akin to squamous cell carcinomas of the head and neck), whereas esophageal adenocarcinomas more closely resemble chromosomally unstable variants of gastric cancer.[37,38]

NATURAL HISTORY AND PATTERNS OF SPREAD

Squamous cell carcinoma is characterized by extensive local growth and proclivity to lymph node metastases. Because the esophagus has no covering serosa, direct invasion of contiguous structures may occur early. Lesions in the upper esophagus can impinge on or invade the recurrent laryngeal nerves, carotid arteries, and trachea. If extraesophageal extension occurs in the mediastinum, tracheoesophageal or bronchoesophageal fistula may occur. Tumors in the lower one-third of the esophagus can invade the aorta or pericardium, resulting in mediastinitis, massive hemorrhage, or empyema.

A review correlating the incidence of lymph node metastases with depth of penetration revealed that 18% of patients with spread to the submucosa had lymph node involvement.[39] For T1 lesions, the reported incidence of nodal spread is 10% to 21%, although this may be higher or lower depending on depth of involvement; for T1a disease, lymph node metastases rates range from approximately 7% to 9%, and T1b 28% to 38%. Increasing tumor size as well as differentiation, lymphovascular invasion, and location may influence these rates.[40] For T2 lesions, this rises to 33% to 69%.[41-44] The location of involved lymph nodes is influenced by the origin of the primary tumor. At autopsy, lymph node metastases are found in approximately 70% of patients.[45-47] In patients with cervical lesions, lymph node metastases to the abdominal lymph nodes are rare. Distant metastasis can occur at almost any site. In a series of 1,470 patients with both adenocarcinoma and squamous cell carcinoma, common sites of distant metastases included liver, distant lymph nodes, lung, bone, and less commonly the brain. Patients with adenocarcinoma were more likely to experience brain and liver metastases, although patients with squamous cell carcinoma were more likely to develop lung metastases (Figure 59.5; see Figure 59.3B).[48]

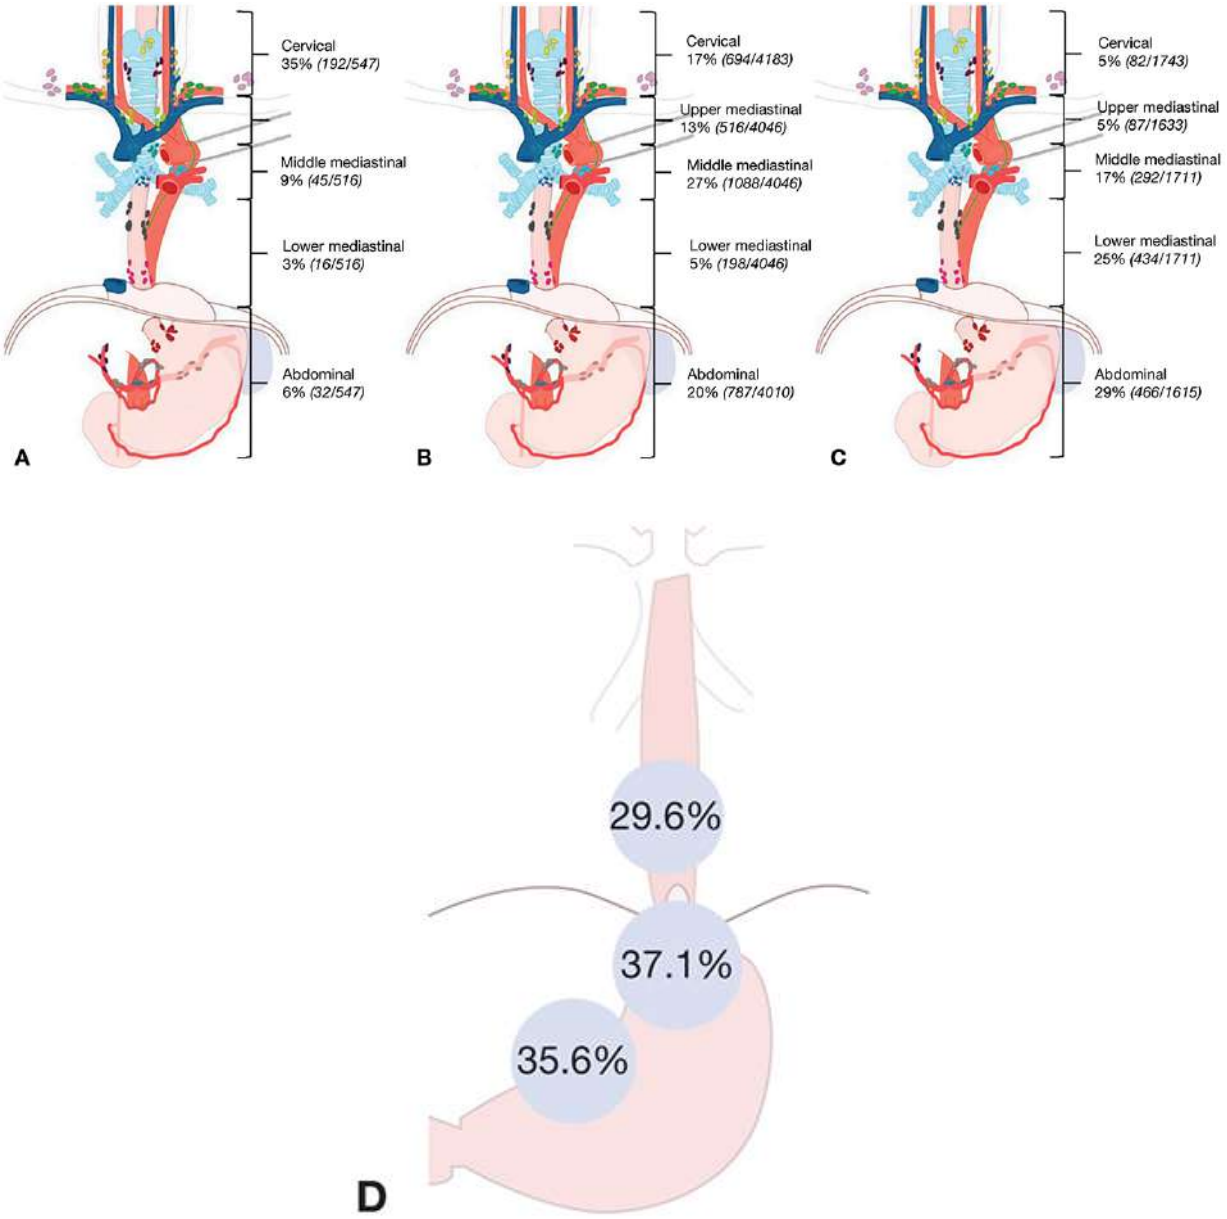

FIGURE 59.5 Prevalence of lymph node metastases per tumor location in patients with squamous cell carcinoma: upper esophageal tumor (A), middle upper thoracic esophageal tumor (B), and distal thoracic esophageal tumor (C). A review of 1,077 patients with squamous cell carcinoma of the thoracic esophagus undergoing esophagectomy further characterized patterns of nodal spread. Primary disease was located in the upper (5%), middle (63%), and lower (32%) thoracic

esophagus. In total, 47% of patients had lymph node metastases. On multivariate analysis, T stage, tumoral length, and degree of differentiation significantly correlated with incidence of lymph node metastases. In approximately 6% of cases, skip metastasis (distant lymph node metastases without regional lymph node metastasis) occurred, usually in patients with poorly differentiated, large, and deeply invasive tumors. Of involved nodes, 37% were macroscopically involved versus 63% microscopically involved, indicating that most lymph node metastases would be below the resolution of detection using contemporary imaging tools. Lymph node involvement was grouped into five categories: cervical, thoracic upper mediastinum, thoracic middle mediastinum, thoracic lower mediastinum, and abdominal lymph nodes.[49] A similar study of 1,893 patients with thoracic squamous cell carcinoma from China mapped patterns of lymph node metastases by primary tumor location, with similar patterns of spread. In this study, independent prognostic factors for lymph node metastases included tumor length, differentiation, and depth of invasion. The authors recommended treating nodal basins according to clinicopathologic factors, including enlargement of fields of patients with adverse histologic features, demonstrating similar rates of spread compared to the previously described series.[50] A systemic review of lymph node metastases in patients undergoing upfront surgery encompassing 8,952 patients similarly demonstrated that both squamous cell carcinoma and adenocarcinoma histologies can metastasize to cervical, thoracic, and abdominal lymph node stations, regardless of primary tumor location, although prevalence was significantly influenced by primary tumor site.

For lower esophageal and GE junctional adenocarcinomas, approximately 70% of patients will have nodal metastases at presentation. In one series of Italian investigators of 132 patients with adenocarcinoma undergoing surgery alone, common sites of metastases included periesophageal (30%), paracardial (37%), perigastric (36%), and celiac axis (14%) (see Figure 59.5D). This is influenced by tumoral depth of penetration, with nearly all T3 and T4 lesions exhibiting metastases in surgical series. Pathologic resection data have demonstrated rates of lymphatic involvement for lower esophageal and GE junctional tumors of 45%, 85%, and 100% for T2, T3, and T4 tumors, respectively (Figure 59.6).[42] In patients with lower esophageal cancer, involvement of both mediastinal and abdominal lymph nodes is common (Figure 59.7).[42] The primary direction for lymphatic flow for the lower esophagus is toward the abdomen. According to the classification by Siewert, nodal metastases are often seen in the mediastinum and abdomen for type I tumors, whereas type III tumors metastasize almost exclusively inferiorly, toward the celiac axis. Type II tumors are intermediate, preferentially spreading inferiorly and less frequently into the mediastinum. The primary value of the Siewert classification is in guiding appropriate surgery (ie, type I tumors are generally treated with esophagectomy and mediastinal lymph node resection, while types II and III are approached through the abdomen), although it may be useful in radiation field design as well.[3] Generally speaking, the incidence of abdominal nodal

involvement increases as one proceeds distally in the esophagus to the GE junction. For patients with tumors arising from the GE junction, mediastinal involvement is less common. Nodal metastases above the level of the carina are rare in lower esophageal and junctional tumors.[51] In addition, histologic analyses of lower esophagus and GE junction adenocarcinoma specimens suggest that many patients without nodal involvement on conventional histopathology actually have involvement when assessed by immunohistochemistry.[52]

Extensive nodal mapping has been performed by Japanese investigators, who have devised the Japanese Gastric Cancer Association Classification (Figure 59.8).[53] Using this system of nodal classification, investigators from Erlangen evaluated 326 patients with esophagogastric junction adenocarcinoma (AEG) undergoing primary resection. Tumors were stratified as AEG type I (distal esophagus), II (gastric cardia), and III (subcardia). Note that there was significant overlap in the majority of tumors for all stages, with an overall incidence of lymph node metastasis of 71%. In T1 patients, only 17% exhibited lymph node metastasis, whereas 78%, 86%, and 90% of T2, T3, and T4, respectively, had involved nodes. Figure 59.9 shows varying patterns of nodal spread based on T stage as well as AEG location. Additional generalizations from this study include that lymph vascular invasion was highly predictive of nodal spread and that proximal extension of type II and III tumors into the distal esophagus (particularly beyond the Z line) predicted an increasing incidence of paraesophageal lymph node involvement.[54]

LOCAL FAILURE

In an older series at the University of Pennsylvania and Fox Chase Cancer Center of patients with adenocarcinoma of the esophagus and GE junction treated with surgery alone, the locoregional recurrence rate was 77%.[55] In contemporary randomized trials, local failure rates with surgery alone range from 29% to 45%.[56-59] Similarly, data from contemporary randomized trials of esophageal cancer using "definitive" chemoradiation also indicate that local failure is a major cause of failure, with approximately 50% of patients failing locally (Table 59.1). In a study of 239 patients receiving definitive

chemoradiotherapy, 50% presented with local failure, 48% distant failure, and 31% no failure. Of local failures, 90% were within the gross tumor volume (GTV), whereas clinical target volume (CTV) and planning target volume (PTV) failures were seen in only 23% and 12%, respectively.[60] In many trials, patterns of failure are reported as first site of recurrence. This fact, along with infrequent post-therapy imaging and inability to detect subclinical recurrences, likely leads to underestimates of local recurrence rates. These data clearly emphasize the need for improvements in local treatment modalities.

CLINICAL PRESENTATION

Symptoms of esophageal cancer often start 3 to 4 months before diagnosis. Location of the primary tumor in the esophagus may influence presenting symptoms. Dysphagia is seen in more than 90% of patients regardless of location. Odynophagia is present in up to 50% of patients.[61] Weight loss is common, with 40% to 70% of patients reporting a loss of more than 5% of total body weight. This extent of weight loss has been associated with a worse prognosis. Less frequent symptoms may include vague chest and upper abdominal pain, hoarseness, cough, and glossopharyngeal neuralgia.[62]

Advanced lesions can produce signs and symptoms due to tumor invasion into local structures. Hematemesis, hemoptysis, melena, dyspnea, and persistent cough secondary to tracheoesophageal or bronchoesophageal fistula may occur. Compression or invasion of the left recurrent laryngeal nerve or the phrenic nerves can cause dysphonia or hemidiaphragm paralysis. Superior vena cava syndrome and Horner syndrome can also occur from more advanced lesions. Pleural effusion and exsanguination resulting from aortic communication may also be rarely seen.[61] Abdominal and back pain may occur with celiac axis nodal involvement with lower esophageal tumors.

DIAGNOSTIC WORKUP

After a thorough history and physical examination, all patients with suspected esophageal cancer should have a workup similar to that outlined in Table 59.2. Attention

should be paid to cervical and supraclavicular lymph nodes. Basic blood counts and a metabolic panel with liver function tests should be obtained.

TABLE 59.2 DIAGNOSTIC WORKUP FOR ESOPHAGEAL CANCER

Multidisciplinary evaluation (surgical, radiation, and medical oncology)
History and physical
Complete blood count and chemistry profile
Upper gastrointestinal endoscopy and biopsy
Chest, abdomen, and pelvic computed tomography (CT) with intravenous and/or oral contrast (combined positron emission tomography [PET]-CT optimal)
PET evaluation (combined PET-CT optimal)
Endoscopic ultrasound, with fine-needle aspiration if indicated (if no evidence of distant metastases)
Bronchoscopy if tumor is located at or above the carina or there is suspected airway involvement
Nutritional assessment and consideration of feeding tube (nasogastric or feeding jejunostomy) in selected situations

Although the esophagogram may be used to define lesion extent, endoscopy is the best tool to diagnose and define the extent of the lesion. During flexible endoscopy, biopsies and/or brushings should be taken of the primary site and suspicious areas harboring satellites or submucosal spread. In addition, accurate endoscopic measurement and characterization of tumor and GE junction in relation to the incisors facilitate radiation treatment planning, as may the strategic placement of radiopaque fiducials at the superior and inferior extent of the primary lesion. Examination with panendoscopy of the oral cavity, pharynx, larynx, and tracheobronchial tree may also be performed at the time of esophagoscopy in patients with squamous cell carcinomas, given the high incidence of second tumors in the head and neck and upper airway.[2] In addition, bronchoscopy should generally be performed in patients with proximal malignancies to evaluate for the presence of tracheal, carinal, or bronchial invasion, particularly for patients with tumors abutting these structures on computed tomography (CT). CT of the thorax and abdomen is critical to identify metastases to the lung, liver, upper abdominal nodes, or adrenals; additionally, the primary tumor can usually be appreciated as well as enlarged regional lymph nodes. However, CT may not adequately assess periesophageal lymph node involvement or accurately define the true extent of the primary tumor.[63,64] Conventional CT scan can accurately determine resectability in only 65% to 85% of cases. Furthermore, CT accurately predicts T stage in approximately 70% of cases and nodal involvement in only 50% to 70% of cases.[69-71] Pelvic CT may be performed as clinically indicated.

To more accurately assess periesophageal and celiac lymph node involvement and transmural extent of disease, endoscopic ultrasonography (EUS) should be performed. EUS provides accuracy rates of 85% to 90% for tumor invasion (T stage) and 75% to 80% for lymph node metastases when matched to surgical pathology.[72-75] A meta-

analysis in nearly 3,000 patients with squamous cell carcinoma concluded that EUS had good diagnostic accuracy for squamous cell carcinoma, albeit with better performance in substaging T1 disease (Ta1 and T1b), as well as T4 tumors, with overall T-staging and N-staging accuracy of 71% and 79%, respectively.[76] However, the accuracy of endoscopic ultrasound following neoadjuvant therapy is significantly less, ranging from 27% to 48% for T staging and 38% to 71% for N staging. This is possibly due to the failure to discriminate tumor from postradiation inflammation and fibrosis.[77-79] Illustrating the potential limitations associated with contemporary staging techniques, in one series of 102 patients with clinically staged (by positron emission tomography [PET], EUS, and/or CT) T2-3 N0 tumors receiving induction chemotherapy alone, 60% of patients were found to have metastatic nodal disease.[80]

Surgical staging procedures, including thoracoscopy, mediastinoscopy, and laparoscopy, may provide additional staging information and are considered in selected patients at some institutions.[81] Laparoscopy would primarily be used for tumors at the GE junction.

Patients with significant obstruction and inability to maintain their weight may require placement of a feeding tube. If surgery is planned, gastric tube placement is generally avoided, given that the stomach will ultimately serve as the “neoesophagus” following resection and a feeding jejunostomy tube may be placed.

PET has proven to be a valuable staging tool in patients with esophageal cancer. The addition of PET to standard staging studies such as CT can improve the accuracy of detecting stage III and stage IV disease by 23% and 18%, respectively.[82,83] Overall, it is estimated that PET will detect distant metastatic disease in approximately 20% of patients who are considered to have locoregional disease only by CT. However, PET also appears to have a lower accuracy in detecting local nodal disease compared to CT alone or in combination with endoscopic ultrasound. Of importance, some series suggest that PET can be used to predict response to therapy, with PET “responders” experiencing significantly improved outcomes compared to “nonresponders.”[84] However, in one pooled analysis, the sensitivity of PET in detecting pathologic complete response following treatment was 0.62, and pooled specificity 0.73, with the authors concluding that current imaging modalities (including PET) are insufficiently accurate to identify complete responders.[85] In addition, PET has been used to predict response to treatment early during the treatment course. The phase II CALGB 0803 study included early response assessment during treatment using PET as a biomarker to individualize therapy, allowing initial chemotherapy-alone nonresponders to cross over to an alternate chemotherapy regimen during radiation. This strategy indicated improved pathologic complete response rates in early PET nonresponders who crossed over, as well as portending improved outcomes in patients responsive to induction therapy.[86] In this study, 257 patients with locally advanced esophageal and GE junction cancers were randomized to induction chemotherapy with modified FOLFOX-6 or carboplatin/paclitaxel. PET scan was subsequently obtained and patients who responded

(≥35% decrease in standard uptake value [SUV]) continued on with the same chemotherapy during chemoradiation, while nonresponders switched to the alternate chemotherapy. Pathologic complete response rates were 40% in the PET responders after FOLFOX who continued on with such, and 18% for nonresponders who crossed over. In comparison, pathologic complete response rate was 14% for the carboplatin/paclitaxel responders and 20% for nonresponders who crossed over to FOLFOX. However, in this trial pathologic complete response did not seem to accurately predict overall survival. Thus far, the ability of intermittent (on treatment) PET to assess early outcomes during combined modality, to date, has not reliably correlated between interim findings on PET parameters and pathologic complete response and/or clinical outcome.[87] This has led to ongoing investigation of early treatment response as measured by PET as a surrogate for therapeutic efficacy and clinical outcomes, with potential subsequent therapy modification based on early response.[88]

STAGING SYSTEMS

Esophageal staging can be based on pathologic or clinical criteria. Pathologic staging is performed after invasive procedures, including esophagectomy, mediastinotomy, or thoracotomy. Clinical staging is often employed with "definitive" and neoadjuvant chemoradiation approaches and is less accurate. With the combination of CT, PET, and EUS, clinical staging closely correlates with pathologic stage. Note that the most recent AJCC staging system takes into consideration tumor type and grade, as well as involved number of lymph nodes (Table 59.3; Figures 59.10 and 59.11).

TABLE 59.3 AMERICAN JOINT COMMITTEE ON CANCER 2017 ESOPHAGEAL CANCER STAGING SYSTEM (8TH EDITION)

Category	Criteria
T category	
TX	Tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	High-grade dysplasia, defined as malignant cells confined by the basement membrane
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa
T1a[a]	Tumor invades the lamina propria or muscularis mucosae
T1b[a]	Tumor invades the submucosa
T2	Tumor invades the muscularis propria
T3	Tumor invades the adventitia
T4	Tumor invades adjacent structures
T4a[a]	Tumor invades the pleura, pericardium, azygos vein, diaphragm, or peritoneum

Category	Criteria
T4b[a]	Tumor invades other adjacent structures, such as the aorta, vertebral body, or trachea
N category	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in 1-2 regional lymph nodes
N2	Metastasis in 3-6 regional lymph nodes
N3	Metastasis in ≥7 regional lymph nodes
M category	
M0	No distant metastasis
M1	Distant metastasis
Adenocarcinoma G category	
GX	Differentiation cannot be assessed.
G1	Well differentiated, with .95% of the tumor composed of well-formed glands
G2	Moderately differentiated, with 50%-95% of the tumor showing gland formation
G3[b]	Poorly differentiated, with tumors composed of nest and sheets of cells with <50% of the tumor demonstrating glandular formation
Squamous cell carcinoma G category	
GX	Differentiation cannot be assessed.
G1	Well differentiated, with prominent keratinization with pearl formation and a minor component of nonkeratinizing basal-like cells, tumor cells arranged in sheets, and mitotic counts low
G2	Moderately differentiated, with variable histologic features ranging from parakeratotic to poorly keratinizing lesions and pearl formation generally absent
G3[c]	Poorly differentiated, consisting predominantly of basal-like cells forming large and small nests with frequent central necrosis and with the nests consisting of sheets or pavement-like arrangements of tumor cells that are occasionally punctuated by small numbers of parakeratotic or keratinizing cells
Squamous cell carcinoma L category[d]	
LX	Location unknown
Upper	Cervical esophagus to lower border of the azygos vein
Middle	Lower border of the azygos vein to lower border of the inferior pulmonary vein
Lower	Lower border of the inferior pulmonary vein to the stomach, including the esophagogastric junction

[a]Subcategories.

[b]If further testing of “undifferentiated” cancers reveals a glandular component, categorize as adenocarcinoma G3.

[c]If further testing of “undifferentiated” cancers reveals squamous cell component or if after further testing they remain undifferentiated, categorize as squamous cell carcinoma G3.

[d]Location is defined by epicenter of esophageal tumor.

PATHOLOGIC CLASSIFICATION

Squamous cell carcinoma and adenocarcinoma constitute 95% of all esophageal tumors, although other rare histologic subtypes are occasionally seen.[89] Immunohistochemical staining may be required in poorly or undifferentiated cancers to differentiate between squamous cell and adenocarcinoma. An updated World Health Organization classification of esophageal cancers is given in Table 59.4.

TABLE 59.4 PATHOLOGIC CLASSIFICATION OF MALIGNANT ESOPHAGEAL TUMORS

Epithelial tumors
Squamous cell carcinoma
Variants of squamous cell carcinoma
Basaloid squamous cell carcinoma
Squamous cell carcinoma with sarcomatoid features
Undifferentiated carcinoma
Spindle cell carcinoma
Pseudosarcoma and carcinosarcoma
Verrucous carcinoma
In situ carcinoma
Adenocarcinoma
Adenoacanthoma
Adenoid cystic carcinoma (cylindroma)
Mucoepidermoid carcinoma
Adenosquamous carcinoma
Carcinoid
Small cell carcinoma
Nonepithelial tumors
Sarcoma, 13 variants reported, most common is leiomyosarcoma.
Malignant melanoma
Myoblastoma
Choriocarcinoma
Lymphoma

Given that there has been a rise in adenocarcinoma compared to squamous cell carcinoma, examinations of outcomes by histology have been performed. Some series have reported that patients with squamous cell carcinomas have improved survival,[90] whereas others have suggested that patients with adenocarcinoma have an improved survival[91] and some others report no survival differences. Overall, there can be no direct comparison until randomized studies are done with stratification based on histology.

Pseudosarcoma is a variant of a poorly differentiated squamous cell carcinoma with spindle-shaped cells in the stroma resembling fibroblasts. Verrucous carcinoma is a well-differentiated, papillary variant of squamous cell carcinoma.[2] Squamous cell carcinoma in situ is rarely seen in the United States and should be distinguished from dysplasia.[92-94]

Adenocarcinoma may arise from foci of ectopic gastric mucosa or intrinsic esophageal glands. However, as described previously, it is believed that the vast

majority arise from Barrett esophagus. If a focus of squamous cell metaplasia is found in an adenocarcinoma, the tumor may be referred to as an adenoacanthoma.[95]

Adenoid cystic carcinomas are rare, with an incidence of 0.75%. Patients with this malignancy present around the sixth decade of life and have a poor median survival.[96] Mucoepidermoid tumors (adenosquamous carcinomas) are more aggressive and carry a poor prognosis.[97] The incidence of small cell carcinoma is approximately 2%. Patients with these malignancies often present in the sixth to eighth decades of life, and the lesion is usually located in the middle to lower esophagus in males.[98,99] These are believed to originate in the argyrophilic cells in the esophagus and may produce paraneoplastic syndromes, such as antidiuretic hormone secretion and hypercalcemia.[100] The clinical course of small cell carcinoma is similar to that of small cell carcinoma of the lung and may be responsive to chemotherapy and radiation therapy.[97,99]

Nonepithelial tumors of the esophagus are rare. Among these, leiomyosarcomas are the most common. Twenty-five percent of patients with this tumor present with metastases.[101-103] Histologically, these tumors have interlacing bundles of spindle-shaped cells. Less aggressive forms have fewer mitotic figures and less anaplasia. Prognosis has been reported to be more favorable than that of squamous cell carcinoma.[97] In patients with Kaposi sarcoma, gastrointestinal involvement of the esophagus can be seen.[104]

Malignant melanoma is rare and can occur as a primary esophageal tumor or as a metastasis. These lesions are usually large and often covered by intact squamous mucosa with focal areas of ulceration. Spread is usually submucosal. Mean survival is approximately 7 months.[105,106] Lymphoma constitutes approximately 1% of esophageal malignancies. It is usually associated with direct extension from other organs, although primary esophageal lymphoma has been reported.[107]

PROGNOSTIC FACTORS

According to the Union Internationale Contre le Cancer/AJCC seventh-edition staging system, R-status, age, and histologic subtype were independent prognostic factors of survival, whereas tumor grade and site were not.[108] It should be recalled that these data consider patients treated with surgery alone and as such do not apply to patients receiving chemotherapy or radiotherapy. A study published by Nomura et al[109] evaluating 301 patients treated with chemoradiotherapy showed that T stage, M stage, and gender were prognostic factors in multivariate analysis.

In addition to stage, other factors portend outcome. Tumor length/size may also impact outcome. In a study of 582 patients undergoing surgical resection as primary treatment, tumoral length adversely affected survival, with 5-year survival rates of 77%, 48%, 38%, and 23% for tumor lengths of 1, 2, 3, or more than 3 cm, respectively ($P <$ .001).[110] Of note, length was not prognostic if patients were N+ or M+. Similarly, in patients with adenocarcinoma, 5-year survival rates have been shown to be significantly higher for patients with tumors 2 cm or less compared to those with tumors more than 2

cm.[111] Another study of 1,553 patients with squamous cell carcinoma of the esophagus determined that tumor size, grade, lymphadenopathy, stage, and family history were prognostic following esophagectomy.[112]

In another large study from the Mayo Clinic, clinicopathologic factors that affected prognosis included T and N status, tumor grade, age .76 years, extracapsular lymph node extension, and the absence of chemotherapy or radiotherapy; anatomic location did not influence survival.[113] In addition, weight loss and low overall performance status also indicate poor prognosis.[114] Deep ulceration of the tumor, sinus tract formation, and fistula formation are other poor prognostic factors.[61]

Obtaining uninvolved pathologic margins at resection is of significant importance with regard to long-term outcome. An Intergroup study (discussed later) evaluating chemotherapy preceding and following esophagectomy showed that outcomes were similar in patients undergoing R1 resection (positive microscopic margins) or R2 resection (gross residual disease) or patients not undergoing resection at all. Only patients undergoing R0 resection (uninvolved margins) had a substantial chance of long-term disease-free survival.[115] A meta-analysis of 17 studies found that major pathologic response following neoadjuvant therapy in patients with GE cancer was predictive of survival.[116] Another meta-analysis of 13 series showed that perineural invasion is an adverse prognostic biomarker in esophageal cancer, often associated with more advanced stage and poor differentiation.[117] A patterns-of-care survey examined the outcomes of patients with adenocarcinoma and squamous cell carcinoma of the esophagus between 1996 and 1999. Patients were treated with radiation therapy across 59 institutions. On multivariate analysis, significant improvements in survival were seen in patients treated at centers with 500 or more patients with new cancers compared to centers seeing less than 500 patients (hazard ratio [HR] 1.32; $P = .03$).[118]

GENERAL MANAGEMENT

Treatment for esophageal carcinoma is characterized as either curative or palliative. According to one historical study,[119] only 20% of patients present with cancer of the esophagus that is truly localized to the esophagus, indicating that at the time of diagnosis, approximately 80% of patients have either locally advanced or distant disease. Figure 59.12 is a treatment algorithm for newly diagnosed esophageal cancer.

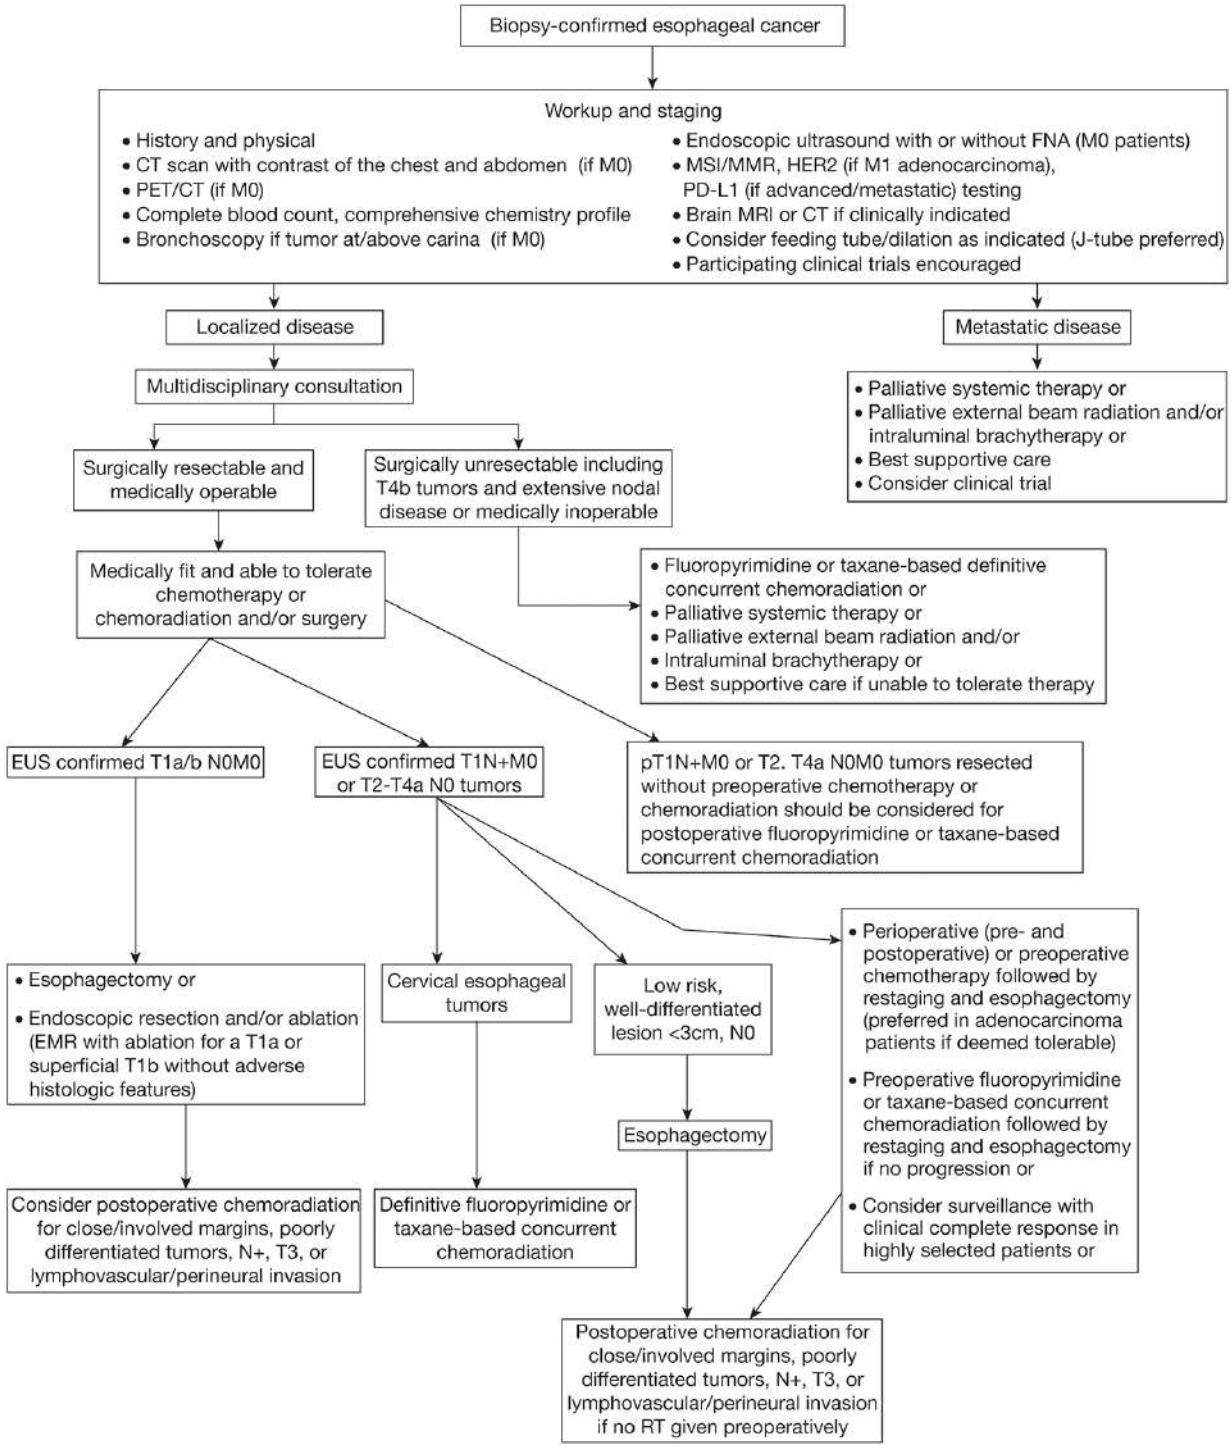

FIGURE 59.12 Treatment algorithm for newly diagnosed esophageal cancer. Treatment approaches are based in location and stage of the tumor, as well as surgical resectability and medical comorbidities of the patient. CT, computed tomography; EMR, endoscopic mucosal resection; EUS, endoscopic ultrasound; FNA, fine-needle aspiration; HER2, human epidermal growth factor receptor 2; MRI, magnetic resonance imaging; MSI/MMR, microsatellite instability/DNA mismatch repair deficiency; PD-L1, programmed death ligand-1; PET, positron emission tomography; RT, radiation therapy.

Surgery With Curative Intent

Surgery of the thoracic esophagus usually requires a subtotal or total esophagectomy and is usually undertaken for lesions of the middle to lower one-third of the thoracic esophagus and GE junction. Patients with stage I to III tumors are often considered for potentially curative resection; however, aortic, tracheal, heart, or great vessel invasion may preclude resection. Esophagectomy may be accomplished by a number of techniques, including a transhiatal esophagectomy, right thoracotomy with laparotomy with intrathoracic anastomosis (Ivor Lewis esophagogastrectomy), right thoracotomy with laparotomy with cervical anastomosis (McKeown or "three-hole" esophagogastrectomy), and left thoracoabdominal, transhiatal, or radical esophagectomy via open or laparoscopic approaches. Each technique has its advantages and disadvantages. In general, advantages of the transthoracic approach include better visualization with access and resection of the upper two-thirds of the esophagus and mediastinal lymph nodes. One potential advantage of the McKeown approach is a cervical anastomosis, which may allow for easier management of anastomotic leaks. Alternatively, the transhiatal approach has less morbidity than does thoracotomy (including respiratory compromise) with easier access to anastomotic leaks. However, a recent randomized trial evaluating intrathoracic versus cervical anastomosis following total or high-grade minimally invasive esophagectomy revealed leakage rates of 12.3% for intrathoracic versus 34.1% for cervical anastomoses, with less severe complications and lower recurrent nerve palsy rates after Ivor Lewis surgery, indicating that intrathoracic anastomosis resulted in better outcomes for patients treated with transthoracic minimally invasive esophagectomy or mid to distal esophageal or GE junction cancers.[120] In any instance, achievement of negative margins at resection has been reported to be a significant prognostic factor and should be the goal of esophageal resection. Exemplifying this, in a study of 500 patients undergoing transthoracic resection, patients undergoing margin-negative resection had a 5-year survival rate of 29% versus no 5-year survivors in patients with involved margins.[121]

Ivor Lewis esophagectomy is the classic approach to expose midesophageal lesions. A left thoracotomy procedure exposes lesions of the GE junction. Transhiatal esophagectomy is performed without a thoracotomy and is useful in lower esophageal lesions, although direct visualization and dissection of varying mediastinal lymph nodes cannot be achieved. An emerging treatment option in addition to the above techniques is the use of minimally invasive esophagectomy, which can include laparoscopy-assisted, thoracoscopic, or more limited thoracotomy. Minimally invasive techniques, including robotic approaches, are being increasingly applied to esophageal cancer. A hybrid minimally invasive esophagectomy (consisting of laparoscopic abdominal phase of gastric mobilization) with an open right thoracotomy may have a lower incidence of intraoperative/postoperative pulmonary complications and tumor spillage compared to an open approach, with a potential improvement in overall and disease-free survival.[122] Despite this, even at specialized centers, postoperative morbidity remains high, with

overall complication rate of 50% to 60% and with 1- and 3-month mortality rates reported to be less than 2% and less than 6%, respectively.[123] The optimal surgical approach is unknown and remains a topic of ongoing investigation.

Laparotomy or laparoscopy can be performed before neoadjuvant therapy or concurrently with esophagectomy to rule out peritoneal-based disease below the diaphragm, particularly in more advanced adenocarcinomas of the GE junction. Multiple reconstruction options are available following definitive surgery; esophagogastrostomy is the most widely used, using the stomach as a conduit to replace the esophagus. Patients with significant obstruction and inability to maintain their weight often require placement of feeding jejunostomy. If surgery is planned, gastric tube placement is generally avoided, given that the stomach will ultimately serve as the "neoesophagus" following resection, with feeding jejunostomy often preferred. Colon interposition, preferably with the left colon, can also be used; however, this approach is generally reserved for patients who have previously undergone gastric surgery or other procedures that have devascularized the stomach. Similarly, jejunal interposition may be utilized.

Squamous cell carcinoma of the cervical esophagus presents a difficult management situation. Proximal esophageal tumors less than 5 cm from the cricopharyngeus are generally treated with definitive chemoradiotherapy. If surgery is performed, resection of portions of the pharynx, the entire larynx, the thyroid gland, and the proximal esophagus is often required. Radical neck dissections are also carried out.[61] Because of the significant morbidity and loss of organ function with surgery, chemoradiation alone has been frequently employed. The survival probability with definitive chemoradiotherapy is similar, without the major functional impairments, morbidity, and mortality associated with surgery.[124] The optimum time to surgery following neoadjuvant therapy remains a topic of investigation, although delaying surgery from the traditional 4 to 6 weeks to greater than 12 weeks might improve tumor response to neoadjuvant therapy and thereby facilitate radical resection. This remains a topic of investigation.

Curative Combination Therapy

In the treatment of patients with esophageal cancer, an approach of radiation therapy with concurrent chemotherapy, with or without surgery, is frequently adopted. Multiagent chemotherapy with cisplatin and 5-fluorouracil (5-FU) has been used historically, although other combinations (eg, paclitaxel and carboplatin; 5-FU with oxaliplatin) are now commonly utilized. Additional combinations of novel systemic agents (that also act as radiosensitizers) with radiation therapy are under investigation.

Palliative Treatment

Palliative treatment is frequently used for the relief of symptoms of esophageal carcinoma, especially dysphagia.[125] Surgical palliation involves resection and reconstruction, if possible, removing the bulk of the disease, potentially preventing abscess and fistula formation, as well as bleeding. Substernal bypass with the colon or entire stomach has also been carried out.[125] However, given the poor prognosis in patients with advanced disease and morbidity associated with resection, a surgical approach is rarely adopted and should be avoided in patients who can be managed with nonsurgical modalities.

Endoscopic dilation is a reasonable alternative. When the lumen of the esophagus is dilated to 15 mm, dysphagia is often no longer experienced. Repeat dilation is often required.[61] Esophageal stenting with either conventional plastic stents or metallic self-expanding stents can also be used to maintain patency.[126]

Palliative irradiation is frequently used to control the primary disease, as well as distant metastases. Resolution of symptoms, especially pain and dysphagia, can be accomplished in up to 87% of patients. Palliative treatment regimens range from 20 Gy over 1 week[62] to 50 Gy over 5 weeks. Laser ablation with or without intraluminal brachytherapy can be used. The addition of three fractions of 7 Gy each can improve the stenosis-free interval and prevent obstruction.[126]

RADIATION THERAPY TECHNIQUES

Simulation

When patients are simulated, the radiation oncologist should know the extent of disease based on imaging (barium swallow, CT, PET, magnetic resonance imaging [MRI]), as well as on endoscopy. CT simulation is appropriate for treatment planning. During simulation, the patient is positioned, straightened, and immobilized on the simulation table. An immobilization device (eg, wing board, alpha cradle, body fix, or Vac-Lok on indexed wing board) is used to minimize variation in daily setup. Arms are generally placed overhead and knee support placed underneath the legs. Palpable neck disease should be marked with a radiopaque wire. The administration of oral contrast to delineate the esophagus is generally used and helps define the extent of mucosal irregularity, whereas small-bowel contrast can help identify any bowel in the field. For GE junctional tumors (particularly with significant gastric involvement), it may be advisable to have the patient come in with an empty stomach. Fasting prior to simulation and treatment each day may allow for greater reproducibility of treatment. In contrast, simulation without fasting and delivery of oral contrast may allow for planning in a “worst-case” scenario, with the patient later instructed to fast prior to treatment delivery. For cervical and upper thoracic lesions, an immobilization mask may assist in creating a reproducible position. Some authors have also advocated that midesophageal primaries be simulated in prone position to maximize distance between the target volumes and spinal cord. The patient is placed on the CT simulator in the treatment

position, and a scan of the entire area of interest with margin is obtained. At a minimum, 3- to 5-mm slices should be used, allowing accurate tumor characterization, as well as improved quality of digitally reconstructed radiographs. If patients lose more than 10% of their body weight during therapy, consideration should be given to repeat CT planning. Intravenous contrast is generally used to delineate mediastinal and abdominal vascular nodal basins, including the celiac axis and to allow the radiation oncologist to discern normal vasculature from other adjacent normal structures, and potential adenopathy. The tumor and vital structures are then outlined on each slice on the treatment planning system. The use of respiratory gating or breath-hold techniques may help to reduce target motion with respiration and, therefore, avoid normal-tissue irradiation associated with larger margins used in free-breathing approaches, particularly for lower esophageal cancers. Additional techniques to minimize physiologic motion include abdominal compression devices. Four-dimensional CT scan may be appropriate to assess tumoral motion, facilitating appropriate margin placement on the target volumes, particularly in lower esophageal tumors and/or diseases involving the stomach.

Treatment Planning

Target Design

In the design of radiation fields for esophageal cancer, it is important to define varying target volumes, including gross disease as well as potential areas of subclinical involvement (ie, the GTVs and CTVs, respectively). Definition of GTV is based on multiple studies, including endoscopic descriptions (from both esophagogastroduodenoscopy [EGD] and EUS). The proximal and distal aspects of the tumor should be standardly defined by the gastroenterologist based on distance from the incisors, as well as relationship to varying landmarks as measured from the incisors (eg, the GE junction). The radiation oncologist is able to use these measurements to help correlate with disease extent visualized on planning CT scan, using varying anatomic landmarks (eg, the GE junction, which is frequently located ~40 cm from the incisors in many patients), as well as carina (which is frequently located at ~25 cm in most patients) to help more accurately define the GTV. Additionally, endoscopists may place radiopaque fiducial markers at the superior and inferior extent of the primary tumor to help facilitate disease extent. Esophageal wall thickening correlating to the GTV can frequently be visualized on diagnostic and radiation planning CT. Similarly, EUS appears to be the most reliable test in detecting lymphadenopathy related to nodal spread. As in EGD, the endoscopist should be encouraged to accurately define not only the primary disease extent on EUS as measured by distances from the incisors but also depth of penetration and potential involvement of adjacent structures, which can also be used to help guide GTV delineation. Similarly, EUS may detect lymph nodes that may not be easily appreciated on CT or PET imaging, and the endoscopist should describe the size as well as the location (eg, distance from incisors, relationship to adjacent

mediastinal structures) of these, further facilitating accurate definition of potentially involved lymph nodes, either adjacent to or well removed from the primary tumor itself. In addition, radiographic areas of lymphadenopathy should similarly be included in the GTV.

Although the utility of PET in esophageal cancer staging primarily lies in its ability to detect distant metastases not fully appreciated on CT imaging (and thereby alter treatment approach of these patients),[127,128] diagnostic PET-CT has more recently been integrated into radiation planning of patients with esophageal cancer and definition of GTV. Generally, gross disease as defined on PET is characterized by a SUV of more than 2 to 2.5.[129] Generally speaking, PET-avid nodes should be included within the GTV volume. In a study from Fox Chase Cancer Center, the mean GTV length as determined by PET-CT closely correlated with endoscopy findings.[74] Another study from Australian investigators reported that CT-alone-based definition of GTV excluded PET-avid disease in the majority of patients, resulting in a potential geographic miss of disease in a significant minority of patients.[130] Similarly, the fusion of CT-PET has been shown to prompt GTV and PTV modification in the majority of patients.[131] Another analysis of PET-CT-based (as compared to CT-alone) radiotherapy planning of patients with esophageal cancer indicated a reduction of intraobserver and interobserver variability in GTV delineation.[132] However, another study compared the planning of patients with CT-alone treatment followed by adjustment based on PET findings. Although PET scan influenced GTV volume in half of the patients, no locoregional recurrences were seen following CT-based radiotherapy that could have been prevented by the addition of PET.[133]

Finally, although the routine use of fluoroscopic barium swallow in esophageal cancer has decreased, this study may still be useful to the radiation oncologist for field design. A study by Chinese investigators suggested that, as compared to CT, endoscopy with barium swallow more accurately defines the true length of middle and lower esophageal tumors, although CT appeared to better determine this for tumors located at the GE junction.[134]

In summary, accurate definition of primary and nodal gross disease is paramount in radiation planning for esophageal cancer. It is important to rely on all diagnostic studies, including barium swallow (when available), EGD, EUS, CT, MRI, as well as PET scan.

The identification of potential direct and nodal pathways for spread of subclinical disease (ie, CTV definition) in esophageal cancer is also of paramount importance. These areas vary significantly, depending on the site of origin of disease, making esophageal cancer planning somewhat complex. In terms of direct disease extension along the esophagus itself, varying reports have assessed the histologic findings at primary esophagectomy to determine subclinical extent of disease. One prospective analysis of 66 resection specimens showed that placement of a 3-cm margin proximally and distally on the primary tumor would cover microscopic disease extension in 94% of squamous cell carcinomas. Similarly, in GE junctional carcinomas, a 3-cm proximal

margin included subclinical disease extension in 100% of patients and 5 cm distally covered 94% of subclinical spread.[135]

As described previously, the esophagus is characterized by a rich submucosal network of lymphatics that facilitates early lymph nodal spread of disease, even for superficial esophageal cancers. The appropriate cranial and caudal margins remain a matter of debate in the treatment of esophageal cancer. Historically, very large fields were treated, encompassing potential pathways and lymphatic spread from the thoracic inlet down to the celiac axis region; however, such fields are potentially fraught with treatment-related toxicity and may be difficult for patients to tolerate, particularly in the context of concurrent chemotherapy delivery. Most contemporary radiation trials used margins of 3 to 5 cm cranially and caudally on the GTV, along with an approximate 2-cm radial margin. With disease located at or above the carina (or middle/upper one-third of the esophagus in some instances), many of these trials recommended fields inclusive of the supraclavicular lymph node basins, whereas celiac axis nodal basin coverage was recommended for disease of the distal esophagus.[135] However, the appropriate field size for patients with esophageal cancer remains controversial, particularly the role of elective nodal irradiation.

Even the concept of what constitutes "involved field" and "extended field" can vary between series. Comparative series have yielded conflicting results to this effect, although recent reviews have suggested that elective nodal irradiation appears to prevent or delay regional nodal relapse. However, its impact on survival in these patients remains less clear, with a higher incidence of esophageal and lung toxicities in the latter.[136] Analysis of a randomized trial from China of patients with squamous cell carcinoma treated with definitive chemoradiation with either paclitaxel plus 5-FU or cisplatin with 5-FU utilized an involved field–alone approach. Elective nodal failure (defined as failure in an unirradiated area not seen pretreatment) as well as "extensive" nodal region (described as anywhere from the bilateral upper neck down through the celiac region) was seen in 8.5% and 11.6% of patients, respectively. The authors concluded that an involved field can achieve low rates of isolated nodal failure and satisfactory survival outcomes and elective nodal irradiation may be unnecessary.[137] This remains a topic of ongoing study and randomized studies are needed. Further description of lymph node basin coverage follows.

Field Design

Historically, the treatment of very proximal (cervical) esophageal cancers has been challenging. Because of the changing contour from the neck to the thoracic inlet, treatment of lesions in the upper one-third of the esophagus may present a difficult technical problem. Lesions in the upper cervical or postcricoid esophagus are often treated from the laryngopharynx to the carina, depending on extent of disease. Supraclavicular and superior mediastinal nodes are irradiated electively. Using older/conventional methods, this was achieved with lateral parallel opposed or oblique

portals to the primary tumor and a single anterior field for the supraclavicular and superior mediastinal nodes.[114] Another historical technique treated lesions in this region by means of a four-field box approach, using a wax bolus to build up the lack of tissue above the shoulders, acting as a compensator. A high-energy beam (.15 MV) is used, and both sides of the neck are treated prophylactically. Other methods of treating lesions at the thoracic inlet include 140-degree arc rotations, anterior wedged pairs, and three- or four-field techniques using posterior oblique portals combined with a single anterior portal or anteroposterior-posteroanterior (AP/PA) fields.[114] Using three-dimensional (3D) approaches, varying techniques have been implemented, including treatment of the primary tumor and lymph nodes using an AP/PA approach to 39.6 to 41.4 Gy at 1.8 Gy/fraction, followed by a left or right opposed oblique pair to bring the total dose to 50.4 Gy, thereby limiting the spinal cord dose. This technique will generally exclude the supraclavicular fossa, and a separate electron field is often added, treating to a depth of 2 to 3 cm, depending upon individual anatomy. In modern field design, intensity-modulated radiation therapy (IMRT)–based planning has facilitated the treatment of upper esophageal lesions and is our preferred method for treating these tumors (Figure 59.13). Strict normal-tissue constraints, including normal lung and spinal cord, are important considerations in using these techniques (discussed later).

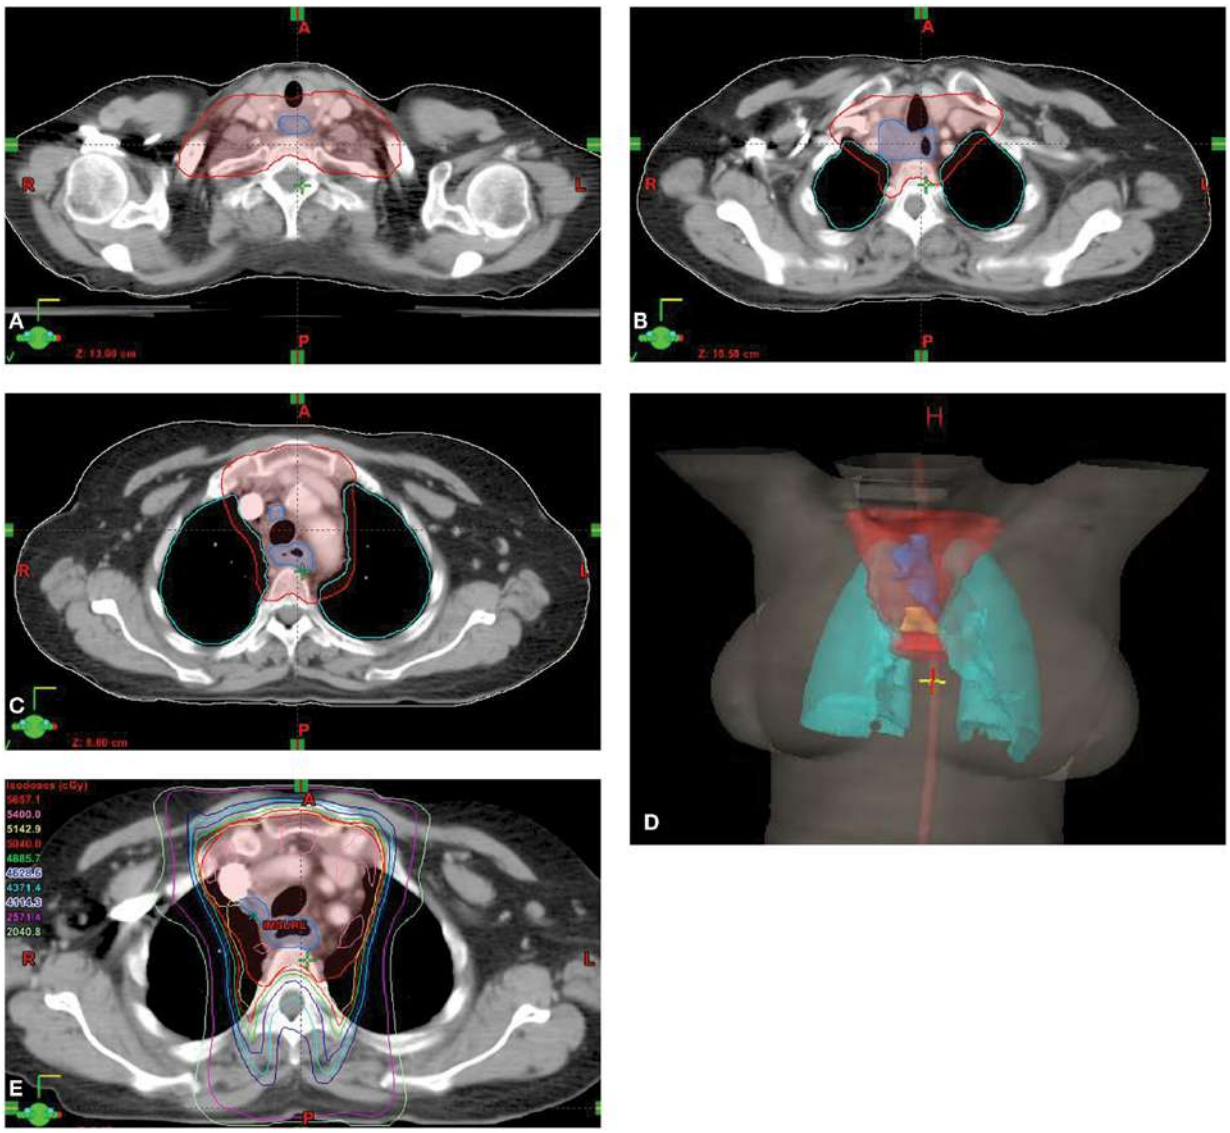

FIGURE 59.13 A-C. Examples of planning target volume (PTV) in a 62-year-old woman with a cT3 N1 squamous cell carcinoma of cervical esophagus. Gross tumor volume (GTV), blue volume; PTV, red volume. D. Three-dimensional reconstruction of PTV from above the patient. Carina, yellow; GTV, dark blue; lungs, light blue; PTV, red; spinal cord, brown. E. Isodose curves of this patient treated with a nine-field intensity-modulated radiation therapy plan. Note that beams are primarily anteriorly oriented. (Courtesy of Rodney Hood, CMD.)

Based on the previously described and other pathologic patterns of spread data in squamous cell carcinoma of the esophagus, general guidelines in terms of field design can be made as follows: for cervical and upper thoracic squamous cell carcinoma, the CTV should generally include nodal basins extending from the lower cervical and supraclavicular region superiorly to the subcarinal lymph node basin inferiorly, inclusive of the upper paraesophageal lymph nodes (Figure 59.14A). For lower esophageal squamous cell carcinomas, lymph node basins from the subcarinal region superiorly to the left gastric and common hepatic artery/celiac lymph nodal basins

inferiorly should generally be included (described further later in this chapter). In a small series of patients without celiac radiation coverage, six (10%) had celiac nodal failure, portending a worse prognosis. The authors concluded that although overt celiac failure only occurred in 1 of 10 patients, the lack of effective salvage in treatments may justify treatment of this basin in patients with distal esophageal cancer.[138] For tumors of the middle esophagus, we recommend individual field design according to clinical scenarios, with a more complete coverage of paraesophageal mediastinal lymph nodes, particularly in patients with a good performance status (Figure 59.14B,C).[48] These are general guidelines, and all plans should be individualized based on available imaging and endoscopic findings.

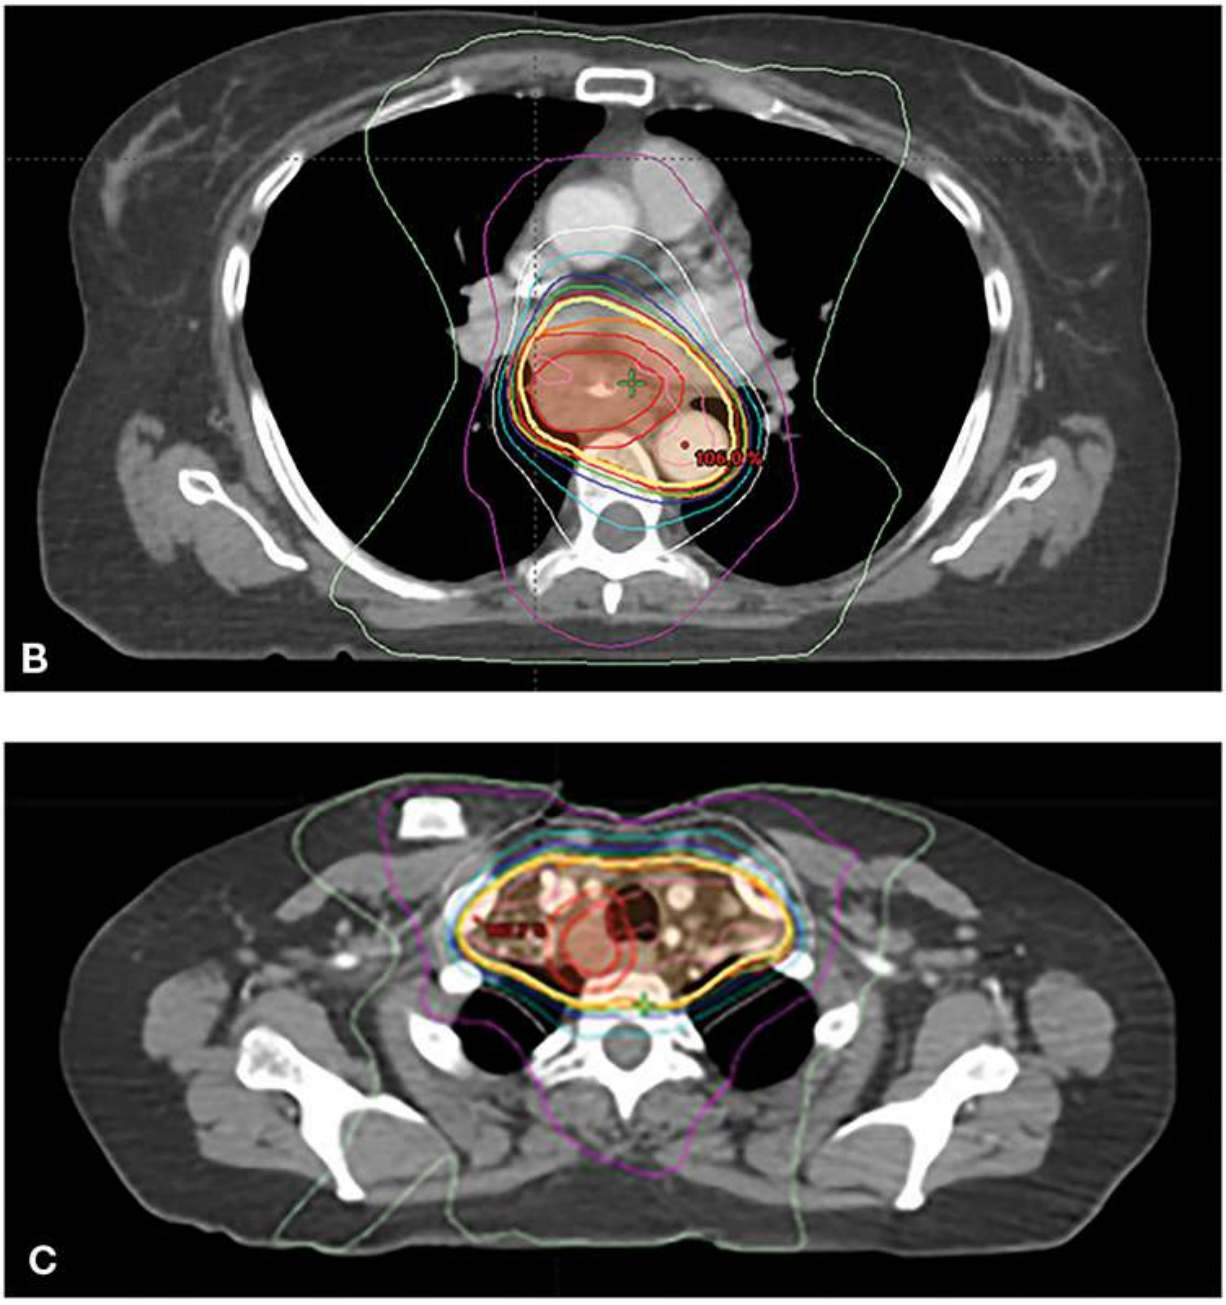

FIGURE 59.14 A. Example field for a midesophageal squamous cell carcinoma. Note that the field is inclusive of adjacent mediastinal/paraesophageal nodes, with approximately 5-cm margin superiorly on the gross tumor volume (GTV), as well as slightly larger margin on the inferior aspect of the GTV based on concern of previously unappreciated spread at the time of endoscopy. B. This 56-year-old woman had a midesophageal squamous cell carcinoma with upper mediastinal involvement. Using a simultaneous integrated boost (SIB) technique (low-dose planning target volume in orange, 45 Gy in 25 fractions; higher dose planning target volume red, with central GTV in red, 50 Gy/25 fractions). C. Upper mediastinal nodal involvement is seen utilizing SIB technique.

In field design, potential nodal involvement (and therefore target volumes) based on nodal size is problematic, given that some reports demonstrated that less than 15% of

metastatic nodes are more than 1 cm and that average size differences between involved and uninvolved nodes are frequently not significantly different.[139] In addition, fluorodeoxyglucose-PET scanning has an estimated sensitivity of only 67% of detecting nodal metastases.[9] Even endoscopic ultrasound, generally considered the most sensitive test for detecting lymph node metastases, is only able to detect such disease in approximately 75% of patients.[140] Therefore, it is not appropriate to rely exclusively on varying imaging modalities to define areas of subclinical spread for esophageal cancer, realizing that patterns-of-spread data are important in determining radiation field design.

The design of radiation fields for the treatment of adenocarcinoma of the esophagus is similar to that of lower thoracic squamous cell carcinomas but deserves special mention. Periesophageal lymph nodes are generally included in all patients. Given that lymph node involvement is clearly associated with depth of tumor penetration (T stage) and the fact that most patients in the United States and Europe presenting with GE junctional carcinoma will have more advanced disease, inclusion of celiac lymph basins for adenocarcinoma of the distal esophagus/GE junction is usually indicated, although it remains an area of controversy. Based on the previously described patterns of spread data from Erlangen and others, specific considerations include the following: Lymph vascular invasion is highly predictive of nodal spread. Proximal extension of tumors (particularly beyond the Z line into the distal esophagus for type II and III tumors) predicts an increasing incidence of paraesophageal lymph node involvement. Based on an estimated nodal incidence cutoff of 20% for inclusion, specific considerations include the following:

- The lower paraesophageal, paracardial, lesser curvature, and left gastric artery nodes should be included in the CTV.
- The presence of lymph vascular invasion predicts a nodal positivity rate of more than 20% in the left and right gastroepiploic, greater curvature, celiac trunk, and splenic hilar regions.
- In T3 to T4 disease, the gastroepiploic, greater curvature, celiac trunk, splenic hilar, splenic artery, and common hepatic artery should be included.
- High-grade tumors should also include the left gastroepiploic, greater curvature, and celiac trunk nodes in CT design.
- Larger and more deeply penetrating tumors should also include the splenic artery and splenic hilar nodes, as well as those along the greater curvature.
- Tumors extending above the diaphragm and those extending more than 1.5 cm beyond the Z line should include the mid paraesophageal nodes, potentially treating up to the carina. Of note, significant involvement of the distal esophagus by GE junctional tumors (.1.5 cm beyond the Z line) should potentially lead to inclusion of not only lower but also middle paraesophageal nodes based on patterns of spread.

However, treating these more extensive fields must be weighed against potential side effects of increased irradiation of normal tissue.

In summary, middle and lower paraesophageal nodes should be included in patients with T2 to T4 type I and T2 to T4 type II tumors extending more than 1.5 cm above the Z line and patients with T3 to T4 type II tumors. The splenic hilar and artery nodes are considered "sparable" in T2 tumors, notably type I.[54]

Although, historically, two-dimensional-based radiation planning has been carried out primarily using anatomic landmarks such as bone and carina, as well as fluoroscopic barium swallow, to determine field borders, contemporary treatment using CT-based planning allows improved visualization of both target and nontarget structures, along with 3D reconstruction and creation of a "beam's-eye" view of varying fields, allowing improved conformity around target structures and improvements in normal-tissue sparing. Because volumetric data can be obtained by CT scans, dose-volume histogram data can also be generated. A variety of 3D techniques are being used and are described later.

Potential beam orientations for the treatment of thoracic esophageal and GE junction tumors (again defined as tumors involving the GE junction with an epicenter within 5 cm proximal or distal to the GE junction) include an initial AP/PA approach followed by AP/right posterior oblique (RPO)/left posterior oblique (LPO) fields with or without boost, an initial AP/PA approach followed by right anterior oblique (RAO)/LPO fields with or without boost, and a three-field technique (AP/PA with left lateral or oblique field). One potential approach in lesions of the thoracic esophagus or GE junction is to use initial AP/PA/RAO/LPO fields, with boost fields using laterally oriented beams. The inferior margin of the initial fields includes the GE junction and, for lower or middle one-third lesions, the celiac axis nodal basins (generally located at the level of T12 and identifiable on CT), as well as gastrohepatic ligament. Initial fields are often treated to a dose of 45 Gy, taking care to avoid as much of the heart as reasonably possible while continuing to minimize the kidney volume in the radiation field, inclusive of the above nodal basins. Reduced fields encompassing gross disease with an approximate 2-cm margin through oblique or lateral fields may then be used for an additional 5.4 Gy. Doses usually do not exceed 50 Gy, and lower doses (eg, 41.4 Gy) may be appropriate (discussed later).

A margin of 5 cm above and below the GTV is generally recommended to cover subclinical submucosal/nodal disease, as well as an approximate 2.0- to 2.5-cm radial margin, although individual margins are case dependent. Because it is imperative to account for daily setup uncertainty as well as physiologic internal organ motion (secondary to respiration, peristalsis, cardiac motion, etc), additional margin must be added to a CTV, particularly to the more mobile distal esophagus. The internal target volume (ITV) has been used to account for physiologic motion of the target volume, which is included in the PTV. Varying reports analyzing esophageal motion have shown average anterior and posterior motion ranges from 0.1 to 4 mm, lateral motion from 0.3

to 4.2 mm, and superior-to-inferior motion from 3.7 to 10 mm.[142] An analysis evaluating interfraction esophageal motion in the right-left and AP direction showed average right-left motion of 1.8 ± 5.1 mm (favoring leftward movement) and average AP motion of 0.6 ± 4.8 mm (favoring posterior movement), with an average absolute motion of 4.2 mm or less in the right-left and AP directions. The authors concluded that 12-mm left, 10-mm posterior, and 9-mm anterior margins are appropriate.[141] Some authors have recommended defining 1-cm radial, 1.5-cm distal, and 1-cm proximal margins from CTV to ITV if target motion data are not available. Image-guided radiation therapy, including cone beam CT, may also be useful in localizing tumor and establishing physiologic variability between daily treatments.

Figures 59.15 and 59.16 show general recommendations for elective target nodal station coverage in a patient with a type I GE junctional tumor with accompanying example field/volumes. Figure 59.17 shows general recommendations for elective target nodal station coverage in a patient with a type II GE junctional tumor. Nodal basins are similar to type I tumors with the exception of inclusion of nodal basins along the splenic artery course. Figures 59.18 and 59.19 show general recommendations for elective target nodal station coverage in a patient with a type III GE junctional tumor with accompanying example fields. Note that in type III tumors, there is less emphasis on more proximal (lower mediastinal) nodes and more comprehensive coverage of the splenic artery course, including splenic hilum. Figure 59.20 shows examples of varying nodal locations on axial CT images.

Another potential treatment planning approach for thoracic esophageal cancer is the use of IMRT. IMRT also uses CT-based planning, again allowing 3D reconstruction of varying structures. However, IMRT differs from 3D planning through the delivery of radiation dose by partitioning a radiation field into multiple smaller fields of varying shapes and sizes, varying the dose intensity between each area. This is carried out with either dynamic IMRT (in which collimating leaves move in and out of the radiation beam path during treatment) or "step-and-shoot" IMRT (in which the leaves change the radiation field shape while the beam is turned off). Either method is particularly effective at conforming radiation dose to the target structures while avoiding dose to normal tissue. Radiation oncologists must determine which structures are most critical and weigh their importance during the treatment planning process. Of importance, the greater the number of "avoidance" normal structures, the more difficult it is to meet all dose constraints. IMRT uses "inverse planning," in which an intended prescription dose is placed on target volumes and dose constraints are placed on normal-tissue structures. Thereafter, computer software algorithms allow design of unconventional treatment fields that would not otherwise be possible with standard planning methods. Radiation oncologists and medical physicists critically evaluate numerous plans until dose constraints are satisfactorily met. The result should be a series of radiation doses that closely conform to the target volumes while minimizing dose to normal tissues. Similarly, volumetric arc therapy (VMAT) also utilizes IMRT delivery, while the gantry is actively rotating during treatment. Dosimetric comparisons of IMRT versus 3D conformal therapy in cervical esophageal cancer have demonstrated superior target volume coverage and conformality with decreased normal-tissue dose.[142] A potential disadvantage of IMRT is the possibility of delivering low doses of radiation therapy to normal-tissue areas that might not normally be irradiated using 2D or 3D techniques. The influence of this on toxicity (eg, low-dose pulmonary irradiation and development of postoperative pulmonary complications, circulating lymphocytes) remains uncertain. Another potential disadvantage of IMRT is possible dose inhomogeneity, leading to potential hot spots in normal organs. Because IMRT requires precise target definition, the potential for marginal miss increases and careful target delineation is of paramount importance. With setup uncertainty, physiologic organ motion must be considered to ensure accurate and reproducible setup, including the use of immobilization devices, possible respiratory gating/breath-hold techniques, etc. Generally, high-energy photons

(4-18 MV) are recommended when using 3D conformal or IMRT therapy, potentially facilitating a reduction of the integral lung dose.

Another approach to treating esophageal cancer is utilization of proton therapy, which is a particle-based therapy that utilizes the unique nature of protons to distribute their energy over a relatively limited range (so-called Bragg peak), thereby further sparing adjacent normal organs. A multi-institutional experience of 580 patients treated across three academic centers compared patients receiving 3D versus IMRT and proton beam therapy. Advanced treatment technologies (IMRT and proton beam) were associated with significantly reduced rates of postoperative complications and length of stay. The authors indicated prospective randomized data will be needed to validate these results.[143] A phase IIB trial by Lin et al randomized 107 patients with esophageal cancer to receive proton beam radiation therapy (n = 46) versus IMRT (n = 61) to a dose of 51.4 Gy in 28 fractions. The primary end point, defined as total toxicity burden, was found to be 2.3 times higher for IMRT versus proton beam therapy, and postoperative complication rate 7.6 times higher for IMRT versus proton beam radiation therapy, although 3-year progression-free survival (51%) and overall survival (45%) rates were similar for both arms. The authors concluded that proton beam therapy reduced the risk and severity of adverse effects compared with IMRT while maintaining similar disease-related outcomes.[144] Long-term toxicity and efficacy outcomes of proton beam versus IMRT are being evaluated in the ongoing NRG-GI006 phase III randomized trial. Additionally, in a registry-based study of patients older than 65 years comparing 3D versus IMRT treatment, IMRT was not associated with esophageal cancer–specific mortality or pulmonary mortality, but was with improved all-cause mortality, including cardiac and other cause mortality.[145] Similarly, in an analysis of the Radiation Therapy Oncology Group (RTOG) 0617 trial randomizing patients with non–small cell lung cancer to receive concurrent carboplatin and paclitaxel with or without cetuximab with a second randomization to 60 versus 74 Gy, no benefit was seen in terms of radiation dose escalation. On secondary analysis, however, IMRT was associated with less grade 3 or more pneumonitis (7.9% vs 3.5%; P = .039), lower heart doses (P < .05), and lower heart V_{40} doses, with the heart V_{40} significantly associated with overall survival (P < .05). Additionally, the lung V_{20} dose was also associated with increased grade 3 or more pneumonitis risk on multivariable analysis (P = .026), with the authors concluding IMRT was associated with lower rates of severe pneumonitis and cardiac doses.[146,147]

An expert panel has published contouring guidelines for esophageal and GE junction CTV volumes for IMRT planning. Examples of consensus CTV are illustrated in Figure 59.21. Delineation of the proximal border of the CTV was described as 3 to 4 cm above the proximal edge of the GTV, or 1 cm above any grossly involved periesophageal nodes, oriented along the esophageal mucosa and not a simple geometric expansion. For proximal tumors, the upper border was not extended beyond the level of the cricoid cartilage unless disease presence precludes such. For proximal or midesophageal tumors, the distal border for CTV creation was described as 3 to 4 cm below the

proximal edge of the GTV, again oriented along the esophagus. For lower tumors, what is described as at least a 2-cm margin along clinically involved gastric mucosa was recommended if treating definitively, or if treating to lower, preoperative-intent doses (≤45 Gy), a 4-cm or greater gastric margin was felt appropriate, particularly with significant gastric extension. CTV radial margin was described as at least 1 cm in all directions on GTV, with a 1-cm radial margin from the outer esophageal wall to encompass periesophageal lymph nodes, with a limit of 5 mm into cardiac tissue, including the pericardium. For more distal tumors involving or approaching the GE junction, the CTV was described as being extended inferiorly to the level of the celiac axis origin, bounded by the lateral aspect of the vertebral body on the right and 0.5 to 1 cm beyond the lateral aspect of the aorta on the left, vertebral body posteriorly and pancreatic body anteriorly. Periaortic and gastrohepatic (sometimes classified as lesser curve or left gastric) lymph nodes were deemed appropriate for inclusion. Examples of CTVs are shown in Figures 59.22 to 59.24. Inclusion of some or all nodes in the splenic hilum and greater curvature region was felt potentially appropriate for Siewert type II GE junction tumors depending on clinical and pathologic features. For tumors above the level of the carina, inclusion of the bilateral supraclavicular nodal basins was recommended. PTV delineation was created by adding 0.5 to 1 cm to the CTV in all directions (which is essentially equivalent to the traditional practice of placing the field border 5 cm above and below the GTV).[148]

Dose Constraints

In radiation therapy planning of esophageal cancer, normal-tissue tolerance should always be considered. The spinal cord dose is generally limited to 45 Gy using 1.8-Gy fractions (and potentially less when delivered with novel systemic agents). Efforts to minimize radiation to the heart (in particular the left ventricle in lower esophageal/GE junction lesions) should be made. Adopting an off-heart approach using oblique orientations (including right anterior and left posterior, described earlier) is one potential way of achieving this, although multiple approaches exist, including IMRT-based techniques. Similarly, efforts to minimize dose to normal pulmonary tissues should be made, based on data suggesting that the volume of irradiated lung may correspond to postoperative complications and worsened pulmonary function (described later). Advanced radiation techniques including IMRT are frequently utilized.

Accurate delineation of adjacent organs, including the lungs, liver, kidneys, heart, and spinal cord, is important. Varying dose-volume normal-organ constraints have been suggested, including achieving a lung V_{20} of less than 20%, limiting more than 2,300 cm^3 of normal lung tissue to less than 5 Gy, and using mean lung dose of less than 18 Gy. Similarly, a V_{10} of 60% or less has been proposed to reduce the incidence of postoperative pulmonary complications. Historically, heart dose constraints have included maintaining one-third, two-thirds, and total heart volumes of less than 45, 40, and 30 Gy, respectively. Recommended heart constraints include keeping less than 30% of the cardiac volume to a total dose of 40 Gy and less than 50% receiving 25 Gy, minimizing dose to the left ventricle, although with careful and advanced treatment planning, significant improvement upon these constraints can often be achieved. In the setting of potentially significant volumes of the heart in the radiation field, consideration of respiratory gating and/or breath-hold techniques can be made. For lower esophageal and GE cancers, it is recommended that at least 70% of one physiologically functioning kidney receive a total dose of less than 20 Gy and that, collectively, no more than 50% of the combined functional renal volume should receive more than 20 Gy.[53] One should also consider the possibility of impaired kidney function in the context of varying comorbidities, using nuclear medicine renal studies to assess individual renal function in such situations or where significant volumes of kidneys are anticipated to be within the radiation field. Generally, 70% of the liver parenchyma should be kept to a dose of less than 30 Gy. Many of these constraints can be achieved with 3D planning with appropriate and careful design of shielding blocks/multileaf collimation and dose-volume histogram analysis, as well as potential improvement in these parameters with the use of IMRT. Examples of normal tissue constraints for esophageal cancer planning are listed in Table 59.5.

TABLE 59.5 INTERNATIONAL CONSENSUS OF CLASSIFICATION OF BR PDAC BASED ON ANATOMICAL DEFINITION USING CT IMAGINGS INCLUDING CORONAL AND SAGITTAL SECTIONS

Resectable: R	• SMV/PV: no tumor contact or unilateral narrowing

	• SMA, CA, CHA: no tumor contact
Borderline resectable: BR	Subclassified according to SMV/PV involvement alone or arterial invasion
BR-PV (SMV/PV involvement alone)	• SMV/PV: tumor contact 180° or greater or bilateral narrowing/occlusion, not exceeding the inferior border of the duodenum. • SMA, CA, CHA: no tumor contact/invasion
BR-A (arterial involvement)	• SMA, CA: tumor contact of less than 180° without showing deformity/stenosis • CHA: tumor contact without showing tumor contact of the PHA and/or CA (The involvement of the aorta is categorized as unresectable. Presence of variant arterial anatomy is not taken into consideration.)
Unresectable: UR	Subclassified according to the status of distant metastasis
Locally advanced: LA	• SMV/PV: bilateral narrowing/occlusion, exceeding the inferior border of the duodenum • SMA, CA: tumor contact/invasion of 180 or more degree[a] • CHA: tumor contact/invasion showing tumor contact/invasion of the PHA and/or CA • AO: tumor contact or invasion
Metastatic: M	Distant metastasis[b]

CA, celiac artery; CHA, common hepatic artery; PHA, proper hepatic artery; PV, portal vein; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

[a]In the cases with CA invasion of 180° or more without involvement of the aorta and with intact and uninvolved gastroduodenal artery thereby permitting a distal pancreatectomy with en bloc celiac axis resection (DP-CAR), some members prefer these criteria to be in the BR-A category.

[b]Including macroscopic para-aortic and extra-abdominal lymph node metastasis.

Doses of Radiation

Because locoregional failure is common after conventional chemoradiation, investigators have evaluated dose escalation techniques. Varying series using doses beyond 50 Gy have shown local control rates ranging from approximately 77% to 88%.[148,149] However, Minsky et al[66,150] reported the results of a randomized trial in which 236 patients with clinical stage T1 to T4, N0/1, M0 squamous cell, or adenocarcinoma of the esophagus were selected for nonsurgical therapy. Patients were randomized to receive 64.8 versus 50.4 Gy, both with concurrent 5-FU and cisplatin chemotherapy. Patients with cervical, mid, or distal esophageal cancer were eligible, with the exception of those with tumors within 2 cm of the GE junction, with approximately 85% of patients with squamous cell histology. This study was closed after interim analysis showed no probability of superiority in the high-dose arm. No significant difference in median survival (13 vs 18.1 months), 2-year survival (31% vs 40%), or locoregional failure/persistence of disease (56% vs 52%) was seen between the high-dose and standard-dose arms. Eleven treatment-related deaths occurred in the high-dose arm

compared with 2 in the standard-dose arm, with 7 of the 11 high-dose arm deaths occurring in patients who received 50.4 Gy or less. The authors performed a separate survival analysis including only patients receiving the assigned radiation dose. Despite this, no survival advantage was noted in the high-dose arm. These authors concluded that higher radiation doses did not increase survival or locoregional control and that the standard radiation dose for patients treated with concurrent 5-FU and cisplatin chemotherapy is 50.4 Gy. Based on these data, standard dose of radiation therapy for esophageal cancer is usually 50 to 50.4 Gy at 1.8 to 2 Gy per fraction, including delivery of similar doses in the definitive, adjuvant (45-50 Gy), or neoadjuvant (41.4-50 Gy) settings. Nonetheless, critics of this trial argue that older radiation techniques were used and that dose escalation should be evaluated using modern techniques. In addition to the above, the Dutch ART-DECO phase III trial randomized 260 patients with T2 to T4, N0 to N3 inoperable esophageal cancer to receive either 50.4 Gy in 28 fractions or dose-escalated 61.6 Gy in 28 fractions using a simultaneous integrated boost technique, both with weekly carboplatin and paclitaxel delivery. At a median follow-up of 50 months, 3-year overall survival was 42% versus 39% (P = .22) with no difference in 3-year local progression presurvival (52% vs 59%; P = .08), including when stratified by histology. Grade 4 and higher toxicity rates were similar between the two groups (17% vs 24%; P = .15).[151] Similarly, the French CONCORDE randomized phase III trial enrolled 160 patients with inoperable esophageal cancer to receive 40 Gy elective nodal irradiation followed by a 10 Gy boost versus dose-escalated 26 Gy boost, using IMRT/VMAT techniques, with concurrent FOLFOX-4 chemotherapy for three cycles followed by three cycles of adjuvant chemotherapy. Preliminary results at a median follow-up of 35.3 months showed no difference in overall (median 25.2 vs 23.5 months; P = .4) or local progression-free survival (median 16.2 vs 18.4 months; P = .88) or difference in grade 3 or higher toxicity (29.5% vs 29.3%).[153] Another trial from China randomized 319 patients with squamous cell carcinoma to receive conventional fractionated 60 vs 50 Gy to the tumor and regional lymph nodes. Concurrent weekly docetaxel and cisplatin were utilized, with two cycles of consolidation chemotherapy. The 60 Gy arm had similar survival outcomes but a higher severe pneumonitis rate compared with the 50 Gy arm. The authors concluded 50 Gy should be considered as the recommended dose in combined-modality therapy (CMT) for patients with squamous cell carcinoma.[152] The UK SCOPE-2 study is a four-arm trial comparing carboplatin/paclitaxel versus cisplatin-/capecitabine-based chemoradiation, with a second randomization to standard versus high-dose radiation therapy (50 vs 60 Gy, both in 25 fractions). Patients will receive a lead-in of chemotherapy and then be further randomized based on intratreatment PET analyses. Finally, a Chinese study is comparing a regimen of 50 Gy in 25 fractions with concurrent cisplatin and 5-FU (CF) versus a simultaneous integrated boost treatment to a total of 66 Gy in 30 fractions with concurrent CF in patients with nonoperable squamous cell carcinoma.

Brachytherapy

In addition to external beam radiation therapy (EBRT), intracavitary therapy can be used with curative or palliative intent. Brachytherapy has also been used as a dose escalation tool in addition to EBRT. The advantage of brachytherapy centers on exploitation of the inverse-square law and quick dose falloff, thus sparing surrounding tissues from radiation while providing focal dose escalation. The radioactive source of choice is usually 192Ir. High-dose-rate (HDR) techniques can deliver 100 to 400 Gy/hour, allowing treatment to be given in 5 to 10 minutes.

With brachytherapy, an afterloading catheter is introduced through the nose into the esophagus to the primary tumor site under fluoroscopic guidance. This is often performed with the patient on the simulation table. Contrast may be used to define the tumor site. CT scan can also be used to discern tumor location. After localization films are taken and dosimetry is generated, the catheter is then attached to a remote afterloader through a guide cable and the 192Ir source inserted through remote control. Doses of 5 to 20 Gy are usually delivered to a depth of 1 cm from the center of the catheter. Dose can be shaped and modified through the use of dwell times.

RESULTS OF THERAPY

The best survival results have been reported in patients who have esophageal tumors that are truly localized. Survival rates range from 25% to more than 35% at 5 years, and these results have been attained using an array of treatment approaches. Problems arise in comparisons of various modalities, however, because of patient selection factors. A historical review of the Princess Margaret Hospital data[154] supported the concept that extent of tumor, rather than therapy, is the most important factor influencing survival. They found a significant correlation between T stage and response to treatment: T1 lesions showed a 100% response rate, whereas T2 and T3 lesions had response rates of 68% and 58%, respectively. Not unexpectedly, they also found differences in survival according to T stage, M stage, and overall stage. Almost 20% of patients with stage I disease were alive at 3.5 years, whereas only 11% of patients with stage II disease were alive after the same interval, and all patients with stage III disease died by approximately 1.5 years following therapy.

Surgery Alone

Surgery remains a benchmark to which other modalities are compared. Surgery removes the tumor, a length of normal esophagus, and lymph nodes. Although multiple techniques exist for the resection of esophageal cancer, no one surgical approach has clearly been shown to be superior with regard to complications or outcomes. Proponents of more extended resection (including transthoracic approaches) have advocated that such procedures result in a superior nodal clearance and therefore offer a more complete "oncologic" resection. A trial from the Netherlands randomized 220 patients with

esophageal adenocarcinoma to transhiatal esophagectomy alone or transthoracic esophagectomy with extended lymph node dissection. Patients undergoing transhiatal resection experienced significantly fewer pulmonary complications and chylous leaks, as well as significantly reduced ventilator dependence and intensive care unit and hospital stays. At a median 4.7-year follow-up, no significant difference in locoregional recurrence was seen between the two groups (32% transhiatal vs 31% transthoracic). Furthermore, no significant differences were seen in median disease-free survival (1.4 vs 1.7 years; $P = .15$) or median overall survival (1.8 vs 2.0 years; $P = .38$). However, there did appear to be a nonsignificant trend favoring the transthoracic approach in improved disease-free survival (5 years, 27% vs 39%) and overall survival (5 years, 29% vs 39%). The authors concluded that a transhiatal approach was associated with less morbidity relative to transthoracic surgery, with no apparent survival advantage with either technique, although a trend toward improved survival with a transthoracic approach was seen with longer follow-up.[56] Updated 5-year survival results were 34% versus 36%, respectively.[155] In contrast, a randomized trial from Japan comparing transhiatal to left thoracoabdominal approaches in patients with esophagogastric junction cancers demonstrated different outcomes. Both groups underwent total gastrectomy and splenectomy with extensive nodal dissection. Ten-year survival was 37% for the transhiatal approach versus 24% for the thoracoabdominal approach ($P = .06$). The authors concluded left thoracoabdominal resection should be avoided in patients with esophagogastric junction or gastric cardia tumors.[156]

In summary, none of the surgical approaches to localized esophageal cancer has clearly been shown to be superior with regard to complications or outcomes, and no one standard surgical approach exists for esophageal cancer resection.

After resection alone, however, locoregional relapse is a common mode of failure. Contemporary randomized trials with surgery-alone arms have reported locoregional failure rates of 32% to 45%.[56,57,115,156] It should be remembered that patterns of failure reports often describe the first site of failure only and may include only patients undergoing R_0 resection, potentially underreporting the true incidence of locoregional recurrence. These and other data suggest that even with modern surgical techniques, locoregional persistence of disease after resection remains a major problem. Prospective, randomized trials using surgery alone in the treatment of esophageal cancer have reported 3-year survival rates ranging from 6% to 48%, with more favorable rates likely reflecting inclusion of patients with earlier-stage disease[58,157-160] (Table 59.6). Given these high rates of relapse and poor long-term survival, the integration of adjuvant or neoadjuvant chemoradiation approaches into the treatment of esophageal cancer is rational and indicated.

Radiation Therapy Alone

A trial from China randomized 269 patients to either surgery alone or radiation therapy alone. Surgery entailed esophagectomy while radiation field varied by location of the primary tumor. Patients received 50 to 50.4 Gy of daily treatment, followed by reduced fields receiving 1.5 Gy BID to a cumulative dose of 68.4 to 71 Gy. The 1-, 3-, and 5-year overall survival rates in the surgery-alone group were 93%, 62%, and 37% versus 89%, 56%, and 35%, respectively. The authors concluded survival might be equivalent between these arms.[163] However, in most series, radiation therapy alone has been usually delivered when lesions are deemed inoperable because of tumor extent or medical contraindications and/or palliative treatment is indicated. Patients receiving radiation as a sole treatment modality have a median survival of 6 to 12 months and 5-year survival of less than 10%.

A historical review analyzing 49 series involving more than 8,400 patients treated primarily with radiation therapy alone found overall survival rates at 1, 2, and 5 years to be 18%, 8%, and 6%, respectively.[164] Hancock and Glatstein[124] reviewed 9,511 patients and found only 5.8% were alive at 5 years. Okawa et al[165] reported 5-year survival rates by stage. For patients with stage I disease, the 5-year survival rate was 20%; stage II, 10%; stage III, 3%; and stage IV, 0%. Overall, the 5-year survival rate was 9%. For cervical esophageal lesions treated with radiation alone, the cure rates were comparable with those in patients treated with surgery alone. Lederman[166] treated 263 patients with radiation therapy alone and reported 3- and 5-year survival rates of 11% and 7%, respectively. In a more contemporary series, an Intergroup randomized study (discussed later) comparing combined chemotherapy with 5-FU and cisplatin with radiotherapy (50 Gy) versus radiotherapy only (64 Gy) showed that 3-year actuarial survival with

radiotherapy alone was 0%. These and other data suggest that treatment with radiation therapy alone for patients with esophageal cancer is palliative in most patients.

Preoperative Radiation Therapy

The use of preoperative radiation therapy has potential biologic and physical advantages, including increased resectability of tumors, increased tumor radioresponsiveness secondary to improved tumor oxygenation, a theoretical decreased likelihood of dissemination at the time of surgery, and avoidance of surgery in patients with rapidly progressive disease.

There are multiple, largely historical randomized studies comparing preoperative irradiation followed by surgery with surgery alone. These studies demonstrate no clinical benefit to the use of preoperative radiation therapy alone (Table 59.7). Launois et al[167] reported delivering 40 Gy over 8 to 12 days with surgery 8 days later versus surgery alone. Resection rates were similar—70% and 58% for preoperative irradiation and for surgery alone, respectively. The 5-year survival rate after resection was 11.5% for those treated with surgery alone, compared with 9.5% for those treated with irradiation and surgery. The second randomized study, published by the European Organisation for Research and Treatment of Cancer (EORTC), used 33 Gy over 12 days.[168] There was no significant difference in survival between those receiving preoperative irradiation and those receiving surgery alone. Arnott et al[169] reported on 176 patients, 86 of whom were treated with esophagectomy alone versus 90 who were treated with preoperative radiation therapy. Preoperative radiation therapy was delivered with 4-MV photons using opposed fields, delivering 20 Gy at 2 Gy/fraction. Resectability and local failure were not reported. Patients receiving low-dose radiation therapy did not demonstrate a benefit in 5-year overall survival rates (17% vs 9% for surgery and preoperative radiation, respectively; $P = .4$). Wang et al[170] randomized 206 patients to surgery alone versus 40 Gy in 2-Gy fractions delivered preoperatively. No significant survival advantage was seen for patients receiving radiation therapy (35% vs 30%; $P > .05$).

[a]Both squamous and adenocarcinoma.

A meta-analysis from the Oesophageal Cancer Collaborative Group updated data from five randomized trials of more than 1,100 patients comparing preoperative radiotherapy alone versus surgery alone. Most patients had squamous cell carcinoma. At a median follow-up of 9 years, the HR was 0.89, suggestive of an overall reduction in the risk of death of 11% and absolute survival benefit of 4% at 5 years with the use of preoperative radiotherapy. However, this was not statistically significant (P = .06). The authors concluded that there was no clear evidence that preoperative radiotherapy improves survival of patients with potentially resectable esophageal cancer.[4]

In general, there were no differences in resection rates or survival in almost all of the individual studies. Interpretation of these studies is complicated by differences in radiation techniques, suboptimal radiation doses, and inadequate radiation volumes. Nonetheless, although preoperative radiation therapy alone may improve local control, there are no convincing data that it results in improved survival in patients with esophageal cancer.

Postoperative Radiation Therapy

The main advantage of adjuvant versus neoadjuvant approaches is knowledge of the pathologic staging for appropriately selected patients for therapy. Postoperative therapy may allow the radiation oncologist to treat areas at risk for recurrence while sparing otherwise normal radiosensitive structures, thereby decreasing toxicity. In addition, patients with pathologic T1, N0, and M0 or metastatic disease may be spared treatment. Postoperative irradiation has historically been delivered to patients with esophageal cancer who have bulky tumors with gross residual disease or histologically proven microscopic residual disease. Potential disadvantages of postoperative radiation include limited tolerance of normal tissues after gastric pull-up or intestinal interposition and irradiation of a devascularized tumor bed, potentially larger fields compared to a preoperative approach, and potential delays in adjuvant treatment delivery.

Three randomized trials have assessed surgery alone versus surgery followed by postoperative radiation therapy.[171-173] In a French trial, 221 patients with squamous cell carcinoma of the mid-lower esophagus undergoing esophagectomy were randomized to postoperative radiation therapy or no further treatment. Patients were stratified by extent of nodal involvement. Total dose was 45 to 55 Gy at 1.8 Gy/fraction, beginning within 3 months of surgery. Five-year survival in patients with node-negative cancer was 38%

versus 7% with involved nodes. No significant survival difference was seen in patients receiving postoperative radiation versus surgery alone. Rates of locoregional recurrence were lower in patients receiving radiation therapy (85% vs 70%; P = NS). However, in patients without nodal involvement, locoregional recurrence was significantly reduced in patients receiving postoperative therapy (90% vs 65%; $P < .2$). The authors concluded that postoperative radiation therapy did not improve survival after resection for squamous cell carcinoma.[171]

Investigators from the University of Hong Kong reported the results of a randomized trial of 130 patients treated with postoperative radiation therapy versus surgery alone. Patients who underwent either curative or palliative resections were included in this trial. Radiation therapy was delivered to a total dose of 49 Gy (curative patients) or 52.5 Gy (palliative patients) using 3.5-Gy fractions. Most patients had squamous cell histology. Local recurrence was noted in 15% of patients receiving radiation and 31% of patients with surgery only (P = .06). In patients with squamous cell carcinoma, the local recurrence rate was 15% with radiation therapy versus 36% with surgery alone (P = .02). Median survival in patients was worse in patients receiving postoperative radiotherapy versus control patients (8.7 vs 15.2 months; P = .02). Ten patients undergoing surgery alone had tracheobronchial recurrence resulting in death versus three patients receiving adjuvant radiation therapy (P = .07). The authors concluded that postoperative radiation therapy was associated with increased morbidity and death caused by radiation injury, as well as with the early appearance of metastatic disease and a reduced overall survival, although patients receiving radiation therapy were less likely to have a tracheobronchial recurrence. However, it should be noted that the high rate of complications associated with radiation therapy in this study might possibly be related to the high dose per fraction and large total dose delivered.[172]

Last, a study conducted by Xiao et al[173] randomized 549 patients to radical resection versus radical resection followed by radiation therapy. All patients had squamous cell carcinoma. The radiation dose delivered was 60 Gy in 6 weeks. Patients were classified into three groups: group 1, no lymph node involvement; group 2, one to two lymph nodes involved; and group 3, three or more lymph nodes involved. Results showed T stage, stage group, and the number of lymph nodes involved by tumor were highly predictive of survival. The 5-year survival rates for groups 1, 2, and 3 were 58.1%, 30.6%, and 14.4%, respectively. Local control and survival were improved in patients receiving postoperative irradiation. For patients with involved lymph nodes, 5-year survival rates for resection-only patients versus patients receiving resection and radiation therapy were 17.6% and 34.1%, respectively (P = .04).

In summary, postoperative radiation therapy may decrease local recurrence, particularly in the setting of involved margins, although the impact of this adjuvant treatment on overall survival remains less clear.

Postoperative Combined Chemoradiation

A large randomized Intergroup trial evaluating the role of adjuvant chemoradiation after surgery versus surgery alone for patients with adenocarcinoma of the stomach and GE junction was reported. In this study, patients with resected, margin-negative gastric or GE junction adenocarcinoma were randomly assigned to surgery alone versus surgery with postoperative chemoradiotherapy. Approximately 20% of patients had lesions in the GE junction. A significant survival advantage was seen in the adjuvantly treated group (median survival 27 vs 36 months; $P = .005$). On subset analysis, this benefit was detected in patients with GE cancer.[174] Long-term results at more than 10-year median follow-up continued to show significant improvement in overall and disease-free survival in the chemoradiation group, benefiting all T- and N-stage patients included in the trial.[175] Therefore, in patients with resected-stage group IB to IV, nonmetastatic GE junctional carcinoma, it is appropriate to advise adjuvant chemoradiotherapy in efforts to potentially improve upon local control and survival. In squamous cell carcinoma, no adjuvant randomized data exist, although institutional series suggests a potential survival benefit in lymph node–positive disease with adjuvant chemoradiation.[176,177] An ongoing phase II-III randomized trial in China is comparing the role of adjuvant radiation therapy alone versus concurrent chemoradiotherapy following resection versus surgery alone in patients with advanced squamous cell carcinoma of the esophagus.

Preoperative Chemotherapy

Six randomized trials showed conflicting results with the use of neoadjuvant chemotherapy alone in the treatment of esophageal cancer, with three of these trials also including gastric cancers. Kelsen et al[115] reported the results of an Intergroup study randomizing 440 patients with squamous cell carcinoma and adenocarcinoma to receive either combined cisplatin or 5-FU chemotherapy for three cycles followed by resection, followed by a similar regimen of adjuvant chemotherapy, versus immediate resection with no chemotherapy. No apparent survival advantage (3-year survival of 23% vs 26%) was seen in patients receiving chemotherapy. In addition, rates of local failure (32% vs 31%) and distant metastasis development (41% vs 50%) were not significantly different between the two groups. The authors concluded that neoadjuvant chemotherapy with CF did not improve survival in patients with resectable esophageal cancer. Long-term results reported that only 59% and 63% of patients undergoing preoperative chemotherapy and surgery alone, respectively, underwent R0 resection, and patients undergoing less than R0 resection had an ominous prognosis, with only 5% of patients undergoing R1 resection surviving more than 5 years and no difference in median survival rates for patients with R1, R2, or no resection. Pathologic complete response rate was 2.5% in patients receiving preoperative chemotherapy. Local regional recurrence rates in patients undergoing R0 resection were 19% with surgery alone versus 25% in the chemotherapy group. In this follow-up study, patients with objective tumor regression after preoperative chemotherapy experienced improved survival. An important caveat from this study is that all long-term R1 survivors received adjuvant

radiation therapy, and the authors concluded that after R1 resection, postoperative chemoradiotherapy offers the possibility of long-term disease-free survival to a small percentage of patients.[178]

In contrast to the Intergroup study, a similar trial from the Medical Research Council (MRC) randomized 802 patients with squamous cell carcinoma or adenocarcinoma of the esophagus to either two cycles of combined CF chemotherapy or surgery alone. Patients receiving neoadjuvant chemotherapy had a statistically improved 2-year survival (43% vs 34%).[159] Follow-up analysis at a median follow-up of 6 years showed a persistent, significant survival benefit in the chemotherapy group (5-year survival 23% vs 17%), with the effect maintained for patients with both squamous cell carcinoma and adenocarcinoma.[179] The reason for outcomes differences between these trials is not clear. A follow-up trial from the MRC (OE05) randomized patients to neoadjuvant CF for two cycles versus four cycles of ECX (epirubicin, cisplatin, and capecitabine) for esophageal adenocarcinoma. R0 resection rates were similar in both groups, with median survival of 23.4 months in the CF group versus 26.1 months in the ECX group (T = 0.19). There was a trend of improved disease-free survival with the ECX regimen, although no overall survival differences were seen. The authors concluded four cycles of neoadjuvant ECX compared with two cycles of CF did not increase survival, and cannot be considered standard of care.[180]

A smaller trial of 169 patients with squamous cell carcinoma of the esophagus randomized patients to receive preoperative chemotherapy alone with two to four cycles of etoposide- and cisplatin-based chemotherapy versus surgery alone. Median and 5-year survival rates significantly favored the chemotherapy group at 16 versus 12 months and 26% versus 17%, respectively. The authors concluded that preoperative chemotherapy with a combination of etoposide and cisplatin improves survival in patients with squamous carcinoma of the esophagus.[181]

A more heterogeneous European study (the Medical Research Council Adjuvant Gastric Infusional Chemotherapy, or MAGIC, trial) randomly assigned patients with resectable adenocarcinoma of the stomach, GE junction, or lower esophagus to preoperative and postoperative chemotherapy with epirubicin, cisplatin, and 5-FU (ECF) versus surgery alone. Although originally designed to include patients with only tumors of the stomach, eligibility was later expanded to include tumors of the lower one-third of the esophagus. Approximately one-fourth of patients had adenocarcinoma involving the lower esophagus or GE junction. Pathologic complete response was noted in 5% of patients receiving perioperative chemotherapy.[182] However, patients receiving perioperative chemotherapy had a HR for death of 0.75, which was highly significant. Five-year survival in patients receiving chemotherapy was 36% versus 23% in patients undergoing surgery alone (P = .009). Subgroup analysis of patients with lower esophageal or GE junction tumors showed benefit to the delivery of perioperative chemotherapy.[182,183]

A follow-up study to the MAGIC trial investigated the role of perioperative ECX, with or without the addition of bevacizumab. One thousand sixty-three patients with esophagogastric adenocarcinoma were randomized. No survival benefit was seen in the bevacizumab arm, whereas wound healing complications were more prevalent with higher rates of postoperative anastomotic leak rates with bevacizumab, prompting discontinuation of recruitment of patients with lower esophageal or junctional tumors planned for esophagogastric resection.[184]

French investigators reported the results of a similar randomized trial of 224 patients assigned to perioperative chemotherapy (CF) versus surgery alone. Although originally designed to include only patients with tumors of the lower one-third of the esophagus or GE junction, eligibility was later expanded to include gastric cancers. Most patients (75%) had disease of the lower esophagus or GE junction. Chemotherapy consisted of planned two or three preoperative and three or four postoperative cycles. This study was prematurely terminated because of low accrual. Patients receiving chemotherapy had improved overall survival (5 years, 38% vs 24%; $P = .02$), disease-free survival (5 years, 34% vs 19%; $P = .003$), and R0 resection rates (84% vs 73%; $P = .04$). Only 50% of patients received postoperative chemotherapy. T0 disease (complete pathologic response at the primary site) was seen in 3% of patients treated neoadjuvantly. Total locoregional recurrence rates were 24% and 26%, respectively, in the chemotherapy versus surgery group, with distant recurrence rates of 42% versus 56%, respectively.[185] In addition to the foregoing studies, two meta-analyses suggested that neoadjuvant chemotherapy resulted in absolute 2- and 5-year survival benefit of 7% and 4%, respectively.[186,187]

Preoperative Chemoradiation Versus Surgery Alone

Walsh et al[158] reported a randomized study to evaluate the role of concurrent preoperative chemoradiation combined with surgery. A total of 110 patients with adenocarcinoma of the esophagus were randomized to receive cisplatin, 5-FU, and concurrent radiation therapy followed by surgery versus surgery alone. Combined-modality patients received two courses of chemotherapy at weeks 1 and 6. Patients were treated using AP-PA fields (later changed to a three-field technique) to a total dose of 4,000 cGy in 15 fractions. Surgery was performed 4 to 6 weeks later, using five separate approaches. Median survival was 16 months with preoperative chemoradiation therapy compared to 11 months for the patients treated with surgery alone ($P = .01$). The 1-, 2-, and 3-year survival rates were 52%, 37%, and 32%, respectively, for patients who received multimodality therapy and 44%, 26%, and 6%, respectively, for those patients assigned to surgery. These results were significant at 3 years ($P = .01$). The authors concluded that neoadjuvant chemoradiation was superior to surgery alone in patients with resectable esophageal adenocarcinoma. A follow-up report of this study described two simultaneously conducted randomized trials in patients with (a) adenocarcinoma and (b) squamous cell carcinoma. Combined trial results suggest that neoadjuvant

chemoradiotherapy conferred a significant survival advantage in both groups, with an associated 54% relative risk reduction in lymph node metastases (64% vs 29%; $P <$ .001). Pathologic complete response was seen in 25% and 31% of patients with adenocarcinoma and squamous cell carcinoma, respectively. Patients receiving neoadjuvant therapy, achieving pathologic complete response, and those with lymph node–negative disease demonstrated superior survival.[188] This trial has been criticized for its poor surgery-alone results, short follow-up, and lack of prerandomization CT staging.

Urba et al[57] reported the results of 100 patients with nonmetastatic esophageal carcinoma (squamous and adenocarcinoma histology) randomized to receive preoperative chemoradiation followed by surgery versus transhiatal esophagectomy alone. Chemotherapy consisted of cisplatin, 5-FU, and vinblastine. Only 69% of the patients were able to receive the intended chemotherapy dose. Radiation was delivered at 1.5 Gy twice daily for 3 weeks to a total dose of 4,500 cGy. No elective nodal irradiation was performed. Surgery was performed on day 42. Tumors more than 5 cm, patient age more than 70 years, and squamous cell histology were associated with inferior survival. At median follow-up of 8 years, no significant difference in survival was seen between treatment arms, with a median survival of 17 months. However, 3-year survival rate was 16% in the surgery-alone arm versus 30% in the combined-modality arm (P = .15). A higher incidence of locoregional failure as first site of failure was seen in patients undergoing surgery alone (42% vs 19%; P = .02). In patients experiencing pathologic complete response, a median survival of 50 months and a 3-year survival rate of 64% were seen versus patients with residual tumor in the surgical specimen, where median survival was 12 months with a 3-year survival rate of 19% (P = .01). The investigators stated that “Although this is not statistically significant, this suggests a possible trend to the benefit of multimodality therapy, but the sample size was too small to detect a more subtle survival difference,” and that surgery should be continued as a standard of care.

Bosset et al[160] reported an EORTC trial randomizing 282 patients with squamous cell carcinoma of the esophagus to either immediate surgical resection or preoperative therapy using concurrent cisplatin chemotherapy with radiation therapy. Patients were treated with split-course radiotherapy with a 2-week interval, using 3.7 Gy/fraction to a total of 37 Gy. Postoperative mortality was significantly higher in patients receiving preoperative therapy (12% vs 4%). Outcomes showed patients receiving neoadjuvant therapy experienced a significant improvement in disease-free survival, cancer-related mortality, margin-negative resection, and local control; however, no improvement in overall survival was seen versus patients undergoing surgery alone (median survival was 18.6 months for both groups). The authors concluded that neoadjuvant chemoradiation improved disease-free survival and local control in patients with squamous cell carcinoma of the esophagus but had no impact on overall survival. They judged that the increase in postoperative mortality in the combined group “could be due

to deleterious effects of the high-dose of radiation per fraction," among other factors, and believed that the dose of 3.7 Gy/fraction "probably had a detrimental effect." This trial has also been criticized for the split-course treatment approach, as well as for potential delivery of suboptimal chemotherapy.

Burmeister et al[161] reported an Australian study randomizing 257 patients with adenocarcinoma and squamous cell carcinoma of the esophagus to surgery alone versus neoadjuvant therapy using concomitant 5-FU and cisplatin. Patients received 2.33 Gy/fraction to a total dose of 35 Gy. Patients undergoing neoadjuvant therapy had a 16% pathologic complete response rate at resection. Patients receiving neoadjuvant therapy were more likely to undergo curative resection and have negative lymph nodes on histologic examination. However, no significant improvement in median survival was seen (19 vs 22 months; HR 0.89; $P = .57$). On subset analysis, there appeared to be a trend toward improved survival in patients with squamous cell carcinoma undergoing neoadjuvant therapy versus surgery alone (progression-free survival HR 0.47; $P = .01$; overall survival HR 0.69; $P = .16$). The authors concluded that neoadjuvant chemoradiation as delivered in their study provided no obvious survival benefit in patients with esophageal cancer, although further study was warranted in patients with squamous cell carcinoma. Potential criticisms of this trial include delivery of a single chemotherapy cycle, as well as delivery of lower radiation doses.

Results of a Cancer and Leukemia Group B study described 56 patients (75% with adenocarcinoma) randomized to either surgery alone or neoadjuvant chemoradiation followed by surgical resection. Patients in the neoadjuvant therapy arm received CF-based chemotherapy and 50.4 Gy of EBRT at 1.8 Gy/fraction. This trial was closed prematurely because of poor accrual. In patients undergoing neoadjuvant therapy, pathologic complete response rate was 40%. A significant improvement in local control and survival was seen in patients receiving neoadjuvant CMT (5-year survival, 39% vs 16%). The authors concluded that neoadjuvant chemoradiation in patients with esophageal cancer significantly improves progression-free and overall survival.[189]

Results of the largest randomized trial (the Chemoradiotherapy for Oesophageal Cancer followed by Surgery Study, or CROSS trial) assessing neoadjuvant chemoradiotherapy in the treatment of esophageal cancer showed a significant survival benefit in patients receiving preoperative therapy, with the majority of patients included in this trial having locally advanced adenocarcinoma.[162] Patients with resectable T1N1 or T2-3 N0-1 tumors received preoperative chemoradiotherapy consisting of weekly paclitaxel and carboplatin with concurrent radiotherapy to a dose of 41.4 Gy versus surgery alone. R0 resection rates were 92% in patients receiving neoadjuvant chemoradiotherapy versus 69% for surgery alone, with a pathologic complete response rate of 29% in patients receiving preoperative therapy. No significant differences were seen in in-hospital mortality (4% vs 4%). Median survival was 49 months in patients receiving chemoradiotherapy versus 24 months in surgery alone, with a significant improvement in 3-year survival (58% vs 44%). An updated analysis of this trial showed

that 95% of patients were able to complete the entire neoadjuvant chemoradiotherapy regimen. After a median follow-up of 84.1 months in surviving patients, median overall survival was 48.6 months in neoadjuvant arm versus 24 months with surgery alone. Most strikingly, median overall survival in patients with squamous cell carcinoma was 81.6 versus 21.1 months ($P = .008$), whereas it was 43.2 versus 27.1 months in patients with adenocarcinoma ($P = .038$). Patients receiving neoadjuvant treatment had a significant decrease in both locoregional progression (22% vs 38%) and distant progression (39% vs 48%).[59] The authors concluded that weekly administration of carboplatin and paclitaxel with concurrent radiotherapy improves overall survival compared to surgery alone and that this regimen can be considered the standard of care for patients with resectable esophageal or esophagogastric junction cancer. Ten-year outcomes from the CROSS trial demonstrated persistent overall survival benefit with use of CMT.[190] At a median follow-up of 147 months, 10-year overall survival rate was 38% in the combined-modality arm versus 25% in the surgery-alone arm ($P = .004$). Local regional recurrence was significantly reduced with CMT (HR 0.40), although the rate of distant recurrence was similar in both arms (27% vs 28%). Additionally, patients with squamous cell carcinoma histology appeared to have improved outcomes with this regimen, compared to adenocarcinoma, with 10-year overall survival rates of 46% versus 36%, respectively. In the squamous cell group, overall survival was 81.6 months for the combined-modality arm versus 21 months for surgery alone ($P = .005$), and 43.2 versus 27.1 months in the adenocarcinoma group ($P = -.059$). Ten-year overall survival results were 46% versus 23% for patients with squamous cell carcinoma and 36% versus 26% in patients with adenocarcinoma. A pattern of recurrence analysis of the CROSS study indicated that preoperative therapy reduced locoregional recurrence from 34% to 14% ($P < .001$) as well as reduction in peritoneal carcinomatosis (14% vs 4%; $P < .001$) and hematogenous spread (35% vs 29%; $P = .025$). Locoregional recurrence occurred in 5% of cases within the target volume, 2% at the field border, and 6% outside the radiation target volume, whereas only 1% had an isolated in-field recurrence.[191]

In contrast, a trial from France of 195 patients with clinically staged early-stage esophageal cancer randomized patients to receive preoperative chemoradiotherapy versus surgery alone. Study outcomes showed no significant difference in survival.[58] In this study, patients with early-stage disease (stage I-II) were randomized to receive surgery alone versus neoadjuvant chemoradiotherapy using concurrent 5-FU and cisplatin with 45 Gy. Postoperative mortality rates were 3.4% in the surgery-alone group versus 11.1% in the neoadjuvant group ($P = .049$). Three-year overall survival was 53.0% versus 47.5% ($P = .749$); however, despite the higher postoperative mortality rates, 5-year survival outcomes were 41% versus 34% in favor of the combined arm (NS). Additionally, patterns of failure analysis showed a significant improvement in local control in patients who were assigned to receive neoadjuvant therapy, nearly halving the rate of locoregional recurrence (29% vs 15%). Disease

recurrence rates were also significantly reduced in patients receiving neoadjuvant treatment. A follow-up report of surgery-alone patients in this trial reported recurrent disease in 47% of patients undergoing surgery alone versus 31% neoadjuvant therapy (P = .03); locoregional recurrence was seen in 17% versus 30% (P = .047) and distant recurrence 23% versus 31% (P = .244) in the neoadjuvant and surgery arms, respectively.[192] The authors concluded that neoadjuvant chemoradiotherapy with CF did not improve survival but increased postoperative mortality for patients with early-stage esophageal cancer. However, the lack of survival benefit with trimodality therapy in this study seems to be a result of increased postoperative mortality, which is likely multifactorial. A report from Chinese investigators of 451 patients with stage IIb-III squamous cell carcinoma of the thoracic esophagus randomized patients to receive neoadjuvant vinorelbine/cisplatin with 40 Gy followed by resection versus resection alone (the NEOCRTEC trial). Pathologic complete response was seen in 43% of patients in the radiation-containing arm. R0 resection (98% vs 91%; P = .002), and overall survival rates were significantly improved in the CMT arm (70% vs 62% 3-year survival; P = .035). The authors concluded neoadjuvant chemoradiotherapy plus surgery improved survival among patients with locally advanced esophageal squamous cell carcinoma. Updated trial results revealed a pathologic complete response rate of 43% in the combined-modality group, along with a higher R0 resection rate (98% vs 91%; P = .002), improved median survival (100 vs 67 months; P = .025), and improved disease-free survival (100 vs 42 months; P < .001). No significant difference was seen in treatment-related mortality (2.2% vs 0.4%).[193] Further analysis revealed the combined-modality group demonstrated a significantly better local regional failure-free survival as well as improved metastases-free survival.[194] At a median follow-up of 54 months, 5-year survival rate of 60% was seen in the combined-modality group (vs 49%), along with improved disease-free survival.[193] Outcomes of these trials are shown in Table 59.8.

5-FU, 5-fluorouracil; adeno, adenocarcinoma; CDDP, cisplatin; CMT, combined-modality therapy; EORTC, European Organisation for Research and Treatment of Cancer; SCC, squamous cell carcinoma; Surg, surgery.

Given these conflicting results of contemporary trials, multiple meta-analyses have been performed. Two of the largest and most contemporary of these demonstrated an absolute 2- and 5-year overall survival benefit of 13% and 6.5% with the use of neoadjuvant chemoradiotherapy, respectively, when compared to surgery-alone approaches, also suggesting a larger benefit of preoperative chemoradiotherapy as

compared to chemotherapy alone.[195,196] It should be kept in mind that some of the included trials used sequential (vs concurrent) chemotherapy, delivered what would be considered suboptimal doses of radiation therapy, used antiquated radiation therapy techniques, delivered (arguably) inadequate chemotherapy, and so on, potentially underestimating the effect of neoadjuvant CMT. That being said, an updated meta-analysis including a total of 24 randomized trials evaluating the role of neoadjuvant chemoradiotherapy, neoadjuvant chemotherapy, or comparison of the two in patients with resectable esophageal cancer was reported,[195,196] evaluating the outcomes of more than 4,000 patients. All-cause mortality for neoadjuvant chemoradiotherapy trials estimated an absolute survival benefit at 2 years of 8.7%, with survival benefits similar between patients with squamous cell carcinoma and adenocarcinoma. By comparison, estimated absolute survival difference at 2 years was 5.1% in patients receiving neoadjuvant chemotherapy and was significant only for patients with adenocarcinoma. The authors concluded that neoadjuvant chemoradiotherapy improves survival compared with surgery alone in operable patients, as does neoadjuvant chemotherapy, although the benefit of neoadjuvant chemotherapy was not as great as with neoadjuvant chemoradiotherapy. They also concluded that a clear advantage of one over the other is not established, and further randomized trials comparing these two strategies are warranted.

In summary, the above data suggest that neoadjuvant concurrent chemoradiation improves local control and overall survival versus surgery alone in patients with potentially resectable esophageal cancer.

Preoperative Chemoradiation Versus Pre-/Perioperative Chemotherapy

A randomized trial comparing neoadjuvant chemotherapy alone versus neoadjuvant CMT was conducted by German investigators (Preoperative Chemotherapy, or Radiochemotherapy in Esophagogastric Adenocarcinoma, or POET, trial).[198,199] Patients with advanced esophagogastric adenocarcinoma were randomized to receive either cisplatin-/5-FU-based chemotherapy alone versus a similar induction chemotherapy, followed by concurrent cisplatin/etoposide with 30 Gy of radiation therapy. Both groups went on to receive surgery. Although this study was closed early because of poor accrual, patients receiving preoperative chemoradiotherapy had significantly higher N0 rates (37% vs 64%; $P = .04$) and pathologic complete response rates (2% vs 16%; $P = .03$), as well as significant trends toward improved local control (59% vs 76%; $P = .06$) and overall survival (3-year survival, 28% vs 47%; $P = .07$; HR 0.67). The authors concluded that preoperative combined modality improves overall survival as compared to chemotherapy alone in patients with locally advanced esophagogastric adenocarcinoma. Long-term results indicated local progression-free survival after tumor resection was significantly improved by CRT (HR 0.37; $P = .01$), with overall survival showing a trend in favor of preoperative CRT (HR 0.65; $P = .055$).[200]

A multicenter phase II Scandinavian trial randomized 181 patients with esophageal or GE cancer to neoadjuvant chemotherapy with CF or the same chemotherapy concurrent with 40 Gy of radiotherapy. Primary trial end point of histologic complete response was higher in the radiation- containing arm (28% vs 9%; P = .02), as was lymph node positivity rate (62% vs 35%; P = .001) and R0 resection rate (74% vs 87%; P = .04), although no significant survival difference was seen. The authors postulated that the lack of survival benefit may be due to increased deaths related to radiation therapy.[200] A smaller phase II study from Australian investigators randomized 75 patients to receive either preoperative chemotherapy with cisplatin and infusional 5-FU or preoperative chemoradiotherapy with the same drugs with radiation therapy commencing on day 21 of chemotherapy, delivering 35 Gy in 15 fractions.[21] Histopathologic response rate and noncurative resection rates were significantly improved in the radiation-containing arm (8% vs 31% and 11% vs 0%, respectively). However, median overall survival was not significantly different between the groups (29 vs 32 months). The authors concluded that despite there being no difference in survival, the potential advantage of achieving negative margins made preoperative chemoradiotherapy a reasonable option for bulky, locally advanced resectable adenocarcinoma of the esophagus. A meta-analysis analyzing five randomized controlled trials (709 patients) demonstrated that neoadjuvant chemoradiotherapy significantly increased rates of pathologic complete response/R0 resection rates in patients with both adenocarcinoma and squamous cell carcinoma compared to chemotherapy alone. A significant increase in 3-year survival was seen only in patients with squamous cell carcinoma (56.8% vs 42.8%; P = .003), whereas in patients with adenocarcinoma, no significant difference was seen (46.3% vs 41%; P = .34).[195] A more recent meta-analysis of randomized controlled trials evaluating surgery, chemotherapy followed by surgery, or chemoradiotherapy followed by surgery, utilizing individual patient data, reported that the approaches led to an improved overall survival when compared to surgery alone, with an overall HR of 0.9 with radiation-contained regimens (P = .27), with chemotherapy-alone appearing to have a larger effect on survival in patients with GE junction versus thoracic tumors, and CMT a more significant impact on female patients (P = .003) relative to surgery alone or chemotherapy alone. The authors concluded a strong overall survival difference was not identified between these approaches.[196]

A randomized trial from China evaluated 264 patients with locally advanced esophageal squamous cell carcinoma, randomizing patients to paclitaxel/cisplatin with or without 40 Gy with concurrent radiotherapy. Patients then went on to resection. No significant difference in post-op morbidity was seen between the groups, with similar rates of R0 resection, although pathologic complete response rate was seen in 36% receiving combined modality versus 4% with chemotherapy (P < .001). Similarly, N0 status was observed in 66% with CMT versus 46% of patients (P = .3). At short interval follow-up, 1-year survival was 87% versus 83% (P = −.3), although deaths related to tumor were significantly lower in the combined-modality arm. The authors concluded

both approaches had similar safety although better histopathologic outcome with combined-modality treatments.[201] At a median follow-up of 44 months, overall survival between the two groups was similar, with a 3-year survival rate of 64% versus 55%, without significant difference in progression-free survival or recurrence-free survival. Pathologic complete response rate was 28% in the combined modality versus 3% in the chemotherapy-alone group ($P < .001$). A trend for lower risk of recurrence was observed in the radiation-containing arm ($P = .06$).[202]

The use of perioperative FLOT (5-FU plus leucovorin, oxaliplatin, and docetaxel) in GE junction and gastric cancers was established in the FLOT 4-AIO trial. This study compared this regimen to the MAGIC trial (ECF) in 716 patients with GE junction and gastric cancer tumors. Forty-four percent of patients had gastric cancer, with the remainder GE junction cancers (24% Siewert 1; 32% Siewert 2-3). Pathologic complete response was seen in 16% of the FLOT group versus 6% in the ECF/ECX group ($P = .02$). R0 resection rate favored the FLOT group (85% vs 78%; $P = .02$). Five-year survival rate was 45% in the FLOT group versus 36% in the ECF/ECX group. This regimen demonstrated a median overall survival of 50 versus 35 months ($P = .12$) in favor of the FLOT regimen.[203] This study changed the choice of perioperative chemotherapy for locally advanced GE junction and gastric cancers to FLOT.

Multiple current trials are evaluating perioperative FLOT versus neoadjuvant chemoradiation in esophageal and GE junction adenocarcinoma, including the European Neo-AEGIS trial comparing perioperative MAGIC or FLOT versus the CROSS regimen. In a preliminary report from this trial (median follow-up of 24.5 months), 3-year survival was similar (56% vs 57%). However, R0 resection rate (95% vs 82%), N0 status, pathologic complete response rate (16% vs 5%), and grade 3 or higher neutropenia (3% vs 14%) were all in favor of the CROSS regimen. Only 15% of patients received the FLOT regimen. Unexpectedly, rates of high-grade neutropenia, diarrhea, and vomiting were significantly higher in the chemotherapy-alone arm. Although there was a decrease in postoperative pneumonia in the CROSS arm (16% vs 20%), there was a higher rate of acute respiratory distress syndrome (ARDS; 4.3% vs 0.6%), although postoperative in-hospital deaths were 3% in both arms.[204] In a follow-up of the Neo-AEGIS trial at a median follow-up of 39 months, median overall survival was 48 months in the perioperative chemotherapy group versus 49.2 months in the trimodality group. No significant difference was seen in disease-free survival or patterns of recurrence (local, regional, or systemic). Pathologic complete response, major pathologic response, and R0 resection rates favored trimodality therapy. Significantly higher rates of grade 3 to 4 neutropenia in diarrhea and pulmonary embolism were seen in the chemotherapy-alone group and no significant difference in perioperative mortality was seen. The authors concluded that although the trial was underpowered and incomplete (closed early due to second interim futility analysis), similar survival outcomes were seen with no major differences in operative and health-related quality of life outcomes.[205] A Japanese three-arm randomized trial (the NExT trial, JCOG1109) is

comparing neoadjuvant CF versus docetaxel, cisplatin, and 5-FU versus radiotherapy with concurrent CF in patients with locally advanced esophageal cancer. Preliminary results of this trial reported that when compared to the doublet regimen, CMT led to an estimated HR of 0.84 (P = .12) in terms of overall survival, with the triplet regimen performing better than the doublet regimen with a HR of 0.68 (P = .006).[206]

The Australian TOPGEAR study randomized patients with resectable gastric adenocarcinoma and GE junction to perioperative ECF versus the same plus preoperative chemo-radiotherapy. Note that patients in this trial were allowed to receive FLOT after the results of the aforementioned FLOT 4-AIO trial were published.[207] Recently published results of this study showed that a high percentage of patients in the chemo-radiotherapy group achieved higher pathologic complete response (17% vs 8%) and greater tumor downstaging; however, at a median follow-up of 67 months, no significant differences in overall or progression-free survival were seen between the groups. Median overall survival was 46 months in the chemo-radiotherapy versus 49 months in the chemotherapy-alone group (HR = 1.05, 0.83-1.31, 95% CI), with a median progression-free survival of 31 versus 32 months, with similar treatment-related toxicities between groups. The authors concluded that the addition of preoperative chemo-radiotherapy to perioperative chemotherapy did not improve survival relative to perioperative chemotherapy alone in patients with resectable gastroesophageal junction and gastric/gastroesophageal junction cancers. The ESOPEC trial from Germany randomized operable patients with esophageal adenocarcinoma to preoperative chemotherapy (FLOT) versus chemoradiation (CROSS regimen). The German RACE study is comparing perioperative FLOT versus preoperative FLOT for two cycles followed by 45 Gy concurrent with oxaliplatin and 5-FU. In this phase III study, a total of 438 patients were randomized to receive either preoperative chemoradiotherapy (41.4 Gy with concurrent carboplatin and paclitaxel) followed by surgery versus perioperative chemotherapy with FLOT followed by surgery. Eligible patients include cT1c, N+ as well as cT2-4a, CN+, or cT2-4aCN0 disease. At a median follow-up of 55 months, overall survival at 3 years was 57.5% in the FLOT group and 50.7% in the preoperative chemoradiotherapy group (HR = 0.7, 95% CI, 0.53-0.92, P = .01). Similarly, progression-free survival was 51.6% versus 35%, with an HR for disease progression or death of 0.66 (95% CI = 0.51-0.85). Grade 3+ adverse events rates were 50%, with serious adverse events 47.3% versus 41.8%, respectively. Ninety-day postoperative mortality was 3.1% versus 5.6%, respectively. The authors concluded that perioperative chemotherapy with FLOT improved survival among patients with esophageal carcinoma as opposed to preoperative chemoradiotherapy and questioned whether de-escalation to a chemotherapy doublet or utilization of preoperative chemoradiotherapy is preferred in patients in whom FLOT cannot be given. Results of this trial will likely lead to change in practice patterns among these patients.[208]

Radiation Therapy Alone Versus Chemoradiation

There are multiple randomized studies comparing radiation therapy alone with concurrent radiation and chemotherapy[65,209,210] as definitive therapy. However, small patient numbers, substandard chemotherapy delivery, and the use of suboptimal radiotherapy techniques handicap many of these studies. This makes treatment results difficult to interpret. The landmark trial establishing the superiority of concurrent chemoradiation to radiation therapy alone was RTOG 85-01. Herskovic et al[211] reported the results of this two-arm trial that treated 60 control patients with radiation alone to a total dose of 64 Gy versus 61 patients with 50 Gy of radiation therapy with concurrent 5-FU and cisplatin. The chemotherapy protocol consisted of four planned courses of infusional 5-FU and cisplatin. Although less radiation was delivered in the concurrent therapy arm, the results demonstrated a significant advantage of the combined-modality arm over the radiation-alone arm. The median survival in patients treated by radiation alone was 8.9 months compared with 12.5 months for those treated with combined therapy, with 2-year survival rate of 10% versus 38%; the incidence of local recurrence decreased from 24% to 16%, and the 2-year distant metastasis rate decreased from 26% to 12%. Because of this highly significant survival difference, the randomization was stopped, and 69 additional patients were treated on the chemoradiation arm. Updated trial results[65,212] showed that at 5 years, survival rates were 26% and 0%, respectively, for chemoradiation and radiation therapy alone. Local recurrence rates were also decreased with the use of CMT versus radiation alone (45% vs 69%), and distant metastases were more frequent in the radiation-alone arm at 40% versus 12% for the combined-modality group. The incidence of acute toxicity, however, was higher for the combined-modality arm versus the radiation-alone arm (44% vs 25%). Similarly, the incidence of life-threatening side effects, including hematologic toxicity and fistula formation, was increased from 3% to 20%. In conclusion, this study demonstrated a significant improvement in local control, median and overall survival, and distant metastasis development with the addition of chemotherapy, at the cost of increased side effects.

Comparison of outcomes data from “definitive” chemoradiation approaches suggests that survival with combined chemoradiation is similar to that achieved by surgery alone. In previously discussed studies, median survival rates of 14 to 20 months and 5-year survival rates of 20% to 30% were achieved with chemoradiation alone; in comparison, in the MRC trial and Intergroup trial evaluating surgery alone, median survival rates were 13 to 16 months, with 5-year survival rates of approximately 20%. In addition, local failure rates appear similar. For example, in the RTOG/Intergroup studies using chemoradiation therapy alone, local failure rates as a first site of failure range from 39% to 45%. In comparison, local failure rate for the Intergroup study evaluating surgery alone was 31%. However, this analysis was limited to patients undergoing R0 resection only (59% of patients).[178] This would undoubtedly be higher if all patients were considered. Therefore, local failure and survival rates appear similar between “definitive” chemoradiation and surgical approaches.

Novel Chemoradiation Approaches/Immunotherapy

In attempts to improve outcomes in patients with nonoperable esophageal cancer, the SCOPE-1 trial was initiated in the United Kingdom. Patients were randomized to receive neoadjuvant cisplatin and capecitabine for two cycles, followed by initiation of radiation therapy cycles three and four (50 Gy in 25 fractions), with or without concurrent cetuximab. Two hundred fifty-eight patients were recruited (73% squamous cell). Median overall survival was 34.5 months in the non-cetuximab arm versus 24.7 months in the cetuximab-containing arm (P = .137), and 3-year overall survival was 47% versus 38%.[68] Similarly, a trial conducted through the RTOG (0436) randomized 344 patients with nonoperable esophageal cancer to weekly cisplatin, paclitaxel, and radiation therapy (50.4 Gy), with or without the addition of weekly cetuximab. Based on interim analyses, the study stopped accrual of patients with adenocarcinoma and later patients with squamous cell carcinoma. The 12- and 24-month survival rates for the cetuximab-containing arm were 64% and 44%, respectively, versus 65% and 42%, respectively (P = .70). Additionally, no difference in outcomes was seen when stratifying by histology. The authors concluded the addition of cetuximab to concurrent chemoradiation did not improve overall survival.[213] In contrast, Xie et al randomized 352 patients with medically inoperable squamous cell carcinoma to 60 Gy plus cisplatin and paclitaxel, with and without erlotinib. Five-year survival was 40% in the erlotinib arm versus 27% in the non-erlotinib arm.[214] Similarly, in the SAKK75/08 trial, 300 patients with esophageal and GE junction adenocarcinoma were randomized to preoperative cisplatin/docetaxel for two cycles followed by 45 Gy with cisplatin-docetaxel, with versus without cetuximab, followed by surgery. Trial results showed a median survival of 5.1 versus 3 years, in favor of the cetuximab arm.[215] It is likely further study is required to better clarify which patients may benefit most from a combination of EGFR inhibitors with chemoradiation.

The French PRODIGE5/ACCORD17 phase III trial compared 5-FU/cisplatin with FOLFOX-4-based chemoradiotherapy. After a median follow-up of 25 months, progression-free survival was 9.4 and 9.7 months, respectively, with no significant differences observed in terms of high-grade toxicities between the two arms.[216]

Based on an overall survival advantage seen in patients with metastatic esophagogastric cancer with the addition of trastuzumab (a monoclonal antibody against HER-2 receptors) to fluoropyrimidine-/cisplatin-based chemotherapy,[217] the RTOG conducted a trial (RTOG 1010) randomizing 606 patients with locally advanced esophageal adenocarcinoma to receive 50.4 Gy with weekly carboplatin and paclitaxel versus the same regimen with concurrent (and maintenance) trastuzumab (patients overexpressing HER-2), with resection. At a medium follow-up of 2.8 years, no difference was seen in overall (median 38.5 vs 38.9 months; P = .85) or disease-free survival (median 19.6 vs 14.2 months; P = .97) between trastuzumab versus placebo arm.[218] These results indicate the benefit of HER-2 inhibitors in combination with chemoradiation appears limited. The PROTECT trial from France is comparing

preoperative chemoradiation with paclitaxel/carboplatin versus a FOLFOX-based regimen in resectable esophageal and GE junction tumors.

The CheckMate 577 trial randomized 1,085 patients in a 2:1 ratio to receive nivolumab for 1 year versus placebo 4 to 16 weeks following CMT followed by resection.[219] Patients with esophageal or GE junction cancer of either histology and undergoing R0 resection with incomplete response to neoadjuvant chemoradiation were eligible. Median disease-free survival favored the nivolumab arm (22.4 vs 11 months; $P < .01$), independent of histology, and seemed to favor esophageal more than GE junction cancers. Patients with a high programmed death ligand-1 (PD-L1) expression tended to have a greater degree of benefit. Overall survival data were pending on initial publication. This favored the nivolumab arm across multiple subgroups independent of PD-L1 expression, HER-2 status, histology, and radiation dose. However, grade 3 or higher toxicity rates occurred in 13% versus 6% in the placebo arm, making this a new standard of care in the adjuvant treatment of these patients. The KEYNOTE-585 trial is randomizing patients with operable esophageal cancer to receive neoadjuvant chemotherapy with/without pembrolizumab, followed by surgery, followed by additional adjuvant chemotherapy with/without ongoing pembrolizumab.

Chemoradiation Versus Chemoradiation Followed by Surgery

Two randomized trials examined whether surgery is necessary after CMT. A report from French investigators randomized 445 patients with clinically resectable squamous cell or adenocarcinoma of the esophagus.[220] All patients received concurrent 5-FU and cisplatin-based chemoradiation. Patients were treated with one of two radiation regimens: 46 Gy over 4.5 weeks (continuous) or 30 Gy at 15 Gy/week (split course). Two hundred fifty-nine patients who had at least a partial response were then randomized to either surgery or additional CMT of 5-FU and cisplatin delivered concurrent with radiation (either an additional 20 Gy at 2 Gy/day or a split course of 15 Gy). No significant difference in 2-year survival (34% vs 40%; $P = .56$) or median survival (18 vs 19 months) was seen between the groups, although 2-year local control results favored the surgical arm (66% vs 57%). The death rate at 3 months following treatment was 9% in the surgery group versus 1% in the CMT-alone group. In addition, patients undergoing surgery were found to have a worse quality of life. However, the rate of stent and dilation requirement was higher in the nonsurgical arm. Additionally, in a separate analysis, patients who were not randomized in this trial (ie, nonresponders) were found to have a survival benefit with surgical resection.[221] The results of this trial suggest that surgery after chemoradiation in responding patients does not further enhance survival.

In another study, from Germany, patients with potentially resectable squamous cell carcinoma of the esophagus received induction chemotherapy with 5-FU, leucovorin, etoposide, and cisplatin for three cycles, followed by concurrent etoposide and cisplatin with 40 Gy of EBRT.[67] Patients were then randomized to receive surgery versus

continuing with combined chemoradiation (total radiation dose increased to 60-65 Gy, with or without brachytherapy). Local control was significantly improved in patients undergoing surgery (2-year local control, 64% vs 41%; $P < .05$). Despite this, no significant difference in survival was seen (median survival, 16 vs 15 months; 3-year survival, 31% vs 24%; P = NS). The "severe" postoperative complication rate (including infection, leak) was 70%, and the hospital mortality rate was 11%. Overall, treatment-related mortality was significantly higher in patients undergoing surgery (13% vs 3.5%). In patients who did not respond to induction chemotherapy, 3-year survival was improved in patients undergoing surgery (18% vs 9%). On regression analysis, only tumor response to induction chemotherapy was found to be a significant prognostic factor. An important caveat to this trial was that only approximately two-thirds of patients in the surgery arm actually had surgery. The authors concluded that (a) surgery after CMT improves local control but had no impact on overall survival and (b) nonresponders to induction chemotherapy may benefit from surgery, and it may be appropriate to individualize therapy based on response to induction treatment. Although it has not been well studied, retrospective experience suggested that definitive chemoradiation in patients with adenocarcinoma of the esophagus results in median survival of 21 months and 2-, 3-, and 5-year survival rates of 44%, 33%, and 20%, respectively.[222]

A large, multicenter study was conducted to assess the impact of salvage esophagectomy following definitive chemoradiotherapy on clinical outcome. Comparisons were performed between patients undergoing salvage (n = 308) versus planned (n = 540) esophagectomy. Additionally, patients were analyzed in the salvage arm by persistent versus recurrent disease. In-hospital mortality was similar in both salvage and planned resections (8.4% vs 9.3%). Anastomotic leak rates (17.2% vs 10.7%) and surgical site infection were both more frequent in the salvage group. Overall and disease-free survival rates were similar between the cohorts. In the salvage group, overall survival was worse in the persistent group. Of note is that doses higher than 55 Gy were linked with increased postoperative morbidity and mortality in this analysis. The authors concluded that salvage esophagectomy can offer acceptable short- and long-term outcomes in selected patients at experienced centers and that persistent cancer following chemoradiotherapy may be more aggressive and associated with a poor survival.[223] Similarly, RTOG 0246 was a single-arm trial in which patients received induction chemotherapy with 5-FU, cisplatin, and paclitaxel followed by concurrent chemoradiation with 5-FU/cisplatin to 50.4 Gy. In follow-up evaluation, if there was clinical suspicion of residual disease, patients were taken immediately to surgery; however, clinically completely responding patients were followed with serial endoscopy and imaging. Of 41 patients entered, 21 (52%) were deemed to have persistent disease with 17 taken immediately to surgery, all with residual disease noted. Of 15 clinical complete responders, 3 (20%) developed recurrent locoregional disease without distant metastases and underwent salvage resection at 3 to 8 months following treatment

completion. Overall, 5-year survival was 37%, and 20/41 patients (49%) did not require esophagectomy. The authors concluded that selective salvage esophagectomy is a viable option in patients who are at higher risk of resection or refuse to undergo surgery.[224]

The role of salvage (vs upfront) esophagectomy following chemoradiotherapy remains a topic of investigation. The French ESOSTRATE trial is currently randomizing patients with operable esophageal cancer achieving clinical complete response following neoadjuvant chemoradiotherapy between systematic surgery and surveillance with selective salvage surgery. The nonrandomized preSANO trial from the Netherlands evaluated the feasibility of salvage surgery with endoscopic ultrasound, biopsies, and PET-CT as response assessment diagnostics, with surgical resection offered only to those patients in whom a locoregional recurrence is highly suspected or proven. This study demonstrated clinical response evaluation with EUS, bite-on-bite biopsies, and fine-needle aspiration of suspicious lymph nodes was adequate for the detection of locoregional residual disease, with PET-CT for detection of interval metastases.[225] The follow-up randomized SANO trial is evaluating patients with both squamous cell and adenocarcinoma of the esophagus or GE junction and treating with CROSS type regimen with PET and EUS-guided evaluation following completion, with consideration of nonoperative management.

In summary, although surgery after combined chemoradiation for esophageal cancer appears to improve local control, its effect on ultimate survival remains unclear.

Brachytherapy

Gaspar et al[226,227] reported the results of a prospective trial evaluating intraluminal brachytherapy in patients with nonoperable esophageal cancer. Patients initially received 50 Gy of external irradiation with concurrent chemotherapy, followed by a 2-week break and brachytherapy administration. Patients received either 15 Gy using HDR techniques over 3 consecutive weeks (5 Gy/fraction) or a single administration of 20 Gy using low-dose-rate (LDR) techniques. Dose was prescribed to 1 cm from the source axis. Treatments were accomplished by placement of a 10- to 12-French applicator inserted transnasally or transorally. The target length was defined as the pretreatment tumor length with 1-cm margin proximally and distally as determined by CT, barium swallow, and endoscopy. Both external irradiation and brachytherapy were given concurrently with 5-FU chemotherapy. After the development of fistulas in six patients, the HDR dose was reduced to 10 Gy in two fractions, and the LDR arm was ultimately closed because of poor accrual. Results showed a median survival of 11 months in all patients. Local disease persistence/recurrence was observed in 63% of 49 eligible patients receiving HDR therapy. Six patients developed esophageal fistulas, resulting in three deaths. These fistulas were deemed treatment related. The 1-year actuarial fistula development rate was 18%. The investigators concluded that esophageal brachytherapy, particularly in conjunction with chemotherapy, should be approached with caution. Chinese investigators randomized 160 patients to receive

either a stent loaded with I-125 seeds or conventional stenting. Median overall survival was 177 days in the irradiation group versus 147 days in the control group ($P = .0046$). Major complications included severe chest pain (23% vs 20%) and fistula formation (8% vs 7%).[228] Review of other combined brachytherapy/EBRT series suggests that fistula formation rates range from 0% to 12%, with a possible trend toward a higher incidence in patients receiving concurrent chemotherapy with brachytherapy. The incidence of brachytherapy-related mortality varies from 0% to 8%, with most series reporting rates of 4% or less.[229] A meta-analysis of prospective studies of brachytherapy encompassing 623 patients concluded that brachytherapy was a highly effective and relatively safe treatment option that was currently underused. However, the severe adverse event rate was 23% (stenosis 12%, fistula development 8%).[230]

Other studies have suggested that HDR brachytherapy is effective for palliation of dysphagia in up to 90% of patients.[229] Danish investigators reported the results of a randomized trial of 209 patients with dysphagia due to inoperable esophageal or GE junctional tumors.[231] Patients were randomized to either endoscopic stent placement or single-dose HDR brachytherapy. Patient exclusion criteria included tumors more than 12 cm, tumors within 3 cm of the upper esophageal sphincter, deeply ulcerated tumors, tracheoesophageal fistula/tracheal involvement, presence of a pacemaker, and previous radiation treatment or stent placement. Brachytherapy was delivered through a flexible 1-cm applicator delivering a dose of 12 Gy prescribed to 1 cm from the source axis. The treatment length was defined as gross disease plus 2 cm proximally and distally. Although trial results showed a more rapid improvement in dysphagia after stent insertion, long-term dysphagia relief was significantly improved in the group receiving brachytherapy. Patients undergoing brachytherapy experienced more days with low-grade or no dysphagia versus patients with stent placement. Complication rates were higher following stent placement (33% vs 21%), primarily because of an increased incidence of late hemorrhage in the stent group. The authors concluded that single-dose brachytherapy is preferable to stent placement as the initial treatment for patients with progressive dysphagia due to inoperable esophageal or GE junction carcinoma. A follow-up study from Dutch investigators compared outcomes from the above stent versus brachytherapy study versus a prospective cohort of patients receiving palliation with EBRT (20 Gy/5 fractions). Improvement in dysphagia was seen in 83% following external beam radiation versus 64% with brachytherapy ($P = .048$). The authors concluded that short-course EBRT appeared at least as effective as brachytherapy in the palliation of patients with esophageal cancer.[232] A trial from the International Atomic Energy Agency randomized 219 palliatively approached patients to HDR brachytherapy (8 Gy × 2), with or without the addition of 30 Gy of EBRT in 10 fractions. Dysphagia relief was significantly improved in the combined approach, with an absolute benefit of 18% at 200 days from randomization ($P = .019$).[233] In a smaller trial, 65 patients with advanced cancer of the esophagus or GE junction were randomized to either expandable stent or HDR endoluminal brachytherapy (7 Gy × 3) delivered over 2 to 4 weeks.

Although the patients receiving stent alone reported significantly better dysphagia scores at 1 month, other health-related quality-of-life scores were worse relative to brachytherapy, and at 3 months, dysphagia-related scores were improved with brachytherapy.[234]

For patients treated with curative intent (unifocal thoracic tumors <10 cm, no distant metastases, no airway involvement or cervical esophageal location), the American Brachytherapy Society recommends a brachytherapy dose of 10 Gy in two weekly fractions of 5 Gy each (HDR) or 20 Gy in a single course at 0.4 to 1 Gy/hour (LDR). The dose is prescribed to 1 cm from midsource and delivered through a 6- to 10-mm applicator. The recommended active length is the visible mucosal tumor with a 1- to 2-cm proximal and distal margin. Ideally, brachytherapy is started 2 to 3 weeks after completion of concurrent external irradiation/chemotherapy to allow mucositis resolution. Concurrent chemotherapy with brachytherapy is not recommended. In palliative cases, a similar approach is recommended, with delivery of 10 to 14 Gy in one or two fractions (HDR) or 20 to 25 Gy in a single course (LDR). In previously untreated patients with a short life expectancy (,3 months), a dose of 15 to 20 Gy in two to four fractions (HDR) or of 25 to 40 Gy (LDR) without external irradiation is recommended (Tables 59.9-59.11).[235] In summary, the use of brachytherapy in the curative approach to esophageal cancer does not appear to significantly improve results achieved with combined EBRT with chemotherapy alone. However, in the palliative setting, brachytherapy has shown good efficacy in the relief of dysphagia.

TABLE 59.9 SELECTION CRITERIA FOR BRACHYTHERAPY IN THE TREATMENT OF ESOPHAGEAL CANCER

Good candidates
Primary tumor ≤10 cm length
Tumor confined to the esophageal wall
Thoracic esophagus location
No regional lymph node or systemic metastases
Poor candidates
Extraesophageal extension
Tumor .10 cm in length
Regional lymphadenopathy
Tumor involving gastroesophageal junction or cardia
Contraindications
Esophageal fistula
Cervical esophageal location
Stenosis that cannot be bypassed

TABLE 59.10 SUGGESTED SCHEMA FOR DEFINITIVE EXTERNAL BEAM RADIATION AND ESOPHAGEAL BRACHYTHERAPY

External Beam Radiation

From 45 to 50 Gy in 1.8-2.0 Gy fractions, 5 fractions/wk, weeks 1-5

Brachytherapy

High dose rate: total dose of 10 Gy, 5 Gy/fraction, 1 fraction/wk, starting 2-3 wk after completion of external beam
Low dose rate: total dose of 20 Gy, single course, 0.4-1.0 Gy/h, starting 2-3 wk from completion of external beam

All doses are specified 1 cm from the midsource or mid-dwell position.

TABLE 59.11 SUGGESTED SCHEMA FOR EXTERNAL BEAM RADIATION AND BRACHYTHERAPY IN THE PALLIATIVE TREATMENT OF ESOPHAGEAL CANCER

Recurrent after external beam radiation and short life expectancy

Brachytherapy:
HDR: total dose of 10-14 Gy, 1 or 2 fractions
LDR: total dose of 20-40 Gy, 1 or 2 fractions, 0.4-1.0 Gy/h

No previous external beam radiation

External beam radiation:
From 30 to 40 Gy in 2-3 Gy fractions
Brachytherapy:
HDR: 10-14 Gy, one or two fractions
LDR: total dose of 20-25 Gy, single course, 0.4-1.0 Gy/h

No previous external beam radiation, life expectancy >6 mo

External beam radiation:
From 45 to 50 Gy in 1.8-2.0 Gy fractions, 5 fractions/wk, week 1 to 5
Brachytherapy
HDR: total dose of 10 Gy, 5 Gy/fraction, 1 fraction/wk, starting 2-3 wk after completion of external beam
LDR: total dose of 20 Gy, single course, 0.4-1.0 Gy/h, starting 2-3 wk after completion of external beam

All doses are specified 1 cm from the midsource or mid-dwell position.
HDR, high dose rate; LDR, low dose rate.

Palliative Treatment

Although treatment advances have occurred in esophageal cancer over the last 20 years, the majority of patients diagnosed with esophageal cancer will die of their malignancy. Therefore, palliation remains an important goal. Dysphagia is a common presenting symptom and may significantly impair patient's quality of life. Many studies report a 60% to more than 80% rate of relief from dysphagia with radiation.[236] Coia et al[236] reported that nearly half of patients with baseline dysphagia experienced an

improvement in swallowing within 2 weeks of treatment initiation. By the completion of the 6th week, more than 80% experienced improvement. A median time to maximal improvement was approximately 1 month. In another series of 148 patients receiving palliative radiation therapy (most received a dose of 20 Gy in five fractions), 75% experienced an improvement in dysphagia, with 26% of these patients requiring stent placement subsequently.[237] Given the superior outcomes of patients receiving concurrent chemotherapy with radiation therapy in nonmetastatic disease, palliative chemoradiation may be preferable to radiation alone for patients with advanced-stage esophageal carcinoma who have a good performance status. However, Trans-Tasman Radiation Oncology Group (TROG) 03.01/National Cancer Institute of Canada (NCIC) CTG (ES.2) investigators enrolled 220 patients with advanced/metastatic esophageal cancer and randomized them to receive 35 Gy in 15 fractions (or alternatively 30 Gy in 10 fractions) with or without the addition of concurrent cisplatin and 5-FU. Forty-five percent of patients in the chemoradiotherapy group and 35% in the radiotherapy group obtained dysphagia relief (P =.13). Median dysphagia progression-free survival was 4.1 versus 3.4 months in the chemoradiotherapy and radiotherapy groups, respectively (P = .58), and median overall survival was 6.9 versus 6.7 months, respectively (P = .88). Grade 3 to 4 acute toxicity occurred in 36% of patients in the chemoradiotherapy group and in 16% patients in the radiotherapy group (P = .0017). The authors concluded that a palliative chemoradiotherapy showed a modest, but not statistically significant, increase in dysphagia relief compared with radiotherapy alone, with minimal improvement in dysphagia progression-free survival and overall survival with chemoradiotherapy but at a cost of increased toxicity, and that a short course of radiotherapy alone should be considered a safe and well-tolerated treatment for malignant dysphagia in the palliative setting.[238] As described earlier, intraluminal brachytherapy has also been used for palliation of dysphagia. The previously described randomized trial from the Netherlands comparing intraluminal brachytherapy to stent placement showed that although patients undergoing stenting experienced a more rapid improvement in dysphagia, long-term palliation was significantly improved in patients treated with brachytherapy.[231]

The palliative management of patients with tracheoesophageal fistula presents a clinical dilemma. Fistulization usually precludes surgery. These patients are often treated effectively with the placement of silicone-covered, self-expanding metal stents, often obviating palliative surgery. In addition, placement of feeding gastrostomy or jejunostomy may be appropriate. Although considered a “relative” contraindication to radiation therapy, limited data from a Mayo Clinic series suggest that radiation therapy may not increase fistula severity and can be administered safely in this setting; however, the presence of fistula is a poor prognostic factor.[239]

REIRRADIATION

Although local control rates with trimodality therapy are high, the incidence of local recurrence remains common in nonoperative patients. Different investigators have

evaluated the role of reirradiation in clinical practice. In one report of 54 patients (21 previously irradiated), radiation was associated with an improvement in dysphagia in 68% and median survival of 1 year. Dose range was 30 to 68 Gy with a median of 45. No grade 5 toxicities were seen, with 1 of 21 patients previously irradiated developing a late esophageal stenosis. The authors indicated that if reirradiation of esophageal carcinoma is contemplated, 3D conformal techniques and a minimum total dose of 45 Gy are recommended.[240] In a smaller series of 10 patients who were reirradiated, the total dose of primary radiotherapy was a median of 50.4 Gy (range, 50.4-63.0 Gy). The total dose of reirradiation was a median of 46.5 Gy (range, 44.0-50.4 Gy). Three patients developed a grade 5 tracheoesophageal fistula, and five experienced progressive disease 3 months following treatment. The authors concluded that reirradiation of recurrent esophageal cancer after primary radiotherapy can cause severe toxicity.[241] A small, prospective trial of 14 patients with a history of prior thoracic radiation with newly diagnosed or locally recurrent esophageal cancer explored the use of proton beam treatment. Median reirradiation prescription dose was 54 Gy and median cumulative prescription dose was 110 Gy. Four of ten symptomatic patients had complete resolution of symptoms and four decreased or stable symptoms. One grade 5 toxicity of esophageal pleural fistula was seen, possibly related to tumor progression. Median time to local failure was 10 months and median survival 14 months. The authors conclude that reirradiation is feasible with encouraging symptom control rate and with a modest toxicity profile.[242] Another report evaluated multiple studies of patients undergoing reirradiation for local regional esophageal cancer, generally between 1 and 2 years following initial treatment of approximately 50%.[243] Reirradiation doses varied from 30 to 60 Gy, with a mean of approximately 42/46 Gy in most series, with variable chemotherapy administration. Reported median survival rates were arranged from 13.6 to 21.6 months, with acute high-grade toxicities ranging from 3% to 50% and late high-grade toxicities form 0% to 17%. Based on this and their own experience, these authors suggested that even in the setting of poor performance status, definitive reirradiation may be given safely and achieved durable response in patients with locally recurrent esophageal cancer after trimodality therapy. Finally, a meta-analysis of 573 patients with esophageal squamous cell carcinoma with locoregional recurrence undergoing reirradiation described a 2- and 5-year survival rate of 25% and 15%, respectively, with rates of complete response and local recurrence of 54% and 62%, respectively, leading to a median survival of 13.9 months. Rates of grade 3 or higher adverse events including esophageal perforation, fistula formation, and pneumonitis were more common in this group.[244]

TREATMENT SEQUELAE

Advances in surgical technique, as well as improved preoperative and postoperative management, have decreased treatment-related mortality. Contemporary operative mortality rates are generally less than 10%.[59,67,245] Complication rates can exceed 75%,

including pulmonary and cardiac complications, anastomotic leak, and recurrent laryngeal nerve paralysis. Stricture formation can occur in 14% to 27% of patients. The addition of preoperative radiation therapy and chemotherapy may enhance surgical complication rates, although this remains a subject of debate.[58,59]

More than 75% of patients receiving radiation experience transient esophagitis and dysphagia, sometimes requiring nutritional support. Chemotherapy-related leukopenia and thrombocytopenia are common, although this may be less common with contemporary chemotherapy regimens.[160] Additional acute toxicities of radiation therapy include esophagitis, dermatitis, fatigue, and weight loss in most patients. Nausea and vomiting are relatively common, particularly in patients with lower esophageal and GE junction tumors. Many symptoms resolve within 1 to 2 weeks of treatment completion. A perforated esophagus is life threatening and can be characterized by substernal chest pain, a high pulse rate, fever, and hemorrhage.[114] The addition of chemotherapy can significantly increase acute complications. Moderate-to-severe and even life-threatening toxicities have been reported in 50% to 66% of patients.[91,245,246] In the previously discussed RTOG study of chemoradiation alone, patients treated with combined therapy had a higher incidence of acute grade 3 (44% vs 25%) and grade 4 toxicity (20% vs 3%) compared to patients receiving radiation therapy alone.[65] Chemoradiation treatment–related mortality rates range from 0% to 3%.[67,91,157,162,246]

The most common late effects following radiation therapy are esophageal stenosis and stricture formation. Stenosis can occur in more than 60% of patients. Symptomatic stricture requiring dilation has been reported to occur at least 15% to 20% of the time. Dysphagia may be relieved with two to three dilations.[91] Long-term results from the RTOG study showed that late grade 3 or greater toxicity was similar in the combined versus radiation-alone arms (29% vs 23%). However, grade 4 or greater toxicity was higher in patients receiving CMT (10% vs 2%).[211] Other complications include clinically apparent damage to organs within the radiation therapy volume, although this is uncommon. Chemotherapy may further increase the risk of late treatment-related toxicities.

The effects of radiation on pulmonary and cardiac function deserve special mention. Pulmonary complications associated with either the definitive or neoadjuvant treatment of esophageal cancer patients can be broadly broken up into symptomatic pneumonitis following treatment completion and postoperative pulmonary complications in patients undergoing resection. Although they are still relatively ill-defined, various institutional series have described predictive factors for these complications (which are not mutually exclusive), which are described in the following.

Radiation pneumonitis is a relatively common complication in the treatment of thoracic (lung) malignancies, which can range from minimally symptomatic to fatal. Common symptoms include nonproductive cough, dyspnea, and, uncommonly, respiratory distress. Generally, this occurs 2 to 6 months after radiation therapy

completion. The ability to predict radiation pneumonitis has been a significant topic of investigation. However, most data come from patients with lung cancer, who may have more underlying intrinsic pulmonary/smoking-related disease. A variety of predictive parameters have been suggested, including V_{20} of more than 25% to 30%, mean lung dose of more than 15 to 20 Gy, V_5 of more than 42%, and absolute V_5 of more than 3,000 cm.[146]

In nonoperative patients, an analysis of patients with esophageal cancer from Japan treated definitively to a dose of 60 Gy with concurrent 5-FU and cisplatin showed a radiation pneumonitis incidence of 27%.[247] The authors concluded that an optimal V_{20} threshold to predict symptomatic pneumonitis was approximately 30%. In a study of 101 both operative and nonoperative patients (88% distal esophagus/GE junction) from the MD Anderson Cancer Center undergoing a mix of 3D and IMRT, 59%, 5%, and 1% of patients experienced grade 2, 3, and 5 radiation pneumonitis, respectively.[248] An analysis from Japan using fields inclusive of supraclavicular, mediastinal, and celiac regions up to a dose of 60 Gy with concurrent CF showed a 2-year cumulative incidence of late, high-grade cardiopulmonary toxicities for patients 75 years or more of 29% versus 3% in younger patients. They concluded that older patients might not tolerate extensive radiation fields.[249] Other studies have shown that significant declines in diffusion capacity and total lung capacity may occur in patients irradiated for esophageal cancer.[250] The RTOG 1010 study recommends maintaining a V_{10} of 40% or less, mean lung dose of less than 20 Gy, V_{20} of 30% or less (ideally <25%), and V_{30} of 20% or less. For IMRT, interval dose is limited to 60% of the lungs receiving 5 Gy or less.

In operative patients, a study of 110 patients treated with preoperative chemoradiotherapy followed by resection at MD Anderson Cancer Center showed that mean lung dose, effective dose, and absolute lung dose receiving 5 Gy or less were predictors of development of postoperative pulmonary complications.[251] In a report on patients from the same institution describing complications in patients receiving neoadjuvant CMT,[252] 18% experienced pulmonary complications, with higher rates when the V_{10} was 40% or more (35% vs 8%) and V_{15} was 30% or more (33% vs 10%), leading the authors to conclude that minimization of lung volume irradiation was important in the preoperative planning of these patients. This increase in postoperative pulmonary complications (pneumonia, ARDS) when the V_{10} was more than 40% suggests that the volume of remaining/undamaged functional lung may determine postoperative pulmonary function, that is, patients with a small lung volume initially may be at higher risk of experiencing pulmonary complications, even if the relative V_5 is low, and that patients with small lung volume with less functional reserve may be more susceptible to postoperative pulmonary complications. Therefore, it is important to consider not only the dose-volume histogram of the lung but also the total lung volume.

A study from China evaluating patients receiving chemoradiotherapy followed by resection showed that the volume of lung spared from doses of 5 Gy or more was the only independent dosimetric factor on multivariate analysis in predicting postoperative pulmonary complications.[253] Wang et al[254] similarly described that the relative V_5 and all spared volumes from 5 to 35 Gy significantly correlated with the incidence of postoperative pulmonary complications, although on multivariate analysis, V_5 was the only significant independent predictive factor, indicating that the volume of "unexposed" lung during induction therapy was predictive. Of note in this study was that the majority of patients were treated with induction chemotherapy alone initially (most paclitaxel), which has been shown to increase rates of pneumonitis in other disease sites. A significant association of induction chemotherapy alone prior to concurrent chemoradiotherapy was seen as a predictor of grade 2 or greater pneumonitis (49% vs 14%; $P = .003$), leading the authors to conclude that induction chemotherapy alone may sensitize lung tissue to radiation damage. In contrast to the foregoing studies, however, another analysis of 98 patients receiving preoperative chemoradiotherapy with 5-FU and cisplatin showed no difference in pulmonary complications versus patients undergoing surgery alone, with no correlation of any lung dose-volume histogram findings with the development of postoperative pulmonary complications seen, leading the authors to conclude that neoadjuvant chemoradiotherapy had no detrimental impact on postoperative course.[255] An analysis from Taiwan of patients with neoadjuvantly, IMRT-treated esophageal cancer undergoing resection suggested that preoperative (not prechemoradiation) forced expiratory volume in 1 second was an independent factor associated with postoperative pulmonary complications and that reducing the absolute volume of the right lung irradiated might decrease the risk of postoperative pulmonary complications.[256] Finally, a review from Fox Chase Cancer Center of 139 patients with esophageal cancer receiving taxane-based trimodality therapy showed that 14% of patients experienced grade 2+ radiation pneumonitis. The V_5, V_{10}, V_{20}, and V_{30} were associated with an increased risk of clinically significant grade 2 pneumonitis. Multivariable analysis showed that V_5 and V_{20} remained associated with this, with V_5 of 65% or less and V_{20} of 25% or less optimal thresholds.[259]

Radiation-induced cardiac toxicity is a broad term describing potential radiation injury to a number of cardiac structures, including the pericardium (as manifested by effusion, pericarditis), coronary arteries, the heart muscle itself/ cardiomyopathy, and cardiac valves, as well as nerve/conduction injury. Radiation injury primarily consists of fibrosis and/or small-vessel injury. "Classic" radiation tolerance (TD5/5) of the heart is about 60 Gy when 25% or less of the heart is irradiated and 45 Gy if 65% of the heart is irradiated, assuming 2 Gy/fraction. The mechanism of radiation-induced cardiac injury is relatively poorly defined, particularly in the context of esophageal cancer. Historical data from the treatment of patients with Hodgkin disease suggest that a dose of more than 40 Gy may increase the risk of cardiac death, as well as of pericarditis.[258,260]

Several studies of cardiac toxicity and patients with esophageal cancer demonstrated that a V_{30} of more than 46% predicted a significant increase in pericardial effusion, and increasing fraction size (particularly ≥3.5 Gy) also predicted the same. In addition, some authors have shown a possible trend for decrease in ejection fraction in patients with increasing V_{20} of the left ventricle.[146] In a study of 150 patients with esophageal cancer receiving chemoradiotherapy (49 neoadjuvantly), the incidence of pericardial effusion was 28%, usually developing within 15 months of radiation therapy, with median onset time of approximately 5 months. The risk of pericardial effusion was associated with mean pericardial doses over an array of dose-volume points to the pericardium from 5 to 45 Gy. A matched-pair analysis of patients in the nonradiation group receiving surgery versus those treated neoadjuvantly was performed, with 42% of patients in the radiation group demonstrating ischemia/scarring on single-photon emission CT images versus 4% in the surgical group, with a median onset to abnormality of 3 months.[256] In a Japanese study, long-term analysis of 139 patients treated with definitive chemoradiotherapy (CF with 60 Gy EBRT) for squamous cell carcinoma revealed grade 2, 3, and 4 late pericarditis occurring in 6%, 5%, and 1% of patients, respectively; grade 4 heart failure in 2 patients; grade 2, 3, and 4 pleural effusion development in 5%, 6%, and 0% of patients, respectively; and grade 2, 3, and 4 radiation pneumonitis development in 1%, 2%, and 0% of patients, respectively.[257] A more recent retrospective review of 343 patients with esophageal cancer demonstrated the rate of symptomatic cardiac disease at 5 years was 14%. Multivariable analysis revealed this increase with increasing heart dose, with the lowest significant cutoff values of V_{45}, V_{50}, and V_{55} of 15%, 10%, and 5%, respectively.[258] A more recent multi-institutional review of 465 patients with esophageal cancer receiving neoadjuvant bimodality therapy showed that heart V_{30} was associated with adverse events, with a risk of 5%, 10%, and 15% when the heart V_{30} dose was 14%, 20%, and 30%, respectively, with every 10% increase in V_{30} associated with a 24% increase in risk of cardiac toxicity.[259] As described previously, an analysis of patients with esophageal cancer showed no difference in disease-specific or pulmonary mortality in patients treated with either conformal therapy or IMRT, but did show an improvement in all-cause cardiac mortality with IMRT.[145] In a literature search concerning cardiac toxicity in patients with esophageal cancer treated with radiotherapy, with or without chemotherapy, the overall accrued incidence of symptomatic cardiac toxicity was as high as 10.8%, corresponding with several dose-volume parameters of the heart. The most frequent complications were pericardial effusion, ischemic heart disease, and heart failure. Most events occurred within 2 years following treatment. The authors concluded that normal-tissue complication probability models for esophageal cancer were not available at present.[260]

FUTURE CONSIDERATIONS

Although modest improvements in survival have been achieved by combining neoadjuvant chemoradiation and surgery, patients treated with chemoradiation alone or with surgery have unacceptably high locoregional relapse rates and mortality rates. Ultimately, approximately 75% of patients succumb to metastatic disease. As described previously, efforts at radiation dose escalation have not resulted in significant gains for this disease, although newer efforts are now underway to further define optimal dose. Current clinical trials are also evaluating new and potentially more effective chemotherapeutic agents with radiation therapy, attempting to optimize combined regimen and integrate novel systemic agent in combination with radiation, as well as to further establish the role of perioperative chemotherapy.

SUMMARY

The prognosis for patients with carcinoma of the esophagus remains poor despite recent advances in combined-modality therapies. No firm recommendation can be made for managing locally advanced disease. The data suggest that neoadjuvant chemoradiation improves outcomes in patients who are candidates for surgery. Alternatively, randomized trials have also suggested that perioperative chemotherapy improves outcomes in these patients, with a recent randomized trial showing this approach improves survival relative to an upfront combined modality therapy approach. However, many patients are not able to tolerate surgery, and combined chemoradiation may be more appropriate in selected patients because definitive chemoradiation has resulted in survival rates comparable to those from surgery alone. Locoregional failure remains a significant pattern of relapse in nonoperable patients. For patients with stage IV disease, palliation with single-modality therapy or several modalities should be used and tailored to the patient's specific symptoms. Current unresolved issues include the following:

1. Which subsets of patients are more likely to benefit from the addition of surgery than others? Is a response-based surgical approach following chemotherapy and/or chemoradiation appropriate for widespread use?
2. Which subsets of patients are more likely to benefit from the addition of neoadjuvant and/or perioperative therapies? Is there a superiority of a neoadjuvant chemoradiation versus a perioperative chemotherapy approach, and will some patients benefit from the addition of combined modality therapy to a perioperative chemotherapy approach?
3. Can introduction of newer chemotherapy/targeted agents in the neoadjuvant or concurrent setting improve the results over "standard" chemoradiation with cisplatin/5-FU or carboplatin/paclitaxel? What is the best sequencing of immunotherapy in patients receiving combined modality therapy? What is the optimal "standard" regimen in combination patients?

4. Will new technologies such as PET-based planning, IMRT, proton therapy, adaptive therapy, and image-guided radiation therapy decrease complication rates and influence cure rates? Is it appropriate to reduce radiation treatment volumes to "involved field" given the high propensity for distant metastases development?
5. Will PET scan allow early prediction of both response to treatment and ultimate outcomes and potentially allow avoidance of delivery of ineffective treatments early on during the course of therapy?
6. Will the identification of molecular prognostic markers allow "individualization" of treatments among patients? Will predicted molecular biomarkers enhance predicting response to neoadjuvant treatments?
7. Will further studies of dose escalation improve local control rates in patients treated with "definitive" chemoradiation?
8. What is the role of immunotherapy in combination with chemoradiation in esophageal cancer, including the Keynote-975 trial examining safety and efficacy of pembrolizumab combined with definitive chemoradiation in locally advanced esophageal cancer? Will the addition of additional targeted therapies (eg, Wee1, vascular endothelial growth factor [VEGF], or heat shock protein 90 [HSP90] inhibitors) in combination with chemoradiation improve outcome in these patients?

CHAPTER 60

Tumors of the Heart, Pericardium, and Great Vessels

Aviva Berkowitz

ANATOMY

The heart is a hollow, conical organ with muscular walls. In the adult, it measures approximately 12 cm in length, 8 to 9 cm in width, and 6 cm in thickness and weighs between 200 and 425 g (7-15 oz). It is located in the inferior aspect of the middle mediastinum, with two-thirds lying to the left of midline and one-third to the right. The heart lies posterior to the sternum and rib cage, and anatomic landmarks on the chest wall may be used to approximate its position. The apex is located roughly 8 cm to the left of midline in the fifth intercostal space, and the base is at the level of the third costal cartilage. It rests on the diaphragm inferiorly. The heart receives its blood supply from the coronary arteries, which are located in the space between the myocardium and the epicardium. The pericardial fat provides a smooth contour and is also located in this space. The heart has four chambers: two ventricles with thick muscular walls and two atria with thin muscular walls. Four valves, including the mitral, tricuspid, aortic, and pulmonary valves, separate these four chambers. Pacemaker cells in the sinoatrial node create an electric current that causes the heart musculature to contract and pump blood across these valves. Although the heart is not attached to surrounding organs, it is held in position by its association with the great vessels (GVs) and the pericardium. The GVs include the aorta, superior vena cava (SVC) and inferior vena cava (IVC), pulmonary artery, and pulmonary veins, which arise from (or terminate in) the left ventricle, right atrium, right ventricle, and left atrium, respectively. The roots of the GVs, along with the heart, are encompassed by the parietal pericardium. In combination with the epicardium, this fibrous layer provides a smooth cavity in which the heart can pump freely. Externally, the pericardium is

adherent to, but separate from, the mediastinal pleura, creating a potential space through which the phrenic nerve traverses.[1]

INCIDENCE AND EPIDEMIOLOGY

Tumors of the heart, GVs, and pericardium are rare and include a range of disease presentations: primary neoplasms; secondary metastases from a known primary malignancy; or direct tumor invasion, which is seen in certain cancers such as Hodgkin or non-Hodgkin lymphoma, lung cancer, or malignant thymoma. The focus of this chapter is to review the epidemiology, diagnosis, natural history, and management of primary tumors arising from the heart, pericardium, and GVs as well as metastatic disease to these sites.

The first described case of a primary cardiac tumor was by Albers in 1835.[2] Reynen[3] performed a compilation of autopsy series consisting of over 700,000 cases and found 157 primary cardiac tumors. The overall incidence of primary tumors is approximately 0.021%, with a range from 0% to 0.3%.[3,4] Approximately 75% of primary tumors of the heart are benign, and about half of those are atrial myxomas arising from the interatrial septum.[4-7] Lipomas, papillary fibroelastomas, and rhabdomyomas each account for approximately 10% of cases. Fibromas, hemangiomas, and teratomas are less common benign cardiac tumors.[8,9] Cystic atrioventricular node tumors are extremely rare congenital tumors, which, despite their small size, may lead to sudden death through disruption of the heart's conduction system.[10,11] There is an increased incidence of cardiac myxomas among females and in patients with Carney complex, an inherited autosomal dominant disorder that also shows hyperpigmented lentigines, blue nevi, schwannomas, endocrine tumors, and endocrinopathies.[12,13] The syndrome is most commonly caused by an inactivating germline mutation of the *PRKAR1 A* tumor suppressor gene on chromosome 17q23-q24.[12,14,15] Variants include the LAMB (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, and *b*lue nevi) and NAME (*n*evi, *a*trial myxoma, *m*yxoid neurofibroma, and *e*phelides) syndromes.[10] Myxomas in patients with Carney complex account for 7% of all cardiac myxomas, are typically found at a younger age, and may have higher recurrence rates.[5,16] Hamartomas, rhabdomyomas, and fibromas are diagnosed almost

exclusively in children.[17] Rhabdomyomas are the most common pediatric cardiac tumor and are associated with tuberous sclerosis.

Malignant primary tumors constitute the remaining 25% of cardiac neoplasms. Primary malignancies of the myocardium constitute the bulk of the remaining cases, of which sarcomas account for the vast majority, and usually occur in the right atrium.[18] Primary cardiac sarcomas make up about 1% of all soft tissue sarcomas.[19] Malignant fibrous histiocytoma, angiosarcoma, fibrosarcoma, and rhabdomyosarcoma are among the more common histologic types.[20] Table 60.1 summarizes the relative frequency of specific subtypes of sarcoma that may be diagnosed. The median age at diagnosis is 30 to 40 years, slightly younger than that for benign tumors, and there is no sex predilection as seen in myxoma.[20,24] Lymphomas account for only about 2% of primary cardiac tumors, but the incidence appears to be increasing.[25] Melanoma and carcinoma may also occur infrequently.

TABLE 60.1 DISTRIBUTION OF HISTOLOGIC SUBTYPES OF CARDIAC SARCOMA[8,20-23]

Subtype of Sarcoma	Number of Cases	Percentage of Cases
Angiosarcoma	105	28
Rhabdomyosarcoma	43	12
Undifferentiated/NOS	43	12
Fibrosarcoma	39	10
Malignant fibrous histiocytoma	33	9
Leiomyosarcoma	26	7
Liposarcoma	20	5
Other	64	17
Total	373	100

NOS, not otherwise specified.

Primary malignant tumors of the pericardium are exceedingly rare and include mesothelioma, fibrosarcoma, angiosarcoma, and malignant teratoma.[26] An American Medical Association survey of nearly 500,000 autopsies revealed a 0.0022% incidence of primary malignant pericardial neoplasms.[27] It appears that malignant mesothelioma is the most common

primary malignancy of the pericardium, accounting for 50% of primary pericardial tumors. Histologic subtypes include epithelioid, sarcomatoid, and biphasic. Asbestos has well-established associations with pleural and peritoneal mesothelioma, and there appears to be some correlation in pericardial mesothelioma as well.[28] Unfortunately, however, because of the low incidence, this association has been inconsistent, and no other risk factors have been identified.[29-31] There were 140 cases reported in the literature in 1994, and several more cases in the following years.[26,27,29-36] A recent review by McGehee et al[36] identified 103 cases in the literature published from 2000 to 2016. Fibrosarcoma, angiosarcoma, synovial sarcoma, and teratoma of the pericardium have also been documented.[26,30,35]

With advances in echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI), the postmortem diagnosis of cardiac tumors is becoming less common. Surgical series seem to demonstrate an increase in the ratio of benign to malignant tumors, with malignant tumors accounting for only 10% of cases in a narrow range of 6% to 20%.[17,21,37-41] This is likely the result of surgical management of benign myxoma, which accounts for over 80% of patients in some series, combined with changes in patient selection.[21,37,40]

The majority of primary cardiac tumors arise in adults with a median age of 45 to 55 years, but they can be seen at any age.[17,21,37-41] Among 533 cases in the database of the Armed Forces Institute of Pathology, McAllister and Fenoglio[8] noted that 83% of patients were adults. Infants (<1 year of age) constituted 9% of the patients, and in this group, 96% of tumors were benign and only 4% were malignant. In a review of the data from the National Cancer Institute Surveillance, Epidemiology, and End Results from 1973 to 1987, Mack[20] reported no sex predilection for the incidence of sarcoma of the mediastinum and heart.

Metastatic disease to the heart and pericardium can occur through several pathways, including the bloodstream, lymphatics, intracavitary diffusion through the IVC or pulmonary veins, or via direct spread.[42] Metastases occur at a frequency much greater than that of primary tumors.[43-49] In a review of more than 12,000 autopsies in Hong Kong, Lam et al[47] noted that cardiac metastases were over 20 times more common than primary tumors and may be present in up to 20% of patients dying of disease. The majority of cases involve the pericardium, whereas myocardial involvement is

uncommon. In a review of autopsy series of patients with a known malignancy, Hanfling[45] noted the rate of reported cardiac involvement increased steadily from 1.5% in the late 1800s to 18.3% in 1960. Contemporary series indicate the rate of cardiac metastases in patients dying of cancer may be as high as 20%.[8,45-48,50-52]

The sites of origin of cardiac metastases from solid tumors are summarized in Table 60.2. Lung cancer is the most common cause of cardiac metastases and accounts for nearly one-half of all cases. Upper gastrointestinal malignancies and breast cancer are also common causes of cardiac metastases, accounting for one-fourth of all cases. The remaining one-fourth of cases arise from a wide variety of other malignancies.[43-48] Melanoma is purported to have the highest propensity for metastatic spread to the heart and tends to involve the endocardium or myocardium, with some series showing its incidence of cardiac metastases rivaling or exceeding that of lung cancers.[2,51] Cardiac metastases may also originate from lymphoma or leukemia. In 1960, Hanfling[45] reported that the proportion of cardiac metastases arising from these malignancies rivals that arising from solid tumors. However, multiple medical advances in both chemotherapy and diagnosis have occurred since then, and modern series consistently report that these histologies account for approximately 17% of cardiac metastases.[43,44,46,47]

TABLE 60.2 SITE OF ORIGIN FOR CARDIAC METASTASES[43-48]

Primary Tumor	Number of Patients	Percentage of Cases
Lung	271	47
Upper gastrointestinal[a]	107	19
Breast	42	7
Genitourinary (nonprostate)	37	6
Melanoma	28	5
Other	93	16
Total	578	100

[a]Includes esophagus, stomach, small bowel, pancreas, and hepatobiliary primary tumors.

Tumors of the GVs are extremely rare, occurring about as often as primary malignant pericardial mesothelioma. The literature consists mainly of case reports, with one of the largest series reported by Burke and Virmani.[53] They evaluated 45 tumors on the files of the Armed Forces Institute of Pathology and found that all of the tumors were sarcomas, including intimal (undifferentiated) sarcoma, angiosarcoma, leiomyosarcoma, and synovial sarcoma. There appeared to be no sex predilection for tumors of the aorta or pulmonary artery, although the female-to-male ratio was 3:1 among patients with tumors of the IVC.

NATURAL HISTORY

Tumors of the Myocardium

Myxomas, as discussed previously, are the most common benign tumors of the heart, are seen in women twice as frequently as men, and are diagnosed at a mean age of 45 to 55 years but have been documented in infants and octogenarians.[21,37-41,54] Benign myxomas tend to be slow growing and are minimally invasive and as such may have a long duration of symptoms before diagnosis. Typically, these tumors arise from the interatrial septum and grow into the adjacent chamber. The left atrium is the most common site of involvement for myxoma, and this is 6 to 7 times more common than myxoma of the right atrium. The tumor may also be located in the ventricles or the valves and can be bilateral. Although they are considered benign, the tumor can elicit dramatic symptoms from valvular insufficiency, congestive heart failure, and embolic phenomena. Polypoid myxomas are more solid and compact in nature, whereas papillary myxomas are softer, less dense, and more fragile.[55] Polypoid myxomas are, therefore, more likely to present with intracardiac obstruction, while fragmentation and embolization are typical of papillary myxomas.[5,55] Surgical excision is the treatment of choice, with local recurrence rates ranging from 0% to 5.4%.[10]

Primary malignant tumors of the myocardium, most commonly sarcomas, do not show a predilection for developing in any particular part of the heart, except for angiosarcomas, which tend to occur more frequently in the right atrium, and often present late with advanced disease and lung metastases.[17,21,37,39,40] The duration of symptoms is on the order of months, and survival is poor. Even after attempts at curative resection, recurrences

are common, and the median survival ranges from 6 to 18 months.[17,21-23,37-41] The cause of death is most often complications of locally recurrent disease with invasion of adjacent chambers, valves, or pericardium. Tamponade, hemopericardium, and distant metastases are common.[23] About 30% of primary cardiac sarcomas have distant metastases at the time of diagnosis.[2] The high incidence of hematogenous dissemination of cardiac sarcoma may be explained by the high rate of blood flow through the heart.[56]

Tumors of the Pericardium

Mesothelioma is the most common pericardial neoplasm and may be either confined to the pericardial sac at diagnosis or present with locoregional spread, involving the myocardium or mediastinal structures.[29-31] In the earlier literature, only 28% of primary malignant pericardial mesothelioma cases were diagnosed antemortem.[30] In contrast, the recent review by McGehee et al[36] reported postmortem diagnosis in 16% of cases, with a median age at diagnosis of 55 years, and a male predominance (61% vs 39%). These tumors have been documented to metastasize by lymphatic and hematogenous routes to involve regional lymph nodes, lung, liver, brain, bone, and adrenal glands.[26,27,29-34] Despite the metastatic potential, pericardial tumors are more often fatal because of local complications, such as constrictive pericarditis with resultant cardiac tamponade, arrhythmia due to myocardial invasion, or vena caval obstruction. Even if the tumor can be diagnosed antemortem, survival is poor. Typically, the onset of symptoms does not occur until the tumor is well advanced, and from that time, the median survival is <6 months, with only a handful of patients surviving beyond 1 year.[32-34]

Tumors of the Great Vessels

The median age at presentation for tumors of the GVs is between 40 and 60 years.[53] The natural history and clinical presentation depend on the exact location of the primary tumor. Depending on the location, symptoms may include dyspnea, cough, hemoptysis, pain, and thromboembolic phenomena, including pulseless extremities, stroke, peripheral edema, and SVC syndrome. In the series by Burke and Virmani,[53] they found that in contrast to the tumors of the aorta and pulmonary artery that were

aggressive sarcomas arising from the vessel lumen, tumors of the IVC were mostly low-grade leiomyosarcomas originating from the medial layer of smooth muscle in the vessel wall.

CLINICAL PRESENTATION

Tumors of the heart have been referred to as the "great imitators" of the cardiovascular system, and clinical correlation is crucial to help differentiate cardiac tumors from other nonneoplastic masses, such as thrombi or vegetations. Although there are no pathognomonic signs or symptoms, cardiac tumors can be detected through careful attention to both cardiac and extracardiac manifestations of the disease.[57,58] It is not surprising that tumors of the heart are often asymptomatic until they become advanced enough to affect blood flow or cardiac function,[45] which is why delay in diagnosis is prevalent, and why cardiac tumors are often fatal. When these do present clinically, the signs and symptoms are variable and depend upon many factors, including the size, location, and invasiveness of the tumor.[59] The scope of clinical presentation is summarized in Table 60.3. Tumors involving the right heart may result in pulmonary emboli, pulmonary hypertension, tricuspid valve disease, or SVC or IVC obstruction. Left-sided tumors can cause mitral valve disease, thromboembolic phenomena, and rapidly progressive congestive heart failure, which may be refractory to treatment. A characteristic auscultation finding referred to as a tumor plop may be heard during early diastole in 30% of patients.[60] Arrhythmias are very common and are predominantly supraventricular tachycardia or nonspecific conduction anomalies.[58] Specific presenting complaints are equally varied. Dyspnea is the most common presenting complaint and is noted in 59% to 88% of patients.[22,43,61,62] Palpitations or syncope is also seen frequently and may be positional, and if the tumor obstructs a valve orifice, sudden death may result. Chest pain can be anginal, resulting from direct myocardial invasion or obstruction of the main coronary ostia. It can also be sharp, due to invasion of the pericardium, with resulting pericarditis. Constitutional symptoms also occur, with fever, malaise, anemia, and weight loss.[22,43,45,58,61,62] Tumors of the pericardium and GVs show a similarly

variable constellation of symptoms, and as such, they pose the same diagnostic difficulties as tumors of the myocardium.

TABLE 60.3 SCOPE OF CLINICAL MANIFESTATIONS OF CARDIAC TUMORS

Cardiovascular Manifestations	Extracardiac Manifestations
Electrocardiogram findings	Pulmonary
Low voltage	Rales
Atrial fibrillation or flutter	Dyspnea
Supraventricular tachycardia	Hemoptysis
Conduction anomalies	Pulmonary hypertension
Bundle branch block	Upper digestive tract
Atrioventricular block (second or third degree)	Hematemesis
Ventricular tachycardia	Dysphagia
Ventricular fibrillation	Embolic phenomena
Pericardial signs	Right-sided tumors
Friction rub	Pulmonary emboli
Pericarditis	Left-sided tumors
Effusion	Stroke
Tamponade	Splinter hemorrhages
Congestive heart failure	Peripheral arterial occlusion
Peripheral edema	Raynaud phenomenon
Jugular venous distention	Peripheral findings
Valvular insufficiency	Clubbing
Chest pain	Ascites
Palpitations	Constitutional symptoms
Syncope	Anemia
Sudden death	Fatigue
Superior or inferior vena caval obstruction	Fever
Myalgia	Weight loss
	Arthralgia

Physical examination may reveal tachycardia, murmur (which may be positional), pericardial rub, gallops, peripheral edema, jugular venous distention, rales, and stigmata of thromboembolic disease. Electrocardiography (ECG) most often reveals nonspecific ST- and T-wave changes, although low-voltage ECG, supraventricular tachycardia, bundle branch block, or second-degree (type II) or third-degree atrioventricular node block may also be noted. Laboratory studies may reveal anemia, erythrocytosis, thrombocytosis, thrombocytopenia, leukocytosis, and elevated erythroid sedimentation rate.[22,58,62,63]

DIAGNOSTIC WORKUP

Cardiac tumors may be symptomatic, as discussed above. They can also be discovered incidentally, during workup for a separate, or seemingly unrelated issue. Before the advent of echocardiography and angiography, 66% of tumors were diagnosed intraoperatively during exploration for suspected valvular disease. With current techniques, the diagnosis can be made reliably in the preoperative setting in almost 90% of cases.[21] The diagnostic evaluation of patients with suspected cardiac tumors is presented in Table 60.4.

TABLE 60.4 DIAGNOSTIC EVALUATION FOR A SUSPECTED OR KNOWN CARDIAC TUMOR

Required Studies	Optional Studies
History	Cardiac catheterization, right or left sided
Physical examination	Pressure and output measurements
Blood work	Coronary angiography
Complete blood count	Endomyocardial biopsy
Liver function tests	Transesophageal echocardiography
Renal profile	ECG-gated MRI
Electrolytes	Radionuclide scintigraphy, including PET
ECG	Pericardiocentesis
Imaging	Staging for malignant tumors
Chest radiography	CT of the abdomen, pelvis, and brain

Required Studies	Optional Studies
Transthoracic echocardiography	Bone scan
Contrast-enhanced dynamic CT	

CT, computed tomography; ECG, electrocardiography; MRI, magnetic resonance imaging; PET, positron emission tomography.

Physical examination and ECG findings have been described above. There is a wide variety of imaging techniques available in the diagnosis and evaluation of cardiac tumors, and these include chest radiography, CT, MRI, echocardiography, radionuclide scintigraphy, and cardiac catheterization. Although there is considerable overlap among these studies, each modality is unique and complements the others in evaluating the tumor. Often, a multifaceted approach, utilizing several of these imaging modalities in tandem, is necessary for diagnosis. Chest radiography shows abnormalities in over 80% of patients. Unfortunately, abnormalities are usually nonspecific and, therefore, of limited usefulness. Findings include cardiomegaly, an abnormal cardiac contour, mediastinal widening, or evidence of congestive heart failure.[58,64,65] Calcifications are present in up to 20% of cases, perhaps relating to the presence of valvular or pericardial disease.[64,66] Calcifications on imaging may also suggest the presence of a fibroma. In the setting of a malignant tumor, chest radiography may also reveal hilar nodal, pulmonary, or osseous metastatic disease.

Echocardiography, M-mode and two-dimensional, is the diagnostic procedure of choice among patients with suspected cardiac tumors. It is generally widely available and has a relatively low cost. Either transthoracic (TTE) or transesophageal (TEE) techniques can be performed, yielding valuable information regarding size, shape, location, mobility, and areas of attachment.[58] For example, a myxoma may be demonstrated as a mobile mass with finger-like projections and heterogeneous hyperechogenicity, whereas thrombi are often seen in the atrial appendage, are not very mobile, and with homogeneous echogenicity.[67] In a review of 533 primary cardiac tumors, Blondeau[21] found echocardiography provided a 98% diagnostic accuracy rate among the 437 patients for whom it was used. Bogren et al[65] found that echocardiography detected abnormalities in 63 (97%) of 65 patients with primary cardiac tumors. With this high level of diagnostic

yield, and because the use of TTE is quite safe, it should be performed for all patients. TEE is a complementary procedure to TTE. It is somewhat more invasive and not required in all patients, but it may be used for guidance during endomyocardial biopsy and may also provide better evaluation of the left atrial appendage and right-sided tumors.[68-70]

Cross-sectional imaging has also become indispensable in the evaluation of nonmyxomatous cardiac tumors. With the development of contrast-enhanced dynamic CT (Figure 60.1B) and ECG-gated MRI (Figure 60.1A, C), real-time imaging of the heart provides fine details of the tumor, including the makeup, size, and, location, with delineation of intraluminal, intramyocardial, and extracardiac extension.[58,71-74] The findings may be used to plan the surgical approach and, should adjuvant therapy be required, could also be used for radiotherapy treatment planning. Compared to chest radiographs, both CT and MRI are more sensitive in detecting metastatic disease. If these studies are positive, tissue diagnosis may be made without the need for endomyocardial biopsy or thoracotomy. If they have not been performed before surgery, CT of the brain, chest, and upper abdomen and a bone scan are recommended in the staging of malignant cardiac tumors.

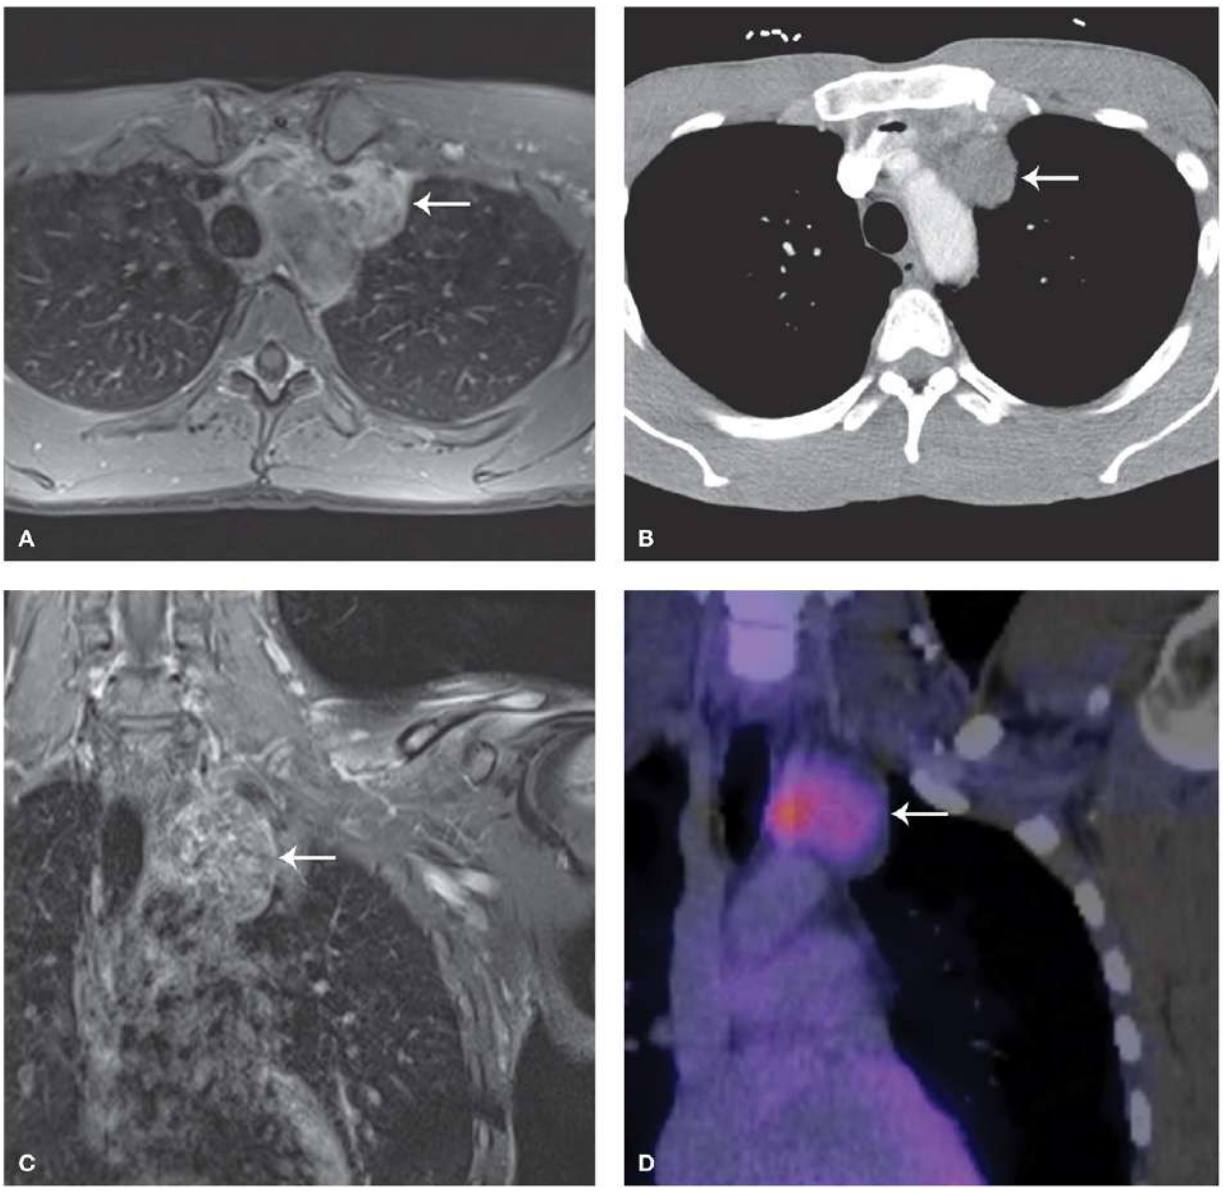

FIGURE 60.1 Axial contrast-enhanced fat-saturated T1 magnetic resonance image (MRI) of a primary cardiac neoplasm arising from the left atrium (A); corresponding axial contrast-enhanced computed tomography (CT) (B), coronal contrast-enhanced fat-saturated T1 MRI (C), and coronal fluorodeoxyglucose positron emission tomography CT (D) images. Tumor indicated by white arrows.

Radionuclide imaging has been used in the evaluation of cardiac tumors. Gated cardiac blood pool scintigraphy has limited resolution, but it may be able to detect tumors when other modalities have failed. Gallium-67 and thallium-201 scans may reveal intramyocardial invasion.[58,65] Positron emission tomography (PET), with or without CT fusion (PET-CT) (Figure

60.1D), is rapidly gaining favor in the staging of many cancers, and there are scattered case reports on its usefulness in evaluating cardiac tumors.[75,76]

Cardiac catheterization was heavily utilized in the past, but its usefulness has diminished with the emergence of the noninvasive techniques noted previously. Catheterization may reveal wall structural or motion abnormalities, intracavitary filling defects, or evidence of neovascularization of the tumor.[58,65] If a malignant tumor is suspected, endocardial biopsy may provide tissue for pathologic diagnosis. For patients who may undergo surgical resection of their tumor, catheterization is still recommended for the detection of coronary artery disease and pulmonary hypertension.

STAGING SYSTEM AND PATHOLOGIC CLASSIFICATION

There is no accepted staging system available for cardiac tumors. With respect to pathologic classification, tumors of the heart and pericardium may be classified as primary (originating from the heart) or metastatic (originating from malignancies of other organs). Primary cardiac tumors can be further subclassified by the site of origin and by malignant potential (Table 60.5).

TABLE 60.5 PATHOLOGIC CLASSIFICATION OF CARDIAC TUMORS

Pericardial Tumors	Myocardial Tumors
Benign Subtypes	*Benign Subtypes*
Teratoma	Myxoma
Pericardial cysts	Lipoma
Fibroma	Papillary fibroelastoma
Angioma	Rhabdomyoma
Lipoma	Fibroma
Malignant Subtypes	Hamartoma
Mesothelioma	Hemangioma
Angiosarcoma	Teratoma
Fibrosarcoma	*Malignant Subtypes*
Malignant teratoma	Sarcoma
	Lymphoma
	Malignant teratoma
	Melanoma
	Carcinoma

PROGNOSTIC FACTORS

In general, the prognosis for patients with either primary or secondary malignant tumors of the heart is poor. The median survival of patients with malignant primary tumors is approximately 1 year, and both local and distant relapses are common. Blondeau[21] reported that angiosarcoma had a median survival of 2.14 years, compared with only 0.75 years for fibrosarcoma. Llombart-Cussac et al,[77] on the other hand, noted a worse survival for angiosarcomas due to their propensity to present late with advanced disease. The series from Burke et al[22] and Putnam et al[23] indicate that the histologic subtype does not appear to have prognostic value, although the microscopic finding of more than 10 mitoses per high-power field does portend a worse prognosis. Tazelaar et al[78] also noted a worse outcome for tumors with high mitotic activity and necrosis. Conversely, the ability to resect all gross tumor and a left atrial site of origin predicts for longer survival.[22,23] Although the duration of symptoms is typically short, some patients have a more protracted course, and outcome may be better in those with symptoms for more than 3 months before diagnosis.[79] The use of adjuvant radiotherapy has been associated with longer median survival (22.7 vs 9.6 months), whereas adjuvant chemotherapy has provided mixed results.[22,79] Given the retrospective nature of these studies, patient selection may be a source of bias. If a controlled, prospective study could be completed, it is unclear if it would confirm an improved prognosis with either type of adjuvant therapy.

The discovery and diagnosis of metastatic disease in the myocardium is rare in the antemortem setting, and hence prognostic factors have not been well elucidated. Malignant pericardial effusion, on the other hand, is more easily diagnosed in life and can be appropriately palliated with pericardiocentesis, pericardiotomy, or pericardial sclerosis. Among patients with metastases from a solid tumor, the median survival after the procedure is approximately 3 to 4 months, and it appears to be improved with better performance status.[80,81]

MANAGEMENT

Primary Pericardial Tumors

As previously discussed, the vast majority of primary pericardial malignant tumors reported in the early literature were diagnosed postmortem,[26,27,29-34,82-85] while a more recent review reported most cases were found prior to autopsy.[36] Even among those diagnosed earlier, locally advanced or metastatic disease is common, and palliative treatment may be the most appropriate option. Relief of pericardial tamponade can be achieved rapidly through pericardiocentesis. Palliative surgical approaches include pericardiectomy or pericardial sclerosis to alleviate the symptoms of effusion and potentially prevent its recurrence. In keeping with the contemporary data supporting the use of radiotherapy in cases of primary pleural mesothelioma, it is appropriate to consider its use in the setting of primary pericardial mesothelioma, although there are few clinical data defining its use.[86] Both external-beam radiotherapy and instillation of radiopharmaceuticals (phosphorus-32, gold-198) have been reported in the palliative setting for this disease.[7,26]

Surgical resection of all gross disease is the treatment of choice in the definitive setting. As with pleural mesothelioma, a high rate of local recurrence is expected without adjuvant therapy, and postoperative chemotherapy and radiotherapy should be considered, though their benefit remains not entirely clear. McGehee et al[36] reported a survival benefit (13 vs 0.5 months) in patients who received platinum chemotherapy with or without pemetrexed. The radiation treatment volume should include the entire pericardial surface and likely should include the mediastinal lymph nodes.

Benign Cardiac Tumors

The most common benign cardiac tumors are atrial myxomas in adults and rhabdomyomas in children. These are both treated surgically with low mortality rates and local control rates in excess of 95%.[17,21,37-40,61,79] Endo et al[38] reported a 5-year overall survival rate of 86% after resection of atrial myxoma. Bogren et al[65] found the 5-year survival rate was 87% for patients with myxoma and 76% for all patients treated for a benign cardiac tumor. Blondeau[21] reported 444 patients had resection of a myxoma with a 4% 30-day surgical mortality rate, a 1% late tumor- or treatment-related mortality rate, and only a 2% risk of local relapse. Given the high rate of cure, with

an acceptable rate of morbidity, surgical resection without adjuvant chemotherapy or radiotherapy is generally appropriate for benign primary cardiac neoplasms. Some rhabdomyomas may even regress spontaneously without the need for aggressive resection.[87] Surgery also plays a role in the management of other less common benign cardiac tumors, such as papillary fibroelastomas, fibromas, and symptomatic lipomas.

Malignant Primary Cardiac Tumors

Surgical resection is the primary treatment of choice for patients with primary malignant cardiac tumors. Unfortunately, local resection is often incomplete because of the extent and invasiveness of the tumor, lack of experience with extended cardiac resection, and partly because of uncertainty of diagnosis at the time of initial surgery.[88] In experienced hands, even tumors requiring complete reconstruction of the entire right and left atria and up to 30% of the right ventricle may be resectable and still retain adequate cardiac function.[88] Even in the presence of a complete excision, local relapse is common and accounts for as much as one-third of deaths. Sarcomas account for almost all primary malignant cardiac neoplasms, and the treatment principles should be similar to those for soft tissue sarcoma arising from other areas of the body.[89] After complete or incomplete resection of the tumor, adjuvant radiotherapy and chemotherapy may be used in an attempt to gain control of local and distant disease, respectively. There are conflicting reports on the effectiveness of chemotherapy, and given the small sample sizes, it is difficult to draw conclusions, but it seems to be less beneficial if patients are not able to obtain a complete resection.[22,23,88] Combination chemotherapy appears to have greater efficacy than single-agent therapy, with different combinations of agents such as cyclophosphamide, ifosfamide, doxorubicin, and paclitaxel in use.[23,90-93]

Anecdotal cases of orthotopic heart transplantation for patients with malignant neoplasms of the heart were first described in 1981 by Jamieson et al[94] and in several reports in the literature since then, with some promising results in selected cases.[95-104] Although this technique should ideally achieve a complete tumor resection, the results have been mixed. There have been some case reports of long-term survivors, whereas many

other patients have developed distant metastases and subsequent death within months of transplant. Some have attempted cardiac explantation, tumor removal, and autotransplantation.[93] Although orthotopic heart transplantation has promise, theoretical dangers exist, including the potential protumor effect of immune suppression and a decreased ability to tolerate adjuvant radiotherapy or chemotherapy.

Primary cardiac lymphomas usually consist of aggressive B-cell lymphomas, and the treatment paradigm is generally chemotherapy and immunotherapy.

Metastatic Tumors of the Heart and Pericardium

There is no known curative therapy for patients with metastatic disease to the heart. Appropriate management of the primary metastatic tumor with systemic therapy may be indicated as a first-line approach for cardiac, pericardial, or GV metastases. Surgery may have a role in both diagnosis and palliation for patients with malignant pericardial disease.[80,81] Emergency pericardiocentesis or pericardiotomy can alleviate cardiac tamponade and yield the diagnosis, and the instillation of a sclerosing agent, such as tetracycline, can often effectively prevent the reaccumulation of the pericardial effusion. Palliative radiotherapy may be used to relieve symptoms of life-threatening outflow obstruction or pericardial disease.

Tumors of the Great Vessels

Resection of the tumor with graft reconstruction of the vessel is the treatment of choice. As with sarcomas of the heart, sarcomas of the GVs are treated based on the same philosophy as used for the treatment of soft tissue sarcoma.[89] Postoperative radiotherapy should be considered for all patients, even those with low-grade tumors, because local recurrence would likely not be amenable to salvage surgical resection.[22,40,53]

RADIOTHERAPY

In general, the most common indication for radiotherapy is in the postoperative setting, for example, as adjuvant therapy after resection of a primary malignant cardiac tumor. Less common is the use of radiotherapy

in the definitive setting for a tumor that is not technically resectable. There are rare reports of preoperative radiotherapy being used to render a technically unresectable cardiac tumor appropriate for surgery. Lastly, palliative radiotherapy may be considered when metastatic tumors to the heart cause clinically significant symptoms causing interference with cardiac function.

Decisions on radiation dose and target definitions for cardiac tumors will be determined by the tumor type and the particular clinical indication for treatment. Given that sarcomas are the most common primary malignant cardiac tumors, the radiotherapy model used in their management has been extrapolated from the approach used for soft tissue sarcomas arising at extracardiac sites. Thus, for completely resected tumors with negative margins, postoperative doses of 45 to 50 Gy at 1.8 to 2 Gy/fraction are recommended.[89] The initial target should include all areas known to harbor tumor before surgery, with a margin of about 2 cm. This target should be derived from diagnostic imaging and other investigations and also by the operative description of the surgeon. In the setting of incomplete resection (ie, involved microscopic margins or gross residual disease), an additional 10 to 20 Gy boost should be added, targeting the postoperative volume at risk. In definitive cases, the goal is to achieve a total dose of at least 70 Gy delivered to the unresected primary tumor, but normal tissues may impose limitations in achieving this. For GV tumors, the target volume will vary depending on the tumor origin but, as with cardiac primaries, should include a minimum expansion of 2 cm around the preoperative mass. Doses from 45 to 50 Gy are suggested for microscopic residual disease and 60 to 70 Gy for gross residual or unresectable disease, allowing for accepted normal tissue tolerances.[105-108] For patients with pericardial mesothelioma, the entire pericardium needs to be included in the initial target volume, but the total dose deliverable will be limited by the tolerance of the myocardium itself and may only be as high as 40 Gy if the whole heart is treated. Focal involvement of the pericardium may be treated to doses as high as 64 Gy.[109] For tumors with a high propensity for nodal involvement (ie, mesothelioma, angiosarcoma, rhabdomyosarcoma, carcinoma, or lymphoma), coverage of the mediastinal lymph nodes is also recommended. With respect to altered fractionation approaches for cardiac tumors, there are few reports on dose variations to improve the efficacy of conventional

radiotherapy. A rare example is a case report on the use of hyperfractionation for a cardiac sarcoma treated to a dose of 70.5 Gy at 1.5 Gy/fraction delivered twice daily with a radiosensitizer, iododeoxyuridine.[56] Regarding palliative radiotherapy, dose schedules should reflect the clinical urgency and the patient's performance status. The origin of the primary tumor may also have a bearing on dose schedules. A survey of palliative case reports showed wide ranges in dose/fractionation schedules with the most common ones being short-course accelerated hypofractionated approaches such as 20 to 30 Gy in 5 to 10 fractions.[110]

With respect to radiation delivery, historic practice has involved two-dimensional planning and static beam arrangements, such as anteroposterior parallel-opposed techniques to cover the desired initial target volume. Contemporary radiotherapy should now be planned using a three-dimensional (3D) conformal approach, with careful delineation of gross tumor volumes, clinical target volumes, and planning target volumes as defined by the nature of the primary tumor, its expected natural history, and the management approach (definitive or adjuvant). When planning radiotherapy, normal tissue constraints should be observed for each case, with an emphasis on cardiac, lung, spinal cord, and esophageal tolerances. If required, advanced techniques such as intensity-modulated radiotherapy (IMRT) may be of use in the delivery of desired doses to target volumes while highly limiting dose to normal structures. IMRT techniques allow for the selective intensification or reduction of dose to areas of specific concern and may allow for greater sparing of normal tissues without sacrificing tumor coverage or dosing. A recent innovation in radiotherapy highly relevant to cardiac tumors is the use of four-dimensional (4D) CT scanning at the time of patient simulation. 4DCT allows an understanding of the effect of breathing motion on the target and normal structures within the chest. For each structure, 4DCT can generate volumetric data sets representing the various phases of the respiratory cycle. By more clearly understanding tumor motion, relevant normal structures at risk can be optimally spared by restricting treatment margins.

One of the more important advances in the field of radiotherapy has been developing technology that can deliver extremely high-dose focused radiation. Stereotactic body radiotherapy (SBRT), also known as stereotactic ablative radiotherapy, involves the precise delivery of very high

(ablative) doses of radiation to discrete targets over a small number of treatment sessions (usually five or less) by treating the target with high degree of conformality and employing rigorous pretreatment setup verification. Given the complexity of heart tumors by virtue of their location and their relationships to a number of organs at risk, SBRT has proved to be of particular interest in their management. Soltys et al[111] treated a recurrent pulmonary artery sarcoma with 33 Gy in three fractions. Bonomo et al[112,113] used SBRT for recurrent and metastatic cardiac tumors, with doses ranging from 24 to 36 Gy in three to five fractions. Although the total doses used for cardiac tumors reported so far have been less than the curative doses seen in the early-stage lung cancer SBRT literature, clinicians treating heart tumors have nonetheless employed the critical organ dose constraints used in lung SBRT planning.[114-117] Mindful of the limited reported use of such high-dose, highly conformal techniques for heart tumors, it is conceivable that they may offer a means to safely escalate doses to those that would theoretically be optimal for tumor control. This is attractive, given the poor outcomes seen with current nonsurgical therapies.[111] Patients who may be the best candidates for using such novel approaches may also be those who have received prior radiotherapy and suffer an isolated in-field recurrence. Because using conventional radiotherapy techniques would likely exceed critical structure dose constraints, SBRT may make high-dose therapy feasible in the setting where otherwise anything other than palliative doses might not have been possible.

Particle-based therapies are also increasingly being investigated in the management of cancers because of their physical properties, which might provide better sparing of normal tissues. A clinical report from Japan (see further in section “Results”) is an example of this modality for a heart malignancy, describing the use of carbon ion radiotherapy for a case of cardiac sarcomas that employed 64 Gy in 16 fractions over 4 weeks.[118]

Advanced technologies must be used with caution, however, because cardiac and respiratory motions introduce considerable uncertainty in tumor localization and predictability of dose delivery. In the setting of SBRT, normal tissue and tumor motion must be, therefore, effectively evaluated using 4DCT techniques. Image guidance (image-guided radiotherapy [IGRT]) at the time of delivery to further ensure targeting accuracy is also

critical. Alternative delivery approaches such as gating procedures may be considered to decrease positioning uncertainty and thus decrease the necessary target expansions for daily setup variations.[119] An advanced method of IGRT that has emerged in recent years is MR-guided radiation therapy, enabling direct visualization of the tumor during treatment, with excellent soft tissue resolution, which is particularly helpful for cardiac tumors. In addition to real-time tumor visualization, the MR-Linac system allows for adaptive radiation therapy planning, correcting for daily changes in position of the heart and surrounding structures. These advancements enable administration of higher doses of radiation to the tumor more safely, with more effective sparing of normal tissues. Several recent reports describe their experience with MR-guided SBRT.[120-123]

As a demonstration of different planning results, representative isodose distributions, and their corresponding dose-volume histogram data, for two primary cardiac tumors are shown in Figure 60.2 for a 3D conformal radiotherapy plan and in Figure 60.3 for an SBRT plan.

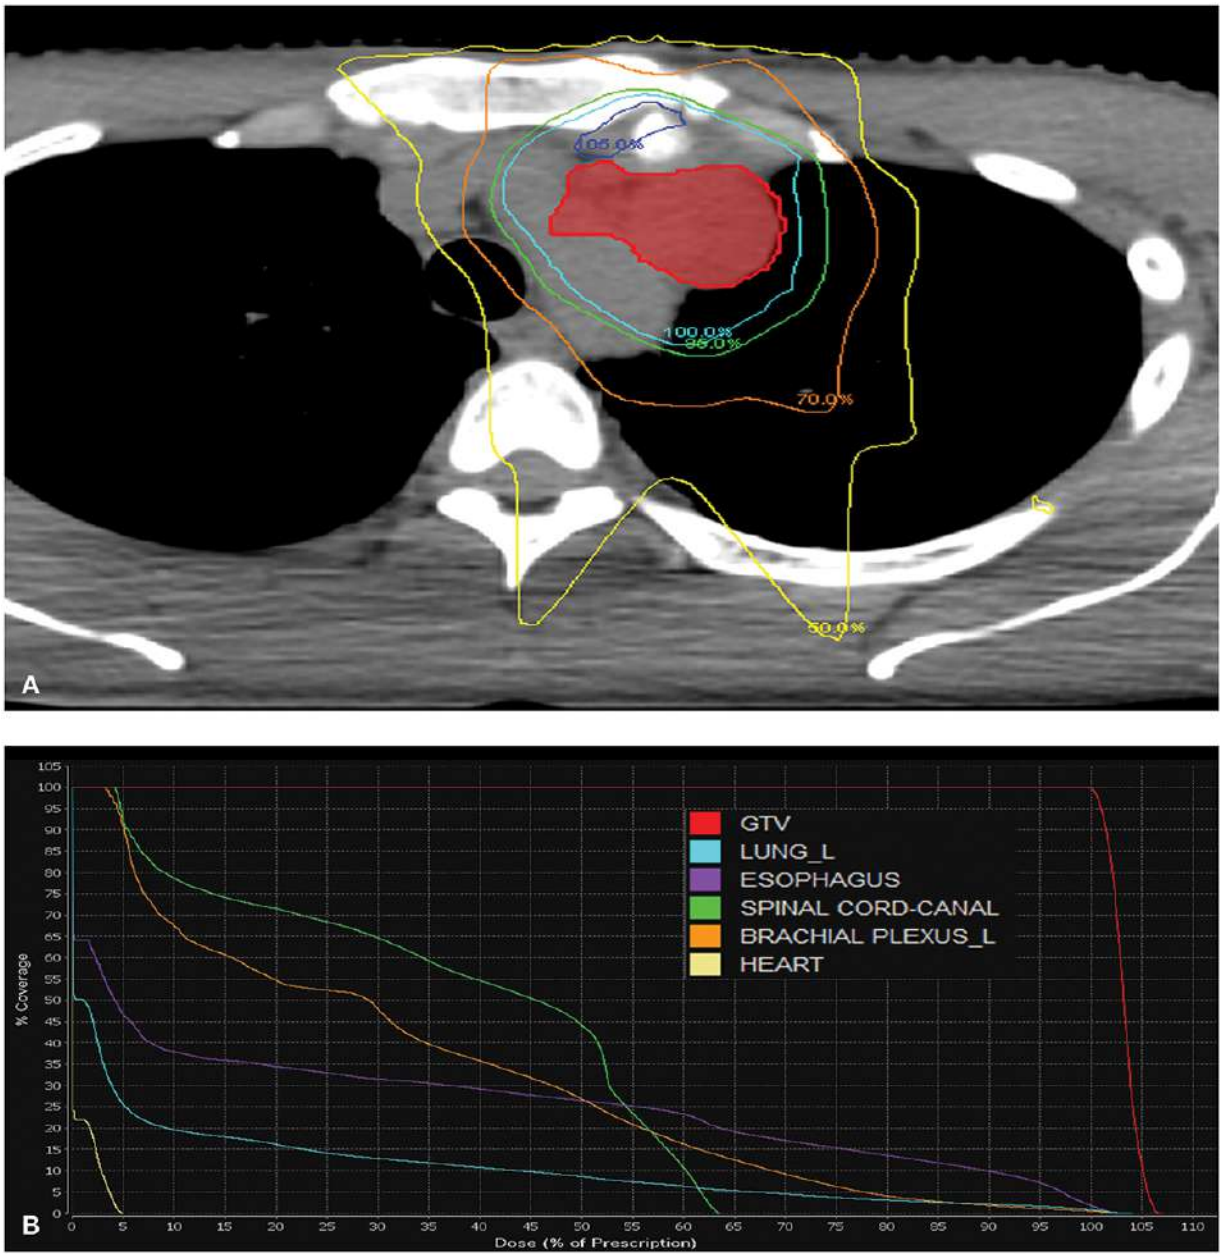

FIGURE 60.2 Sample three-dimensional conformal plan developed for a patient with an unresectable epithelioid hemangioendothelioma of the aortic arch (A) and corresponding dose-volume histogram data (B). GTV, gross tumor volume.

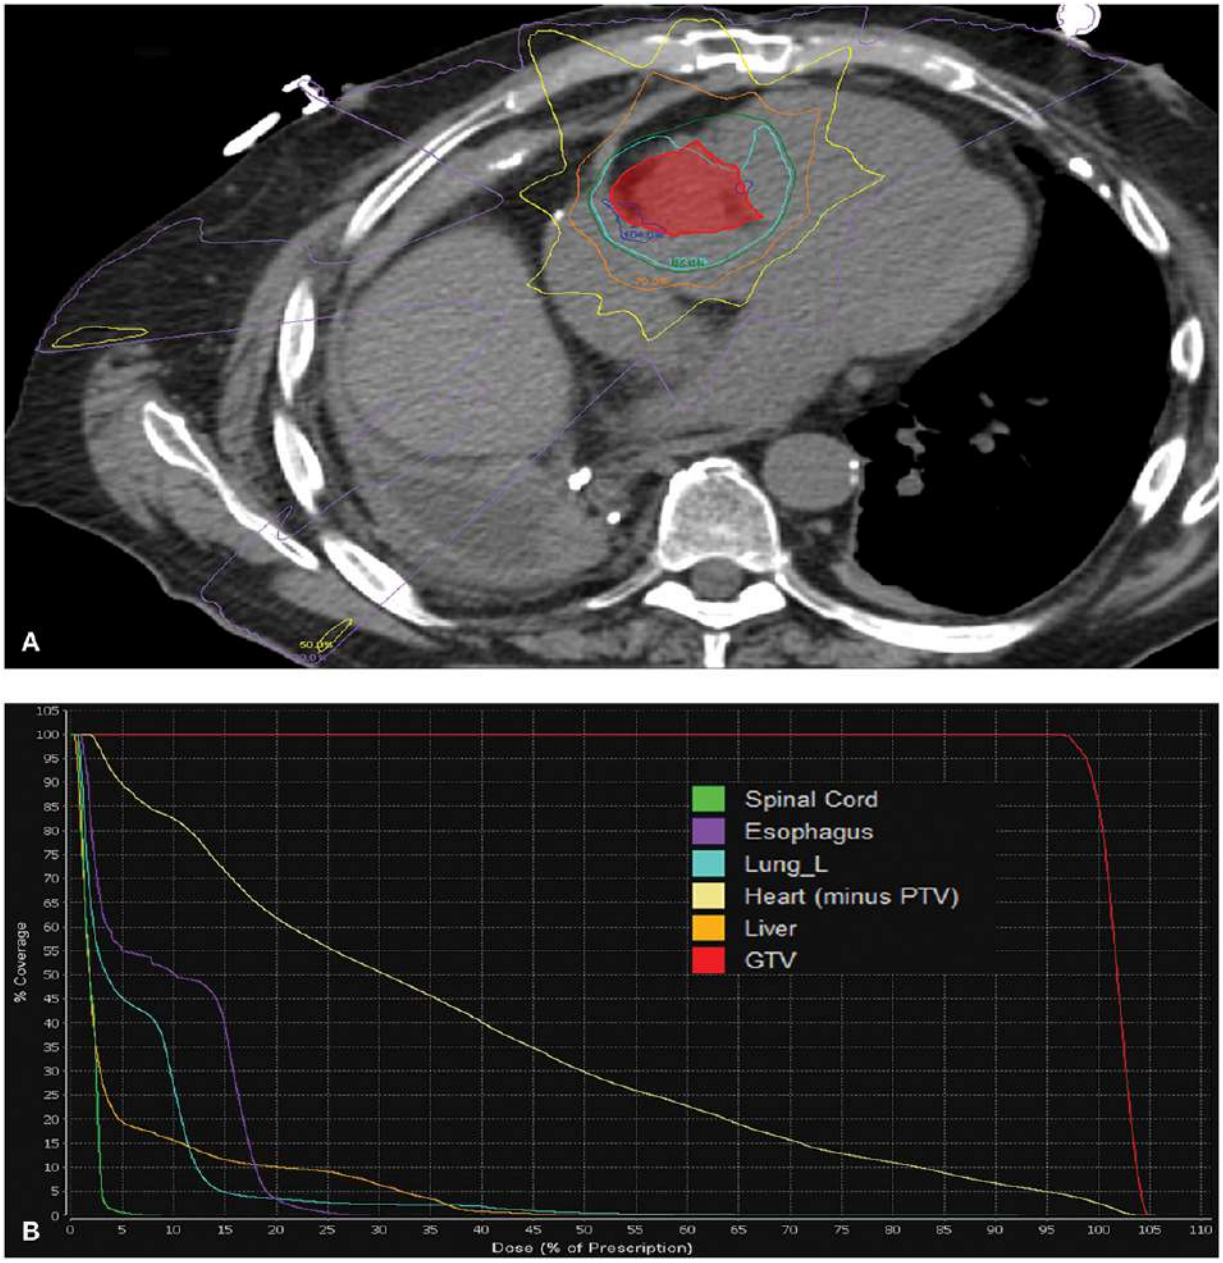

FIGURE 60.3 Sample stereotactic body radiotherapy plan developed for a patient with a local recurrence of a pleomorphic sarcoma of the pulmonary artery (A) and corresponding dose-volume histogram data (B). GTV, gross tumor volume; PTV, planning target volume.

As noted above, the total dose deliverable to any given cardiac tumor is primarily limited by heart and lung tolerance. Much of the available evidence on tolerance of the heart is based on patients previously treated for malignancies, such as Hodgkin lymphoma or breast cancer. In general, radiation-induced heart disease (RIHD) may manifest as pericarditis,

myocarditis, conduction defects, or coronary vascular disease.[124,125] Damage to the pericardium is most often observed clinically. Risk factors for developing RIHD include total dose, dose per fraction, irradiated volume, radiation technique, age at exposure, and use of concurrent or anthracycline-based chemotherapy. Emami et al[105] estimated the tolerance dose for the heart to be 40 Gy for the whole heart and 60 Gy for one-third of the heart based on a 5% complication rate of developing pericarditis within 5 years of treatment (TD5/5). However, current estimates of normal tissue tolerances tend to be more accurate, and administration of chemotherapeutic agents must also be taken into account as enhancing risk.[125] Most recently, Gagliardi et al[106] reviewed all the available data on cardiac toxicities and concluded that the whole-organ dose at which toxicity occurs in 50% of cases (TD50) is on the order of 48 to 50.6 Gy, but that side-effect profiles must be considered in relation to the probability of tumor control for the specific patient. Certainly, in aggressive tumors with poor outcomes, recurrence is equally or more morbid than the potential treatment-related toxicities, and this must be balanced and discussed with the individual patient. With respect to other normal structures relevant to 3D target planning for cardiac or GV tumors, Werner-Wasik et al[108] have reported that doses as high as 74 Gy with concurrent chemotherapy can be delivered safely to segments of the esophagus, but that no single best threshold is identifiable for limiting esophageal toxicity. In a comprehensive literature review on lung tolerances performed by Marks et al,[107] the authors recommended limiting the volume of lung receiving 20 Gy (V20) to ≤30% to 35%, and the mean lung dose to ≤20 to 23 Gy in order to minimize lung toxicity. All of these values are for patients receiving conventionally fractionated radiotherapy because as noted earlier, SBRT-based approaches employ a different set of normal tissue constraints.

RESULTS

Case reports and small retrospective series have been the primary means of understanding outcomes for this rare class of tumors. A classic example is the 1964 report by Sagerman et al,[126] which included one of the earliest descriptions of adjuvant radiotherapy for attempted cure. The patient was a 55-year-old woman with a primary cardiac fibromyxosarcoma. After

incomplete resection, she underwent external-beam radiotherapy to a dose of up to 75 Gy to the primary site, with proper shielding of the spinal cord. As a result of the use of lateral fields, the left lung received 35 Gy to a large volume. The patient was treated with prophylactic steroids to prevent radiation pneumonitis and fibrosis. She died 8 months later with brain and lung metastases. Autopsy revealed complete sterilization of the primary tumor.

Despite the use of aggressive treatment regimens including surgical resection, postoperative radiotherapy, and chemotherapy, the overall survival for patients with primary malignant cardiac tumors is poor, and this is true even in light of more recent reports that have suggested better outcomes with contemporary adjuvant radiotherapy or chemoradiotherapy.[22,90,91,93] Operative mortality is relatively common, at 8% to 9%, and is twice as high compared to that following resection of benign tumors.[88,127] The median survival in most surgical series is in the range of 9 to 12 months,[17,21,23,37,39,77,90,127,128] with outliers as low as 6 months[22,40,129] and as high as 23.5 months among patients who survived surgery in one of the most recent reports.[88] Putnam et al[23] reported a median survival of 11 months and a 2-year overall survival rate of only 14%. In this series, the authors also noted the importance of complete resection. For patients in whom complete resection was possible, the median survival was 24 months, compared with only 10 months for those with incomplete resection. Llombart-Cussac et al[77] also noted improved survival with complete resection (22 vs 7 months). Burke et al[22] reported significantly improved median survival of 12 months among patients who underwent adjuvant radiotherapy, chemotherapy, or both, compared with 3 months in those who did not have adjuvant therapy.

With respect to the use of definitive carbon ion radiotherapy in the treatment of a patient with cardiac angiosarcoma,[117] the tumor volume reduced by 86% following treatment and became negative on PET scan. After 18 months, the primary tumor remained controlled, but the patient had developed bilateral lung metastases 4 months after treatment.

Selected patients who develop recurrence after undergoing combined modality therapy may still benefit from aggressive management of their disease, with one author reporting an improvement in median survival from 25 months with no treatment to 47 months with resection, radiofrequency

ablation, or radiotherapy.[88] Others have shown similar benefits to this approach at the time of recurrences.[93]

The median survival for patients with metastatic disease to the heart is approximately 3 to 4 months, but rare cases of long-term survival, some as long as 3 years, have been documented and may be related to primary tumor histologic type and performance status.[80,81,130] Pericardiotomy or pericardial sclerosis appears to offer at least temporary control of tamponade and effusion in up to 90% of cases.[80,81] Palliative treatment with radiation is well tolerated and is effective in controlling cardiac tamponade in approximately 60% of patients. Cham et al[131] reported the results of radiotherapeutic palliation for 38 patients with secondary tumors of the heart and pericardium. Thirty-seven patients were noted to have pericardial involvement, nine also had invasion of the myocardium, and one had only endocardial involvement. The radiation dose was 25 to 30 Gy in 3 to 4 weeks for 32 patients. The dose was 15 to 20 Gy in 1.5 to 2 weeks for the remaining six patients, all of whom had lymphoreticular tumors. The overall response rate was 61%, with a median duration of response of 3 to 4 months. Lymphoreticular tumors had the best response rate (6/7 cases) followed by breast cancer (11/16 cases). Only 6 of the remaining 15 cases showed a response. Although the median survival among patients with metastases to the heart and pericardium is short, palliative efforts are not in vain because tamponade appears to be effectively controlled with these measures.

Among patients treated for GV tumors, median survival depends on the location, resectability, and grade of the primary tumor. Burke and Virmani[53] reported the median survival was 5 months for aortic sarcoma, 23 months for sarcoma of the pulmonary artery, and 37 months for sarcoma of the IVC. Two patients with sarcoma of the SVC were alive and without disease 10 and 72 months after treatment. Local relapse was documented in two patients, although metastatic disease occurred in 19 of 45 patients. The sites most commonly involved by metastases were the lung, liver, and bone. Involvement of the peritoneum, adrenals, kidneys, skin, and lymph nodes was also noted.

Treatment Sequelae

Late radiation-induced cardiac or pulmonary sequelae after the definitive treatment of cardiac tumors have not been well documented, probably as a result of the poor overall survival for these malignancies. In a recent report of 17 patients treated for different cardiac malignancies, with follow-ups ranging from 5 to 137 months, Lestuzzi et al[132] described late toxicities from cardiac radiotherapy in six of these cases. Three patients developed recurring atrial fibrillation, two segmental hypokinesis and one constrictive pericarditis. The cardiotoxic effects of doxorubicin have been well documented, and there is evidence for increased risk when it is given in conjunction with radiotherapy[125]; therefore, concurrent therapy should be avoided to the degree possible.

ACKNOWLEDGMENTS

The author gratefully acknowledges the critical contributions of Drs. Gregory Videtic and Roger Macklis, the authors of the previous edition of this chapter.

PART E

Breast

CHAPTER 61

Breast Cancer: Stage Tis

Alfredo I. Urdaneta, Todd Adams, David E. Wazer, and Douglas W. Arthur

Noninvasive carcinoma of the breast (stage Tis) includes Paget disease of the nipple and two histopathologic entities that are distinct in both their clinical presentation and biologic potential: lobular carcinoma in situ (LCIS) and ductal carcinoma in situ (DCIS). As a result of the increase in the use of mammography, these three histopathologic entities comprise a larger percentage of all breast cancer cases seen today. There remains considerable controversy regarding the optimal treatment approach, and as a consequence, treatment recommendations range from observation to breast conservation therapy to mastectomy. It is, therefore, important to understand the distinguishing pathologic appearances, biologic characteristics, and natural history of these three noninvasive breast disease entities to appropriately formulate coherent treatment recommendations.

LOBULAR CARCINOMA IN SITU

LCIS is characterized by multicentric breast involvement and consists of loose, discohesive epithelial cells that are large in size, variable in shape, and contain a normal cytoplasm-to-nucleus ratio.[1] The extent of involvement of the lobular lumen ranges from simple filling to moderate to severe distention with extension into the adjacent extralobular ducts.[2] As such, the lines of histologic delineation can become blurred between atypical ductal hyperplasia, LCIS, and, when ductal extension is seen,

DCIS. This overlap of histologic morphology may complicate the interpretation of studies from different institutions.[1-4]

LCIS has been reported to present with a multicentric distribution in up to 90% of mastectomy specimens, with bilateral involvement in 35% to 59%.[5-7] LCIS cells are commonly estrogen receptor positive, although overexpression of c-erbB-2 and p53 is uncommon.[4,8-10] The loss of E-cadherin is often observed,[8,11,12] and the absence of this adhesion molecule may explain the growth pattern seen with LCIS.

LCIS represents <15% of all noninvasive breast cancer.[13-15] Most women are premenopausal at diagnosis, with an average age of 45 years.[1,3,16] Risk factors for the development of LCIS correspond to those identified for invasive carcinoma.[17] Because the male breast lacks lobular elements, this entity has not been described in men.[3] As there are no clinical or mammographic indicators that are characteristic of LCIS, it is often detected as an incidental biopsy finding.[1,4] In a minority of cases, LCIS can be detected with mammographic calcifications; however, more commonly, calcifications are in adjacent tissue and are not histologically associated with LCIS.[18-20] In excisional biopsy specimens, DCIS or invasive carcinoma is frequently identified even when LCIS is the sole histologic entity seen on core biopsy.[21-23]

LCIS is considered a marker of increased risk for the subsequent development of invasive (usually ductal) carcinoma[3,13,14,16] that may be greatest for high-grade or more extensive lesions.[1,24] This risk appears to be nearly equal for both breasts.[25]

The question as to whether LCIS can serve as a direct precursor lesion to the subsequent development of invasive lobular carcinoma is unresolved. Some studies have suggested a clonal link of synchronously detected LCIS and invasive lobular carcinoma,[26] whereas others have not.[27] In an analysis of 182 patients with LCIS who were inadvertently enrolled on the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-17 trial for DCIS and treated with lumpectomy only, there was a 14.4% in-breast tumor recurrence (IBTR) rate and a 7.8% contralateral breast tumor recurrence rate after a median follow-up of 12 years.[28] Nine IBTRs (5% of the total cohort) were invasive carcinoma, and 17 (9% of the total cohort) were DCIS. Although the frequency of contralateral breast tumor recurrence rate was less than that of IBTR, the frequency of invasive contralateral breast

tumor recurrence rate (5.6% of the total cohort) was similar to invasive IBTR (5% of the total cohort). Of note, all of the IBTR were documented to be at the site of the index lesion, except for one, characterized as pure LCIS, that was found at a remote site.

The evidence associating LCIS with the subsequent development of invasive disease raises the question as to whether magnetic resonance imaging (MRI) would be a useful screening tool. Limited data exist to formulate a firm recommendation. In 2007, the American Cancer Society stated there were insufficient data; however, in 2009, a national expert consensus panel published guidelines reflecting a panel consensus opinion that annual breast MRI should be considered in patients with LCIS. Several studies have been published evaluating the role of MRI in patients with LCIS.[29-32] Each document revealed a small but defined 3.3% to 4.5% breast cancer detection rate and a positive predictive value of 31% based on biopsies performed supporting consideration for an annual MRI in this subset of patients. Management for LCIS depends on whether it is associated with another malignancy (DCIS or invasive carcinoma) or if LCIS is the sole histologic diagnosis. Approximately 10% of early-stage breast cancers have an associated component of LCIS.[33-35] The effect that LCIS has on the outcome of conservative management of early-stage breast cancer has been evaluated. Limited studies suggest that the presence of LCIS should influence treatment approach[36]; however, the most widely accepted treatment approach is to manage the breast according to the dominant malignant histology (DCIS or invasive carcinoma) and disregard the LCIS. In such circumstances, it is not necessary to pursue additional surgery to obtain clear margins for LCIS.[27,33,34,37,38]

If LCIS is the sole histologic diagnosis, treatment recommendations range from conservative to radical. When first described as an entity, the significance of LCIS was unknown and mastectomy was often performed.[39] The high frequency of contralateral breast involvement was subsequently used to justify contralateral biopsy and even bilateral mastectomy.[16,39] Observational studies after wide local excision alone have led to a better understanding of the natural history of this condition, and a more conservative approach is now commonly practiced.[3,13,14] In patients with LCIS as the sole histologic diagnosis, the most widely accepted clinical practice is close observation with regular physical examination and

mammographic surveillance.[3,13-15,28] There is no role for radiotherapy in the management of LCIS. The fact that LCIS commonly involves both breasts makes treatment with unilateral mastectomy both inadequate and illogic. Bilateral prophylactic mastectomy is likely excessive in all but those patients believed to be at highest risk: young age, diffuse high-grade lesion, and significant family history. A less radical prophylactic approach in high-risk patients is to consider the use of tamoxifen. Tamoxifen has demonstrated efficacy in the prevention of invasive carcinoma and, in the context of LCIS, has been shown to reduce risk by 56%.[40,41]

PAGET DISEASE

The clinical presentation of crusting and eczematous changes of the nipple-areola complex was first described in 1856. However, it was not until 1874 that the association with an underlying breast cancer was reported by Sir James Paget.[42] Paget disease of the nipple is characterized by the presence of Paget cells that are located throughout the epidermis.[43] Paget cells are large and have hyperchromatic, round to oval nuclei with abundant amphophilic to clear cytoplasm. Mitoses are commonly seen, and the cells can be found in clusters or individually in the basal layers. The fact that Paget disease is associated with an underlying malignancy in over 95% of cases has generated discussion regarding the origin of these malignant cells. The epidermotropic theory appears to be the prevailing opinion, with the belief that the disease originates from the underlying in situ or invasive disease. This is supported by histologic evidence of intraepithelial extension, immunohistochemical studies, and evidence suggesting that the epidermal keratinocytes release a motility factor, heregulin-*a*, that results in the chemotaxis of Paget cells that migrate to the overlying nipple epidermis.[44,45]

Paget disease is a rare entity representing less than 5% of all breast cancer cases[46,47] and is typically diagnosed in the fifth or sixth decade of life. Synchronous bilateral Paget disease and male Paget disease have been reported.[44,48,49]

Patients with Paget disease describe itching and burning of the nipple and areola. There is a slow progression toward a crusting eczematoid appearance that can extend to the periareolar skin. If neglected, bleeding,

pain, and ulceration can occur.[47,50] Alternatively, Paget disease can be asymptomatic and present as a pathologic finding after incidental surgical removal of the nipple-areolar complex.[51] The differential diagnosis includes superficial spreading melanoma, pagetoid squamous cell carcinoma in situ, and clear cells of Toker.[43,52] A palpable mass is detected in approximately 50% of patients at diagnosis; in over 90% of cases, this will be an invasive carcinoma. In contrast, if no palpable mass is detected, 66% to 86% will have an underlying DCIS. These associated malignancies are usually located centrally, although they can occur elsewhere in the breast.[44,47,53] Mammographic findings are frequent in the presence of a palpable mass; however, normal mammograms are reported in as many as 50% of cases.[47,54]

At presentation, clinical evaluation includes bilateral breast examination, mammography, and biopsy to confirm the diagnosis of Paget disease and to fully evaluate the extent of the associated malignancy. The prognosis does not depend on the diagnosis of Paget disease but rather on the associated malignancy. Therefore, local treatment, as well as systemic and regional nodal disease risk management, should be based on the associated disease.

Management of Paget disease continues to evolve. Mastectomy was employed in the past, although this has been increasingly supplanted by breast-conserving treatment.[55-58] The infrequent occurrence of this disease entity, the range of disease presentations (nipple involvement with or without an underlying mass and association with invasive vs noninvasive disease), and the variable extent of surgical resection have made the evaluation of treatment options difficult. Small series have described results with various forms of breast-conserving treatment, including wide local surgical resection alone, radiotherapy alone, and wide excision followed by whole-breast radiotherapy. Conservative surgery alone for Paget disease appears to be inadequate, with reported local recurrence rates of 25% to 40%.[5,57,59-62] The use of radiotherapy alone has been reported as achieving an 85% local control rate in a small series of patients with Paget disease of the nipple who presented without an associated palpable mass.[63] However, this approach has not been widely adopted because of the undefined histologic type and extent of the underlying disease leading to uncertainty in field design and total radiation dose.

The combination of limited surgical resection and postoperative radiotherapy appears to be the most practical breast-conserving approach.

Two studies have evaluated the combined use of surgery and radiotherapy in Paget disease of the nipple. The European Organization for Research and Treatment of Cancer (EORTC) Study 10873 was a multi- institutional registry trial that reported a 5-year local recurrence rate of 5.2%.[64] In this study, complete excision with tumor-free margins of the nipple-areolar complex and underlying breast tissue was followed by whole-breast radiotherapy. The median follow-up was 6.4 years, and most of these patients were found to have an underlying DCIS without a palpable mass. A separate study consisted of a seven-institution collaborative review of 36 patients with Paget disease without a palpable mass or mammographic density.[65,66] Patient follow-up was a median of 9.4 years. The extent of surgical resection varied as patients underwent complete (69%) or partial (25%) excision of the nipple-areolar complex and underlying breast tissue, with 6% reported as biopsy only. The final margin status was documented as negative in 56%, positive in 6%, and unknown in 39%. All received whole-breast irradiation, and most received an additional boost dose to the tumor bed. The actuarial rate of local failure as the only site of first recurrence was 9% at 5 years and 13% at both 10 and 15 years. Two additional patients recurred in the treated breast simultaneously with regional and distant metastasis at 69 and 122 months. Despite the differences in clinical, pathologic, and treatment factors, statistical evaluation did not identify any factors that significantly predicted for risk of local recurrence.

Current data suggest that a combined modality approach that conserves the breast is an appropriate alternative to mastectomy in properly selected patients with underlying noninvasive or invasive carcinoma of limited extent. As with any breast-conserving approach, patients with multicentric disease extension should be excluded. Surgical resection should include the nipple-areolar complex with microscopically clear margins surrounding both the Paget disease and the associated malignancy. Whole-breast radiotherapy is delivered with standard techniques. Management of regional nodes and the risk of systemic disease are dictated by the associated malignancy.

DUCTAL CARCINOMA IN SITU

Clinical Presentation and Epidemiology

DCIS is a neoplastic process that is confined to the ductal system of the breast and lacks histologic evidence of invasion. These cells neither disrupt the basement membrane nor involve the surrounding breast stroma. This entity lacks the ability to metastasize and is confined to the breast.[67-70] Axillary node involvement is rare (0%-5%) and most likely is associated with an undetected focus of invasive carcinoma.[71] Risk factors for the development of DCIS are the same as those identified for invasive carcinoma,[17] including family history, reproductive events such as delayed age of first live birth and nulliparity, history of benign breast biopsy, and dietary factors such as alcohol consumption. Before the use of screening mammography, DCIS typically presented as a palpable mass or nipple discharge. An invasive component commonly was found, and pure DCIS rarely was encountered. The widespread use of mammography now routinely detects DCIS smaller than 1 cm in diameter and results in breast cancer–free survival rates that approach 100%.[71]

With the increased use of mammography and as pathologists began to recognize DCIS as a pathologic entity, the incidence of DCIS has markedly increased.[72-74] The incidence of DCIS in the United States rose from 4,800 cases in 1983 to more than 50,000 cases in 2004, representing a 10-fold increase in only 20 years.[75] Of the close to 300,000 new breast cancers that occur annually, approximately 65,000 are anticipated to be noninvasive, of which 85% will be DCIS.[76] Of these, 90% are expected to be nonpalpable.[45] Studies have shown that the rate of screen-detected DCIS increases with age despite that it accounts for a progressively smaller proportion of the total breast cancers detected.[77] The rate of DCIS detection has been reported to increase from 0.56 per 1,000 mammograms among women aged 40 to 49 years to 1.07 per 1,000 mammograms among women aged 70 to 84 years.[77]

Imaging

Ninety-five percent of new cases of DCIS present with mammographic abnormalities, of which microcalcifications are most typical.[78] Noncalcified mammographic abnormalities make up the remaining findings, with asymmetric densities identified in 10%, dominant masses in 8%, and abnormal galactograms (performed for evaluation of nipple discharge) in

6%. Amorphous, coarse, fine pleomorphic, and fine linear are all forms of calcifications that can be related to DCIS. Linear and segmental calcifications are considered suspicious distribution and can be associated with DCIS in up to 80% of cases.[79] Linear and branching calcifications are frequently associated with high-grade DCIS and necrosis, whereas fine and granular calcifications are associated more commonly with low-grade DCIS[80-83] (Figure 61.1A,B).

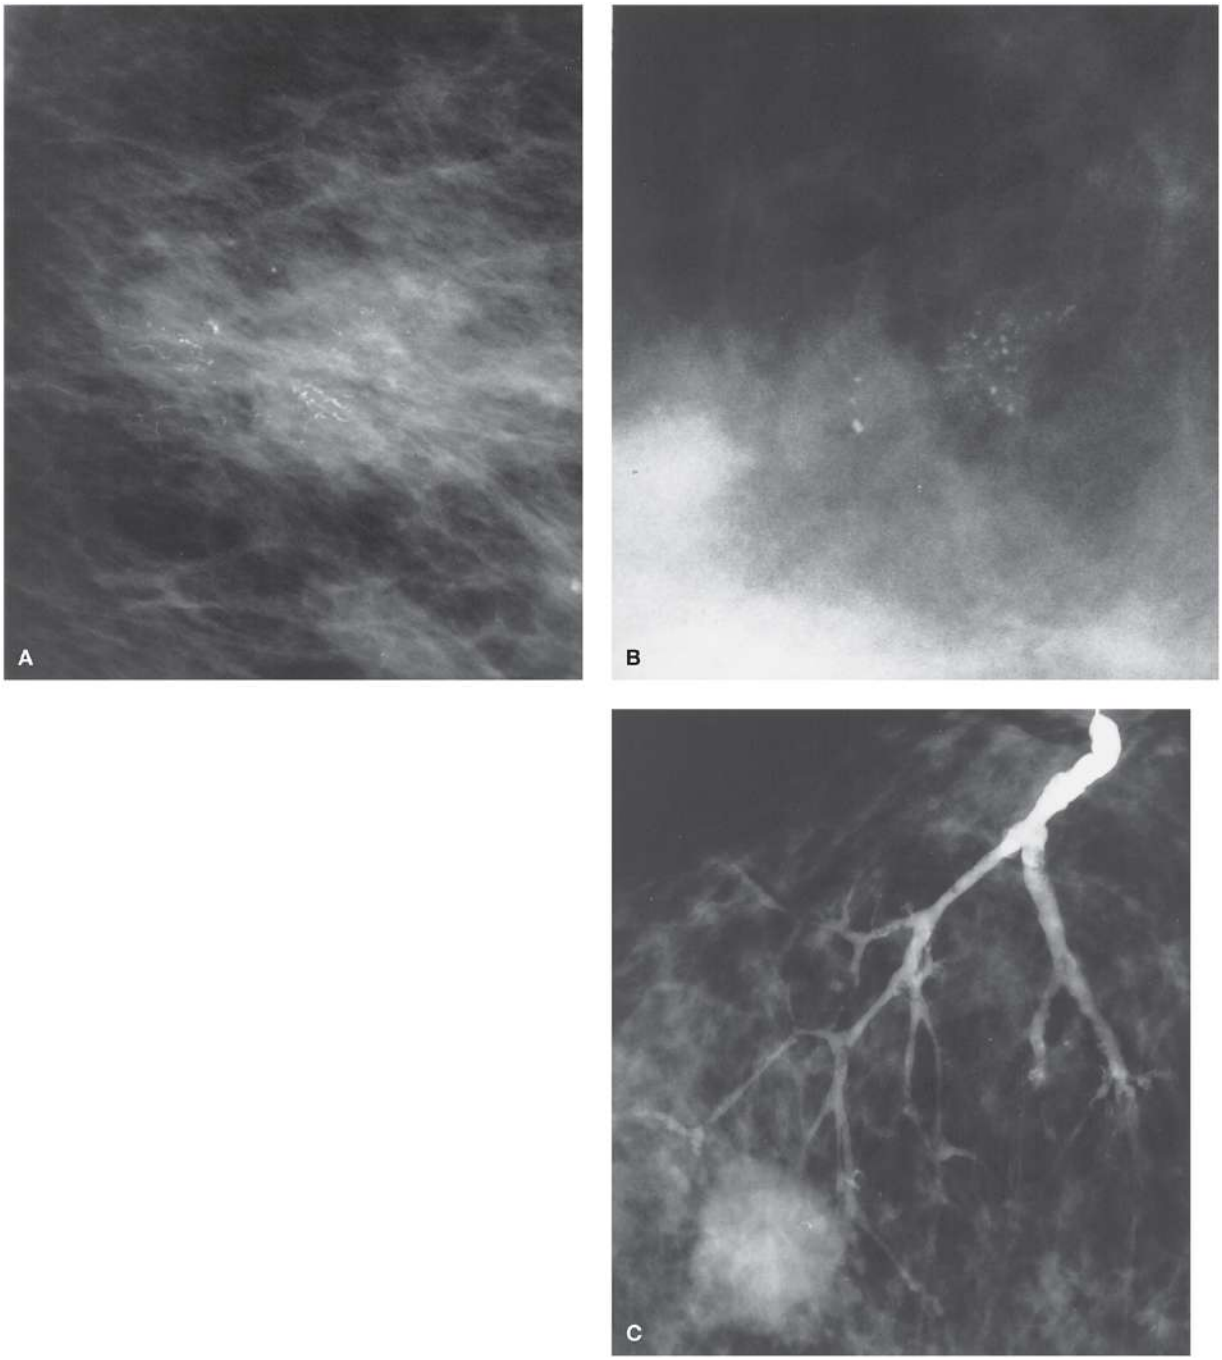

FIGURE 61.1 A. Linear and branching calcifications frequently associated with high-grade ductal carcinoma in situ (DCIS). B. Fine and granular calcifications commonly associated with low-grade DCIS. C. Galactogram with the multiple filling defects associated with DCIS.

Initial evaluation should include magnification views that allow for complete characterization of mammographic findings and determination of the need for biopsy. The extent of the lesion as determined

mammographically may be used as a guide for excision; however, the size is typically underestimated by 1 to 2 cm when compared with pathologic measurements.[81,84,85] Prior to 2000, MRI was not considered a useful imaging modality for DCIS. However, change in MRI imaging acquisition and an improved understanding of non–mass-like malignant lesion imaging characteristics now has MRI considered a valuable imaging tool for DCIS.[86] MRI now presents as the imaging modality with the highest sensitivity to detect DCIS, particularly high-grade DCIS. MRI has additionally been shown to better establish the extent of DCIS, thus aiding treatment planning.[87] In cases that present with nipple discharge and a negative mammogram, galactography may be helpful in determining the likelihood of underlying DCIS versus papilloma[88] (Figure 61.1C).

Pathology and Biology

The histologic diversity of DCIS can lead to difficulty in distinguishing it from other pathologic entities.[69,70] The spectrum of DCIS extends from noncomedo, low-grade DCIS that can be similar in appearance to atypical ductal hyperplasia to comedo, high-grade DCIS. In addition, DCIS can extend into lobules, making it difficult to distinguish from LCIS.[89] Traditionally, classification of DCIS has followed its architectural or morphologic appearance. The five subtypes of DCIS are comedo, solid, cribriform, micropapillary, and papillary,[69,70,90] and it is common to encounter a mixture of subtypes within the same specimen.[88] The characteristic features of each type are shown in Figure 61.2. Less common subtypes have been described and include apocrine, neuroendocrine, signet cell cystic hypersecretory carcinoma, and clinging DCIS.[91]

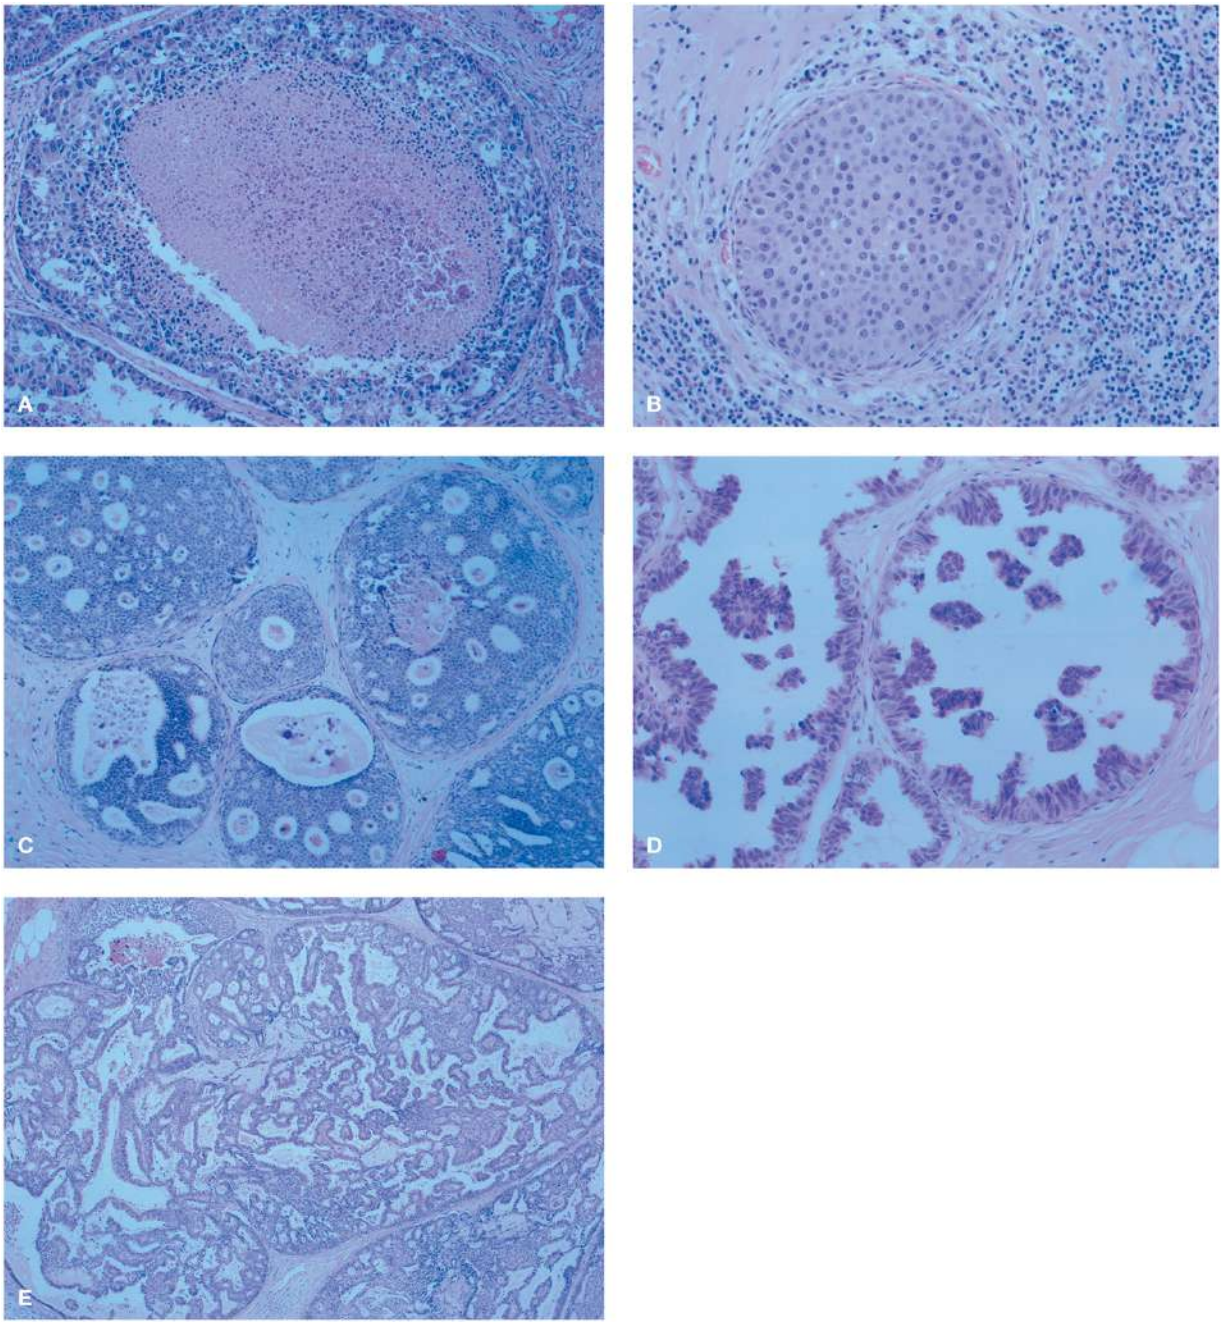

FIGURE 61.2 A. Comedo ductal carcinoma in situ (DCIS) characterized by central necrosis, large cells, and poorly differentiated nuclei. B. Solid DCIS characterized by ductal spaces filled with neoplastic cells with limited necrosis. C. Cribriform DCIS characterized by microlumens and fenestrations. D. Micropapillary DCIS characterized by intraluminal projections with no fibrovascular core. E. Papillary DCIS characterized by intraluminal projections with a fibrovascular core.

In 1997, a consensus conference committee was convened to reach an agreement on the pathologic classification of DCIS and the identification of

specific features that may convey prognostic significance.[68] Methods of processing and evaluating the pathologic specimen were also addressed. Rather than endorsing any specific classification system, the committee recommended and described features that should be documented for each case of DCIS, thus separating out important pathologic components and providing a comprehensive evaluation of the pathologic findings. These features include nuclear grade, the presence of necrosis, polarization, and architectural pattern(s). The committee extended its recommendations to include margin status, lesion size, extent of microcalcifications, and correlation between specimen x-ray and mammographic findings. The DCIS Working Party of the EORTC arrived at similar conclusions and emphasized the importance of cytonuclear and architectural differentiation.[92]

Three-dimensional examination and reconstruction techniques have resulted in a better understanding of the enormously complex structure of the mammary duct-lobular system and the patterns by which DCIS can spread within the breast[6,84,93] (Figure 61.3). Knowledge of the anatomy and distribution of DCIS within the mammary ductal tree can be useful in selecting patients for breast conservation and ensuring maximal surgical clearance of the lesion while preserving an acceptable cosmetic result. For example, Ohtake et al[6,84] studied the duct-lobular system with computer graphic reconstruction and found that the breast consists of 16 to 24 duct-lobular systems, each culminating in a corresponding collecting duct at the nipple. They also identified ductal anastomoses that established a connection between the various ductal-lobular units and provided a potential pathway for tumor extension and subsequent diffuse involvement.[6,84] Their proposed model for the development of widespread intraductal tumor extension within the breast is seen in Figure 61.4.

Faverly et al[94] have described the DCIS growth pattern within the ductal tree and the implications for surgical excision. The growth patterns documented include unicentric (one area only), multicentric (two distinct areas separated by >4 cm), continuous (extension along ductal system without gaps), and discontinuous or multifocal (two or more areas separated by <4 cm). They found that in mammographically detected DCIS, a multicentric growth pattern was rare (<2%), with most cases showing an even distribution between discontinuous and continuous growth patterns. Of cases with a discontinuous growth pattern, 63% had foci separated by gaps that measured under 5 mm, 83% had foci separated by less than 10 mm, and only 8% had foci separated by more than 10 mm. There was a correlation between differentiation and growth pattern such that 90% of poorly differentiated DCIS showed a continuous growth pattern, whereas 70% of well-differentiated DCIS had a discontinuous growth pattern. Based on these findings, the authors concluded that a 1-cm margin of normal tissue around the lesion would lead to complete surgical clearance of histologically evident DCIS in 90% of cases. DCIS is a precursor lesion to invasive ductal carcinoma and exists along an evolutionary continuum that starts with benign breast tissue and ends with an invasive breast carcinoma.[95] This concept has been validated in several ways. For years,

pathologists have recognized and documented confirmation of a histologic progression from benign breast cells to invasive breast cancer. The evolutionary concept is supported by the recognized association between the presence of DCIS and the subsequent increased risk of developing an invasive breast cancer.[75,96,97] In some series, a 10-fold risk of developing an invasive lesion has been reported. At the biologic and molecular levels, many studies have demonstrated that DCIS and invasive breast cancer are highly similar at the cellular and molecular levels.[95,98-102] These similarities have now been shown to extend to global gene expression profiles as DCIS has been classified under luminal, basal, and erbB2 intrinsic molecular subtypes.[98,103] In addition, these shared identical genetic abnormalities between DCIS and synchronous invasive breast cancer demonstrate a clonal relationship of biologic progression.[75,96,97,104] The biologic evolution from benign breast cells to invasive breast cancer occurs through highly diverse genetic mechanisms.

Genetic and molecular differences have been documented that differentiate DCIS from normal breast tissue. Genetic alterations have been evaluated with an analysis of loss of heterozygosity that has demonstrated gain or loss of multiple loci.[96,97,104-106] Loss of heterozygosity is not seen in normal breast tissue. The frequency of loss of heterozygosity correlates with histologic progression of breast tissue from benign to malignant. Loss of heterozygosity is seen in approximately 50% of atypical ductal hyperplasia. Among specimens harvested from cancerous breasts, 77% of noncomedo and 80% of comedo DCIS lesions share loss of heterozygosity with the synchronous invasive lesion in at least one locus.[104]

Molecular markers have been studied in DCIS and are found to have a heterogeneous distribution of expression.[75] The estrogen receptor is present in 70% of DCIS; however, the rate of expression is higher in low-grade lesions (90%) than in high-grade lesions (25%). This association with histologic grade is reversed for the rate of overexpression of HER2/neu proto-oncogene and the p53 tumor suppression gene. Approximately 50% of all DCIS lesions have overexpression of HER2/neu, and in 25%, the p53 tumor suppressor gene is also detected. Both of these molecular markers are noted in less than 20% of low-grade lesions but are present in approximately two-thirds of high-grade lesions.

Alterations in the surrounding breast parenchyma may also be seen with DCIS. High-grade DCIS, in particular, has been associated with the breakdown of the myoepithelial cell layer and basement membrane surrounding the ductal lumen,[107] proliferation of fibroblasts, lymphocyte infiltration, and angiogenesis in the surrounding stromal tissues.[108,109] Whether these stromal changes reflect important steps that facilitate primary tumor transformation or secondary alterations in response to ductal epithelium that is being transformed is unknown. Quantitative changes in the expression of genes related to cell motility, adhesion, and extracellular matrix composition—all of which may be related to the acquisition of invasiveness—occur as DCIS evolves into invasive carcinoma.[110]

Data suggest that DCIS represents a stage in the development of breast cancer in which most of the molecular changes that characterize invasive breast cancer are already present, although the lesion has not yet assumed a fully malignant phenotype. A final set of events, which probably includes gain of function by malignant cells and loss of function and integrity by surrounding normal tissues, is associated with the transition from a preinvasive DCIS lesion to invasive cancer. Most, if not all, clinically relevant features of breast cancer, such as hormone receptor status, the level of oncogene expression, and histologic grade, are probably determined by the time that DCIS has evolved.[111-114]

An occult microinvasive tumor (one that does not exceed 0.1 cm in diameter) may be seen with some cases of DCIS. Such cases are classified as *microinvasive breast cancer*[115] and are generally treated according to the guidelines for invasive disease. Occult microinvasive tumors are most common in patients with DCIS lesions that are more than 2.5 cm in diameter,[116] those presenting with palpable masses or nipple discharge, and those with high-grade DCIS or comedonecrosis.[88,117]

Natural History of Ductal Carcinoma In Situ

The overall incidence of DCIS in the general population is unclear. In an attempt to address this incidence, a small number of autopsy studies have been reported. One series examined 185 randomly selected breasts from 101 women in which a subgross sampling technique was used,[118] and one or more foci of DCIS were found in 6% of cases. A review of seven autopsy

series of women not known to have breast cancer during life showed a median prevalence of DCIS of 8.9% (range, 0%-14.7%).[119] The fact that some autopsy series document a greater incidence of DCIS in asymptomatic women than most clinical series suggests the possibility that DCIS is either underdiagnosed or that many cases are not clinically significant.

A primary consideration in the natural history of DCIS is the risk of progression to invasive carcinoma. The published evidence on the clinical course of untreated DCIS is sparse because it has been recognized as a distinct entity for only a relatively brief period, having been considered rare before the widespread use of mammography and having been treated most frequently by mastectomy. Those cases for which long-term follow-up data are available were grossly palpable DCIS—a form that may not be equivalent to the mammographic DCIS that is seen more commonly today. The few published long-term follow-up studies of DCIS after only biopsy document an overall incidence of subsequent invasive carcinoma of over 36%.[7,120-122] Most of these subsequent malignancies occur within 10 years, although as many as one-third may develop after 15 years.[7,120]

Women with DCIS in one breast are at risk for a second tumor (either invasive or in situ) in the contralateral breast[123]; the rate at which such tumors develop is similar to that among women with primary invasive breast cancer at approximately 0.5% to 1% per year.

DCIS is a part of the breast/ovarian cancer syndromes defined by BRCA1 and BRCA2, with mutation rates similar to those found for invasive breast cancer.[124] These findings suggest that patients with DCIS with an appropriate personal or family history of breast and/or ovarian cancer should be screened and followed according to the same high-risk protocols as developed for invasive breast cancer.

Treatment Options for Ductal Carcinoma In Situ

Prognostic Factors and Their Interpretation

The goal of treatment with DCIS is prevention of local recurrence, with particular emphasis on the prevention of invasive breast cancer. Treatment decisions are largely based on information provided by mammography and, most especially, pathologic evaluation of the biopsy specimen. As such, in the consideration of treatment options, it is important for the clinician to be

aware of some of the technical limitations associated with the clinical and histopathologic assessment of DCIS.

Studies performed during the past two decades clearly have suggested that DCIS is not a single disease. Rather, DCIS encompasses a diverse group of lesions that differ with regard to their clinical presentation, mammographic features, extent and distribution within the breast, histologic characteristics, and biologic markers. Moreover, clinical follow-up studies have indicated that these lesions vary in their propensity to recur or progress to invasive breast cancer. As a consequence, a significant proportion of patients diagnosed with DCIS can be treated adequately with breast-conserving therapy (ie, excision with or without radiation therapy). Which patients with DCIS can be treated safely with excision alone and which patients require radiation therapy after excision are pressing clinical questions. Attempts to resolve this issue have focused on the identification of risk factors for local recurrence after breast conservation therapy for DCIS. Through multiple retrospective studies, several factors have been identified that may be important in defining local failure risk. These include symptomatic presentation,[125,126] lesion size,[126,127] histopathologic subtype,[125] nuclear/cytologic grade,[126,128,129] central necrosis,[126,128,129] margin status,[126,130,131] and patient age.[125,131-133]

The relative importance of any histopathologic factor in predicting the probability of local recurrence and in turn selecting the appropriate therapeutic option for a given patient is unclear. This is partly the result of the inherent difficulty associated with the establishment of standardized and reproducible systems of pathologic classification, including such apparently straightforward assessments of grade, margin width, and lesion size.

Efforts to classify DCIS have been based primarily on the nuclear grade of the lesion and/or the presence or absence of necrosis. Several studies have shown that there is an association between high nuclear grade and/or necrosis and the risk of local recurrence and progression to invasion.[126,128,129] Although the criteria for histologic grading systems have been published, there are limited data regarding the ability of pathologists to apply them in a reproducible manner.

Several studies have shown that the status of the microscopic margins appears to be important in predicting the likelihood of recurrence in the breast for patients with both invasive breast cancer and DCIS treated with

breast- conserving therapy.[126,130,131] In 2016, a consensus guideline was published from the Society of Surgical Oncology, the American Society for Radiation Oncology, and the American Society of Clinical Oncology (ASCO) on appropriate margins for breast-conserving surgery with whole-breast radiation in DCIS.[134] The consensus panel recommended a 2-mm margin as the standard adequate margin and clinical judgment be used to determine the need for further surgery in patients with negative margins of less than 2 mm. However, there are numerous technical problems in the evaluation of margins of breast excision specimens. First, if a specimen is removed in more than one fragment, the margins cannot be evaluated. Second, there is no standardized method for sampling or reporting margins, and this process is subject to sampling error. Finally, it is often difficult to provide an accurate assessment of the margin width for patients who undergo a reexcision because the initial biopsy site can be eccentrically located in the surgical specimen. Furthermore, the group at MD Anderson analyzed the contemporary outcomes of women with DCIS managed with breast conservation surgery with or without adjuvant radiation therapy and the impact of margin width. Over 1,500 women were identified with a median follow-up of 8.9 years. The researchers found no difference in 10-year locoregional recurrence rates (LRRs) in patients who underwent radiation therapy with or without margins larger than 2 mm (4.8% vs 3.3%); however, in women who did not undergo adjuvant radiation therapy, there was a significant difference in 10-year LRR (5.4% vs 30.9%) in favor of wide negative margins.[135]

Most DCIS lesions present as a nonpalpable, grossly inapparent mammographic abnormality, which can make accurate determination of the size or extent of the lesion difficult (Figure 61.5). The modalities available to assess the size of the lesion are mammography, MRI, and pathologic examination. Mammography frequently will underestimate the pathologic extent of DCIS, particularly for well-differentiated lesions in which substantial areas of the tumor may not contain microcalcifications. MRI has been demonstrated to more accurately estimate the disease extent; however, it should be recognized that pathologic assessment of lesion size can be difficult. Macroscopic examination of a specimen containing DCIS rarely reveals a grossly evident tumor that can be measured. Therefore, the

assessment of the size of the lesion must be estimated from histologic sections.

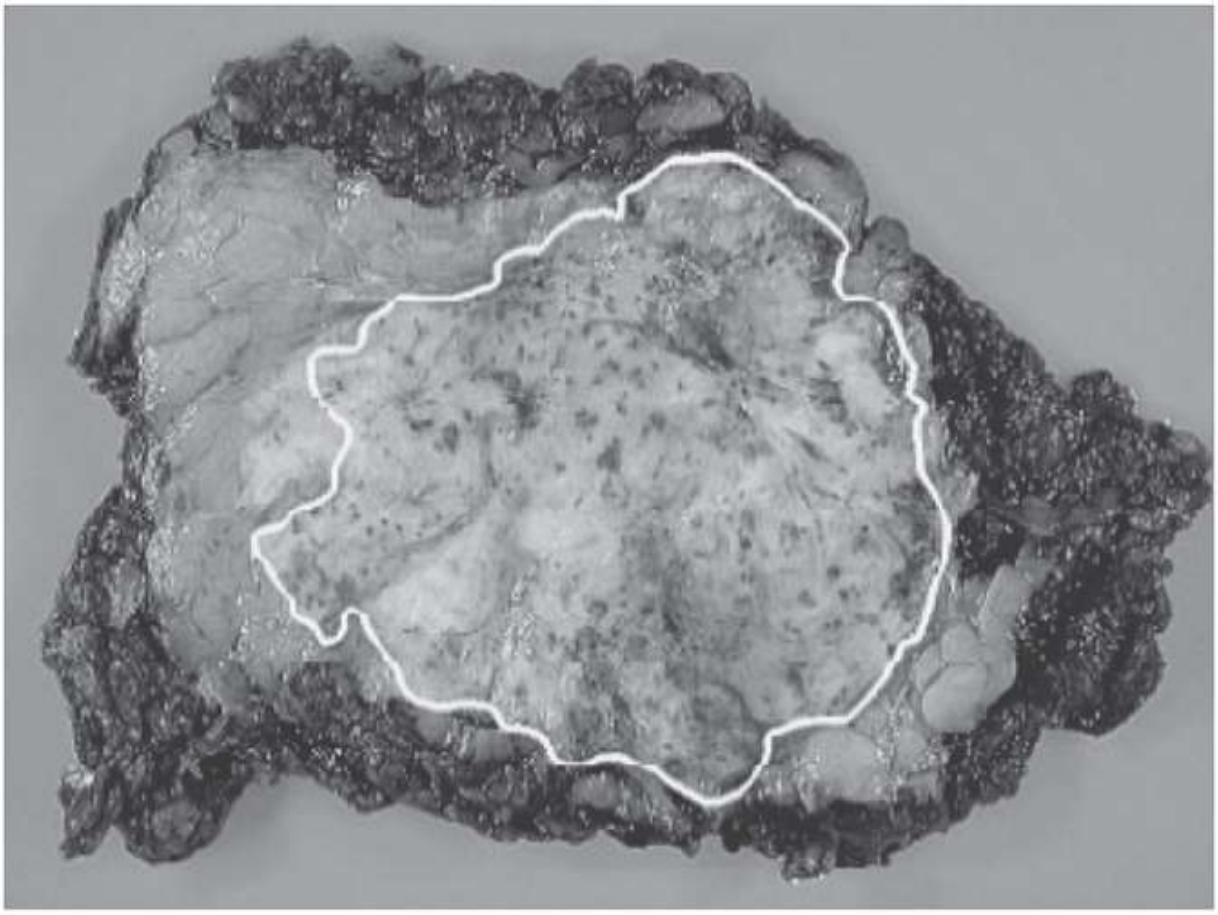

FIGURE 61.5 Extensive ductal carcinoma in situ (DCIS) in a mastectomy breast sectioned in the coronal plane. Every parenchymal structure (duct or lobule) within the marked perimeter is colonized by DCIS; outside that boundary there is none. (From Going JJ, Moffat DF. Mastectomy for Ductal Carcinoma In Situ

Mastectomy was the standard treatment of DCIS through the first four decades of its recognition as a distinct histopathologic entity. Mastectomy is a highly effective treatment for DCIS, with a locoregional control rate of 96% to 100% and cancer-specific mortality rates of 4% or less.[37] No randomized study has compared mastectomy with breast conservation

treatment for DCIS. Therefore, the relative outcomes for mastectomy and breast conservation treatment can be estimated only by reviewing nonrandomized, retrospective studies. Local treatment failure after mastectomy[136] may occur because of unrecognized invasive carcinoma that results in local recurrence or distant metastasis, or it may be the result of incomplete removal of breast tissue with the subsequent formation of a new primary tumor.

Data from some surgical trials[137] and large treatment registries[138] suggest that the rates of local or regional recurrence are significantly lower after mastectomy than after breast-conserving surgery, although there have been no significant differences in overall survival. Metastatic breast cancer can follow the recurrence of an invasive tumor or the development of invasive cancer in the contralateral breast. However, death related to breast cancer within 10 years after the diagnosis of DCIS occurs in only 1% to 2% of all patients, irrespective of whether mastectomy or breast-conserving surgery was performed.[138]

The role of postmastectomy chest wall radiation following mastectomy or skin-sparing mastectomy and close pathologic margins has been debated in the literature but is not presently considered the standard of care. Some studies show an increased risk of chest wall failure in selected cases of high-grade DCIS undergoing mastectomy with pathologic margins smaller than 1 mm, leading to a routine recommendation of postmastectomy radiation in these cases.[139] The empiric use of a close or positive margins as a trigger for postmastectomy radiation has been challenged, providing a strong argument against postmastectomy radiation.[140] This retrospective review evaluated the risk of chest wall recurrence following mastectomy, specifically looking at skin-sparing mastectomy and high-risk features of high-grade and close margins. In this series, the overall risk of chest wall recurrence was rare at 1.7% and only 3.3% for high-grade DCIS. Margins less than 5 mm were not at increased risk. It was concluded that the chest wall failure rate was sufficiently low that a routine recommendation of postmastectomy radiation DCIS with high-risk features was not warranted. Furthermore, a population-based analysis using the Ontario Cancer Registry identified more than 1,500 women with DCIS who underwent mastectomy without radiotherapy. With a median follow-up of 10 years, the overall rate of chest wall recurrence was 2.3% with no significant difference seen

between positive, close (2 mm or less), or negative margins. Univariate and multivariate analysis failed to show a significant effect of age, nuclear grade, necrosis, or multifocality.[141]

Recent interest has surged regarding active surveillance in women with low-risk DCIS. The COMET trial is comparing guideline concordant care, which includes surgery with or without radiation therapy and choice of endocrine therapy versus active surveillance with choice of endocrine therapy in women aged 40 years or above, with a diagnosis of grade I/II DCIS with estrogen and/or progesterone receptors present and lack of comedonecrosis. Primary end point is rate of ipsilateral invasive disease development at 2 years. Three additional trials, LORIS of the United Kingdom (completed accrual in 2020), LORETTA from Japan, and LORD sponsored by the EORTC continue accrual with similar randomizations.

Breast Conservation for Ductal Carcinoma In Situ

Four prospective randomized studies of excision only versus excision plus breast irradiation for DCIS have been performed with reported results, and all have shown that the rate of local recurrence was reduced with the addition of radiation (Table 61.1). The NSABP B-17 trial[142,143] consisted of 813 patients who were stratified by age (≤49 vs >49 years), DCIS versus DCIS plus LCIS, method of detection, and whether an axillary dissection was performed. Tumor size was determined by mammogram, gross pathologic measurement, or clinical examination. Of the patients enrolled, 83% had nonpalpable tumors. The 17.5-year rate of local recurrence was 19.8% with radiation and 35.9% without radiation. The average annual incidence rates of ipsilateral noninvasive recurrences and ipsilateral invasive recurrences were reduced with breast irradiation by 47% and 52%, respectively.[144] An analysis of clinical variables showed that microcalcifications extending beyond a maximum dimension greater than 1 cm were associated with an elevated risk of breast recurrence. A central pathology review was performed, including a multivariate analysis of histopathologic variables (Table 61.2). Comedonecrosis in patients treated on NSABP B-24 did not correlate with an increased risk of IBTR; however, comedonecrosis did relate to the risk of DCIS-IBTR. The prognostic value of margin status (free vs unknown/involved) depended on the treatment

group and was greater among those treated with lumpectomy and radiotherapy alone as compared to those who also received tamoxifen.[132,143,144]

The EORTC 10853 trial[145,146] randomly allocated 1,010 patients with 5 cm or smaller DCIS and negative margins to excision versus excision plus breast irradiation. Lesions were nonpalpable in 79% of patients, and the mean maximal tumor diameter was approximately 2 cm. The 15-year rate of local recurrence was 18% for patients treated with radiation, as compared with 31% for patients treated without radiation ($P < .0001$). At a median follow-up of 15.7 years, radiation therapy resulted in risk reduction for both invasive and noninvasive breast relapse of 48%. As with the NSABP B-17 study, a central pathology review was performed.[125,145,146] In a multivariate analysis, factors associated with an increased risk of local recurrence were no older than 40 years of age, clinically symptomatic presentation (nipple discharge or palpable mass), intermediate or poorly differentiated DCIS, solid/comedo and cribriform histologic growth pattern, involved or uncertain margins, and treatment by local excision alone. The risk of DCIS recurrence was documented to be less following treatment of clinging/micropapillary DCIS; however, in this group, breast irradiation reduced the rate of invasive recurrence in over 50%. Although early publications suggested a relationship between histologic type and risk of distant metastasis and death, with additional follow-up, no statistically significant relationship is now appreciated.

The EORTC 10853 trial did not allow the identification of an appropriate margin width for treatment with or without radiotherapy because the eligibility criteria did not require reporting of the margin status. Nonetheless, the central review of cases did provide some information regarding the relative importance of surgical margin as related to local failure risk. A recurrence rate of 24% at 4 years was observed in cases with close/involved margins after excision alone. Radiotherapy was not adequate to compensate for involved margins because even with the application of

irradiation, the recurrence rate was 20% in this group.[147] These data and others[126,127,130,131] are strongly suggestive that obtaining a microscopic complete excision is essential for optimal local control in breast- conserving therapy for DCIS. Of further note, even in the group of DCIS cases for which margins could be considered optimal (ie, those patients who underwent a surgical reexcision in which no residual DCIS was found), a 4-year local recurrence rate of 18% was observed when these patients were treated with surgery alone.[125]

The United Kingdom, Australia, and New Zealand (UK/ANZ) DCIS trial was a randomized trial investigating the role of adjuvant radiotherapy.[148,149] With a 2 × 2 factorial protocol design, the aim of this study was to compare excision alone versus excision plus tamoxifen versus excision plus radiotherapy versus excision plus radiotherapy and tamoxifen. Tamoxifen was prescribed at 20 mg/day, and radiotherapy was delivered through whole-breast tangential fields to a total dose of 50 Gy. A boost was not recommended, and elective decision to withhold or provide one of the treatments was permitted. Data have been reported with a median follow-up of 12.7 years. The addition of radiotherapy was demonstrated to reduce the risk of IBTR. Of the 1,030 patients randomized between no radiotherapy versus radiotherapy, ipsilateral IBTR was 19.4% versus 7.1%, respectively ($P < .0001$). The addition of tamoxifen offered no benefit toward overall ipsilateral local control when administered in addition to radiotherapy; however, tamoxifen reduced the ipsilateral recurrence rate of DCIS (but not invasive carcinoma) in the absence of radiotherapy.[148,149]

The Swedish Breast Cancer Group SweDCIS study was a randomized trial that enrolled 1,067 patients from 1987 to 1999, with 1,046 of these patients followed for a median of 17 years. Patients were randomized between lumpectomy followed by radiotherapy and lumpectomy only for the treatment of DCIS.[150] Following sector resection, microscopically clear resection margins were not required, and 50 Gy in 25 fractions to the whole breast was delivered in the majority of patients. A split course, 54 Gy in 2 Gy fractions, delivered in two treatment series separated by a 2-week break was allowed. No boost dose was delivered. The in-breast failure risk reduction for the addition of radiotherapy was 12% at 20 years (95% confidence interval [CI] 6.5%-17.7%) with a relative risk reduction of 37.5% (95% CI 0.30-0.54). Detailed analysis did not identify any patient or

tumor characteristic subgroups, which did not benefit from the addition of postoperative radiotherapy. In addition, despite combining factors entailing a low risk of recurrence without radiotherapy, a low-risk group without significant benefit from the addition of radiotherapy could not be identified.

A meta-analysis was completed utilizing the individual patient data from each of the four randomized trials discussed above, and an overview of results was reported by the Early Breast Cancer Trialists' Collaborative Group.[151] With a total of 3,729 women eligible for analysis, it was demonstrated that radiotherapy reduced the absolute 10-year risk of any ipsilateral breast event (recurrent DCIS or invasive disease) by 15.2% (standard error 1.6%, 12.9% vs 28.1%, $P < .00001$). This analysis further establishes strong and consistent evidence that the addition of radiotherapy following breast- conserving surgery for DCIS approximately reduces the risk of IBTR by 50%. Subgroup analyses from these randomized trials have demonstrated that the absolute benefit of radiotherapy is greater in women at increased risk for tumor recurrence, such as women with involved surgical margins (identified on retrospective pathologic review), younger women, and those with tumors that have high-grade or comedonecrotic features.[125,142,143,145,151] However, this meta-analysis confirmed that no matter what the underlying rate of ipsilateral IBTR was within subgroups evaluated, the risk reduction of approximately 50% remained. This was demonstrated across categories defined by patient age, type of excision, use of tamoxifen, method of detection, margin status, tumor focality, and histologic or nuclear grade. There was little impact of radiotherapy on contralateral or distant events, and a difference in the risk of death from breast cancer was not appreciated.

Patient age is an important prognostic variable for local recurrence after breast conservation for DCIS.[125,131-133] In younger patients, DCIS more frequently contains adverse pathologic features and extends over a greater distance in the breast than in older patients.[133] In series with adequate follow-up, younger patients treated with lumpectomy and radiation therapy had a significantly higher rate of local recurrence than older patients, especially invasive local recurrences.[133] Some studies have suggested that careful attention to margin status and excising larger volumes of tissue can reduce this difference substantially.[131,133] No available data show that younger patients have better long-term cancer-free survival rates if treated

by mastectomy rather than lumpectomy and radiation therapy. Successful treatment of younger patients with DCIS with lumpectomy and radiation therapy requires careful attention to patient evaluation, selection, and surgical technique. When this is done, age at diagnosis should not be a contraindication to breast-conserving therapy.

The randomized trials discussed were designed and conducted over a decade ago. Since then, imaging technology, surgical techniques, and pathologic evaluation have continued to advance, suggesting that the patients encountered with DCIS presently may represent a group of patients with smaller, less extensive disease that is better surgically cleared as compared to those included in the randomized trials. As a result, the value of adjuvant radiotherapy has been hypothesized to be lower than indicated in previous trials. However, it should be noted that the tumor characteristics of those included in the randomized trials represented limited and mammographically detected disease. Despite this, several recent studies have attempted to identify and treat patients with highly selected favorable tumor characteristics with excision alone (ie, without whole-breast irradiation) and report 10-year local failure rates of 3% to 25%.[130,136] One of these studies[127] has proposed a scoring system using histopathologic features including tumor size, grade, and margin width in an attempt to stratify patients according to local failure risk after excision plus or minus whole-breast irradiation. Each variable was assigned a score of 1 to 3, and the sum total defined the Van Nuys Prognostic Index. Although appealingly simple, this schema[127] is drawn from the retrospective analysis of a patient cohort in which there existed several methodologic shortcomings, and it has not been independently validated.[152]

The Radiation Therapy Oncology Group (RTOG) published the results of a prospective randomized trial of 585 women who were defined as having good-risk DCIS (low or intermediate grade, <2.5 cm size primary, and ≥3 mm margins) treated with adjuvant whole-breast irradiation (50.4 Gy in 28 fractions and later amended to allow 42.5 Gy in 16 fractions without a boost) or observation. The use of tamoxifen was optional. The study was closed early because of low accrual (expected accrual 1,790). With a median follow-up of >7 years, the rate of local failure was 6.7% and 0.9% for the observation and radiation groups, respectively. Grade 1 to 2 acute toxicity was higher in the external beam radiotherapy (XRT) arm, 76%

versus 30%, with no difference in grade 3 to 4 toxicity in either arm. Despite the lower than expected accrual in this good-risk population, adjuvant XRT improved local failure. Additional follow-up is needed to determine long-term benefits.[153]

McCormick et al[154] performed a prospective study that attempted to identify patients with "low-risk" DCIS who can be spared whole-breast radiation therapy. This trial enrolled 158 patients with lesions that were mostly grade 1 or 2 and with a mammographic extent of no more than 2.5 cm who were treated with wide excision, with final margin 1 cm or more or a reexcision without residual DCIS. Tamoxifen was not permitted. The median age was 51 years. The most recent data, with a median follow-up of 11 years,[155] reported an estimated annual local recurrence percentage rate of 1.9%. Of those with an IBTR, 68% had a DCIS recurrence and 32% experienced recurrence with invasive carcinoma. These data provide prospective evidence that despite margin of more than 1 cm, the local recurrence rate is substantial, even in patients with small grade 1 or 2 DCIS following treatment with wide excision alone.

In an intergroup trial run by the Eastern Cooperative Oncology Group and North Central Cancer Treatment Group, wide excision only in a population of conservatively selected patients with DCIS was evaluated.[156,157] Eligibility included patients with low- or intermediate-grade DCIS measuring ≤2.5 cm (cohort 1, $n = 561$) or high-grade DCIS measuring no more than 1 cm (cohort 2, $n = 104$). Microscopic margin width was required to be at least 3 mm, with no residual calcifications on postoperative mammograms. Most of these patients had a more favorable profile than that reflected by the eligibility criteria with median lesion size of 6 and 7 mm for cohorts 1 and 2, respectively, and the majority having margins greater than 5 mm. The use of tamoxifen was optional after the year 2000, potentially impacting recurrence rates and/or time to recurrence intervals (30% and 24% for cohorts 1 and 2, respectively). With a median follow-up of 12.3 years, the 12-year rates of ipsilateral in-breast failure and invasive in-breast failure were 14.4% and 7.5%, respectively, for the low-intermediate group and 24.6% and 13.4%, respectively, for the high-grade group. Whether this identifies the low- intermediate grade group as a group that could avoid radiotherapy remains to be demonstrated, as this may represent a group with a delayed IBTR pattern, as no plateau was identified.

The NSABP and the RTOG published the results of a phase III accelerated partial-breast irradiation trial, which randomly allocated patients with early-stage breast cancer including DCIS between standard whole-breast irradiation following lumpectomy versus accelerated partial-breast irradiation. More than 4,200 women were enrolled, of which 24% had DCIS. Although the overall results did not meet the criteria for equivalence in part driven by the heterogeneous pool of patients, in a post hoc analysis, the 10-year cumulative incidence of IBTR for patient with DCIS was 6.5% versus 6.0% for whole-breast irradiation versus accelerated partial breast, with a hazard ratio of 1.01 (0.61-1.68).[158]

The value of a tumor bed boost was evaluated by the Breast International Group in association with the Trans-Tasman Radiation Oncology Group in women with non–low-risk DCIS, defined as having any of the following: age less than 50 years, symptomatic presentation, palpable tumor, microscopic tumor size 15 mm or larger, multifocal disease, grade 2 to 3, central necrosis, comedo histology, or surgical margins less than 10 mm. Patients underwent breast-conserving surgery with at least 1 mm negative radial margin followed by whole-breast radiation therapy (50 Gy in 25 fractions or 42.5 Gy in 16 fractions) with or without a tumor bed boost of 16 Gy in eight fractions. Over 1,600 patients were enrolled with a median follow-up of 6.6 years. Local recurrence was significantly lower in the boost versus no boost arm (2.9% vs 7.3%). This was at the expense of significantly higher grade 2 breast pain and induration (14% vs 10% and 14% vs 6%).[159]

Follow-Up and Management of Recurrence

Ipsilateral tumor recurrences in patients with DCIS are usually detected on surveillance mammography, although one-quarter may be detected on the basis of changes on physical examination of the breast or chest wall.[160,161] For this reason, patients should be scheduled for a baseline mammogram 6 to 12 months after initial therapy and at least annually thereafter. Distant breast cancer metastases in the absence of regional recurrence are unusual. Local recurrences after breast-conserving surgery and radiotherapy are generally treated with mastectomy. Selected patients with local recurrences who have not previously received radiotherapy may be candidates for local

excision and radiotherapy. The clinical outcome of ipsilateral tumor recurrence is governed by the nature of the recurrence. Patients with recurrent DCIS have an excellent prognosis, with less than 1% risk of further recurrence after salvage mastectomy. Patients with invasive recurrence after breast-conserving surgery for DCIS have a prognosis similar to those with early-stage breast cancer, with a 15% to 20% risk of metastatic recurrence at 8 years.[161]

The Role of Tamoxifen and Aromatase Inhibitors for Ductal Carcinoma In Situ

The use of tamoxifen in the treatment of DCIS has been studied; however, results have been conflicting. Therefore, its role is not yet clearly defined. Preliminary results on the role of Her2Neu-targeted treatment were presented in the 2020 ASCO annual meeting. In the NSABP B-43 trial, patients with Her2Neu-positive DCIS were treated with post-lumpectomy radiotherapy and randomized between trastuzumab or observation, and 2014 women were included with 6.6-year median follow-up. Of the 114 IBTR, 63 occurred in the radiation-alone arm and 51 in the radiation plus trastuzumab, which was not statistically significant.[162] The NSABP B-24 trial[132,144] compared excision plus radiotherapy to excision, radiotherapy, and tamoxifen. Patients who received tamoxifen had a decreased incidence of breast cancer events (invasive or noninvasive ipsilateral or contralateral breast cancer) compared with patients who did not receive tamoxifen. With a median follow-up of 163 months, the addition of tamoxifen translated into a significant 32% reduction in invasive IBTR (9.0% vs 6.6%, $P = .025$), a nonsignificant 16% reduction in DCIS-IBTR (7.6% vs 6.7%, $P = .33$), and a 32% reduction in contralateral breast cancer (8.1% vs 4.9%, $P = .023$); however, no survival benefit was found (Table 61.3). Positive tumor margins were significantly associated with breast recurrence. The 15-year cumulative incidence of invasive IBTR was reduced from 17.4% in patients with positive margins to 11.5% with the addition of tamoxifen. In those with tumor-free margins, tamoxifen did not improve in-breast disease control with a 7.4% and 7.5% incidence of invasive IBTR with and without tamoxifen, respectively.

TABLE 61.3 TAMOXIFEN VERSUS NO TAMOXIFEN: RANDOMIZED CLINICAL TRIALS FOR DUCTAL CARCINOMA IN SITU

Trial Group	Number of Patients	Follow-Up	Local Recurrence (Cumulative %) DCIS + Invasive Carcinoma		
			− TAM	+ TAM	*P* Value
NSABP B-24	1,798	13.6-y median	16.6	13.2	–
UK/ANZ	1,053	12.7-y median	17.0	13.2	.04
No radiotherapy	523		2.6	2.4	.8
Radiotherapy					

DCIS, ductal carcinoma in situ; NSABP, National Surgical Adjuvant Bowel and Breast Project; TAM, tamoxifen; UK/ANZ, United Kingdom, Australia, and New Zealand.

In contrast to the findings of the NSABP B-24 trial, the UK/ANZ DCIS trial found that tamoxifen had no effect in reducing local recurrence rate when combined with whole-breast radiation therapy (Table 61.3). When used as a single agent without radiation therapy after lumpectomy, tamoxifen had no effect on the incidence of invasive recurrence but did show a statistically significant reduction in the risk of DCIS recurrence (10.4% vs 7.4%, $P = .04$).[148,149] As such, the role of tamoxifen for DCIS in the absence of whole-breast radiotherapy remains to be defined.

The role of tamoxifen versus anastrozole (an aromatase inhibitor) in the management of DCIS has been evaluated in the NSABP B-35 trial.[163] Eligibility included postmenopausal women with DCIS, with or without associated LCIS with estrogen- or progesterone-positive receptors who underwent lumpectomy with clear margins and adjuvant whole-breast radiation therapy. Patients were stratified by age less than 60 years versus 60 years or above. A total of 3,104 women were enrolled, with 3,084 women having a median follow-up of 9 years. Breast cancer–free interval improved with the use of anastrozole (7.8% vs 5.7%), with no significant difference in regard to the rates of in-breast recurrence, contralateral breast cancer, or distant disease. Improvement in disease-free survival was reported in women under the age of 60 years with the use of anastrozole compared to the tamoxifen arm (89.8% vs 85.7%). Except for higher rates

of thrombosis in the tamoxifen arm, no significant difference with regard to toxicity or treatment adherence was seen.[163] Because DCIS is a precursor to invasive breast cancer and shares many biologic features of invasive carcinoma, it is increasingly recognized as a target for preventive measures. In the largest trials of the prevention of primary breast cancer among women at high risk for breast cancer by virtue of age, family history, or prior benign breast disease, tamoxifen reduced the risk of DCIS by 50% to 70%.[40,164]

A Decision Tree for Ductal Carcinoma In Situ

The management of DCIS requires the coordinated, multidisciplinary interaction of radiologists, surgeons, pathologists, and oncologists. Patients are first assessed to determine if they are candidates for breast-conserving surgery. Women with multicentric DCIS, as defined by the presence of two or more tumors in separate quadrants of the breast, and those with extensive or diffuse DCIS or suspicious-appearing microcalcifications throughout the breast are candidates for mastectomy, as are women in whom negative margins or acceptable cosmesis cannot be achieved with the use of breast-conserving surgery. Some women may prefer mastectomy to breast conservation to minimize the chance of ipsilateral recurrence or for other reasons.

Patients deemed to be appropriate candidates for breast conservation require complete surgical excision of the affected area. The extent of DCIS in the breast and the existing margin determine the likelihood of identifying residual disease on reexcision. Nearly half of patients with margin <1 mm have residual DCIS on reexcision.[38]

Neither dissection of axillary lymph nodes nor mapping of sentinel lymph nodes is routinely warranted in patients with DCIS because of the very low incidence of axillary metastases.[165] Three to 13% of patients with DCIS, and a slightly greater percentage with DCIS and microinvasion, have isolated tumor cells in sentinel axillary lymph nodes.[166] The prognostic significance of these cells is not clear. Clinical experience suggests that patients have a much better outcome than would be predicted by such rates of nodal metastases, and in most instances, these represent micrometastases of unclear metastatic potential. However, sentinel lymph node mapping may

be used in selected patients with a higher likelihood of occult invasive cancer—those with extensive, high-grade DCIS or palpable masses—and those undergoing mastectomy as sentinel node mapping cannot be performed afterward if an invasive tumor is identified.[167]

After breast-conserving surgery, radiotherapy is administered using tangential fields to the whole breast with a standard dose of 42.5 to 50 Gy delivered in 16 to 25 daily fractions. Accelerated partial-breast irradiation may also be considered in appropriately selected patients. On the basis of randomized data, a radiation boost to the tumor bed may be added to whole-breast treatment, particularly for women with non–low-risk DCIS. There is no role for postmastectomy or nodal irradiation in the treatment of DCIS.

It is not yet possible to prospectively identify women who are at sufficiently low risk that radiotherapy may not be of some clinical advantage in preventing recurrences. After discussing the various options, patients may elect not to receive radiation treatment; however, they must understand and accept the increased risk of recurrence that this choice probably entails.[168]

In summary, despite considerable advances in our clinical knowledge base, the answer to the question "When should radiotherapy be used for DCIS?" remains complex and surrounded by considerable controversy. Two fundamental considerations must be emphasized:

1. A primary goal of breast-conserving therapy for DCIS is to achieve the best possible cosmetic outcome. Attempts to obtain wide surgical margins through deforming, large-volume breast excisions represent cosmetic failures and defeat the purpose of breast conservation.
2. Breast irradiation reduces the risk of subsequent invasive or noninvasive carcinoma in the treated breast and thus reduces the risk of the ultimate cosmetic failure— mastectomy.

According to prospectively randomized trials of breast-conserving therapy for DCIS, radiotherapy reduces subsequent breast recurrence in all patient groups, irrespective of prognostic risk factors. That is not to say, however, that radiotherapy must be used for all patients with DCIS. In all cases, a realistic and balanced discussion of the relative risks and benefits of treatment options should be presented to the patient. Reasonable estimates

of breast recurrence during the ensuing decade with or without radiotherapy are available based on level I evidence from prospective clinical trials.

CHAPTER 62

Breast Cancer: Early Stage

Nisha Ohri, Sharad Goyal, Thomas Buchholz, and Bruce G. Haffty

Radiation therapy (RT) plays an essential and critical role in the management of early-stage breast cancer. This chapter provides an overview of general concepts in breast cancer and then focuses on the management of early-stage invasive disease in the breast conservation setting. Postmastectomy radiation, as well as advanced invasive disease and locoregional recurrence (LRR), will be covered in the advanced disease chapter that follows. Management of ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS) is the focus of the previous chapter.

ANATOMY

The female breast lies on the anterior chest wall superficial to the pectoralis major muscle. The breast can extend from the midline to near the midaxillary line and cranial caudally from the second anterior rib to the sixth anterior rib. The upper outer quadrant of the breast extends into the region of the low axilla and is frequently referred to as the axillary tail of Spence. This anatomic feature results in the upper outer quadrant of the breast containing a greater percentage of total breast tissue compared with the other quadrants, and, therefore, a greater percentage of breast cancers occur in this anatomic location.

The breast is made up of the mammary gland, fat, blood vessels, nerves, and lymphatics (Figure 62.1). The surface of the breast has deep attachments of fibrous septa, called Cooper ligaments, which run between the superficial fascia (attached to the skin) and the deep fascia (covering the pectoralis major and other muscles of the chest wall). Skin dimpling may be caused by tumors affecting these supporting structures. It is important to realize, from a staging perspective, that the chest wall includes the ribs, intercostal muscles, and the serratus anterior muscle, but not the pectoral muscles.

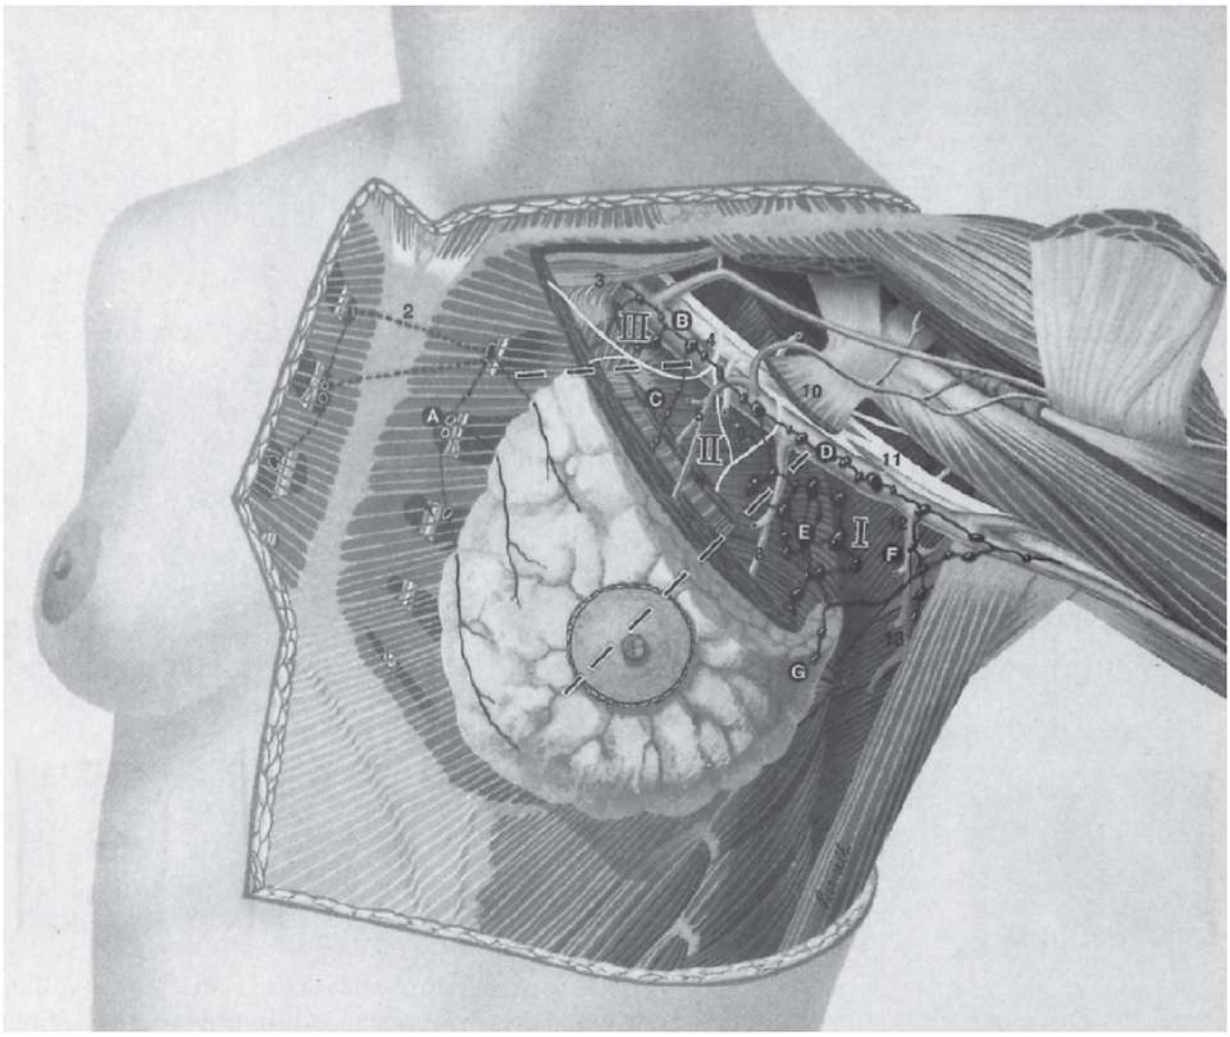

FIGURE 62.1 Anatomy of the breast and lymphatic drainage. (Reprinted with permission from Osborne MP. Breast development and anatomy. In: Harris JR, Hellman S, Henderson IC, et al, eds. *Breast diseases*. J.B. Lippincott; 1987:1-14.)

The breast parenchyma is composed of lobules and ducts. The function of the lobules is to produce milk, and the function of the ducts is to transport lactation products to the nipple. The peripheral ducts converge into major lactiferous ducts, which then communicate with the nipple-areola complex. Most breast cancers develop at the interface between the ductal system and the lobules, a region called the terminal ductal lobular unit.

The breast parenchyma is intermixed with connective tissue, which has a rich vascular and lymphatic network. Mammary gland lymphatics begin in the interlobular or prelobular spaces, follow the ducts, and end in the subareolar network of lymphatics of the skin. The predominant lymphatic drainage of the breast is to the axillary lymph nodes, which is commonly described in three levels, based on the relation of the lymph node regions to the pectoralis minor muscle (Figure 62.2). The level I axilla is caudal and lateral to the muscle, level II is beneath the muscle, and level III (also known as the infraclavicular region) is cranial and medial to the muscle. A standard axillary lymph node dissection (ALND) resects the tissue and lymph nodes within levels I and II. It is very unusual for level III of the axilla to be involved without disease in level I or II. The axillary lymph

nodes continue underneath the clavicle to become the supraclavicular lymph nodes, which can be involved in locally advanced breast cancers.

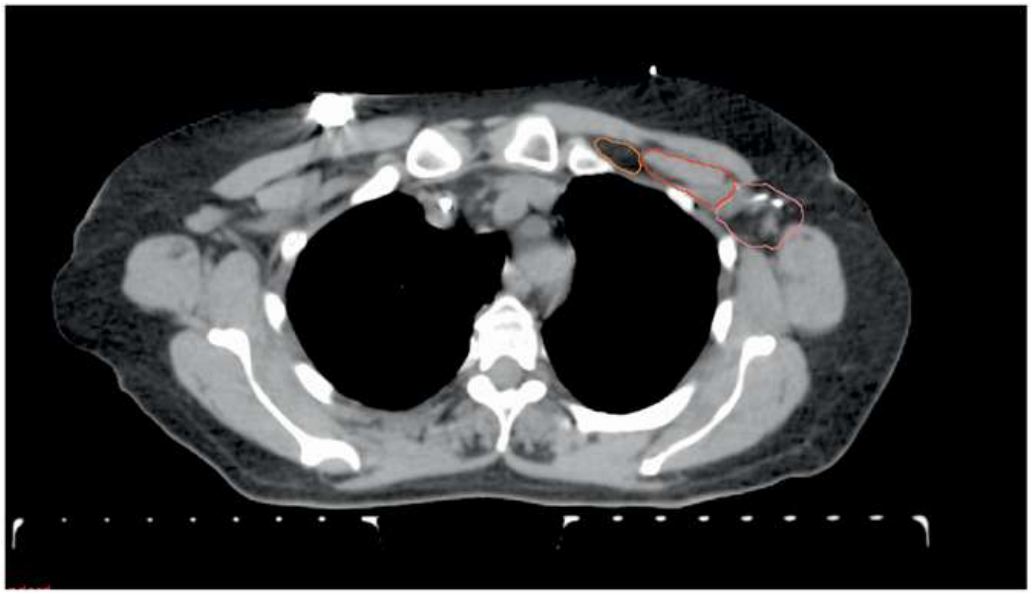

FIGURE 62.2 Location of the three levels of axillary lymph nodes (level 1—pink; level 2—red; level 3—orange).

Lymphatics can also drain directly into the internal mammary lymph node chain (IMC), which are intrathoracic structures located in the parasternal space. Although these nodes are not usually visualized on computed tomography (CT), the anatomic region of the IMC can be determined by the internal mammary artery and vein, which are easily visualized by CT (Figure 62.3) and usually lie 3 to 4 cm lateral to midline. When breast cancer involves the IMC, the majority of patients will have disease that is limited to lymph nodes in the first three interspaces. Regardless of the location in the breast, the axilla is the most common site of lymphatic involvement. However, breast cancers that develop in the medial, central, or lower breast more commonly drain to the IMC (in addition to the axilla) than do those occurring in the lateral and upper quadrants.

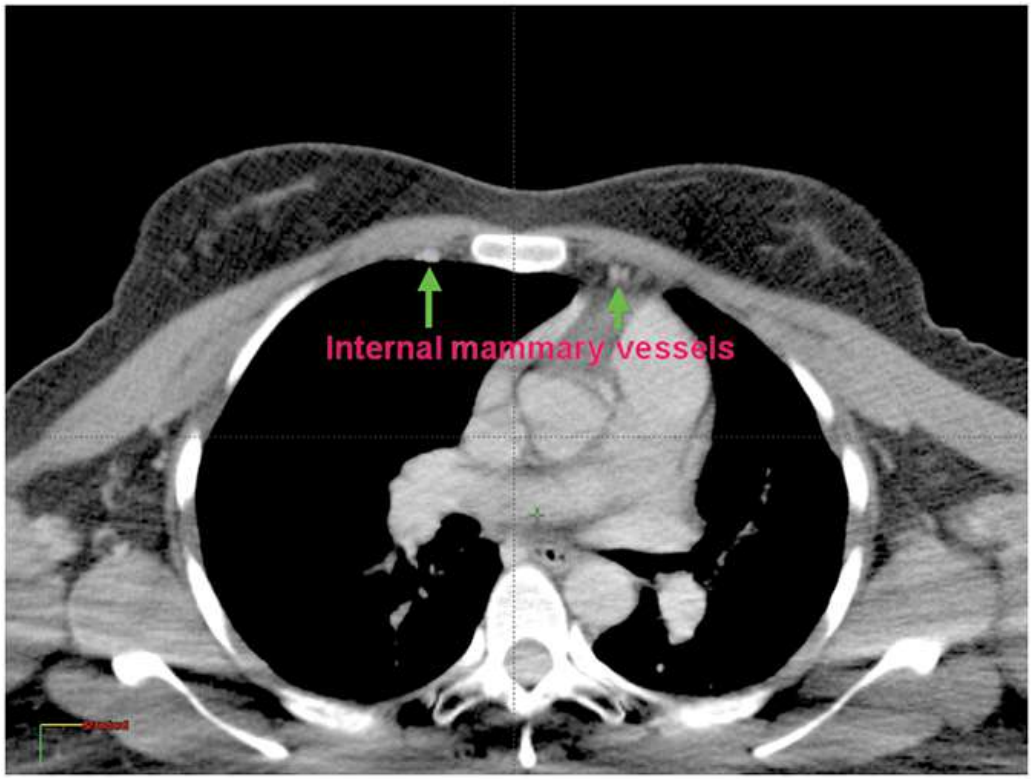

FIGURE 62.3 Treatment planning computed tomography scan of the chest demonstrating the location of the internal mammary vessels, which are typically located approximately 3 to 4 cm lateral to midline and approximately 3 cm deep to the surface. The internal mammary nodes are in close proximity to the vessels, with the most critical nodes being located in the first three intercostal spaces.

The use of lymphoscintigraphy, by injecting technetium-99 radiocolloid into the peritumoral region followed by scintillation scanning, is used for sentinel lymph node (SLN) imaging. This technique has helped to delineate primary lymphatic drainage patterns of breast cancer. Dual tracing techniques using both technetium-99 and blue dye may reduce false-negative rates. The distribution of axillary and internal mammary drainage is summarized in Figure 62.4.[1] Even in inner quadrant lesions, axillary drainage is more common than internal mammary drainage. However, internal mammary drainage was present in over 50% of lower inner quadrant lesions.

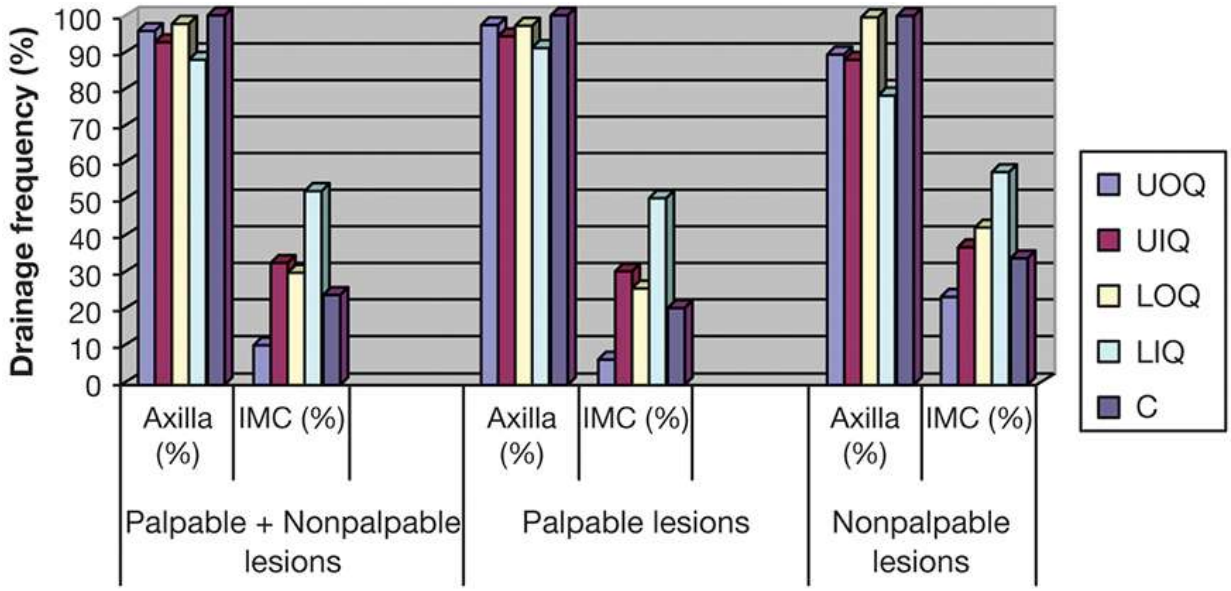

FIGURE 62.4 Distribution of lymphatic drainage of the breast to axillary and internal mammary chains (IMCs) according to the location within the breast. (Data extracted from study of 700 patients undergoing sentinel lymph node mapping by Estourgie SH, Nieweg OE, Olmos RA, et al. Lymphatic drainage patterns from the breast. *Ann Surg*. 2004;239[2]:232-237.)

EPIDEMIOLOGY

Breast cancer is the most frequently diagnosed cancer in women, and it is estimated that there will be 297,790 new cases of invasive breast cancer and 55,720 new cases of in situ breast cancers among women in the United States in 2023.[2] Primarily because of increased utilization of screening mammography, breast cancer incidence rates increased rapidly in the 1980s. Since the mid-2000s, female breast cancer incidence rates have slowly increased by about 0.5% per year, a trend that is attributed, in part, to increases in excess body weight and fertility issues. Breast cancer alone is expected to account for 31% of all new cancer diagnoses in women. It is estimated that 43,170 breast cancer deaths will occur in 2023, with breast cancer ranking second among cancer deaths in women after lung cancer. In contrast to the significant number of breast cancer cases in women, it is expected that 2,800 cases of breast cancer will be diagnosed in men in 2023, with approximately 530 breast cancer deaths in men. Because of a combination of early detection, increased awareness, and improvements in therapy, the female death rate from breast cancer has declined by 43% from 1989 to 2020.

There is considerable geographic, ethnic, and racial variability in breast cancer incidence. Ethnicity and national origin rank highly as predictors of risk for breast cancer, with up to a 10-fold variation throughout the world.[3] Compared with other well-established risk factors such as age of menarche and menopause, age at first childbirth, and family history, geographic and ethnic variability is quite significant. It is likely that a complex interaction of multiple factors, including genetic, environmental, and socioeconomic, contribute to the wide variability in age-adjusted incidence across populations.

In the United States, the incidence of breast cancer in White women is higher than in all other populations. Notably, Black women have a slightly lower incidence of breast cancer but 40% higher breast cancer mortality. This disparity has persisted over the years.[2]

Risk Factors

Table 62.1 summarizes the major risk factors associated with the development of breast cancer. With the exception of the female gender, increasing age is the most consistent and significant risk factor, with most populations demonstrating increasing incidence rates with age. Other risk factors include personal history and family history of breast cancer, nulliparity or late age at first childbirth, early menarche and late menopause, prior breast biopsy with hyperplasia or atypical hyperplasia, high breast tissue density, radiation exposure at a young age, alcohol consumption, and use of postmenopausal hormone therapy. Some of the national origin or ethnicity variability discussed earlier may be explained, in part, by differences in established risk factors, such as age of menarche, parity, and age at first childbirth. However, these factors explain only part of the variability observed in national origin, indicating underlying genetic, environmental, and dietary factors are likely to contribute to the differences in the worldwide incidence of breast cancer. Breastfeeding, physical activity, and maintaining a healthy body weight have been demonstrated in various studies to be associated with a lower risk of breast cancer.[4]

TABLE 62.1 RISK FACTORS FOR BREAST CANCER IN WOMEN

Risk Factors	Category at Risk	Comparison Category
Established Risk Factors		
Older age	Older than 50	Younger than 50
Country of residence	North America or Northern Europe	Asia or Africa
Germline mutation	With *BRCA1* or *BRCA2* mutations	Without *BRCA1* or *BRCA2* mutations
Personal history of breast cancer	With history of invasive breast carcinoma	No history of invasive breast carcinoma
High radiation exposure to chest area	With high radiation exposure to chest	Without radiation exposure
Atypical hyperplasia in breast biopsy	With atypical hyperplasia	Without hyperplasia
Cytologic findings (fine-needle aspiration; nipple aspiration fluid)	Proliferation with atypia	No abnormality detected
Family history of breast cancer	With one or more close relatives with breast cancer	No close relatives with breast cancer
Early menarche	Menarche before age 12	Menarche after age 14
Late menopause	Menopause after age 55	Menopause before age 55
Older age at first full-term birth	Older than 30 y when first child was born	Younger than 20 y when first child was born
Not having children	Without children	With one or more children
Using menopausal hormone therapy	With hormone treatment after menopause	Without hormone treatment after menopause
Obesity after menopause	Obese after menopause	Not obese after menopause
Other Reported Risk Factors		
Using birth control pills	Current use	None
Tall height	>5 ft 9 inches	<5 ft 3 inches
Regular alcohol consumption	Regularly consume alcoholic beverages	No alcoholic beverages consumption
Breastfeeding	None	>1 y

Risk Factors	Category at Risk	Comparison Category
Postmenopausal body mass index (BMI)	Higher BMI	Lower BMI
Jewish heritage	Yes	No
Possible Risk		
High-density breasts on mammograms	With high-density mammograms	With low-density mammograms
High socioeconomic position	Have high socioeconomic position	Have low socioeconomic position
Physical activity	Lower	>3 h/wk
Dietary factors	High-fat, low fiber	Low-fat, high fiber

Age

The risk of breast cancer increases exponentially up to the age of menopause, at which time the rate of increase in the risk slows significantly. After the age of 80, the incidence of breast cancer begins to show a slight decline. For women in their late 30s, the annual increase in risk of developing breast cancer is approximately 0.07% per year. This increases to 0.44% per year for women in their late 70s. Although these percentages may seem low, they represent only the risk for a given year; the lifetime risk is a summation of the annual breast cancer risks. Because younger women have a longer life expectancy than do older women, younger women have a greater lifetime risk. Only 1.9% of women develop breast cancer before the age of 50, whereas 2.3% of women develop breast cancer between the ages of 50 and 59 years, 3.5% of women develop breast cancer between the ages of 60 and 69 years, and 6.8% of women develop breast cancer over the age of 70.[5]

Childbearing/Parity/Breastfeeding

The protective effect of childbearing at younger ages on breast cancer risk is well established. In a worldwide case-control study, MacMahon et al[3,6] demonstrated a nearly linear relation between relative risk (RR) of breast cancer and age at first birth, with women aged 20 to 25 years having nearly a 50% reduction in the RR of breast cancer compared with nulliparous women. Interestingly, for women whose first childbirth occurred over age 35, the risk appears greater than that for nulliparous women. Data on the effect of breastfeeding are not as strong as the data on age at first childbirth, but they do suggest a protective effect.

Ovarian Function

The relation between ovarian function and breast cancer risk has long been recognized, with long menstrual history (early menarche and late menopause) contributing significantly to breast cancer risk. In experimental models and observational studies, removal of the ovaries reduces the risk of breast cancer. Women with surgically induced menopause have been shown to have significantly reduced risks of breast cancer compared with women whose menopause occurred naturally. In comparison with women whose menopause occurs between the ages of 45 and 54 years (RR = 1), women with early menopause before age 45 have an RR of breast cancer of 0.73, and women with late menopause at age 55 years or above have an RR of 1.48. The data on the early onset of menses and its association with breast cancer risk are also well established.[3]

Exogenous Hormone

The relationship between breast cancer risk and exogenous hormone exposure is controversial. A collaborative meta-analysis from 51 epidemiologic studies of over 150,000 women did show an increased RR of 1.35 for current or recent users of hormonal replacement therapy.[7] The authors

reported that postmenopausal hormone replacement therapy increased the annual RR of developing breast cancer by 2.3% for each year of hormonal therapy. A randomized trial of postmenopausal hormone therapy from the Women's Health Initiative Study comparing estrogen and progestin with placebo was closed prematurely, demonstrating a 24% increase in breast cancer, coronary heart disease, stroke, and pulmonary emboli.[8] This study of 46,000 women reported that the combined use of estrogen and progesterone increased the RR of breast cancer by 8% compared with the risk in nonusers, whereas the use of estrogen alone increased the RR by only 1%. After publication of this study, a dramatic decrease in almost 7% between 2002 and 2003 was primarily attributed to the reduction in the use of hormone replacement therapy.[5]

There is no clear relationship between the use of oral contraceptives and breast cancer risk, as data are conflicting.

Family History

The increased risk of breast cancer as a function of family history is well established. For women with a second-degree relative (aunt, grandmother) with breast cancer, the risk is about 1.5, and for women with a history of first-degree relatives (mother or sister), the risk is 1.7 to 2.5.[9] This may be explained, in part, by inheritance of a genetic condition that predisposes an individual to breast cancer development (eg, mutations in *BRCA1* or *BRCA2*), shared lifestyle, and inheritance of genes that affect risk factors, such as body habitus and age at menarche. Between 20% and 25% of women diagnosed with breast cancer have a positive family history of the disease, and approximately 10% of women with breast cancer are from families who display an autosomal dominant pattern of breast cancer inheritance.[10] The actual risk that family history conveys depends on the number of relatives affected and their age at diagnosis (having a first-degree relative with premenopausal breast cancer conveys a greater risk than does having a first-degree relative with postmenopausal cancer). Women with one first-degree relative affected by the disease have an increased RR of developing breast cancer 2 to 3 times that of women with no family history. Women with two or more first-degree relatives with a diagnosis of breast cancer have a still greater risk, 4 to 6 times that of women with no family history.[9]

National consensus guidelines provide an outline for testing criteria for high-penetrance breast cancer susceptibility genes (*BRCA1, BRCA2, CDH1, PALB2, PTEN*, and *TP53*). Genetic testing is recommended for patients with a personal history of breast cancer and the following features:

- Diagnosed age 50 years or below
- Diagnosed at any age with
  - Triple-negative (TN) breast cancer
  - Multiple primary breast cancers
  - Lobular breast cancer with a personal or family history of diffuse gastric cancer
  - Male breast cancer
  - Ashkenazi Jewish ancestry
  - To aid in systemic treatment decisions in the adjuvant or metastatic setting
  - One or more close blood relatives with any of the following: breast cancer age 50 or below, male breast cancer, ovarian cancer, pancreatic cancer, or prostate cancer with metastatic or high-risk group
  - Three or more diagnoses of breast cancer in the patient and/or close blood relatives
  - Two or more close blood relatives with breast or prostate cancer

Personal History of Breast Cancer and History of "Benign" Breast Biopsy

Women with a prior history of breast cancer are at an elevated risk of developing a second contralateral breast cancer. Studies with long-term follow-up have demonstrated a risk of breast cancer in the contralateral breast of approximately 10% to 15%, depending on the patient population and length of follow-up.[11] The risk of contralateral breast cancer as a function of prior radiation treatment is discussed in detail later.

Although women with a history of fibrocystic changes have been reported to have an elevated risk of breast cancer, evidence suggests that the majority of the elevated risk is due to the smaller proportion of women whose biopsy reveals atypical hyperplasia. Results from the Breast Cancer Detection Demonstration Project, which included over 280,000 women in 29 centers, demonstrated that women with atypical hyperplasia had 4.3 times the breast cancer risk of women without proliferative disease (95% confidence interval [CI], 1.7-11.0).[12] In women with proliferative disease lacking atypical hyperplasia, the RR was 1.3 (95% CI, 0.77-2.2). In that study, the joint occurrence of family history and atypical hyperplasia had a strong synergistic effect on breast cancer risk.

Radiation Exposure

Exposure to ionizing radiation during or after puberty increases the risk for the development of carcinoma of the breast. Land et al[13,14] reviewed reports on three populations of patients exposed to ionizing radiation by atomic bombings, multiple fluoroscopic examinations for tuberculosis, and multiple examinations for mastitis. They concluded that the risk of radiation-induced cancer of the breast increased approximately linearly with increasing dose and was heavily dependent on age at exposure.

In a study of 31,710 women who had tuberculosis and were examined with repeated fluoroscopic studies, a substantial proportion (26.4%) received doses to the breast of 0.1 Gy or higher; the breast cancer risk was greatest among women who had radiation exposure between the ages of 10 and 14 years (RR 4.5 per 0.01 Gy and an additive risk of 6.1 per 104 person-years per 0.01 Gy); there was substantially less excess risk with increasing age at first exposure.[15]

A high risk of solid tumors, especially breast cancer, has been described in women treated with RT at a young age for Hodgkin lymphoma. In a prior study, RRs of breast cancer were defined by radiation dose to the chest (0, 20 ≤40 Gy, or ≥40 Gy). Estimates were from a case-control study conducted within an international population-based cohort of 3,817 female survivors of Hodgkin lymphoma diagnosed at age 30 years or below.[16] For a survivor who was treated at age 25 years with a chest radiation dose of at least 40 Gy without alkylating agents, estimated cumulative absolute risks of breast cancer by age 35, 45, and 55 years were 1.4% (95% CI, 0.9%-2.1%), 11.1% (95% CI, 7.4%-16.3%), and 29.0% (95% CI, 20.2%-40.1%), respectively. The current practice of limiting radiation fields may help to further reduce the risk of radiation-related breast cancers in Hodgkin survivors.[17]

Body Mass Index, Physical Activity, and Dietary Factors

The inherent complex interaction between body mass, physical activity, and diet complicates the interpretation of epidemiologic studies correlating these factors with breast cancer risk. Body mass index (BMI) has been clearly associated with breast cancer risk in a number of studies, but it appears to influence breast cancer risk predominantly in postmenopausal women. In premenopausal women, most studies have not observed a strong relation between BMI and breast cancer risk. In postmenopausal women, a pooled analysis of prospective studies demonstrated the risk of breast cancer to be 30% higher in postmenopausal women with a BMI over 31 kg/m^2 compared with

women with a BMI of 20 kg/m^2.[18] The higher risk of breast cancer with increased BMI in postmenopausal women is likely due to higher estradiol levels associated with increased adipose tissue and increased aromatase, which is involved in the conversion of androgens to estradiol. In postmenopausal women, this is the primary source of estradiol. In premenopausal women, estradiol is predominantly from the ovaries, so there is little association with BMI and estradiol levels.

Physical activity can have a significant impact on BMI, so it is sometimes difficult to separate these two effects in interpreting breast cancer risk. A majority of studies, however, have observed a lower risk of breast cancer among women who are more physically active compared with women who are sedentary.

Although it has been suggested that obesity and high intake of meat, dairy products, and fat may increase risk and fiber, fruits and vegetables, and phytoestrogens (soy products) may reduce risk, strong links between diet and breast cancer risk have not been clearly established.

Alcohol Consumption

Chen et al[19] reported on a prospective observational study of 105,986 women enrolled in the Nurses' Health Study between 1980 and 2008. With 2.4 million person-years of follow-up, 7,690 cases of invasive breast cancer were diagnosed. They found that increasing alcohol consumption was associated with increased breast cancer risk that was statistically significant at levels as low as three to six drinks per week (RR 1.15; 95% CI, 1.06-1.24). Moreover, binge drinking, but not frequency of drinking, was associated with breast cancer risk after controlling for cumulative alcohol intake. They concluded that low levels of alcohol consumption were associated with a small increase in breast cancer risk, with the most consistent measure being cumulative alcohol intake throughout adult life.

Although the relation among physical activity, BMI, and dietary factors may be difficult to separate, it is apparent that maintaining a healthy diet and weight, limiting alcohol intake, and engaging in moderate physical activity are modifiable behaviors that can impact breast cancer risk (as well as other health-related issues) and should be encouraged.

Mammographic Density

There is a large body of evidence suggesting a correlation between mammographic breast density and breast cancer risk.[20] The risk of breast cancer associated with the highest category of density has been estimated to be 2 to 6 times greater than in the lowest category. Although the causal link between mammographic density remains poorly understood, breast density is, in part, attributable to genetic factors.

Determining an Individual's Risk

It is important to consider the combination of risk factors when a generalized risk profile is determined. Gail et al[21] have used these epidemiologic risk factors to derive a model for predicting an individual's annual and lifetime risks of breast cancer. In the Gail model, an individual's annual risk of breast cancer is based on their present age, number of first-degree relatives with breast cancer, age at first birth, age at menarche, number of breast biopsies, and history of atypical ductal hyperplasia. The use of exogenous hormones and many of the other risk factors discussed earlier are not incorporated into this specific model.

BREAST CANCER PREVENTION

Tamoxifen

Several pharmaceuticals that affect the estrogenic pathways have been studied as chemopreventive agents, but the only agent for which mature data from clinical trials are available is tamoxifen.[22-27]

Interest in tamoxifen as a chemopreventive agent arose after a number of randomized trials designed to test the efficacy of hormonal therapy for invasive breast cancer reported that tamoxifen reduced the incidence of contralateral breast cancer. On the basis of these data, in 1992, the National Surgical Adjuvant Breast and Bowel Project (NSABP) began a randomized, placebo-controlled study (the P-1 trial) to test the efficacy of 5 years of tamoxifen in the prevention of breast cancer.[27] Between 1992 and 1997, 13,388 women with a 1.67% or greater predicted risk of developing breast cancer within 5 years were enrolled in this trial. Risk was assessed using a modification of the Gail model, which permitted enrollment of any woman older than 60 years and selected women younger than 60 years with additional risk factors that increased their annual risk to at least that of a 60-year-old. In addition, women with a history of LCIS were included. Women were not allowed to use estrogen replacement therapy during their participation in the trial. The results of the NSABP P-1 trial indicated that tamoxifen reduced the rates of invasive and noninvasive breast cancer by 49% and 50%, respectively. The benefit of tamoxifen was seen in all age groups (≤49, 50-59, and ≥60 years). In addition, women with a history of atypical ductal hyperplasia had an 86% risk reduction, and women with a history of LCIS had a 56% risk reduction. Finally, the benefit was seen across all subgroups specified according to family history of breast cancer. Tamoxifen selectively reduced the incidence of estrogen receptor (ER)-positive tumors; ER-negative tumors developed at an equal rate in the tamoxifen and placebo groups. No evidence was shown of a cardioprotective effect of tamoxifen in this trial, but the number of osteoporosis-related fractures was reduced in the tamoxifen-treated cohort. Tamoxifen increased the risk of developing stage I endometrial cancer (risk ratio of 2.53).

Subsequently, a landmark study was published that compared tamoxifen to raloxifene as a preventive agent in postmenopausal women with breast cancer. Raloxifene, a drug that is primarily used in the prevention of osteoporosis, had been shown in prior studies to decrease the incidence of breast cancers. The NSABP study of tamoxifen and raloxifene was a prospective, double-blind, randomized clinical trial.[28] There were 19,747 postmenopausal women of mean age 58.5 years with increased 5-year breast cancer risk. Patients were randomized to oral tamoxifen (20 mg/day) or raloxifene (60 mg/day) for 5 years. There were 163 cases of invasive breast cancer in women assigned to tamoxifen and 168 in those assigned to raloxifene, which was not significantly different between the two arms. The main benefit of raloxifene was in toxicity. There were 36 cases of uterine cancer with tamoxifen and 23 with raloxifene. No differences were found for other invasive cancer sites, ischemic heart disease events, or stroke. Thromboembolic events also occurred less often in the raloxifene group. The number of osteoporotic fractures in the groups was similar, and there were fewer cataract surgeries with raloxifene. There was no difference in the total number of deaths (101 vs 96 for tamoxifen vs raloxifene) or in causes of death. It appeared from this study that raloxifene was as effective as tamoxifen in reducing the risk of invasive breast cancer and had a lower risk of thromboembolic events. Of note, there were slightly more noninvasive cancers in the raloxifene group, but that was not statistically significant.

A comparison of the tamoxifen prevention trials is outlined in Table 62.2.[22-26,29,30]

TABLE 62.2 RESULTS OF CHEMOPREVENTION TRIALS

	Royal Marsden (Tamoxifen vs Placebo)[29]	NSABP P-1 (Tamoxifen vs Placebo)[27]	Italian (Tamoxifen vs Placebo)[30]	IBIS-1 (Tamoxifen vs Placebo)[24]	MORE (Raloxifene vs Placebo)[23]	STARR (Tamoxifen vs Raloxifene)[28]

Negative	17 vs 10	38 vs 31	—	19 vs 19	9/2 vs 4	44 vs 51

ER, estrogen receptor.

Prophylactic Surgery

An alternative strategy used to prevent breast cancer development is prophylactic surgical intervention. Hartmann et al[31] analyzed outcomes in women with a family history of breast cancer who underwent bilateral prophylactic mastectomy at the Mayo Clinic between 1960 and 1993. With a median follow-up time of 14 years, only 4 of the 639 treated patients developed breast cancer. According to the Gail model, 37.4 cases of breast cancer would have been expected to develop in this population, so the prophylactic surgery resulted in an 89.5% risk reduction ($P < .001$).

Breast cancer prevention strategies will continue to be a dynamic area of preclinical and clinical research.

NATURAL HISTORY AND ORIGINS

All forms of breast cancer are believed to develop as a consequence of unregulated cell growth and the development of phenotypic changes, such as the ability to invade, recruit a new blood supply, and metastasize. These changes in phenotypes are secondary to the development of aberrations in genetic pathways. Some of these aberrations are inherited (germline mutations), whereas others develop during the life of a breast cell (somatic mutations). It is currently believed that most breast cancer is a consequence of a series of somatic mutations. As previously noted, only 20% to 25% of patients with breast cancer have a history of breast cancer in a first-degree relative. However, it is possible that some women without a first-degree relative with breast cancer still inherit a genetic background that predisposes to breast cancer. These mutations may be insufficient to cause breast cancer unless accompanied by other mutations and, therefore, would be predicted to have a low

penetrance. Historically, it has been much more difficult to discover low-penetrance mutations than to discover germline mutations that result in an autosomal dominant pattern of breast cancer development. However, with newer molecular techniques, such as DNA array assays, the identification of low-penetrance predisposing mutations may be more feasible.

The most common site of origin of breast cancer is the upper outer quadrant, followed by the central area, the upper inner quadrant, the lower outer quadrant, and the lower inner quadrant. These rates correlate with the amount of breast tissue in the various quadrants. As noted earlier, women with a history of breast cancer have a 10% to 15% risk of developing a new primary in the contralateral breast.

As the cancer grows, it travels along the ducts, eventually breaking through the basement membrane of the duct, invading adjacent lobules, ducts, fascial strands, and the mammary fat, spreading through the breast lymphatics and into the peripheral lymphatics. The tumor can grow through the wall of blood vessels, spread into the deep lymphatics of the dermis, and eventually produce edema of the skin (*peau d'orange*), which usually indicates that the superficial as well as deep lymphatics are involved. Skin dimpling can be caused by involvement of Cooper ligament. Ulceration and infiltration of overlying skin, which may develop late in the course of the disease, are usually preceded by fixation and localized redness of the skin over the tumor.

Axillary Spread

Breast carcinoma will typically first spread through the axillary lymph nodes, with the incidence increasing with larger and biologically more aggressive tumors. Depending on the mode of detection, tumor size, histology, and other clinical or pathologic factors, between 10% and 40% of newly diagnosed stage T1 and T2 breast cancers have pathologic evidence of axillary nodal metastases.

Up to 30% to 40% of T1 or T2 clinically node-negative breast cancers may have pathologically involved lymph nodes. However, data from NSABP-04 suggest that less than half of clinically negative but pathologically positive axilla will experience a clinical relapse in the axilla.[32] In this study, patients with operable breast cancer, who were primarily diagnosed with palpable breast tumors in the premammography era, were randomized to one of three arms: simple mastectomy without axillary dissection, simple mastectomy with axillary dissection, or simple mastectomy with comprehensive chest wall and regional nodal irradiation (RNI). In the arm undergoing axillary dissection, nodal positivity was approximately 40%. Nodal control was excellent (>97%) in this arm as well as in the arm treated with radiation. In the simple mastectomy arm, where no nodal treatment by radiation or dissection was administered, the axillary failure rate was approximately 20%. Assuming equal distribution among the arms, it is presumed the pathologic involvement was approximately 40%, indicating that half of those with pathologic involvement eventually failed clinically.

Internal Mammary Spread

Less commonly, breast carcinoma may spread to the internal mammary nodes (IMNs). Metastases to the IMNs are correlated with tumor size, are more frequent from medial half and central lesions, and occur more frequently when there is axillary node involvement. Clinical failure of the IMNs is rare (<1%).[33]

Supraclavicular Spread

Spread to supraclavicular lymph nodes usually follows involvement in the high axillary lymph nodes or IMNs depending on the location of the primary lesion and is also less common. Clinical failure in the supraclavicular fossa is relatively rare in patients with early-stage breast cancer and is dependent on the degree of axillary involvement. For patients with no or minimal nodal involvement (<3 involved axillary nodes), supraclavicular failure is extremely rare. In an analysis of 691 patients with zero to three nodes involved undergoing breast-conserving surgery and RT to tangential fields only without RNI, Galper et al[33] reported failure in the supraclavicular fossa in 1.3% of patients.

Local Control and Systemic Metastasis

Patients treated for breast cancer are at risk for locoregional failure as well as systemic metastasis. It is evident from the available literature that optimizing local control can impact systemic metastasis and survival, and similarly, systemic therapy can impact local control. Integration of systemic therapy with radiation will be discussed in detail later, but numerous studies have clearly demonstrated a significant improvement in local control with the use of RT and systemic therapy (both cytotoxic and hormonal) compared with RT alone.[34-38] Appropriate integration of both local and systemic treatments through a multidisciplinary approach is thus essential to optimize outcome. Although there is some overlap, prognostic factors for locoregional control and systemic metastasis often differ.

For patients with early-stage invasive breast cancer, even with appropriate systemic therapy, development of metastasis can vary from less than 5% in women with T1a disease and favorable histology to more than 40% for women with T2 tumors and pathologically involved lymph nodes. Similarly, locoregional failure rates can vary from less than 5% to over 40% depending on local treatment and prognostic factors for local failure.[34-37,39,40]

The impact of local control on systemic metastasis in breast cancer as well as other malignancies has been the subject of considerable debate and controversy. Although the benefits of local control with respect to cosmesis and quality of life are apparent, the independent effect of local control on systemic disease and survival has been questioned. Many studies have identified local control as an independent predictor of disease-free (DFS) or overall survival (OS).

One of the most convincing and authoritative studies related to this subject is the analysis of the Early Breast Cancer Trialists' Collaborative Group (EBCTCG).[41] In this analysis, over 42,000 women were enrolled in 78 randomized trials that compared 24 types of local treatment (RT vs no RT, more vs less surgery, or more surgery vs RT). The EBCTCG attempted to relate the effect of local control to breast cancer mortality by grouping studies into whether the 5-year local relapse risk difference between the two comparisons of local therapy exceeded 10%. In those comparisons in which the difference in 5-year local recurrence (LR) risk was less than 10%, there was no impact on 15-year breast cancer mortality. However, there were 25,000 women enrolled in trials in whom the comparisons involved more than 10% differences in local control. In those studies, the difference in LR risks at 5 years was 7% versus 26%, and the 15-year mortality risk was 44.6% versus 49.5% ($P < .00001$). Figure 62.5 summarizes the results of this meta-analysis with respect to the impact of radiation on breast cancer mortality both in breast conservation and following mastectomy.

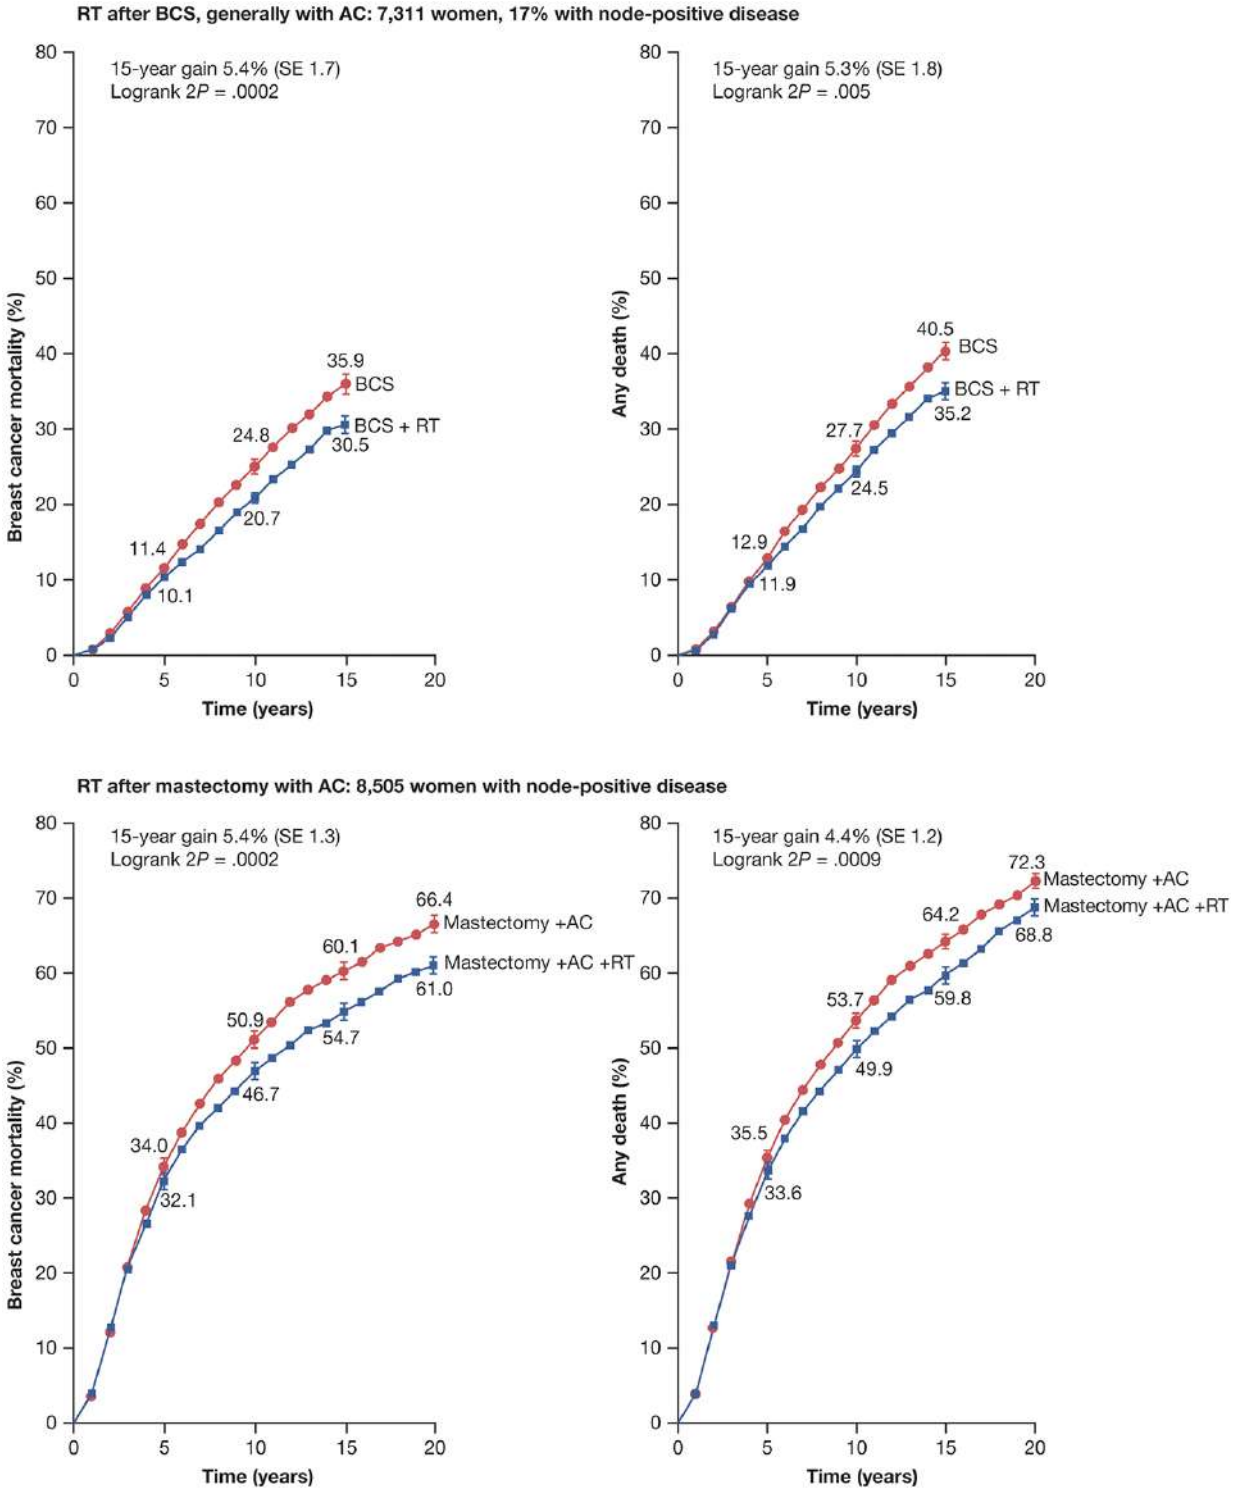

FIGURE 62.5 Effect of radiotherapy (RT) on breast cancer mortality and on all-cause mortality after breast-conserving surgery (BCS) or after mastectomy (AC) with axillary clearance: 15- or 20-year probabilities. SE, standard error. (Reprinted from Clarke M, Collins R, Darby S, et al. Effects of radiotherapy and of differences in the extent of surgery for early breast cancer on local recurrence and 15-year survival: an overview of the randomised trials. *Lancet*. 2005;366[9503]:2087-2106. Copyright © 2005 Elsevier. With permission.)

An update from the EBCTCG focused on 10,801 women enrolled in 17 randomized trials of RT versus no RT after breast-conserving surgery and relates the absolute reduction in 15-year risk of breast cancer death to the absolute reduction in 10-year recurrence risk.[42] Overall, RT reduced the 10-year risk of any first recurrence from 35.0% to 19.3% (*log-rank 2p < 0.00001*) and reduced the 15-year risk of breast cancer death from 25.2% to 21.4% (*log-rank 2p = 0.00005*). In women with pN+ disease (n = 1,050), RT reduced the 10-year recurrence risk from 63.7% to 42.5% (*log-rank 2p < 0.00001*) and the 15-year risk of breast cancer death from 51.3% to 42.8% (*log-rank 2p = 0.01*). Overall, about one breast cancer death was avoided by year 15 for every four recurrences avoided by year 10.

DIAGNOSIS AND WORKUP

Most patients with T1 or T2 breast cancers present with a painless or slightly tender breast mass or have an abnormal screening mammogram. The patient should be examined both sitting up and lying down (to confirm masses felt on the sitting-up examination and to detect lesions deeper in the breast or against the chest wall). Careful inspection of both breasts should be made, including size, form, and symmetry; changes in pigmentation; scaling or discharge from the nipple; and dilated veins or edema of the skin in a patient who is nonpregnant. The location, size, consistency, tenderness, and mobility of the palpable tumor should be recorded. In addition to examination of the breast, careful evaluation of the axilla and supraclavicular node areas is mandatory. The number, consistency, tenderness, mobility or fixation, and size of lymph nodes should be noted.

The comprehensive workup of a patient with a breast mass, including complete clinical and family history, is summarized in Table 62.3.

TABLE 62.3 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE BREAST, STAGES T1 AND T2

General
History with emphasis on presenting symptoms, menstrual status, parity, family history of cancer, other risk factors
Physical examination with emphasis on breast, axilla, supraclavicular area, abdomen
Special Tests
Biopsy (core biopsy directed by physical examination, ultrasound, or mammography as indicated, or needle localization)
Radiologic Studies
Before biopsy
Bilateral diagnostic mammography/ultrasonography
Chest radiographs
Magnetic resonance imaging of breast (selected cases)
After positive biopsy
Bone scan (when clinically indicated, for stage II or III disease or elevated serum alkaline phosphatase levels)
Computed tomography of the chest, abdomen, and pelvis for stage II or III disease and/or abnormal liver function tests
Laboratory Studies
Complete blood cell count
Comprehensive metabolic panel, including liver function tests and alkaline phosphatase
Other Studies
Hormone receptor status (ER, PR)

HER2/neu status
Consider genetic counseling/*BRCA* testing in high-risk patients
Counseling for fertility if premenopausal
Assess for distress

ER, estrogen receptor; PR, progesterone receptor.

Imaging in Breast Cancer Diagnosis and Workup

Mammography

Mammography remains the most critical component of diagnostic imaging in patients with breast cancer, and bilateral mammograms should be performed routinely in the workup of the patient with breast cancer. The Breast Imaging Reporting and Data System classification system, outlined in Table 62.4, has been widely adopted in classifying mammograms with respect to appropriate follow-up and intervention.[43]

TABLE 62.4 CONCORDANCE BETWEEN BI-RADS® ASSESSMENT CATEGORIES AND MANAGEMENT RECOMMENDATIONS

Assessment	Management	Likelihood of Cancer
Category 0: Incomplete – Need Additional Imaging Evaluation and/or Prior Mammograms for Comparison	Recall for additional imaging and/or comparison with prior examination(s)	N/A
Category 1: Negative	Routine mammography screening	Essentially 0% likelihood of malignancy
Category 2: Benign	Routine mammography screening	Essentially 0% likelihood of malignancy
Category 3: Probably Benign	Short-interval (6-month) follow-up or continued surveillance mammography (Figure 155, see page 152)	> 0% but ≤ 2% likelihood of malignancy
Category 4: Suspicious	Tissue diagnosis	> 2% but < 95% likelihood of malignancy
Category 4A: *Low suspicion* for malignancy		> 2% to ≤ 10% likelihood of malignancy
Category 4B: *Moderate suspicion* for malignancy		> 10% to ≤ 50% likelihood of malignancy
Category 4C: *High suspicion* for malignancy		> 50% to < 95% likelihood of malignancy
Category 5: Highly Suggestive of Malignancy	Tissue diagnosis	≥ 95% likelihood of malignancy
Category 6: Known Biopsy-Proven Malignancy	Surgical excision when clinically appropriate	N/A

The radiation oncologist should be familiar with the difference between diagnostic and screening mammography, because a majority of conservatively treated patients with breast cancer will have undergone diagnostic mammography prior to treatment, as well as in follow-up. Screening mammography refers to routine mammographic images in asymptomatic women and consists of two views: craniocaudal and mediolateral oblique of each breast. Diagnostic mammography is used to characterize abnormalities detected at screening or in women with palpable masses, employs additional magnification views, and is generally done with the radiologist present to determine the need for additional views or follow-up studies. Following breast conservation, most patients will undergo diagnostic mammograms. Some mammographers recommend reverting to screening studies after several years of stable mammography in the conservatively managed patient with breast cancer.

Classically, breast carcinoma is seen as an ill-defined mass that may have spiculated margins (Figure 62.6), although rarely cancers may also be seen with a knobby, lobulated, or even a smooth contour (ultrasonography may distinguish them from cystic masses). Architectural distortion of the breast tissue may be present. The appearance of linear, radiated, or spiculated changes around a central focus should always be considered suspect for carcinoma. The tumor may be hidden by dense parenchyma; review of previous mammogram compression views, tomosynthesis views, and sometimes ultrasonograms can all be very important in detecting subtle interval changes in the appearance of the breast.

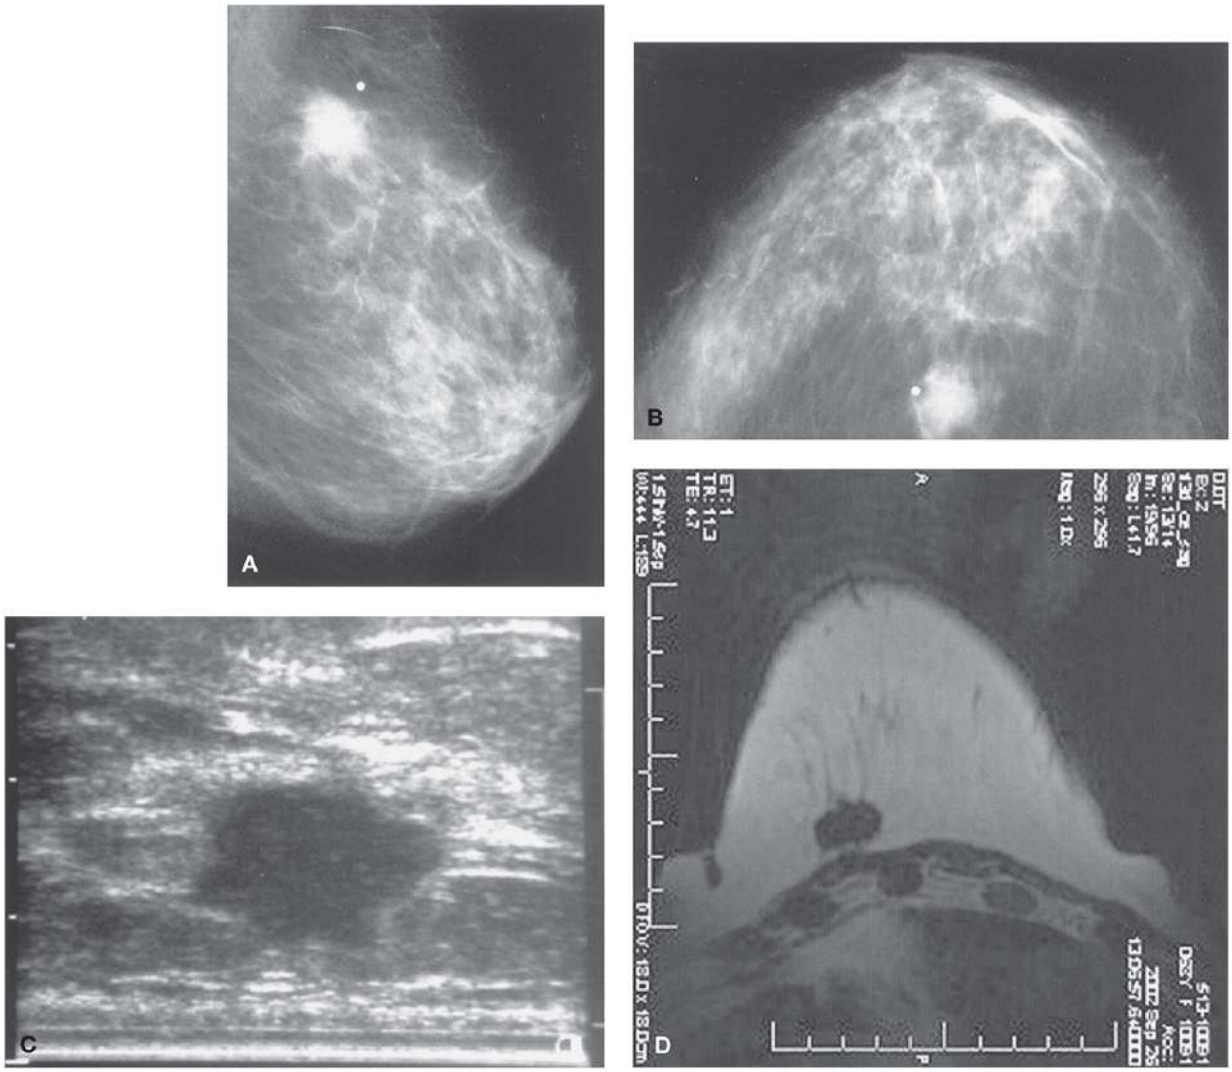

FIGURE 62.6 Mediolateral (A) and cephalocaudal (B) views of mammogram depicting a 1-cm mass with stellate margins deeply located in the upper quadrant of the left breast, histologically proven to be an invasive ductal carcinoma. Example of ultrasonogram of the breast showing a hypoechoic mass with "shadowing" deeper to the lesion, characteristic of invasive carcinoma (C). T1-weighted magnetic resonance image of the breast demonstrating a mass that proved to be an invasive carcinoma (D).

Calcifications can be associated with either benign or malignant conditions of the breast. However, calcifications associated with malignant tumors are typically 100 to 300 μm in size and are rodlike, tubular, branching, or punctate. Clusters of microcalcifications (>5) are suggestive of intraductal disease, and in nonpalpable lesions, needle localization aids in the diagnosis (Figure 62.7). For patients undergoing biopsy of a suspicious mass or calcifications, about 30% will yield a diagnosis of malignancy. The average sensitivity of mammography is approximately 90% (60%-95%), and the specificity is 94% (50%-98%). The positive predictive value is approximately 8% to 14% for screened patients but is significantly higher for patients with symptoms or palpable masses.[44] If microcalcifications were initially present, radiographs of the surgical specimen and postlumpectomy mammography are important to rule out residual disease for patients considering breast conservation therapy.

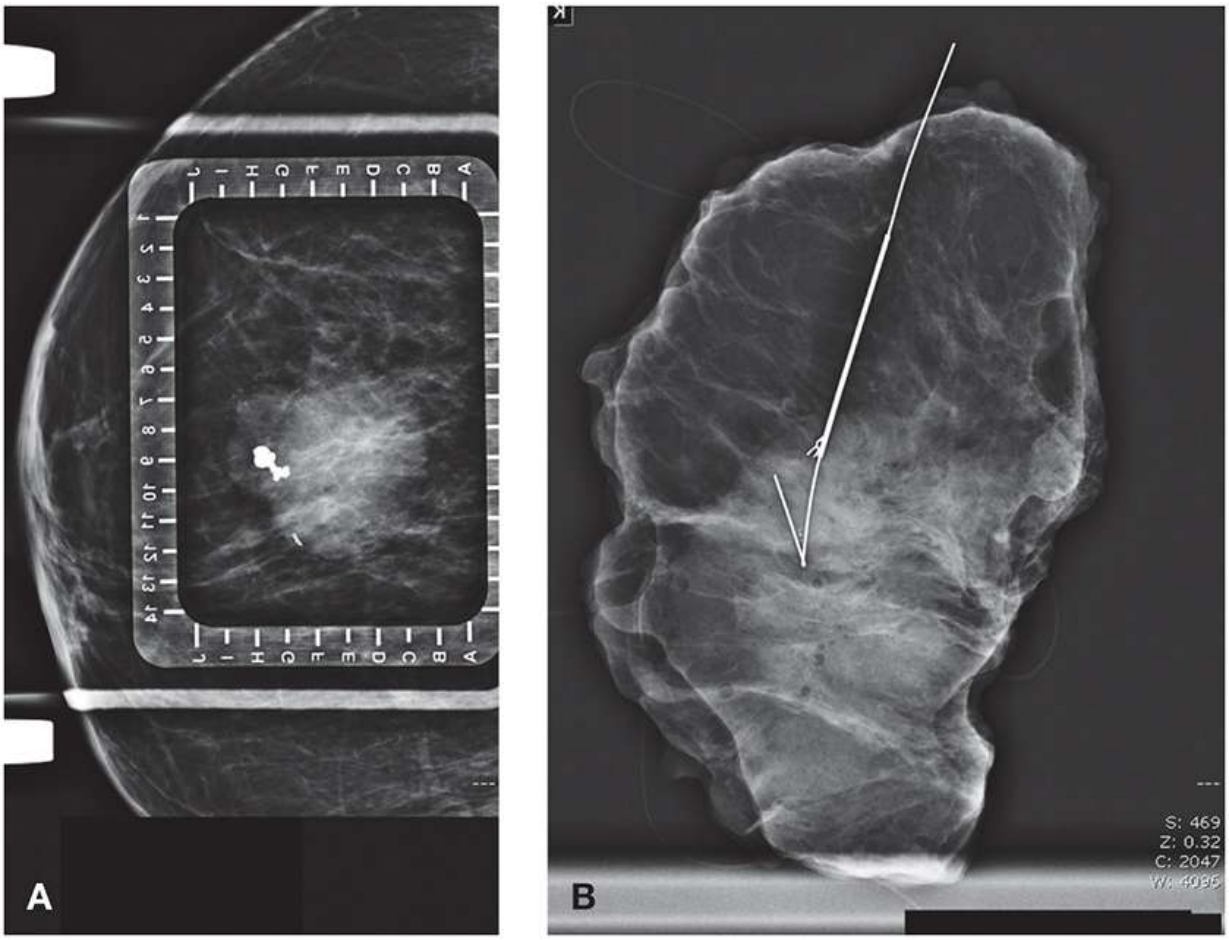

FIGURE 62.7 A. Mammogram demonstrating microcalcifications in the central portion of the breast with needle localization in place. B. Radiograph showing microcalcifications in the central portion of the wide excisional biopsy specimen. Pathologic diagnosis was intraductal carcinoma. Postlumpectomy mammogram showed no residual calcifications in the breast. The patient was treated with breast conservation surgery and irradiation years ago and remains tumor free.

Ultrasound

Ultrasound can be a useful tool to complement physical examination and mammography in the diagnosis and treatment of breast cancer. Ultrasonography has a reported sensitivity of 73% and specificity of 95%.[45] It is very helpful in differentiating cysts from solid tumors, and its primary use is the identification and characterization of palpable and nonpalpable abnormalities of the breast detected by physical examination or mammography. In the evaluation of a palpable mass in 420 patients, if both mammography and ultrasound are negative, Soo et al[46] reported the negative predictive value to be more than 99%.

In addition to complementing physical examination and mammography in diagnosis, ultrasound is often used as a guide for interventional procedures. Ultrasound-guided core biopsies are routinely performed in the diagnosis of breast cancer and have been shown to be more cost-effective than stereotactic biopsy. Ultrasound can also be used for fine-needle aspiration (FNA) biopsies, cyst aspirations, presurgical localizations, and evaluation of breast tissue surrounding implants.

Magnetic Resonance Imaging

The routine use of breast magnetic resonance imaging (MRI) as part of the breast cancer workup is controversial. National consensus guidelines recommend breast MRI for staging evaluation to define the extent of cancer or presence of multifocal or multicentric cancer in the ipsilateral breast or as screening of the contralateral breast at the time of initial diagnosis. They also indicate MRI would be useful for evaluation before and after neoadjuvant chemotherapy, to identify the primary cancer in women with axillary nodal carcinoma or occult primary cancer, or in patients with invasive lobular carcinoma (ILC) poorly defined on mammography.

Computed Tomography

There is no established role for computed tomography (CT) scans in routine staging of patients with early-stage breast cancer. The need for iodine contrast material to differentiate benign from malignant conditions, high radiation dose, cost per study, and inability to detect small lesions precludes the use of CT for initial evaluation, except under special circumstances. Most patients with node-negative breast cancer do not need to undergo routine CT scans for staging, because the yield is exceeding low. A small percentage of women with very high-risk node-negative disease or with node-positive disease may be upstaged by routine CT scans, and although the yield is low, it is common practice to CT stage patients with high-risk node-negative and node-positive breast cancer. Many women undergoing breast-conserving surgery and radiation do have CT scans as part of RT treatment planning. Without the use of contrast and specific diagnostic imaging protocols, these scans should not be considered as part of a staging procedure.

Bone Scans

Similar to CT imaging, routine bone scan at the time of initial treatment of stage I and II breast cancer is of limited value and should be reserved for patients with symptoms, such as bone pain.

Positron Emission Tomography Scanning

Positron emission tomography (PET) using ^{18}F-labeled fluorodeoxyglucose scanning is not a routine component of staging. Its application in patients on initial presentation with early-stage disease has not been established. However, per national consensus guidelines, PET staging may have a role in patients with metastatic, locally advanced, or recurrent disease.

Pathologic Studies

Histopathologic diagnosis may be obtained by FNA, core-needle biopsy (CNB), or surgical biopsy. During an FNA, a small amount of breast tissue or fluid is removed with a thin, hollow needle. If there is a palpable breast abnormality, the procedure can be done by physical examination, but it can also be done using image guidance. FNA biopsies can provide quick results; however, the sample obtained may not be sufficient for additional laboratory testing, such as receptor testing. During a CNB, a hollow needle is used to take out a higher volume of tissue from the breast. This is typically performed with image guidance, such as mammogram (stereotactic-guided CNB), ultrasound (ultrasound-guided CNB), or MRI (MRI-guided CNB). A clip is placed at the biopsy site for future localization. Compared to an FNA biopsy, a CNB can more reliably establish an accurate diagnosis and provide sufficient tissue for further testing and breast cancer subtype categorization. A surgical biopsy may be necessary after an FNA or CNB returns as nondiagnostic or benign but discordant with imaging findings.

In the United States, ER and progesterone receptor (PR) assays are routinely done for patients with breast cancer. The *HER2/neu* assay is also done routinely, either by immunohistochemical

(IHC) analysis, which tests for protein expression, or by fluorescence in situ hybridization (FISH), which tests for gene amplification. FISH testing is often employed for patients with equivocal IHC results. Patients who exhibit overexpression are candidates for *HER2/neu*-targeted therapies.

Staging

Two staging systems are widely used for breast cancer: the American Joint Committee on Cancer (AJCC) (Table 62.5) and the Union Internationale Contre le Cancer systems.[47,48] Major changes made in the eighth edition of the *AJCC Cancer Staging Manual* include the following[49]:

TABLE 62.5 AMERICAN JOINT COMMITTEE ON CANCER STAGING OF BREAST CANCER

Primary Tumor (T)	
Definitions for classifying the primary tumor (T) are the same for clinical and pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1-cm increment.	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (Paget)	Paget disease of the nipple with no tumor
Note: Paget disease associated with a tumor is classified according to the size of the tumor.	
T1	Tumor ≤20 mm in greatest dimension
T1mic	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin (ulceration or macroscopic nodules); invasion of the dermis alone does not qualify as T4.
T4a	Extension to the chest wall; invasion or adherence to pectoralis muscle in the absence of invasion of chest wall structures does not qualify as T4.
T4b	Ulceration and/or ipsilateral macroscopic satellite nodules and/or edema (including peau d'orange) of the skin that does not meet the criteria for inflammatory carcinoma
T4c	Both (T4a and T4b)
T4d	Inflammatory carcinoma
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed (eg, previously removed).
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary lymph node(s)
N2	Metastasis to ipsilateral axillary lymph node(s) fixed or matted or in clinically apparent[a] ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
N2a	Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures

N2b	Metastasis only in clinically apparent[a] ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
N3	Metastasis to ipsilateral mammary lymph node(s) with or without axillary lymph node involvement or in clinically apparent[a] ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)
Pathologic Classification (*p*N)	
*p*NX	Regional lymph nodes cannot be assessed (eg, previously removed or not removed for pathologic study).
*P*N0	No regional lymph node metastasis histologically, no additional examination for isolated tumor cells (ITCs)
Note: ITCs are defined as single tumor cells or small cell clusters not >0.2 mm, usually detected only by immunohistochemical (IHC) or molecular methods but which may be verified on hematoxylin and eosin stains. ITCs do not usually show evidence of malignant activity (eg, proliferation or stromal reaction).	
p N0(i−)	No regional lymph node metastasis histologically, negative IHC
p N0(i+)	No regional lymph node metastasis histologically, positive IHC, IHC cluster no >0.2 mm
p N0(mol−)	No regional lymph node metastasis histologically, negative molecular findings (reverse transcriptase polymerase chain reaction [RT-PCR])
p N0(mol+)	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR)
p N1	Metastasis in 1-3 axillary lymph nodes and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection, but not clinically apparent[b]
p N1mi	Micrometastasis (approximately 200 cells, >0.2 mm, none >2.0 mm)
p N1a	Metastasis in 1-3 axillary lymph nodes, one >2.0 mm
p N1b	Metastasis in internal mammary nodes with microscopic disease detected by sentinel node dissection, but not clinically apparent[c]
p N1c	pN1a and pN1b combined
p N2	Metastasis in 4-9 axillary lymph nodes or in clinically apparent[b] internal mammary lymph nodes in the absence of axillary lymph node metastasis
p N2a	Metastasis in 4-9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
p N2b	Metastasis in clinically apparent[b] internal mammary lymph nodes in the absence of axillary lymph node metastasis
p N3	Metastasis in ≥10 axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent[b] ipsilateral internal mammary lymph nodes in the presence of ≥1 positive axillary lymph nodes; or in >3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes or in ipsilateral supraclavicular lymph nodes
p N3a	Metastasis in ≥10 axillary lymph nodes (at least one tumor deposit >2.0 mm) or metastasis to the infraclavicular lymph nodes
p N3b	Metastasis in clinically apparent[b] ipsilateral internal mammary lymph nodes in the presence of ≥1 positive axillary lymph nodes or in >3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection, but not clinically apparent[c]
p N3c	Metastasis in ipsilateral supraclavicular lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis

cM0(i+)	No clinical or radiographic evidence of distant metastases in the presence of tumor cells and/or no deposits no >0.2 mm detected microscopically or by using molecular techniques in circulating blood, bone marrow, or other nonregional lymph node tissue in a patient without symptoms or signs of metastases
M1	Distant metastases detected by clinical and radiographic means (cM) and/or histologically proven metastases >0.2 mm (pM)

[a]Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.

[b]Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

[c]Not clinically apparent is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

- The inclusion of two-stage grouping systems. The *anatomic* stage group table is based solely on anatomic extent of cancer as defined by the T, N, and M categories. The *prognostic* stage group table is based on populations of persons with breast cancer who have been offered—and mostly treated with—appropriate endocrine and/or systemic chemotherapy, which includes anatomic T, N, and M plus tumor grade and the status of the biomarkers human epidermal growth factor receptor 2 (HER2), ER, and PR.
- LCIS is removed as a pathologic tumor in situ (pTis) category for T categorization. LCIS is a benign entity and is removed from TNM staging.
- The general rules for rounding to the nearest millimeter do not apply for tumors between 1.0 and 1.5 mm so that these cancers are not classified as microinvasive (T1mi) carcinomas (defined as invasive tumor foci ≤1.0 mm). Tumors greater than 1 and less than 2 mm should be reported rounding to 2 mm.

The T categorization of multiple synchronous tumors is identified clinically and/or by macroscopic pathologic examination, and their presence is documented using the (m) modifier for the T category. Figure 62.8 depicts the various clinical stages according to tumor and nodal characteristics.

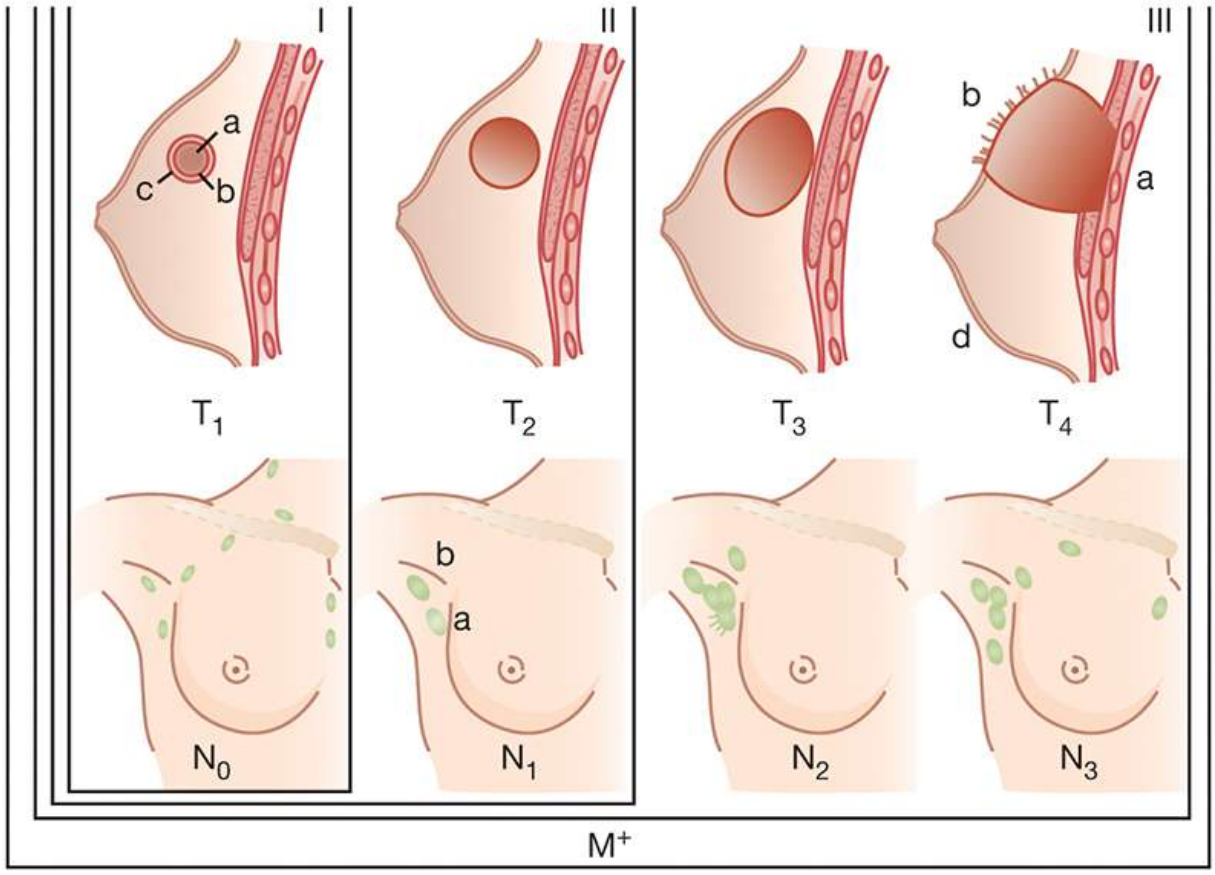

FIGURE 62.8 Clinical staging of carcinoma of the breast. Stages, in part, reflect curability by locoregional treatment modalities prognostically (surgery and radiation therapy). The equivalence of T and N categories are as follows: T2 = N1, T3 = N2, T4 = N3. The American Joint Committee on Cancer and Union Internationale Contre le Cancer classification systems use similar categories and stages. (Reprinted from Langmuir VK, Poulter CA, Qazi R, et al. Pathologic Classification

The World Health Organization (WHO) has classified proliferative conditions and tumors of the breast into the following categories: benign mammary dysplasias, benign or apparently benign tumors, carcinoma, sarcoma, carcinosarcoma, and unclassified tumors. The AJCC has adopted the WHO classification of tumors as shown in Table 62.6.[47]

TABLE 62.6 AMERICAN JOINT COMMITTEE ON CANCER HISTOPATHOLOGIC CLASSIFICATION OF BREAST TUMORS

Type
Precursor lesions
Ductal carcinoma in situ
Lobular neoplasia
Lobular carcinoma in situ
Classic lobular carcinoma in situ
Pleomorphic lobular carcinoma in situ
Atypical lobular hyperplasia
Intraductal proliferative lesions

- Usual ductal hyperplasia
- Columnar cell lesions including flat epithelial atypia
- Atypical ductal hyperplasia

Papillary lesions
- Intraductal papilloma
  - Intraductal papilloma with atypical hyperplasia
  - Intraductal papilloma with ductal carcinoma in situ
  - Intraductal papilloma with lobular carcinoma in situ
- Intraductal papillary carcinoma
- Encapsulated papillary carcinoma
  - Encapsulated papillary carcinoma with invasion
- Solid papillary carcinoma
  - In situ
  - Invasive

Invasive carcinoma of no special type (NST)
- Pleomorphic carcinoma
- Carcinoma with osteoclast-like stromal giant cells
- Carcinoma with choriocarcinomatous features
- Carcinoma with melanotic features

Invasive lobular carcinoma
- Classic lobular carcinoma
- Solid lobular carcinoma
- Alveolar lobular carcinoma
- Pleomorphic lobular carcinoma
- Tubulolobular carcinoma
- Mixed lobular carcinoma

Tubular carcinoma

Cribriform carcinoma

Mucinous carcinoma

Carcinoma with medullary features
- Medullary carcinoma
- Atypical medullary carcinoma
- Invasive carcinoma NST with medullary features

Carcinoma with apocrine differentiation

Carcinoma with signet-ring cell differentiation

Invasive micropapillary carcinoma

Metaplastic carcinoma of NST
- Low-grade adenosquamous carcinoma
- Fibromatosis-like metaplastic carcinoma
- Squamous cell carcinoma
- Spindle cell carcinoma
- Metaplastic carcinoma with mesenchymal
  - Differentiation
  - Chondroid differentiation
  - Osseous differentiation
  - Other types of mesenchymal differentiation
- Mixed metaplastic carcinoma
- Myoepithelial carcinoma

Epithelial-myoepithelial tumors

Adenomyoepithelioma with carcinoma

Adenoid cystic carcinoma

Rare types

Carcinoma with neuroendocrine features
Neuroendocrine tumor, well differentiated
Neuroendocrine carcinoma poorly differentiated (small cell carcinoma)
Carcinoma with neuroendocrine differentiation
Secretory carcinoma
Invasive papillary carcinoma
Acinic cell carcinoma
Mucoepidermoid carcinoma
Polymorphous carcinoma
Oncocytic carcinoma
Lipid-rich carcinoma
Glycogen-rich clear cell carcinoma
Sebaceous carcinoma

Data from Amin MB, Edge SB, Greene FL, et al, eds. *AJCC Cancer Staging Manual*. 8th ed. Springer; 2017.

The radiation oncologist should be familiar with the histologic characteristics of breast cancer because many of them affect prognosis and may have important therapeutic implications. Brief descriptions of several types of carcinoma of the breast follow.

Microinvasive carcinoma is defined as "the extension of cancer cells beyond the basement membrane into the adjacent tissues with no focus more than 0.1 cm in greatest dimension." Lesions that fulfill this definition are staged as T1mic, a subset of T1 breast cancer. The AJCC staging manual further states that "when there are multiple foci of microinvasion, the size of only the largest focus is used to classify the microinvasion" and that the sizes of the individual foci should not be added together. They also state that "the prognosis of microinvasive carcinoma is generally thought to be quite favorable, although the clinical impact of multifocal microinvasive disease is not well understood at this time." Widely varying definitions of microinvasion have been used, and some differ substantially from that offered here.[47]

Invasive (infiltrating) ductal carcinoma is the most common type of breast cancer, constituting more than 50% of all cases. It appears as solid cords or groups of ductal tumor cells varying in size and cytoplasmic content and degree of differentiation. An associated in situ component is frequently seen.

Tubular carcinoma is composed of tubular structures typically lined by a single layer of well-differentiated epithelium. The tubular cells simulate those of normal ducts or ductules, are arranged in multiglandular cribriform or adenocystic configurations, and are frequently associated with other in situ carcinomas of the breast.[50] Tubular carcinomas have a nonaggressive growth pattern with an excellent prognosis.

Medullary carcinoma is composed of cords and masses of large cells with reticular pleomorphic nuclei containing prominent nucleoli. There is a scant fibrous stroma, but lymphoid infiltrate is prominent. These tumors are microscopically and grossly well circumscribed. Prognosis, in general, is better than for other tumors. These tumors are more frequently seen in younger women and are commonly associated with patients with *BRCA1* mutations.[51]

Lobular invasive carcinoma may be interspersed; the cells appear singly or in small clusters in a targetoid or single-file pattern. Some scirrhous carcinomas probably are invasive lobular lesions; these tumors tend to be aggressive and multicentric and are prone to the development of distant metastases. Du Toit et al[52] reported five subtypes of lobular carcinomas in 171 cases and observed a 12-year actuarial survival rate of 100% for the tubulolobular subtype but only 47% for the solid variant. Two other characteristics of ILC is that it is often "mammographically silent," meaning its detection or the full appreciation of extent of disease is often not visualized mammographically.

Invasive lobular cancers are much more commonly ER positive than is invasive ductal carcinoma (IDC). Infiltrating pleomorphic lobular carcinoma is an aggressive variant of ILC.

Mucinous carcinoma, also called mucoid or colloid carcinoma, has been observed in older women with relatively long duration of symptoms. It is slow growing with a pushing border. Necrosis, lymphatic invasion, and nodal metastasis are rare. Survival is typically better than with IDC.[53]

Adenocystic carcinoma is rarely found in the breast. Histologic features and clinical behavior are similar to its counterpart in the salivary gland and the upper respiratory tract. Limited data demonstrate low LR and high DFS rates.[54]

Invasive micropapillary carcinoma of the breast is characterized by growth of tumor cell clusters in prominent clear spaces resembling dilated angiolymphatic vessels. Nassar et al[55] reported on 83 invasive micropapillary carcinomas; the mean tumor size was 4 cm, 22% invaded skin, 58% were poorly differentiated, and 71% were ER positive. Axillary node metastases were present in 77% of cases and were typically multiple (51% had three or more positive). Forty-six percent of the patients died from their disease (mean interval to death, 36 months). Skin involvement and nodal status were the only parameters predictive of poor survival ($P = .01$).

Metaplastic carcinoma is relatively rare. Beatty et al,[56] of the Swedish Cancer Institute, identified 24 cases that were compared with typical breast cancer cases matched for age; date of diagnosis; stage; and ER, PR, and *HER2* status. The mean metaplastic primary tumor diameter was 2.5 cm. The histologic or nuclear grade was high in 21 of 24 cases. ER or PR status was negative in all cases. *HER2* was negative in 10 of 11 cases tested. Epidermal growth factor receptor (EGFR; *HER1*) was positive in seven of seven cases tested. Five-year survival was 83% (95% CI, 66%-100%). Comparison with matched typical breast cancer cases revealed no significant difference in multidisciplinary treatment patterns, recurrence, or survival. The increased expression of EGFR (*HER1*) may provide an opportunity for targeted therapy in these tumors.

In an analysis of the MD Anderson Cancer Center experience and the Surveillance, Epidemiology, and End Results (SEER) database, Hennessy et al[57] identified 100 patients with metaplastic sarcomatoid carcinoma and 213 patients in the SEER database with similar histology. They concluded that these are aggressive tumors with poor response to therapy and poor outcomes, suggesting that studies evaluating novel targeted therapy are needed for these patients.

Paget disease describes involvement of the nipple by tumor. The tumor seems to travel linearly down the ducts and may appear to be multicentric. There may be an associated subareolar tumor. Breast-conserving surgery followed by radiation is effective in this disease.[58]

Cystosarcoma phyllodes is usually a benign lesion; in broad, fibrous beads that look “leaflike” are cystic clefts lined by a single layer of cells. These tumors are large; usually, they are encapsulated, without invasion of the adjacent breast. The lesions frequently develop from preexisting fibromas and have a long initial period of slow growth followed by a sudden, rapid increase in size. The grade (mitotic rate), surgical margins, and proliferative index have prognostic importance.

Primary mammary lymphomas are rare and constitute approximately 0.5% of breast malignancies and approximately 1% of all non-Hodgkin lymphomas. Diffuse large B-cell lymphoma is the most common histologic subtype of primary breast lymphoma (50%-80%). The indolent histologic subtypes of marginal zone lymphoma (10%-30%) and follicular lymphoma (10%-20%) are the next most frequent. Burkitt lymphoma (typically in pregnancy or lactation) constitutes approximately 5%, with the more recently described entity of breast implant–associated anaplastic large cell lymphoma making up an increasing proportion of the remaining cases.[59]

Sarcoma

Primary breast sarcomas are occasionally seen. McGowan et al[60] described 78 cases of primary breast sarcoma without metastatic disease (76 women, 2 men); 32 patients had malignant cystosarcoma phyllodes, and the others had stromal sarcomas (14 patients), angiosarcomas (8 patients), fibrosarcomas (7 patients), carcinosarcomas (5 patients), liposarcomas (4 patients), or other lesions (8 patients). The cause-specific survival rate was 48%, the relapse-free rate was 42%, and the local relapse–free rate was 75% at 10 years. No statistically significant difference in outcome was noted between those treated with conservation surgery and those undergoing mastectomy. Patients with negative margins had a significantly better local relapse–free rate than did those with positive margins (80% vs 33%; $P = .009$).

PROGNOSTIC FACTORS FOR SURVIVAL AND METASTASIS

Carcinoma of the breast represents a wide spectrum of tumors with a variety of clinical, biologic, and genetic characteristics resulting in a considerable variation in prognosis. It is important to understand, particularly from the radiation oncologists' perspective, that prognostic factors for systemic relapses and prognostic factors for local relapse differ significantly. Furthermore, prognostic factors for local relapse after mastectomy differ substantially from prognostic factors for local relapse after lumpectomy and radiation. For example, tumor size and nodal status are clearly among the strongest predictors of OS and metastasis and are also strong predictors of postmastectomy chest wall relapse when radiation is not used. However, these factors have not been consistently reported to be prognostic for an in-breast relapse after cancer surgery. On the other hand, margin status is a strong predictor of relapse in the conservatively treated breast but is not strongly correlated with distant metastasis. Young age is also a very strong predictor of local relapse after breast-conserving therapy (BCT), and although it has been shown to be predictive of systemic metastasis, the effect of young age on distant metastasis as an independent factor is clearly not as significant as it is for local relapse in the conservatively managed patient. Patients, as well as clinicians, often become confused regarding these issues, resulting in misconceptions regarding appropriate decision-making and treatment. Below, prognostic factors for systemic relapse (ie, distant metastasis and DFS and OS) are discussed. A more in-depth discussion of prognostic factors for local relapse following lumpectomy and radiation is included later in the section on selection factors for the conservative management of breast cancer. Prognostic factors related to postmastectomy chest wall recurrence for patients with early-stage disease are discussed in Chapters 63.

Tumor Size

The size of the primary tumor ranks among the strongest predictors of distant metastasis and DFS and OS. Although tumor size correlates strongly with the presence and number of involved axillary lymph nodes, it is clearly an independent prognostic factor. Among patients with documented node-negative disease, tumor size remains a strong and independent predictor of DFS and OS. In a classic study with over 20 years of follow-up, Rosen et al[61] reported a recurrence-free survival of 88% for tumors less than 1 cm, 72% for tumors 1.1 to 3.0 cm, and 59% for tumors 3.1 to 5.0 cm.

Axillary Nodal Status

Of all prognostic factors, nodal status continues to be the strongest predictor of DFS and OS and is the primary factor that governs breast cancer staging (Figure 62.9).[47] Although there is a direct

relation between the number of axillary nodes involved and the risk of distant metastasis, the most commonly employed schema is to group patients into four prognostic categories (node negative, 1-3 involved nodes, 4-9 involved nodes, and >10 involved nodes). These nodal prognostic categories are employed in the N staging of the current AJCC staging system. Although outcomes will continually improve as systemic therapies advance, data from previous NSABP trials treated primarily with locoregional therapy alone revealed 5-year survival rates of 82.8% for node negative, 73% for 1 to 3 positive nodes, 45.7% for 4 to 12 positive nodes, and 28.4% for more than 13 positive nodes.[32,62,63]

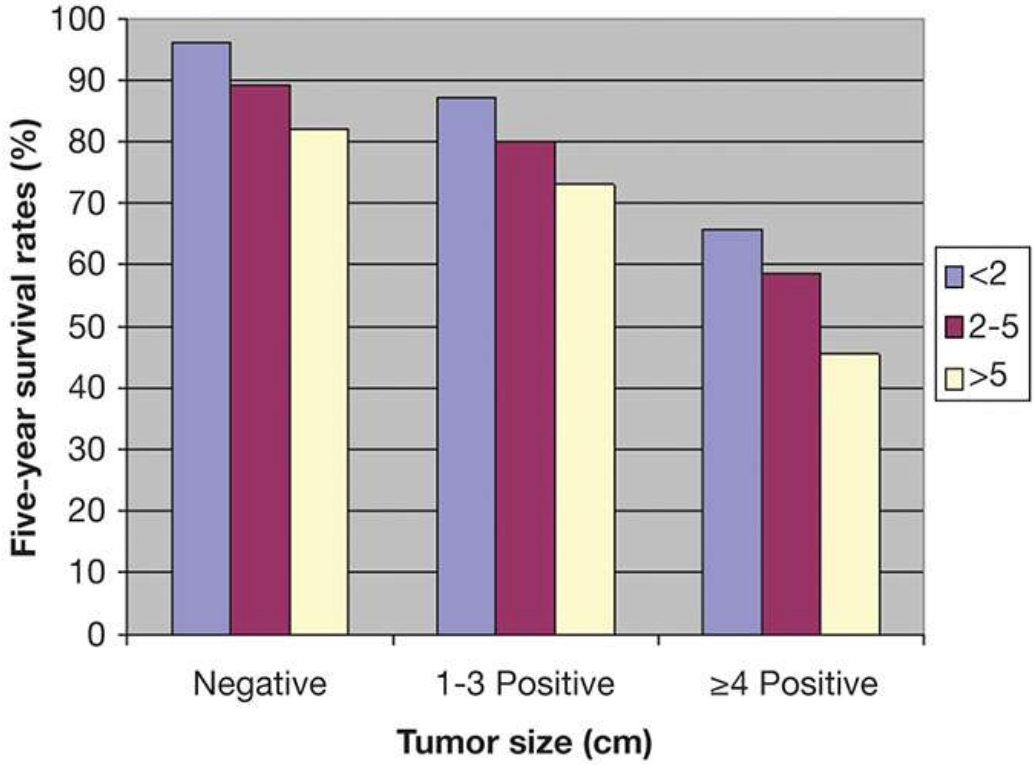

FIGURE 62.9 Five-year survival according to tumor size and nodal status. (Adapted from Carter CL, Allen C, Henson DE. Relation of tumor size, lymph node status, and survival in 24,740 breast cancer cases. *Cancer*. 1989;63[1]:181-187. Copyright © 1989 American Cancer Society. Micrometastasis

The influence of microscopic disease in the lymph nodes has been the subject of several analyses because of the increased detection of micrometastasis in the era of sentinel lymph node biopsy (SLNB). Most studies have demonstrated that using a combination of blue dye and radiolabeled colloid techniques, the sentinel node can be identified in more than 95% of cases.[64-66] In experienced hands, false-negative sentinel node rates are low (<10%), and prognosis of sentinel node–negative patients is similar to that of node-negative patients who have undergone a complete axillary dissection. Although the standard of care for sentinel node–positive patients has traditionally been completion axillary dissection, results of the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial have challenged the need for completion axillary dissection in selected sentinel node–positive patients.[67] The need for axillary dissection in node-positive patients will likely continue to be highly individualized and will be further evaluated in ongoing clinical trials.[68]

Hansen et al[69] evaluated the sentinel node in 696 women by hematoxylin and eosin staining and IHC. With a median follow-up of 38 months, the size of the sentinel node metastasis (<2 or >2 mm) was a significant prognostic factor. There was no difference in DFS or OS, however, between true node-negative and IHC-only–positive cases.

Tumor Type

The histologic subtype of invasive cancer has been shown to be of prognostic value in several studies. The tubular, mucinous, and medullary subtypes have been shown to have a more favorable prognosis, compared with invasive ductal.[61,70] Invasive lobular tumors appear to have a prognosis similar to invasive ductal tumors.[71] Poor prognostic categories include metaplastic, undifferentiated, and other rarer subtypes. In a classic analysis of 293 T2N0 breast cancers with over 20 years of follow-up treated by mastectomy, Rosen et al[61] reported more favorable relapse rates in medullary, mucinous, tubular, and papillary subtypes compared with invasive ductal and invasive lobular tumors.

Tumor Grade

Multiple tumor grading systems have been proposed in an effort to standardize and improve interobserver variability. The Scarff-Bloom-Richardson classification system utilizes mitotic index, differentiation, and pleomorphism, each with scores of 1 to 3. Total scores of 3 to 5 are well differentiated, 6 to 7 moderately differentiated, and 8 to 9 poorly differentiated. This system is commonly employed and has been shown to be of independent prognostic significance.[72]

Elston and Ellis of the Nottingham group refined this methodology.[73] The revised technique involves evaluation of three morphologic features—the percentage of tubule formation, the degree of nuclear pleomorphism, and an accurate mitotic count using a defined field area. A numerical scoring system is used, and the overall grade is derived from a summation of individual scores for the three variables: three grades of differentiation are used. Histologic grade, assessed in 1,831 patients, shows a very strong correlation with prognosis; patients with grade 1 tumors have a significantly better survival than do those with grade 2 and 3 tumors ($P < .0001$). If the protocol is followed, reproducible and consistent results regarding prognosis can be obtained.

Estrogen and Progesterone Hormonal Receptors in Tumor Cells

Hormone receptor–positive breast cancers have either the ER, PR, or both. The majority of breast cancers are hormone receptor positive, and they can be treated with hormone therapy drugs. Hormone receptor–positive tumors typically grow more slowly compared to hormone receptor–negative tumors, and their associated outcomes are more favorable. Recurrences of hormone receptor–positive breast cancer can, however, occur many years after treatment.

HER2/neu

The *HER2/neu* proto-oncogene (also called c-*erbB-2*) located on chromosome 17 codes for a transmembrane glycoprotein, p185, which has tyrosine kinase activity and is homologous to the EGFR.[74] It is amplified or overexpressed in up to 20% of human breast carcinomas. Overexpression of the protein is associated with tumor aggressiveness and decreased DFS in node-positive patients, with variable prognostic significance among node-negative patients. The conflicting reports regarding the prognostic significance of *HER2/neu* may be related to interobserver variability in interpretation of staining and uncertainty regarding the significance of intermediate staining.[74-76]

Staining for overexpression of *HER2/neu* is interpreted on a 0 to 3+ scale. The available data suggest that the majority of 0 to 1 staining is clearly negative and 3+ is clearly positive, while the classification of those patients with 2+ staining remains uncertain. Amplification of the oncogene identified using FISH techniques has been found to be of more prognostic value.[74-77]

Patients who are found to be positive for *HER2/neu* are candidates for targeted therapies. Romond et al[78] reported on the combined results of two trials comparing adjuvant chemotherapy with or without concurrent trastuzumab, a monoclonal antibody that binds to the *HER2/neu* protein, in patients with surgically resected *HER2/neu*-positive breast cancer. At 3 years, the DFS was 75.4% in the control group and 87.1% in the trastuzumab group (absolute difference 11.8%; 95% CI, 8.1-15.4).

Lymphatic and Vascular Invasion

Lymphatic and vascular invasion (LVI) in the peritumoral region has been clearly demonstrated to be of independent prognostic significance.[79] In the study by Rosen et al,[61] recurrence rate for patients who are LVI-positive stage I was 38% compared with 22% for patients who are LVI-negative.

Proliferative Indices, S-Phase, and Thymidine Labeling Index

Various techniques for evaluating the proliferative rate of a tumor have been shown to correlate with distant metastasis and survival. The most common are the fraction of cells in SPF, thymidine labeling index (TLI), mitotic index, or antibodies directed against proliferative markers such as Ki-67 and proliferating cell nuclear antigen.

Thymidine labeling represents the fraction of cells in S-phase of the cell cycle and is based on the active incorporation of labeled thymidine into DNA; the TLI of primary breast cancers appears closely related to steroid receptor status and generally unrelated to pathologic stage.[80] Retrospective analyses have shown that TLI is a prognostic indicator, independent of tumor size, steroid receptors, and *p53* and Bcl-2 protein expression. Together with patient age and tumor size, TLI is able to identify patients at different levels of risk for locoregional or distant metastases.

DNA Ploidy Index

Chromosomal instability (CIN), either past or present, is indicated whenever tumor cells harbor an abnormal quantity of DNA, termed "aneuploidy."[81] The most widely used approach to detecting aneuploidy is DNA cytometry—a method that involves staining of DNA in the nuclei of cells from a tissue sample, followed by analysis using quantitative flow cytometry or microscopic imaging. Most breast cancers exhibit a bimodal distribution of DNA values. DNA ploidy as measured by flow cytometry correlates with nuclear grade, with low-grade tumors being diploid and high-grade tumors being aneuploid. Ploidy was found to be associated with histologic type, tumor grade, and SPF values, but not with patient age, menopausal status, tumor size, axillary nodal status, ER status, or PR status.[82] Diploid tumors tend to be ER positive with more favorable prognosis, whereas aneuploid tumors are frequently ER negative with less favorable prognosis. Older patients are more likely to have hyperdiploid tumors.[83]

p53 Gene

The *p53* tumor suppressor gene encodes a nuclear phosphoprotein that is thought to be important to cell cycle regulation and DNA repair and may regulate induction of apoptosis by ionizing radiation.

The *p53* gene is most frequently mutated in sporadic breast cancer; alterations of this gene were identified in 43 (22%) of 192 tumors.[84] Mutations of *p53* were found more often in tumors of younger women ($P = .002$) and African American women ($P = .04$) and in tumors lacking ER ($P = .03$), PR ($P = .04$), or both ($P = .06$). In 843 cases of breast cancer, *p53* mutations were not found in low-grade carcinomas (tubular, mucinous, papillary, and invasive cribriform types) but were observed in 4.2% of ILCs (6/140 cases), 15.5% of high-grade IDCs (99/640 cases), and 50% of pure medullary carcinomas (5/10 cases).[85] The OS rates were not significantly different in patients with mutant or wild-type *p53* tumors.

Genetic Profiling

DNA microarray technologies allow for extensive profiling of tumors based on their gene expression signatures. Using this technology, investigators from the Netherlands Cancer Institute screened thousands of genes to develop a 70-gene prognostic signature that in 295 women demonstrated a 10-year DFS of 50.6% in 180 poor prognosis signature patients compared with 85.2% in 115 women with a favorable signature. In a validation study, the profiling outperformed classic prognostic criteria, but the magnitude of the prognostic value was not as strong.[86-88]

Gene expression profiling has had a marked impact on our understanding of the biology of breast cancers and is routinely used in clinical decision-making. Categorizing breast cancer into distinct clinical subtypes of luminal A, luminal B, *HER2/neu*, and basal-like has significant prognostic value and impacts on decisions regarding systemic therapy options. Although gene profiling forms the basis of this subtyping, most clinicians rely on common molecular markers of ER, PR, *HER2/neu*, Ki-67, and others as a surrogate to classify patients into these intrinsic subtypes of breast cancer for clinical decision-making.[89]

An assay using gene profiling on paraffin-embedded specimens has been developed by Genomics Health Inc.[90] The Oncotype DX Breast Recurrence Score (RS) Assay measures RNA expression levels of 21 genes (16 cancer-related and 5 reference genes) using quantitative real-time reverse transcriptase polymerase chain reaction on formalin-fixed, paraffin-embedded tissue samples to compute an RS (0-100), which is used to estimate the odds of relapse over 10 years. Specimens from patients in NSABP trials with ER-positive HER2-negative tumors treated with tamoxifen alone were used to validate this scheme in which patients were categorized as low risk (<18 score), intermediate risk, or high risk. As shown in Figure 62.10, the likelihood of distant metastasis is low in those patients with favorable scores treated with tamoxifen alone.

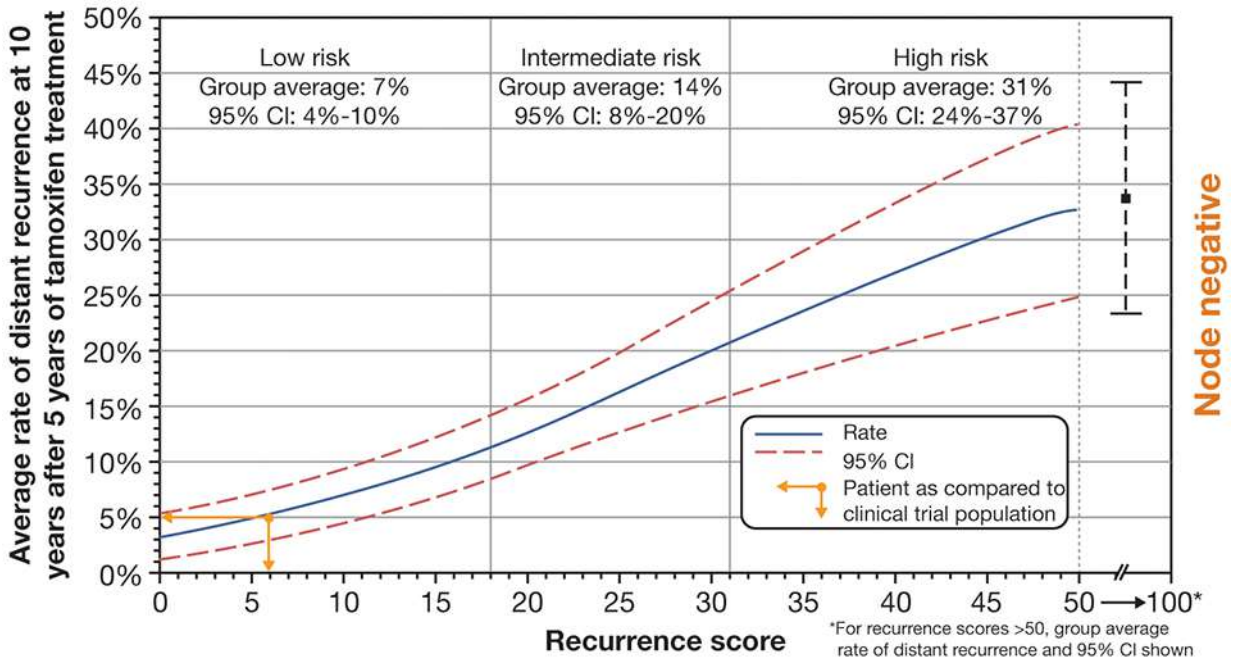

FIGURE 62.10 Risk stratification in patients with receptor-positive tumors treated with hormonal therapy broken as a function of recurrence score using the Oncotype DX gene profiling scheme. CI, confidence interval.

The Trial Assigning Individualized Options for Treatment was designed to further clarify the risk stratification groups and investigate the clinical significance of midrange scores of 11 to 25.[91] Over 10,000 women were registered and assigned to a treatment group. Women with scores of 10 or less received endocrine therapy alone, and women with scores of 26 or more received chemotherapy. Those with midrange scores of 11 to 25 were randomly assigned to receive either endocrine therapy alone or chemotherapy and endocrine therapy. Trial results demonstrated that endocrine therapy had noninferior invasive DFS compared to chemotherapy and endocrine therapy. At 9 years, invasive DFS was similar in both groups (83.3% endocrine therapy vs 84.3% chemotherapy and endocrine therapy), and OS rates were nearly identical (93.9% endocrine therapy vs 93.8% chemotherapy and endocrine therapy). It was noted that the chemotherapy benefit varied with the combination of RS and age, and there was some benefit with chemotherapy for women aged 50 years or below with an RS of 16 to 25.

Age

Although young age has consistently been shown to be a predictor of local relapse following breast-conserving surgery, there are conflicting data regarding its prognostic significance for distant metastasis and OS. The available data are confounded by the fact that younger women often present with palpable disease and have larger tumors with a higher percentage of positive nodes. Several studies, however, have shown that when corrected for stage, young age remains a significant prognostic factor for distant metastasis.[92,93]

Race

African American women are commonly diagnosed with more advanced stages of breast cancer than are White women.[5] Simon and Severson,[94] in a review of 10,502 women diagnosed with breast

cancer (82% White and 18% African American), observed that African American women were more likely to present with regional or distant disease (45%) than were White women (37%). White women had a better survival rate than did African American women during the first 4 years after diagnosis ($P < .0001$), but there were no significant differences in survival by race in women who lived longer than 4 years ($P = .64$). Other studies have also indicated that Black women more commonly develop breast cancers that are high grade and negative for ER, PR, and *HER2/neu*.[95,96]

Obesity and Body Mass Index

Obesity and elevated BMI have been associated with poor outcomes in breast cancer. Daling et al,[97] in a study of 1,177 women aged 45 years and below who had invasive ductal breast carcinoma, found that women with breast carcinoma who were in the highest quartile of BMI were 2.5 times more likely to die of their disease within 5 years of diagnosis compared with women in the lowest quartile of BMI.

Smoking

High plasma levels of estrogens are associated with increased breast cancer risk. Manjer et al,[98] in an analysis of 792 women in a mammographic screening trial with a mean follow-up of 12.1 years, observed that 145 patients died of breast cancer. The RRs for smokers and ex-smokers, compared with those who had never smoked, were 1.44 and 1.13, respectively. The association with smoking remained significant after adjustment for age and stage at diagnosis and other potential confounders.

Pregnancy

Pregnancy can transiently increase the risk of breast cancer after childbirth but has been shown to have a protective effect in later years. In women with multiple pregnancies, the short-term increase may be offset by the long-term protection from the first pregnancy.[99]

Tumor Location

There is some evidence that medially located tumors have a poorer prognosis than do laterally located tumors. An analysis of 45,880 patients from the SEER database by Gaffney et al[100] demonstrated that the hazard ratio (HR) for the inner quadrant location compared with the outer quadrant was 1.27 for breast cancer–specific survival and 1.11 for OS. Both were significant in multivariate analysis. It has been suggested that this may be due to occult spread to IMNs.

Selected Other Prognostic Factors

A wide variety of other prognostic factors have been extensively evaluated. Although some of these have been promising in initial reports, they have not been applied in routine clinical decision-making. However, these markers may help supplement information obtained with more established prognostic factors. Furthermore, with additional testing and validation, some of these markers may serve as targets for therapeutic interventions. Extensively evaluated and reported factors that may be prognostic significance include cathepsin-D, vascular endothelial growth factor, EGF, *Bcl-2*, carcinoembryonic antigen, prostate-specific antigen, E-cadherin, and others. The reader is referred elsewhere for an extensive review of molecular prognostic factors in breast cancer.[101]

SURGICAL MANAGEMENT OF BREAST CANCER

Management of invasive breast cancer should be based on the clinical extent and pathologic characteristics of the tumor, in addition to the age of the patient (menopausal status), some biologic prognostic factors, and the preference and psychological profile of the individual patient, optimally in a multidisciplinary setting. Although surgical, medical, and radiation oncology remain the primary therapeutic disciplines in the management of breast cancer, the patient's management is often dependent on input from diagnostic radiology and pathology, the primary physician involved, and support services, such as genetic counseling, social work, nursing, and others.

The surgical management of patients with early-stage operable breast cancer addresses both the primary tumor and regional lymphatics. The primary tumor may be managed by mastectomy or lumpectomy, and the nodal regions may be surgically addressed by lymph node dissection or sentinel node biopsy. The radiation oncologist should be aware of the various surgical procedures, as it may influence the radiotherapeutic management. Procedures that remove the bulk of parenchymal breast tissue include radical mastectomy, extended radical mastectomy, modified radical mastectomy, simple mastectomy (also referred to as total mastectomy), skin- sparing mastectomy, and nipple-sparing mastectomy. Partial mastectomy, lumpectomy, tylectomy, and quadrantectomy are collectively referred to as breast-conserving surgery.

Breast-conserving approaches, as well as the skin- and nipple-sparing mastectomy, used in early-stage breast cancers, are briefly discussed here as they are often used in early-stage disease. Details of the mastectomy procedures are summarized in Chapters 63.

Skin-Sparing Mastectomy

Skin-sparing mastectomy is a standard mastectomy with minimal skin sacrifice at the mastectomy site. This is often performed when immediate reconstruction is planned. This technique attempts to remove all breast tissue, but the preservation of skin provides cosmetic and reconstructive advantages. The procedure is oncologically sound, and patients undergoing skin-sparing mastectomy do not require postmastectomy radiation unless they have pathologic factors that place them at higher risk (ie, positive nodes, positive margins, large primary tumors), as discussed in Chapters 63.

Nipple-Sparing Mastectomy

The nipple-sparing mastectomy is distinct from the skin-sparing mastectomy in that the nipple and/or nipple-areola complex are conserved. This procedure may be contraindicated in patients with disease near the nipple-areola complex.

Lumpectomy

Various terms have been used to describe the breast-conserving surgical approach, including lumpectomy, wide local excision, tylectomy, tumorectomy, segmental mastectomy, partial mastectomy, and quadrantectomy. This approach is extensively discussed in this chapter. BCT includes breast-conserving surgery followed by breast irradiation. The NSABP recommends specific types of incisions depending on the location of the tumor (Figure 62.11). The radiation oncologist may play an advisory role, as in many cases the patient may be evaluated by both the surgeon and the radiation oncologist before the definitive operation.

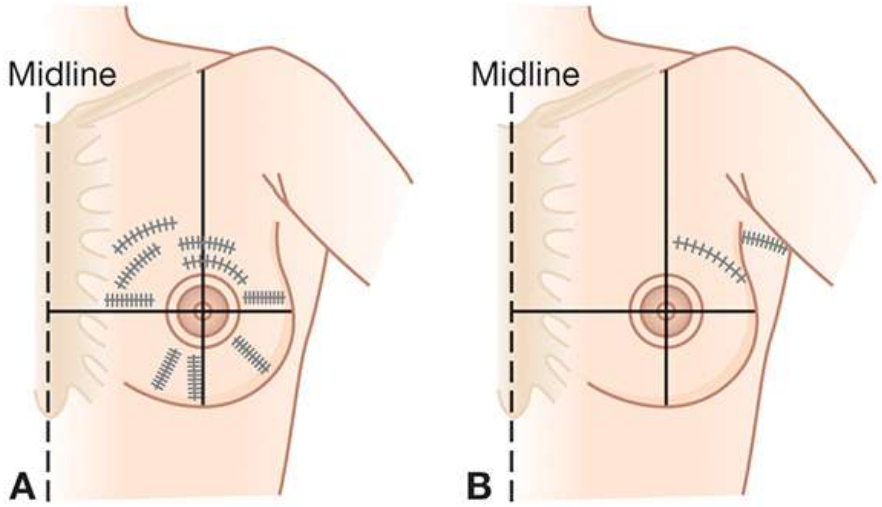

FIGURE 62.11 National Surgical Adjuvant Breast Project recommendations for the direction of incisions used for tumorectomy (A) and for axillary node dissection (B). (Courtesy of Bernard Fisher, MD, Chairman, National Surgical Adjuvant Breast Project. From Bedwinek JM. Treatment of stage I and II adenocarcinoma of the breast by tumor excision and irradiation. *Int J Radiat Oncol Biol Phys*. 1981;7[11]:1553-1559. Copyright © 1981 Elsevier. With permission.)

The optimal extent of breast resection for the treatment of T1 and T2 breast cancer has not been defined. Increasing the size of the resection may not only lower the risk of LR but also has an adverse impact on the cosmetic outcome. Because cosmesis is a critical reason for performing tumor excision and irradiation instead of mastectomy, wide local excision with microscopically negative margins is preferable to segmental mastectomy or quadrantectomy.

Surgical removal of additional breast tissue surrounding the original excision site is indicated when margins are positive and there is a substantial probability that the tumor cell burden exceeds what can be controlled by the usual doses of radiation. The percentage of patients with residual tumor at the time of reexcision varies widely depending on the criteria used for taking a patient back to the operating room for more breast surgery. Tumor size alone is not usually considered an indication for reexcision in the absence of other factors.

Other factors that may have an impact on the rate of positive reexcisions include extensive intraductal carcinoma (EIC) and residual calcifications on a postlumpectomy preirradiation mammogram. In a series from Yale by Lally et al,[102] of 34 patients with a postlumpectomy mammogram that showed suspicious residual calcification who underwent reexcision, 20 (59%) were found to have residual disease. Patients whose initial tumor was associated with calcifications with questionable, close, or positive margins should be evaluated with a postlumpectomy mammogram with guided reexcision if suspicious residual calcifications are present.

Based on these findings, the authors recommend reexcision at the primary tumor site (a) when the surgical procedure was less than a complete lumpectomy, such as an initial incisional biopsy or core biopsy; (b) when pathologic margins on the initial excisional biopsy are shown to be involved by tumor; and (c) when there are residual suspicious microcalcifications on a postlumpectomy mammogram. As discussed later, although reexcision for involved margins is indicated, selected patients with a focally involved margin may be treated with RT with acceptable local control rates.

Choices Between Mastectomy and Breast-Conserving Surgery in Early-Stage Disease

For most patients with early-stage breast cancer, breast-conserving surgery and mastectomy are both reasonable options, and patients are often conflicted regarding the choice. Patients should be reassured that provided they meet the criteria for breast-conserving surgery, all of the available medical evidence demonstrates equivalent long-term survival rates with both modalities.

A modified radical mastectomy may be preferable for some patients who wish to avoid radiation, for those in whom removal of clinical and radiographically apparent disease will result in a suboptimal cosmetic result, for those with diffusely positive margins that cannot be cleared with reexcision, and those with diffuse suspicious microcalcifications. Even patients who are ideally suited for BCT may have a personal preference for mastectomy, based on a number of factors.

Some patients with early-stage breast cancer will choose mastectomy to avoid the course of radiation. However, patients selecting mastectomy should also be made aware that this procedure does not totally eliminate the need for radiation treatment. For patients with early-stage operable breast cancer treated by a modified radical mastectomy, postoperative irradiation of the chest wall and peripheral lymphatics may be indicated in selected patients with high-risk characteristics, positive nodes, or positive resection margins. Indications for postmastectomy radiation are discussed in Chapters 63.

Surgical Management of Axillary Lymph Nodes

An axillary node dissection or sentinel node biopsy is a standard component of the staging process for a majority of women with early-stage invasive breast cancer.[47] Although the role of complete axillary dissection is evolving, there is compelling evidence that ALND is not necessary in most women with early-stage breast cancer. Two randomized trials, the ACOSOG Z0011 trial and the International Breast Cancer Study Group 23-01 (IBCSG 23-01) trial (discussed later), demonstrated that many of these patients with one or two metastatic sentinel nodes can safely avoid a completion axillary node dissection. It is not uncommon for clinicians to avoid axillary staging altogether if it is not going to influence further management. This is relevant in older women with receptor-positive tumors who will receive hormonal therapy, regardless of nodal status, and who are not thought to be candidates for cytotoxic chemotherapy. The decision to omit SLNB in older women should be discussed in a multidisciplinary setting with input from the treating oncologists to ensure all providers are in agreement as to whether axillary staging information is important for adjuvant therapy decisions. As discussed later, axillary radiation, as with axillary dissection, results in a high rate of regional control.

Axillary Node Dissection

The axillary contents are divided into three levels: Level I represents tissue between the axillary vein and the latissimus dorsi muscle and the lateral border of the pectoralis minor muscle; level II is located between the lateral and medial borders of the pectoralis minor muscle; and level III is between the medial border of the pectoralis minor and the Halsted ligament (the apex of the axilla). Thorough dissection of levels I and II has traditionally been the most common axillary surgical procedure in patients with clinically node-negative breast cancer. Complete axillary dissection, including level III, may be performed in patients with clinically positive lymph nodes. Pigott et al[103] reported on 146 patients treated with radical mastectomy (either modified or Halsted) for IDC or ILC of the breast. Eighty patients (55%) had histologically proven axillary lymph node metastases. If only the low (level I) axillary lymph nodes had been removed, 18 (25%) patients would have had metastases confined to levels II and III that would have gone undetected. However, only 1.4% of patients showed positive level III lymph nodes if levels I and II were negative.

Approximately 20% to 40% of patients with carcinoma of the breast and clinically negative lymph nodes have pathologic evidence of lymph node metastases.[63,104] Yet, in patients with stage I or II breast cancer and clinically negative axillary lymph nodes, if an axillary dissection is not performed, axillary recurrence develops in only approximately 20%. In patients with clinically positive axilla, 20% to 30% have no histologic evidence of nodal metastatic disease.[32]

In a randomized trial evaluating the necessity of axillary dissection in older women, Martelli et al[105] reported on 219 women, 65 to 80 years of age, with early breast cancer and clinically negative axillary nodes who were randomized to conservative breast surgery with or without axillary dissection. Tamoxifen was prescribed to all patients for 5 years. With a follow-up of 60 months, there were no significant differences in overall or breast cancer mortality or crude cumulative incidence of breast events between the two groups. Only two patients in the no axillary dissection arm (8 and 40 months after surgery) developed overt axillary involvement during follow-up. They concluded that older patients with T1N0 breast cancer can be treated by conservative breast surgery and no axillary dissection without adversely affecting breast cancer mortality or OS.

In light of the increased use of primary tumor-related factors, including molecular profiling, for decision-making regarding systemic therapy, combined with sentinel node procedures and low rates of regional relapse with RT or observation in selected patients, axillary dissection has been less frequently employed in the management of patients with early-stage breast cancer.

Sentinel Lymph Node Biopsies

In recent years, there has been a substantial increase in the use of SLNBs to stage patients with breast cancer. Patients are injected around the tumor with technetium-99m (^{99m}Tc) sulfur colloid and vital blue dye, and a hand-held γ-probe is used to identify areas of highest radioisotope uptake in the lymphatic system. The lymph nodes underlying this area (SLNs) are removed.[65,106-108] The sentinel node procedure has been widely embraced as an acceptable standard for women with breast cancer and has a high degree of sensitivity and specificity.[109]

The standard of care that mandated performing an ALND in patients who are node-positive was reexamined after the publication of IBCSG 23-01 and the ACOSOG Z11 studies.[110] The IBCSG 23-01 study randomized 931 patients with micrometastatic (<2 mm) deposit in the SLNB to ALND or no additional surgery.[111] The majority of the patients (97%) received adjuvant RT without RNI. In the ALND arm, additional axillary nodal involvement was detected in 13% of the patients. There was no difference in the OS or DFS between the two study arms. Although the study closed before meeting target accrual, the authors concluded that patients with breast cancer with limited SLN involvement could be spared the morbidity of an ALND.

The ACOSOG Z11 study was a prospective trial examining survival of patients with sentinel node metastases detected by standard hematoxylin and eosin staining, who were randomized to undergo ALND after sentinel lymph node dissection (SLND) versus SLND alone.[112] All patients received whole-breast irradiation. There were 446 patients randomized to SLND alone and 445 to SLND plus ALND. Those randomized to SLND plus ALND had a median of 17 axillary nodes removed compared with a median of only 2 sentinel nodes removed with SLND alone ($P < .001$). At a median follow-up time of 6.3 years, there were no statistically significant differences in LR ($P = .11$) or regional recurrence ($P = .45$) between the two groups. Interestingly, ALND also removed more positive lymph nodes ($P < .001$) in 27% of the patients in this group. The patients in this trial all had whole-breast irradiation, but RNI was not allowed. However, there was no RT quality assurance, and field design was not uniform. The reason for the low regional relapse rates is likely a combination of factors, including a favorable subset of patients with a low likelihood of a high

residual axillary burden of disease, the use of systemic therapy, and incidental radiation to the residual nodes in level I or II from the tangential breast irradiation. A subsequent review of radiation treatment records on a subset of patients from this trial noted the use of high tangent fields (cranial border within 2 cm of the humeral head) in roughly 50% of patients and directed RNI using three or more fields in roughly 20% of patients.

Several studies describe an approach to radiation field design based on probability of additional axillary nodal involvement in patients with positive sentinel nodes (Table 62.7).[68,113-116]

TABLE 62.7 SUGGESTED APPROACH FOR RADIATION FIELD DESIGN IN SENTINEL NODE–POSITIVE PATIENTS NOT UNDERGOING AXILLARY LYMPH NODE DISSECTION

Clinical Scenario	Sentinel Nodes +/Total Sentinel Nodes Sampled	Probability of Additional Nodes MSKCC[113] (%)	Probability of Additional Nodes MDACC[114] (%)	Probability of Four or More Nodes Involved[115] (%)	Field Design
IDC, 1.0 cm, ER+, LVI−	1 (IHC only)/3	3	8	<1	Tangents only
IDC, 1.8 cm, G3, ER+, LVI−, Unifocal	1 (macro)/2	27	24	2	High tangents
IDC, 2.0 cm, ER−, LVI+	2 (macro)/2	63	55	30	High tangents/consider full nodal treatment
ILC, 4.0 cm ER+, multifocal, LVI−	2 (macro)/2	77	64	40	High tangents/consider full nodal treatment
IDC, 3 cm, ER−, LVI+, multifocal	3 (macro with ENE)/3	78	95	80	Full nodal treatment

ENE, extranodal extension; ER, estrogen receptor; G, grade; IDC, infiltrating ductal carcinoma; IHC, immunohistochemistry; ILC, infiltrating lobular carcinoma; LVI, lymphovascular invasion; macro, macroscopic.

Quality-of-life measures have also been studied in the setting of SLNB and ALND, and several studies have demonstrated superior outcomes with SLNB.

The ALMANAC (Axillary Lymphatic Mapping Against Nodal Axillary Clearance) trial was a multicenter randomized trial of 1,031 patients randomly assigned to sentinel node biopsy (n = 515) or standard axillary dissection (n = 516). Mansel et al[107,108] reported the primary outcome measures, which were arm and shoulder morbidity and quality of life. Drain usage, length of hospital stay, and resumption of normal activities after surgery were all highly significantly better in the SLN group. In addition, patient recorded quality of life and arm functioning scores were also significantly better, with no increase in anxiety levels in the sentinel node group. The authors concluded that sentinel node biopsy is the treatment of choice for patients who have early-stage breast cancer and clinically negative nodes.

Veronesi et al[117] also reported on a randomized trial of 516 patients with T1 tumors, randomized to either sentinel node biopsy or total axillary dissection. Axillary dissection was performed in the sentinel node group if the sentinel node contained metastases. In the axillary dissection group, the overall accuracy of the sentinel node status was 96.9%, the sensitivity 91.2%, and the specificity 100%. There was less pain and better arm mobility in the patients who underwent sentinel node biopsy only than in those who also underwent axillary dissection. There were 15 events associated with breast cancer in the axillary dissection group and 10 such events in the sentinel node group.

Among the 167 patients who did not undergo axillary dissection, there were no cases of overt axillary metastasis during follow-up.

The role of SLN procedures in patients undergoing neoadjuvant chemotherapy is covered in Chapters 63.

SYSTEMIC MANAGEMENT OF BREAST CANCER

Systemic therapy is an essential component of both early-stage node-negative breast cancer and advanced-stage disease. Hormonal therapy, cytotoxic chemotherapy, and, the more recently introduced, biologic therapies are routinely employed in the vast majority of patients with early-stage breast cancer. For patients with all stages of breast cancer, systemic therapy has been shown to decrease the RR of relapse and mortality. However, there are subsets of patients with a very favorable prognosis and extremely low rate of relapse, in whom the risk reduction results in only a very small absolute benefit. These issues are also discussed in more detail in Chapters 63.

RADIATION THERAPY IN THE MANAGEMENT OF EARLY-STAGE INVASIVE BREAST CANCER

The radiation oncologist plays a critical role in the management of early-stage breast cancer. As noted previously, the role of RT in postmastectomy radiation and in the neoadjuvant treatment of advanced breast cancers will be discussed in Chapters 63. The remainder of this chapter is focused primarily on the role of RT in the conservative management of early-stage invasive breast cancer.

This will include an extensive discussion of the studies establishing breast-conserving surgery and radiation as the preferred standard of care for the majority of women with early-stage invasive disease and studies evaluating the avoidance of RT in selected patients. Integration of RT with systemic therapy will be discussed, as will selection of patients for BCT. Risk factors for local relapse and controversies in the management of patients with special circumstances will be discussed. Technical issues in the delivery of RT for early-stage breast cancer, including dosing and fractionation, matching techniques, and newer technical approaches, will be presented. The rapidly evolving area of partial-breast irradiation will also be discussed. Follow-up of the patient with breast cancer and sequelae of treatment will be presented. Management of local relapse in the conservatively treated breast and postmastectomy will be covered in Chapters 63. The role of RT in the management of DCIS and LCIS was discussed in Chapters 61.

Breast-Conserving Therapy and Patient Selection

Breast-conserving surgery followed by RT to the intact breast is clearly established as the most acceptable standard of care for the majority of women with early-stage invasive breast cancer. In addition to tumor control and survival, conservation of the breast with optimal cosmetic results is a crucial goal of this therapy, which is associated with improved psychoemotional adjustment of the patient to the diagnosis and treatment of carcinoma of the breast. It also enhances the acceptance by women of mammographic screening for early detection of this disease. The widespread embracement of breast-conserving surgery followed by RT is based on numerous mature and well-documented studies, both prospectively designed randomized trials and large retrospective series of appropriately selected patients treated with breast conservation followed by RT.

It is important to select appropriate patients and tumors for breast conservation therapy, with close consultation between the surgeon, medical oncologist, and the radiation oncologist and after thorough discussion of therapeutic alternatives with the patient. The risks and benefits of BCT

compared with mastectomy should be discussed. Despite the clear evidence of equivalence, some patients will still prefer mastectomy, which remains an acceptable standard of care for women with operable breast cancers. Although avoidance of radiation may be a primary rationale for some patients in choosing mastectomy, patients should realize that even with early-stage operable disease, postmastectomy radiation may be indicated based on the pathologic findings at mastectomy.

Ideally, patients electing breast-conserving surgery and radiation will have unicentric primary tumors that are less than 4 to 5 cm in diameter, as cosmesis is affected by the amount of tissue that must be removed in relation to the size of the breast. For patients in whom the size of the tumor, compared with the size of the breast, will result in an unacceptable cosmetic outcome, neoadjuvant therapy can be considered to facilitate breast conservation. This was discussed in detail in Chapters 63.

With careful attention to surgical margins, radiation technique, and the appropriate use of systemic therapy, local relapse rates in most conservatively managed patients are low, and only a minority of patients with early-stage invasive breast cancer are not suitable for BCT. There are several perceived relative "contraindications" to BCT, including patients with collagen vascular disease (CVD), patients with germline mutations that predispose to breast cancer development, those with positive margins, more advanced disease, multicentric disease, pregnancy, or patients who have had prior radiation. Although many of these factors require careful consideration and discussion between the treating physicians and the patient, as discussed in the section on special circumstances, selected patients faced with breast cancer in the setting of these controversial circumstances can be offered BCT with acceptable outcomes. Although some clinicians believe that patients at higher risk for the development of LR should not be treated with conservation surgery, there are relatively few absolute contraindications.

Perhaps with the exception of the patients with persistently positive diffuse margins or gross multicentric disease, where removal of clinically and radiographically apparent disease would result in an unacceptable cosmetic outcome, BCT followed by radiation can be offered to most women with early-stage breast cancer and may be offered to a high percentage of women with advanced cancers following neoadjuvant chemotherapy or hormonal therapy. The decision regarding BCT compared with mastectomy is often based on personal preference, as the available medical and scientific evidence suggests equivalent OS and DFS in all subsets of patients.

Randomized Studies Comparing Breast-Conserving Surgery Plus Radiation Therapy to Mastectomy

There have been numerous randomized trials that have now established breast-conserving surgery followed by RT as equivalent to mastectomy for appropriately selected patients with early-stage breast cancer. Table 62.8 summarizes these randomized trials. In all of these trials, local tumor excision (tylectomy, lumpectomy), segmental mastectomy, or quadrantectomy combined with irradiation to the breast yielded survival and tumor control rates similar to those achieved with modified or classic radical mastectomy.[34,39,40,118-122] Each of these randomized trials, as well as meta-analyses of the trials, clearly demonstrates equivalent mortality rates in conservatively treated patients compared with mastectomy.[123-125]

The earliest prospective, randomized trial comparing breast conservation with radical mastectomy was conducted at Guy's Hospital in London. Three hundred and seventy women with stage I or II breast cancer were randomly assigned to receive either standard radical mastectomy or wide local excision plus irradiation.[128] Although the rates of survival and distant metastasis were not significantly different for stage I disease, in stage II, the recurrence rates in the breast and axilla were higher in the group treated with local excision and irradiation, and survival was significantly lower because of a higher rate of distant metastasis. Major weaknesses of this study were the low doses of irradiation used (35-38 Gy to the breast and 25-27 Gy to the axilla), patient selection, and surgical techniques.

Veronesi et al[122] reported on 701 patients with tumors less than 2 cm in diameter and without palpable axillary nodes of whom 352 were randomly assigned to treatment with either quadrantectomy and axillary dissection plus irradiation (50 Gy in 5 weeks to the breast and 10-Gy boost) and 349 to radical (Halsted) mastectomy. Women with positive axillary lymph nodes also received 12 cycles of adjuvant chemotherapy with cyclophosphamide, methotrexate, and fluorouracil (CMF). Actuarial 20-year OS and DFS rates were comparable in the two groups (58%). The death rates from breast cancer were 26.1% and 24.3%. The incidence of local failure was 2.3% with mastectomy and 8.8% with quadrantectomy and irradiation. There was no difference in the incidence of contralateral breast cancer (10.2% and 8.7%, respectively).[40]

Fisher et al[34,120] updated the results of the NSABP protocol B-06 in 1,843 women with clinical stage I or II carcinoma of the breast less than 4 cm in diameter. Patients were randomly assigned to be treated with total mastectomy or lumpectomy (segmental mastectomy), with or without irradiation. Patients who are irradiated received 50 Gy to the breast through tangential field irradiation, and a boost to the operative site was not given. With a 20-year follow-up, there was no significant difference in survival among patients treated with mastectomy, lumpectomy alone, or lumpectomy combined with irradiation. For the patients treated with lumpectomy alone, the ipsilateral breast relapse rates were approximately 40% if the nodes were negative and 50% if they

were positive. For patients treated with lumpectomy and irradiation, the corresponding rates were 10% for all patients and those with negative nodes and 5% for those with positive nodes, illustrating the interaction of irradiation and adjuvant chemotherapy in local tumor control.

The Institut Gustave-Roussy conducted a prospective, randomized trial comparing mastectomy with local excision plus irradiation for women with cancers measuring 2 cm or less.[126,129] The 15-year DFS rate was 55% for the tumorectomy group and 45% for the mastectomy group (P = .23). The 15-year LR rate was 9% in the conservation surgery and irradiation group and 14% in the mastectomy group.

The European Organisation for Research and Treatment of Cancer (EORTC) Breast Cancer Cooperative Group conducted a randomized trial of women with stage I or II breast cancer comparing modified radical mastectomy (420 patients) with breast conservation therapy (448 patients).[118] The actuarial 8-year local tumor control rate was similar in both arms, 91% in the mastectomy group and 87% in the breast conservation therapy group. There was one axillary recurrence in the mastectomy group and three in the conservation therapy group.

A Danish Cooperative Study carried out a similar randomized trial in 905 women (another 248 patients were treated with mastectomy or breast conservation therapy according to preference without randomization).[119] High-risk patients (tumor >5 cm, invasion to skin or deep fascia, metastatic axillary lymph nodes) who were treated with breast conservation therapy received RT to the regional lymph nodes. Those who were treated with mastectomy also received irradiation of the same target volume, and all high-risk patients received adjuvant CMF. At 6 years, the recurrence-free survival rate in 430 patients treated with breast conservation therapy was 70%, compared with 66% in 429 patients treated with mastectomy. OS rates were 79% and 82%, respectively. There were 12 (3%) breast relapses in the former group and 19 (4%) chest wall recurrences in the latter group. In the breast conservation therapy group, 31% of patients had excellent and 41% had satisfactory cosmesis.

The U.S. National Cancer Institute (NCI) reported the results of a randomized study in which 122 patients with T1-2N0M0 disease were treated with modified radical mastectomy and 125 with breast conservation therapy (45-50 Gy to breast plus 15- to 20-Gy boost). Updated by Poggi et al[127] with a median follow-up of 18.4 years, there was no detectable difference with regard to OS between patients treated with mastectomy and those treated with BCT (58% vs 54%; P = .67 overall). Twenty-seven (22%) women in the BCT arm experienced an in-breast event. After censoring in-breast events in the BCT arm that were salvaged successfully by mastectomy, DFS also was found to be statistically similar (67% in the mastectomy arm vs 63% in the BCT arm; P = .64 overall). There was no statistically significant difference in the incidence of contralateral breast carcinoma between the two treatment groups.

Van Dongen et al[39,118] reported on an EORTC trial comparing modified radical mastectomy with BCT (lumpectomy, axillary clearance, and irradiation to the breast, 50 Gy in 5 weeks and a 25-Gy boost with iridium implant) in 168 patients with stage I and 734 with stage II disease. Patients with microscopically incomplete excision of the tumor were included. Updated analysis from this trial with a median follow-up period of 13.4 years revealed that LRR rates were higher in the breast conservation therapy group (10-year rate, 19.7%) than in the mastectomy group (10-year rate, 12.2%, P = .0097). The OS rate at 10 years was 66.1% for patients undergoing mastectomies and 65.2% for patients undergoing breast conservation therapy (P = .11).

PROGNOSTIC FACTORS FOR LOCAL RELAPSE FOLLOWING BREAST-CONSERVING SURGERY PLUS RADIATION THERAPY

Local relapse in the conservatively managed breast is an active area of investigation, with numerous studies dedicated to the evaluation of factors that identify patients at increased risk for local relapse following lumpectomy and RT. Although prognostic factors for local relapse are not as well evaluated as they have been for systemic relapse, there have been numerous studies demonstrating the prognostic value of molecular and genetic markers for local relapse. Local relapse following breast-conserving surgery and radiation can be governed by a complex array of host, primary tumor, and treatment factors.

Given the complex interaction of these factors, it is sometimes difficult to separate out the independent significance of any one factor. There have, however, been several factors that have been consistently reported in influencing local relapse in the conservatively managed patient with breast cancer. Table 62.9 summarizes some of the more commonly reported prognostic factors for local relapse. The factors that most consistently have been reported to influence local relapse, namely, young age, margin status, and the use of systemic therapy, are discussed first, followed by several other commonly evaluated prognostic factors.

TABLE 62.9 SUMMARY OF RISK FACTORS FOR LOCAL RELAPSE

Prognostic Factor	Effect	Strength of Data	Comment
Age	Young age increases local relapse.	Multiple studies Upheld in multivariate analysis Few conflicting reports	Remains among the strongest factors
Margins	Positive margins increase local relapse.	Multiple studies Upheld in multivariate analysis Few conflicting reports	Remains among the strongest factors Data on “close” margins are less consistent.
Systemic therapy	Systemic therapy (chemo and hormonal) lowers risk of local relapse.	Multiple studies support Some conflicting reports	May delay rather than counteract risk
Radiation dose	Higher doses decrease local relapse.	Multiple studies support Confirmed in randomized trials (boost vs no boost) Some conflicting data regarding doses >50 Gy	Interaction with margins and age Necessity of “boost” in women over 50 and with widely negative margins unclear
Extensive intraductal component (EIC)	EIC-positive tumors have higher rates of local relapse.	Initial studies supportive Some confirmatory studies Some conflicting studies	Recent data suggest that negative margin status eliminates this as a risk factor.
LCIS as a component	LCIS as a component increases risk of local relapse.	Conflicting data with no clear consensus	Patients with LCIS are suitable candidates for BCS. Debate remains regarding need for clear LCIS margins.
Lobular histology	Lobular histology has higher local relapse rates.	Conflicting data with no clear consensus	Should be treated similar to invasive ductal cancers
BRCA1/2	Higher late local relapses in patients with *BRCA1/2*.	Several confirmatory studies Some conflicting data	Higher relapse rates related to late “new primaries.” This may be minimized by prophylactic hormonal manipulation.

Prognostic Factor	Effect	Strength of Data	Comment
Tumor size	Larger tumors result in higher local relapses.	Some confirmatory studies Several conflicting studies	Data are confounded by more frequent use of systemic therapy in larger tumors.
Nodal status	Higher local relapse rates in patients who are node-positive.	Several conflicting studies	As with tumor size, data are confounded by more frequent use of systemic therapy in node-positive patients.
Receptor status	Higher local relapse rates in patients who are triple-negative and *HER2*-positive.	Some confirmatory studies Few conflicting studies Under active investigation	Would offer these patients conventional whole-breast irradiation

BCS, breast-conserving surgery; LCIS, lobular carcinoma in situ.

Age

Young age has been shown in numerous studies to be a risk factor for breast recurrence in conservation surgery and irradiation. Different investigators have used various age cutoffs, such as 40, 35, and 30 years.

One of the most significant and powerful studies correlating young age with local relapse was the large EORTC boost versus no-boost trial.[130] Overall in this study, young patient age was a significant predictor of local relapse. As shown in Figure 62.12, the use of a boost, as discussed later, was most effective in younger women, although a later update found an advantage to the boost in all age groups.[131] In a review of 3,602 women who underwent surgery (breast conservation, 55%, or mastectomy, 45%) for early breast cancer and were rolled in EORTC studies, de Bock et al[132] clearly demonstrated the impact of young age on local relapse. The results of multivariate analysis showed that younger age and breast conservation were risk factors for isolated LRR (breast cancer under 35 years of age vs over 50 years of age: HR 2.80; 95% CI, 1.41-5.60; breast cancer age 35-50 years vs over 50 years: HR 1.72; 95% CI, 1.17-2.54; breast conservation: HR 1.82; 95% CI, 1.17-2.86). After perioperative chemotherapy, less isolated LRRs were observed (HR 0.63; 95% CI, 0.44-0.91). It was concluded that young age and BCT were both independent predictors for isolated LRR. The authors noted that as an isolated LRR is a potentially curable condition, women treated with breast conservation or diagnosed with breast cancer at a young age should be monitored closely to detect LR at an early stage.

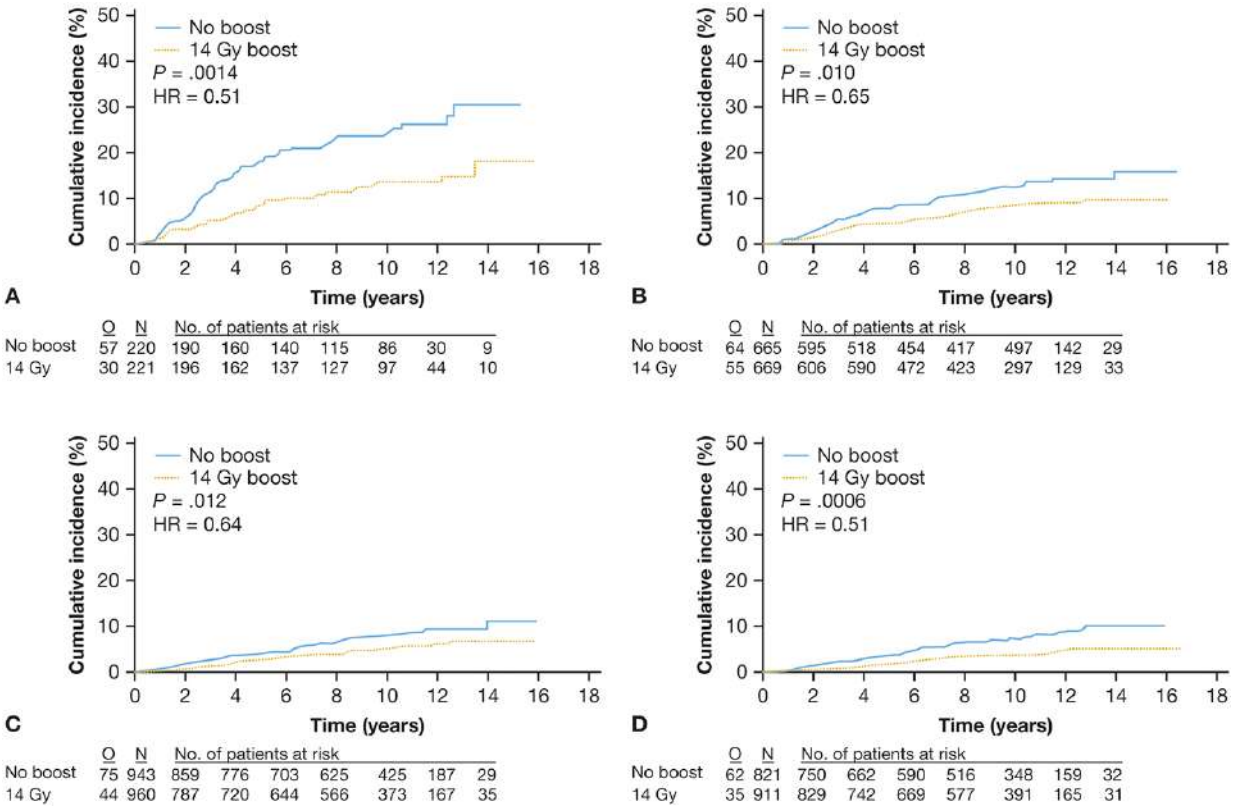

FIGURE 62.12 Cumulative incidence of recurrence of tumor in the ipsilateral breast after whole-breast irradiation at 50 Gy, with or without an additional dose to the tumor bed as a function of age group. HR, hazard ratio. (A) Age ≤ 40; (B) Age 41 to 50; (C) Age 51 to 60; (D) Age > 60 years. (Reprinted with permission from Bartelink H, Horiot JC, Poortmans PM, et al. Impact of a higher radiation dose on local control and survival in breast-conserving therapy of early breast cancer: 10-year results of the randomized boost versus no boost EORTC 22881-10882 trial. *J Clin Oncol*. 2007;25[22]:3259-3265. Margin Status

Positive margin status has been one of the most consistently reported factors associated with higher local relapse rates. Because of the varying definitions of margin status and the complex interaction between margin status and use of systemic therapy, radiation dose, and patient age, there are conflicting conclusions regarding the influence of margin status on local relapse. Definition of a negative margin is variable between institutions and in national studies. Although some consider no tumor cells seen on the inked margin definitive, as defined by the NSABP, others consider negative as margins of 1 or 2 mm beyond invasive cancer. Of note, many of the studies evaluating margin status utilized pathologic reports without a central re-review of the original pathology.

The degree of margin involvement (ie, whether it is focally involved or more diffusely involved) is also a critical issue in determining the significance of margin involvement and how it should influence management. Although there are clearly conflicting reports, it is evident that obtaining a wide negative margin is desirable. However, a focally involved margin, particularly when reexcision is not technically feasible, as may be the case with a focally involved deep margin at the pectoralis facia, is not a contraindication to BCT.

A multidisciplinary panel of breast experts from the Society of Surgical Oncology-American Society for Radiation Oncology examined the relationship between margin width and ipsilateral breast tumor recurrence (IBTR) and developed a guideline for defining adequate margins in the

setting of breast-conserving surgery and adjuvant RT.[133] The meta-analysis was based on 33 eligible studies published between 1965 and 2013 and included 28,162 patients, of whom 1,506 (5.3%) had an IBTR. The median follow-up was 79.2 months. Their conclusions and recommendations are as follows:

1. A positive margin, defined as ink on invasive cancer or DCIS, is associated with at least a 2-fold increase in IBTR. This increased risk in IBTR is not nullified by (a) delivery of a boost dose of radiation, (b) delivery of systemic therapy (endocrine therapy, chemotherapy, or biologic therapy), or (c) favorable biology.
2. Negative margins (no ink on tumor) minimize the risk of IBTR. Wider margin widths do not significantly lower this risk. The routine practice to obtain negative margin widths wider than no ink on tumor is not indicated.
3. The rates of IBTR are reduced with the use of systemic therapy. In the uncommon circumstance of a patient not receiving adjuvant systemic therapy, there is no evidence suggesting that margins wider than no ink on tumor are needed.
4. Margins wider than no ink on tumor are not indicated based on biologic subtype.
5. The choice of whole-breast RT (WBRT) delivery technique, fractionation, and boost dose should not be dependent on margin width.
6. Wider negative margins than no ink on tumor are not indicated for ILC. Classic LCIS at the margin is not an indication for reexcision. The significance of pleomorphic LCIS at the margin is uncertain.
7. Young age (≤40 years) is associated with both increased IBTR after BCT and increased local relapse on the chest wall after mastectomy and is also more frequently associated with adverse biologic and pathologic features. There is no evidence that increased margin width nullifies the increased risk of IBTR in young patients.
8. An extensive intraductal component (EIC) identifies patients who may have a large residual DCIS burden after lumpectomy. There is no evidence of an association between increased risk of IBTR and EIC when margins are negative.

Interaction Between Margin Status and Other Variables

The complex interaction between margin status and other treatment-related factors is demonstrated in a recent study by Park et al.[134] They demonstrated that local relapse was significantly higher in patients with diffuse margin involvement than in patients with negative margins. Patients with focally involved margins also had a higher risk of local relapse than did patients with negative margins. However, in those women with focally involved margins who received systemic therapy, the local relapse rate was similar to those with negative margins. Whether systemic therapy delays or negates the effect of a focally involved margin is a matter of debate, but clearly, there are confounding factors that complicate interpretation of the available data.

Freedman et al[135] studied 1,262 patients with clinical stage I or II breast cancer treated by breast-conserving surgery, axillary node dissection, and RT. The final margins were negative in 77%, positive in 12%, and close (≤2 mm) in 11%. The 5-year incidence of IBTR was not significantly different among patients with negative (4%), positive (5%), or close (7%) margins. However, by 10 years, a significant difference in IBTR became apparent (negative 7%, positive 12%, close 14%; $P = .04$). The 5-year cumulative IBTR rate in patients with close or positive margins was 1% with adjuvant systemic therapy and 13% with no adjuvant therapy. However, by 10 years, the IBTR rate

was similar (18% vs 14%), because of more late failures in the patients who received adjuvant systemic therapy.

A study by Jobsen et al[136] demonstrated some of the difficulties associated with interpretation of studies related to margin status and local relapse as it relates to other prognostic factors. In a study of 1,752 patients with known margin status and a median follow-up of 78 months, the 10-year local relapse rate was 5.6% and 12.2% for negative and positive margins, respectively. An interaction between age category and margin status was noted in relation to local relapse–free survival. The 5-year local relapse rate for women younger than 40 years of age was 8.4% for negative margins and 36.9% for positive margins ($P = .005$). On the other hand, the 5-year local relapse rate for women over 40 years old was 2.6% for negative and 2.2% for positive margins.

Although it is clear that margin status is a significant risk factor for local relapse, and negative margins are desirable, the available data suggest that patients with a focally involved margin are suitable candidates for BCT followed by RT to the intact breast.

Effect of Systemic Therapy on Local Control

The use of systemic therapy, in the form of adjuvant tamoxifen or adjuvant chemotherapy, has been clearly shown to impact local control in numerous retrospective series and prospective randomized trials. Although it has been clearly demonstrated in randomized trials that chemotherapy and tamoxifen are not appropriate substitutes for RT, in patients who are treated with RT, the use of systemic therapy improves local control.[34,35,38] As with the other critical prognostic factors, the degree to which systemic therapy influences local control is confounded by other factors.

In the NSABP B-06 trial, patients with lymph node–positive disease who were treated with RT and chemotherapy had an 8-year LR rate of 5% compared with an LR rate of 12% in patients who are lymph node–negative treated with surgery and RT alone.[120] In the NSABP B-21 trial, tamoxifen similarly improved local control rates in patients with lymph node–negative breast tumors smaller than 1 cm. The crude rate of breast tumor recurrence was only 3% in women randomly assigned to undergo lumpectomy, RT, and tamoxifen compared with 7% in women treated with lumpectomy and RT alone.[36] A retrospective analysis from the MD Anderson Cancer Center investigating the impact of systemic therapy on local control after BCT in patients with lymph node–negative breast cancer further confirmed these data.[38] In this study, 277 patients treated with systemic therapy had improved 5-year (97.5% vs 89.8%) and 10-year (95.6% vs 85.2%) local control rates compared with 207 patients who received no systemic treatment. No statistically significant difference was evident in local control between patients treated with chemotherapy and those treated with tamoxifen alone ($P = .219$). In a Cox regression analysis, the use of systemic therapy was the most powerful clinical, pathologic, or treatment predictor of local control, producing a 3.3-fold reduction in the risk of LR. Table 62.10 summarizes several of these studies that have evaluated local control as a function of systemic therapy. It is evident that both hormonal therapy and cytotoxic chemotherapy influence local relapse rates.[137-139]

TABLE 62.10 IPSILATERAL BREAST RECURRENCE RATES BY SYSTEMIC TREATMENT (SYSTX)

CTX, chemotherapy; NSABP, National Surgical Adjuvant Breast and Bowel Project; Tam, tamoxifen.

Tumor Size

Although tumor size is clearly a strong predictor of systemic relapse and OS, its prognostic value in local relapse has not been consistently reported. Differences are probably related to the treatment techniques used (eg, completeness of tumor excision, use of irradiation boost) and the complex interaction of other prognostic factors, as noted earlier.

Extensive Intraductal Carcinoma

According to the Harvard definition of EIC, 25% or more of the primary tumor is intraductal carcinoma, and intraductal carcinoma is seen outside (adjacent to) the infiltrating tumor border. Some studies reported higher incidence of breast recurrences with EIC, while others found no significant impact on local tumor control. This discrepancy may be related to the definition of EIC, adequacy of tumor excision, doses of irradiation delivered to the boost volume, and interactions with other factors.

From a group of 885 patients treated for clinical stage I or II invasive breast cancer, Schnitt et al[140] limited their study to 181 patients with IDC who received a radiation dose to the surgical site of 60 Gy or greater, whose final microscopic margins of resection were evaluable, and who had at least 5 years of follow-up. In 157 (87%) patients, the tumor was evaluable for the presence or absence of EIC. The 5-year rates of recurrence among patients with negative, close, focally positive, and more than focally positive margins were 0%, 4%, 6%, and 21%, respectively. Among the 127 patients with EIC-negative tumors, the 5-year recurrence rate was less than 10% in all margin groups. Among the 30 patients with EIC-positive tumors, the 5-year recurrence rate was 0% when margins were negative or close but 50% when margins were more than focally positive. These results provided support for the use of BCT (including an irradiation boost to the primary site) for patients with EIC-positive tumors and negative margins.

Histology

In general, studies that have evaluated local relapse in relation to histologic subtypes of breast cancer have not demonstrated higher relapse rates associated with specific histologic patterns.

Thurman et al,[70] in an analysis of the Harvard series, identified 20 clinical stage I and II patients with mucinous carcinoma, 27 with medullary carcinoma, 28 with tubular carcinoma, and 1,055 with IDC. No significant difference was seen in the site of first failure among the four histologic types within the first 10 years after treatment. Local failure was significantly associated with age less than 50 years ($P = .04$), positive surgical margins ($P = .007$), lymphovascular invasion ($P = .04$), and the presence of EIC ($P < .001$).

An analysis of medullary carcinomas treated conservatively was performed by the Yale group, who identified 46 cases of conservatively treated patients with medullary histology who were compared with 1,444 patients with infiltrating ductal carcinoma.[51] The medullary cohort presented at a younger age with a higher percentage of patients in the 35 years or below age group (26.1% vs 6.6%; $P < .00001$). Twelve patients with medullary histology underwent genetic screening, and six patients were identified with deleterious mutations. This group showed greater association with *BRCA1/2* mutations compared with screened patients in the control group (50.0% vs 15.8%; $P = .0035$). The medullary cohort was also significantly associated with greater T stage and tumor size (37.0% vs 17.2%; T2 mean size 3.2 vs 2.5 cm; $P = .00097$) as well as negative ER (84.9% vs 37.6%; $P < .00001$) and PR (87.5% vs 48.1%; $P = .00001$) status. Breast relapse-free rates were not significantly different from the invasive ductal cancers (76.7% vs 85.2%); however, 10-year distant relapse–free survival in the medullary cohort was significantly better than in the control group (94.9% vs 77.5%; $P = .028$).

Infiltrating Lobular Carcinoma

A review of the literature strongly supports local tumor resection and breast irradiation as an appropriate therapy for invasive lobular breast cancer, following the same guidelines used for invasive ductal tumors. Breast tumor control and survival after BCT are equivalent in patients with invasive ductal or lobular carcinoma. Because of the presumed multicentric nature of lobular carcinomas, several groups have attempted to assess whether these subtypes are more prone to local failure with breast-conserving approaches.[71,141-145] Table 62.11 summarizes results of several selected series of patients treated with breast-conserving surgery and radiation comparing outcomes in lobular carcinoma to IDCs. Although some of the studies show higher contralateral rates in lobular carcinomas, local relapse, DFS, and OS appear to be comparable to IDCs. The majority of studies show locoregional control, DFS, and OS rates in lobular carcinomas that are comparable to patients with IDCs.

NR, no results; NS, not significant.

Lobular Carcinoma In Situ as a Component of Invasive Cancers

Several groups have evaluated whether patients with LCIS as a component of invasive cancer or DCIS were associated with higher local relapse rates. Conflicting results from these studies preclude firm conclusions. In a series of 56 patients with an LCIS component, Jolly et al[146] reported

a higher risk of local relapse at 10 years (14%) compared with a rate of 7% in cases without an LCIS component. In multivariate analysis, a component of LCIS was associated with a higher risk of local relapse.

In contrast, Ben-David et al[147] reported on 64 cases treated at the University of Michigan and found no association between local failure and presence of LCIS. The presence of LCIS at the margins and the size and presence of multifocal LCIS did not alter the rate of local control. Ciocca et al,[148] in an analysis of 290 patients with LCIS as a component compared with 2,604 without LCIS as a component, showed no difference in local control, even if LCIS was present at the final margin.

Nodal Status

Although nodal status is the strongest predictor of distant metastasis and OS, most studies have not clearly demonstrated an effect of nodal status on local control in the conservatively managed patient with breast cancer. This may be because a majority of patients who are node-positive receive chemotherapy or hormonal therapy, which may counteract any adverse effects on local relapse. There are some data, however, that suggest an effect of nodal status on local relapse in conservatively managed patients. At the Institut Gustave-Roussy, among 356 patients, LR was noted in 26% of those with and 6.5% of those without nodal involvement; the greater the number of nodes involved, the more likely the occurrence of local failure and the lower the survival rate.[71] However, other reports noted lower survival rates but fewer breast relapses after breast conservation therapy in patients with positive nodes. Again, this is likely a result of the interaction of irradiation to the breast with adjuvant chemotherapy. Because many patients who are node-positive receive chemotherapy, which is synergistic with radiation in lowering the local relapse rate, any potential adverse effect of positive nodes on local relapse may be lost.

Molecular Factors and Local Relapse

In comparison with an explosion of data regarding molecular markers as risk factors for OS and distant metastasis in breast cancer, there are relatively few data relating molecular markers to local relapse in the conservatively managed breast. There have been several studies, however, that demonstrate the potential application of molecular markers in predicting locoregional relapse in patients with breast cancer.

Haffty et al[149] examined patients treated with BCT plus radiation and identified 482 patients with ER, PR, and *HER2* available for analysis. Patients were then stratified into TN and non-TN status. They found that at 5 years, the TN cohort had a poorer distant metastasis–free rate compared with the other subtypes (67% vs 82%; $P = .002$). TN subtype was an independent predictor of distant metastasis (HR 2.14; 95% CI, 1.31-3.53; $P = .002$) and cause-specific survival (HR 1.79; 95% CI, 1.03-3.22; $P = .047$). However, there was no significant difference in local control between the TN and other subtypes (83% vs 83%). The authors concluded that although patients classified as TN have a poor prognosis, there was no evidence that these patients are at higher risk for local relapse after conservative surgery (CS) and radiation.

In contrast, Nguyen et al[150] reported on 793 patients with invasive breast cancer who received BCT and radiation. With a median follow-up of 70 months, the 5-year rate of LR was 1.8%: 0.8% (0.3, 2.2) for luminal A, 1.5% (0.2, 10) for luminal B, 8.4% (2.2, 30) for *HER2*, and 7.1% (3.0, 16) for basal. In addition, on multivariate analysis, *HER2* and basal subtypes were associated with increased LR as compared with luminal A ($P < .01$). Luminal B and basal subtypes were associated with increased distant metastases as compared with luminal A ($P < .04$).

Voduc et al[151] investigated the rate of local and regional relapse in 2,985 patients stratified by molecular subtype. With a median follow-up of 12 years, they found that after BCT and radiation, patients with luminal A tumors had the most favorable prognosis, with local relapse and regional relapse rates of only 8% and 3% at 10 years, respectively. *HER2*-enriched and basal-like groups exhibited the highest rates of LR (21% and 14%, respectively) and regional relapse (16% and 14%, respectively). After mastectomy, patients with luminal A tumors again had the best prognosis, with rates of local relapse and regional relapse (8% and 4%, respectively, at 10 years). All non–luminal A subtypes exhibited a greater risk of local relapse and regional relapse.

An analysis of TN breast cancers from a large Canadian database revealed an interesting observation. Abdulkarim et al[152] reported a higher rate of local relapse among patients who had T1/T2 node–negative mastectomy treated without radiation and who had TN disease compared with a similar node-negative cohort treated with breast-conserving surgery and radiation. These results emphasize the point that TN breast cancers do not necessarily fare better with mastectomy, possibly because of the incidental irradiation of lymphatics in the low axilla.[153] Wang et al conducted a prospective trial where patients with stages I to II TN breast cancer were treated with mastectomy and randomized to chemotherapy with or without postmastectomy RT (PMRT). With 86.5 months of follow-up, the 5-year DFS rates were 88.3% and 74.6% for adjuvant chemotherapy plus radiation and adjuvant chemotherapy alone, respectively (P = .02). The 5-year OS was significantly improved in adjuvant chemotherapy plus radiation group compared with chemotherapy alone (90.4% and 78.7%, respectively; P = .03).[153]

Mamounas et al[154] investigated the risk of LRR in patients with early-stage, node-negative ER-positive breast cancer treated on the NSABP B14 and NSABP B20 protocols based on the Oncotype DX RS. The RS was available in 355 placebo-treated patients (B14), 424 chemotherapy plus tamoxifen patients (B20), and 895 tamoxifen patients (B14 and B20). In the tamoxifen-treated patients, the risk of LRR was 4.3% for patients with low RS (<18), 7.2% for those with intermediate RS (18-30), and 15.8% for those with high RS (>30). In placebo-treated patients, the risk of LRR was 10.8% for patients with low RS, 20.0% for those with intermediate RS, and 18.4% for those with high RS. In chemotherapy-treated patients, the risk of LRR was 1.6% for patients with low RS, 2.7% for those with intermediate RS, and 7.8% for those with high RS. The authors concluded that the Oncotype DX RS was a significant predictor of LRR.

These analyses, while showing a consistent trend, should be considered exploratory and are not significant enough to alter clinical decision-making. This is clearly an active area of investigation, ideally with molecular studies linked to large clinical trials to help identify molecular markers predictive of locoregional outcomes and potential targets for improving outcomes.

BREAST-CONSERVING SURGERY WITHOUT RADIATION

Based on the mature data from the well-conducted randomized trials outlined earlier and on long-term follow-up from several large retrospective series, it is apparent that breast-conserving surgery followed by RT is a safe and effective modality for the majority of women with early-stage invasive breast cancer. Whether subsets of patients can be treated with breast-conserving surgery alone without irradiation has been the subject of considerable debate and several randomized trials. With the possible exception of selected older women, which is discussed in a later section, subsets of patients in whom RT can be safely avoided have yet to be clearly identified. Collectively, the randomized studies to date consistently demonstrate an approximately 3-fold greater local relapse rate in the unirradiated cohorts.[155] Although the majority of these trials did not demonstrate an

impact on survival, a pooled analysis of these randomized trials demonstrates a small but statistically significant impact on mortality as a result of the omission of radiation.

Vinh-Hung and Verschraegen[155] conducted a pooled analysis of published randomized clinical trials that compared RT versus no RT after breast-conserving surgery. The outcomes studied were IBTR and patient death from any cause. A search of the literature identified 15 trials with a pooled total of 9,422 patients available for analysis. The RR of IBTR after breast-conserving surgery, comparing patients treated with no RT or RT, was 3.00 (95% CI, 2.65-3.40). Mortality data were available for 13 trials with a pooled total of 8,206 patients. The RR of mortality was 1.086 (95% CI, 1.003-1.175), corresponding to an estimated 8.6% (95% CI, 0.3%-17.5%) relative excess mortality if RT was omitted (Figure 62.13A,B).

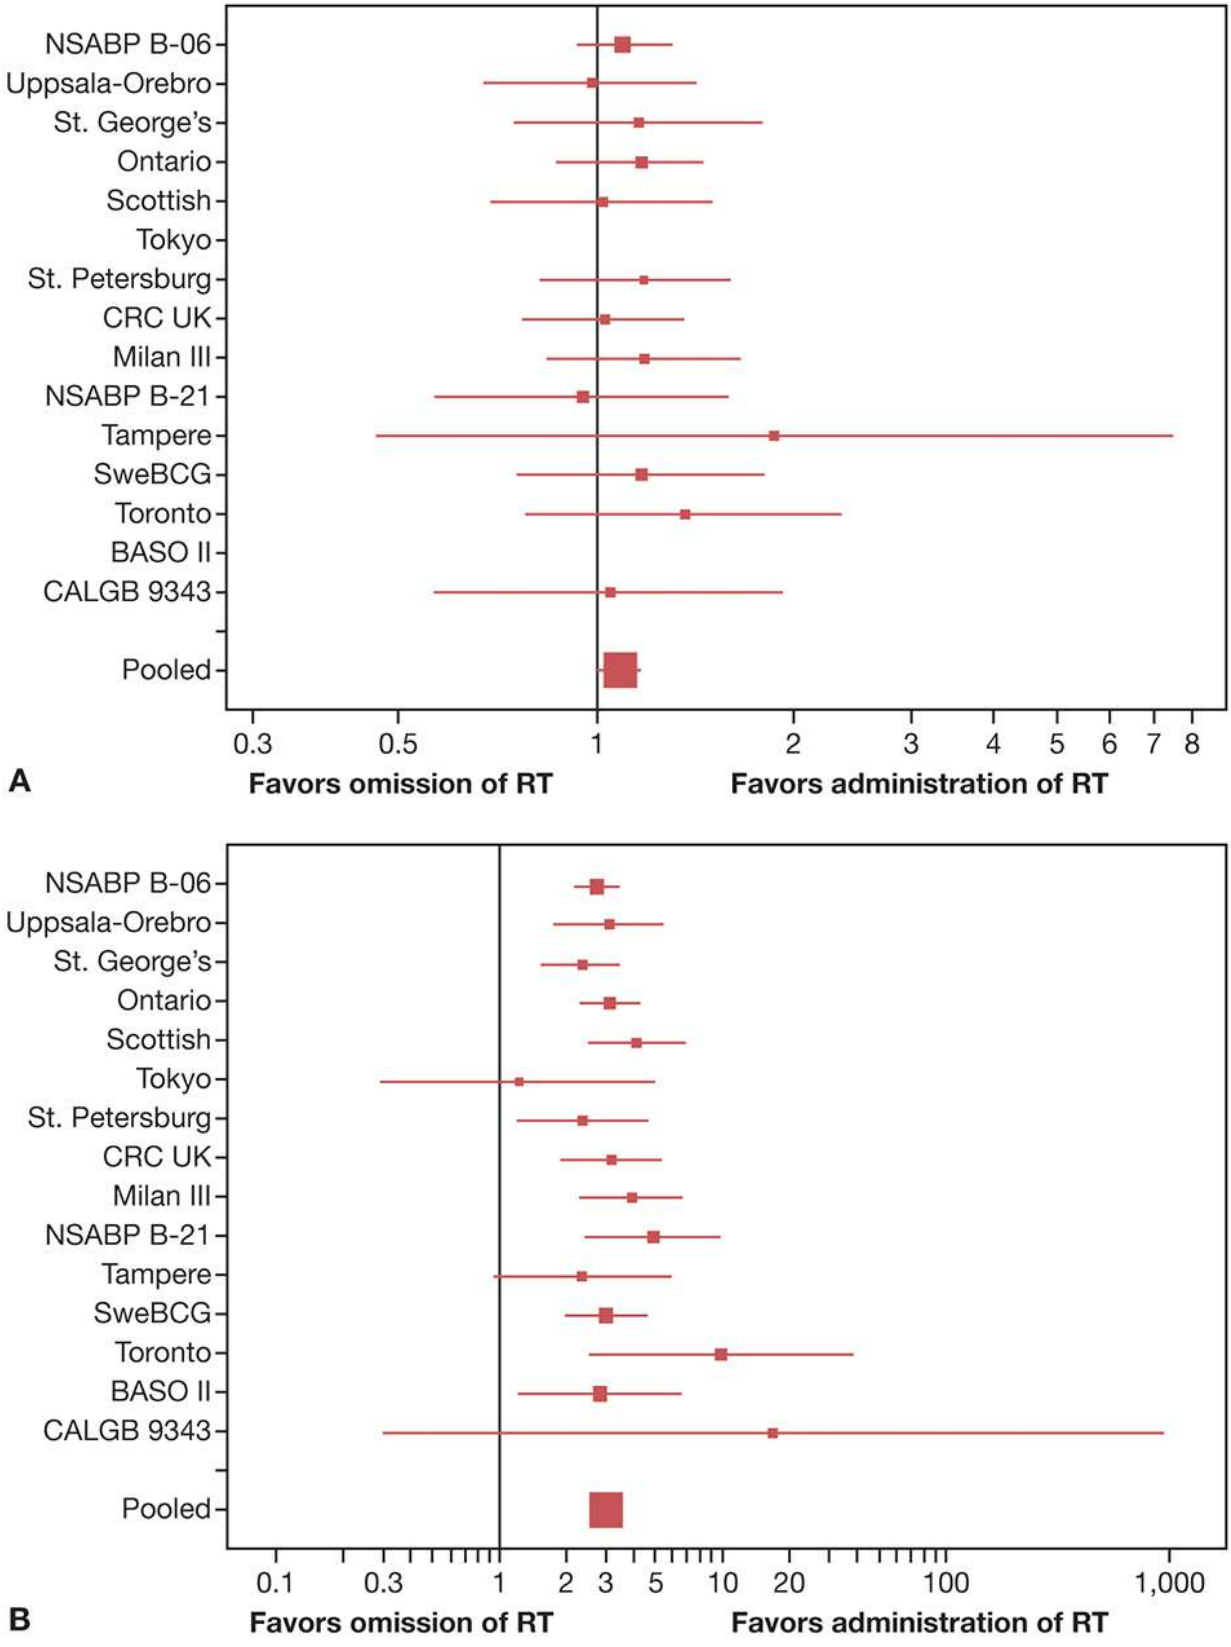

FIGURE 62.13 Meta-analysis of survival (A) and local control (B) in randomized trials comparing breast-conserving surgery with or without radiation. This meta-analysis demonstrated a 3-fold reduction in local relapse and a small but

significant increase in survival with the use of radiation therapy (RT) following lumpectomy. NSABP, National Surgical Adjuvant Breast and Bowel Project. (From Vinh-Hung V, Verschraegen C. Breast-conserving surgery with or without radiotherapy: pooled-analysis for risks of ipsilateral breast tumor recurrence and mortality. *J Natl Cancer Inst*. 2004;96[2]:115-121. Reproduced by permission of Oxford University Press.)

In an analysis from the EBCTCG, similar conclusions were reached evaluating various forms of local therapy.[41,42] Within this meta-analysis were 10,801 women treated with breast-conserving surgery in trials randomizing patients to RT versus no RT. The majority included patients with axillary clearance of node-negative disease and generally were treated with radiation to the conserved breast alone. The reduction in LR (mainly in the conserved breast) in patients treated with RT was highly significant ($P < .00001$) in every separate trial. As seen in Figure 62.14, the recurrence rate ratio, comparing those allocated RT with those not, is about 0.3 in every trial, corresponding to a proportional reduction of 70%. Considering all 17 trials together, the 10-year risk of LR is 19% among those allocated RT and 35% among those not, corresponding to an absolute reduction of 16% in this 10-year risk. The proportional risk reduction for breast cancer mortality is much less than that for LR, and none of the trial-specific breast cancer mortality results are clearly significant on their own. However, collectively, there is a significant impact on breast cancer mortality (breast cancer death rate ratio 0.83, standard error [SE] 0.05; 95% CI, 0.75-0.912; $P = .0002$), indicating a reduction of about one-sixth in the annual breast cancer mortality rate. The 15-year risk of death from breast cancer (in the hypothetical absence of other causes) is 30.5% among those allocated post–breast- conserving surgery RT and 35.9% among those not (corresponding to an absolute reduction of 5.4%; SE 1.7). Figure 62.15 highlights an update of the EBCTCG, demonstrating the impact of RT on outcome in early-stage breast cancer.[42]

The Uppsala-Orebro Breast Cancer Study group reported on a trial in which women with stage I breast carcinoma were randomly assigned to be treated with either sector resection and axillary dissection plus 54 Gy breast irradiation (184 patients) or the same surgical procedure alone (197 patients).[156] The actuarial LR rates after a median follow-up of 63 to 65 months were 2.3% in the irradiated group and 18.4% with surgery only. The 5-year DFS rates were 91% and 87%, and the 5-year OS rates were 91% and 90%, respectively.

Clark et al[158] reported on a randomized study of 421 patients with tumors 4 cm or smaller and negative nodes who were treated with wide local excision and axillary dissection alone and 416 patients who were treated with the same surgery plus breast irradiation (40 Gy in 3 weeks, 16 fractions, and 12.5-Gy boost in 5 fractions). With 7.6 years' median follow-up, breast recurrences were seen in 148 (35%) of the patients who are nonirradiated and in 147 (11%) of the patients who are irradiated ($P < .0001$); 99 (24%) patients in the former group and 87 (21%) in the latter group died during the study period.

One of the most significant trials addressing the issue of local relapse following lumpectomy alone was from the NSABP-06.[34] This trial included three arms—modified radical mastectomy, lumpectomy with radiation, and lumpectomy without radiation—and included both patients who are node-positive and those who are node-negative. In this trial, breast irradiation decreased the likelihood of a recurrence in the ipsilateral breast in the group of 1,137 lumpectomy-treated women whose surgical specimens had tumor-free margins. The cumulative incidence of a recurrence in the ipsilateral breast 20 years after surgery was 14.3% among the women who underwent irradiation after lumpectomy and 39.2% among those who underwent lumpectomy without irradiation ($P < .001$). The benefit of RT was independent of the nodal status. Among the women with negative nodes, 36.2% of those who did not receive RT and 17.0% of those who did have a recurrence in the ipsilateral breast within 20 years ($P < .001$). Among the women with positive nodes, 44.2% of those who did not undergo irradiation and 8.8% of those who did have a recurrence in the ipsilateral breast ($P < .001$). Among the lumpectomy-treated women whose surgical specimens had tumor-free margins, the HR for death among the women who underwent postoperative breast irradiation, as compared with those who did not, was 0.91 (95% CI, 0.77-1.06; $P = .23$). RT was associated with a

marginally significant decrease in deaths due to breast cancer. This decrease was partially offset by an increase in deaths from other causes.

Because of continued uncertainty regarding the need for radiation in more favorable tumors, the NSABP continued to investigate this issue of elimination of irradiation. In the B-21 trial, 1,009 women treated by lumpectomy were randomly assigned to tamoxifen (n = 336), RT and placebo (n = 336), or RT and tamoxifen (n = 337).[36] End points were divided into rates of breast relapse, distant recurrence, and contralateral breast cancer. Radiation and placebo resulted in a 49% lower hazard rate of local relapse as opposed to tamoxifen alone; radiation and tamoxifen resulted in a 63% lower rate as opposed to radiation and placebo. When compared with tamoxifen alone, radiation plus tamoxifen resulted in an 81% reduction in hazard rate of IBTR. Cumulative incidences of local relapse through 8 years were 16.5% with tamoxifen, 9.3% with radiation and placebo, and 2.8% with radiation and tamoxifen. The authors concluded that in women with tumors 1 cm or less, local relapse occurs with enough frequency after lumpectomy to justify considering RT, regardless of ER status.

In another landmark trial, Veronesi et al[157] randomly assigned 567 women with small cancers of the breast (<2.5 cm in diameter) to quadrantectomy followed by RT or to quadrantectomy alone. All patients underwent total axillary dissection. The number of IBTRs was significantly higher in patients treated with surgery alone (59 cases of 273; 10-year crude cumulative incidence of 23.5%) than in patients treated with surgery plus RT (16 cases of 294; 10-year crude cumulative incidence of 5.8%). The difference in IBTR frequency between the two treatments was high in women up to 45 years of age, tending to decrease with increasing age up to no apparent difference in women older than 65 years. OS curves for the two groups did not differ significantly (P = .326). However, a limited survival advantage was evident after RT for node-positive women.

Conservative Surgery Alone in Older Women

Given the lower reported local relapse rates in older women, the absolute benefit of RT following breast-conserving surgery may be less. The question of whether radiation can be eliminated following BCT has been addressed in retrospective studies and prospective randomized trials.

In the trial of quadrantectomy versus quadrantectomy plus radiation reported by Veronesi et al,[157] although there was a clear benefit in local control overall with radiation, the benefit was significant and apparent only in younger women; for patients over age 65, there was no significant benefit.

The Cancer and Leukemia Group B (CALGB) 9343 trial, published by Hughes et al,[160] randomly assigned 636 women with clinical stage I, ER-positive breast carcinoma treated by lumpectomy to receive tamoxifen plus RT (317 women) or tamoxifen alone (319 women). The only significant difference between the two groups was the rate of LR or regional recurrence at 5 years (1% in the group given tamoxifen plus irradiation and 4% in the group given tamoxifen alone; P < .001). There were no significant differences between the two groups with regard to the rates of mastectomy for LR, distant metastases, or 5-year rates of OS. The authors concluded that lumpectomy plus adjuvant therapy with tamoxifen alone was a reasonable choice for the treatment of women aged 70 years or above who have early, ER-positive breast cancer. An update of this trial revealed that at 10 years, 98% of patients receiving tamoxifen plus irradiation compared with 90% of those receiving tamoxifen alone were free from LR and regional recurrence. There were again no significant differences in mastectomy rates, distant metastases, or 10-year rates of OS.[161]

The PRIME II trial randomized 1,326 women aged 65 years or above with low-risk early-stage breast cancer who underwent breast-conserving surgery to receive adjuvant endocrine therapy alone or adjuvant endocrine therapy and adjuvant whole-breast radiation. Low-risk was defined as

hormone receptor-positive, node-negative, T1-T2 tumors up to 3 cm, with negative surgical margins. High-grade disease or lymphovascular space involvement (LVSI) was allowed, but not both. The primary end point was IBTR. With a median follow-up of 5 years, IBTR was 1.3% (95% CI, 0.2-2.3; $n = 5$) in the RT group and 4.1% (2.4-5.7; $n = 26$) in the no RT group ($P = .0002$). There were no differences in regional recurrence, distant metastases, or OS (93.9% in both groups; 95% CI, 91.8-96.0; $P = .34$). Trial results were overall similar to the CALGB 9343 study.[162]

Collectively, these studies indicate that the benefit of RT for older women is significant in terms of local control, but this absolute benefit is relatively small and must be weighed against comorbidities and other competing risks.

HYPOFRACTIONATED WHOLE-BREAST IRRADIATION

In breast cancer, the conventional RT schedule treatment delivers 1.8 to 2.0 Gy/day for 25 to 28 days for a total dose of 45 to 50.4 Gy. This can be followed by a five to eight fraction boost (10-16 Gy), for a total dose of 60 to 66 Gy delivered over 6 to 7.5 weeks. There has been a growing trend toward hypofractionation, which involves delivering a higher dose per fraction with fewer fractions but a biologically equivalent total dose. This has been shown to be safe and effective in multiple randomized trials and is discussed later.

The UK Standardisation of Breast Radiotherapy (START) Trial A randomized patients with early breast cancer (pT1-3a pN0-1 M0); these patients received either 50 Gy in 25 fractions of 2.0 Gy versus 41.6 Gy or 39 Gy in 13 fractions of 3.2 Gy or 3.0 Gy over 5 weeks after surgery.[163] Thus, the overall treatment time was kept constant in all three arms. The trial did allow treatment of regional lymph nodes (supraclavicular and axillary) with additional radiation fields, and these were used in 20% of the patients. With the primary end point of locoregional tumor relapse, 749 women were assigned to the 50 Gy group, 750 to the 41.6 Gy group, and 737 to the 39 Gy group. With a median follow-up of 5.1 years, the rate of locoregional tumor relapse at 5 years was 3.6% (95% CI, 2.2-5.1) after 50 Gy, 3.5% (95% CI, 2.1-4.3) after 41.6 Gy, and 5.2% (95% CI, 3.5-6.9) after 39 Gy. The authors concluded that a lower total dose in a smaller number of fractions could offer similar rates of tumor control as standard fractionation. A major limitation of the study is the use of a conventionally fractionated boost of 14 Gy in seven fractions. How this boost interacted with the altered fractionation effects is unclear.

The UK START Trial B randomized patients with early breast cancer (pT1-3a pN0-1 M0) at 23 centers in the United Kingdom who were assigned after primary surgery to receive 50 Gy in 25 fractions of 2.0 Gy over 5 weeks or 40 Gy in 15 fractions of 2.67 Gy over 3 weeks.[164] In contrast to the START Trial A, the overall treatment time was shorter in the experimental arm. With the primary end point of locoregional tumor relapse, 1,105 women were assigned to the 50 Gy group and 1,110 to the 40 Gy group. With a median follow-up of 6.0 years (interquartile range 5.0-6.2), the rate of locoregional tumor relapse at 5 years was 2.2% (95% CI, 1.3-3.1) in the 40 Gy group and 3.3% (95% CI, 2.2-4.5) in the 50 Gy group, representing an absolute difference of −0.7% (95% CI, −1.7% to 0.9%).

Whelan et al[165] reported on a study of women with invasive breast cancer who had undergone breast-conserving surgery and were randomized to whole-breast irradiation either at a standard dose of 50.0 Gy in 25 fractions over a period of 35 days (the control group) or at a dose of 42.5 Gy in 16 fractions over a period of 22 days (the hypofractionated radiation group). Notably, women with breast separations greater than 25 cm were excluded. The risk of LR at 10 years was 6.7% among the 612 women assigned to standard irradiation as compared with 6.2% among the 622 women assigned to the hypofractionated regimen (95% CI, −2.5 to 3.5). At 10 years, 71.3% of women in

the control group as compared with 69.8% of the women in the hypofractionated radiation group had a good or excellent cosmetic outcome. The authors concluded that hypofractionated whole-breast irradiation was not inferior to standard radiation treatment in women who had undergone breast-conserving surgery for invasive breast cancer with clear surgical margins and negative axillary nodes.

In 2011, a task force authorized by the American Society for Radiation Oncology (ASTRO) weighed evidence from a systematic literature review and produced recommendations regarding the use of hypofractionated RT in patients with breast cancer.[166] They stated that hypofractionated whole-breast irradiation was likely equivalent to conventional fractionation in patients who meet all of the following criteria: (a) age over 50 years, (b) pathologic state T1-2N0 treated with lumpectomy, (c) patient has not received systemic chemotherapy, and (d) the minimum and maximum dose along the central axis was not less than 93% and not more than 107% of the prescription dose, respectively. For patients not receiving a radiation boost, the task force favored a dose schedule of 42.5 Gy in 16 fractions when hypofractionated RT was planned; there was no conclusion regarding the use of a tumor bed boost in patients treated with hypofractionation. Lastly, the task force also recommended that the heart should be excluded from the primary treatment fields when hypofractionated whole-breast irradiation was used because of lingering uncertainty regarding the late effects of this treatment on cardiac function.

In 2018, an ASTRO task force provided updated guidelines, which focused on five key clinical topics, summarized in the following[167]:

1. For patients receiving whole-breast irradiation only (no additional fields to cover the regional lymphatics), the preferred dose fractionation scheme is hypofractionated whole-breast irradiation (HF-WBI) to a dose of 40 Gy in 15 fractions or 42.5 Gy in 16 fractions. The decision to offer HF-WBI should be independent of tumor grade, receptor status, margin status, laterality, receipt of systemic therapy, and age. In patients with breast augmentation or a history of CVD, HF-WBI or conventional fractionation whole-breast irradiation (CF-WBI) may be used.
2. A tumor bed boost is recommended for patients with invasive breast cancer who are 50 years or below with any grade tumor, age 51 to 70 with a high-grade tumor, or patients who have a positive margin. Tumor bed boost can be omitted for patients who are older than 70 years with low-intermediate hormone receptor–positive tumors that are resected with widely negative (≥2 mm) margins. For patients not meeting these criteria, individualized decision- making was suggested.
3. The recommended dose fractionation for tumor bed boost is 10 Gy in four to five fractions, regardless of whole-breast dose fractionation, stage, or histology. If there is a high risk of LR, such as with a positive margin, a higher boost dose of 14 to 16 Gy in 7 to 8 fractions or 12.5 Gy in 5 fractions can be used.
4. To achieve acceptable dose homogeneity, three- dimensional (3D) conformation treatment planning with a “field-in-field” technique is recommended, and the volume of breast tissue receiving greater than 105% of the prescribed dose should be minimized. The whole breast can be contoured or defined clinically, with the goal of covering at least 95% of the whole breast with 95% of the prescription dose. The tumor bed should be contoured and covered by at least 95% of the prescription dose. The heart should be contoured, and the mean heart dose should be as low as possible. Techniques to minimize cardiac exposure include deep inspiration breast-hold, prone positioning, and/or heart blocks. Dose to the contralateral breast, lung, and other normal tissues should also be minimized.

5. Tumor bed boost is recommended to be delivered sequentially after whole-breast treatment. Resimulation can be considered for repositioning or in patients with very large seromas at the time of initial planning. The tumor bed should be delineated, and conformal planning should be performed with an adequate margin. Exposure to normal tissues should be minimized.

After the publication of the updated ASTRO guidelines, HF-WBI has become the new standard of care for the majority of patients with early-stage breast cancer requiring treatment to the breast only. Newer trials are investigating even shorter courses of whole-breast irradiation with promising results thus far. The UK FAST-Forward trial, for example, was a randomized phase 3 multicenter noninferiority trial that compared a 3-week course of whole-breast or chest wall irradiation (40 Gy in 15 fractions) to two 1-week courses of whole-breast or chest wall irradiation (27 Gy in 5 fractions of 26 Gy in 5 fractions).[168] At a median follow-up of 71.5 months, the HR for IBTR compared to the 40 Gy arm was 0.86 (95% CI, 0.51-1.44) for the 27 Gy arm and 0.67 (0.38-1.16) for the 26 Gy arm. Any moderate or marked clinician-assessed normal tissue effects compared to the 40 Gy arm had odds ratios (ORs) of 1.55 (95% CI, 1.32-1.83; $P < .0001$) for the 27 Gy arm and 1.12 (0.94-1.34; $P = .20$) for the 26 Gy arm. Patient and photographic assessments of normal tissue effects were higher for the 27 Gy arm compared to the 40 Gy arm, but not for the 26 Gy arm compared to the 40 Gy arm. The authors concluded that 26 Gy in 5 fractions to the whole breast or chest wall was noninferior to the 40 Gy in 15 fractions for local tumor control and was safe for normal tissue effects up to 5 years. Longer term follow-up from this trial is awaited.

RADIATION MANAGEMENT OF THE REGIONAL LYMPHATICS

RT of the regional lymphatics remains one of the most variable aspects of BCT.[169,170] The role of RT in the management of the regional lymphatics is influenced by the risk of subclinical microscopic disease in regional nodal basins and patterns of failure. This risk is in part determined by disease characteristics and in part by the extent of surgical evaluation of the axilla, which has become increasingly relevant as a result of increased use of sentinel node biopsy, and whether completion axillary dissections are performed for those patients with sentinel node–positive disease. Furthermore, clinicians differ significantly regarding their philosophy with respect to the treatment of subclinical microscopic disease, particularly as it relates to the internal mammary chain.

The issue of whether one treats the “axilla” in conservatively managed patients is further complicated by both uncertainty and misconceptions about the degree to which the axilla receives radiation from a standard tangential (ST) field. Although this will vary considerably, as discussed in the section on radiation techniques, tangential radiation ports will likely treat most level I nodes and a portion of level II nodes.[171]

Although in the earlier years of breast conservation therapy, patients who are node-negative as well as those who are node-positive often received regional nodal treatment, most would later agree that it is not necessary to irradiate the regional lymphatics if the nodes are pathologically negative and an adequate axillary dissection has been performed.[172] This general practice has now been extended to those patients with a negative sentinel node, because available studies have demonstrated a low rate of pathologically involved nodes after a negative sentinel node procedure performed by an experienced surgeon.[64,107,173] However, several published studies have swung the pendulum toward treating the regional nodes, even in some patients who are node-negative.[174,175] As noted previously, the clinically negative axilla harbors subclinical microscopic disease in up to 40% of patients with early-stage operable breast cancer, and both axillary dissection and axillary radiation result in high rates of regional nodal control.[104,172]

Radiation Compared With Axillary Surgery

Sentinel node sampling, with or without full axillary dissection, is now the most common method of axillary management in women with early-stage breast cancer. For patients in whom full axillary staging will not affect subsequent systemic management, who have not undergone any axillary staging procedure, or who have a positive sentinel node and did not undergo further axillary staging, axillary radiation has been shown to result in high rates of regional nodal control.[172,176] Table 62.13 summarizes the results of randomized trials comparing axillary surgery to radiation or observation.[32,105,177-186]

TABLE 62.13 AXILLARY FAILURE RATES IN PATIENTS IN RANDOMIZED TRIALS COMPARING AXILLARY TREATMENTS

Trials (Reference)	Study Design	Number of Patients	Follow-Up (Month)	Positive LNs (%)	Axillary Failure Rates		
					AxD (%)	AxRT (%)	OBS (%)
NSABP B-04[104]	M (AxD vs AxRT vs OBS)	1,079	126 (ave)	40	1	3	19
Institut Curie[177]	CS (AxD vs AxRT)	658	180 (med)	18	1	3	NA

ave, average length of follow-up; AxRT, axillary radiotherapy; CS, breast-conserving surgery; LNs, lymph nodes; M, simple or radical mastectomy; med, median length of follow-up; min, minimum length of follow-up; NA, not applicable; OBS, observation; Positive LNs, incidence of pathologically involved lymph nodes in patients undergoing axillary lymph node dissection.

Randomized Studies

One of the largest and earliest comparisons of axillary surgery to radiation was the NSABP-04 study, in which operable patients who were clinically node-negative were randomly assigned to radical mastectomy, simple mastectomy, or simple mastectomy with radiation to the chest wall and regional lymphatics.[32] The nodal relapse rate approached 20% in those assigned to simple mastectomy without radiation. The nodal control rates in the radical mastectomy arm and simple mastectomy plus radiation arm were comparable, with less than 3% relapse rate in each of these arms.

A direct comparison of axillary treatment by dissection compared with radiation was reported by Louis-Sylvestre et al,[177] in which 658 patients with a breast carcinoma less than 3 cm in diameter and clinically uninvolved lymph nodes were randomly assigned to axillary dissection or axillary RT after breast-conserving surgery with radiation to the breast. Of the group undergoing dissection, 21% of the patients in the axillary dissection group were node positive. At 10 and 15 years, survival rates were identical in both groups (73.8% vs 75.5% at 15 years). Recurrences in the axilla were less frequent in the axillary dissection group at 15 years (1% vs 3%; P = .04). There was no difference in recurrence rates in the breast or supraclavicular region or distant metastases between the two groups.

Veronesi et al[183] carried out a study in which women older than 45 years of age with breast cancer up to 1.2 cm were randomized, 214 of whom were treated with breast conservation surgery and irradiation without axillary treatment and 221 with conservation surgery plus breast and axillary RT (50 Gy in 5 weeks). After a median follow-up of 63 months, overt axillary metastases were fewer than expected: three cases in the no axillary treatment group (1.5%) and one in the RT group (0.5%). This study suggests that occult axillary metastases might never become clinically overt and axillary dissection might be avoided in patients with small carcinomas and a clinically negative axilla. Axillary RT seems to protect patients from axillary recurrence almost completely. It is possible that systemic therapy, the undamaged immunocompetent tissue in the axillary lymph nodes, and axillary irradiation may all be factors contributing to the low incidence of axillary failures in these patients. Also, in the patients receiving no axillary irradiation, it is highly likely that the level I lymph nodes were included in the ST fields.[171,186]

Irradiation of Lymphatics in Patients With Positive Axillary Lymph Nodes

Although there is general consensus that radiation to the regional lymph nodes is not necessary in patients with pathologically node-negative disease, there is variability in radiation to the regional lymphatics in patients with pathologically node-positive disease.[33,176] Based on the potential DFS and OS advantage, as well as the risk of failure in the supraclavicular region, most radiation oncologists favor at least supraclavicular nodal irradiation in patients with four or more positive lymph nodes. For patients with one to three positive lymph nodes, many radiation oncologists now favor irradiation of the regional lymphatics, given the more recent randomized data discussed later.

The Canadian MA.20 intergroup study showed the benefit for RNI in node-positive or high-risk node-negative disease.[174] The study randomized 1,832 women after lumpectomy, ALND, and adjuvant therapy (91% of patients received adjuvant chemotherapy and 71% received hormonal therapy) to either WBI with or WBI without regional nodal coverage (axillary, supraclavicular, and ipsilateral IMN in the upper three intercostal spaces). Eighty-five percent of patients had one to three positive nodes. RNI improved 10-year DFS (82% vs 77%, HR 0.76, P = .01), distant DFS (86.3% vs 82.4%, HR 0.76, P = .03), and isolated locoregional DFS (95.2% vs 92.2%, HR .59, P = .009). Certain high-risk patient populations, such as the TN subgroup, had a greater benefit with RNI. OS was not significant.

Similarly, the EORTC 22922/10925 study randomized 4,004 women with node-positive or node-negative breast cancer with central or medial tumors after lumpectomy or mastectomy and adjuvant therapy (85% of patients received either chemotherapy, hormonal therapy, or both) to either RNI or observation.[175] At a median follow-up of 11 years, RNI improved DFS (72.1% vs 69.1%, HR 0.89, P = .04), distant DFS (78% vs 75%, HR 0.86, P = .02), and breast cancer mortality (12.5% vs 14.4%, HR 0.82, P = .02).

The European After Mapping of the Axilla Radiation or Surgery Trial randomized patients after positive sentinel node biopsy to axillary dissection or axillary radiation.[187] Between 2001 and 2010, 4,806 patients were enrolled in this phase III noninferiority trial, and 1,425 had a positive sentinel node biopsy. Of these patients, ALND was performed in 744 patients and axillary RT in 681 patients. Updated 10-year results showed an axillary recurrence rate of 0.93% (95% CI, 0.18-1.68; seven events) after ALND and 1.82% (95% CI, 0.74-2.94; 11 events) after axillary RT (HR, 1.71; 95% CI, 0.67-4.39). There were no differences in OS or DFS. ALND was associated with a higher lymphedema rate at 5 years (24.5% vs 11.9%; $P < .001$). It was thus concluded that axillary RT is preferred to ALND for patients with positive sentinel nodes and cT1-2 breast cancer.

Internal Mammary Node Irradiation

The role of internal mammary nodal irradiation in patients with node-positive breast cancer remains a controversial issue. Although the MA.20 and EORTC 22922 trials provide some support for internal mammary nodal irradiation, as the IMNs were included in the RNI arms, there is no clear consensus on the role of internal mammary irradiation.

A prospective Danish study reported the results of 3,089 patients with early-stage breast cancer treated according to national guidelines that directed RNI (including IMNs) of all right-sided disease but RNI (excluding IMNs) of all left-sided disease.[188] RT was given 48 Gy in 24 fractions, regardless of cancer laterality. With a median follow-up of 8.9 years, the OS rates (75.9% vs 72.2%, HR 0.82, $P = .005$), breast cancer mortality (20.9% vs 23.4%, HR 0.85, $P = .03$), and risk of distant recurrence (27.4% vs 29.7%, HR 0.89, $P = .07$) all favored internal mammary irradiation. Subgroup analysis suggested that tumor size 51 mm or larger and four or more axillary nodes positive (especially if the primary cancer was in the lateral quadrants) predicted an OS benefit for internal mammary irradiation.

In a study by Stemmer et al[189] of 100 patients who are node-positive scheduled to receive radiation to the internal mammary chain, 67 received the radiation and 33 did not because of technical difficulties. At a median follow-up of 77 months, DFS was significantly prolonged in patients receiving internal mammary radiation compared with those without internal mammary radiation (73% vs 52%; $P = .02$). A trend was seen for OS (78% vs 64%; $P = .08$). Cox regression multivariate analysis found IMN RT to be significant for both DFS and OS. There was no treatment-related mortality.

In contrast, Fowble et al[190] compared the outcomes of 1,383 women with stage I or II breast cancer who underwent wide excision, axillary node dissection with 10 or more nodes removed, and breast irradiation. A total of 114 women had radiation to the IMNs with deep tangents and 1,269 did not. All axillary node–positive women received adjuvant chemotherapy or tamoxifen or both. There were no significant differences in IBTR, regional node recurrence, and initial or total distant metastases for the two groups. No IMN failures were observed among the 114 patients whose IMNs were treated, and only 4 IMN failures were found in the 1,269 other patients (2 of whom had distant metastases). Similarly, 5- and 10-year actuarial OS and cause-specific survival rates were not significantly different.

In a series from Yale, Obedian and Haffty[191] found no difference in the 10-year DFS rate after breast irradiation and excision, regardless of whether IMNs were irradiated. Of 984 patients with invasive breast cancer who were treated with CS and RT, patients were divided into two groups: those treated by intentionally targeting the IMNs ($n = 535$) and without intentionally targeting the IMNs ($n = 411$). The decision not to use a separate internal mammary field was a result of a change in treatment policy over time and generally not based on the number of nodes or tumor location.

There were no significant differences between the groups with respect to age, ER or PR status, or use of adjuvant chemotherapy or hormone therapy. There were more patients with T2 tumors, positive nodes, medial lesions, indeterminate margins, and slightly longer follow-up in the group treated to the internal mammary chain. There were no significant differences between the groups with respect to OS or distant metastasis–free survival.

It is evident that data are conflicting, and opinions regarding the role of internal mammary radiation remain unresolved. The presence of other high-risk features, such as extensive nodal disease, TN receptor status, or medial/central tumor location, can be used to guide decision-making on the inclusion of the internal mammary lymph nodes in the radiation fields. The radiation oncologist must be familiar with the various techniques to treat IMNs, which are summarized later in the section on techniques.

SEQUENCING CHEMOTHERAPY AND HORMONAL THERAPY

Sequencing Chemoradiation in the Conservative Management of Breast Cancer

With the increasing use of systemic therapy in patients with early-stage breast cancer, the integration of this treatment with surgery and RT has become an important clinical question. Initial retrospective series evaluating treatment sequencing suggested that a delay in the onset of RT to permit delivery of chemotherapy increased LR rates.[192-194] Most of these data were subject to criticism because of their retrospective nature, the fact that patients were treated in an earlier era with different surgical techniques and lack of attention to margins, and inclusion of heterogeneous groups of patients. However, any suggestion of a higher local relapse rate with delays in RT is an appropriate concern with respect to the integration of RT and chemotherapy in conservatively managed patients.

Initial data regarding these concerns related to the delay in radiation while chemotherapy was being delivered led the Harvard group at Joint Center for Radiation Therapy (JCRT) to investigate the sequencing of RT and chemotherapy in a randomized prospective clinical trial.[193,194] In this trial, women treated with breast-conserving surgery were randomly assigned to four cycles of doxorubicin-based combination chemotherapy followed by RT or RT followed by four cycles of the same chemotherapy. In an update of this trial, Bellon et al[195] reported no statistically significant treatment difference in the rates of freedom from any event, including breast cancer recurrence, contralateral breast cancer, second malignancy, or death (Figure 62.16). The 10-year rate of any event was 46% for patients in the chemotherapy-first arm compared with 51% in the radiation-first arm. The 10-year rates of distant metastasis were 35% and 36% in the two arms, respectively, and the 10-year rates of death were 28% and 33%, respectively. For the 123 patients with negative margins, the crude LR rates for chemotherapy- and radiation-first patients were 6% and 13%, respectively. Corresponding rates of distant and regional recurrences were 18% and 26%. Among women with close margins (n = 47), crude LR rates were 32% and 4%, respectively; distant or regional recurrences were 37% and 43%, respectively. In the group with positive margins (n = 51), LRs occurred in 23% of chemotherapy-first and 20% of radiation-first patients.

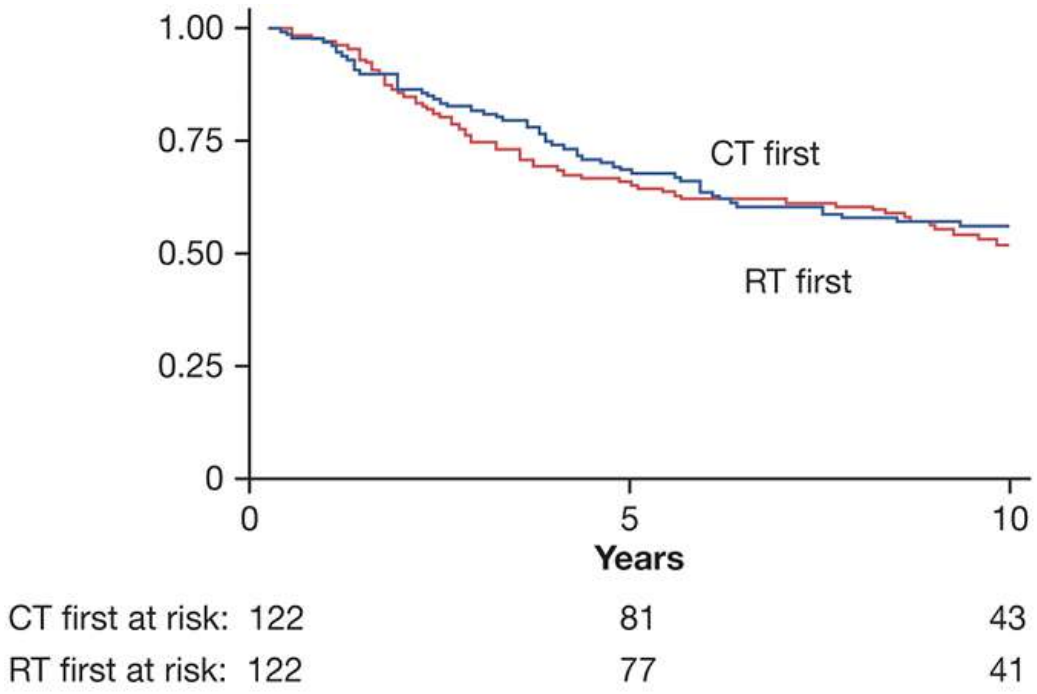

FIGURE 62.16 Event-free survival (including breast cancer recurrence, contralateral breast cancer, second malignancy, or death) by sequencing of chemotherapy (CT) and radiation therapy (RT) following breast-conserving therapy, from the Harvard randomized trial. (Reprinted with permission from Bellon JR, Come SE, Gelman RS, et al. Sequencing of chemotherapy and radiation therapy in early-stage breast cancer: updated results of a prospective randomized trial. *J Clin Oncol*. 2005;23[9]:1934-1940. Copyright © 2005 by American Society of Clinical Oncology.)

Although the JCRT study provided important data concerning treatment sequencing, this study predominantly focused on patients with lymph node–positive disease. Investigators from the MD Anderson Cancer Center performed a retrospective analysis of sequencing of chemotherapy and radiation in 124 patients with lymph node–negative disease treated with BCT.[196] In this series, 79% of the patients had negative margins. The 5-year actuarial rates of local control were 100% for the chemotherapy-first group (most commonly six cycles of doxorubicin-based chemotherapy) and 94% for the radiation- first group (P = .351). The 5-year recurrence-free survival rates for the chemotherapy- and radiation-first groups were 92% and 77% (P = .083), respectively. The median delays in radiation delivery were 6.7 months in the MD Anderson Cancer Center series and 16 weeks in the JCRT series.

With the addition of taxane-based chemotherapy to adriamycin- based regimens, concerns have arisen regarding the additional delays in initiating RT in conservatively managed patients. This was addressed in a study by Sartor et al.[197] In this randomized CALGB study evaluating adriamycin and cytoxan versus adriamycin and cytoxan followed by taxane, there were 345 conservatively managed patients. Although the sequencing of radiation was not randomized, patients in the adriamycin plus taxane arm had radiation delayed by an additional 84 days (four 21-day cycles of taxol). Despite this added delay, locoregional relapses were lower in the adriamycin plus taxane arm compared with the adriamycin arm (9.7% vs 3.7%; P = .04).

For the majority of patients undergoing breast-conserving surgery with negative margins, these data collectively indicate that administration of chemotherapy prior to RT does not result in excessive rates of local relapse, provided all modalities are given in a timely manner without

excessive delays. Whether patients with positive/close margins or other risk factors for local relapse would benefit from earlier administration of radiation remains an unresolved issue.

Concurrent Systemic Treatment in Breast-Conserving Therapy

The historical data on the use of concurrent chemoradiation for early-stage breast cancer are largely outdated, as many of the prior chemotherapy regimens are no longer utilized. More recent randomized clinical trials, however, have demonstrated improved outcomes with a variety of adjuvant systemic drugs. Some were studied in the setting of concurrent delivery with radiation, and others were given sequentially.

The CREATE-X study enrolled patients with HER2-negative breast cancer with residual disease after neoadjuvant chemotherapy and randomized patients to standard adjuvant therapy, including RT when indicated, with or without capecitabine.[198] The primary end point of DFS was longer in the capecitabine group compared with the control group at 5 years (74.1% vs 67.6%; 95% CI, 0.52-0.92; $P = .01$). The secondary end point of OS was also longer in the capecitabine group at 5 years (89.2% vs 83.6%; 95% CI, 0.39-0.90; $P = .01$). There was a greater improvement in both end points among patients with TN disease. In this study, capecitabine was initiated sequentially with RT, either after or before. Smaller, nonrandomized studies have demonstrated the feasibility of concurrent therapy with adjuvant capecitabine and RT.[199]

The KATHERINE trial enrolled patients with HER2-positive early breast cancer who had residual invasive disease in the breast or axilla after neoadjuvant chemotherapy with HER2-targeted therapy.[200] Patients were randomized to receive adjuvant trastuzumab or trastuzumab emtansine (T-DM1) for 14 cycles. On interim analysis, the 3-year invasive DFS was significantly higher in the T-DM1 group than in the trastuzumab group (88.3% vs 77.0%; 95% CI, 0.39-0.64; $P < .001$). In this study, it was recommended that RT be initiated within 60 days of surgery and be given concurrently with study treatment. Though grade 3 or higher adverse events were more common in the T-DM1 group, the most common events were decreased platelet count and hypertension. Radiation pneumonitis of any grade was slightly more common with T-DM1 (1.5% vs 0.7%).

The KEYNOTE-522 trial enrolled patients with TN breast cancer to neoadjuvant chemotherapy with or without pembrolizumab, followed by adjuvant pembrolizumab or placebo every 3 weeks for up to nine cycles.[201] At first interim analysis, the primary end point of pathologic complete response among the first 602 patients who underwent randomization was 64.8% in the pembrolizumab-chemotherapy group and 51.2% in the placebo-chemotherapy group, for an estimated treatment difference of 13.6 percentage points (95% CI, 5.4-21.8; $P < .001$). On subsequent planned interim analysis, the primary end point of event-free survival at 36 months was 84.5% in the pembrolizumab-chemotherapy group and 76.8% in the placebo-chemotherapy group (HR for event of death 0.63; 95% CI, 0.48-0.82; $P < .001$). It was noted that most treatment- related adverse events occurred during the neoadjuvant phase of therapy rather than the adjuvant phase. In patients requiring postoperative RT, adjuvant pembrolizumab or placebo could be given concurrently with radiation or begin 2 weeks after completion of radiation.

The OlympiA trial randomized patients with HER2-negative early high-risk breast cancer found to have BRCA1 or BRCA2 germline pathogenic or likely pathogenic variants to receive 1 year of oral olaparib therapy, a PARP (poly [ADP-ribose] polymerase) inhibitor, or placebo.[202] The majority (82.2%) of the study population had TN breast cancer. The primary end point was invasive DFS. At a prespecified interim analysis, the 3-year invasive DFS was higher in the olaparib group (85.9% vs 77.1%; HR for invasive disease or death 0.58, 99.5% CI, 0.41-0.82; $P < .001$). In this trial, olaparib was initiated after completion of neoadjuvant and/or adjuvant chemotherapy and local RT. To take

advantage of the potential radiosensitizing effects of PARP inhibitors in the highest risk subset of breast cancer patients, a phase II NCI trial is randomizing patients with nonmetastatic inflammatory breast cancer (IBC) to receive standard RT to the chest wall and regional lymph nodes with or without concurrent olaparib.

As data emerge on additional systemic agents, it will be important to identify the patients who might benefit most from concurrent therapy as well as the associated risks and benefits of combined modality treatment.

Sequencing Hormonal Therapy in Breast-Conserving Therapy

The question of optimal scheduling of hormonal therapy and radiation has been raised because of theoretical concerns that tamoxifen may decrease the radiation sensitivity of tumors. In cell culture studies, tamoxifen causes arrest of breast cancer cells in the relatively radioresistant G_0/G_1 phases of the cell cycle. Although there are conflicting data, clinicians and patients have been in a quandary as to whether it is reasonable to begin tamoxifen during radiation. In addition, clinical studies have suggested increased pulmonary and breast fibrosis, possibly related to increased concentrations of transforming growth factor-β with the concurrent use of tamoxifen.[203] A series of three separate retrospective series performed independently but published simultaneously reached similar conclusions that sequential and concurrent use of tamoxifen were both acceptable.

The largest study by Ahn et al[204] from the Yale group compared 254 patients treated with concurrent tamoxifen and RT to 241 treated by RT followed by tamoxifen. There were no significant differences in the risk of IBTR, DFS, or OS. The HR for IBTR comparing sequential with concurrent tamoxifen and RT was 0.93 (95% CI, 0.42-2.05; $P = .86$). In this study, morbidity outcomes were not reported.

The second study by Harris et al,[205] the group at the University of Pennsylvania, compared 174 patients treated with concurrent tamoxifen and RT with 104 patients treated with RT followed sequentially by tamoxifen. Similar to the Yale study, patients were accrued throughout a long period between 1980 and 1995, and again no significant differences in IBTR, DFS, or OS were observed between groups. The HR for IBTR (sequential vs concurrent) was 1.23 (95% CI, 0.33-4.49; $P = .78$). In this study, breast edema and arm edema as well as cosmetic outcome and pneumonitis were analyzed, and no significant differences were observed.

The third study by Pierce et al[206] evaluated results from a randomized trial in which patients were randomly assigned to cyclophosphamide, doxorubicin, and fluorouracil (CAF) followed by tamoxifen, CMF, or CMF followed by tamoxifen. Although the sequencing of tamoxifen was not randomized, 202 patients received concurrent tamoxifen and RT and 107 received RT followed sequentially by tamoxifen. In this study, no differences were noted in the risk of IBTR, DFS, or survival between RT followed sequentially by tamoxifen and concurrent tamoxifen and RT group. The HR for the risk of IBTR (RT followed sequentially by tamoxifen vs concurrent tamoxifen and RT) was 0.73 (95% CI, 0.26-2.04; $P = .54$).

Although these studies are limited by their retrospective design, they do offer some reassurance that the concurrent use of hormonal therapy with RT does not result in excessive rates of local relapse. Given the lack of more definitive data, it appears that either the concurrent or the sequential use of tamoxifen is acceptable in the patient with conservatively managed breast cancer.

The majority of available data on the use of hormonal therapy and radiation are with tamoxifen. In a prospective phase II randomized trial evaluating concurrent or sequential letrozole, Azria et al[207] reported no difference in local relapse (one in each arm) at 26 months of follow-up. In addition, only two patients in each group had grade 2 or worse late effects. An update to this trial showed no

difference between treatment arms at 74 months in grade 2 or higher radiation-induced subcutaneous fibrosis. These authors concluded that letrozole can be safely delivered concomitantly with radiation.[208]

BREAST-CONSERVING THERAPY: CONTROVERSIES AND SPECIAL CIRCUMSTANCES

The available evidence from the abovementioned trials suggests that although there are clearly cohorts of patients who are at increased risk of local relapse, there are relatively few contraindications to BCT. There is little evidence that treatment of patients at higher risk for local relapse with BCT compromises OS. Careful attention to patient selection, surgical technique, radiation technique, and the integration of systemic therapy should minimize the probability of local relapse. There are several areas of controversy and special circumstances in the selection of patients for BCT that warrant specific discussion.

Breast-Conserving Surgery and Radiation in Familial Breast Cancer and Carriers of *BRCA1/2* Mutations

BRCA1 and *BRCA2* are tumor suppressor genes located on chromosomes 17q21 and 13q12, respectively. BRCA proteins encourage genomic stability through repair of double-strand DNA breaks. Mutations in the *BRCA1/2* genes account for 5% to 10% of breast cancers. Carriers of *BRCA1* and *BRCA2* pathogenic mutations have a mean cumulative risk of breast cancer at age 70 of 57% (95% CI, 47%-66%) and 49% (95% CI, 40%-57%), respectively. Ovarian cancer risks are 40% (95% CI, 35%-46%) and 18% (95% CI, 13%-23%), respectively.[209]

Tumor characteristics of *BRCA1* carriers have been well described. Histopathologic features are often more aggressive, with high nuclear grade, aneuploidy, and high proliferation indices. Tumors with a medullary component are more common. ER and PR are more likely to be negative when compared with *BRCA2* or sporadic counterparts. Although there are some conflicting data, *BRCA1/2* carriers with breast cancer appear to have equivalent survival when compared with age- and stage-matched patients with sporadic disease.[10,210-213]

There is considerable controversy and uncertainty regarding the role of breast-conserving surgery and radiation in carriers of *BRCA1/2* mutations. The role of *BRCA1/2* in DNA repair suggests the possibility of hypersensitivity to radiation, as well as the potential for radiation-induced complications, including second cancers. The risk of local and contralateral breast cancers as a function of *BRCA1* and *BRCA2* status has been evaluated by numerous groups over the years. These are summarized in Table 62.14.[212-218]

HR, hazard ratio; IBTR, ipsilateral breast tumor recurrence.

Robson et al[213] studied breast conservation therapy in Ashkenazi women with the *BRCA* gene founder mutations (*BRCA1* 185delAG, *BRCA1* 5382insC, and *BRCA2* 617delT). Archival tissue samples were retrieved from 305 women, and 28 *BRCA* gene founder mutations were detected. *BRCA1/2* carriers had a nonsignificant trend toward increased ipsilateral breast cancer recurrence and decreased OS at 5 and 10 years. This trend may be related to the greater likelihood of young age and axillary lymph node involvement in women with *BRCA* founder mutations. On univariate analysis, age, but not *BRCA* mutation status, was associated with IBTR. The significance of age was maintained on multivariate analysis, with an RR of 2.5. The risk of contralateral breast cancer at 5 and 10 years was 14.8% and 27.0%, respectively.

This series from Memorial Hospital was later combined with data from McGill University, yielding a total of 56 women with founder mutations. Again, *BRCA1/2* carriers had an increased risk of contralateral breast cancer at a median follow-up of 9.7 years (27% vs 8%; $P < .001$). Ipsilateral breast cancer recurrence for *BRCA1/2* carriers was similar to noncarriers, and age less than 50 at diagnosis was the only significant predictor of metachronous ipsilateral disease ($P = .002$).[214] *BRCA1* mutations were an independent predictor of breast cancer mortality on multivariate analysis but only for women who did not receive chemotherapy. *BRCA2* mutations had no impact on breast cancer–specific survival.

Haffty et al[215] studied breast conservation therapy in germline carriers with early-onset breast cancer. One hundred and twenty-seven women diagnosed with breast cancer at age 42 years or below agreed to undergo genetic testing, and 22 were found to have *BRCA1/2* mutations. Adjuvant tamoxifen or oophorectomy was not used in any of the carriers of *BRCA1/2* mutations. Patients in the genetic group were younger than sporadic patients, and this difference was significant on multivariate analysis. Treatment outcomes were compared with results from patients with sporadic disease. With a median follow-up of 12.7 years, the genetic group had a higher rate of ipsilateral (49% vs 21%; $P = .007$) and contralateral breast events (42% vs 9%; $P = .001$). Nine of the 11 IBRs were classified as second primary tumors, based on a difference in tumor location ($n = 7$) or histology ($n = 8$). The rate of ipsilateral and contralateral events was much higher than those reported in earlier series and may be attributable to both the young age of the patients at diagnosis and longer duration of follow-up. The proportion of relapse-free *BRCA1/2* carriers was similar to

noncarriers at 5 years and then progressively declined with time (Figure 62.17). It is promising that all of the second events in *BRCA1/2* carriers were successfully salvaged and remained disease free.

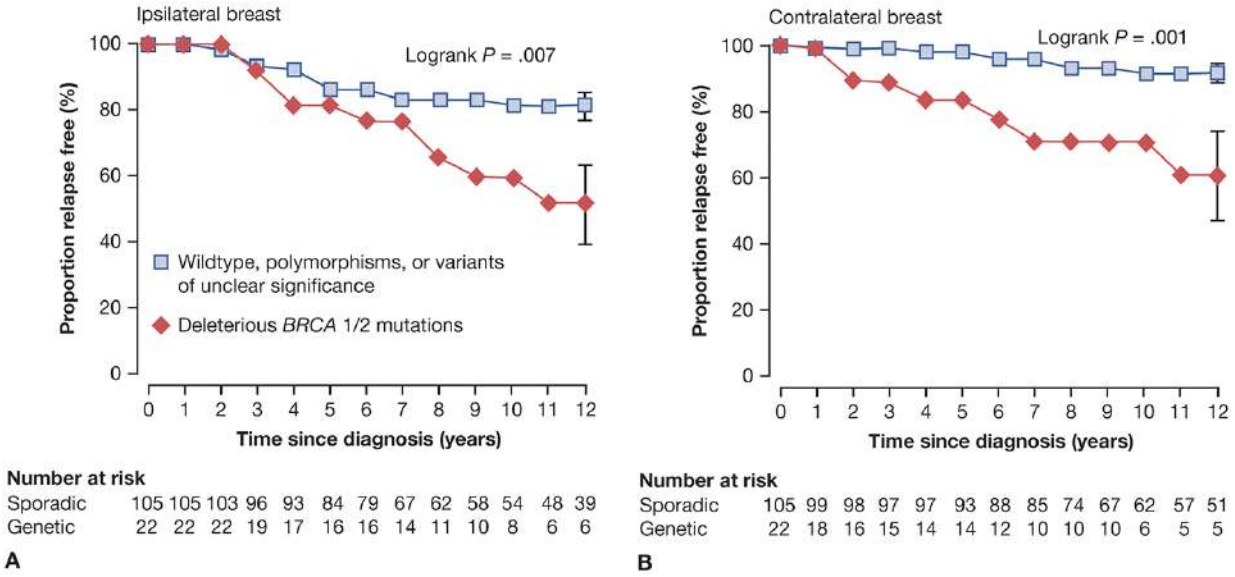

FIGURE 62.17 Risk of ipsilateral (A) and contralateral breast tumor relapse (B) as a function of *BRCA1/BRCA2* mutation status in a cohort of patients with conservatively managed breast cancer. (Reprinted from Haffty BG, Harrold E, Khan AJ, et al. Outcome of conservatively managed early-onset breast cancer by BRCA1/2 status. *Lancet*. 2002;359[9316]:1471-1477. Copyright © 2002 Elsevier. With permission.)

Case-control–type studies were undertaken by Garcia- Etienne et al[216] and Kirova et al[217] The study by Kirova et al did not show a statistically higher local relapse rate in *BRCA1/2* carriers. However, the study by Garcia-Etienne et al, comparing 54 genetic cases to 162 sporadic cases, reported a 15% local relapse rate in the genetic group compared with a 4% local relapse rate in the sporadic group ($P = .03$).

Although the above-presented data have some apparent conflicting conclusions, a study by Pierce et al[218] helped to resolve some of these issues. In a large collaborative study, these authors evaluated a total of 160 *BRCA1/2* mutation carriers with breast cancer matched to 445 controls with sporadic breast cancer (Figure 62.18). Median follow-up was 7.9 years for mutation carriers and 6.7 years for controls. Although there was no significant difference in IBTR overall between carriers and controls (15-year estimates were 24% for carriers and 17% for controls; HR 1.37; $P = .19$), a subset analysis revealed higher rates of local relapse in those carriers who had not undergone prophylactic oophorectomy. Multivariate analyses for IBTR found *BRCA1/2* mutation status to be an independent predictor of IBTR when carriers who had undergone oophorectomy were removed from analysis (HR 1.99; $P = .04$); the incidence of IBTR in carriers who had undergone oophorectomy was not significantly different from that in sporadic controls ($P = .37$). Contralateral breast cancers were significantly more frequent in carriers versus controls, with 10- and 15-year estimates of 26% and 39% for carriers and 3% and 7% for controls, respectively (HR 10.43; $P < .0001$). Tamoxifen use significantly reduced the risk of contralateral breast cancers in mutation carriers (HR 0.31; $P = .05$). Thus, it appears that this study confirms the findings of Haffty et al[215] that *BRCA1/2* carriers have a high rate of both contralateral and ipsilateral breast events if they do not undergo specific measures to reduce the risk of subsequent breast cancers by undergoing oophorectomy or tamoxifen.

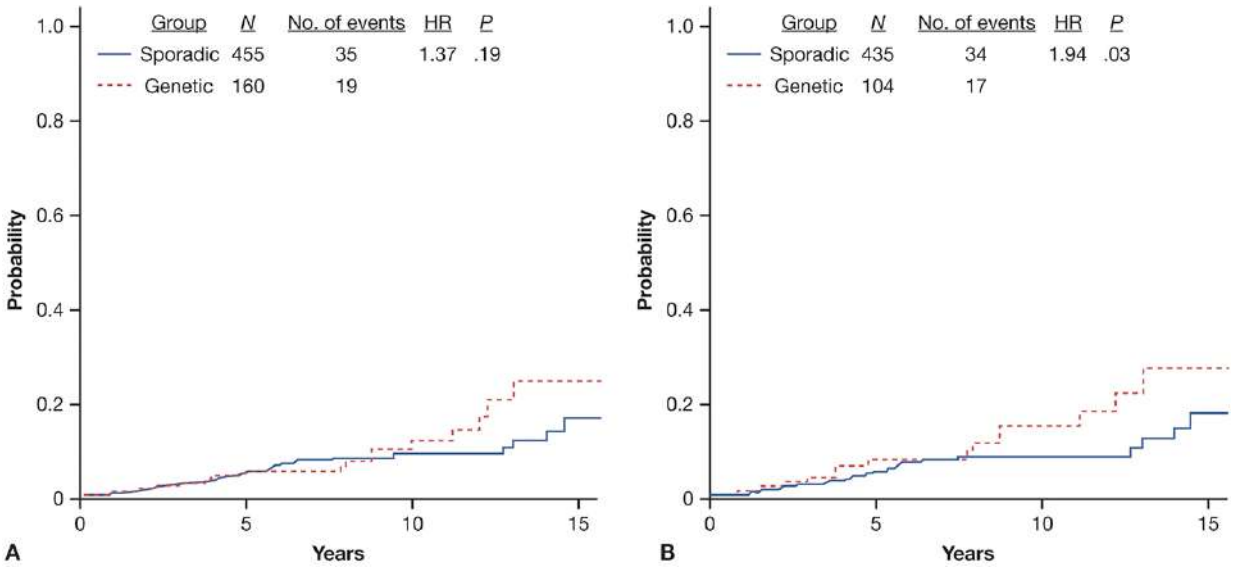

FIGURE 62.18 A.Risk of ipsilateral breast tumor relapse in *BRCA* carriers as a function of whether carriers had undergone prophylactic oophorectomy. In *BRCA* carriers who did not undergo oophorectomy (B), the risk of late local relapses was significantly greater than in sporadic controls. HR, hazard ratio. (Reprinted with permission from Pierce LJ, Levin AM, Rebbeck TR, et al. Ten-year multi-institutional results of breast-conserving surgery and radiotherapy in BRCA1/2-associated stage I/II breast cancer. *J Clin Oncol*. 2006;24[16]:2437-2443. Copyright © 2006 by American Society of Clinical Oncology.)

Prophylactic mastectomy has been shown to significantly reduce the incidence of breast cancer in women with a family history of breast cancer and specifically women with *BRCA1/2* mutations.[31] This risk reduction strategy has complex emotional and psychological implications, and there are no data to suggest an improvement in survival when compared with close surveillance. Most preventive strategies have focused on primary prevention, but prophylactic strategies should also be considered at the time of breast cancer diagnosis. Oophorectomy and tamoxifen appear to offer risk reduction for patients with breast cancer with germline mutations. These agents have not been widely used in studies of patients with conservatively managed breast cancer with *BRCA1/2* mutations. Their potential benefits must be weighed against the possible complications of premature menopause following oophorectomy and the side effects of tamoxifen.

Collagen Vascular Disease

Increased acute and late effects of irradiation have been reported in patients with preexisting CVD. Selected studies addressing this issue are summarized in Table 62.15.[219-226]

TABLE 62.15 STUDIES EVALUATING COLLAGEN VASCULAR DISEASE IN BREAST-CONSERVING THERAPY

Study (Reference)	CVD		Design	Findings
	Total Number	Number With Breast Cancer		
De Naeyer et al[219]	3	1	Case report	Necrosis and progressive fibrosis
Fleck et al[220]	9	4	Case report	Necrosis, brachial plexopathy, and severe moist desquamation

Study (Reference)	CVD		Design	Findings
	Total Number	Number With Breast Cancer		
Robertson et al[221]	2	2	Case report	Severe breast fibrosis, erythema, and pain
Chen et al[222]	36	36	Case-control	Late complication rates higher only in scleroderma
Morris and Powell[223]	209	19	Retrospective	Increased radiation late effects appear in nonrheumatoid arthritis cases.
Ross et al[224]	61	61	Case-control	No differences in acute/chronic complications
Phan et al[225]	38	38	Case-control	No difference was observed in the incidence of acute or late complications between the two groups.
Rakfal and Deutsch[226]	6	4	Case report	No severe acute or late radiation complications

CVD, collagen vascular disease.

Fleck et al[220] reported on five women in whom CVD developed 3 months to 10 years after RT and who had no complications. However, in three of four women with preexisting CVD, severe complications developed, characterized by persistent moist desquamation, paresthesias in the ipsilateral arm, chest wall necrosis requiring surgical resection, and osteonecrosis of the clavicle, sternum, and rib cage.

On the other hand, Ross et al[224] evaluated a group of 61 patients with CVD who were compared with a matched control group of 61 patients without CVD. The CVD group included 39 patients with rheumatoid arthritis, 13 with systemic lupus erythematosus, 4 with scleroderma, 4 with dermatomyositis, and 4 with polymyositis. Overall, there was no significant difference between the CVD and control groups in terms of postirradiation acute complications (11% and 7%, respectively) or late complications (10% and 7%, respectively). This was also true when only patients who were treated definitively were considered. Three patients in the CVD group had fatal complications, compared with none in the control group. Rheumatoid arthritis was associated with a slight increase in late complications in definitively treated patients, whereas systemic lupus erythematosus was associated with a slight increase in acute reactions. No significant acute or late reactions were observed in the patients with scleroderma, dermatomyositis, or polymyositis.

Morris and Powell[223] treated 96 patients with documented CVD with breast conservation therapy (127 sites irradiated). Grade 3 or higher acute complications were seen in 15 (11.8%) of the 127 sites, and the actuarial rate of significant late complications was 24% at 10 years. There was a single in-field sarcoma. Patients with rheumatoid arthritis had less severe late effects than did those with other CVD (6% vs 37% at 5 years; $P = .0001$).

In a study specifically evaluating patients with conservatively treated breast cancer, Chen et al[222] identified 36 patients with documented CVD treated for early-stage breast cancer between 1975 and 1998. All of these patients were treated with conventional RT to a median total dose of 64 Gy. Seventeen had rheumatoid arthritis; four, scleroderma; four, Raynaud phenomenon; five, lupus erythematosus; two, Sjögren disease; and four, polymyositis. Each of these patients was matched to two control patients without a history of CVD. Acute and late complications were assessed using a 6-point scale from the toxicity criteria of the Radiation Therapy Oncology Group (RTOG) and the EORTC. No significant difference was detected between the CVD and control groups with respect to acute complications (14% vs 8%). With respect to late complications, a significant difference was

observed (17% vs 3%) between the two groups. However, when patients in the CVD group were analyzed by specific disease, this significance disappeared in all but the scleroderma group.

Collectively, these data suggest that with the exception of patients with scleroderma, there does not appear to be a significantly greater late complication rate associated with CVD. Nevertheless, when patients with CVD are irradiated, it is prudent to discuss with patients the potential increased risks of radiation sequelae. There are limited data on treating breast cancer in patients with CVD with hypofractionated WBRT or partial- breast RT.

Pregnancy

Breast Cancer During Pregnancy

Breast cancer is the most common cancer diagnosed during pregnancy and represents a significant therapeutic challenge. The incidence of breast cancer associated with pregnancy is estimated to be 1.5 to 2 in 10,000 pregnancies. An expert international panel published general recommendations for breast cancer developing during pregnancy.[227] The panel noted that the goal for the pregnant women with breast cancer is the same as that of the nonpregnant women: local control of disease and prevention of systemic metastasis. However, because of adverse effects on the fetus, certain treatment modalities, including radiation, must be avoided.

The prognosis of patients developing breast cancer during pregnancy, stage for stage, appears to be similar to age-matched controls. The overall poorer prognosis in breast cancer associated with pregnancy may be related to delay in diagnosis because pregnancy impedes early detection and possibly to the more aggressive biology of the tumor.[228] Contrary to popular belief, pregnancy does not appear to stimulate the growth of breast cancer. Therefore, therapeutic abortion is not indicated in most cases, with the exception of patients with rapidly progressing disease such as IBC or metastatic disease.

As discussed later, selected chemotherapy agents can be administered during the second and third trimesters. Although therapeutic abortion is not necessary, women with high-risk disease may find this preferable. The available evidence suggests that in women with a history of breast cancer, subsequent pregnancy does not increase the risk of recurrence. In addition to requiring close coordination among multidisciplinary cancer care givers, management of breast cancer during pregnancy also benefits from having obstetricians and pediatricians closely involved in therapeutic decision-making. It is likely that as pregnancy in Western society is delayed to older ages, the incidence of breast cancer developing during pregnancy will increase.

Breast cancers during pregnancy are usually diagnosed after an abnormal physical examination finding. There may be a delay in diagnosis because the breast mass is thought to represent obstructed milk ducts, and inflammatory changes of the breast may be misdiagnosed as cellulitis. For patients who present with a breast mass, a careful history and physical examination should be performed. The overall goal of managing breast cancer during pregnancy requires attention to both the mother and the fetus. Certain diagnostic and therapeutic interventions are known to be teratogenic and, therefore, are best avoided. Although theoretically a chest radiograph may be safely performed, radiographic and scintigraphic imaging for staging should be minimized or deferred. Mammography is somewhat controversial, although the irradiation dose to the fetus is minimal. Ultrasound evaluations of the breast and lymph nodes can provide diagnostic information and serve as a method of guidance for core biopsy.[229] Pathology of breast cancer during pregnancy is most frequently invasive ductal with high nuclear grade and lower rates of ER and PR positivity.[230]

The management of the patient and the risks of certain interventions are also highly dependent on the week of gestation. In general, potentially harmful interventions carry the greatest risk during the

period of organogenesis (first trimester) and are safest during the final trimester. For patients with operable disease, data suggest that surgery can be safely performed after the 12th week of pregnancy. The type of surgical procedure is dependent on the extent of disease and the trimester of the pregnancy.[230] Few data exist concerning the safety and efficacy of SLNB. Although the blue dye used in SLN surgery is not approved for use in pregnant patients, the estimated radiation dose to the fetus from the radiocolloid tracer is low. Except for radiation, treatment should not be altered or delayed because of pregnancy. Either a modified radical mastectomy or lumpectomy with axillary dissection is acceptable local treatment. Immediate breast reconstruction should not be performed.

Systemic chemotherapy with 5-fluorouracil, doxorubicin, and cyclophosphamide (FAC) has been used in pregnancy. Investigators from MD Anderson Cancer Center reported a prospective series of 57 pregnant patients with breast cancer who were treated on a single-arm, multidisciplinary, protocol with FAC in the adjuvant (n = 32) or neoadjuvant (n = 25) setting.[231] Parents and guardians were surveyed by mail or telephone regarding outcomes of children exposed to chemotherapy in utero. All women who delivered had live births. One child had Down syndrome and two had congenital anomalies (club foot; congenital bilateral ureteral reflux). They concluded that breast cancer can be treated with FAC chemotherapy during the second and third trimesters without significant short-term complications for the majority of children exposed to chemotherapy in utero. It has been shown that administration of chemotherapy in the first trimester is associated with a high risk of birth defects (17%, 24/139), in terms of the probability of intrauterine growth retardation, prematurity, fetal malformation, or death; this risk is less in the second and third trimesters (1.3%, 2/150).[232]

As a general principle, hormonal therapy and RT should be avoided until after delivery. In one study, the estimated dose to the fetus from breast or chest wall radiation to a dose of 0.5 Gy is 0.02 Gy in the first trimester, 0.022 to 0.246 Gy during the second trimester, and 0.02 to 0.586 Gy during the third trimester. Doses to the fetus in the range of 0.1 to 0.9 Gy during the first trimester have been associated with mental retardation. Hall[233] suggested that 0.1 Gy in utero exposure be used as a dose beyond which a therapeutic abortion should be considered.

Pregnancy After Breast Cancer

Almost one-third of women of reproductive age in whom breast cancer develops later have one or more pregnancies, and 70% of these occur within 5 years of treatment.[234] No data are available to suggest that subsequent pregnancy hastens or induces breast cancer recurrence.

A population-based matched survival study assessed the risk of death for patients with breast cancer in relation to whether they delivered a live child subsequent to their cancer diagnosis.[235] Among 2,548 women younger than 40 years of age diagnosed with carcinoma of the breast, 91 experienced subsequent deliveries (10 months or longer after the diagnosis) and 471 control patients were matched for stage, age, and year of breast cancer diagnosis. The control subjects had to survive at least the interval between the cancer diagnosis and the delivery of their matched counterparts. The control subjects had a 4.8-fold greater risk of death compared with those who delivered after the diagnosis of breast cancer. These authors' interpretation of this result was that there was a "healthy mother effect" (only women who felt healthy gave birth, and those who were affected by the disease did not). Nevertheless, 6 of 8 deaths among the 91 patients who did give birth were related to breast cancer.

It may be helpful to suggest a waiting time (2-3 years) for the patient to regain health before attempting the physical stress of pregnancy and deferral of childbearing until after the period of greatest risk of recurrence of the tumor.[234] The individual woman's prognosis, well-being, desire for

children, support from spouse or significant other, and other sociodemographic factors must be carefully considered in this difficult decision-making process.

Lactation After Breast Conservation Therapy

Successful breastfeeding, from the untreated as well as the treated breast, is possible after conservation surgery and irradiation. From over 3,000 patients treated from 1965 to 2003, a cohort of 21 premenopausal women who underwent BCT and subsequently sustained full-term pregnancies were identified.[236] Lactation outcome parameters (breast swelling, ability to lactate, and volume of lactation in the treated and untreated breasts) were the main outcome measures. There were 28 pregnancies in 21 patients. One patient underwent bilateral breast treatment; therefore, a total of 22 breasts were irradiated. All patients interviewed reported little or no swelling of the treated breast during pregnancy. Of the patients studied, 4 (18.2%) elected pharmacologic suppression of lactation. Of the remaining 18 breasts, lactation occurred in 10 (55.6%), did not occur in 7 (38.9%), and was unknown for 1 (5.5%). The volume was reported as significantly diminished in 80% of breasts treated. Lactation in the contralateral breast occurred in all patients who did not undergo pharmacologic suppression. The authors confirmed that successful lactation occurs in the contralateral, untreated breast after BCT. In the treated breast, functional lactation is possible but is significantly diminished in most patients.

Breast Irradiation in Patients Previously Irradiated for Hodgkin Lymphoma

There is an increased incidence of breast cancer in female patients who have previously undergone mantle irradiation for Hodgkin lymphoma. Numerous studies have demonstrated a significantly increased RR of breast cancer in women treated for Hodgkin lymphoma, with the risk significantly increasing with decreasing age of exposure.[16,17,237-240]

Travis et al[16] estimated that for a female Hodgkin lymphoma survivor who was treated at age 25 years with a chest radiation dose of at least 40 Gy without alkylating agents, the cumulative absolute risks of breast cancer by age 35, 45, and 55 years were 1.4% (95% CI, 0.9%-2.1%), 11.1% (95% CI, 7.4%-16.3%), and 29.0% (95% CI, 20.2%-40.1%), respectively. In addition to radiation dose, treatment volumes may also play a role in determining a woman's risk of developing breast cancer after RT for Hodgkin lymphoma. A study by De Bruin et al[17] reported on a cohort of 1,122 female patients with Hodgkin lymphoma treated between 1965 and 1995. The overall cumulative incidence 30 years after treatment was 19%; for those treated before age 21 years, it was 26%. Moreover, mantle field irradiation was associated with a 2.7-fold increased risk in developing breast cancer compared with similarly dosed (36-44 Gy) mediastinal irradiation alone.

Elkin et al[241] reported on a retrospective multicenter, cohort study of 253 patients treated for Hodgkin lymphoma with RT who developed breast cancer and matched 3 to 1 with 741 patients with sporadic breast cancer. They found that patients had a median time from diagnosis of Hodgkin to breast cancer of 18 years, with a median age at breast cancer diagnosis of 42 years. Breast cancer after RT for Hodgkin lymphoma was more likely to be detected by screening, was more likely to be diagnosed at an earlier stage, and was more likely to be bilateral at diagnosis. Hodgkin lymphoma survivors had an increased risk of metachronous contralateral breast cancer (HR 4.3; 95% CI, 1.7-11.0) and death as a result of any cause (HR 1.9; 95% CI, 1.1-3.3).

Hodgkin survivors and others who receive RT to the breast at a young age are at high risk for developing breast cancers and should be carefully monitored. Women who develop breast cancer should be advised that mastectomy remains the treatment of choice. However, for patients highly

motivated for breast preservation, anecdotal experiences using a variety of approaches have revealed acceptable toxicity and cosmesis.

Patients With More Than One Invasive Carcinoma (Multicentric/Multifocal Disease)

Conservation surgery and breast RT as an alternative to mastectomy is controversial in patients with two or more lesions in the same breast. Several studies have addressed this issue, and it appears that the risk of relapse in the conservatively treated patient is slightly higher than if there is one lesion. Still, however, that risk may be acceptable in patients who achieve negative surgical margins and are highly motivated for breast conservation.

The ACOSOG Z11102 trial is a single-arm noninferiority trial of breast conservation in women with two to three sites of malignancy in the breast.[242] Of the 204 patients who underwent protocol-directed breast conservation therapy, the 5-year cumulative incidence of LR was 3.1% (95% 1.3-6.4). Age, number of biopsy-proven foci, ER/Her2 status, and pathologic T and N categories were not significantly associated with LR. However, exploratory analysis showed that the 5-year LR in patients without a preoperative MRI was 22.6% compared to 1.7% in patients with a preoperative MRI. The authors concluded that breast conservation is reasonable approach for patients with multifocal disease, particularly when evaluated with a preoperative breast MRI. Longer term follow-up is awaited to confirm the feasibility of breast conservation in patients with multiple foci of disease.

Conservation Surgery and Irradiation After Breast Augmentation

A growing number of breast cancers occur in women with prior augmentation mammoplasty. The stage of breast cancer at diagnosis in women who have undergone augmentation mammoplasty has been examined with conflicting results. In a retrospective review, Clark et al[243] reported that 24% of 33 patients with augmented breasts and 42% of 1,735 patients with nonaugmented breasts had mammographically detected cancers (P = not significant). The incidence of DCIS in the two groups was similar (18% vs 15%). Sizes of the mammographically detected tumors in the two groups were comparable. However, palpable tumors in the augmented group were significantly smaller than those in the nonaugmented group. Axillary lymph node involvement was detected in 19% of the augmented group and 41% of the nonaugmented group. Among those with mammographically detected tumors, there was no significant difference in axillary lymph node metastases between patients with augmented versus nonaugmented breasts (13% vs 15%).

Breast conservation therapy in 17 augmented patients with breast cancer was reported by Handel et al,[244] where 15 patients were available for follow-up. In 10 (67%) patients, significant capsular contracture occurred in the irradiated breast an average of 12 weeks after completion of treatment. Four patients underwent revision surgery to correct symptoms arising from contracture. These authors concluded that irradiation of the breast for cancer in augmented women results in a high incidence of scar tissue contracture and poor cosmetic results.

In contrast, Guenther et al[245] evaluated 20 women in whom breast cancer developed after augmentation mammoplasty (14 subcutaneous implants and 6 retromuscular implants). Patients were treated with wide local tumor excision and level I and II ALND. Irradiation was delivered to the breast (45-50 Gy), and a boost (14-21 Gy) was given to the tumor excision site with either photons, electrons, or iridium-192 (^{192}Ir) implant. With a median follow-up of 3.8 years (range, 6 months to 9.3 years), there were no LRs, although distant metastases developed in two patients. Seventeen patients (85%) had good or excellent cosmetic results.

Patients with breast augmentation who are diagnosed with breast cancer can be treated with conservation therapy but should be counseled on the potential cosmetic consequences of treatment.

Breast Conservation and Mammoplasty

Women with large, pendulous breasts have been documented to have poorer cosmetic outcomes when undergoing irradiation after breast conservation surgery (thought to be caused by dose inhomogeneity) compared with women who have small- or medium-sized breasts. Smith et al[246] evaluated 10 women who had undergone bilateral reduction mammoplasty for breast malignancy followed by RT. A variety of reduction techniques were used to include the malignant lesions. Patients received 50 Gy in 25 fractions in 5 weeks after surgery. RT was usually initiated within 4 weeks after surgery. With a follow-up of 37 months, no patients had complications from the surgery or RT. No locally recurrent malignancies were detected. Cosmesis was good to excellent in all patients.

TECHNICAL ISSUES IN RADIATION MANAGEMENT OF EARLY-STAGE DISEASE

Treatment Position

Most patients are treated in the supine position, with the arm abducted (≥90°). Commercially available or custom-made breast tilt boards with armrests that maintain the patient's daily position with the slope of the chest wall parallel to the table, often in combination with immobilization devices (eg, Alpha cradle, plastic molds), are typically used to reproduce daily positioning and minimize day-to-day setup errors (Figure 62.19).

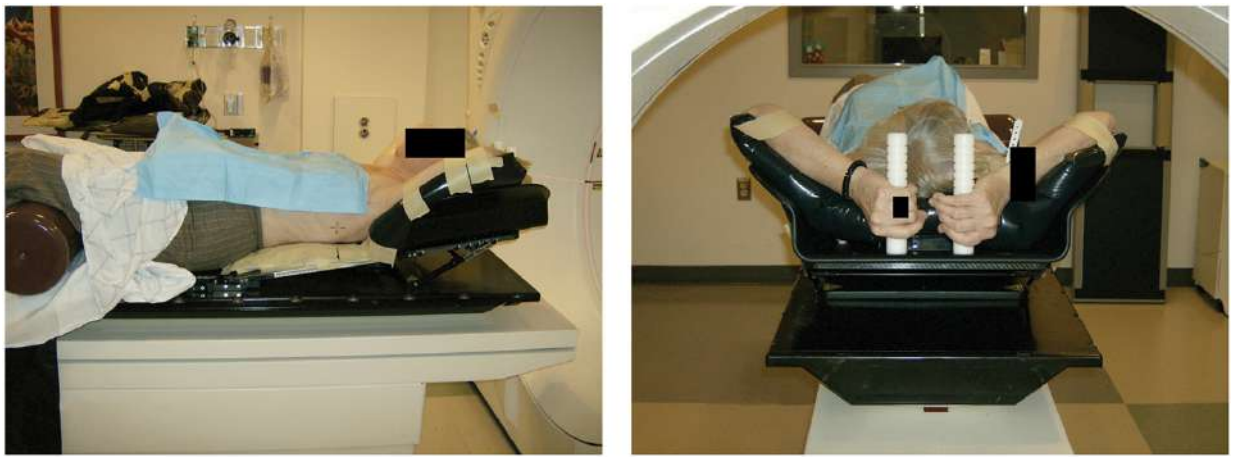

FIGURE 62.19 Patient immobilized for breast irradiation on a slant board with custom mold to minimize day-to-day positioning errors.

Irradiation in the prone position can improve dose homogeneity, particularly for patients with larger breasts. It can also reduce normal tissue exposure to the nearby heart, lungs, and contralateral breast. Patient positioning and a corresponding CT image are shown in Figures 62.20 and 62.21.

Dosimetric analysis of a simplified intensity modulation technique for prone breast radiotherapy. *Int J Radiat Oncol Biol Phys*. 2004;60[1]:95-102. Copyright © 2004 Elsevier. With permission.)

Treatment Volume

The entire breast and chest wall are included in the irradiated volume as shown in Figures 62.22 and 62.23. Radiopaque surgical clips placed at the margin of the tumor bed may assist in defining the target volume. The upper margin of the portals should be placed at the head of the clavicle to include the entire breast. The medial margin, if no internal mammary portal is used, should be at or 1 cm over the midline. If an internal mammary field is used, the medial tangential portal is located at the lateral margin of the internal mammary field. (See later discussion of RNI.) The lateral-posterior margin should be placed 2 cm beyond all palpable breast tissue, which is usually near the midaxillary line. The inferior margin is drawn 2 to 3 cm below the inframammary fold. The RTOG

published their consensus definitions for breast cancer RT planning, which are listed in Table 62.16. An illustration of nodal volumes drawn on an axial planning CT scan is shown in Figure 62.24.

TABLE 62.16 RADIATION THERAPY ONCOLOGY GROUP CONSENSUS DEFINITIONS FOR BREAST CANCER RADIATION THERAPY PLANNING

	Cranial	Caudal	Anterior	Posterior	Lateral	Medial
Breast	Clinical reference + second rib insertion	Clinical reference + loss of CT apparent breast	Skin	Excludes pectoralis muscles, chest wall muscles, ribs	Clinical reference/midaxillary line typically, excludes latissimus dorsi	Sternal–rib junction

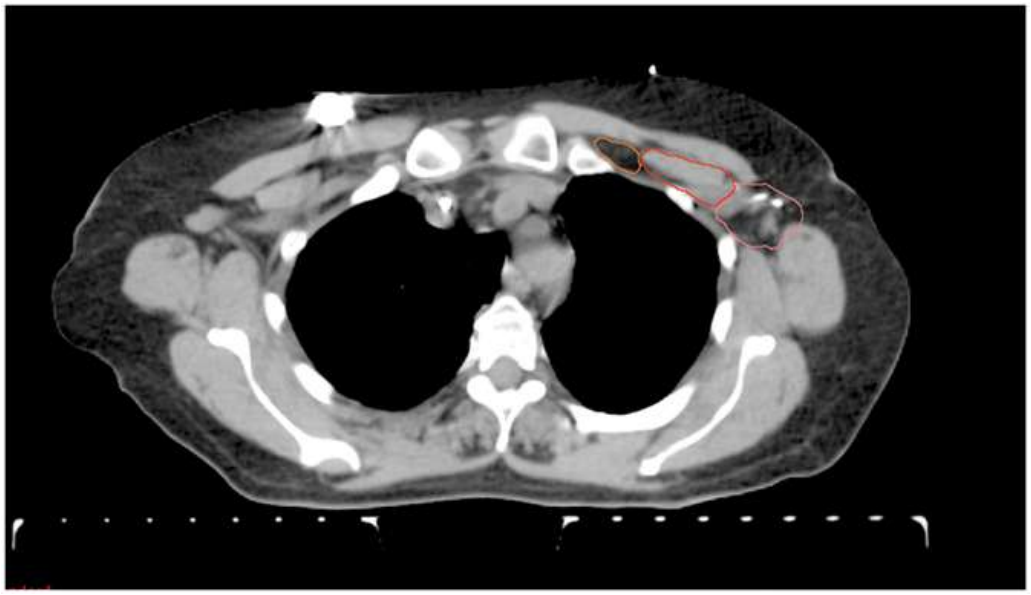

FIGURE 62.24 Nodal volumes drawn on axial planning computed tomography scan.

In patients treated with 6-MV or lower energy photons with wide tangential fields and large separation, there may be significant dose inhomogeneity in the breast, which can compromise cosmetic outcomes. This problem can be minimized by using higher energy photons (10-18 MV) to deliver a portion of the breast radiation (~50%) as determined with treatment planning to maintain

the inhomogeneity throughout the entire breast to between 93% and 105%. If desired, the buildup of the beam may be modified with a "degrader." "Simple intensity-modulated RT (IMRT)" techniques such as field-in-field or dynamic multileaf collimators (MLCs) to achieve electronic tissue compensation may be utilized to reduce dose inhomogeneity as well. Bolus should be avoided in conservatively managed patients. A variety of immobilizing devices or molds may be constructed to support the breast in the treatment position (Figure 62.25). A polyvinyl chloride, ring-shaped device, held by a strap, has been used around the breast to aid in positioning of patients with large, pendulous, or flaccid breasts.[247] Skin reactions where material is in contact with the skin should be closely monitored.

FIGURE 62.25 Immobilization material placed over breast tissue to help maintain the day-to-day positioning of the breast.

Alignment of the Tangential Beam With the Chest Wall Contour

The anterior chest wall slopes downward from the midchest to the neck. To make the posterior edge of the tangential beam follow this downward-sloping contour, the collimator of the tangential beam may be rotated, or the patient may be placed on a slant so that the slope of the chest wall is parallel to the table. An alternative is to make the deep posterior edge of the tangential beam follow the chest wall contour by means of a rotating beam splitter mounted on a tray without rotation of the collimator or using multileaf collimation. In this way, the superior edge of the tangential beam remains in the true vertical and matches perfectly the vertical inferior edge of the supraclavicular field if used.

Usually up to 2 to 3 cm of underlying lung may be included in the tangential portals. The amount of lung included in the irradiated volume is greatly influenced by the portals used. Bornstein et al[248] determined the amount of lung irradiated in 40 patients with breast cancer using CT scans for treatment planning in the treatment position. Parameters measured from simulator films included the perpendicular distance from the posterior tangential field edge to the posterior part of the anterior chest wall at the center of the field (central lung distance [CLD]), the maximum

perpendicular distance from the posterior tangential field edge to the posterior part of the anterior chest wall (maximum lung distance), and the length of lung as measured at the posterior tangential field edge on the simulator film (Figure 62.26). The best predictor of the percentage of ipsilateral lung volume treated by the tangential fields was the CLD. A CLD of 1.5 cm predicted that approximately 6% of the ipsilateral lung would be included in the tangential field; a CLD of 2.5 cm, approximately 16%; and a CLD of 3.5 cm, approximately 26% of the ipsilateral lung. A typical acceptable dose-volume histogram of a left-sided breast cancer treated with external beam radiation is given in Figure 62.27.

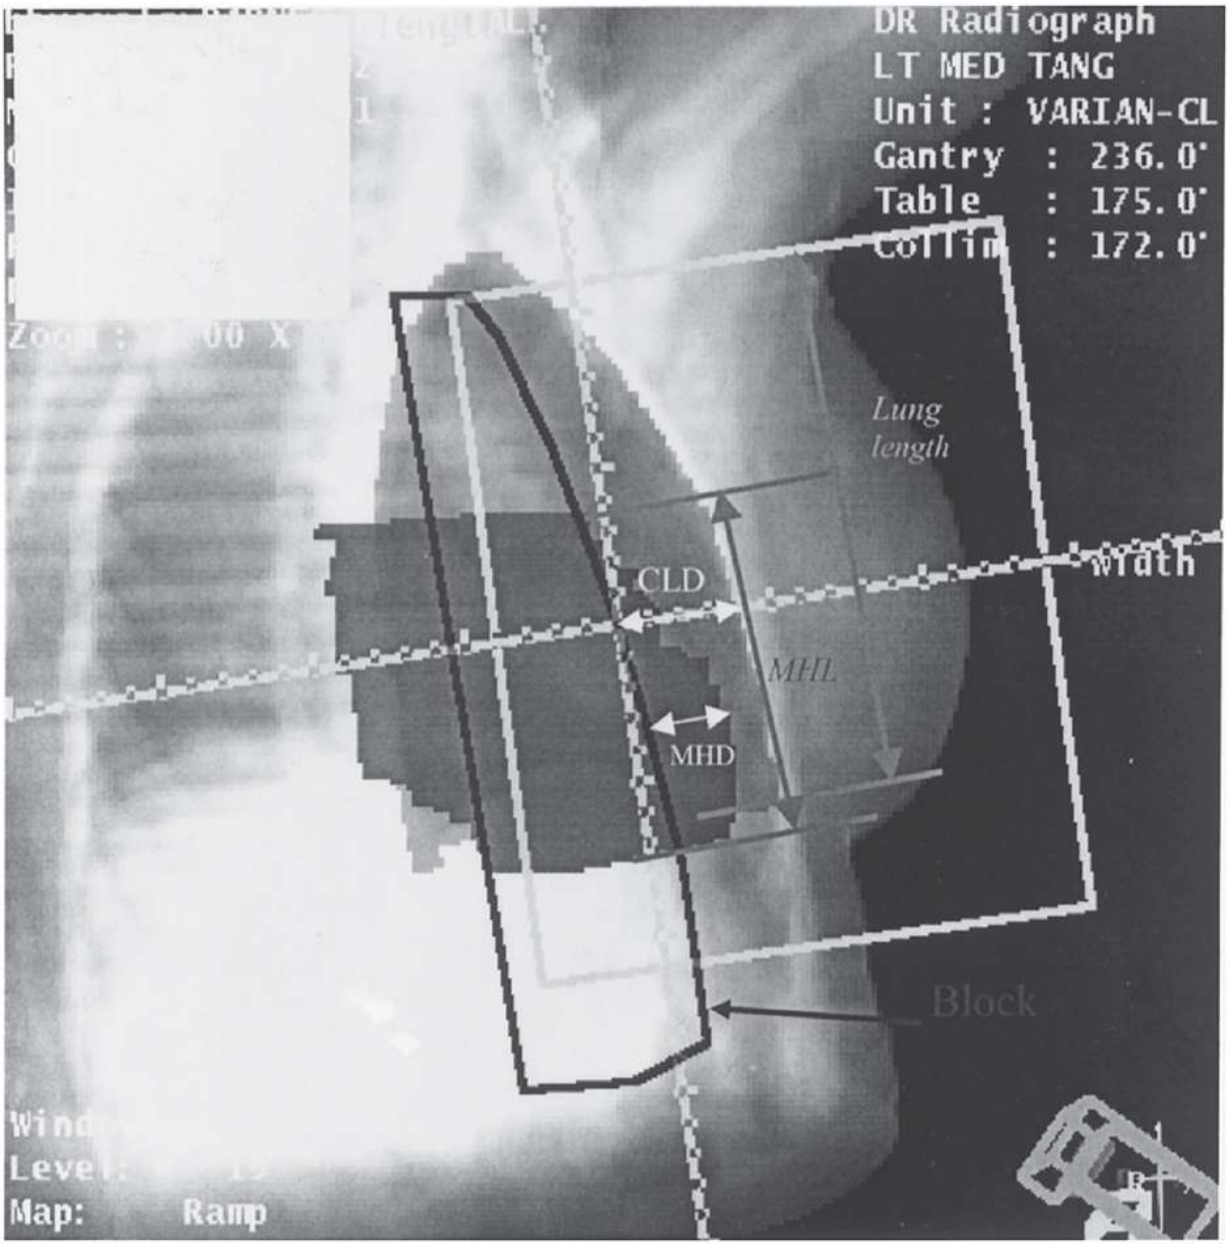

FIGURE 62.26 Measurement of the radiographic parameters using a virtual simulator. The contoured heart is shown in black and the lung in gray. The central lung distance (CLD) is the lung distance in the projection of the tangential fields at the level of the central axis. Lung length is the vertical lung distance included in the radiation port. The maximal heart distance (MHD) is the width of the heart in the tangent fields at its maximal level, whereas the maximal heart length (MHL) is the maximal length in tangential fields referring to the heart contour in a digitally reconstructed radiograph (DRR). (Reprinted from Kong F-M, Klein EE, Bradley JD, et al. The impact of central lung distance, maximal heart distance, and radiation technique on the volumetric dose of the lung and heart for intact breast radiation. *Int J Radiat Oncol Biol Phys*. 2002;54[3]:963-971. Copyright © 2002 Elsevier. With permission.)

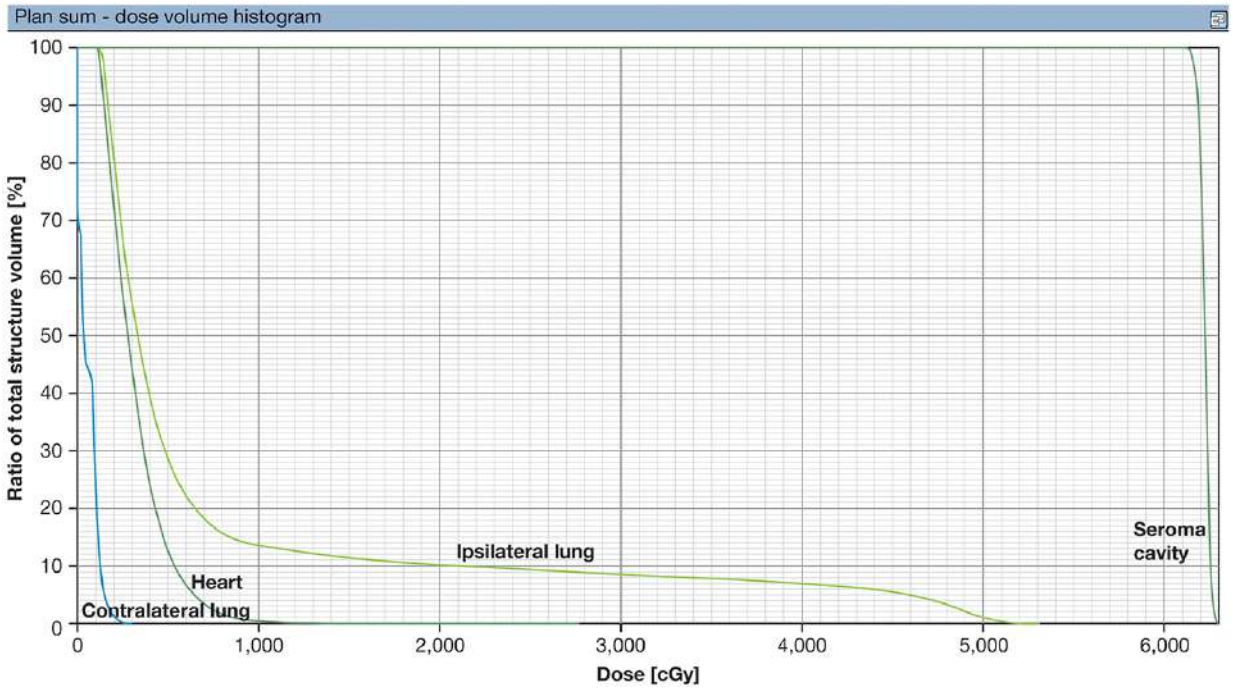

FIGURE 62.27 Dose-volume histogram of left-sided breast cancer treated with external beam radiation.

When the CLD is greater than 3 cm, in treatment of the left breast, a significant volume of heart will also be irradiated. To avoid this, a medial tangential breast port (3- to 5-cm wide), somewhat similar to an internal mammary port, may be designed. The beam is angled 10° to 15° laterally to conform to the angle of the medial breast port. The dose is prescribed to the posterior border of the chest wall as determined by CT scanning.

Special attention should be paid to minimizing the volume of heart irradiated.[249] As discussed later in the section on cardiac sequelae, even small amounts of heart in the field can affect cardiac function. Marks et al[250] have suggested the use of a cardiac block if the heart is in the tangential field, which can be supplemented by an electron field as shown in Figure 62.28. The use of short (10- to 15-second) treatments while the patient holds their breath is also feasible as a way of reducing cardiac radiation during left-sided breast cancer treatment.[251]

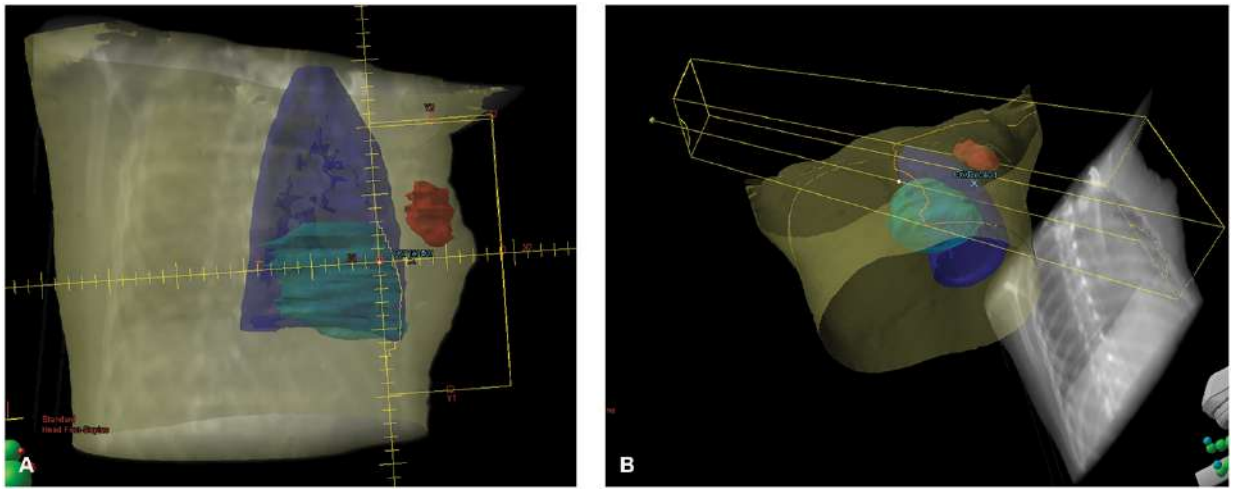

FIGURE 62.28 A and B: Left tangential breast field with heart block to shield left ventricle from radiation port. Projection of heart block on breast shields a minimal amount of breast tissue. If necessary, a shadow electron field may be added to cover the portion of breast tissue shielded by heart block.

Doses of Radiation and Fractionation

Whole-Breast Dose

Conventional fractionation delivers 45 to 50 Gy to the whole breast over 5 to 6 weeks (1.8- to 2-Gy tumor dose daily, 5 weekly fractions) and was previously the standard of care. After the publication of the updated ASTRO guidelines in 2018, HF-WBI has become the new standard of care for the majority of patients with early-stage breast cancer requiring treatment to the breast only. HF-WBI delivers 40 Gy in 15 daily fractions or 42.5 Gy in 16 daily fractions.

Alternative fractionation schemes have been investigated and have been shown to be acceptable. These are discussed in greater detail in the hypofractionation section.

Radiation Beams

X-ray energies of 4 to 6 MV are preferred to treat the breast. Photon energies greater than 6 MV underdose superficial tissues beneath the skin surface, but higher energy photons may be helpful in large breasts to decrease the integral breast dose. In these patients, the high-energy photon beam may be "degraded" to bring the maximum dose to more superficial tissues. It is not necessary to apply bolus to the breast because the skin is usually not at risk for recurrence after complete excision of a T1 or T2 lesion, as is the skin of the chest wall after a mastectomy.

Wedges or compensating filters must be used for a portion of the treatment to achieve a uniform dose distribution in the breast (5%-8% dose variance from the chest wall to the apex). Although conventional wedges improve dose homogeneity at the central axis of the breast, significant inhomogeneity can occur in the superior and inferior portions of the breast. With the use of MLCs and more sophisticated treatment planning techniques, optimization of homogeneity throughout the breast can be achieved. Dose homogeneity in a breast plan uncompensated (without wedges), with standard wedges, and with electronic dynamic wedge technique to improve homogeneity in the superior-inferior plane is outlined in Figure 62.29. These techniques are discussed in more detail later.

Boost to Tumor Site

It is well known that most recurrences after breast conservation occur near the primary tumor site, which provides a strong rationale for a tumor bed boost. In low-risk patients, however, it may also be safe to omit a tumor bed boost.

Randomized Data

The Lyon Breast Cancer Trial conducted a randomized study to assess the role of the boost in BCT in patients with stage I and II breast cancer (≤3 cm) who were treated with complete local tumor

excision, axillary dissection, and 50 Gy to the breast in 20 fractions over 5 weeks.[252] Patients were randomly assigned to receive or not receive a boost of 10 Gy with electrons to the tumor bed. At 5 years, 10 (3.6%) of 521 women who received a boost and 20 (4.5%) of 503 who received no further treatment experienced a local breast relapse ($P = .044$). More patients failed after 7 years in the no-boost arm.

Bartelink et al[130] reported the results of the EORTC trial in which, after complete lumpectomy and axillary dissection, patients with stage I or II breast cancer received 50 Gy of radiation to the whole breast in 2-Gy fractions over a 5-week period and were randomly assigned to receive either no further local treatment (2,657 patients) or a boost of 16 Gy, usually given in 8 fractions by electron beam (2,661 patients). In the initial report, with a median follow-up of 5.1 years, LRs were observed in 182 of the 2,657 patients in the standard-treatment group and 109 of the 2,661 patients in the additional-radiation group. The 5-year actuarial rates of LR were 7.3% and 4.3%, respectively ($P < .001$). Patients aged 40 years or below benefited most; at 5 years, their rate of LR was 19.5% with standard treatment and 10.2% with additional radiation (RR 0.46; 99% CI, 0.23-0.89; $P = .002$). In an update of this study published in 2007, with a median follow-up of 10.8 years, a significant benefit to the boost was noted in all age groups, with an overall HR of 0.59 in favor of the boost[131] (see Figure 62.12).

If a decision is made not to use a boost, careful assessment of pathologic features, particularly lumpectomy margins, is critical.

Boost Techniques

For an electron boost, the patient is positioned with the arm toward the head to flatten the breast contour and may be rolled so the tumor bed is parallel to the table and the accelerator head can point straight down onto the target volume. An electron energy is selected that covers the target volume depth (usual range is 9-16 MeV electrons), based on review of the physical examination, mammogram, ultrasound, CT, or other imaging used to ascertain the location and depth of the tumor or metallic surgical clips. The 90% prescription isodose line is limited to the chest wall to decrease dose to the lung. The clinical setup for electron boost involves marking the projection of the postlumpectomy volume on the skin and adding 2 to 3 cm in all directions. A conformal photon boost can be utilized when the tumor bed is too deep for adequate coverage with an electron plan.

Accurate target volume definition is critical with any boost technique. Surgical clips are ideal for the localization of the tumor bed but require the cooperation of the surgical team. Despite the fact that it would theoretically take an infinite number of clips to define every extension of a typical tylectomy cavity, in practice six clips suffice (superficial, deep, medial, lateral, cephalad, and caudal). The combination of surgical clips with a treatment planning CT scan to define the lumpectomy site for boost is most ideal. In the absence of surgical clips, CT scan evaluation of the biopsy cavity or postsurgical changes, in combination with clinical information including mammography findings, scar location, operative reports, and patient input, can guide tumor bed delineation.

A multi-institutional study reported interobserver variabilities in the delineation of the seroma cavity and organs at risk in patients with breast cancer undergoing breast-conserving surgery and whole-breast irradiation.[253] Nine radiation oncologists specializing in breast RT from eight institutions independently delineated target volumes on the same three patients with breast cancer. They concluded that “variations in delineating the targets and OARs [organs at risk] for breast RT by well-experienced observers from different institutions are substantial for all relevant structures.”

To reduce these variations, guidelines for contouring the seroma cavity have been established; the Seroma Clarity Scale (SCS), developed by the British Columbia Cancer Agency and the Cavity Visualization Score (CVS), developed by a Stanford group.[254,255] Both scoring systems are remarkably similar, with the distinction being the SCS is a scale from 0 to 5, with 0 being no visible seroma cavity and 1 being a scar or shadow, and the CVS is a scale from 1 to 5, with 1 being no visible seroma cavity, and omits the presence of a scar or shadow on the scale. The score of 2 to 5 is relatively consistent between the two classification methods.

It is pertinent to note that each of these classification systems was developed without noting the presence of surgical clips or fiducial markers with respect to the seroma cavity. However, the authors, along with other investigators, have previously published that the presence of surgical clips or fiducial markers in the surgical bed improve the interphysician accuracy in the delineation of the seroma cavity in patients with early-stage breast cancer.[256,257] In a study by Shaikh et al,[258] the presence of fiducial markers improved the mean CVS score (from 2.5 to 3.5) and accuracy of physician contours compared with patients without fiducial markers. The use of titanium clips in patients treated with accelerated partial-breast irradiation (APBI) is a focus of the United Kingdom IMPORT LOW (Intensity Modulated and Partial Organ Radiotherapy) trial.[259] An audit of the trial was performed to determine inter- and intraphysician variation for tumor bed localization for RT planning. Although no control group was used, clips were essential for the localization of the surgical cavity in 22 (73%) of 30 patients and led to modifications in RT field borders in 18 (60%) of 30 patients. A study by Dzhugashvili et al[257] found that the visualization of the lumpectomy cavity was greatly improved in treatment planning CT scans when clips were present; this was found to be even more pronounced in patients with very dense mammary glands, regardless of the physician reading the CT image.

Irradiation of Regional Lymphatics

RT to the breast or chest wall and regional lymphatics can be technically challenging and, as previously discussed, remains one of the more variable and controversial aspects in management. A wide variety of available techniques, in combination with difficulties associated with matching fields, anatomic variability between patients, and lack of clear evidence regarding the superiority of any single approach, has resulted in a lack of consensus in regional nodal management.

Supraclavicular Lymph Nodes

The inferior border of the supraclavicular field is matched to the tangential field, usually just below the clavicular head. The medial border is 1 cm across the midline, extending upward, following the medial border of the sternocleidomastoid muscle to the thyrocricoid groove. The lateral border is a vertical line at the level of the coracoid process, just medial to the humeral head. This field is angled approximately 10° to 15° laterally to spare the cervical spine (Figure 62.30). The typical width of the supraclavicular field is 7 to 9 cm. The supraclavicular field is extended laterally to treat the full axilla, as clinically indicated. Figure 62.30 demonstrates a supraclavicular field with the supraclavicular and level I, II, and III nodes outlined. Level I as well as a portion of level II nodes will often be included in the tangential field; level III and supraclavicular nodes are covered in the supraclavicular field.

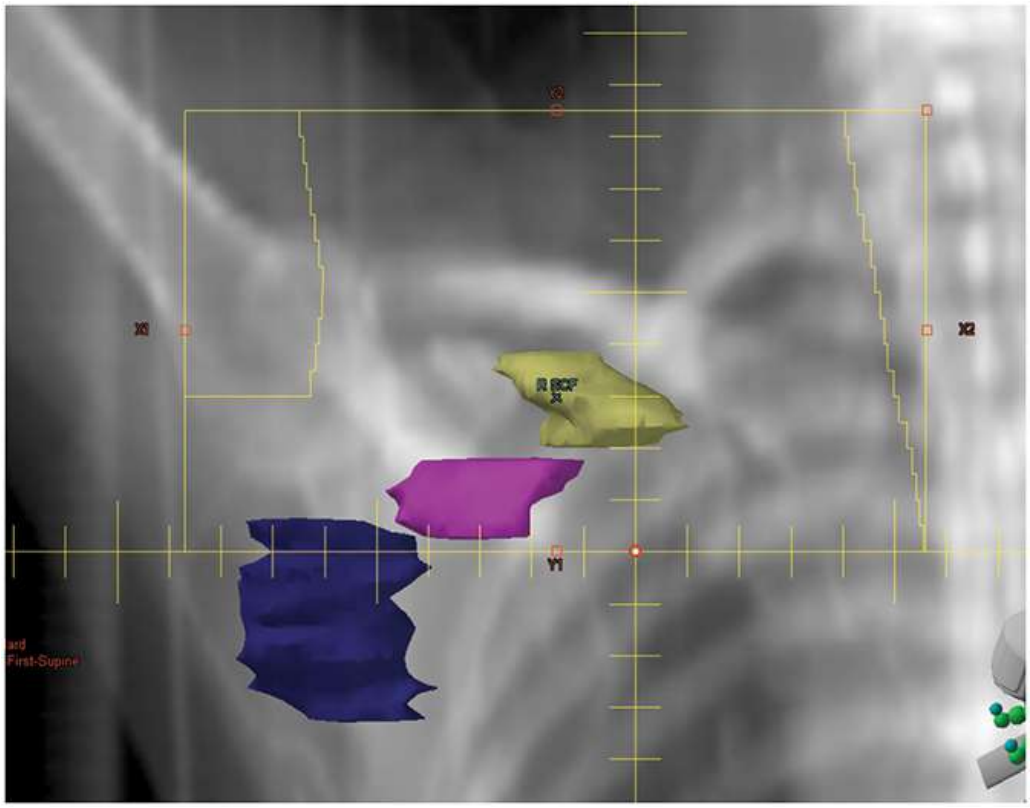

FIGURE 62.30 Supraclavicular and axillary field and field borders. Level I, II, and III nodes are demonstrated on the film. Note that level I nodes are included primarily in the tangential field in this case.

The total dose delivered to the supraclavicular field is 46 to 50.4 Gy at 1.8 to 2 Gy/day (calculated at a depth of 3 cm) in 5 fractions per week. For patients in whom the target is deeper than 3 cm, higher energy photons should be considered.

Axillary Lymph Nodes

When the axilla is treated in patients with positive nodes, or in patients with inadequate or undissected axillae, the supraclavicular field is extended laterally to cover at least two-thirds of the humeral head, as demonstrated in Figure 62.30. The dose to the midplane of the axilla from the supraclavicular field is calculated at a point approximately 2 cm inferior to the midportion of the clavicle. Depending on the dose distribution and patient's anatomy, a posterior axillary boost may be considered.

Posterior Axillary Boost

The posterior axillary boost can be employed to supplement axillary dose, as shown in Figure 62.31. The axilla should be contoured in CT treatment planning, as the depth of the axilla from the anterior-posterior skin surface varies from patient to patient, and the supplement prescription point and dose can be adjusted accordingly. When a posterior axillary boost is used, the borders are as follows: Medially, the border is drawn to allow 1.5 to 2 cm of the lung to show on the portal film; inferiorly, the border is at the same level as the inferior border of the supraclavicular field; laterally, the border just blocks fall-off across the posterior axillary fold; and lastly, the superior border splits the clavicle and the superolateral border shields or splits the humeral head.

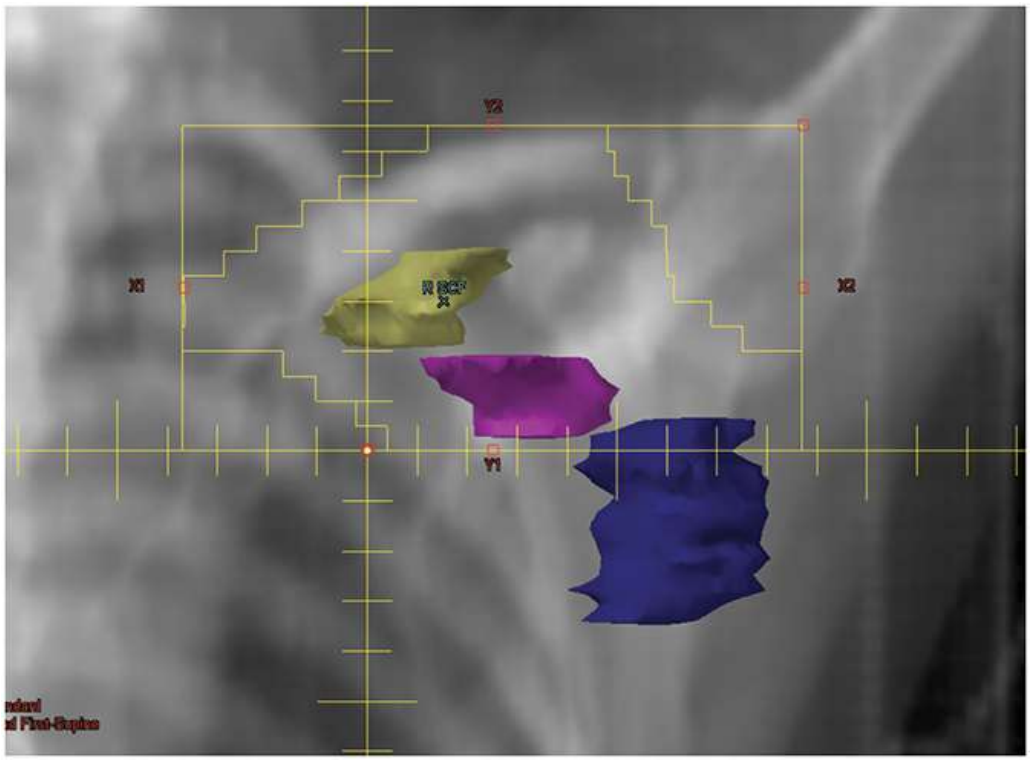

FIGURE 62.31 Posterior axillary field used to supplement the dose at the midplane of the axilla. Note the small amount of lung included and the shielding of the humeral head (whenever possible).

If the supraclavicular nodes are not felt to be at risk, a separate axillary field may not always be necessary to treat the axilla. In a study of 39 women with surgical clips in the axilla, Schlembach et al[171] demonstrated that with tangential fields, placing the caudal border of the field within 2 cm of the humeral head and 2 cm deep to the chest wall-lung interface (also called "high tangents") includes the majority of level I and level II lymph nodes (Figure 62.32).

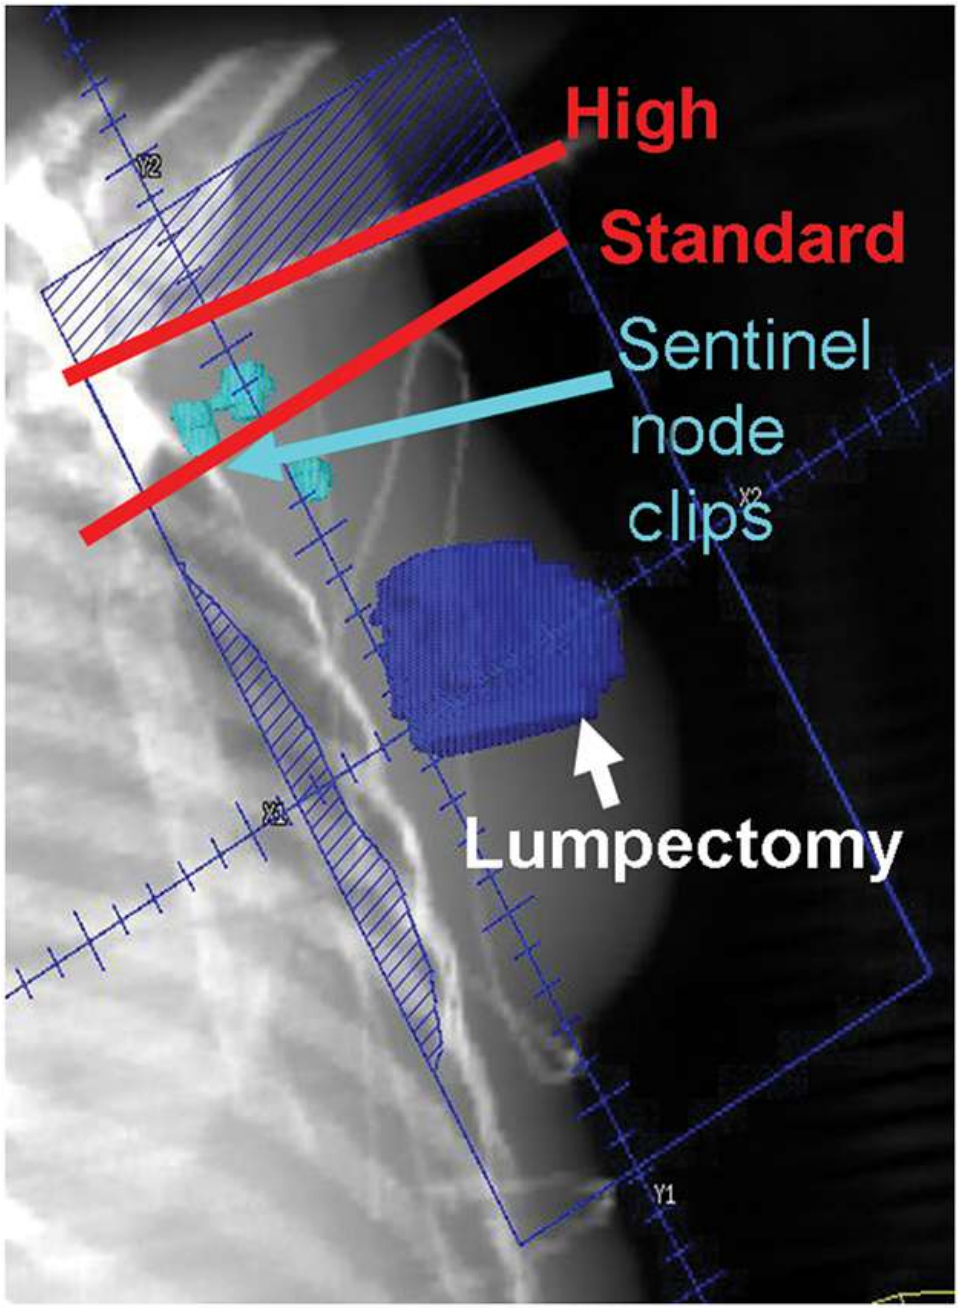

FIGURE 62.32 "High" tangential field showing coverage of level I and portion of level II nodes. With the caudal edge of the field within 2 cm of the humeral head and leading edge approximately 2 cm from lung-chest wall interface, most nodes in level I and level II will be covered by this technique.

Internal Mammary Lymph Nodes

The benefit of irradiation of the IMNs is an unresolved issue because clinical failures at this site are very rare, and most patients at risk receive adjuvant therapy.[191] However, the IMNs are difficult to treat because their exact location is often uncertain, and the radiation fields that include them irradiate more normal tissue.

One technique used to treat the IMNs is a direct anterior field matched to tangential fields, which was developed for PMRT and increases the volume of heart and lung tissue in the field. With this

technique, the rising contour of the intact breast interferes with dosimetry, which may affect the traditional dose prescription point at depths of 4 to 5 cm and may prevent an easy match to the breast tangential fields.

The medial border of the IMN field is the midline. The lateral border is usually 5 to 6 cm lateral to the midline. The superior border abuts the inferior border of the supraclavicular field, and the inferior border is at the xiphoid or higher. If only the IMNs are to be treated, the superior border of the field is at the first intercostal space (superior border of the head of the clavicle). The field is set, as described previously, with an oblique incidence to match the medial tangential portal (Figure 62.33).

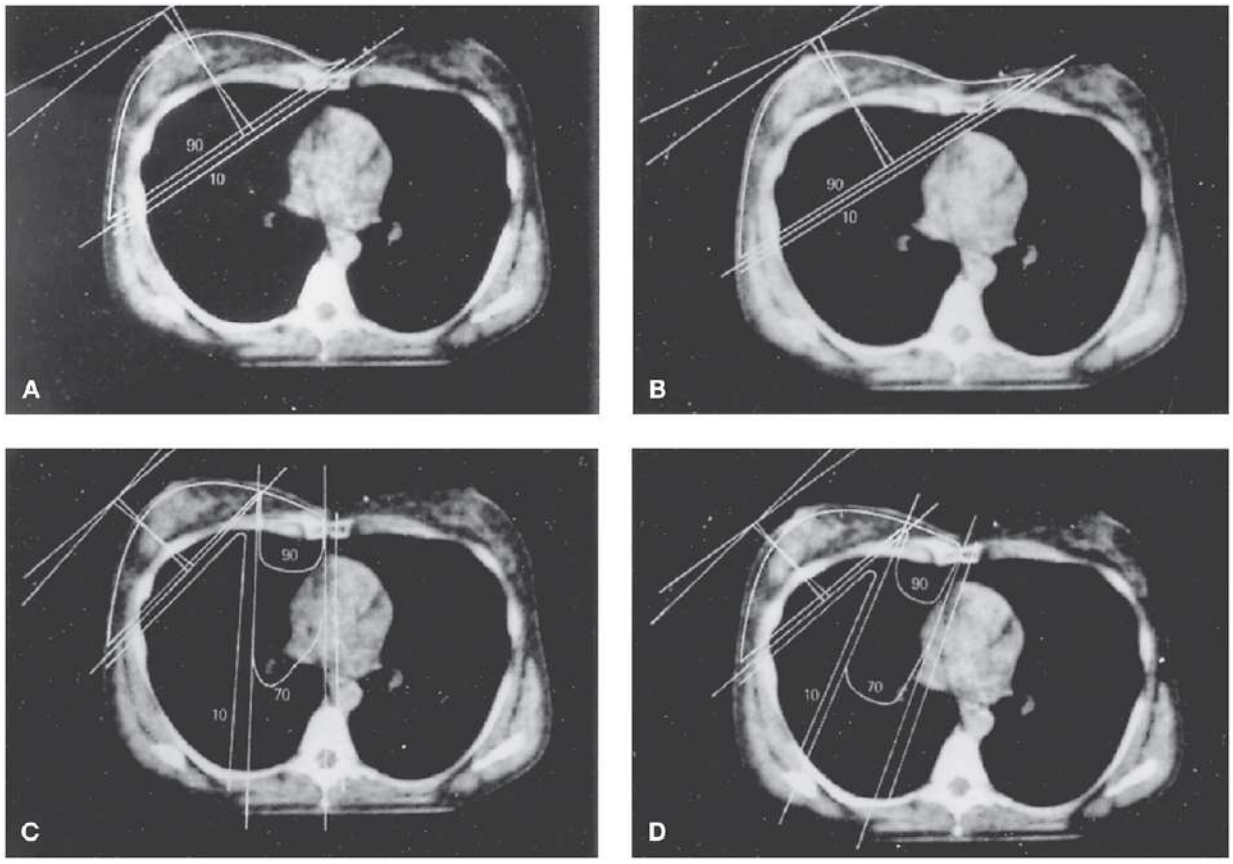

FIGURE 62.33 Irradiation of the breast: field configurations and isodose lines for 6-MV photons. A. "Standard tangents" technique. B. Deep tangents technique. C. En face internal mammary field technique. D. Twenty-degree intermaxillary fixation technique. (Reprinted from Roberson PL, Lichter AS, Bodner A, et al. Dose to lung in primary breast irradiation. *Int J Radiat Oncol Biol Phys*. 1982;9[1]:97-102. Copyright © 1982 Elsevier. With permission.)

A solution that avoids matching of fields is the use of partially wide tangential (PWT) fields to treat the internal mammary chain. However, this can result in more heart, lung, and contralateral breast exposure. Although IMNs can be imaged more clearly by radionuclide techniques, the nodes are typically located by identification of the internal mammary vessels, which can be seen on the CT simulator. The nodes in the first three intercostal spaces are thought to be most clinically significant. The medial border of the tangential field is moved 3 to 5 cm across the midline to cover the IMNs in the first three intercostal spaces. To minimize lung and cardiac exposure, a block is drawn, as demonstrated in Figure 62.34, to block the inferior mediastinal nodes. The portal films

should be inspected carefully to ensure that an excessive amount of lung or heart is not being irradiated. It is important to verify on the clinical setup that targeted breast tissue is not covered by the block.

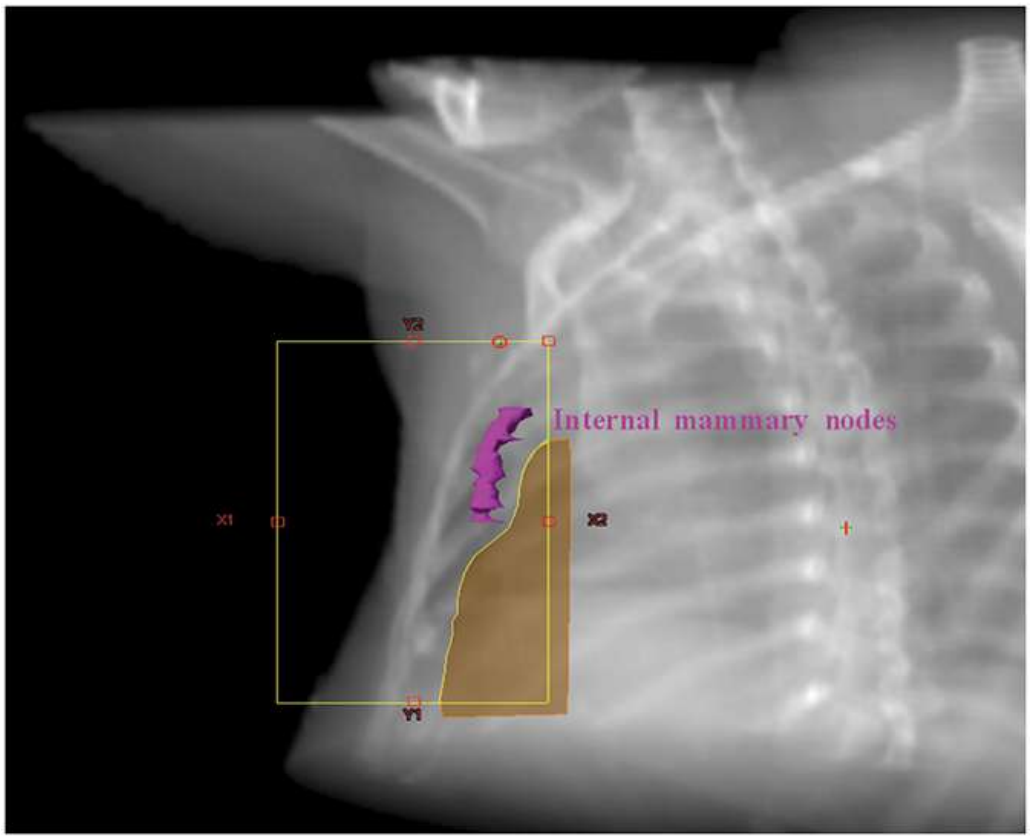

FIGURE 62.34 Partially wide tangential field covering internal mammary chain. The medial border of the tangential field is set 2 to 3 cm to the contralateral side to include the internal mammary chain. Below the fourth intercostal space, the field is blocked to minimize dose to the lungs and heart. Projection of the field on the patient's surface demonstrates adequate coverage of the involved breast-chest wall with this technique. With this technique, there may be a small amount of overlap onto the superior contralateral breast.

Severin et al[260] compared the PWT technique of breast and internal mammary chain irradiation with photon/electron (P/E) and ST techniques in terms of dose homogeneity within the breast and the dose to critical structures such as the heart and lung in 16 patients who underwent CT simulation for left-sided breast cancers. The mean dose to the left breast with the ST, P/E, and PWT techniques was 94.7%, 98.4%, and 96.5%, respectively ($P = .029$). The left lung received the lowest mean dose with the ST technique (13.9%) compared with PWT (22.8%) and P/E (24.3%). The internal mammary chain volume was most consistently treated with the PWT (mean dose 99%) versus P/E (86%) and ST (38.4%) techniques, although this technique was associated with the greatest amount of contralateral breast (mean dose 5.8%) versus ST (3.2%) versus P/E (2.8%). The heart received the least dose with ST (mean dose 6.7%) versus PWT (10.3%) and P/E (19%).

Matching the Tangential Fields With the Supraclavicular Field

A hot spot caused by divergence of the tangential beams into the supraclavicular field and of the supraclavicular beam into the tangential fields can exist just beneath the skin surface at the junction

of the inferior border of the supraclavicular field and the superior border of the tangential fields. The sharp beam of a linear accelerator and the “horns” at the edge of this beam produce a marked increase in dose beneath the match line if these divergences are not corrected. This increased dose may result in severe match line fibrosis or even rib fracture.

There are numerous methods to adjust for divergence of the beams and minimize match line fibrosis. The divergence of the tangential fields can be eliminated by angling the foot of the treatment couch away from the radiation source to direct the tangential beams inferiorly so that the superior edges of these beams line up perfectly with the inferior border of the supraclavicular field (Figure 62.35). In addition, the collimator may be rotated to geometrically eliminate overlap at this junction. Alternatively, the “hanging block” technique, in which a vertical block is affixed to the superior portion of the collimator to block off the nonvertical portion of the tangential beam, can be used (Figure 62.36).

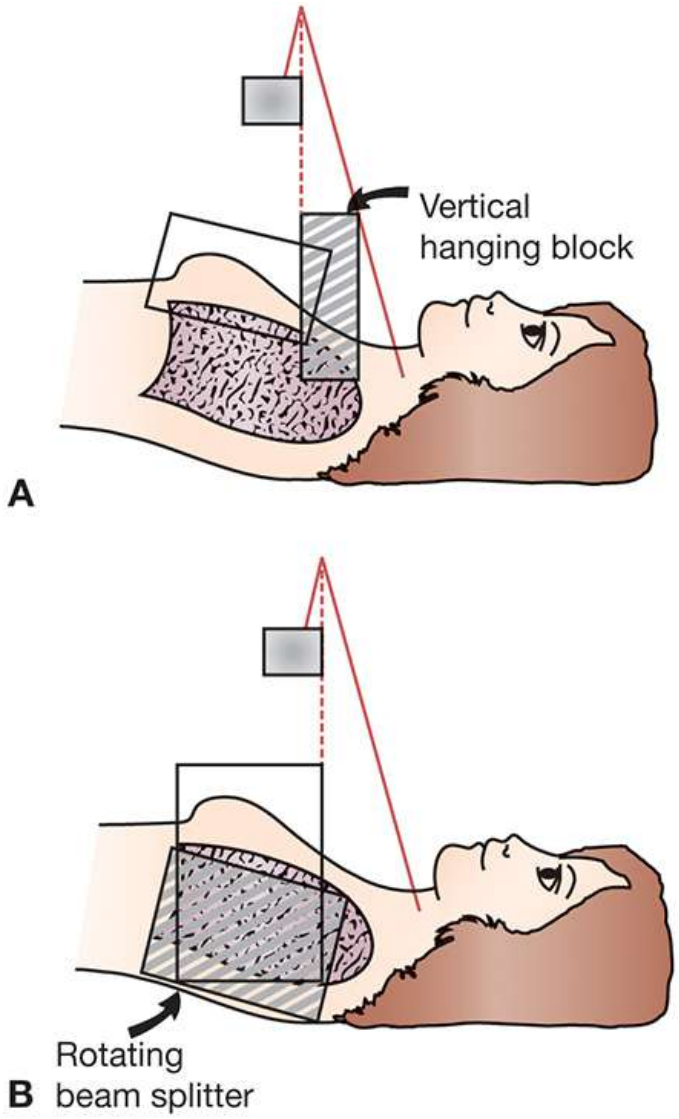

FIGURE 62.36 The superior edge of the tangential beams can be made perfectly vertical by means of the "hanging block" technique (A) or by avoiding collimator rotation with the use of a rotating beam splitter (B). (Reprinted from Bedwinek JM. Treatment of stage I and II adenocarcinoma of the breast by tumor excision and irradiation. *Int J Radiat Oncol Biol Phys*. 1981;7[11]:1553-1559. Copyright © 1981 Elsevier. With permission.)

The inferior divergence of the supraclavicular beam can be eliminated by blocking the inferior half of the beam. This can be accomplished with a beam splitter or with multileaf collimation so that the central, nondiverging portion of the beam becomes the inferior border of this field (see Figure 62.37B). The combination of the half-beam block supraclavicular field and the couch kick technique for the tangential field results in minimal overlap and has essentially eliminated the problem of match line fibrosis.

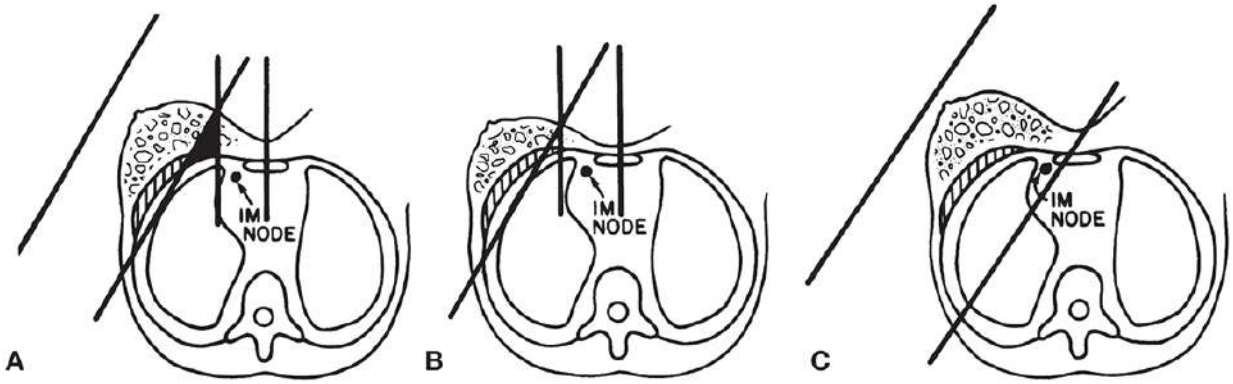

FIGURE 62.37 Diagrams showing several relationships between internal mammary (IM) and tangential fields. A. A significant cold region exists if the IM tangential match line overlies a large amount of breast tissue. B. The cold area may be negligible if the breast tissue beneath the match line is thin. C. The lack of a separate IM field can result in irradiation of an excessive volume of lung, particularly in patients with large chest. (Reprinted from Bedwinek JM. Treatment of stage I and II adenocarcinoma of the breast by tumor excision and irradiation. *Int J Radiat Oncol Biol Phys*. 1981;7[11]:1553-1559. Copyright © 1981 Elsevier. With permission.)

The Single Isocenter Technique for Matching Supraclavicular and Tangential Fields

An alternative and attractive method for minimizing field matching problems between the supraclavicular and tangential fields is to use a technique that employs a single isocenter placed at the junction of the supraclavicular and tangential fields, as demonstrated in Figure 62.38. This single isocenter serves as the isocenter for both the supraclavicular field and the tangential field, such that the nondivergent central axis single isocenter results in a perfect match of the supraclavicular and tangential fields. As demonstrated, when treating the supraclavicular field, the beam below the isocenter is completely blocked. The supraclavicular field is typically angled 5% to 10% away from the spinal cord. Without moving the isocenter or patient, the tangential field is treated by closing the field above the isocenter and angling the beam to treat the tangential fields. Using this technique, there is not an option for rotating the collimator. If the patient's anatomy and positioning are ideal, the tangential field is closed down to the central axis, an acceptable amount of lung is exposed (<3 cm), and no block may be required. In some cases, the tangential field needs to be opened up beyond the central axis and a block drawn to minimize lung exposure while maintaining coverage of the breast. Because much of the setup is performed on the CT simulator, it is critical when using this technique to clinically view the medial and lateral setups on the patient to ensure that the entire breast is covered, the medial border is not extending to the contralateral breast, and the blocks are not covering any of the targeted breast tissue.

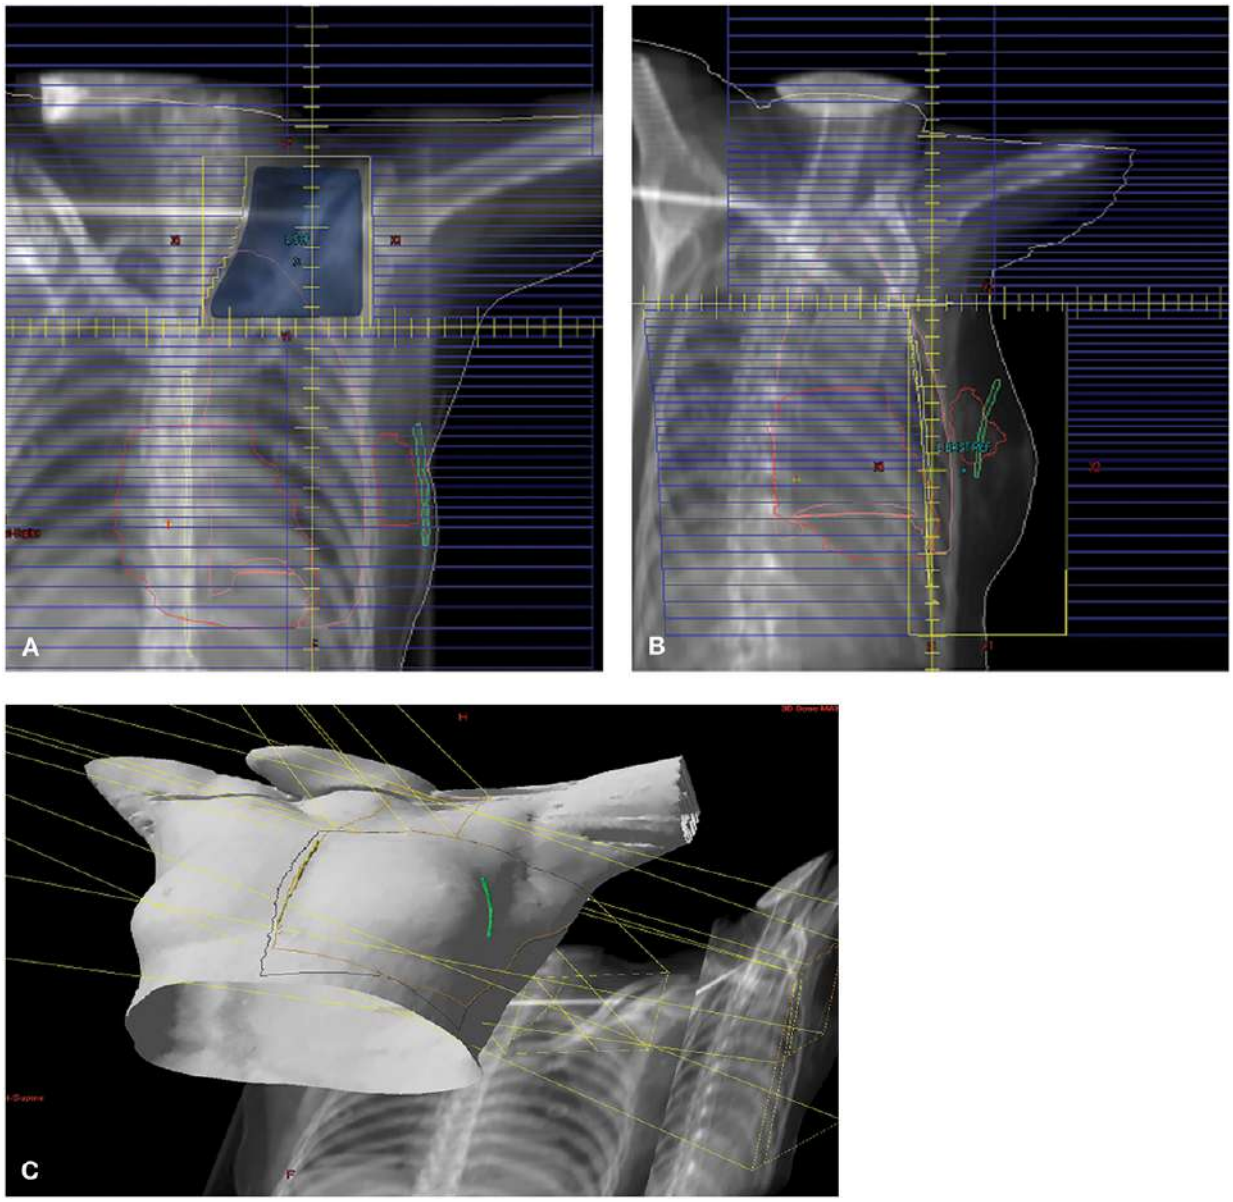

FIGURE 62.38 A-C: Monoisocentric matching technique. Single isocenter is set at the match between the supraclavicular and tangential fields. The inferior portion of the beam is blocked for the supraclavicular treatment and the superior blocked for the tangential field, with no movement of the isocenter, resulting in an ideal match. Blocks are drawn as indicated to shield lung and heart. The field should be viewed clinically to ensure that the blocks drawn to shield the heart and lungs to not block target tissue on the breast-chest wall. Projection of fields onto patient's surface demonstrates a perfect match of the supraclavicular and tangential fields.

Matching the Tangential Fields With the Internal Mammary Field

When an internal mammary field is required, the match between it and the medial tangential field can be a problem if there is a significant amount of breast tissue beneath the match line. In this situation, a cold spot can exist (Figure 62.37). The effect may be negligible if the breast tissue beneath this match line is thin (see Figure 62.37B), or it can be avoided by including the IMNs in the tangential field, as described earlier (see Figure 62.37C). Woudstra and van der Werf[261] described a technique using an oblique incidence of the internal mammary portal to match the orientation of the adjacent medial tangential portal; this results in a more homogeneous dose

distribution at the junction of the two fields (Figure 62.39). One potential advantage of the PWT field in the conservatively managed patient is that it avoids the problem of matching over breast tissue.

The target volume is enclosed by the 90% isodose line (= 40.5 Gy). Electron beam, 16 MeV; photon beam, 6 MV. (Reprinted from Woudstra E, van der Werf H. Obliquely incident electron beams for irradiation of the internal mammary lymph nodes. *Radiother Oncol*. 1987;10[3]:209-215. Copyright © 1987 Elsevier Ireland Ltd. With permission.)

Irradiation Dose to the Contralateral Breast

Irradiation dose to the contralateral breast is of concern because of the potential long-term carcinogenic effect of scattered radiation. The data on the risk of the contralateral breast are extensively discussed later. Although this risk appears to be minimal with modern techniques, the goal must be to expose all normal tissues not within the target volume to as low a dose as is reasonably achievable. A dosimetric study demonstrated that most of the scatter dose received by the opposite breast originates in the collimator and accessories of the accelerator, and it can be significantly decreased by increasing the distance between the source and the patient's skin. Therefore, an isocentric source-skin distance technique may be desirable. The use of half-field blocks (beam splitter) or, even better, independent jaws combined with tailored beam splitters or an MLC following the contour of the chest wall of the patient is very helpful in decreasing the dose to the contralateral breast (Figures 62.40 and 62.41).

The clinical significance of this inadvertent radiation dose to the opposite breast is uncertain, as various investigators have shown no increased risk of contralateral breast malignancy after treatment of the original breast by RT.[11,34,262]

Three-Dimensional Conformal or Intensity-Modulated Radiation Therapy

A number of publications have explored the potential advantages of three-dimensional conformal radiation therapy (3D-CRT) or IMRT to treat patients with breast cancer. Theoretically, 3D-CRT involves a reduction in the volume of normal tissues receiving a high dose, with an increase in dose to the target volume that includes the tumor and a limited amount of normal tissue. IMRT potentially can further improve the dose distribution between the target and nontarget tissue but may also increase the volume of tissue exposed to lower doses of radiation. As suggested in a review by Hall and Wuu,[233] this may increase the risk of second malignancies; the potential gains and limitations of advanced planning techniques must be weighed carefully .

In a trial of patients undergoing BCT, 358 patients undergoing whole-breast irradiation were randomized to radiation to the breast with standard wedges or with IMRT. Those randomized to IMRT experienced significantly lower degrees of moist desquamation due to the improved homogeneity with the IMRT techniques employed.[263,264] In another randomized trial of IMRT in breast cancer, 306 women were randomized to standard treatment with tangential fields with wedge compensators compared with IMRT. The standard control patients were 1.7 times more likely to have a change in photographic appearance compared with those in the IMRT arm.[265]

It is important to recognize that the term *IMRT* has been used in various ways to describe breast cancer treatment. In some studies, IMRT is described as a method of 3D dose compensation without a change in the gantry angles of predesigned tangential fields. In such instances, dose distribution has been improved, but the fields are not more conformal. Accordingly, low dose to other organs is

not an issue. For others, IMRT attempts to improve conformality of the high-dose region by using multiple field angles that increase the volume of normal tissues that receive low radiation doses.

ACCELERATED PARTIAL-BREAST IRRADIATION

For some women, the 4- to 6-week course of daily radiation, with its associated time and travel issues, is not feasible. In response to this, a wide variety of accelerated forms of treatment have been developed and have been proven safe and effective in multiple studies. These approaches include multicatheter interstitial implants placed around the excision cavity, a single balloon catheter that can be after-loaded with a central radiation source (MammoSite) that is placed into the excision cavity, external beam conformal partial-breast irradiation, and intraoperative single-dose irradiation. Although these techniques vary considerably, they share the common strategy of delivering the radiation to a smaller volume of breast tissue around the lumpectomy site, using fewer larger fractions delivered over a shorter time. The rationale behind this approach is that the majority of breast relapses occur at or near the lumpectomy site. Randomized trials investigating partial-breast irradiation are summarized in Table 62.17.

TABLE 62.17 RANDOMIZED TRIALS OF ACCELERATED PARTIAL-BREAST IRRADIATION

Institution/Trial	Number of Cases	Control Arm	Experimental Arm
NSABP B-39 RTOG 0413	3,000	50-50.4 Gy WB+/− 10-16 Gy boost	1. Interstitial Brachytx 2. MammoSite 3. 3D conformal EBRT
National Institute of Oncology, Budapest, Hungary	570	50 Gy WB	1. Interstitial Brachytx (5.2 Gy × 7) or 2. Electrons (50 Gy)
European Brachytherapy GEC-ESTRO Working Group	1,170	50-50.4 Gy WB + 10 Gy boost	Brachytherapy only 32.0 Gy 8 fractions HDR 30.3 Gy 7 fractions HDR 50 Gy PDR
European Institute of Oncology (ELIOT)	824	50 Gy WB + 10 Gy boost	Intraoperative Single-fraction EBRT 21 Gy × 1
University College of London (TARGIT)	1,600	WBRT (per center) + boost	Intraoperative Single-fraction EBRT 5 Gy × 1
Canadian Trial (RAPID)	2,128	WBRT 42.5 in 16 or 50 in 25	3D-CRT 38.5 Gy in 10
Medical Research Council-UK IMPORT LOW	1,935	WB 2.67 Gy × 15	PBI 2.67 Gy × 15

3D-CRT, three-dimensional conformal radiation therapy; EBRT, external beam radiation therapy; HDR, high-dose rate; NSABP, National Surgical Adjuvant Breast and Bowel Project; PBI, partial-breast irradiation; PDR, pulsed-dose rate; RTOG, Radiation Therapy Oncology Group; WB, whole breast.

The NSABP-39/RTOG-0413 phase 3 equivalence trial randomized 4,216 women with early-stage breast cancer (including DCIS) to whole-breast irradiation versus APBI. This trial allowed for any one of the three techniques of partial-breast irradiation, namely, interstitial brachytherapy, MammoSite, or 3D-CRT. The techniques were selected based on physician or patient preference prior to randomization. Fraction size was slightly higher for external beam CRT (3.85 vs 3.4 Gy),

but all three techniques employed twice-daily radiation for a total of 10 treatments for a total dose of 38.5 or 34 Gy, respectively, over 5 days. Each of the various techniques of partial-breast irradiation is discussed in more detail below. At a median follow-up of 10.2 years, there were 90 (4%) patients with IBTR in the APBI group and 71 (3%) in the whole-breast group (HR 1.22, 90% CI, 0.94-1.58), for a 10-year cumulative incidence of IBTR of 4.6% for APBI (95% CI, 3.7-5.7) and 3.9% for whole breast (95% CI, 3.1-5.0). Treatment toxicities and second cancers were similar between the two groups. The authors concluded that APBI did not meet the criteria for equivalence to WBRT. However, it was noted that the study had broad eligibility criteria and thus a heterogeneous patient population and, given an absolute difference of less than 1% in 10-year cumulative IBTR rates, APBI may be an acceptable alternative for some women.[266]

Multicatheter Interstitial Techniques

Partial-breast experience is greatest with the multicatheter interstitial technique, as it was initially developed as a boost technique following whole-breast irradiation. As demonstrated in Figure 62.42, multiple catheters are generally positioned at 1.0- to 1.5-cm intervals, with the total number of catheters and planes employed dependent on the size, extent, and shape of the target. With refinements in image-guided techniques, this approach is generally quite adaptable to most cavities and locations within the breast. Because of its complexity, user dependence, and logistics, however, the use of this technique has been less widely embraced, compared with the MammoSite (described later) and external beam techniques.

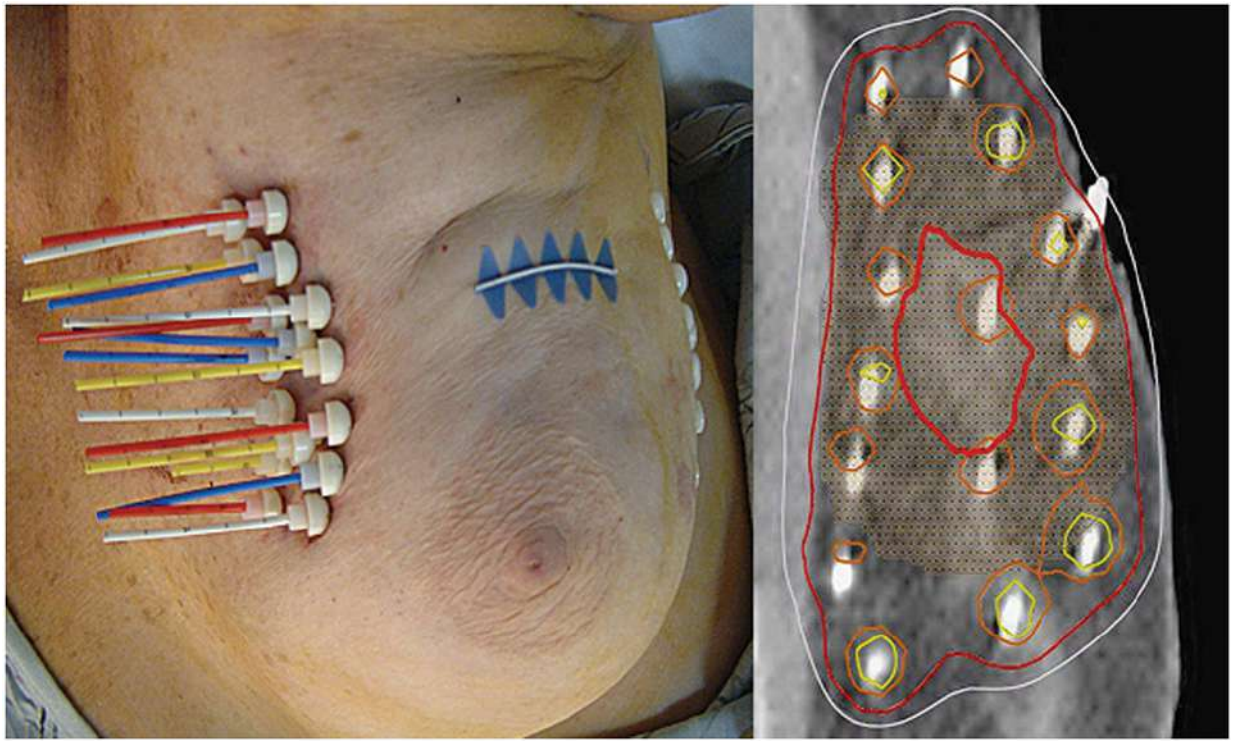

FIGURE 62.42 Partial-breast irradiation demonstrating the multiplane interstitial implant technique. (Reprinted with permission from Arthur DW, Vicini FA. Accelerated partial breast irradiation as a part of breast conservation therapy. *J Clin Oncol*. 2005;23[8]:1726-1735. Copyright © 2005 by American Society of Clinical Oncology.)

Kuske et al[267] reported the results of RTOG-95-17, a phase I and II study employing APBI using multiplane interstitial catheters in 99 women with early-stage breast cancer. The inclusion criteria for this study included invasive nonlobular tumors 3 cm or less after lumpectomy with negative surgical margins and axillary dissection with zero to three positive axillary nodes without extracapsular extension. The patients were treated with either low-dose rate (LDR) APBI (45 Gy in 3.5-5 days) or high-dose rate (HDR) APBI (34 Gy in 10 twice-daily fractions within 5 days). Chemotherapy and/or tamoxifen were administered at the discretion of the treating physicians. Of the 99 women, 33 were treated with LDR and 66 with HDR APBI. Of the 66 patients treated with HDR APBI, 2 (3%) had grade 3 or 4 toxicity. Of the 33 patients treated with LDR, 3 (9%) had grade 3 or 4 toxicity during brachytherapy. No patient experienced late grade 4 toxicity; the rate of grade 3 toxicity was 18% for the LDR and 4% for the HDR groups.

In a matched-pair analysis by Shah et al.[268], 199 patients received interstitial APBI and 199 patients received whole breast irradiation. Patients were matched by age, tumor size, nodal status, and ER status. With 12 years of follow-up, there was no difference in the rate of LR (3.8% vs 5.0%; $P = .40$), regional recurrence (0% vs 1.1%; $P = .15$), DFS (87% vs 91%; $P = .30$), cause-specific survival (93% vs 95%; $P = .28$), or OS (78% vs 71%; $P = .06$) between the WBI and APBI groups.

Wazer et al[269] reported the results of APBI using HDR interstitial brachytherapy in a phase I/II single multi-institutional study in 33 women with early-stage breast cancer. Eligible patients included those with T1, T2, N0, N1 (≤3 nodes positive), and M0 tumors of nonlobular histologic features with negative surgical margins, no extracapsular lymph node extension, and a negative postexcision mammogram. High-activity ^{192}Ir (3-10 Ci) was used to deliver 3.4 Gy per fraction, 2 fractions per day, for 5 consecutive days, to a total dose of 34 Gy to the target volume. The mean tumor size was 1.3 cm, and 55% had an EIC. Three patients had positive axillary nodes. The RTOG late radiation morbidity scoring scheme was applied. Clinically evident fat necrosis occurred in eight patients at a median of 7.5 months after HDR brachytherapy completion. The only variables significantly associated with grade 3 or 4 toxicity were the number of source dwell positions and the volume of tissue encompassed by the prescription isodose shell. The global cosmetic scores after a minimum of 18 months' follow-up were 0 cases with poor, 4 with fair, 5 with good, and 24 with excellent scores. One case of IBTR was diagnosed.

MammoSite

MammoSite as an alternative method of delivering APBI has been widely embraced because of its simplicity and less dependence on user experience.[270,271] The technique employs a single balloon catheter introduced into the lumpectomy site either at the time of lumpectomy or percutaneously after the procedure. As shown in Figure 62.42, the catheter is located centrally within a distal balloon, which is inflated once the catheter is placed in the lumpectomy cavity. Adequacy of placement requires symmetry of the balloon, conformance of the balloon surface to the lumpectomy cavity, and a minimum distance between the surface of the balloon and skin of greater than 5 mm (ideally >7 mm). Treatment is delivered via an HDR remote afterloading system to a circumferential 1-cm distance from the balloon surface.

The most extensive experience with this technique has been reported by the American Society of Breast Surgeons MammoSite Registry Trial, which included 1,419 patients treated in 87 institutions.[272,273] This was a nonrandomized single-arm registration trial in which data were collected prospectively on the clinical use of the MammoSite breast brachytherapy catheter for delivering breast irradiation. They reported on 1,237 patients (87% of enrolled patients) who received APBI (34 Gy to 1.0 cm in 10 fractions); 91% of the patients with invasive carcinoma

(977/1,068 patients) had negative lymph node status, and 99% of all patients had negative margins. The median patient age was 65 years. Five hundred fifty-four catheters (45%) were placed with an open cavity at the time of lumpectomy, and 683 (55%) catheters were placed after lumpectomy. Skin spacing ranged from 2 to 75 mm (median, 10 mm). At 5 years, 37 (2.6%) cases developed an IBTR, for a 5-year actuarial rate of 3.80% (3.86% for IBC and 3.39% for DCIS). Negative ER status (P = .0011) was the only clinical, pathologic, or treatment-related variable associated with IBTR for patients with IBC and young age (<50 years; P = .0096) and positive margin status (P = .0126) in those with DCIS. The percentage of breasts with good or excellent cosmetic results at 60 months (n = 371) was 90.6%. The authors concluded that treatment efficacy, cosmesis, and toxicity 5 years after treatment with APBI using the MammoSite device were good and similar to those reported with other forms of APBI with similar follow-up.

External Beam Conformal Radiation

3D-CRT, as shown in Figure 62.43, generally employs multiple conformal fields, although plans as simple as two opposing small conformal fields may be adequate. Challenges with this technique include daily positioning of the target, movement with breathing, and delivery of higher doses to surrounding normal breast tissue than with the brachytherapy. Nonetheless, this approach has been widely embraced and has been shown to be reproducible.

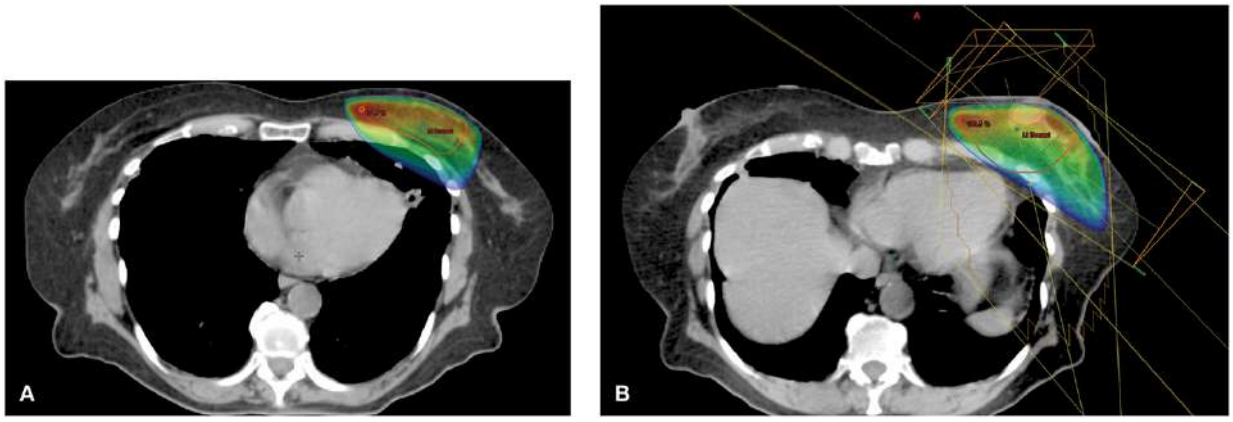

FIGURE 62.43 A and B. Partial-breast irradiation demonstrating the external beam conformal radiation technique.

In the phase I and II RTOG-0319 trial of external beam conformal radiation, Vicini et al[274] examined the use of 3D-CRT to deliver APBI. Reproducibility, as measured by technical feasibility, was the primary end point. This study was designed such that if fewer than five cases in the first 42 patients evaluable were scored as unacceptable, the treatment would be considered reproducible. Patients received 38.5 Gy in 3.85 Gy per fraction delivered twice daily. The clinical target volume (CTV) included the lumpectomy cavity plus a 10- to 15-mm margin bounded by 5 mm within the skin surface and the lung-chest wall interface. The planning target volume (PTV) included the CTV plus a 10-mm margin. A total of 58 patients were enrolled in this study over an 8-month period, 5 of whom were ineligible or did not receive protocol treatment. There were 4 cases with major variations and a total of 32 cases with minor variations in treatment plans. Based on this analysis, the authors concluded that APBI using 3D conformal EBRT was technically feasible and reproducible in a multi-institutional trial using exceptionally strict dosimetric criteria. An update of this study found that the ipsilateral breast failure rate was 6%, in-field failure rate was 2%, and

contralateral breast failure rate was 0%.[275] Only two (4%) grade 3 toxicities were observed. There have, however, been some reports of increased toxicity with external beam radiation using the fractionation schedule of 3.85 Gy per fraction, twice daily for 10 fractions.[276,277]

Whelan et al[278] published a report on the Randomized Trial of Accelerated Partial Breast Irradiation Using Three-Dimensional Conformal External Beam Radiation Therapy trial where 2,135 women older than 40 years with invasive or in situ breast cancer 3 cm or less were randomly assigned after breast-conserving surgery to 3D-CRT APBI (38.5 Gy in 10 fractions twice daily) or WBI (42.5 Gy in 16 or 50 Gy in 25 daily fractions ± boost irradiation). The 8-year cumulative incidence of IBTR was 3.0% (95% CI, 1.9-4.0) in the APBI group and 2.8% (95% CI, 1.8-3.9) in the whole-breast group. Grade 2 or higher acute toxicity occurred less frequently in the APBI group, but late toxicity (after 3 months) occurred more frequently in the APBI group. Adverse cosmesis as assessed by trial nurses was more common with APBI at 3 years (absolute difference 11.3%, 95% CI, 7.5-15.0), 5 years (16.5%, 12.5-20.4), and 7 years (17.7%, 12.9-22.3). The authors concluded that external beam APBI was noninferior to whole-breast irradiation in preventing IBTR but was associated with an increase in late toxicity and adverse cosmesis. It was suggested that this may have been a consequence of the twice-daily treatment on the APBI arm.

The University of Florence (Florence, Italy) performed a randomized phase III single-center trial of 520 patients comparing conventionally fractionated whole-breast irradiation (50 Gy in 25 fractions followed by a surgical bed boost to 10 Gy in 5 fractions) to external beam APBI (30 Gy in 5 nonconsecutive once-daily fractions) using an IMRT technique.[279] Patients aged 40 years or above with tumors 2.5 cm or less who were suitable for breast conservation were eligible. Multifocality, EIC, and surgical margins less than 5 mm were exclusion criteria. A minimum of four surgical clips were placed to mark the borders of the surgical bed. In the APBI arm, the CTV was drawn with a 1-cm margin around the surgical clips and was limited to 3 mm from the skin surface. Another 1-cm margin was added to create the PTV, which was also limited 3 mm from the skin surface but allowed to extend 4 mm inside the ipsilateral lung. Five step-and-shoot IMRT coplanar fields were used for treatment delivery. The 10-year cumulative incidence of IBTR was 2.5% in the whole-breast arm and 3.7% in the APBI group (HR, 1.56; 95% CI, 0.55-4.37; $P = .40$), with an absolute difference of 1.2%. The APBI group had lower rates of acute and late adverse effects, and a smaller proportion of APBI patients experienced adverse cosmesis (defined as fair or poor) compared to the whole-breast group when assessed by the physician (0% vs 1.9%; $P = .0001$) and patient (0.8% vs 14.6%; $P = .0001$). The authors concluded that the 10-year cumulative IBTR with external beam APBI using IMRT with five once-daily fractions was low and not significantly different from whole-breast treatment, and APBI had more favorable toxicity and cosmetic outcomes.

Intraoperative Accelerated Partial-Breast Irradiation

APBI using intraoperative therapy has been most widely employed outside the United States.[280,281] Radiation is delivered in a single intraoperative dose to the lumpectomy site at the time of surgery using electrons or photons (Figure 62.44). Vaidya et al[282] published the results of a phase III study that randomized 3,451 women to either targeted intraoperative RT (IORT) with a 50-kV spherical source delivering 20 Gy to a depth or 1 cm or whole-breast irradiation. The 5-year risks for LR in the conserved breast for IORT versus EBRT were 3.3% (95% CI, 2.1-5.1) versus 1.3% (0.7-2.5; $P = .042$). The European Institute of Oncology performed a randomized equivalence trial comparing conventionally fractionated whole-breast irradiation to a single dose of intraoperative radiation to the tumor bed during surgery.[283] The whole-breast group received 50 Gy in 25 fractions followed by a boost of 10 Gy in 5 fractions, and the intraoperative radiation group received a single dose of 21

Gy. The 5-year IBTR rate was 4.4% (95% CI, 2.7-6.1) in the intraoperative radiation group and 0.4% (95% CI, 0.0-1.0) in the whole-breast group (HR 9.3 [95% CI, 3.3-26.3]). The authors concluded that although the IBTR rate was within the prespecified equivalence margin for the intraoperative radiation group, the rate was significantly greater than with whole-breast radiation, and the IBTR with intraoperative radiation may be improved with better patient selection.

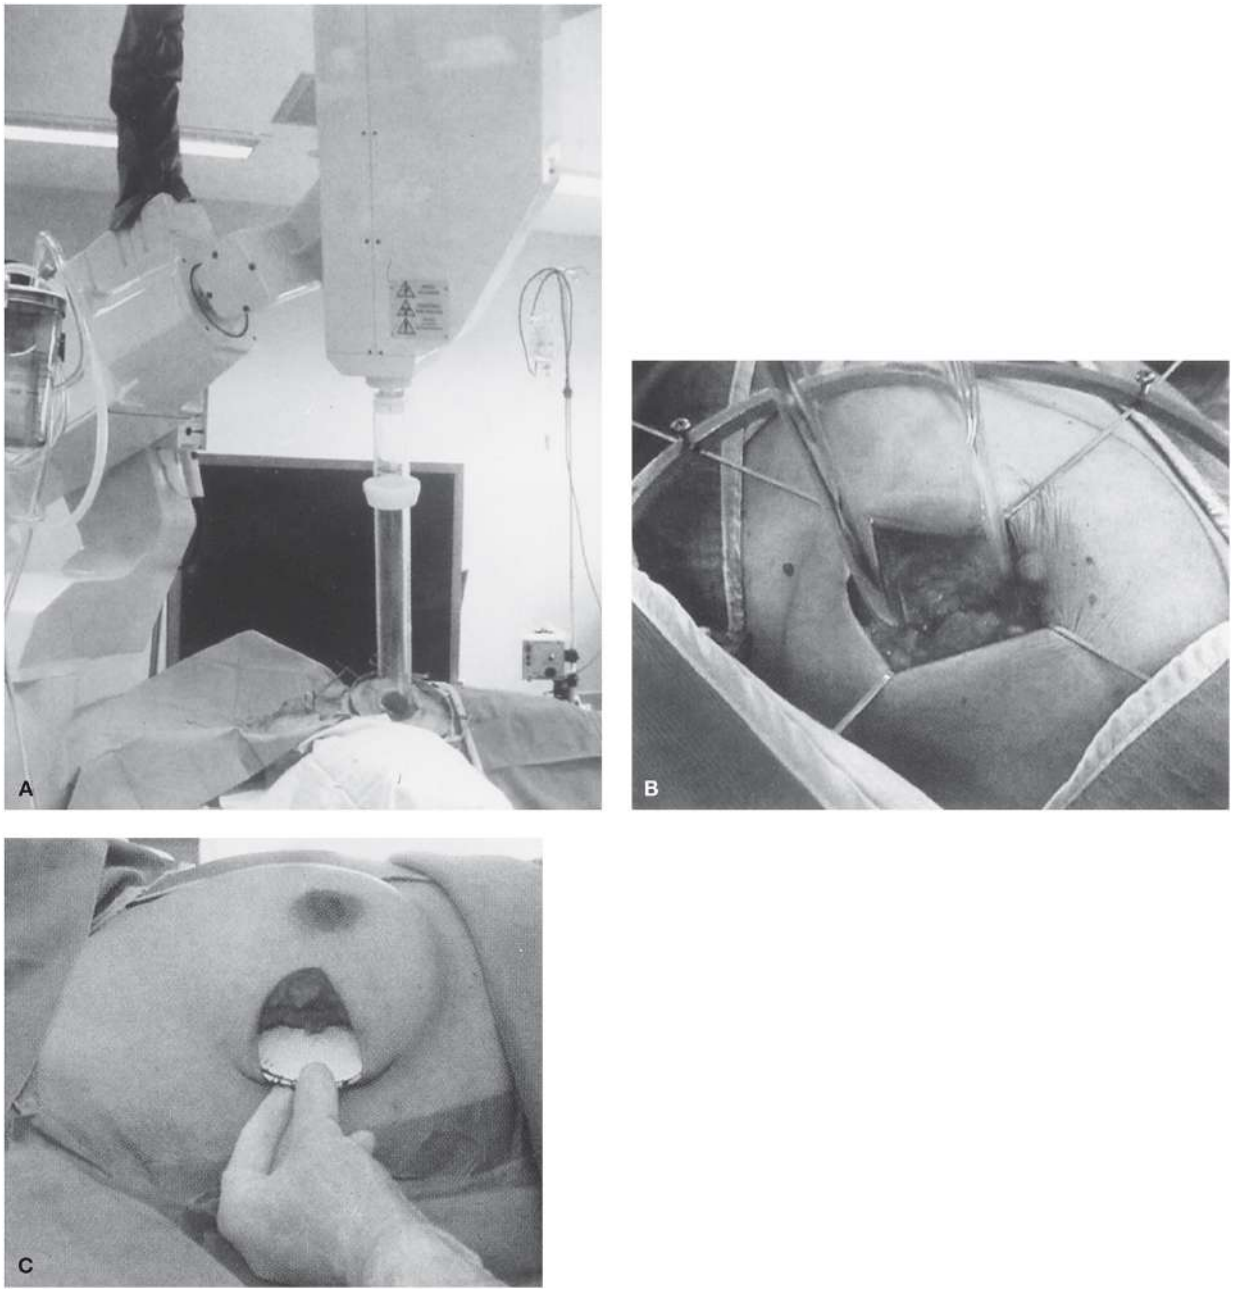

FIGURE 62.44 A. Linear electron beam accelerator in operating room during intraoperative radiation therapy. B. Proper placement of applicator in the breast. C. Before intraoperative radiation therapy delivery, an aluminum-lead disc (4-mm Al and 5-mm Pb thick) is placed between the deep face of residual breast and pectoralis muscle. (Reprinted from Veronesi U, Oreechia R, Luini A, et al. A preliminary report on intraoperative radiotherapy [IORT] in limited-stage breast cancers that are conservatively treated. *Eur J Cancer*. 2001;37[17]:2178-2183. Copyright © 2001 Elsevier. In 2009, a task force of experts in the field of breast cancer developed a consensus statement on behalf of ASTRO on the use of APBI. These guidelines have since been updated in 2016. They reported their recommendations on the suitability of patients receiving APBI outside the context of a clinical trial and divided patients into three categories: suitable, cautionary, and unsuitable (Table 62.18).[284,285] In general, patients aged 50 years or above, with node negative, invasive ductal or DCIS tumors 2 cm or less, with negative margins, ER positive, and no LVSI were deemed suitable for the use of APBI off-trial. The task force hoped their recommendations would provide guidance regarding the use of APBI outside a clinical trial and serve as a framework to promote additional research into the optimal role of APBI in the treatment of breast cancer (Figure 62.45).

TABLE 62.18 ASTRO CONSENSUS GUIDELINES FOR SUITABILITY OF PATIENTS TO RECEIVE ACCELERATED PARTIAL-BREAST IRRADIATION (APBI) OFF-TRIAL

Patient Group	Risk Factor	Factor
Suitability	Age	≥50 y
	Margins	Negative by at least 2 mm
	T stage	Tis or T1
	DCIS	If all of the following: Screen detected • Low to intermediate nuclear grade • Size ≤2.5 cm • Resected with margins negative at ≥3 mm
Cautionary	Age	• 40-49 y if all other criteria for "suitable" are met • ≥50 y if patient has at least 1 of the following pathologic factors and does not have any "unsuitable" factors *Pathologic factors:* • Size 2.1-3.0 cm[a] • T2 • Close margins (<2 mm) • Limited/focal LVSI • ER(−) • Clinically unifocal with total size 2.1-3.0 cm[b] • Invasive lobular histology • Pure DCIS ≤3 cm if criteria for "suitable" not fully met • EIC ≤3 cm
	Margins	Close (<2 mm)
	DCIS	≤3 cm and does not meet criteria for "suitable"
Unsuitable	Age	• <40 y • 40-49 y and do not meet the criteria for cautionary
	Margins	Positive
	DCIS	>3 cm

APBI, accelerated partial-breast irradiation; DCIS, ductal carcinoma in situ; EIC, extensive intraductal carcinoma; ER, estrogen receptor; LVSI, lymphovascular space involvement; T, tumor stage.

[a] The size of the invasive tumor component;

[b] Microscopic multifocality is allowed if the lesion is clinically unifocal and the total lesion size (including foci of multifocality and intervening normal breast tissue) is between 2.1 and 3.0 cm.

SEQUELAE OF IRRADIATION IN BREAST CANCER

Potential complications associated with conservation surgery plus irradiation include arm or breast edema, breast fibrosis, painful mastitis or myositis, pneumonitis, and rib fracture. Apical pulmonary fibrosis can be noted when the regional lymph nodes are irradiated.

Lymphedema and Breast Edema

Complications from axillary surgery, regardless of breast surgical procedure, can occur. It should be emphasized that before the treatment of arm lymphedema after breast carcinoma, it is mandatory to differentiate between treatment-associated complications and tumor recurrence in the regional lymphatics. In general, the incidence of breast or arm edema after conservation therapy varies, and it is related to the performance and technique of axillary dissection, whether the axillary lymph nodes were irradiated, and the dose of radiation delivered.

An extensive review of the literature related to arm edema following breast surgery was conducted by Erickson et al.[286] They found that arm edema is a common complication of breast cancer therapy that can result in substantial functional impairment and psychological morbidity. The risk of arm edema increases when axillary dissection and axillary RT are used. Preventive measures have not been well studied. Nonpharmacologic treatments, such as massage and exercise, have been shown to be effective therapies for lymphedema, but the effect of pharmacologic interventions remains uncertain.

Sentinel node sampling appears to be associated with a much lower degree of lymphedema. Sener et al[287] reported that 9 (3%) of 303 patients who underwent only sentinel lymphadenectomy had lymphedema, compared with 20 (17%) of 117 patients who underwent sentinel lymphadenectomy combined with axillary dissection ($P < .0001$). Among 303 patients who underwent sentinel lymphadenectomy only, lymphedema developed in 8 (5%) of 155 patients who had tumors in the upper outer quadrant and in 1 (0.7%) of 148 patients whose tumors were in other locations. The ALMANAC randomized trial also confirmed lower morbidity and improved quality of life following sentinel node biopsy compared with axillary dissection.[107]

Various treatment regimens have been used to treat lymphedema.[288] The compression pump, along with skin care, exercise, and compression garments, is one. A second treatment is known as *complex decongestive physiotherapy* or *complex physical therapy*. Arm care, therapeutic exercises, manual lymph node drainage, and compression bandages or garments constitute this treatment regimen. Decreases in lymphedema are noted if women are compliant with the prescribed treatment program.

Skin and Breast Complications

A wide variety of local symptoms may occur following radiation treatment to the conservatively treated breast, including change in skin appearance, breast discomfort, breast edema, and rib pain. In addition to host factors such as CVS and diabetes, underlying genetic factors may play a role in radiation complications.

Rayan et al[289] reported on a randomized clinical trial of breast-conserving surgery and tamoxifen with or without RT in women aged 50 years and above treated for stage T1 or T2, node-negative breast cancer. A companion study to assess breast pain was carried out during the trial, in which 86 patients participated. Forty-one received RT and tamoxifen and 45 tamoxifen alone. The median age was 70 years. Baseline pain and quality-of-life scores were similar for the two groups. At 3 months, patients receiving RT experienced more breast pain compared with those receiving tamoxifen alone, but this did not reach statistical significance. At 3 months, the pain scores for the RT and tamoxifen and tamoxifen alone groups were 2.39 and 1.83, respectively (P = .47). At 12 months, pain scores were lower and fairly similar in both groups, with a difference of 0.20 (P = .71).

Markiewicz et al[290] analyzed complications in 1,053 women with stage I or II breast cancer treated with BCT. Of this group, 206 received chemotherapy alone, 141 had hormonal therapy alone, 94 had both, and 612 received no adjuvant therapy. The incidence of grade 4 or 5 arm edema (≥2 cm difference in arm circumference) was 2% without chemotherapy and 8% with chemotherapy (P = .00002). However, the incidence of arm edema was not affected by sequencing or type of chemotherapy; it occurred in 10% and 7% of patients with sequential or concurrent treatment, respectively, and in 8% and 18% of patients treated with CMF or CAF, respectively. The incidence of clinical pneumonitis and rib fracture was not influenced by the use of chemotherapy, sequencing of drugs, or use of hormonal therapy.

Hyperbaric oxygen therapy has been shown to be effective in the treatment of some late radiation sequelae. Carl et al[291] reported on 44 patients with persistent local symptoms after BCT. Hyperbaric oxygen therapy (100% oxygen at 240 kPa for 90-minute sessions) was administered to 32 patients for a median of 25 sessions (range, 7-60 sessions). The remaining 12 patients declined hyperbaric treatment and acted as control subjects. The patients given hyperbaric oxygen therapy demonstrated a significant reduction in pain, edema, and erythema scores compared with untreated control subjects (P < .001). Seven of the 32 women who were treated with hyperbaric oxygen therapy were free of symptoms after treatment, whereas all 12 patients in the control group had persistent complaints. However, hyperbaric oxygen therapy did not have a significant effect on fibrosis and telangiectasia in the irradiated breast.

Brachial Plexopathy

Brachial plexus dysfunction is a possible complication of regional nodal RT. In a review of 1,624 patients, Pierce et al[292] found that brachial plexus sequelae were observed in 1.8% of patients. The incidence of brachial plexopathy was significantly higher when the axillary dose was greater than 50 Gy (P = .004). However, dose alone did not determine whether radiation damage would develop in a given patient. Treatment technique (two vs three fields; P = .0009) and concomitant chemotherapy were also risk factors. Other investigators have found the incidence of this complication to be 1% or less.[293] It is very important but difficult to distinguish between metastatic and radiation-induced brachial plexopathy.

Treatment for radiation brachial plexopathy consists of transdermal electrical nerve stimulation, dorsal column stimulators, neurolysis, and neurolysis with omentoplasty. Physical therapy, tricyclics, antiarrhythmics, anticonvulsives, nonsteroidal anti-inflammatory drugs, and steroids are helpful in therapy of both radiation-induced and metastatic brachial plexopathies.[294]

Pritchard et al[295] used hyperbaric oxygen in 34 volunteers with radiation-induced brachial plexopathy who were randomized to hyperbaric oxygen or a control group. The hyperbaric oxygen group breathed 100% oxygen for 100 minutes in a hyperbaric chamber (30 sessions over 6 weeks).

The control group breathed a gas mixture equivalent to breathing 100% oxygen at surface pressure. Normalization of the warm sensory threshold was seen in two of the patients receiving hyperbaric oxygen therapy. Two cases with marked chronic arm lymphedema reported major improvement in arm volume. These authors concluded that there was no reliable evidence to support hyperbaric oxygen therapy to slow or reverse radiation-induced brachial plexopathy, although improvements in warm sensory threshold and arm lymphedema suggested a therapeutic effect and justified further investigation.

Pulmonary Sequelae

Symptomatic pneumonitis is infrequent. This clinical syndrome is noted one to several months after irradiation. Patients present with dry cough, shortness of breath, fever, and on radiographic studies, a pulmonary infiltrate is observed in the irradiated volume. The risk for the development of radiation pneumonitis may be related to the volume of lung irradiated.

The addition of regional nodal RT to breast irradiation significantly increases the incidence of symptomatic pneumonitis. In the previously discussed randomized MA.20 trial, patients who received radiation treatment to the whole breast and regional lymph nodes had a 1.3% rate of grade 2 or higher pneumonitis, which was significantly higher than the 0.2% rate seen in the whole-breast–only arm.[174] Taghian et al,[296] in 41 patients treated with RT and paclitaxel (21 concurrent, 20 sequential), described a higher incidence of pneumonitis (14.6%) compared with control patients irradiated and not receiving chemotherapy (1.1%; $P < .0001$). However, an analysis of patients treated with radiation as a component of a randomized trial, in which 50% of the patients were treated with paclitaxel and 50% were treated with a nontaxane regimen, found that the rates of pneumonitis were very low and not significantly different between the two arms.[297]

Cardiac Sequelae

The potential for excess cardiac morbidity associated with the use of RT in breast cancer has been extensively evaluated. It has been clearly demonstrated, based on data from randomized trials, overviews, and meta-analyses, that when using older techniques, excess cardiac mortality from radiation offsets some of the benefits that RT clearly produces with respect to breast cancer mortality. Although modern techniques can minimize exposure to the normal cardiac and pulmonary structures, the radiation oncologist must be cognizant of the potential for adverse cardiac effects of incidental irradiation. This is particularly relevant in the setting of left-sided breast cancers in patients receiving other cardiotoxic therapies, including adriamycin, epirubicin, and trastuzumab.

Earlier techniques of RT from large pools of randomized data have clearly been implicated in excess cardiac mortality. In an analysis of over 90,000 Swedish women, comparing left- to right-sided cancers, Darby et al[298] from the Oxford group reported excess ischemic heart disease mortality more than 10 years after initial treatment in the left-sided cancer group (HR 1.13; 95% CI, 1.03-1.25; $P = .01$). The majority of cardiovascular deaths were from earlier studies using techniques that are no longer used. However, for patients treated after 1980, although the ratio was still 1.11, the CIs were much larger (0.95-1.29), so the hazard remained uncertain for the more modern techniques.

In a separate report, Darby et al[299] conducted a population- based case-control study of major coronary events (ie, myocardial infarction, coronary revascularization, or death from ischemic heart disease) in 2,168 women who underwent RT for breast cancer between 1958 and 2001 in Sweden and Denmark. They found that rates of major coronary events increased linearly with the mean dose

to the heart by 7.4% per Gy (95% CI, 2.9-14.5; $P < .001$), with no apparent threshold. The increase started within the first 5 years after RT and continued into the third decade after RT.

Although clinical evidence of cardiac morbidity has decreased with modern techniques, care should be taken to exclude the heart from the tangential radiation field. In an analysis of 114 patients, Marks et al[250] assessed RT-induced left ventricular perfusion defects and whether these perfusion defects are related to changes in cardiac wall motion or alterations in ejection fraction. Patients were imaged 30 to 60 minutes after injection of ^{99m}Tc sestamibi or tetrofosmin. Post-RT perfusion scans were compared with the pre-RT studies to assess for RT-induced perfusion defects as well as functional changes in wall motion and ejection fraction. The incidence of new perfusion defects 6, 12, 18, and 24 months after RT was 27%, 29%, 38%, and 42%, respectively. New defects occurred in approximately 10% to 20% and 50% to 60% of patients with less than 5% and more than 5% of their left ventricle included within the RT fields, respectively. The rates of wall motion abnormalities in patients with and without perfusion defects were 12% to 40% versus 0% to 9%. These authors noted that RT causes volume-dependent perfusion defects in approximately 40% of patients within 2 years of RT and that these perfusion defects are associated with corresponding wall motion abnormalities. However, additional study is necessary to determine if these defects are associated with functional consequences.

Given these findings, the authors suggested the use of a heart block if needed to reduce or eliminate cardiac irradiation. CT-based 3D treatment planning is used to design such cardiac blocks and select the optimal gantry angle to minimize the need for a heart block. There may be a small amount of breast tissue underdosed if the block overlies the medial inferior breast, but this tissue is typically less than 5%. In situations where the heart block may underdose the high-risk volume of the breast or chest wall, an “electron patch” can be used to treat the target tissue in the shadow of the heart block. A tangential field with a heart block is demonstrated in Figure 62.27.

Patt et al[300] analyzed data from the SEER-Medicare database for women who were diagnosed with nonmetastatic breast cancer from 1986 to 1993, had known disease laterality, underwent breast surgery, and received adjuvant RT; 8,363 patients had left-sided breast cancer, and 7,907 had right-sided breast cancer. With a mean follow-up of 9.5 years (range, 0-15 years), there were no significant differences in patients with left- versus right-sided cancers for hospitalization for ischemic heart disease (9.9% vs 9.7%), valvular heart disease (2.9% vs 2.8%), conduction abnormalities (9.7% vs 9.6%), or heart failure (9.7% vs 9.7%). The adjusted HR for left- versus right-sided breast cancer was 1.05 (95% CI, 0.94-1.16) for ischemic heart disease, 1.07 (95% CI, 0.89-1.30) for valvular heart disease, 1.07 (95% CI, 0.96-1.19) for conduction abnormalities, and 1.05 (95% CI, 0.95-1.17) for heart failure.

The potential for cardiac vessel injury from radiation was explored in an elegant study by Nilsson et al[301] who analyzed radiation fields and subsequent coronary angiograms in a Swedish breast cancer cohort study. For right-sided compared with left-sided breast cancers, the OR for grade 3 to 5 stenosis in arteries likely to be within the tangential radiation port was 4.38 (95% CI, 1.64-11.7) and 7.22 (95% CI, 1.64-31.8) for grade 4 or 5 stenosis. They concluded there was an increased risk and direct link between radiation and the location of the coronary stenosis. In a related editorial, Zagar and Marks[302] emphasized the potential effects of radiation on the heart but noted that improved radiation techniques, including custom blocking of the heart and other techniques to manipulate the radiation dose, are likely to minimize these risks and improve the therapeutic ratio.

Collectively, these data suggest that although there may be excess cardiac morbidity using tangential fields to treat left-sided breast cancers, these effects can be minimized through careful treatment planning. It remains prudent to minimize cardiac exposure in all patients and particularly in those receiving left-sided radiation in combination with other potentially cardiotoxic drugs.

Risk of Stroke With Supraclavicular Radiation

For patients with node-positive disease undergoing supraclavicular radiation, there is a theoretical concern regarding the potential for the development of accelerated carotid artery stenosis. In a study by Jagsi et al,[303] rates of stroke in 820 eligible patients with early-stage breast cancer treated with RT were compared with expected rates. The relation between potential risk factors and actuarial rate of the first stroke was analyzed. On multivariate analysis, only age ($P < .001$) and hypertension ($P = .003$) remained significant predictors of cardiovascular accident or transient ischemic attack. Age was the only significant predictor of cardiovascular accident alone ($P < .001$). This study found no significant association between supraclavicular RT and stroke after controlling for other factors. Another study by Woodward et al[304] of the SEER database compared 5,281 women presumably without supraclavicular radiation with negative nodes to 482 women presumably treated to the supraclavicular region with more than four nodes and did not find any increased rate of hospitalization for stroke in the treated population. However, a nested case-control study by Nilsson et al[305] showed a significant increase in stroke (OR 1.8; 95% CI, 1.1-2.8) when comparing patients treated to the supraclavicular and internal mammary regions with those not treated to these regions.

Contralateral Breast Cancer and Irradiation

Although all patients with a diagnosis of breast cancer are at increased risk for developing a contralateral breast cancer, the additional risk contributed by radiation treatment appears to be minimal, particularly when one uses modern techniques and maintains a dose to the contralateral breast that is as low as is reasonably achievable. The available data using modern radiation techniques do not suggest a significant increase in the risk for contralateral breast cancers in patients with breast cancer who have been irradiated compared to similar cohorts of patients with breast cancer who have not undergone radiation.[11,34,262,306-308] Although there is some evidence suggesting a slight excess risk in women who are irradiated at a relatively young age (ie, <45 years at diagnosis), the risk is extremely small and may be related to the use of older techniques. Most experts would agree that the benefit of radiation far outweighs the risk. Nonetheless, it appears prudent to be aware of these potential risks and employ techniques that minimize scattered dose to the contralateral breast.

The EBCTCG overview analysis does suggest an elevated incidence of contralateral breast cancer in patients receiving radiation compared with those who did not receive radiation.[41] This overview analysis of all randomized trials comparing radiation to surgery demonstrated an increased RR of contralateral breast cancers of 1.18 ($P = .002$). Although the excess risk appears to be driven primarily by older trials using antiquated techniques, these data do demonstrate the potential long-term effects of radiation-related secondary cancers and highlight the need to minimize contralateral breast exposure.

Boice et al[306] evaluated the risk of second cancers associated with RT to the breast in 41,109 women with breast cancer who were registered in the Connecticut Tumor Registry between 1935 and 1982. They reviewed the records of 655 women in whom a second breast cancer developed 5 years or longer after initial treatment and compared the radiation exposure in these patients with the exposure in 1,189 matched control patients who did not have a second cancer. The average dose to the contralateral breast in women exposed to radiation was 2.82 Gy. The RR for the development of a second breast cancer was 1.9 in the women who received RT, and among patients who survived for 10 years or longer, the RR was 1.33. Women younger than 45 years of age had an RR of 1.59 for the development of a second breast cancer compared with 1.01 for older women. According to these authors, younger patients should be informed that, based on the results of this study, after 10 years,

the risk for the development of a second cancer increases from 14% if they do not receive irradiation to 22% if they choose treatment involving irradiation.

Obedian et al[11] compared 1,029 patients with breast cancer treated with breast-conserving surgery and radiation to a cohort of 1,387 patients with breast cancer who underwent surgical treatment by mastectomy and who did not receive postoperative radiation during the same time period. The median follow-up was 14.6 years for the conservatively treated group and 16 years for the mastectomy group. The 15-year risk of any second malignancy was nearly identical for both cohorts (17.5% vs 19%). The second breast malignancy rate at 15 years was 10% for both groups. In the subset of patients aged 45 years or below at the time of treatment, the second breast and nonbreast malignancy rates at 15 years were 10% and 5% for patients undergoing BCT versus 7% and 4% for patients undergoing mastectomy (probability not statistically significant).

To address whether radiation administered may influence the development of breast cancers on the contralateral side, Khan and Haffty[309] evaluated the location of contralateral breast cancers developing after radiation. There was not a preponderance of medial lesions developing in the contralateral group (where radiation dose would be higher), suggesting that there was no cause-effect relation with respect to the prior radiation. In a study by Hill-Kayser et al,[310] the 20-year risk of contralateral breast cancer in 1,801 patients treated with breast-conserving surgery and radiation was 15.4%. They also demonstrated that the distribution of location of the contralateral tumors did not appear to be influenced by the prior irradiation.

In an update of the Danish randomized trials of postmastectomy radiation, Nielsen et al[262] also reported no excess risk of second malignancies in the contralateral breast in patients randomized to receive radiation. In this long-term follow-up performed among 3,083 patients from the Danish Breast Cancer Cooperative Group 82B and 82C trials randomized to postmastectomy radiation or not, there was no significant difference in the risk of contralateral breast cancers (6% RT vs 5% no RT) between the two groups.

Hooning et al,[308] in a study from Amsterdam of over 7,000 predominantly young women treated with or without radiation, did note an increase in contralateral breast cancer with decreasing age with tangential breast irradiation, particularly in young women with a strong family history. Of note, patients treated with mastectomy and chest wall electrons, where scattered dose to the contralateral breast was less, did not experience an increased contralateral breast cancer risk. The joint effects of tangential breast irradiation following lumpectomy and strong family history of contralateral breast cancer resulted in an HR of 3.52 (95% CI, 2.07-6.02; $P = .043$).

With modern technology and radiation techniques, scattered dose to the contralateral breast is lower and should minimize this issue, but care should be taken, particularly in younger women, to ensure that the dose to the contralateral breast is as low as possible.

Incidence of Other Second Malignancies

The incidence of secondary malignancies, as with the issue of contralateral breast cancer, appears to be very low, and it is evident that the appropriate use of RT far outweighs the risk of radiation-induced malignancy. Nonetheless, there is some evidence, with very long-term follow-up, of higher rates of secondary cancers. Although this may be more prevalent with older techniques, it is an important component of treatment planning to minimize dose to nontarget normal tissues. In addition to the excess risk of contralateral breast cancers discussed previously, the EBCTCG overview analysis did demonstrate an excess risk of secondary cancers of the lung and esophagus as well as leukemia and sarcoma in all randomized trials of breast cancer that compared patients treated with and without radiation.[41] The increased RR for each of these secondary malignancies as

a function of radiation treatment for breast cancer was lung cancer, 1.61 (±0.18; P = .007); esophageal cancer, 2.06 (±0.53; P = .05); leukemia, 1.71 (±0.36; P = .03); and sarcoma, 2.34 (±0.62; P = .03). The total RR for all secondary nonbreast malignancies was 1.20 (±0.06; P = .001). Although the increased risk of secondary malignancies may be driven primarily by trials using older techniques, they highlight the importance of limiting dose to nontarget tissues.

Huang and Mackillop,[311] in an analysis of 194,798 women from the SEER database who were diagnosed with invasive breast carcinoma (exclusive of those with distant metastasis) between 1973 and 1995, identified 54 women in an RT cohort and 81 women in a non-RT cohort in whom soft tissue sarcoma subsequently developed. In the RT cohort, the standardized incidence ratio was 26.2 for angiosarcoma and 2.5 for other sarcomas; in the non-RT cohort, the standardized incidence ratios were 2.1 and 1.3 (95% CI, 1.0-1.7), respectively. The elevated RR was significant even within 5 years of RT, but it reached a maximum between 5 and 10 years.

More contemporary retrospective series have not reported an excess risk of secondary malignancies. However, interpretation of these series is limited by follow-up periods of less than 20 years, which may not be adequate. Obedian et al[11] reported no increased risk of second nonbreast malignancies in patients treated with conserving surgery and radiation compared with a cohort treated with mastectomy without radiation during the same time interval. The 15-year risk of a second nonbreast malignancy was 11% for the radiation group and 10% for the mastectomy group.

Deutsch et al,[312] in a long-term analysis of the NSABP-04 and NSABP-06 trials, suggested an excess risk of lung cancers associated with the extent of radiation. The records of all patients who developed a recurrence in the lung or a new primary lung tumor were reviewed to determine the incidence and laterality of confirmed and probable primary lung carcinoma. For the NSABP-04 trial, which employed more comprehensive radiation with larger lung volumes, there were a total of 23 subsequent confirmed and probable ipsilateral or contralateral primary lung carcinomas. In those patients who had received comprehensive PMRT, there was a statistically significant increase in the incidence of these new primary tumors (P = .029). With regard to the development of confirmed new primary ipsilateral lung carcinoma alone, the incidence was statistically significantly increased (P = .013) in those patients who had received RT as part of their treatment, and when confirmed and probable ipsilateral lung carcinomas were analyzed, there was a strong trend toward a statistically significant increase in those patients who had received RT (P = .066). From NSABP-06 (mean follow-up of 19.0 years), there was a total of 30 second primary lung carcinomas but no increase in either ipsilateral or contralateral primary tumors of the lung in those patients who had received RT. They concluded that extensive postmastectomy irradiation of the chest wall and regional lymphatic areas, with consequent exposure of a greater volume of lung to higher doses as administered in the NSABP-04 trial, compared with postlumpectomy breast irradiation in the NSABP-06 trial, was associated with an increased incidence of subsequent primary lung tumors. Unfortunately, data regarding smoking were not available in this analysis.

Postirradiation Angiosarcoma of the Breast

Special attention should be paid to uncommon skin changes of the treated breast because clinical suspicion is the main clue to the diagnosis of postirradiation angiosarcoma. The primary therapy is simple mastectomy if wide tumor-free margins can be achieved. There is no clear indication for standard adjuvant chemotherapy or irradiation. Angiosarcomas arising in the field of RT are rare. Unlike other radiation-induced sarcomas, cutaneous angiosarcoma often occurs within a short time after irradiation. It is important to differentiate atypical vascular lesions from angiosarcoma, but currently, there is no evidence that they represent a precursor to radiation-induced angiosarcoma.

Marchal et al[313] reported on nine breast angiosarcomas identified in a review of 18,115 patients who underwent breast-conserving treatment for carcinomas at 11 French cancer centers over a 20-year period ending in 1997. The estimated prevalence of angiosarcomas after BCT for carcinomas was 5 per 10,000, which is approximately the same as for primary angiosarcomas in healthy breasts. The patients had a mean age of 62.5 years when the primary breast cancer was treated and 69 years when the angiosarcoma was diagnosed. Most angiosarcomas were stage T1N0M0 and were treated with radical mastectomy; two patients underwent reirradiation, and two patients were given adjuvant chemotherapy. The median time to the median survival after diagnosis of an angiosarcoma was 15.5 months. One patient was alive without progression of disease 32 months after a salvage mastectomy and the rest had died.

Cost Versus Benefit in Breast Cancer Treatment

Barlow et al[314] compared the total medical care costs from a regional nonprofit health management organization of breast conservation therapy versus a mastectomy 5 years after diagnosis in 1,675 women with early-stage breast cancer who had initial diagnoses between 1990 and 1997 and were 35 years of age or older. These women were classified into four groups according to treatment: mastectomy only (group 1, $n = 183$), mastectomy plus adjuvant therapy (group 2, $n = 417$), breast conservation therapy plus RT (group 3, $n = 405$), and breast conservation therapy plus RT and adjuvant therapy (group 4, $n = 670$). At 6 months, the costs of the treatments differed significantly ($P < .001$). Breast conservation therapy was more expensive than mastectomy. At 1 year, costs still differed significantly ($P < .001$) but were influenced more by the use of adjuvant therapy. By 5 years, the overall cost for breast conservation therapy was lower than for a mastectomy, presumably because of costs of reconstruction or complications of mastectomy.

Warren et al[315] linked data of older women with breast cancer from the SEER cancer registries with their Medicare claims from 1990 through 1998. Initial care costs for the 6 months after diagnosis for women who underwent breast conservation therapy and irradiation were approximately $450 per month higher than for women with modified radical mastectomy. In the continuing-care phase, costs for women undergoing breast-conserving surgery with RT were significantly less than for modified radical mastectomy cases. The two groups had similar costs in the terminal-care phase. Long-term costs for women undergoing BCT with RT were not statistically different from those for women undergoing modified radical mastectomy.

The usage of hypofractionation, with its associated reduced number of treatments, has been evaluated with respect to its costs by Bekelman et al[316] in a retrospective, observational cohort study, using administrative claims data from 14 commercial health care plans covering 7.4% of U.S. adult women. They classified patients with early-stage breast cancer treated with lumpectomy and WBI into two cohorts: (1) the hypofractionation- endorsed cohort ($n = 8,924$) included patients aged 50 years or older without prior chemotherapy or axillary lymph node involvement and (2) the hypofractionation- permitted cohort ($n = 6,719$) included patients younger than 50 years or those with prior chemotherapy or axillary lymph node involvement. They published that hypofractionated WBI increased from 10.6% in 2008 to 34.5% in the hypofractionation-endorsed cohort and from 8.1% in 2008 to 21.2% in the hypofractionation-permitted cohort. Adjusted mean total health care expenditures in the 1 year after diagnosis were $28,747 for hypofractionated and $31,641 for conventional WBI in the hypofractionation-endorsed cohort. Hypofractionated WBI was associated with savings of 9.1% and 11.8% in the hypofractionation-endorsed cohort and hypofractionation-permitted cohort, respectively. The adjusted mean total 1-year patient out-of-pocket expenses were not significantly different between hypofractionated versus conventional WBI in either cohort.

COSMESIS AND FOLLOW-UP AFTER BREAST CONSERVATION

Cosmesis

Surgical, radiotherapeutic, chemotherapeutic, and host factors may influence long-term cosmetic outcomes. Surgical factors to be considered include the extent of surgical resection, reexcision, orientation and length of the scar, closure or not of the tylectomy cavity, separate or continuous axilla-tylectomy scars, extent of the axillary dissection, and whether an ellipse of skin over the tumor was removed. RT factors are doses to the whole breast with tangential portals, homogeneity of dose throughout the breast, use of bolus, fractionation, overall duration of therapy including breaks, type and dose of boost, beam energy, and volume treated (whole breast only vs whole breast and regional lymph nodes). Chemotherapy issues include cytotoxic agents used, timing and sequence relative to RT, and doses and combinations of drugs. Host factors include size and shape of the breast, age, race, compliance with care and hygiene, concurrent medical illnesses (eg, hypertension, diabetes, CVD), and intrinsic sensitivity to radiation.

Different methods have been used to evaluate breast cosmesis after breast conservation therapy. Some are flawed because they do not establish strict guidelines or criteria for objectively judging cosmetic outcome. A commonly employed and simple categorization, developed by the Harvard group, employs a 4-point scale: excellent, good, fair, and poor.[317] "Excellent" indicates the treated breast is nearly identical to the untreated breast. "Good" indicates the treated breast is slightly different from the untreated breast. "Fair" indicates the treated breast is clearly different from the untreated breast. "Poor" indicates that the treated breast is significantly distorted.

At Washington University, questionnaires were completed by 458 patients and their radiation oncologists at regular 6-month intervals after treatment.[318] Cosmetic outcome analysis of these patients was done for clinical and treatment-related factors. Approximately 80% of patients had excellent or good cosmesis (Figure 62.46). A variety of factors were associated with a lower proportion of excellent cosmetic scores, including patient age over 60 years ($P = .001$), larger T2 tumor ($P = .05$), volume of resection greater than 100 cm^3 ($P = .0001$), scar orientation compliance with NSABP guidelines ($P = .0034$), more than 20 cm^2 skin resection ($P = .0452$), radiation treatment volumes (tangential fields only vs three or more fields; $P = .034$), whole-breast dose greater than 50 Gy ($P = .0243$), total dose to tumor site greater than 65 Gy ($P = .06$), and use of concomitant chemotherapy with radiation ($P = .02$). Notably, Black race was also associated with lower excellent cosmetic scores ($P = .0034$). The extent of axillary surgery and sequential chemotherapy did not reduce excellent cosmetic outcomes.

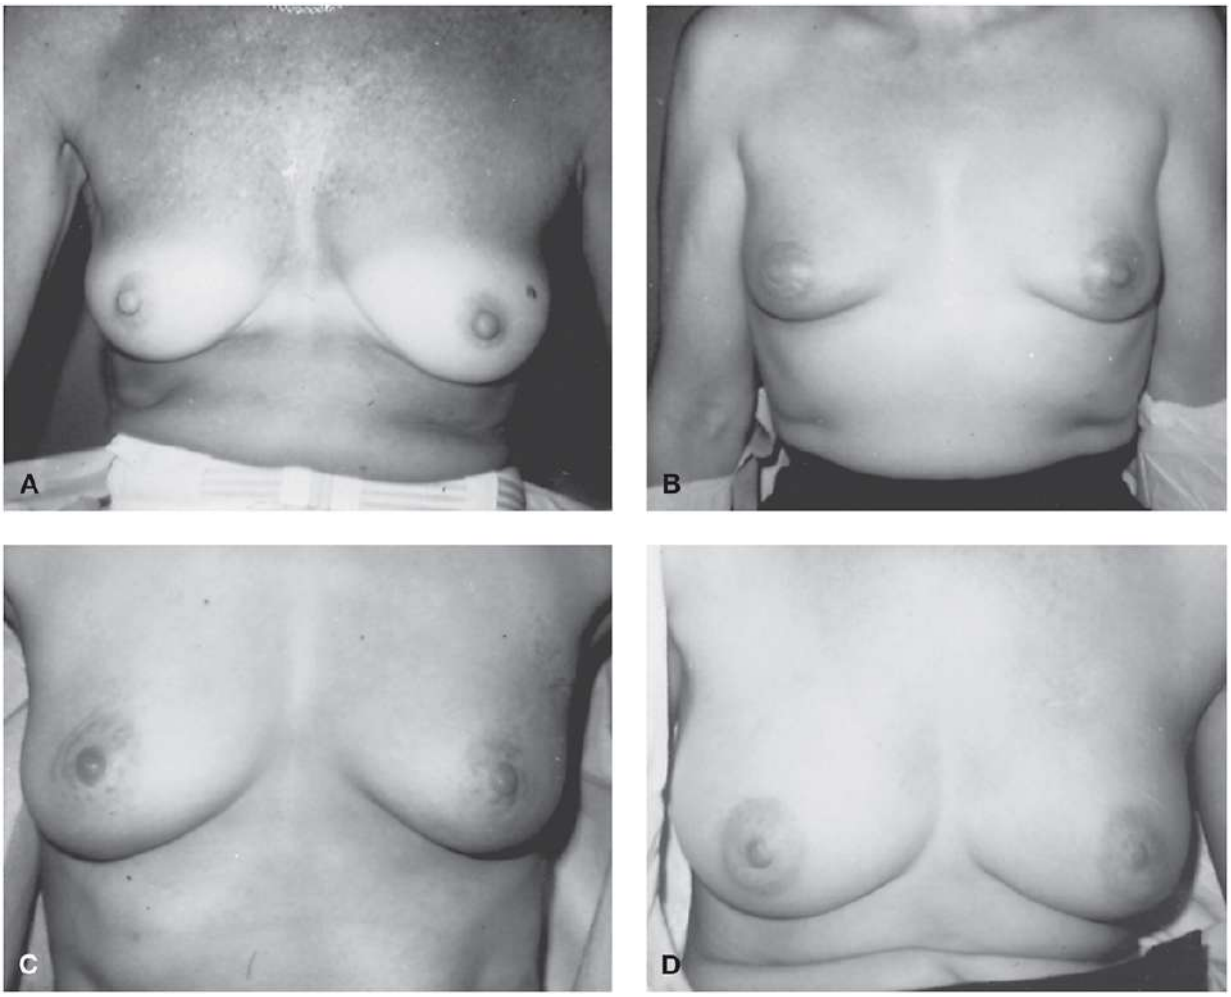

FIGURE 62.46 A-D: Photographs of patients showing excellent cosmetic results obtained with conservation surgery and irradiation for patients with T1 and T2 carcinomas of the breast. The patient in C has minimal telangiectasia in the area treated with a boost (upper region of left breast).

Poorer cosmetic outcomes in African American women have also been reported by Tuamokumo and Haffty.[96] A detailed cosmetic analysis was performed on a subset of 20 African American patients and 20 White patients. The two groups were intentionally matched by age, follow-up, adjuvant therapy, and breast size and were asked to participate in a detailed cosmetic evaluation. With respect to overall cosmetic outcome and all specific cosmetic measures (edema, fibrosis, and pigmentation), African American patients fared more poorly than did White patients. Overall cosmesis was good to excellent in 55% of African Americans, compared with 90% of Whites.

Breast Cosmetic Surgery After Irradiation

Breast deformities after conservation therapy may represent difficult reconstructive problems. When partial mastectomy is followed by RT, breast defects characterized by parenchymal loss, nipple-areola complex distortion, and cutaneous abnormalities can occur.

In a review of the MD Anderson Cancer Center experience, Kronowitz et al[319] evaluated the results of 69 patients who underwent repair of a partial mastectomy defect after radiation. They concluded that immediate repair of partial mastectomy defects with local tissues (also termed

oncoplastic rearrangement) results in a lower risk of complications and better aesthetic outcomes than does immediate repair of partial mastectomy defects with a latissimus dorsi flap.

Follow-Up of Patients Treated With Breast Conservation Surgery and Irradiation

It is important to closely monitor patients treated with conservation surgery and irradiation because early detection of an LR may allow for another wide local excision or a total mastectomy without significantly compromising the OS of the patient. According to the American Society of Clinical Oncology's follow-up guidelines, a careful history and physical examination are indicated every 3 to 6 months for 3 years, every 6 months for the following 2 years, and annually thereafter.[320] For patients who have undergone BCT, a post-treatment mammogram should be completed 1 year after the initial mammogram and at least 6 months after completion of RT. Yearly mammographic evaluation should continue unless more frequent examinations are specifically recommended. Blood and radiographic testing are not recommended for routine follow-up of an asymptomatic patient.

Radiographic Findings After Breast Conservation Therapy

Common mammographic findings after breast conservation therapy include fibrosis, fluid collection, skin thickening, and calcifications. These changes tend to peak within the first year after treatment before subsiding thereafter. Ultrasound and MRI can be used to supplement radiographic follow-up if mammographic findings are equivocal. If there is strong evidence of suspect microcalcifications, masses, or architectural distortions, a biopsy should be obtained to rule out a recurrence.

Tian et al[321] longitudinally compared the incidence of common mammographic sequelae seen after breast-conserving surgery and RT in patients treated with APBI, HF-WBI, and CF-WBI. In their cohort of 89 patients, 29 had received APBI, 30 had received HF-WBI, and 30 had received WBI. A total of 605 mammograms were evaluated, with a median follow-up of 48 months. The fractionation scheme did not affect the severity of architectural distortion when the groups were evaluated longitudinally. The likelihood of finding skin thickening decreased with increasing follow-up duration (OR 0.6; $P < .001$) adjusted for fractionation schemes. No differences were seen with respect to changes in skin thickening, fluid collections, or calcifications among the treatment groups after adjustment for the follow-up time. The clinical characteristics including age, race, T stage, and chemotherapy use were not linked to the likelihood of finding several mammographic phenomena over time. The authors concluded that fractionation did not alter the relative incidence or severity of architectural distortion, skin thickening, fluid collections, or calcifications.

CONCLUSION

RT plays an essential and critical role in the management of breast cancer, the most common cancer diagnosed in women. Early detection by mammography, followed by appropriate oncologic therapy, may be associated with reduced breast cancer mortality rates for women aged 50 years and above. After breast-conserving surgery, WBI improves local control and survival rates in appropriately selected patients and, therefore, should be considered for all patients. The development of molecular signatures predictive for LRR may revolutionize how we select patients for RT; significant progress has been made in this area with systemic therapy but, similar work is needed with regard to locoregional therapies. Accelerated forms of treatment including HF-WBI and APBI may increase

the utilization rate of RT after breast-conserving surgery. Ongoing research will help to further define the safety and acceptability of these techniques in women with early-stage breast cancer.

CHAPTER 63

Breast Cancer: Locally Advanced and Locally Recurrent

Christin A. Knowlton, Nancy Chan, Serena Wong, Meena S. Moran, and Jennifer R. Bellon

BACKGROUND

This chapter focuses on the management of locally advanced breast cancer (LABC) as well as locally recurrent breast cancer and selected unusual presentations of breast cancer. The emphasis is on locoregional therapy, though systemic treatments are also reviewed.

LABC is not clearly defined, though it commonly encompasses stage III disease including T3N1, any T4, and any N2/N3 disease as delineated in the *AJCC Cancer Staging Manual*, eighth edition.[1] Patients who present with LABC require care from a multidisciplinary team that includes radiologists, pathologists, surgical oncologists, medical oncologists, and radiation oncologists. Incorporating and coordinating the input of each specialty is of utmost importance in the management of patients with locally advanced disease, as these patients are at high risk of disease recurrence and require complex integrated decision-making. Breast cancer management is evolving toward an era of personalized medicine with treatment decisions increasingly made based on biologic subtypes.

Fortunately, the outcome for patients who present with LABC has improved substantially in recent decades. Prior to the routine use of chemotherapy, patients treated with mastectomy, radiation, or both had high rates of distant metastases and death.[2-4] Chemotherapy, targeted drug therapy, and endocrine therapy (ET) regimens in both the neoadjuvant and adjuvant settings have significantly improved prognosis. By decreasing the burden of distant metastases, modern chemotherapy and biologic therapies have resulted in the increased importance of local disease control. At the same time, increasingly effective systemic therapy has led to decreased rates of local recurrence and overall improved outcomes.

NATURAL HISTORY

Prior to recent decades, a diagnosis of LABC portended a poor prognosis. However, treatment advances have allowed many individuals with locally advanced disease to be cured. The clinical course of LABC may vary based on several factors, including the specific disease characteristics at presentation, the biologic features of the cancer, and the treatment given.

Infiltrating ductal and infiltrating lobular carcinomas are the two most common invasive breast cancer types. Locally, as the disease grows within the breast, the tumor

may infiltrate or invade the dermis or chest wall. Invasion of Cooper ligaments may lead to skin retraction; this can also occur in early-stage disease but is more likely as the tumor grows. When blockage or alteration of the lymphatic drainage of the breast or skin occurs, edema may develop, leading to dilated dermal hair follicles appearing like the skin of an orange; this peau d'orange appearance is often, but not exclusively, associated with inflammatory breast cancer (IBC).

Because of the propensity of more advanced tumors to invade the lymphatic system, many clinical T3 and T4 primary tumors have spread to the axillary lymph nodes (LNs) at the time of diagnosis. The axillary LN region is divided into three levels, each defined in relationship to the pectoralis minor muscle. Level I LNs are inferolateral to the muscle, level II LNs are posterior to the muscle, and level III LNs are superomedial. Level III LNs are also known as infraclavicular LNs. Other LNs that may be involved include the supraclavicular nodes, internal mammary nodes (IMNs), and Rotter nodes, located between the pectoralis minor and major muscles. Figure 63.1 shows computed tomography (CT) scans from patients with LABC presenting with involvement of the level II axilla (Figure 63.1A), an infraclavicular LN (Figure 63.1B), a Rotter LN (Figure 63.1C), and an IM LN (Figure 63.1D).

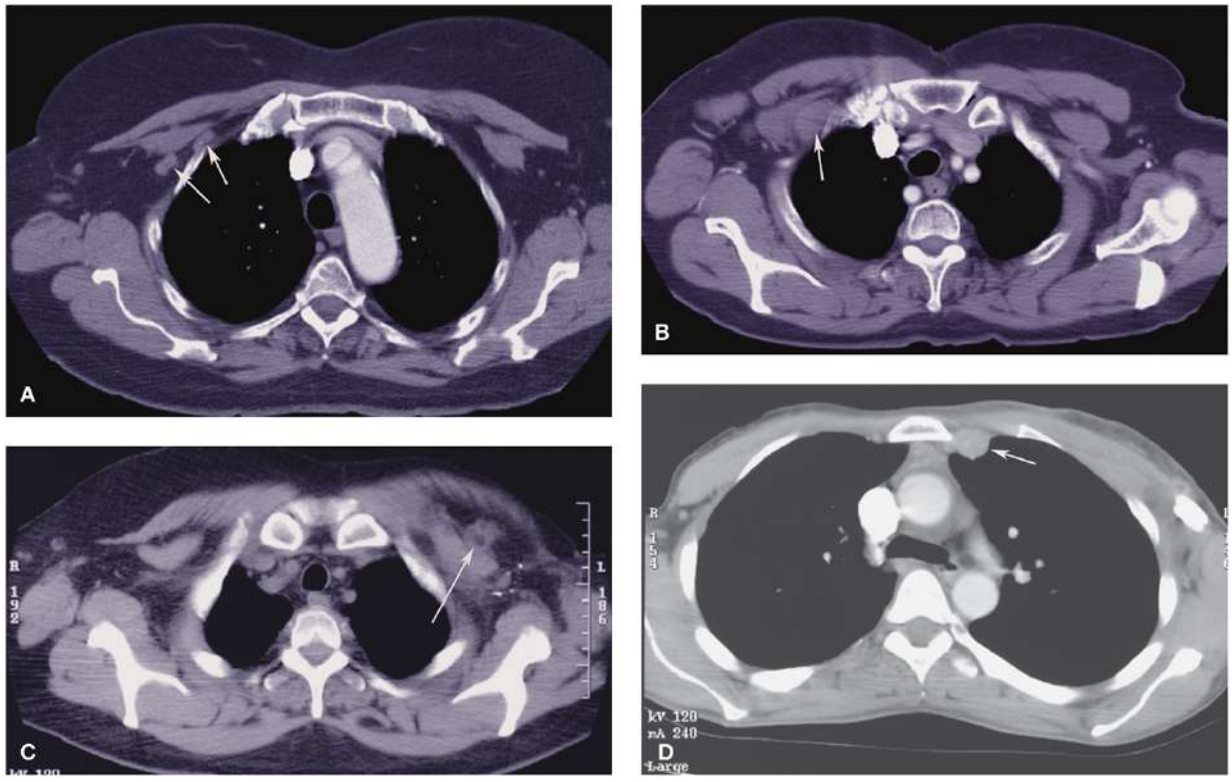

FIGURE 63.1 Computed tomography images of patients with lymph node involvement at the time of diagnosis. A. Image from a patient with involvement of axillary lymph nodes in the level II axilla. The *white arrows* show the involved lymph nodes, which are just beneath the pectoralis minor muscle. B. An involved level III axillary lymph node (*white arrow*) that extends superomedially to the pectoralis minor muscle. C. An involved Rotter lymph node (*white arrow*), which is anterior to the pectoralis minor and beneath the pectoralis major muscle. D. Image from a patient with an involved internal mammary lymph node (*white arrow*).

Local disease progression can lead to ulceration of the breast skin, pain, bleeding, and infection. In addition, arm edema, brachial plexopathy, and obstruction and thrombosis of the brachial vasculature may also occur due to the progression of regional lymphatic disease. Primary tumor growth also increases the risk of spread through the lymphatic system to regional LNs or hematogenous spread to distant sites, such as the liver, lung, bone, and brain. Without treatment, almost all LABCs will metastasize to visceral organs and eventually become life-threatening.[2,3]

Survival rates for women with LABC have improved largely due to advances in systemic therapy. Before the use of systemic treatment, individuals with advanced disease treated with mastectomy, radiation therapy (RT), or both had 5-year survival rates of only 25% to 45%.[2-4] With the development of molecular testing and the introduction of combined modality treatments including surgery, RT, chemotherapy, and targeted biologic therapy, modern 5-year survival rates range from approximately 68% to over 90% for patients with anatomic stage IIIA disease and approximately 33% to 84% for patients with anatomic stage IIIC disease depending upon the grade and molecular subtype.[1,5]

Although treatment advances may be credited for much of the improvement in prognosis for individuals with stage III disease in recent decades, it is important to recognize how stage migration has affected the statistics as well. Diagnostic imaging has improved over time, increasing the likelihood of detecting metastatic disease. As a result, some cases that would have been classified as stage III historically may now be classified as stage IV. The reclassification of patients with a relatively low burden of metastatic disease from stage III to stage IV may improve the outcome statistics for both stage III and stage IV diseases.

HISTOPATHOLOGY AND CLINICAL PRESENTATION OF LOCALLY ADVANCED BREAST CANCER

The two most common infiltrative breast cancer histologic subtypes, invasive ductal carcinoma and invasive lobular carcinoma, can present as early-stage or locally advanced disease. Less aggressive subtypes (eg, tubular carcinoma, mucinous carcinoma, and medullary carcinoma) are unlikely to present at an advanced clinical stage unless present for an extended period of time.

LABC is most commonly diagnosed after a palpable mass is detected within the breast. Locally advanced disease that has developed between annual interval screening mammograms is most often estrogen receptor (ER) negative with a high nuclear grade and a high proliferative index. These cancers may be of the luminal B, human epidermal growth factor receptor 2 (HER2)-positive, or triple-negative subtypes. In contrast, patients who present with extensive locoregional disease after years without treatment more often are found to have ER-positive disease with a low nuclear grade and a low proliferative index (luminal A subtype).[6] Advanced disease can cause symptoms such as local or regional pain, bleeding, paresthesia, and paresis. It is critically important to determine the onset of symptoms and the rate of disease progression to reach an accurate diagnosis as to

whether an advanced breast cancer should more accurately be designated IBC, which is discussed in detail in the section on IBC later in this chapter.

Diagnostic Workup

For patients with LABC, the workup should start with a careful history and physical examination. The breast examination should include a note of the breast symmetry, as well as careful inspection for involvement or edema of the skin. Peau d'orange and skin erythema can sometimes be subtle, particularly in patients of color; comparison with the contralateral side can often be helpful.

Other times, physical examination findings are more obvious. Figure 63.2 shows a photograph of a patient with a long-standing, untreated LABC presenting with peau d'orange, breast retraction and involution, and effacement of the nipple-areola complex (NAC). Medical photographs are helpful to document the extent of visible abnormalities before treatment is begun and can also be used to assess disease response.

FIGURE 63.2 Photograph of a patient with a neglected locally advanced breast cancer presenting with peau d'orange, breast retraction and involution, and effacement of the nipple-areola complex.

The extent of palpable disease should be measured and documented. Fixation of a breast mass to the pectoralis muscle or chest wall is determined by assessing the mobility of the mass with the pectoralis muscle relaxed and contracted. Regional LNs should be thoroughly evaluated by careful clinical examination with the patient in both supine and

sitting positions. Bilateral diagnostic mammography is mandatory, and supplemental breast ultrasound should be strongly considered. Biopsy of the breast tumor(s) with histologic evaluation per College of American Pathologists is standard. Ultrasonographic imaging of the axilla should be performed with fine-needle aspiration or core biopsy of suspicious LNs with clip placement.[7-9] Magnetic resonance imaging (MRI) of the bilateral breasts may be helpful to determine the extent of disease within the ipsilateral breast and regional LNs including the IM lymph chain and to gauge response to treatment in the setting of neoadjuvant systemic therapy.

All cases of locally advanced disease require complete staging before initiation of therapy. Laboratory studies should include a complete blood cell count and serum chemistry profile with liver function tests. Radiographic studies should include a CT scan of the chest, abdomen, and pelvis; a bone scan; and plain radiographs of symptomatic regions or areas of increased uptake on bone scans. If any neurologic symptoms suggestive of cerebral metastases are present, a gadolinium-enhanced MRI scan of the brain should be obtained. The use of MRI to screen asymptomatic patients has not been widely adopted. There are retrospective data suggesting that subsets of patients with breast cancer may have a higher risk of intracranial disease and may be appropriately screened with MRI. These include women with HER2-positive and triple-negative subtypes who present with extracranial metastatic disease[10] and women with IBC who present with extracranial metastases.[11]

There is increasing interest in the use of 18F- fluorodeoxyglucose (FDG) positron emission tomography (PET)/CT for staging of patients with LABC, particularly those with IBC. Several small retrospective studies have shown that PET/CT increases detection of both previously unsuspected sites of metastatic disease and additional sites of regional nodal disease when compared to conventional imaging.[12,13] Researchers from MD Anderson showed that the addition of PET/CT in the staging of 41 women with IBC not only detected new sites of disease in 44% of patients when compared to standard imaging but also resulted in a change in radiation doses or fields in 18%.[14] FDG PET/CT can be particularly helpful when standard staging studies are equivocal. 18F-fluoroestradiol PET/CT may have clinical utility in the setting of ER-positive breast, especially invasive lobular carcinoma; however, additional studies are needed.[15]

The patient's personal and family oncologic history should be obtained and documented. The American Society of Breast Surgeons recommends that all patients with breast cancer should be offered genetic testing for deleterious mutations BRCA1/BRCA2 and PALB2 as well as other genes deemed appropriate based on the patient's personal and family history.[16] Referral to a trained genetic counselor for genetic testing recommendations is preferred.

Staging of Locally Advanced Breast Cancer

Previously, the American Joint Committee on Cancer (AJCC) staging system for breast cancer relied exclusively on the anatomic TNM staging system in which *T* refers to the size and extent of the primary tumor, *N* refers to the number and/or extent of regional

nodal involvement, and *M* refers to the presence of distant metastatic disease. As a result of a greater understanding of the importance of tumor biology in relation to prognosis and patient outcomes, the amended 2018 eighth edition of the AJCC prognostic staging system for breast cancer incorporates tumor grade, molecular markers (ER, progesterone receptor, and HER2 expression), as well as the results of the Oncotype DX (Exact Sciences) multigene panel. The AJCC breast cancer staging system continues to include clinical and anatomic staging for areas of the world where detailed molecular analysis is not widely available. Tumor registries and treating practitioners in the United States and Canada should use the AJCC eighth edition Clinical and Pathologic Prognostic Stage Groups.

A comprehensive discussion of disease staging systems for breast cancer is provided in the previous chapter. Some staging considerations are particularly relevant to patients with stage III disease. Stage III breast cancer can represent either T3 disease (tumors >5.0 cm) with involved LNs, N2 or N3 disease, or T4 disease.[1] Specific aspects of both primary tumor and nodal staging in LABC warrant additional consideration. Specifically, T4 disease may represent invasion into the chest wall (T4a), tumors associated with ulceration or satellite nodules of the skin and/or breast edema (T4b), both chest wall invasion and T4b characteristics (T4c), or IBC (T4d). Invasion of disease into the pectoralis major muscle without invasion of the chest wall structures and dimpling or fixation of the overlying skin does not qualify as T4 disease. Both clinical and pathologic staging systems have been established for N2 and N3 disease. Clinical N2 disease signifies either involved axillary LNs that are fixed to one another or to surrounding structures (N2a) or involved IM LNs without concurrent disease in the axilla (N2b), as determined by physical examination or imaging studies. Clinical N3 disease includes nodal metastases that involve the infraclavicular region (N3a), both the axilla and IM LNs (N3b), or the supraclavicular region (N3c). Pathologic N2 disease represents involvement of four to nine axillary LNs with at least one focus measuring greater than 2.0 mm (N2a) or clinical involvement of IM LNs (with or without microscopic confirmation) with pathologically negative axillary LNs (N2b). Pathologic N3 disease represents involvement of an infraclavicular LN or 10 or more involved LNs with at least one focus measuring greater than 2.0 mm (N3a), clinical involvement of IM LNs with one to nine axillary LNs involved or pathologic involvement of a sentinel IM LN with four or more axillary LNs involved (N3b), or a metastasis in the supraclavicular region (N3c).[1]

Neoadjuvant chemotherapy is recommended for most patients with LABC. The initial extent of disease is an important factor for later locoregional treatment decisions and for future research. It is, therefore, imperative that the full extent of the initial disease is assessed and documented prior to beginning any treatment.

OVERVIEW OF TREATMENT APPROACHES

Combined Modality Therapy

LABC is most appropriately treated with multimodality therapy aimed at eradicating all disease in the locoregional area and preventing distant disease recurrence. These goals are best achieved through the use of systemic therapy (generally chemotherapy and, when appropriate, endocrine, HER2-directed, or targeted therapy), surgery, and radiation.

LABC can present as either operable or inoperable disease. In general, disease is considered inoperable if an initial surgical procedure is unlikely to completely resect all gross disease with achievement of negative surgical margins. Most patients with T4 disease and/or advanced nodal disease and all patients with IBC are considered inoperable at presentation. Inoperable disease requires the administration of upfront systemic therapy to reduce tumor volume in order to facilitate definitive local therapy. Neoadjuvant therapy (also known as preoperative therapy) usually takes the form of chemotherapy with the addition of anti-HER2 therapy in the setting of HER2-positive disease, although, in certain situations as discussed later, ET may also be an option. In addition to downstaging the tumor, systemic therapy also reduces the risk of recurrence and breast cancer mortality by eradicating occult micrometastatic disease and aiding radiation in obtaining long-term local control.

For most patients with LABC, neoadjuvant systemic therapy is now the standard approach. Neoadjuvant systemic therapy is also commonly used in the setting of node-positive, HER2-positive, and triple-negative disease. Neoadjuvant systemic therapy may render some patients eligible for breast-conserving surgery (BCS) and/or sentinel lymph node biopsy (SLNB).[17-19] In addition, response to neoadjuvant systemic therapy can also help tailor adjuvant systemic therapy treatment recommendations.[20,21]

Neoadjuvant Chemotherapy

The landmark NSABP B-18 trial randomized 1,523 patients with operable breast cancer to receive neoadjuvant doxorubicin and cyclophosphamide (AC) for four cycles followed by surgery versus surgery followed by four cycles of AC.[22] Although this trial included only patients with operable breast cancer, the results demonstrated the feasibility of preoperative chemotherapy. The planned surgical approach was determined prior to randomization, with approximately two-thirds of patients in each group deemed initially eligible for lumpectomy. There was no difference in overall survival (OS) or disease-free survival (DFS) between the two groups, but a larger proportion of patients who received neoadjuvant chemotherapy were able to undergo BCS compared to those who received adjuvant chemotherapy (68% vs 60%).[22,23] This increase was largely due to a higher percentage of patients with T3 disease being offered breast conservation after responding to neoadjuvant chemotherapy. The percentage of patients with pathologically negative nodes was also higher in the neoadjuvant group compared to the adjuvant group (59% vs 43%, $P < .001$). Results from another pivotal neoadjuvant trial European Organisation for Research and Treatment of Cancer (EORTC) 10902 also demonstrated an increase in the percentage of patients eligible for BCS, with 23% of patients initially requiring mastectomy being able to undergo lumpectomy after the receipt of chemotherapy. OS and

recurrence rates were equivalent between the preoperative and postoperative chemotherapy groups.[24]

A key finding that emerged from the early neoadjuvant trials was the correlation between response to therapy and long-term outcome. In B-18, patients who achieved a pathologic complete response (pCR) in the breast after neoadjuvant chemotherapy had improved DFS (hazard ratio 0.47, $P = .0001$) and OS (hazard ratio 0.32, $P = .0001$) compared to those who did not.[17] This finding has been replicated in several other studies, though the definition of pCR varied, with some studies using the definition of absence of invasive tumor in the breast and nodes and others the absence of invasive disease in the breast. The currently accepted definition of pCR is the lack of residual invasive cancer in the breast and nodes. Patients who achieve a pCR consistently demonstrate improved long-term outcomes compared to those with significant residual disease.[25,26]

In addition to downstaging the tumor to improve surgical outcomes and providing valuable prognostic information, neoadjuvant chemotherapy also allows an *in vivo* assessment of the tumor's response to chemotherapy. Patients whose tumors demonstrate resistance to initial therapy should be offered a non–cross-resistant regimen or proceed directly to local therapy.

For patients with locally advanced but operable disease at presentation, primary surgery followed by adjuvant therapy may be a consideration. A potential advantage of this approach is a shorter time interval between diagnosis and effective treatment for patients with disease that is resistant to chemotherapy. Primary surgery also allows for more accurate pathologic staging of the tumor and axillary nodes, which is important to guide prognosis and selection of appropriate adjuvant treatment. However, the amount of residual disease after neoadjuvant chemotherapy may ultimately provide a more individualized assessment of prognosis. Furthermore, tumor biology has become a driving force in the selection of appropriate systemic therapy, and appropriate treatment decisions can often be made at the time of diagnosis based on the clinical stage and molecular subtype of the tumor. Given equivalent DFS and OS between the two approaches, there has been a paradigm shift in the treatment of LABC, with increased use of neoadjuvant chemotherapy.

As discussed earlier, pathologic evaluation of the tumor bed and LNs after neoadjuvant chemotherapy provides important prognostic information. However, the value of pCR as a prognostic tool is highly dependent on the molecular subtype of the tumor. Tumors that are highly proliferative (luminal B, nonluminal/HER2 positive, and triple negative) tend to demonstrate increased chemosensitivity and are associated with higher rates of pCR compared to low proliferative subtypes with high expression of hormone receptors (HRs) (luminal A).[27] pCR appears to be most predictive of DFS and OS in nonluminal/HER2-positive (treated with trastuzumab) and triple-negative subtypes, with those achieving a pCR having an excellent prognosis and those with significant residual disease having a high risk of recurrence and overall worse survival. pCR in patients with luminal A tumors does not appear to be a good predictor of long-term outcome, whereas the utility of pCR as a predictive tool in patients with luminal B (HER2-negative or HER2-positive) tumors

seems to be better than for luminal A tumors but worse than for nonluminal/Her2-positive or triple-negative tumors.[26,27]

HER2-Negative Disease

The optimal neoadjuvant chemotherapy regimen for patients with HER2-negative disease has not been established, but it is generally accepted that regimens with proven effectiveness in the adjuvant setting may also be used in the neoadjuvant setting. Because patients with LABC are considered to have high-risk disease, a regimen containing an anthracycline (eg, doxorubicin, epirubicin) and a taxane (eg, paclitaxel, docetaxel) is usually preferred.

These recommendations are based on results from the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analyses, which demonstrated that adjuvant polychemotherapy reduced the risk of recurrence and breast cancer mortality in patients with node-positive and node-negative disease.[28] Anthracycline-based regimens were found to be superior to CMF (cyclophosphamide, methotrexate, fluorouracil) regimens, and the addition of taxanes to anthracyclines further improved outcomes.[29] Overall, taxane-plus- anthracycline–based regimens reduced 10-year breast cancer mortality by one-third.

For patients with contraindications to anthracyclines or taxanes, alternate regimens are available. A non– anthracycline- containing regimen may be preferred in patients who have cardiac disease or who have other risk factors for anthracycline-associated congestive heart failure, such as hypertension, diabetes, or advanced age. For patients with a hypersensitivity reaction to solvent-based paclitaxel, nanoparticle albumin–bound paclitaxel (nab-paclitaxel) may be used.

HER2-Positive Disease

One of the most significant advances in breast cancer treatment has been the introduction of trastuzumab, a monoclonal antibody directed against the HER2 protein, into the adjuvant treatment for patients with HER2-overexpressing cancer. Several prospective randomized trials have demonstrated that the addition of trastuzumab to chemotherapy in the adjuvant setting confers an approximate 50% improvement in DFS and 35% improvement in OS in this population.[30,31] Subsequent studies in the neoadjuvant setting have confirmed an important role for trastuzumab in the neoadjuvant setting as well, with an approximate doubling of pCR rate to around 40% with the addition of trastuzumab to chemotherapy.[26,32] pCR was also found to be a predictor of event-free survival (EFS) and OS. The subsequent development of pertuzumab, a monoclonal antibody that binds to the HER2 protein at the site of HER2/HER3 dimerization, has led to even further improvements in pCR rates when added to trastuzumab and chemotherapy.[33,34]

As there are few randomized data comparing different neoadjuvant chemotherapy regimens, a number of regimens may be considered appropriate in the locally advanced setting for HER2-positive breast cancer. The randomized phase II TRYPHAENA trial yielded a pCR rate of 56% in patients receiving neoadjuvant FEC (fluorouracil,

epirubicin, cyclophosphamide)-docetaxel, trastuzumab, pertuzumab and 64% for docetaxel, carboplatin, trastuzumab, pertuzumab.[34] The study was not powered to compare the pCR rate between the different regimens as it was primarily a cardiac safety study. Rates of cardiac toxicity were low overall, and slightly lower with the non–anthracycline-containing regimen.

The phase III TRAIN-2 trial randomized patients with stage II or III HER2-positive breast cancer to three cycles of FEC followed by three cycles of weekly paclitaxel and carboplatin or to nine cycles of weekly paclitaxel and carboplatin without an anthracycline. Trastuzumab and pertuzumab were administered with all chemotherapy cycles. pCR rates (67% vs 68%), 3-year EFS (92.7% vs 93.6%), and OS (97.7% vs 98.2%) were similar between the two arms.[35,36] There was a higher incidence of significant decline in left ventricular ejection fraction in patients who received an anthracycline (8% vs 3%), and two patients in the anthracycline group developed acute leukemia.

Given the above, a regimen containing a taxane, carboplatin, trastuzumab, and pertuzumab is preferred in the neoadjuvant setting for locally advanced HER2-positive breast cancer, although an anthracycline-containing regimen is an acceptable alternative.

Triple-Negative Disease

Chemotherapy for locally advanced triple-negative breast cancer (TNBC) should ideally incorporate an anthracycline and a taxane. In addition, randomized trials have demonstrated significantly higher pCR rates with the incorporation of a platinum, though results were conflicting with respect to the impact of carboplatin on DFS. In CALGB 40603 and GeparSixto, the addition of carboplatin resulted in an incremental increase in pCR of approximately 10% to 15% compared to standard anthracycline- and taxane-based regimens.[37-39]

These results led to the inclusion of carboplatin in the chemotherapy backbone used in the subsequent pivotal KEYNOTE-522 study.[40,41] This was a phase III trial that randomized patients with stage II or III TNBC to receive neoadjuvant paclitaxel and carboplatin followed by doxorubicin (or epirubicin) and cyclophosphamide with either the immune checkpoint inhibitor pembrolizumab or placebo. Pembrolizumab or placebo was continued in the adjuvant setting for 27 weeks, regardless of pathologic response. The co-primary end points were pCR and EFS (defined as the time from randomization to the date of disease progression that precluded definitive surgery, local or distant recurrence, occurrence of a second primary cancer, or death from any cause). The addition of pembrolizumab to chemotherapy led to a significant improvement in pCR (64.8%) compared to the placebo-chemotherapy arm (51.2%). A subsequent update demonstrated improved EFS at 36 months in the pembrolizumab-chemotherapy group compared to the placebo-chemotherapy group (84.5% vs 76.8%; hazard ratio 0.63, 95% confidence interval [CI] 0.48-0.82). Improvement in EFS was seen in both programmed death-ligand 1 (PD-L1)-positive and PD-L1–negative subsets and in patients with pCR or residual disease at surgery.[40,41]

The abovementioned data led to a paradigm shift in the treatment of locally advanced TNBC, and patients without a contraindication to an anthracycline or immunotherapy should receive pembrolizumab plus a chemotherapy backbone similar to that used in KEYNOTE-522.

Neoadjuvant Endocrine Therapy

Given the lower response rates to neoadjuvant chemotherapy in patients with tumors having high HR expression, there has been interest in evaluating the role of neoadjuvant ET in this population as an alternative method of downstaging tumors and rendering breast conservation feasible.

The IMPACT trial randomized 330 postmenopausal patients with clinical stage II or III HR-positive breast cancer to receive tamoxifen versus anastrozole versus tamoxifen plus anastrozole for 12 weeks.[42] There was no difference in clinical and radiographic response rates among the three groups, but a higher percentage of women receiving anastrozole were eligible for BCS compared with those receiving tamoxifen (44% vs 22%, $P = .022$). The authors also found that higher expression of ER was associated with increased response rates.[42] The P024 trial compared the efficacy of letrozole to tamoxifen in the neoadjuvant setting in 324 postmenopausal women with HR-positive breast cancer. After 16 weeks, treatment with letrozole resulted in improved clinical response rates compared to treatment with tamoxifen.[43]

Several efforts are underway to correlate response to neoadjuvant ET with long-term outcomes to identify patients with endocrine-sensitive disease who may be able to safely omit chemotherapy completely, including in the adjuvant setting. In patients treated with neoadjuvant ET, pathologic tumor stage, pathologic nodal stage, surgical specimen Ki67 level, and ER Allred score have been shown to be associated with relapse-free survival and breast cancer–specific survival (BCSS). The preoperative endocrine prognostic index (PEPI score) was developed based on these findings, with a PEPI score of 0 (pT1-2, pN0, Ki67 $\leq$ 2.7%) being associated with an extremely low risk of relapse (ROR).[44]

The ALTERNATE study was designed to assess a biomarker-driven treatment strategy based on Ki67 values after 4 and 12 weeks of neoadjuvant ET and employed the PEPI score to identify patients with a low risk of recurrence.[45] Approximately 1,300 patients with stage II or III HR-positive breast cancer were randomized to 6 months of neoadjuvant ET with the selective ER degrader fulvestrant or anastrozole or both. Patients with Ki67 greater than 10% at week 4 or 12 were recommended to switch to chemotherapy. Patients who remained on ET with a modified PEPI score of 0 at surgery continued their assigned ET for 1.5 years followed by anastrozole for a total of 5 years of ET (without chemotherapy). The primary end point of the neoadjuvant phase of the study was endocrine-sensitive disease rate (ESDR), defined as pCR or PEPI-0 residual disease. ESDR was similar between the treatment arms, ranging from 18.6% to 22.7%, with no difference between the fulvestrant-containing arms and the anastrozole arm.[45] However, baseline RNA-seq–based intrinsic breast cancer subtypes (by PAM50 [Veracyte] breast cancer assay) appeared to predict overall outcomes, and the combination of anastrozole

and fulvestrant was associated with enhanced antiproliferative effects compared to either agent alone in the luminal B molecular subtype.[46] Further analysis from ALTERNATE is ongoing.

The addition of CDK4/6 inhibitors (palbociclib, ribociclib, abemaciclib) to ET has led to improvements in response rates, progression-free survival, and OS in HR-positive/HER2-negative metastatic breast cancer.[47-50] As a result, there has been an interest in studying these agents in combination with neoadjuvant ET. The addition of CDK4/6 inhibitors to neoadjuvant ET consistently showed improved complete cell cycle arrest across multiple studies including PALLET, NeoPalAna, and NeoMONARCH compared to neoadjuvant ET alone.[51-53] Whether this translates into improved clinical benefit or survival remains unclear at this time.

CORALLEEN compared neoadjuvant chemotherapy to neoadjuvant ET and ribociclib in high-risk HR-positive/ HER2-negative and luminal B (by PAM50 gene signature) breast cancer.[54] The primary end point was the rate of PAM50 ROR low disease at the time of surgery. PAM50 ROR integrates gene expression data, tumor size, and nodal status to define a low-risk group in the adjuvant setting with more than 90% distant relapse-free survival at 10 years. Both arms demonstrated similar molecular downstaging to low risk by PAM50 ROR score at the time of surgery, with significantly less treatment-related toxicities in the nonchemotherapy arm.[54] However, survival data have not been reported.

Neoadjuvant ET may, therefore, be considered for select postmenopausal patients, and in particular those who may be medically unfit to receive chemotherapy. Treatment with an aromatase inhibitor appears to be superior to tamoxifen, and the recommended duration is at least 4 to 6 months. Close monitoring is advised to ensure that patients who are not responding or who lose response to neoadjuvant ET are offered alternative strategies.

The use of neoadjuvant ET in the premenopausal population has not been established. A randomized trial comparing 24 weeks of neoadjuvant chemotherapy versus 24 weeks of neoadjuvant ET in premenopausal women showed improved response rates in those receiving chemotherapy.[55] At this time, the use of neoadjuvant ET in this population is not routinely recommended.

Selection of Patients for Breast-Conserving Surgery

The decision to offer BCS is dependent on both the extent of tumor at presentation and after completion of neoadjuvant therapy and the relative breast size. Clinical and radiographic assessments are used to determine eligibility for BCS. Patients with residual tumor greater than 5 cm, residual skin edema, continued skin involvement, and/or chest wall fixation after neoadjuvant chemotherapy are not considered candidates for BCS.[19]

Surgical Management of the Axilla

Historically, axillary lymph node dissection (ALND) has been the standard surgical approach to the axilla following neoadjuvant systemic therapy in the setting of upfront axillary LN involvement. Three prospective studies, the SENTINA trial, ACOSOG Z1071, and SN FNAC, have examined the use of SLNB for patients who convert from clinically node positive (cN+) to clinically LN negative (cN−).[56-58] The false-negative rate (FNR) of SLNB for all three trials exceeded the threshold of 10%, which is the standard set by the NSABP B-32, the seminal trial that established SLNB as standard of care for patients with early-stage breast cancer.[59] Subgroup analyses have demonstrated that using dual tracers (blue dye and dual tracer), identifying and removing three or more sentinel LNs, and clip placement in the involved node(s) with removal of the clipped nodes(s) at time of surgery lead to a FNR of less than 10%.[8,56-58] Another study found that targeted axillary dissection, defined as SLNB plus localization and removal of the clipped nodes, yields an FNR of approximately 2%.[9] Based on these results, SLNB performed with the abovementioned techniques is reasonable for cN1-2 patients who become cN− after neoadjuvant systemic therapy. If any of the excised nodes are positive, ALND is indicated. Following neoadjuvant systemic therapy, ALND should be performed when the axillary disease remains palpable (cN+) as well as in the setting of infraclavicular involvement (cN3a), supraclavicular involvement (cN3c), and IBC even if the patient has been rendered cN−.

Systemic Therapy After Surgery

A full discussion of adjuvant systemic therapies is beyond the scope of this chapter. However, the following section highlights the salient points of adjuvant therapy as they pertain to patients with LABC who have completed neoadjuvant chemotherapy.

Hormone Receptor–Positive/HER2-Negative Disease

Patients with HR-positive breast cancer should receive adjuvant ET to reduce the risk of recurrence and breast cancer–specific mortality. The choice of therapy is influenced by menopausal status. Tamoxifen remains a standard for both premenopausal and postmenopausal women, whereas the use of aromatase inhibitors is limited to women who are in a low-estrogen state (ie, postmenopausal or receiving ovarian function suppression [OFS]).

The EBCTCG meta-analysis demonstrated that 5 years of adjuvant tamoxifen was associated with a one-third proportional reduction in breast cancer mortality at 15 years in patients with ER-positive disease, irrespective of age, nodal status, or receipt of chemotherapy.[60] Subsequent data from the ATLAS trial demonstrated a further reduction in recurrence risk and breast cancer mortality with 10 years of tamoxifen compared to 5 years, suggesting that compared to no ET, 10 years of tamoxifen was associated with an almost 50% reduction in disease-specific mortality.[61]

For postmenopausal women with HR-positive breast cancer, the use of an aromatase inhibitor is recommended in the adjuvant setting, either as upfront therapy or following

tamoxifen. Multiple studies have demonstrated improvement in recurrence rates and breast cancer mortality with the use of an aromatase inhibitor compared to tamoxifen. In a meta- analysis conducted by the EBCTCG, 5 years of aromatase inhibitor therapy was associated with a 15% reduction in 10-year breast cancer mortality compared with 5 years of tamoxifen.[62]

Subsequent data from the SOFT and TEXT trials established a role for OFS plus either tamoxifen or aromatase inhibition in select premenopausal women with HR-positive breast cancer. The addition of OFS resulted in a clinically meaningful improvement in recurrence rates, particularly in very young women (≤35 years) and in those whose disease was considered to be of sufficiently high risk to warrant the administration of chemotherapy. Given that women with LABC comprise a high-risk group, those who are premenopausal should be offered this strategy in the adjuvant setting.[63-65]

The landscape of adjuvant ET continues to evolve as CDK4/6 inhibitors are being evaluated in patients with high-risk disease. The monarchE study randomized 5,637 patients with HR-positive/HER2-negative high-risk disease (defined as either ≥4 involved nodes, or N1 disease with either tumor size ≥5 cm, grade 3, or Ki67 ≥20%) to receive adjuvant ET with or without 2 years of abemaciclib. At 4 years, the absolute improvement in invasive DFS (IDFS) was 6.4% (85.8% in the abemaciclib plus ET group vs 79.4% in the ET-alone group).[66,67] Based on these data, abemaciclib was approved in the adjuvant setting for patients with node-positive high-risk HR-positive/HER2-negative early-stage breast cancer.

NATALEE investigators reported at ASCO 2023 the benefit of adjuvant ribociclib in stage II and II breast cancer with high risk of recurrence including those with T2N0 disease. At a median follow-up of 34 months, adjuvant ribociclib added to ET led to a significant improvement in IDFS over ET alone, with a 3-year IDFS of 90.4% compared to 87.1%.[68] The benefit was observed across all subgroups including patients with N0 and N1 disease. In both monarchE and NATALEE, about 88% to 95% of patients also received adjuvant chemotherapy.

For patients with early-stage high-risk HER2-negative breast cancers who harbor a germline BRCA1 or BRCA2 pathogenic mutation, the addition of 1 year of the PARP inhibitor olaparib should be considered based on results from the OlympiA trial. This was a phase III study that randomized 1,836 patients to olaparib or placebo in the adjuvant setting. The 3-year IDFS was 85.9% in the olaparib group and 77.1% in the placebo group. With longer follow-up, an OS benefit was demonstrated, with a 4-year OS of 89.8% in the olaparib group compared to 86.4% in the placebo group (hazard ratio = 0.68, CI 0.47-0.97; $P = .009$).[69,70] The IDFS benefit of adjuvant olaparib was seen, regardless of HR status, carboplatin administration, or whether chemotherapy was administered in the neoadjuvant versus adjuvant setting.

HER2-Positive Disease

For patients with HER2-positive breast cancer, trastuzumab should be continued in the adjuvant setting to complete 1-year total of HER2-directed therapy. Patients who achieve

a pCR after neoadjuvant chemotherapy should continue with trastuzumab with or without pertuzumab in the adjuvant setting. Those with residual disease should be offered the option to switch to trastuzumab emtansine (T-DM1), a HER2-directed antibody-drug conjugate, based on results from the KATHERINE trial. This trial randomized patients with HER2-positive breast cancer with residual disease after neoadjuvant therapy to T-DM1 versus trastuzumab as adjuvant therapy. Patients who received adjuvant T-DM1 had improved 3-year IDFS compared to those in the trastuzumab group (88.3% vs 77.0%; hazard ratio = 0.50, $P < .001$).[21] The benefit was seen across all subgroups, regardless of HR status, pathologic nodal status, or amount of residual disease in the breast.

Neratinib is an oral pan-HER2 tyrosine kinase inhibitor. When administered for 1 year after completion of adjuvant trastuzumab in the ExteNET study, it was shown to improve IDFS, especially in patients with HR-positive/HER2-positive disease, and serves as an additional option to further reduce the risk of recurrence in the adjuvant setting.[71]

Triple-Negative Disease

Patients with TNBC who have completed neoadjuvant chemotherapy and achieve a pCR generally do not require additional chemotherapy in the adjuvant setting. If they received neoadjuvant pembrolizumab, they may continue this in the adjuvant setting to complete 1 year total of immunotherapy as was done in the KEYNOTE-522 trial.[40,41] However, as this trial did not include an arm with neoadjuvant pembrolizumab plus chemotherapy followed by no adjuvant immunotherapy, it is not clear how much incremental benefit is derived from pembrolizumab in the adjuvant setting.

In the CREATE-X study, 910 women with HER2-negative breast cancer with residual disease after neoadjuvant therapy with an anthracycline and/or taxane were randomized after surgery to either standard therapy (ET for patients with HR-positive disease or no systemic therapy for HR-negative disease) or to standard therapy plus capecitabine for eight cycles.[20] At 5 years, DFS was 74% for the capecitabine arm compared to 68% for the control arm (hazard ratio 0.70, $P = .01$). OS was also improved (89% vs 84%, hazard ratio = 0.59, $P = .01$). In the triple-negative subgroup, DFS was 70% versus 56% (hazard ratio 0.58) and OS was 79% versus 70% for the capecitabine and controls groups.[20] Patients who have residual disease after neoadjuvant chemotherapy may be offered adjuvant capecitabine based on these results. If pembrolizumab was administered in the neoadjuvant setting, it may be given concurrently with capecitabine in the adjuvant setting, although there is currently no defined standard.

Patients with locally advanced TNBC who carry a deleterious germline BRCA1/2 mutation should be offered adjuvant olaparib based on the OlympiA trial discussed earlier.[69,70] Whether to administer this in place of or in sequence with adjuvant capecitabine is not known, although given the targeted nature of PARP inhibitors for BRCA-associated cancers many favor olaparib over capecitabine in this situation.

Treatment Results for Locally Advanced Breast Cancer

As noted earlier, stage III breast cancer has historically been associated with a very poor prognosis, with high rates of locoregional recurrence (LRR), distant metastases, and death. However, advances in all disciplines, including systemic therapy with taxanes and anthracyclines as well as HER2-directed therapy and other targeted agents when appropriate, surgical interventions, and locoregional irradiation, have led to improved outcomes. Outcomes for patients with LABC vary by molecular subtype. Researchers out of MD Anderson analyzed the California Cancer Registry 2005-2008 and found 5-year rates of BCSS and OS for patients with stage III breast cancer were most favorable for patients with luminal cancers (HR positive) followed closely by HR-positive/HER2-positive cancers. Patients with triple-negative disease had the least favorable outcomes. Their analyses found that 5-year survival rates anatomic stage IIIA disease varied between approximately 68% to over 90%, while for those with anatomic stage IIIC disease, the survival rates ranged from about 33% to 84%, contingent upon grade and molecular subtype.[1,5]

Patients with supraclavicular lymph node (SCV) disease at diagnosis have a poorer prognosis than other patients with stage III disease. However, because some patients treated with chemotherapy were found to have 10-year survival rates of 30%,[72] the AJCC recategorized this stage of disease from stage IV to stage IIIC with the publication of the sixth edition of the *AJCC Staging Manual* in 2002.[73] One study investigating the outcome of 71 patients with supraclavicular disease who were treated with neoadjuvant chemotherapy, surgery, and radiation reported a 5-year locoregional control rate of 77% and a 5-year OS rate of 47%. Patients in whom the supraclavicular disease showed a clinical CR to neoadjuvant chemotherapy had better locoregional control and DFS than did those with persistent disease after chemotherapy.[74]

IMN involvement at presentation also confers a poor prognosis, although the incidence of IMN involvement is difficult to assess in modern series as extended radical mastectomies are not typically performed. Older series, prior to the use of routine screening mammography, have shown that IMN involvement is a risk factor for poor OS, independent of axillary nodal status.[75] A more modern series from the European Institute of Oncology included 107 patients with either IMN or SCV involvement between 1997 and 2009. Nodal involvement was determined by a combination of clinical examination, surgical biopsy, FDG PET/CT, and ultrasound. Five-year outcomes were better in those with IMN compared to SCV disease (DFS 84% vs 39% and OS 96.9% vs 57.1%).[76] Patients with both IMN and SCV involvement have a particularly high risk of distant disease. A study from Korea found a 33% 5-year DFS among 18 patients with disease involving both nodal sites.[77]

Patients presenting with SCV or IMN disease should receive treatment similar to other patients with stage III disease. Typically, this includes preoperative systemic therapy and breast and axillary surgery, followed by comprehensive adjuvant RT. As neither SCV nor IMN sites are readily amenable to surgery, these areas should be included in the radiation fields. There are insufficient data to guide radiation dose selection in this setting, but

consideration should be given to boost to the area of clinical involvement. Dose may be limited because of the adjacent brachial plexus (SCV) and heart and/or lung (IMN).

INFLAMMATORY BREAST CANCER

Epidemiology of Inflammatory Breast Cancer

IBC is an important subcategory of LABC that is notable for both its similarities to and differences from noninflammatory LABC. IBC is not common and accounts for 0.5% to 2% of all invasive breast cancers diagnosed in the United States but is disproportionately lethal, accounting for about 10% of breast cancer deaths.[78] In a study of nine Surveillance, Epidemiology, and End Results (SEER) registries, the incidence of IBC was found to have increased slightly during the 1990s, even while the incidence of LABC and non-T4 breast cancer decreased.[79] The rates of IBC, and mortality from IBC, were higher in Black women than in White women. IBC tends to occur in younger patients than non-IBC. Women with IBC are more likely to have positive axillary LNs, higher tumor grade, and negative HRs.[78-80] Distant metastases at diagnosis are also more common with IBC. Risk factors for IBC, including menstrual/reproductive factors, obesity, smoking, alcohol, and exposure to the mouse mammary tumor virus, have been evaluated, but results are not consistent.[80] The strongest epidemiologic associations of IBC are with Black race, young age, and high body mass index (BMI).[81]

Natural History of Inflammatory Breast Cancer

IBC, as defined by the AJCC, is a composite clinical-pathologic entity characterized by diffuse edema and erythema of the breast with acute/subacute onset and pathologic demonstration of invasive breast cancer. The erythema and skin changes must involve at least one-third of the breast, and the duration of symptoms must be less than 6 months. A critical and determinative feature of IBC is the rapid onset of clinical findings, including skin erythema, peau d'orange, brawny breast induration, warmth, and asymmetric enlargement (Figure 63.3).

FIGURE 63.3 Photograph of a patient with erythema and peau d'orange consistent with inflammatory breast cancer.

One hallmark of IBC is extensive lymphovascular invasion (LVI) of the superficial plexus of vessels in the papillary and high reticular dermis by tumor emboli. These emboli can be demonstrated with skin punch biopsies directed to areas of erythema in up to 75% of cases.[81] However, the presence of invasive cells in the dermal lymphatics alone is neither sufficient nor necessary for the diagnosis.

It is important to distinguish IBCs from LABC with secondary lymphatic congestion. Neglected primary tumors can also lead to breast erythema, edema, warmth, and asymmetric enlargement, particularly when bulky axillary adenopathy impedes the

normal lymphatic flow from the breast. However, the former has a history of rapid onset, whereas the latter tends to have a long interval between the first symptom and the presentation for medical treatment. Despite these general guidelines, the diagnosis of IBC can be uncertain. In order to establish more reproducible and objective criteria, Jagsi and colleagues proposed a scoring system based on clinical, pathologic, and imaging characteristics.[82]

Despite the natural history of IBC being one of rapid disease progression and early distant dissemination, in the United States, approximately 70% of patients with IBC have only evidence of locoregional disease at the time of diagnosis.[78] Patients with IBC typically have a worse clinical outcome than do other patients with T4 disease, suggesting that IBC is a distinct biologic entity.[83] However, the prognosis for patients with IBC has improved with combined (or tri-) modality therapy, including neoadjuvant chemotherapy, mastectomy, and postmastectomy radiation therapy (PMRT). Before the availability of combination chemotherapy, IBC was almost uniformly fatal. Fewer than 5% of patients treated with surgery, RT, or both survived the past 5 years, and the expected median survival time for such patients was less than 15 months.[84] Local recurrence rates after surgery or RT were also high at approximately 50%.[85,86] The introduction of doxorubicin-based chemotherapy was the first step toward improved outcomes.[87,88] An evaluation of the outcome of patients with IBC registered in the SEER Program found that BCSS rates for patients with IBC improved continuously throughout the 1990s.[78] Currently, local control rates for patients treated with chemotherapy, mastectomy, and postmastectomy radiation approach 80% to 95%, and 5-year survival rates are approximately 40% to 60%.[89-93] In one recent retrospective series from an institution with a dedicated IBC center, LRR rates were as low as 6.9% among patients undergoing trimodality therapy from 2007 to 2019.[94]

Diagnostic Workup

Although mammograms are considered a routine part of imaging workup for unspecified breast cancer, they are often of limited value for IBC. The diagnosis of IBC is often made without a clinically detectable mass. There are no specific IBC findings on mammography, but skin and trabecular thickening are the most frequent findings. MRI, with dynamic contrast enhancement studies, is the most accurate test for identifying primary breast lesions in IBC. MRI abnormalities on MRI can include asymmetric non–mass-like enhancement, multifocality/centricity, and postcontrast peak signal intensity higher than that for other presentations of LABC. As discussed earlier in the chapter, there is increasing interest in the use of FDG PET/CT for disease staging of patients with LABC, particularly those with IBC.[95]

General Management and Treatment Results for Inflammatory Breast Cancer

Because IBC is relatively uncommon, no data from randomized studies are available regarding the optimal therapeutic approach for this disease. From the aggregate of data reporting on IBC, it is quite clear that the best reported outcomes are with trimodality therapy, with a general sequence of neoadjuvant chemotherapy, mastectomy, and PMRT. Clearly, the management of IBC requires integrated care by a multidisciplinary team. Ideally, such patients should be evaluated in a multidisciplinary center by all specialists at the time of presentation to confirm the diagnosis of inflammatory disease, document the extent of disease (including photographs of areas of the involved skin), and agree on a treatment plan.

Chemotherapy for Inflammatory Breast Cancer

IBC is considered inoperable at presentation and should be treated initially with neoadjuvant chemotherapy (with the addition of trastuzumab and pertuzumab if the tumor is HER2 positive, and pembrolizumab if triple negative). The optimal chemotherapy regimen for patients with IBC includes both an anthracycline and a taxane. Patients should be carefully monitored for response, and after achievement of the maximal clinical response, patients should be reevaluated for mastectomy.

Surgery for Inflammatory Breast Cancer

Locoregional treatment is an essential component of therapy for IBC. Before the routine use of chemotherapy, mastectomy, with or without postmastectomy radiation, was associated with a dismal prognosis, and so many physicians abandoned mastectomy in favor of radiation-only treatments. Outcomes after RT as the sole treatment modality were equally poor. After neoadjuvant chemotherapy became routine, combinations of surgery and radiation have been reevaluated.

De Boer et al[96] reported on 54 patients with IBC treated after neoadjuvant chemotherapy with either radiation only (n = 35) or mastectomy plus radiation (n = 19). For the patients treated with radiation only, the median progression-free survival time was only 16 months, and the local recurrence rate was 34%. These results were not statistically different from the patients treated with mastectomy, and the authors concluded that surgery provided no clinical advantage over chemotherapy and radiation alone. In contrast, Perez et al[97] found that the addition of mastectomy to local treatment significantly improved the outcome of IBC treatment. Patients given neoadjuvant chemotherapy, mastectomy, and PMRT had a local control rate of 79% and a 5-year DFS of 40%. This was among the earliest demonstrations of the efficacy of trimodality therapy. These data were supported by the report from Panades et al[98] who evaluated 308 patients given chemotherapy as a component of their treatment and found that the 10-year local recurrence-free survival (LRFS) rates were significantly better for patients who underwent mastectomy than for those who did not (about 60% vs 34%; P = .0001), as were the 10-year BCSS rates (about 34% with mastectomy vs 23% without, P = .005). A multivariate analysis that considered other potential prognostic factors found that the use of mastectomy remained a significant factor for improved LRFS (P = .04). Results from

an MD Anderson study also confirmed these results, with multivariate analysis revealing that a CR or partial response to neoadjuvant chemotherapy, the use of RT, and the addition of mastectomy to the therapeutic regimen all significantly improved disease-specific survival.[99]

Radiation Therapy for Inflammatory Breast Cancer

RT also has an important role in the management of IBC. The randomized data supporting PMRT for LABC are discussed elsewhere and are not reviewed. Although IBC was not represented in those trials, the lessons are still germane to IBC. Furthermore, the best reported outcomes in IBC have all employed trimodality therapy and had aggressively designed and dosed RT. Because IBC has a rapid doubling time, investigators from MD Anderson investigated an accelerated hyperfractionated radiation delivery schedule in which 51 Gy is delivered to the chest wall and draining lymphatic fields by giving 1.5 Gy twice a day.[100] Subsequently, the chest wall was boosted to an additional 15 Gy, given in ten 1.5-Gy fractions twice daily. This approach was found to significantly improve locoregional disease control compared with a group treated with only 60 Gy, but also with a twice-daily schedule. Respective 10-year locoregional control rates were 77% versus 58% (P = .04). Statistically significant improvements were also seen in 5- and 10-year OS rates between these two groups (P = .03), and a trend toward improvement in 5- and 10-year DFS rates was noted as well (P = .06). In a more recent update from these investigators in which the outcome of 192 patients treated with neoadjuvant chemotherapy, mastectomy, and postmastectomy radiation was evaluated, the authors reported a 5-year locoregional control rate of 84%.[93] Factors associated with higher rates of locoregional control included partial response to chemotherapy, negative margins, three or fewer positive LNs, and the use of taxane chemotherapy. Similarly, good outcomes have also been reported from centers that used once-daily RT with high doses or daily use of bolus.[89]

In summary, all patients with IBC require management by a multidisciplinary team. After initial staging and careful documentation of the extent of disease, patients should receive initial chemotherapy. The chemotherapy course should include both an anthracycline and a taxane; anti-HER2 therapy with trastuzumab and pertuzumab should be given with chemotherapy for patients with HER2-positive disease, and pembrolizumab should be included for patients with triple-negative disease barring any contraindication to immunotherapy. The majority of patients who exhibit a disease response and become operable should then undergo a modified radical mastectomy. Comprehensive and aggressive postmastectomy radiation treatments to the chest wall and draining lymphatics should be given as adjuvant therapy. This approach was recently endorsed by a consensus panel of IBC experts.[93] The dose of radiation to the initial fields should be 50 Gy in 25 fractions given once a day or 51 Gy in 1.5-Gy fractions given twice a day. Subsequently, the chest wall and any areas of gross disease that have not been resected should be boosted to 60 to 66 Gy. Attention should be paid to skin dose, and many institutions use

tissue equivalent bolus material to ensure full dose to the skin of the chest wall. Patients with ER-positive disease should also receive hormonal therapy.

Clearly, great strides have been made over the past two decades in the management of IBC, and patients whose disease is managed with trimodality therapy can have locoregional control rates more than 80% and 5-year survival rates of more than 40% to 60% or more. Improvements in systemic therapy will, it is hoped, further augment these results.

LOCOREGIONAL RADIATION THERAPY AFTER MASTECTOMY OR BREAST-CONSERVING SURGERY FOR LOCALLY ADVANCED BREAST CANCER

An overview of the general management of strategies for LABC including IBC has been provided. The next section of the chapter concentrates on the role of RT as an adjunct to mastectomy or BCS in the setting of LABC. Data from meta-analyses and prospective randomized trials conducted in the past several decades that provide valuable data to define the role of locoregional RT are reviewed. RT decision-making in the context of the expanded use of neoadjuvant systemic is discussed.

In contemporary practice, the goal of safe and effective implementation of locoregional RT for patients with LABC has been advanced by technological innovations in treatment planning and delivery. The upcoming sections review locoregional RT techniques, including standardized contouring methods and dose-volume constraints. Dosimetric considerations to achieve conformal targeting and dose homogeneity to the breast/chest wall and regional nodes are discussed. The effects of RT on critical organs at risk (OAR), particularly the cardiovascular structures, along with modern techniques to minimize cardiac exposure, are examined.

Early Phase III Randomized Trials and Meta-Analyses: Postmastectomy Radiation Therapy

PMRT has been used for decades following surgery in the setting of LABC with the goal of achieving improved locoregional control and OS. Early randomized trials performed in the 1950s and 1960s demonstrated some improvement in LRR rates and no change in OS, with approximately 40% rate of distant metastases with the use of PMRT.[101-103] This lack of improvement in OS is likely due to the inferior efficacy of early systemic therapy regimens as well as the use of more rudimentary RT techniques with inadequate dose to the areas at risk and greater exposure of the heart and lungs. Nonetheless, by the mid-1970s, PMRT in the setting of LABC with involved axillary LNs was the generally accepted practice, with the goal of improved locoregional control,[103,104] although its use was controversial. For example, in 1987, Cuzick et al[105] published a meta-analysis of 7,941 patients enrolled in eight PMRT trials initiated before 1975 that reported no difference in survival in the first 10 years of follow-up; however, beyond 10 years, an excess of deaths among radiated patients was observed. RT was associated with reduced

breast cancer– specific mortality, but this was counterbalanced by an increased risk of cardiovascular death.[105,106] The work by Cuzick et al provided relevant early lessons in the association between locoregional control and improved BCSS and the importance of using heart-sparing radiation techniques to mitigate the risks of cardiac injury and death.

Three impactful randomized trials—the Danish Breast Cancer Cooperative Group (DBCG) 82b and 82c trials, and the British Columbia trial—demonstrated that PMRT was associated with not only improved locoregional control but also improved OS.[107-109] These landmark trials, which employed protocol-defined radiation techniques treating the chest wall, the IMN, supraclavicular, and axillary nodes in patients treated with adjuvant systemic therapy, contributed important prospective data that defined the role of PMRT in contemporary practice. These trials are discussed in more detail later and summarized in Table 63.1. In addition, work by the EBCTCG has provided evidence to support the use of PMRT in the setting of LABC.

TABLE 63.1 SUMMARY OF RESULTS OF THE BRITISH COLUMBIA TRIAL AND THE DBCG 82B AND DBCG 82C TRIALS EVALUATING PMRT AFTER MRM

	British Columbia[110]	DBCG 82b[107]	DBCG 82c[108]
Number of subjects	318 Premenopausal, N+	1,708 Premenopausal, high-risk pathologic stage II or III	1,460 Postmenopausal, high risk pathologic stage II or III
Accrual period	1976-1986	1982-1989	1982-1990
Breast surgery	MRM[a]	MRM[b]	MRM[b]
Randomization	PMRT vs no PMRT	9 cycles CMF vs 8 cycles CMF + PMRT	PMRT vs no PMRT
Chemotherapy	CMF	CMF	Tamoxifen[c]
Follow-up	20 y	10 y	10 y
Outcomes (PMRT vs control)	OS 47% vs 37%, $P = .03$ LRR 10% vs 26%, $P = .002$ DFS 48% vs 30%, $P = .001$	OS 54% vs 45%, $P < .001$ LRR 9% vs 32%, $P < .001$ DFS 48% vs 34%, $P < .001$	OS 45% vs 36%, $P = .03$ LRR 8% vs 35%, $P < .001$ DFS 36% vs 24%, $P < .001$

DFS, disease-free survival; LRR, locoregional recurrence rate; MRM, modified radical mastectomy; N+, node positive; OS, overall survival; PMRT, postmastectomy radiation therapy.

[a]Axillary dissection included levels I and II.

[b]Axillary dissection included level I and part of level II with median of seven nodes removed.

[c]Tamoxifen given for 1 year.

The Danish Breast Cancer Cooperative Group Trials

The DBCG 82b trial enrolled 1,708 premenopausal women with high-risk pathologic stage II or III breast cancer, accrued between 1982 and 1989.[107] High-risk status was defined as the presence of one or more of the following features: involvement of axillary

nodes, primary tumor greater than 5 cm, or invasion of the skin or pectoral fascia. After mastectomy and levels I to II axillary surgery removing a median of seven nodes, patients were randomized to systemic therapy with nine cycles of CMF chemotherapy without RT versus eight cycles of CMF plus RT of 50 Gy in 25 fractions or 48 Gy in 22 fractions to the chest wall and regional LNs, defined as the supraclavicular, infraclavicular, and axillary nodes, and IMNs in the four upper intercostal spaces. At a median follow-up of 9.5 years, women who received PMRT had significantly lower LRR (9% vs 32%, $P < .001$), improved DFS (48% vs 34%, $P < .001$), and improved OS (54% vs 45%, $P < .001$).[107]

The DBCG 82c trial evaluated 1,375 postmenopausal patients with high-risk pathologic stage II or III breast cancer, accrued between 1982 and 1990, who were randomized to mastectomy plus 1 year of tamoxifen versus mastectomy, tamoxifen, and RT.[108] Similar to the DBCG 82b results, PMRT was associated with reduced 10-year LRR (8% vs 35%, $P < .001$), improved DFS (36% vs 24%, $P < .001$), and improved OS (45% vs 36%, $P = .03$).

In the updated analysis of both DBCG 82b and DBCG 82c trials with 15-year follow-up, which also analyzed outcomes stratified by nodal subgroups (1-3 vs ≥4 positive nodes), PMRT significantly reduced LRR from 51% to 10% in patients with four or more positive nodes and from 27% to 4% in patients with one to three positive nodes.[111] OS improvement with PMRT use was demonstrated in both subgroups with one to three positive nodes (57% vs 48%, $P = .03$) and with four or more positive nodes (21% vs 12%, $P = .03$).

British Columbia Trial

The British Columbia trial was a smaller study that randomized 318 premenopausal women with node-positive disease after modified radical mastectomy and CMF chemotherapy to PMRT or no additional treatment.[109] PMRT consisted of hypofractionated prescriptions of 37.5 Gy in 16 fractions to the chest wall and 35 Gy in 16 fractions to the IMN and to the midaxilla through an anterior supraclavicular-axillary field. In the 20-year update, women treated with PMRT were confirmed to have significantly reduced rates of LRR (10% vs 26%, $P = .002$) and improved distant relapse-free survival (31% vs 48%, $P = .004$) and OS (47% vs 37%, $P = .03$).[110] The rates of cardiac death were 1.8% in the PMRT group and 0.6% in the control group ($P = .62$). Women treated with PMRT had higher rates of lymphedema (9% vs 3%, $P = .035$).

Early Breast Cancer Trialists' Collaborative Group Meta-Analyses

In 1983, the EBCTCG formed an international organization with the goal of generating and regularly updating meta- analyses using data from randomized trials of breast cancer treatment. The group defined early breast cancer as a disease "in which all clinically apparent disease can be removed surgically."[112] As such, the trials analyzed in the EBCTCG overview may include data from patients with stage III disease.

In 1995, the first published EBCTCG meta-analysis included 36 randomized trials comparing surgery alone versus surgery plus RT. Among 17,273 women enrolled in these trials, the use of RT after surgery was associated with a 3-fold reduced rate of local recurrence compared with surgery alone; however, there was no difference in the 10-year survival.[112] Similar to the work by Cuzick,[105,106] the reduced risk of death from breast cancer with RT was offset by an increased risk of death from other causes.

In 2000, the EBCTCG published findings from 40 randomized trials involving 20,000 women, half of whom had node-positive disease (EBCTCG 2000).[113] In these trials, adjuvant RT encompassed not only the breast or chest wall but also the axillary, supraclavicular, and IMN. The results showed that RT reduced local recurrence rates by about two-thirds (8.8% vs 27.2% at 10 years) and decreased breast cancer mortality ($2P$ = .0001). However, it led to an increase in cardiovascular mortality ($2P$ = .0003) while showing no significant impact on OS at 20 years (37.1% with RT vs 35.9%; $2P$ = .06).[113]

In 2005, the EBCTCG published an influential analysis reporting that, among 8,500 women with node-positive breast cancer treated with mastectomy and axillary dissection, PMRT to the chest wall and regional lymphatics reduced 5-year LRR by 17% from 22.8% to 5.8%.[114] By 15 years, breast cancer mortality was reduced by 5.4% (54.7% vs 60.1%, $2P$ = .0002) and overall mortality was reduced by 4.4% (64.2% vs 59.8%, $2P$ = .0009), suggesting the concept that for every four local recurrences prevented by RT in this group, one breast cancer death may be spared at 15 years. Although the relative risk (RR) of LRR was consistently decreased by two-thirds across trial subjects, the absolute risk reduction in individual subjects was dependent upon the baseline risk without RT. As such, PMRT was found to have the greatest impact on patients with a higher volume of nodal disease and larger primary tumors.

In the 2014 update of the EBCTCG meta-analysis, 8,135 women in 22 PMRT trials from 1964 to 1986 were analyzed.[115] The 20-year breast cancer mortality reduction associated with PMRT was statistically significant for all patients with node-positive disease, including those with one to three and four or more positive nodes. Among 3,786 subjects who underwent axillary dissection, 700 had node-negative disease, 1,214 had one to three positive nodes, and 1,772 had four or more positive nodes. Distinct from patients with node-negative disease in whom RT had no significant effect on LRR or breast cancer mortality, patients with one to three positive nodes treated with radiation experienced significantly reduced rates of LRR ($2P$ < .00001), overall recurrence (RR 0.68; 95% CI 0.57-0.82; $2P$ = .00006), and breast cancer mortality (RR 0.80; 95% CI, 0.67-0.95; $2P$ = .01). These improved outcomes were also observed among 1,133 patients with one to three positive nodes who received systemic therapy with CMF or tamoxifen. In these patients, PMRT was associated with significantly lower rates of 10-year isolated LRR (4.3% vs 21.0%, P < .00001), overall recurrence (33.8% vs 45.5%, P < .00001), and 20-year breast cancer mortality (41.5% vs 49.4%, P = .01). Among 1,677 patients with four or more positive nodes treated with systemic therapy, PMRT similarly reduced LRR (13.6% vs 31.5%, P < .00001), overall recurrence (RR 0.79; 95% CI 0.69-0.90; $2P$ = .0003), and 20-year breast cancer mortality (70.0% vs 78.0%, P = .08). Importantly, for

the 3,131 subjects with node-positive disease who underwent ALND, PMRT significantly reduced overall mortality (RR 0.89, 95% CI 0.81-0.97, 2*P* = .01). Ultimately, the 2014 meta-analysis suggested that for every 1.5 recurrences of any type avoided during the first 10 years after RT, one breast cancer death would be avoided at 20 years.[115]

The EBCTCG recently published a meta-analysis of individual patient data of 14,324 women from all randomized trials of regional nodal irradiation (RNI) versus no RNI that began before January 1, 2009, with available data.[116] In all, 2,451 patients whose data were included in the meta- analysis had four or more pathologically involved nodes. The 16 included trials were categorized as older (1961-1978) or newer (1989-2008) with the goal of assessing the effects of RNI on breast cancer recurrence and mortality for each group. In the eight older trials, RNI did not affect breast cancer mortality (RR 1.04, 95% CI 0.91-1.20; *P* = .55); however, RNI led to an increase in non-breast cancer mortality (RR 1.42, 95% CI 1.18-1.71; *P* = .00023) and all-cause mortality (RR 1.17. 1.04-1.31; *P* = .0067). In the eight newer trials, with 15 years of follow-up, there was a significant reduction in breast cancer recurrence (RR 0.88, 95% CI 0.81-0.95; *P* = .0008) and breast cancer mortality (RR 0.87, 95% CI 0.80-0.94; *P* = .0010) with the use of RNI. There was no significant difference in non-breast cancer mortality between the two groups, leading to a significant reduction in all-cause mortality with the use of RNI (RR 0.90, 95% CI 0.84-0.96; *P* = .0022). At 15 years, the absolute improvement in breast cancer mortality was 3.0% and the absolute improvement in overall mortality was 3.0% with the use of RNI. For patients with no involved axillary nodes, one to three axillary nodes, and four or more involved nodes, the absolute reduction in 15-year breast cancer mortality with RNI was 1.6%, 2.7%, and 4.5%, respectively.[116] This interesting meta-analysis indicates that with improvement in RT techniques as well as advances in systemic therapy, RNI improves breast cancer outcomes and survival for patients with high-risk disease.

In summary, the Danish and British Columbia PMRT trials reported that patients with high-risk breast cancer treated with PMRT and systemic therapy had significantly reduced risks of LRR. These improvements led to improved DFS and OS at 15- and 20-year follow-up.[111,110] These trials, taken together with the EBCTCG meta-analyses, have supported the principle that by reducing LRR in the setting of effective systemic therapies, RT contributed to improved OS. As systemic treatment lowered the competing risk of distant metastasis and RT techniques improved, the effect of optimal locoregional control on improved survival became evident.

Recent Phase III Randomized Trials: Regional Nodal Irradiation After Breast-Conserving Surgery or Mastectomy

In the setting of LABC, particularly in patients presenting with large T3 tumors or T4 disease, standard surgical treatment remains mastectomy, typically with ALND, although SLNB after neoadjuvant systemic therapy is an option for select patients (see “Surgical Management of the Axilla”). The use of BCS for patients with LABC has been increasing. BCS may be applied to patients with T2 tumors with positive nodes, selected patients with operable T3 tumors with clinically node-negative disease or limited N1

involvement, and may be considered on an individualized basis with multidisciplinary review for patients with LABC with adequate response to neoadjuvant systemic therapy. Chen et al published a retrospective study demonstrating acceptable rates of ipsilateral breast tumor recurrence (IBTR) and LRR in patients with advanced disease (cT3/T4 and cN2/N3) who underwent neoadjuvant systemic therapy with excellent response including resolution of skin findings or chest wall fixation in the setting of cT4 tumors.[19] In patients with operable stages II to III breast cancer who are candidates for BCS, prospective trial results have emerged evaluating the role of RNI as a component of adjuvant management. The characteristics and results of these trials are summarized in Table 63.2.

TABLE 63.2 SUMMARY OF RESULTS OF THE MA.20 AND EORTC 22922 TRIALS EVALUATING REGIONAL NODAL IRRADIATION IN THE SETTING OF BCS

	MA.20[117]	EORTC 22922[118] 10 y	EORTC 22922[119] 15 y
Number of subjects	1,832 N+ or high-risk N0	4,004 N+ or medial/central tumor	4,004 N+ or medial/central tumor
Accrual period	2000-2007	1996-2004	1996-2004
Breast surgery	All BCS	75% BCS	75% BCS
Randomization (radiation targets)	Breast alone vs breast + IMN/SCN/level III ± level I-II	Breast/chest wall alone vs breast/chest wall + IMN/SCV	Breast/chest wall alone vs breast/chest wall + IMN/SCV
Node positive	90% (85% 1-3N+)	56%	56%
Chemotherapy	90%	55%	55%
Outcomes (RNI vs control)	LRRFS 95.2% vs 92.2%, *P* = .009 BCM 10.3% vs 12.3&, *P* = .11 DMFS 86.3% vs 82.4%, *P* = .03 DFS 82% vs 77%, *P* = .01 OS 82.8% vs 81.8%, *P* = .38	LRRFS not reported BCM 12.5% vs 14.4%, *P* = .02 DMFS 78.0% vs 75.0%, *P* = .02 DFS 72.1% vs 69.1%, *P* = .04 OS 82.3% vs 80.7%, *P* = .06	LRRFS not reported BCM 16.0% vs 91.8%, *P* = .0055 DMFS 70.0% vs 68.2%, *P* = .18 DFS 60.8% vs 59.9%, *P* = .18 OS 73.1% vs 70.9%, *P* = .36

BCM, breast cancer mortality; BCS, breast-conserving surgery; DFS, disease-free survival; DMFS, distant metastasis-free survival; IMN, internal mammary node; LRRFS, locoregional recurrence-free survival; N+, node positive; OS, overall survival; SCV, supraclavicular lymph node; RNI, regional nodal irradiation.

National Cancer Institute of Canada Clinical Trial Group MA.20 Trial

In 2015, the National Cancer Institute of Canada Clinical Trial Group (NCIC-CTG) MA.20 trial was published after a median follow-up time of 9.5 years.[117] In this multicenter trial, 1,832 patients who underwent BCS and systemic therapy were randomized to receive RT to the whole breast (50 Gy in 25 fractions) with or without radiation to the regional nodes (45 Gy in 25 fractions). Axillary dissection was performed in 96% of subjects. Overall, 85% had one to three positive nodes, 5% had four or more positive nodes, and 10% had high-risk node- negative disease, defined as tumors >2 cm

with 10 or less nodes removed, plus one or more of the following features: grade 3 histology, LVI, or ER-negative disease. While representation of true LABC is limited in this trial, the enrolled subjects represent a higher risk cohort. RNI included the ipsilateral IMN as well as the supraclavicular and level III axillary nodes. For patients with less than 10 nodes removed or four or more positive nodes, the target volume also included level I and II axillary nodes.[117]

At 10 years, RNI was associated with improved locoregional DFS (95.2% vs 92.2%, *P* = .009), distant DFS (86.3% vs 82.4%, *P* = .03), and DFS (82.0% vs 77.0%, *P* =.01), but no difference in OS (82.8% and 81.8%, *P* = .38). In a planned subset analysis, women with ER-negative disease randomized to RNI had improved OS compared to no RNI (81.3% vs 73.9%, *P* = .05) and patients with ER-negative or PR-negative disease had a more robust improvement in DFS. The rate of lymphedema was higher in the RNI group (8.4% vs 4.5%, *P* = .001). The rates of grade 2 or higher cardiac toxicities were low (<1%) in the two study groups. The rate of acute pneumonitis was higher in the RNI group at 1.2% compared to 0.2% in the control group.[117]

European Organisation for Research and Treatment of Cancer 22922 Trial

The EORTC 22922 trial evaluated elective RNI to the IMN plus the medial supraclavicular (MS) fossa in conjunction with whole-breast radiation after BCS or chest wall radiation after mastectomy.[118] Between 1996 and 2004, 4,004 patients with stages I to III breast cancer with a central or inner quadrant tumor with node-negative or node-positive disease or an outer quadrant tumor with axillary node– positive disease were enrolled after BCS (76%) or mastectomy (24%). Initially, all patients underwent ALND; however, in the past years of the trial, SLNB with completion ALND in the setting of a positive node was allowed. The majority of patients had early-stage breast cancer; however, 13% of subjects had pN2 or pN3 disease. Systemic therapy was used in 99% of node-positive and 66% of node-negative subjects. Subjects were randomized to IM-MS RT (50 Gy in 25 fractions) or no IM-MS. IM-MS was delivered to the MS fossa and the IMN in the first three intercostal spaces and up to and including the first five intercostal spaces in patients with lower inner quadrant tumors. Dedicated full axillary irradiation was performed in 8.3% of the IM-MS group and 7.4% in the control group. Per the authors, the "operated part of the axilla was not irradiated unless adverse risk factors were present."[118] At 10 years, the IM-MS RT group had lower rate of any first recurrence (19.4% vs 22.9%, *P* = .02) and higher rates of distant DFS (78% vs 75%, *P* = .02). OS was 82.3% in the IM-MS irradiation group and 80.7% in the control groups (*P* = .06). As in the MA.20 trial, the EORTC trial demonstrated that IM-MS was beneficial for patients with node-positive disease with respect to breast cancer–specific outcomes, but the difference in OS at 10 years was small and did not reach statistical significance. The rate of lung fibrosis was higher in the IM-MS group (4.4% vs 1.7%, *P* < .001), whereas the rate of cardiac disease was comparable in the two groups (6.5% vs 5.6%, *P* = .25).[118]

After publication of the MA.20 and the EORTC 22922, Budach et al[120] performed a meta-analysis that included these two trials. RNI of the IMN and supraclavicular

nodes/upper axilla as delivered in the MA.20 and EORTC trials was associated with significant improvement in DFS (hazard ratio 0.86; 95% CI, 0.78-0.95), distant DFS (hazard ratio 0.84; 95% CI, 0.75-0.94), and OS (hazard ratio 0.88; 95% CI, 0.78-0.99).

The 15-year follow-up of EORTC 22922 was recently published in 2020.[119] While any breast cancer recurrence (24.5% vs 27.1%, *P* =.02) and breast cancer mortality (16.0% vs 19.8%, *P* =.0055) were significantly decreased in the IM-MS RT group compared to the control group, there was no significant difference in OS (73.1% vs 70.9%, *P* =.36), DFS (60.8% vs 59.9%, *P* =.18), and metastasis-free survival (70.0% vs 68.2%, *P* = .18). There was an imbalance in missing data regarding the cause of death and non-breast cancer–related deaths in the treatment arm that may play a role in the lack of OS difference. Of note, death from cardiovascular disease was the same (1.4%) in both arms.[119] As most patients in the trial had early-stage disease, it is unclear if outcomes would have been different with a higher risk cohort.

In summary, the meta-analyses and randomized PMRT trials with 15- to 20-year follow-up and the more recent trials of RNI after BCS or mastectomy with 10-year follow-up have advanced our insight into the role of RT in the management of patients with operable breast cancer with involved axillary nodes. Although LABC is a heterogeneous entity, consistent improvements in outcomes reported across these trials support the use of locoregional RT as a component of management for these patients, a population with high risks of LRR and distant recurrence. When used in conjunction with systemic therapy, RT can optimize locoregional and distant disease control, reduce the morbidity of uncontrolled cancer progression, and provide incremental improvements in survival. That said, it is not clear if these results will persist into the modern era of more effective systemic therapy.

Internal Mammary Nodal Irradiation

There has been controversy regarding indications for specifically targeting of the IMN. Historically, studies of extended radical mastectomy have identified IMN metastases in a significant proportion of patients with LABC, particularly in association with extensive nodal disease and central or medial tumor location.[121] An older, large multicenter trial that randomized patients to radical mastectomy versus extended radical mastectomy with surgical removal of the IMN was not found to improve survival or recurrence outcomes,[122] and isolated IMN recurrences are rare at approximately 0.1%.[123] While patients with clinically or pathologically involved IM LNs clearly warrant RT targeting the IMN, the role of IMN-directed therapy in patients without evident IM nodal involvement has been less clear. It is noted that in all of the randomized trials that demonstrated benefits with RNI, the IMNs were routinely included in the target volume. Although the benefits observed with RNI in these trials may be attributed to the principle of radiation eradicating subclinical disease that may be a source for distant metastasis, it is not possible to assess how much of the benefits observed may be specifically attributed to IMN treatment. Several trials have sought to address this question.

The contribution of IMN-directed RT has been examined in several trials. A French multicenter prospective trial attempted to evaluate the impact of specific IMN targeting in patients undergoing total mastectomy and axillary dissection.[124] From 1991 to 1997, 1,334 patients with stages I to III disease were enrolled, at least 30% of whom had LABC. All subjects received radiation with two-dimensional (2D) planning to the chest wall, supraclavicular, and apical axillary nodes, with randomization to radiation to the IMN in the first five intercostal spaces to 50 Gy versus no IMN inclusion. Ten-year OS rates were 62.6% in the IMN-treated group and 59.3% in the control group, but this difference was not statistically significant ($P = .8$).[124] Although the trial attempted to address an important question, its design was limited. The sample size was calculated to detect a 10% difference in 10-year OS, an expectation inconsistent with the finding from the EBCTCG meta-analysis that the survival benefit with PMRT was approximately 4% to 5%.[114] The trial was, therefore, underpowered to detect a small survival difference. Other limitations include the use of 2D planning and limited information on late-term toxicity, further limiting the trial's applicability to modern practice. That said, there was no significant difference in late-term cardiac events between groups.[124]

The DBCG-IMN study, a prospective population-based cohort study with 3,089 patients with node-positive breast cancer, provides additional insight into the effect of IMN-directed RT.[125,126] Forty percent of patients had pN2-N3 disease (ie, LABC). In this study, all subjects received whole breast or chest wall irradiation plus RT to the supraclavicular, infraclavicular, and axillary level II and III nodes to 48 Gy in 24 fractions. Patients with right-sided disease were treated with IMN irradiation, and patients with left-sided disease were not. At a median follow-up of 14.8 years, statistically significant improvements in OS (absolute difference of 4.7%), distant recurrence-free survival, and BCSS were observed with IMN irradiation.[126] While subgroup analysis found a larger benefit for patients with higher risk cancers (≥4 involved LN, medial/central tumors), all subgroups benefited from IMN irradiation and the test for heterogeneity was not significant. Cardiac-specific mortality was not elevated in the IMN-treated group, and there were no statistical differences in risk of non-breast cancer death.[126] While the study was nonrandomized, the decision to treat was made based only on laterality, which provides a reasonable randomization framework with balanced characteristics between the two study groups.[125] It is important to consider that enrollment predated the use the taxane chemotherapy as standard adjuvant therapy; however, all pN2 and N3 patients received chemotherapy.[126]

The Korean Oncology Group (KROG) 08-06 study is a multicenter randomized phase III trial investigating the role of IMN irradiation in women with node-positive breast cancer after BCS or mastectomy and ALND with the primary end point of 7-year DFS.[127] Enrollment was 2008 to 2013, and patients who received neoadjuvant systemic therapy were excluded. A total of 735 patients were enrolled. Of the subjects, 58.6% had pN2-3 disease. All patients received whole breast/chest wall and supraclavicular nodal irradiation to 45 to 50.4 at 1.8 to 2 Gy using CT-based planning. Nearly all patients were treated with taxane-based chemotherapy. The 7-year DFS did not demonstrate a

significant difference between the two groups (81.9% without IMN irradiation and 85.3% with IMN irradiation, $P = .22$). There was also no significant difference in breast cancer mortality rates and distant metastasis-free survival. Ad hoc subgroup analysis showed significantly improved DFS (hazard ratio 0.42, 5% CI 0.22-0.82, $P = .008$), lower breast cancer mortality rates (10.2% vs 4.9%, $P = .04$), and distant metastases-free survival (hazard ratio 0.44, 95% CI 0.23-0.85, $P = .01$) with IMN irradiation for patients with mediocentral tumors. There was no significant difference in cardiac morbidity and a nonsignificant difference in radiation pneumonitis between the two study groups. There were no cases or grade 3 or higher radiation pneumonitis among all patients.[127]

While KROG 08-06 suggests that IMN irradiation should be abandoned, the study was highly underpowered to detect a 10% difference in DFS. It does, however, provide reassurance that pulmonary and cardiac toxicity is low with modern CT-based treatment planning. As mentioned, an unplanned subgroup analysis did show a benefit to IMN-directed irradiation in the setting of mediocentral tumors.[127]

Based on the inclusion of IMN irradiation in all major trials in support of RNI in the setting of node-positive disease following surgery, the compelling data from the DBCG-IMN trial, and the low levels of toxicity seen with modern treatment planning techniques in the KROG 08-06 trial, the IMN should be included in the treatment fields for most patients with LABC. That said, the decision to include IMN-directed therapy should be made on a case-by-case basis. There should be strong consideration for IMN-directed RT with higher risk disease (T4/IBC, N2/N3, higher grade, medially or centrally located tumor) balanced with the risk of cardiovascular and pulmonary toxicity as seen in the dose distribution after optimal RT plan design.

Omission of Regional Nodal Irradiation

The Canadian Center Trials Group (CCTG) MA.39 trial called TAILOR RT: A Randomized Trial of Regional Radiotherapy in Biomarker Low Risk Node Positive and T3N0 Breast Cancer is an example of investigation of de-escalation of RT based on biologic subtype and cancer genomics to provide personalized medicine.[128] This trial is investigating omission of RNI in women with pT3N0 or pT1-2N1a disease with nonmetastatic invasive breast cancer, ER-positive and Her2-negative status post-BCS, or mastectomy with axillary surgery demonstrating low- volume nodal disease (1-3 positive nodes with ALND or 1-2 positive nodes with SLNB) with a low-risk Oncotype DX Recurrence score of 25 or less who have not received neoadjuvant chemotherapy, although limited neoadjuvant ET is allowed. The Oncotype DX Recurrence score is a genetic assay that measures expression of 21 genes within the tumor and provides a score from 0 to 100 that is indicative of the risk of distant metastases in patients with early-stage HR-positive breast cancer who are taking tamoxifen.[129] Although there is some nuance, an Oncotype DX Recurrence score of 25 or less is predictive of a lower risk of distant metastasis and less benefit from chemotherapy. MA.39 randomizes patients to receive whole-breast irradiation (following BCS) or no RT (following mastectomy) on arm 1 or whole-breast/chest wall irradiation plus RNI (including the supraclavicular,

nondissected axillary, and IM LNs). The primary end point is breast cancer recurrence-free interval. This trial continues to accrue. While MA.39 is not applicable for patients with LABC (defined as stage III), it is noteworthy as it represents the future direction of our field.[128]

LOCOREGIONAL RADIATION THERAPY AFTER NEOADJUVANT CHEMOTHERAPY

Treatment with neoadjuvant chemotherapy (plus anti-HER2 agents and immunotherapy when appropriate) is well established and recommended for all patients with LABC. Neoadjuvant systemic therapy provides the potential for disease downgrading, which may allow for BCS and/or less extensive axillary surgery. As discussed previously, the use of neoadjuvant systemic can provide information on tumor response to chemotherapy, which provides valuable information that can affect subsequent systemic therapy treatment recommendations. Landmark trials and choice of systemic agents are discussed in detail in the section "Overview of Treatment Approaches." Data regarding the role of RT and treatment field design in the setting of neoadjuvant systemic therapy are limited.

Retrospective Data of Local-Regional Recurrence Following Neoadjuvant Chemotherapy and Mastectomy With or Without Postmastectomy Radiation Therapy From MD Anderson

MD Anderson has published several retrospective studies regarding outcomes for patients who have undergone neoadjuvant chemotherapy. In these series, locoregional RT encompassed the chest wall, IMN, and undissected lymphatics in the supraclavicular and axillary regions.

In one series, Huang et al[130] retrospectively compared 542 patients treated with neoadjuvant chemotherapy and mastectomy with PMRT to 134 patients treated with neoadjuvant chemotherapy and mastectomy without PMRT. At 10 years, PMRT was associated with reduced LRR (11% vs 22%, $P = .0001$). Of note, the patients who received RT had statistically significant higher risk disease in regard to upfront clinical stage, response to neoadjuvant chemotherapy, number of pathologically positive nodes, and margin status. Patients with clinical stages III to IV disease and pCR who received PMRT had lower rates of LRR at 10 years compared to counterparts who did not receive PMRT (3% vs 33%, $P = .006$). (Stage IV patients had supraclavicular involvement as per AJCC staging 1988.) While there was no statistical difference in 10-year OS (54% with PMRT vs 47% without PMRT, $P = .063$) and cause-specific survival, on univariate analysis, there was a statistically significant OS benefit to PMRT for patients with clinical stage IIIB or higher (42% vs 20%), clinical T4 tumors (42% vs 20%), and more than four involved LNs at surgery (38% vs 15%, all $P < .0002$).[130]

McGuire et al[131] reported a series of 106 patients without IBC treated at MDACC who achieved pCR after NAC and mastectomy. Patients with stages I to II disease with pCR who were treated with PMRT did not experience LRR. The 10-year LRR rate among

patients with stage III disease who had pCR treated with PMRT was 7.3%, compared to 33% without PMRT (P = .04). These findings support the use of PMRT, even in the setting of a pCR. Patients with stage III disease also experienced significantly improved rates of distant metastasis-free survival, cause-specific survival, and OS (77.3% ± 6% vs 33.3% ± 14%, P = .0016).[131]

Despite selection biases inherent in retrospective studies, these contributions from MD Anderson were instructive in highlighting the finding that patients with locally advanced or T3N0 disease, despite having pCR to NAC, still have high LRR risk in the absence of PMRT. This supports the concept that PMRT decision-making must take prechemotherapy disease extent into strong consideration. In addition, PMRT was shown to have a survival benefit for patients with LABC following neoadjuvant chemotherapy and surgery. These studies indicate that PMRT has a very important role in the treatment paradigm for these patients.

NSABP B-18 and NSABP B-27 Combined Analysis of Recurrence Patterns After Neoadjuvant Chemotherapy and Mastectomy

Prospective data regarding RT for LABC in the setting of neoadjuvant chemotherapy and surgery for breast cancer are limited. As discussed previously, the NSABP B-18 and NSABP B-27 randomized trials investigated the use of neoadjuvant chemotherapy with AC alone or followed by neoadjuvant/adjuvant docetaxel.[22,132] These trials did not permit the use of chest wall/RNI after mastectomy or RNI after BCS. Trial participants had operable cT1-3N0-1 breast cancer. Patients with T4 or N2/3 disease were not included. Surgery included modified radical mastectomy or lumpectomy and ALND. In the combined analysis with 3,088 patients (1,947 mastectomy and 1,100 BCS), the 10-year cumulative incidence of LRR after mastectomy was 12.3% and 10.3% after breast-conserving therapy (8.1% local and 2.2% regional).[133] The 10-year LRR risks after neoadjuvant systemic therapy and mastectomy according to pretreatment clinical stage and postneoadjuvant chemotherapy pathologic response are summarized in Table 63.3. Among patients treated with mastectomy, independent predictors of LRR were clinical tumor size (>5 cm), clinically node-positive disease, and lack of pCR in the breast or nodes. In the setting of pathologic node-positive disease after NAC and mastectomy, LRR risks ranged between 11.2% and 22.5%, a risk magnitude at which locoregional RT should be considered. Interestingly, in patients with clinically node-positive disease before NAC but who achieved pCR at mastectomy, the LRR rate was 0% at 10 years, suggesting that this may be a favorable-risk subset in whom PMRT avoidance may be studied in a clinical trial setting. In patients with clinically node-positive disease treated with breast-conserving therapy who had pathologically involved LNs at surgery, the risk of regional nodal recurrence was approximately 7% to 9%, supporting consideration for RNI.[133] Although the NASBP combined analysis provided useful data from a large patient cohort documenting the 10-year LRR risks without adjuvant PMRT or post-BCS RNI after neoadjuvant systemic therapy, interpretation of these results in the modern context is

limited as the study was conducted before the era of more effective chemotherapy and targeted anti-HER2 therapy.

TABLE 63.3 SUMMARY OF RESULTS OF THE NSABP B-18 AND NSABP B-27 COMBINED ANALYSIS OF 10-YEAR RISK OF LOCOREGIONAL RECURRENCE AFTER NEOADJUVANT CHEMOTHERAPY IN PATIENTS TREATED WITH MASTECTOMY[133]

	ypN0; Breast pCR		ypN0; No Breast pCR		ypN+; Any Breast Response	
	N	10-y LRR (%)	*N*	10-y LRR (%)	*N*	10-y LRR (%)
≤5 cm; cN0	46	6.5	178	6.3	184	11.2
>5 cm; cN0	16	6.2	95	11.8	179	14.6
≤5 cm; cN+	21	0	37	10.8	143	17.0
>5 cm; cN+	11	0	33	9.2	128	22.5

cN0 or cN+, clinically node-negative or node-positive before neoadjuvant chemotherapy; pCR, pathologic complete response; ypN0 or ypN+, pathologically node-negative or node-positive after neoadjuvant chemotherapy.

Until additional data from more modern prospective trials become available, the outcomes derived from available institutional series and the NSABP B-18 and NSABP B-27 combined analysis[133] support the position that PMRT should be recommended after neoadjuvant chemotherapy and mastectomy and ALND for patients presenting with stage III disease. Off trial, PMRT including RNI to the undissected axilla, supraclavicular fossa, and IMNs is recommended even if the patient is rendered pathologically node negative after neoadjuvant systemic therapy.

Additional Studies Examining the Role of Radiation Therapy After Neoadjuvant Systemic Therapy

Since the publication of the combined analysis of the NSABP B-18 and NSABP B-27 trials,[133] other investigators have examined the impact of PMRT or post-BCS RNI in patients with clinically node-positive disease treated with neoadjuvant systemic therapy. In an analysis of 15,315 patients identified in the National Cancer Database with cT1-3cN1 disease, stratified into four subgroups by the type of surgery and pathologic nodal status after neoadjuvant chemotherapy (ypN0 vs ypN+), the use of PMRT was associated with improved OS for all pathologic nodal subgroups (ypN0, ypN1, and ypN2-3, all $P < .05$), whereas the addition of post-BCS RNI to breast RT was not associated with OS differences.[134]

Interesting reports have also emerged suggesting that molecular subtype correlates with recurrence rates. For example, investigators at *Memorial Sloan Kettering Cancer Center* retrospectively analyzed outcomes for 233 patients who received neoadjuvant systemic therapy, mastectomy, and PMRT between 2000 and 2009.[135] 74% of patients received trastuzumab. Following neoadjuvant systemic therapy, all patients underwent mastectomy and 99% of patients underwent ALND. The 5-year LRR rate was 0% for patients with

pCR compared to 9% without pCR (P = .05). A higher rate of LRR was associated with triple-negative disease (20%) compared to HER2-positive (6%, P = .005) and HR-positive disease (4%, P = .005). Pathologic node positivity was associated with a significant increase in LRR (hazard ratio 4.4, P = .003).[135] Investigators from MD Anderson also found that patients with triple-negative disease, clinical stage III disease, and failure to reach a pCR were associated with a higher rate of LRR. Of note, these patients received modern systemic therapy agents.[136]

Ultimately, prospective trial data are needed to address the role of locoregional RT after neoadjuvant systemic therapy and surgery. Two North American multicenter trials are underway for patients with biopsy-proven node-positive disease before neoadjuvant systemic therapy. The NRG Oncology Group 9353 (NSABP B-51/RTOG [Radiation Therapy Oncology Group] 1304) trial, initiated in 2013, randomizes patients with clinical T1-3, N1 breast cancer of all biologic subtypes (after fine-needle aspiration cytology or core biopsy confirmation of nodal involvement) who undergo neoadjuvant systemic therapy followed by mastectomy or BCS and axillary dissection or SLNB with two or more LNs removed and have pathologically negative nodes, to either no radiation or PMRT to the chest wall and regional nodes following mastectomy or radiation to the breast or breast plus RNI following BCS (ClinicalTrials.gov identifier NCT01872975).[137] This trial enrolls patients with all biologic subtypes. The Alliance for Clinical Trials in Oncology A011202 trial randomizes patients with a positive sentinel node biopsy after NAC to axillary dissection versus axillary RT without axillary surgery (ClinicalTrials.gov identifier NCT01901094). This trial is closed to accrual, and we are awaiting the results. These trials will provide valuable data to improve our understanding of the role of locoregional radiation after neoadjuvant chemotherapy for patients with limited node-positive disease. Unfortunately, randomized trials and prospective data in the setting of LABC are sparse.

Based on the abovementioned data, PMRT or whole-breast irradiation plus RNI is recommended in the setting of cT4 tumors, cN2-N3 disease, and pathologically involved LNs after neoadjuvant systemic therapy and surgery. Postsurgical RT decisions following neoadjuvant systemic therapy are generally made based on the maximum clinical stage prior to systemic therapy as well as pathologic stage at definitive surgery. Radiation field should encompass the breast or chest wall, the supraclavicular nodes, the IMNs, and the undissected axilla.[138]

RADIOTHERAPY PLANNING AND TECHNIQUES FOR LOCALLY ADVANCED BREAST CANCER

Most patients with LABC will receive RT in the postoperative setting on a linear accelerator (LINAC) with high energy photons and, at times, electrons, using 3D treatment planning with the goal of delivering the prescribed dose to the target volumes while sparing uninvolved tissues, especially the OARs including the heart, lungs, and contralateral breast. Treatment fields in the setting of LABC typically encompass the breast (after BCS) or chest wall (after mastectomy), the supraclavicular fossa, the

undissected axilla, and the IMN chain. Conformal 3D treatment planning and delivery are facilitated by tools such as CT simulators, computerized treatment planning software, and onboard imaging systems. It is now widely recognized that the techniques utilized in the early breast conservation therapy and PMRT trials using cobalt machines and older radiation delivery techniques unintentionally subjected patients to excessive doses to normal tissues with the associated risks of cardiovascular, pulmonary, and soft tissue complications including cardiac-related deaths (in left-sided treatment) and secondary malignancies. As evident in the evolution of trials in the setting of chest wall or whole-breast irradiation with RNI, the toxicity profile of RT to the breast/chest and regional nodes has markedly improved.

With improvements in treatment planning and delivery, the benefits of radiation for locoregional and disease-free outcomes for breast cancer after BCS and mastectomy have resulted in a small but significant survival benefit.[114,115,139-142] Though it is unlikely that modern radiation advances have improved the *absolute* magnitude of the benefits in locoregional control, these technological improvements have resulted in more precise and conformal treatment delivery that better spares normal tissue. In this context, improved techniques have the potential to significantly affect survival outcomes, by shifting the proportions in risks to benefits to ultimately achieve an improvement in the therapeutic ratio. This section examines the traditional tangential and more conformal radiation techniques for breast, chest wall, and RNI. We discuss considerations in target volume delineation, dose prescriptions, optimal dosimetry, and methods of delivery to maximize locoregional control and minimize toxicity.

Simulation

The first step in the treatment planning process is the virtual simulation, which is typically performed with a CT simulator. CT slice thicknesses of 2 to 3 mm should be used. It is important that the patient's treatment position is reproducible each day and that the patient remains immobile during the treatment. Immobilization devices including commonly utilized commercial supine breast boards or prone boards and/or customized molds or casts are used. The standard treatment position for a patient with LABC is supine with the ipsilateral or both arms positioned above the head but may be adjusted as needed for patient comfort, ensuring that the arm(s) do not intercept with treatment beams. It is important to have the soft tissues of the arm cranial to the junction of the tangent and supraclavicular fossa field. Raising the patient's chin and turning the head to the contralateral side can help flatten the skin folds within the supraclavicular fossa and displace the mandible and chin from the treatment fields. Patients are placed on a 10° to 15° angle board to flatten the slope of the chest wall in the region of the sternum. Radio-opaque wires are placed at the superior border (sternoclavicular junction and above palpable breast tissue), the inferior border (2 cm below the inframammary fold or best estimate using contralateral breast as guide if present), the medial border (mid-sternum), and the lateral border (midaxillary line) to use as guides when treatment planning. A radio-opaque wire is placed on the mastectomy scar to ensure that it is fully included in

the treatment fields. This will also be helpful if planning and setting up a mastectomy scar boost. Radiation oncologists at some institutions place a radio-opaque marker at any drain sites to ensure their inclusion in the treatment field, although data regarding isolated drain site recurrences in breast cancer are lacking. Figure 63.4 shows a patient undergoing CT simulation with radio-opaque wires at the superior border, lateral border, inferior border, medial border (not shown), and on the mastectomy scar, as well as two small wires placed on the drain sites.

FIGURE 63.4 Photograph of a patient undergoing computed tomography simulation. Radio-opaque wires are visible at the superior border, lateral border, inferior border, medial border (not shown), and on the mastectomy scar, as well as two small wires placed on the drain sites, to help guide treatment planning.

Target Volume Considerations

Treatment field design and target coverage are of the utmost importance in the treatment of patients with LABC. Based on the trials outlined earlier, treatment fields for these patients typically include the breast or chest wall, the SCVs, the undissected axilla, and the IMNs as these were target volumes included in the major studies in the setting of LABC/LNs-positive breast cancer outlined earlier that have found an LRR reduction and improved survival outcomes with the use of RT.

After mastectomy without RT, the most common site of locoregional relapse is the chest wall, occurring in more than 50% of patients who experienced LRR.[143-146] Another common site of LRR is the supraclavicular nodes and axillary apex, representing 20% to 40% of all LRR events.[143-146] Based on these relapse patterns, for patients with LABC who are candidates for locoregional RT, the target volume should encompass at a minimum the entire chest wall, supraclavicular nodes, and the axillary apex/level III, that is the undissected axilla. For patients who have undergone a level I and II ALND, the risk of recurrence in the inferior axilla is low. In an analysis of regional nodal failure patterns in 1,031 patients treated with mastectomy including level I to II axillary dissection and enrolled in five trials doxorubicin-based chemotherapy with no PMRT at MD Anderson,

Strom et al[146] reported that the 10-year rates of recurrence were 3% within the low-mid axilla. The risk of failure in the low-mid axilla was not significantly higher for patients with increasing numbers of involved nodes, percentage of involved nodes, nodal size, or gross extranodal extension. This was a high-risk population with more than 85% having at least one pathologically involved LN and more than 50% of patients with four than four involved nodes at surgery. These findings suggest that radiation targeting the dissected axilla may not be warranted for most patients, when balanced against increased risks of lymphedema and arm morbidity. That said, the risk versus benefit balance has shifted with the increased use of SLNB alone in the setting of LABC following neoadjuvant chemotherapy[56-58]; in this setting, the full axilla (levels I, II, and III) should be deemed target volumes. Following ALND, treatment coverage of the dissected axillary may be considered in certain higher risk situations such as IBC with pathologically involved axillary LNs after neoadjuvant systemic therapy; a large number of pathologically involved axillary LNs (often defined as ≥4 nodes), especially after neoadjuvant systemic therapy; an incomplete axillary dissection (often defined as <10 nodes dissected but varies by institution); a high nodal ratio of pathologically involved axillary nodes to dissected nodes (often defined as >20%); and extensive extranodal extension in the setting of other risk factors. As in all therapeutic decision-making for locoregional irradiation, the estimated risks of regional nodal recurrence and estimated benefits that axillary RT may provide should be carefully balanced against risks of adverse effects including lymphedema, chronic arm morbidity, and brachial plexopathy on a case-by-case basis and per institutional standards.

There are variations in physician judgment regarding which nodal basins require treatment (ie, supraclavicular, IM, axilla). Nevertheless, the vast majority of patients with LABC treated with either BCS or mastectomy have node-positive disease with high LRR risk, and therefore, the ipsilateral supraclavicular fossa and axillary apex (level III) are generally included in the treatment volume. The intentional inclusion of the dissected axilla and IMN is significantly more variable, and decisions regarding their inclusion require individualized consideration.[147,148] Typically, the volume for the IM vessels is within the first three intercostal interspaces, though the depth of the supraclavicular fossa and level III axilla varies greatly depending on individual anatomy and patient habitus. Inclusion of the intended nodal volumes in the clinical target volume (CTV) will ensure that these targets are adequately covered within the desired isodose volumes.

Target Volume Delineation

In the era of 3D treatment planning, consistent delineation of the breast, chest wall, regional LNs, and OAR is critical for accurate assessment of the dose distributions prior to approving a treatment plan. Inadequate delineation of target tissues and OAR can result in the misinterpretation of dose-volume histograms (DVHs) and ultimately influence treatment plan evaluation, which, in turn, may affect patient outcomes and toxicity.[149] The OAR include the heart, ipsilateral/contralateral lung, and contralateral breast as well as the ipsilateral brachial plexus, esophagus, thyroid, and spinal cord.

Significant variations have been reported in contoured volumes among radiation oncologists.[150,151] For example, the RTOG conducted an investigation of interobserver and inter-institutional variability in target and OAR delineation in the setting of breast cancer irradiation including the breast, boost volume, chest wall and all regional LN regions as well as the heart and lungs.[152] There was substantial variability seen with structure overlaps as low as 10% and volume variation as high as 60%. This led to meaningful differences in dosimetric planning and DVH results. To reduce these inconsistencies, several contouring guidelines have been published, with the goal of reducing variability in target delineation.[153-157] For example, the RTOG has established a breast cancer atlas based on target delineation of three illustrative patient cases performed by nine breast radiation oncologists and describes the general principles of contouring for CTVs of the breast, chest wall, axilla, supraclavicular fossa, and IMN regions (Table 63.4).[152,154] Similarly, the European Society Therapeutic Radiation Oncology (ESTRO) has developed a breast-contouring consensus for delineation of the CTV for the breast, chest wall, and regional LN basins, which additionally includes the interpectoral (Rotter) nodes and describes planning target volume (PTV).[153] In addition, the DBCG has published a national guideline and contouring atlas, which additionally provides recommended dose-volume constraints as depicted in Table 63.5.[155] More recently, the Radiotherapy Comparative Effectiveness (RADCOMP) was created for use in the RTOG 3509/3510 protocol that randomizes patients with nonmetastatic breast cancer receiving RNI to photon versus proton therapy.[157,158]

TABLE 63.4 RTOG CONSENSUS DEFINITIONS FOR BREAST CANCER TREATMENT PLANNING

	Breast/Chest Wall	Axilla			Supraclavicular Fossa	Internal Mammary Nodes
		I	II	III		
Cranial	Clinical reference + second rib insertion	Axillary vessels cross lateral edge of pectoralis minor muscle	Axillary vessels cross medial edge of pectoralis minor muscle	Pectoralis minor muscle insert on cricoid	Caudal to the cricoid cartilage	Superior aspect of the medial first rib
Caudal	Clinical reference + loss of CT apparent breast	Pectoralis major muscle insert into ribs	Axillary vessels cross lateral edge of pectoralis minor muscle	Axillary vessels cross medial edge of pectoralis minor muscle	Junction of brachiocephalic-axillary veins/caudal edge clavicle head	Cranial aspect of the fourth rib

	Breast/Chest Wall	Axilla			Supraclavicular Fossa	Internal Mammary Nodes
		I	II	III		
Lateral	Clinical reference/mid Axillary line, excludes latissimus dorsi muscle	Medial border of latissimus dorsi muscle	Lateral border of pectoralis minor muscle	Medial border of pectoralis minor muscle	Caudal: junction first rib, clavicle Cranial: lateral edge of SCM muscle	Encompass the IM/thoracic vessels
Medial	Sternal-rib junction	Lateral border of pectoralis minor muscle	Medial border of pectoralis minor muscle	Thoracic inlet	Excludes thyroid and trachea	Encompass the IM/thoracic vessels
Posterior	Br: excludes pectoralis muscles, chest wall muscles, ribs CW: includes ribs, pectoralis muscles, pleural interface. ribs, chest muscles	Anterior surface of subscapularis muscle	Ribs and intercostal muscles	Ribs and intercostal muscles	Anterior aspect of the scalene muscle	Encompass the IM/thoracic vessels
Anterior	Skin	Plane defined by anterior surface of pectoralis major muscle and lateral dorsi muscle	Anterior surface pectoralis minor muscle	Posterior surface of the pectoralis major muscle	SCM muscle	Encompass the IM/thoracic vessels

CT, computed tomography; IM, internal mammary; SCM, sternocleidomastoid.

TABLE 63.5 EXAMPLE OF DOSE-VOLUME CONSTRAINTS AS RECOMMENDED BY DANISH BREAST CANCER COOPERATIVE GROUP

Organ at Risk	Danish Guideline Dosimetric Parameter
Heart	LAD $V_{20\ Gy}$ = 0% $V_{20\ Gy}$ = 10% $V_{40\ Gy}$ = 5%
Ipsilateral lung	$V_{20\ Gy}$ = 25% (no SCNI) $V_{20\ Gy}$ = 35% (with SCNI)

Organ at Risk	Danish Guideline Dosimetric Parameter
Spinal cord	Max 45 Gy
Brachial plexus	Max 54 Gy
CTV	CTV_{max}: $V_{107\%}$ = 53.5 Gy
PTV	Max dose outside PTV = 54 Gy

CTV, clinical target volume; LAD, left anterior descending artery; PTV, planning target volume; SCNI, supraclavicular nodal irradiation.

Reprinted with permission from Nielsen MH, Berg M, Pedersen AN, et al. Delineation of target volumes and organs at risk in adjuvant radiotherapy of early breast cancer: national guidelines and contouring atlas by the Danish Breast Cancer Cooperative Group. *Acta Oncol*. 2013;52(4):703-710.

Typically, in early-stage patients, the pectoralis muscle, chest wall muscles, and ribs may be excluded when contouring the breast; but for locally advanced cases, the chest wall and ribs should be included in both the breast conservation and mastectomy setting.[154] In the case of LABC, it is important to note that the abovementioned guidelines can be used as a starting point for contouring but require individual adaptation based on the extent of the primary tumor and the LN involvement. An evaluation of the RTOG Breast Cancer Atlas in the setting of LABC analyzed the validity of the atlas for patients with initial axillary nodal involvement who underwent neoadjuvant chemotherapy.[159] Of the 30 patients included in the study, 100%, 93%, and 37% had clinical involvement of axillary levels I, II, and III, respectively. In 97% of the patients, part of an involved LN was located outside the recommended anatomic borders of the axillary levels. In over 80% of patients, tumor extension was seen outside at least one of the borders of level I, ranging from 0.24 to 3.58 cm. In 80% of patients, tumor extension was seen outside the caudal border of level II (1.36 ± 1.0 cm, range, 0.27-3.86 cm), The authors state the RTOG guidelines may not sufficiently cover the axilla in patients with cN+ disease who have undergone neoadjuvant systemic therapy and incomplete axillary dissection and/or will be treated with intensity-modulated radiation therapy (IMRT). Fusion of pretreatment imaging within the treatment planning system to guide contouring and planning is recommended in these settings.[159]

The differences between the RTOG, ESTRO, and RADCOMP atlases are thoroughly described in a manuscript by Logandale et al[158] from the international TransAtlantic Radiation Oncology Network. Three main differences in regard to nodal CTVs were seen between the atlases. First, the cranial border for the supraclavicular CTV was higher for the RTOG/RADCOMP atlases, with the border at the cricoid cartilage, compared to the ESTRO atlas, with the border at the subclavian artery. Next, the posterior neck is given as an optional volume to extend supraclavicular coverage in the RADCOMP atlas. Third, to create the IMN CTV, the ESTRO and RADCOMP atlases have additional margins around the IM vessels while the RTOG CTV consists of only the IM vessels.[154,155,157,158] For patients with more advanced disease (T3-4, N2-3) or who have undergone neoadjuvant treatment, the authors recommend using the RTOG for all target volumes, except for the

IMN, which will get better coverage following the guidelines from ESTRO or RADCOMP.[158]

Ultimately, there are variations in philosophies regarding the target volumes requiring irradiation and the contouring of these volumes for LABC. Often, they are based on specific clinical/pathologic details of an individual case and patient anatomy but can be influenced also by the treating physician's opinions regarding these issues and policies of the treating institution. In the modern era, it is expected that breast/chest wall and nodal target volumes will be contoured to allow for optimal plan design and evaluation of coverage in the DVH.

Treatment Techniques

Various methods to incorporate the regional nodes in the locoregional treatment volume have been described. Older 2D tangential techniques have used bony and soft tissue landmarks to treat the entire breast or chest wall and typically only assessed the dose at the level of the isocenter. In contrast, 3D treatment planning uses CT imaging to delineate the volume and permits dosimetric and volumetric assessment at all levels above and below the central axis. Traditional 3D planning used wedges to attenuate the beam depending on the slope and thickness of the breast or chest wall to achieve a more uniform distribution and match anatomic contour using wedge-shaped pieces of metal in the head of the machine. Wedges have largely been replaced by 3D conformal radiation therapy (3DCRT) using a dynamic field-in-field technique to be discussed in detail in this chapter. When electron beams are used, such as for IMN treatment or delivery of a "boost" to the tumor bed after BCS or, in selected cases, the mastectomy scar, physical blocks made of Cerrobend or other material are placed in the path of beam in the machine head to deliver a more conformal electron beam dose.

Various forward and inverse planning solutions have been described to generate 3DCRT and IMRT plans that have been shown to significantly improve dose distribution over the standard wedge pair.[160,161] In addition, methods using a combination of both forward and inverse planning have been described and are termed *hybrid plans*.[162,163] Unlike other disease sites such as head and neck and prostate cancer where IMRT, by definition, is inverse planned, for breast treatment planning, the modulation of the tangential beams can be achieved with forward planning, inverse planning, or a combination of both. For this reason, the exact definitions of breast IMRT versus 3D treatment in breast cancer radiation treatment remain broad.[164]

Several forward-planned, "field-within-field" techniques have been described to deliver a more conformal dose by shaping the radiation beam and modulating high-dose regions.[165] Note that in some published investigations, this technique is referred to as "IMRT," although today it is considered a 3DCRT technique using subfields to obtain better dose homogeneity. Initially, the diverging posterior edges of the medial and lateral borders of the tangential beams are aligned to be nondivergent and the fields are weighted and optimized with adjustments to the beam depth, gantry angles, and collimator angles to minimize irradiation to OAR and ensure full coverage of the treatment volume, as in

traditional tangent 3D planning with wedges. Unlike a standard 3D treatment plan with wedges, forward-planned 3DCRT with the field-in-field technique has additional subfields with manually created apertures that are used to block specific hot spots in the original tangential fields. The dose distribution for these tangential fields is typically equally weighted, with open medial and lateral fields, and the normalization point is defined at approximately mid-depth and 1 to 1.5 cm superficial to the deep edge of the chest wall in the plane of the central axis of the beams. Next, the highest dose cloud of the more than 115% isodose curve volume is projected in the beam's-eye view of the treatment fields. A new segment is created using multileaf collimators (MLCs) onto the medial/lateral tangent fields to account for 15% of the dose. This process can then be repeated for the 110% dose cloud, the 107% dose cloud, and so on, typically requiring two to six additional subfields to optimize dose homogeneity, as shown in Figure 63.5.[164,166] When using forward planning techniques, modifications to the weighting of the subfields and mixing of 4 to 6 MV with higher energy photons should be manually adjusted to enhance dose homogeneity, particularly when the patient separation is large.[167] The criteria used for choosing the number of additional subfields are generally based on reducing maximum isodose volumes down to a goal of 107% of the prescription dose or until the PTV coverage starts to break up.

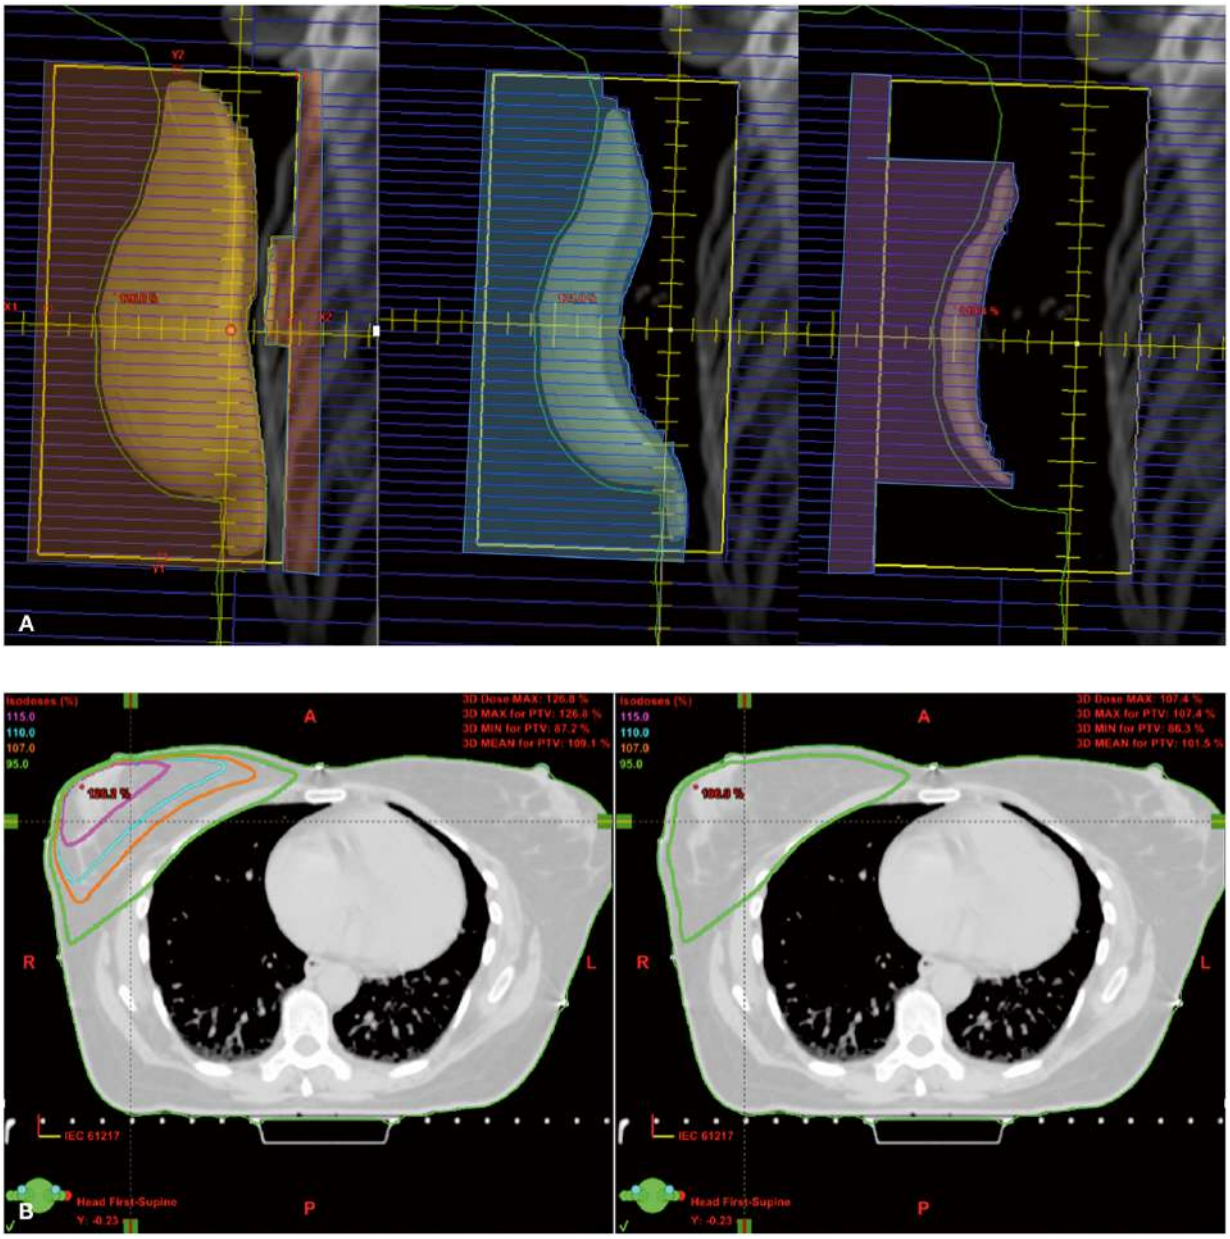

FIGURE 63.5 Field-in-field technique. A. Each segment is created as a subfield of the medial/lateral tangent fields blocking more than 115%, then more than 110%, then more than 107% dose cloud, so on. Typically, two to six additional subfields are used to optimize dose homogeneity. B. Treatment plan showing improvement in dose homogeneity with the addition of subfields. (Courtesy of Gifty Arthur, BS, CMD, Yale New Haven Hospital, New Haven, CT.)

There are now computer programs that assist with field-in-field treatment planning, such as EZFluence (RADformation). Studies have found that EZFluence creates equivalent to improved plans with greater efficiency compared to manually designed field-in-field plans.[168,169] Regardless of the field-in-field technique that is used, a careful review of the treatment plan by the dosimetrist and by the radiation oncologist with attention to the number of subfields is required. Too many subfields can lead to a longer

time on the treatment table, which can lead to increased patient movement and make deep inspiration breath-hold (DIBH) more challenging for the patient. DIBH is discussed in more detail in the section "Cardiac Avoidance Techniques."

With fully inverse treatment planning, that is, IMRT, multisegment fields are created using inverse planning software that makes use of computer-generated intensity-modulated fields by adding dose to particular areas of the breast or chest wall using individually shaped beam portals (segments) that are coplanar to the tangential fields. The inverse-planned IMRT technique uses optimization algorithms to create fluence maps to shape dose distributions[170] and can be performed using a LINAC with either dynamic or static MLCs, arc therapy, or tomotherapy.[171,172] Similar orientations and angles used for forward planning are often used with inverse planning when the intent is to deliver a more homogeneous plan with less dose to the contralateral breast, although noncoplanar beams are often necessary to generate a more conformal treatment plan. The PTV is the same used for the 3D plans plus an extension into the air anteriorly of the chest of 1.5 cm to ensure appropriate opening of the MLC. The dose is prescribed to the PTV, and initial dose-volume constraints are provided. These automated priority-based computer algorithms deliver the prescribed dose to the predefined PTV volume while taking into consideration the relative prioritized dose constraints for normal tissues. Although the use of automated inverse software provides excellent homogeneity and normal tissue sparing, particularly for anatomically challenging cases, a more conformal plan typically requires rotational IMRT techniques (ie, volumetric-modulated arc therapy [VMAT]) or fixed-gantry IMRT techniques using multiple angles and noncoplanar beams, which result in larger volumes of normal tissue structures being exposed to low-dose radiation and potential increased risk of secondary malignancy.[173,174] In addition, due to this low-dose spread, there can be difficulty in achieving heart and lung constraints, particularly with the use of VMAT, which can lead to higher mean heart dose (MHD) and increased lung V_{5Gy}, lung V_{20Gy}, and mean lung doses.[175] IMRT and VMAT expose a larger amount of cardiac and pulmonary tissue to low radiation dose. In this setting, the best metrics to follow to limit potential cardiac and pulmonary toxicity are still being explored.[176] For these reasons, full inverse planning with IMRT/VMAT is generally reserved for more challenging cases. Figure 63.6 shows an example of an inverse-planned IMRT plan treating the chest wall and regional LNs in the postmastectomy setting.

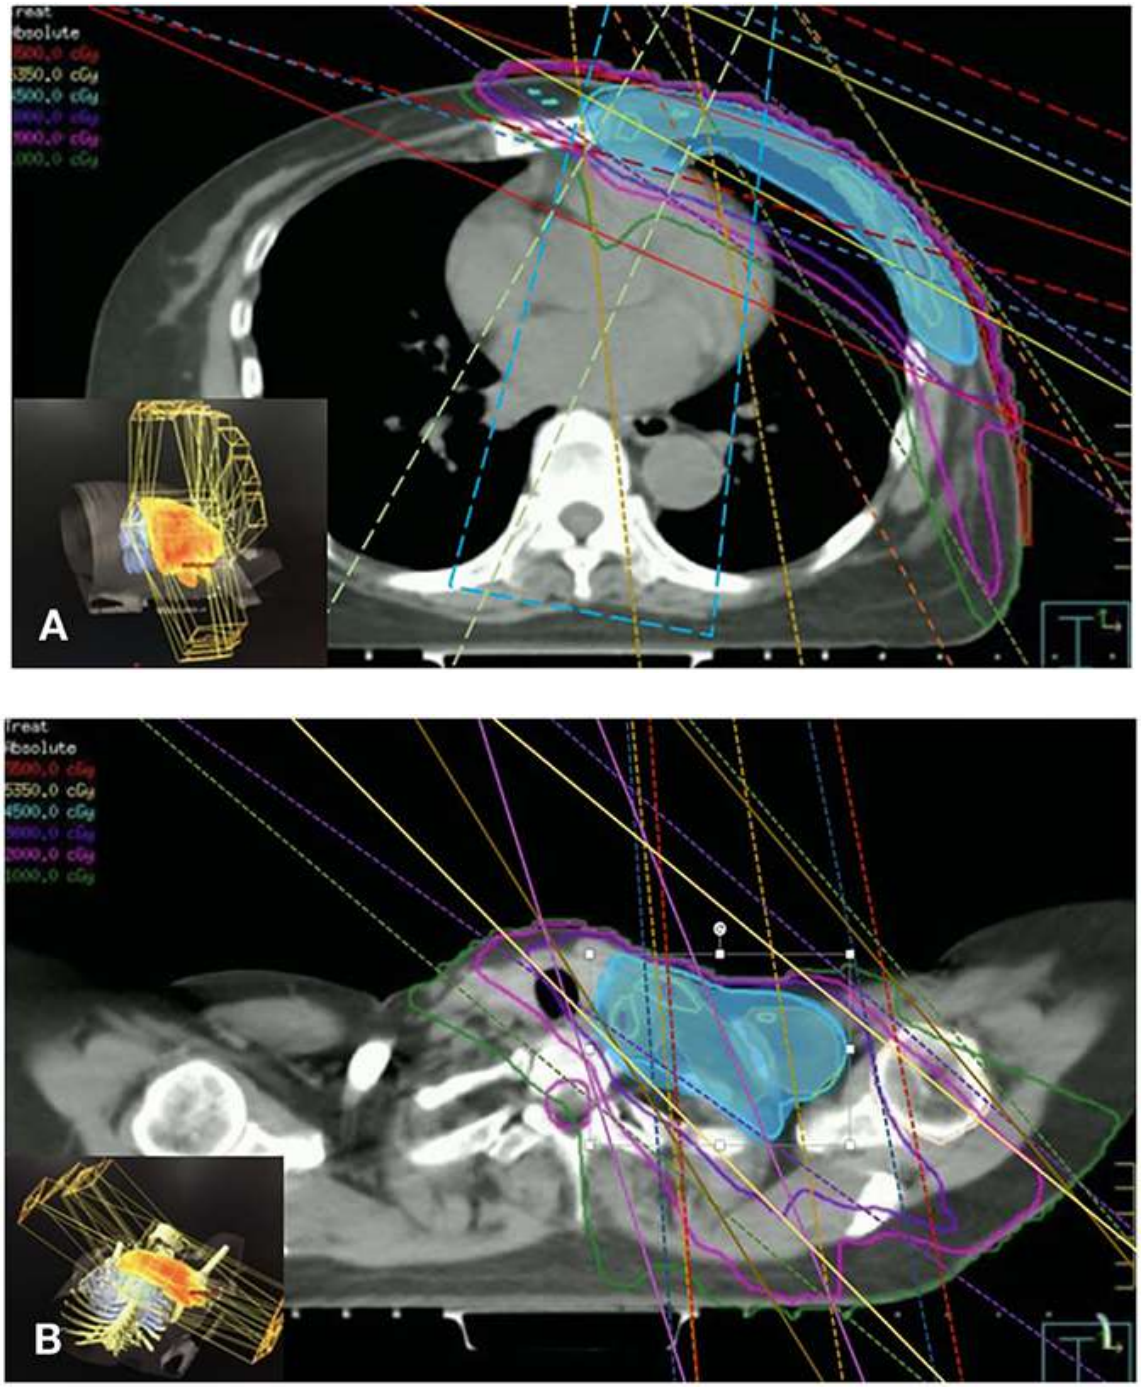

FIGURE 63.6 Inverse-planned intensity-modulated radiation therapy (IMRT) plan of postmastectomy and comprehensive regional nodal radiation. As depicted in *blue*, the prescribed dose is very conformal to the planning target volume, but multiple beams and beam angles are required, resulting in a greater volume of low-dose radiation to normal tissue structures. *Inset* depicts the multiple coplanar beams, resulting in exposure to contralateral and posterior normal tissue. A. Chest wall and internal mammary chain inverse IMRT plan. B. Supraclavicular, high axillary lymph node inverse IMRT plan.

As discussed in detail in Chapters 11 and 20, proton therapy can be more conformal than photon-based therapy techniques due to how protons deposit their dose at the Bragg

peak with a rapid dose fall off. There are limited data on the use of proton therapy in the treatment of breast cancer. Several dosimetric modeling studies have evaluated the potential benefit of decreased cardiac toxicity with proton therapy. For example, one study of 41 patients undergoing breast and RNI in Europe created optimized proton and photon plans for comparative analysis of potential cardiotoxicity using the model put forth by Darby et al.[177,178] Excess absolute risk of cardiac morbidity was small in both groups with median values of 1.0% (range 0.2%-2.9%) and 0.5% (range 0.03%-1.0%) for those with and without cardiac risk factors treated with photons compared to 0.13% (range 0.02%-0.05%) and 0.06% (range 0.004%-0.3%) with for patients with and without cardiac risk factors treatment with protons. The authors conclude that for an individual patient, proton therapy can decrease the risk of cardiac toxicity by up to 2.9%.[177] A prospective phase II study at Massachusetts General Hospital (MGH) enrolled 70 patients who were deemed suboptimal candidates for photon treatment to the breast/chest wall and regional nodes for treatment with photon therapy.[179] In all, 36% of patients had stage III disease. The 5-year LRR rate was 1.5% and OS was 91%. There were no grade 4 or 5 toxicities. In addition, 83% developed grade 2 skin toxicity, and one patient developed grade 2 radiation pneumonitis. Of note, 7% of patients developed rib fracture, which is higher than the reported risk in the modern literature with photon therapy of less than 2%.[180-182]

Although proton therapy has become more widely available in North America over the past decade, the number of centers remains limited requiring many patients to travel and to arrange accommodations to receive treatment.[183] In addition, it is more expensive than photon therapy, and due to a lack of data demonstrating a DFS and OS advantage, insurance coverage may be lacking for certain patients. That said, with its unique dose distribution, proton therapy holds promise in the treatment of LABC with potentially improved dose homogeneity and decreased dose to the cardiac structures and the ipsilateral lung. The results from MGH were used a preliminary data for the RADOMP Consortium Trial (Pragmatic Randomized Trial of Proton Versus Photon Therapy for Patients with Nonmetastatic Breast Cancer: A Radiotherapy Comparative Effectiveness; ClinicalTrials.gov identifier: NCT02603341), a phase III trial comparing photon and proton RT that is currently enrolling patients.[179] This trial will provide valuable data regarding the potential benefits as well as the cost-effectiveness of proton therapy.

Photon 3DCRT with a field-in-field technique is currently the most commonly used treatment technique for RT planning in the setting of breast cancer. For the remainder of this chapter, unless specifically stated, it is assumed that a 3DCRT technique with field-in-field as appropriate is used within the tangent fields. Field-in-field technique can also be used in the supraclavicular field, which is discussed further in the next section.

Coverage of the Supraclavicular, Axillary, and Internal Mammary Lymph Nodes

Supraclavicular and Axillary Lymph Nodes

The SCV CTV should be contoured prior to field design. Treatment of the supraclavicular and superior node basins (III and sometimes level II if targeted) typically requires the addition of a third anterior-posterior (AP) field to deliver a dose to a depth that will adequately cover the supraclavicular and axillary regions. This anterior field is typically angled 10° to 20° to avoid the spinal cord and esophagus as seen in Figure 63.7. In all cases, it is important that the inferior border of the supraclavicular (with or without axilla) field be nondivergent to avoid overlap with the tangents. This can be accomplished using either independent collimator jaws or a half-beam block. A commonly used method is the single isocenter technique, in which the isocenter is identified on the axis conjoining the tangential fields and AP supraclavicular field. The supraclavicular field can have a half-beam block at the inferior aspect of the field. The tangents can be treated with a couch kick that eliminates divergence superiorly. With this technique, the inferior border of the supraclavicular field and the superior border of the tangent fields should match with essentially no overlap. Collimator rotation of the tangents should not be performed to prevent unnecessary overlap. MLCs can be used in lieu of a collimator to create blocking to conform to the slope and shape of the chest wall for the breast/chest wall tangents. Modern treatment planning software has built in features to help facilitate the match between the supraclavicular field(s) and the breast/chest wall tangents.

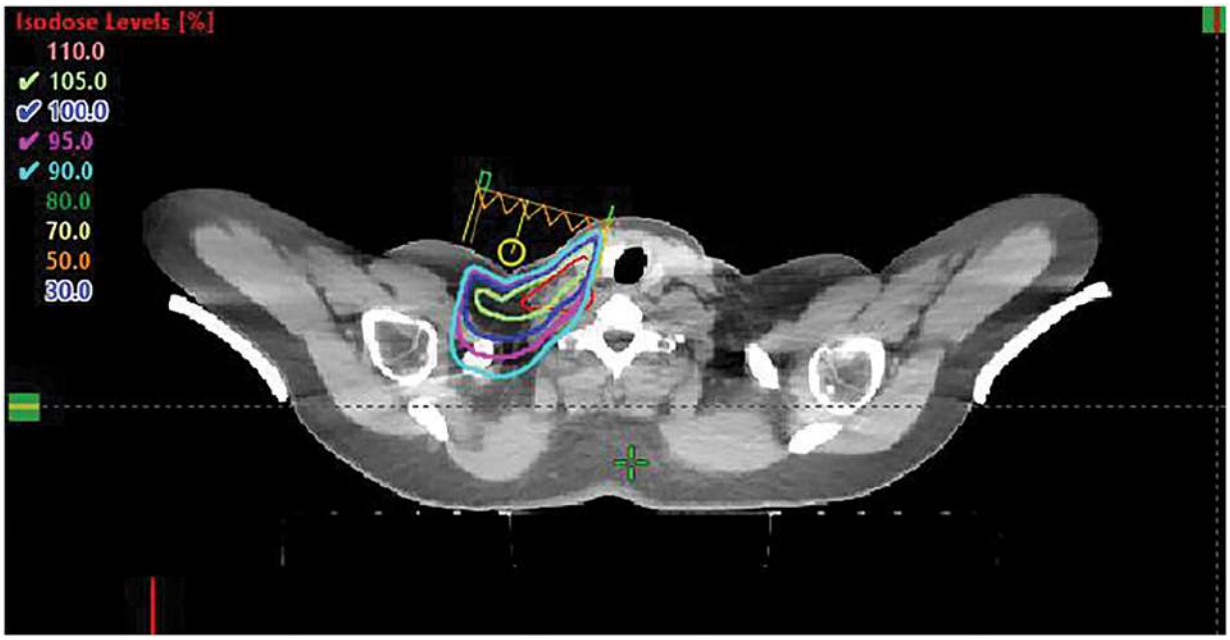

FIGURE 63.7 A left anterior oblique field designed to cover the supraclavicular and level III axillary lymph nodes. The supraclavicular lymph node region is drawn in red. Note that the beam is angled by 15° to avoid the thyroid, trachea, esophagus, and spinal cord.

When the depth of the superior axillary nodes that are included in the supraclavicular field is not adequately covered with the AP photon field, the use of higher photon energy or anterior-medial/posterior-lateral beam arrangement may be considered (ie, opposed

fields). More commonly, an additional posterior-anterior (PA) supplemental field, traditionally referred to as the posterior axillary boost, allows delivery of additional dose to the posterior aspect of the axillary target volume(s).

Axilla I is typically covered well by the tangent fields, although the most superior portion may overlap with the inferior aspect of the supraclavicular field. Axilla level II may be partially covered by the tangent fields and the matched supraclavicular field or be fully within the supraclavicular field (with the potential need of a posterior field to ensure full coverage of the most posterior aspect.) When treating the full axilla, the lateral axillary field border is opened to cover the region between the top of the tangent fields and the humeral head. The abovementioned treatment techniques to ensure coverage of the supraclavicular and designated axillary nodal targets are covered in more detail in the previous chapter.

More challenging is the coverage of the IMN, particularly in patients with left-sided disease, because the heart is located directly below the IMN and inevitably will receive more dose than when the IMNs are not covered. Several commonly described methods for IMN inclusion are described in the subsequent section.

Internal Mammary Lymph Nodes: Partially Wide Tangents

The widely used technique of partially wide tangents, that is, the use of modified tangent fields to include the IMN in the first through the third intercostal spaces while better sparing heart and lung, was described in a seminal publication by investigators from Duke in 1994.[184] This is particularly useful when DIBH techniques are available. The IMNs should be contoured to allow for proper field arrangement and to evaluate dose coverage. Three photon beams are used including the supraclavicular, wide medial and wide lateral tangential fields, with the isocenter at the inferior border of the supraclavicular photon beam. Overlapping the inferior supraclavicular field with the tangents is ensured without divergence using half-beam blocking and prohibiting collimator rotation. As earlier, in lieu of collimator rotation, MLCs can be used to allow the posterior aspect of the breast/chest wall beams to follow the chest wall at the rib cage so that the IMN, breast, and chest wall receive adequate dose while sparing normal lungs. The superior aspect of the medial border is extended onto the opposite breast/chest wall, to ensure that the ipsilateral IMNs are covered. When the wide tangents are arranged with optimized gantry angles and blocking with MLCs to minimize dose to heart and lung, this technique is termed *partially wide tangents*, as depicted in Figure 63.8. This technique avoids the issue of matching fields and, depending on the patient's anatomy, offers a preferred alternative to a separate IMN field in most patients. Care must be taken to ensure complete coverage of all target tissue and the entire chest wall and mastectomy scar in the inferior portion of the field, in the region of the block if a partially wide tangent is used.

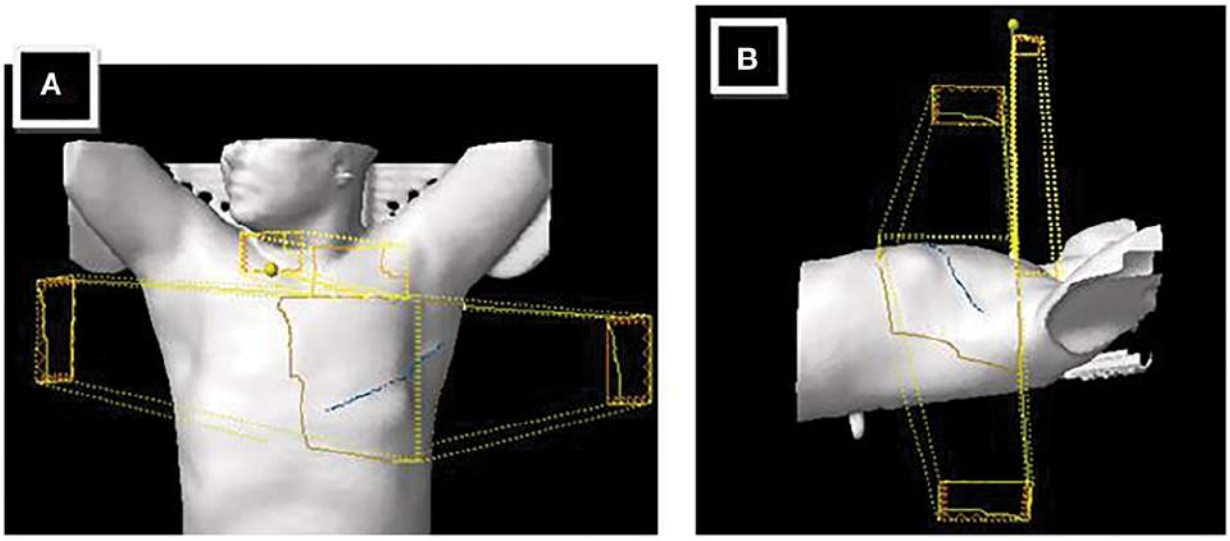

FIGURE 63.8 Skin renderings depicting the radiation therapy fields of a patient treated with postmastectomy radiation therapy using partially wide tangents. A. An anterior view that shows the widened tangents superiorly to cover the internal mammary node in the first three intercostal spaces with blocking inferiorly to better spare organ at risk. The tangent fields are nondivergent superiorly and are matched with the supraclavicular field. B. A left lateral view. The mastectomy scar is nicely included within the tangent fields.

Photon/Electron Matching Techniques

The use of an electron field to treat the IMN that is matched to the medial aspect of breast or chest wall tangents is an older technique that may be considered when attempts to encompass the IMN in partially wide tangential fields result in excessive heart and lung exposure and when DIBH techniques are not available or successful. The supraclavicular and tangential photon fields are created using the standard single isocenter, three-field technique described earlier. An IMN field using an electron beam is matched on the skin to the medial tangential field, with the medial tangential border moved laterally so that it does not include the IMN. Traditionally, IMN portals have been 5 to 6 cm in width, extending from midline medially, just below the clavicular head superiorly to include the first three intercostal spaces, with the inferior border at the fourth interspace, but should be tailored 3D based on the CT contour.[164] The electrons may be a combination of two electron beam energies, a higher energy superiorly to provide full coverage to the IM region at risk, whereas lower energy electron beams are used at the inferior portion to encompass the breast/chest wall while better sparing the underlying OAR. The electron IM field can be treated with either electrons alone or a combination of low energy photons and electrons, with a maximum of 50% of the dose being delivered by photons to minimize the dose to underlying heart and lung tissue. One technique is to tilt the gantry angle of the electron field 5° to 15° less than the medial tangent, minimizing the cold triangle just below the skin match of the two fields, and to feather this junction 1 to 3 times during the treatment course. Attempts to limit the cold triangle at the photon-electron match can lead to a hot spot at the match, as seen in Figure 63.9. This treatment technique leads to less homogeneous plans than the use of partially wide tangents and is

less commonly used in the modern era. That said, for certain patients, including patients with left-sided disease who are unable to perform DIBH, this technique may be helpful to decrease dose to the heart.

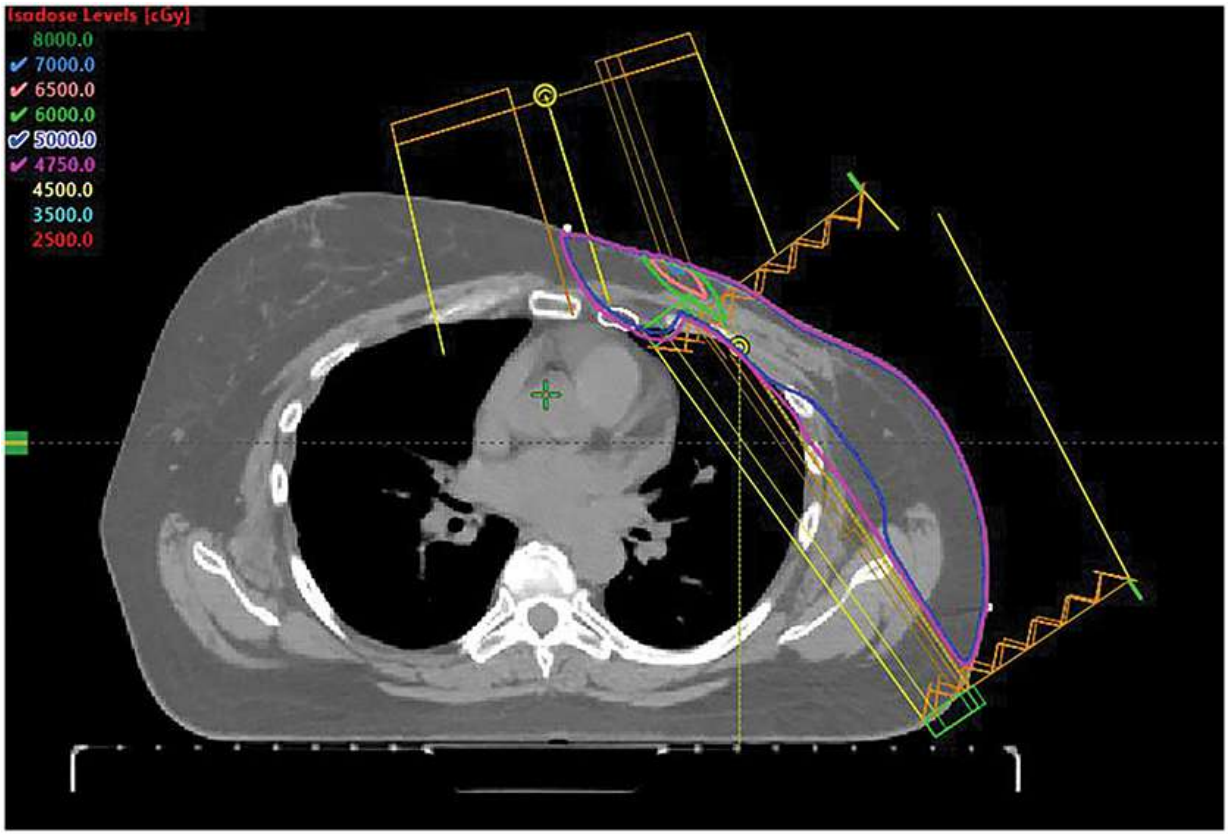

FIGURE 63.9 A radiation plan using a photon-electron matching technique to treat the internal mammary node (contoured in white, white arrow, partially obscured by isodose lines) and chest wall following mastectomy. There is a visible "hot spot" at the match line to avoid a cold triangle posteriorly. This junction was feathered twice during the treatment course.

Intensity-Modulated Radiation Therapy Inverse-Planned Internal Mammary Lymph Node Treatment

As discussed earlier, IMRT planning uses the contoured volumes to define the PTV. The treatment planning software uses a set of procedural guidelines to include specifications of the clinical planning goals to fulfill. Dose constraints for the OAR are prioritized, and the software program automatically generates an optimized treatment plan. Intended dose distributions for targets are achieved while reducing OAR doses with the use of MLCs (dynamic or static), arc therapy,[172] or tomotherapy.[171] Although the development of a plan that will meet heart and lung dose constraints is achievable with inverse-planned IMRT, this typically comes at the cost of spreading low-dose radiation to larger volumes of normal healthy tissue (see Figure 63.6).[173]

Dosimetry, Fractionation, and Dose

Fractionation Schemes

For treatment planning purposes, the breast/CTV volume is defined as clinically demarcated tissue at CT simulation, and the volume may be adjusted to include all glandular breast tissue visualized by CT. In patients with early-stage disease, the breast CTV is typically limited anteriorly to within 5 mm from the skin and excludes the chest wall. In patients with LABC, it is particularly important to contour volumes that correlate with the clinical presentation, pathology, and residual disease, if present when planning treatment. For advanced breast cancer and recurrent disease, it is important to remember that the target delineation guidelines can only be used as a starting point for contouring, but individual adaptation is essential to ensure coverage of all gross disease and tissues at risk.

The recommended dose prescription for whole-breast irradiation for most patients without RNI is 40 to 42.5 Gy in 15 to 16 fractions delivered 5 days per week, with a boost to the tumor bed of 10 to 12.5 Gy in 4 to 5 or 14 to 16 Gy in 7 to 8 fractions for higher risk patients.[185] There are additional fractionation schemes plus partial breast irradiation techniques for early-stage breast cancer that are discussed in the previous chapter. In the setting of LABC, with the addition of RNI, conventional fractionation remains the standard when treating the breast and regional nodes, that is 45 to 50.4 in 1.8 or 2 Gy fractions to all areas with tumor bed boost of 10 to 16 Gy in 5 to 8 fractions. In the postmastectomy setting, standard fractionation is also 45 to 50.5 Gy in 1.8 or 2 Gy fractions to the chest wall and regional nodal targets. A scar or chest wall boost of 10 to 16 Gy in 5 to 8 fractions may be considered. Figure 63.10 shows a postmastectomy scar boost field and dose distribution. The original ASCO postmastectomy guidelines state that there is insufficient evidence to recommend or suggest a scar boost.[186] There is a lack of prospective data regarding the use of a scar boost. One retrospective study of 140 patients who received PMRT to 50 to 50.4 Gy with or without a scar boost found that the use of a scar boost of 9 to 10 Gy was not associated with a statistically significant improvement in LRFS. Ninety four (67.1%) patients received a scar boost, and 46 (32.9%) did not.[187] Interestingly, the use of a scar boost decreased the absolute percentages of local recurrences at 5 years in the setting of high-risk features, including lymphovascular space invasion (LVSI) or positive margin (LRFS of 79.3% with scar boost and 71.1% without) and T3 or T4 tumor (LRFS of 80.9% with scar boost and 71.6% without); however, these differences were not found to be statistically significant.[187]

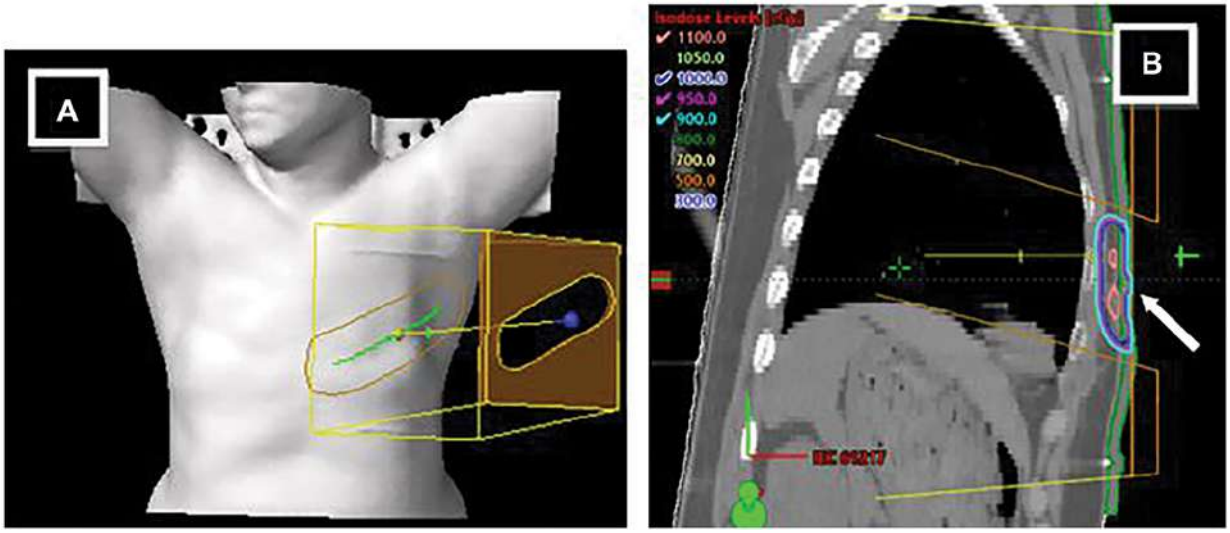

FIGURE 63.10 A. A skin rendering of a postmastectomy scar boost electron field. There is a virtual rendition of the physical electron block that shapes the beam. B. A sagittal view of the dose distribution of the scar boost electron plan. The wire over the scar is contoured in light green (white arrow). There is 0.5 cm of bolus used in this plan (dark green) to ensure adequate skin dose.

Another retrospective study of 746 patients who underwent mastectomy and breast reconstruction of various techniques (autologous reconstruction, single-stage direct-to-implant reconstruction, and two-stage expander implant) analyzed the rate of reconstruction complications including skin necrosis, fat necrosis, and infection in the patients who received a chest wall boost to those who did not.[188] At a median follow-up of 5.2 years, the patients who had chest wall boost had a significantly higher rate of skin necrosis (8% vs 3%, $P < .01$) and infection (13% vs 6%, $P < .01$). The increased risks to patients with implant-based reconstruction were striking. The rates of implant exposure (76% vs 1.76%, $P = .0025$), absolute reconstruction failure (10.18% vs 3.8%, $P < .01$), and overall implant failure with or without salvage reconstruction (34.5% vs 19.3%, $P < .0001$) were all statistically greater for the chest wall boost group. The use of chest wall boost was not found to be beneficial in regard to local recurrence, with a 10-year LRR of 5.4% in the no boost cohort and 4.3% in the boost cohort (nonsignificant). Subgroup analysis did not find an LRR benefit for patients with LVI, close or positive margins, partial response or tumor progression after neoadjuvant systemic therapy, T4 disease, or patients less than 40 years.[188]

In summary, for patients who have undergone mastectomy without reconstruction, a mastectomy scar boost encompassing 2 cm or more around the scar while remaining within the original field borders may be considered for patients with risk factors associated with an increased risk of local recurrence, such as a close or positive margin, epidermal invasion, T4 disease, extensive LVSI, and others. In the setting of IBC, which, by definition, includes the involvement of the dermal lymphatics, a generous scar/chest wall boost is typically given. A chest wall boost is often planned using electrons, although

tangent fields may also be used. In either case, bolus is usually employed. Caution is advised when considering the use of a scar boost in the setting of breast reconstruction.

While the use of hypofractionation to treat RNI is growing, it remains controversial.[189,190] There are limited phase III data regarding moderate hypofractionation treating the breast or chest wall without reconstruction plus the regional nodes. The START-A and START-B phase III randomized trials that investigated moderately hypofractionated RT to conventionally fractionated RT in the setting of BCS of mastectomy without immediate reconstruction for patients with pT1-3a, pN0-N1, M0 disease.[180] Both studies enrolled over 2,000 women. In all, 14% of patients in START-A and 7% in START-B received dedicated RT to the lymphatic regions. Also, 29% of patients in START-A and 23% of patients in START-B had positive axillary nodes. The control arm in both trials received 50 Gy in 25 fractions. The experimental arms in START-A received 41.6 or 39 Gy in 13 fractions over 5 weeks. The experimental arm in START-B received 40 Gy in 15 fractions. START-B included an optional 10-Gy boost in five fractions. AT 10 years, LRR, DFS, and OS were similar between all three arms on START-A. For START-B, the local recurrence rate was 5.2% in the conventionally fractionated arm and 3.8% in the hypofractionated arm ($P = .21$). There was a surprising increase in distant relapse (16.0% vs 12.3%, $P = .014$) and overall mortality (19.2% vs 15.9%, $P = .042$) in the 50-Gy (control) arm. An unplanned subgroup analysis supported the use of moderate hyperfractionation regardless of type of surgery and with inclusion of the regional lymphatics. In analysis of both studies, only one subject developed brachial plexopathy during the 10-year follow-up period. Ischemic heart disease was low (≤1.1%) in both trials.[180] In a detailed examination of arm and shoulder symptoms for patients on the START trials, there was no difference in physician-assessed arm shoulder symptoms between the control arm (50G) and the respective experimental arms (hypofractionated) in both the START-A and START-B trials.[191]

More recently, investigators in Beijing, China, randomized 820 patients with LABC (T3-4 or N2) who had mastectomy with ALND to receive either standard fractionation PMRT (50 Gy in 25 fractions) or hypofractionated PMRT (43.5 Gy in 16 fractions).[192] All patients received chemotherapy. Radiation treatment covered the unreconstructed chest wall, supraclavicular region, and level III axillary region; the level I to II axillary regions and the IMNs were not targeted. The chest wall was treated with 6 to 9 MeV electrons and a 5-mm tissue equivalent bolus. The supraclavicular region was predominantly treated using a 2D technique to a depth of 3 cm beneath the skin. After a median follow-up of 58.5 months, the 5-year cumulative LRR rates were 8.1% for conventional fractionation group and 8.3% for hypofractionation group, indicating the noninferiority of PMRT with hypofractionation ($P < .0001$ for noninferiority). Similarly, DFS and OS did not significantly differ between the arms, at 74% versus 70% and 84% versus 86%. There were no differences in toxicities, except that the hypofractionated patients had less grade 3 acute toxicity than the 50-Gy arm (3% vs 8%, $P < .0001$).[192] The START trials and the Beijing experience also offer data to support the use of moderate hypofractionation to the breast or nonreconstructed chest wall plus regional LNs.

The safety and efficiency of treatment to the IMNs is uncertain as the IMNs were not included in the Beijing trial, and the treatment to the regional lymphatics on the START trials is described as covering the axilla or supraclavicular fossa.[180,192] The FABREC trial, titled Study of Radiation Fractionation on Patient Outcomes After Breast REConstruction, seeks to address these questions. This multi-institutional trial randomizes mastectomy patients with immediate expander and implant placement for whom PMRT is recommended and determined to be medically necessary to the conventional RT arm (50 Gy in 25 fractions to the chest wall with or without IMN, 46-50 Gy in 2-Gy fractions to supraclavicular with or without axillary LNs) or the hypofractionation arm (2.66 Gy × 16 fractions to the chest wall with or without IMN and 2.66 Gy × 15 to the supraclavicular with or without axillary LNs). Patients with stages Tis-T3 and any *N* breast cancer were allowed. Patients with T4 cancers were excluded. Bolus was at the discretion of the treating physician. A boost was not allowed. The trial is closed to accrual. Five-year data were presented at the American Society of Radiation Oncology 2023 annual meeting.[193] At a median follow-up of 31.8 months, the number of distant (8 per arm), local (2 per arm), and regional recurrences (1 per arm) were the same in each arm. Chest wall toxicity was experienced by 19 patients in the hypofractionated arm and 16 patients in the conventionally fractionated arm ($P = .58$). Physical well-being scores were similar between arms, except that patients under 45 years of age were less bothered by side effects of treatment in the hypofractionated arm compared to the conventional fractionation arm ($P = .045$). Of note, people who took unpaid days from work reported requiring fewer hours of time off on the hypofractionated arm compared to the conventionally fractionated arm (73.7 vs 125.8 hours, $P = .046$).[193] These early results are promising; however, further follow-up is needed to more firmly establish the safety and efficacy of hypofractionated PMRT with IMN coverage and/or in the setting of implant-based reconstruction.

RT CHARM: Phase III Randomized Trial of Hypofractionated Post Mastectomy Radiation with Breast Reconstruction is an exciting trial exploring hypofractionated PMRT in the setting of all types of breast reconstruction (ClinicalTrials.gov NCT03414970). The trial closed to accrual in September 2021. The primary objective of the trial is to evaluate whether the reconstruction complication rate at 24 months is noninferior with hypofractionation compared to conventional fractionation. Secondary objectives include to evaluate acute and late-term complications, evaluate local recurrence rate and LRR, and compare complication rates based on the method (autologous with or without implant vs implant only) and timing (immediate vs intent for delayed). Mastectomy with nodal surgery of SLNB or ALND as appropriate is required. Reconstruction can include implant only before radiation, autologous reconstruction (with or without implant) prior to radiation, temporary expander with delayed implant reconstruction or autologous reconstruction, or mastectomy without tissue explained with delayed reconstruction to be performed after RT with implant or with autologous tissues with or without implants. Conventional fractionation PMRT is defined as 50 Gy in 2 Gy fractions to chest wall and/or reconstructed breast and regional nodes, to the undissected

axilla, supraclavicular fossa, and IMN. The hypofractionated PMRT arm received 42.56 Gy in 2.66 Gy fractions to the same target volumes. A boost is not allowed. Patients with T1-T3, N1-N2, M0 disease may enroll. If the patient's disease is converted to pathologically node negative by neoadjuvant chemotherapy, a pretreatment nodal biopsy confirming disease involvement is required. We are awaiting results from this very important trial.

The future direction of PMRT or intact breast irradiation with RNI is heading to even shorter fractionation schemes. The HYPORT-Adjuvant trial (ClinicalTrials.gov NCT03788213), Ontario Clinical Oncology Group Hypofractionated LocoREgional Radiotherapy in Breast Cancer (RHEAL) trial (ClinicalTrials.gov NCT04228991), and the FAST-Forward nodal study are prospective trials investigating the use of ultra hypofractionated radiation in five fractions versus moderate hypofractionation of 40 Gy in the setting of RNI. Information from these trials will provide valuable guidance for the treatment of LABC with RNI.

Radiation Treatment Plan Evaluation

Although standards for dose homogeneity vary across institutions, most 3DCRT planning techniques with inverse field-in-field or other dose modulation typically achieve a plan with a maximum dose of no more than 110% of the prescribed dose to the intact breast. Achieving this level of homogeneity in postmastectomy cases can be more challenging depending upon patient anatomy. In the supraclavicular and upper axillary targets, the "hot spot" is typically higher. With field-in-field, careful choice of beam energy and the selective use of a posterior axillary field, it is usually less than 115% unless there are anatomic challenges; for example, the SCV CTV is particularly deep (>3 cm). While target coverage goals vary by institution and per patient, a common planning criterion is to strive for at least 95% of the target volume (CTV or PTV) to be covered by at least 95% of the dose (ie, $V_{95\%} \geq 95\%$).

For all plans, DVHs of the PTV and OAR of the 3D/IMRT plans should be generated and compared. All attempts should be made to observe dose constraints for OAR, though these parameters vary depending on the volumes targeted and varying protocols. For example, the Danish Breast Cancer Guideline/Atlas suggests that the heart $V_{20\ Gy}$ should be less than 10%, heart $V_{40\ Gy}$ should be less than 5%, and the ipsilateral lung $V_{20\ Gy}$ should be less than 25% using tangents only and less than 35% when a third supraclavicular/axillary field is included[155] (Table 63.5). These dose constraints typically pertain to early-stage disease, and occasionally, despite the use of contemporary techniques in the PMRT setting, left-sided PMRT heart dose constraints may be difficult to meet. Bolus is a tissue equivalent material that increases skin and superficial dose by shifting the 95% isodose line more superficially to the skin and subcutaneous tissues.[194] In an international survey performed in 2004, the use of bolus with PMRT was found to be highly variable.[195] For example, 82% of respondents from the Americas, 31% from Europe, and 65% from Australia reported using bolus daily. There was variability in

application scheduled (33% used it daily, 46% used it alternate days) and thickness, with 35% using bolus of less than 1 cm thickness and 48% using bolus of 1 cm or higher.[195] An international consensus group of multidisciplinary experts in breast cancer initiated by ESTRO published a large systemic review regarding the use of bolus in PMRT.[194] Bolus use led to higher rates of acute grade 3 radiation dermatitis (9.6% with bolus and 1.2% without). Local recurrence rates were 3.5% with bolus and 3.6% without bolus.[194] In 2021, this expert panel published consensus recommendations in which the use of bolus was recommended only for selected cases.[196] The group recommended the use of bolus in cases of high risk of skin involvement/recurrence where the area of concern of not covered by the 95% to 100% isodose line. Indications for bolus include a positive anterior margin without removal of the overlying skin, IBC and preoperative skin involvement (T4b, T4c, and T4d tumors), chest wall recurrence, and in the setting of inoperable breast cancer or fungating mass. The thickness and shape of the bolus should be determined on a case-by-case basis. If the bolus is not found to conform adequately, a custom 3D printed bolus should be considered.[196]

While the expert panel recommended daily bolus,[196] the bolus thickness and schedule can be adjusted based on the dose distribution in the planning system and the level of risk of skin involvement or recurrence. In addition, this must be balanced against the risk of acute toxicity and the impact on the patient's reconstruction, if present. In a high-risk case, such as IBC, bolus should be used daily throughout treatment. The radiation oncologist will often remove the bolus once the skin reaction has become brisk with moist desquamation and discomfort (CTCAE grade 2 skin reaction).[197]

BREAST RADIOTHERAPY AND THE HEART

Cardiac Toxicity With Breast X-Ray Technique

It has been well documented that standard tangential RT fields used for breast cancer consequentially result in irradiation of cardiac tissues, particularly in women receiving left-sided RT, who have been demonstrated to have more cardiac exposure when comparing right-sided versus left-sided breast cancer patients receive RT.[198] It is now established that incidental dose to the heart results in coronary events, such as pericarditis, pericardial fibrosis, diffuse myocardial fibrosis, coronary artery disease, and, in more rare cases, valvular disease.[199] Although breast cancer–related cardiac toxicity typically takes a decade or more years to manifest, there is a dose gradient such that high-dose exposure above 30 Gy results in cardiac complications that become apparent within a year or 2 of exposure, with the risk of cardiac complications increasing with younger age of exposure and the presence of conventional risk factors.[199]

As a direct result of older techniques, cardiac exposure historically mitigated some of the benefits of adjuvant radiation, though more recently, with improvements in technology and treatment planning to sparing normal tissue, more recent meta-analyses in both the breast conservation and mastectomy setting demonstrate the ultimate benefits of radiation in reducing breast cancer–specific mortality.[28,139]

In 2013, Darby et al[178] published a population-based case-control study of women under 70 years of age who were treated with RT for breast cancer. The authors established a connection between the mean radiation dose to the heart (referred to as mean heart dose or MHD) and the likelihood of experiencing a cardiac event. Their findings indicated that in patients treated with pre-3D RT techniques, the RR of an acute ischemic event increased by 7.4% for each additional 1 Gy increase in MHD, without a defined safe threshold. This elevated risk emerged within the initial 5 years following RT and persisted for over 20 years post-treatment.[178] Nevertheless, the study did have certain limitations. As it was retrospective in nature, baseline cardiovascular risk was not available, real dosimetric data were lacking for all patients (MHD had to be estimated), and there were imbalances in comorbidities among the treatment groups. In 2017, van den Bogaard and colleagues validated Darby's model in a patient cohort treated with 3D RT, where actual dosimetric data were accessible. After a 9-year follow-up, they concluded that the cumulative incidence of coronary events increased by 16.5% per Gy of MHD.[200] These and other studies have demonstrated a correlation between MHD and radiation-induced cardiac toxicity and established the importance of reducing the MHD as much as possible in treatment planning. MHD is the most widely used dosimetric constraint used in radiation treatment planning for breast cancer.[176] In the modern era, a cardiac dose of an MHD less than 4 Gy has generally been considered an achievable standard to decrease the risk of radiation-induced heart disease from breast cancer RT.

Cardiac Avoidance Techniques

Efforts have been made to understand how radiation exposure to the cardiac substructures can affect the risk of ischemic and fibrotic heart disease. van den Bogaard et al found a correlation between MHD and adverse coronary events and conclude that the volume of the left ventricle receiving 5 Gy was the most predictive factor for risk.[200] Other investigators have found that strain reduction (change in myocardial fiber length over the cardiac cycle that is a measure of cardiac muscle function)[201] correlated to dose exposure of the left ventricle.[202,203] Marks et al found a greater incidence of new perfusion defects in patients with more than 5% of the left ventricle included in the radiation field.[204] Exposure of the left anterior descending artery to certain dose thresholds has been associated with increased serum levels of troponin-T during RT[205] and with coronary stenosis. There are no clearly defined dose constraints for the cardiac substructures in the treatment of breast cancer currently. While the German Society for Radiooncology has published recommended dose constraints for the left ventricle and the left anterior descending coronary artery,[206] they have not been globally adopted. That said, the importance of limiting cardiac exposure in RT planning is clear.

Heart Blocks

A heart block is one of the oldest and possibly the simplest methods for minimizing heart dose, though it is only technically possible in certain patients in whom the lumpectomy

cavity is readily identifiable to be remote from the heart block (Figure 63.11). The relationship between the tumor(s) to the chest wall is particularly important in the setting of oncoplastic reduction or any situation in which the lumpectomy cavity is ambiguous, to avoid placing the heart block in a location even remotely close to the original tumor(s). With selective and appropriate use of the heart block, the dose to the PTV has been shown to be reduced by only 2.8% and has been demonstrated to have no effect on compromising local control in appropriately selected patients.[207] A heart block is more commonly used when treating the intact breast as opposed to the chest wall.

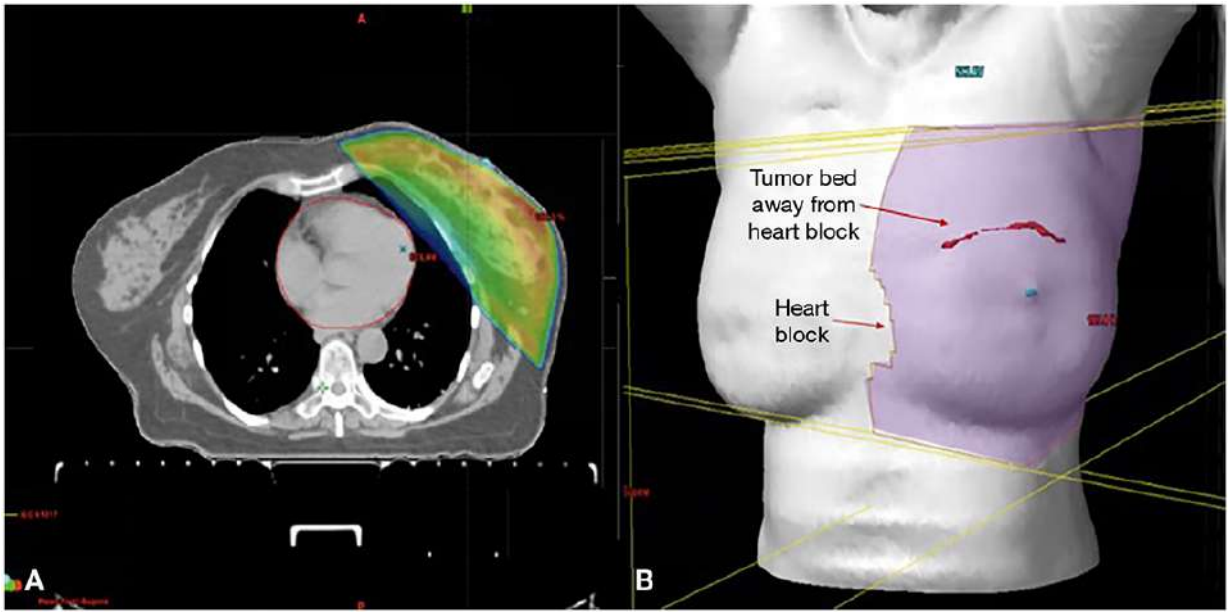

FIGURE 63.11 Multileaf collimators are used to block the heart from the direct beam in the treatment planning software and should be confirmed on the skin rendition clinically on the patient to verify that block placement is away from the tumor bed. A. Axial dose distribution at the level of the heart. B. Skin rendition showing that the heart block placement does not compromise coverage when limited to the cardiac silhouette and tumor bed is remote from the heart block.

Proton Therapy

As discussed in the section "Treatment Techniques," proton therapy is a promising technique for reduction of cardiac exposure during breast/chest wall irradiation, particularly in the setting of RNI. The RADCOMP trial, a prospective phase III randomized trial that randomizes patients to photon versus proton therapy, is currently accruing.

Deep Inspiration Breath-Hold/Respiratory Gating Method

There are several commercially available products for delivering radiation in patients with breast cancer, which synchronize the delivery of radiation with the respiratory cycle. This concept makes use of the normal physiologic inferior and posterior-medial movement of the heart relative to the chest wall when a patient takes (and holds) a deep breath and only

delivers radiation when the patient is in specified portions of the breath (or breath-hold) cycle. This, in turn, reduces the irradiated volume and the dose to the heart. Figure 63.12 shows an example of a DIBH setup that allowed for a meaningful reduction in exposure to the heart. Multiple studies have demonstrated a significant reduction in MHD with the use of DIBH for the treatment of the left-sided breast/chest wall with and without the inclusion of the regional nodes.[208,209] In one study, the percentage of patients with MHD less than 4 Gy went from 56% using the free-breathing scan to 100% using the DIBH scan for planning.[209] While the reductions in cardiac exposure are considerable in most patients with left-sided breast cancers, it is particularly notable that the benefits in decreasing cardiac dose with DIBH appear to be of greater magnitude in patients receiving PMRT, for which treatment planning to minimize cardiac dose can be more challenging because of the need to treat the much larger surgical bed including scars, compared to whole-breast irradiation following BCS.[210]

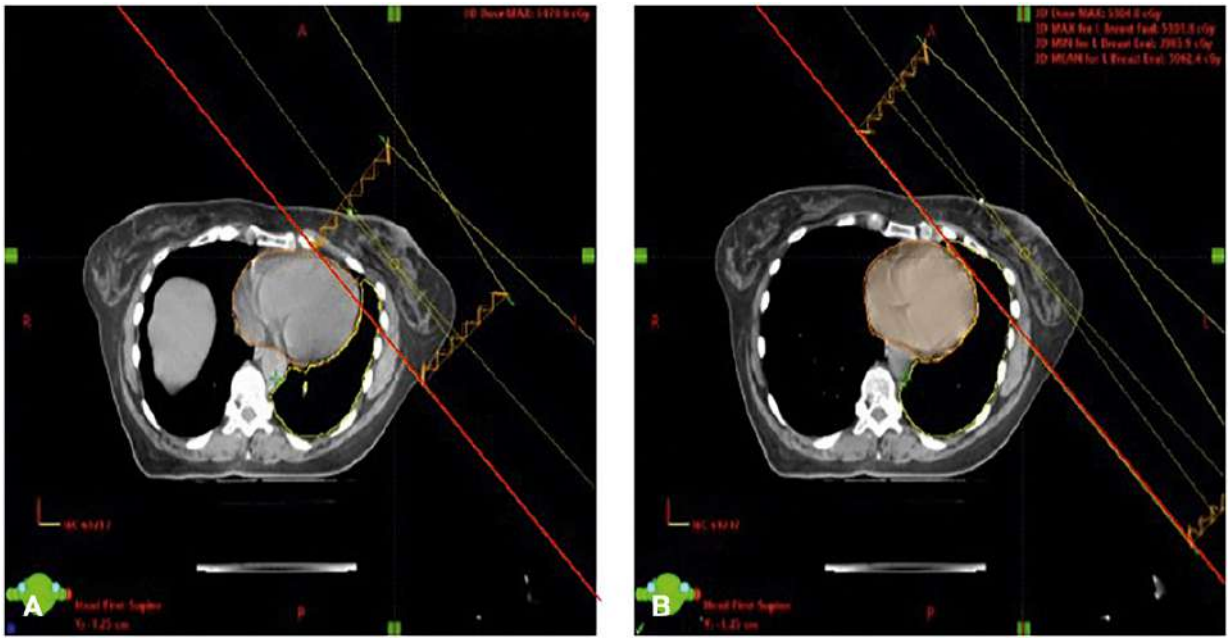

FIGURE 63.12 The use of deep inspiration breath-hold (DIBH) significantly reduces cardiac volume irradiated. A. Free-breathing scan showing tangential beams with a substantial portion of the left ventricle in the radiated field. B. DIBH scan—heart moves away from the chest wall with expansion of the diaphragm. Using the same clinical borders, the mean heart dose was reduced from 377 to 195 cGy (not shown).

The use of DIBH in right-sided breast cancer for the treatment of the breast/chest wall plus RNI has been studied. Investigators in Australia created optimized 3DCRT treatment plans using field-in-field for 10 patients with right whole-breast irradiation only and 10 patients with right whole-breast treatment plus RNI.[211] In the group receiving RNI, there was significant reduction in the right lung mean dose (18.9 ± 3.2 Gy vs 15.9 ± 2.3 Gy, P = .002) and V_{20Gy} (45.3 ± 13.3% vs 32.9 ± 9.4%, P = .03) as well as the maximum dose to the right coronary artery (11.6 ± 7.2 Gy vs 5.6 ± 2.9 Gy, P = .03).[211] A similar study for

right-sided patients at Yale University found a significant reduction in all lung and liver dose parameters with the use of DIBH.[212] The use of DIBH in the setting of RNI should be considered for better OAR sparing.

CONCLUSIONS RE: LOCALLY ADVANCED BREAST CANCER

Indications for RT have expanded with contemporary prospective trials and meta-analyses providing evidence-based data that RT reduces not only LRR but also distant recurrence and improves survival for women with breast cancer. In the setting of node-positive breast cancer, including LABC, locoregional treatment decision-making is complex and requires multidisciplinary assessment to generate individualized recommendations. With improved outcomes seen with multimodality therapy, systemic therapy, surgery, and RT will play a role in the treatment of most patients with LABC. A meticulous approach should include interdisciplinary input to coordinate systemic therapy, RT, surgery, and potentially reconstruction. Modern technological advances in radiation planning and delivery, using CT-based 3D treatment planning to minimize radiation to OAR and deliver a homogeneous treatment plan using techniques described in this chapter, will increase the potential for radiation oncologists to improve the therapeutic ratio for patients with breast cancer.

GENERAL MANAGEMENT AND TREATMENT RESULTS FOR LOCALLY OR REGIONALLY RECURRENT BREAST CANCER

Women who receive initial potentially curative therapy for invasive cancer with either breast conservation therapy or mastectomy are at risk of developing LRR. LRRs are relatively uncommon with recurrence rates at approximately 5% to 15% after mastectomy and breast conservation therapy, often in the original quadrant following BCS or at the chest wall scar following mastectomy, although the ipsilateral nodal regions are also at risk.[138,186] Patients may present clinically with a palpable mass or with findings on post-BCS surveillance imaging. Although still potentially curable, the development of an LRR after primary treatment of an invasive breast cancer portends a high risk for distant metastases and death because of breast cancer. Accordingly, patients should undergo disease restaging at the time of recurrence to rule out metastatic disease and should have a biopsy for histopathologic confirmation and reevaluation of HR and HER2 status. Given that LRRs are relatively uncommon and are heterogeneous in presentation and prior treatment, treatment strategies must be individualized.

Recurrence in the Breast After Breast Conservation Therapy

Local recurrences after breast conservation therapy can sometimes be distinguished from second primary cancers based on location, appearance on imaging, histologic subtype, and HR/HER2 status. Risk factors for local recurrence following BCS include positive margin, omission of RT, larger primary tumor size, younger age, and HR-negative disease.[213,214] Although much of the breast cancer literature does not clearly differentiate

between a new primary and recurrent cancer, it is important to try to identify true relapses from a new primary as this information has prognostic value and aides in treatment decision-making. The importance of this distinction was made evident with data from Yale University showing that compared with patients with new primaries, patients with true relapses have poorer 10-year OS (55% vs 75%; $P < .0001$) and distant DFS (41% vs 85%; $P < .0001$).[215] Subsequently, a retrospective series from MD Anderson of 126 patients suggested that patients with a new primary tumor had significantly better 10-year survival (77% vs 46%, $P = .0002$), cancer-specific survival (83% vs 49%, $P = .0001$), and distant DFS (77% vs 26%, $P < .0001$).[216] Both studies found that patients considered to have new primary tumors had significantly longer intervals between their initial primary tumor and the recurrence and had significantly lower rates of distant metastasis and death after the recurrence. These data were later validated in a study of 447 patients.[217] Patients with a triple-negative locally or regionally recurrent breast cancer have worse DFS, OS, and risk of a subsequent recurrence relative to other subtypes.[218,219]

Appropriate management for LRR after breast-conserving therapy depends on initial disease presentation and management. For an in-breast recurrence in the setting of prior BCS and RT, mastectomy is the standard salvage treatment and is associated with an approximately 80% or better local control rate depending on other prognostic factors of the disease; however, these patients are at high risk of distant metastases.[220-223] RT is usually not given following salvage mastectomy in the setting of prior RT; however, it may be considered in patients with positive nodes, tumors larger than 5 cm, or multiple adverse risk factors, particularly in patients in whom their initial radiation was many years prior to the recurrence.

As most patients treated with initial lumpectomy also receive breast irradiation, mastectomy is the generally preferred surgical approach to treat a local recurrence in the absence of metastatic disease, although repeat BCS with reirradiation can be considered. Some single-institutional studies have investigated repeat BCS with or without radiation. Salvadori et al[224] compared the outcome of 134 patients treated with mastectomy for a localized breast recurrence to 54 highly selected patients treated with a second BCS alone. They found that a second breast recurrence at 5 years was more common in the reexcision group (19% vs 4%). Interestingly, the rate of distant metastases was 47% after mastectomy compared to 20% after reexcision.[224] This may reflect the inherent biases in a nonrandomized trial. Ishitobi et al[225] also reported a relatively high rate (21.8%) of a second breast relapse at 40 months after local surgery only for recurrent disease. A disease-free interval of more than 2 years and ER-positive disease were associated with a significant reduction in the risk of a second IBTR.[225] Gentilini et al[226] examined outcomes for BCS alone after local recurrence and found that the 5 year risk of local recurrence in patients with IBTR of $\leq$2 cm and time to recurrence of $\leq$48 months was 15.2% compared to 31.2% for IBTR of less than 2 cm with time to recurrence of greater than 48 months. In addition, the rate of 5 year risk of local recurrence for IBTR of greater than 2 cm was 71.2%.[226] This suggests that the best candidates for second BCS may be those with small tumors and late recurrence.

A recent meta-analysis of 34 studies reporting on BCS with or without reirradiation in the setting of IBTR after initial lumpectomy and RT found that the 5-year OS and local control rates were 77% and 76% for repeat BCS alone and 87% and 89% for BCS plus reirradiation, respectively.[227] Among the included studies, grade 3 to 4 toxicity rates were 0% to 21% and cosmesis was unacceptable in 0% to 18% of the patients who underwent reirradiation.[227] The authors acknowledge that experience with giving a second course of RT following local resection of a breast recurrence is limited, with partial breast reirradiation preferred because of concerns for the morbidity of reirradiation to the whole breast. Updated results of RTOG 1014 at a median follow-up of 5.5 years are now available.[228] RTOG 1014 is a phase II trial of 55 patients who received external beam partial breast irradiation consisting of 1.5 Gy fractions delivered twice daily to 45Gy using a 3D conformal technique following repeat lumpectomy for in-breast recurrence. Of note, 40% of recurrent tumors were classified as noninvasive, 91% were 2 cm or smaller, 7% were HER2 positive, and 23% were triple negative. All patients had cN0 disease; 24% of patients underwent axillary surgery with pN0 disease. The range of time from initial radiation to recurrence was 1.6 to 27.7 years, with a median of 13.4 years. There were four repeat in-breast recurrences demonstrating a 5-year cumulative incidence of 5.2%. Four (7%) patients experienced grade 3 toxicity.[228] While longer follow-up and additional studies are warranted, these results indicate that for well-selected patients who are highly motived to undergo repeat BCS, this approach is reasonable.

Patients with recurrence in the breast or chest wall are also at risk for axillary metastases. No high-level evidence or consensus exists regarding the management of the axilla in this setting. Rates of positive nodes in the recurrent setting in older series where axillary dissection was standardly employed at initial diagnosis are approximately 25% but are as high as 50%.[229] In patients who have already had an axillary dissection at initial presentation, radiographic staging followed by surgical resection of gross axillary disease should be attempted if technically feasible. For patients who initially underwent sentinel LN surgery, ALND is recommended for most patients. Restaging with repeat sentinel node evaluation may be feasible, but its diagnostic accuracy and prognostic significance are unknown. A systemic review of 34 publications found that a repeat SLNB was successfully performed in 64.3% of patients (75.7% after prior SLNB and 46.1% after prior ALND).[230] Repeat SLNB can be considered in select patients with ALND performed if the SLNB is not successful.

There are no high-level data regarding radiation of the regional nodes in the setting of locally recurrent breast cancer with nodal involvement. In this setting, maximal debulking with surgical resection and/or systemic therapy is recommended to maximize local control. RT that targets the axillary and SCV nodal basins is ideally limited to patients who did not have prior RT to these areas. Reirradiation fields that include the axilla and/or the supraclavicular fossa should be approached with caution. Prior radiation records must be obtained to allow for reconstruction of the initial dose distribution. Consideration of DIBH and use of complex planning techniques such as electrons, IMRT, or protons to better spare the OAR are recommended, although often retreatment of the plexus cannot

be avoided when including SCVs. Great care must be taken to limit the cumulative maximum dose to the brachial plexus to decrease the risk of brachial plexopathy.[231]

Reconstructive surgery should be considered for patients treated with mastectomy, although previous history of breast radiation may limit the success of implant-based procedures. Historically, autologous tissue reconstruction has been favored. More recently, investigators from Memorial Sloan Kettering published a single surgeon's experience with immediate tissue expander followed by implant reconstruction in patients who underwent salvage mastectomy after prior BCS and radiation (121 patients) and patients who underwent primary mastectomy with the same reconstruction without a history of RT using a prospectively maintained database.[232] The early complication rate was higher in the irradiated group than in the nonirradiated group (29.7% vs 15.5%, $P < .001$), with the most common complication being flap necrosis. While over 95% of patients in both groups had a good or excellent aesthetic result, a proportionally greater number of patients in the nonirradiated group had excellent results ($P = .04$). In all, patient satisfaction was relatively high (84% in the previously irradiated group and 90% in the nonirradiated group), indicating that tissue expander followed by implant is reasonable in a properly consented patient undergoing salvage mastectomy after prior BCS and irradiation.[232] Researchers at the Cleveland Clinic performed a retrospective review of 103 patients with 107 reconstructions and analyzed outcomes for patients who underwent tissue expander/implant reconstruction and those who underwent autologous reconstruction following salvage mastectomy after local recurrence in the setting of prior BCS and radiation. Complications requiring reoperation and reconstruction failure were significantly greater in the tissue expander/implant-based reconstruction patients compared to the autologous reconstruction patients at 5 years (50.9% vs 25.5%; $P = .02$ and 42.1% vs 5.8%; $P < .001$).[233]

Locoregional Recurrence After Mastectomy

Recurrences after mastectomy tend to occur earlier and are more likely to be diagnosed on examination when compared to recurrences after breast-conserving therapy. The major risk factors for recurrence after mastectomy as initial therapy are the number of axillary LNs positive at surgery in addition to other poor prognostic factors, including younger age, higher grade histology, HR-negative disease, extracapsular extension, and LVI.[234-236]

Patients with recurrent disease after initial mastectomy may have a worse prognosis than those with recurrent disease after initial breast conservation therapy. In the Canadian and Danish postmastectomy radiation randomized control trials, patients who developed LRR had very high rates of subsequently developing metastatic disease.[110,143] In the Vancouver trial, of the 39 patients who developed an LRR, 37 eventually developed metastatic disease.[110] In the Danish trial, the 5-year rate of distant metastatic disease development after an isolated LRR was 73%. This rate was no different for those in whom disease recurred after mastectomy only versus those with recurrent disease after mastectomy and radiation,[143] though the ability to use radiation for combined modality

salvage therapy, especially in isolated chest wall recurrences, may lead to better outcomes.[237]

The general management strategy for an isolated LRR after mastectomy requires input from a multidisciplinary team. The initial evaluation should define the sites of disease involvement in order to determine whether the patient is able to undergo resection of all gross disease with negative surgical margins. Surgical therapy consisting of wide local excision and removal of involved axillary LNs is recommended for patients with resectable disease, provided surgery can be done with acceptable morbidity. If the patient had not previously been given RT, a standard approach would be comprehensive locoregional radiation with similar techniques used for newly diagnosed disease. An older study from Washington University found that patients with LRR who had RT to the chest wall and regional lymphatics had better outcomes than those in whom radiation fields were limited to the site of the recurrent disease, with 10-year freedom of chest wall recurrence of 63% in the patients who received larger field radiation versus 18% for patients who received small field radiation.[238]

Outcomes for patients with locally recurrent breast cancer have been found to be improved with the use of combined modality therapy. For example, a retrospective series of 115 patients with recurrence after mastectomy suggest that patients who receive combined modality therapy with wide local excision and RT plus systemic therapy have better DFS (52% vs 39%) and OS (63% vs 50%) compared to patients who get more limited treatment.[239] Patients presenting with bulky unresectable disease or who are poor surgical candidates should be considered for preoperative systemic therapy if active agents are available. If the disease responds favorably, some of these patients may become candidates for surgical resection, which then can be consolidated with comprehensive radiation. The prognosis for those with persistent gross disease is poor,[240] and radiation treatments alone are unlikely to render such patients free of disease. Nevertheless, aggressive locoregional radiation may be used to help stabilize the disease and to avoid the significant adverse consequences of uncontrolled growth of locoregional disease. For patients who have not had prior RT and do not have residual gross disease, treatment to the chest wall and draining lymphatics to a dose of 50 Gy followed by a boost to the site(s) of prior disease to 60 to 66 Gy are standardly used.[238,240] When treating unresectable gross disease with RT, concurrent systemic therapy, such as a taxane or capecitabine, can be considered.[241-243] In addition, in the setting of chest wall radiation or reirradiation for locally recurrent breast cancer, the use of hyperthermia may enhance the efficacy of RT.[244]

Few data are available to quantify the benefits of systemic therapy for patients with LRR, and decisions should be made on an individual basis according to the risk of metastatic disease, previous systemic treatments, and breast cancer subtype. The role of chemotherapy was studied in the phase III CALOR trial in which 162 patients with LRR after mastectomy or breast- conserving therapy were randomized to chemotherapy versus no chemotherapy.[245] At 9 years of follow-up, chemotherapy was associated with improved DFS in patients with ER-negative (70% vs 34%; hazard ratio = 0.29, 95% CI 0.13-0.67)

but not ER-positive disease (50% vs 59%; hazard ratio = 1.07, 95% CI 0.57-2.00). OS in the ER-negative group was 73% with chemotherapy versus 53% without (hazard ratio = 0.48, 95% CI 0.19-1.20) and in the ER-positive group 76% versus 66% (hazard ratio = 0.70, 95% CI 0.32-1.55). These data support the use of chemotherapy in the locoregionally recurrent setting for ER-negative disease. However, the trial was limited by its small size and relatively few events in the HR-positive group and thus firm conclusions regarding the role of chemotherapy in select HR-positive patients cannot be made. Patients who undergo chemotherapy in the locally recurrent setting should be given a standard adjuvant regimen, preferably with agents not previously received.

There are limited studies evaluating the use of ET in HR-positive locally recurrent disease. A randomized trial evaluated tamoxifen versus no systemic therapy after salvage local therapy for patients with recurrent disease after mastectomy found an improvement in 5-year DFS from 40% to 61% with the use of tamoxifen.[246]

Despite the lack of randomized data, given the effectiveness of ET in early- and late-stage HR-positive breast cancer and its relative lack of toxicities, all patients with a local recurrence should be treated with ET, usually with an agent different from what was previously used. Patients with HER2-positive locally recurrent disease should be offered HER2-directed therapy with a regimen different from what was previously received.

Several publications have provided insight into the factors of prognostic significance for patients with LRR after mastectomy. One of the largest series was an analysis of the 535 patients who developed a postmastectomy recurrence after treatment in the Danish 82b and 82c randomized trials.[143] In multivariable analyses, the investigators found the following factors to be associated with a poorer outcome at recurrence: large initial primary tumor, a high number of positive LNs, extracapsular extension, recurrence in the infraclavicular or supraclavicular regions, and a disease-free interval of less than 2 years.[143] Several other series have reported similar findings. Investigators from MD Anderson found that initial nodal status, time to recurrence, and ability to use radiation to treat the recurrence were all independent predictors of outcome for patients with a chest wall recurrence. The 19 patients in whom these three factors were favorable had a 5-year OS of 86%. The 5-year survival rate for the 89 patients who had one or two unfavorable features was 48%, and all 22 of the patients who had all three unfavorable factors died within 5 years of the recurrence.[237] In general, patients who present with an isolated chest wall recurrence more than 2 years out from treatment, particularly those with resectable disease and have not undergone radiation, have a greater probability of disease control and improved outcome.

UNIQUE PRESENTATIONS OF BREAST CANCER

Axillary Metastases With Unknown Primary

The presentation of metastatic disease within axillary LNs without an identifiable primary source is unusual, accounting for less than 1% of newly diagnosed breast cancer cases.[247,248] The initial workup for patients who present with axillary disease and an occult

primary is directed toward establishing if the axillary findings represent a regional metastasis from breast cancer or a distant metastasis from an unrelated site. As such, the initial evaluation should include a history and physical examination, routine serum studies, bilateral diagnostic mammography, and ipsilateral breast and axillary ultrasound. If no primary breast disease is detected with mammography and ultrasound, MRI of the bilateral breasts is indicated. Contrast-enhanced MRI can detect in-breast primary tumors in about 70% of patients with axillary metastasis and a mammographically occult breast tumor.[249,250] Cytologic confirmation of disease within axillary LNs must be obtained with ultrasound-guided core-needle biopsy or fine-needle aspiration. Core biopsy is preferred to better ensure that there is adequate tissue for full histologic evaluation. Testing for tumor markers, including ER, PR, and HER2/neu, should be performed. In the absence of evidence for a non–breast primary, and a negative mammogram/ultrasound and MRI, a patient can be assumed to have an occult or unknown breast primary and treated as such, particularly if the nodal biopsy results support a breast primary. Systemic staging studies including a CT scan of the chest, abdomen, and pelvis plus bone scan or FDG PET/CT should be performed.

Modified radical mastectomy and PMRT have been the historical locoregional treatments for patients with occult breast primary and axillary metastases. Studies vary significantly with respect to the frequency with which a primary is found within the breast during pathologic examination. Most of these studies predate the use of MRI screening or other improvements in diagnostic imaging and are less relevant in the modern era. For patients with cT0 with cN2-N3 disease, neoadjuvant systemic therapy is usually given prior to surgery and radiation. Patients with cT0N1 disease may be treated with upfront surgery or neoadjuvant systemic therapy. Pretreatment multidisciplinary evaluation is encouraged.

The safety of breast conservation therapy with ALND for patients with occult primary disease has been explored. Early attempts at breast conservation without breast irradiation resulted in high subsequent breast recurrence rates.[251] More recent studies that incorporate breast irradiation have yielded improved results. In one of the largest series, investigators from MD Anderson evaluated 45 patients with an occult breast tumor and cN1-N2 disease and compared the outcome of those treated with mastectomy (n = 13) to those treated with breast conservation (n = 32).[252] Locoregional control, DFS, and OS were equivalent between the mastectomy and breast conservation cohorts. With a median follow-up of 7 years, only 2 of the 25 breast conservation patients who received breast irradiation developed a local recurrence while 2 of the 7 who did not receive breast irradiation recurred locally.[252] Similar results have been reported from The Royal Marsden Hospital. In a series of 48 patients with axillary metastases in the setting of an occult breast primary who underwent axillary surgery with breast conservation, they found a 14% LRR rate after breast radiation and an unacceptable rate of 85% if breast radiation was omitted.[253] Several other retrospective/population-based studies and a recent meta-analysis have found equivalent outcomes with ALND with either breast conservation plus x-ray technique or mastectomy.[247,248,254,255] These data suggest that undetectable primary breast

lesions can be successfully sterilized with the combination of systemic therapy and RT. One can feel particularly reassured with this strategy for patients treated in the MRI age with lesions below the threshold for MRI detectability. Patients presenting with an occult breast primary and axillary disease should receive RNI, whether as a part of PMRT or breast conservation therapy.[117,118]

There are no studies looking at de-escalation of ALND to SLNB in the setting of occult breast cancer and axillary metastasis. That said, de-escalation of axillary surgery to SLNB to well-selected patients with cT0N1 disease who are rendered cN0 following neoadjuvant systemic therapy is not unreasonable to consider and may become the accepted treatment strategy in the future.[256] See the section "Surgical Management of the Axilla."

Male Breast Cancer

Breast cancer developing in males is uncommon and accounts for less than 1% of total new breast cancer cases in the United States.[257] The American Cancer Society estimated that in 2017, there would be approximately 2,470 new cases of male breast cancer and 460 deaths because of male breast cancer in the United States. The incidence of male breast cancer is positively correlated with age, and the highest rates occur in Black males (2.7/100,000) and White males (1.9/100,000).[257]

The presenting symptom for male patients with breast cancer is typically a breast mass or axillary adenopathy, and most male patients with breast cancer present with locally advanced disease. The ratio of the number of deaths to new cases is 19% for males, compared to a ratio of 16% for females, with a 5-year OS of 84% in men compared to 90% in women.[257] Retrospective national database evidence suggests differences in cancer-specific mortality may be attributable to stage migration, as there are no gender-specific differences when comparing outcome within stage II or stage III.[258] Leone et al compared BCSS estimates in men over three decades (1988-1997, 1998-2007, and 2008-2017) within the SEER registry. In contrast to improvements in cancer-related survival in women, there was no statistically significant changes over time among men.[259]

The known risk factors for male breast cancer, similar to those in postmenopausal female breast cancer, include family history, age, conditions that affect testosterone and estrogen levels, BRCA2 mutations, and prior history of RT.[260] Germline mutations in the *BRCA2* gene have been reported in 4% to 16% of men with breast cancer and, unlike female breast cancer, are more common than germline mutations in BRCA1.[261,262] Nevertheless, most male breast cancers present without an identifiable risk factor.

Males have a similar histopathologic spectrum of breast cancers to females with the exception of lower rates of invasive lobular carcinoma, given the lack of acini and lobules in normal breast tissue. Specifically, less than 2% of invasive male breast carcinomas are lobular, as compared to approximately 15% in female cancers.[263] In addition, male breast cancers more frequently are ER positive (estimated rate of 90%) and HER2 negative compared to female breast cancer.[258] In addition, tumor subtype in a large SEER database was shown to be associated with survival among men, as in women.[264] Diagnostic workup

and staging are similar to that for female breast cancer and should include bilateral mammography, biopsy, and staging workup. Treatment decisions are also similar to those used in women.

Mastectomy with or without postmastectomy radiation is the most common locoregional treatment approach, with increasing attention being placed on postmastectomy reconstruction and potential psychological distress related to cosmetic outcomes. Investigators at MD Anderson reviewed 142 patients treated with mastectomy without RT and found that, similar to female patients, margin status, number of positive nodes, and tumor size predicted locoregional failure.[145] Accordingly, decisions concerning postmastectomy radiation should be based on the same criteria used in the treatment of breast cancer in women.

Similarly, systemic treatments are indicated for male patients with breast cancer who have a clinically relevant risk of distant metastases, and treatment decisions should follow those for female breast cancers. Level 1 data supporting the use of particular chemotherapy regimens specifically in men are lacking, given the rarity of the disease. In addition to chemotherapy, because most male breast cancers are receptor positive, tamoxifen is indicated for the majority of cases. Retrospective series have suggested that tamoxifen can reduce the risk of recurrence and death.[265] The role of aromatase inhibitors in males is unclear, but retrospective data support the adjuvant use of tamoxifen rather than aromatase inhibitors.[266] If an aromatase inhibitor is to be used, it should be given in conjunction with a gonadotropin-releasing hormone agonist as aromatase inhibitor therapy alone does not suppress testicular production of estrogen.

PART F

Gastrointestinal

CHAPTER 64

Stomach Cancer

Brian G. Czito and Christopher G. Willett

ANATOMY

The stomach begins at the gastroesophageal (GE) junction and ends at the pylorus. The stomach is generally divided into anatomic regions, including the gastric cardia (the region surrounding the superior opening of the stomach where it connects with the GE junction/level of the lower esophageal sphincter), the fundus (situated superiorly, a rounded portion superior to the body and to the left of the cardia), the body (a large, central portion of the stomach), and the pyloric canal (distally, connecting to the duodenum). The pylorus is composed of two parts: the pyloric antrum, which connects to the body of the stomach, and the pyloric canal, which empties into the duodenum (Figure 64.1). The pylorus communicates with the duodenum of the small intestine via the pyloric sphincter (valve). This valve regulates the passage of chyme from the stomach to the duodenum and prevents backflow from the duodenum to the stomach. A plane passing through the incisura angularis on the lesser curvature divides the stomach into the body and the pyloric portion (antrum). The anterior surface of the stomach is covered with the peritoneum of the greater sac. At the left and cranially, it abuts the diaphragm. In view of the increasing incidence of gastric cancer at the GE junction, it is important to note that there is either no or variable visceral peritoneal covering at the most proximal portion of the GE junction.[1] Positive radial margins at this site are often "true" positive margins, whereas many other positive margins in the stomach are free

serosal margins unless the tumor is adherent to an adjacent organ or structure. The right portion of the anterior gastric surface is adjacent to the left lobe of the liver and the anterior abdominal wall. Posteriorly, the stomach is covered with peritoneum of the lesser sac or omental bursa. The stomach contacts many visceral structures; from superior to inferior, it is adjacent to the spleen, left adrenal gland, superior portion of the left kidney, ventral portion of the pancreas, and transverse colon. The hepatogastric ligament or lesser omentum is attached to the lesser curvature and contains the left gastric artery and the right gastric branch of the hepatic artery. Histologically, the wall of the stomach has five layers: the mucosa, submucosa, muscularis layer, subserosa, and serosa. The muscularis layer is composed of an outer longitudinal layer, a middle circular layer, and an inner oblique layer.

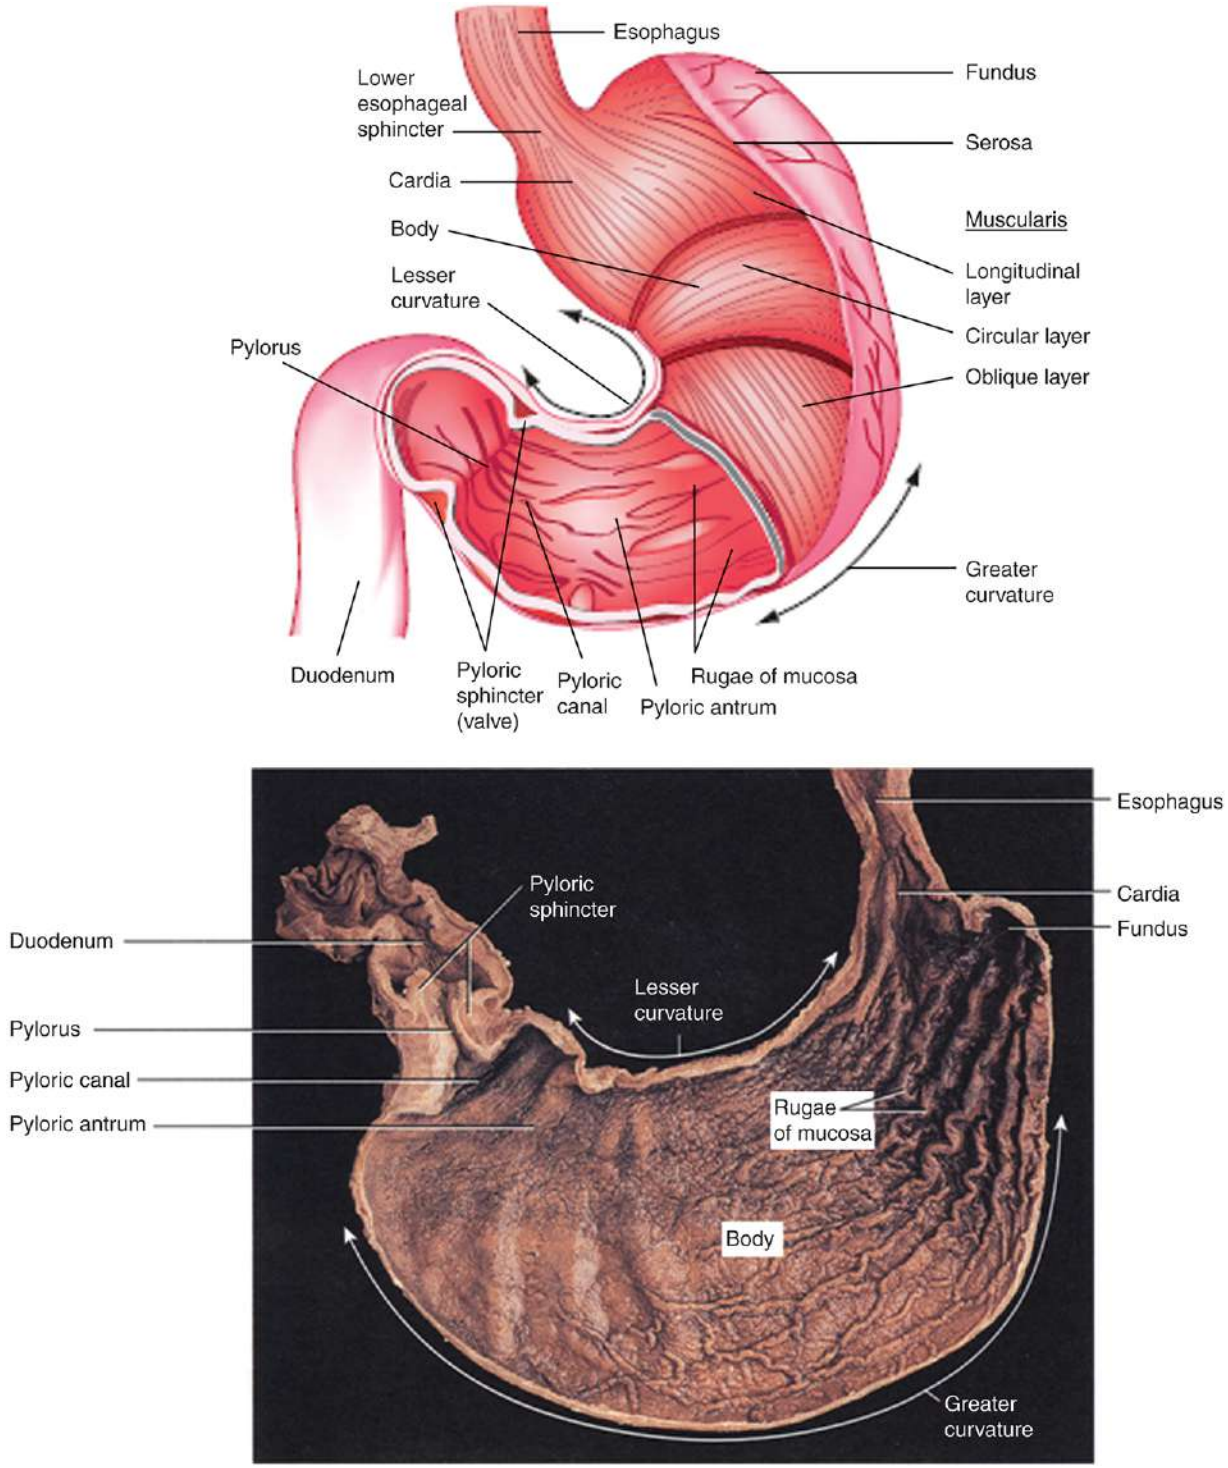

FIGURE 64.1 Gastric anatomy. (Used with permission of John Wiley & Sons—Books from Tortora GJ, Grabowski SR. *Principles of Anatomy and Physiology*. 10th ed. John Wiley & Sons; 2002. The stomach's vascular supply is derived from the celiac axis. The celiac artery usually has three branches: the left gastric artery, which supplies the upper right portion of the stomach; the common hepatic artery, which gives rise to the right gastric artery supplying the lower right portion of the stomach and the right gastroepiploic branch supplying the lower portion of the greater curvature; and the splenic artery, which gives rise to the left gastroepiploic supplying the upper portion of the greater curvature and the short gastric arteries supplying the fundus. Variations in this normal vascular supply are common. The celiac axis originates at or below the pedicle of T12 in approximately 75% of patients and at or above the pedicle of L1 in 25% of patients.[2] The lymphatic drainage of the stomach follows the arterial supply. Although most lymphatics ultimately drain to the celiac nodal basin, lymph drainage sites can include the splenic hilum, suprapancreatic nodal groups, porta hepatis, and gastroduodenal areas.

EPIDEMIOLOGY

Gastric cancer afflicted an estimated 26,500 people in the United States in 2023 and resulted in 11,130 deaths.[3] Worldwide, gastric cancer remains a significant cause of cancer-related mortality, with approximately 1,313,000 new cases annually and an estimated 819,000 deaths, making it the third-leading cause of cancer-related deaths.[4] During the past 70 years, there has been a significant decline in the incidence of gastric cancer in both sexes in Western countries. The causes of this decline are unknown, although it may possibly be due to decreased rates of *Helicobacter pylori* infection, improvements in socioeconomic conditions, use of antibiotics and better medical treatment, and decreasing smoking rates.[4-6] Although the overall decrease in gastric cancer incidence is encouraging, there has been a steady and dramatic increase in the incidence of proximal lesser curvature, cardia, and GE junction tumors over the past 20 years, especially in White males. In contrast to the increasing incidence of more proximal gastric cancers seen in the Western Hemisphere and parts of Europe, distal tumors continue to constitute most gastric cancers in the Far East and other parts of the world.

Risk factors for gastric cancer can be classified as modifiable or nonmodifiable (Table 64.1). Race or ethnicity, specifically being of East

Asian or Pacific Islanders descent, portends increased risk. Although potentially related to environment, this incidence persists following immigration and into offspring when migrating to the West. Age is also an important risk factor, with 90% of cases occurring in patients older than 45 years. Family history similarly contributes to risk, with studies from the East and West demonstrating that a first-degree relative likely increases an individual's risk from 2- to 4-fold. Similarly, male sex portends a 2- to 5-fold increased risk, possibly accounted for by protective effects of estrogen in females. Approximately 10% of gastric cancers are linked to genetic syndromes, with the most common being hereditary diffuse gastric cancer (HDGC), which is characterized by an autosomal dominant inheritance, portending a 60% to 80% increased risk of gastric cancer and 40% to 50% increased risk in breast cancer. Some of these cases are believed to be due to mutations in E-cadherin (*CDH1*). The presence of CDH1 mutations portends a lifetime risk of gastric cancer development of 70% to 80%.[7] Prophylactic gastrectomy is often recommended once patients are more than 20 years of age. Other syndromes associated with increased risk include Lynch syndrome (a DNA mismatch repair gene mutation), familial adenomatous polyposis (an adenomatous polyposis coli gene mutation), Peutz-Jeghers syndrome, juvenile polyposis syndrome, hereditary breast and ovarian cancer syndrome, and Li-Fraumeni syndrome.[8]

TABLE 64.1 RISK FACTORS FOR GASTRIC CANCER DEVELOPMENT

Modifiable
Helicobacter pylori infection
Tobacco smoking
Alcohol use
Obesity
High-salt diet; low-fruit or -vegetable diet
Smoked and pickled foods
Intrinsic
Ethnicity (East Asian or Pacific Islander)
Male gender
Age

Family history

In terms of modifiable risk factors, the most common is *H. pylori* infection. Although the risk of developing gastric cancer is approximately 1% once present, more than 90% of patients with gastric cancer diagnosis have been previously infected. *H. pylori* appears to contribute to gastric cancer development through development of gastritis with subsequent histopathologic changes. The increased association of *H. pylori* appears to be confined to patients with distal gastric cancer and intestinal-type histology. The Epstein-Barr virus (EBV) has been found in 5% to 16% of gastric cancer patients, supporting its possible role in the genesis of such.[7] Additionally, cigarette use appears to increase the risk of both cardia and noncardia cancers, whereas obesity (body mass index >30) appears to increase the risk of noncardia cancers. A high-salt diet seems to increase risk, whereas diets high in fruit and vegetables seem to be protective.[5,8-10]

Historically, gastric adenocarcinomas have been labeled as intestinal or diffuse types per the Lauren classification system. Intestinal types are more prevalent in high-incidence areas and responsible for much of the observed global ethnic variation of disease, although the incidence is believed to be decreasing. Intestinal-type carcinomas are primarily well to moderately differentiated. Histologically, these tumors generally show malignant epithelial cells in hyperchromatic, irregular, angulated glands with cohesiveness and glandular differentiation infiltrating the stroma. These tumors can be polypoid with a wide base, ulcerated with sharp/heaped-up margins, and ulcerated disease without obvious limits. These are generally seen more in males than in females in a 2:1 ratio. In contrast, the incidence of the less common diffuse gastric cancer appears to be increasing and is fairly uniform among geographic regions or race. More recently, there has been an emergence of another distinct subtype—proximal gastric (cardia) cancers. These are often grouped with GE junction and distal esophageal adenocarcinomas, with a rapidly rising incidence in industrialized nations. Gastric cardia cancers are associated with reflux and obesity, resembling esophageal adenocarcinomas. These malignancies are generally more aggressive and carry a worse prognosis than do noncardia tumors. These tumors are associated with White populations with a strong male predominance.

The risk factors for these individual types appear to vary significantly. Risk factors for intestinal, noncardia gastric cancers appear to center around inflammatory causes and environmental factors, primarily *H. pylori*, as well as chronic gastritis, tobacco, high salt intake, and alcohol consumption. The less common diffuse gastric cancer subtype appears to be distinct, with E-cadherin mutations/silencing thought to be a common precursor event with this histology. HDGC is a genetic syndrome in which there is loss of function/mutation in the E-cadherin gene. In proximal gastric cancer (and in contrast to intestinal types), *H. pylori* infection has been found to be potentially protective in several randomized trials, possibly through associated atrophic gastritis and reduced acid production with subsequent reduction in gastroesophageal reflux disease, although this remains controversial.[11] As opposed to intestinal types, there is often no precancerous lesion seen, and histologically, cells generally lack cohesion and invade independently or in smaller clusters. Diffuse carcinomas are poorly differentiated. These are often more diffusely infiltrating and nonulcerated and can present as a "signet ring" carcinoma, which is a variant with cytoplasmic mucin that displaces the cell nucleus peripherally. The presence of signet ring (or poorly differentiated) phenotype has been associated with therapy resistance and poor prognosis[11] (Figure 64.2). However, a large database analysis indicated patients with signet ring gastric cancer, when compared to patients with adenocarcinoma, tended to present at a younger age and less often in men. Additionally, despite more advanced stage, median survival was not different relative to patients with "traditional" adenocarcinoma.[12,13]

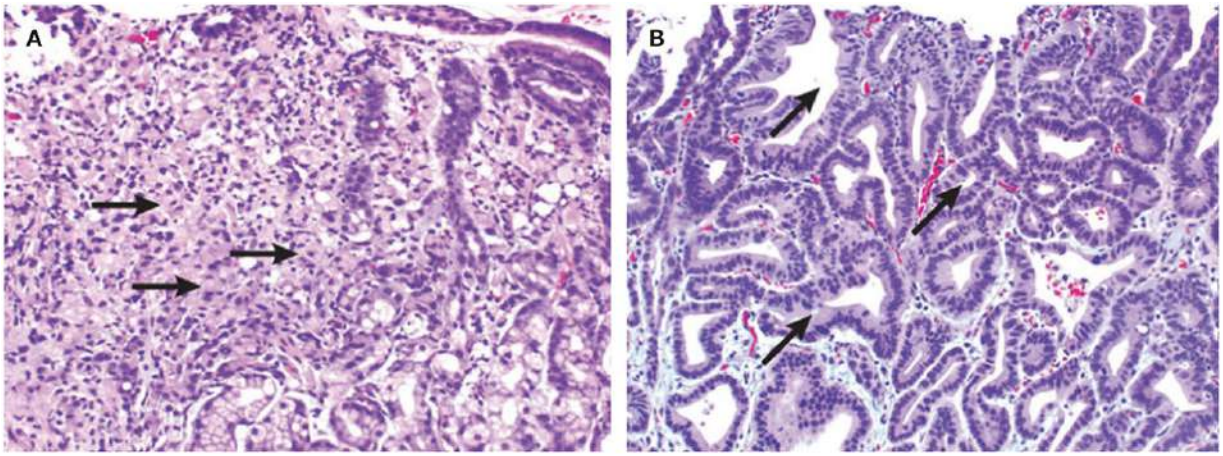

FIGURE 64.2 A. Hematoxylin and eosin–stained slide of Lauren classification diffuse-type gastric adenocarcinoma (GAC) with many cancer cells isolated from other cells. *Arrows* point to signet ring cells, in which the nucleus is pushed out to the periphery of the cytoplasm. B. Hematoxylin and eosin–stained slide of Lauren classification intestinal-type GAC. *Arrows* are pointing to gland formation by tumor cells. An alternative gastric cancer classification from the World Health Organization is based predominantly on histologic cancer patterns (tubular, papillary, mucinous, poorly cohesive, and rare variants). The tubular and papillary subtypes roughly correspond to the Lauren intestinal type and poorly cohesive to the diffuse type. More recently, the Cancer Genome Atlas Research Network published the results of genomic profiling of 295 primary gastric adenocarcinomas. Four tumor subtypes were identified: (a) EBV (9%), (b) microsatellite-unstable tumors (22%), (c) genomically stable tumors (20%), and (d) chromosomally unstable tumors (50%). This classification has the potential to determine prognosis and help individualize treatment in the future.[12]

PATTERNS OF SPREAD

Cancer of the stomach may extend directly into the omentum, pancreas, diaphragm, transverse colon or mesocolon, and duodenum. Peritoneal contamination with carcinomatosis is possible after a lesion extends beyond the gastric wall to a free peritoneal (serosal) surface.[14]

Microscopic or subclinical spread beyond the visible gross lesion occurs frequently because of the abundant lymphatic channels within the

submucosal and subserosal layers of the gastric wall. The submucosal plexus in the esophagus and subserosal plexus in the duodenum allow proximal and distal spread.

It is difficult to perform a complete node dissection because of the numerous pathways of lymphatic drainage from the stomach (Figure 64.3). Initial drainage is not only to lymph nodes along the lesser and greater curvatures (ie, gastric and gastroepiploic nodes) but also includes the celiac axis, porta hepatis, splenic, suprapancreatic, pancreaticoduodenal, adjacent para-aortic, and distal paraesophageal system. The relative risks for nodal involvement in gastric cancer depend on the location of the primary tumor as well as extent of gastric wall involvement.

Gastric venous drainage is primarily to the liver by the portal system. Liver involvement is found in as many as 30% of patients at initial exploration, and it can occur as a result of venous metastasis, peritoneal-based spread, and direct extension (Figure 64.4).

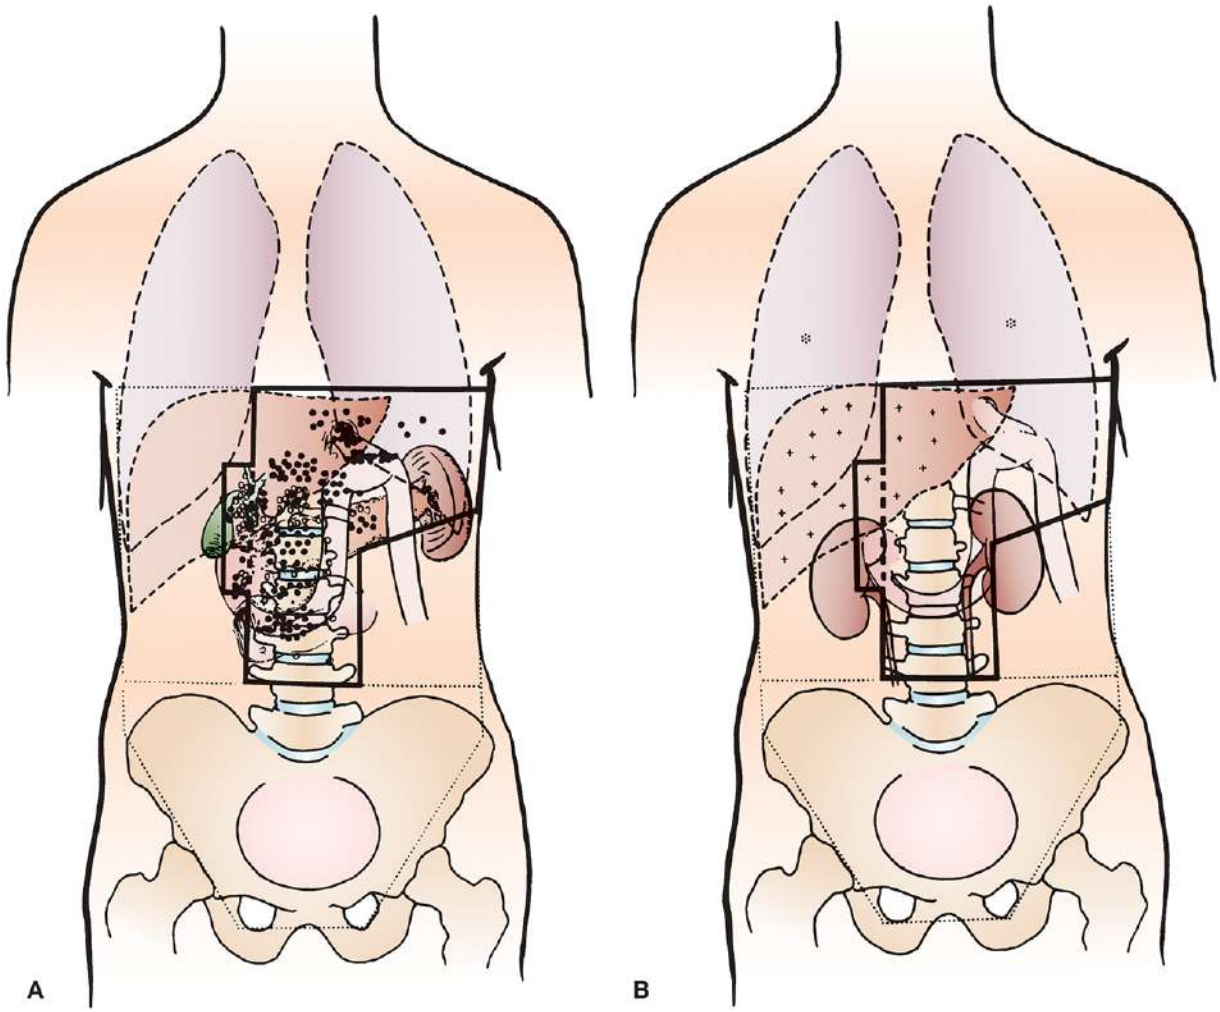

FIGURE 64.4 Patterns of failure in 82 evaluable patients in the University of Minnesota Reoperation series. A. Large bold circles indicate local failures in surrounding organs or tissues; large open circles indicate lymph node failures. B. Asterisk (*) indicates lung metastasis; *plus* (+) indicates liver metastasis. Superimposed irradiation portals encompass postsurgical gastric remnant, anastomoses, duodenal stump, gastric bed structures, and primary and secondary areas of lymph node drainage; broken lines represent upper and total abdomen fields. CLINICAL PRESENTATION

The most common presenting symptoms of stomach cancer are anorexia, early satiety, abdominal discomfort, unintentional weight loss, dysphagia (notably if GE junction or proximal stomach involvement), anemia-related weakness, nausea and vomiting, and tarry stools. Duration of symptoms is

less than 3 months in almost 40% of patients and more than 1 year in 20%. Physical examination can reveal advanced disease, for which the presentation may include an abdominal mass (epigastric or liver mass as well as a periumbilical node [ie, Sister Mary Joseph node]), palpable left supraclavicular nodes (ie, Virchow node), an enlarged left axillary lymph node (Irish node), or a rectal shelf (representing peritoneal seeding [ie, Blumer shelf]).

DIAGNOSTIC WORKUP

Many patients with early-stage gastric cancer are asymptomatic, and therefore patients are often diagnosed at a more advanced stage. Diagnosis is usually confirmed by upper gastrointestinal endoscopy as well as imaging studies in some instances. Double-contrast x-ray studies may reveal small lesions limited to the inner layers of the gastric wall. Endoscopy with direct visualization, cytology, and biopsy yields the diagnosis in 90% or more of exophytic lesions; however, infiltrative (linitis plastica), small (<3 cm), or cardia lesions may be more difficult to diagnose endoscopically. Endoscopic ultrasonography is the most accurate method of determining depth of tumor invasion (intramural vs extramural extension) prior to resection but is less accurate in detecting regional nodal metastases.[15,16] In some institutions, needle biopsies of suspicious nodes are performed at the time of endoscopic ultrasound.

One principal goal of staging computed tomography (CT) is the identification of distant metastases, although it can also provide T- and N-stage data. Abdominal CT is useful in determining the abdominal extent of disease and may help to determine which lesions extend to surgically unresectable structures but are of lesser value in detecting small lymph node metastases or peritoneal spread. Distant metastases should be ruled out with contrast-enhanced CT of the chest, abdomen, and pelvis. CT may provide valuable tumor localization information if radiation is indicated. If a proximal gastric cancer extends to involve the esophagus, CT of the chest will help to rule out involvement of mediastinal nodes or the lung parenchyma. A meta-analysis suggested that CT accuracy in terms of T stage was 72% although there was an indication that multidetector (four or more) scanners demonstrated an overall accuracy of 80%.[17] However,

multidetector status did not seem to influence nodal or distant metastatic assessment. In the same study, CT accuracy, compared to histologic findings, was 66% in terms of N stage.

The value of laparoscopy in the staging of gastric cancer remains a subject of study. The primary value of laparoscopy lies in the detection of occult metastatic deposits. A large series from Memorial Sloan Kettering Cancer Center of more than 600 patients with potentially resectable gastric adenocarcinoma by conventional imaging underwent laparoscopic staging, resulting in distant metastases being detected in 31% of patients.[18] A systematic review of the role of diagnostic laparoscopy showed that change in patient management occurred in 9% to 60% of patients initially deemed resectable by preoperative imaging, with 9% to 44% avoiding laparotomy, predominantly through the identification of patients with metastatic disease who would not benefit from either laparotomy or neoadjuvant therapy, thereby avoiding unnecessary interventions. This is primarily related to patients with advanced (T3, T4) gastric cancer, with relatively minimal benefit in patients at an early stage, prompting the authors to recommend diagnostic laparoscopy for patients with locally advanced-stage disease.[19,20] In addition, peritoneal fluid can be sampled for cytology at laparoscopy by direct aspiration of ascitic fluid or peritoneal lavage. If positive, this is a poor prognostic indicator, and although the bearing on treatment approach remains somewhat controversial, the patient should be considered as having M1 disease. Some experts recommend laparoscopy with obtaining cytology in patients with T1b and higher disease who are potentially resectable, with consideration of the same in patients who are surgically unresectable.

Overall treatment planning in gastric cancer may be improved by accurate preoperative classification of key prognostic factors, namely, depth of invasion (T category) and lymph node involvement (N category). A prospective study in 108 patients evaluated endogastric ultrasonography (EUS), CT, and intraoperative surgical assessment for T and N classifications.[21] T staging was accurately characterized by CT in 43% of cases, EUS in 86% of cases, and intraoperative assessment in 56% of cases. Staging of N1 and N2 lymph nodes was correct with CT in 51% of the cases, 74% with EUS, and 54% with intraoperative assessment. EUS is particularly relevant in accuracy and sensitivity for local regional staging, including an 85% sensitivity toward distinguishing T1 from T2 disease as

well as 87% for T1a versus T1b disease, with distinguishing between early and advanced tumors with sensitivity and specificity of 86% and 90%, respectively. Advanced gastric tumors tended to be more accurately staged with CT, although CT, in general, overstages the T category and understages the N category. EUS showed a high accuracy for all the T categories, although it also tends to understage N categories. Finally, intraoperative assessment was equally accurate for all N categories but tended to overstage early T stages and to understage N categories. A meta-analysis and systematic review of the role of EUS in T and N staging in nearly 2,000 patients with gastric cancers suggested that the sensitivity for detecting T1, T2, T3, and T4 disease was 88%, 82%, 90%, and 99%, respectively. Nodal staging sensitivity for N1 and N2 disease was 58% and 65%, respectively, also suggesting that accuracy was higher with more advanced disease.[23] Another meta-analysis demonstrated the ability of endoscopic ultrasound to discriminate between T1-T2 versus T3-T4 gastric cancers, with a sensitivity of 0.86 (CI 0.81-0.90); additionally, the sensitivity for diagnosis of superficial (T1a vs T1b) and lymph node involvement was 0.87 (0.81-0.92) and 0.83 (0.79-0.87), respectively.[24] Another meta-analysis showed a pooled accuracy for T-stage diagnosis of 75%, with individual studies reporting rates from 57% to 88%. However, the diagnostic accuracy for N staging was less, with a wide range from 30% to 90%, pooled accuracy of 64%, sensitivity of 74%, and specificity of 80%.[25] EUS accuracy depends highly on the experience and expertise of the operating physician.

The role of magnetic resonance imaging (MRI) in gastric cancer remains the subject of investigation. Early reports suggest that there is good agreement with histologic T staging, with an accuracy of 83% (range 77%-87%), although experience with this technique is more limited and the subject of ongoing investigation.[20] Another systematic review concluded that EUS, multidetector CT, and MRI achieve similar results in terms of diagnostic accuracy of T staging and assessing serosal involvement.[26] Presently, MRI is primarily used in further characterization of indeterminate liver lesions seen on other staging investigations in patients with gastric cancer.

Positron emission tomography (PET) scan has a lower detection rate in some cases of gastric cancers owing to the low fluorine-18 fluorodeoxyglucose accumulation in patients with diffuse or

mucinous/signet ring tumors.[27] PET alone displays a lower sensitivity than CT in detecting nodal involvement, although specificity is improved.[28] Because of its low-resolution images, the value of PET-CT primarily lies in its ability to detect metastatic disease, with a relatively low T-stage sensitivity for T1-T2 tumors and improvement for more advanced disease. A systematic review of the role of PET in patients with gastric cancer evaluating 2,101 patients demonstrated that PET changed management between 3% and 29% of cases, with intestinal subtypes exhibiting more PET-avidity versus diffuse/signet ring subtypes. The authors concluded that the evidence for PET use is limited, but all studies reported a positive impact by preventing patients with CT-undetected metastatic disease from undergoing surgery.[29] Estimated sensitivity for N stage is 40%, although specificity has been reported as high as 98%. As mentioned earlier, the accuracy in identifying distant metastases was 88% and higher than CT alone, and PET has been reported to detect occult metastases in operable patients in 10% and to change patient management in 15%. Additionally, PET response to neoadjuvant therapy, including treatment modification in poor responders as well as a potential indicator of prognosis in these patients, remains an active area of investigation.[20] The ongoing Alliance A021302 study is comparing overall survival of patients with locally advanced gastric cancer classified as PET nonresponders following one cycle of preoperative chemotherapy, with nonresponding patients receiving either salvage chemotherapy before and after surgery or immediate surgery followed by fluorouracil (FU)-sensitized radiotherapy. Given the earlier-mentioned fact, PET alone is likely not an adequate diagnostic procedure for the evaluation of gastric cancer and generally should be used in conjunction with CT scan for correlation, allowing more accurate preoperative staging than either modality alone. A suggested diagnostic evaluation for gastric cancer is shown in Table 64.2.

TABLE 64.2 DIAGNOSTIC WORKUP FOR GASTRIC CANCER

History and Physical
Upper gastrointestinal endoscopy and biopsy
MSI/MMR testing

Chest, abdomen, pelvic CT with oral and intravenous contrast (preferably correlated with PET when PET is performed)
Complete blood count and comprehensive metabolic panel
Endoscopic ultrasound if no evidence of metastases with fine-needle aspiration as indicated
Consider laparoscopy in locoregional patients
Biopsy confirmation of suspected metastatic gastric cancer
HER2 testing if metastatic
Helicobacter pylori testing performed and treatment delivered where clinically indicated

CT, computed tomography; MMR, mismatch repair; MSI, microsatellite instability; PET, positron emission tomography.

STAGING

The current tumor-node-metastasis (TNM) system is depicted in Table 64.3.[30] In the most recent American Joint Committee on Cancer (AJCC) staging of gastric cancers, cancers whose midpoint is in the lower thoracic esophagus, GE junction, or within the proximal 2 cm of the stomach (cardia) *and* extending to the GE junction or esophagus are staged as esophageal neoplasms. All other cancers with a midpoint in the stomach lying more than 2 cm distal to and involving the GE junction or those within 2 cm of the GE junction (but not involving the GE junction or esophagus) are staged using the gastric cancer staging system.

TABLE 64.3 AMERICAN JOINT COMMITTEE ON CANCER (AJCC) EIGHTH EDITION GASTRIC CANCER STAGING

T Category	T Criteria
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial tumor without invasion of the lamina propria, high-grade dysplasia
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades the lamina propria or muscularis mucosae
T1b	Tumor invades the submucosa

T Category	T Criteria
T2	Tumor invades the muscularis propria[a]
T3	Tumor penetrates the subserosal connective tissue without invasion of the visceral peritoneum or adjacent structures[b,c]
T4	Tumor invades the serosa (visceral peritoneum) or adjacent structures[b,c]
T4a	Tumor invades the serosa (visceral peritoneum)
T4b	Tumor invades the adjacent structures/organs

Definition of Distant Lymph Node (M)

N Category	N Criteria
NX	Regional lymph node(s) cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in one or two regional lymph nodes
N2	Metastasis in three to six regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes
N3a	Metastasis in 7-15 regional lymph nodes
N3b	Metastasis in 16 or more regional lymph nodes

Definition of Distant Metastasis (M)

M Category	M Criteria
M0	No distant metastasis
M1	Distant metastasis

The specific regional nodal areas are as follows:

- Perigastric along the greater curvature (including greater curvature, greater omental)
- Perigastric along the lesser curvature (including lesser curvature, lesser omental)
- Right and left paracardial (cardioesophageal)
- Suprapyloric (including gastroduodenal)
- Infrapyloric (including gastroepiploic)
- Left gastric artery
- Celiac artery
- Common hepatic artery
- Hepatoduodenal (along the proper hepatic artery, including portal)
- Splenic artery
- Splenic hilum

[a]A tumor may penetrate the muscularis propria with extension into the gastrocolic or gastrohepatic ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified as T3. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified as T4.

[b]The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.

[c]Intramural extension to the duodenum or esophagus is not considered invasion of an adjacent structure but is classified using the depth of the greatest invasion in any of these sites.

PATHOLOGY

Adenocarcinomas account for 90% to 95% of all gastric malignancies. Lymphomas are the second-most common malignancies. Rarely, gastrointestinal stromal tumors, carcinoid (neuroendocrine) tumors, adenoacanthomas (1%), and squamous cell carcinomas (1%) occur.

The site of origin of gastric cancers within the stomach has changed in the United States over recent decades, and proximal lesions are being diagnosed and treated more frequently. Although the highest frequency is

still in the antrum/distal stomach (~40%), the lowest frequency is now in the body (~25%) rather than the proximal portion of the stomach, with intermediate frequency in the proximal stomach and GE junction (~35%). Several investigators have reported an increased frequency of cardia lesions. As described previously, cardia lesions appear to have different epidemiologic factors, exhibit different tumor biology, and have an inferior prognosis relative to lesions in the other sites.[31-35] Gastric cancers have historically been categorized according to Borrmann's five types. Type I tumors are polypoid or fungating; type II are ulcerating lesions surrounded by elevated borders; type III have ulceration with invasion of the gastric wall; type IV are diffusely infiltrating (linitis plastica); and type V are unclassifiable.[36]

PROGNOSTIC FACTORS
